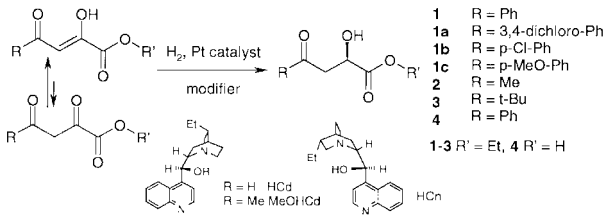
Chiral 2-hydroxy-4-keto acid derivatives are interesting starting materials for the synthesis of a wide variety of intermediates and active substances.[1–3] Considering that many different 2,4-dioxo keto esters are easily synthesized *via* a Claisen condensation of methyl ketones with oxalate esters,[4] a chemo- and enantioselective reduction would give direct access to the desired compounds (Scheme 1). However, this enantioselective hydrogenation has not been reported until recently[2] due to the difficulty of discriminating between the two keto functions. The Pt–cinchona system is known to be very specific for the enantioselective hydrogenation of 2-keto esters[5] and a few other activated C=O bonds,[6–8] whereas unfunctionalized ketones are not suitable substrates. This high specificity is usually a disadvantage, but this paper shows that the underlying chemoselectivity can also be used to good advantage. Here, we report the hydrogenation of various 2,4-diketo acid derivatives with excellent chemoselectivity and medium to high ee's, and describe a new synthesis of enantiomerically pure (*R*)-2-hydroxy-4-phenylbutyric acid ethyl ester (HPB-ester), a building block for the synthesis of several commercially important ACE inhibitors[1] (Scheme 2).†



Scheme 1 Hydrogenation of 2,4-diketo acid derivatives, structure of substrates and modifiers.

Because **1** and **4** are cheap and easily accessible precursors for the HPB-ester,[4] their hydrogenation was investigated in some detail (selected results are summarized in Table 1). Based on our experience with the enantioselective hydrogenation of 2-keto acid derivatives,[5] heterogeneous Pt catalysts modified by 10,11-dihydrocinchonidine (HCd) and 10,11-dihydrocinchonine (HCn) were our favorites to obtain the (*R*)- and (*S*)-HPB-ester. With these modifiers, an extensive screening of the influence of catalyst type, solvent and reaction conditions was carried out. As hoped for, the chemoselectivity of all modified systems was always > 95% at 25 °C, regardless of catalyst type and solvent, provided that the reaction was stopped after the uptake of one mole of hydrogen. It is well known that for ethyl pyruvate or 4-phenyl-2-oxobutyric acid ethyl ester, by far the highest ee's are obtained with *O*-methyl-10,11-dihydrocinchonidine (MeOHCd) in AcOH.[5] In contrast, the highest ee for **1** of 86% (*R*) as well as the highest rate were observed in toluene with HCd and 5% Pt–Al_2O_3 catalysts. Pt on SiO_2 or other supports always gave lower ee's and most of the time lower rates. Other apolar or slightly polar solvents like benzene, xylene, cyclohexane, hexane, ethyl acetate, or diisopropyl ether led to ee's between 85 and 71%. In protic solvents like *t*-BuOH, AcOH or EtOH ee's between 40 and 61%, and in DMF an ee of

DOI: 10.1039/b002538k

25% were obtained. Temperature and pressure affected the results only slightly. The optimal modifier concentration was 5.3×10^{-4} M at a modifier to catalyst ratio of 1:10 (w/w), similar to the results obtained with ethyl pyruvate.[9] Analogous experiments were carried out with the pseudoenantiomeric HCn as modifier. All trends were similar, but the best ee's in toluene were always lower by about 20%. Furthermore, the reactions were always slower by a factor of about three and a doubling of the modifier concentration was necessary for the highest ee. Surprisingly, the ee's in AcOH were comparable, as described by LeBlond *et al.* for ethyl pyruvate.[10] Obviously the small difference between HCd and HCn (attachment point of the side chain in the quinuclidine unit) is quite important in toluene but not so much in AcOH. For the 2,4-diketo acid **4**, the ee's were significantly lower than for the corresponding ethyl ester **1**. More polar solvents gave better results as observed for mono keto acids, where the highest ee's were obtained in a EtOH–H_2O mixture.[11]

To obtain the HPB-ester with the desired ee of > 99%, further enrichment of the 2-hydroxy-4-keto ester was necessary. This worked remarkably well: a single crystallization from $^{i}Pr_2O$ brought the ee from > 72% to > 99% with a chemical yield of approx. 50–60%. Hydrogenolysis of the keto group with Pd–C in EtOH–HCl finally gave the desired HPB-ester in high yield with an ee of > 99% (overall yield starting from **1** approx. 50–60%).[12]

In order to expand the scope of this chemo- and enantioselective reaction, substrates **1a**–**c**, **2** and **3** were also tested (Table 2), and proved to be highly chemoselective. This is remarkable considering that only a few of the homogenous catalysts mentioned above showed high chemoselectivity for **2** and **3**, and even fewer both high chemo- and enantioselectivity.[2] As observed for **1**, the highest ee's (70–80%) were usually obtained in toluene. The only exception was **3**, where AcOH gave 74% and toluene 63% ee. For all esters investigated, the reactions in EtOH proceeded with the lowest ee's but often the highest rates. Comparing **1**, **1a**, **1b** and **1c**, it seems that electron withdrawing groups on the Ph groups give slightly higher ee's and rates. For all these substrates, HCn was also investigated as modifier to give the (*S*)-2-hydroxy-4-keto esters. The ee's were again lower by 20–30%. Enrichment by recrystallization to > 98% ee was possible for **1a**, **1b** and **1c** but not for **2** and **3** which are not crystalline at rt.

The hydrogenation of all 2,4-diketo esters with the unmodified Pt catalysts was slower than the modified systems, typically by a factor of 3–60 (ligand accelerated catalysis[5,10]). However, all rates were relatively low compared to ethyl pyruvate (rates up to 300 mmol g^{-1} min^{-1}) or 4-phenyl-2-oxobutyric acid ethyl ester (rates up to 40 mmol g^{-1} min^{-1}).[13] For ethyl pyruvate it was demonstrated by reaction with D_2 that hydrogenation occurs by addition across the C=O bond.[5] In contrast to mono keto esters where only the keto form is observed, diketo esters showed > 80% enol in the solvents used for the hydrogenation (NMR results). Therefore, one possible explanation for these rate differences between mono and diketo esters could be the different keto–enol ratio. Unfortunately, a reaction with D_2 was not conclusive due to a massive exchange of H/D in the starting material and product, and it is uncertain whether the keto or the enol form is hydrogenated. In addition, the modified catalyst gave significantly less 2,4-dihydroxy ester than unmodified catalyst. This improved chemoselectivity is mainly due to the acceleration of the hydrogenation of the 2-keto group, but there are also indications that the reaction of the 4-keto group is slowed down.

In conclusion, the scope of the cinchona modified Pt catalysts has been expanded to the enantio- and chemoselective hydrogenation of various 2,4-diketo ester derivatives. For a range of 2-hydroxy-4-keto esters enrichment to > 98% ee is possible by a simple crystallization thereby enabling an efficient technical access to enantiomerically pure building blocks for ACE inhibitors and related compounds.

This project was carried out for and in collaboration with the Life Science Molcules Unit of Ciba Specialty Chemicals (Ciba LSM). We thank P. Herold, H. P. Jalett, F. Spindler and A. Hafner for valuable discussions and G. Thoma for careful experimental work.

Notes and references

† Hydrogenations were carried out as described in ref. 6. Example for ethyl (*R*)-2,4-dioxo-4-phenylbutyrate **1**: 2.0 g diketo ester **1** in 30 ml toluene were hydrogenated at 25 °C and 60 bar H_2 pressure in a 50 ml stainless steel autoclave in the presence of 50 mg 5% Pt–Al_2O_3 (pretreated for 2 h in H_2 at 400 °C) and 5 mg HCd. After H_2 uptake had stopped (*ca.* 160 min), the catalyst was filtered and the solution was evaporated to dryness at reduced pressure. Yield: 1.97 g (98%), product content > 97% (NMR), ee 86% (HPLC, OD-H, hexane–EtOH 98.5:1.5, flow 0.7 ml min^{-1}; retention time: (*S*)-enantiomer 46.0 min, (*R*)-enantiomer 49.6 min).

The experiments with the other substrates were carried out in a similar manner. In cases with low activity, higher catalyst loadings were used (constant catalyst–modifier ratio). With HCn, a modifier–catalyst ratio of 1:5 was normally used. All new substrates and products gave satisfactory analytical results (^{13}C, ^{1}H, and MS).

HF–pyridine promoted Friedel–Crafts type arylation of 2-acetoxy-D-glucal. Stereoselective synthesis of 1-arylhex-3-enopyranosiduloses

Masahiko Hayashi,* Shu-zo Nakayama and Hirotoshi Kawabata

Received (in Cambridge, UK) 25th April 2000, Accepted 7th June 2000

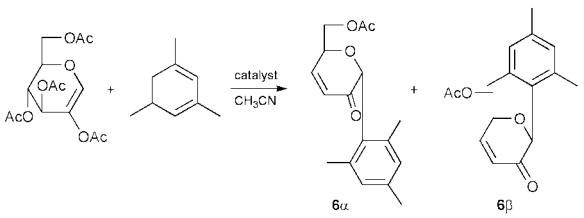
A variety of aromatic substrates were treated with 2-acetoxy-D-glucal in the presence of HF–pyridine to give 1-arylhex-3-enopyranosiduloses in high yield and in high α-selectivity.

C-Glycosylarenes or *C*-aryl glycosides are *C*-glycosides found in natural products.[1] These compounds often exhibit interesting biological activity, such as antibacterial, anti-tumor, enzyme inhibitory effects, and inhibition of platelet aggregation.[2] Therefore, the study of the synthesis of *C*-glycosylarenes is of interest to synthetic organic chemists. The most straightforward synthesis of *C*-glycosylarenes should be the Friedel–Crafts type reaction between glycosyl donors and aromatic compounds.[3,4]

We recently reported the reaction of acetylated and unprotected D-glucal with trimethylsilyl cyanide which led to the synthesis of 2,3-unsaturated glycosyl cyanides.[5] During the course of this study, we became interested in the reaction of D-glucal with aromatic compounds, which should be an efficient synthetic route to *C*-aryl glycosides.[6] Here we would like to report the Friedel–Crafts type reaction of acetylated D-glucal with aromatic compounds.

First, we examined the reaction of 3,4,6-tri-*O*-acetyl-D-glucal with mesitylene (1,3,5-trimethylbenzene) in the presence of a variety of Lewis acids such as Me_3SiOTf, $BF_3{\cdot}OEt_2$ and $Sc(OTf)_3$. However, all reactions resulted in the formation of complex mixtures and the desired 1-aryl glycoside was not obtained. Then we employed the reaction of 2,3,4,6-tetra-*O*-acetyl-D-glucal (**1**) with mesitylene using the above Lewis acids. In these cases, 1-arylated hex-3-enopyranosidulose (**6**) was obtained in high yield.[7] Some of the results are summarized in Table 1. Among the Lewis acids we examined, Me_3SiOTf showed the best results (20 mol%, 0 °C, 1 h, 90% yield, α:β = 88:12). The configuration of the major anomeric center was determined as α by ^{1}H NMR spectral analysis.

Table 1 Reaction of 2,3,4,6-tetra-*O*-acetyl-D-glucal with mesitylene[a]



6α 6β

	Conditions			Product	
Entry	Catalyst (mol%)	*T*/°C	*t*/h	Yield (%)[b]	α:β[c]
1	Me_3SiOTf (20)	0	1	90	88:12
2	$BF_3{\cdot}OEt_2$ (20)	15	20	58	80:20
3	$Sc(OTf)_3$ (10)	20	24	65	79:21
4	HF–pyridine	0	1	90	90:10

[a] All reactions were carried out in acetonitrile except for entry 4. [b] Isolated yield after silica-gel column chromatography. [c] ^{1}H NMR analysis.

Interestingly, rare-earth metal triflates other than $Sc(OTf)_3$, such as $Sm(OTf)_3$, $Y(OTf)_3$ and $Yb(OTf)_3$ were inactive in the above reaction. HF–pyridine was found to work as an effective promoter and to be superior to the conventional Lewis acids as for a variety of aromatic compounds (Table 2). HF–pyridine is used as a fluorinating agent,[8] for example in the synthesis of glycosyl fluorides.[9] However, in the present case, HF–pyridine worked as a promoter in the Friedel–Crafts coupling reaction. As shown in Table 2, a variety of α-1-arylated hex-3-enopyranosidulose products were obtained in high yields. As for the relative reactivity, among the aromatic compounds we examined, anisole reacted with **1** faster than the other aromatic compounds. For methylated benzene derivatives, the order of the reactivity is as follows; mesitylene > *m*-xylene > *o*- and *p*-xylene, toluene. Isomerization was not observed under the reaction conditions, indicating that the observed stereochemical outcome resulted from kinetic control.

The reactions proceed *via* a Ferrier type reaction.[10] The reaction is initiated by the reaction of 2-acetoxy-D-glucal with HF–pyridine to generate an oxocarbenium ion which then reacts with aromatic substrates such as xylene and mesitylene to give 1-aryl-2,3-unsaturated glycosides, though these compounds were not isolated. Then deacetoxylation at the 4-position affords the 1-arylhex-3-enopyranosiduloses. In the case of the reaction of 3,4,6-tri-*O*-acetyl-2-bromo-D-glucal with mesitylene, a Ferrier type product, that is, the 2,3-unsaturated 1-arylated product was obtained in 86% yield (α:β = 77:23).

A typical experimental procedure is as follows: In a 50 mL polyethylene vessel, 2,3,4,6-tetra-*O*-acetyl-D-glucal (1.0 g, 3.04 mmol) and mesitylene (0.84 mL) were placed. To this mixture was added 70% HF–pyridine (1.5 mL) at 0 °C and the whole mixture was stirred for 1 h at 0 °C. After the confirmation of the completion of the reaction by TLC, the mixture was poured into saturated $NaHCO_3$ solution and extracted with ethyl acetate (20 mL × 3). The combined organic layer was washed with brine (20 mL × 3), and then evaporated. Chromatography of the residue on a silica gel column afforded **6** (777 mg, 90%). Separation of the anomers was effected by column chromatography on silica gel (1:2 ethyl acetate–hexane as an eluent): **6**α (less polar) $[\alpha]_D^{23}$ −149.1° (*c*. 1.2, $CHCl_3$); **6**β (more polar) $[\alpha]_D^{22}$ −53.1° (*c*. 1.2, $CHCl_3$).

In conclusion, we have developed a HF–pyridine promoted Friedel–Crafts type arylation of 2-acetoxy-D-glucal with a variety of aromatic compounds which facilitated the synthesis of 1-aryl-2-hex-3-enopyranosiduloses.

We would like to acknowledge Dr Hidemitsu Uno of the Center for Advanced Chemical Analysis and Instrumentation of Ehime University for his help in the structure determination of compound **6**. Chemical tuning of ferromagnetism and superconductivity in $RuSr_2GdCu_2O_8$†

A. C. Mclaughlin,[ab] V. Janowitz,[ab] J. A. McAllister[ab] and J. P. Attfield[ab]

[a] *Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: acm43@cus.cam.ac.uk*

[b] *Interdisciplinary Research Centre in Superconductivity, University of Cambridge, Madingley Road, Cambridge UK CB3 0HE*

Received (in Cambridge, UK) 11th April 2000, Accepted 12th June 2000

When substituted for Ru in the ferromagnetic superconductor $RuSr_2GdCu_2O_8$, both Sn^{4+} and Nb^{5+} suppress the ferromagnetism in the RuO_2 layers, but they respectively enhance and diminish superconductivity in the CuO_2 planes through hole transfer to and from the CuO_2 layers, showing that these materials are underdoped with an estimated maximum T_c of 65 ± 10 K.

Ferromagnetism and superconductivity are considered to be incompatible in homogenous solids, but a remarkable coexistence of these properties has recently been discovered in the mixed oxide $RuSr_2GdCu_2O_8$.[1–10] This has a tetragonal '1212' type structure, similar to that of $YBa_2Cu_3O_7$, with layers stacked in the sequence …RuO_2.SrO.CuO_2.Gd.CuO_2.SrO…[6,9,10] Resistivity measurements show that this material displays bulk superconductivity in the CuO_2 planes, with a critical temperature (T_c) of up to 46 K, whilst the ferromagnetic transition at T_M = 136 K results from ordering of moments in the RuO_2 planes.[4,5,7] The presence of ferromagnetism is confirmed by hysteresis loops in magnetisation *vs.* field measurements, with remnant and saturated moments of 0.1 and 1.0 μ_B per Ru atom. However, recent neutron diffraction measurements detected only an antiferromagnetically ordered component,[8] so that the overall magnetic arrangement may be canted with both ferro- and antiferro-magnetic components. This canting may result from antisymmetric exchange between Ru moments as a result of local rotations and tilts of the RuO_6 octahedra owing to a size mismatch between the ruthenate and cuprate layers.[6,9,10] $RuSr_2GdCu_2O_8$ is cation and oxygen stoichiometric, and the hole-doping (oxidation) of the CuO_2 planes needed to induce superconductivity arises from the overlap of the Ru t_{2g} and the Cu $d_{x^2-y^2}$ bands. The formula may thus be written as $Ru^{5-2p_0}Sr_2Gd(Cu^{2+p_0})_2O_8$ to show the average Ru and Cu oxidation states. Transport measurements suggest that the intrinsic hole doping is $p_0 \approx 0.07$,[7] showing that this material is strongly underdoped, as optimum superconductivity in copper oxides is generally found for a hole-doping of $p \approx 0.16$. The average oxidation states are thus $Ru^{4.86+}$ and $Cu^{2.07+}$.

To investigate the relationship between the charge distribution, superconductivity and magnetism in $RuSr_2GdCu_2O_8$ further, we have attempted to replace Ru by non-magnetic, fixed valent cations. Samples of $Ru_{1-x}Sn_xSr_2GdCu_2O_8$ were previously prepared with nominal compositions x = 0–0.4.[11] Tin doping was found to suppress T_M and enhance T_c, but firm conclusions about the origin of this effect could not be drawn as the samples were not phase pure. We have subsequently prepared phase pure Sn-doped samples for $x < 0.1$, and a series of > 98% pure Nb doped samples, as summarised here.

Ceramic samples of $Ru_{1-x}M_xSr_2GdCu_2O_8$ (M = Sn: x = 0, 0.025, 0.05, 0.075; M = Nb: x = 0, 0.05, 0.1, 0.15, 0.2) were prepared by solid state reaction of stoichiometric powders of RuO_2, SnO_2, Nb_2O_5, $SrCO_3$, Gd_2O_3 and CuO. These were ground, die-pressed into pellets and reacted in flowing nitrogen at 1010 °C for 20 h, in flowing oxygen at 1050 °C and at 1055 °C for 10 h each, then at 1060 °C for 4 days, and finally slow cooled to room temperature. X-Ray diffraction patterns demonstrated that the $Ru_{1-x}Sn_xSr_2GdCu_2O_8$ solid solutions were phase pure, however there was a trace of $SrRuO_3$ in the $Ru_{1-x}Nb_xSr_2GdCu_2O_8$ samples. The greatest amount was estimated to be 2.2(1)% $SrRuO_3$ in the x = 0.20 sample by Rietveld analysis. Thermogravimetric analyses gave oxygen contents between 7.95 and 8.05 for all samples, showing them to be stoichiometric within the experimental error of ±0.05.

Magnetisations were measured on a Quantum Design SQUID magnetometer in an applied field of 1 kOe after zero-field cooling. A broadening of the magnetic transition and a reduction in the Curie temperature T_M (Table 1) is observed with increasing Nb [Fig. 1(a)] or Sn substitution. Variable field measurements between ±50 kOe at 10 K revealed hysteresis loops for all samples. The hysteretic parameters all decrease smoothly with Nb or Sn substitution; the coercivity falls from 410 Oe in the undoped material to 320 Oe for 7.5% Sn substitution and 240 Oe for 20% Nb substitution and the remnant Ru moments are 0.13, 0.09 and 0.05 μ_B, respectively. The saturated Ru moments, estimated by subtracting the Gd contribution following a procedure described elsewhere,[11] are 1.0, 0.8 and 0.6 μ_B in the same three samples. These results are all in keeping with a dilution of the ferromagnetism in the RuO_2 layers by substitution of diamagnetic Sn^{4+} or Nb^{5+}.

The resistivities of sintered polycrystalline bars were measured between 7 and 300 K using the standard four-probe ac technique. Superconducting transitions are observed for the $Ru_{1-x}Nb_xSr_2GdCu_2O_8$ samples with x = 0–0.15 [Fig. 1(b)] but not for x = 0.2 down to 7 K. All the $Ru_{1-x}Sn_xSr_2GdCu_2O_8$ samples are superconducting and the onset T_c increases up to 50 K for x = 7.5%. The thermoelectric powers of the same sintered bars were measured at 290 K. The derived Seebeck coefficient decreases from 80 μV K^{-1} in the undoped material to 70 μV K^{-1} in $Ru_{0.925}Sn_{0.075}Sr_2GdCu_2O_8$ but increases to 120 μV K^{-1} in $Ru_{0.8}Nb_{0.2}Sr_2GdCu_2O_8$. The proportion (< 2%) of $SrRuO_3$ is too small to affect these bulk transport measurements.

The charge distribution in the doped materials may be written as $(Ru^{5-2p_0})_{1-x}M^q{}_xSr_2Gd(Cu^{2+p^+\Delta p})_2O_8$ where the extrinsic

doping introduced by the substituents M of charge q is $\Delta p = (5 - q - 2p_0)x/2$. This assumes that the substituent does not change the intrinsic band structure. This description is verified by the transport data for the $Ru_{1-x}M_xSr_2GdCu_2O_8$ solid solutions, which show that the electronic doping can be increased or decreased relative to the intrinsic level. Substitution of $Ru^{4.86+}$ by Nb^{5+} leads to removal of holes from the CuO_2 planes (chemical reduction), so that the materials become more underdoped and T_c decreases. This is supported by the increase of the 290 K Seebeck coefficient with x in the $Ru_{1-x}Nb_xSr_2GdCu_2O_8$ series, as this is known to increase from ≈ 0 in optimally doped materials with $p \approx 0.16$ to $\approx 10^2$ μV K^{-1} in very underdoped materials.[12] $NbSr_2GdCu_2O_8$ was previously reported to be non-superconducting and could not be doped sufficiently to induce superconductivity,[13] but we note that this is achieved for > 85% replacement of Nb by Ru. The trend in superconductivity of the $Ru_{1-x}Sn_xSr_2GdCu_2O_8$ solid solutions is opposite to that of the $Ru_{1-x}Nb_xSr_2GdCu_2O_8$ series. The replacement of $Ru^{4.86+}$ by Sn^{4+} transfers more holes into the CuO_2 planes (chemical oxidation), so T_c increases and the Seebeck coefficient decreases.

The variation of T_c with doping level has been established in many cuprate superconductors and to a good approximation varies quadratically as $T_c = T_c^{max}[1 - 82.6(p - 0.16)^2]$.[14] This equation has been fitted to the onset T_c values in Table 1 by writing $p = p_0 + \Delta p$, giving values of $p_0 = 0.080(5)$ for the intrinsic doping, in good agreement with the previous value of 0.07,[7] and $T_c^{max} = 65(10)$ K as an estimate for the maximum T_c at optimum doping. This is somewhat lower than the highest T_c of ≈105 K in comparable 1212 cuprates such as $(Tl_{0.5}Pb_{0.5})Sr_2(Ca,Y)Cu_2O_7$.[15] This suppression could reflect a pairbreaking interaction with the ferromagnetic moments in the RuO_2 plane, but this effect should be greater in the undoped compound than in the less ferromagnetic $Ru_{1-x}M_xSr_2GdCu_2O_8$ derivatives, leading to a greater reduction of T_c at $p \approx p_0$ which is not observed in Fig. 2. Lattice strain from the mismatch of the cuprate and ruthenate layers is a more probable explanation for the low T_c's in this system. This has previously been evidenced by the unusually short apical Cu–O bond of 2.16 Å in

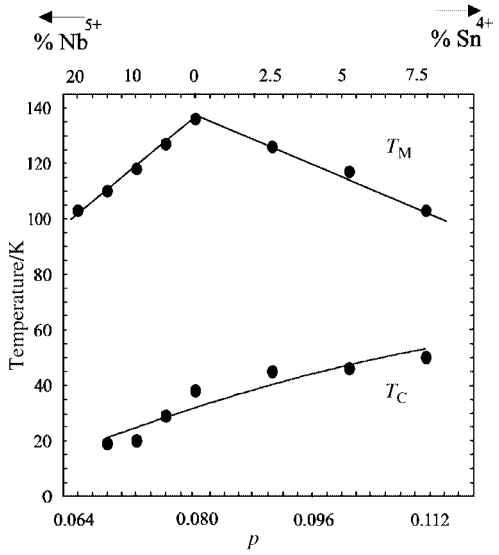

Fig. 2 The variation of the superconducting critical temperature (T_c) and the Curie temperature (T_M) with doping level p (lower scale) and %Nb or Sn substitution (upper scale) in the $Ru_{1-x}M_xSr_2GdCu_2O_8$ solid solutions. The T_c values are fitted by the quadratic expression given in the text.

$RuSr_2GdCu_2O_8$,[6] suggesting that the geometry of the structure is not optimal for superconductivity.

In conclusion, this study shows that up to 20% Nb^{5+} or 7.5% Sn^{4+} can be substituted for Ru in $RuSr_2GdCu_2O_8$. These diamagnetic substituents tune the physical properties by lowering the magnetic ordering temperature and ferromagnetic moment of the ruthenate layers, and respectively removing or adding holes to the copper oxide planes. The $Ru_{1-x}M_xSr_2GdCu_2O_8$ materials behave as typical underdoped cuprates and the maximum T_c that could be obtained at optimum doping is estimated to be 65 ± 10 K, which is less than those in comparable materials. This could reflect a magnetic pairbreaking effect but more probably results from lattice strains in the cuprate layers.

We thank EPSRC for provision of Research Grant No. GR/M59976 and a studentship for A. C. M., and S. Rycroft and J. R. Cooper for help with transport measurements.

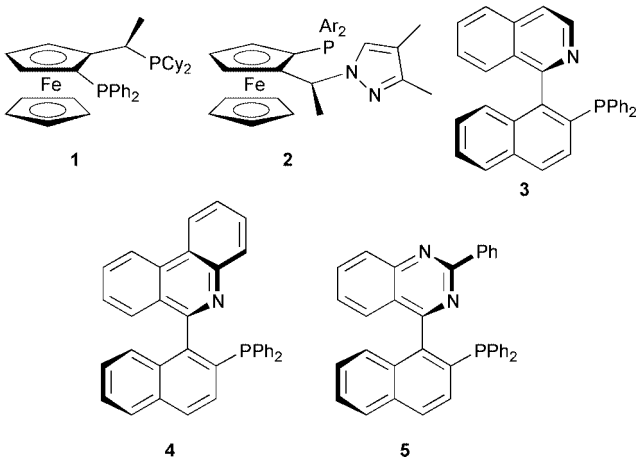
Received (in Liverpool, UK) 9th May 2000, Accepted 7th June 2000

Cationic rhodium complexes of 2-phenylquinazolin-4-yl-2-(diphenylphosphino)naphthalene catalyse the hydroboration of indene, tetrahydronaphthalene and a range of styrenes in high yields, regioselectivities and with enantiomer excesses of up to 97%

The report by Männig and Nöth[1] that Rh–phosphine complexes successfully catalysed the hydroboration of olefins added a new dimension to the hydroboration methodology developed by Brown.[2] With catecholborane as the borane source, the catalysed variant offered potential advantages in terms of chemo-, regio- and enantioselectivity.[3] Burgess[4] first reported catalytic enantioselective hydroboration and Hayashi subsequently used Rh–BINAP complexes for the hydroboration of styrene in ees of up to 96%.[5] Togni applied Rh complexes of the diphosphine Josiphos **1** (92% ee) and the related pyrazole-



1 **2** **3** **4** **5**

containing phosphinamine **2** (98% ee).[6,7] Brown used the axially chiral phosphinamine ligands QUINAP **3** (91% ee)[8] and PHENAP **4** (67% ee)[9] and also extended the standard hydroboration–oxidation sequence to include hydroboration–amination.[10] We have recently reported the synthesis and resolution of the related ligand, 2-phenylquinazolin-4-yl-2-(diphenylphosphino)naphthalene **5**, and, in view of the success of **3** and **4**, we wished to test its enantiodifferentiating ability in Rh-catalysed olefin hydroboration and we now report our preliminary results.[11]

The required cationic Rh catalyst was prepared in a standard manner from TMS triflate and (cycloocta-1,5-diene)(pentane-2,4-dionato)rhodium(I) and (*R*)-**5**.[12] Because of its susceptibility to oxidation, the catalyst was freshly made *in situ* and we also used freshly distilled catecholborane. We focused on vinylarene substrates, paying particular attention to those which would highlight the effect on reactivity and enantioselectivity of different aryl substituents and β-substitution, as exemplified by olefins **6**–**12**. In each of the reactions the catalysed hydroboration was followed by direct oxidation with H_2O_2 to afford the corresponding alcohol. The results of our investigations are given in Table 1.

The α:β regioselectivity obtained using phenylethene **6** was found to increase using lowered reaction temperatures and the optimised values obtained were 80:20 with an ee value of 79% after a reaction time of 2 h. This ee value compares favourably with PHENAP **4** (67%) but is lower than that obtained with QUINAP **3** (88%) and our regioselectivity was poorer than both **3** and **4** (97:3 and 90:10, respectively).[8a,9] The sense of

[a] *Typical procedure*: Freshly distilled catecholborane (0.5 mmol) in THF (1 ml) was added dropwise to a solution of olefin (0.5 mmol) and [(*R*)-diphenyl[1-(2-phenylquinazolin-4-yl)(2-naphthyl)]phosphine]rhodium(cycloocta-1,5-diene)trifluoromethanesulfonate (5 μmol) in THF (1 ml). The solution turned brown and was stirred at room temp. for 2 h. The reaction was placed in an ice bath and quenched with EtOH (1 ml). 30% H_2O_2 (aq.) (3 ml) and 1 M NaOH (aq.) (3 ml) were added and the mixture was allowed to warm and stirred for 1 h at room temp. The mixture was transferred to a separating funnel and Et_2O was added (10 ml). The organic extracts were washed with 1 M NaOH (aq.), brine and then dried over $MgSO_4$. The solvent was removed *in vacuo* to give the product as an oil. ^{1}H NMR obtained gave % conversion and regioselectivity. Enantioselectivities were determined by either GC or HPLC. [b] Regioselectivities and conversions by ^{1}H NMR. [c] Absolute configuration assigned by similarity in order of elution in the GC analysis and from the sign of the optical rotation.[8] [d] Enantiomeric excesses were determined by GC (β-Dex®120 column, 30 m × 0.25 mm, 0.25 μm film thickness). [e] Enantiomeric excesses were determined by HPLC (Chiralcel OD column 99.5:0.5 Hex–*i*PrOH.

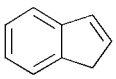
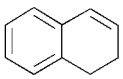
asymmetry was identical to **3** and **4**, *i.e*. the (*R*)-ligand affords the (*R*)-product alcohol. The more electron-rich 4-methoxyphenylethene **7** gave similar regioselectivities and an increased ee of 81%, but again lower than the 94% ee value observed with QUINAP **3**.[8a] The electron-deficient substrate, 4-chlorophenylethene **8**, afforded similar regioselectivities but significantly lowered ees of 46–49%, which is in agreement with trends observed employing QUINAP **3** and analogues.[8b] More promising results in terms of regio- and stereoselectivity were obtained using β-substituted arylethenes. Both the (*E*)- and (*Z*)-isomers of propenylbenzene **9** demonstrated a preference for reaction at the benzylic position and similarly in high ees of 94 and 91%, respectively. Similar values were obtained with QUINAP **3** and PHENAP **4**[9] whereas BINAP afforded an ee of 42% for (*E*)-**9** and 18% for (*Z*)-**9**.[5] (*Z*)-Propenyl-4-methoxybenzene **10** was a similarly successful substrate giving up to 92% ee in 72% yield after reaction for 6 days at 0 °C. The combination of an even more electron-rich arene and β-substituted olefin **11** gave the best ee of 97% using ligand **5**. Again it was noted that increasing the electron richness of the arene was beneficial in terms of enantioselectivity but led to a retardation of the reaction as seen by the poorer yields obtained. In order to determine the effect of increasing the bulk at the β-position we tested (*E*)- and (*Z*)-stilbene **12** and found that (*E*)-**12** was an unreactive substrate whereas (*Z*)-**12** afforded up to 62% ee in excellent yield. This result is similar to that obtained with QUINAP **3** where high ees (85–91%) were obtained with both isomers, although it was noted that (*E*)-**12** reacted at a significantly lower rate (45 turnovers after 20 h).[8b] The best ee reported for (*Z*)-**12** using BINAP was significantly lower at 16%.[5]

The cyclic olefins, indene **13** and 1,2-dihydronaphthalene **14**, are two of the most challenging substrates in Rh-catalysed



13



14

hydroboration. We tested Rh complexes of **5** with these substrates and the results are shown in Table 2. Excellent conversions and regioselectivities were obtained and optimised ees of 84% and 89% were obtained with **13** and **14**, respectively. The result for **13** is slightly lower than that reported for QUINAP **3** (86%),[8b] but compares favourably to PHENAP **4** (64%)[9] and even more so when compared to BINAP (19%).[5] A similar trend is observed for substrate **14** as our result of 89% is again lower than that reported for QUINAP **3** (96%),[8b] but is higher than the value obtained with PHENAP **4** (84%)[9] and in this case no result has been quoted for BINAP.

All the reactions noted in Table 1 were run on a 0.5 mmol scale with 1 mol% catalyst. In a further study, the hydroboration of (*E*)-propenylbenzene **9** was carried out using 0.5 mol% catalyst and our results are given in Table 3. Using 0.5 mol% catalyst, the ee obtained after 15 min was slightly lower than the values obtained after 1 h (94% ee), 4 h (96% ee), and 16 h (95% ee) which were not lowered in comparison with the value obtained with 1 mol% catalyst (Table 1, entry 7).

In conclusion, our results demonstrate that **5**, applied in Rh catalysed hydroboration of substituted arylethenes, β-substituted arylethenes and cyclic olefins, gives excellent conversions, good regioselectivities and ees of up to 97%. For substituted arylethenes our ligand, 2-phenylquinazolin-4-yl-2-(diphenylphosphino)naphthalene **5**, as with QUINAP **3** and PHENAP **4**, afforded lower ees than both BINAP and Josiphos **1**. However, for β-substituted arylethenes and cyclic olefins these axially chiral phosphinamine ligands are far superior. This can be explained by inferring that the increased steric demand of the olefin is more easily accommodated by these less sterically demanding ligands. Further hydroboration studies employing structurally related quinazoline-containing ligands[13] are in progress and will be reported in due course from these laboratories.[14]

Received (in Cambridge, UK) 3rd April 2000, Accepted 6th June 2000

A polyrotaxane composed of γ-cyclodextrin and azobenzene containing polyester undergoes UV light induced isomerization of *trans*- to *cis*- azobenzene, whereas the reverse isomerization does not occur under the usual conditions of irradiation with visible light.

Interactions of various compounds with photoisomerizable azobenzene groups with cyclodextrins have been investigated to develop new photoresponsive materials.[1] Much attention has been directed toward cyclodextrin-based polyrotaxanes and pseudopolyrotaxanes of azobenzenes.[2] Recently, a rotaxane system composed of cyclodextrin (CD) and an azobenzene-containing polymer exhibited quick and reversible molecular shuttle type behavior induced by photoisomerization of the azobenzene group.[3] In the course of our study of the preparation and properties of various pseudopolyrotaxanes with cyclodextrins,[4] we observed a significant influence of the host CD molecules on the photoinduced *cis*–*trans* isomerization of the azobenzenes. Here we report syntheses of a new pseudopolyrotaxane of polyazobenzene and of a corresponding CD free polyazobenzene, as well as the effect of CD on the photoisomerization of polyazobenzene.

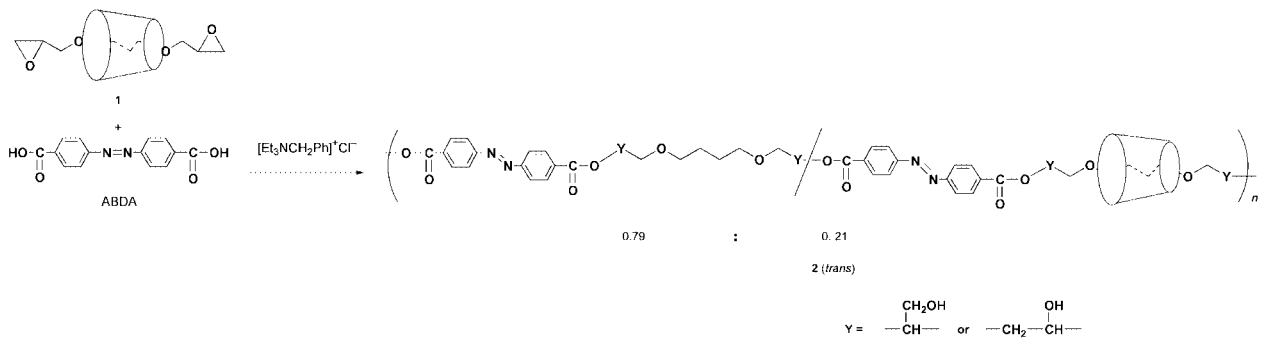
A 1:1 inclusion complex of butane-1,4-diol diglycidyl ether (BDGE) [1,4-bis(2,3-epoxypropoxy)butane] and γ-CD (**1**)[5] reacts with azobenzene-4,4′-dicarboxylic acid (ABDA) in the presence of a catalytic amount of $[Et_3NCH_2Ph]^+Cl^-$ to afford the pseudopolyrotaxane **2**(*trans*), which, on average, contains 0.21 γ-CD unit per repeating unit as evaluated from elemental analysis and NMR spectroscopy (Scheme 1). The azobenzene groups in the polymer take the *trans* configuration, as revealed by UV-vis spectroscopy. The pseudopolyrotaxane **2**(*trans*) gives a DSC scan which is quite different from that of a physical mixture of **2**(*trans*) and γ-CD. Analysis by GPC gives values for M_n of 9500 and M_w of 17 100 (*vs.* polystyrene standards).

Cyclodextrin-free polyester (**3**(*trans*)) having azobenzene groups with M_n = 8750 and M_w = 15100 was also obtained as an orange solid (76%) in a similar fashion from the polyaddition of BDGE to ABDA (Scheme 2). The ratio of –CH(CH$_2$OH)– and –CH$_2$–CH(OH)– linkages formed *via* α- and β-cleavage of the oxirane ring, respectively, is determined to be 0.62:0.38. Similar ratios have been reported for polymers obtained by the ring-opening polyaddition of diglycidyl ethers and dicarboxylic acids.[6] An attempt to prepare **2**(*trans*) from a mixture of γ-CD and **3**(*trans*) was not successful, indicating that the polymers, once formed, do not form the supramolecular system with γ-CD, presumably due to the presence of the bulky azobenzene units.

Photoisomerization of the azobenzene group[7] of **2**(*trans*) and **3**(*trans*) was investigated, and the results were compared. Upon irradiation of a DMSO solution of **2**(*trans*) with UV light (245 nm), the absorption peak at 331 nm due to the π–π* transitions of the *trans* azobenzene unit decreased accompanied by growth of the peak at 433 nm due to the n–π* transition of the *cis* azobenzene unit.[8] Fig. 1 shows changes in the absorption spectrum during the reaction, which follows first-order kinetics with a rate constant of 1.7×10^{-3} s^{-1} at 30 °C and 1.5×10^{-3} s^{-1} at 25 °C. The γ-CD free polyester **3**(*trans*) undergoes a similar *trans* to *cis* photoisomerization under irradiation with UV light (245 nm) and gives a first-order rate constant (1.3×10^{-3} s^{-1}, 25 °C) comparable to that of **2**(*trans*). These results clearly indicate the occurrence of the photoinduced isomerization of **2**(*trans*) and **3**(*trans*) to **2**(*cis*) and **3**(*cis*), respectively.

As for **3**(*cis*), irradiation with visible light (> 440 nm) causes a reverse isomerization, increasing the strength of the peak at 330 nm and decreasing the strength of the peak at 432 nm. It has been reported that various azobenzenes undergo a similar reverse photoisomerization under irradiation with visible light. However, irradiation of the DMSO solution of **2**(*cis*) with visible light (> 440 nm) caused no observable isomerization of **2**(*cis*) to the original **2**(*trans*). Heating of **3**(*cis*) at 50 °C also leads to its isomerization to **3**(*trans*) within 15 min, whereas **2**(*cis*) does not undergo such thermally induced isomerization. Since **2** and **3** have similar molecular weights and polydispersities, the large difference in the photo and thermally induced isomerization may be ascribed to a difference in the molecular structure or aggregation behavior between **2** and **3** in solution.

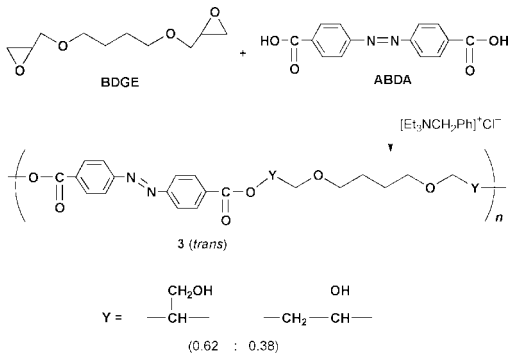
Fig. 2 shows plots of η_{sp}/c against c for **2**(*trans*), **3**(*trans*), **2**(*cis*), and **3**(*cis*). As shown in Fig. 2, **2**(*cis*) gave a larger η_{sp}/c value and a larger slope in the η_{sp}/c *vs.* c plots, compared with



Scheme 1

DOI: 10.1039/b002642p

the other three polymers. The larger slope suggests the presence of intermolecular interactions between the polymer molecules. On the other hand, for polyamide type polyazobenzenes –(amide unit–N=N–)$_n$–, it is reported that the *cis* and *trans* polymers give the same slope in the η_{sp}/c *vs. c* plots.[9] In this case, photoinduced *cis* to *trans* isomerization proceeds smoothly. The viscometric results of **2**(*cis*) suggest the presence



Scheme 2

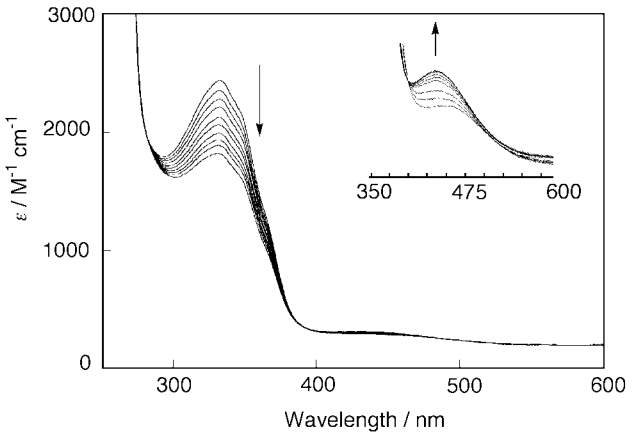


Fig. 1 Change of the absorption spectra of DMSO solution of **2** during isomerization from the *trans* to the *cis* form irradiated with UV light (245 nm) at 30 °C. The spectra were recorded at t = 0, 2, 4, 6, 8, 10, 12, 14, 16 and 18 min.

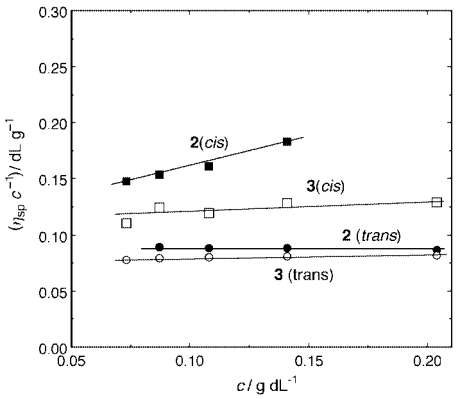

Fig. 2 Viscosity of **2**(*trans*) and **3**(*trans*) in DMSO at 25 °C before and after irradiation with UV light (245 nm).

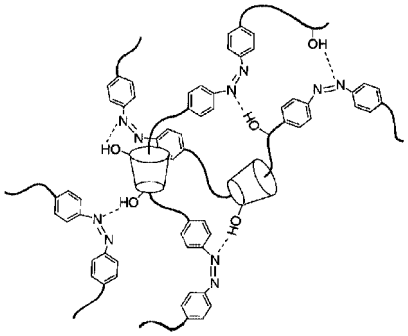
of significant intermolecular interactions between **2**(*cis*) molecules assisted by CD, which may effect the *cis* to *trans* isomerization of the azobenzene group. Chart 1 depicts a



schematic drawing of intermolecular interactions between the pseudopolyrotaxane molecules caused by N···H–O hydrogen bonds. The *cis* azobenzene group is sterically less crowded and has a higher proton affinity than the *trans*-azobenzene groups. By forming the hydrogen bond, the cis form of azobenzene seems stabilized. Addition of large excess amounts of γ-CD to a DMSO solution of **3**(*cis*) retards the photoinduced *cis* to *trans* isomerization, but γ-CD contained in **2** (0.21 molarity of the monomer units) blocks the isomerization much more effectively. This may also be due to stabilization of the *cis*-azobenzene unit by hydrogen bonding with γ-CD. The retardation effect appears to be more effective in **2**(*cis*) which has the γ-CD unit in its own polymer chain.

The authors are grateful to Professor Takahiro Seki and Dr Shinya Morino in our laboratory for their helpful discussions. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Culture, and Sports, Japan.

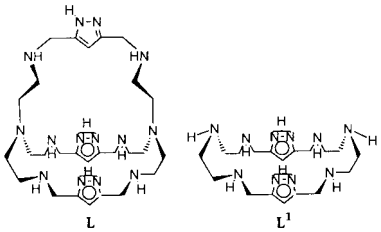
Received (in Cambridge, UK) 20th April 2000, Accepted 5th June 2000

The crystal structure of the binuclear Cu^{2+} complex $[Cu_2(H_{-1}L)](ClO_4)_3{\cdot}2H_2O$ of the cryptand L = 1,4,7,8,11,14,17,20,21,24,29,32,33,36-tetradecaazapentacyclo[12.12.12.1^{6,9}.1^{19,22},1^{31,34}]hentetraconta-6,9(41),19(40),21,31,34(39)-hexaene is presented; evidence for the formation in solution of binary L–dopamine and ternary Cu^{2+}–L–dopamine complexes is presented.

Supramolecular chemistry has developed through the preparation of sophisticated molecular receptors which are able to discriminate and induce characteristic properties in given substrates.[1] Tridimensional cryptand-like receptors with appropriate arrangements of binding sites have yielded interesting patterns in many aspects of molecular recognition like metal ion or anion coordination chemistry.[1,2] We have previously reported the synthesis, basicity and complexing properties of polyamine coronands of 1*H*-pyrazole able to form Zn^{2+} and Cu^{2+} pyrazolate salts.[3,4] Herein we report on a polyamine cryptand of related structure.[5] We advance the results of a study on its interaction with Cu^{2+} and on the formation of mixed complexes with the biologically relevant neurotransmitter dopamine.[6]

Ligand L was prepared as reported in ref. 5 by reacting 3,5-pyrazoledicarbaldehyde and tris(2-aminoethyl)amine in 3:2 molar ratio in MeOH, followed by reaction *in situ* with $NaBH_4$. Crystals of $[Cu_2(H_{-1}L)(ClO_4)_3]{\cdot}2H_2O$ **1** were prepared



L L^1

mixing methanolic solutions of free L (57 mg, 0.1 mmol) and $Cu(ClO_4)_2{\cdot}6H_2O$ (74 mg, 0.2 mmol). Evaporation of the solution gave a blue solid that after re-dissolution in a minimum amount of hot water, gave crystals of $[Cu_2(H_{-1}L)(ClO_4)_3]{\cdot}2H_2O$ **1** suitable for X-ray diffraction analysis.† The crystal structure of **1** consists of $[Cu_2(H_{-1}L)]^{3+}$ cations, ClO_4^- anions and water molecules. The coordination geometry around each Cu^{2+} is square pyramidal, the base of the pyramid being formed by two secondary nitrogens of the bridge and two nitrogen atoms of two different pyrazolate moieties which act as exobidentate ligands. The axial positions are occupied by the bridgehead nitrogen atoms, with distortion being more pronounced in one of the two sites [Cu(1)–N(1) 2.29(2) Å, Cu(2)–N(6) 2.403(9) Å]. The Cu^{2+}–L distances involving the sp^2 pyrazolate nitrogen atoms [Cu(1)–N(3) 1.90(1) Å, Cu(1)–N(9) 1.93(1) Å, Cu(2)–N(4) 1.92(1) Å, Cu(2)–N(8) 1.91(1) Å] are much shorter than those of the secondary nitrogen atoms [Cu(1)–N(2) 2.11(1) Å, Cu(1)–N(10) 2.06(1) Å, Cu(2)–N(5) 2.08(1) Å, Cu(2)–N(7) 2.11(2) Å]. The Cu(1)···Cu(2) distance is 3.960(3) Å. Similar coordination features were observed in the crystal structure of the binuclear complex $[Cu_2(H_{-2}L^1)](ClO_4)_2$, in which L^1 is the coronand ligand that constitutes the base of cryptand L,[3] and in several crystal structures of pyrazole containing ligands.[7] Interestingly, we have observed that Cu^{2+} leads to the ready deprotonation of the two pyrazole fragments involved in the coordination, without requiring any addition of base (*vide infra*). However, the pyrazole in the non-coordinating bridge of L (see Fig. 1) does not deprotonate, and lies to one side of the macrocyclic cavity. One of the nitrogen atoms of the aliphatic chains is protonated and hydrogen bonded to a water molecule [N(11)···O(1) 2.79(2) Å] placed at one side of the macrocyclic cavity and further connected to the sp^2 nitrogen of the pyrazole group through an additional hydrogen bond [N(12)···O(1) 3.12(2) Å]. The distances of the water molecule to the non-protonated nitrogen atom of the bridge and to the other pyrazole nitrogen are much longer (5.38 and 3.79 Å, respectively). The other water molecule, which is located completely outside of the cavity, is hydrogen bonded to N(10) [N(10)···O(2) 2.98(2) Å].

The coordination arrangement keeps both Cu^{2+} metal ions close to one face of the cage [the elevation of the Cu atoms over the mean plane defined by the nitrogen donors of the base of the square pyramid are 0.142(7) and 0.272(7) Å for Cu(1) and

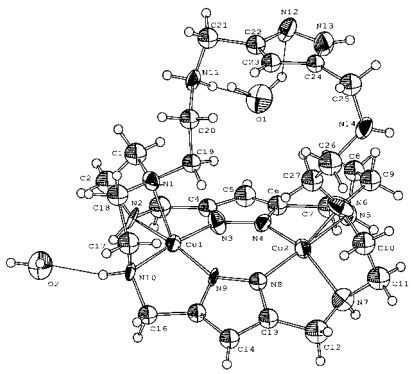


Fig. 1 ORTEP drawing of the $[Cu_2(H_{-1}L)]^{3+}$ complex cation also showing the hydrogen bonds to the water molecules. Selected distances (Å) and angles (°): Cu(1)–N(3) 1.90(1), Cu(1)–N(9) 1.93(1), Cu(1)–N(10) 2.06(1), Cu(1)–N(2) 2.11(1), Cu(1)–N(1) 2.29(2), Cu(1)–Cu(2) 3.96(3), Cu(2)–N(8) 1.91(1), Cu(2)–N(4) 1.92(1), Cu(2)–N(5) 2.08(1), Cu(2)–N(7) 2.11(2), Cu(2)–N(6) 2.403(9), O(1)–N(11) 2.79(2), O(1)–N(12) 3.12(3), O(2)–N(10) 2.98(2); N(10)–Cu(1)–N(2) 103.7(5), N(2)–Cu(1)–N(3) 81.4(6), N(3)–Cu(1)–N(9) 94.7(6), N(9)–Cu(1)–N(10) 79.6(6), N(1)–Cu(1)–N(2) 82.0(5), N(10)–Cu(1)–N(1) 81.4(5), N(3)–Cu(1)–N(1) 102.9(6), N(9)–Cu(1)–N(1) 111.3(5), N(8)–Cu(2)–N(4) 94.6(5), N(4)–Cu(2)–N(5) 80.2(6), N(5)–Cu(2)–N(7) 101.4(7), N(8)–Cu(2)–N(7) 81.4(6), N(4)–Cu(2)–N(6) 123.7(6), N(5)–Cu(2)–N(6) 81.1(4), N(7)–Cu(2)–N(6) 81.7(5), N(8)–Cu(2)–N(6) 105.6(5).

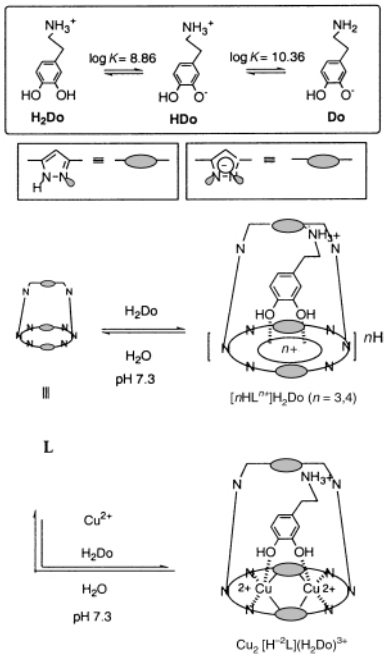

Scheme 1

Cu(2), respectively] leaving enough free room within the cavity to allow the encapsulation of further substrates as exogenous ligands. Owing to the biological relevance that ternary Cu^{2+}–dopamine complexes have in enzyme mimicking and neurotransmitter regulation, we have preliminarily studied this system.

pH-Metric analysis shows that free L displays up to six protonation steps in the pH range 2.5–10.5 with pK_a values in the range 9.5–5.2.[8] This makes this compound highly charged in solution at physiological pH and a promising receptor for encapsulating anionic or polar substrates.

The cryptand heterocyclophane L displays high affinity for Cu^{2+} forming in aqueous solution very stable binuclear complexes of stoichiometries $[Cu_2L]^{4+}$, $[Cu_2H_{-1}L]^{3+}$ and $[Cu_2H_{-2}L]^{2+}$,[9] at a molar ratio Cu^{2+}:L = 2:1, which are the only species over a wide pH range ($[Cu_2L]^{4+}$ from pH 3 to 5, $[Cu_2H_{-1}L]^{3+}$ from pH 5.5 to 8 and $[Cu_2H_{-2}L]^{2+}$ above pH 8.5). Taking into account that in the crystal structure of **1**, the two pyrazole groups involved in the coordination of Cu^{2+} are deprotonated and that the constant of the equilibrium $[Cu_2L]^{4+}$ = $[Cu_2H_{-1}L]^{3+}$ + H^+ is log K = −5.37, Cu^{2+} coordination to L induces a decrease of more than six pH units in the protonation constant of pyrazole with respect to the free heterocycle. A similar behaviour has also been observed in the system Cu^{2+}–L[1],[10] and in a related system containing two 1,4,7-triazacyclononane units linked by a 3,5-pyrazole bridge.[7]

The interaction of L with dopamine (Do) has been analysed in the pH range 2.5–9.0 with 1:1 dopamine:receptor species being detected with degrees of protonation varying between 7 and 1. Around physiological pH, the magnitude of the interaction reaches values close to 5 logarithm units (K_{app} = $\Sigma[DoH_{i+j}\cdot L]/\Sigma[H_jDo]\Sigma[H_iL]$ = 10^5:[11] therefore, the neurotransmitter forms a remarkably stable complex with the receptor. UV studies confirm this interaction. UV spectra of solutions containing a constant amount of L and variable amounts of dopamine at pH 7 show an increase in absorptivity and eventual saturation of an absorption band centred at 214 nm. Fitting of the absorbance *vs.* [Do]/[L] plots confirms the 1.1 Do:L stoichiometry and allows an estimation of an affinity constant of *ca.* 5 logarithmic units, in agreement with the pH-metric studies. Molecular models suggest the possibility of a partial inclusion of the dopamine molecule in the cavity of the receptor and its stabilisation by a variety of intermolecular forces such as electrostatic and/or hydrogen bonding interactions (Scheme 1).

Finally, we comment on the formation of ternary complexes Cu^{2+}–L-dopamine of stoichiometry $[Cu_2H_2LDo]^{5+}$, $[Cu_2HLDo]^{4+}$, $[Cu_2LDo]^{3+}$ and $[Cu_2H_{-1}LDo]^{3+}$ which, taking into account the pH range of their formation, can be formulated formally as deriving from the following equilibria: H_2Do^+ + $[Cu_2L]^{4+}$ = $[Cu_2H_2LDo]^{5+}$, log K = 3.7; H_2Do^+ + $[Cu_2H_{-1}L]^{3+}$ = $[Cu_2HLDo]^{4+}$, log K = 4.0; H_2Do^+ + $[Cu_2H_{-2}L]^{2+}$ = $[Cu_2LDo]^{3+}$, log K = 3.7; HDo + $[Cu_2H_{-2}L]^{2+}$ = $[Cu_2H_{-1}LDo]^{2+}$, log K = 4.0.

The formation of the ternary complexes implies breaking of the Cu–N axial bonds and their replacement by strong Cu–phenolate bonds[12] as suggested by modelling of the system. An interaction of the ammonium group of dopamine with the sp^2 bond of the pyrazole moiety might also contribute to the final stabilisation of the complexes (Scheme 1).

The observed recognition patterns and crystal structure suggest interesting developments of this receptor in the fields of medicinal chemistry and enzyme mimicking.

8 Potentiometry was carried out in 0.15 mol dm^{-3} NaCl at 298.1 K using concentrations of L, Cu^{2+} and dopamine in the range 1–3 × 10^{-3} mol dm^{-3}. The program HYPERQUAD (A. Sabatini, A. Vacca and P. Gans, *Coord. Chem. Rev.*, 1992, **120**, 389) was used to derive the values of the protonation and stability constants. Protonation constants of L under the same experimental conditions: log $K_{HL/H.L}$ = 9.54(2), log $K_{H_2L/HL.H}$ = 8.71(1); log $K_{H_3L/H_2L.H}$ = 7.72(2); log $K_{H_4L/H_3L.H}$ = 6.55(3), log $K_{H_5L/H_4L.H}$ = 6.51(3), log $K_{H_6L/H_5L.H}$ = 5.23(3). Protonation constants of dopamine (Do, see Scheme 1): log $K_{HDo/Do.H}$ = 10.36(1), log $K_{H_2Do/HDo.H}$ = 8.86(1).

9 At a molar ratio of 2:1 the species $[Cu_2HL]^{5+}$, $[Cu_2L]^{4+}$, $[Cu_2H_{-1}L]^{3+}$ and $[Cu_2H_{-2}L]^{2+}$ are found in solution with stability constants: $2Cu^{2+}$ + H^+ + L = $[Cu_2HL]^{5+}$, log K = 38.73(7); $2Cu^{2+}$ + L = $[Cu_2L]^{4+}$, log K = 36.61(3), $2Cu^{2+}$ + L = $[Cu_2H_{-1}L]^{3+}$ + H^+, log K = 31.39(3); $2Cu^{2+}$ + L = $[Cu_2H_{-2}L]^{2+}$ + $2H^+$, log K = 24.24(4).

10 P. Navarro and E. García-España, work in preparation.

11 Potentiometric titrations indicate that between pH 3 and 9.5 the formation of the species H_jDoL with j = 1–7: Do + H^+ + L = $HDoL^+$, log K = 16.19(2); Do + $2H^+$ + L = H_2DoL^{2+}, log K = 25.72(2); Do + $3H^+$ + L = H_3DoL^{2+}, log K = 34.57(2); Do + $4H^+$ + L = H_4DoL^{4+}, log K = 43.04(2); Do + $5H^+$ + L = H_5DoL^{2+}, log K = 50.39(2); Do + $6H^+$ + L = H_6DoL^{2+}, log K = 57.08(2); Do + $7H^+$ + L = H_7DoL^{7+}, log K = 63.40(2). Conditional constants defined as K_{app} = $\Sigma[DoH_{i+j}L]/\Sigma[H_jDo]\Sigma[H_iL]$ range from 2 to 5.5 logarithmic units in the pH range studied.

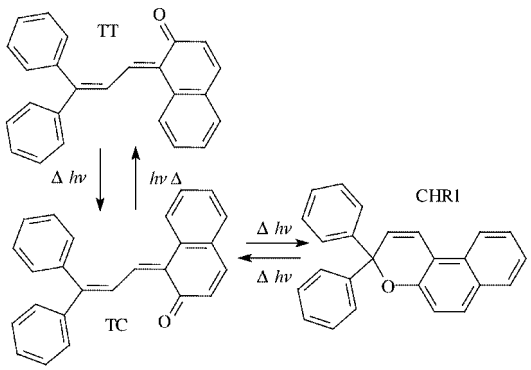
Of the four chromene compounds; 3,3-diphenyl-5,10a-dihydro-3*H*-benzo[*f*]chromene (CHR1), 6-methoxy-2,2-diphenyl-2*H*-benzo[*h*]chromene (CHR2), 2,2-diphenyl-2*H*-benzo[*h*]chromene (CHR3) and 6,7-dimethoxy-2,2-diphenyl-2*H*-chromene (CHR4), CHR2–4 exhibited crystalline state photochromism.

Solution and dispersed state photochromism are well known phenomena, however there are relatively fewer examples of crystalline state photochromism.[1–5] Photochromic crystals are especially unusual, although not unknown,[3–5] when the photochromism involves large structural changes such as *cis–trans* isomerisation. This is due to the small free volume in a crystal lattice. In the case of spiropyrans and spirooxazines such crystalline photochromism, involving a minimum of two isomerisation steps, has been reported using femtosecond laser pulses where there is a laser fluence threshold that must be reached before any colouration reaction is observed.[5] Prior to our work, photochromic chromene (CHR) crystals, having a similar photochemistry to the spirooxazines, had not been reported.[6] The CHR reaction mechanism in solution[7,8] is shown in Scheme 1 exemplified for CHR1. As can be seen the reaction is complex involving several isomerisation steps.

CHR1–4 were synthesised by Great Lakes Technology using the standard synthetic routes.[6,9] UV/VIS spectra were measured using a Hewlett Packard HP8452 diode array spectrophotometer in reflectance mode. Macroscopic UV irradiation was carried out using a nitrogen laser at 337 nm (10 nanosecond pulse duration, repetition rate 100 Hz, 0.1 mW pulse^{-1} cm^{-2}) or a 100 W Hg lamp emitting in the visible and UV. HPLC was used to assign CHR2 photochromic reaction products with a reverse phase C-18 column on an HP 1090 chromatograph with a 1 : 9 ratio of water to acetonitrile at a flow rate of 1 mL min^{-1}



Scheme 1

† Microscopic colour images showing photo-colouration and bleaching are available as electronic supplementary information (ESI). Microscopic images were obtained with a Nikon Eclipse E800 Fluorescence microscope using the microscope's Hg lamp excitation source to photo-convert the crystals. See http://www.rsc.org/suppdata/cc/b0/b003480k/

with diode array UV/VIS detection. X-Ray diffraction data[10] were collected before and after 1 h of irradiation of a single CHR2 crystal (0.5 × 0.5 × 0.4 mm) using the nitrogen laser.

After UV irradiation (nitrogen laser or CW source) pale yellow CHR2 crystals turned deep orange. The orange colour was partially photobleachable with visible light, but did not thermally bleach. This is shown in Fig. 1. The non-permanent component of the CHR2 colouration could be cycled between photocoloured and photobleached states.

For CHR2 it is possible to isolate the TT isomer from the TC isomer since it can crystallise in a mixed lattice with the CHR2 form.[12] From solutions of such mixed crystals HPLC retention times were established for the CHR2-form (5.45 min) and the TT isomer (6.55 min). From HPLC on mixtures of the TT, TC and CHR2-form, produced photochemically in acetonitrile, the TC isomer retention time (8.31 min) was also found. The λ_{max} of the TT isomer was blue shifted by only 10 nm with respect to that of the TC isomer. Retention times from HPLC carried out on dissolved photocoloured crystals (nitrogen laser 1 h) showed that the crystals contained a mixture of mainly the CHR2 form, but with TT and TC isomers also present. The integrated absorption/elution time profiles of TT and TC were approximately equal, implying similar fractional conversion to TT and TC if we assume similar extinction coefficients. The overall fraction of photoconversion to TT and TC suggested from this HPLC and separately determined by ^{1}H NMR was < 1% even after prolonged irradiation (nitrogen laser 1 h). Also from X-ray analysis of a single CHR2 crystal we found no detectable increase in the bulk lattice disorder even after prolonged irradiation (nitrogen laser 1 h). We must therefore conclude that under these conditions photoisomerisation is probably not a feature of every lattice site, although this may be because conversion is concentrated at the surfaces by consideration of Beers Law.

Using HPLC on photoconverted and subsequently photobleached CHR2 we found that photobleaching reduces the

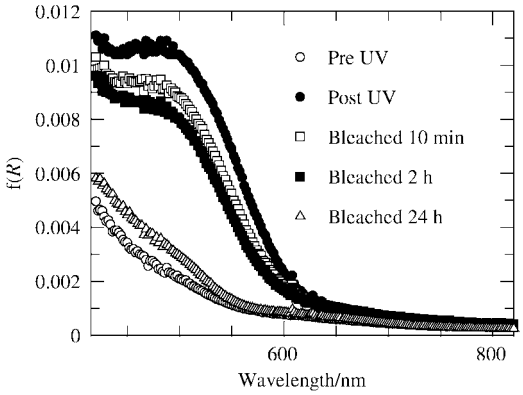

Fig. 3 Diffuse reflectance spectra (Kubelka Munk)[11] of CHR4 crystals before and after UV irradiation and during and after photobleaching.

proportion of the TC isomer relative to the TT form. The TT isomer is persistent both photochemically and thermally. Conversely CHR3 and CHR4 crystals photocoloured with UV light could be almost fully photo and thermally bleached back to the CHR-form. This is shown in Figs. 2 and 3.

All of the compounds CHR2–4 could be photoconverted with relatively weak CW UV irradiation sources. For example, photocolouration was even observed after irradiating the samples with the excitation beam from a standard fluorimeter (Shimadzu RF5300PPC 350 nm). From this we conclude that this colouration reaction is activated by a single photon non-cooperative (no simultaneous excitation of adjacent sites required[5]) solid-state reaction. We also note that CHR1 did not exhibit any photochromism in its the crystalline state.

The synthesis of (−)-calicheamicinone (2), the carbohydrates 88, 101, 111, 119 and 120, and the hexasubstituted benzene 139, is described; these compounds formally represent the subunits of the antitumor antibiotic calicheamicin γ_1^I (1).

Professor Derrick Clive was born in London and received his B.Sc. and Ph.D. (D. H. R. Barton and J. E. Baldwin) from Imperial College.

Dr Yong Tao was born in Ningbo and educated at Zhejiang Medical University (B. Pharm. Sci.) and the Shanghai Institute of Materia Medica, Chinese Academy of Sciences (Ph.D., Dr Jiasen Liu). He is now a Senior Research Scientist at Pfizer (Groton, Conn.).

Dr Yunxin Bo comes from Jiangsu and was educated at Suzhou University (B.Sc.) and the Shanghai Institute of Materia Medica (Ph.D., Professor Donglu Bai). He is a Research Scientist at Amgen Inc. (California).

Professor Yong-Zhou Hu was born in Zhejiang Province and obtained his B.Sc. at the Zhejiang Medical University and his Ph.D. (Professor Donglu Bai) at the Shanghai Institute of Materia Medica. He is Professor and Dean in the School of Pharmaceutical Science, Zhejiang University, Hangzhou.

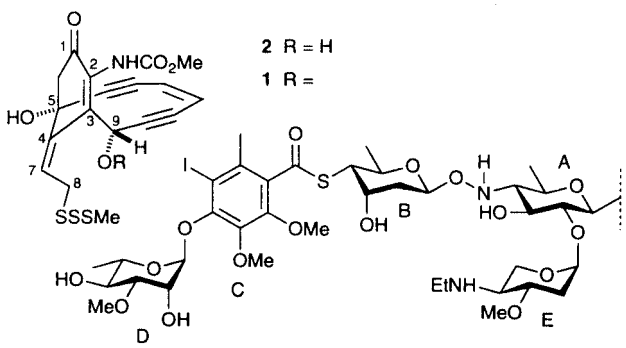
Dr Natesan Selvakumar was born in Salem (Tamil Nadu State) and studied for his B.Sc. at Periyar E.V.R. College. He obtained his Ph.D. (Professor G. S. R. Subba Rao) from the Indian Institute of Science (Bangalore), and is now a Senior Scientist at Dr Reddy's Research Foundation (Hyderabad).

Dr Shaoyi Sun is from Qingdao and was educated at Qufu Normal University (B.Sc.) and the Chinese Academy of Medical Sciences and Peking Union Medical College (Ph.D., Professor Dequan Yu). He is currently a postdoctoral fellow in Professor Clive's group..

Dr Sylvain Daigneault is from Montreal and obtained his B.Sc. at the University of Sherbrooke and Ph.D. (D. Clive) at the University of Alberta. He is a Senior Research Scientist at Ayerst Canada (Montreal).

Dr Yong-Jin Wu is from Hunan and was educated at Hunan Normal University (B.Sc.) and Memorial University of Newfoundland (Ph.D., Professor D. J. Burnell). He is a Research Scientist at Bristol–Myers–Squibb.

The antitumor antibiotic calicheamicin γ_1^I (**1**)[1] has attracted much attention as a synthetic target.[2] Two syntheses have been reported,[3] but the structure is so complicated that further synthetic work will surely provide many opportunities for new discoveries.



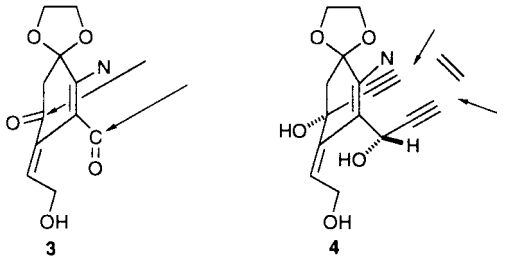
Synthesis of calicheamicin γ_1^I is a major undertaking—both chemical and financial—and a suitably cautious approach would be guided by the dominant structural characteristic that the compound is composed of several subunits—the aglycone (**2**), four carbohydrates, and a hexasubstituted benzene ring. Accordingly, synthetic work would first involve construction of each subunit, and the information thus gained might then be used in the more complex task of modifying the routes so that they can be integrated harmoniously into a composite synthesis of the whole structure. We describe here our own work[4–6] on the simpler of these tasks—synthesis of the subunits.[7,8]

Synthesis of (−)-calicheamicinone

The aglycone, (−)-calicheamicinone (**2**), presented the most difficult synthetic problem among the subunits of calicheamicin γ_1^I, because the substance is a rare structural type which had not been made before when we began our studies; in contrast, the carbohydrate segments and the aromatic unit—unusual though they are—did at least possess much in common with well-known compound classes.

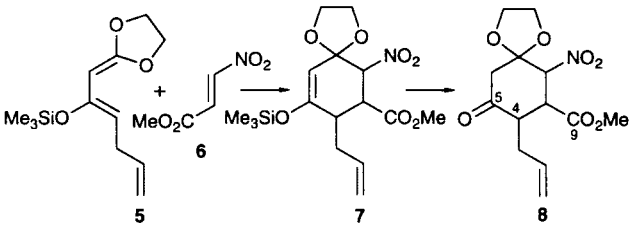
Synthetic plan

Exploratory work by the Magnus group[9] had indicated that the allylic trisulfide of **2** should be accessible from the corresponding alcohol. Further analysis of the synthetic problem showed that two very suggestive features of calicheamicinone are the tertiary and secondary acetylenic alcohols. Their presence suggested that they might be assembled by acetylide addition to a suitably protected form of the hypothetical dicarbonyl subunit **3** (see arrows). It was then obvious that the enediyne might be



added in several ways: as an intact six-carbon enediyne unit, as an acetylene and an enyne, or as two acetylenes, followed by addition of a two-carbon unit and, in the event, this last process (see **4**, arrows), was the one we eventually used.

Although the above analysis is straightforward, the proper choice of dicarbonyl compound (*cf.* **3**) required a great deal of experimental effort before a promising structure was identified. This was based on the Diels–Alder reaction summarized (without stereochemical implications) in Scheme 1.



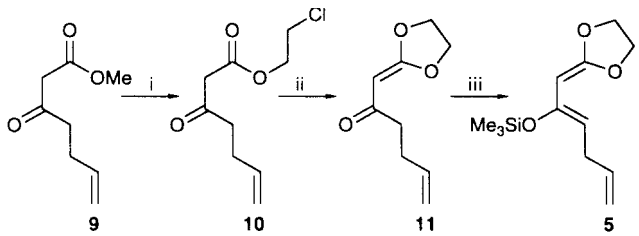
Scheme 1

Mild hydrolysis of the initial adduct **7** would be expected to afford **8**, which has many of the features of the schematic structure **3**: the carbonyl groups at C(5) and C(9) could serve as points of attachment for the acetylene units, the nitro group could eventually provide part of the carbamate, and the chain at C(4) would serve as the precursor to the allylic trisulfide. The choice of a cyclic ketal (see **8**) was based on the expectation that this form of protection would be more stable than the corresponding dimethyl ketal.

A number of ketene acetals (*cf.* **5**) had been reported[10] and an analogy for the proposed cycloaddition (*cf.* **5** + **6** → **7**) was also available.[11] On the basis of this encouraging background, we then proceeded with work along the lines of Scheme 1.

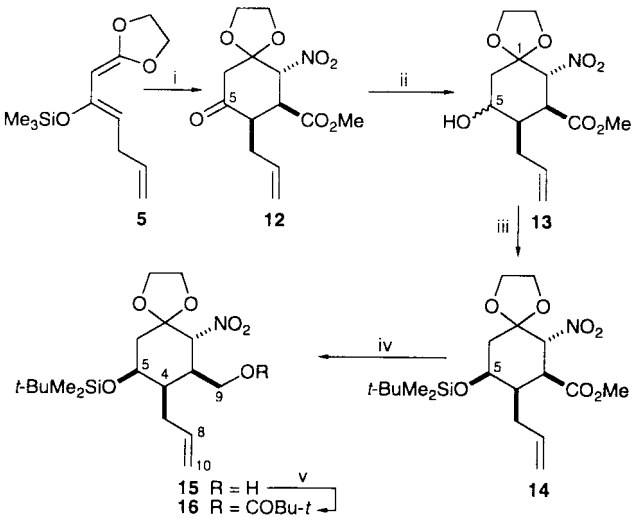
Formation of the central ring by Diels–Alder reaction

The readily available β-keto ester **9**[12] was subjected to ester exchange with 2-chloroethanol (**9** → **10**), and the resulting (2-chloroethyl) ester was converted into the required acyl ketene acetal **11** by the action of anhydrous potassium carbonate in DMF (Scheme 2).[10b] Attempts to effect the cyclization with sodium hydride were unsuccessful.



Scheme 2 *Reagents and conditions*: i, 2-chloroethanol, Ti(OPr-*i*)$_4$, 55 °C, 16 h, 75 °C, 24 h, 63%; ii, K_2CO_3, DMF, 80%; iii, $(Me_2PhSi)_2NLi$, Me_3SiCl, THF, −78 °C.

The next task was to convert the acyl ketene acetal into the *Z* silyl enol ether **5**, the *Z* geometry being preferred to facilitate the intended Diels–Alder reaction. For generating the silyl enol ether, LDA, lithium hexamethyldisilazide, and the very hindered base $(Me_2PhSi)_2NLi$ were evaluated, but only the latter produced the required geometry, which it did exclusively, and silylation *in situ* then gave **5**. This compound is not very stable but, fortunately, it can be used without purification, as even in the presence of $(Me_2PhSi)_2NH$ it reacts (Scheme 3) with the



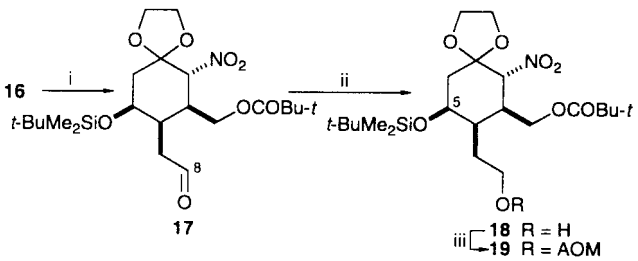
Scheme 3 *Reagents and conditions*: i, methyl (*E*)-2-nitropropenoate (**6**), THF, 0 °C, 1.5 h; aqueous NH_4Cl, 2 h, room temperature, 56% from **11**; ii, $NaBH_4$, MeOH, 0 °C, 99%; iii, *t*-$BuMe_2SiOTf$, 2,6-lutidine, CH_2Cl_2, 65% 5β epimer, 33% 5α epimer from **12**; iv, DIBAL-H, CH_2Cl_2, 99% for 5β, 99% for 5α; v, *t*-BuCOCl, DMAP, PhMe, 99% for 5β, 99% for 5α.

nitro ester **6**, and mild acidic workup affords crystalline ketone **12** in 56% yield overall from the acyl ketene acetal **11**.

Keto ester **12** is a key intermediate, and its structure was confirmed by X-ray analysis. From **12**, the first task was to protect the C(5) carbonyl. This was best done by simple reduction to give, in the event, a 2 : 1 mixture of alcohols, which were then silylated and separated (**12** → **13** → **14**). Although efficient *and* stereoselective ketone reduction was not possible, both of the C(5) epimers could be used; they were each subjected to the same reactions and, after several steps, both epimeric series converge to a single compound. These circumstances make the whole process quite efficient.

Next, the ester group in **14** (and in its 5α epimer) was reduced and the resulting alcohol protected by pivaloylation (**14** → **15** → **16**). At that point, with the C(5) and C(9) oxygen functions protected, it was appropriate to remove C(10) and introduce an oxygen at C(8), as these operations would adjust the side chain to the correct length and appropriate functionality.

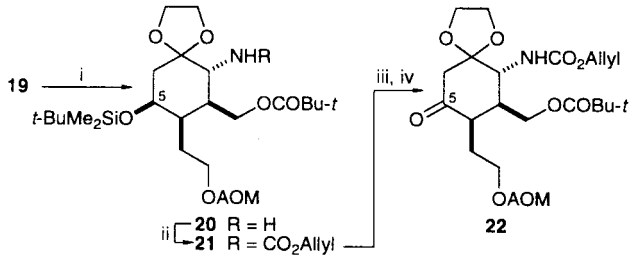
Cleavage of the C(8)-C(10) double bond under classical conditions (Scheme 4), with osmium tetraoxide and sodium periodate, and reduction of the resulting aldehyde **17** gave the



Scheme 4 AOM = $CH_2OC_6H_4OMe$-*p*. *Reagents and conditions*: i, OsO_4, $NaIO_4$, CCl_4, H_2O, *t*-BuOH, 73% for 5β, 77% for 5α; ii, $NaBH_4$, MeOH, 96% for 5β, 92% for 5α; iii, *p*-$MeOC_6H_4OCH_2Cl$, *i*-Pr_2NEt, DMAP, PhMe, 91% for 5β, 89% for 5α.

expected alcohol; this was protected with *p*-anisyloxymethyl chloride (**16** → **17** → **18** → **19**). Each of these steps was efficient in both the 5β series shown in Scheme 4, and in the corresponding 5α series.

With **19** and its 5α epimer in hand, the time had come to reduce the nitro group. Reduction of aliphatic nitro compounds is not as easy as in the aromatic series, but we found that the reagent generated by sonication of nickel(II) chloride hexahydrate and sodium borohydride[13] works very well (Scheme 5,



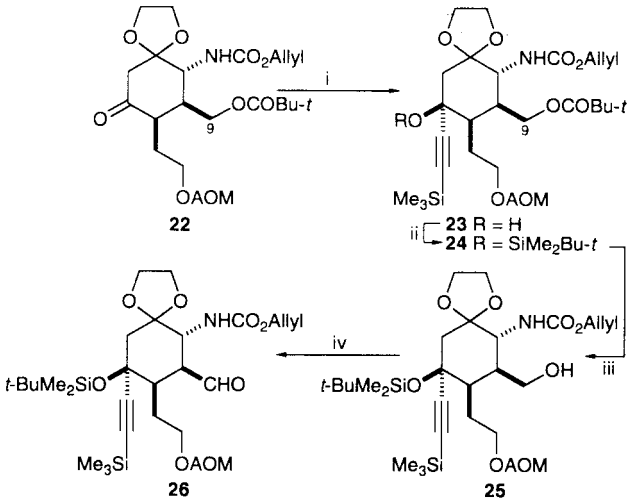
Scheme 5 AOM = $CH_2OC_6H_4OMe$-*p*. *Reagents and conditions*: i, $NaBH_4$, $NiCl_2.6H_2O$, MeOH, sonication, 95% for 5β, 95% for 5α; ii, allyl chloroformate, pyridine, THF, 82% for 5β, 82% for 5α; iii, Bu_4NF, THF, 95% for 5β, 96% for 5α; iv, CrO_3, pyridine, CH_2Cl_2, 95% for 5β, 90% for 5α.

19 → **20**) for both C(5) epimers. In each case, the resulting amine was protected as its allyl carbamate and, finally, the C(5) oxygen function was deprotected and oxidized by the Collins procedure (**21** → **22**).

At the stage of the resulting ketone (**22**) both of the C(5) epimers converge to the same product, and in both series identical reactions have been used, with almost identical results.

Attachment of two acetylene units

Ketone **22** gave a complex mixture with lithium trimethylsilylacetylide—a result that was very worrying—but we quickly found that it reacts cleanly (91%) with the corresponding cerium salt[14] to afford alcohol **23** (Scheme 6), in which the

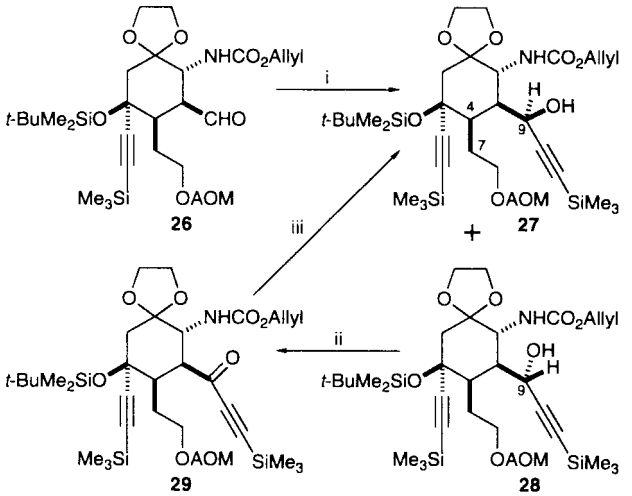


Scheme 6 AOM = $CH_2OC_6H_4OMe$-*p*. *Reagents and conditions*: i, $Me_3SiC{\equiv}CLi$, $CeCl_3$, THF, −78 °C, 91%; ii, *t*-$BuMe_2SiOTf$, 2,6-lutidine, CH_2Cl_2, 97%; iii, DIBAL-H, CH_2Cl_2, 95%; iv, CrO_3, pyridine, CH_2Cl_2, 90%.

acetylide has added from the same face as the nitrogen substituent. The hydroxy group was then protected by silylation (**23** → **24**), and preparations could now be made to introduce the second acetylene.

To that end, the pivaloyl group at C(9) was removed by the action of DIBAL-H, and the resulting alcohol was oxidized by the Collins procedure (**24** → **25** → **26**), with all the steps proceeding in high yield.

Treatment of aldehyde **26** with the cerium salt of trimethylsilylacetylene at −90 °C gave a 7:2 separable mixture of the required alcohol **27** and its C(9) epimer **28** (Scheme 7).

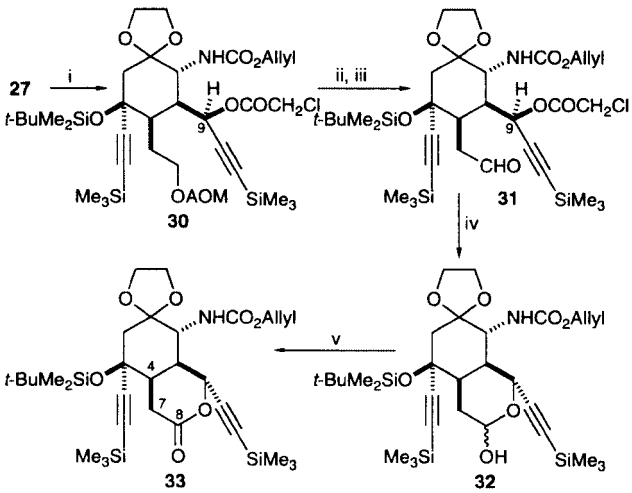


Scheme 7 AOM = $CH_2OC_6H_4OMe$-*p*. *Reagents and conditions*: i, $Me_3SiC{\equiv}CLi$, $CeCl_3$, THF, −90 °C, 79% for **27**, 16% for **28**; ii, PCC, 4 Å molecular sieves, CH_2Cl_2, 93%; iii, $NaBH_4$, MeOH, 0 °C, 88%

Attempts to improve the stereoselectivity by running the reaction at an even lower temperature, or by use of the ytterbium salt[15] of the acetylene were not successful. Fortunately, oxidation of the undesired isomer **28** gave a ketone that was reduced stereoselectively (11.6:1) to **27**, by sodium borohydride; thus, the overall transformation of **26** into **27** is quite efficient (92%), but required several experiments.

Introduction of the C(4)–C(7) double bond

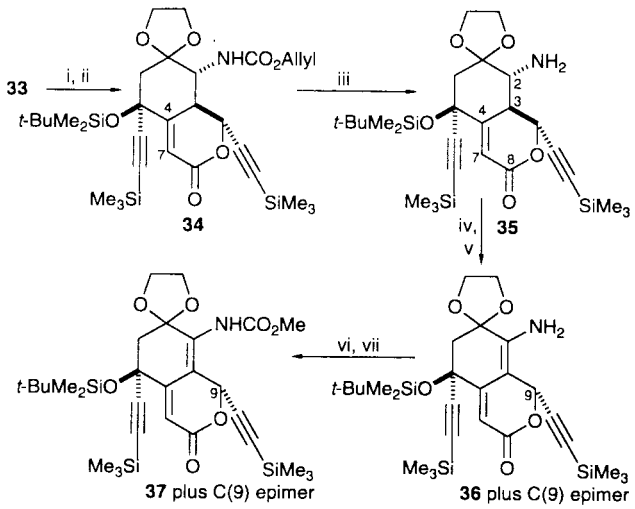
With both acetylenic units in place, the next task was to incorporate the two-carbon chain at C(4) into a ring, so as to be able to generate the C(4)-C(7) double bond with the correct geometry (see **2**). Ring formation was accomplished by the straightforward operations summarized in Scheme 8.



Scheme 8 AOM = $CH_2OC_6H_4OMe$-*p*. *Reagents and conditions*: i, $(ClCH_2CO)_2O$, pyridine, 99%; ii, $(NH_4)_2Ce(NO_3)_6$, pyridine, MeOH, H_2O, 89%; iii, CrO_3, pyridine, CH_2Cl_2, 91%; iv, NH_3(aq), MeOH, 0 °C; v, CrO_3, pyridine, CH_2Cl_2, 92% from **31**.

Protection of the C(9) hydroxy as a chloroacetate (**27** → **30**), followed by removal of the *p*-anisyloxymethyl group by exposure of the chloroacetate to ceric ammonium nitrate, gave an alcohol that was oxidized with the Collins reagent. Treatment of the resulting aldehyde **31** with dilute aqueous ammonium hydroxide released the C(9) hydroxy group, and this closed spontaneously onto the aldehyde group, so as to afford a mixture of lactols **32**. Another Collins oxidation then gave lactone **33**.

At this point the C(4)–C(8) chain is restrained within a ring so that the C(4)–C(7) double bond could be introduced (see Scheme 9) with the required *E* geometry. Phenylselenenylation



Scheme 9 *Reagents and conditions*: i, LDA, THF, PhSeBr, −78 °C; ii, dimethyldioxirane, −42 °C, 67% from **33**; iii, $(Ph_3P)_4Pd$, dimedone, THF, 80%; iv, *t*-BuOCl, Et_2O–THF; v, DABCO, PhMe; vi, $Cl_3COCO_2CCl_3$, pyridine, CH_2Cl_2; vii, MeOH, 78% (as an 8:1 isomer mixture) from **35**.

at C(7) and oxidation with dimethyldioxirane—an excellent reagent for use in selenoxide elimination—gave the desaturated lactone **34**. The intermediate phenyl selenide is not very stable and was not characterized, but the fact that it undergoes the selenoxide fragmentation indicates that the phenylseleno group must be on the same face as the C(4) hydrogen. We next removed the nitrogen protecting group by the action of tetrakis(triphenylphosphine)palladium(0) in the presence of dimedone,[16] the latter nucleophile being the best of several we tried. The resulting amine (**35**) was crystalline, and X-ray analysis confirmed the structure.

Introduction of the C(2)–C(3) double bond

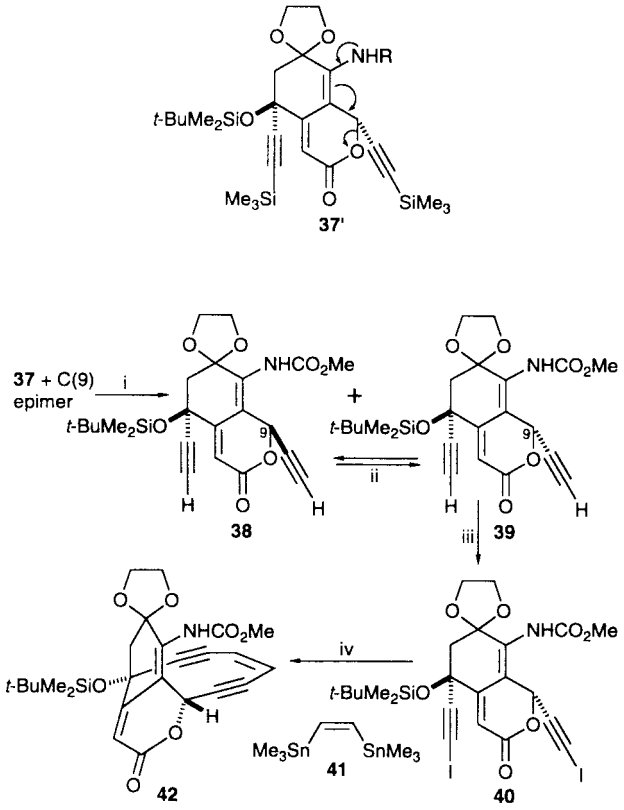
Introduction of the C(2)–C(3) double bond required a great deal of exploratory work before we identified the structural features that would allow efficient desaturation. This exploratory work guided many details of the synthetic plan discussed so far and directed us to the route leading ultimately to **35**, which has the two features we identified as important: the presence of a C(4)–C(7) double bond and incorporation of C(7) and C(8) into a ring.

Freshly prepared *t*-butyl hypochlorite converted **35** into its *N*-chloro derivative, and treatment with an excess of DABCO generated the corresponding imine, which underwent tautomerization to afford the fully conjugated enamide **36** and its C(9) epimer in an 8:1 ratio. The mixture of enamides is not very stable, and it was necessary to convert them promptly into the corresponding isocyanates, by treatment with triphosgene; the isocyanates, in turn, were immediately quenched with methanol. These operations gave carbamate **37** as an 8:1 mixture of C(9) epimers, the predominant one being that shown in Scheme 9. Neither of the epimer mixtures—enamide or carbamate—could be separated, but separation and isomerization of the *anti* isomer into the desired *syn* compound was easily achieved after the next step.

We assume that isomerization occurs by ring opening (see arrows in **37′**), followed by reclosure.

Formation of the enediyne ring

Our plan for closing the enediyne ring called for use of a double Stille reaction, and so we had first to remove the acetylenic silicon groups from **37**. Treatment with tetrabutylammonium fluoride did indeed give the corresponding terminal acetylene (Scheme 10), but under the reaction conditions further epimerization occurred at C(9). Fortunately, the epimeric acetylenes **38** and **39** were very easily separated, and the *anti* bisacetylene



Scheme 10 *Reagents and conditions*: i, Bu_4NF, THF, 39% for **38**, 46% for **39**; ii, Bu_4NOAc, 100% of a 4:6 mixture of **38** and **39**; iii, NIS, $AgNO_3$, acetone, 89%; iv, **41**, $(Ph_3P)_4Pd$, DMF, 60 °C, 72%.

could be converted in 100% yield into a 4:6 mixture in favor of **39**. After one recycling the yield of **39** was 69% from the mixture of **37** and its C(9) epimer. X-Ray analysis of the desired *syn* bisacetylene showed that the distance between the terminal acetylenic carbons is 4.154 ± 0.005 Å.

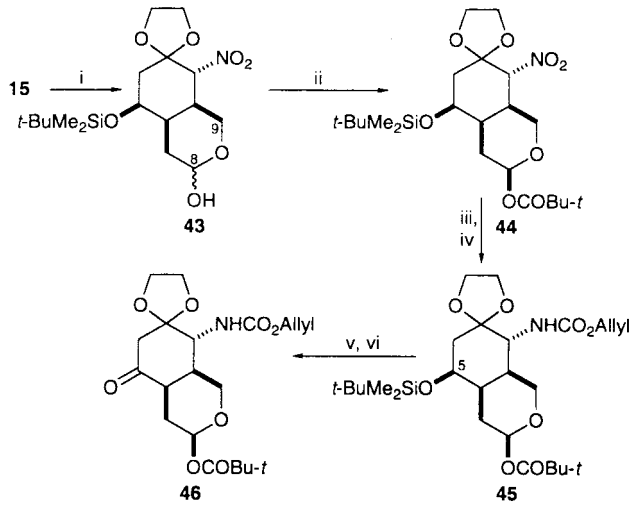
The acetylenic hydrogens were next replaced by iodine (**39** → **40**), using *N*-iodosuccinimide in the presence of silver nitrate.[17] Finally, a double Stille coupling of the diiodide with (*Z*)-1,2-bis(trimethylstannyl)ethene (**41**) gave the cyclic enediyne **42** in 72% yield, bringing the synthesis to a point where we needed to build up the allylic trisulfide and remove any remaining protecting groups.

Second route to the *syn* bisacetylene 39

During our development of the above route to **39** we encountered so many unexpected difficulties that we took the precaution of seeking another route to the same compound; in the event, this additional work had unusual and beneficial consequences.

The second route begins with the same Diels–Alder adduct used earlier and, as before, this was converted into alcohol **15** (see Scheme 3) and its C(5) epimer. In the first route the C(9) hydroxy group was protected before cleavage of the pendant double bond, but in the present case (Scheme 11), the double bond was cleaved without hydroxyl group protection and, as expected, the lactols **43** were formed. These were then protected by treatment with pivaloyl chloride. During the reaction epimerization of **43** occurs at C(8), so as to give only the product **44**, with the pivaloyl group equatorial. The nitro group was then reduced in high yield, again using the sodium borohydride–nickel chloride combination, and the resulting amine was protected as its allyl carbamate (**44** → **45**).

Finally, the C(5) oxygen was desilylated and oxidized, just as before (**45** → **46**). An identical set of reactions was done in the 5α series, and, at the stage of ketone **46**, both series converge to the same product, just as in the earlier route. Although both C(5) epimers were processed individually, the same reaction condi-

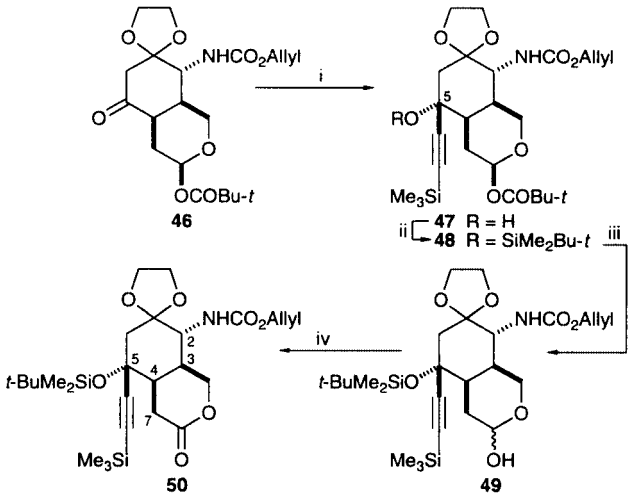


Scheme 11 *Reagents and conditions*: i, OsO_4, $NaIO_4$, CCl_4, H_2O, *t*-BuOH, 98% for 5α, 98% for 5β; ii, *t*-BuCOCl, pyridine, CH_2Cl_2, 96% for 5α, 96% for 5β; iii, $NaBH_4$, $NiCl_2{\cdot}6H_2O$, MeOH, sonication, 95% for 5β, 91% for 5α; iv, allyl chloroformate, pyridine, THF, 94% for 5β, 93% for 5α; v, Bu_4NF, THF, 97% for 5β, 95% for 5α; vi, PCC, 4 Å molecular sieves, CH_2Cl_2, 91% for 5β, 92% for 5α.

tions were used for both, and in each step the corresponding yields were almost identical.

Second route—introduction of the first acetylene

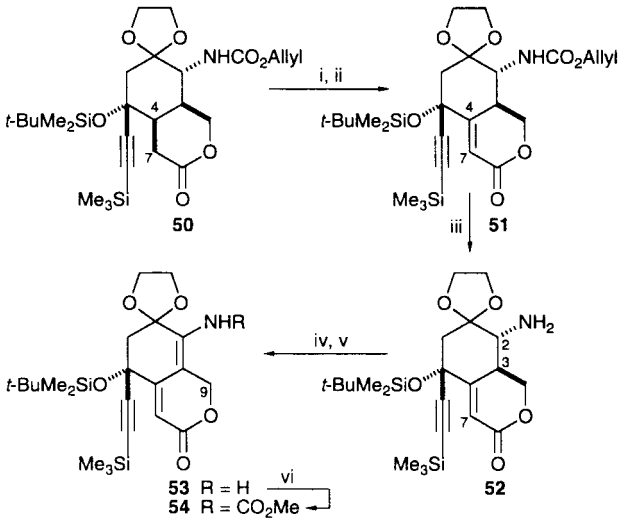
For introducing the first acetylene unit we again used the cerium salt of trimethylsilylacetylene and obtained, in high yield, alcohol **47** (Scheme 12), in which the acetylide had entered *anti*



Scheme 12 *Reagents and conditions*: i, $Me_3SiC{\equiv}CLi$, $CeCl_3$, THF, −78 °C, 91%; ii, *t*-$BuMe_2SiOTf$, 2,6-lutidine, CH_2Cl_2, 93%; iii, DIBAL-H, CH_2Cl_2, 96%; iv, CrO_3, pyridine, CH_2Cl_2, 97%.

to the nitrogen, in contrast to the result in the first route (*cf.* **22** → **23**, Scheme 6). The stereochemical assignment in the present case was made by X-ray analysis. The alcohol was protected by silylation (**47** → **48**), and the pivaloyl group was then removed by treatment with DIBAL-H. Oxidation of the resulting lactols took the route to a point (**50**) where we had again to introduce double bonds at C(4)–C(7) and at C(2)–C(3). Both of these operations were done by the methods that had worked well in the first route.

The C(4)–C(7) double bond was introduced by phenylselenenylation and dimethyldioxirane oxidation of the intermediate selenide (Scheme 13, **50** → **51**), for which we again assume on mechanistic grounds that the phenylseleno group is *syn* to the C(4) hydrogen. Removal of the allyloxycarbonyl group (**51** → **52**) by the action of a palladium catalyst in the

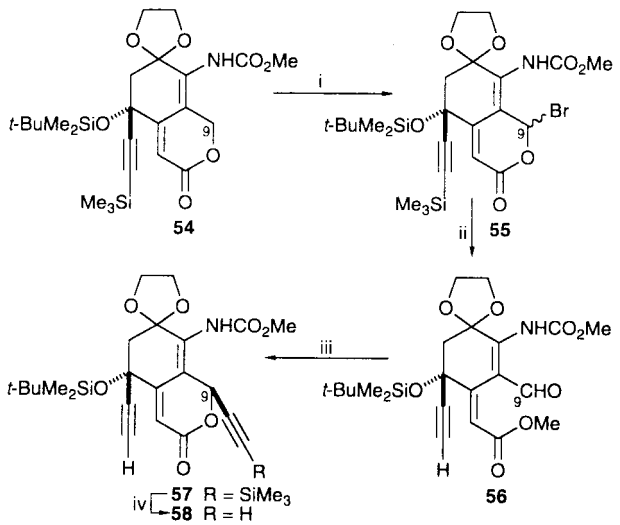


Scheme 13 *Reagents and conditions*: i, LDA, THF, PhSeBr, −78 °C; ii, dimethyldioxirane, 85%; iii, $(Ph_3P)_4Pd$, dimedone, THF, 93%; iv, *t*-BuOCl, Et_2O–THF; v, DBU, PhMe, 81% from **52**; vi, $Cl_3COCO_2CCl_3$, pyridine, CH_2Cl_2, then MeOH, 91%.

presence of dimedone liberated the free amine and, once again, that was chlorinated with *tert*-butyl hypochlorite. Exposure to a hindered base—in this case DBU—gave an imine, which immediately isomerized to the fully conjugated enamide **53**. This was converted into its isocyanate, which was quenched with methanol, thereby generating the required methyl carbamate **54**.

Second route—introduction of the second acetylene

Introduction of the second acetylene—that at C(9) in lactone **54**—required, of course, that the C(9) carbon be oxidized. In the event, we were very pleased to find that our first attempt at oxidation was successful (Scheme 14). We took advantage of



Scheme 14 *Reagents and conditions*: i, NBS, $(PhCO)_2O_2$, light, CCl_4; ii, $AgNO_3$, THF, H_2O, pyridine; then CH_2N_2, 77% from **54**; iii, $Me_3SiC{\equiv}CLi$, $CeCl_3$, THF, −78 °C, 91%; iv, Bu_4NF, THF, 46% for **58**, 42% of the C(9) epimer of **58**.

the fact that the C(9) hydrogens are allylic and are part of an ether subunit; consequently, these hydrogens should be susceptible to free radical reactions, and treatment with NBS under standard bromination conditions (dibenzoyl peroxide, tungsten lamp irradiation) gave a mixture of epimeric bromides **55**. These were hydrolyzed with aqueous silver nitrate to an aldehyde acid which, though it existed largely as a mixture of epimeric hydroxy lactones (OH instead of Br in **55**), was easily trapped as the methyl ester **56** by reaction with diazomethane.

During hydrolysis the acetylenic trimethylsilyl group is lost, but it would eventually have had to be removed and so its loss at this stage was of no consequence. The overall yield from **54** to **56** was 77%—a value that is most satisfactory in view of the fact that several transformations have been performed in one operation on a rather complex and sensitive structure.

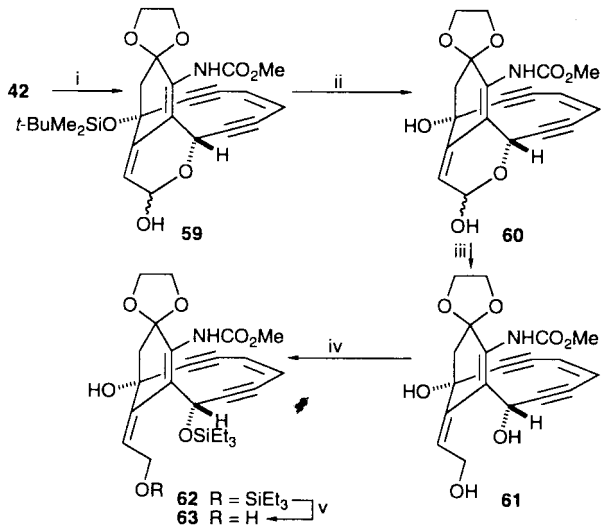
We were now ready to introduce the second acetylene. Naturally, we intended to use the cerium salt of trimethylsilylacetylene, but we had no idea of what stereochemical outcome to expect, and so we really were very pleased to find that a single compound (**57**) was formed in excellent yield (91%) and with the desired *syn* stereochemistry. When we removed the acetylenic trimethylsilyl group, the product (**58**) was, of course, identical to the material obtained by the first route. Two points need to be made about the formation of **58**. The first is that, during the desilylation, epimerization occurs at C(9), but this problem was handled in the same way as in the first route: the undesired *anti* bisacetylene was treated with tetrabutylammonium acetate to obtain an equilibrium mixture of the *syn* and *anti* isomers, so that the yield of the desired *syn* material was 71% from **57** after one recycling.

The second point also concerns stereochemistry. Up to this point we have been dealing with racemic compounds, but representing them by a single enantiomer. In the two routes, the first acetylene [at C(5)] has a different stereochemical relationship to the nitrogen function, being in one case *syn* (*cf.* **23**) and in the other *anti* (*cf.* **47**). However, all the stereogenic centers in **47** except C(5) are ultimately converted into sp^2 hybridization, and so both racemic monoacetylenes give the same *racemic* product, *i.e.* **58** and **39** are identical, but are drawn in different ways merely to emphasize the *initial* relationship between the C(5) acetylene and the nitrogen. Later on we were able to make good use of this stereochemical outcome in order to prepare optically pure material.

Formation of (±)-calicheamicinone

By the time we had made the cyclic enediyne **42** Danishefsky and coworkers[7a] and Nicolaou and coworkers[8] had shown how substances of very similar structure could be converted into calicheamicinone, and we used a method similar to theirs.

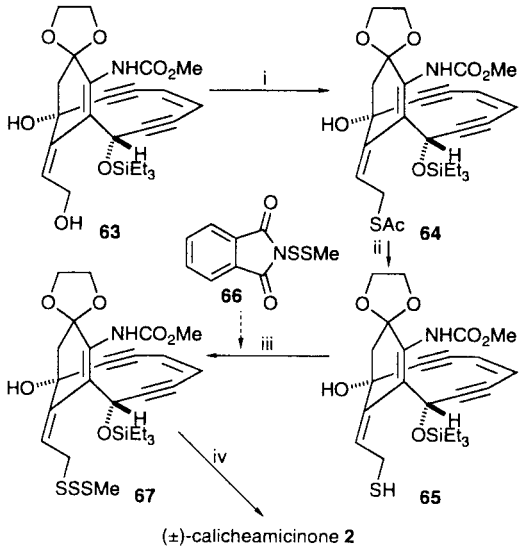
Lactone **42** was first reduced with DIBAL-H (Scheme 15) to a mixture of lactols (**59**) and then the silicon protecting group was removed in the usual way (**42** → **59** → **60**). The DIBAL-H



Scheme 15 *Reagents and conditions*: i, DIBAL-H, CH_2Cl_2, 98%; ii, Bu_4NF, THF, 94%; iii, $NaBH_4$, MeOH, 76%; iv, Et_3SiOTf, 2,6-lutidine, CH_2Cl_2, 95%; v, AcOH, THF, H_2O, 94%.

reduction must be done before desilylation in order to avoid solubility problems with the desilylated lactone and, in turn, desilylation must precede installation of the trisulfide because the latter is sensitive to tetrabutylammonium fluoride. Thus, the timing of the last two reactions is critical. Lactols **60** were further reduced with sodium borohydride to triol **61**, and at this point it was necessary to protect the secondary hydroxy group so as to block its participation in a subsequent Mitsunobu reaction. Selective protection was achieved by silylating both the primary and secondary hydroxy groups and then storing the resulting product (**62**) in a mixture of acetic acid, THF and water. Under these conditions the primary allylic hydroxy group was released (**62** → **63**), and the stage was set to introduce the trisulfide unit.

The primary hydroxy group was replaced by a thioacetyl group, under typical Mitsunobu conditions (Scheme 16, **63** → **64**), and the free thiol was then liberated by treatment with



Scheme 16 *Reagents and conditions*: i, *i*-PrO_2CN = NCO_2Pr-*i*, Ph_3P, AcSH, 94%; ii, DIBAL-H, CH_2Cl_2; iii, *N*-(methyldithio)phthalimide, CH_2Cl_2, 88% from **64**; iv $TsOH·H_2O$, THF, H_2O, 84%.

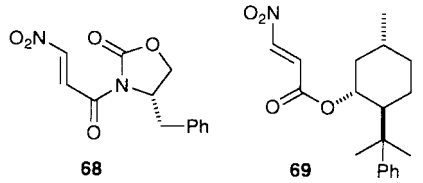
DIBAL-H. The next step proved to be troublesome until we recognized that freshly chromatographed thiol must be used. As soon as that was established, we found that treatment of **65** with an eight-fold excess of reagent **66** gave the desired trisulfide **67** in 88% yield over the two steps from **64**. Finally, the remaining protecting groups were removed by mild acid hydrolysis, affording (84%) racemic calicheamicinone as a white foam.

Synthesis of optically pure and crystalline (−)-calicheamicinone

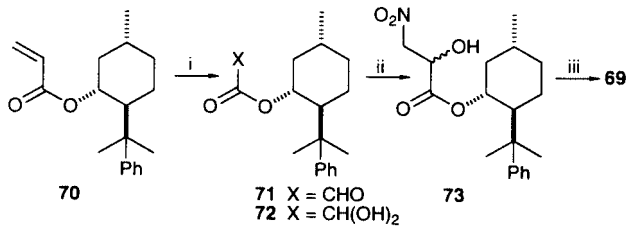
In the two syntheses of racemic calicheamicinone described above, the stereochemical relationship between the first acetylene and the nitrogen is different, but both modes of acetylide addition ultimately lead to the same *racemic* product. However, if the initial Diels–Alder adduct is made optically pure, then each route would give a different enantiomer of calicheamicinone. Moreover, the *absolute* stereochemistry of the initial Diels–Alder adduct is immaterial—provided it is known—since calicheamicinone of natural or unnatural stereochemistry can be reached from either enantiomer of the Diels–Alder adduct simply by selecting one or other of the two routes. With this unusual situation as background, we set out to prepare optically pure calicheamicinone,[5] a task for which the only new problem was the preparation of the Diels–Alder adduct in optically pure form and the determination of its absolute configuration.

In our initial Diels–Alder reaction (*cf.* Scheme 1) we had used the *methyl* ester of β-nitroacrylic acid; consequently, nitroacrylates such as **68** and **69** were obvious candidates for use in an asymmetric Diels–Alder reaction.

Our first choice was the oxazolidinone derivative **68**, but we were unable to prepare it. Perhaps we were too impatient but, in



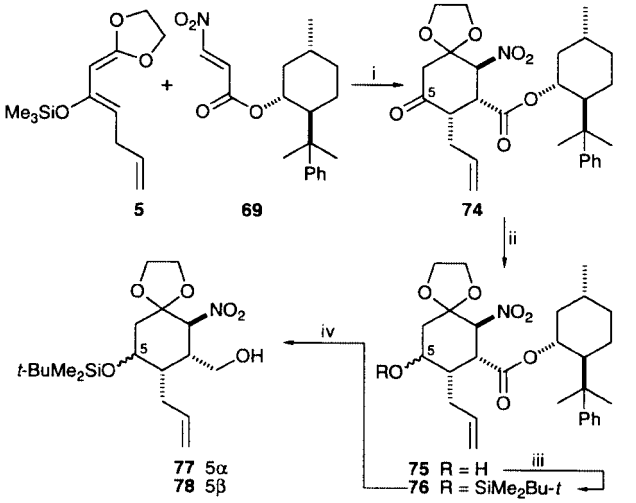
any event, our second choice—the 8-phenylmenthol derivative **69**—served the desired purpose admirably. Preparation of **69** was initially problematic, but it did not take long to devise an acceptable route (Scheme 17).



Scheme 17 *Reagents and conditions*: i, $NaIO_4$, OsO_4, H_2O, dioxane, 98%; ii, $MeNO_2$, alumina, 90%; iii, MsCl, Et_3N, 89%.

Optically pure 8-phenylmenthol[18] was acylated with acryloyl chloride and the double bond in the product **70**[19] was cleaved by the Lemieux–Johnson method to provide a mixture of the glyoxylate **71** and its hydrate **72**. This mixture underwent a Henry reaction with nitromethane in the presence of neutral alumina[20] to give a mixture of nitro alcohols (**71**, **72** → **73**), which was easily dehydrated by mesylation and spontaneous elimination.

For the asymmetric Diels–Alder reaction the diene component **5** was again generated *in situ*; it reacts smoothly with the optically pure nitroacrylate to give, after mild acid workup, the ketone **74** in slightly higher yield than for the *methyl* ester—64 versus 56%. X-Ray analysis of the ketone showed that the absolute configuration was as drawn in Scheme 18. The C(5)



Scheme 18 *Reagents and conditions*: i, THF, −78 °C, 35 min, then aqueous NH_4Cl, 4 h, 64% based on **11**; ii, $NaBH_4$, MeOH, 99%; iii, *t*-$BuMe_2SiOTf$, 2,6-lutidine, CH_2Cl_2, 100%; iv, DIBAL-H, CH_2Cl_2, −78 to −30 °C, 52% for **77** and 27% for **78**.

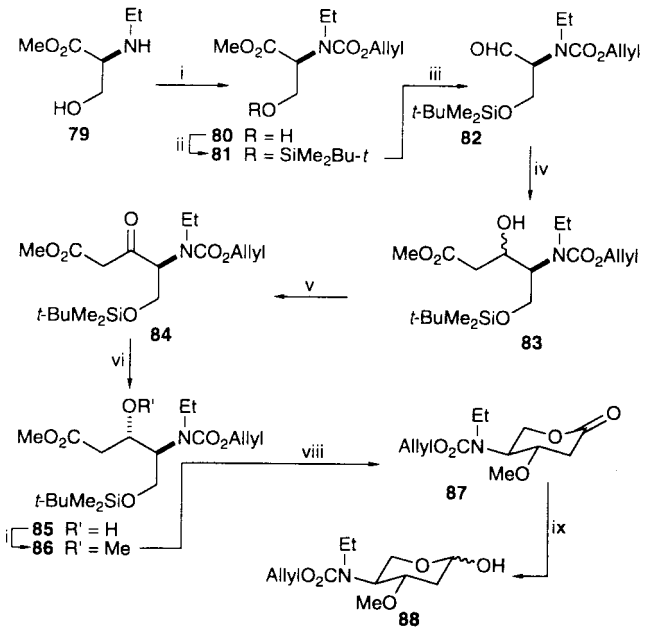
carbonyl was reduced as before to a mixture of epimeric alcohols, and these were then silylated (**74** → **75** → **76**). Finally, the chiral auxiliary was removed by treatment with DIBAL-H, first at −78 °C and then at −30 °C. With proper temperature control the two optically pure alcohols **77** (52% from ketone **74**) and **78** (27%) can be obtained, and the chiral auxiliary is recovered (96%). Alcohols **77** and **78** correspond to the racemic compounds used earlier (see Scheme 3), and the absolute configuration of ketone **74** indicated that the second route (Schemes 11–14) developed with racemic material would lead to calicheamicinone of natural configuration. Accordingly, the earlier experiments were repeated using both **77** and **78**; the sequence afforded (−)-calicheamicinone. Our material was crystalline, and we were able to obtain the first X-ray crystallographic data for calicheamicinone.

Synthesis of model compounds representing the sugar units

Once the aglycone had been completed we began work on the sugars and the aromatic unit. We arbitrarily decided to make each of the sugars from materials in the chiral pool—but excluding other sugars—or by asymmetric synthesis.

Synthesis of a ring E model

Our starting material for the ring E unit (see structure **1**) was serine, which is easily converted[21] into the *N*-ethyl ester **79**. *N*-Carbamoylation and silylation of the remaining hydroxy group (see Scheme 19) gave the fully protected derivative **81** (**79** → **80** → **81**). DIBAL-H reduction furnished aldehyde **82**, and

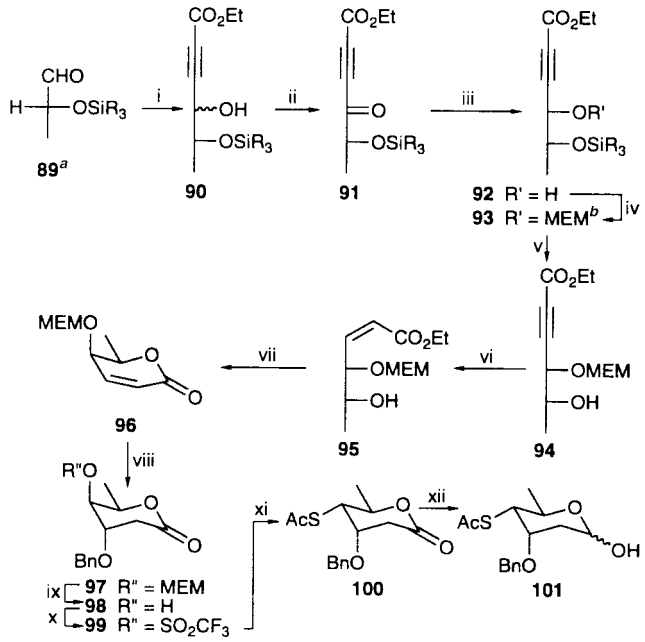


Scheme 19 *Reagents and conditions*: i, allyl chloroformate, K_2CO_3, THF, water, 0 °C, 94%; ii, *t*-$BuMe_2SiOTf$, imidazole, DMF, 97%; iii, DIBAL-H (added over 1 h), CH_2Cl_2, −78 °C, 30 min; iv, SmI_2, THF, −78 °C, MeO_2CCH_2Br, 1 h, 56% from **81**; v, PCC, 4 Å molecular sieves, CH_2Cl_2, 1 h; vi, $NaBH_4$, MeOH, 0 °C, 83% from **83**; vii, $MeOSO_2CF_3$, 2,6-di-*tert*-butyl-4-methylpyridine, CH_2Cl_2, reflux, 82%; viii, 3:1:1 AcOH–THF–water, 24 h; azeotrope with PhMe; PhMe, AcOH, 80 °C, 5 h, 86%; ix, DIBAL-H, CH_2Cl_2, −78 °C, 88%.

condensation with methyl bromoacetate, mediated by samarium iodide,[22] served to generate the required carbon skeleton (**82** → **83**). The condensation gave a mixture of isomers with the major one having a stereochemistry at the hydroxy-bearing carbon opposite[23] to that required. Consequently, an oxidation-reduction sequence (**83** → **84** → **85**) was needed to adjust the stereochemistry; alcohol **85** was obtained in 89% ee. Methylation and desilylation then led directly to lactone **87**, and DIBAL-H reduction gave the lactols **88**, corresponding to a protected version of the ring E sugar of calicheamicin γ_1^I.[24]

Synthesis of a ring B model

Synthesis of the ring B unit began with methyl (*R*)-lactate, which was converted by silylation and reduction into aldehyde **89** (Scheme 20), following a literature procedure.[25] Addition of the magnesium acetylide derived from ethyl propiolate afforded



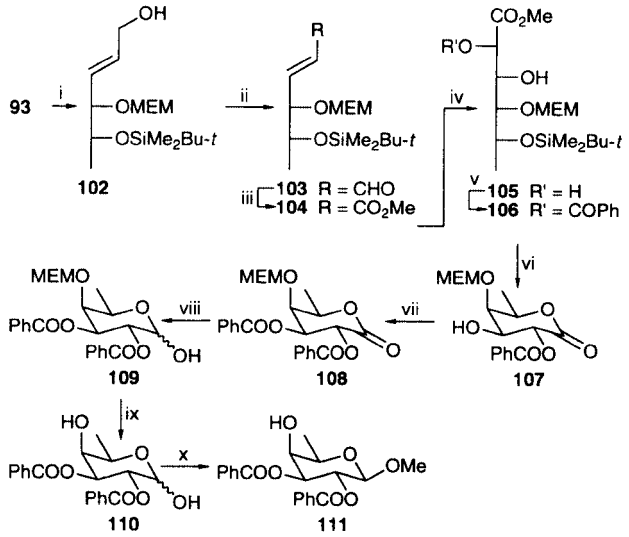
Scheme 20 [a]R_3 = Me_2Bu-*t*. [b]MEM = $CH_2OCH_2CH_2OMe$. *Reagents and conditions*: i, $EtO_2CC{\equiv}CMgBr$, THF, HMPA, **89** in CH_2Cl_2, −78 °C, 72%; ii, Jones reagent; iii, K-Selectride, THF, −78 °C, 68% from **90**; iv, MEMCl, *i*-Pr_2NEt, CH_2Cl_2, 86%; v, 48% aqueous HF, MeCN, 94%; vi, 5% Pd–$BaSO_4$, quinoline, H_2, 1 atm, 86%; vii, PhMe, AcOH, 80 °C, 95%; viii, BnOH, $Hg(OAc)_2$, $HClO_4$, 2 days; then THF, aqueous pH 8 buffer, $NaBH_4$, 52% overall, 71% corrected for recovered **96**; ix, Me_3SiCl, NaI, MeCN, 86%; x, $(CF_3SO_2)_2O$, pyridine, CH_2Cl_2; xi, AcSK, DMF, 48% from **98**; xii, DIBAL-H, CH_2Cl_2, −95 °C, 90%.

a 9.6 : 1 mixture of alcohols **90**, in which the minor isomer was the desired one.[25] Accordingly, the alcohols were subjected to Jones oxidation (**90** → **91**) and then treated with K-Selectride, so as to generate the required stereochemistry (**91** → **92**).[25] The hydroxy group was now protected as its MEM ether, and the other oxygen was deprotected with aqueous HF in acetonitrile (**92** → **93** → **94**). Semihydrogenation gave the *Z* alkene **95**, which lactonized (**95** → **96**) on heating in the presence of acetic acid. At this point, treatment with benzyl alcohol and mercuric acetate served to effect alkoxymercuration of the double bond, and reduction with sodium borohydride released the desired benzyloxy lactone **97**.[26] The C(4) oxygen was next deprotected with iodotrimethylsilane, generated *in situ*, and sulfonylated with triflic anhydride (**97** → **98** → **99**). These operations took the route to a point where a thioacetyl group could be introduced by S_N2 inversion, using potassium thioacetate in DMF (**99** → **100**). Finally, DIBAL-H reduction at −95 °C gave the lactols **101** (94%), the thioacetyl group remaining intact. Lactols **101** represent a model of the ring B sugar unit of calicheamicin γ_1^I.[27]

Synthesis of a ring A model

Our ring A model is one having a hydroxy group at C(4) that can be converted into a leaving group (for displacement by a hydroxylamine nitrogen), a C(2) hydroxy group for glycosylation with a suitable ring E precursor, and C(1) blocked as a methyl glycoside. Structure **111** satisfies these requirements, and the route we used to prepare it should allow differential protection of the C(2) and C(3) oxygen functions.

Intermediate **93**, used in the synthesis of the ring B model, served as the starting point for the ring A model. The acetylenic ester unit was converted by reduction ($LiAlH_4$) and oxidation into aldehyde **103** (see Scheme 21), and the latter was converted in one step into the *E* olefinic ester **104**. The double bond was then hydroxylated, giving as the major product (80% yield) the desired diol **105**, this structural assignment being made after ring closure. Selective benzoylation of the C(2) hydroxy group



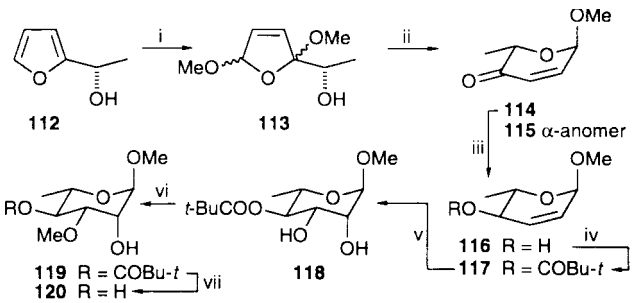
Scheme 21 *Reagents and conditions*: i, $LiAlH_4$, THF, 83%; ii, MnO_2, hexane; iii, MnO_2, NaCN, MeOH, AcOH, 87% from **102**; iv, OsO_4, NMO, *t*-BuOH, 8:1 acetone–water, 78% (isolated) plus an isomer (16%); v, PhCOCl, Et_3N, DMAP, CH_2Cl_2, 0 °C, room temperature, 84%; vi, Bu_4NF, THF, AcOH, 92%; vii, PhCOCl, pyridine, DMAP, CH_2Cl_2, 98%; viii, DIBAL-H in CH_2Cl_2, THF, −78 °C, 87%; ix, Me_3SiCl, NaI, MeCN, −20 °C; x, $(MeO)_3CH$, camphorsulfonic acid, MeOH, reflux, 78% from **109**.

afforded **106** and, when the silyl group was removed, under standard conditions, spontaneous lactonization occurred, generating lactone **107**. For convenience in this model study we chose to mask the C(3) hydroxy group as a benzoate (**107** → **108**). At that point, DIBAL-H reduction selectively modified the lactone carbonyl, providing a mixture of lactols (**109**), and the C(4) oxygen was deprotected, using iodotrimethylsilane, generated as before, *in situ*. Finally, the anomeric position was blocked as a methyl glycoside (**110** → **111**).[28]

Synthesis of a ring D model

We arbitrarily decided to prepare our ring D model by asymmetric synthesis rather than from rhamnose; consequently, our route, which is closely related to prior methods,[24f] is longer than that starting with a preformed sugar, but does offer additional possibilities for incorporating isotopic labels.

The (*S*) furyl alcohol **112**[29] (Scheme 22) was prepared by asymmetric[29,30] transfer hydrogenation from the corresponding

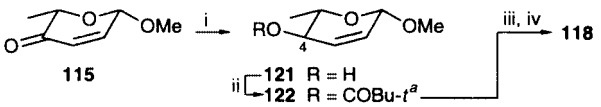


Scheme 22 *Reagents and conditions*: i, Br_2, MeOH, −40 °C, 89%; ii, HCO_2H, MeOH, 61% **114**, 20% **115**; iii, $LiAlH_4$, Et_2O, −50 °C, then warm to room temperature, 94%; iv, *t*-BuCOCl, pyridine, DMAP, CH_2Cl_2, 93%; v, OsO_4, *t*-BuOH, NMO, 9:1 acetone–water, 97%; vi, Bu_2SnO, 10 : 1 MeOH–PhH, reflux 70 min, cool, MeI, 45 °C, 17 h, 95%; vii, $LiOH{\cdot}H_2O$, 4 : 1 MeOH–water, 5 days, 85 or 95%, corrected for recovered **119**.

ketone. Following a literature procedure,[31] bromination in methanol (**112** → **113**) and treatment with formic acid then gave a mixture of the desired pyranosidulose **114**[32] (61%) and the α-anomer (20%), both of which were used in the synthesis, as described below.

Reduction of the ketone with lithium aluminium hydride proceeded[31] with the required stereochemical result in high yield (**114** → **116**, 94%). At this point, the optical purity of the compound was confirmed by NMR comparison of its Mosher ester with corresponding material made from racemic **112**. The C(3) hydroxy group was now protected as its pivaloyl ester, and dihydroxylation, under standard conditions, produced diol **118**, which could be selectively and efficiently (95%) methylated[33] (Bu_2SnO, MeI) on the C(3) oxygen (**118** → **119**). Mild basic hydrolysis gave diol **120**. Both **119** and **120** serve as models for the D ring.[34]

The ring closure step from **113** afforded as a byproduct the α-anomer **115** in 20% yield, but the stereochemistry could be adjusted (Scheme 23), so that some of this material could be used for the main sequence of Scheme 22.

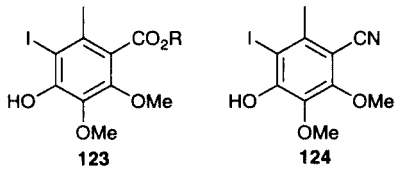


Scheme 23 [a]Yield of C(4) epimer 22%. *Reagents and conditions*: i, $NaBH_4$, THF, water, 0 °C; ii, *t*-BuCOCl, pyridine, DMAP, $CHCl_3$, 66% **116**, 22% for the C(4) anomer; iii, camphorsulfonic acid, MeOH; iv, OsO_4, *t*-BuOH, NMO, 9:1 acetone–water, 75% from **115**.

Reduction of ketone **115** with sodium borohydride, and pivaloylation gave **122** as the predominant product. Without purification, this was subjected to conditions for acetal exchange, so as to form mainly the α-glycal. Finally, dihydroxylation gave pure **118** in 75% overall yield from **122**. We did not investigate the use of other hydride agents, in an attempt to improve the isomer ratio (*ca*. 3:1) in the first step.

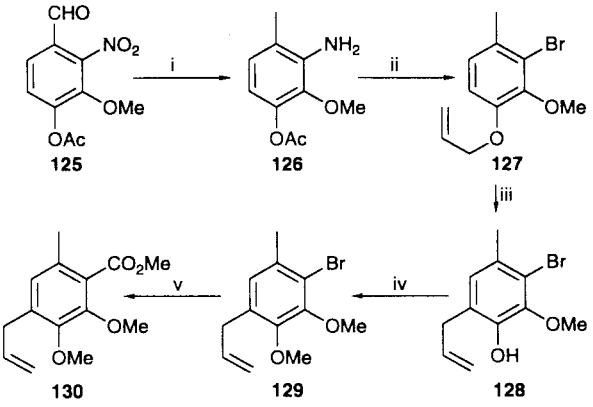
Synthesis of the aromatic unit

The carbohydrate domain of calicheamicinone is interrupted by the hexasubstituted benzene, which is flanked by a monosaccharide and a trisaccharide. Before we began our own work,[6] methods had been published for making the parent aromatic system **123** (R = H),[35] the corresponding ester **123** (R = Me),[21,35] and the nitrile **124**.[24f] We prepared ester **123** (R = Me) by two routes, using very simple reactions. Both routes lead to compound **130** (Scheme 24), from which the target is easily reached, as described below.

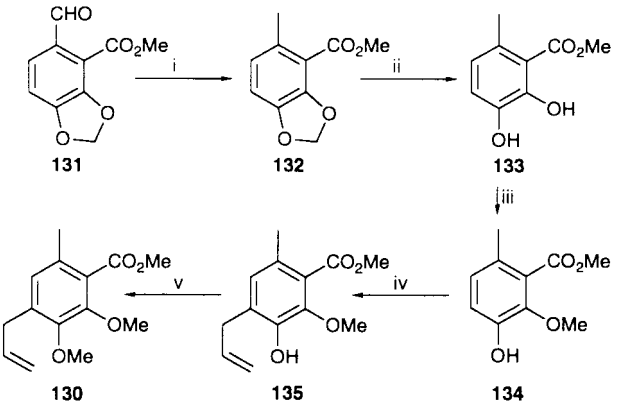


Our first route begins with the known nitro acetate **125**[36] (Scheme 24), which is available in good yield from vanillin by acetylation (Ac_2O, aqueous NaOH; 94%) and nitration (fuming HNO_3; 83%). Catalytic hydrogenation served to reduce both the nitro and formyl groups, and in this way the required methyl and amino functions are introduced (**125** → **126**). Sandmeyer reaction, acetate hydrolysis, and allylation of the resulting phenol then gave the bromo allyl ether **127**. This rearranged in high yield when heated in refluxing decalin, to produce the *ortho* allyl phenol **128**, which was methylated under standard conditions. Finally, halogen–metal exchange and acylation with methyl chloroformate gave **130**, which is an advanced intermediate common to both the routes we developed to the aromatic ring.

The second route (Scheme 25) starts with piperonal. The derived cyclohexylimine (*ca*. 97%) is easily converted into aldehyde ester **131** by lithiation and treatment with methyl chloroformate (88%).[37] Hydrogenolysis again converts the formyl group into a methyl, and then the phenolic hydroxy



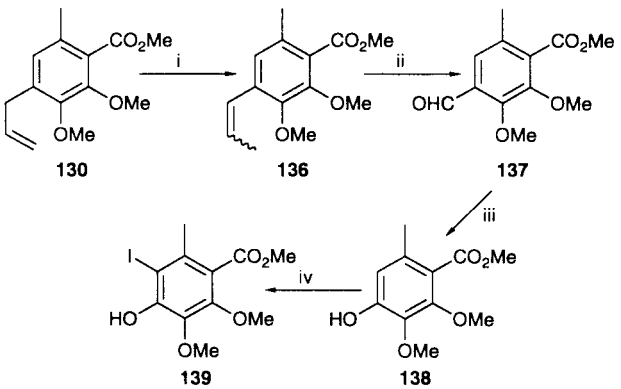
Scheme 24 *Reagents and conditions*: i, AcOH, MeOH, Pd-C, H_2, 93%; ii, (a) $NaNO_2$, HCl, CuBr, (b) MeOH, KOH, heat, 81%, (c) K_2CO_3, allyl bromide, acetone, 96%; iii, refluxing decalin (*ca*. 190 °C), 91%; iv, K_2CO_3, Me_2SO_4, acetone, 92%; v, *n*-BuLi, THF, MeOCOCl, 81%.



Scheme 25 *Reagents and conditions*: i, AcOH, MeOH, Pd–C, H_2, 93%; ii, $AlBr_3$, EtSH, 93%; iii, Li_2CO_3, MeI, DMF, 71%, after correction for recovered **133** (30%); iv, (a) K_2CO_3, allyl bromide, acetone, 92%, (b) refluxing decalin (*ca*. 190 °C), 86%; v, K_2CO_3, Me_2SO_4, acetone, 97%.

groups were released by the action of aluminium tribromide in ethanethiol. The critical next step (**133** → **134**) involved selective methylation of the C(2) hydroxy group. This was accomplished[38] by using methyl iodide and lithium carbonate in DMF at room temperature and, under these conditions, it was possible to isolate the desired monomethyl ether **134** in acceptable yield (50%, or 71%, after correction for recovered **133**). The remaining hydroxy group was then allylated as before, and Claisen rearrangement gave the new phenol **135**. This was then methylated (**135** → **130**), bringing the sequence to a point that overlaps with the first route.

Having a supply of **130** in hand, we had next to degrade the allyl pendant to a formyl group (Scheme 26). To this end, the



Scheme 26 *Reagents and conditions*: i, $RhCl_3·3H_2O$, EtOH, heat, 89%; ii, OsO_4, $NaIO_4$, *t*-BuOH, CCl_4, H_2O, 83%; iii, MCPBA, CH_2Cl_2, then MeOH, KOH, water, 81%; iv, ICl, CH_2Cl_2, 95%.

double bond was shifted into conjugation with the aromatic ring, using rhodium trichloride in refluxing ethanol,[39] and oxidative cleavage of the product (**136**) under Lemieux–Johnson conditions gave aldehyde **137**. At that point, Baeyer–Villiger oxidation and base hydrolysis produced the known phenol **138**,[35] which reacted with iodine monochloride to afford in 95% yield the target **139**—a substance that represents the aromatic unit of calicheamicin.

Conclusion

Our synthetic work has led to each of the subunits of calicheamicin γ_1^I, including the first preparation of *crystalline* (−)-calicheamicinone, for which the molecular dimensions were established by X-ray analysis. At several points a remarkable level of stereoselectivity was observed with alkynyl cerium reagents, and the stereochemical aspects of the synthesis of **2** are very unusual.

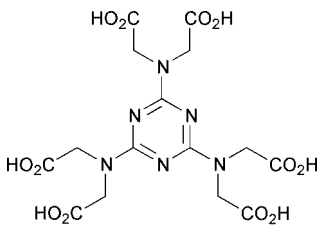
Received (in Cambridge, UK) 13th March 2000, Accepted 6th June 2000
Published on the Web 30th June 2000

Single crystals of a symmetrically substituted molecule, 1,3,5-triazine-2,4,6-triaminehexaacetic acid, (TTHA) and its Ca^{2+} salt have been synthesized, the analysis of which reveals the existence of novel channel type cavities and helical packing organizations in the crystals.

Nanoporous inorganic structures of widely varying three-dimensional arrangements are well known.[1] However, organic molecules are generally more amenable to chemical functionalization. Consequently there has been a steady rise in attempts to design organic molecules that can self-assemble *via* non-covalent interactions.[2] Indeed, intelligent use of the directional nature of the hydrogen bonding and other structure directing forces have generated solids with a whole variety of structural motifs from man-made organic templates.[3,4]

Due to our continuing interest in the synthesis of organic solids[5] with controllable crystalline packing, we considered the design of solids with framework structures, in which the building blocks within the individual infinite networks are linked either *via* H-bonds, or through metal-to-ligand bonds. One way to develop solids with predictable 3D organization requires design of a molecule with a symmetrical and well-defined spatial arrangement of subunits, that can associate through one or more non-covalent interactions. For this purpose we chose the aromatic triazine nucleus in melamine as a core which possesses -NH_2 substituents at the 2-, 4- and 6-positions. The ability of the melamine pendant residues to undergo H-bonding interactions with other molecules or ions has been exploited in both solution and the solid state.[3] It occurred to us that the -NH_2 groups in melamine could be replaced by -$N(CH_2CO_2H)_2$ moieties, giving a core triazine nucleus with three symmetrically placed, strongly metal-complexing bidentate sites. The resulting ligand, 1,3,5-triazine-2,4,6-triamine hexaacetic acid (**TTHA**, **1**)† provides a symmetrical array of



TTHA (1)

three bidentate sites at which selected metal ions can be strongly bound, each site closely resembling those in the 'textbook' chelating agent EDTA and related derivatives. One important feature of the connecting ligands providing three bidentate residues on the triazine hub is that when a metal ion binds to three of them, the metal itself adopts the role of three nodal points from which further connections could be engineered. Therefore ligands like **TTHA** should be well poised to generate a range of supramolecular framework structures in the solid state.

Crystallization of **TTHA** from its aqueous solution yields a solid which could be examined by single-crystal X-ray diffraction.‡ In monoclinic crystals of **1** four molecules of **TTHA** were found to be packed in the unit cell in the space group *C*2/*c*, the molecular symmetry in the crystal lattice being $C_2(2)$ which passes through the atoms N(11), C(12) and N(22) (not shown). The nature of the intramolecular bond lengths in the aromatic core is indicative of extensive π-electron delocalization, which results in the planarity of this molecular entity. From the values of the torsional angles it is clear that the conformations of each -$N(CH_2CO_2H)_2$ side-chain are slightly different. These conformations adjust according to the need to accommodate efficient intermolecular H-bonding interactions in the lattice and deviate out of the plane of the triazine rings.

TTHA forms H-bonded (O–H···O) dimers through the CO_2H residues. Other weak interactions such as C–H···O and C–H···N also exist. The supramolecular architecture produced upon non-covalent association of **TTHA**, results in a 'crinkled' molecular tape supported by O–H···O H-bonds, which extend in the direction of the *c*-axis (not shown). All six CO_2H groups in **TTHA** participate in such interactions and this association extends infinitely (Fig. 1). Such supramolecular sheets of **TTHA** are stacked along the *a*-axis giving exquisite channels of various sizes. While the polar CO_2H ends maintain the channels, the columns in the channels in such aggregates are made of triazine rings. The arrangement is reminiscent of pillared inorganic layered structures, the CO_2H residues

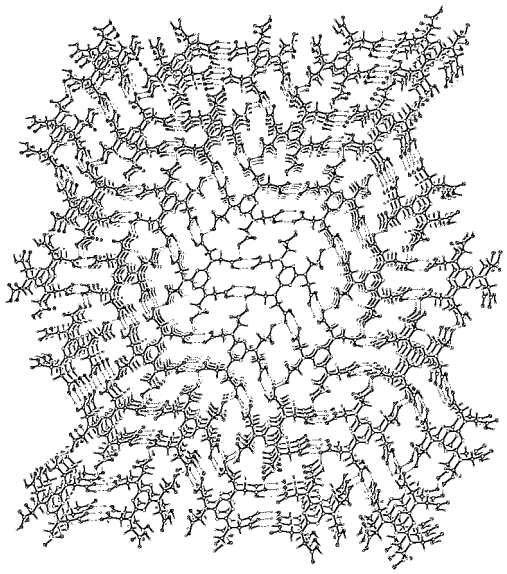


Fig. 1 Crystal packing of layers of **TTHA** in 3D showing the superposition of eight layers of **TTHA** molecules leading to the formation of channels.

DOI: 10.1039/b002016h

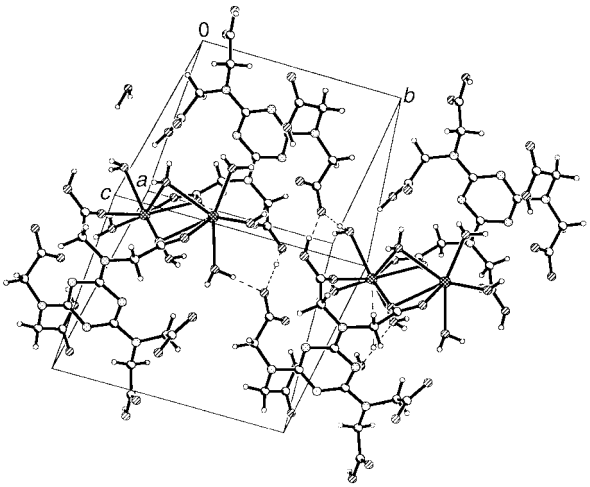

Fig. 2 Ca^{2+} ion induced supramolecular motif of **TTHA** showing the helical organization.

forming pillars between the layers formed by **TTHA** in **TTHA**.

This observation prompted us to explore the possibilities of generating an open-framework metal-coordination polymer of **TTHA**, using an oxophilic metal such as the Ca^{2+} ion. Indeed, crystals of a suitable quality for single-crystal X-ray diffraction of the Ca^{2+} salt of **TTHA**‡ were obtained upon prolonged incubation in water. The structure of the Ca^{2+} salt of **TTHA** consists of two molecules of **TTHA**, bound to two Ca^{2+} ions in the asymmetric unit (not shown). The two crystallographically independent **TTHA** molecules are related by an approximate non-crystallographic centre of symmetry. However, the side-arm $-N(CH_2CO_2^-)_2$ anions projecting from the same triazine hub show appreciable differences in their conformations.

From the crystal structure it is also evident that the two Ca^{2+} ions, Ca1 and Ca2 are octa-coordinated and are bridged by two carboxy groups maintaining a distance of 4.84 Å. As many as eight water molecules in the asymmetric unit are also found to be involved in the formation of a 3D network of O–H···O H-bonds. The most predominant feature of the solid state organization is that Ca^{2+} and the water molecules are confined to the crystal space between the two independent **TTHA** molecules. This feature is shown in Fig. 2, which omits the intermolecular H-bond connectivities for clarity. This also shows that the supramolecular architecture of the molecules along the *b*-axis is stabilized by O–H···O H-bonds. The planar triazine part of the **TTHA** moieties is essentially perpendicular to the *c*-axis of the unit cell. In this situation, the side-arms of **TTHA** project out in such a manner that its terminal carboxy groups not only participate in the intermolecular O-H···O H-bonds but are also able to ligate with the Ca^{2+} ions. The planar rings of the crystallographically independent triazines are parallel to one another, separated by ~3.5 Å. However, the triazine rings do not overlap completely and are partially displaced from one another. Further inspection shows that a helical organization exists in this polymeric network where multiple, short triazine–triazine π or C–H···π triazine contacts probably assist in stabilizing such helical organizations.

In summary, we were able to design a new supramolecular scaffold utilizing **TTHA** as a central tecton which can form self-organized entities in the solid state. The results presented herein augur well for the future generation of a whole variety of crystalline coordination polymers based on templates bearing aminediacetic acid (EDTA and related ligands) with a wide choice of metal centers, in some cases with channel-like organizations. In view of the increasing demand for the synthesis of planar molecular templates with trigonal and hexagonal symmetry for materials design,[6] **TTHA** should provide convenient routes to prepare a new family of solids, the packing organizations of which could be controlled by crystal engineering. Other metal substitution may allow the generation of porous solids with redox or charged subsites and these might offer new matrices with altered physical properties for specific catalytic and separation science applications. Synthesis and investigation of the properties of these novel solid materials are underway.

We thank Professor C. N. R. Rao for helpful discussions. This work was supported by the Swarnajayanti Fellowship Grant of the Department of Science and Technology, Govt. of India.

Notes and references

† **TTHA** and its precursors have been characterized spectroscopically and also by elemental analysis and the corresponding data were consistent with their proposed structures.

‡ Single crystal X-ray diffraction studies. X-Ray diffraction intensities were measured at room temperature by ϖ scans using a Siemens three-circle diffractometer attached to a CCD area detector and a graphite monochromator for the Mo-Kα radiation (50 kV, 40 mA). The crystal structures were solved by direct methods using the SHELXTL program[7] and refined by full matrix least squares on F^2. All the non-hydrogen atoms were refined anisotropically. H atoms were located by the difference Fourier method and were refined isotropically. CCDC 182/1677.

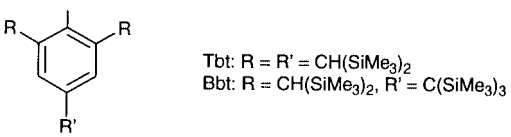
Received (in Cambridge, UK) 8th March 2000, Accepted 14th June 2000
Published on the Web 30th June 2000

The condensation reaction of an overcrowded dihydrostibine with dibromobismuthine using 1,8-diazabicyclo[5.4.0]undec-7-ene as a base afforded the first stable stibabismuthene, the formation of which was evidenced by UV–VIS and Raman spectra and its chemical reactivity.

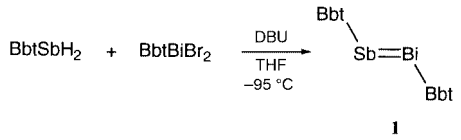
In recent years there has been much interest in compounds with a double bond between heavier group 15 elements. Since the first isolation of a stable diphosphene (Mes*P=PMes*; Mes* = 2,4,6-tri-*tert*-butylphenyl) in 1981,[1] a number of examples of kinetically stabilized diphosphenes (RP=PR)[2] and diarsenes (RAs=AsR)[2c,3] have been isolated and fully characterized. Recently, we have succeeded in the synthesis and characterization of the first stable distibene (TbtSb=SbTbt)[4] and dibismuthene (TbtBi=BiTbt),[5] even heavier congeners of azo compounds, by taking advantage of an efficient steric protection group, Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl.[6] Very recently, Power and coworkers also synthesized another type of stable distibene and dibismuthene substituted by bulky 2,6-$Ar_2C_6H_3$ groups (Ar = mesityl or 2,4,6-triisopropylphenyl).[7] As for the case of heteronuclear double-bond compounds between heavier group 15 elements, several phosphaarsenes[3a,8] and phosphastibenes[8,9] have been synthesized as stable compounds. However, there are no examples of a heteronuclear doubly bonded system between antimony and bismuth, *i.e.* stibabismuthene. Although the successful results on the kinetic stabilization of distibene and dibismuthene (TbtE=ETbt; E = Sb, Bi) naturally prompted us to apply the Tbt group to the synthesis of stable stibabismuthene, we were apprehensive that the extremely low solubility of the Tbt-substituted doubly bonded system of heavier group 15 elements may prevent us from utilising the possible synthetic approaches or spectroscopically detecting the reaction products. On the other hand, during the course of our investigation on the kinetic stabilization of low-coordinated highly reactive species we have developed another bulky aromatic substituent, 2,6-bis[bis(trimethylsilyl)methyl]-4-[tris(trimethylsilyl)methyl]phenyl (Bbt),[10] which is expected to be a potentially more useful steric protecting



group than TbT. In fact, a new distibene and dibismuthene substituted by Bbt groups, which have relatively high solubility compared with TbtE=ETbt (E = Sb, Bi), have been successfully synthesized and characterized.[11] We now report the successful application of the Bbt group to the synthesis of the first stable stibabismuthene, BbtSb=BiBbt **1**.

† *Present address*: Institute for Chemical Research, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan. E-mail: tokitoh@boc.kuicr.kyoto-u.ac.jp

The condensation reaction of $BbtBiBr_2$ with $BbtSbH_2$, which was prepared by the reaction of $BbtSbBr_2$ with $LiAlH_4$, in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in THF at −95 °C afforded stibabismuthene **1**‡ as red–purple crystals quantitatively (Scheme 1). Stibabismuthene **1** showed satisfactory spectral data, as discussed below.



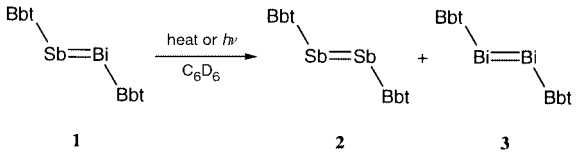
Scheme 1

In the Raman spectrum (in the solid state) of **1**, a strong line attributable to the Sb–Bi stretching was observed at 169 cm^{-1}. This wavenumber lies between the value of the Sb–Sb stretching vibration in TbtSb=SbTbt (207 cm^{-1})[4] and that of the Bi–Bi stretching vibration in TbtBi=BiTbt (135 cm^{-1}),[5] and is higher than the Sb–Sb and Bi–Bi stretching frequencies for Ph_2E–EPh_2 (E = Sb, Bi).[12] The UV–VIS spectrum of **1** in hexane shows two absorption maxima at 709 nm (ε 200 dm^3 mol^{-1} cm^{-1}) and 516 (7500), which are most likely assignable to the forbidden n → π* and the allowed π→ π* transitions of the Sb=Bi chromophore, respectively.

These results are consistent with the characteristic red-shifts in the electronic spectra of previously reported heavier congeners of azo compounds, and the λ_{max} value for the π → π* transition of **1** lies between those of BbtSb=SbBbt **2** [λ_{max} 490 nm (ε 6000 dm^3 mol^{-1} cm^{-1})][11] and BbtBi=BiBbt **3** [λ_{max} 537 nm (ε 6000 dm^3 mol^{-1} cm^{-1})].[11] These spectral data suggest that **1** features a double bond between antimony and bismuth in solution as well as in the solid state. The reason for the additional red-shift for the n → π* transition of **1**, which is 39 nm longer than that of **3** [λ_{max} 670 nm (sh, ε 20)], is not clear at present.

The molecular structure of stibabismuthene **1** was also supported by X-ray crystallographic analysis, but definite structural parameters for **1** have not been obtained yet owing to the inevitable disorder of the antimony and bismuth atoms, which cannot be solved by data collection with a number of different single crystals of **1** even at low temperature (−180 °C).§

Stibabismuthene **1** is stable at ambient temperature in hydrocarbon solvents in the absence of air and light. When a solution of **1** in benzene-d_6 was heated at 70 °C, **2** and **3** were formed very slowly as judged by ^{1}H NMR spectroscopy

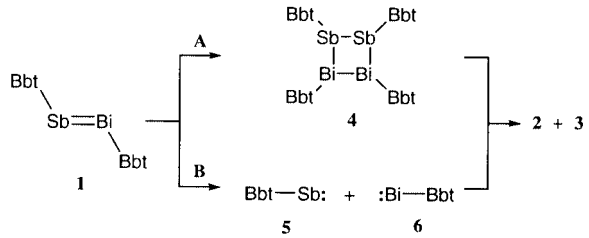


Scheme 2

DOI: 10.1039/b001900n

(Scheme 2). Heating a solution of **1** at 80 °C for 20 days led to the formation of a mixture of **1**, **2** and **3** with the ratio of 1:1.4:1.1, respectively. On the other hand, when a solution of **1** in benzene-d_6 was irradiated with a medium pressure mercury lamp (100 W) in a sealed Pyrex NMR tube at room temperature, the disproportionation reaction was complete in 4 h to give a 1:1 mixture of **2** and **3**. The results of the thermal and photochemical disproportionation reactions of **1** into the homonuclear double-bond species **2** and **3** can be regarded as chemical evidence for the formation of stibabismuthene **1**.

Taking the previous reports on the reactivities of diphosphenes[2,13] into consideration, two different pathways can be postulated for the disproportionation reactions of stibabismuthene **1** (Scheme 3). The first is the dimerization of **1** by heating or irradiation followed by decomposition of the resulting four-membered dimer **4** into the homonuclear double-bond species **2** and **3** (path A), while the other is based on the dissociation of **1** giving the corresponding monovalent species, *i.e.* stibinidene **5** and bismuthinidene **6**, both of which might undergo ready dimerization leading to the formation of **2** and **3**, respectively (path B).



Scheme 3

Although we have examined the thermolysis and photolysis of **1** in the presence of 2,3-dimethylbuta-1,3-diene in expectation of trapping the intermediary monovalent species **5** and **6**, no [4 + 1] cycloadducts of **5** and **6**, but only distibene **2** and dibismuthene **3**, were obtained in high yields. Since we have already found that the stibinidene **5** generated by thermal cycloreversion of the corresponding overcrowded stibolene derivative readily undergoes [4 + 1] cycloaddition with 2,3-dimethylbuta-1,3-diene to give the stable stibinidene adduct,[10,11] the disproportionation reaction of stibabismuthene is not rationalized by the mechanism *via* stibinidene and bismuthinidene intermediates but most likely interpreted in terms of the association–dissociation mechanism *via* the head-to-head dimerization of **1**.

In summary, we have succeeded in the synthesis of the first stable stibabismuthene **1** by taking advantage of kinetic stabilization afforded by a new and effective steric protecting group, Bbt. Further investigations on the physical and chemical properties of stibabismuthene and syntheses of other variations of heteronuclear doubly bonded systems between heavier main group elements are currently in progress.

This work was partially supported by Grants-in-Aid for Scientific Research on Priority Areas (No. 09239101 and 11166250) from the Ministry of Education, Science, Sports and Culture of Japan. T. S. thanks Research Fellowships of the Japan Society for the Promotion of Science for Young Scientists. We acknowledge Professor Y. Furukawa of Waseda University for measuring the Raman spectra. We are also grateful to Shin-Etsu Chemical Co. Ltd., for the generous gifts of chlorosilanes.

Dicobalt(II) cofacial bisporphyrins anchored by dibenzofuran (DPD) and xanthene (DPX) are efficient electrocatalysts for the four-electron reduction of oxygen to water despite their *ca*. 4 Å difference in metal–metal distances, suggesting that the considerable longitudinal 'Pac-Man' flexibility of the pillared platforms is the origin for the similar catalytic reactivity of these structurally disparate systems.

Enzymatic systems are remarkable in their ability to accommodate the large range of motion required for the binding and catalysis of small molecules. In many cases, the kinetic steps of the processes involved are ultimately predicated on conformational changes of the active site upon substrate binding, activation, and/or product release. An outstanding example is the binding and biological reduction of dioxygen to water by cytochrome *c* oxidase (C*c*O).[1] The critical O–O bond cleavage chemistry is mediated by a flexible, dinuclear iron–heme/copper (Fe_{a3}/Cu_B) assembly.[1,2] Nevertheless, the pursuit of structural and functional models for O_2 activation have emphasized, for the most part, bimetallic reaction centers poised within well-defined, rigid pockets.[3–7] For example, pillared cofacial dicobalt bisporphyrins bridged by anthracene (DPA) and biphenylene (DPB)[8–11] impair ring slippage, and as a result, these complexes efficiently electrocatalyze the direct four-electron reduction of oxygen to water (as opposed to the two-electron pathway involving peroxide) with little structural reorganization of juxtaposed subunits. Can efficient oxygen-activation chemistry be preserved when this cofacial structural motif exhibits a large range of motion? To address this issue, we have developed methods for the facile assembly of new cofacial bisporphyrins, incorporating dibenzofuran (DPD)[12] or xanthene (DPX)[13] pillars that exhibit variable pocket sizes with minimal lateral displacements. Herein, we report that dicobalt(II) complexes of both DPD and DPX efficiently mediate the direct four-electron reduction of oxygen to water despite a *ca.* 4 Å difference in their metal–metal distances (as determined from their X-ray crystal structures), suggesting that the longitudinal 'Pac-Man' flexibility of these molecular clefts allows the designed binding pocket to structurally accommodate reaction intermediates during multielectron catalysis.

Co_2(DPD) **1** was obtained in excellent yield (91%) from reaction of the corresponding free base bisporphyrin with $CoCl_2$ and 2,6-lutidine.† Crystals suitable for X-ray diffraction studies were grown from dichloromethane–methanol solutions.‡ The structure of **1** (Fig. 1) shows that two methanol solvent molecules are coordinated *inside* the bisporphyrin pocket to the two cobalt(II) centers. In order to accommodate the two exogeneous ligands, the DPD framework opens its 'bite' considerably. The interplanar angle between the two macrocycles is 56.5°, resulting in metal–metal (8.624 Å) and center-to-center (8.874 Å) distances that are markedly larger than found in Zn_2(DPD) ($d_{Zn–Zn}$ = 7.775 Å, $d_{Ct–Ct}$ = 7.587 Å).[12]

The Co(II) cores adopt an approximate square-pyramidal geometry, as the N–Co–N bond angles are 90 ± 1.3° and the N–Co–O bond angles are 90 ± 5.3°. The Co centers are displaced slightly from the porphyrin meanplane (d_{av} = 0.1355 Å) toward the axial ligand. The average axial Co–O bond length (2.272 Å) is significantly longer than that of the average equatorial Co–N bond (1.982 Å), owing to the occupancy of the d_{z^2} orbital by a single unpaired electron in Co(II). A conformational analysis of the two macrocycles indicates inequivalent ring systems. The porphyrin ring containing Co(1) exhibits an S_4 ruffle with a mean deviation from planarity of 0.1416 Å. In contrast, the ring with Co(2) is essentially flat (average deviation 0.0307 Å). Lastly, the most important structural feature of **1** in relation to its O_2 reactivity (*vide infra*) is the small tortional twist (9.3°, defined as the torsion angle between the two *meso*-carbon to

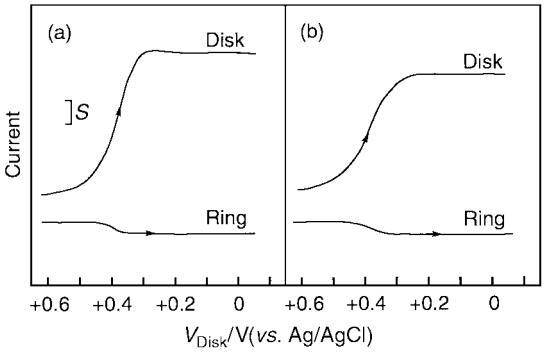

Fig. 2 Rotating Pt ring-disk voltammograms for reduction of O_2 at pyrolytic graphite disks coated with (a) **1** and (b) **2**. Rotation rate, 100 rpm; disk current, S = 10 μA; ring current, S = 5 μA; supporting electrolyte, 0.5 M $HClO_4$–1.5 M CF_3CO_2H saturated with air.

spacer bonds) between the porphyrinic subunits, giving a cofacial binding pocket with a directed longitudinal reaction coordinate for substrate binding and activation.

Cyclic voltammograms of **1** in nitrobenzene give a single, reversible oxidative wave at +0.33 V (*vs*. AgCl/Ag), consistent with two non-interacting metal centers. The complex was screened as an electrocatalytst for the reduction of dioxygen.[14,15] Fig. 2(a) displays a rotating ring-disk voltammogram for the reduction of O_2 at a graphite electrode coated with **1**. Remarkably, **1** catalyzes the reduction of oxygen at the unusually positive potential of 0.37 V (*vs*. AgCl/Ag) with 80% of the O_2 reduction proceeding along the four-electron pathway to produce water; the longitudinal 'Pac-Man' flexibility of this molecular cleft apparently allows it to 'bite' down on the O_2 substrate resulting in efficient catalytic activation.

We sought to compare the reactivity of **1** to a dicobalt(II) cofacial complex where the bite size of the cleft is preorganized for oxygen activation. The six-membered center ring of the xanthene spacer of Co_2DPX **2**† causes the two porphyrin macrocycles to bend slightly in toward each other (Fig. 1), giving a mean interplanar distance of 3.519 Å between the two porphyrin rings,‡ which is quite similar to that found in Co_2DPB (3.381 Å).[10,11] However, the torsional twist (21.1°) between the two rings results in a metal–metal distance of 4.582 Å (Co_2DPB, 3.726 Å). The square geometry for the Co(II) cores is confirmed by the N–Co–N bond angles of 90 ± 1.7°. As observed for **1** and for other structurally characterized DPX metal complexes,[13] the two ring systems of **2** are structurally inequivalent in the solid state. The macrocycle with Co(1) exhibits a pronounced ruffled conformation with a mean deviation from planarity of 0.2227 Å, while the macrocycle containing Co(2) has a less pronounced ruffle with a mean deviation from planarity of 0.1118 Å. The more compressed structure of **2** engenders mixed-valence behavior, as two reversible electrochemical oxidations are observed at +0.28 and +0.17 V; the Co(II)/Co(III) DPX complex reacts with dioxygen in the presence of 1,5-dicyclohexylimidazole to give a 15-line EPR spectrum typical of a symmetrical biscobalt(III) superoxo complex (g = 2.02, A_{Co} = 11.14 G).[8–10] Nevertheless, **2** efficiently catalyzes the reduction of oxygen at a potential (0.38 V *vs*. AgCl/Ag) and with a selectivity for the four-electron pathway to produce water (72%) commensurate to **1** [Fig. 2(b)].

The observation that both complexes are efficient catalysts for the four-electron reduction of oxygen to water, despite their notable differences in structure and redox behavior, is striking. The results suggest that the longitudinal open-to-closed conformational change in the presence of oxygen, especially dramatic in the DPD framework, involves only a small change in conformational energy. The structure of the bisiron(III) μ-oxo complex of DPD provides further evidence of the 'Pac-Man' effect, as the framework readily closes its structure to give a complex with a compressed metal–metal distance of 3.504 Å.[12] Accordingly, the conformational flexibility of these 'Pac-Man' porphyrins provides a directed reaction coordinate for facile substrate activation and product release. With the synthetic availability of both the DPD and DPX frameworks, we are poised to incisively investigate structural and electronic effects on the small-molecule reactivity of these pillared cofacial bisporphyrins. Current studies are aimed at photoactivating the dioxygen molecule to address mechanistic issues concerning the proton-coupled O–O bond cleavage chemistry[16] of these and related complexes.

Synthesis and characterization of 2,6-di-*tert*-butyl-1-thio-1,4-benzoquinone, the first isolable monothio-1,4-benzoquinone

Riho Suzuki, Kouzou Matsumoto, Hiroyuki Kurata and Masaji Oda*

Department of Chemistry, Graduate School of Science, Osaka University, Toyonaka, Osaka 560-0043, Japan. E-mail: moda@chem.sci.osaka-u.ac.jp

Received (in Cambridge, UK) 26th April 2000, Accepted 14th June 2000
Published on the Web 30th June 2000

The title compound, a labile but isolable substance owing to appreciable steric protection, shows substantially higher electron affinity than the corresponding 1,4-benzoquinone and is reduced by water.

While *p*-benzoquinones have been extensively studied,[1] little has been known about the corresponding sulfur analogues. A major reason may be the general lability of thiocarbonyl compounds that makes their handling and isolation in pure form difficult.[2] Bock and co-workers have reported the pyrolytic generation and spectroscopic characterization of the parent dithio- and monothio-1,4-benzoquinones, **1** and **2**, in low temperature matrices.[3] Recently 2,6-dialkyl-4-thio-1,4-benzoquinones **3** have been generated and trapped by cycloaddition with 1,3-dienes.[4] The only isolable, related monothioquinone so far known is monothioanthraquinone **4**.[5] We have recently reported the synthesis and properties of thioquinone methides **5** in which *tert*-butyl groups give steric protection to a considerable extent.[6] Here we report the synthesis and characterization of 2,6-di-*tert*-butyl-1-thio-1,4-benzoquinone **6**, the first isolable, monothio-1,4-benzoquinone.

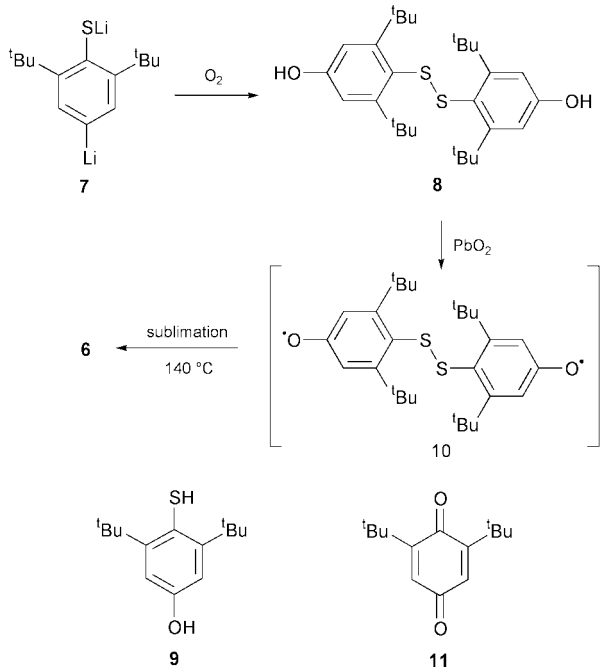
6

We have already described the generation of lithium 2,6-di-*tert*-butyl-4-lithiothiophenoxide **7** as the key synthon for **5**.[6] The exposure of a THF solution of **7** to O_2 at −70 °C followed by the usual work-up afforded bisphenol disulfide **8**† in 50% yield. A major byproduct was 2,6-di-*tert*-butylthiophenol, a reduction product. Obviously, the two *tert*-butyl groups at the *ortho*-positions are not bulky enough to hinder the coupling of the intermediate thiophenoxy radical as reported for the 2,6-di-*tert*-butylthiophenoxy radical itself.[7] The initially expected mercaptophenol **9**† was obtained by reduction of **8** with zinc powder in acetic acid (60%). The attempted oxidation of **9** to **6** with DDQ in benzene or acetone resulted, however, in the formation of **8**. We therefore expected that oxidation of **8** to its bis(phenoxy radical) **10** would cause cleavage of the rather weak disulfide bond, leading to the generation of **6**. In fact, NMR monitoring of a mixture of **8** and excess DDQ (3.5 equiv.) in deaerated benzene-d_6 in a sealed tube at room temperature gave rise to new proton signals as singlets at δ 1.14 and 6.48 and a ^{13}C signal at δ 233.45 (C=S) which are reasonable for the desired **6**. However, in spite of the use of excess DDQ, the reaction seemed to form a 2:1 equilibrium mixture of **6** and **8** probably by mediation of DDQ and its hydroquinone. Although the signals of **6** remained almost unchanged in the solution for at least two months, the attempted isolation of **6** from the mixture failed because of its lability. This failure suggests that the isolation of **6** from solutions should be difficult. In the end, the isolation of **6** in almost pure form was achieved in 70% yield by its sublimation to a water-cooled cold finger from a solid-state mixture of **8** and PbO_2 (1:30 w/w) heated at 140 °C under vacuum.



The monothiobenzoquinone **6**† thus obtained is a greenish yellow solid. Although relatively stable in the solid state as well as in neutral aprotic solvents such as benzene and acetone at room temperature, **6** is sensitive to moisture and other protic substances. The IR spectrum of **6** shows an intense carbonyl absorption at 1639 cm^{-1} and a less intense thiocarbonyl absorption (intense in the Raman spectrum) at 1141 cm^{-1}. This thiocarbonyl stretching frequency is considerably lower than that of **4** (1212 cm^{-1})[5] and even lower than the significantly dipolar 4*H*-pyran-4-thione (1168 cm^{-1}).[8] The electronic spectrum of **6** exhibits a weak absorption (ε = 32) at 758 nm, which is assignable to the n → π* transition of the thiocarbonyl group, as well as a strong absorption at 321 nm. The visible absorption of **6** is at an appreciably longer wavelength than those of **2** (500 nm)[3] and **4** (697 nm).[5] The IR and visible absorption spectral

DOI: 10.1039/b003330h

results suggest a substantial polarization of the thiocarbonyl group of **6**. In this context, a semiempirical theoretical calculation (PM3) predicts that **6** should take the boat form, due to steric congestion, with bow and stern angles of 50° and 27°, respectively. This molecular deformation from planarity could be responsible for the enhanced polarization (elongation) of the thiocarbonyl bond.

Thiocarbonyl compounds are usually more easily reduced than the corresponding carbonyl compounds.[9] Upon cyclic voltammetry, **6** shows two irreversible reduction waves at −0.60 and −1.33 V (both peak potentials *vs*. Ag/Ag^+, in 0.1 M *n*-Bu_4NClO_4–CH_3CN, ferrocene/ferrocene$^+$ = 0.10 V). These reduction potentials are about 0.5 V lower than those of 2,6-di-*tert*-butyl-1,4-benzoquinone **11** (the corresponding peak potentials: 1.07 and 1.88 V) measured under the same conditions, indicating that **6** is a substantially strong electron acceptor. Surprisingly, **6** was found to be reduced rather than hydrolysed by water: when a small amount of D_2O was added into an acetone solution of **6** either in the dark or light at room temperature, the signals of **6** at δ 1.37 (s) and 6.46 (s) disappeared within 1 h with the concurrent appearance of new signals at δ 7.00 (s), 6.93 (br s), 6.73 (br s) and 6.52 (s) in the olefinic to aromatic region. The products were identified to be monothiohydroquinone **9**, disulfide **8** and benzoquinone **11**, formed in a 45 : 50 : 5 ratio (^{1}H NMR and TLC comparison with those of the authentic samples). The formation of **8** (probably also **9**) points to the intermediate formation of the corresponding thiophenoxy radical. In addition, the ferricyanide test as a preliminary qualitative test afforded a positive result, conforming the formation of hydrogen peroxide in the solution. Thus, hydrolysis of **6** to **11** is a very minor process, different from the usually easy hydrolysis of thioketones to ketones.

In conclusion, although the two *tert*-butyl groups at the *ortho* positions are not bulky enough for steric protection, 2,6-di-*tert*-butyl-1-thio-1,4-benzoquinone **6** was synthesized as a labile but isolable compound at around room temperature and was found to show a considerably high electron affinity and to undergo an unusual reaction with water. We are now investigating the detailed chemical properties of **6**.

$[Co_4(\mu\text{-}Cl)_6Cl_2(thf)_4(MeOH)_2]_n$, a *catena*-polycobalt(II) complex with an unusual linear chain of octahedral/tetrahedral/octahedral cobalt sites, is obtained quantitatively from the reaction between cobalt chloride hydrate and trimethylorthoformate in THF.

Literature reports on infinite polymeric chains based on copper, manganese or cobalt, indicate the most common routes to obtaining *catena*-complexes are to use polydentate ligands as bridges between metallic units,[1–5] or to take advantage of potential intermolecular hydrogen bonding.[6] Numerous copper complexes,[2,6] and a few cobalt compounds were obtained in these ways.[1,3–5] Halide-bridged polymeric structures have also been characterised for these metals.[7] Interestingly, X-ray structure determinations describing chain-type cobalt complexes still remain scarce, apparently because these polymeric structures are difficult to grow as single crystals.[8] Of the reported structures the majority feature repeating linear chloro-bridged chains of monomeric cobalt octahedra,[7b] or elegant halide-bridged 'zigzag' chains (non-linear) as the polymeric network.[8–10] We report the isolation and structural characterisation of a new family of inorganic polymers of cobalt, showing an unprecedented chain of three different cobalt sites.

$[Co_4(\mu\text{-}Cl)_6Cl_2(thf)_4(MeOH)_2]_n$ **1** was obtained in quantitative yield from a mixture of $CoCl_2\cdot 6H_2O$ and trimethylorthoformate in tetrahydrofuran solution.‡ Crystals used for X-ray diffraction were kept under dry diethyl ether to prevent any decomposition before measurements.§ The structure of **1** consists of an infinite regular chain of three distinct successive cobalt sites (Fig. 1) connected in different ways. Co(1) and Co(3) are located on crystallographic inversion centres linked, respectively, by two and one bridging chloride ions to Co(2) centres. This creates a *repeating* pattern of tetranuclear units $[-Co(thf)_2(\mu\text{-}Cl)_2CoCl(\mu\text{-}Cl)Co(MeOH)_2(thf)_2(\mu\text{-}Cl)CoCl(\mu\text{-}Cl)_2-]$, or more simply $[Co_4(\mu\text{-}Cl)_6Cl_2(thf)_4(MeOH)_2]$. The strict asymmetric unit, from which the entire chain can be built, is formulated $[Co_2Cl_4(thf)_2(MeOH)]$. The geometry around Co(1) is octahedral having four μ-chloro bridges in equatorial sites, linked to two symmetry related Co(2) centres, and two thf molecules in axial positions, Co(1) thus being part of a $CoCl_4O_2$ chromophore. Each Co(2) centre is in a distorted tetrahedral environment made up of a terminal chloride and three μ-chloro bridges; two connected to Co(1) and the third bridged to Co(3). The bridging properties force the tetrahedral Cl(1)–Co(2)–Cl(2) angle to contract to 97.31(3)°, whilst the mono-bridged angle Cl(2)–Co(2)–Cl(4) has opened to 118.44(3)°. The coordination sphere around Co(3) consists of four oxygen donors atoms from two *trans*-thf and two *trans*-methanol molecules located at the equatorial positions. The axial positions are occupied by the bridging atoms Cl(4) producing a $CoCl_2O_4$ chromophore. The longer Co(3)–Cl(4) distances relative to Co(3)–O, result in a tetragonal *elongation* along the pseudo-four-fold axis of the Co(3) octahedral environment. The Co(1)–Cl(2) bond length is very long, 2.5488(7) Å, so that in this case a pronounced compressed octahedral geometry, *i.e.* a tetragonal *contraction* along the pseudo-four-fold axis is suggested around the Co(1) atom.

The Co–Cl bond distances are in agreement with the values reported for tetrahedral and octahedral chloride geometries in related cobalt/chloride complexes.[7,11,12] The terminal chloride on Co(2) is involved in a O–H···Cl hydrogen bond interaction to the *cis*-methanol molecule coordinated to Co(3). A closely related trinuclear cobalt chloride anion, $[Co_3Cl_8(thf)_2]^{2-}$, has recently been described.[13] The X-ray structure determination revealed three successive cobalt sites: tetrahedral/octahedral/tetrahedral each connected *via* di-μ-chloro bridges. The molecular structure of $[\{Co_4(\mu\text{-}Cl)_6Cl_2(thf)_4(H_2O)_2\}\cdot 2THF]_n$ **2**§ (Fig. 2) is very similar to **1**, except that the methanol molecules coordinated to Co(3) are replaced by water molecules, and two additional thf molecules per tetranuclear unit have cocrystallised in the lattice. The most significant difference between the two complexes involves the hydrogen bonding network; both complexes form an intramolecular OH···Cl(terminal) interaction [O(1)···Cl(3) 3.041(2) Å, O(1)–H(1)···Cl(3) 170(4)° in **1**; O(1)···Cl(3) 3.117(2) Å, O(1)–H(1B)···Cl(3) 168(3)° in **2**]. In **2** the water molecule forms an additional strong intermolecular bond with the thf molecule in the lattice. This results

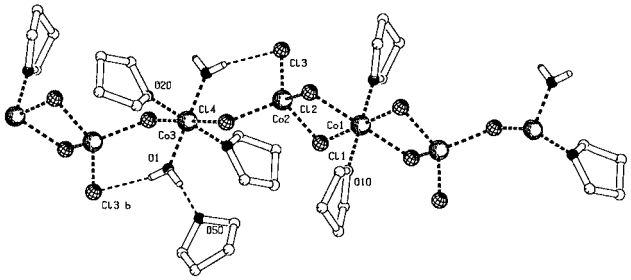

Fig. 2 Schematic representation of the crystal structure of **2**: hydrogen bonding geometries: distances (Å), O(1)–H(1B)···Cl(3) 2.36(3), O(1)···Cl(3) 3.117(2), O(1)–H(1A)···O(50) 1.81(3), O(1)···O(50) 2.625(3); angles (°), O(1)–H(1B)–Cl(3) 168(3), O(1)–H(1A)–O(50) 174(3). Bond lengths and angles generally differ from **1** by < 0.05 Å and 2° respectively, except for Cl(2)–Co(2)–Cl(4) 109.57(3)° [118.44(3)° in **1**].

in a slight contraction of the tetranuclear unit in **2** compared to **1** [intra Co(1)···Co(3) distances in the two complexes: 7.3608(2) Å for **1** and 7.0407(3) Å for **2**].

VIS–NIR spectroscopy in diffuse reflectance of **1** shows the dominance in intensity of tetrahedral coordination typical bands (a broad band at 6600 cm^{-1}, and a more intense band at 15000 cm^{-1}). The bands corresponding to an octahedral environment around cobalt are present but partially obscured (shoulders at 12000 and 19000 cm^{-1}). Temperature dependent solid-state magnetic susceptibility (χ_m) measurements on crystals of **1** were performed. The effective magnetic moment (μ_{eff}/Co_2) slowly decreases from 7.27 μ_B at 260 K to 6.91 μ_B at 80 K, and then more steeply to 4.72 μ_B at 12 K. It then increases rapidly to 6.66 μ_B at 5 K. The observed μ_B of 7.27 at 260 K is close to the spin-only value of 6.93 μ_B for a dinuclear high-spin Co^{II}_2 (S = 3) system. Octahedral and tetrahedral Co^{II} ions can behave as spin-1/2 and spin-3/2 depending on temperature and spin–orbit coupling. The temperature dependence of μ_{eff} is thus consistent with linear repeating Co^{II} dimers with S = 3/2 at higher temperatures. The decrease of μ_{eff} between 100 and 12 K is likely due to depopulation of higher Kramers levels, and the increase at 12 K is ascribed to weak ferromagnetic interactions possibly occurring between di-μ-chloro linked Co^{II}.[7a]

Previously, tetranuclear $[M_4(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_4Cl_2(thf)_6]$ species (M = Co, Fe) have been synthesised from anhydrous metal chlorides in THF, and only in the case of manganese was a polymeric compound isolated.[9] It has now been shown that cobalt in presence of THF can also form polymeric species. Compound **2** has been isolated repeatedly from attempts of recrystallisation of a cobalt chloride oxime microcrystalline powder,[14,15] in a mixture of THF–diethyl ether as solvent; experiments are ongoing to obtain the product by a more direct route. The mechanisms of formation of **2**, and especially the insertion of residual water molecules are not yet completely understood; nevertheless, we assume that the weak oxime ligands are readily replaced by water and THF molecules during the time of crystallisation. From the previous observations, it is clear that the thermodynamic driving force leading to this family of self-assembly compounds should be important. If we consider **1**, MeOH is generated *in situ* from the action of trimethylorthoformate on water following the global equation:

$$HC(OMe_3)_3 + H_2O \rightarrow 2\ MeOH + O{=}CHOMe$$

as a consequence the MeOH:THF molar ratio is *ca.* 1:20. Assuming the coordination abilities of THF and MeOH are similar, the explanation for the formation of the complex should be self-assembly likely continuously carried out in the coordination sphere of cobalt or at least in a close vicinity to the metal centres. This means that methanol molecules should be readily accessible to grow the structure, despite their poor ratio relative to THF. These two examples show that unusual self-assembly can occur even in the absence of polydentate ligands. Further studies are in progress to extend this class of compounds.

Financial support has been provided by the Dutch Ministry of Economic Affairs (BTS 98141). This work was also supported (A. L. S., D. D. E.) by the Council for Chemical Sciences of the Netherlands Foundation for Scientific Research (CW-NWO). We are grateful to Mr O. Roubeau for working on magnetic susceptibilities measurements. We thank Dr S. T. Warzeska, Mr A. Eikelboom and Dr J. Bieleman for fruitful discussions.

Notes and references

‡ Although the synthesis can be carried out in air, experiments under inert atmosphere using Schlenk techniques and a vacuum line ensure the protection of the sensitive final product. To 0.2 g (0.85 mmol) of $CoCl_2{\cdot}6H_2O$ was added an excess of trimethylorthoformate (1.5 ml). The mixture was gently heated (50 °C) in 15 ml of THF until complete dissolution of the solid. After cooling to ambient temperature for 30 min, the deep blue solution was evaporated to dryness resulting in a shiny blue powder which is very moisture sensitive (0.17 g, 0.39 mmol, yield 92%). From a diethyl ether–tetrahydrofuran two layer recrystallisation, nice shiny blue prisms suitable for X-ray diffraction can be obtained after a few hours.

§ Data were collected on a Nonius Kappa CCD area detector, using Mo-Kα radiation with a graphite monochromator (λ = 0.71073 Å), on a rotating anode at 150 K. Lorentz polarisation and absorption corrections were applied in both instances. Refinement was carried out using full-matrix least squares on F^2 (SHELXL-97).

Crystal data: for **1**: $C_9H_{20}Cl_4O_3Co_2$, M_r = 435.91, monoclinic, space group $P2_1/c$ (no. 14), a = 10.9390(3), b = 12.1510(4), c = 12.6313(3) Å, β = 103.068(2)°, V = 1635.47(8) Å^3, F(000) = 880, Z = 4, μ(Mo-Kα) = 2.677 mm^{-1}. 15654 reflections measured, 3728 independent, R_{int} = 0.0501. Received (in Cambridge, UK) 18th May 2000, Accepted 14th June 2000
Published on the Web 4th July 2000

Inclusion crystals of 7-bromo-1,4,8-triphenyl-2,3-benzo[3.3.0]octa-2,4,7-trien-6-one (1) showed a reversible color change from yellow to green on exposure to UV-light, and this depends on the guest molecules present.

Organic photochromic compounds have received considerable attention in recent years due to their potential applications such as information storage, electronic display systems, optical switching devices, ophthalmic glasses, and so on.[1] Several types of organic photochromic compounds such as naphthopyrans, spiropyrans, fulgides (dialkylidenesuccinic anhydrides), anils (*N*-phenyl imines), hydrazones, stilbenes, and diarylethenes have been discovered and their properties investigated.[2] Recently, we have reported the novel photochromism of crystalline biindenylidene, which shows a reversible color change from yellow to reddish-purple upon photoirradiation.[3] We have now found that the title compound **1**[4] forms inclusion complex crystals with various kinds of organic guest molecules and some of these inclusion crystals show a reversible color change from yellow to green upon photoirradiation in the solid state (Scheme 1). It was also found that the stability of the photochromism depends on the type of guest molecule included. This is the first example of guest-dependent photochromism in host–guest inclusion crystals.

When a mixture of **1** and various kinds of guest compounds was recrystallized from AcOEt solution, inclusion complex crystals of **1** were obtained† (Table 1). Some of these inclusion crystals show a reversible color change from yellow to green upon photoirradiation in the solid state, although **1** itself does not show any photocoloration. For example, upon photoirradiation yellow crystals of the 2 : 1 inclusion compound of **1** with *p*-dimethoxybenzene turned green. These crystals revert to yellow on storage in the dark for 6 h at room temperature or quickly on heating at 60 °C. The UV spectral change of the 2 : 1 inclusion crystals is shown in Fig. 1. Similarly, the inclusion crystals with acetone (1 : 1), butan-2-one (1 : 1), cyclopentanone (1 : 1), cyclohexanone (1 : 1), dioxane (1 : 1), carbon tetrachloride (1 : 1), 1,1-dichloroethane (1 : 1), 1,1,2,2-tetrachloroethane (1 : 1), benzene (1 : 1), *o*-xylene (1 : 1), *p*-xylene (2 : 1), anisole (2 : 1), *m*-dimethoxybenzene (2 : 1) and 2-picoline (1 : 1) showed photochromism in the solid state. Interestingly, the photochromism of the inclusion crystals of **1** was very sensitive to the structure of the guest compounds. For example, cyclopentanone shows photochromism, while pentan-3-one does not. Similar structural effects were observed in the following cases: dioxane *vs*. tetrahydropyran, 1,1-dichloroethane *vs*. 1,2-dichloroethane, *o*-dimethoxybenzene *vs*. *m*- and *p*-dimethoxybenzene and 2-picoline *vs*. 3- and 4-picoline. An electronic effect of the guest compounds may be important, because the dimethoxybenzene derivatives as guest showed photochromism, while dichlorobenzene derivatives did not (Table 1).

It is also remarkable that the stability of the photochromism depends on the type of guest molecule. For example, the bleaching times of the green color which developed upon photoirradiation of the various inclusion crystals of **1** were 3 h (benzene), 4 h (cyclopentanone), 5 h (2-methylpyridine), 6 h (*p*-dimethoxybenzene), 9 h (*m*-dimethoxybenzene), 10 h (cyclohexanone and 1,1-dichloroethane), 12 h (anisol and *o*-xylene), 24 h (*p*-xylene), 164 h (butan-2-one), and 504 h (acetone and dioxane), respectively.

The solid-state IR spectrum of the green crystals was identical with that of the yellow crystals, and no EPR signal developed upon photoirradiation. The photochromic properties of **1** are probably due to π–π interactions owing to its suitable molecular packing in the inclusion crystals, because photoirradiation of **1** in solution did not show any photochromic properties. Further detailed studies of the relationship between crystal structures and photochromic properties of the inclusion complexes of **1** are in progress.

† Representative procedure for preparation of inclusion crystals and measurement of the diffuse reflectance UV spectra: When a mixture of **1**[4] and *p*-dimethoxybenzene was recrystallized from ethyl acetate in the dark, a 2 : 1 inclusion crystal of **1** and *p*-dimethoxybenzene was obtained as pale yellow prisms (mp 165–169 °C). The colored inclusion crystals were developed by photoirradiation with a high-pressure Hg lamp through a Pyrex filter for 10 min under aerobic conditions, and their diffuse reflectance UV spectra monitored by using a Shimadzu MPS-2000 spectrophotometer.

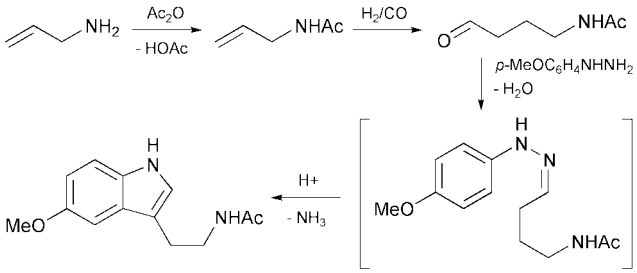
Water increases the selectivity in the Rh–phosphine catalysed hydroformylation of *N*-allylacetamide; an aqueous–organic biphasic system, containing a hydrophobic Rh-catalyst, provided facile catalyst/product separation, after which the aqueous product phase could be used in a one-pot synthesis of *N*-acetyl-5-methoxytryptamine (melatonin).

Olefin hydroformylation is one of the most commercially important reactions that makes use of a homogeneous catalyst.[1] Rh–phosphine complexes are active catalysts for this reaction with high selectivities towards linear aldehydes and a number of successful methods for the recycling of these catalysts have been developed.[2] Unfortunately, the feedstock is mainly restricted to linear, non-functionalised α-olefins, such as propene, styrene, *etc*.

Aldehydes bearing various functional groups are widely applied in the synthesis of, for example, flavours, fragrances and pharmaceuticals.[3] Their preparation by hydroformylation of a hetero-atom functionalised olefin, however, is not straightforward since these substrates react slowly, require high catalyst loadings and harsh reaction conditions, which leads to the formation of condensation products, such as acetals, hemiacetals, imines, *etc*.[4]

In connection with an alternative synthesis of *N*-acetyl-5-methoxytryptamine (melatonin), a human hormone which regulates sleep,[5] we required 4-acetamidobutanal. When combined with 4-methoxyphenylhydrazine this aldehyde affords an intermediate hydrazone, which in the presence of an acid undergoes a Fischer-indole reaction (Scheme 1).[6] 4-Acetamidobutanal was previously prepared by hydroformylation of *N*-allylacetamide in THF using 1% of $HRh(CO)(PPh_3)_3$.[7] After 18 h at 80 °C and 83 bar ($CO:H_2 = 1:1$), a conversion of 76% was reached with the product distribution: 4-acetamidobutanal (11%), 3-acetamido-2-methylpropanal (63%), *N*-acetylpyrrolidine (13%) and 2-formyl-*N*-acetylpyrrolidine (13%).

We found that the $Rh–PPh_3$ catalysed hydroformylation of *N*-allylacetamide gave the best results in a polar, protic solvent, such as methanol. Since *N*-allylacetamide is also soluble in water, we decided to carry out the hydroformylation in a one-phase aqueous medium, employing the water-soluble Rh–tppts catalyst (tppts = $P(C_6H_4$-*m*-$SO_3Na)_3$). To our surprise we found that the reaction proceeded smoothly under mild conditions. At 70 °C and a 10 bar pressure of a H_2–CO (1:1) mixture, the reaction was completed in 45 min using as little as 0.04% catalyst (Table 1, Exp. 2), with an initial rate of 3891 turnovers h^{-1}. The isomeric aldehydes were obtained in 99% selectivity. It was demonstrated by Mortreux and co-workers previously that the hydroformylation of acrylesters, such as methylacrylate, into their α- and β-formylesters also proceeds at a faster rate in a toluene–water two-phase system, employing the Rh–tppts catalyst, compared to the rate of $Rh–PPh_3$ in toluene alone (initial TOF = 545 *vs*. 225 h^{-1} (50 °C, 50 bar)).[8]



Scheme 1 Alternative synthesis of *N*-acetyl-5-methoxytryptamine.

In a series of $MeOH–H_2O$ mixtures we found that both the reaction rate and the selectivity towards the aldehydes increased with the water content. A direct comparison of the two catalysts in neat MeOH showed that $Rh–PPh_3$ is slightly more active than Rh–tppts and yields a product mixture with a slightly higher linear/branched (l/b) ratio (1.15 *vs*. 1.05, Table 1). The rather low regioselectivity compared to non-functionalised linear olefins, such as propene (l/b = 23),[2] suggests that coordination of the amide may take place during the insertion of the olefin into the Rh–hydride bond. The possible formation of a 6-membered chelate ring (Scheme 2) is expected to enhance the formation of the branched aldehyde.

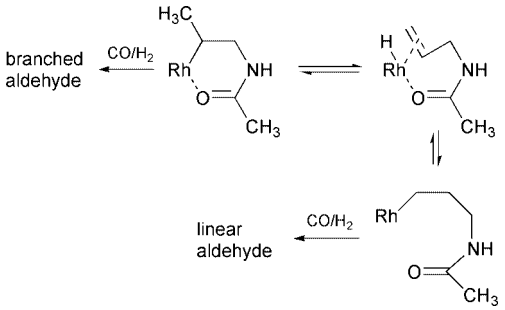
[a] Reaction conditions: 0.010 mmol $Rh(acac)(CO)_2$, 0.25 mmol ligand, 25 mmol *N*-allylacetamide, 70 °C, 10 bar H_2O–CO (1/1), 1000 rpm, 125 ml total reaction volume. [b] 0.010 mmol [$Rh(acac)(CO)_2$], 0.050 mmol Xantphos. [c] 0.050 mmol [$Rh(acac)(CO)_2$], 0.250 mmol Xantphos, 90 °C. [d] $MeOH–H_2O$ = 1/1 (v/v), 125 ml total. [e] 100 ml toluene, 100 ml H_2O. [f] TOF = initial turnover frequency in mol aldehyde per mol catalyst per hour.



Scheme 2 Proposed intermediates in the Rh/tppts catalysed hydroformylation of *N*-allylacetamide.

The high partition coefficients of 4-acetamidobutanal and 3-acetamido-2-methylpropanal in the water layers forestalled our attempts to extract them from the aqueous reaction mixtures with an organic solvent. Especially in the synthesis of pharmaceuticals the presence of traces of heavy metals is undesirable. In order to achieve efficient product/catalyst separation, we turned to an 'inverse two-phase catalyst system', containing the hydrophobic Rh–PPh_3 catalyst in a toluene–water mixture. In such a system the catalyst remains dissolved in the organic phase, while the products will move to the water layer; the opposite of standard aqueous biphasic catalysis.

In the biphasic system, the Rh–PPh_3 catalysed reaction (Exp. 6) proceeded considerably slower compared to Rh–tppts (Exp. 5), consistent with our observation (see above) that the reaction rate decreases when the hydroformylation is carried out in an apolar solvent, such as toluene. In addition, due to mass transfer limitations, the reaction rate decreased substantially after *ca.* 50% conversion (see Fig. 1). Such a decrease was less pronounced in the case of Rh–tppts, that operates in the aqueous layer, where the substrate concentration remains sufficiently high, resulting in a zero-order reaction profile until *ca.* 80% conversion. Nevertheless, due to the presence of water, the selectivity towards the aldehydes remained high (98%, Exp. 6) and the Rh–PPh_3 catalyst could conveniently be separated from the aqueous product phase.

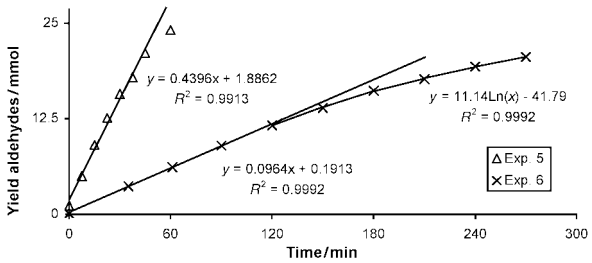


Fig. 1 Reaction profiles of Exp. 5 and Exp. 6.

To increase the regioselectivity towards the linear aldehyde, generally, rigid diphosphine ligands with a large bite angle are used.[9] We tested the Rh–Xantphos combination[10] (Xantphos = 4,5-bis(diphenylphosphino)-9,9-dimethylxanthene) in our inverted two-phase system and, indeed, the l/b ratio increased to 20. The reaction rate, however, decreased dramatically to 31 h^{-1} (Table 1, Exp. 7). At 90 °C, in the presence of 0.2% catalyst, a nearly quantitative conversion was reached in 10 h reaction time with a small compromise in the l/b ratio. The organic catalyst phase could be recycled in 5 consecutive runs without loss in activity. Rh-analysis of the water layers by means of atomic absorption spectrometry confirmed a quantitative (> 99%) catalyst/product separation.

N-Acetyl-5-methoxytryptamine was subsequently prepared in a one-pot procedure starting from allylamine (see ESI). By successive acetylation of allylamine, selective hydroformylation, hydrazone formation with 4-methoxyphenylhydrazine (HCl salt) and a Fischer indole reaction, melatonin was isolated from the aqueous reaction mixture in 44% yield (not optimised).

In conclusion, we have demonstrated that the hydroformylation of *N*-allylacetamide proceeds smoothly in a one-phase aqueous medium, as well as in an aqueous–organic two-phase protocol under mild reaction conditions. Although we could not take full advantage of the rate accelerating effect of water in the inverted two-phase catalyst system, the linear aldehyde was obtained in high selectivity and efficient catalyst/product separation was achieved. The organic soluble catalyst was recycled and the aqueous product phase was applied without purification in the synthesis of *N*-acetyl-5-methoxytryptamine. Mechanistic details and the scope of the inverted two-phase system are currently under investigation.

We thank Dr G. Papadogianakis and Dr G. Besenyei for the fruitful discussions and Mr J. Padmos for the Rh-analysis. Financial support by NWO-CW is also gratefully acknowledged.

Theanaphthoquinone, a novel pigment oxidatively derived from theaflavin during tea-fermentation

Takashi Tanaka, Yayoi Betsumiya, Chie Mine and Isao Kouno*

School of Pharmaceutical Sciences, Nagasaki University, 1-14 Bunkyo-machi, Nagasaki 852-8521, Japan. E-mail: ikouno@net.nagasaki-u.ac.jp

Received (in Cambridge, UK) 2nd May 2000, Accepted 15th June 2000
Published on the Web 4th July 2000

Treatment of a mixture of epicatechin and epigallocatechin with extracts of fresh tea leaf or banana fruit generated a new pigment named theanaphthoquinone, which has a 1,2-naphthoquinone moiety oxidatively derived from the benzotropolone unit of theaflavin.

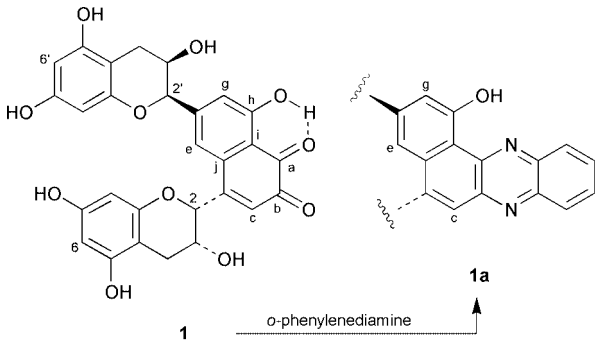
Theaflavins and thearubigins are major pigments of black tea and it is generally accepted that these are formed from flavan-3-ols (catechin) during tea fermentation.[1] Although structures and biogenesis of theaflavins having a benzotropolone unit are well studied, little is known about thearubigins despite many spectroscopic and chemical studies on these heterogeneous polymers.[2] Biochemical studies on tea fermentation indicated that oxidation of theaflavins might participate in thearubigin formation.[1]

For the purpose of clarification of the oxidative metabolism of flavan-3-ols in tea fermentation and characterization of thearubigins, a mixture of (−)-epicatechin (EC) and (−)-epigallocatechin (EGC), the major flavan-3-ols of tea leaf, was treated with aqueous extract of fresh tea leaf (*Camellia sinensis* var. *sinensis*). Prior to the reaction, almost all flavan-3-ols in the tea extract were removed by homogenization with Polyclar AT and subsequent filtration.[3] Analysis of the reaction mixture by HPLC equipped with a photodiode-array detector showed accumulation of theaflavin (**2**) at the initial stage (5 h). Subsequently, a peak due to an unknown product (**1**) having an absorption maximum at 440 nm appeared (10–20 h). Although an attempt to isolate **1** from the reaction mixture failed owing to the presence of many minor products, we found that **1** and **2** were also synthesized in a similar reaction using banana fruit instead of tea leaves.

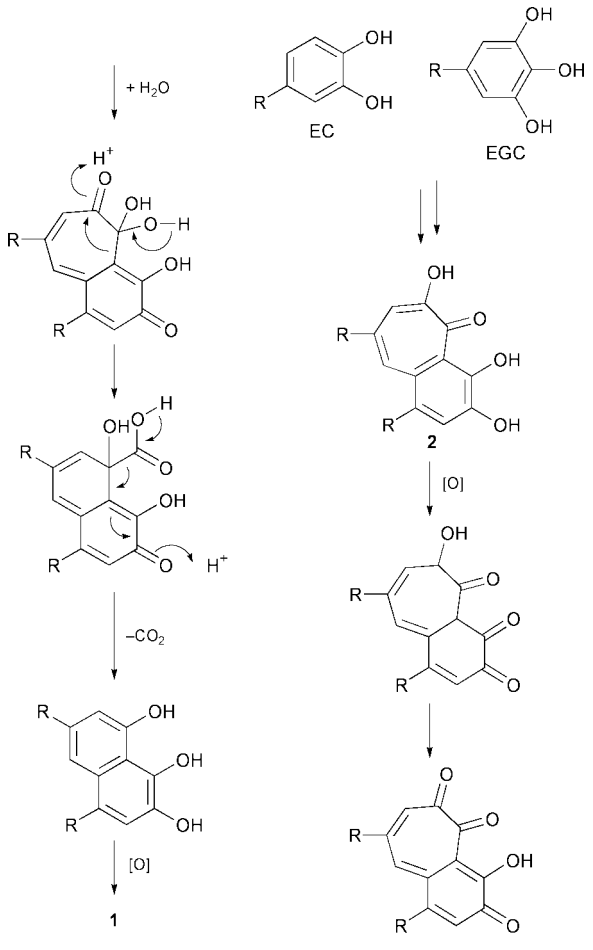
Separation of **1** and **2** from the reaction mixture treated with banana fruit was much easier than that in the tea leaf experiment (isolation yield from EGC: **1**, 16%; **2**, 39%).[4] Extracts of apple, potato, sweet potato, persimmon and black mushroom were also examined and found to be capable of synthesizing **2**; however, **1** was not detected in their reaction mixtures.

Structure elucidation of the dark yellow pigment **1**, named theanaphthoquinone, was as follows: ^{1}H and ^{13}C NMR spectra[5] resembled those of **2** and showed signals arising from two sets of A and C rings of flavan-3-ols. The ^{13}C NMR spectrum indicated the presence of two conjugated carbonyl groups [δ_C 180.62 (C-a) and 183.38(C-b)] and 8 sp^2 carbons besides those of the A and C rings. The HMBC correlation[6] of these carbons with three aromatic protons [δ_H 6.789 (H-c), 7.327 (H-g), 7.441(H-e)] and H-2 (δ_H 5.377) and H-2′ (δ_H 5.163) of the two C-rings revealed the presence of a 1,2-naphthoquinone structure. In addition, the appearance of a signal due to a phenolic hydroxy group at very low field (δ_H 12.28) indicated an intramolecular H bond with one of the C=O groups. The negative FABMS showed a pseudo-molecular ion peak at *m/z* 535, which was two mass units larger than that expected (*m/z* 533 [M − H]$^-$), and probably arose from a reduction product of **1**, because similar phenomena are known for some quinones with low redox potentials.[7] The final confirmation for the structure was made by condensation with *o*-phenylenediamine affording a phenazine derivative **1a** (*m/z* 605 [M − H]$^-$) and its spectral analysis (Scheme 1).[8]

1 and **2** were not detected when EC and EGC were treated separately with banana extract, and it was clear that **2** was



Scheme 1



Scheme 2

DOI: 10.1039/b003510f

synthesized from a combination of EC and EGC.[1] Therefore, it is suggested that **1** is biosynthesized from **2** with the aid of polyphenol oxidase as shown in Scheme 2. The discovery of **1**, the first pigment generated by oxidation of **2**, is of great interest from the viewpoint of food manufacturing. In addition, a prolonged experiment using tea leaf extract until 30 h showed a decrease of **1** and **2** and an increase of polymeric substances, since only a broad peak was detected on HPLC analysis, suggesting that **1** was further metabolized during tea fermentation and might be related to thearubigin formation.

3 Fresh tea leaves (30 g) were homogenized with 150 ml of water in the presence of Polyclar AT (10g). After filtration, the filtrate (3 ml) was mixed with an aqueous solution (0.5 ml) of EC (10 mg) and EGC (10 mg) and vigorously stirred at 20 °C. An aliquot of the mixture was extracted with aqueous acetone and analyzed by reverse phase HPLC.

4 Isolation of **1**: Banana fruit flesh (*Musa acuminata* Colla cv. giant cavendish) (200 g) was homogenized with water (600 ml) in a Warring blender and filtered with four layers of muslin. The filtrate (300 ml) was mixed with an aqueous solution (50 ml) of EC (1.0 g, 3.45 mmol) and EGC (1.0 g, 3.27 mmol) and stirred vigorously for 5 h at 20 °C. The mixture was poured into acetone (800 ml) and filtered. The filtrate was concentrated and extracted with AcOEt (300 ml × 4) and the extract was applied to a column of Sephadex LH-20. Elution with EtOH afforded **1** (280 mg, 0.524 mmol) and **2** (728 mg, 1.29 mmol).

Alcohol dehydrogenase from *Geotrichum candidum* was found to be active in supercritical carbon dioxide at 10 MPa; high activities and excellent enantioselectivities were observed for the asymmetric reduction of aromatic and cyclic ketones.

Supercritical fluids have been used as solvents for organic synthesis as well as for extraction and chromatography by taking advantage of both their gas-like low viscosities and high diffusivities and their liquid-like solubilizing power.[1] Moreover, the tunability of these properties is unique to supercritical fluids; small changes in pressure or temperature lead to significant changes in density-dependent solvent properties such as the relative permittivity, the solubility parameter, and the partition coefficient.[1] Among many fluids, supercritical carbon dioxide ($scCO_2$) has the added benefits of an environmentally benign nature, nonflammability, low toxicity, high availability, and ambient critical temperature (T_c = 31.0 °C) that make it suitable for biotransformations.[1] The attraction of combining natural catalysts with a natural solvent has been the driving force behind a growing body of literature[2] on the stability, activity and specificity of enzymes in $scCO_2$.[1] Since the first report on biotransformations in supercritical fluids in 1985 by Randolph *et al.*,[3] Hammond *et al.*[4] and Nakamura *et al.*,[5] the benefits of using supercritical fluids for biotransformations have been demonstrated by Mori *et al.*[6] and Kamat *et al.*:[7] *e.g.* improved reaction rates, control of selectivities by pressure, *etc.*

However, most of the biocatalysts used in supercritical fluids are hydrolytic enzymes[1–7] such as lipases and proteases with the exception of cholesterol oxidase,[8] and no report on the use of alcohol dehydrogenases in supercritical fluids has yet been published, despite the fact that they are an important class of enzymes for the asymmetric reduction of ketones to produce chiral alcohols. There is growing demand for such alcohols as the chiral synthones for natural products, pharmaceuticals, agrochemicals, and ferroelectric liquid crystals. Here we report the first achievement of a highly enantioselective reduction of ketones by alcohol dehydrogenase in $scCO_2$ (Scheme 1).

The resting cells of a fungus, *Geotrichum candidum*[9] IFO 5767, were employed for the reduction of ketones owing to its high reactivity with unnatural substrates and the simplicity of its growth. The whole-resting cell instead of an isolated enzyme was used for the reduction, and thus the addition of expensive coenzyme was not necessary and the solubilities of the coenzymes in $scCO_2$ did not need to be considered. The cell was immobilized on a water-absorbing polymer[9c] to spread it on the large surface of the polymer. At first, the reduction of *o*-fluoroacetophenone in $scCO_2$ at 10 MPa was conducted, which resulted in (*S*)-1-(*o*-fluorophenyl)ethanol at 81% after 12 h. A control experiment to prove that the reduction did not proceed before the supercritical condition was also conducted.[10] The time course of the reaction (Fig. 1) shows that the yield increased with the reaction time, which proved that the alcohol dehydrogenase catalyzed the reduction even in the supercritical condition.

The substrate specificity was investigated, and as listed in Table 1, the biocatalytic reduction in $scCO_2$ proceeded for various ketones. Acetophenone, acetophenone derivatives, benzyl acetone and cyclohexanone were used as substrates, and it was found that all of them were reduced by the alcohol dehydrogenase in $scCO_2$. The effects of fluorine substitution at the *ortho*, *para* and α positions of acetophenone were obvious. Compared with the unsubstituted analogue, substitution at the *ortho* or α position increased the yield, whereas substitution at the *para* position decreased the yield. Systematic study of the relationship between the effect of the fluorine substituent and the effect of properties of $scCO_2$ as well as isolation of the enzyme responsible for the reduction, tasks which are in progress in our laboratory, would give a better understanding of the fluorine recognitions by the protein.

The finding that the alcohol dehydrogenase is active in $scCO_2$ is significant, but not sufficient for practical use; high enantioselectivity of the reduction is also necessary for synthetic purposes. In our case, very high enantioselectivities (> 99% ee) were obtained for the reduction with the majority of the substrates tested, while slightly lower enantioselectivities (96, 97% ee) were observed for a few of them. The enantioselectivities obtained in this system are superior to or at least equal to those for most other biocatalytic and chemical systems.[11]

In a typical experiment, *G. candidum* IFO 5767 was grown as described previously.[9d] The freshly prepared cell (0.25 g wet wt) was suspended in H_2O (0.75 mL) and propan-2-ol (0.050 mL), and immobilized on water absorbing polymer (BL-100®, 0.125 g) as described previously.[9c] In the experiment, we used a stainless steel pressure-resistant vessel (Taiatsu Techno, Co., Osaka, TVS-N2 type, 10 mL) equipped with a stop valve (Whitey Co. SS3NBS4G), manometer (Taiatsu Techno, Co., Osaka, 15 MPa), and HPLC pump (Jasco PU-1580 pump) connected to a cooler (−5 °C) and CO_2 gas cylinder. In this vessel, the immobilized cell, a magnetic stirrer, and a ketone (0.017 mmol, placed in a glass tube to prevent it from contacting the biocatalyst before achieving the supercritical conditions) were charged. Then the vessel was warmed to 35 °C, and CO_2 preheated to 35 °C was introduced until a pressure of 10 MPa was reached. The mixture was stirred at 35 °C for 12 h, and the CO_2 was liquefied at −10 °C and then the gas pressure was

released. The resulting residue was dissolved in ether, and the mixture was put on Extrelut and quickly eluted with ether. Chemical yield and ee were measured using a chiral GC-column (Chirasil-DEX CB; 25 m; He 2 mL min^{-1}). The absolute configurations were determined by comparing the GC retention times with those of authentic samples.

In conclusion, the alcohol dehydrogenase from *G. candidum* was found to be active in $scCO_2$ at 35 °C and 10 MPa and to catalyze asymmetric reduction of various ketones with excellent enantioselectivities. For practical use, there has so far been some hesitation to use alcohol dehydrogenases in spite of their high enantioselectivities because of the difficulties in extracting the product from aqueous solvents. We believe that this report opens up new possibilities for asymmetric reduction by an enzyme with a natural and easily-removable solvent.

The authors greatly appreciate the advice and technical support in assembling the $scCO_2$ reactor given by Professor Okamoto at Kyoto Institute of Technology, Professor Okahata and Dr Mori at Tokyo Institute of Technology, Dr Ozaki at Osaka University and Professor Hori and Dr Tabata at Fukui University. This work was supported by a Grant-in-Aid for Encouragement of Young Scientists (No. 12740400) and a Grant-in-Aid for Scientific Research (C) (No. 11640602) from the Ministry of Education, Science, Sports and Cultre of Japan. The authors are grateful to Osaka Yuki Kagaku Kogyo Co., Ltd. for providing BL-100® (water-absorbing polymer).

Lanthanide co-ordination frameworks of 4,4′-bipyridine-*N*,*N*′-dioxide†

De-Liang Long, Alexander J. Blake, Neil R. Champness* and Martin Schröder*

School of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: M.Schroder@nottingham.ac.uk, Neil.Champness@nottingham.ac.uk

Received (in Cambridge, UK) 24th March 2000, Accepted 19th May 2000
Published on the Web 5th July 2000

Metal–ligand co-ordination frameworks of 4,4′-bipyridine-*N*,*N*′-dioxide (L) have been prepared; $\{[Sm(L)_2(NO_3)_3]\cdot 0.5H_2O\}_\infty$ 1, $\{[Er_2(L)_3(NO_3)_6]\cdot 2CH_3OH\}_\infty$ 2; 1 shows rare two-fold interpenetrating three-dimensional $CdSO_4$-like nets, and 2 shows an unprecedented two-dimensional 4.8^2 network.

The construction of inorganic co-ordination networks and crystal engineering have developed rapidly in recent years, the vast majority of reported work being based upon the use of polydentate ligands bound to d-block transition metal ions.[1] Ligands based upon aromatic N-donor ligands, such as 4,4′-bipyridine, have been particularly studied as they can be readily varied, giving a high degree of control over co-ordination framework structure. Aspects of such ligands that can be tuned include: denticity, ligand donor-atom separation, and, consequently, the degree of interpenetration, steric and electronic properties, and even the degree of inter-ligand interaction.

Far less common has been the use of lanthanide ions as nodes in the construction of co-ordination framework polymers.[2] Such structures can be expected to be more difficult to control than their d-block metal analogues due to the higher co-ordination numbers of lanthanide ions. However, the inherent flexibility of their co-ordination geometry is particularly attractive for the preparation of new network types as this greater structural ambivalence will lead to the synthesis of unprecedented structures. Based on the fact that lanthanide ions have a high affinity for hard oxygen-containing ligands, we have developed a new, widely applicable strategy using, for the first time, 4,4′-bipyridine-*N*,*N*′-dioxide (L) as a bridging ligand in the construction of fully characterised co-ordination networks. This strategy using poly(*N*-oxide) ligands offers exciting possibilities as the degree of structural manipulation seen in d-block coordination frameworks can now be developed for networks based upon f-block metals.

Although the co-ordination of pyridine-*N*-oxides to lanthanide ions in discrete molecular compounds is reasonably well established,[3] we are aware of only one report in the literature of a complex of 4,4′-bipyridine-*N*,*N*′-dioxide,[4] with another of a copper(II) co-ordination polymer of the related azobis(pyridine-4,4′-dioxide).[5] We now report two compounds with very different structures, $\{[Sm(L)_2(NO_3)_3]\cdot 0.5H_2O\}_\infty$ **1** and $\{[Er_2(L)_3(NO_3)_6]\cdot 2CH_3OH\}_\infty$ **2** (L = 4,4′-bipyridine-*N*,*N*′-dioxide).

Yellow crystals of **1**, and pale pink crystals of **2**, were prepared‡ by slow diffusion of $Sm(NO_3)_3$ or $Er(NO_3)_3$ and 4,4′-bipyridine-*N*,*N*′-dioxide in a MeOH–CH_2Cl_2 solvent mixture, the latter component acting to slow the rate of diffusion and thus the reaction. The crystals of **1** were very stable in air and did not decay upon continuous exposure to moisture, but crystals of **2** lost crystallinity quickly following removal from the mother liquor. Single crystal X-ray analyses§ confirm that these materials have polymeric structures, based on networks of ten-co-ordinate lanthanide centres for **1** and nine-co-ordinate centres for **2**, with L bridging the metal centres. Whereas the Sm(III) ions in **1** have a regular SmO_{10} co-ordination environment with the oxygen atoms forming a hexadecahedron (Fig. 1a), the Er(III) ions in complex **2** have an ErO_9 co-ordination environment, with nine oxygen atoms forming a distorted tricapped trigonal prism (Fig. 1b), reflecting the reduction in the ionic radius from Sm(III) to Er(III).

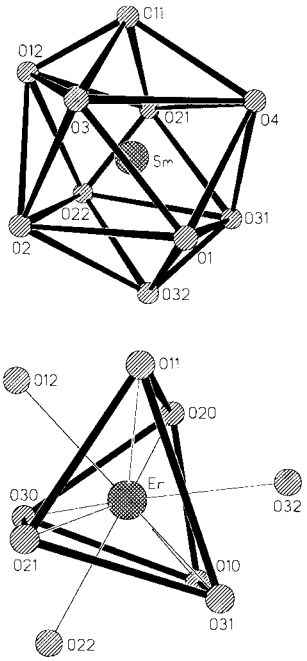

Fig. 1 Metal co-ordination environments in **1** (a) and **2** (b).

1 adopts a two-fold interpenetrating three-dimensional $CdSO_4$-like framework (a in Scheme 1, Fig. 2). The 4,4′-bipyridine-*N*,*N*′-dioxide ligands sustain a 3-D framework motif through two different linkages. The first propagates along the two diagonal directions of the *ab* face; the ligand is slightly bent, with the two pyridyl rings twisted at an angle of 14.8° and bridging two Sm(III) centres at a distance of 12.7 Å. The other linkage exists as a zigzag line propagating along the *c* axis; in this case the ligand is more bent, with the two pyridyl rings twisted at an angle of 29.9° and bridging the two Sm(III) centres at a much shorter distance of 11.6 Å. The framework found here

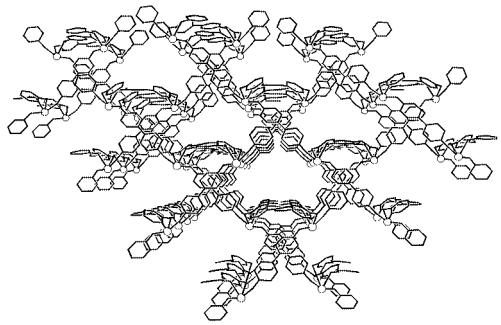

Fig. 2 Packing diagram of compound **1** showing one component of the two interpenetrating frameworks (viewed down the *c* axis). Nitrate groups, solvent molecules and hydrogen atoms are omitted for clarity.

is a severely distorted $CdSO_4$-like net,[6,7] The previous examples of $CdSO_4$-type nets, $\{Cu[1,2\text{-bis}(4\text{-pyridyl})ethane]_2(NO_3)_2\}_\infty$ reported by Zaworotko *et al*.[6] and the related 'dense-net' structure of copper complexed with 1,2-bis(4-pyridyl)ethyne reported by Ciani *et al*.,[7] are both constructed from *d*-metal junctions. As the conformation of the linking ligands is flexible, the junction at Sm(III) is distorted from square-planarity causing the connection propagating along the *c* direction to develop into a zigzag line. When viewed along the *c* direction, the structure is seen to contain 12.0 × 12.0 Å channels (Fig. 2). However, these channels are occupied by a second interpenetrating independent framework.

The smaller ionic radius for Er(III) compared to Sm(III) results in nine-co-ordinate Er(III) centres in **2** *via* six oxygen donors from three nitrates and three from three 4,4′-bipyridine-*N*,*N*′-dioxide ligands. These latter ligands link the Er(III) ions to form a 2-D sheet of 4.8^2 topology (b in Scheme 1, Fig. 3). This type of net, predicted by Wells[8] but not previously observed for co-ordination frameworks, consists of three connected nodes shared by one tetragonal square unit and two octagons. The octagonal unit forms an 88-membered ring, comprising eight metal ions and eight ligands, of *ca.* 2.6 nm diameter. This large cavity is occupied by the four-membered ring motif of an adjacent layer thus inhibiting interpenetration. When viewed along the *c* axis, tetragonal channels with dimensions of 10.0 × 10.0 Å can be seen (Fig. 3), in which methanol solvent molecules are accommodated.

The isolation of complexes **1** and **2** suggests the possibility of constructing designed inorganic networks with lanthanide metal salts and bridging pyridine-*N*-oxide ligands. We have every reason to believe that, in the same way that polypyridines are important for d-block metal ions, poly(pyridine-*N*-oxides) may become equally important for f-block metal ions, thus leading to a new family of inorganic co-ordination networks and framework materials.

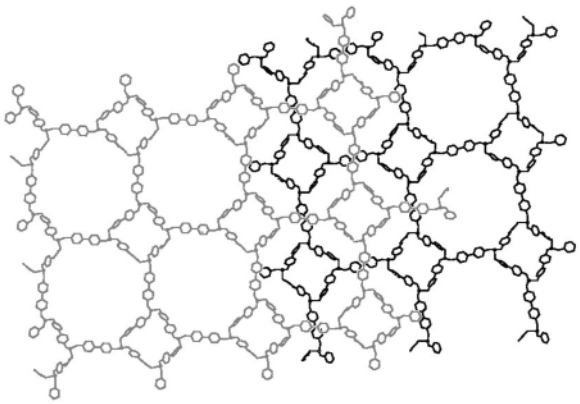

Fig. 3 View of the 4.8^2 nets in compound **2** with two adjacent layers in different colours. Nitrate groups, solvent molecules and hydrogen atoms are omitted for clarity.

$Zn_{0.999}Ni_{0.001}S$ photocatalysts (energy gap = 2.3 eV) heat-treated at 773 K in an N_2 flow showed activity for hydrogen evolution from aqueous solutions containing K_2SO_3 and Na_2S as reducing reagents under visible light irradiation without co-catalysts such as Pt.

Water splitting using photocatalysts is an important reaction from the viewpoint of global energy and environmental concerns. Although some photocatalysts have been reported to show high activities for the water splitting, they are active only under UV-light irradiation.[1,2] However, photocatalysts which are active for the water splitting under visible light irradiation have not been developed. Even in the presence of sacrificial reagents, the only well-known photocatalysts that can produce hydrogen or oxygen from aqueous solutions under visible light irradiation are Pt/CdS and WO_3.[3–5] Therefore, development of new visible-light-driven photocatalysts is a priority. One of us has recently found that $BiVO_4$ prepared in an aqueous process showed high activity for oxygen evolution from aqueous solutions containing Ag^+ as an electron scavenger.[6,7] On the other hand, it is important to develop new and less harmful visible-light-driven photocatalysts than Pt/CdS for hydrogen evolution from aqueous solutions. We have studied the development of new visible-light-driven photocatalysts based on ZnS and have previously reported a CuS–ZnS solid solution photocatalyst.[8] However, this CuS–ZnS photocatalyst has poor thermal and chemical stability. The present work reports thermally and chemically stable Ni-doped ZnS photocatalysts for hydrogen evolution from aqueous K_2SO_3 and Na_2S solutions under visible light irradiation.

Ni-doped ZnS photocatalysts were prepared by mixing an aqueous $Zn(NO_3)_2$ and $Ni(NO_3)_2$ solution with an aqueous Na_2S solution. The obtained precipitates were washed with distilled water using a centrifuge and then were heat-treated at 773 K in an N_2 flow. Photocatalytic reactions were carried out in a closed gas circulation system by using a 300 W Xe illuminator (CERMAX, LX300) and optical cut-off filters. The Ni-doped ZnS photocatalyst (1 g) was dispersed in aqueous K_2SO_3 and Na_2S solutions in a Pyrex reaction cell. The amounts of H_2 evolved were determined by using a gas chromatograph (Ohkura, Model 802, TCD, Ar carrier). Quantum yields were measured using an interference filter (λ_{max}: 420 nm, half width; 11 nm) and chemical actinometry measured using ammonium ferrioxalate.

Fig. 1 shows photocatalytic H_2 evolution from an aqueous solution containing K_2SO_3 and Na_2S as reducing reagents on $Zn_{0.999}Ni_{0.001}S$ powder heat-treated at 773 K in an N_2 flow under visible light irradiation. H_2 efficiently evolved even without co-catalysts such as Pt. The rate of H_2 evolution was 280 μmol h^{-1}, a relatively large value under the present experimental conditions (300W Xe lamp, λ > 420 nm). The turnover number of reacted electrons to the amount of Ni doped reached 170 at 8 h of the reaction time and the quantum yield at 420 nm was 1.3%. More than 7500 μmol of H_2 was formed in a prolonged experiment (> 50 h). The number of electrons reacted exceeded the amount of the catalyst (10 mmol),

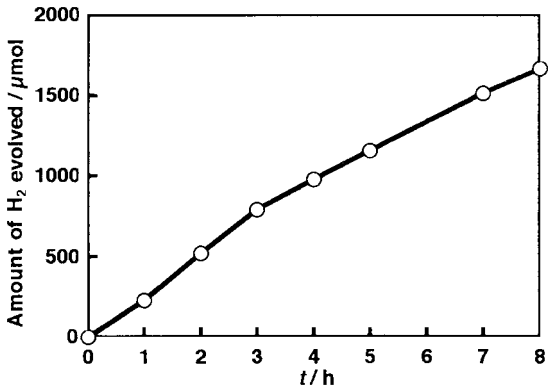

Fig. 1 Photocatalytic H_2 evolution from an aqueous K_2SO_3 (0.5 mol l^{-1})–Na_2S (0.005 mol l^{-1}) solution (300 ml) on $Zn_{0.999}Ni_{0.001}S$ powder (1 g) heat-treated at 773 K in an N_2 flow under visible light irradiation (λ > 420 nm). Light source: 300 W Xe lamp.

indicating the reaction proceeded photocatalytically with negligible photocorrosion.

Fig. 2 shows diffuse reflectance spectra of non-doped ZnS and $Zn_{0.999}Ni_{0.001}S$ heat-treated powders. The spectrum of $Zn_{0.999}Ni_{0.001}S$ showed a visible light absorption band with the onset around 540 nm in addition to the UV light absorption band derived from ZnS. The energy gap estimated from the onset of the visible light absorption band was 2.3 eV. The color of the photocatalyst was pale yellow and did not change after photocatalytic reactions. The shape of the diffuse reflectance spectrum of $Zn_{0.999}Ni_{0.001}S$ indicates that the doped nickel forms a new energy level in the band structure of ZnS. The visible light absorption band is assigned as due to the transition from the Ni 3d level to the conduction band level of ZnS, since the $Zn_{0.999}Ni_{0.001}S$ photocatalyst possesses highly active H_2 evolution sites as well as ZnS. Unless the conduction band was not derived from that of ZnS, such a high activity for the H_2 evolution without co-catalysts as evidenced in Fig. 1 would not be obtained. The photoexcitation of electrons from the Ni 3d level to the conduction band suggests that the photocorrosion

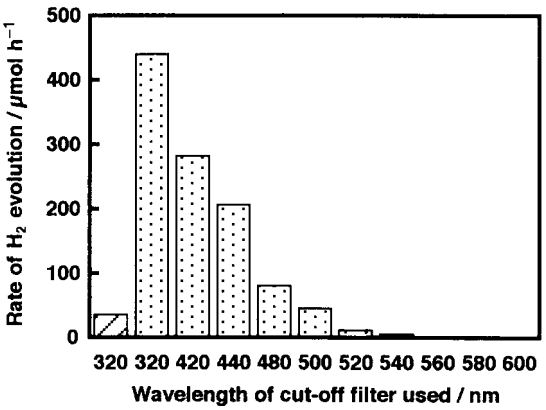

Fig. 3 The dependence of photocatalytic activities for H_2 evolution from an aqueous K_2SO_3 (0.5 mol l^{-1})–Na_2S (0.005 mol l^{-1}) solution (300 ml) over $Zn_{0.999}Ni_{0.001}S$ (dotted bar) and ZnS (hatched bar) powder heat-treated at 773 K in an N_2 flow upon wavelength (controlled *via* cut-off filters). Light source: 300 W Xe lamp.

observed for ZnS photocatalysts under band gap irradiation should be suppressed in the present system.

The wavelength dependence of the photocatalytic H_2 evolution on the $Zn_{0.999}Ni_{0.001}S$ photocatalysts was investigated as shown in Fig. 3. The number of incident photons was increased as the wavelength of cut-off filters was shortened. Although Fig. 3 is different from an ordinary action spectrum, it indicates the following points. When a cut-off filter of 540 nm was used, H_2 evolution was clearly observed. This wavelength corresponds to the onset of the diffuse reflectance spectrum as shown in Fig. 2. The $Zn_{0.999}Ni_{0.001}S$ photocatalyst showed considerably higher activity than non-doped ZnS even under full-arc irradiation ($\lambda > 320$ nm). It is often observed that doping transition metals with partly-filled d orbitals into photocatalysts such as TiO_2 strongly decreases the photocatalytic activities. However, such an suppression effect by the doping was not predominant in the present metal ion-doped ZnS photocatalyst system.

There were some problems concerning the thermal and chemical stability for the previously reported Cu-doped ZnS photocatalyst.[8] When the Cu-doped ZnS photocatalyst was dried or heat-treated to obtain good crystallinity, the photocatalytic activity for H_2 evolution was drastically decreased and the color of the photocatalyst changed after the photocatalytic reaction. In contrast to the Cu-doped ZnS photocatalyst, although the activity of the Ni-doped ZnS photocatalyst was lower, it was thermally and chemically stable. Moreover, the energy gap of Ni-doped ZnS (2.3 eV) was smaller than that of Cu-doped ZnS (2.5 eV) indicating that Ni-doped ZnS can utilize a wider spectral region of visible light than Cu-doped ZnS. The Ni-doped ZnS photocatalyst can produce H_2 using reducing reagents of sulfur compounds which are formed as by-products in petrochemical industries. Therefore, the Ni-doped photocatalyst is expected to be a practically useful photocatalyst.

In conclusion, Ni-doped ZnS has been developed as a new visible-light-driven photocatalyst for H_2 evolution from aqueous solutions. The development seems to suggest a way in making UV respondent photocatalysts respondent also to visible light.

The first water-soluble main-chain polyfullerene†

Shashadhar Samal, Bum-Jin Choi and Kurt E. Geckeler*

Laboratory of Applied Macromolecular Chemistry, Department of Materials Science and Engineering, Kwangju Institute of Science and Technology, 1 Oryong-dong, Puk-gu, Kwangju 500-712, South Korea. E-mail: keg@kjist.ac.kr

Received (in Cambridge, UK) 15th May 2000, Accepted 12th June 2000

The synthesis of the first water-soluble polyfullerene is accomplished by nucleophilic reaction of a diamine supramolecularly shielded in a cyclodextrin cavity with fullerene, leading to a versatile new field for main-chain fullerene polymers.

Although a versatile derivatization chemistry of fullerenes has been developed,[1] solubilizing fullerenes in water while preserving the intrinsic properties of the carbon allotropes has met with limited success and consequently only a few reports are available in this field.[2] Previous attempts to synthesize fullerene main-chain polymers have been based on multi-step synthetic concepts and resulted in water-insoluble products.[3] In view of the potential biological and biomedical applications of water-soluble fullerene compounds,[4] we synthesized polyfullerenes following a general strategy, which we call the supramolecular masking concept, in which fullerene molecules are connected in the polymer main chain with bifunctional guest compounds that are supramolecularly shielded by a macrocyclic host. In a typical experiment, the cyclodextrin–amine complex (**2**), dissolved in dimethylformamide, was treated with a solution of [60]fullerene in dichloromethane, at room temperature, facilitating a nucleophilic polyaddition reaction between the accessible amino groups of the diamine moiety in the cyclodextrin cavity and C_{60}, leading to the water-soluble polyfullerene (**3**) (Scheme 1).

Initially, we thought of using *p*-phenylenediamine (PPD) as the simplest aromatic diamine for complexation with β-cyclodextrin (CD), the cyclic glucose hepta-oligomer, and subsequent use of the complex (CD–PPD) as the monomeric precursor for the synthesis of the fullerene main-chain polymer. The result was a species with a molecular mass of ~2.8 kg mol^{-1} (GPC data). Spectral data provided evidence of reaction between the inclusion complex and C_{60}. Formation of a short segment instead of a polymer was ascribed to the low probability of reaction of C_{60} with the PPD nitrogens (N–N distance 576 pm) embedded in the depth of the CD cavity (780 pm).

A similar reaction between the inclusion complex CD–bis(*p*-aminophenyl) ether (CD–BPE, N–N distance 968 pm) and C_{60} resulted in polymer **3**, (poly[(β-cyclodextrin–bis(*p*-aminophenyl) ether)-*co*-[60]fullerene], M_n = 18.9, M_w = 20.0 kg mol^{-1}; polydispersity 1.06) that exhibited a high solubility in water (> 10 mg ml^{-1}). The inclusion complex registered absorption peaks in the UV-Vis spectrum at 243 and 295 nm, whereas **3** registered peaks at 243, 286, and 343 nm (Fig. 1). Additionally there was substantial peak broadening beyond 350 nm (inset). Dynamic light scattering studies of water-soluble fullerenes have established that this peak broadening is due to scattering

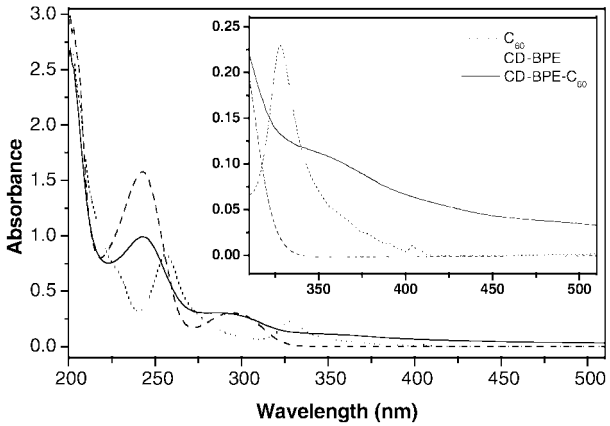

Fig. 1 UV-Vis spectra of C_{60} inclusion complex CD–BPE, and the polyfullerene CD–BPE–C_{60} (**3**).

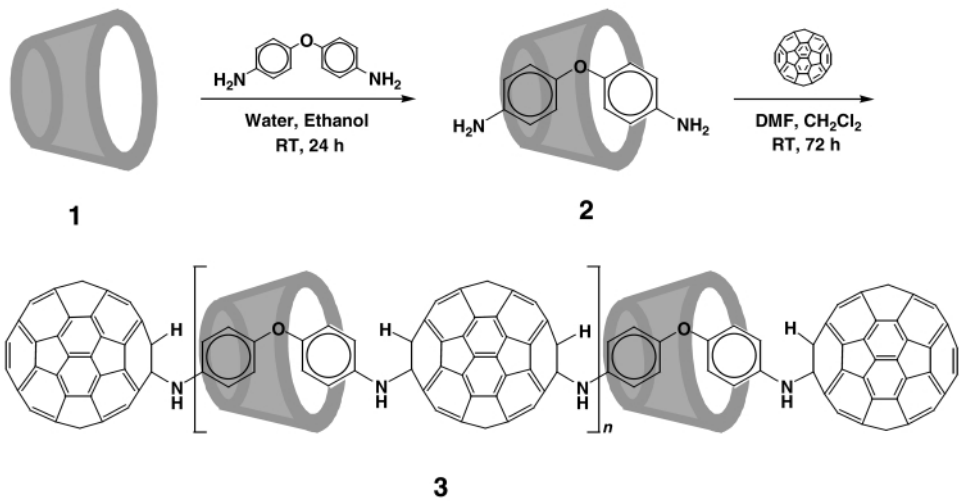
† A colour version of the space-filling model of the supramolecularly shielded polyfullerene (Fig. 2) is available as electronic supplementary information (ESI). See http://www.rsc.org/suppdata/cc/b0/b003881o/



Scheme 1 Reaction scheme for the synthesis of polyfullerene (**3**).

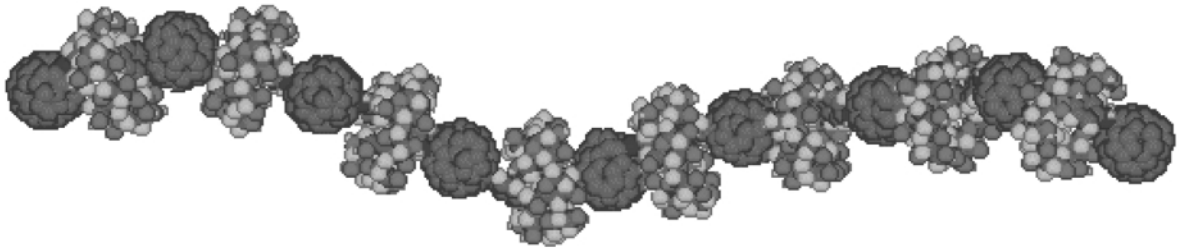


Fig. 2 Space-filling model of the supramolecularly shielded polyfullerene. For colour version, see http://www.rsc.org/suppdata/cc/b0/b003881o/

by fullerene aggregates.[5] The FT-IR spectra of the polyfullerene had distinct differences from the inclusion complex. In the case of the species from the reaction of CD–PPD and C_{60}, the fullerene peak was seen at 527 cm^{-1}, whereas for **3**, this peak was prominent at 513 cm^{-1}.

The ^1H NMR spectrum of the complex CD–BPE was well-defined, with the aromatic protons at 6.48, 6.51, 6.59, 6.62 ppm, contrary to the weak aromatic proton peaks of the CD–PPD complex, possibly due to the guest being deeply embedded in the CD cavity. The aromatic ring carbon atoms were registered at 114.7, 118.8, 144.0 and 148.3 ppm. All the characteristic peaks of the CD and BPE components were present in the polyfullerene **3**. Additionally, in the ^{13}C NMR spectra, there were peaks between 139–144 ppm assigned to the fullerene component.

In a comparative study without CD, C_{60} and BPE reacted to furnish a water-insoluble product. The material was characterized and found to be a polysubstituted fullerene, as could be expected of fullerene–amine reactions. Interestingly, such polysubstitution could be effectively prevented by the simple routine of placing the amine moiety within a cyclodextrin ring. The spatial dimensions of the macrocycle effectively prevented multifunctionalization of the fullerene units. At the moment we have not ascertained if C_{60} is connected at the *trans*-1 positions with the diamine and if there is any branching. Branching would mean strong stereochemical constraints, since each fullerene ball in the copolymer chain is already flanked by two CD units (see Fig. 2 for a space-filling model). Studies in this direction are being pursued, examining the spatial dimensions of the macrocycle and the fullerene in the molecular models.

In exploring the application potential of this novel polymer, preliminary experiments have shown that the material could be useful in biological and biomedical fields. The polyfullerene was found to strongly scavenge a living free radical, 1,1-diphenyl-2-picrylhydrazyl, even more strongly than [60]fullerene itself. Furthermore, the polymer was also found to cleave DNA oligonucleotide in the presence of light, which was ascertained from the GPC studies in conjunction with membrane filtration of the nucleotide before and after cleaving experiments. These preliminary results indicate that the polymer has retained the properties of the pristine [60]fullerene.

Although the above model reaction involves β-cyclodextrin and [60]fullerene, it is rather unlikely that the results described here are confined to these specific molecules. It might also allow the direct use of other fullerenes of the fullerene family such as higher homologues and exo- and endohedrally modified species, and the macrocyclic part may also be modified using a great variety of building units. The materials are expected to have a strong application potential in the biomedical area due to their hydrophilicity, but also many other applications of these interesting molecules can be envisaged such as their use as building blocks for molecular machines and robotics.[6] Further studies to elucidate the full potential of the approach are in progress.

Iminophosphorane-mediated carbodiimide metathesis

Stephen A. Bell, Steven J. Geib and Tara Y. Meyer*

Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA. E-mail: tmeyer+@pitt.edu

Received (in Irvine, CA, USA) 10th April 2000, Accepted 5th June 2000
Published on the Web 5th July 2000

Iminophosphorane Cl_3P=NAr (Ar = 2-fluorophenyl) is an active carbodiimide metathesis catalyst and the cycloaddition product, a 1,3-diaza-2-phosphetidine, is an intermediate in the reaction.

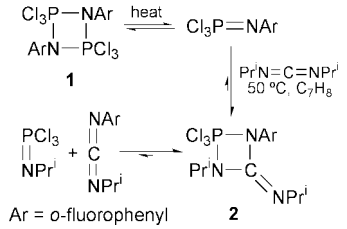
We study the metathesis of C=N bonds with the intention of developing the diverse synthetic and polymerization applications that depend on a single, well-defined reaction site. Until now, both our efforts[1–3] and those of others[4] have focused on metal–imide-mediated process. There are intriguing examples in the literature of stoichiometric metathesis of iminophosphoranes with carbodiimides as well as catalytic disproportionation of isocyanates using phosphine oxides.[5–9] These examples of heterocumulene reactivity inspired us to extend our search for C=N metathesis catalysts to include phosphorus systems. Here, we describe our discovery that iminophosphoranes can act as catalysts for metathesis of carbodiimides, and we provide evidence for a diazaphosphetidine intermediate.

Trichloroiminophosphoranes can self-dimerize in solution, a behavior that should, theoretically, correlate with a potential for reactivity with the similarly polarized C=N bond. In particular, we have focused on the *o*-fluorophenyl derivative, **1** which is known[10] to exist as an equilibrium mixture of dimer and monomer (K_{eq} = 0.17 dm^3 mol^{-1} at 50 °C, Scheme 1). ^{31}P NMR spectroscopy easily differentiates the two forms: −45.2 ppm (monomer) and −76.4 ppm (dimer).

The addition of an equivalent of diisopropylcarbodiimide to the iminophosphorane equilibrium mixture, followed by heating to 50 °C for 24 h gives a single product† by ^{31}P NMR spectroscopy (−58.2 ppm). ^1H NMR spectroscopic data‡ are consistent with the formulation of diazaphosphetidine **2** arising from the addition of the C=N bond across the P=N bond, with the expected N-to-P regiochemistry. The observed 31 Hz phosphorus coupling of the methyne proton of one of the two inequivalent isopropyl groups is diagnostic for this product.

X-Ray diffraction studies of a single crystal,§ isolated from a preparative scale reaction, confirmed the guanidinate-type structure (Fig. 1). Complex **2** crystallized into a pseudo-*TBPY* geometry with one chlorine and the aryl-substituted nitrogen located in axial positions. Although electronegativity arguments would predict two axial chlorines, the small guanidinate ring size dictates that the more electronegative of the two nitrogens, the N-2-fluorophenyl, will occupy one axial site. The notably unsymmetric ring can then be explained by normal axial/equatorial bond length differences.

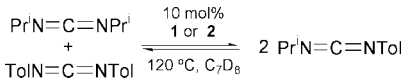
Although one example of a similar guanidinate-type structure was found in a search of the Cambridge Crystal Database,[11] the compound was not prepared by cycloaddition. Analogous urea-derived structures are more common.[12] It is interesting to note



Scheme 1

that Molina *et al*., as part of their extensive studies on the preparation of heterocycles from carbodiimides, isocyanates and iminophosphoranes, isolated and characterized crystallographically an example of a zwitterionic, betaine form of this type of intermediate.[13]

Heating diisopropylcarbodiimide and di(*p*-tolyl)carbodiimide at 120–125 °C in toluene in the presence of iminophosphorane **1** (10 mol%) induced metathesis of the carbodiimides as indicated by the growth of ^1H NMR resonances associated with the mixed carbodiimide (Scheme 2). No =NR exchange was noted when the carbodiimides were heated without catalyst present. The reaction proceeded in < 24 h to give equilibrium mixtures of the carbodiimides. In an independent experiment, the same carbodiimides were metathesized at a similar rate in the presence of 10 mol% of the guanidinate complex **2**. The parallel activity of the guanidinate complex is consistent with its role as an intermediate in the catalytic process, although further studies will be required before other mechanisms, such as acid- or amine-catalyzed reactions,[4a] can be ruled out.



Scheme 2

The similarities of Wittig chemistry and metal-catalyzed metathesis are interesting. Until now, however, phosphorus-ylide and -imine reactions have nearly always exploited the formation of a thermodynamically more stable P=E (E = O,S) bond as a driving force. In contrast, the preliminary results described here establish that truly catalytic metathetical processes are also possible for phosphorus. We are currently investigating the generality of these reactions.

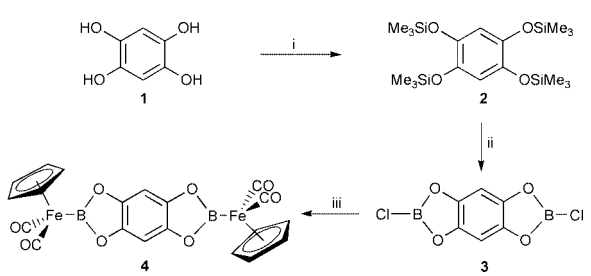
The synthesis, spectroscopic and structural characterisation of the symmetrically bridged boryl complex $CpFe(CO)_2BO_2C_6H_2O_2BFe(CO)_2Cp$ are reported, together with analysis of the bonding by structural and DFT methods.

Transition metal boryl complexes (L_nMBR_2) have been the subject of considerable recent research effort,[1] in part because of their involvement in versatile organic transformations such as the metal-catalysed hydroboration and diboration of multiple bonds.[1,2] Furthermore, derivatives of the type $(C_5R_5)M(CO)_n$-$BO_2C_6H_2Me_2$ (M = Fe, Ru, n = 2; M = W, n = 3) have been shown to functionalise alkanes under photolytic conditions, with the unusual activity and regiochemistry of the reaction being tentatively ascribed to the presence of a ligand with Lewis acidic properties.[3,4] Recent studies have sought to probe the nature of the metal–boron interaction in metal boryl complexes by spectroscopic and crystallographic methods.[1] Almost exclusively,[5] such studies have focussed on monodentate boryl ligands adopting a terminal mode of coordination with respect to the metal centre.[1] Here, we describe a novel synthetic route to metal complexes featuring bidentate boryl ligands together with the structural and spectroscopic characterisation of the symmetrically bridged (μ_2,η^1,η^1) boryl system $CpFe(CO)_2$-$BO_2C_6H_2O_2BFe(CO)_2Cp$ **4**. Comparison of the mode of coordination of the bridging boryl ligand with that found for terminally bound analogues allows significant insight into the nature of the metal–boron interaction.

In our recent work we have been seeking to develop synthetic approaches to multifunctional boranes and boron halides based on polyhydroxybenzene frameworks (*e.g.* **3**) as potential precursors to multinuclear metal boryl complexes.[6] The synthetic route to compound **4** is outlined in Scheme 1; fuller details of the preparation of the trimethylsilyl and chloroborane precursors have been reported recently.[6] Addition of a toluene solution of **3** to 2 equivalents of $CpFe(CO)_2Na$ suspended in toluene at −30 °C, followed by warming to room temperature and stirring for 1 week led to the formation of an orange–red solution and a beige precipitate. Removal of the supernatent by filtration, extraction of the beige precipitate with CH_2Cl_2 and subsequent crystallisation by layering with 40/60 petroleum led to the formation of **4** in 45% yield. This compound is air sensitive, although thermally robust enough to survive unchanged at room temperature for several weeks under an argon atmosphere. It is sparingly soluble in non-polar organic media and decomposes rapidly in donor solvents such as thf or diethyl ether. Compound **4** has been characterised† by ^{1}H, ^{13}C and ^{11}B NMR, IR spectroscopy, high-resolution mass spectrometry, elemental analysis and single crystal X-ray diffraction.



Scheme 1 Synthesis of the bridged boryl complex **4**. *Reagents and conditions*: i, Me_3SiCl (10 equiv.), Et_3N, toluene, 12 h at room temp., 78%; ii, BCl_3 (2 equiv.), 40/60 petroleum, 3 h at 50 °C, 89 %; iii, $CpFe(CO)_2Na$ (2 equiv.), toluene, 1 week at room temp., 45%.

The single ^{11}B NMR shift at δ_B 48 is entirely consistent with the formation of a symmetrically bridged molecule in which both of the B–Cl linkages in **3** have been replaced by Fe–B bonds, being very similar to those reported by Hartwig *et al*. for the terminally coordinated Bcat (cat = *ortho*-$O_2C_6H_4$) complexes $(C_5R_5)Fe(CO)_2Bcat$ [δ_B 51.8 (R = H)[4] and 54.3 (R = Me),[4] respectively]. Similar chemical shifts have also been reported by Braunschweig *et al*. for other terminal boryl ligands bound to iron.[7,8]

A single crystal X-ray diffraction study was undertaken on **4**,‡ the results of which confirm the formulation predicted on the basis of spectroscopic data and are illustrated in Fig. 1. The molecular structure consists of two piano-stool $CpFe(CO)_2X$ fragments linked in μ_2,η^1,η^1 fashion by the $BO_2C_6H_2O_2B$ ligand.

The synthesis and structural characterisation of **4** allows, for the first time, the opportunity to compare the coordination behaviour of a bridging boryl ligand ($BO_2C_6H_2O_2B$) with that of the analogous terminally bound ligand (Bcat). The complex $CpFe(CO)_2Bcat$ features near co-planarity of O–B–O and B–Fe–Cp centroid moieties consistent with the existence of a Fe–B π interaction involving the $CpFe(CO)_2$ HOMO and the ligand-based LUMO.[4] In the case of **4**, however, the crystal structure reveals a near orthogonal relationship [82.2(1)°] between the corresponding planes and implies no π interaction between ligand LUMO and Fp HOMO. This observation is consistent with the fact that the ν(CO) stretching frequencies for **4** are somewhat lower than those observed for $CpFe(CO)_2Bcat$ (2006 and 1954 cm^{-1} *vs*. 2024 and 1971 cm^{-1}).[4] Given that the steric

DOI: 10.1039/b003901m

requirements at the iron centre of the terminal Bcat and bridging $BO_2C_6H_2O_2B$ ligands are likely to be very similar it seems evident that the difference in ligand coordination is due to electronic factors. The presence of two extra oxygen-based substituents on the central benzene ring in **4** might be expected to render the ring more electron rich, thereby increasing the degree of O–B π interaction and reducing the π acidity of the boron centre with respect to the iron.

Interestingly, although these structural and spectroscopic observations imply a weaker Fe–B interaction, the Fe–B bond length is lengthened only marginally in **4** compared to the terminally bound $CpFe(CO)_2Bcat$ system [1.971(2) *vs.* 1.959(6) Å].[4] Conceivably this may reflect the fact that the bond length in such systems is relatively insensitive to the π contribution to bonding. However, the Fe–B distance in **4** is also significantly shorter than that found in any other terminally bound iron boryl complex for which the B–Fe–Cp centroid and BR_2 planes are close to orthogonal [average 2.048(5) Å§]. Such a shortening of the Fe–B bond might also be consistent with a weak π interaction between the boryl LUMO and the Fp HOMO − 2 (a 1a′ π type MO which is perpendicular to the HOMO[9]). Such an interaction has been suggested for the complex $CpFe(CO)_2BPh_2$ [which, at 2.034(3) Å,[4] has a markedly longer Fe–B bond than **4**] and has been discussed by Hoffmann and coworkers in their analysis of ligand orientation in Fp–carbene complexes.[9]

Comparison of the bonding in **4** and $CpFe(CO)_2Bcat$ was further aided by DFT calculations[10] carried out for the model compound $CpFe(CO)_2BO_2C_2H_2$, **5**, the preliminary results of which are reported here.¶ Total energies were calculated for various rotamers of the molecule **5** in which the angle between the B–Fe–Cp centroid and O–B–O planes was varied by rotation about the Fe–B bond in 10° intervals between 0 and 90°. Energy minima are found for θ = *ca.* 10 and 80°. These observations are indeed consistent with the presence of weak π type interactions between the Fp HOMO and boryl-based LUMO for the near parallel orientation of the B–Fe–Cp centroid and O–B–O planes and between the Fp HOMO − 2 and boryl LUMO for the perpendicular orientation. The calculated energy difference between these two minima is very small (0.1 kJ mol^{-1} at the gradient corrected DFT level of theory), such that the adoption of one particular orientation in the solid state may well be influenced by crystal packing forces.

The structure of **4** illustrates the coordination behaviour of a symmetrical μ_2,η^1,η^1 boryl ligand and demonstrates significant differences in metal–boron interaction compared to terminal η^1 analogues. The synthetic methodology outlined in Scheme 1, together with the recent synthesis of the *bis*(borane) $HBO_2C_6H_2O_2BH$,[6] open up routes to a wide range of bridging boryl complexes *via* metathetical or oxidative addition pathways.

The support of the Nuffield Foundation, the Royal Society and Cardiff University are gratefully acknowledged. We would also like to thank the EPSRC National Mass Spectrometry Service. The calculations presented in this paper were carried out with the help of support from the EPSRC, Synetix and OCF. In addition, J. W. S thanks the EPSRC and King's College London for the provision of the X-ray diffractometer and the Nuffield Foundation for the provision of computing equipment.

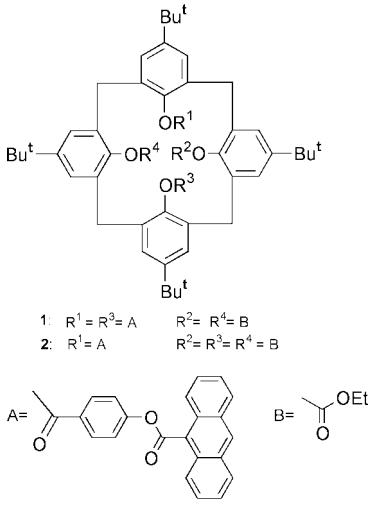
Published on the Web 5th July 2000

Photocontrol of Na^+ transport across a phospholipid bilayer membrane can be undertaken by using a new calix[4]arene carrier bearing two anthracene moieties.

Photoresponsive compounds are of great interest for the development of photocontrolled transport systems where ion and electron fluxes across membranes can be regulated by light.[1] Since a first report[2] of photoresponsive crown ethers, a number of the photocontrolled ion transport systems using bulky liquid membranes have been reported.[3] However, there are very limited studies of photocontrol of ion fluxes across lipid bilayer membranes.[4] The photoresponsive ionophores, by which ion fluxes across lipid bilayers can be controlled, are expected to be useful for the study of the response of cellular systems to ion concentrations. Here, we report the first example of photocontrol of Na^+ transport across a phospholipid bilayer containing a bisanthroylcalix[4]arene carrier **1**.

Calix[4]arene esters are known to have selective complexing abilities[5] toward Na^+ ions, and act as selective Na^+ carriers[6–8] in lipid bilayer membranes. It has been shown that the rates of Na^+ transport by a calix[4]arene ester across a phospholipid bilayer membrane are comparable to the rates by an antibiotic ionophore, monensin.[6] To synthesize a phoresponsive calix[4]arene-based Na^+ carrier, we introduced two photo-dimerizable anthracenes into the terminal positions (-OCH_2COR) of sodium binding sites in a calix[4]arene ester.[9] Anthracene



appended calix[4]arenes **1** and **2** were prepared from the reaction of *p*-(9-anthroyloxy)phenacyl bromides (Molecular Prob. Inc.) and bis- or trisethoxycarbonylmethyl ether[10] of *p*-*tert*-butylcalix[4]arene in the presence of K_2CO_3 in THF. The compounds were identified by ^1H NMR and field desorption mass spectroscopy.† The signal patterns in $ArCH_2Ar$ protons confirmed that both **1** and **2** adopted cone conformations in $CDCl_3$. The Na^+ complexing abilities of **1** and **2** were checked by the ^1H NMR titration experiments.[5]

Photoirradiations were carried out in THF at 25 °C using a 150 W Xe lamp through a band pass filter (λ 360 nm). As shown in Fig. 1(a), the UV irradiation of the solution of the bisanthroylcalix[4]arene **1** caused a decrease in the absorbance of anthracene moieties with two isosbestic points. However, the UV irradiation of the solution of the monoanthroyl calix[4]arene **2** did not cause a significant spectral change (Fig. 1(b)). These results indicate that the photodimerization of the two anthracene moieties in **1** readily takes place in THF (Scheme 1), but not in **2**. The slight decrease in the absorption of **2** may be explained by the photobreaching of the anthracene moiety. In the case of **1**, the thermal decomposition of the photodimeric form was hardly observed even after 24 h in the dark, suggesting that the photodimeric form of **1** is very stable compared to the monomeric form of **1**.

The ion transport experiments were conducted by a planar bilayer membrane[11] (soybean phospholipid) with the aid of a voltage-clamp technique.‡ The ion transport selectivity of **1** was evaluated by the measurements of the current–voltage relationships in the unsymmetrical ionic conditions of LiCl (*cis*)–NaCl (*trans*) and KCl (*cis*)–NaCl (*trans*), where the salt concentrations in two chambers were set to 100 mM containing 25 mM HEPES–Tris Buffer (pH 7.2). The reverse potentials were obtained as −80 and −37 mV for the LiCl–NaCl and KCl–NaCl systems at 25 °C. From the Goldman–Hodgkin–Katz equation,[12] the ion permeability ratios (P_{X^+}/P_{Na^+}) across the bilayer membrane were calculated as P_{Li^+}/P_{Na^+} = 0.044 and P_{K^+}/P_{Na^+} = 0.24, showing that **1** can act as a selective Na^+ carrier in a phospholipid bilayer membrane.

Fig. 2 shows the effect of UV (> 310 nm) irradiation on the membrane currents resulting from Na^+ transport by **1** and **2**. Upon UV irradiation of the bilayer membrane containing **1**, the Na^+ currents (at 100 mV) immediately decreased (Fig. 2(a)), while UV irradiation of the membrane containing **2** did not cause any change (Fig. 2(b)). This behavior is consistent with the results of the spectral change of **1** and **2** in THF by UV irradiation. In the case of **1**, it should be noted that the Na^+ currents are going to recover after the light-off, which can be explained by the increase in the concentration of the monomeric

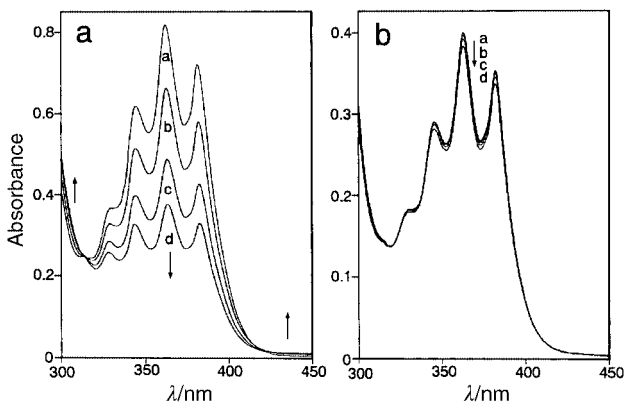


Fig. 1 The absorption spectra of **1** (a) and **2** (b) in THF before and after UV irradiation (360 nm) : (a) 0 s; (b) 30 s; (c) 1 min; (d) 5 min.

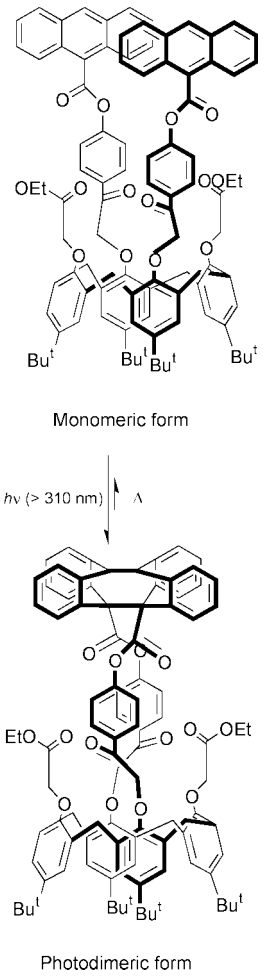
DOI: 10.1039/b002034f



Scheme 1

form of **1** in the membrane region at the aperture in a Teflon film. This may be due to the lateral diffusion of the monomeric form of **1** from the membrane which is not irradiated by light. In fact, after a long irradiation time (*ca*. 30 min), the membrane current decreased to be the current (0.5 pA) of a control level. The increase in Na^+ currents, which result from the thermal decomposition of the dimeric form of **1**, was not observed within 1 h. These results indicate that the photodimerization of two anthracene moieties in **1** takes place in the lipid membrane and the Na^+ transport activity diminishes in the photodimetric form of **1**.

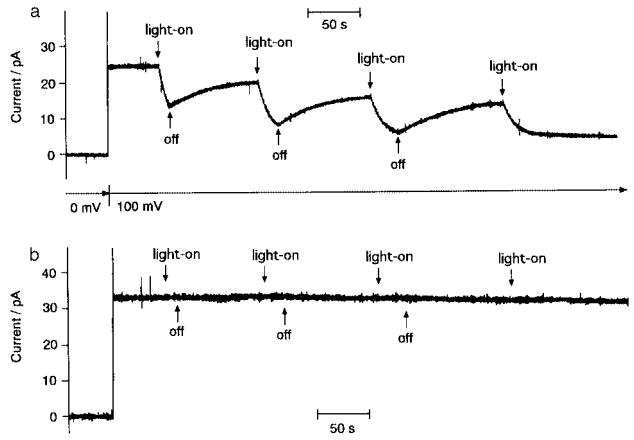


Fig. 2 The changes in Na^+ currents across the lipid bilayer membrane containing **1** (a) or **2** (b) at 100 mV by UV irradiation (> 310 nm). Two chambers were filled with 100 mM NaCl aq. solutions (pH 7.2, 25 mM HEPES–Tris buffer). The bilayer membranes were prepared by the lipid–calix[4]arene mixtures (lipid: **1** or **2** = 100: 1 w/w). The UV irradiation (3.2 mW mm^{-2}) was performed through a glass fiber, where the spot of the light was *ca*. 5 mm diameter.

In conclusion, we have demonstrated that photocontrol of Na^+ fluxes across a bilayer membrane can be undertaken by using a bisanthroylcalix[4]arene **1**. This is the first report of a photoresponsive Na^+ carrier which is active in a phospholipid bilayer. We believe that the new calix[4]arene **1** has potential for use as a photoresponsive Na^+ carrier for the regulation of Na^+ concentrations in biological membrane systems.

The author thanks Dr G. Nishimura and Mr T. Ohta for technical support. The author also thanks Mr E. Yamada for the measurements of ^{1}H NMR spectra.

† *Selected data* for **1**: δ_H(400 MHz, $CDCl_3$), 1.06 and 1.24 (s, 18H, CMe_3), 1.30 (t, 6H, CH_2CH_3), 3.32 (d, 4H, $ArCH_2Ar$, *J* 13.0), 4.19 (q, 4H, CH_2CH_3), 4.87 (s, 4H, OCH_2CO_2), 5.09 (d, 4H, $ArCH_2Ar$, *J* 13.0), 5.83 (s, 4H, OCH_2COPh), 6.76 and 7.00 (s, 4H, ArH), 7.36–8.49 (26H, COPh and anthracene); field desorption mass spectrum, *m/z* 1497 (M^+).

‡ Planar bilayer membranes were formed at an aperture (diameter, 0.2 mm) in a Teflon film (thickness, 12.5 μm) which separated two Teflon chambers (internal volume of each chamber is 1.7 ml with surface area of 1 cm^2). The side to which compounds were added was defined as the '*cis*' chamber and the opposite side was the '*trans*' chamber. A patch clamp amplifier (CEZ-2300; Nihon Kohden, Ltd., Tokyo, Japan) was used in a voltage clamp mode to amplify the currents and to control the voltages across the bilayer membranes. The command voltage was fed to the *trans* chamber *via* an Ag/AgCl electrode through an agar bridge and the *cis* chamber was grounded *via* an Ag/AgCl electrode through an agar bridge. The voltage was referenced to the *cis* side with respect to the *trans* side.

Received (in Cambridge) 27th April 2000, Accepted 15th June 2000
Published on the Web 5th July 2000

Quantitative extraction (30–70%) of alkali metal ions (K^+, Na^+: 1.7×10^{-4} mol dm^{-3}) from aqueous solutions with supercritical carbon dioxide (40 °C, 10–18 MPa) could be achieved using glymes (triethylene glycol dimethyl ether (triglyme: 3G), tetraethylene glycol dimethyl ether (tetraglyme: 4G)) and the addition of pentadecafluoro-*n*-octanoic acid (HPFOA) that supplies a CO_2-philic counter ion and makes the metal–ligand complex soluble in the CO_2 solvent *via* counter ion exchange.

CO_2 in its supercritical state ($scCO_2$) is being proposed for many analytical and industrial applications. Although $scCO_2$ can dissolve many non-polar organic compounds,[1–3] it has difficulty in solubilizing metal ions due to its low relative permitivity. To address this, many researchers have examined the use of added ligands, surfactants or microemulsions. Some success in extracting transition metals such as Cu^{2+}, Pb^{2+}, Hg^{2+}, and lanthanoids, has been found using ligands (β-diketones, dithiocarbamates, organic phosphorus acids, *etc.*) *via* chelation,[4–6] but this technique seems unsuitable for alkali metals, since these do not form coordinate bonds with the above-mentioned ligands. Alkali metal ions, *e.g.* Na^+ or K^+, form complexes with only a few ligands, *e.g.* crown ethers or non-macrocyclic compounds such as surfactants having polyoxyethylene (POE) groups.[7–9] The polyethylene glycol compounds, glymes ($CH_3(OCH_2CH_2)_nOCH_3$), are attractive because of their ability to coordinate to metal ions. Darr *et al.* synthesized Ag^+(fluorinated-β-diketone)(glyme) complexes[10] and Pollard *et al.* examined Ce^{3+}(fluorinated-β-diketone)$_3$(glyme)[11] with the hope of obtaining $scCO_2$ soluble complexes. However, there are no reports of using glymes for extracting alkali metal ions with $scCO_2$.

In previous work, we developed a technique whereby alkali metal ions could be extracted with $scCO_2$, using an appropriate ligand with the addition of a small amount of additive that supplies a CO_2-philic counter ion.[12,13] The technique was applied to the extraction of Na^+ and K^+ using crown ether ligand and perfluorocarboxylic acid additive. Semi-quantitative (*ca.* 50%) recoveries were obtained. The perfluorocarboxylic acid additive made the metal ion–ligand complex soluble in $scCO_2$ by generating a CO_2-philic counter anion that exchanged with the anion of the metal–ligand complex. In this work, we report the experimental results on glymes, which are a new class of ligands that have not previously been identified as being applicable to alkali metal extractions with $scCO_2$ and which provide an inexpensive and practical alternative to crown ethers.

Materials NaCl (99.5%), KCl (99.5%), triethylene glycol dimethyl ether (triglyme: 3G, 93%), tetraethylene glycol dimethyl ether (tetraglyme: 4G, 98%), pentadecafluoro-*n*-octanoic acid (HPFOA, 95.0%) and HCl (analytical grade) were purchased from Wako Pure Chemical and used without further purification. The extraction apparatus used in this work has been previously described.[10] Briefly, an aqueous solution (6 ml) of the alkali metal salt (1.7×10^{-4} mol dm^{-3}; ionic strength (I) = 1.0×10^{-1} mol dm^{-3} (H, Cl)), a given amount of ligand and HPFOA (molar ratio; metal : ligand : HPFOA = 1 : 30–300 : 30–300) were loaded into an extraction cell (internal volume: 50 ml). The cell was immersed in a water bath (40 °C) and then pressurized by introducing CO_2 (99.9%). The solution in the cell was stirred by a magnetic stirrer for about 30 min to ensure complex formation and phase partitioning equilibrium. After equilibration, a vapor phase sample was taken by opening the stop valve and depressurizing. The extract in the vapor phase was trapped in a collection vessel that contained 10 ml of EtOH. After sampling, the residual aqueous phase in the cell was analyzed by HP 4500 ICP-MS to determine the metal ion concentration. The pH of the aqueous phase after extraction was also measured. The amount of metal in the collection vessel was analyzed to check the mass balance. The extraction recovery was determined by the difference in concentration of metal ions in the cell before and after extraction and was calculated by the following equation: Recovery = $([\text{metal}]_{\text{init}} - [\text{metal}]_{\text{resid}})/[\text{metal}]_{\text{init}}$, where $[\text{metal}]_{\text{init}}$ and $[\text{metal}]_{\text{resid}}$ represent the initial and residual concentration of metal ion in the cell, respectively.

Fig. 1 shows the extraction results for K^+ using 3G with $scCO_2$ at 40 °C. The recovery was negligibly small with only 3G, indicating that glymes may form complexes with K^+ but that their equilibrium constant is either very small or their solubility in $scCO_2$ is low. On the other hand, the addition of HPFOA gave a recovery that was between 10 and 20%. This can be explained by the fact that glymes form a complex with K^+, which has a low solubility in $scCO_2$. When HPFOA is added, the acid dissociates and gives a CO_2-philic $PFOA^-$ anion. The $PFOA^-$ anion undergoes exchange with the Cl^- anion of the complex in the aqueous phase, and consequently the affinity of the complex for $scCO_2$ increases due to the $scCO_2$-philic PFOA chain. This mechanism seems to be similar to that described in our previous work on crown ether ligands.[10,11] More importantly, the recoveries are semi-quantitative for this type of ligand. However, for the case of 3G, the recoveries were not as high as those obtained for the crown ether ligands, which could be attributed to the difference in the formation constants (K) between the alkali metal ion and glymes or crown ethers, those logarithmic values in MeOH at 25 °C were reported as 1.72 and 6.10, respectively.[14]

We examined the concentration dependence of HPFOA on the complex. The metal ion concentration ratio (D) between the

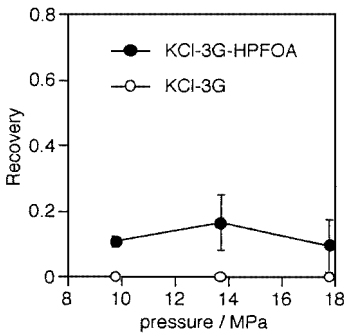

Fig. 1 Variation of recovery with pressure for K^+ using 3G. Extraction conditions: 40 °C, molar ratio; alkali metal : ligand = 1 : 100.

DOI: 10.1039/b003411h

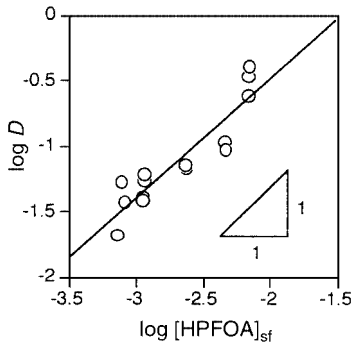

Fig. 2 Variation of log *D* with [HPFOA] using 3G. Extraction conditions: 40 °C, 13.7 MPa, molar ratio; alkali metal : ligand : HPFOA = 1 : 100 : 30–300.

supercritical phase and aqueous phase was calculated from the data and plotted on a logarithmic scale against $[HPFOA]_{(sf)}$ for the KCl–3G–HPFOA system as shown in Fig. 2, where (sf) refers to species in the supercritical phase. The log *D* increased proportionally with an increase in $[HPFOA]_{(sf)}$ and its slope was found to be about unity, indicating that one HPFOA molecule took part in the extraction for each alkali metal ion–glyme complex. This trend is similar to that observed for extractions made with crown ether ligands in $scCO_2$.[13] However, when we plotted log *D versus* log [ligand] as in the previous work, a linear relationship was not obtained as shown in Fig. 3.

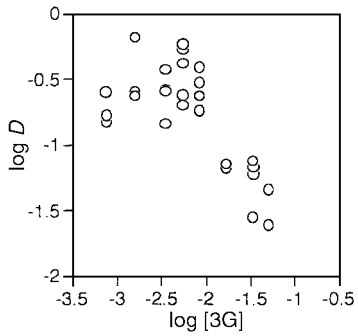

Fig. 3 Variation of log *D* with 3G concentration. Extraction conditions: 40 °C, 13.7 MPa, molar ratio; alkali metal : ligand : HPFOA = 1 : 30–300 : 100.

We considered that the range of ligand and additive concentrations studied might affect the observed recoveries. Since the ligand and additive concentrations were higher than that of the metal ions, strong HPFOA–glyme interactions in the liquid phase may occur. To check this, UV measurements of aqueous samples were made at 20 °C and atmospheric pressure. The spectra did not provide any evidence for HPFOA–glyme interaction. Another possibility is consecutive complex formation that might occur between alkali metal ion and glyme in aqueous phase such as 1 : 2 (metal : glyme), 1 : 3, *etc*. This would lead to a decrease in metal ion recovery since the larger complex would make ions unavailable for extraction if only the 1 : 1 complex was assumed to be extracted *via* counter ion exchange. Regardless of the solution interaction, at 3G concentrations of log [3G] from −2 to −2.7, the recovery increased remarkably up to around 80%.

Table 1 Recoveries (%) for alkali metal ions using 3G and 4G ligands and HPFOA additive. Extraction conditions: 40 °C, 13.7 MPa

Molar ratio[a]	Alkali metal	3G	4G
1 : 100 : 100	Na^+	14.8	20.5
	K^+	16.5	23.6
1 : 33 : 100	Na^+	36.0	40.9
	K^+	71.8	32.9

[a] Metal : glyme : HPFOA.

We ran additional experiments with a longer oxyethylene chain glyme, 4G (see Table 1). Two molar ratios were considered at 40 °C and 13.7 MPa. At conditions of 1 : 100 : 100 (metal : glyme : HPFOA), recoveries were higher for K^+ than Na^+ for both glymes and it was found that 4G gave higher recoveries than 3G for the corresponding Na^+ and K^+ extractions. These results can be explained to some extent by the difference in complex formation ability. For the Na^+–4G and K^+–4G systems, the 1 : 1 (metal : ligand) formation constants (log *K*) in MeOH at 25 °C are 1.28 and 1.72, respectively.[14] However, when we changed the ligand concentration to 1 : 33 : 100, the recoveries did not follow the formation constant data. In conclusion, the molar ratios are not optimized for the highest recoveries, but with the use of glyme ligands and a CO_2-philic counter ion exchange technique, we demonstrate quantitative extraction. Our next step in this research is to perform more detailed measurements and to develop a model based on successive complex formation.

Received (in Cambridge, UK) 4th January 2000, Accepted 23rd May 2000
Published on the Web 5th July 2000

Condensation of coordinated propargylamine into the unprecedented 1,3-di(propargylimino)propylateanion, an analogue of the acetylacetonate anion, is initiated by dioxygen in the Co(II) polymeric trimethylacetate complex/ $NH_2CH_2C{\equiv}CH$ system; molecular structures of the intermediate complex, $Co(O_2CCMe_3)_2(H_2NCH_2C{\equiv}CH)_4$ and final product $Co(O_2CCMe_3)_2(NH_2CH_2C{\equiv}CH)_2[N,N'$-$(HC{\equiv}CCH_2NCHCHCHNCH_2C{\equiv}CH)]$ were established by X-ray analysis.

The chemistry of transition metal complexes with propargylic amines is rather poorly studied. Here, we describe unexpected condensation of Co(II) coordinated propargylamine into the unprecedented 1,3-di(propargylimino)propylateanion bound to a Co(III) centre.

Upon reacting the cobalt(II) containing polymeric complex $[Co(OH)_n(O_2CCMe_3)_{2-n}]_x$ or oligomeric complex $Co_6(\mu_3$-$OH)_2(O_2CCMe_3)_{10}(HO_2CCMe_3)_4$[1] with propargylamine under an anaerobic atmosphere, the paramagnetic mononuclear complex $Co(O_2CCMe_3)_2(H_2NCH_2C{\equiv}CH)_4$ **1** was obtained as the main product (95% yield)†. The four propargylamine molecules occupy the four positions in the equatorial plane [Co–N 2.206(2)–2.214(2) Å] of the octahedral Co(II) atom according to X-ray diffraction data‡ as shown in Fig. 1.

Complex **1** is fairly stable under Ar atmosphere in toluene solution containing an excess of propargylamine up to the solvent boiling point. However, complex **1** readily transforms in the diamagnetic cobalt(III) complex, $Co(O_2CCMe_3)_2(NH_2CH_2C{\equiv}CH)_2[N,N$-$(HC{\equiv}CCH_2NCHCHCHN$-$CH_2C{\equiv}CH)]$ **2**, upon reaction with an excess of propargylamine (CH_2Cl_2, 20 °C) in air; even traces of air initiate the reaction (Scheme 1).§

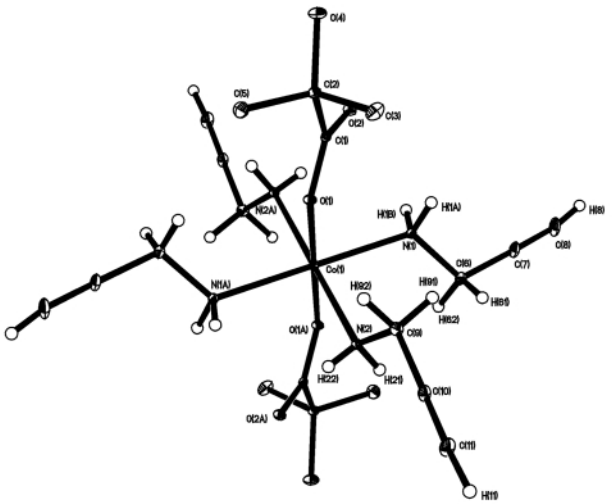

Fig. 1 Molecular structure of $Co(O_2CCMe_3)_2(H_2NCH_2C{\equiv}CH)_4$ **1**; Co–O 2.064(1), C–N 1.452(3)–1.453(3), C≡C 1.158(4)–1.162(4) Å.

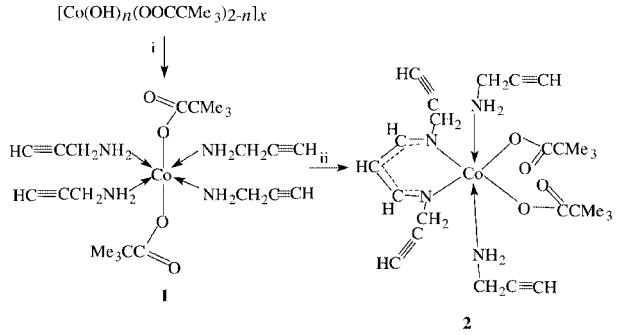

Scheme 1 Interconversions of cobalt(II/III) complexes. *Reagents and conditions*: i, 4 equiv. propargylamine, CH_2Cl_2, Ar atmosphere; ii, 1–2 equiv. propargylamine, CH_2Cl_2 or toluene, in air.

According to an X-ray diffraction study‡ the Co(III) atom has an octahedral environment with two propargylamine ligands occupying apical positions [Co–N 1.974(2) Å] and three anionic ligands [two O_2CCMe_3 groups (Co–O 1.976(2) Å) and one *N*,*N*′- coordinated RNCHCHCHNR (R = propargyl) fragment (Co–N 1.936(2)Å)] in the equatorial plane of the complex coordination sphere as shown in Fig. 2. The metal atom and the planar C–N=CHCHCH=N–C fragment lie in the same plane

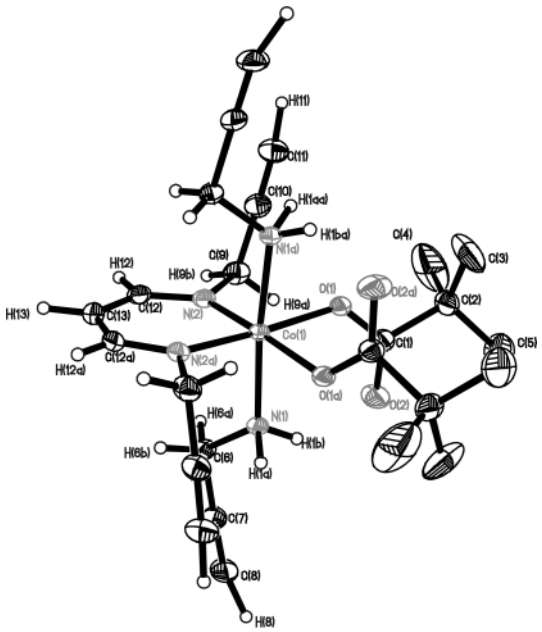

Fig. 2 Molecular structure of $Co(O_2CCMe_3)_2(NH_2CH_2C{\equiv}CH)_2[N,N$-$(HC{\equiv}CCH_2NCHCHCHNCH_2C{\equiv}CH)]$ **2**: C≡C 1.167(5) Å in the propargylamine ligands and 1.172(6) Å in the 1,3-di(propargylimino)propylateanion).

forming an aromatic system with shortened C=N bonds [1.303(4) Å] lying in the same plane of the H atoms [C–C–H 118.4(9)°] and equivalent C(H)–C(H) bonds [1.375(4) Å]. This geometry is very similar to that observed in six-membered metal–acetylacetonate rings.[2,3]

Complex **2** could be also prepared *via* direct reaction between a cobalt trimethylacetate polymer and propargylamine (reagent ratio Co: L = 1: 5–6) in air in toluene solution at 20 °C.

The reaction of an oligomeric nonanuclear nickel(II) complex and an excess of propargylamine gives rise to the complex $Ni(O_2CCMe_3)_2L_4$ **3**.[4] Geometric parameters of complex **3** are very similar to those of complex **1**. Unlike cobalt complex **1**, the nickel compound **3** is stable in air and does not react with propargylamine present in excess even at elevated temperature in solution. This fact suggests that the redox properties of the metal centre and its capability to be involved in one-electron transfer reactions are of importance for the observed amine condensation to form complex **2**. A study addressed toward mechanistic aspects of the reaction is in progress.

New versatile approach to α-hydrazonoesters and amino acid derivatives through a modified Japp–Klingemann reaction

V. Atlan, L. El Kaim* and C. Supiot

Laboratoire Chimie et Procédés, Ecole Nationale Supérieure de Techniques Avancées, 75015 Paris, France. E-mail: elkaim@ensta.fr

Received (in Liverpool, UK) 25th April 2000, Accepted 22nd May 2000
Published on the Web 5th July 2000

Addition of diazonium tetrafluoroborates to an acyl chloride pyridine mixture affords hydrazonoacid derivatives in smooth conditions; this new Japp–Klingemann reaction emphasizes the synthetic potential of electrophilic addition to ketenes.

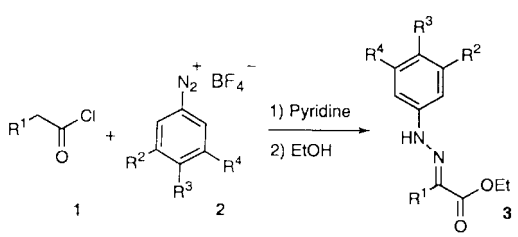
Hydrazones are associated with a wealth of well-known reactions such as the Wolff–Kishner,[1] the Shapiro[2] reactions or the Eschenmoser rearrangement.[3] Numerous asymmetric catalytic reductions of compounds with carbon–nitrogen double bonds have been carried out,[4] among these α-hydrazonoesters have shown a great potential as enantiopure amino acid precursors.[5] The importance of these reductions has given us the impetus to search for new selective access to these valuable intermediates.

α-Hydrazonoesters are usually prepared by a Japp–Klingemann[6] reaction between an arenediazonium salt and a malonic acid derivative. It is a two step process involving coupling of the active methylene compounds followed by a final decarboxylation. Simple acid derivatives are not acidic enough and their use as starting materials for Japp–Klingemann reactions often requires preliminary carboethoxylation of the compound. Recently Sakakura *et al.*[7] described a direct preparation of α-hydrazonoester from ester *via* ketene silyl ketals but their reaction requires the use of a strong base (*e.g.* LDA) which may not be compatible with sensitive substrates.

In connection with our previous study on the trifluoroacetic anhydride additions to ketenes,[8] we believed that α-hydrazonoesters could be prepared in one step directly from the acid chloride. This reaction would involve electrophilic diazonium salt attack on the corresponding ketene generated under weak base treatment. Electrophilic attacks on ketenes are well precedented[9] but this reactivity has been poorly explored in comparison to nucleophilic attack. Indeed, by adding diazonium salt **2b** to a mixture of acid chloride **1a** and pyridine, we observed the formation of α-hydrazonoester **3b** with a yield of 63% (Scheme 1, Table 1).

The interest of this method lies in the generation of the ketene with a large excess of pyridine (3 equiv.) which avoids ketene dimerisation by forming zwitterion **A**. The latter can be attacked by the diazonium giving the azocompound **B** and **C** through further deprotonation (Scheme 2); ethanolysis of **C** finally gives hydrazonoesters **3**.

The reaction is performed at room temperature in dichloromethane using 3 equiv. of pyridine and 1.1 equiv. of diazonium salt (added 10 min after the ketene–pyridine adduct formation).

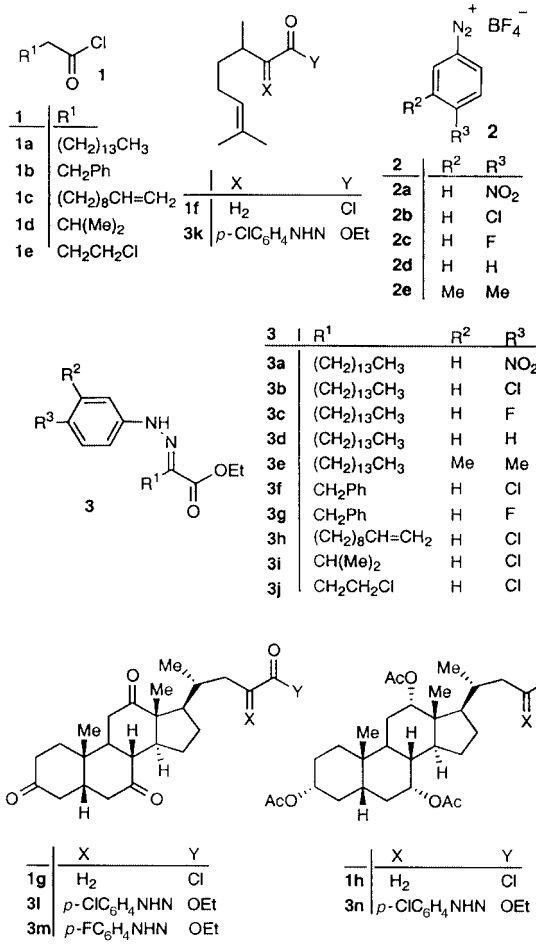


Scheme 1 Addition of diazonium salts to acyl chlorides.

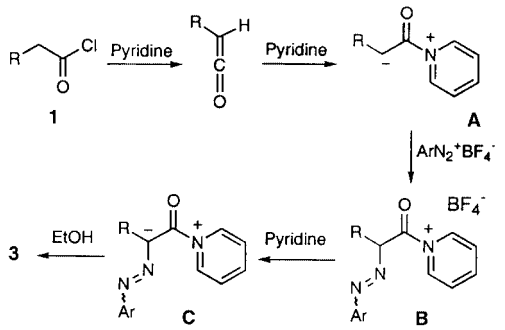
Table 1 Formation of hydrazones **3** from diazonium salts **2**

Chloride **1**	Diazonium **2**	Product **3**[a]	Yield (%)
1a	**2a**	**3a**	33
1a	**2b**	**3b**	63
1a	**2c**	**3c**	66
1a	**2d**	**3d**	56
1a	**2e**	**3e**	55.5
1b	**2b**	**3f**	78
1b	**2c**	**3g**	67
1c	**2b**	**3h**	83
1d	**2b**	**3i**	40
1e	**2b**	**3j**	65
1f	**2b**	**3k**	41
1g	**2b**	**3l**[b]	63
1g	**2c**	**3m**[b]	55
1h	**2c**	**3n**[b]	57

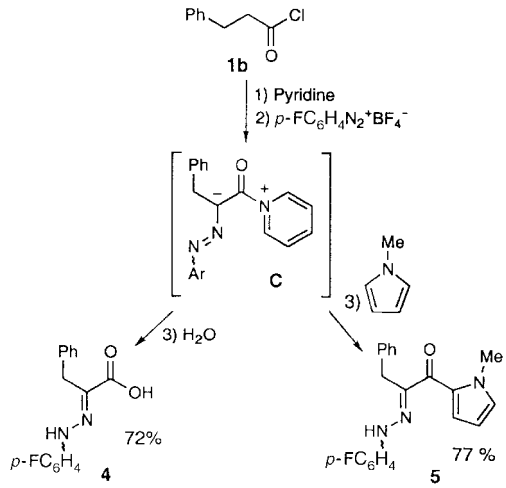
[a] To a dichloromethane solution of acid chloride (0.25 M) was added pyridine (3 equiv.) and after 10 min the diazonium salt **2** (1.1 equiv.). [b] Same procedure but with 0.12 M concentration.



DOI: 10.1039/b003361h



Scheme 2 Possible intermediates in α-hydrazono ester formation.



Scheme 3 Acid chloride–diazonium manifold.

The reaction is best carried out at 0.25 M concentration except for steroids **3n**, **3o**, **3p** for which it was reduced to 0.12 M. The results, reported in Table 1, show that moderate to good yields were obtained for most diazonium salts tested and that this new method is compatible with various sensitive functions such as esters and ketones (**3n**, **3o**, **3p**).

The strength of this approach is further underlined by the manifold provided by the final treatment: when ethanolysis gives esters, hydrolysis can form directly free α-hydrazonoacids whereas addition of *N*-methylpyrrole in the mixture forms pyrrole substituted derivatives in a Friedel–Craft acylation type reaction (Scheme 3).

The potential of this new reaction as well as other additions of electrophiles to ketenes are still under investigation in our research group.

We wish to thank Drs Samir Zard and Jean Boivin for help and encouragement.

Metal-promoted assembly of organic-based cages into a porous material

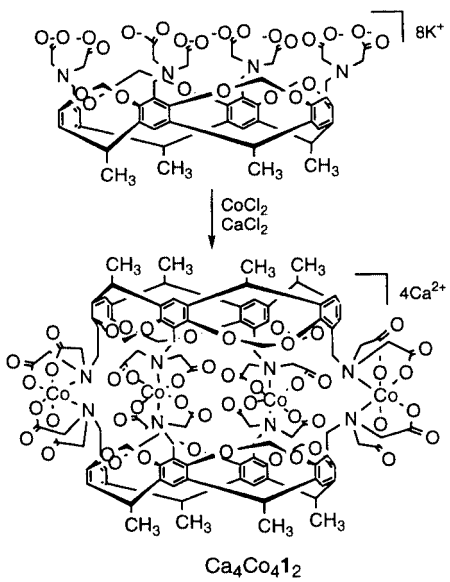
Metal-assembled cages form grids in the solid-state and pack into a manner that creates a material with pores and channels.

Zeolites are very valuable because of their extensive use as molecular sieves, catalysts, and ion exchange materials.[1] One essential feature to zeolites is their porous structure. We have synthesized a porous material, $Ca_4Co_4\mathbf{1}_2{\cdot}xH_2O$, composed of metal and organic components that has a zeolite like porous structure and adsorbs water. This material is a part of an expanding area of metal–organic frameworks which have porous structures, but are not based on silicates or aluminates.[2] These new materials are important because they have different properties than those of zeolites, and may be used as specific catalysts for organic transformations or selective trapping agents. Even though part of their framework is organic, these materials retain their structure after water or solvent molecules are removed and up to temperatures of 300 °C.[2]

Similar to porous metal–organic materials are the metal-assembled supramolecular compounds that form squares, arrays, grids, ladders, sheets and even cages.[3] The assembly of nonporous metal compounds, like the formation of porous metal–organic frameworks, relies on the coordination ability of metal ions and the proper choice of organic ligand. Both of these classes of compounds may have infinite structures, however, the porous materials have often been investigated for adsorptivity. The non-porous metal-assembled compounds sometimes have cavities that encapsulate guests or solvent molecules.[4] The metal-assembled cages act as molecular boxes that bind guests until the cages are signaled by pH change to open and allow guest release.

During our research on metal-assembled cage molecules (Scheme 1), we have discovered that the cages assemble into arrays linked by coordinating cations. The array formation is promoted by the presence of carboxylate groups on four sides of the cages, which are positioned 90° apart in a nearly planar arrangement. Carboxylate groups, having two oxygens and more than one lone pair of electrons on each oxygen, can bind to more than one metal ion and in some cases help create porous materials. Examples of bridging carboxylate groups are very common in metalloproteins and small molecule models of metalloproteins, where metal centers are linked by carboxylates from amino acids or alkyl carboxylates.[5] The four carboxylate groups in $Ca_4Co_4\mathbf{1}_2{\cdot}xH_2O$ come from **1**, which is a cup-shaped resorcinarene molecule that has four pairs of carboxylates positioned on its upper rim. These carboxylates coordinate to transition metal ions and, in the process, form octaanionic cage complexes.[6] One can think of the carboxylate groups on the cages as four metal binding sites equally spaced from each other around the middle of an ellipsoid.



Scheme 1

Owing to the anionic nature of these metal-assembled cages, counter cations are associated with them. When calcium is the counter cation and an aqueous solution of cobalt-assembled cages is allowed to crystallize by slow diffusion of isopropyl alcohol, the calcium ions coordinate to oxygen atoms of the carboxylates and in so doing form $Ca_4Co_4\mathbf{1}_2{\cdot}xH_2O$.† This bonding of oxophilic calcium ions to carboxylate oxygens is not unusual, but what is novel is that the calcium ions coordinate to carboxylates from two cages and create a bridge between two cages. In addition to coordinating to carboxylate oxygens, the calcium ions also coordinate to water molecules, which complete their coordination sphere. As the calcium ions bring together two cages, they assemble a two-dimensional array of cages (Fig. 1)‡ The cages are *ca*. 18 Å apart from each other (center of one cage to the center of the next nearest cage). When the rows of cages line up, voids are formed which would have diameters of *ca*. 15 Å, except that they contain water molecules that are a part of a ring of molecules hydrogen-bonded together around the cages. Thus, the voids have edge lengths of *ca*. 9.5 Å (Ca to Ca van der Waals radii).

The placement of the next layer of cages is also of interest. Though the voids of one layer would seem to be the optimum place for the cages of the next layer, the cages do not position themselves there, but rather lie over the cation bridges of the first layer.[7] In so doing, rhombic pores and channels form

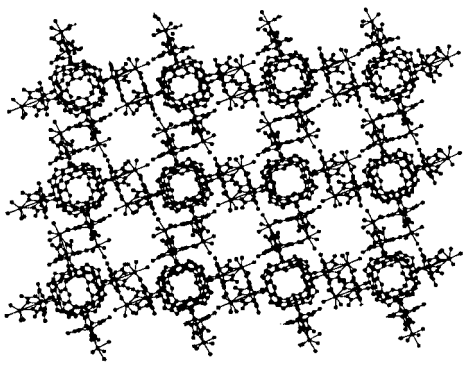


Fig. 1 A top view of $Ca_4Co_4\mathbf{1}_2$ from the X-ray crystal structure showing the packing of the cages into two-dimensional arrays with linking calcium ions. Note the four carboxylate groups are on the exterior of the cages, 90° apart, and help connect the cages together.

DOI: 10.1039/b003187i

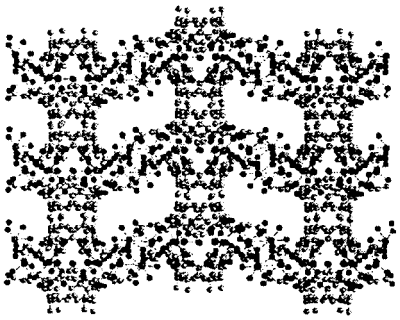

Fig. 2 A side view of $Ca_4Co_4\mathbf{1}_2$ showing the packing of three layers of cages and the channels connecting the pores. The cages in the middle layer are behind the first and third layers. The first and third layers are separated by carboxylate groups of the middle layer. The water molecules within the channels have been omitted for clarity.

(Fig. 2). Cages line two sides of the pores while carboxylates and calcium ions occupy the other four sides. Owing to the presence of both phenyl, methyl, and carboxylate groups on the cages, the pores have both a nonpolar and polar nature. Since the carboxylates do not fill the whole side of a pore as the cages do, channels lead into the pores from two directions. The pores are roughly shaped like hexagons, 9.5 × 9.5 × 21 Å, with two of the long sides occupied by cages. The connecting channels have 5 × 12 Å edges and since they are lined with carboxylate oxygens and water molecules bound to calcium ions, they are expected to be hydrophilic and variable in size depending on the amount of water bound to calcium. Fig. 2 shows that a line of cages is linear in one direction and zigzaged in the other. This is because the bridging carboxylate arms of the cages are side-by-side or one on top of the other.

An important property of porous materials is their ability to retain molecules within their pores. The pores of $Ca_4Co_4\mathbf{1}_2{\cdot}xH_2O$ are occupied by water and isopropyl alcohol molecules. Some water molecules are bound to the counter cations, some hydrogen bonded around the cages, and others disordered within the pores. This is similar to zeolites, where water is bound to cations within a silica or alumina framework. In an attempt to understand the material's affinity for water, we used thermogravametric analysis to measure the change in mass of the material as a function of temperature. When the temperature of the material is raised at a rate of 1 °C min^{-1} from 25 to 250 °C, initially, a fast rate of weight loss is observed up to 120 °C, after which weight is lost more slowly until the weight of the material becomes constant. The total weight loss accounts for 20% of the material and gives a 40 : 1 water to $Ca_4Co_4\mathbf{1}_2$ ratio. A composition of 20% water ranks this material with zeolites in water content.[1] The water to complex ratio of 40 : 1 is in good agreement with the ratio found by X-ray crystallography: 43 : 1.

Not surprisingly, after releasing water, this material adsorbs water. When the dehydrated material is cooled in the presence of a stream of water vapor (20 mm Hg), an initial fast rate of water uptake is observed below 90 °C, which leads into a slower rate of water adsorption as the temperature reaches ambient. The amount of water that was lost is regained. This process of dehydration and adsorption can be repeated without a significant change to the amount of water adsorbed. This is an indication that the material's internal structure remains intact and that heating and water removal do not cause decomposition. Another indication of retention of structural integrity is that the external block-shape of the crystals does not change during adsorption and dehydration. Further studies on the retention of structure are under way.

In conclusion, $Ca_4Co_4\mathbf{1}_2{\cdot}xH_2O$ is a new metal–organic porous material composed of elaborate organic cage molecules and cations. Four perpendicular carboxylate-binding groups on the cage part of $Co_4\mathbf{1}_2{}^{8-}$ provide sites for calcium binding and the assembly of the cages into arrays. The packing of the layers of cages over the bridges of other layers creates pores and channels within the material. Metal-assembled cages and water molecules line the channels that link the pores. These pores and channels contain water, which can be removed and adsorbed. Future research will focus on the use of $C_4CO_4\mathbf{1}_2$ as a small molecule trapping agent, and the affect on pore size by the substitution of the calcium ions by other metal ions.

We thank Brigham Young University for supporting this research.

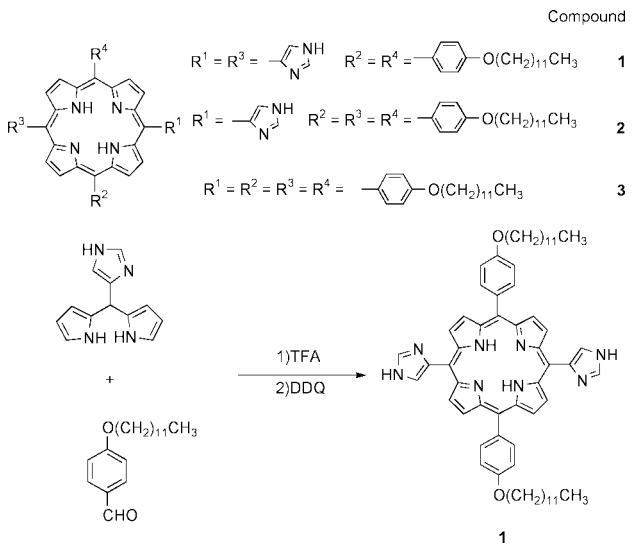
The title bis(imidazol-4-yl)porphyrin 1 gave supramolecular assemblies through hydrogen bonding; efficient excited energy transfer followed by electron transfer to quenchers has been observed in toluene.

Chromophore assemblies play important roles in light-harvesting antenna functions of photosynthesis. In bacterial antenna complexes, 18[1a] or 16[1b] bacteriochlorophylls are arranged in a macro-ring with slipped cofacial structures by coordination of imidazolyl side chains from transmembrane α-helices in B850,[1a,b] and 9[1a] or 8[1b] bacteriochlorophylls are arranged in a macro-ring of coplanar orientation in B800.[1a,b] In contrast to these well-organized structures in bacterial antennae, antenna complexes from plant sources are more or less disordered.[1c] In both cases the arrangements are provided by non-covalent interactions, and supramolecular assembly formation by hydrogen bonding and metal-to-ligand coordination is thought to be a promising way to achieve the construction of artificial antenna models.[2,3]

In this communication, we introduce the use of bis(imidazolyl)porphyrin **1** to mimic light-harvesting antenna function by supramolecular assembly formation through hydrogen bonds between imidazol-4(5)-yls substituted at two facing *meso* positions of the porphyrin ring.[4] 5,15-Bis(imidazolyl)porphyrin **1** was prepared conventionally[5] from imidazol-4(5)-yl-2,2′-dipyrrylmethane and 4-dodecyloxybenzaldehyde as shown in Scheme 1.

The ^{1}H NMR spectrum of **1** in $CDCl_3$ gave broad peaks, which were sharpened gradually by the addition of CD_3OD.



Scheme 1 Preparation of bis(4-imidazolyl)porphyrins.

† Electronic supplementary information (ESI) is available: experimental details and ^{1}H NMR of **1** in $CDCl_3$. See http://www.rsc.org/suppdata/cc/b0/b003267k/

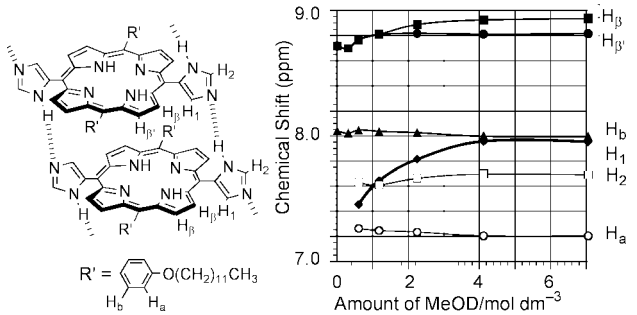


Fig. 1 NMR Titration of **1** (4 mmol dm^{-3}) in $CDCl_3$ with CD_3OD at 20 °C.

Fig. 1 shows the titration behaviour of the imidazolyl, pyrrolic and aromatic protons. The characteristic up-field shift with decreasing CD_3OD concentration was observed most specifically at the *meso*-imidazol-4-yl proton (H_1),[6] and less significantly at one of the β-pyrrolic protons (H_β). Other peaks were insensitive to CD_3OD addition. The shift behaviour is accounted for by the breaking of hydrogen bonds between imidazolyl substituents by the addition of CD_3OD. The selective shielding of the H_1 proton compared to H_2 in the aggregate suggests that H_1 is brought above the facing porphyrin plane by hydrogen bond formation between imidazolyl substituents of different porphyrins. Therefore, the slipped cofacial arrangement **1** is proposed as the structural unit of hydrogen bonded porphyrin rather than the head-to-tail one. The former orientation can be stabilized by cooperative interaction of maximal hydrogen bonds of imidazolyls and π-stacking of porphyrins and is thought to be the more stable. In accord with this orientation, the H_β proton received the second largest up-field shift with decreasing CD_3OD concentration. In contrast, monoimidazolyl-substituted porphyrin **2**, gave quite a normal NMR spectrum without any specific shielding or peak broadening.

This porphyrin–porphyrin interaction is sensitively reflected in their UV spectra. Characteristics of the Soret band of **1** are compared with those of mono- and non-imidazolyl substituted porphyrins **2** and **3**, respectively, in Table 1. The half bandwidth of **1** (29 nm) in a $CHCl_3$ solution (free from EtOH) is significantly broadened compared with that of **2** (16 nm) at the same concentration in the same solvent. A further broadening is

2	419(16)	424(16)	424(16)	422(18)
3	421(13)	420(13)	420(13)	420(13)

[porphyrin] = 1.6 μmol dm^{-3}; [a] EtOH free, $CHCl_3$ was used.

Table 2 Comparison of fluorescence intensities of **1** in various solvents

Compound	Relative intensity at peak maximum (λ_{max}/nm)			
	MeOH	$CHCl_3$[a]	Toluene	cyclohexane
1	507 (662)	442 (668)	428 (669)	36 (664)

[**1**] = 1.6 μmol dm^{-3}; [a] EtOH free, $CHCl_3$ was used.

observed in toluene for **1**, but there is observed solvent dependence in the halfwidth of the Soret band observed for **2**. This behaviour is explained by exciton coupling theory for two porphyrin chromophores in a slipped cofacial orientation,[7] where two transition moments interact in face-to-face and parallel orientations to give rise to blue and red shifts, respectively. The peak splitting could not be observed in the present case and the overall spectral maxima shifted to longer wavelengths. The increased broadening of Soret bands of **1** in increasingly less polar solvents was incompatible with the idea that they contained split absorptions as components. In the case of **3**, having no hydrogen bonding group, no solvent dependence was observed for MeOH, $CHCl_3$ and toluene either for absorption maxima or half bandwidths. Monoimidazolyl-substituted porphyrin **2** seemed to be too weak to interact significantly in this fashion and showed behaviour similar to unsubstituted porphyrin **3** in the range 2×10^{-3}–4 mmol dm^{-3}. This may suggest the cooperation of hydrogen bonds and π-stacking interaction in the present supramolecular structure formation.[8] Interestingly, the fluorescence intensity of bis(imidazolyl)porphyrin **1** remained almost constant for the change of solvent from MeOH to toluene as shown in Table 2. This result indicates that bis(imidazolyl)porphyrin **1** in the supramolecular assembly showed no significant self-quenching by supramolecular complex formation.

In order to obtain direct evidence of assembly formation, the toluene solution of **1** was analyzed by static light scattering at 26 °C. From a Zimm plot[9] of the data obtained at 3.3, 6.6, 9.9 and 13 μmol dm^{-3}, the radius of gyration was estimated as 23 nm. Although the molecular weight could not be obtained because the refractive indices of the solution and pure solvent were too close, we could observe particles from **1** in similarly dilute concentrations (3.3–13 μmol dm^{-3}) in toluene.

The efficiency of energy–electron transfer from the assembly to external acceptors was estimated by fluorescence quenching experiments. Stern–Volmer plots for two acceptor molecules, chloranil and tetraphenylporphyrinatoMn(III) chloride (ClMntpp) in toluene, are illustrated in Figs. 2a and b, respectively, together with the plot obtained by using non-imidazolyl substituted porphyrin **3** as the reference.

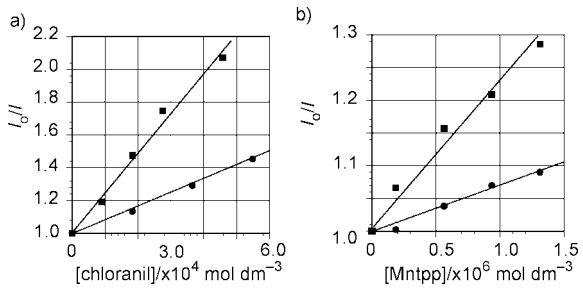

Fig. 2 Stern–Volmer plots for **1** (1.6 μmol dm^{-3}, ■) and **3** (1.6 μmol dm^{-3}, ●) with (a) chloranil and (b) ClMntpp in toluene.

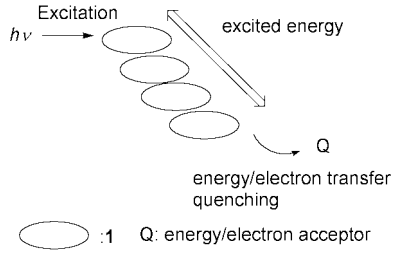
Chloranil quenched the fluorescence of **1** 2.9 times faster than that of **3**. This result suggests that the supramolecule **1** is a more efficient energy–electron donor than the monomeric species. There is a possibility, however, that chloranil becomes a better acceptor through the formation of a hydrogen bonded complex with the imidazolyl part of **1**, but not with **3**. This possibility was excluded by experiment: ClMntpp, having no hydrogen bond site, quenched the fluorescence of **1** more efficiently than that of **3** by the same factor of 2.9. The possibility that **1** specifically interacts with ClMntpp through coordination of an imidazolyl group to Mn was safely excluded by there being no shift of the Soret band of ClMntpp, in accord with the small coordination equilibrium constant reported for imidazole and ClMntpp.[8] A possible explanation for efficient energy transfer and/or electron transfer from the supramolecule may be based on the idea that the excitation energy is delocalized over the whole supramolecule and transferred to acceptors from any components of the supramolecule as in the oxinylporphyrin.[10] These results establish the usefulness of the supramolecular porphyrin assembly as a mimic of the energy storage function of light harvesting antenna complexes (see Scheme 2).



Scheme 2 Excitation energy storage in supramolecular bis(imidazolyl)porphyrin assembly.

In conclusion, imidazolyl porphyrin is a useful component for obtaining porphyrin assemblies, not only through hydrogen bonding but also by metal coordination.[3] Further applications for bis(imidazolyl)porphyrin **1** and its derivatives are now under active investigation.

Another possibility was suggested by a referee, who pointed out that lowering of S_1 or even S_0 could affect either the pre-exponential or Marcus like terms and mediate the rate favourably. Photophysical studies may address the mechanism and will be reported elsewhere.

Chalcogen atom transfer reactions. Kinetics of terminal bonded sulfur atom transfer between main group metal centers

Stephen R. Foley and Darrin S. Richeson*

The first comprehensive investigation of S atom transfer between two different metal centers is presented using the reaction of the terminal chalcogen atom bearing complex $[CyNC(^tBu)NCy]_2SnS$ with $[CyNC(^tBu)NCy]_2Ge^{II}$; this multielectron redox reaction between Ge^{II} and Sn^{IV} proceeds *via* a second-order process with an inner sphere mechanism involving a μ-S intermediate as the proposed pathway; results of S and Se atom transfer between $[CyNC(^tBu)NCy]_2Ge$ and PPh_3 are also presented.

Atom transfer reactions are an active area of fundamental investigation that have attracted considerable attention in large part due the manifest role of oxygen atom transfer in many oxidation processes and in several biological processes.[1,2] The oxygen atom transfer reactions that have been studied are dominated by metal–oxo donor reactions with a non-metal acceptor. In comparison, transfer of heavier group 16 elements and/or complete inter-metal transfer of a multivalent atom are less established.[3,4] Some chalcogen complexes of Ti(IV) are known to function as effective sources of chalcogen atoms. However, the atom transfer reactivity of Cp_2TiE_5 (E = S, Se)[5] and of (OEP)TiE_2 (OEP = octaethylporphyrinato; E = O, S, Se)[6] are based on ligand reduction and are therefore categorized as secondary atom transfer reactions. When attention is focussed on main group metal complexes the number of clear examples of this class of reaction dwindles to a single detailed investigation.[7] In fact this example, shown by eqn. (1), represents the sole comprehensive study for inter-metal two electron transfer mediated by heavy elements of group 16 (*i.e.* S or Se) and involved the reversible transfer of sulfur and selenium atoms between tin porphyrin complexes of *meso*-tetraphenylporphyrinato (TPP) and *meso*-tetra-*p*-tolylporphyrinato (TTP) ligands.

$$(TTP)Sn^{II} + (TPP)Sn{=}S \rightleftarrows (TTP)Sn{=}S + (TPP)Sn^{II} \quad (1)$$

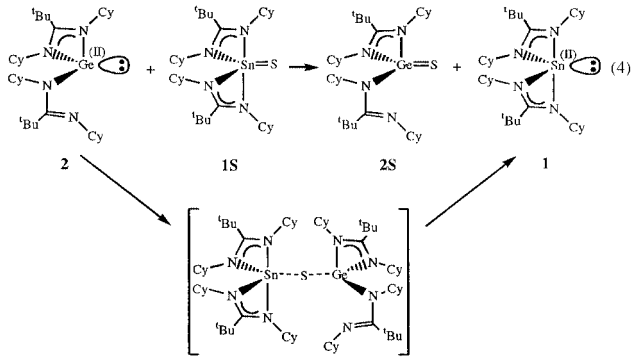
The limited examples of primary atom transfer reactions involving sulfur and selenium atoms include the exchange between the terminal chalcogenido complexes [η⁴-Me_8taa]SnE (E = S, Se; Me_8taa = octamethyldibenzotetraazaannulene) and the Ge(II) species [η⁴-Me_8taa]Ge [eqn. (2)].[8] More recently the preparation of terminal selenido complexes of gallium and indium supported by tris(3,5-di-*tert*-butylpyrazolyl)hydroborato (^{tBu}Tp) ligation allowed for the observation of selenium atom transfer from indium to gallium [eqn. (3)].[9] Kinetic parameters have not been established for either of these systems.

$$[\eta^4\text{-}Me_8taa]SnE + [\eta^4\text{-}Me_8taa]Ge^{II} \rightarrow [\eta^4\text{-}Me_8taa]Sn^{II} + [\eta^4\text{-}Me_8taa]GeE \quad (2)$$

$$[^{tBu}Tp]InSe + [^{tBu}Tp]Ga^{I} \rightarrow [^{tBu}Tp]In^{I} + [^{tBu}Tp]GaSe \quad (3)$$

Our interest in the formation of multiple bonds between main group elements and the subsequent reactivity of these unusual species led us to prepare a family of amidinato complexes of Ge and Sn $[CyNC(^tBu)NCy]_2ME$ [M = Sn, E = S (**1S**); M = Ge, E = S (**2S**), Se (**2Se**)] that possess terminal chalcogenido functions.[10,11] These compounds were prepared by oxidative addition of styrene sulfide or elemental selenium to the corresponding M(II) precursors, $[CyNC(^tBu)NCy]_2M$ [M = Sn (**1**), Ge(**2**)]. These results now allow us to report the first comprehensive study of heteronuclear inter-metal sulfur atom transfer reactions.

When the bis(amidinato)tin(IV) sulfide species **1S** and bis(amidinato)germanium(II) complex **2** are mixed at room temperature complete sulfur atom exchange between these complexes can be achieved according to eqn. (4) in Scheme 1.



Scheme 1

At room temperature this reaction proceeded smoothly over several days and could be conveniently monitored by ^{1}H NMR in C_6D_6. The ^{t}Bu groups for the four different amidinate complexes provided an excellent spectroscopic handle to monitor this reaction. For example, as the reaction progresses, the ^{t}Bu resonances of **1S** at δ 1.17 continuously decrease in intensity concomitant with the appearance of new ^{t}Bu resonances at δ1.35, signifying the formation of **1**.

The corresponding ^{t}Bu resonances for the germanium complexes are slightly more complicated. Instead of having both amidinate ligands bidentate and equivalent as with compounds **1** and **1S**, both **2** and **2S** are known to exhibit one bidentate and one monodentate ('dangling') ligand as shown in Scheme 1. This feature has been demonstrated through structural and spectroscopic characterization for both **2** and **2S** and is a general feature for a number of other germanium amidinate complexes that we have prepared.[12] As a result, the two amidinate ligands in the Ge complexes are inequivalent and two separate ^{t}Bu signals are observed for **2** and for **2S**. Thus, during the progress of the reaction, two new ^{t}Bu resonances appear at δ 1.70 and 1.07 signifying the formation of **2S** while the two resonances for the ^{t}Bu groups of **2** (δ1.61, 1.16) simultaneously decrease in intensity.

The progress of S atom transfer between **1S** and **2** can be monitored by following the changes in integration of the ^{t}Bu resonance of any of the four complexes in Scheme 1. In all kinetic runs, the data for this transfer reaction was found to obey an integrated rate law for second-order reactions.† Plots of reciprocal concentration *vs.* time were linear for more than two half lives. In all cases the data indicated a complete, non-reversible transfer of a terminally bonded sulfur atom from Sn to Ge.

Rate constants for this reaction could be determined over a temperature range of 40 °C and a summary of this data is given in

DOI: 10.1039/b003146l

Table 1. Measurements from 25 to 65 °C resulted in k values that ranged from 1.18×10^{-3} to 2.14×10^{-2} M^{-1} s^{-1} with resulting half-lives of 18 h to 31 min. The thermal decomposition of **2S** precluded studies at higher temperatures. An Eyring plot of these results indicated a linear relationship with associated activation parameters of $\Delta H^{\ddagger} = 17.6 \pm 0.2$ kcal mol^{-1} and $\Delta S^{\ddagger} = -14.4 \pm 0.3$ cal K^{-1} mol^{-1}.

The first-order dependence of the reactants was confirmed by imposing pseudo-first-order conditions on the reaction by having **1S** in large excess compared to **2**. Under these circumstances the disappearance of **2** and subsequent formation of **2S** exhibited first order behavior.

The only comparable system for which kinetic information is available is given by eqn. (1). In this case the kinetic analysis was consistent with a reversible second-order reaction.[7] The equilibrium constant for this reaction was near unity between −40 and −10 °C in toluene-d_8. Kinetic measurements for eqn. (1) at temperatures ranging from 30 to 60 °C resulted in k_f values from 0.40 to 2.39 M^{-1} s^{-1}.

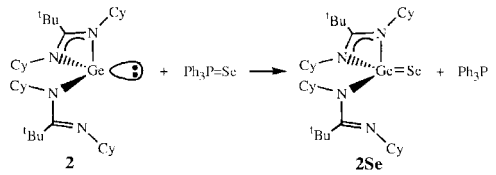
The rate law and activation parameters that we obtained for eqn. (4) in Scheme 1 support an inner-sphere mechanism which likely proceeds *via* interaction of the chalcogen atom on tin and the Ge(II) center resulting in a sulfur bridged intermediate (Scheme 1). While this species was not observed in our experiments, the negative entropy of activation ($\Delta S^{\ddagger} = -14.4$ cal K^{-1} mol^{-1}) is consistent with an associative type reaction involving a μ-sulfido intermediate. This observation is in line with the value of $\Delta S^{\ddagger}$ (-24.1 cal K^{-1} mol^{-1}) determined for eqn. (1) for which a similar μ-S species was suggested.[7] Consistent with this proposition is the low $\Delta H^{\ddagger}$ value, which suggests that significant bond formation between Ge and the bridging sulfido ligand that offsets the energy are required for the cleavage of the Sn=S during the transfer. Again the $\Delta H^{\ddagger}$ value obtained for eqn. (4) is similar to that obtained for the homonuclear exchange reaction shown in eqn. (1) ($\Delta H^{\ddagger} = 10.9 \pm 0.9$ kcal mol^{-1}).[7]

The direction of this sulfur atom exchange reaction demonstrates the thermodynamic stability of the terminal GeS bond relative to the corresponding SnS bond. This is consistent with the notions that both the tendency to engage in multiple bonding and the stability of M(IV) *vs.* M(II)[13] decreases for the heavier congeners of the group 14 elements (Ge > Sn > Pb). This is further supported by the fact that the π-bond energy associated with the Sn=S bond has been estimated to be 31.8 kcal mol^{-1} which is considerably lower than that of the Ge=S bond (40.0 kcal mol^{-1}).[14]

Keeping in mind that the common acceptors for oxygen atom transfer reactions are tertiary phosphines[1,2] we also examined the chalcogen atom exchange reactions between the germanium complexes **2**, **2S** and **2Se** and Ph_3PE/Ph_3P (E = S, Se). This should also provide some indication of the relative bond strengths for these species. Complex **2** reacts with 1 equiv. of triphenylphosphine selenide‡ in C_6D_6 according to eqn. (5). ^1H NMR spectroscopy indicated a complete conversion of Ph_3P=Se to Ph_3P while germylene **2** was converted to **2Se**. Under these conditions complete selenido atom exchange was achieved from the phosphorus to the germanium in < 4 min at room temperature with no indication of remaining starting materials. However, when the same reaction was performed with Ph_3PS in place of the Ph_3PSe, no reaction with **2** was observed even at elevated temperatures.

Table 1 Rate constants for eqn. (4) in C_6D_6

T/°C	k M^{-1} s^{-1}
25	$(6.28 \pm 0.84) \times 10^{-4}$
35	$(1.46 \pm 0.13) \times 10^{-3}$
45	$(4.19 \pm 0.06) \times 10^{-3}$
55	$(1.08 \pm 0.04) \times 10^{-2}$
60	$(1.53 \pm 0.06) \times 10^{-2}$
65	$(2.14 \pm 0.05) \times 10^{-2}$



(5)

We have found complete primary sulfur atom exchange between tin and germanium amidinates can be achieved and the kinetic parameters of this reaction have been fully determined. This represents the first comprehensive study of a heteronuclear inter-metal two-electron sulfur atom transfer. The data indicate an inner-sphere mechanism with μ-S formation. Chalcogen atom exchange between PPh_3 and **2** provide results that are consistent with increasing strength of interaction for the terminal sulfido species in the order $[CyNC(^tBu)NCy]_2SnS$ **1S** < $[CyNC(^tBu)NCy]_2GeS$ **2S** < Ph_3PS while for terminal selenido species the order appears to be Ph_3PSe < $[CyNC(^tBu)NCy]_2GeSe$ **2Se**. Our current efforts are directed at extending this investigation of inter-metal chalcogen atom transfer and exploring transfer to non-metal acceptors.

Notes and references

† All kinetic measurements were carried out in duplicate and were monitored by NMR spectroscopy using a Bruker 500 MHz or a Gemini 200 MHz spectrometer. Benzene-d_6 was distilled from Na/K alloy and used as solvent and internal standard. $[CyNC(^tBu)NCy]_2Sn$=S **1S** and $[CyNC(^tBu)NCy]_2Ge$ **2** were prepared according to literature procedures.[10,11]

Solutions of **1S** and **2** were prepared at concentrations ranging from 0.011 to 0.075 M and in ratios from 1 : 1 to 7 : 1. Samples were monitored in a temperature controlled NMR probe for at least two half lives. During remote ^1H NMR experiments, spectra were obtained at regular intervals that varied with temperature (*e.g.* 45 min at 35 °C and 3 min at 65 °C). For measurements at 25 °C, a temperature controlled water bath set at 25.0 °C was used and spectra were recorded manually every 2 h. Pseudo-first-order conditions were investigated at 35 °C where the initial concentrations were: $[(CyNC(^tBu)NCy)_2Sn=S] = 0.075$ M and $[(CyNC(^tBu)NCy)_2Ge] = 0.011$ M.

‡ Ph_3P=Se was prepared by dissolving triphenylphosphine (2.038 g, 7.78 mmol) in 35 ml THF followed by addition of excess elemental selenium (1.023 g, 13 mmol). The mixture was stirred for 24 h and filtered. The product was subsequently recrystallized from THF in 66% yield (1.66 g).

ChemComm

Novel aluminium– and gallium–nitrogen heteronorbornanes†

Christian Lustig and Norbert W. Mitzel*

Anorganisch-chemisches Institut, Technische Universität München, Lichtenbergstr. 4, 85747 Garching, Germany. E-mail: n.mitzel@lrz.tu-muenchen.de

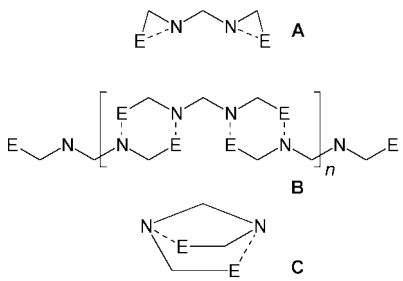
Received (in Basel, Switzerland) 5th May 2000, Accepted 16th June 2000
Published on the Web 6th July 2000

Selective formation of 2,5-dialumina-3,6-diaza- and 2,5-digalla-3,6-diaza-norbornane is achieved by reaction of bis(lithiomethyl-methylamino)methane with dimethylaluminium and dimethylgallium chloride by simultaneous formation of two metal–carbon and two metal–nitrogen bonds accompanied by two ring closure reactions; the norbornane-basket structures are favoured over potential isomers containing three-membered rings and over polymeric aggregation.

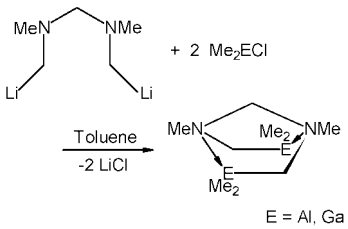
Small molecule nitrogen compounds of aluminium and gallium are the subjects of recent interest owing their potential as molecular precursors for III/V materials.[1] Investigations on both donor–acceptor adducts and metal amides have been intensely pursued.[2] Recent interest in compounds with acceptor and donor atoms in geminal position revealed various types of possible aggregates, either intramolecular *via* formation of three-membered ring systems as in compounds containing *BCN*,[3] *BNN*,[4] *AlCN*[5] and *AlNN*[6] but also *SiON*,[7] *GeON*[8] and *SnON*[9] units or intermolecular *via* formation of dimers with cyclohexane-like six-membered rings as in $[(H_2BCH_2SMe)_2]$,[10] $[Me_2Al(CH_2PMe_2)]_2$ and $[Al(CH_2PMe_2)_3]_2$,[11] and $[(Me_3C\text{-}CH_2)_2InCH_2PPh_2]_2$.[12] We intended to construct systems with two *ECN* functions joined by a bridging unit which have at least three possibilities for aggregation as depicted in Scheme 1 two three-membered rings (**A**), six-membered rings in either polymeric aggregation (**B**) or aggregated to form a norbornane-like structure (**C**).

In this contribution we demonstrate by preparation of the first alumina- and galla-azanorbornanes that the structural motif **C** is preferred for the saturated AlCN and GaCN systems. The reaction of a slurry of Karsch's dilithiated aminale $[LiCH_2(Me)N]_2CH_2$[13] with 2 equiv. of dimethylaluminium chloride or dimethylgallium chloride in toluene at −78 °C leads to a simultaneous formation of four chemical bonds and two ring closures to give the norbornane-like aggregates depicted in Scheme 2.‡ The reactions proceeds uniformly, and no sign of structures of type **A** and **B** were observed.

Compounds **1** and **2** show the typical NMR spectra of norbornane units with two non-equivalent signals for the two geminal methyl groups at Al or Ga (E) and the geminal hydrogen atoms at the carbon atom connecting E and N. These signals do not coalesce upon heating toluene solutions to 110 °C, proving the absence of rapid rearrangement reactions involving cleavage of the donor acceptor bonds, required for a positional exchange of the metal bound methyl groups.



Scheme 1



Scheme 2

Single crystals of both compounds, obtained from toluene solutions upon cooling, were examined by X-ray diffraction, and the structure of **1** is shown in Fig. 1.‡§ Compound **1** and the isostructural **2** are the first structurally characterised aminomethyl-aluminium and -gallium compounds. The molecules reside on C_2 axes passing through the aminal carbon atom and are chiral, but occur in the crystal as a racemate. The methylene bridge between the two N atoms causes the $E_2C_2N_2$ six-membered ring to adopt a boat conformation with compressed angles at the metal centres [**1**: 86.2(1)°, **2**: 85.1(1)°] and widened angles at the methylene groups in the six-membered ring [**1**: 105.8(1), **2**: 106.3(2)°] relative to the C_{2v} symmetric hydrocarbon norbornane where the C–C–C angles at the methylene groups in the six-membered ring are 102.7°.[14] This leads to a geometry at the metal atoms which deviates drastically from an ideal tetrahedron. The endocyclic E–N and E–C bond lengths are long when compared to the gas phase values of simple reference compounds such as Me_3Al–NMe_3 [Al–N 2.099(10), Al–C 1.987(5) Å][15] and Me_3Ga–NMe_3 [Ga–N 2.09(3), Ga–C 1.992(6) Å].[16]

The N–C bonds involving the metallated carbon atoms in the norbornane cages of **1** and **2** (N–C2) are *ca*. 3 pm longer than the N–C1 and N–C2 bonds. This elongation of bonds within the ring system indicates the presence of some strain. B3LYP/6-311G(d) calculations were conducted to obtain an estimate for

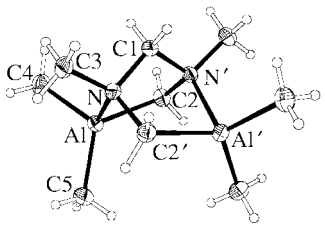


Fig. 1 Molecular structure of $(Me_2AlCH_2MeN)_2CH_2$ **1**. † Electronic supplementary information (ESI) available: selected geometry parameters for **1** and **2** (X-ray and DFT). See http://www.rsc.org/suppdata/cc/b0/b003813j/

the difference in energy between the monomolecular structures **A** and **C**, which were predicted to be 162 and 206 kJ mol^{-1} for **1** and **2**, respectively, and their three-membered ring isomers. As the norbornane structures of **1** and **2** cannot be regarded as strain-free, although much less strained than the three-membered-ring isomers, these values indicate that the *AlCN* units in the three-membered-ring isomers contain at least 80 kJ mol^{-1} more strain energy relative to their six-membered ring dimers. The observation of compounds containing *AlCN* and also *AlNN* three-membered rings can therefore only be rationalised by steric shielding of the small ring unit.

The compact structures of **1** and **2** leads to their comparatively high volatility, and both can be sublimed at *ca*. 90 °C under a pressure of 0.01 mbar without decomposition. The volatility of **1** and **2** leads to the expectation of a small molecular dipole moment for **1** and **2**. Calculations give estimates for dipole moments of 3.95 and 3.43 D for **1** and **2**. The value for **1** is higher than for its three-membered-ring isomer (2.14 D).

We have shown that introduction of two linkages containing acceptor and donor atoms in geminal positions are useful for the synthesis of organometallic heterocyclic systems without the necessity for sterically demanding ligands. Variations of the donor and acceptor centres and the bridging unit opens a field for many novel structural motifs generated through intra- and inter-molecular coordination and for the construction of new macrocyclic compounds.

We are grateful to the Deutsche Forschungsgemeinschaft, the Leonhard–Lorenz-Stiftung and the Fonds der Chemischen Industrie for financial support. Selected geometry parameters for crystalline **1** and **2** accompanied by the results of B3LYP/6-311G(d) calculations is available as ESI.†

The temperature dependence of bimolecular rate constant and product cage escape yields for the photoelectron transfer reaction between $[Ru(bpy)_3]^{2+}$ and MV^{2+} in the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate is reported.

Ionic liquids have been the subject of considerable interest in recent years. Potential applications include battery electrolytes,[1] solvents for homogeneous catalysis or other organic reactions,[2] novel extraction solvents[3] and liquid crystals.[4] The interest is stimulated in particular by their potential application as 'green' solvents in industrial processes.[5] However, there is very little quantitative information regarding their influences on chemical reactions. To date there are also only three papers that describe the use of ionic liquids as solvents for photochemical reactions.[6]

The simplest of all chemical reactions is electron transfer; this type of process occurred in the photochemical systems so far investigated in ionic liquids.[6] We decided to start a quantitative examination of the influence of ionic liquids on reaction rates in one of the most thoroughly investigated of photoinduced electron transfer systems: the ruthenium tris(4,4′-bipyridyl)/methylviologen ($[Ru(bpy)_3]^{2+}/MV^{2+}$) couple. The effects of the medium on this reaction have been studied extensively with variation in temperature, solvent, pH and ionic strength.[7] These results may be summarised with reference to Schemes 1 and 2.

$$*R^{2+} + MV^{2+} \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} [*R^{2+}\cdots MV^{2+}] \xrightarrow{k_e} [R^{3+}\cdots MV^{\bullet+}]$$

Scheme 1

$$\begin{array}{ccc} [R^{3+}\cdots MV^{\bullet+}] & \underset{k_d}{\overset{k_{-d}}{\rightleftharpoons}} & R^{3+} + MV^{\bullet+} \\ \Big\downarrow k_b & & \\ [R^{2+}\cdots MV^{2+}] & \underset{k_d}{\overset{k_{-d}}{\rightleftharpoons}} & R^{2+} + MV^{2+} \end{array}$$

Scheme 2

First there is the forward electron transfer step (Scheme 1) involving the reaction between the photoexcited $[Ru(bpy)_3]^{2+}$, $*R^{2+}$, and methylviologen, MV^{2+}, forming an encounter complex/exciplex $[*R^{2+}\cdots MV^{2+}]$. This occurs with a bimolecular rate constant corresponding to diffusion control, k_d. Once formed, $[*R^{2+}\cdots MV^{2+}]$ can either regenerate reactants with a unimolecular rate constant k_d, or electron transfer may occur from $*R^{2+}$ to MV^{2+} with a rate constant k_e. The composite bimolecular rate constant for the overall luminescence quenching reaction, k_q, is given by eqn. (1)

$$k_q = k_d k_e/(k_{-d} + k_e) \quad (1)$$

After forward electron transfer has occurred within the encounter complex, there are two competing reaction pathways as summarised in Scheme 2.

Back electron transfer within the $[R^{3+}\cdots MV^{+}]$ cage, with a rate constant k_b, competes with diffusion apart of R^{3+} and $MV^{\cdot+}$, which occurs with a rate constant k_{-d}. The cage escape efficiency, η_{ce}, is given by eqn. (2)

$$\eta_{ce} = k_{-d}/(k_b + k_{-d}) \quad (2)$$

This photochemical system has a number of features that could be influenced by a purely ionic environment. It has previously been shown that ion pairing of the encounter complexes with a variety of solvated anions in aqueous solution increases k_q and decreases η_{ce}.[8] In an ionic liquid, there is the question as to the extent to which solvent anions will reduce electrostatic repulsion between the two reactant cations *via* a charge screening effect on formation of an encounter complex. Such effects may also reduce k_{-d}. Furthermore, k_b could be affected by alterations in electronic coupling between caged donor/acceptor pairs, or changes in ΔG and solvent reorganisation energy. A combination of these effects would be expected to result in significantly different k_q and η_{ce} values in ionic liquids.

We have examined the temperature dependence of k_q and η_{ce} in the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate ([bmim][PF_6]) using laser flash photolysis methods.[9] The value of k_q was determined from plots of the first order rate constant for the decay of $*R^{2+}$, k_{obs}, as a function of MV^{2+} concentration at a series of temperatures over the range 6–70 °C. The concentrations of MV^{2+} employed ranged from 5 to 15 mM. The results are shown in Fig. 1 together with the resulting Arrhenius plot. The Arrhenius behaviour fits the equation $\ln k_q = 33.98\ (\pm 1.7) - 5003\ (\pm 480)/T$, giving an activation energy (E_a) of 41.6 (±4) kJ mol^{-1} and a pre-exponential factor of 5.72×10^{14} mol^{-1} dm^3 s^{-1} for the luminescence quenching reaction. At 20 °C, this corresponds to a k_q value of 2.19×10^7 mol^{-1} dm^3 s^{-1}. This should be compared with values of 1.7×10^9 and 2.2×10^7 mol^{-1} dm^3 s^{-1} previously recorded at this temperature in water and acetonitrile respectively.[10] The viscosity of [bmim][PF_6] at 20 °C is 0.330 Pa s, compared with 0.001 and 0.00036 Pa s for water and acetonitrile, respectively. Given the high viscosity of [bmim][PF_6], we would anticipate that this reaction becomes diffusion controlled, *i.e.* $k_e \gg k_{-d}$, and therefore $k_q = k_d$. To this end, we determined an E_a for viscous flow of 37.6 kJ mol^{-1} in [bmim][PF_6] over the temperature range 10–70 °C. Clearly, E_a for the reaction between MV^{2+} and $*R^{2+}$ is very close to that of viscous flow. Electrostatic repulsions should result in an increase in the barrier to formation of an encounter complex/exciplex between two divalent cations in a typical, non-ionic solvent. This leads us to conclude that such repulsions contribute no more than *ca.* 4 kJ mol^{-1} to our observed activation energy in [bmim][PF_6], which is effectively our estimated error in E_a. Finally, the pre-exponential factor is extremely large for a bimolecular reaction,

DOI: 10.1039/b003754k

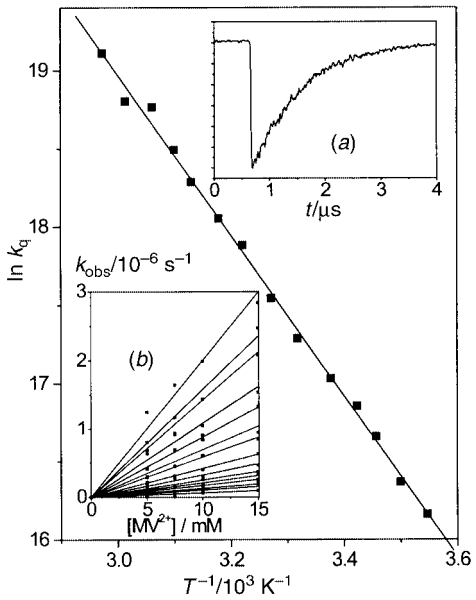

Fig. 1 Arrhenius plot for the bimolecular rate constant for the reaction between *[Ru(bpy)$_3$]$^{2+}$ and Mv^{2+} in [bmim][PF$_6$]. Insert (a) *[Ru(bpy)$_3$]$^{2+}$ emission recorded at λ = 630 nm (λ_{ex} = 355 nm) and 19 °C under N_2-saturated conditions; (b) plot of k_{obs} as a function of [MV^{2+}] over the temperature range 5–70 °C.

and corresponds to a value of ΔS = 29.3 (±14) J K^{-1} mol^{-1} at 298 K. Such a positive $\Delta S^{\ddagger}$ value suggests a structure-breaking process involving the freeing up of solvent ions on formation of the encounter complex. This in turn suggests that the solvent itself is a significantly ordered environment, as has previously been indicated from NMR studies on related ionic liquid systems.[11] We are currently investigating the influence of solute charges on diffusion-controlled reaction rates within ionic liquids and will report our results in due course.

Values of η_{ce} were calculated by measuring the intensity of the signal observed for MV$^{\cdot+}$ at 605 nm relative to that of *R^{2+} at 450 nm (values previously reported in acetonitrile of 1.37 × 10^4 and −1.0 × 10^4 mol^{-1} dm^3 cm^{-1} respectively were used for the difference molar absorptivities).[10] The rate of formation of MV$^{\cdot+}$ was always the same as the rate of decay of *R^{2+} fluorescence. The calculated values of η_{ce} range from 0.35 at 25 °C to 0.8 at 60 °C, compared with 0.29 at 20 °C and 0.45 at 65 °C in acetonitrile.[10] Such large values of η_{ce} are unexpected in a viscous ionic solvent due to the much larger E_a reducing k_{-d} in the ionic liquid with respect to that a non-viscous solvent such as acetonitrile. Previous studies have clearly shown that η_{ce} decreases with increasing ionic strength, primarily because of the anionic counter ions counteracting the electrostatic repulsion between R^{3+} and MV$^{\cdot+}$ within the encounter complex. This leads to k_{-d} decreasing with respect to k_b as ionic strength increases, which in turn results in a decrease in η_{ce}.[8] Clearly, our results are in complete contrast to these earlier studies. Our assumption that the relative molar absorptivities of *R^{2+} and MV$^{\cdot+}$ are independent of solvent may of course be incorrect; nonetheless we do not expect such ratios to alter greatly in different solvents. For comparable cage escape yields to be observed in [bmim][PF$_6$] and acetonitrile at room temperature (assuming Schemes 1 and 2 are valid), k_b must decrease in the ionic liquid relative to acetonitrile in order to compensate for the lower k_{-d} value in the former solvent. Back electron transfer from MV$^{\cdot+}$ to R^{3+} is thought to occur in the so-called Marcus inverted region.[12] Therefore reduction in k_b in [bmim][PF$_6$] with respect to acetonitrile must either be due to ΔG becoming more negative, or else a smaller solvent reorganisation energy in [bmim][PF$_6$], or a combination of both. At this stage we do not have reliable estimates of ΔG in this solvent, nor can we reliably estimate the reorganisation energies; these are usually estimated using the dielectric continuum model. Using pyrenecarbonaldehyde fluorescence as a probe of solvent dielectric, ε, we estimate ε < 10 for [bmim][PF$_6$] at 20 °C.[13] It is quite possible that ΔG is more negative and the solvent reorganisation energy is smaller in [bmim][PF$_6$] than acetonitrile, given such a low dielectric in the former solvent. We are currently determining the temperature dependence of ΔG in a range of ionic liquids, and will report our results in full at a later date.

However, there may be a non-electrochemical explanation for the large η_{ce} values in the ionic liquid. A weak dependence of k_b on ΔG has been reported for a number of [Ru(diimine)$_3$]$^{2+}$/MV^{2+} systems;[12] a suggested explanation is that significant molecular reorientation is required within the solvation sphere *prior* to back electron transfer. In such a situation the reorientation step is rate determining and competes with diffusion apart of the products. Our results are consistent with this hypothesis: both the diffusion apart of the charge separated pair and geometric reorganisation could be expected to require significant contributions from those processes driving viscous flow. The activation energies of both k_{-d} and k_b would then be affected by [bmim][PF$_6$] solvation to a similar extent, and therefore cage escape yields are not greatly altered with respect to less viscous solvents such as acetonitrile.

In conclusion, we have been able to show that the photoelectron transfer reaction between *R^{2+} and MV^{2+} in [bmim][PF$_6$] occurs, within experimental error, at a diffusion-controlled rate. We believe this is the first detailed report of quantified reaction kinetics in an ionic liquid, and also the first indication of the magnitude of diffusion-controlled rate constants in such media. The yield of MV$^{\cdot+}$ is surprisingly larger than expected for such a viscous medium. We are currently investigating the influence of solvent viscosity on diffusion-controlled processes and cage escape yields with a range of ionic liquids, and will report our results in due course.

We thank the Royal Society of Edinburgh for the award of a BP Research Fellowship (C. M. G.), EPSRC (C. M. G.) and the University of Paisley (A. M.) for financial support, Mr Jim Morrow for assistance with viscosity measurements, and Mr David Stirling for assistance with the flash photolysis measurements.

Received (in Cambridge, UK) 2nd May 2000, Accepted 15th June 2000
Published on the Web 7th July 2000

The title pale yellow photochromic compound 11b in toluene, on irradiation at 366 nm, cyclises to the thermally stable infrared active blue–green photochrome, 8-amino-7-cyano-4,4-dicyclopropyl-3a,4-dihydro-6-hydroxy-2,3a-dimethylnaphtho[2,1-*b*]furan-5,6-carbolactone, 12b which has a λ_{max} value of 720 nm for its broad long wavelength absorption band.

E-Fulgides, (*E*)-3-[1-(2,5-dimethyl-3-furyl)ethylidene]-4-isopropylidenetetrahydrofuran-2,5-dione **1a**, (*E*)-3-[1-(2,5-dimethyl-3-furyl)ethylidene]-4-(cyclopropylmethylene)tetrahydrofuran-2,5-dione **1b**, (*E*)-3-[2,5-dimethyl-3-thienyl)-ethylidene-4-isopropylidene tetrahydrofurandione **1c** and (*E*)-3-[2-methyl-5-phenyl-3-thienyl)ethylidene-4-(dicyclopropylmethylene)tetrahydrofuran-2,5-dione **1d** reacted with malononitrile and diethylamine in THF to give exclusively (*E*)-2-dicyanomethylene derivatives **3a–d** which, in toluene, cyclised to photochromes **4a–d** on irradiation at 366 nm. The thermally stable blue photochromes **4a–d** underwent reverse reactions on exposure to white light. Previous papers[1,2] reported erroneously that *E*-fulgides (*e.g.* **1a**) gave the corresponding (*E*)-5-dicyanomethylene derivatives (*e.g.* **8a)** on reaction with malononitrile (1 equiv.) and diethylamine (2 equiv.) in THF, followed by cyclisation with acetyl chloride.

Z-Fulgides **6a–d** gave exclusively the corresponding pale yellow (*Z*)-5-dicyanomethylene derivatives **7a–d** under similar experimental conditions. The latter, in toluene, isomerised to *E*-isomers **8a–d** and cyclised to photochromes **9a–d** on irradiation at 366 nm. The thermally stable blue photochromes **9a–d** underwent reverse reactions to pale yellow *E*-isomers **8a–d** on exposure to white light.

Deprotonation of the methyl group *syn* to the dicyanomethylene group in (*Z*)-2-dicyanomethylene derivative **3b**, by boiling with diisopropylamine in THF, gave anion **5b**, which reacted with the adjacent cyano group to form imine **10b**, which isomerised to 6-amino-7-cyano-3-(dicyclopropylmethylene)-4-(2,5-dimethyl-3-furyl)-1-benzofuran-2(3*H*)-ones **11b**,† obtained as bright yellow crystals (from chloroform–petrol). Its structure was confirmed by X-ray crystallographic analysis (Fig. 1). Amines **11a–d** were prepared in a similar manner.

All new compounds were fully characterised. Spectral data, melting points and yields are given in Table 1.

On irradiation at 366 nm, amines **11a–d** in toluene cyclised to thermally stable blue-green photochromes **12a–d** (Table 2) which underwent the reverse reactions on exposure to white light.

Photochromes **2a–d**, **4a–d**, and **9a–d** showed bathochromic shifts when the push-pull effect is enhanced, as reported for infrared active dyes.[3] Photochromes **12a–d** have increased intramolecular charge-transfer character, due to the tendency to

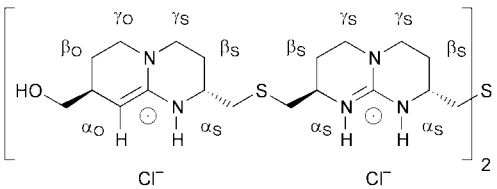
In binding to tetraguanidinium compounds, the average side chain length of tetraanionic peptides determines the thermodynamics of binding, the degree of helix induction and the rigidity of the complex formed.

Protein–protein interactions play an essential role in the regulation of biochemical events in living organisms.[1] Although the increasing number of structures deposited in the structural databases reveals some interesting trends in the biophysical properties of protein–protein interfaces,[2] the design of protein surface receptors able to disrupt such interactions remains a challenge. However, peptide surface binding by synthetic receptors has been studied intensively and is providing interesting candidates for protein surface recognition.[3,4] We have reported the association between tetraguanidinium receptor **1** and peptide **2** with an *i*, *i* + 3, *i* + 6, *i* + 9 arrangement



1

of aspartate residues in 10% aqueous methanol.[4] Although side chain length has been shown to affect important properties of amino acids such as helical propensity[5] and the ability to make side chain-to-backbone hydrogen bonds[6] little attention has been paid to its importance in peptide and protein recognition.

† Electronic supplementary information (ESI) available: isothermal titration calorimetry, ^{1}HNMR and NOE data. See http://www.rsc.org/suppdata/cc/b0/b003728l/

With the aim of further developing the approach to protein surface receptors we have now investigated the effect of increasing side chain length. We have sequentially replaced aspartate by glutamate so that the Asp–Glu ratio spans gradually from the all aspartate peptide **2** to the all glutamate peptide **6**. This family of peptides has been studied by CD, NMR and isothermal titration calorimetry (ITC) in order to explore which molecular recognition parameters are affected by increasing side chain length. As reported below we have found that lengthening the side chain has a dramatic effect on the thermodynamics of binding, which shifts from enthalpically driven to entropically driven.

The helical content of the peptides in solution was assessed by circular dichroism spectroscopy and showed (Table 1) that replacement of aspartate by glutamate gradually increases the helical content of the peptide (Hel_i) as predicted from their helix propensities.

Binding of **1** to **2** causes a large increase in the helicity of the peptide because the alignment of atoms necessary for intermolecular hydrogen bond formation requires that the peptide adopts a helical conformation. CD binding[7] titrations of **3** to **6** were carried out to assess the effect of side chain length on helix induction. The results (Table 1) show that the effect of the stepwise replacement of aspartate by glutamate is a gradual decrease in the helical induction due to complex formation (ΔHel). The absolute increase of fractional helicity decreases from 24% for **2** to nearly no conformational change for **5** and **6**.

ITC was used to detect binding and measure affinity constants in the cases where there was no change in ellipticity at 222 nm. The data confirm the 1 : 1 stoichiometry of complexation and give an independent measurement of K_a for peptide **2**, validating the results previously reported by CD. Peptide **2** shows an overall negative enthalpy change (−5.64 kcal mol^{-1}) whereas **6** shows a positive enthalpy change upon binding (3.68 kcal mol^{-1}). Peptide **4**, which has an equal number of aspartate and glutamate residues in its surface shows an enthalpically

neutral binding curve. Despite this variation in thermodynamic behavior, the affinity constants obtained by the combination of CD and ITC methods reveal that affinity does not greatly depend on the individual nature of the residues involved with complex formation, as shown in Table 1.

Chemical shift changes in **1** upon complexation of **2** and **6** have been monitored by NMR spectroscopy.[8] Unbound **1** has a C_2 axis of symmetry which simplifies its spectrum and is no longer present in the complex with tetra acid peptides. Fig. 1(a) shows an expansion of the TOCSY spectrum of unbound **1**. The splitting of resonances in **1** due to the asymmetry of the **1**:**2** complex can be observed in Fig. 1(b). However, this splitting is not observed in the NMR spectrum of **1** bound to **6**. Although chemical shift changes occur, no loss of symmetry is detected as shown in Fig. 1(c). Further evidence for the different rigidity of the complexes is provided by the existence of intermolecular NOEs between the CH_2S and α_S protons of **1** and the methyl groups of leucine 6 and/or leucine 9 of **2** which are not observed in the complex formed between **1** and **6**.

Recognition of **2** is enthalpy driven. Because of the relative rigidity of the aspartate side chains in contact with the receptor, a change in the backbone conformation of **2** towards higher helicity is necessary as shown in Table 1. Despite the entropic penalty associated with preorganization, complex formation takes place due to the large negative enthalpy of α-helix formation[9] and the entropy of liberation of counterions and solvent. Complexation of **6** is however entropy driven. The longer side chain of glutamate allows complex formation to take place without major re-organization: the overall conformation does not change as observed by CD (Table 1). The large entropy change on complexation is probably due to the liberation of solvent and counterions initially bound to the peptide and the receptor. The rigidity of the complex, related to the change in entropy, is also side chain length dependent: close proximity of **1** and the all aspartate peptide **2** in the **1**:**2** complex is indicated by the existence of intermolecular NOEs and the extent of chemical shift changes compared to **1**. The lack of intermolecular NOEs and the less pronounced chemical shift changes suggest that **1**:**6** is significantly less rigid. Binding of **4**, which displays two Asp and two Glu residues on its anionic surface, is enthalpically neutral (Table 1), confirming that side chain length modulates to a great extent the features of recognition between **1** and tetraanionic peptides.

Although the binding of sulfate anions by guanidinium receptors has recently been reported to be entropy driven,[10] in our case the thermodynanic behavior can be tuned by changing side chain length. These results can be analyzed in the context of enthalpy–entropy compensation.[11] This phenomenon has often been described in ligand–protein interactions and is defined as a compensating behavior of the relative changes to ΔH and $T\Delta S$ of binding within a series of ligands or receptors of similar structure.[12]

In summary, we have shown how recognition of *i*, *i* + 3, *i* + 6, *i* + 9 tetra-carboxylate peptides by **1** is a general phenomenon that takes place both with Asp and Glu containing peptides but that length of the side chain has a dramatic impact on the thermodynamics of binding. A recent survey of 'hot spots' shows that Asp is 2–3 times more likely than Glu to contribute to the stability of protein–protein complexes.[13] Our results suggest that this may be due to the tighter nature of Asp *vs.* Glu complexation.

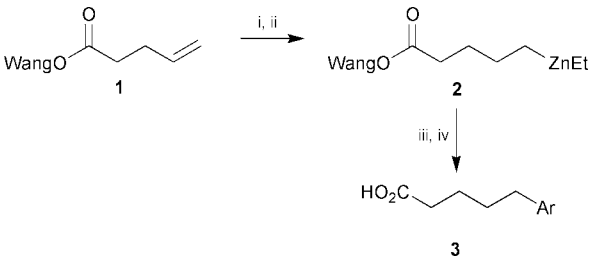
Received (in Liverpool, UK) 10th May 2000, Accepted 15th June 2000
Published on the Web 7th July 2000

Hydroboration of Wang-supported pent-4-enoic acid 1, followed by transmetallation with Et_2Zn, gives a solid-supported zinc reagent, 2, which undergoes palladium-catalysed coupling with aryl iodides, to give the corresponding 5-arylpentanoic acids 3 in moderate to good yields, after cleavage from the resin using TFA.

Solid phase synthesis has developed into one of the main methods used in the construction of libraries of compounds in the search for biological activity. While a vast amount is known about the formation of carbon–heteroatom bonds on solid phase, the area of carbon–carbon bond formation has been less well-developed.[1] More specifically, the application of organometallic chemistry to carbon–carbon bond formation in solid phase synthesis has not been extensively investigated. There are examples of reaction of solid supported electrophiles with solution phase organometallic reagents, for example stannanes[2] and organozinc halides,[3] and this approach offers the advantage of being able to use a large excess of the organometallic reagent to ensure high conversion of the solid-supported electrophile. However, this approach has the dual disadvantages that each electrophile has to be loaded separately onto solid support, and also that the limited number of 'off-the-shelf' organometallic reagents means that most would need to be prepared separately. This clearly militates against the use of this chemistry in real library synthesis. By contrast, the large number of readily available electrophiles means that the preparation of solid-supported organometallic reagents has the potential to be much more generally applicable.

The preparation of solid-supported organometallic reagents was originally limited to the lithiation of cross-linked polystyrene, and this approach is widely used for the synthesis of modified polystyrene resins.[4] The use of solid-supported stannanes has been reported,[5] but these reagents are only appropriate for the transfer of unsaturated functionality. More recently, both aryl Grignard reagents[6] and aryl zincates[7] have been prepared from iodobenzoic acid derivatives supported on Wang resin. There is clearly a great need for the development of methods for the preparation of solid-supported alkylmetal derivatives, and the well-established functional group tolerance of alkylzinc reagents suggested that these might be good candidates.[8,9]

Organozinc reagents have most often been prepared by the heterogeneous reaction of alkyl iodides with metallic zinc, a process which is clearly not applicable to solid phase. A very attractive alternative is the overall conversion of an alkene into a dialkylzinc compound by initial hydroboration with diethylborane, followed by transmetallation with diethylzinc.[10] We have therefore prepared Wang-supported pent-4-enoic acid **1** (using 3 equivalents of pent-4-enoic acid relative to Wang resin). This material was subsequently treated with an equivalent of Et_2BH in THF, and after washing, an excess of Et_2Zn was added at 0 °C. Subsequent reaction with iodobenzene under palladium catalysis,† followed by cleavage from the resin using TFA,‡ gave 5-phenylpentanoic acid **3a** (78%, based on resin loading of pent-4-enoic acid as determined by cleavage using TFA–CH_2Cl_2 from a sample of the resin **1**), Scheme 1. A brief survey of the applicability of the process established that other substituted aromatic iodides are also appropriate coupling partners (Table 1).



Scheme 1 *Reagents and conditions:* i, Et_2BH (1 equiv.), 5 °C, 30 min; ii, Et_2Zn (10 equiv.), 0 °C, 30 min; iii, ArI (2 equiv.), $Pd_2(dba)_3$ (2.5 mol.%), P(*o*-tol)$_3$ (10 mol.%), room temp., 16 h; iv, TFA, CH_2Cl_2, room temp, 1 h.

Table 1 Preparation of 5-aryl valeric acids

Ar–I	Product	Ar	Yield (%)
Ph–I	**3a**	Ph	78

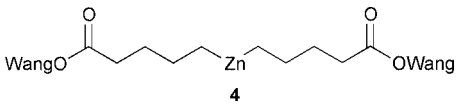
The usual product of zinc–boron exchange reactions is the symmetrical dialkylzinc species **4**,[10] towards which the equilibrium is shifted by removal of the triethylborane by distillation, although it is likely that the ethylalkylzinc species **2** is also formed in the presence of an excess of diethylzinc. On solid phase, the distinction between these two species is not important, since the ethylbenzene arising from coupling of the ethyl group in **2** with the electrophile is removed during the washing process after the coupling reaction and before the cleavage with trifluoroacetic acid.



This demonstration that simple functionalised alkylzinc reagents can be prepared on solid-support opens the possibility of the use of such reagents in library synthesis.

We thank Astra Zeneca for support (L. J. O.)

Notes and references

† Wang pent-4-enoate resin (500 mg, 0.55 meq) was allowed to swell with dry (distilled) THF (5 cm^3) under N_2 in dry glassware. This mass of resin typically absorbed 3.8 cm^3 of THF. The excess solvent was decanted *via* a syringe, and the resin washed with THF (2 × 5 cm^3). THF (2 cm^3) was added, and the reaction cooled in ice–water before addition of diethylborane (80 μl, 0.56 mmol), prepared from triethylborane and borane–dimethyl sulfide complex. After 30 min the solvent was decanted, and the resin washed with THF (5 cm^3). THF (2 cm^3) was added and the suspension cooled to 0 °C, followed by the addition of Et_2Zn (400–500 μl, 4–5 mmol).

After 30 min the solvent was decanted, and the resin washed with THF (2 × 5 cm^3). THF (5 cm^3) was added, followed by Pd_2dba_3 and P(*o*-tolyl)$_3$ (1:4 molar ratio 20–25 μmol Pd) and the electrophile (1.1 mmol). The reaction was allowed to proceed overnight at rt (20–22 °C). The resin was poured into a sintered-funnel, drained in air, and washed thoroughly with THF until the washings ran clear. The resin was then treated with acetic acid–THF (50:50, 50 cm^3, 30 min), washed with THF (3 × 20 cm^3) and then with CH_2Cl_2 (4 × 20 cm^3).

‡ The resin was placed in a sintered-funnel and washed with dry (distilled) CH_2Cl_2 (3 × 10 cm^3). The funnel was covered with aluminium foil, a mixture of CH_2Cl_2 (1.5 cm^3) and TFA (5 cm^3) was added and the mixture allowed to stand for 1 h. The solvent was drained into a flask under N_2, and the resin washed with dry CH_2Cl_2 (2 × 20 cm^3). The solvent(s) were evaporated to give the crude products as oils, from which the products crystallised upon standing. All products were recrystallised from petroleum ethers or petroleum ether–$CHCl_3$ systems.

A novel ATRP initiating system $Fe(dtc)_3/FeCl_3/PPh_3$ for MMA polymerization

Xiao-Ping Chen and Kun-Yuan Qiu*

Department of Polymer Science and Engineering Chemistry Building, Peking University, Beijing 100871, China. E-mail: kyqiu@chemms.chem.pku.edu.cn

Received (in Cambridge, UK) 5th June 2000, Accepted 14th June 2000
Published on the Web 7th July 2000

A 'living'/controlled radical polymerization of MMA was carried out with a novel ATRP initiation system: iron(III) tri(diethyldithiocarbamate) $[Fe(dtc)_3]/FeCl_3/PPh_3$, where neither an organic halide nor a radical initiator was used.

As we know, atom transfer radical polymerization (ATRP) is one of the effective controlled/'living' radical polymerization systems to synthesize well-defined polymers with low polydispersities and complex architectures;[1,2] and up to now, two types of ATRP, *i.e.* (conventional) ATRP and reverse ATRP,[3–5] have been known.

In ATRP, organic halides (RX) are used as initiators, transition-metal compounds in their lower oxidation state (M^n) are used as catalysts and electron-donating compounds are used as ligands (L). In reverse ATRP, a radical initiator and a higher oxidation state transition-metal catalyst complex $M^{n+1}XL_m$ are used instead of an organic halide initiator RX and lower oxidation state catalyst complex M^nL_m. As in ATRP, a controlled/'living' radical polymerization can also be carried out in a reverse ATRP system, under which a dynamic equilibrium is established, where the dormant polymer chains are reversibly activated *via* a halogen atom transfer reaction.

More recently, we have first reported a third ATRP process, *i.e. in situ* ATRP of MMA polymerization using the tetraethylthiuram disulfide (TD)/$FeCl_3/PPh_3$ system.[6] In the *in situ* ATRP process, RX and M^{n+} are both created *in situ* from the reaction between a radical initiator TD and $FeCl_3$ at a given polymerization temperature. The polymerization proceeds following a conventional ATRP and is well-controlled.

So far, from the reported literature, one of components in an ATRP initiating system must be either an organic halide[1,2] (in ATRP) or a radical initiator[3–5] (in reverse ATRP or *in situ* ATRP). Recently, however, a paper concerning a living radical polymerization of styrene with $Fe(dtc)_3$/AIBN system in a halogen-free living process was published.[7]

Here we report a novel initiating system $Fe(dtc)_3/FeCl_3/PPh_3$, in which neither an organic halide nor a radical initiator as the initiator for ATRP was used. The polymerization of MMA with this initiating system proceeded *via* an ATRP process.

The bulk polymerization of MMA was carried out using the $Fe(dtc)_3/FeCl_3/PPh_3$ initiation system at 80 °C. With $[MMA]_0:[Fe(dtc)_3]_0:[FeCl_3]_0:[PPh_3]_0 \approx 300:1:30:90$, a plot of $\ln([M]_0/[M])$ *vs.* time as shown in Fig. 1, showed a straight line, indicating that the kinetics was first order in monomer and that the concentration of propagating radicals was unchanged during the polymerization. It can be seen in Fig. 2 that the $M_{n\,(GPC)}$, number-average molecular weight measured by GPC, increased linearly with conversion from 1300 to 7200. A quite narrow polydispersity index (1.10–1.16) was obtained as the monomer conversion increased from 11 to 79% in 40 min. The value of $M_{n\,(GPC)}$ was almost equal to $M_{n(th)}$, a theoretical number-average molecular weight calculated from $M_{n(th)} = ([MMA]_0/3[Fe(dtc)_3]_0) \times MW_{MMA} \times$ conversion. The efficiencies (f) of initiator as computed from $f = M_{n(th)}/M_{n(GPC)}$ were ≈ 1.0.

When the ratio of feeds in a separate experiment was the same as in bulk, similar results of solution polymerization of MMA in anisole were obtained although with a lower rate of polymerization, *e.g.* the conversion was 52% at 40 min, $M_{n(GPC)}$ was 4700 and M_w/M_n was 1.19.

Accordingly, the above results clearly suggested that the MMA polymerization with the $Fe(dtc)_3/FeCl_3/PPh_3$ initiation system at 80 °C exhibited some 'living'/controlled radical polymerization characteristics.

We investigated the effects of initial initiator concentration on the polymerization of MMA under fixed conditions: $[MMA]_0 = 9.38$ mol l^{-1}, $[Fe(dtc)_3]_0:[FeCl_3]_0:[PPh_3]_0 = 1:30:90$, at 80 °C. When $[Fe(dtc)_3]_0$ is 3.13×10^{-3} mol l^{-1}, the conversion was 62%, $M_n = 55\,800$, $M_w/M_n = 1.23$, while when $[Fe(dtc)_3]_0$ was increased to 6.25×10^{-3} mol l^{-1}, the conversion was 68.7%, $M_n = 28\,100$, $M_w/M_n = 1.32$ after the same polymerization time of 5 h. This indicated that PMMA with higher number-average molecular weight and narrow polydispersity can be obtained using a lower initial concentration of $Fe(dtc)_3$.

The polymers obtained are well-defined PMMA with α-Et_2NCS_2– and ω-chlorine groups according to FTIR, UV and

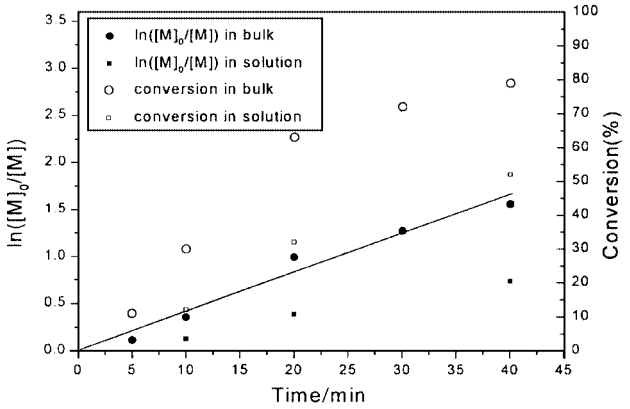

Fig. 1 Time dependence of $\ln[M]_0/[M]$ and conversion at 80 °C, where $[M]_0$ and [M] are the MMA concentration at times 0 and t, respectively. *Conditions*: in bulk, $[MMA]_0 = 9.38$ mol l^{-1}, $[Fe(dtc)_3]_0 = 3.13 \times 10^{-2}$ mol l^{-1}, $[FeCl_3]_0 = 9.38 \times 10^{-1}$ mol l^{-1}, $[PPh_3]_0 = 2.81$ mol l^{-1}; in anisole, $[MMA]_0 = 5.25$ mol l^{-1}, $[Fe(dtc)_3]_0 = 1.75 \times 10^{-2}$ mol l^{-1}, $[FeCl_3]_0 = 5.25 \times 10^{-1}$ mol l^{-1}, $[PPh_3]_0 = 1.57$ mol l^{-1}.

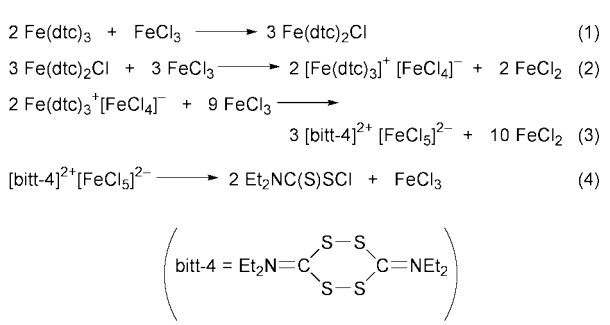
DOI: 10.1039/b004471g



Scheme 1

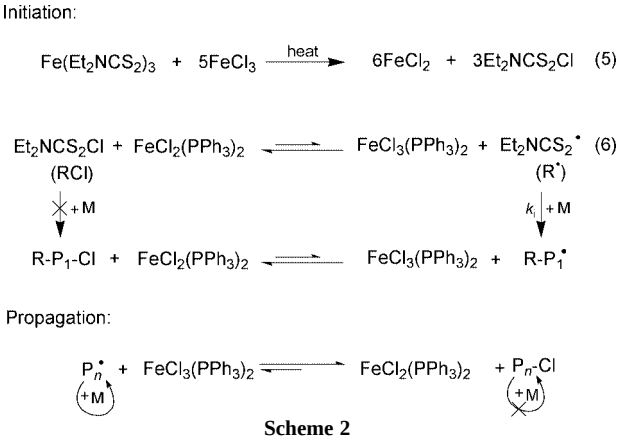
NMR spectra. In the FTIR spectrum of the PMMA, signals at 1272 and *ca.* 3440 cm^{-1} are characteristic absorption bands of the Et_2NCS_2– group while the UV spectrum of the PMMA powder identifies Et_2NCS_2– (*ca.* 276.8 nm) as an end group. In the ^1H NMR spectrum, the chemical shift at δ 3.07 corresponds to the methylene protons $Et_2NCS_2CH_2$, whilst that at δ 3.70 is due to $(CH_3CH_2)_2NCS_2$–. A signal at δ 3.79 arises from protons of the methoxy group, whilst that at δ 2.50 arises from the methylene protons of the terminal MMA unit capped with an ω-end chlorine, similar to that reported by Sawamoto and coworkers[8] and by us.[6] The $M_{n(NMR)}$ value (5100) is close to $M_{n(GPC)}$ (4700), indicating that all the polymer chains have chlorine ends. The presence of an ω-chlorine end group at the polymer chains suggests the polymerization proceeds in an ATRP process.

Some control experiments were carried out to clarify the polymerization mechanism. The polymerization of MMA with $Fe(dtc)_3$ alone did not take place after 160 minutes at 80 °C or after 60 min at 100 °C indicating that $Fe(dtc)_3$ was not a thermal radical initiator. Addition of PPh_3 did not modify the observed behavior, and polymerization only occurred in the presence of all three components $Fe(dtc)_3$, $FeCl_3$ and PPh_3, *e.g.* the conversion was 11% after 5 min at 80 °C. Using $Fe(dtc)_3$ and $FeCl_3$ in the absence of PPh_3 at 80 °C, led to precipitation of $FeCl_2$ after *ca.* 10 min whilst no polymer was obtained even after 15.5 h.

According to the above results and the reaction of $Fe(dtc)_3$ with $FeCl_3$ reported in the literature[9] and our previous work,[6] we propose the reaction of $Fe(dtc)_3$ with $FeCl_3$ as shown in Scheme 1.

Reactions (1) and (2) are the same as the results reported by Victoriano *et al.*,[9] whilst in the step (3), bis(dialkylimonium)tetrathiolane (bitt-4) is possibly formed instead of bis(dialkylimonium)trithiolane (bitt-3)[9] in the presence of the monomer MMA and PPh_3. Bitt-4 may discompose into (diethylthiocarbamoyl)sulfur chloride (Et_2NCS_2Cl) as shown in step (4).

Therefore, the mechanism of polymerization proposed is as depicted in Scheme 2.



Scheme 2

At the temperature of polymerization, $Fe(dtc)_3$ reacts with $FeCl_3$ *via* a redox process to form an organic halide, (Et_2NCS_2Cl) and $FeCl_2$ [eqn. (5) in Scheme 2; simplified from the combination of the reactions in Scheme 1]. Thus, the initiator (Et_2NCS_2Cl) and the transition-metal catalyst in the lower oxidation state ($FeCl_2$) for an ATRP system are created *in situ*. The primary radical $Et_2NCS_2^{\cdot}$, formed from the reaction of Et_2NCS_2Cl with $FeCl_2(PPh_3)_2$, probably initiates MMA polymerization [eqn. (6) in Scheme 2]. with subsequent reactions following a conventional ATRP.

Chain extension polymerization of PMMA with an ω-chlorine end group can be carried out using the ATRP catalyst system. For a bulk process at 100 °C, using PMMA with M_n = 2500, M_w/M_n = 1.14, $[PMMA]_0 = 2.73 \times 10^{-2}$ mol l^{-1} and $[MMA]_0$ = 8.32 mol l^{-1}, $[CuCl]_0 = 2.73 \times 10^{-2}$ mol l^{-1}, $[2,2'\text{-bipyridine}]_0 = 8.19 \times 10^{-2}$ mol l^{-1}; a conversion of 96.4% was achieved after 12 h, with M_n of the chain-extended PMMA = 41900, M_w/M_n = 1.12.

The chelate iron(allyloxy)carbene complexes [Fe(C_5H_5)(CO){η^3-C(OCHR^{1}CH=CR^{2}R^3)(C_6H_4-*o*-Cl)}][BF_4] (2a-e) yield in the presence of [*n*Bu_4N][I] the corresponding β,γ-unsaturated ketones R^{3}R^{2}C=CHCHR^{1}C(O)(C_6H_4-*o*-Cl) (3); this reaction proceeds with high regioselectivity without rearrangement of the allyl fragment.

The design of transition metal complexes capable of selective C–C bond formation under mild conditions is highly desirable. Such a reaction can be achieved by carbene complexes which are good candidates to promote processes within the coordination sphere of the metal. For instance, chelate (allyloxy)carbene complexes have been postulated as key intermediates in the [Ru(Cp)(PPh_3)$_2$Cl)]-catalysed coupling of allylic alcohol and terminal alkynes, affording β,γ-unsaturated ketones.[1,2] Although [Ru](allyloxy)carbene ([Ru] = Ru(Tp)(Cl)) complexes have been recently described,[3] no direct evidence of such transformation from these species has been reported.[4] The related chelate iron (allyloxy)carbene complexes[5] can be useful models for providing an insight into the mechanism of this reaction, and this is likely to be important in the development and design of new catalysts. Iron (alkoxy)carbene complexes [Fe(C_5H_5)(CO)$_2${C(OR)R′}] are known to undergo facile *O*-dealkylation reactions in the presence of iodide anions,[6] regenerating the starting acyl precursor [Fe(C_5H_5)(CO)$_2${C(O)R′}] along with RI. This prompted us to examine the deallylation reaction of *chelate* (allyloxy)carbene complexes under the same conditions, the coordinated allyl fragment thus generated is expected to be involved in a metal-mediated C–C coupling. We report herein the reactivity of the chelate (allyloxy)carbene complexes [Fe(C_5H_5)(CO){η^3-C(OCHR^{1}CH=CR^{2}R^3)(C_6H_4-*o*-Cl)}][BF_4] (**2**) towards iodide salts, and the formation of the corresponding β,γ-unsaturated ketones **3**. Since the iron moiety is not sterically encumbered, this facilitates the study of different substituted allyloxy derivatives, showing that this transformation is efficient and proceeds with excellent regioselectivity.

The *chelate* (allyloxy)carbene complexes (η^3-*C,C,C*) [Fe(C_5H_5)(CO){η^3-C(OCHR^{1}CH=CR^{2}R^3)(C_6H_4-*o*-Cl)}][BF_4] (**2a**–**e**), are readily accessible from the methoxycarbene complexes containing a labile CH_3CN ligand [Fe(C_5H_5)(CO)(CH_3CN){C(OMe)(C_6H_4-*o*-Cl)}][BF_4] (**1**).[5] The structure of **2c**, containing a trisubstituted C=C fragment, has been confirmed by X-ray crystallography (Fig. 1).§ The reaction of **2** (**a**, R^2 = Ph, R^1 = R^3 = H; **b**, R^2 = Me, R^1 = R^3 = H; **c**, R^2 = R^3 = Me, R^1 = H; **d**, R^1 = Me, R^2 = R^3 = H; **e**, R^1 = R^2 = R^3 = H) with [*n*Bu_4N][I] in CH_2Cl_2 gives quantitatively the ketones R^{3}R^{2}C=CHCHR^{1}C(O)(C_6H_4-*o*-Cl) (**3**) (Scheme 1). If the reaction is carried out in the presence of CO (1 atm), the organometallic fragment is recovered as [Fe(C_5H_5)(CO)$_2$(I)].[7] The *E*-configuration of **3a**–**b** is confirmed by the ^{1}H NMR data. The resonances of the olefinic protons of

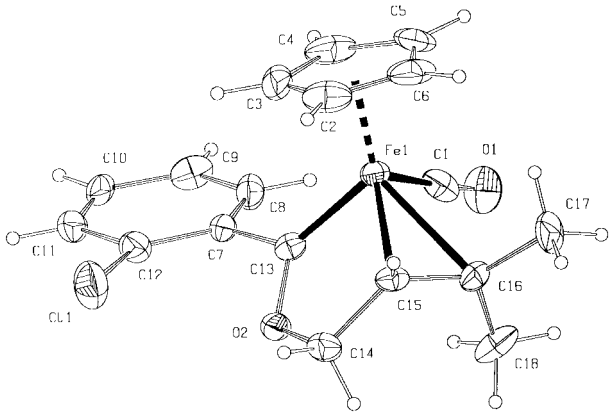

Fig. 1 ORTEP drawing of **2c**. Selected bond distances (Å) and angles (°): O2–C13 1.344(14), O2–C14 1.430(14), Fe–C13 1.828(11), C15–C16 1.41(2), C17–C16–C18 117.8(14), O2–C13–C7 108.9(9), C13–O2–C14 115.4(8).

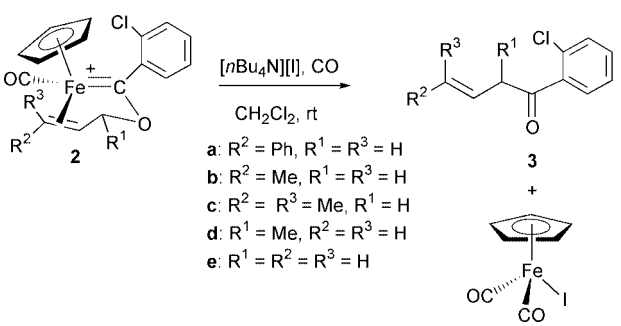
3a are located at δ 6.54 (=CH) and 6.41 (=C*H*Ph) with a typical coupling constant ^3J(H,H) = 16 Hz, whereas those of **3b** appear at δ 5.66 (=CH, ^3J(H,H) = 15.3 Hz) and 5.35 (=C*H*Me). Moreover, the formation of the conjugated isomer *i.e.* the α-enone, which would result from isomerisation of the C=C double bond, does not occur. Remarkably, no rearrangement of the initial allyl group is observed. Depending on the precursor used, the α- and γ-methyl substituted ketones **3d** and **3b** are formed, respectively. The above data indicate that the carbon atom of the allyl substituent, which is involved in the C–O bond cleavage, recombines to form the new C–C bond. The proposed mechanism showing the participation of the iodide is depicted in Scheme 2. Rupture of the C–O bond[8,9] by nucleophilic attack of I^- on the carbon atom yields a coordinated allyl iodide fragment, which then could oxidatively add to the iron center, inducing the decoordination of the olefinic unit. Then, the transient 18-electron Fe(IV) species reductively eliminates the acyl and the η^1-allyl ligands to afford the observed ketone **3**, and the iron-containing compounds. The first step has been already



Scheme 1

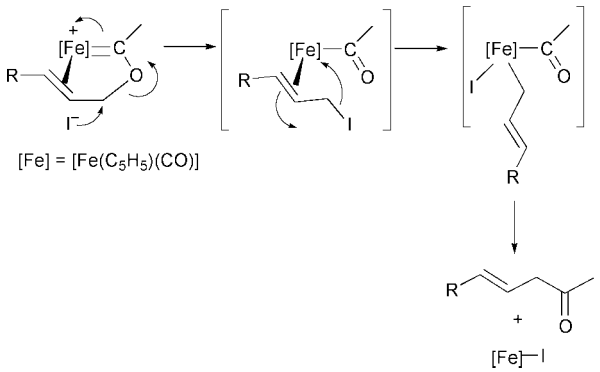

Scheme 2

observed for unchelated iron (alkoxy)carbene complexes,[6] it can be explained by the substantial contribution of the resonance oxonium form, in which the C–O bond is weakened. Moreover, this shows that the C–C bond forming reaction occurs within the co-ordination sphere of the metal, and this requires pre-coordination of the allyloxy group, as previously suggested.[1,10]

These results provide the direct evidence of the formation of β,γ-unsaturated ketones from *chelate* (allyloxy)carbene complexes. Moreover, the role of the iodide is crucial to initiate this process. Finally, the above data on the $[Fe(Cp)(CO)]^+$ iron moiety, capable to coordinate tri- and disubstituted C=C bonds, show that the arrangement of the allyl group is maintained during this transformation, allowing regioselective reactions.

Cluster stabilization by an open-chain tetrapyrrolic ligand: first evidence for NH activation as an initial step in tetrapyrrole metalation processes

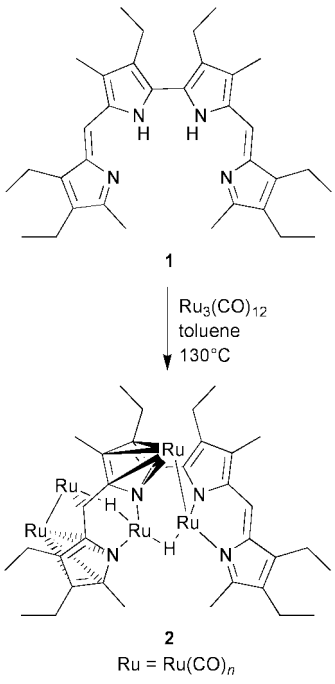
Published on the Web 10th July 2000

Bisdipyrrin 1 reacts with $Ru_3(CO)_{12}$ to yield the pentanuclear cluster 2; the X-ray structure of 2 sheds new light on the metalation processes of oligopyrrolic ligands.

The coordination chemisty of bile pigments and related ligands,[1] an emerging branch of porphyrin research, has been developed mainly in the last decade.[2] Most of the structurally characterized complexes of this class were found to exhibit metalloporphyrin-like structures with the metal ion bound to the four central nitrogen atoms of the ligand. The higher flexibility of the open-chain tetrapyrroles with respect to the porphyrins, however, also allows other coordination modes, and some examples of M_2L_2 arrangements[3] as well as complexes coordinated through donor atoms of the ligand periphery[4] were obtained. In our efforts to explore the coordination chemistry of open-chain oligopyrroles and to apply helical chiral chelates in catalytic processes, ruthenium complexes have become a major goal. This communication reports the unprecedented coordination of ruthenium to the bile pigment analogue bisdipyrrin **1**[5] and provides the first example for the role of NH activation in tetrapyrrole metalation processes.

The method most widely used to introduce a ruthenium ion into a porphyrin is the reaction of the ligand with an excess of $Ru_3(CO)_{12}$ in a high boiling solvent.[6] When applying these conditions (Scheme 1) to the bisdipyrrin **1** (twofold molar excess of ruthenium carrier, toluene, 130 °C), a single defined product was observed by TLC and could subsequently be isolated using radial chromatography (13% yield). Upon slow evaporation from hexane–CH_2Cl_2, dark red crystals suitable for X-ray diffraction were obtained. As the structural analysis[7] revealed, the product was not the anticipated (carbonyl)ruthenium bisdipyrrin, but the pentanuclear cluster **2**.[8]



Scheme 1

The complicated arrangement of the Ru_5H_2 cluster core found in **2** can best be understood as composed from three subunits. Two Ru_2 moieties are located above and below the tetrapyrrolic ligand. While one of these is bound through a normal dipyrrin N_2 chelate and a η^5-coordinated pyrrole [Ru(2)–Ru(5)], the other is found to bind to the *meso*-carbon atom C(34) of the second dipyrrolic half of the bisdipyrrin, supported by another η^5 coordination [Ru(3)–Ru(4)].[9] Finally, the fifth ruthenium center Ru(1) is situated in between the two remaining nitrogen atoms N(3) and N(4) and acts as a central unit, connecting the two Ru_2 fragments *via* μ-hydrido bridges to Ru(2) and Ru(3), respectively. Fig. 1 demonstrates the action of the flexible and severely twisted bisdipyrrin ligand on the Ru_2–H–Ru–H–Ru_2 moiety. In addition, eleven surrounding CO ligands serve to saturate the coordination spheres of the ruthenium centers of cluster **2**, allowing octahedral geometries for all five metal atoms (Fig. 2). The cluster core and the tetrapyrrolic ligand thus both adopt conformations optimized for the stabilization of the uncommon structure. This synergysm accounts for the surprising fact that **2** shows enhanced resistance against thermal cluster degradation and decomposition.

Since the assignment of hydride ligands bound to heavy metal atoms through X-ray diffraction is generally problematic, a ^{1}H NMR spectroscopic investigation of **2** was undertaken which showed signals at −15.30 and −18.40 corresponding to the two hydrido ligands in **2** (Fig. 3). The coupling (4 Hz) between these hydrides is in accord with them both being bound to the same ruthenium center. In addition, the signal at δ −18.40 shows a coupling of 1 Hz with the resonance of the *meso* proton

H(34), indicative of the close vicinity of H(2) and H(34), so strongly supporting the structural findings.

The bridging hydrides originate from the NH functionalities of the bisdipyrrin ligand and indicates that the well-established mechanism for tetrapyrrole metalation, deformation of the macrocycle, subsequent binding of a metal ion to two nitrogen donors, and insertion into the porphyrin cavity with concomitant deprotonation,[10] is not the only plausible mechanistic pathway. Obviously, a route involving the oxidative addition of an NH moiety on an appropriate metal carrier constitutes a suitable alternative, especially if carriers with metal centers in low oxidation states are employed.[11] For porphyrins, the initial structures formed during metalation processes using metal carbonyls probably resemble cluster fragment complexes similar to that found for bisdipyrrin **2**; owing to the rigid macrocyclic character of porphyrins, however, cluster degradation should be fast and inevitably result in the well-known N_4-coordinated metal porphyrins.[12]

This work was funded by the Deutsche Forschungsgemeinschaft (Emmy-Noether-Programm Brö 2010/1-1). We thank Christian Galka for fruitful discussions and Professor Helmut Werner for his generous support.

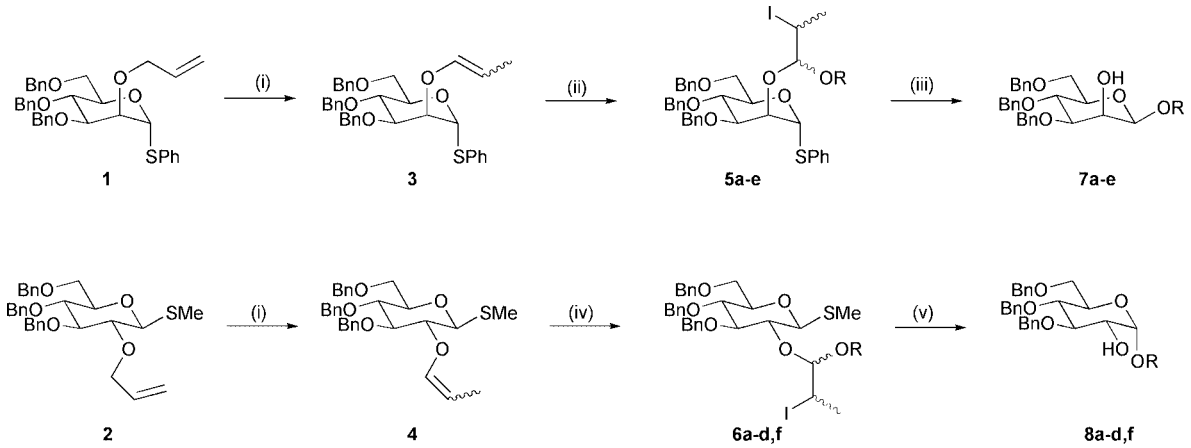
Received (in Liverpool, UK) 6th June 2000, Accepted 19th June 2000
Published on the Web 10th July 2000

2-*O*-Allyl protected glycosyl donors may be glycosylated stereoselectively *via* a three step sequence involving double bond isomerization, *N*-iodosuccinimide mediated tethering to a glycosyl acceptor and subsequent intramolecular glycosylation (intramolecular aglycon delivery, IAD).

Stereoselective intramolecular glycosylation of glycosyl acceptors temporarily tethered to the 2-hydroxy group of the glycosyl donor is a synthetically useful technique allowing access to a range of *cis*-1,2-glycosides which can otherwise be problematic to synthesise. A number of methods have been developed for the temporary linking of donor and acceptor prior to glycosylation.[1–4] Modification of the donor 2-hydroxy protecting group commonly provides a tethering site. Thus the Hindsgaul approach involves Tebbe methylenation of a 2-*O*-acetate to produce a vinyl ether which is then coupled with the acceptor using acid catalysis to produce a mixed ketal.[3] Alternative methodology developed by Ogawa and co-workers employs oxidation of a *p*-methoxybenzyl (PMB) protecting group, which allows linking of donor and acceptor as a mixed acetal.[4] We would herein like to report the first use of the 2-*O*-allyl protecting group as the means of tethering donor to acceptor. It was envisaged that Wilkinson's catalyst mediated isomerisation of the double bond would efficiently produce a vinyl ether, which could then be subjected to tethering with *N*-iodosuccinimide (NIS) and subsequent intramolecular glycosylation according to our recently reported procedure.[5]

The 2-*O*-allyl protected glycosyl donors **1** and **2**, which are readily available through standard manipulations,† were isomerized using a combination of Wilkinson's catalyst and n-butyllithium according to a procedure recently reported by Boons and Isles.[6] This straightforward method proceeded extremely efficiently to yield the enol ethers **3** and **4** respectively in quantitative yield (Scheme 1). NIS mediated tethering was then undertaken for both *manno* and *gluco* donors **3** and **4** with a series of alcohols (ROH, Table 1) in the presence of 4 Å molecular sieves.‡ In all cases tethering proceeded efficiently in either THF or 1,2-dichloroethane (DCE) as solvent to yield mixed acetal intermediates **5a–e**, **6a–d**,**f** as diastereomeric mixtures.§ Subsequent intramolecular glycosylation proved more sluggish than we had previously experienced.[5] In the case of the less reactive anomeric thiophenyl *manno* mixed acetals **5a–e**, efficient reaction required the addition of silver triflate and more protracted reaction times at either room temperature or higher. However in all cases intramolecular glycosylation occurred in a stereospecific fashion to furnish the corresponding β-mannosides **7a–e**. The more reactive thiomethyl *gluco* mixed acetals **6a-d**,**f** were efficiently activated by the addition of methyl triflate, yielding α-glucosides **8a–d**,**f** again as single anomers following work-up.¶‖

Attention then turned to the potential one-pot reaction, whereby tethering and glycosylation are achieved in a single reaction vessel. Unlike our previous results[5] which were obtained with the Hindsgaul mixed ketal system, attempted one-pot glycosylation of donors **3** and **4** with an excess of cyclohexanol (typically 3 equivalents) produced anomeric mixtures, clearly indicating competitive intermolecular reaction by the excess of acceptor in solution. In order to find a solution to this problem, and also to overcome the sluggishness of the thiophenyl *manno* glycosylation reaction, attention turned to the use of the readily available thiomethyl substituted *manno* glycosyl donor **9**.† Isomerisation of **9** proceeded efficiently to yield the enol ethers **10** which were subsequently examined as



Scheme 1 *Reagents and conditions*: (i) $(Ph_3P)_3RhCl$, *n*-BuLi, THF, reflux, > 99%; (ii) ROH, *N*-iodosuccinimide, 4 Å molecular sieves, 1,2-dichloroethane, −40 °C to RT, 76–100%; (iii) *N*-iodosuccinimide, AgOTf, 2,6-di-*tert*-butyl-4-methylpyridine, 4 Å molecular sieves, 1,2-dichloroethane, RT (or 50 °C), 59–81%; (iv) ROH, *N*-iodosuccinimide, 4 Å molecular sieves, 1,2-dichloroethane, −40 °C to RT, 63–98%; (v) MeOTf, 2,6-di-*tert*-butyl-4-methylpyridine, 1,2-dichloroethane, RT, 65–77%.

DOI: 10.1039/b004522p

Table 1 Yields for tethering and glycosylation

Alcohol ROH	Product/yield of mixed acetals	Product/yield of glycosylation[7]

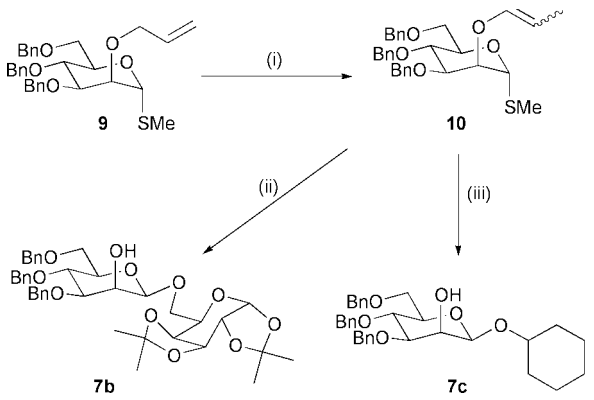
	**5d**/ > 99% **6d**/95%	**7d**/76% **8d**/67%
	**5e**/90%	**7e**/57%
	**6f**/63%	**8f**/72%



Scheme 2 *Reagents and conditions*: (i) $(Ph_3P)_3RhCl$, *n*-BuLi, THF, reflux, > 99%; (ii) diacetone galactose, *N*-iodosuccinimide, 4 Å molecular sieves, CH_3CN, −40 °C to RT, then MeOTf, 72%; (iii) cyclohexanol, *N*-iodosuccinimide, 4 Å molecular sieves, 1,2-dichloroethane, −40 °C to RT, then MeOTf, 67%.

substrates for tethering and glycosylation. Conditions initially employed for the one-pot reactions of **10**, involving NIS mediated tethering with cyclohexanol and subsequent glycosylation by the addition of methyl triflate to the reaction mixture, again resulted in the formation of anomeric mixtures. The β : α ratio could be increased from 2 : 1 to a respectable 5 : 1 by simple dilution of the reaction mixture once tethering was complete before the addition of the methyl triflate, but α products could not be entirely eliminated. However by the use of an excess of glycosyl donor any competing intermolecular reaction could be avoided. Thus reaction of the donor **10** (2.0 equivalents) with either diacetone galactose or cyclohexanol (in acetonitrile and 1,2-dichloroethane respectively) produced the corresponding β-mannosides **7b** and **7c** as single anomers in 72% and 67% yield respectively (Scheme 2).

In summary we have demonstrated that 2-*O*-allyl protected glycosyl donors may be employed for the synthesis of a variety of *cis*-1,2-glycosides. Of particular note is that isomerization of the allyl group is a very efficient process, and is superior to the often troublesome and messy Tebbe methylenation reaction. In addition the use of an excess of glycosyl donor allows both tethering and glycosylation to be performed in a single reaction vessel, obviating the need for handling of sensitive mixed acetal intermediates. Further investigations into the use of allyl derived enol ethers for *cis* glycosylation procedures, particularly employing hindered secondary carbohydrate glycosyl acceptors are currently in progress, and the results will be reported in due course.

C.), and also the use of the Chemical Database Service (CDS) at Daresbury, UK and the EPSRC National Mass Spectrometry Service at Swansea.

Notes and references

† 2-*O*-Allyl protected donor **1** was prepared from the corresponding 2-*O*-acetate[5] *via* deprotection with sodium methoxide in methanol and allylation with sodium hydride and allyl bromide in DMF. 2-*O*-Allyl protected donors **2** and **9** were prepared from the corresponding 2-*O*-acetyl-1-bromo and 2-*O*-acetyl-1-chloro glycosides respectively by reaction with dimethyl disulfide and butyllithium in THF followed by allylation as above.[8] Full experimental details will be published in due course.

‡ Typical procedure for *manno*/*S*-phenyl tethering: the vinyl ether (0.15 mmol), the alcohol (3 equiv.) and powdered 4 Å molecular sieves (*ca*. 500 mg) were stirred in 3.5 ml dry DCE under argon at −40 °C. NIS (2.5 equiv.) was added and the mixture was allowed to warm slowly to room temperature. After 16 h, dichloromethane was added, the mixture was filtered through Celite®, washed with aqueous sodium thiosulfate, dried, filtered and concentrated *in vacuo*. The resulting residue was purified by flash column chromatography to give the mixed acetal as a clear oil.

§ No attempt was made at separation, and the mixtures were used as such for subsequent glycosylation.

¶ In line with our previous observations, the oxonium ion produced after aglycon delivery may be trapped, either by any available alcohol in solution or alternatively by succinimide. Simple treatment of the crude reaction mixture with either aqueous TFA or aqueous lithium hydroxide respectively efficiently hydrolyses these trapped products, typically increasing the yield of glycosylated product by 10–15%.

‖ Typical procedure for *manno*/*S*-phenyl glycosylation: the mixed acetals (0.1 mmol), NIS (5 equiv.), silver triflate (1 equiv.), 2,6-di-*tert*-butyl-4-methyl pyridine (DTBMP) (5 equiv.) and powdered 4 Å molecular sieves (*ca*. 250 mg) were dissolved in dry DCE under argon. The solution was then stirred at room temperature (or 50 °C) until TLC indicated disappearance of the starting material. TFA (10 ml), methanol (4 ml) and water (2 ml) were added and the solution was stirred for a further 1–4 h. Dichloromethane was added, the mixture filtered through Celite®, washed with saturated aqueous sodium bicarbonate and the aqueous layers were re-extracted with dichloromethane. The combined organic extracts were washed with aqueous sodium thiosulfate, dried ($MgSO_4$), filtered and concentrated *in vacuo*. The resulting residue was purified by flash column chromatography to give the pure β-mannoside.

The formation of sulfur macrocycles containing dialkyne units

John E. Davies, Louisa J. Hope-Weeks, Martin J. Mays* and Paul R. Raithby

Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: mjm14@cus.cam.ac.uk

Received (in Cambridge, UK) 9th May 2000, Accepted 14th June 2000
Published on the Web 10th July 2000

Treatment of the dialkyne complex [{$Co_2(CO)_6$}$_2${μ-η^2:μ-η^2-$HOCH_2C{\equiv}CC{\equiv}CCH_2OH$}] with $HBF_4{\cdot}OEt_2$ at −78 °C and the subsequent addition of $[HS(CH_2)_2]_2X$ (X = S or O) affords the novel macrocyclic complexes [{$Co_2(CO)_5$}{$Co_2(CO)_6$}{(μ-η^2-$C{\equiv}CCH_2SCH_2CH_2)_2S$}] 1a, [{$Co_2(CO)_6$}$_2${(μ-η^2-$C{\equiv}CCH_2SCH_2CH_2)_2O$ }] 2a and [{$Co_2(CO)_6$}$_2${(μ-η^2-$C{\equiv}CCH_2SCH_2CH_2)_2X$}]$_2$ [X = S 1b or O 2b].

Crown thioethers and related sulfur macrocycles have been the subject of numerous studies owing to their ability to bind metal ions more strongly than mono- or bi-dentate thioethers.[1] Structural studies on uncoordinated sulfur macrocycles have shown that the sulfur atoms tend to adopt an exodentate conformation in which all the sulfur lone pairs are orientated out of the macrocyclic cavity.[2] Therefore these macrocycles must undergo substantial conformational change in order to coordinate to an added metal ion. Several sulfur macrocycles undergo this type of conformational change on reaction with added metal ions such as Pd(II),[3] Hg(II),[4] Ni(II)[5] or Ag(I)[6,7] to give cyclic systems in which at least two of the sulfur atoms have co-ordinated to the metal and are in an endodentate configuration.

We now report the synthesis of several new sulfur macrocycles† (Fig. 1) and, in particular, of the novel complex [{$Co_2(CO)_5$}{$Co_2(CO)_6$}{(μ-η^2-$C{\equiv}CCH_2SCH_2CH_2)_2S$}] **1a** which contains a dialkyne unit and three sulfur donor atoms of which only one is endodentate and coordinated to a metal.

The X-ray crystal structure‡ of **1a** (Fig. 2) confirms that a 13-membered macrocyclic ring has formed. Two of the sulfur atoms are exodentate to the ring but the central sulfur atom is endodentate and coordinated axially to one of cobalt atoms already present in the molecule rather than to an added metal ion. This mode of coordination of a sulfur macrocycle containing three sulfur atoms is unprecedented. In contrast complex **1b** (Fig. 3),‡ the dimer of **1a**, contains no Co–S interactions.

All the carbon–sulfur bond lengths in **1a** and **1b** fall within the expected range for macrocylic thioethers, ranging from 1.793(6) to 1.846(9), as do all the carbon–carbon single bond lengths which range from 1.48(2) to 1.531(4).[1] The carbon–carbon triple bond lengths range from 1.351(4) to 1.359(5), typical of coordinated alkynes.[6,8] The cobalt–sulfur bond distance of 2.2702(8) in **1a** is also typical of other reported values.[9]

The novel macrocycle **1a** and its dimer **1b** are synthesized† by the reaction of $[\{Co_2(CO)_6\}_2\{\mu\text{-}\eta^2\text{:}\mu\text{-}\eta^2\text{-}HOCH_2C{\equiv}CC{\equiv}C\text{-}CH_2OH\}]$ with 1 equiv. of $[HS(CH_2)_2]_2S$ in the presence of catalytic amounts of $HBF_4{\cdot}OEt_2$ at −78 °C and separated by chromatography in an analogous manner to that reported by Went and coworkers for the related mono-alkyne complexes.[6] Substitution of $[HS(CH_2)_2]_2S$ by $[HS(CH_2)_2]_2O$ affords the related macrocyclic compounds **2a**, **2b** in which the central sulfur atom in **1a**, **1b** is replaced by an oxygen atom. The combined yields of the monomer (**a**) and the dimer (**b**) are in excess of 90% in each case.

The X-ray crystal structure‡ of **2a**, (Fig. 4), again confirms the presence of a 13- membered macrocyclic ring as in **1a**.

The central oxygen atom of the ring, although it is endodentate as is typical of crown ethers, does not coordinate to a cobalt centre in contrast to the central sulfur atom in **1a** and, as a consequence, there is no loss of a carbonyl group from either of the $Co_2(CO)_6$ units in **2a** both of which remain intact. The two sulfur atoms in **2a** adopt the same geometry as the corresponding sulfur atoms in **1a** and are exodentate. All carbon–sulfur bonds in **2a** fall within the expected range of values, as do the carbon–carbon single bonds of the crown thioether.[1]

An inspection of the crystal structures reveals that in each case the CH_2 protons are in different environments; this results in complicated ^{1}H NMR spectra in the SCH_2 and OCH_2 regions comprising of overlapping multiplets. The ^{13}C NMR spectra exhibit only one resonance due to a CO group, as is common for alkyne-bridged dicobalt complexes; localized site exchange[10] or a trigonal twist[11] has been proposed previously to explain this fluxionality.

In linear diyne complexes containing two coordinated dicobalt hexacarbonyl fragments these fragments are co-ordinated *trans* to each other such that the two Co-Co vectors are almost parallel.[12] The steric demands of the cyclic diynes in **1a**, **1b** and **2a** do not allow this relative orientation and the two fragments are twisted to varying degrees such that the two Co–Co vectors approach an orthogonal configuration.

The influence of the nature of the linking groups and of the donor atoms on the geometry of these macrocyclic dialkyne complexes is under further study.

We gratefully acknowledge the financial support of EPSRC, DERA and the Isaac Newton Trust (to L. J. H). EPRSC support for the purchase of the Nonius Kappa CCD diffractometer is also gratefully acknowledged.

Pt(0) and Pd(0) based metallocryptands: metallophilic hosts for Pb(II) ion†

Received (in Irvine, CA, USA) 9th May 2000, Accepted 16th June 2000

Metallocryptands based on trigonally coordinated Pt(0) or Pd(0) with P_2phen [2,9-bis(diphenylphosphino)-1,10-phenanthroline] bind Pb(II) ion through very strong, closed-shell metallophilic interactions; their syntheses, characterization and X-ray crystallography are presented.

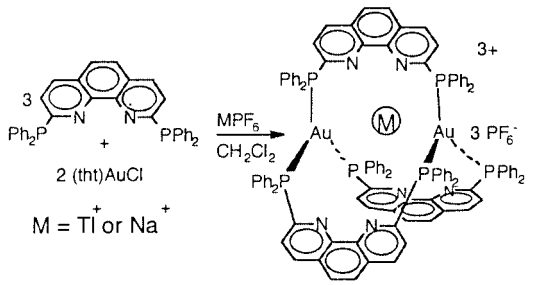
The bonding interaction between closed-shell, heavy metal ions is gaining increasing attention.[1] In the absence of unpaired electrons to form covalent bonds or opposite charges to form strong ionic bonds, the close approach of closed-shelled species might be expected to exhibit no net attraction or be repulsive; however, there are numerous examples of heavy metal ions like Au(I), Tl(I) or Pb(II) associating with other metals or aggregating with short separations.[2] The origin of this metallophilic attraction is not completely understood, but relativistic effects appear to be important.[3]

Recently (Scheme 1), we reported the application of a unique Au(I)-based inorganic host complex to probe the resulting aurophilic interactions between the capping metal and the encapsulated guest ion.[4] In this work we observed a very strong and short (*ca*. 2.9 Å) Au(I)–Tl(I) interaction. The highly luminescent Tl(I) containing species is substitution inert and stable in solution while the Na^+ containing species readily dissociates the sodium ion indicating that the Au–Tl interaction is strong enough to maintain this assembly. We were unable to explore any Au(I)–Pb(II) interactions using this system probably because of the higher charge on the purported complex leads to dissociation and ultimately decomposition.

We now have extended this system to include zero-valent d^{10} metals and report the synthesis and characterization of the Pd(0)- and Pt(0)-based metallocryptates with exceptionally short Pd(0)–Pb(II) and Pt(0)–Pb(II) interactions. To our knowledge this is the first report of an unsupported Pd(0) or Pt(0)–Pb(II) bond. Further, these metallocryptands represent a new type of host complex that employ attractive metallophilic interactions for metal ion binding rather than Lewis acid–base interactions.

The deep green–brown, air-stable $[Pd_2(P_2phen)_3Pb](ClO_4)_2$ **1** or $[Pt_2(P_2phen)_3Pb](ClO_4)_2$ **2** [P_2phen = 2,9-bis(diphenylphosphino)-1,10-phenanthroline], are easily synthesized in good yield in acetonitrile according to eqns. (1) and (2).‡ Although the

$$Pd_2(dba)_3{\cdot}CHCl_3 + 3\ P_2phen + Pb(ClO_4)_2 \rightarrow [Pd_2(P_2phen)_3Pb](ClO_4)_2 + 3dba + CHCl_3 \quad (1)$$



Scheme 1

† Electronic supplementary information (ESI) available: preparation, spectral data and MALDI-TOF spectrum for compound **2**. See http://www.rsc.org/suppdata/cc/b0/b003758n/

$$2\ Pt(dba)_2 + 3\ P_2phen + Pb(ClO_4)_2 \rightarrow [Pd_2(P_2phen)_3Pb](ClO_4)_2 + 2dba \quad (2)$$

solutions of **1** or **2** are stable, the Pb(II) can be replaced by addition of an excess of Tl(I) ion. The $^{31}P\{^1H\}$ NMR spectra contain a single resonance at +29.8 ppm for **1** and +48.1 ppm ($^1J_{Pt-P}$ 4085 Hz) for **2**. Interestingly coupling to ^{207}Pb (22% spin 1/2) is not observed. A similar phenomena is observed in the Tl^+ containing species reported elsewhere.[5] The ^{195}Pt NMR spectrum of **2** shows the anticipated quartet at 2916 ppm without resolvable $^1J_{Pt-Pb}$ coupling. For comparison, Balch *et al*.[6] reported a $^1J_{Pt-Pb}$ coupling of 214 Hz for the Pt(II) containing species, $[(MeCO_2)Pb(P_2\text{-crown})Pt(CN)_2]^+$ (P_2-crown = 1,10-bis[(diphenylphosphino)methyl]-1,10-diaza-4,7,13,16-tetraoxaoctadecane). Direct observation of a ^{207}Pb resonance was unsuccessful likely due to the low receptivity and natural abundance of ^{207}Pb coupled with the moderate solubility of **2**.

The X-ray crystal structure§ of **1** (Fig. 1) confirms the formulation. The Pb atom resides in the center of the D_3 symmetric cavity formed by the P_2phen ligands coordinated to the two trigonal Pd(0) centers. The Pd(1)–Pb(1) and Pd(2)–Pb(1) separations are nearly identical at 2.7095(6) and 2.6902(6) Å respectively, and a Pb center is nearly linearly bonded with the Pd(1)–Pb(1)–Pd(2) angle of 178.75(1)° indicating the lone pair is stereochemically inactive. The Pb–N separations range from 3.095(1) to 3.215(1) Å (av. Pb–N 3.142(1) Å] and are considered non-bonding. Each Pd atom is slightly displaced out of the respective trigonal plane towards the central Pb atom by *ca*. 0.2 Å.

As shown in Fig. 1, the molecule crystallizes in a non-centrosymmetric space group with an overall helical geometry. However, the bulk material is racemic because both enantio-

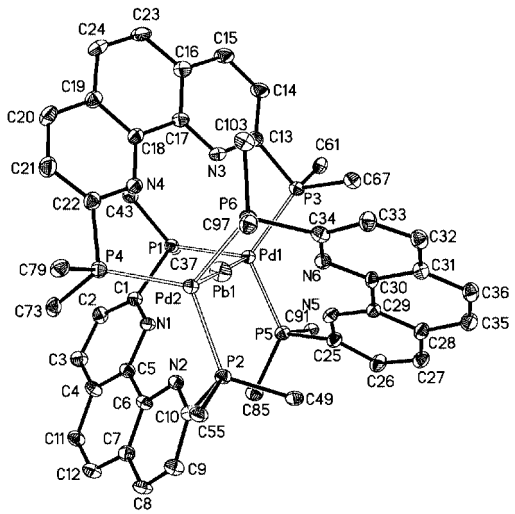


Fig. 1 Thermal ellipsoid plot for the cation of **1**. Hydrogen atoms and phenyl rings are removed for clarity. Selected distances (Å) and angles (°): Pd1–Pb(1) 2.7095(6), Pd2–Pb1 2.6902(6), Pb1–N1 3.090(2), Pb1–N2 3.095(2), Pb1–N3 3.090(2), Pb1–N4 3.215(2), Pb1–N5 3.156(2), Pb1–N6 3.166(2); Pd1–Pb1–Pd2 178.75(1), P1–Pd1–P3 119.41(5), P1–Pd1–P5 117.27(4), P3–Pd1–P5 121.30(5), P2–Pd2–P4 120.15(4), P2–Pd2–P6 116.42(4), P4–Pd2–P6 120.21(5).

DOI: 10.1039/b003758n

mers are present in the crystal. The helicity is reflected in the large P(1)–Pd(1)–Pd(2)–P(2), P(3)–Pd(1)–Pd(2)–P(4) and P(5)–Pd(1)–Pd(2)–P(6) torsion angles of 116.9, 123.1 and 115.9°, respectively. This twisting of the trigonal planes compresses the metallocryptate to accommodate the requisite Pd(1)···Pd(2) separation of 5.399(1) Å.

Crystals of **2** were obtained but did not produce satisfactory refinement.§ However, reliable Pt–Pb separations of 2.7469(6) and 2.7325(6) Å were measured, and the cation is nearly identical to **1** in every other respect.

Pd– or Pt–Pb bonding is rare, and a search of the Cambridge Crystallographic Data Centre produced only a few examples of structurally characterized Pd– or Pt–Pb bonds,[5,7] and none of these contained a formally zero-valent transition metal. Most of these are formed either through strong ligand interaction or through insertion reactions producing covalently bonded M–Pb complexes;[8] however, a few cases exist for unsupported Pb(II)–M bonds.[9] For example, Usón *et al*. reported the structure of $Pb[Pt(C_6F_5)_4]_2^{2-}$ that contains short Pb(II)–Pt(II) separations of 2.769(2) and 2.793(2) Å along with short Pb···F contacts believed to stabilize the complex. In contrast, neither **1** or **2** have any stabilizing Pb···ligand interactions.

The MALDI-TOF mass spectra of **1** and **2** (not shown here) confirm the presence of Pb in each complex. Molecular ion peaks corresponding to $[M_2Pb(P_2phen)_3]^+$ (M = Pt or Pd) with and without the perchlorate counter ion are easily identified. Interestingly, the intensity of the peak corresponding to the empty metallocryptand is very small, indicating that the Pb ion is strongly held in the gas phase.

The attractive metal–metal interactions observed here can be rationalized by employing a qualitative MO diagram (Fig. 2) similar to that proposed by Balch *et al*.[10] by combining the filled d_{z^2} and empty p_z orbitals on the transition metals with the filled Pb 6s and empty Pb 6p_z orbitals. Mixing between levels stabilizes the filled orbitals relative to their unfilled counterparts leading to an attractive interaction between these metals. Further, Fackler and coworkers[11] have employed a similar model with additional relativistic contributions from the 6s orbital to describe attractive Au–Tl interactions.

The electronic absorption spectra of **1** and **2** in acetonitrile contain absorptions attributable to ligand π–π* transitions between 230 and 310 nm. Both complexes exhibit a low energy band at 481 for **1** and 470 for **2** tentatively assigned to the $M_{d\sigma^*} \rightarrow M_{p\sigma^*}$ transition depicted in the MO scheme. For comparison, both $Pd(PPh_3)_3$ and $Pt(PPh_3)_3$ exhibit weak absorptions in the same region,[12] but unlike these trigonal complexes, neither **1** or **2** are luminescent in solution, nor do these complexes exhibit reversible cyclic voltammetry.

The compounds reported here are examples of a rapidly expanding class of easily synthesized inorganic host complexes that employ strong, closed-shell attractive interactions for metal ion binding. By eliminating ligand–ion interactions these metallocryptands provide a simple probe the metal–metal bonding both in solution and in the solid state. Substitution of Pb(II) for other heavy metal ions should provide a numerous combination of heavy metal interactions for further study. We are currently probing these systems.

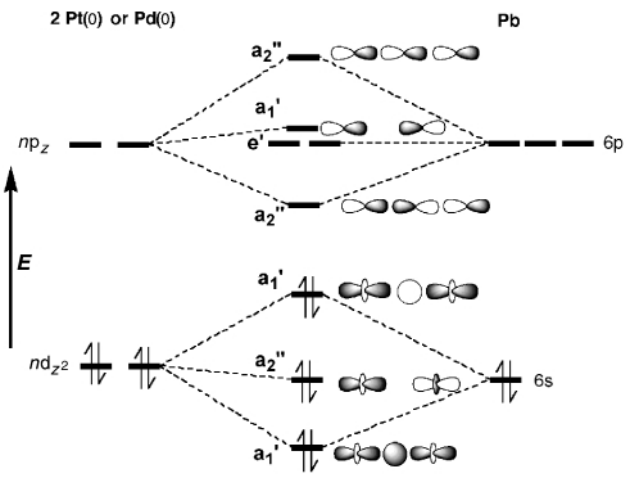

Fig. 2 Simplified molecular orbital diagram depicting the interaction between two trigonally coordinated d^{10} metal ions with the filled s and empty p_z orbital on a Pb^{2+} ion in the D_{3h} point group.

‡ *Preparations*: $[Pd_2Pb(P_2phen)_3](ClO_4)_2$ **1**: a 100 mL Schlenk flask was charged with 0.100 g (0.182 mmol) of 2,9-bis(diphenylphosphino)-1,10-phenanthroline dissolved in 10 mL of CH_2Cl_2. To this solution was added 1.39 g (0.304 mmol) of $Pb(ClO_4)_2$ (dissolved in 5 mL of 1 : 1 DCM–MeOH) with stirring. After 10 min the vessel was capped and the contents subjected to two freeze-pump-thaw cycles and moved to a glovebox. A suspension of 0.063 g of $Pd_2(dba)_3{\cdot}CHCl_3$ (0.0061 mmol) in MeCN (10 mL) was added dropwise affording an dark solution. After stirring an additional 30 min and volatiles were removed and the residue dissolved in a minimum amount of MeCN. Flash chromatography (alumina) eluting with MeCN and precipitation with Et_2O afforded a brown solid. Yield: 100 mg (73 %). $C_{108}H_{78}N_8Cl_2O_8P_6PbPd_2{\cdot}2DCE$ Calc. Selective synthesis of anatase and rutile *via* ultrasound irradiation

Weiping Huang, Xianghai Tang, Yanqin Wang, Yuri Koltypin and Aharon Gedanken*

Department of Chemistry, Bar-Ilan University, Ramat-Gan 52900, Israel. E-mail: gedanken@mail.biu.ac.il

Received (in Oxford, UK) 25th April 2000, Accepted 12th June 2000

A simple and efficient methodology has been established for the selective synthesis of anatase and rutile as well as their mixtures with various precursors using ultrasound irradiation; the products, the particle sizes of which are nanometric (< 9 nm), are dependent both upon the reaction temperature and the precursor used; a substantial reduction in reaction time as well as reaction temperature is observed as compared to the corresponding hydrothemal processes.

Since Fujishima and Honda[1] discovered the photocatalytic splitting of water on titania electrodes, intensive, world-wide research activity based on titania has ensued. Titania has three crystalline phases: rutile, anatase and brookite, of which rutile is the most stable while anatase exhibits the highest photocatalytic activity.[2] Up to now, many methods have been established for the synthesis of titania,[3–8] the sol–gel technique being the most often used. Unfortunately, the sol–gel derived precipitates are amorphous in nature, which requires further treatment to induce crystallization.[9,10] The hydrothermal technique is widely employed to enhance crystallinity in laboratory and commercial preparations. However, many factors, *e.g.* reaction temperature, reaction time and the medium, may influence the crystallization process. A recent paper demonstrated that the optimum temperature for the hydrothermal treatment is 473–493 K.[11] In order to obtain crystalline titania at lower temperature, a longer aging time is required. On the other hand, the photocatalytic activity of titania is particle size dependent, *i.e.* the smaller the titania particles, the higher their photocatalytic activity.[12] Hence, it is of great importance to improve the synthesis methodology. Here we describe a new, simple route for the direct, selective synthesis of nanosized anatase and rutile employing ultrasound irradiation for a short reaction time.

The sonochemical synthesis has been described elsewhere,[13] which has been employed to prepare amorphous metals[14,15a] and oxides.[15b] In the present work, it has been found that ultrasound irradiation can also accelerate the crystallization process of titania. The most important result of this investigation is the dependence of the product phase on both the used precursor and the reaction temperature. Under the same reaction conditions, anatase was formed when tetraisopropyltitanate (TPT) was employed as the precursor, rutile was obtained when titanium tetrachloride (TTC) was used, while a mixture of anatase and rutile was obtained when the precursor was a mixture of TPT and TTC.

In a typical synthesis, 110 mL of deionized water was sonicated by employing a direct immersion titanium horn (Sonics and Materials, VC-600, 20 kHz, 100 W cm^{-2}) for 10 min. At this stage 10 mL of the precursor (TPT, TTC or TPT+TTC, Aldrich) was injected into the sonication cell. The mixture was further sonicated continuously for 3 h. The sonication was conducted without cooling so that a temperature of 353 K was reached at the end of the reaction. The precipitates were separated by centrifugation and washed twice with deionized water and once with ethanol. The product was further dried under vacuum overnight. The detailed synthesis conditions for various samples are summarized in Table 1.

The powder X-ray diffraction (PXRD) patterns of the as-prepared samples are presented in Fig. 1. The reflections in Fig. 1(a) can be indexed to rutile (JCPDS 21-1276) while those in Fig. 1(b) are indexed to anatase (JCPDS 21-1272), which correspond to the as-prepared products using TTC and TPT as precursors, respectively. The sonication of a TPT and TTC mixture yielded sample C, which was a mixture of anatase and rutile [Fig. 1(c)]. Unlike the sol–gel method, the as-prepared products of the sonication process are always perfectly crystalline. For comparison, sample D was synthesized by employing the same precursor and reaction conditions (353 K) as sample C except that the reaction was carried out without sonication. Sample D is poorly crystalline or amorphous as shown in Fig. 1(d).

By employing the well-known formula[16] $X_A = [1 + 1.26(I_R/I_A)]^{-1}$, where X_A is the fraction of anatase in the mixture, and I_R and I_A are the intensities of reflections (110) of rutile and (101) of anatase, respectively, it is estimated that sample C contains 47.6% anatase and 52.4% rutile. This is quite surprising because the molar ratio of TPT to TTC in the irradiated solution is 63.4 : 36.6. Taking into account that rutile and anatase were the sole corresponding products when TTC and TPT acted as the precursors, separately, it is obvious that part of rutile formed at the expense of TPT.

The strong influence of the reaction temperature and the acidity of the medium on the crystallization of titania were further demonstrated in the syntheses of samples E–H. When TPT was used as precursor and sonication was carried out at 303 K, sample E was obtained as a mixture of brookite (JCPDS 29-1360) and anatase [Fig. 1(e)] while for TTC sonicated at *ca.* 283 K the product obtained (*i.e.* sample F) was mainly rutile [Fig. 1(f)]. However, at the same temperature when TTC was

Table 1 Synthesis conditions for samples A–H and their crystalline phases

Sample	Precursor	Synthesis conditions[a]	Sample phase	Particle size[b]/nm	$S_{BET}/m^2\ g^{-1}$
A	TTC	Hydrolyzed in water, sonicated for 3 h	Rutile	8.2	103.5
B	TPT	Hydrolyzed in water, sonicated for 3 h	Anatase	3.5	201.5
C	TPT+TTC	Hydrolyzed in water, sonicated for 3 h, TPT : TTC = 63.4 : 36.6 (molar ratio)	Rutile + anatase (52.4 : 47.6)	6.8	
D	TPT+TTC	Hydrolyzed in water, aged at 353 K for 3 h	Poorly crystalline	—	
E	TPT	Hydrolyzed in water, sonicated at 303 K for 3 h	Brookite + anatase	2.5	
F	TTC	Hydrolyzed in water, sonicated at *ca.* 283 K for 3 h	Rutile	5.9	
G	TPT	Hydrolyzed in 0.2 mol/L HCl (pH = 0.7), sonicated for 3 h	Rutile + anatase	6.5	
H	TPT	Precipitated the supernatant of G at pH 8.6 with $NH_3 \cdot H_2O$ (24% aq.), sonicated for 3 h	Anatase	2.9	289.8

[a] Sonication was carried out under atmospheric pressure without cooling if no other conditions are specified. [b] Average particle size was estimated from PXRD line-broadening employing Scherrer formula.

DOI: 10.1039/b003349i

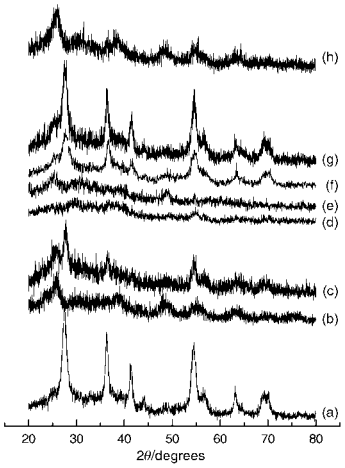

Fig. 1 PXRD patterns of the as-prepared samples A–H (from bottom to top).

hydrolyzed and aged, no precipitates appeared without sonication. It is interesting that when TPT was dissolved in a dilute HCl solution (pH = 0.7) and sonicated, only little solid product (sample G) was obtained showing a rutile phase [Fig. 1(g)]. However, after adjustment of the pH of the above supernatant to 8.6 by addition of ammonia, a white precipitate appeared, and further sonication resulted in the formation of sample H, which was pure anatase [Fig. 1(h)]. These results imply that, although the ultrasonic irradiation promotes the crystallization process of titania, the final crystalline phase of the product is also determined by the acidity of the medium. The particle sizes of samples A, B, C, E, F, G and H, were below 9 nm (Table 1) and were calculated using the Scherrer formula. A TEM image of sample H is shown in Fig. 2, and reveal particles of 4–6 nm diameter.

The results from liquid-N_2 adsorption measurements may aid understanding of the formation of the products. Fig. 3 shows the N_2 adsorption isotherms and pore size distributions of samples A, B and H. The isotherms are characteristic of types H2 (for samples B and H) and H3 (for sample A).[17] Many porous absorbents tend to give a type H2 loop. For sample B a very broad pore size distribution with an average pore size of 5.0 nm was measured, while for sample H a narrower pore size distribution was observed. However, unlike the mesoporous samples B and H (anatase) the results obtained for sample A (rutile) indicate its non-mesoporous nature. The mesopores in samples B and H may be constructed through the aggregation of particles.

A close examination of the PXRD patterns reveals a curious phenomenon. The reflections assigned to anatase are always broader than those for rutile, which implies smaller mean

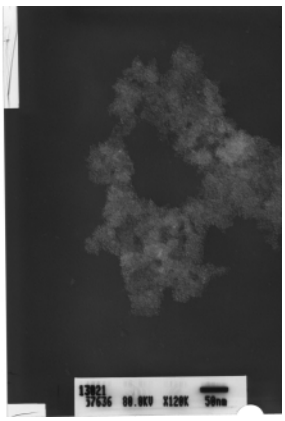

Fig. 2 TEM image of sample H obtained on a JEOI-JEM1200EX electron microscope.

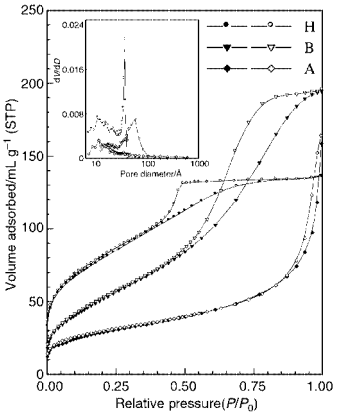

Fig. 3 Adsorption (filled)–desorption (open) isotherms of N_2 for samples A, B and H. Inset: pore size distributions of samples A, B and H.

particle sizes of the bulk anatase products. In fact, according to the Scherrer formula, the particle sizes of all rutile samples are almost twice that of the anatase samples (Table 1). As TTC hydrolyzes violently in water, part of the titanium hydroxide precipitates before dissolving in the acidic solution. Meanwhile, some of the titanium ions that exist as titanyl can be further coordinated by chloride anions. In contrast, the hydrolysis of TPT in water is slower, which results in a nearly neutral, partly condensed and more homogeneous gel. In the latter case, ultrasound irradiation generates many localized hot spots within the gel, outside which the polycondensation of ≡Ti–OH species is promoted. This further causes the homogeneous formation of a large number of seed nuclei, which leads to a smaller particle size. We propose that the interactions caused by sonication amongst the titanium species in the gel is stronger than those in the mixture containing ≡Ti–Cl species, which leads to the formation of anatase, a less condensed metastable phase.

Received (in Oxford, UK) 10th March 2000, Accepted 26th June 2000

Labelling of silica grains and energy dispersive X-ray spectroscopy (EDX) in a TEM-FEG (field emission gun) were used to demonstrate the migration of $Pt(NH_3)_4^{2+}$ species from one grain to another during Pt/SiO_2 catalyst preparation by the ion-exchange procedure.

The reaction of $Ti(OPr)_4$ with the surface of silica grains can be used to graft Ti species. It is therefore possible to mark out some grains incorporated into a silica grains population in order to trace their behavior during for example, the adsorption processes of metal precursors in aqueous media.

The concept of interfacial coordination chemistry was proposed by Che[1] to describe the interaction of transition metal ions with oxide surfaces. In aqueous solution, the transition metal ions are complexed and interaction occurs frequently *via* ionic exchange. For platinum supported on silica, the silica surface protons are exchanged by $Pt(NH_3)_4^{2+}$ ions to form a surface complex $(SiO^-)_2Pt(NH_3)_4^{2+}$.[2] The decomposition of this complex under oxygen or hydrogen leads to Pt particles.[3] Although this method is commonly used, the fixation and dispersion processes of the species are not well-characterized. The aim of this work is to show that the use of Ti labelled silica grains demonstrates that the exchanged species migrate from one silica grain to another when impregnated and non-impregnated silica grains are mixed.

The concentration of Pt in aqueous solution for increasing interaction time with silica[4] is reported in Table 1. Clearly, the adsorption equilibrium of $Pt(NH_3)_4^{2+}$ on the silica surface is reached within < 1 min. For low metal loading (*ca.* 1 wt%), one may thus wonder whether the adsorbed platinum complex is homogeneously distributed all over the silica surface and among the silica particles.

In an initial experiment,[5] EDX analyses[6] of 1 wt% Pt/SiO_2 samples (Fig. 1) demonstrate that after 5 min of contact between the solution and silica, some of the silica grains do not support any Pt whilst others exhibit Pt/Si ratios far from the expected value corresponding to 1 wt% (*ca.* 0.003). Conversely, after 24 h, most of the particles exhibit a Pt/Si atomic ratio close to 0.004. This is most certainly due to the fast fixation of $Pt(NH_3)_4^{2+}$ ions on some silica grains and subsequent redistribution to the other grains. The migration of $Pt(NH_3)_4^{2+}$ can occur either on the silica surface or *via* the liquid phase.

In a second experiment,[7] Ti-labelled[8] silica grains were mixed with previously impregnated unlabelled silica. EDX analysis of the sample clearly shows (Fig. 2) that the migration of species from previously impregnated grains to other grains occurs even at low contact times (5 min) since all Ti-labelled grains that were analyzed contain Pt. After 24 h, the Pt content tends to become homogeneously distributed over all the grains and the average atomic ratio Pt/Si reaches 0.004. Before addition of unlabelled silica, the amount of $Pt(NH_3)_4^{2+}$ present in solution (3.3 μmol) is much smaller than the amount of Pt complex adsorbed on silica (48.0 μmol), and thus these results clearly demonstrate that $Pt(NH_3)_4^{2+}$ ions can migrate between silica grains, even at low metal loading and thus at very low liquid phase concentration, at the adsorption equilibrium.

This is, to our knowledge, the first time that Ti labelled silica grains and EDX analysis have been used for the study of the migration of adsorbed species from one grain to another.

Table 1 Concentration of $Pt(NH_3)_4^{2+}$ in solution for increasing times of interaction with 1 g of silica

Time/min	0	1	10	40
[Pt]/mmol l^{-1}	0.97	0.13	0.11	0.11
pH of solution	11.8	8.2	7.9	7.9

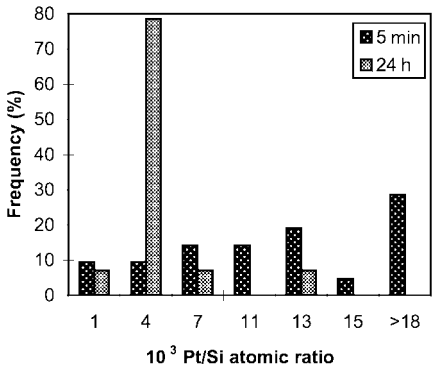

Fig. 1 Pt/Si atomic ratio obtained by EDX on silica grains after 5 min and 24 h of contact during the preparation of the Pt (1 wt%) catalyst.

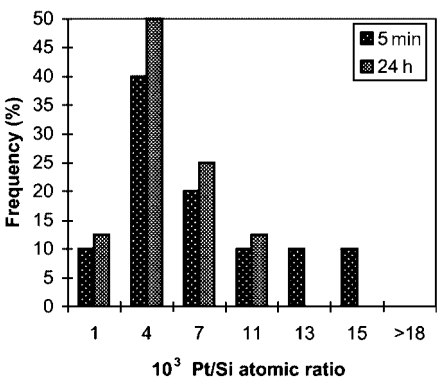

Fig. 2 Pt/Si atomic ratio obtained by EDX on Ti-labelled silica grains after 5 min and 24 h of contact between unlabelled and Ti-labelled silica.

4 Aérosil Degussa silica grains (SiO_2, 200 $m^2\ g^{-1}$, 10–20 nm) were used as the support. These were freshly treated under flowing dry air at 520 °C for 5 h (heating rate 2 °C min^{-1}) before use. Platinum tetraamine hydroxide [$Pt(NH_3)_4(OH)_2$], prepared from $Pt(NH_3)_4Cl_2$ (Aldrich) by ionic exchange[1] was used as the platinum precursor. 1 g of silica was introduced into a magnetically stirred flask with 30 ml of deionized H_2O and 51.3 mmol of $Pt(NH_3)_4(OH)_2$ at 20 °C. The amount of Pt introduced corresponds to an expected loading value of 1 wt% of dry silica. The adsorption rate of $Pt(NH_3)_4^{2+}$ ions onto the silica surface was measured by elemental (Pt) analysis of samples of the solution taken at regular time intervals. Elemental analysis was performed with a ICP Jovin Yvo apparatus.

5 1 g of silica was impregnated in a solution of 51.3 μmol of $Pt(NH_3)_4(OH)_2$ in 30ml of deionized H_2O at 20 °C. Samples taken after 5 min and 24 h of contact were analyzed.

6 EDX analysis of solid samples: EDX experiments where performed with a Pentafet-LinK ISIS (Oxford Instruments) spectrometer in a JEOL JEM 2010-F TEM (200 kV) equipped with a high resolution pole piece. The samples were dried in an oven at 80 °C before EDX measurement. The probe size was adjusted to the grain size of *ca.* 10 nm. Only isolated grains were analyzed in order to avoid simultaneous analysis of two different grains.

7 0.5 g of silica was impregnated in a solution of 51.3μmol of $Pt(NH_3)_4(OH)_2$ in 30ml of deionized H_2O at 20 °C for 1 h. Then 0.5 g of Ti-labelled silica was mixed with 0.5 g of unlabelled impregnated silica and samples corresponding to 5 min and 24 h of contact between the two silica populations were analyzed.

8 Ti labelled silica grains: 1 g of silica was treated at 500 °C under vacuum during 24 h, then $Ti(OPr)_4$ in hexane solution was introduced at room temperature under flowing argon and the suspension stirred for 4 h at room temperature. Next, the solid was extracted by filtration under argon, dried under vacuum for 24 h and then treated at 500 °C under flowing O_2–N_2 (20 : 80) for 2 h. The Ti loading, measured by elemental analysis, was 0.4 wt%. EDX measurements indicated that the silica grains were labelled with Ti. It was also established that the loading of 1 g of Ti labelled silica does not vary when it is impregnated with 30 ml of deionized H_2O and NH_4OH (pH 10) at 20 °C, stirred for 24 h and then washed four times with deionized water. The Ti loading of the sample is low with only 3% of the silica surface being covered by TiO_2. Two samples of Pt/SiO_2 prepared in the same manner, using unlabelled and Ti labelled silica exhibit the same Pt loading (1 wt%) and the same metallic particle size distribution. We thus concluded that Ti labelling did not influence the results.

Hydroformylation of epoxides catalyzed by cobalt and hemilabile P–O ligands

R. Weber,[a] U. Englert,[b] B. Ganter,[b] W. Keim[a] and M. Möthrath*[a]

[a] *Institute of Technical and Macromolecular Chemistry, RWTH Aachen, Worringer Weg 1, 52074 Aachen, Germany. E-mail: moethrath@itc.rwth-aachen.de*

[b] *Institute of Anorganic Chemistry, RWTH Aachen, Professor-Pirlet-Straße 1, 52056 Aachen, Germany*

Received (in Cambridge, UK) 5th April 2000, Accepted 7th June 2000

Complexes of cobalt efficiently catalyze the hydroformylation of epoxides in the presence of hemilabile P–O chelating ligands to give β-hydroxyaldehydes in high selectivities and yields.

The hydroformylation of epoxides provides an elegant and inexpensive pathway to β-hydroxyaldehydes which may easily be hydrogenated to 1,3-diols which have a wide variety of uses.[1] Lately propane-1,3-diol has attracted considerable industrial interest as an intermediate in the production of polyester fibers and films.[2]

For the hydroformylation of epoxides, special catalysts and ligands are needed to suppress side reactions such as isomerization and hydrogenation.

Previously, chelating diphosphine ligands have been reported for the cobalt catalyzed hydroformylation of epoxides.[3] For the rhodium catalyzed hydroformylation of olefins and for carbonylation reactions P–O ligands have been found to be superior to their phosphine analogues.[4] This fact prompted us to apply P–O ligands to the hydroformylation of epoxides. To the best of our knowledge, P–O ligands have not been reported for the hydroformylation of epoxides, whereas various diphosphine ligands such as dppm, dppe, dppp and dppb have been reported for this process (Scheme 1).

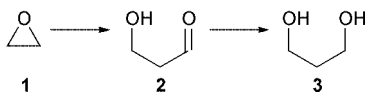
		dppb	4

Scheme 1 Structures of investigated ligands.

Using a catalyst prepared *in situ* under the applied reaction conditions from $Co_2(CO)_8$ and dppmO (for abbreviations see Scheme 1) in toluene, ethylene oxide **1** was converted to 3-hydroxypropanal **2** with 89% selectivity. Hydrogenation of **2** yielded 32% of propane-1,3-diol (1,3-PDO), **3** (Scheme 2).†



Scheme 2

In comparison to dppe (Table 1, run 2) the dppmO system proved to be much more efficient in terms of higher selectivities and yields. The reaction with diphosphines strongly depends on the solvents applied. Performing the reaction in a mixture of toluene and chlorobenzene, which is known to yield the best results for dppe, we could only achieve a 17% maximum yield of 1,3-PDO under the conditions selected.

To examine the role of the chelate effect of the ligands, the reaction was run with monodentate triphenylphosphine ($Co:PPh_3$ = 1:2) and with triphenylphosphine and diphenylmethylphosphine oxide ($Co:PPh_3:Ph_2MeP(O)$ = 1:1:1) as ligands (Table 1, runs 3 and 4). Scarcely any 1,3-PDO was observed after hydrogenation. Obviously, the presence of a chelating ligand is an important condition for a catalytically active system.

The use of dppeO and dpppO (Table 1, runs 5 and 6) as ligands led to a significant decrease in selectivity and yield, indicating that ligands which are capable of forming a five-membered chelate ring are preferred. A similar trend was observed employing dppm, dppp and dppb (Table 1, runs 7, 8, 9) as ligands.

As is well known in homogeneous catalysis, the variation of the ligand to metal ratio can have a strong influence on the activity and selectivity of the reaction. We thus varied the dppmO to cobalt ratio (Table 1, runs 10–14) and found that an increase of the amount of dppmO employed led to a steady enhancement of the 1,3-PDO yield, whereas an inverse relationship was observed for dppe.[5] The maximum yield of 1,3-PDO was obtained for a 1:1 ratio of dppe to cobalt and increasing the ligand to cobalt ratio resulted in a dramatic loss of activity. An explanation for the different behavior of the dppmO–Co system may be understood from ^{31}P NMR investigations of the reaction mixture after a pre-formation period. For a dppmO to cobalt ratio > 1, free ligand can be detected. It is known that triphenylphosphine oxide is used as a promoter for the hydroformylation of ethylene oxide[6] and excess dppmO may act in a similar manner. By increasing the amount of the free ligand the activity of the system is improved and therefore, dppmO can act as ligand and promoter at the same time.

We were able to isolate a stable cobalt complex $[(dppmO)Co(CO)_3]_2$, a single crystal X-ray analysis of which confirmed the dimeric structure (Fig. 1). The coordination geometry around cobalt is trigonal bipyramidal.‡

A comparison of the catalytic behavior of the isolated complex (Table 1, run 15) to the *in situ* system gave nearly

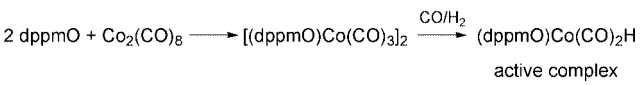
identical results and thus it can be assumed that for both runs the same catalytically active species are formed. The reaction sequence shown in Scheme 3 is proposed for this catalytic system.



Scheme 3 Proposed catalytic sequence.

Cobalt catalyzed hydroformylation with dppmO as ligand can be readily applied to other epoxides affording the corresponding 1,3-diols after hydrogenation of the 3-hydroxyaldehydes (Table 2).

Propylene oxide and *trans*-2,3-epoxybutane (Table 2, runs 1, 2) are especially suitable for hydroformylation. The poorer results for styrene oxide and cyclohexene oxide can be explained in terms of increased isomerization to the corresponding aldehydes. It is known that $Co_2(CO)_8$ may catalyze those isomerization reactions.[7] Assuming that the isomerization occurs *via* an ionic mechanism and that the stabilization of the intermediate carbocation is of importance, the extent of the isomerization of styrene oxide becomes understandable.

Table 2 Cobalt catalyzed hydroformylation of different epoxides with dppmO

[a] Yields are based on the substrate and were determined by gas chromatography with standard compounds. For simpler GC detection all samples were hydrogenated. [b] Selectivity = products/(by-products + products).

In conclusion, the hydroformylation of epoxides employing hemilabile P–O ligands and cobalt metal salts has been successfully carried out for the first time. Suitable hemilabile ligands must be able to form a chelate ring with cobalt, preferably a five membered-ring chelate. An excess of the hemilabile ligands further enhances the yield of the β-hydroxyaldehydes. The reaction can be extended to different epoxides establishing a new route to synthesize 1,3-diols or 3-hydroxyaldehydes.

We thank Degussa Hüls AG and the DFG for support of our work.

Notes and references

† All reactions were carried out in a 100 ml steel autoclave with all manipulations carried out under argon. In a typical experiment, the appropriate amount of ligand in 10 ml of toluene was added to a Schlenk tube containing a stirring bar and 68.4 mg (0.2 mmol) of $Co_2(CO)_8$ in 10 ml of toluene. The mixture was transferred into the autoclave and the dropping funnel of the autoclave was filled with 50 mmol of the epoxide. The charged autoclave was pressurized with CO and H_2 (100 bar) and stirred at 100 °C for 1 h. The epoxide was dropped into the reaction mixture and the reaction carried out for 3 h, with temperature and pressure being constantly monitored throughout. After the reaction, the autoclave was allowed to cool in an ice-bath to room temperature, and the gases were vented. The liquid reaction mixture was collected in methanol and analyzed by GC. A small part of the reaction mixture (1 ml) was hydrogenated and analyzed by GC.

Received (in Cambridge, UK) 15th May 2000, Accepted 23rd June 2000

A new catalytic property of supported rhenium oxides has been found for selective methanol oxidation to methylal; high performances for the selective catalytic oxidation are observed with V_2O_5-, ZrO_2-, Fe_2O_3- and TiO_2-supported Re–oxide catalysts, which are characterized by pulse experiments, XRD and XPS.

Numerous efforts have been made to develop selective oxidation catalysts for methanol conversions to formaldehyde, methyl formate and dimethoxymethane (methylal). Methanol oxidation to formaldehyde has been extensively studied and commercialized on silver and ferric molybdate catalysts.[1] High-yield production of methyl formate from methanol has also been accomplished on mixed metal oxides such as V–Ti oxides,[2] Sn–Mo oxides,[3] and Bi-based oxides.[4] Methylal is used as a gasoline additive, a solvent in perfume industry, a key intermediate for preparing high concentration formaldehyde, and a reagent in organic synthesis. The catalytic methylal synthesis from methanol ($3\ MeOH + 1/2\ O_2 \rightarrow CH_2(OMe)_2 + 2\ H_2O$) has been reported on V/TiO_2,[1] V–Mo–O,[5] PMoH–5.75/SiO_2,[6,7] Mo/MCM-41,[8] and MoO_3(100),[9,10] but the selectivities to methylal on those catalysts were low. Recently, we found a crystalline binary oxide compound SbR_2O_6 which was selective for the methylal formation.[11] The selectivity reached 93.5% at a conversion of 6.5% at 573 K. However, the crystalline oxide $SbRe_2O_6$ has a very low surface area (1 $m^2\ g^{-1}$), resulting in insufficient activity for methylal production. The performance of SbR_2O_6 was attributed to the Re–oxide octahedra connecting with Sb–O chains.[11] The property of Re species capable of adopting a variety of oxidation states that are illustrated in both binary and ternary oxides,[12–14] may provide rich and interesting chemistry. Nevertheless, Re oxides have not widely been used as catalysts for selective oxidation reactions owing to sublimation under pretreatment and reaction conditions.[15] In this study we have found the new catalytic property of supported and unsupported Re oxides for the selective methanol oxidation to methylal.

Inorganic oxide-supported Re oxide catalysts were prepared by an incipient wetness impregnation method using an aqueous solution of ammonium perrhenate (NH_4ReO_4), followed by drying at 383 K for 12 h. The samples were put into a glass-made fixed-bed reactor in a flow system and heated to 673 K at a heating rate of 4 K min^{-1} in a He flow and held at 673 K for 6 h. The samples thus obtained were further treated *in situ* in the fixed-bed flow reactor under the He flow at 573 K for 1 h before use as catalysts. A typical Re loading was 10 wt% as Re/support. Methanol (Wako, purity 99.8%) was introduced to the flow reactor by bubbling He gas through a glass saturator filled with methanol. Unsupported Re oxides were also pretreated at 673 K in a similar way. The catalytic reactions on the supported and unsupported Re–oxide catalysts were carried out at 513 K under the reaction conditions GHSV = 40 000 ml h^{-1} g_{cat}^{-1} and $He:O_2:MeOH = 86.3:9.7:4.0$ (mol%) at 1 atm. The products were analyzed by an on-line gas chromatograph using Porapak N and Unibeads C columns.

Table 1 shows the performances of the supported Re–oxide catalysts for the selective methanol oxidation to methylal. The performances of unsupported Re oxides (ReO_3 and ReO_2) and two typical supports (α-Fe_2O_3 and V_2O_5) are also listed in Table 1 for comparison.

It was found that Re oxides supported on TiO_2 (rutile and anatase), V_2O_5, ZrO_2 (monoclinic), Fe_2O_3 (α and γ) and α-Al_2O_3 were active in order of the reaction rates per g_{Re} for the supports, TiO_2(anatase) > TiO_2(rutile) > γ-Fe_2O_3 > ZrO_2 > V_2O_5 > α-Fe_2O_3. Among them, Re/V_2O_5, Re/γ-Fe_2O_3, Re/α-Fe_2O_3, Re/ZrO_2 and Re/α-Al_2O_3 showed selectivities of 88–94% to methylal (Table 1). When the conversion for Re/γ-Fe_2O_3 was further increased by decreasing the space velocity, the methylal selectivity decreased a little, while the formaldehyde selectivity increased. Re oxides supported on SiO_2

DOI: 10.1039/b003870i

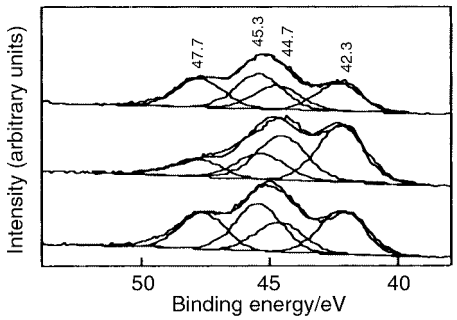

Fig. 1 Re 4f XPS spectra for 10.0 wt% Re/α-Fe_2O_3 catalysts: (a) after pretreatment at 673 K for 6 h in He, (b) after ten methanol pulses at 513 K and (c) after catalytic methanol oxidation at 513 K for 2 h in the presence of O_2. The XPS binding energies were referred to 284.6 eV for C 1s.

produced a significant amount of CO_x and those supported on Sb_2O_3 and Bi_2O_3 showed no activity at 513 K (Table 1). α-Fe_2O_3 and V_2O_5 themselves were almost inactive for methylal formation though V_2O_5 produced formaldehyde. When these oxides were supported by Re oxides, the obtained Re/α-Fe_2O_3 and Re/V_2O_5 showed selectivities to methylal as high as 91–94%. ReO_3 was most selective (99%), while the selectivity of ReO_2 was much lower (64.6%). When the mixture of He–MeOH–O_2 was admitted to Re_2O_7 at 513 K, the color changed from yellow (Re_2O_7) to read (ReO_3) in <3 min, accompanied with sublimation of some of the Re_2O_7, and showed a selectivity to methylal $>90\%$ after 10 min of time-on-stream. Under the reaction conditions below 553 K, there was no loss of Re oxides by sublimation in Re/TiO_2, Re/V_2O_5, Re/Fe_2O_3, Re/ZrO_2, Re/SiO_2, Re/Al_2O_3 and Re/MoO_3. It indicates that bulk Re_2O_7 is not a stable phase in the methylal synthesis conditions. It was concluded from plots of the selectivities against the reaction rates per surface area or the conversions in Table 1 that Re/α-Fe_2O_3, Re/γ-Fe_2O_3, Re/V_2O_5 and Re/ZrO_2 exhibit high catalytic selectivity on Re/α-Fe_2O_3 increased with increasing Re loading and reached saturation values at 2.0 wt% Re (15.5 and 92.0%, respectively). The highest reaction rates per g_{Re} of the supported Re–oxide catalysts were thus achieved in the range of Re loadings 1–3 wt%.

Recently, a high selectivity of 76.2% was reported on 2 mol% Mo supported on MCM-41, but it was achieved at a very low conversion of 0.7% at 543 K.[8] Further, the Mo/MCM-41 catalyst was rapidly deactivated owing to a significant leaching of Mo species from the channels of MCM-41.[8] On the other hand, no deactivation of the supported Re oxides occurred for 6 h of time-on-stream at 513 K. Methylal formation from methanol was also reported on PMoH–5.75/SiO_2[6,7] and V/TiO_2,[1] but the selectivities toard methylal were as low as 40–56%.[11]

The XPS spectrum [Fig. 1(a)] for the as-pretreated Re/α-Fe_2O_3 showed a peak at 42.3 eV which is assigned to the Re $4f_{7/2}$ level for Re^{4+} species (also deconvolued at 44.7 eV for $4f_{5/2}$). The XPS spectrum also showed peaks at 45.3 and 47.7 eV assigned to Re $4f_{7/2}$ and $4f_{5/2}$ levels possibly for a Re^{6+} species, respectively [Fig. 1(a)]. The Re $4f_{7/2}$ binding energy (45.3 eV) is lower by 1.2–1.6 eV than that reported for Re_2O_7 (R^{7+}), but higher by 0.8–1.0 eV than that for ReO, (Re^{6+}).[17,18] We measured XPS spectra for the Re/α-Fe_2O_3 catalysts with different Re loadings in the range 0.1–10.0 wt%. The Re^{6+} peaks at 45.3 and 47.7 eV were observed in all the samples, while the Re^{4+} peaks at 42.3 and 44.7 eV developed only for the catalysts with Re > 2.0 wt%. The XRD lines for ReO_2 appeared for the Re/α-Fe_2O_3 catalysts with Re > 3.0 wt%, while no diffraction lines due to Re_2O_7 and ReO_3 were detected. It is most likely from these results that the initial Re^{7+} precursors were reduced to Re^{6+} and also to Re^{4+} for Re loadings above 2.0 wt% under the pretreatment conditions.[16] We estimate 2 wt% of Re as a monolayer of Re oxides at the α-Fe_2O_3 surface. The fact that neither Re^{4+} (XPS) nor ReO_2 (XRD) were detected on the catalysts with Re loadings below 2.0 wt% indicates that dispersed Re oxides are scarcely reduced to Re^{4+} under He at 673 K probably because of interaction with the α-Fe_2O_3 surface.

When pulses of 1 ml of He–MeOH = 96.0 : 4.0 (mol%) were introduced onto the 10.0 wt% Re/α-Fe_2O_3 catalyst at 513 K, methylal was formed during the course of the first to fourth methanol pulses with decreasing selectivities, and after the fifth pulse no methylal was produced. It is evident from the pulse experiments in the absence of gaseous O_2 that lattice oxygen atoms of the Re oxides work as active oxygen species for the selective oxidation of methnol. From the pulse experiments where the 10 wt% Re/α-Fe_2O_3 catalyst reacted with the methanol pulses at 513 K, we estimated that the amount of lattice oxygen atoms incorporated into the produced methylal was 1.88×10^{19} atom m^{-2}. Exhaustion of the active oxygen atoms increased the formation of H_2, CH_4 and CO_2 in a molar ratio of nearly 2 : 1 : 1 probably through decomposition of HCO_2Me produced preferable on the reduced Re oxides. After ten methanol pulses at 513 K, the intensities of the XPS peaks at 45.3 and 47.7 eV assigned to Re^{6+} species decreased drastically, while the Re^{4+} peak intensities increased significantly [Fig. 1(b)]. The consumed lattice oxygen atoms were regenerated by gaseous O_2 as established by XPS spectroscopy [Fig. 1(c)].

In summary, we have developed supported Re–oxide catalysts which show high performances for selective catalytic oxidation of methanol to methylal. The high performances of the Re oxides were obtained when V_2O_5, ZrO_2 and Fe_2O_3 were used as supports. The redox capability of Re oxides at the support surfaces (possibly $Re^{6+} \leftrightharpoons Re^{4+}$) may be responsible for the selective oxidation of methanol to formaldehyde, while the appropriate acidy Re oxides may also be necessary for the acetalization of formaldehyde with methanol to form methylal.

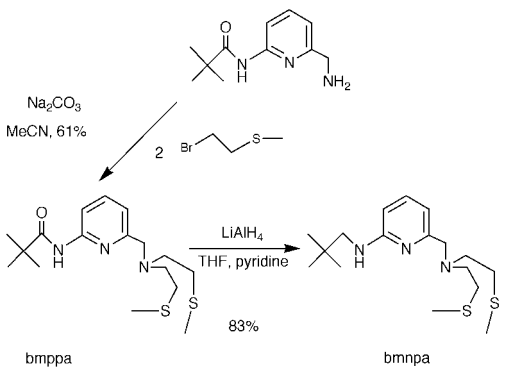
Received (in Irvine, CA, USA) 12th April 2000, Accepted 20th June 2000

Using a novel secondary amine-appended nitrogen/sulfur ligand, the first example of a nitrogen/sulfur-ligated zinc hydroxide complex, a species relevant to the active forms of several zinc-containing metalloenzymes, has been prepared and structurally characterized.

Zinc-containing metalloenzymes utilize active site structural motifs of varying nuclearity and supporting primary and secondary coordination environments to catalyze a diverse array of chemical transformations.[1] Distinctive among active site structures in these enzymes are those which have sulfur ligation to a Zn(II) ion that also binds a water/hydroxo moiety that is directly involved in catalysis.[1a] Specifically, the presence of cysteine sulfur ligation at the mononuclear Zn(II) active site ions of alcohol dehydrogenase,[2] peptide deformylase,[3] cytidine deaminase,[4] spinach carbonic anhydrase,[5] and at one of the two active site Zn(II) ions found in the metallo-β-lactamases from *B. fragilis*, *B. cereus*, and *A. hydrophila*,[6] has prompted research efforts toward the goal of generating Zn(II) complexes, supported by a mixed nitrogen/sulfur coordination environment, that possess an available coordination position for water/hydroxo binding.[7] However, despite the construction of several new ligand systems, a discrete zinc hydroxide species supported by a metal coordination sphere possessing sulfur donors has remained elusive, in part because of the tendency of thiolate ligands to produce oligomeric structures.[8] Herein we describe the synthesis and structural characterization of the first zinc hydroxide complex supported by a mixed nitrogen/sulfur ligand environment.

Reasoning that hydrogen bonding interactions might prove useful toward the stabilization and isolation of a nitrogen/sulfur-ligated zinc hydroxo species,[9] we prepared a new ligand system, *N*-bis-2-(methylthio)ethyl-*N*-(6-neopentylamino-2-pyridylmethyl)amine (bmnpa, Scheme 1), that combines a nitrogen/sulfur coordination environment with a secondary amine functionality that may serve as a hydrogen bond donor in metal complexes. As shown in Scheme 1, this ligand was prepared *via* a two-step reaction sequence. Treatment of 2-pivalolylamido-6-aminomethylpyridine[10] with 2 equivalents of 1-bromo-2-methylthioethane yielded *N*-bis-2-(methylthio)ethyl-*N*-(6-pivalolyamido-2-pyridylmethyl)amine (bmppa) in 61% yield.‡ Reduction of bmppa with $LiAlH_4$ in THF-pyridine followed by purification by column chromatography yielded the desired bmnpa ligand.‡ Zinc complexation of bmnpa was achieved *via* admixture of equimolar amounts of bmnpa, $Zn(ClO_4)_2·6H_2O$ and KOH (Scheme 2) in methanol at ambient temperature followed by crystallization from MeCN–Et_2O, which produced a colorless crystalline material with an analytical composition consistent with the empirical formula $[(bmnpa)Zn(OH)]ClO_4$ **1**.§¶ It is notable that in the absence of added KOH, a different zinc complex is generated. Specifically, treatment of bmnpa with $Zn(ClO_4)_2·6H_2O$ in MeOH followed by crystallization from MeCN–Et_2O yielded $[(bmnpa)Zn(ClO_4)](ClO_4)$ **2** (Scheme 2), which deposited as plate-type crystals.§¶



Scheme 1

X-Ray crystallographic analysis of **1** revealed an asymmetric, dinuclear nitrogen/sulfur-ligated zinc hydroxide structure (Fig. 1, top), with only one of the two available thioether sulfur donors ligated to each Zn(II) center. The five-coordinate zinc ions, which are related by an inversion center, exhibit a slightly distorted trigonal bypyramidal geometry (τ = 0.80)[11] with the pyridyl nitrogen [Zn(1)–N(2) 2.068(3) Å], a thioether sulfur [Zn(1)–S(1) 2.514(1) Å] and a hydroxide oxygen atom [Zn(1)–O(1) 1.974(3) Å] occupying equatorial positions. The observed Zn(1)–O(1) bond length falls within the range (*ca.* 1.9–2.3 Å) of distances previously reported for bridging hydroxo moieties in multinuclear zinc complexes.[12] The second zinc oxygen bond [Zn(1)–O(1′)] is slightly longer [2.028(3) Å] and is a structural component of a six-membered ring [Zn(1)-O(1′)···H-N(3)–C(9)–N(2)][13] created by a hydrogen bonding interaction between the secondary amine hydrogen [N(3)–H] and a lone pair on the hydroxyl oxygen [O(1′)···N(3) 2.82 Å, O(1′)···H–N(3) 161.0°].[14] Because this intramolecular hydrogen bonding interaction involves the longer Zn(1)–O(1′) bond, it appears to contribute toward the stabilization of the asymmetric dinuclear $Zn_2(OH)_2$ core.

Complex **2** is mononuclear in the solid state (Fig. 1, bottom), adopting a distorted trigonal bipyramidal geometry (τ = 0.65)

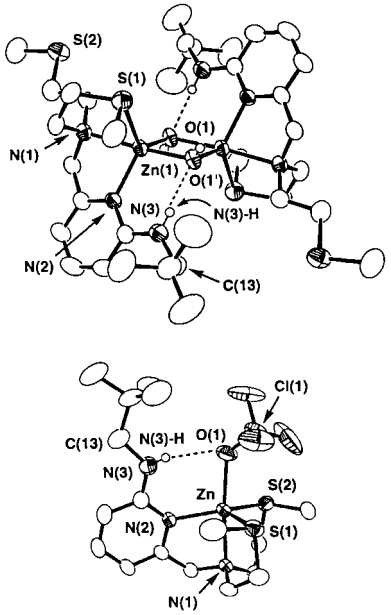

Fig. 1 Drawings of the cationic portions of the X-ray crystal structures of **1** (top) and **2** (bottom). All ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°): **1**: Zn(1)–O(1) 1.974(3), Zn(1)–S(1) 2.514(1), Zn(1)–N(1) 2.189(3), Zn(1)–N(2) 2.068(3), Zn(1)–O(1′) 2.028(3); S(1)–Zn(1)–N(1) 82.8(1), N(1)–Zn(1)–N(2) 80.70(12), N(2)–Zn(1)–O(1) 114.2(1), N(2)–Zn(1)–O(1′) 102.6(1), N(1)–Zn(1)–O(1) 98.7(1), N(1)–Zn(1)–O(1′) 174.5(1), S(1)–Zn(1)–O(1) 126.8(1), S(1)–Zn(1)–O(1′) 91.7(1); **2**: Zn–O(1) 2.174(3), Zn–S(1) 2.432(1), Zn–S(2) 2.390(1), Zn–N(1) 2.191(3), Zn–N(2) 2.042(3); O(1)–Zn–N(1) 174.8(1), N(2)–Zn–S(2) 136.1(1), N(2)–Zn–S(1) 109.3(1), S(1)–Zn–S(2) 111.8(1).

with both thioether sulfur atoms of the ligand bound to the Zn(II) center [Zn–S(1) 2.432(1) Å, Zn–S(2) 2.390(1) Å] in the equatorial plane. The Zn–S bond distances of **2** fall between those reported for the monomeric, four-coordinate [$(Ph_2CHS)Bp^{But,Pri}$]ZnI [2.460(2) Å][7b] and [$HB(tim^{Me})_2pz$]ZnI [2.320(2), 2.352(2) Å][7c] complexes, but are slightly shorter than the Zn–S(1) distance found in **1** [2.514(1) Å]. Located *trans* to the apical nitrogen atom in **2** is a coordinated perchlorate anion [Zn–O(1) 2.174(3) Å]. An intramolecular hydrogen bonding interaction between the zinc-bound oxygen atom of this anion and the secondary amine donor [O(1)···N(3) 2.93 Å, N(3)–H···O(1) 158°] is present in the solid state.

Importantly, the isolation of complex **1** confirms the feasibility of using ligand systems possessing a single hydrogen bond donor to stabilize biologically relevant metal hydroxide species. Evidence for the hydrogen bonding interaction found in the solid state between the metal-bound hydroxide and the secondary amine proton [N(3)–*H*] in **1** remaining intact in solution is derived from examination of ^{1}H NMR spectra of the complex obtained in dry CD_3CN. Specifically, the N(3)–*H* resonance of **1**, which is found as a broad triplet at δ 8.97 (*J* 6.3 Hz), with the observed multiplicity being indicative of a slow rate of exchange and coupling with the adjacent methylene unit [C(13)-H_2, δ 2.71, d, *J* 6.3 Hz], is shifted significantly downfield from the position of the same resonance in the free ligand [N(3)–*H*, δ 5.01]. This deshielding of the N(3)–*H* resonance in **1** indicates a decrease in the electron density surrounding this proton due to its involvement in a hydrogen bonding interaction. It is also intriguing that the chemical shift of the secondary amine proton of the bmnpa ligand is highly dependent upon the nature of the anions present in zinc complexes, as **2** exhibits a N(3)–*H* resonance at δ 5.79.

In summary, we have synthesized a new secondary amine-appended nitrogen/sulfur ligand system and have utilized it to prepare and structurally characterize the first example of a nitrogen/sulfur-ligated zinc hydroxide complex. As such, it the first relevant synthetic complex for the catalytic site of several nitrogen/sulfur-ligated zinc enzymes that possess a water/hydroxo moiety that is directly involved in catalysis. The results outlined herein lay the groundwork for extensive reactivity studies directed at examining the influence of sulfur ligation on the reactivity of a zinc hydroxide moiety toward a variety of biologically-relevant substrates including alcohols, amides and CO_2.

We thank Utah State University for financial support and John C. Price and Peter Jeppson for assistance in ligand preparation.

Enhanced mobility of the cluster $Ru_3(CO)_{12}$ in the solid state formed *in situ* by the reaction of CO and $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ on silica

Received (in Basel, Switzerland) 28th March 2000, Accepted 20th June 2000

The reaction of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ (physisorbed on SiO_2) with CO in the solid state leads to $Ru_3(CO)_{12}$ and acenaphthylene in quantitative yields; the $Ru_3(CO)_{12}$ generated *in situ* is highly mobile leading to a reduced chemical shielding anisotropy.

The large magnetic anisotropy of carbonyl groups makes the solid state ^{13}C MAS NMR spectra of metal carbonyls highly characteristic,[1,2] as they show a large number of spinning sidebands (SSBs) flanking the isotropic peaks. The onset of molecular motion in the solid state is indicated by the disappearance of these SSB manifolds. This effect is neatly illustrated by the comparison of the ^{13}C MAS spectra of $(C_6H_6)Cr(CO)_3$ as bulk crystals and included in the cavity of β-cyclodextrin.[3,4] The large mobility of $(C_6H_6)Cr(CO)_3$ inside the β-CD cavity appears to be the result of a lack of strong intermolecular interactions which usually lock organometallic molecules rigidly in the crystalline state.[5]

We have previously attempted many solid gas reactions with clusters. However, in almost all cases the products were disordered but static on the NMR timescale.[6] The subject of this communication, is the novel enhanced mobility of $Ru_3(CO)_{12}$ on a silica surface, occurring solely when the $Ru_3(CO)_{12}$ is deposited by the solid state, *in situ*, carbonylation of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ leading to substantial reduction in the chemical shift anisotropy.

$Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ is synthesised by the previously reported method.† All the samples used were synthesised using *ca.* 30% ^{13}CO enrichment.‡ At low temperature the solution spectrum of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ shows seven ^{13}CO absorptions, one (269.3 ppm) in the bridging region and six (205.0, 202.7, 201.7, 193.9, 190.0 and 186.8 ppm) in the terminal region, consistent with the structure previously proposed.[7] $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ reacts readily in solution with CO quantitatively affording $Ru_3(CO)_{12}$ and free acenaphthylene. However, this reaction is considerably inhibited in the solid state at room temperature. Contrastingly, by physisorbing $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ on a surface of SiO_2 (Sigma; 450–550 $m^2\ g^{-1}$ surface area, 10% coverage of the silica surface) the same reaction occurs readily. After 5 min at RT under 100 Torr of CO, 7 mg of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ was transformed into $Ru_3(CO)_{12}$ and acenaphthylene (IR spectrum, KBr disk).[8]

Therefore we decided to further investigate this process by ^{13}C solid state NMR spectroscopy. The ^{13}C CP-MAS spectrum of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ shows the bridging carbonyl at 270 ppm while the six terminal CO resonances overlap in three broad signals at 205, 190 and 185 ppm respectively. As has been previously observed for a number of examples the SSB pattern of bridging CO resonances is quite different from that of the terminal CO resonances.[9] This difference may be explained in terms of the reduced chemical shift anisotropy of the bridging CO ligands in respect to the terminal CO ligands, thus providing further confirmation for the assignments.

The ^{13}C CP-MAS spectrum of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$, physisorbed on SiO_2 displays close similarity with the corresponding ^{13}C CP-MAS spectrum of the crystalline compound [Fig. 1]. On following the reaction of CO with $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)/SiO_2$ by $^{13}C\text{-}\{^1H\}$ HPPD-MAS (high power proton decoupled—magic angle spinning) there is a progressive decrease in the intensity of the resonances of the starting material, which are in turn replaced by an intense peak at 199.8 ppm which is unambiguously assigned to $Ru_3(CO)_{12}$.

The most striking feature of the ^{13}C MAS spectrum of the reaction products is the totally unprecedented absence of any SSB manifold flanking the carbonyl resonance of $Ru_3(CO)_{12}$ [Fig. 2(c)]. This indicates that $Ru_3(CO)_{12}$ produced *in situ* on the surface of the silica possesses a very high mobility on the NMR time scale as compared with that of the normal bulk $Ru_3(CO)_{12}$ [Fig. 2(a)].[10] In order to gain a fuller understanding of the causes and the generality of this uniquely enhanced mobility we carried out further experiments: (a) the physisorbtion of $Ru_3(^{13}CO)_{12}$ and acenaphthylene on silica; (b) the reaction of $Ru_3(CO)_{11}(MeCN)$ on silica with CO to form $Ru_3(CO)_{12}$ *in situ*; (c) the physisorbtion of an identical amount of $Ru_3(CO)_{12}$ to that used in (a) directly onto silica. In all three cases the presence of $Ru_3(CO)_{12}$ was confirmed by solid state IR spectra (KBr disk). However, in none of the three cases was the absence of sidebands, in the MAS spectra, reproduced. This indicates that the fast molecular motion was absent in the $Ru_3(CO)_{12}$ obtained in all three of these experiments. The most striking spectrum is that obtained from the direct physisorbtion of $Ru_3(CO)_{12}$ onto silica: the ^{13}C MAS experiment [Fig. 2(b)] carried under identical conditions to highly mobile $Ru_3(CO)_{12}$ on silica produces no discernible signal. This is due to two factors; firstly all the signals of crystalline $Ru_3(CO)_{12}$ (dispersed over 350 ppm) are averaged into one signal in the highly mobile $Ru_3(CO)_{12}$, and secondly the relaxation properties of the highly mobile $Ru_3(CO)_{12}$ are more favourable. The most plausible explanation for the motion of $Ru_3(CO)_{12}$ obtained

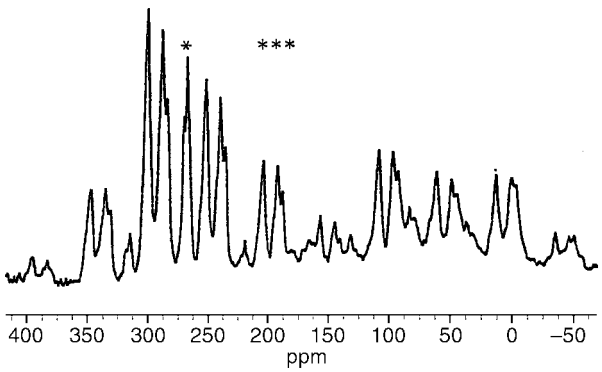

Fig. 1 ^{13}C HPPD MAS spectrum of a ^{13}CO enriched sample of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ supported on SiO_2: 67.8 MHz, spinning speed 3200 Hz, 500 scans (* denotes isotropic peaks).

DOI: 10.1039/b002641g

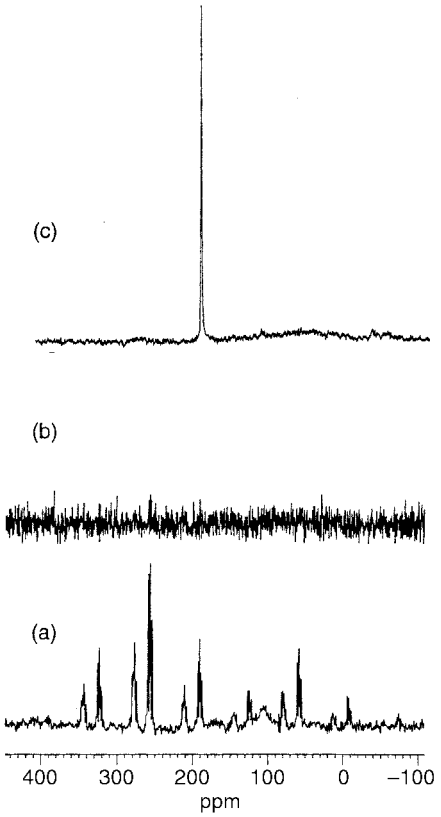

Fig. 2 ^{13}C HPPD MAS spectrum of (a) crystalline $Ru_3(CO)_{12}$, 240 transients, 5 kHz; (b) $Ru_3(CO)_{12}$ physisorbed on silica, 240 transients, 5 kHz; (c) $Ru_3(CO)_{12}$ on silica obtained by the reaction of $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3:\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ physisorbed on SiO_2 with ^{13}CO: 67.8 MHz, spinning speed 5300 Hz, 24 scans. The net amount of $Ru_3(CO)_{12}$ on the silica in samples (b) and (c) is identical.

from $Ru_3(CO)_6(\mu\text{-}CO)(\mu_3{:}\eta^2:\eta^3:\eta^5\text{-}C_{12}H_8)$ with CO on SiO_2 surface is that $Ru_3(CO)_{12}$ and $C_{12}H_8$ formed are unable to yield microcristalline aggregates. This would fully account for the lack of the observed SSB manifold in the solid state experiments.

T_1 measurements on a ^{13}CO enriched sample of the highly mobile $Ru_3(^{13}CO)_{12}$/acenaphthylene/silica samples were carried out. The experiments, although carried out in the solid state, were performed using a commercial solution spectrometer (operating frequency 100.5 MHz for ^{13}C) in normal 5 mm solution tubes and a standard solution probehead. The fact that the signal was observable in this way indicates just how fast the molecular motion is in order to average the shielding anisotropy to this extent. At ambient temperature the measured T_1 is markedly shorter than that found for the same compound in solution at the same magnetic field strength (350 ms *vs.* 4280 ms) indicating that the extent of motion occurring in the solid state system is significantly lower than that occurring in a highly mobile liquid phase.

An analysis of T_1 *versus* temperature shows that there is an incipient minimum value at 250 K, from which it is possible to obtain an estimate of the molecular reorientation time. By using this calculated τ_c value and assuming that the observed T_1 is determined mainly by the chemical shift relaxation pathway,[11] it is possible to obtain a $\Delta\sigma$ value of 350 ppm that is not dissimilar to the values reported in literature measured respectively from wideline,[1] MAS[12] and variable field-solution state experiments.[10] On fitting the observed T_1 *vs.* temperature data an activation energy of 16.9 kJ mol^{-1} for the molecular reorientational motion of $Ru_3(CO)_{12}$ in this system is obtained.

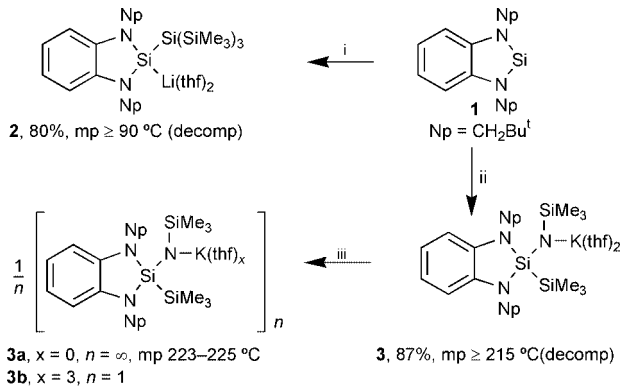
Received (in Cambridge, UK) 15th May 2000, Accepted 15th June 2000

The silylene Si[(NCH$_2$Bu^t)$_2$C$_6$H$_4$-1,2] 1 inserts into the Li–Si bond of Li[Si(SiMe$_3$)$_3$](thf)$_3$ to afford the new silyllithium compound Li[(1)Si(SiMe$_3$)$_3$](thf)$_2$ 2, whereas 1 with K[N(SiMe$_3$)$_2$] yields the amidopotassium compound K[N(SiMe$_3$){(1)(SiMe$_3$)}](thf)$_x$ [x = 0 (3a) or 3 (3b)]; the X-ray structures of the crystalline mononuclear complex 2 and the polymeric aggregate 3a are reported, and NMR spectra show that in solution 2 is in equilibrium with its factors.

We report the first examples of reactions of a divalent, two-coordinate group 14 element compound EX_2, which with an anionic reagent MX′ yield four-coordinate E-atom adducts. For the present, they relate to systems in which EX_2 is the thermally stable silylene **1**[1] and MX′ is Li[Si(SiMe$_3$)$_3$](thf)$_3$ **A** or K[N(SiMe$_3$)$_2$]. Although these reactions took place under mild conditions, their outcome was different (Scheme 1). Thus, the 1:1-adduct was the product of insertion in the former case, but a rearranged product in the latter. They were isolated as (i) the crystalline, mononuclear bis(thf)[(sisyl)silyl]lithium complex **2**; and (ii) the solid bis(thf)potassium amide **3**, which upon recrystallisation gave the polymeric neutral donor-free potassium amide **3a** and the tris(thf) complex **3b**. The molecular structures of **2**, **3a** and **3b** have been determined;‡ discussion of **3b** is deferred to the full paper, as is the formation of the Li analogue of **3** from Li[N(SiMe$_3$)$_2$] and **1**.

Each of the yellow (**2**) or colourless (**3** and **3b**) complexes gave satisfactory microanalyses. The EI-mass spectra of **3** and **3a** were identical and, as for **2**, the major *m/z* peaks corresponded to the appropriate fragments: [anion]$^+$ and [anion − Bu^t]$^+$.

In solution, the lithium complex **2** was shown to be in equilibrium with its precursors, as demonstrated particularly clearly by VT ^{29}Si{^{1}H}-NMR spectra. Thus, dissociation was complete at ambient temperature, but was negligible at 213 K; a ^1J(^{29}Si^{7}Li) was not observed, probably due to the fast exchange process. Complex **3b** retained its structural integrity at 298 K. The data, with those for **1**,[1] Li[Si(SiMe$_3$)$_3$](thf)$_3$,[2]



Scheme 1 Synthesis of the alkali metal complexes **2**, **3**, **3a** and **3b**. *Reagents and conditions*: i, [Li{Si(SiMe$_3$)$_3$}(thf)$_3$], C$_6$H$_{14}$, −30 °C; ii, ½ [KN(SiMe$_3$)$_2$]$_2$, thf, −30 °C; C$_6$H$_{14}$–thf, 0 °C (**3a**), −25 °C (**3b**); iii, **3a** (at *ca*. 20 °C), **3b** (at −25 °C) recrystallised from hexane–thf solution.

[a] Solvent (*T*/K): **A**, C$_7$D$_8$ (298); **1**, C$_6$D$_6$ (298); **2**, C$_7$D$_8$–thf (213, [298]); **3a**, C$_7$D$_8$–thf (298); **B**, C$_6$D$_6$ (303); **C**, thf (273).

Li[N(SiMe$_3$){Si(SiMe$_3$)$_3$}]^3 **B** and Li[Si(Ph)(NEt$_2$)$_2$](thf)$_3$,[4] are shown in Table 1.

Complex **2** (Fig. 1) has the lithium atom in a three-coordinate, distorted trigonal-planar environment. The silyl anion is pyramidal at the Si(1) atom with respect to its contiguous Si(2), N(1) and N(2) atoms; the sum of the angles subtended by these three neighbouring atoms is low, 295.4°, as a consequence of the small bite angle of the adjacent chelating ligand; *cf*. 307.2° in Li[Si(SiMe$_3$)$_3$](thf)$_3$ **A**[2] and 309.8° in Li[Si(Ph)(NEt$_2$)$_2$](thf)$_3$ **C**.[4] The Li–Si(1) distance of 2.609(4) Å in **2** is slightly shorter than the 2.644(12) Å in **A** or 2.732(7) Å in **B**. The Si(1)–Si(2) bond length of 2.493(1) in **2** is longer than the mean Si$_\alpha$–Si$_\beta$ bond length of 2.330(2) Å in **A**. The mean Si–N bond length of 1.801(3) Å in **2** [1.800(4) Å in **3a**] is longer than the 1.75(1) Å in **1**, and the N(1)–Si(1)–N(2) bond angle of 87.25(8)° is slightly more acute than the 88.2(1)° in **1**, or the 88.15(6)° in **3a**.

The potassium amide **3a** comprises mononuclear units (Fig. 2), each linked to its neighbours by close K···*C*(17)H$_3$ [3.268(2) Å] and K··η^3-C$_6$H$_4$ [mean K···*C*(*o, m, m'*) 3.17 Å] contacts (Fig. 3). Similar intermolecular contacts are known in various potassium amides and alkyls.[5] Associated with K···*C*(17)H$_3$ is

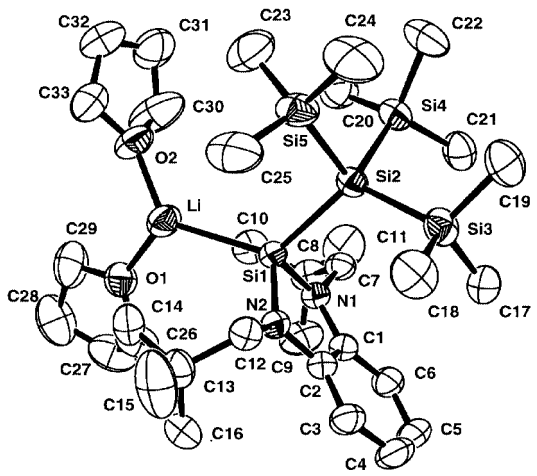

Fig. 1 Crystal structure of **2**.

DOI: 10.1039/b003833o

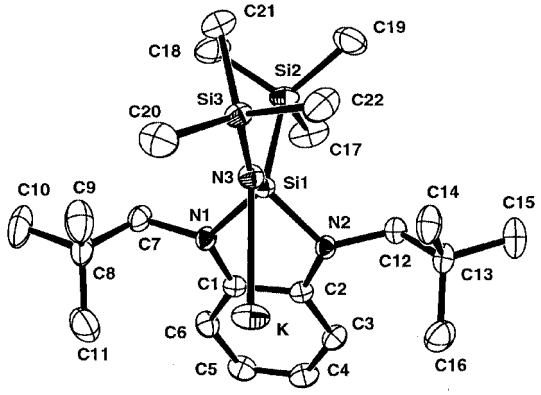

Fig. 2 Crystal structure of **3a**.

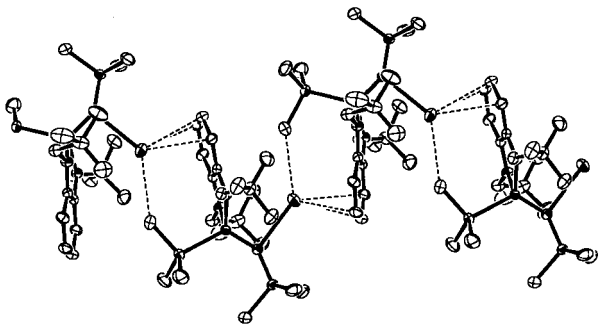

Fig. 3 Intermolecular contacts in **3a**.

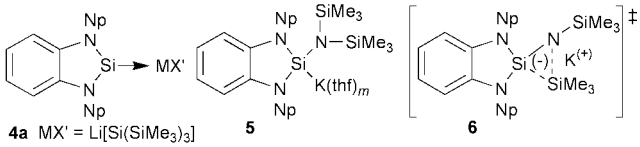
the narrower Si(1)–Si(2)–C(17) angle of 105.84(7)°, compared with the mean of Si(1)–Si(2)–C(18 or 19) of 113.7(3)°. The amido nitrogen atom N(3) is in a planar environment, the Si(1)–N(3)–Si(3) angle of 144.40(9)° being only *ca.* 10° narrower than that in the separated $[N(SiPh_3)_2]^-$ anion of $[Li(12\text{-crown-}4)_2][N(SiPh_3)_2]\cdot thf$,[6] but much wider than the 136(1)° in $[K\{N(SiMe_3)_2\}(thf)_2]$.[7] The N–Si bond lengths of 1.64(1) Å in the latter is close to the 1.6302(13) Å for Si(1)–NK in **3a**, but is significantly shorter than the Si(3)–NK bond length, 1.6739(14) Å. The N–K distance of 2.6938(14) Å in **3a** is unexceptional; *cf.* 2.70(2) Å in $[K\{N(SiMe_3)_2\}(thf)_2]$.[7]

The pathways to **2** or **3**, from **1** and $Li[Si(SiMe_3)_3](thf)_3$ or $K[N(SiMe_3)_2]$, probably require that in the first step the silylene **1** behaves as a nucleophile yielding the appropriate adduct



$X_2E{:}MX'$ (**4a** or **4b**). Complex **2** is presumed to arise from **4a** by insertion of X′ into the E–M bond, and a similar step from **4b** would yield **5**. Complex **3** is believed to be formed by a final Me_3Si shift from the N to Si, either from **5** (a 1,2-shift; *cf.* the transition state **6**) or **4b** (a 1,3-shift). Although anionic trimethylsilyl shifts are well documented,[8] this, we believe, is the first N→Si example. Precedents for $X_2E{:}MX'$ adducts in group 14 element chemistry include (i) silylene–(Ni^0 or Pt^{II}) complexes such as $[Ni(\mathbf{1})_4]$ and *trans*-$[Pt\{(\mathbf{1})Cl_2\}_2(\mathbf{1})_2]$[9] and (ii) carbene–(MX′) complexes such as $[Li\{C[N(Bu^t)CHCHN\text{-}Bu^t]\}\{\eta^5\text{-}C_5H_2(SiMe_3)_3\text{-}1,2,4\}]$[10] and $[K\{C[N(Pr^i)(CH_2)_3N\text{-}Pr^i]\}\{\mu\text{-}N(SiMe_3)_2\}]_2$,[11] and (iii) stannylene–MCp complexes such as $SnCp_2(\mu\text{-}Cp)Na$ from $SnCp_2$ + NaCp.[12] Alternative EX_2/MX' reactions have led to X/X′ exchange as in (i) $SnCp_2$ + $LiN(SiMe_3)_2$ yielding $Sn(Cp)[N(SiMe_3)_2](\mu\text{-}Cp)Li(pmdeta)$,[13] and (ii) $SnCp^*_2$ + $Li[CH(SiMe_3)_2]$ affording $Sn[CH(SiMe_3)_2]_2$ + $LiCp^*$.[14] Insertion reactions of **1** into O–H, C–I, Ge^{II}–N, Sn^{II}–C, Sn^{II}–N or Pb^{II}–N bonds have been reported, as with $M'[N(SiMe_3)_2]_2$ to give $M'[\mathbf{1}\{N(SiMe_3)_2\}]_2$ (M′ = Sn **7** or Pb).[15] The rearrangement **5**→ **3** cannot be due to the lability of the anion $\{(\mathbf{1})\{N(SiMe_3)_2\}\}^-$, since it is found in **7** as a ligand. We suggest that **3** may be favoured, at least in part, by the strong Si–Si bond, as evident by its short [2.359(1) Å in **3a**] bond length, comparable with the av. Si–Si bond distance of 2.379 Å in **2**. However, according to bond dissociation energy data a migration of Me_3Si from nitrogen to silicon is unexpected.[16] The facile dissociation of **2** is probably due to steric constraints, consistent with the long Si–Si($SiMe_3$) bond of 2.493(1) Å and the narrow N–Si–Si angles, av. 103.9(6)°.

The present results significantly extend the already substantial boundaries of silylene reaction types. From work in progress, we anticipate that several new silicon-centred ligands $[(\mathbf{1})X']^-$ (that in **2** being a forerunner) will become available for use for a wide range of metals, and that the exceedingly bulky amido ligand present in **3** will find a useful role.

We thank the EPSRC for an Advanced Fellowship for B. G., the Free University of Amsterdam for support for J. C. S., and Dr A. G. Avent for the ^{29}Si NMR spectroscopic data.

Received (in Cambridge, UK) 9th May 2000, Accepted 19th June 2000

Tripodal ligand 1,3,5-tris(1-methylimidazol-2-ylmethyl)-2,4,6-trimethylbenzene (3) forms a parachute-like non-covalent complex with zinc tetrachloride, 5·[Zn_2Cl_6]$_{0.5}$, where the imidazoles of the ligand are protonated and bind to the metal ion through NH···Cl hydrogen bonds.

Although biological systems efficiently organize simple units into aggregates with intricate and wonderful functions by non-covalent interactions, self-assembly of frameworks with specific topology, interesting properties and functions is still a challenge for chemists.[1] A number of hydrogen-bonded aggregates have been obtained by self-organization of organic or organic–inorganic components.[1–3] We herein report a parachute-like complex obtained by assembly of organic tripodal ligand 1,3,5-tris(1-methylimidazol-2-ylmethyl)-2,4,6-trimethylbenzene (**3**) and inorganic zinc tetrachloride. In this complex, protonation of the imidazoles of the ligand and its binding to the metal ion through NH···Cl hydrogen bonds provides a good example of a dual role for a single ligand.

We are currently engaged in the systematic study of self-assembly of tripodal ligands **1**–**4** (Scheme 1) with various metal ions and are investigating the influence of linkage mode of bridging ligands on the assembly process of supramolecular complexes.[4] Up to now, tripodal ligands **1** and **2**, and others also having benzene or other arene as the ring core such as 2,4,6-tris(4-pyridyl)-1,3,5-triazine, 1,3,5-tris(pyrazol-1-ylmethyl)-2,4,6-triethylbenzene have been reported to form polymeric networks or multinuclear metallocages with metal ions.[4,5] The ligand **3** was demonstrated for the first time to form a parachute-like non-covalently bonded complex with zinc tetrachloride. [$ZnCl_4$]$^{2-}$ has been used as a counterion for crystallization of Ru(II) and Co(II) complexes.[6,7] In the present complex, this anion binds to **3** through NH···Cl interactions in which the Cl atom acts as an acceptor of hydrogen bonds.

	R	X
1	CH_3	Imidazol-1-yl
2	H	Imidazol-1-yl
3	CH_3	1-Methylimidazol-2-yl
4	H	Benzimidazol-2-yl

Scheme 1 *Reagents*: i, $ZnCl_2$ + HCl; ii, $Ru(DMSO)_4Cl_2$. For details see notes of preparations.

Assembly of **3**† with $ZnCl_2$ in hydrochloric acid solution gave the hydrogen bonded complex, **5**·[Zn_2Cl_6]$_{0.5}$ (Scheme 1).‡ As shown in Fig. 1,§ all three imidazole groups of **3** are protonated which was confirmed by IR spectral measurements. The distances between each imidazole proton and Cl(12) ranges from 2.32 to 2.45 Å which indicates the presence of triple N–H···Cl hydrogen bonds. Therefore, **5** looks like a parachute in which [$ZnCl_4$]$^{2-}$ acts as an appending group. The atom Cl(12) is located under **3** with a distance of 3.43 Å between Cl(12) and the center of the benzene ring plane. Two adjacent molecules of **5** with normal and upside down orientations linked by hydrogen bonds are illustrated in Fig. 2(a). There are four additional hydrogen bonds in each [$ZnCl_4$]$^{2-}$ unit excluding the triple N–H···Cl(12) bonds described above: C(14)–H···Cl(11) [$r_{C(14)–Cl(11)}$ = 3.517(8) Å], C(11A)–H···Cl(11) [$r_{C(11A)–Cl(11)}$ = 3.707(6) Å], C(54)–H···Cl(13) [$r_{C(54)–Cl(13)}$ = 3.602(7) Å] and C(101A)–H···Cl(14) [$r_{C(101A)–Cl(14)}$ = 3.768(8) Å]. The unit shown in Fig. 2(a) can be repeated and joined by

$[Zn_2Cl_6]^{2-}$ through hydrogen bonds to generate an infinite one-dimensional chain [Fig. 2(b)]: C(301A)–H···Cl(22) [$r_{C(301A)–Cl(22)}$ = 3.620(8) Å] and C(21A)–H···Cl(22) [$r_{C(21A)–Cl(22)}$ = 3.530(8) Å].

Another coordination mode of such a tripodal ligand is the encapsulation of the metal ion with additional coordination to the benzene ring as demonstrated by Hartshorn and Steel.[6] We are also studying the reactions of **3** with other metal salts. The reaction between **3** and $Ru(DMSO)_4Cl_2$ was investigated by electrospray mass (ES-MS) spectrometry and NMR spectroscopy.¶ Four main peaks at *m*/*z* 202.3, 252.3, 403.4 and 420.8 were observed which correspond to $[\mathbf{3} + 2H]^{2+}$, $[Ru(\mathbf{3})]^{2+}$, $[\mathbf{3} + H]^+$ and $[\mathbf{3} + H_2O + H]^+$, respectively. All these assignments were confirmed by good agreements between the observed and calculated isotopic distributions. The results of ES-MS imply that only the mononuclear Ru(II) complex is formed by the reaction of **3** with $Ru(DMSO)_4Cl_2$. In the ^{13}C NMR spectrum of **6**·Cl_2, the benzene ring carbons were shifted upfield by *ca.* 32 ppm compared with the corresponding signals of **3**. The NMR study suggests the coordination of Ru to the benzene ring of **3**.[6]¶ This means that **3** may encapsulate the Ru(II) ion (**6**) as shown in Scheme 1.

In conclusion, the present study shows that the novel tripodal ligand **3** can append to the metal ion through non-covalent interactions and encapsulate the metal ion through chelation and η^6-arene coordination.

The authors are grateful for funding from the National Nature Science Foundation of China for financial support of this work.

Notes and references

† The ligand **3** was prepared from 1,3,5-tris(bromomethyl)-2,4,6-trimethylbenzene, 1-methylimidazole and *n*-BuLi using standard Schlenk techniques in 45% isolated yield. $\delta_H(CDCl_3)$: 7.05 (s, 3H), 6.91 (s, 3H), 4.24 (s, 6H), 3.90 (s, 9H), 2.07 (s, 9H).

‡ *Experimental*: a solution of **3** (40.2 mg, 0.1 mmol) in MeOH (5 ml) was added to a 1 M HCl (10 ml) solution of $ZnCl_2$ (40.8 mg, 0.3 mmol) at room temperature. The mixture was filtered after stirring for about 10 min and the filtrate was stood at *ca*. 40 °C for several days. Light yellow crystals were collected in *ca*. 60% yield. Macroanal. Found: C, 36.64; H, 4.22; N, 10.66. $C_{24}H_{33}N_6Cl_7Zn_2$ requires C, 36.75; H, 4.24; N, 10.71%. $\delta_H(D_2O$, 298 K): 7.32 (s, 3H), 7.12 (s, 3H), 4.42 (s, 6H), 3.83 (s, 9H), 2.05 (s, 9H).

§ *Crystal data* for **5**·$[Zn_2Cl_6]_{0.5}$ ($C_{24}H_{33}N_6Cl_7Zn_2$): M = 784.50, triclinic, space group $P\bar{1}$, a = 13.593(4), b = 13.788(4), c = 10.821(3) Å, α = 108.41(2), β = 112.25(2), γ = 104.09(2)°, U = 1621(1) Å^3, Z = 2, D_c = 1.606 g cm^{-3}, μ = 2.081 mm^{-1}, $F(000)$ = 796, T = 296(1) K. The data collection was carried out on a Rigaku AFC5R four-circle diffractometer by $\omega - 2\theta$ scan techniques using graphite-monochromated Mo-Kα radiation (λ = 0.7107 Å). Total 7720 reflections were collected of which 7408 are independent (R_{int} = 0.017). The structure was solved by direct methods with SIR92 and refined by full-matrix least-squares calculations. The final $R1$ = 0.0431[$I > 2\sigma(I)$], max., min. residual density: +0.80, −0.96 e Å^{-3}. CCDC 182/1693. A novel open-framework aluminophosphate $[AlP_2O_6(OH)_2][H_3O]$ containing propeller-like chiral motifs

Wenfu Yan, Jihong Yu, Zhan Shi and Ruren Xu*

Key Lab of Inorganic Synthesis and Preparation Chemistry, Department of Chemistry, Jilin University, Changchun 130023, P.R. China. E-mail: rrxu@mail.jlu.edu.cn

Received (in Cambridge, UK) 25th May 2000, Accepted 21st June 2000

A new open-framework aluminophosphate containing propeller-like chiral motifs has been synthesized solvothermally using 2-aminopyridine as the structure-directing agent and its structure is determined by single-crystal X-ray diffraction.

During recent decades, a large number of microporous aluminophosphates have been synthesized which exhibit various novel framework topologies, as well as analogous structures with known zeolites.[1–3] However, the preparation of chiral open-framework aluminophosphates, of potentially important application in asymmetric synthesis and separation, has been less successful. The introduction of chirality into the open-framework using traditional template molecules, such as chiral organic amines, is found to be particularly difficult. However, recently the employment of chiral metal complexes as template agents has promoted the formation of a few layered compounds with chirality or chiral motifs in their porous sheets, such as GeTex1,[4] GeTex2,[5] GeTex3[6] and d-$Co(en)_3 \cdot Al_3P_4O_{16} \cdot 3H_2O$.[7] To our knowledge, there are no three-dimension (3D) open-framework aluminoposphates with chirality or chiral structural subunits. Here, we report a novel 3D open-framework aluminophosphate (denoted AlPO-CJ4) synthesized using 2-aminopyridine as a structure-directing agent. It consists of propeller-like chiral motifs with both Δ and Λ configurations.

Large single crystals of AlPO-CJ4 were prepared in a gel system with molar composition 1.0 $Al(OPr^i)_3$: 2.4 H_3PO_4: 2.0 2-aminopyridine: 20 2-BuOH. Typically, 1.0 g of finely ground aluminium triisopropoxide was first dispersed into 9 mL butan-2-ol solvent with stirring, followed by addition of 0.9 g of 2-aminopyridine. Phosphoric acid (85 wt%, 0.8 mL) was finally added dropwise to the above reaction mixture with stirring. A sticky gel was formed, and was transferred into a Teflon-lined stainless autoclave and heated at 180 °C for 8 days under autogeneous pressure. The product was filtered off and washed thoroughly with deionized water and dried at 70 °C. X-Ray powder diffraction patterns were recorded on a Simens D5005 X-ray diffractometer with Cu-Kα radiation (λ = 1.5418 Å). The experimental powder X-ray diffraction (XRD) pattern of AlPO-CJ4 accords with the simulated pattern derived from structural data (Fig. 1), establishing the as-synthesized product as a single phase.

Inductively coupled plasma (ICP) analysis performed on a Perkin-Elmer Optima 3300 DV ICP instrument gives Al and P contents in the product as 11.7 and 25.3%, respectively. This is in agreement with calculated values of 11.3% and 26.1% based on the formula of $[AlP_2O_6(OH)_2][H_3O]$ revealed by single-crystal structure analysis. Single crystal structure analysis, as well as elemental analysis, shows that no 2-aminopyridine is involved in the product. However, 2-aminopyridine is found to be necessary for the formation of AlPO-CJ4. If other organic amines such as 2-methylpyridine are used instead to 2-aminopyridine in the reaction mixture, only the dense phase berlinite is obtained. This demonstrates that the organic additive plays an important structure-directing role as in case of VPI-5.[8]

A single crystal of AlPO-CJ4 with dimensions of 0.08 × 0.06 × 0.04 mm was glued to a fine glass fiber and mounted on a three-circle fixed Siemens diffractometer fitted with a Bruker SMART CCD detector.

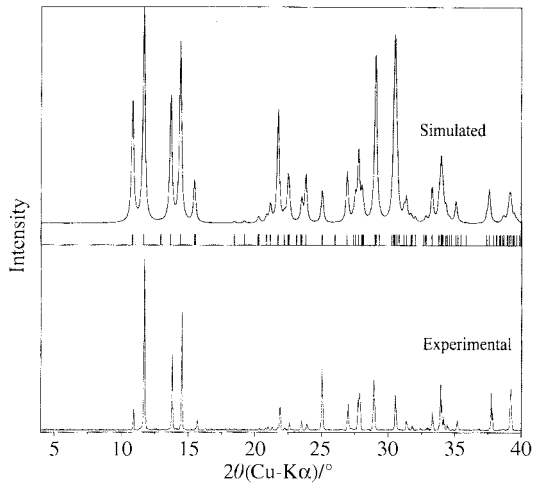

Fig. 1 Experimental and simulated powder X-ray diffraction patterns of AlPO-CJ4.

Structure analysis† indicates that AlPO-CJ4 crystallizes in the $P\bar{1}$ space group. The structure of AlPO-CJ4 is constructed by alternation of AlO_6 octahedra and $PO_3(OH)$ tetrahedra *via* vertex oxygen atoms. To our knowledge, this is the first open-framework AlPO, in which the primary Al building unit is solely made up of AlO_6 octahedra with all six oxygen vertices being shared by adjacent P atoms. Also, it is the first 3D aluminophosphate with an Al:P ratio of 1:2, distinct from previous $AlP_2O_8^{3-}$ aluminophosphates with 1D chain[9,10] and 2D layer structures.[11–13]

Interestingly, the structure of AlPO-CJ4 features chiral propeller-like motifs as found for $Co(en)_3^{3+}$, as can be seen in Fig. 2. This chiral motif is formed by Al(2)-centered octahedra with three cyclic four-membered rings. The O–Al–O bond

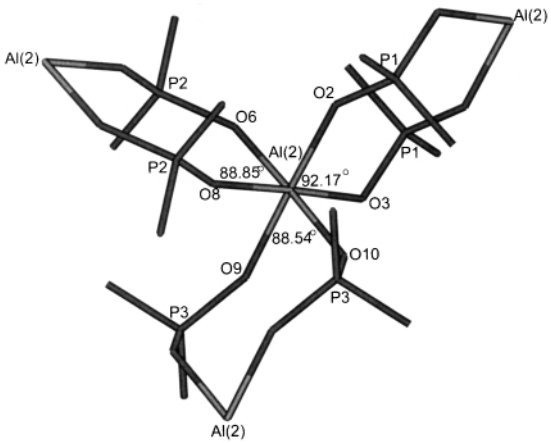

Fig. 2 A propeller-like chiral motif formed by three cyclic four-membered rings.

angles for the three blades of the propeller are 88.85, 88.54 and 92.17°. These chiral motifs are connected with each other to form a puckered 2D layer parallel to the *ab* plane, which contains double crown-like 12-membered rings as shown in Fig. 3. Each 12-membered ring is surrounded by six chiral motifs with three of Δ- and three of Λ-configuration. The 2D layers are connected *via* Al(1) atoms lying at inversion centers to form the 3D open-framework ofAlPO-CJ4 (Fig. 4), with interconnecting 8-MR channels along the [100], [010] and [001] directions.

The protonated water molecules, which balance the negative charge of the framework, are trapped in the channels, and interact with the terminal oxygens attached to P atoms through

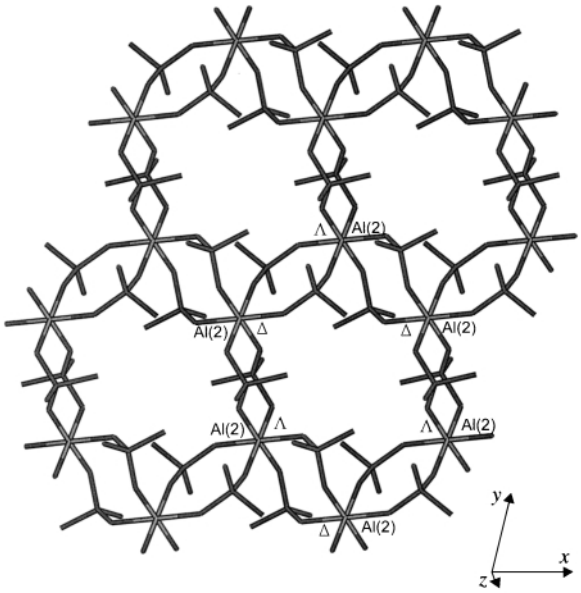

Fig. 3 2D layer formed by connecting the chiral motifs; Δ and Λ indicate the absolute configurations of the motifs.

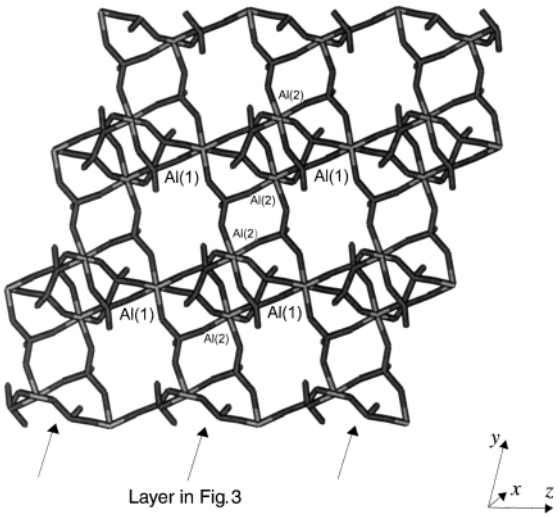

Fig. 4 3D open-framework forming by connecting the 2D layers *via* Al(1) atoms, viewed along the [100] direction. Water molecules in the channel are not shown.

H-bonds with $O_W \cdots O_{terminal}$ distances in the range 2.853–3.086 Å. Energy calculations employing Cerius[2] using the Burchart 1.01-Dreiding 2.21 force field[14,15] gives the H-bonding interaction energy between the framework and occluded water molecules as −10.0 kcal mol^{-1} per unit cell. It is believed that the water molecules play an important role in the stabilization of the open-framework of AlPO-CJ4. By contrast, the structure-directing agent 2-aminopyridine is too large to be accommodated in the 8-MR channel of AlPO-CJ4 and may be the reason why 2-aminopyridine is not involved in the structure.

In summary, a novel 3D aluminophosphate compound consisting of chiral motifs was synthesized from a solvethermal system using 2-aminopyridine as a structure-directing agent. Propeller-like chiral motifs are connected to each other and form a 2D layer and further construct a 3D open-framework *via* Al(1) atoms. The discovery of such chiral structural motifs will open up the possibility for the rational design of chiral microporous materials.

Received (in Oxford, UK) 23rd May 2000, Accepted 21st June 2000

A new kind of nanoreactor has been prepared by the incorporation of a channel protein into the shell of (polymerized) vesicles formed from an amphiphilic ABA-triblock copolymer.

A major goal in material science is to miniaturize processes down to the nanometer level. One typical example is the formulation of hollow nanoparticles of reproducible size. For such nanocontainers a widespread range of applications have been suggested. For example, one can think about chemistry in a confined volume under controlled conditions, or protection of guest molecules like enzymes against an hostile outside environment (*e.g.* protease). Such an environment requires a stable shell with a selective permeability.[1] In recent years considerable progress has been made in developing synthetic approaches to control the size and morphology of such particles.[2] Recently we reported a mild procedure for the preparation of stable nanocapsules from an amphiphilic poly(2-methyloxazoline)-block–poly(dimethylsiloxane)-block–poly(2-methyloxazoline) triblock copolymer (PMOXA-PDMS-PMOXA) which carried polymerizable groups at both ends.[3]

This polymer aggregates spontaneously in dilute aqueous solution into vesicular structures, the sizes of which can be controlled in the range 50 to 500 nm.[3] These aggregates can be considerably stabilized by a subsequent crosslinking polymerization of the reactive end groups of the underlying triblock copolymers. In the resulting nanocapsules all the individual block copolymers are interconnected *via* covalent bonds to a giant 'supermacromolecule'. Fig. 1 shows a characteristic cryogenic transmission electron micrograph (Cryo-TEM) of polymerized triblock copolymer vesicles. The thickness of the triblock copolymer shells is estimated to be about 10 nm, in good agreement with previous findings.[3,4]

Prior to any use of these polymer shells as nanosized reactors one had to find ways to control their permeability. Here we suggest the encapsulation of an enzyme. The enzyme should stay trapped in the interior of the particles while the substrates should be able to diffuse into, and the products out of, the nanoreactors. However, owing to their higher hydrophobic thickness, the triblock copolymer shells are even less permeable to small hydrophilic solutes than conventional phospholipid bilayers.[4–7]

Nature provides a great variety of passive or specific channels which allow the permeation of specific substrates across biological membranes. The lipid bilayer serves as a matrix for such channel proteins. However, many of the membrane proteins require a specific lipid composition, hydrophobic thickness or change distribution to be fully functional. The PMOXA-PDMS-PMOXA triblock copolymer behaves in aqueous solution in many respects like a higher molecular weight analogue of conventional lipids.[3,4] Therefore, in order to control the permeation we wanted to make use of such natural membrane proteins and tried to reconstitute them into our polymeric nanocapsules. (See Fig. 2 for a schematic representation of the resulting nanoreactor).

The block copolymer membranes are considerably thicker than conventional lipid bilayers ($d \approx 5$ nm)[3–7] due to the larger size of the underlying block copolymer molecules. The hydrophobic–hydrophilic pattern of membrane proteins are naturally optimized with respect to the thinner biological membranes and the hydrophobic part of channel forming proteins may therefore be too small to fit through the polymer membranes. This raises the question of whether the proteins can preserve their activity within a block copolymer membrane. However, the high flexibility and the conformational freedom of the polymer molecules may allow a block copolymer membrane to adapt to the specific geometric and dynamic requirements of membrane proteins without considerable loss of free energy. In such a case it is expected that the protein will remain functional.

To control the permeability of the nanocapsules we used a well-characterized nonspecific membrane channel, the bacterial porin OmpF.[8,9] Porins are transmembrane proteins which form trimeric channels in the outer membrane of Gram-negative bacteria. These water-filled channels allow passive diffusion of small solutes like ions, nutrients or antibiotics across the

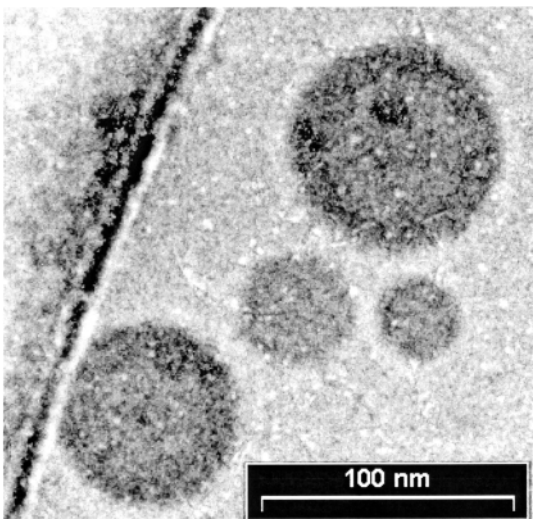

Fig. 1 Cryo-transmission electron micrograph of polymerized triblock copolymer vesicles.

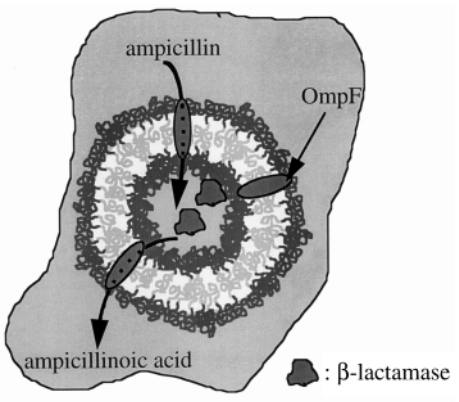

Fig. 2 Schematic representation of a β-lactamase-containing nanoreactor prepared from an amphiphilic triblock copolymer and the porin OmpF.

DOI: 10.1039/b004280n

membrane. Molecules with a molecular weight above 400 Da are sterically excluded.

The procedure used to prepare the nanoreactors was analogous to that of the (polymerized) triblock copolymer vesicles described previously.[3] Although the porin could also be incorporated into performed vesicles the following procedure turned out to be more convenient. A stock solution of the porin (13.3 mg mL^{-1} in 1 wt% octylpolyoxyethylene, 100 nM NaCl and 10 mM HEPES,† pH 7.4) was mixed with a 17 wt% solution of the triblock copolymer (M_n = 9000 Da) in ethanol to a final molar ratio of 1:1000 (protein:polymer). For encapsulation of the enzyme in the interior of the porin-containing vesicles, the clear and homogeneous solution was slowly added to an aqueous β-lactamase solution (0.024 mg mL^{-1} in 10 mM HEPES, 100 mM NaCl, pH 7.4) to a final triblock copolymer concentration of 1 wt%. Then the resulting dispersion was repeatedly extruded through filters of a defined pore size (Nucleopore filters (Millipore); pore width 200 nm). This gave rather monodisperse triblock copolymer vesicles with an average diameter of 250 nm.[3] Non-encapsulated protein was removed chromatographically (Sephadex G-200) from the porin-containing vesicles. If desired, a crosslinking polymerization of the methacrylate end-groups of the underlying triblock copolymers could subsequently be initiated by irradiating the vesicles dispersion for 2 min with UV-light. Previous investigation had shown that under these conditions the conversion of the methacrylate end-groups is > 90%.[3]

It is well-known that the enzyme β-lactamase is able to hydrolyze β-lactam antibiotics like ampicillin. This reaction can be used to assay, *via* a secondary reaction, the activity of the enzyme.[10,11] In contrast to ampicillin, the product of the hydrolysis (the ampicillinoic acid) can reduce iodine to iodide. This can readily be monitored by micro-iodometry, *i.e. via* the decolorization of a starch–iodine complex.[10,11]

In the present system the enzyme is immobilized in the aqueous core domain of the nanocapsules. Consequently, prior to hydrolysis the ampicillin has to enter the interior of the polymer particles. To check the functionality of the system we added 10 μL of a 1 mM ampicillin solution (in 10 mM HEPES, 100 mM NaCl, pH 7.4) to the nanoreactor dispersion and incubated the resulting mixture for 30 min. Starch-iodine reagent was prepared by mixing 5 mL of a 8 mM iodine, 320 mM potassium iodide solution with 20 mL 1 M sodium wolframate in 2 M acid acetic and then adding 5 mL of 2 wt% soluble starch which had been dissolved in 1 M acetic acid by gentle boiling for 3 min. Subsequently 0.5 mL of the starch–iodine reagent was added to the reaction mixture and the absorbance of the starch–iodine complex at 623 nm was measured as a function of time.[10,11] The results are shown in Fig. 3 together with the control experiments for the free, non-encapsulated enzyme and nanocapsules without OmpF channels. It is important to note that within the experimental error the results before and after polymerization of the triblock copolymer shells were always the same and subsequently discussed together.

For the nanocapsules made in the absence of porin the absorbance remained constant over the time course of the experiment. As expected, the ampicillin is not able to diffuse across the thick triblock copolymer shells. It is not therefore hydrolyzed by the enzyme and the iodine is not reduced. In contrast to that for the OmpF-containing nanoreactors the absorbance of the complex decreases slowly with time due to the reduction of the iodine. Obviously the channel protein remains functional despite the extreme thickness of the triblock copolymer shells and even the crosslinking polymerization of the reactive triblock copolymers does not affect its conformation. This is in agreement with systematic investigations on membrane proteins reconstituted into planar triblock copolymer membranes.[4]

Inspection of Fig. 3 shows that the reaction rate of encapsulated enzyme is lower than in the control experiment using free enzyme. This is due to the slow diffusion of the ampicillin and the ampicillinoic acid through the rather limited

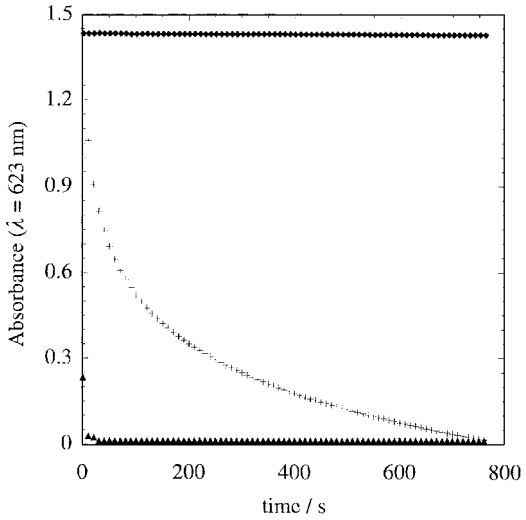

Fig. 3 Time profile of the absorbance of the starch–iodine complex at 623 nm after 30 min incubation in the presence of 10 μL of a 1 mM ampicillin solution (10 mM HEPES, 100 mM NaCl, pH 7.4). +: poly(2-methyloxazoline)–poly(dimethylsiloxane)–poly(2-methyloxazoline) triblock copolymer (PMOXA-PDMS-PMOXA) nanoreactors; ▲: control with free, non encapsulated enzyme; ◆: control with PMOXA-PDMS-PMOXA nanocapsules without OmpF channels.

number of narrow OmpF channels in the shells of the reactors.

In conclusion, we have shown that functional OmpF channels can be incorporated into the shells of triblock copolymer vesicles. Despite the artificial surrounding within such a polymerized triblock copolymer shell the functionality of the membrane protein is fully preserved. These channels therefore allow a direct access to enzymes encapsulated in the interior of these vesicles. We are currently investigating the extension of this principle to other enzymes and other transport proteins, with the goal of substrate-specific nanoreactors which could find interesting applications in areas like drug delivery or catalysis.

We thank Drs Patrick van Gelder and Alexandra Graff for stimulating discussions. Financial support to the Swiss National Science Foundation is gratefully acknowledged.

Novel layer-type triple salts of silver(I), $AgCN{\cdot}AgF{\cdot}4AgCF_3CO_2{\cdot}2L$ (L = MeCN or H_2O)†

Quan-Ming Wang and Thomas C. W. Mak*

Department of Chemistry, The Chinese University of Hong Kong, New Territories, Hong Kong SAR, P.R. China. E-mail: tcwmak@cuhk.edu.hk

Received (in Cambridge, UK) 12th May 2000, Accepted 19th June 2000

The novel silver(I) triple salts $AgCN{\cdot}AgF{\cdot}4AgCF_3CO_2{\cdot}2L$ (L = MeCN or $2H_2O$) exhibit the same type of layer structure, in which [F@Ag_6] units each representing a fluoride-centred octahedral silver cage are interconnected by μ_4-κ*C*,κ*C*:κ*N*,κ*N*-cyanide and μ_4-*O*,*O*:*O*′,*O*′-trifluoroacetato bridges.

Current interest in cyanide-bridged one-, two- and three-dimensional complexes is focused on not only their structural variety but also their unusual magnetic and electrical properties.[1] In contrast to the common usage of soluble $[Ag(CN)_2]^-$ in the construction of coordination networks, we choose to combine AgCN with soluble silver salts to form crystalline double salts, anticipating that in such a silver-rich environment the cyanide ligand may display unusual bridging modes that lead to the formation of novel 2D or 3D coordination networks. This strategy has yielded a variety of silver(I) double salts of the general formula *m*AgY·*n*AgZ·*x*L (Y, Z = anions; L = solvate molecule that may be present).[2–5] Interestingly, when we attempted to synthesize double salts of the type *m*AgCN·*n*-$AgCF_3CO_2$, an unexpected product $AgCN{\cdot}AgF{\cdot}4AgCF_3CO_2{\cdot}$2MeCN **1** was obtained and structurally characterized. Subsequently, another closely related triple salt $AgCN{\cdot}AgF{\cdot}4AgCF_3$-$CO_2{\cdot}2H_2O$ **2** was accessible by a simple route.

Compound **1** was obtained by dissolving AgCN in an aqueous solution of CF_3CO_2Ag and $AgBF_4$ in the presence of acetonitrile.‡ Deliberate addition of $AgBF_4$ into the solution was intended to increase the Ag^+ concentration to the threshold that is necessary for dissolving AgCN. Although thermal decomposition of CF_3CO_2Ag can release AgF,[6] $AgBF_4$ is more likely the source of F^- in the product. It has been demonstrated that, in some instances, decomposition of BF_4^- into F^- and BF_3 (presumably coordinated to ligand or solvent molecules) can occur in the reactions of transition metal (also including silver) tetrafluoroborate derivatives.[7] Repeating the preparative procedure using AgF instead of $AgBF_4$ improved the yield of **1** and resulted in the formation of **2**.

Single crystal X-ray analysis§ revealed that **1** has a layer structure, a portion of which is illustrated in Fig. 1. The F^- ion located at an inversion center is surrounded by six Ag(I) atoms in the form of a slightly elongated octahedron. The Ag–F distances in the equatorial plane are almost the same at 2.4520(4) and 2.4490(4) Å, whereas the significantly longer axial distance of 2.5759(5) Å can be ascribed to the attachment of a terminal acetonitrile ligand to an axial Ag(I) atom. This [F@Ag_6] octahedron may be compared with the regular one in rock salt-type AgF with Ag–F 2.46 Å.[8] In the 3D framework of $Ag_2C_2{\cdot}8AgF$, in which the fluoride ions act as bridges between [C_2@Ag_9]Ag moieties, the Ag–F distances fall in the range 2.196(2)–2.571(2) Å.[5c] It is noteworthy that there are very few examples of metal polyhdedra enclosing a fluoride ion,[9,10] and to our knowledge the [F@Ag_6] octahedron occurs only in AgF and the present triple salts.

The trifluoroacetato ligand usually acts as a μ_2-bridge in its metal complexes,[11a] and the μ_3-coordination mode is much less common.[11b] In contrast, each trifluoroacetato ligand in **1** functions in an asymmetric μ_4-*O*,*O*:*O*,*O*′ mode [Ag(1)–O(4) 2.455(4), Ag(3)–O(4) 2.562(4) Å, Ag(2)–O(3) 2.458(4), Ag(3)′–O(3) 2.537(3) Å], with its carboxylato group bridging an edge of a [F@Ag_6] octahedron while linking the vertices of two adjacent octahedra (see Fig. 1). Compound **1** thus provides the first example of a trifluoroacetato ligand coordinated to four metal centers, although several carboxylato complexes (especially oxalates) containing a μ_4-carboxylato group have been reported.[12]

The four equatorial Ag(I) atoms of each [F@Ag_6] octahedron are connected to neighboring octahedra through bridging cyanide ligands to generate a 2D $\{[(F@Ag_6)(CN)]^{4+}\}_\infty$ coordination network, as shown in Fig. 2. This linkage pattern is different from those in the double salts $Ag_2C_2{\cdot}2AgClO_4{\cdot}2H_2O$[5a] and $Ag_2C_2{\cdot}AgNO_3$,[5b] in which the [C_2@Ag_6] octahedra share vertices or edges to generate a 2D or 3D network, respectively. The cyanide ion is disordered about a $\bar{1}$ site, and is modeled by atom C1 with an assigned site-occupancy factor of $(6 + 7)/(6 \times 2) = 1.083$ [Ag1–C1 2.232(5) and Ag2–C1 2.234(5)]. The cyanide ligand with C–N bond length 1.108(9) Å bridges four [F@Ag_6] octahedra in a rare μ_4-κ*C*,κ*C*:κ*N*,κ*N* ligating mode, the only precedent being found in $3AgCN{\cdot}2AgF{\cdot}3H_2O$,[2] in which bent Ag_2F_2 and triangular [$Ag_3(H_2O)_3$] units are interconnected by μ_4- and μ_3-cyanide groups.

The 2D network lies in the (100) plane, and the acetonitrile ligands and hydrophobic tails of trifluoroacetato groups are accommodated in the interlayer region with a layer-to-layer separation of $a\sin\beta$ = 13.90 Å.

The layer structure of **2**§ is formally derived from that of **1** with each acetonitrile ligand replaced by a smaller aqua ligand. The [F@Ag_6] octahedron in **2** exhibits some distortion in the equatorial plane with Ag–F bond lengths of 2.371(3), 2.379(3), 2.464(3) and 2.484(3) Å, whereas the axial Ag–F distances are 2.585(3) and 2.589(3) Å. The more condensed packing of layers

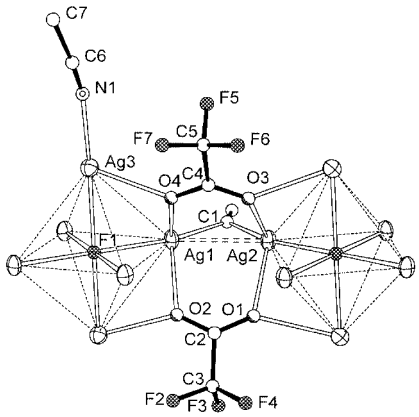

Fig. 1 A portion of the layer structure of $AgCN{\cdot}AgF{\cdot}4AgCF_3CO_2{\cdot}2$MeCN **1** with labeling of atoms in the independent unit. Ag(I) atoms are drawn as 30% thermal ellipsoids and the remaining atoms are differentiated by size and shading. The edges of each Ag_6 octahedron, which lie in the range 3.463–3.562 Å, are outlined by dotted lines. The Ag1···Ag2 distance is 2.8835(8) Å.

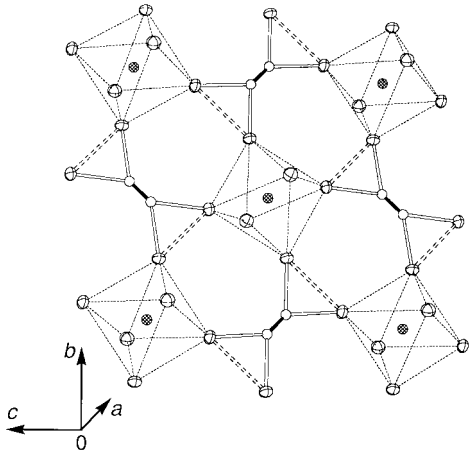

Fig. 2 A two-dimensional $\{[(F@Ag_6)(CN)]^{4+}\}_\infty$ network in **1**.

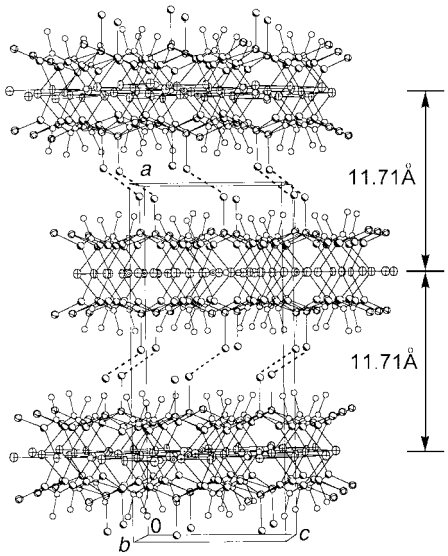

Fig. 3 Crystal structure of $AgCN{\cdot}AgF{\cdot}4AgCF_3CO_2{\cdot}2H_2O$ **2** viewed approximately in the *b* direction. Hydrogen bonds between aqua ligands of adjacent layers are represented by broken lines. All F atoms have been omitted for clairty.

in **2** yields an interlayer separation of $(a\sin\beta)/2$ = 11.71 Å, shorter by *ca.* 2.1 Å than that in **1**. Adjacent layers are related by a 2_1 axis along the *b* direction, which leads to the ABAB··· packing shown in Fig. 3 This is different from the case in **1**, where the layers are related by lattice translation *a*. The outstretched aqua ligands of adjacent layers in **2** form weak hydrogen bonds of the type O1w··O1w′ = 3.020 and O2w··O2w′ = 3.027 Å in successive interlayer regions, linkings the layers into a 3D network. This kind of packing may account for equatorial distortion of the $[F@Ag_6]$ unit in **2**, in contrast to that in **1**.

The present work describes the first structural characterization of novel silver(I) triple salts of the type *l*AgX·*m*AgY·*n*AgZ·*x*L, in which octahedral $\{F@Ag_6\}$ units are consolidated by μ_4-κ*C*,κ*C*:κ*N*,κ*N*-cyanide and μ-*O*,*O*:*O*′,*O*′-carboxylato groups. Notably, the propensity of all three anions to attain their highest ligation numbers,[4a] along with agentophilicity [attractive interaction between silver(I) atoms to form aggregates],[2,13] provide the driving force to assemble the robust $[(F@Ag_6)(CN)(CF_3CO_2)_2]_\infty$ layer from its components.

Dissolving AgCN in a concentrated silver salt solution may lead to the formation of some $[Ag_n(CN)]^{(n-1)+}$ species, which is comparble to the complexation of CuI to yield $[CuI_4]^{3-}$. The self-assembly of such polynuclear species to generate a 2D network in **1** and **2** is envisaged to be a complex process in which the fluoride ion draws six Ag(I) atoms together, the cyanide ion bridges the resulting $[F@Ag_6]$ octahedra, and the trifluoroacetato ligand further stabilizes the octahedra while providing for charge balance. The terminally coordinated, neutral ligand L plays a secondary role as either acetonitrile or aqua ligand can be attached to each layer with little effect on its structural integrity. Extension of this work by inserting other solvent molecules such as fumaronitrile or succinonitrile between the layers is in progress.

This project is supported by Hong Kong Research Grants Council Earmarked Grant CUHK 4022/98P.

Notes and references

‡ *Synthesis*: AgCN was added to 1 mL of a concentrated aqueous solution of $AgCF_3CO_2$ and $AgBF_4$ (molar ratio *ca.* 1:1) in a plastic beaker with stirring until saturated. The excess amount of AgCN was filtered off, and a few drops of MeCN were added to the filtrate. (Note: excess MeCN would lead to deposition of AgCN as a white precipitate.) The resulting solution was placed in a desiccator charged with P_2O_5. Colorless plate-like crystals of **1** were obtained in *ca.* 10 yield after several days.

Using AgF instead of $AgBF_4$ in the above preparation produced colorless plate-like crystals of **1** in *ca.* 20% yield as the first crop, and a second crop of colorless block-like crystals of **2** was obtained in *ca.* 40% yield. Both complexes are light-sensitive and decompose readily in common solvents such as water, methanol and acetonitrile. The structure of the new phase, $La_{24}Li_{18.67}Ti_{5.33}O_{56}$, tetragonal, space group *P*4/*mbm*, a = 13.2443(13), c = 14.9258(20) Å, consists of alternating columns, rotated by 45° relative to each other, of perovskite-like structure, with Ti and Li in alternate octahedral sites, and twinned, distorted, zinc blende-like structure.

Distorted crystal structures commonly occur when one type of atom is too small for the sites available to it. The perovskite family, ABO_3, provides many examples of structural distortions involving either distorted octahedra, BO_6 if the B cation is slightly too small or tilted octahedra if the A cation is too small. In the latter case, the A cations and oxygen, collectively, form close packed, *cp*, layers but the A cation may be too small to occupy a site surrounded by 12 equidistant oxygens. Additional complications occur, in, for example, the tungsten bronzes, $A_{1-x}BO_3$, when vacancies are introduced into the A cation array.

We report here, the crystal structure of $La_{24}Li_{18.67}Ti_{5.33}O_{56}$ which represents a new kind of distorted, partially-collapsed, *cp* structure. The structure contains large packing atoms, La, and smaller atoms, Li and Ti, which can occupy either tetrahedral or octahedral sites, but the La : O ratio is 1 : 2.33 rather than 1 : 3 as in perovskite. Consequently, instead of a uniformly distorted structure, as in, *e.g.* $GdFeO_3$, the structure separates into infinite columns of relatively undistorted *cp* structure.

The new phase, $La_{24}Li_{18.67}Ti_{5.33}O_{56}$ was synthesised during an investigation of compound formation in the system La_2O_3–Li_2O–TiO_2; this system is of interest as it contains the perovskite-related phase $La_{1/2+x}Li_{1/2-3x}TiO_3$[1] which exhibits exceptionally high lithium ion conductivity, 1×10^{-3} Ω^{-1} cm^{-1} at room temperature. At the outset, the composition of the new phase was uncertain since volatilisation of Li_2O was significant under the conditions used, *viz.* 12–24 h at 900 °C in Au foil boats. Nevertheless, a sample which was essentially phase-pure by powder X-ray diffraction, (XRD), was obtained on reacting the mixture ($7La_2O_3$+$10Li_2CO_3$+$3TiO_2$); this had the same La : Ti ratio as deduced in the final formula, but an excess of Li. Its powder XRD pattern could not be indexed by trial-and-error methods but it was found by selected area electron diffraction, SAED, to be tetragonal, which then enabled the XRD pattern to be indexed on a primitive cell with a = 13.2443(13) and c = 14.9258(20) Å.

For the structure determination, a sub-cell with halved c, was used since all observed XRD lines as well as the neutron diffraction (ND) data could be satisfactorily indexed on a tetragonal cell with a = 13.2443(13) and c = 7.4629(10) Å, in the space group *P*4/*mbm* (no. 127); hence the structure contains a weak supercell that is observed only by SAED. It was not possible to solve the structure from either XRD or ND data alone. Using electron density maps obtained by applying 'Direct Methods' to the XRD data set, La positions were located and this enabled an iterative solution and refinement of the structure to be carried out using combined XRD and ND data as input to the Rietveld programme GSAS.[2] After refinement of partial structure models at each stage, difference Fourier maps were constructed for both XRD and ND data and this gradually allowed the positions of more atoms to be identified, which were then inputted into the Rietveld refinement and the process repeated. This process was continued until a model corresponding to the stoichiometry '$La_{24}Ti_6O_{48}$' was obtained, at which point the difference maps became relatively featureless. The remainder of the structure was determined using a combination of crystal chemical intuition, based on examination of coordination environments of the various atoms and their bond distances and bond valence analysis to indicate which oxygens were underbonded and whether Ti, Li sites contained Ti or Li alone or had mixed occupancy. A comparison of the goodness-of-fit parameter (χ^2) and R values of the partial structure $La_{24}Ti_6O_{48}$ with those of $La_{24}Li_{18.67}Ti_{5.33}O_{56}$ is given in Table 1, showing a clear improvement in the fit when the extra O site and Li sites are added. The observed, calculated and difference profiles of the XRD and ND data from the refinement of $La_{24}Li_{18.67}Ti_{5.33}O_{56}$ are provided as ESI†. Full details of the structure determination will be reported elsewhere together with a detailed description of the crystal structure.

During the final stages of refinement, the composition of the new phase was determined from site occupancy factors. The absolute Li,Ti contents are slightly uncertain since some sites contained mixed Li,Ti occupancy; it was assumed that overall, these sites were full, but it is also possible that they contain some vacancies, compensated by a higher Ti/Li ratio.

The structure contains layers perpendicular to c (not shown) of La and O atoms that are alternately planar and buckled. The layers at z = ¼ and 0, ½, shown in projection in Fig. 1 and Fig. 2 are not *cp* in this orientation: for them to be *cp*, each packing atom (La, O) should be surrounded by a hexagonal ring of six other packing atoms. It is, however, possible, if we consider for a moment La and O to be equivalent, to identify fragments of *cubic close packed, ccp*, unit cells, *e.g.* four La(1) atoms around O(8) at both corner and face centre positions, Fig. 1, giving rise to the 'domino-five' arrangement of a *ccp* cell face; in addition, parallel to c, the 'domino-fives' alternate with square arrangements of O(7), Fig. 2, which represent side face centres of the *ccp* unit cells. Centred at corner and face centre positions,

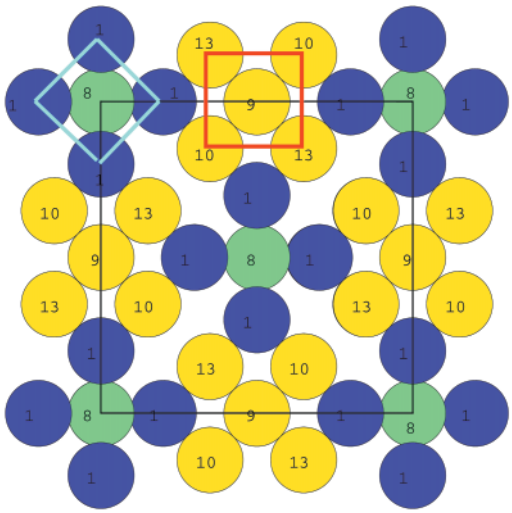

Fig. 1 *ab* Section at $z = 0.25$, with idealised La–O and O–O bond lengths: La(1): purple; O(9), O(10), O(13): yellow; O(8): green. The zinc blende-related columns are yellow, with the subcell outlined in red; the perovskite columns are green/purple with the subcell outlined in blue.

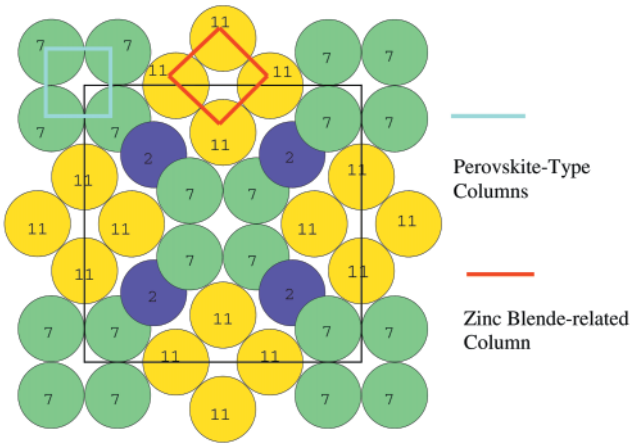

Fig. 2 *ab* Section at $z = 0$, with Idealised La–O and O–O bond lengths. La(2): purple; O(11): yellow; O(7): green. Column colours as in Fig. 1. Section at $z = \frac{1}{2}$ (not shown) is very similar, but with La(3) instead of La(2), O(5) instead of O(11) and O(6) instead of O(7).

therefore, columns of mixed La,O *ccp* cells run parallel to *c*. These have the perovskite structure, not only as regards the La, O distribution but also the octahedral positions at, *e.g.* 000 and $00\frac{1}{2}$, which are occupied, alternately, by Ti and Li.

A second set of *ccp* columns is centred on the edge-centre positions, *i.e.* in Fig. 1 oxygens O(10), O(13), around O(9) at $0\frac{11}{24}$ and $\frac{1}{2}0\frac{1}{4}$, with oxygens O(11) at $z = 0$, Fig. 2, and O(5) at $z = \frac{1}{2}$ (not shown). These columns are somewhat distorted from the idealised, square symmetry. An *ab* projection of one such

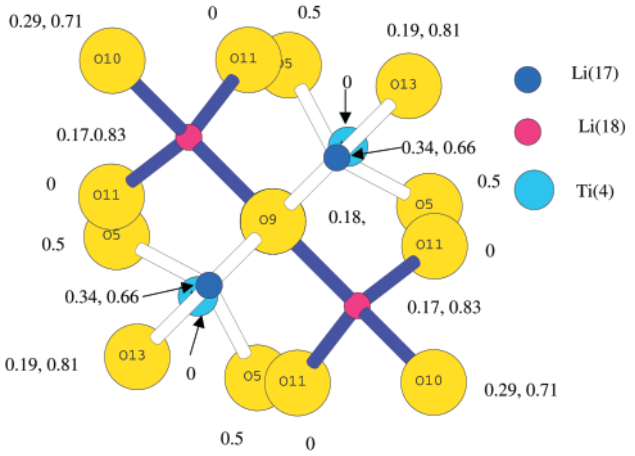

Fig. 3 Distorted zinc blende-related columns with Ti octahedrally co-ordinated in the basal plane.

column is shown in Fig. 3; Li occupies one set of tetrahedral sites to give a zinc blende arrangement, but, a twin plane exists at each unit cell face (*i.e.* $z = 0, \frac{1}{2}$) and the pattern of tetrahedral site occupancy parallel to *c* is –empty–empty–occupied–occupied–… rather than …empty–occupied –... as in zinc blende. Additionally, these distorted *ccp* cells contain Ti in sites at $z = 0$; in an undistorted structure, these sites would be two-coordinate, but because of the distortions, are octahedral, (oxygens O(11) at $z = 0$, O(13) at $z = 0.19,0.81$ and O(9) at $z = 0.18, 0.82$).

To complete the structure, it is necessary to see how the columns of perovskite-like and cation-excess, zinc blende-like structure are connected. From Figs. 1 and 2, it can be seen that adjacent columns are rotated by 45° about *c*, relative to each other. In the sections at $z = 0$ and $z = \frac{1}{2}$ (not shown), extra La(2) and La(3) atoms are located between the two types of column, whereas at $z = \frac{1}{4}, \frac{3}{4}$, all La, O atoms belong to one or other of the two column types.

The coordination numbers of the packing atoms vary, depending on their location, from a maximum of 12 for O(8) in the centres of the perovskite columns. Overall, the structure is not a continuous *cp* structure but nevertheless, the average volume of an La, O packing atom, 16.3 Å^3, is close to the lower limit found for ideal *cp* structures. Thus, within the two types of column, the packing arrangement of La, O approximates to *cp* but between the columns the structure cannot be idealised to *cp*.

Received (in Cambridge, UK) 2nd May 2000, Accepted 21st June 2000

The reaction of $[(Bu^tNH)P(\mu\text{-}NBu^t)_2PCl]$ (1) with CyPHLi and Bu^nLi in toluene gives $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)\text{-}Li_2\cdot thf]_2$ (2), an unusual aggregate containing the first example of a phosphine-functionalised cyclodiphosphazane anion $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)]^{2-}$.

In recent years there has been increasing interest in the synthesis and coordination chemistry of anionic ligand systems based on imido group 15 molecular frameworks.[1] The most extensively studied have been complexes containing $[E_2(NR)_4]^{2-}$ anions, (E = P,[2] As,[3] Sb,[4] Bi[5]), capable of coordinating a variety of metal centres using a combination of their μ-N and terminal N donor functionality.[6] Although imido frameworks of this type are comparatively robust, we found recently that the analogous phosphide systems of the heavier group 15 elements decompose at low temperatures to give cyclic $[(RP)_nE]^-$ anions (n = 3, 4; E = As–Bi) and Zintl compounds.[7] Indeed, the only group 15 phosphide which has been stable enough to isolate (< 30 °C) and structurally characterise so far is the $[Sb(PCy)_3]^{3-}$ trianion, present in the cage complex $[\{Sb(PCy)_3\}_2Li_6\cdot 6Me_2NH]$.[8] Motivated by the scarcity of stable phosphide ligands of this type, we have turned our attention to those based on phosphorus frameworks which are likely to be more stable. We report here the first example of a phosphine-functionalised cyclodiphosphazane anion present in the unusual cage complex $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)Li_2\cdot thf]_2$ (**1**).

Complex **1** was prepared by the reaction of $[(Bu^tNH)P(\mu\text{-}NBu^t)_2PCl]$ (1 equiv.) with CyPHLi (1 equiv.) followed by reaction with Bu^nLi (2 equiv.),† the formation of the dianion resulting from a combination of addition of $CyPH^-$ to the framework of $[(Bu^tNH)P(\mu\text{-}NBu^t)_2PCl]$ and deprotonation with Bu^{n-} (Scheme 1).

Low-temperature X-ray crystallography‡ reveals that **1** is composed of centrosymmetric dimers, which are constructed from the association of two $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)Li_2\cdot thf]$ cubane units through a central P_2Li_2 ring (Fig. 1). In addition there is a thf molecule within the lattice. The unusual manner of the association of the cubane units of **1** can be compared to related group 15 complexes containing $[E_2(NR)_4]^{2-}$ anions. Complete solvation of the Li^+ cations in $[\{E_2(NBu^t)_4\}Li_2\cdot 2thf]$ (E = P,[2a] Bi[5]) results in discrete cubane structures, whereas in $[\{E_2(NBu^t)_4\}Li_2]_2$ (E = P,[2b] As,[3] Sb[4]) the absence of Lewis base solvation results in aggregation into 'interlocked-cubane' cages. The arrangement in **1** can be regarded as representing an intermediate situation in which solvation of only one of the Li^+ cations within the cubane constituents leaves 'side-on' aggregation as the most viable method of increasing the coordination number of the unsolvated Li centre.

The presence of the CyP substituent has little effect on the P–N framework of the $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)]^{2-}$ dianions of **1**, the geometry of the $[(Bu^tN)P(\mu\text{-}NBu^t)_2P]$ fragment and bond lengths involved being very similar to those found in complexes containing the related $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(NBu^t)]^{2-}$ dianion.[2] In particular, the endocyclic P–N bonds (mean 1.78 Å) and endocyclic P–N–P and N–P–N angles (mean 96.9 and 83.1°, respectively) present in the planar P_2N_2 rings of **1** are similar to those found in the bis-thf solvate $[\{P_2(NBu^t)_4\}Li_2\cdot 2thf]$.[2a] This similarity suggests that the relatively short exocyclic P–P(Cy) bond in the $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)]^{2-}$ dianions of **1** [P(2)–P(3) 2.171(3) Å; *cf.* single P–P *ca.* 2.21 Å and double P=P bond *ca.* 2.1 Å[9]] is largely the result of electrostatic factors (*i.e.*, stemming from the bonding of P(2) to two electronegative N

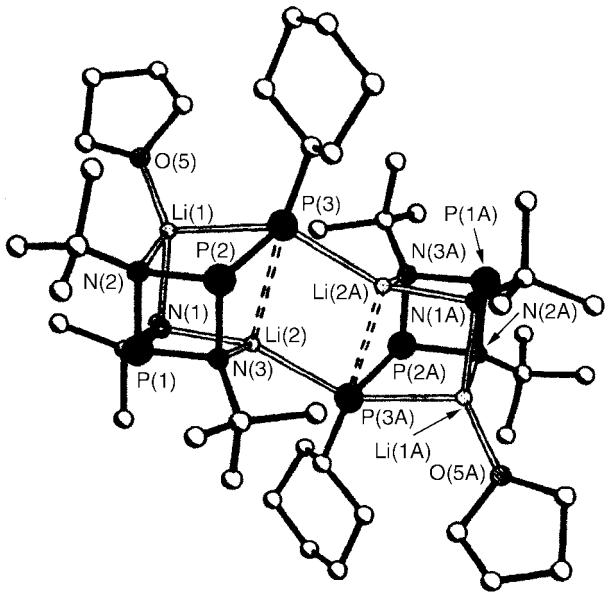

Fig. 1 Structure of dimeric molecules of **1**. H-atoms and the lattice-bound thf molecules have been omitted for clarity. Key bond lengths (Å) and angles (°); P(1)–N(1) 1.651(5), P(1)–N(2) 1.787(5), P(1)–N(3) 1.792(5), P(2)–N(2) 1.773(6), P(2)–N(3) 1.772(5), P(2)–P(3) 2.171(3), N(1)–Li(1) 2.09(1), Li(1)–O(5) 1.94(1), N(1)–Li(2) 1.98(1), N(2)–Li(1) 2.11(1), N(3)–Li(2) 2.11(1), P(3)–Li(1) 2.62(1), P(3)–Li(2) 2.88(1), P(3)–Li(2A) 2.57(1), N(1)–P(1)–N(2) 101.0(3), N(1)–P(1)–N(3) 97.9(3), N(2)–P(1)–N(3) 82.6(2), P(1)–N(2)–P(2) 97.0(3), P(1)–N(3)–P(2) 96.8(2), N(2)–P(2)–P(3) 104.1(2), N(3)–P(2)–P(3) 98.6(2), N(2)–P(2)–N(3) 83.6(2), Li(1)–N(1)–Li(2) 92.6(5), Li(1)–P(3)–Li(2) 64.4(4), N(1)–Li(1)–P(3) 102.4(5), N(1)–Li(2)–P(3) 97.1(5), Li(2)–P(3)–Li(2A) 67.6(4), P(3)–Li(2)–P(3A) 112.4(4), Li(1)–P(3)–Li(2A) 125.2(4).

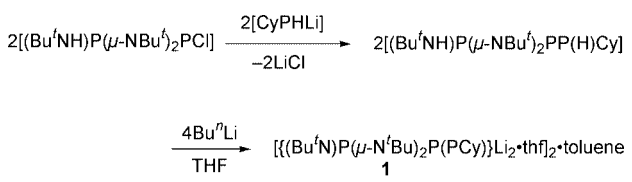

Scheme 1

DOI: 10.1039/b003468l

centres, rather than indicating the presence of any partial multiple bonding).

The coordination of the bifunctional $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)]^{2-}$ ligand to the Li^+ cations in **1** inherently results in major distortion of the $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)Li_2]$ cubane framework. The NLi_2P ring unit in **1** is butterfly-shaped primarily as a consequence of the relative shortness of the terminal P–N(Bu^t) bond [P(1)–N(1) 1.651(5) Å] of the ligand compared to the terminal P–P(Cy) bond. In addition, this distortion is exacerbated further by the relative shortness of the Li–N bonds [range 1.98(1)–2.11(1) Å[10]] compared to the P–Li bonds [P(3)–Li(1) 2.62(1), P(3)–Li(2) 2.88(1) Å]. Finally, it is interesting to note that the P(3)–Li(2) interaction is well outside the range found in lithium phosphide complexes (*ca.* 2.6[11]) and significantly longer than the P–Li bonds linking the cubane units [P(3A)–Li(2) 2.57(1) Å]. This observation may indicate that aggregation of the monosolvated cubane units of **1** *via* P–Li bonding, rather than the attainment of a discrete cubane structure by thf-solvation of both cations, is a consequence of the inability of the exocyclic P donor centre to coordinate both of the Li^+ cations effectively within a discrete cubane arrangement.

In summary, the first example of a phosphine-functionalised cyclodiphosphazane anion, $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)]^{2-}$, has been prepared, structural studies showing that the Li salt $[(Bu^tN)P(\mu\text{-}NBu^t)_2P(PCy)Li_2{\cdot}thf]_2$ has a unique arrangement in the solid state. In view of this structural pattern and of the very different geometric demands of this anion compared to related amides, further studies of the coordination chemistry of this and other phosphides should be of interest.

† *Synthesis of* **1**: the novel precursor $[(Bu^tNH)P(\mu\text{-}NBu^t)_2PCl]$ was prepared by the reaction of PCl_3 with Bu^tNH_2 (2:8 equiv.) in toluene. It was characterised by elemental analysis (C,H,N) and ^1H and ^{31}P NMR spectroscopy, and X-ray crystallography.[12] A suspension of CyPHLi (6.43 mmol) in hexane (20 ml) was added to a solution of $[(Bu^tNH)P(\mu\text{-}NBu^t)_2PCl]$ (2.0 g, 6.43 mmol) in toluene (5 ml)/hexane (20 ml) at room temperature. The white solid produced (LiCl) was removed by filtration and the orange filtrate reduced to *ca.* 5 ml under vacuum. To this was added Bu^nLi (8.6 ml, 1.50 mol dm^{-3} in hexanes, 12.9 mmol). A yellow precipitate was produced which was dissolved by the dropwise addition of thf (*ca.* 5 ml) to the suspension at reflux. Storage of the solution at 5 °C (48 h) gave small colourless cubes of **1**. Yield 1.33 g (40%). Decomp. to red solid *ca.* 180 °C. ^1H NMR ($[^2H_8]$thf, +25 °C, 400.129 MHz), 3.50 (m, *ca.* 6H, thf), 1.70 (m, *ca.* 6H, thf), *ca.* 2.1–1.0 (overlapping m, 11H, Cy), 1.13 (s, 27H, Bu^t). ^{31}P NMR ($[^2H_8]$thf, +25 °C, 161.975 Hz, rel. to 80% H_3PO_4/D_2O), 187.9 (d, J_{P-P} = 376 Hz, Cy*P*), 167.6 (s, *P*NBu^t), −10.2 (d, J_{P-P} = 376 Hz, Cy*P*). Correct analysis (C, H, N) were obtained for **1**.

‡ *Crystal data for* **1**: $C_{50}H_{104}Li_4N_6O_3P_6$, M = 1022.92, monoclinic, space group $P2_1/n$, Z = 2, a = 10.679(2), b = 21.224(8), c = 13.847(3) Å, β = 95.46(2) Å, V = 3124.0(15) Å^3, μ(Mo–Kα) = 0.211 mm^{-1}, T = 223(2) K. Data were collected on a Siemens *P*4 four circle diffractometer and corrected for absorption using Ψ scans. Of a total of 4884 reflections collected, 3836 were independent (R_{int} = 0.075). The structure was solved by direct methods and refined by full-matrix least squares on F^2.[13] Final $R1$ = 0.077 [$I > 2\sigma(I)$] and $wR2$ = 0.242 (all data). Three peaks of electron density were interpreted as a molecule of thf disordered across an inversion centre in such a way that the carbon atoms in the two components overlap. CCDC 182/1696. Received (in Cambridge, UK) 17th April 2000, Accepted 20th June 2000

The sol–gel entrapment of TEMPO within a silica matrix yields an efficient and recyclable catalytic system for the selective oxidation of methyl α-D-glucopyranoside (MGP) in water with NaOCl as primary oxidant, thus opening the way to the heterogeneous catalysis of the conversion of sugars into valuable uronates.

The selective oxidation of carbohydrate primary alcohols into carboxylic acids yields uronates, compounds with valuable biochemical properties.[1] Stable organic nitroxyl radicals belonging to the TEMPO family are excellent catalysts for this selective oxidation.[2] The radicals are soluble in H_2O (*ca.* 1% w/w) where, in the presence of alkaline (pH 9–10) NaOCl as primary oxidant along with a catalytic amount of bromide, they mediate the conversion of $–CH_2OH$ groups into $–COO^-$ with complete selectivity for the primary alcohol groups:

$$RCH_2OH + OH^- + 2OCl^- \xrightarrow[\text{NaBr, pH 10, 2°C}]{\text{TEMPO}} RCOO^- + 2Cl^- + 2H_2O \qquad (1)$$

A catalytic amount of bromide is added in order to increase the reaction rate upon fast formation of OBr^- that in its turn generates *in situ* the catalytic oxidant, the oxoammonium salt $TEMPO^+$.[3] In this way the important detoxifying agent D-glucuronic acid,[1] previously produced enzymatically on a small scale,[4] can now be easily obtained through the catalytic oxidation of D-methylglucose.

Apart from being clean and selective, reaction (1) is rapid and quantitative; its comparison with the heterogeneous oxidative dehydrogenation of methyl 4-*O*-methylglucose on Pt/C reveals the superiority of TEMPO mediated oxidation.[5] Of relevance to this report is also the commercial production of ascorbic acid currently prepared either through the enzymatic oxidation of the $–CH_2OH$ group in D-sorbose under cumbersome reaction conditions, or by the oxidation of sorbose primary alcohols with HNO_3.[4]

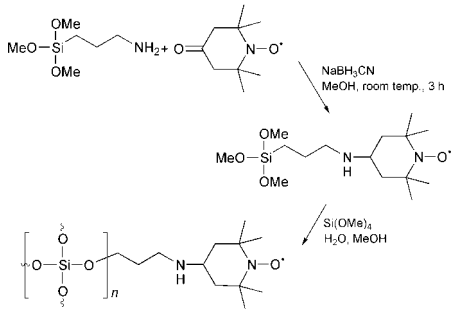
Clearly, considering the efficiency mentioned above and the commercial relevance of uronates, the immobilization of the nitroxyl radicals within a solid support would be a major advantage in the prolonged quest for heterogeneous catalysts for liquid-phase oxidations of sugars. An obvious prerequisite is that the catalytic material retains the activity of the radicals and is stable over prolonged time of use.

With these aims, several immobilization procedures have been reported in which the TEMPO moiety has been covalently linked either to organic polymers[6,7] or to a functionalized aminopropyl silica.[8,9] In all of the reported cases, the immobilization was carried out by heterogeneous reaction between a radical (or a precursor) functionalized in position 4 and a suitable function of the polymer. The catalytic organic polymers thus obtained were tested in the oxidation of organic alcohols and showed *lower* activity and stability of the radicals under solution homogeneous reactions.[6,7] On the other hand, TEMPO supported on aminopropyl-derivatized silica employed in the oxidation of various alcohols in a biphasic (H_2O–CH_2Cl_2) reaction system with NaOCl as co-oxidant, was found to be highly active, selective and recyclable.[9] However, an attempt to use this anchored TEMPO with sacrificial NaOBr for the oxidation of anomerically protected D-glucose in water, resulted in rapid loss of activity upon 3 consecutive oxidative runs.[9] Heeres *et al.* concluded that azeotropic distillation is the optimal method for the recovery of organic nitroxyl radicals in aqueous oxidations of carboyhdrates.[8b]

The *sol–gel* technology offers several advantages over the classical immobilization procedures employed in the preparation of heterogeneous catalysts.[10] Depending on the needed utilization, sol–gel materials employed in catalysis are microporous (pore sizes < 15 Å) or mesoporous (20–100 Å); very often, provided that the reagents in solution have smaller size than the average pore diameter, these materials afford superior catalytic performances compared with similar heterogeneous catalysts prepared by classical impregnation or surface derivatization methods.[11] Inorganic sol–gel supports are indeed superior in their thermal stability, inertness towards and protectability of the entrapped molecules, and in their porosity and high surface areas (several hundreds of $m^2\ g^{-1}$); moreover, the sol–gel doped materials show chromatographic properties, *i.e.* they *concentrate* the reagent at the surface enhancing (even by orders of magnitude) the chemical sensitivity and selectivity of the reactions with the dopant.[10]

Here we report that sol–gel silica organically modified with TEMPO (Scheme 1) is an effective, recyclable catalyst for the NaOBr oxidation of sugars into uronates.† The TEMPO moiety was tethered to $(CH_3O)_3Si(CH_2)_3NH_2$ by reductive amination of TEMPON (4-oxo-TEMPO). The reaction was followed by FTIR where the C=O peak at 1720 cm^{-1} decreased rapidly and the C=N peak increased at 1670 cm^{-1} showing clear evidence of CO amination. The C=N bond was thus reduced with $NaBH_3CN$ and the radical monomer homogeneously entrapped within a silica matrix by the sol–gel process, *i.e.* by hydrolysis and co-polycondensation of the radical precursor with $Si(OCH_3)_4$ in aqueous methanol.

The catalyst was then used in the oxidation of MGP to the corresponding uronic acid.† In each reaction run no other products apart from the uronate (whose content was also



Scheme 1

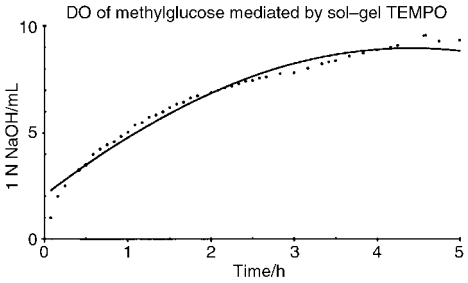

Fig. 1 The kinetics of the selective oxidation of MGP with NaOBr mediated by sol–gel entrapped TEMPO.

measured with the colorimetric test for uronic acids[12]) were detected in the reaction mixture and the catalyst retained its activity, as well as its shape and appearance, in the 4 consecutive reaction cycles in which it was tested affording at each run a high degree of oxidation (DO, *ca*. 95%); no leaching of entrapped radicals in solution was detected (with a spectroscopic limit of detection of 10 ppm). This is important since many heterogeneous oxidations can actually be promoted by catalyst leached in solution.[13] Separating the catalyst from the reaction mixture shortly (30 min) after the beginning the oxidation, we tested the mother liquor and no extra formation of uronate was observed (Fig. 1).

According to the known stability of sol–gel materials mentioned above, we observed high activity of the material and *no* modification of the EPR spectrum of the doped glass before *and* after the oxidative runs (Fig. 2). Comparing the EPR spectra of sol–gel silica TEMPO and TEMPO impregnated on commercial silica, Lev *et al.* reported that sol–gel TEMPO yields absorption peaks similar to TEMPO dissolved in H_2O, *i.e.* considerably *narrower* than those shown by TEMPO impregnated on SiO_2; since the width of EPR absorption peaks is inversely proportional to the speed of rotational motion of the molecule containing unpaired electrons (spin label), this means that the molecular environment sensed by TEMPO within sol–gel hydrophilic cages closely resembles that sensed by *free* radicals in H_2O.[14] With our organically modified silica (Ormosil), the radicals experience a situation in between these extremes, *i.e.* they are entrapped within sol–gel hydrophilic cages which resemble the aqueous medium *but* are limited in motion due to covalent linkage to the cage surface, resulting in EPR peaks of width comparable to impregnated TEMPO (Fig. 2). To explain the low activity and lack of recyclability of TEMPO linked to commercial aminopropyl silica (BioSil-NH_2),[8] one should consider that surface derivatization requires the formation of a new covalent bond through a slow *heterogeneous* reaction and leaves the anchored molecule unprotected at the pore surface; the sol–gel entrapment, on the other hand, greatly protects the radical *within* the silica cage of the final xerogel starting from an *homogeneous* solution of the dopant species in the alcoholic solution of silicon alkoxide. Furthermore, within the sol–gel cage the entrapped radical senses a hydrophilic environment similar to that of polar aqueous solutions; these cages in fact contain all types (vicinal, geminal, isolated) of silanol groups as well as water and methanol molecules and it is in this inner surface that reactions take place due to the internal porosity and accessibility of the cages (380 $m^2\ g^{-1}$ *vs.* few $m^2\ g^{-1}$ of the outer surface regions of the gel).[10,11] It may be assumed that the hydrophilic nature of the cage favours the diffusion of hydrophilic sugar molecules toward the active oxoammonium ion tethered at the surface of the cage. In fact, the origin of selectivity of sol–gel entrapped catalysts, which has also been observed in other cases,[11] has been attributed to two factors: the effect of the spatial confinement of the narrow pores, imposing a specific approach of the substrate to the catalysts *and* the participation of the intracage silanol groups in hindering free tumbling of the substrate molecule, directing specific orientational approach to the catalyst through the hydrogen bonds between the substrate and the pore–cage surface.

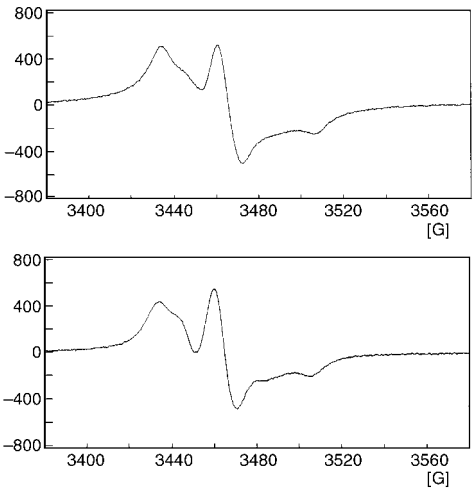

Fig. 2 The EPR spectrum of sol–gel entrapped TEMPO does not change before (a) and after (b) 4 consecutive reaction runs.

In conclusion, we found that sol–gel entrapped TEMPO is an efficient heterogeneous catalyst for the selective oxidation of D-methylglucose rapidly (turnover frequency $\sim 5\ h^{-1}$) affording high yields of the uronate and retaining its activity and selectivity upon several consecutive reaction cycles. The rates are 15 times lower than an homogeneous reaction[3] due to diffusional limitations imposed by the narrow pore network. A limitation, however, that is balanced by the advantages of the heterogenization. With the aim of practical, industrial application where continuous processes are often sought[15] it should be kept in mind that fundamental properties of the sol–gel catalytic materials (including the form: monoliths, rods, granules, powders and films, surface area, hydrophobicity, *etc*.) can be *tailored*, varying parameters such as the ratio of metal to H_2O, the amount of alcohol employed as co-solvent, the nature of alkoxide, the pH, the temperature, the drying time and other important parameters. These and other aspects have been patented.[16]

We thank Professor Mariella Brai (Institute of Medical Physics, Palermo) for the EPR measurements, and Dr. Filippo Saiano (Laboratory of Agricultural Chemistry, Palermo) for the FTIR measurements *and* for his continuous support. This work has been inspired by Arjan de Nooy's pioneering work: M. P. thanks him for sharing his intelligence with him throughout recent years. D. A. thanks the Israel Science Foundation for supporting this study.

Photocatalytic performance of TiO_2 and Fe_2O_3 immobilized on derivatized polymer films for mineralisation of pollutants

M. R. Dhananjeyan, J. Kiwi and K. Ravindranathan Thampi*

Laboratory of Photonics and Interfaces (LPI), Swiss Federal Institute of Technology (EPFL), CH-1015 Lausanne, Switzerland. E-mail: ravindranathan.thampi@epfl.ch

Received (in Oxford, UK) 17th April 2000, Accepted 15th June 2000

TiO_2, Fe_2O_3 and Fe^{3+} have been immobilized on low cost polyethylene films containing anhydride anchoring groups showed enhanced mineralisation rates for chlorophenols and Orange II, compared to previously reported immobilized catalysts with rates which are comparable to or greater than catalytic suspensions.

Photocatalysis and photo-Fenton processes are able to break down many organic pollutants totally or partially so that cheaper biological processes can be used as a second stage to achieve complete mineralisation. Since photocatalysts are often applied as suspensions, costly problems associated with catalyst leaching, settling, flocculation and the need for eventual catalyst separation by filtration during post treatment, hinders their wide scale application in industry. In systems using photo-Fenton processes, removal of Fe ions after treatment is expensive. Therefore, catalyst immobilisation related research has attracted wide attention.[1] Simple coating[2,3] of the catalyst over glass, ceramics and polymers often lead to catalyst leaching and dissolution. There are reports on buoyant TiO_2-coated glass micro-bubbles[4] and polystyrene beads made by thermal treatment.[5] Immobilized catalysts may show reduced activity. Another problem generally noticed is the chemical attack by OH· radicals on the polymer substrates.[6] Photocatalysts immobilized on Nafion films[1] are expensive.

The present study was targeted to produce stable and efficient photocatalysts on low cost polymers, which could be used over many cycles without loss of activity. Chlorophenols and azo dyes like Orange II have been selected as model pollutants. The immobilized photocatalysts are based on TiO_2, Fe_2O_3 and Fe^{3+}.

In order to bind catalyst particles on the polymer, suitable anchor groups are required on the polymer surface. In this study, a polyethylene based anhydride-modified block copolymer (30 μm), specially prepared by E.I. Dupont de Nemours & Company, was used.

To prepare the immobilized catalyst,[7] the anhydride derivatized polyethylene film is washed with water before immersing in an aqueous suspension containing 5 g L^{-1} TiO_2 (Degussa P25). The suspension was sonicated 30 min prior to use. Together with the polymer, it is then heated to 75 °C for 1 h. The film was dried at 100 °C and washed with water to remove the loosely attached TiO_2 particles. For anchoring Fe_2O_3, α-Fe_2O_3 was used as the powder precursor and for Fe^{3+}, $FeCl_3$ (Fluka) was used as the starting compound.

Photocatalytic experiments were carried out using a 125 W medium pressure mercury lamp (2.5×10^{15} photons s^{-1}; λ = 360–390 nm) when TiO_2 is used and a Hanau Suntest lamp (80 mW cm^2 total intensity; 1.6×10^{16} photons s^{-1}; λ = 350–560 nm) for experiments using Fe_2O_3 and Fe^{3+} coated layers. The short UV radiation was filtered by the Pyrex wall of the reaction vessel. The decrease in the concentration of chlorophenols and Orange II was monitored by means of UV–VIS absorption spectroscopy and Total Organic Carbon (TOC) analyser. In control experiments with light, but without catalysts, the reactions did not proceed. Merckoquant paper® was used for estimating peroxide concentration.

Illumination of chlorophenol solutions (0.5 mM) in the presence of oxygen and TiO_2 coated films, at pH 6, results in rapid mineralisation of the organic compound. Fig. 1 shows the gradual decrease of TOC value of the chlorophenol solutions: 2-chlorophenol (Fig. 1A), 4-chlorophenol (Fig. 1B) and 2,4-dichlorophenol (Fig. 1C). 95% degradation was observed within 10 h for 2-chlorophenol. For both 4-chlorophenol and 2,4-dichlorophenol this time period was only 9 h. Control experiments showed no dark reaction on TiO_2 layers. The pseudo-first-order rate constants for the total mineralization of 2-chlorophenol (2-CP), using polymer–TiO_2 and powder suspensions (75 mg L^{-1} TiO_2), are 1.5×10^{-4} and 7.5×10^{-4} s^{-1}, respectively. For 4-CP, the rate constants are 1.7×10^{-4} s^{-1} for polymer–TiO_2 and 2.3×10^{-4} s^{-1} for the suspension (75 mg L^{-1}). For 2,4-DCP, the polymer catalyst showed a rate constant of 1.2×10^{-3} s^{-1}. With a higher amount of TiO_2 (1 g L^{-1}) suspension, the pseudo-first-order rate constant is determined as 1.5×10^{-3} s^{-1} for 2,4-DCP.

It is interesting to compare the results obtained with TiO_2 suspensions containing 25, 75, 500 and 1000 mg L^{-1}, with data using polymer–TiO_2, for the same reactions. With 75 mg L^{-1} suspension, the photocatalytic activity for 2-CP and 4-CP are

comparable to the activity of the TiO_2 layer on the catalyst. By increasing TiO_2 to 0.5–1 g L^{-1}, complete mineralisation was obtained in *ca.* 6 h, compared to 9 h recorded for the TiO_2–polymer. However the amount of TiO_2 in the polymer is only 1.5 mg (48 cm^2 sheet size), corresponding to 37 mg L^{-1}. This shows that TiO_2 layers on the derivatized polymer are twice as efficient as a photocatalyst compared to the corresponding suspensions (3 mg in 40 mL dispersion). The reaction rates as well as the total mineralisation time of 2,4-DCP are similar when data of polymer catalyst and TiO_2 (1 g L^{-1} suspension) are compared, in which case the polymer catalyst is 25 times more active than the powder suspension. Since the polymer is transparent, it will not block light from reaching the photocatalyst during illumination. Furthermore, the TiO_2 particles do not mask each other from light and in a way are far more effectively dispersed than powder suspensions. When particles are suspended in water, besides causing shadows, they tend to aggregate causing inefficient surface utilization.

The inset Fig. 1B shows the change in light absorption by the TiO_2 polymer film before and after using six illumination cycles. We did not find any TiO_2 in solution when analysed by high resolution inductively coupled plasma spectrometry. The activity of the immobilized catalyst did not decrease during six runs. This confirms that the adhesion of TiO_2 is aided due to the chemical bond formed between the TiO_2 surface and the anhydride groups on the polymer. There is no significant change in the BET surface area of the loaded (1.45 m^2 g^{-1}) and unloaded sample (1.34 m^2 g^{-1}).

The TOC values never increased during the photodegradation run, indicating that the polymer is not chemically attacked by OH· radicals. Recycling experiments were carried out six times and no decrease in catalytic activity for the film was noticed.

The pH before the reaction was 6 and it decreased to 4.2 during the reaction. This is due to the production of HCl as a reaction product. It was also found that the H_2O_2 concentration, due to the formation and consumption of H_2O_2, was steady at *ca.* 0.5 mg L^{-1} throughout the reaction. The formation of H_2O_2 proceeds due to the capture of conduction band electrons by dissolved O_2.[8] There was no need to add H_2O_2 to effect the degradation of the organic compounds.

Illumination of aqueous solutions of 0.7 mM 4-chlorophenol and 0.2 mM Orange II in the presence of Fe_2O_3 coated polymer film and H_2O_2 results in mineralisation of the above compounds at pH 3. Fig. 2 shows the degradation of 4-chlorophenol (Fig. 2A) and Orange II (Fig. 2B) on Fe_2O_3 polymer film at pH 3. The pseudo first-order rate constants for Fe_2O_3 polymer and Fe_2O_3 suspension are 4.6 × 10^{-4} and 8.7 × 10^{-4} s^{-1}, respectively.

To compare the catalyst loaded polymer and the corresponding powder suspension, four experiments with different weights of iron oxide and different concentrations of $[H_2O_2]$ were also carried out. It was found that with 25 mg L^{-1} Fe_2O_3 susension and 1 mM H_2O_2 (4CP-susp1-Light, in Fig. 2A), the degradation was slower than with the polymer catalyst indicating that the production of OH· radical is not sufficient. When the amount of iron oxide is increased three times without simultaneously increasing H_2O_2 (4CP-susp2-Light), the rate of degradation was much slower. When $[H_2O_2]$ is increased ten times, maintaining the same weight of iron oxide as 4CP-susp1-Light (4CP-susp3-Light), the rate of degradation also increased. This rate is comparable to that observed with the polymer catalyst and is also higher than 4CP-susp1-Light and 4CP-susp2-Light. In this situation, the Fe^{3+} and Fe^{2+} cycle proceeds and hence the OH· radical production is higher than in the other two cases. Here, the degradation of the compound is moderate and the activity is equal to that of the polymer catalyst. When both iron oxide and $[H_2O_2]$ are increased three times and ten times respectively (4CP-susp4-Light), the rate of degradation is found to be faster than with the polymer catalyst. This confirms that an increased production of OH· radical and increased light absorption by the particle are both necessary to attain higher activity when the catalyst is in a suspended form.

The same trend was observed for degradation of Orange II and it takes 7 h to achieve 90% degradation as shown in Fig. 2B. No Fe^{3+} or Fe^{2+} was detected in solution, using thiocyanate as a complexing agent for Fe^{3+} and phenanthroline for Fe^{2+}. There was no change in the absorption spectra of Fe_2O_3 layers before and after six experimental cycles and this confirms the stability of the loaded Fe_2O_3 polymer film. The BET surface areas of the naked polymer film and Fe_2O_3 loaded film were measured and a noticeable surface area change was observed for the loaded polymer (2.77 m^2 g^{-1}) when compared to the free polymer (1.34 m^2 g^{-1}).

Illumination of aqueous solutions of 0.7 mM 4-CP and 0.2 mM Orange II in the presence of Fe^{3+} ions, loaded polymer film and H_2O_2 results in complete mineralisation of these compounds at pH 3 and no dark degradation was observed. The results were similar to those shown in Fig. 2A and B.

For comparison between polymer catalyst and the corresponding suspensions, experiments with homogeneous $[Fe^{3+}]$ and $[H_2O_2]$ solutions were carried out. By changing the Fe^{3+} and H_2O_2 concentrations, it was concluded that the polymer loaded film requires a lower amount of Fe^{3+} and H_2O_2, when compared to the amount required in homogeneous Fenton systems.

Stable immobilized TiO_2, Fe_2O_3 and Fe^{3+} on low cost derivatized polymer films do not compromise the catalytic activity of the powders. These composite catalysts are shown to be efficient for the photodegradation of industrial pollutants like chlorophenols and an azo-dye Orange II. The immobilized catalysts were shown to be stable in acidic as well as slightly basic (pH 9) media.

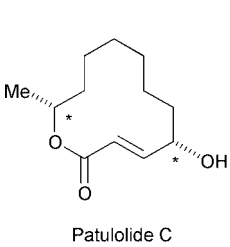
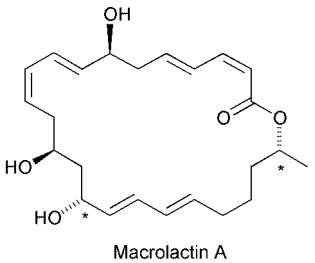
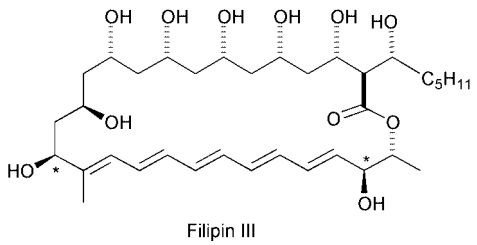
Received (in Cambridge, UK) 12th June 2000, Accepted 21st June 2000

Novel strategies for the stereoselective synthesis of molecules with remote stereogenic centers across double bonds have been developed *via* organoiron methodology allowing highly diastereoselective syntheses of 1,8- and 1,10-diol $Fe(CO)_3$ complexes using the stereospecific 1,3- and 1,5-migration of an $Fe(CO)_3$ group; this strategy could be used for stereoselective functionalization of remote terminal substituents on acyclic polyene compounds.

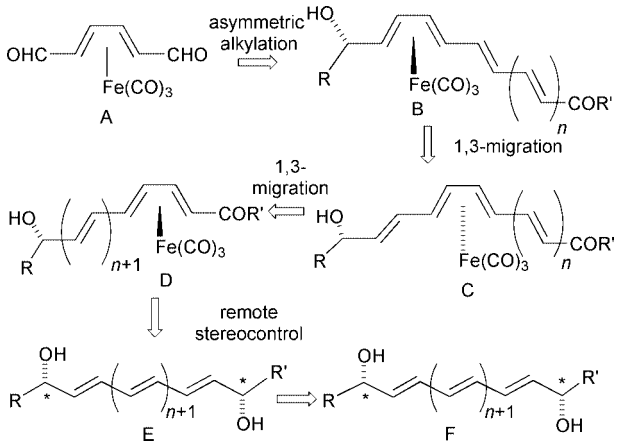
One of the more challenging aspects of organic synthesis is the stereoselective construction of molecules with remote (*i.e.* greater than 1,3-related) stereogenic centers with high levels of diastereo- and enantioselectivity.[1] A particularly challenging goal would be the development of a general strategy for the control of remote stereogenic centers related across double bonds of fixed configuration, because this moiety is present in many natural products, including polyene macrolide antibiotics such as filipin III.





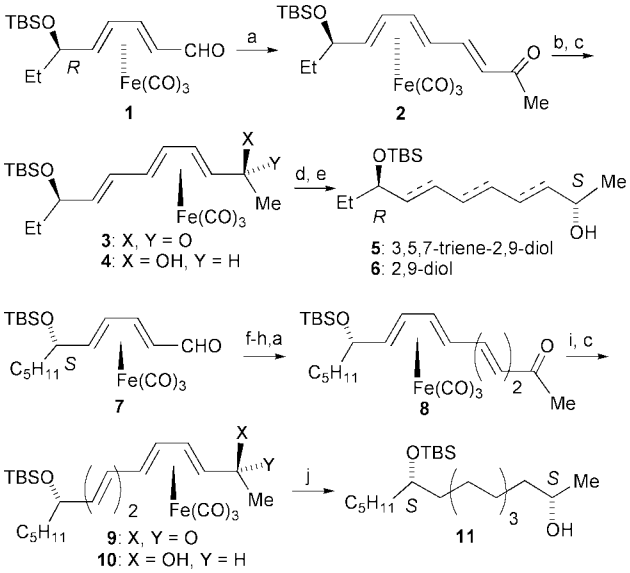


In the course of our studies on the mobility of the $Fe(CO)_3$ group on polyenes with the aim of constructing several stereogenic centers using a single chiral auxiliary,[2] we have found that the $Fe(CO)_3$ moiety of (triene)$Fe(CO)_3$ complexes shifts to the electron-deficient double bond stereospecifically on treatment with a base such as potassium bis(trimethylsilyl)-amide (KHMDS) and NaH. By taking advantage of this 1,3-migration of the $Fe(CO)_3$ group, the (polyenone)$Fe(CO)_3$ complexes **B** could be converted *via* **C** into the corresponding migrated complexes **D**, where the $Fe(CO)_3$ groups are situated in the ideal position for controlling several reactions of the ketone (Scheme 1). We herein report a novel strategy for highly diastereoselective preparation of polyene- and saturated 1,8- and 1,10-diols **E** and **F** by a combination of the 1,3- or 1,5-migration of the $Fe(CO)_3$ group and subsequent hydride reduction of the ketone, together with a formal asymmetric synthesis of epipatulolide C.



Scheme 1 Remote stereocontrol based on the 1,3-migration concept of an $Fe(CO)_3$ group.

The requisite (trienone)- and (tetraenone)$Fe(CO)_3$ complexes **2** and **8** were prepared from the chiral aldehydes **1** and **7** (Scheme 2).[3] We first examined the 1,2-reduction of the α,β-unsaturated ketone **2** *via* 1,4-asymmetric induction. In contrast to the reduction of (dienone)$Fe(CO)_3$ complex,[4] the reduction of **2** with sodium borohydride in methanol in the presence of $CeCl_3{\cdot}6H_2O$ gave a nearly equimolar ratio of the two diastereomeric trienol complexes.[5] To overcome this problem, we next



Scheme 2 *Reagents and conditions*: (a) $CH_3COCH_2P(O)(OMe)_2$, $LiOH{\cdot}H_2O$, MeOH (90% for **1**, 78% for **7**); (b) NaH, THF (81%), (c) $NaBH_4$, MeOH (91% for **3**, 72% for **8**); (d) H_2O_2, 1 M NaOH, MeOH, 0 °C (83%); (e) H_2, PtO_2, AcOEt (85%); (f) $(EtO)_2P(O)CH_2CN$, NaH, THF, 0 °C (69%); (g) DIBAL-H, −50 °C (49%); (h) n-Bu_3P, CH_2Cl_2 (71%); (i) $KN(SiMe_3)_2$, THF, 0 °C (70%); (j) H_2O_2, 1 M NaOH; H_2, PtO_2 (89%).

investigated the 1,2-reduction of the 1,3-migrated complex **3**, which was easily accessible from **2** by the stereospecific 1,3-migration of the $Fe(CO)_3$ group. According to the reported procedure,[2] **2** was treated with 1.5 equiv. of NaH in THF at 0 °C to give the desired product **3** in 81% yield along with the recovered starting material (2%). The stereochemistry of **3** was deduced from the previous result, namely, that the 1,3-migration of the $Fe(CO)_3$ group proceeded with inversion of configuration. In contrast to **2**, the reduction of the migrated product **3** with $NaBH_4$ provided the alcohol **4** as the single isomer in 91% yield. The desired 3,5,7-triene-2,9-diol **5** was easily synthesized by reaction of **4** with 30% hydrogen peroxide in the presence of 1 M NaOH solution. Furthermore, subsequent hydrogenation of **5** on platinum oxide in AcOEt gave the 1,8-*anti*-diol **6** in 85% yield. To confirm the absolute stereochemistry, the diastereomerically pure alcohol **6** was converted into the corresponding (*R*)- and (*S*)-MTPA esters, respectively. As expected, the absolute stereochemistry of the C2 position was revealed to be (*R*)-configuration by comparing their ^1H NMR spectra.[6]

To extend the applicability of this method, we next examined the reduction of the (tetraenone)$Fe(CO)_3$ complex **8**, which was prepared stereoselectively from **7** in 4 steps. The key reaction in this case would be a double 1,3-migration reaction of the $Fe(CO)_3$ group (*i.e.*, 1,5-migration). Then we investigated the migration reaction of **8** with several bases. Although we could not obtain the migration product by treatment of **8** with NaH, the reaction of **8** with 0.3 equiv. of KHMDS in THF at 0 °C provided the 1,5-migration product **9** in 70% yield along with the recovered starting material (7%). In the latter case, the 1,3-migration product of the $Fe(CO)_3$ group, an intermediate of the 1,5-migration reaction, could not be observed in the crude reaction mixture. Similarly, the reduction of **9** with $NaBH_4$ in methanol gave rise to the alcohol **10** in 72% yield as a single isomer. The transformation of **10** into **11** was performed by the same reaction sequence as that of **4** to give the 1,10-*syn*-diol **11** in 89% yield. The absolute stereochemistry was also determined by the MTPA-ester method.[6] The result revealed that the 1,5-migration of the $Fe(CO)_3$ group should occur with retention of configuration as a result of a double inversion mechanism.

Finally, we applied this method to a formal asymmetric synthesis of epipatulolide C (Scheme 3).[7] By a similar 5-step sequence, the chiral aldehyde **12** was transformed into the (2*S*,9*R*)-triol derivative **13** as a single isomer. After protection and deprotection of the hydroxy groups of **13**, the resulting alcohol was oxidized, and Wittig condensation of the aldehyde so obtained and subsequent removal of the TBS group gave the unsaturated ester **14**, which had been converted into racemic epipatulolide C in three steps.

This work shows how a combination of the mobility and the stereodirecting ability of the $Fe(CO)_3$ group can be used to prepare stereoselectively compounds with remote stereogenic centers. Further applications to the construction of more remote stereogenic centers across double bonds are underway in these laboratories.

This article is dedicated to the memory of Professor Toshiro Ibuka. This work was supported in part by The Japan Health Sciences Foundation, Suzuken Memorial Foundation and Grant-in-Aid for Scientific Research (C) from the Ministry of Education, Science, Sports, and Culture, Japan.

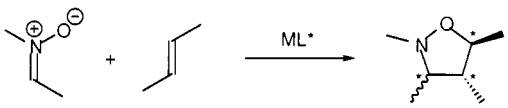
Published on the Web 11th July 2000

The rapid developments in the field of catalytic enantioselective 1,3-dipolar cycloaddition reactions of nitrones which have occurred during the last six years are reported. A series of catalysts has been applied for both the normal electron-demand and inverse electron-demand 1,3-dipolar cycloaddition reaction of nitrones with electron-deficient and electron-rich alkenes, respectively. In several cases a high degree of control of both the diastereo- and enantioselectivity has been achieved.

Introduction

After the Diels–Alder reactions, the second most important cycloaddition reaction is probably the 1,3-dipolar cycloaddition.[1] The 1,3-dipolar cycloaddition reaction of nitrones with alkenes in particular has received considerable attention in asymmetric synthesis over the past 15 years.[2,3] One of the reasons for the success of the synthetic application of nitrones is that, contrary to the majority of other 1,3-dipoles, most nitrones are stable compounds that do not require *in situ* formation. In the 1,3-dipolar cycloaddition reaction of nitrones with alkenes, up to three new contiguous chiral centers can be formed in the adduct (Scheme 1)[4,5] and the isoxazolidine formed can be



Scheme 1

transformed into numerous attractive building-block molecules for organic synthesis. The absolute majority of these 1,3-dipolar cycloaddition reactions are diastereoselective and involve chiral alkenes or nitrones.[2,3] It would, however, be highly desirable to develop a catalytic enantioselective version of this reaction. Compared to the successful development of the catalytic enantioselective Diels–Alder reaction in the late 1980s, the first examples of the catalytic enantioselective 1,3-dipolar cycloaddition reactions of nitrones did not appear until 1994.

In the early development of the catalytic enantioselective 1,3-dipolar cycloaddition reaction of nitrones with alkenes the catalysts were 'borrowed' from Diels–Alder chemistry, but in the more recent developments a series of catalysts that are optimised for the 1,3-dipolar cycloaddition reaction have been developed. A few catalysts are highly selective for both types of reaction.

In this article we wish to present to the reader an overview of this field, which has gone through rapid developments during the last six years. Several research groups have been engaged in the area and it has been attempted to include all the major contributions in which catalytic enantioselective reactions have been described. The article is divided into two major parts: (*i*) the normal electron-demand reactions and (*ii*) the inverse electron-demand reactions, which are two fundamentally different approaches to the catalytic control of the reaction. A final short part (*iii*) describing alternative catalytic approaches to the reaction is also included.

Normal electron-demand reactions

The relative FMO energies of the substrates of the 1,3-dipolar cycloaddition reaction are important for catalytic control of the reaction.[2,6,7] In order to be able to control the stereochemistry of the reaction with a sub-stoichiometric amount of a ligand–metal catalyst it is desirable that large reaction rate accelerations are obtained to assure that the reaction only takes place in the sphere of the metal and the chiral ligand. The strategy that was applied for the catalytic enhancement of the reaction rate has therefore been to alter the relative energies of the FMOs of one of the substrates using chiral Lewis acids.[6] This principle of activation can be applied to the 1,3-dipolar cycloaddition of nitrones in two different ways. The normal electron-demand involves the reaction of a nitrone with an electron-deficient alkene such as an α,β-unsaturated carbonyl compound. This reaction is primarily controlled by the interaction between $HOMO_{nitrone}$–$LUMO_{alkene}$ (Fig. 1). By the application of a Lewis acid (LA) catalyst which acts as an electron acceptor, the LUMO energy of the alkene is lowered by coordination of the α,β-unsaturated carbonyl to the Lewis acid. As a result of the decreased energy gap between the interacting FMO's a rate acceleration of the reaction is achieved.[6]

One of the problems related to the Lewis-acid activation of α,β-unsaturated carbonyl compounds for reaction with a nitrone is the competitive coordination of the nitrone and the α,β-unsaturated carbonyl compound to the Lewis acid (Scheme 2).[6] Calculations have shown that coordination of the nitrone to the Lewis acid is more feasible than a monodentate coordination of a carbonyl compound. However, this problem could be

Kurt Vesterager Gothelf (b. 1968) studied chemistry at Aarhus University, Denmark, and at Heidelberg University, Germany. He performed the two first years of his PhD studies under supervision of Professor K. B. G. Torssell and the last two under Professor K. A. Jørgensen. Following a period as a post-doctoral researcher in Professor K. A. Jørgensen's group he joined Professor M. C. Pirrung's group at Duke University. Since 1999 he has been an Assistant Professor at Aarhus University. His research interests range from asymmetric metal catalysis to studies and application of self-assembled monolayers in electron-transfer reactions.

Karl Anker Jørgensen (b. 1955) is Professor at Center for Metal Catalyzed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark. Following a PhD from Aarhus University 1984 and a post-doctoral period with R. Hoffmann, Cornell University, he joined the Aarhus University faculty. The development and understanding of metal-catalyzed reactions in organic chemistry is the main goal of his research.

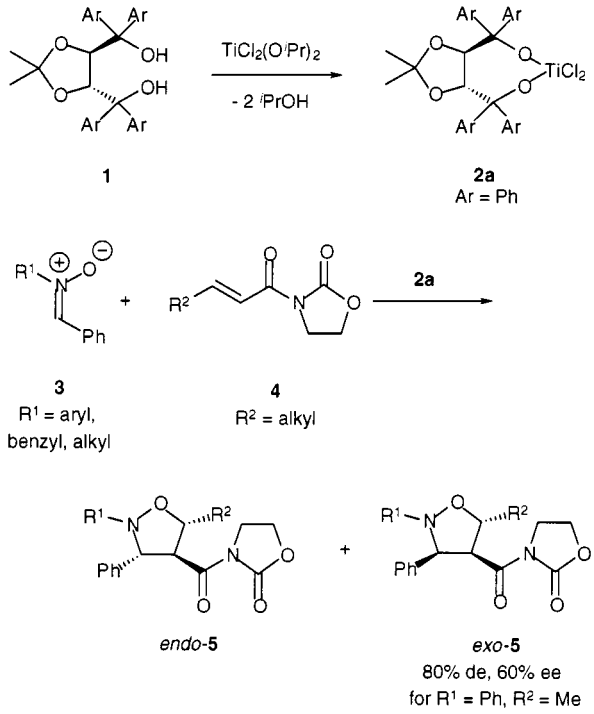
circumvented by the application of alkenes such as 3-alkenoyl-oxazolidinones enabling a bidentate coordination to the Lewis acid which is favoured over the monodentate coordination.

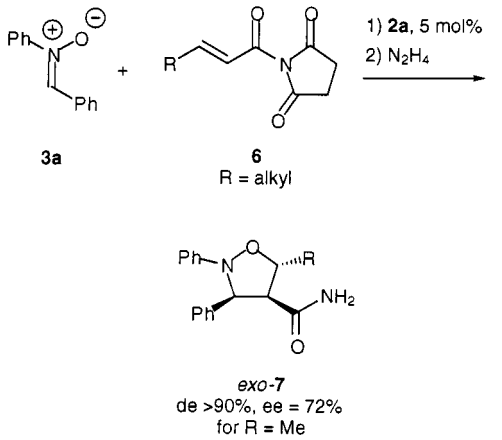
Titanium catalysts

Several titanium(IV) complexes are efficient and reliable Lewis acid catalysts and they have been applied to numerous reactions, especially in combination with the TADDOL (α,α,α′,α′-tetraaryl-1,3-dioxolane-4,5-dimethanol) (**1**) ligands.[7–10] In the first study on normal electron-demand 1,3-dipolar cycloaddition reactions between nitrones and alkenes, which appeared in 1994, the catalytic effect of a series of chiral $TiCl_2$–TADDOLates on the reaction of nitrones **3** with alkenoyl-oxazolidinones **4** was studied (Scheme 3).[11] These substrates have turned out to be the model system of choice for most studies on Lewis-acid catalysed normal electron-demand 1,3-dipolar cycloaddition reactions of nitrones. When 10 mol% of the catalyst **2a** was applied in the reaction depicted in Scheme 3 the reaction proceeded to give a yield of up to 94%. The reaction led primarily to *exo*-**5** and in the best case an *endo*:*exo* ratio of 10:90 was obtained. The chiral information of the catalyst was transferred with a fair efficiency to the substrates as up to 60% ee of one of the isomers of *exo*-**5** was obtained.[11]

In the majority of $TiCl_2$–TADDOLate catalysed Diels–Alder and 1,3-dipolar cycloaddition reactions oxazolidinone derivatives are applied as auxiliaries for the alkenoyl moiety in order to obtain the favourable bidentate coordination of the substrate to the catalyst.[12] In a more recent study on 1,3-dipolar cycloaddition reactions the use of succinimide instead of the oxazolidinone auxiliary was introduced (Scheme 4).[13] The succinimide derivatives **6** are more reactive than **4** in the 1,3-dipolar cycloaddition reaction with nitrone **3a**. In the presence of the $TiCl_2$–TADDOLate catalyst **2a** (5 mol%), the reaction of **3a** with **6** (R = Me) gives *exo*-**7** as the only diastereomer. Additionally, the enantioselectivity of the reaction of 72% ee is also an improvement compared to the analogous reaction of the oxazolidinone derivative **4**. Similar improvements were obtained in reactions of other related nitrones.



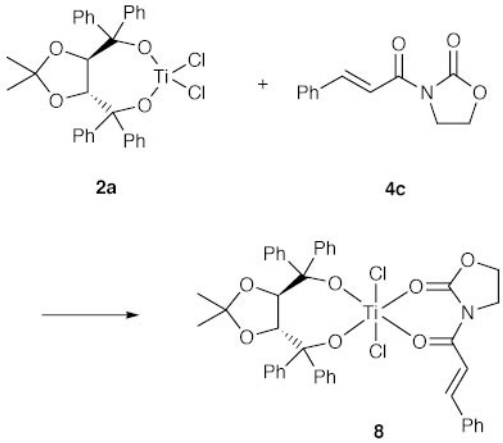
Scheme 3

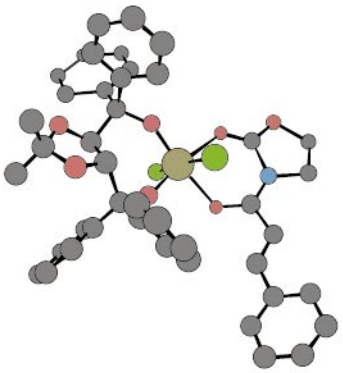


Scheme 4

In connection with the investigations of the $TiCl_2$–TADDOLate-catalysed 1,3-dipolar cycloaddition reactions between nitrones and alkenoyloxazolidinones, a complex between the chiral titanium catalyst and the alkene substrate **4c** was isolated (Scheme 5).[14] This crystalline compound **8** was characterised by X-ray crystallography and the X-ray structure showed that the oxazolidinone is coordinated to the titanium center in a bidentate fashion. The four oxygen atoms, two from the chiral ligand and two from **4c**, are located in a plane around the titanium center, while the two chloride ligands are located in the apical positions. This crystal structure is a highly valuable verification of how the mechanism of the catalytic activation is operating. To some extent, information can also be derived about how one of the faces of the alkene is shielded by the ligand leading to the enantioselective addition of the nitrone to the opposite face of the alkene. However, there are several other possible arrangements of the ligands around the titanium center and whether **8** actually represents the reactive intermediate has been the subject of some dispute.[15–18]

Based on the structure of intermediate **8**, investigations of the impact on the *endo/exo*-selectivity in the 1,3-dipolar cycloaddition reaction of changing the chloride ligands in the $TiCl_2$–TADDOLate catalyst **2a** to bulkier groups were performed.[19] In Table 1 some results of reactions between **3a** (R^1 = Ph) and **4a**





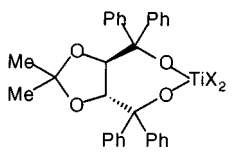
3D structure of **8**
(hydrogens are omitted for clariety)

Scheme 5

Table 1 Application of TiX_2–TADDOLate **2a–d** as catalyst for the 1,3-dipolar cycloaddition reaction between **3a** (R^1 = Ph) and **4a** (R^2 = Me) (Scheme 3)

Entry	Catalyst	Catalyst amount	Conversion (time)	*endo*:*exo*	Ee *endo* (*exo*) (%)
1	**2a**	10	98% (48)	10:90	62 (60)
2	**2b**	10	98% (20)	64:36	76 (64)
3	**2c**	10	73% (20)	79:21	0
4	**2d**	50	99% (48)	>95:<5	93

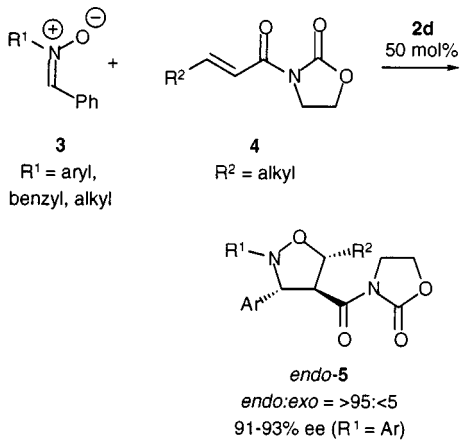
(R^2 = Me) in the presence of various TiX_2–TADDOLate catalysts are listed (see reaction in Scheme 3). By the application of **2b**, the bromide analogue to **2a**, the diastereoselectivity changes (entry 2). This reaction proceeds with a low *endo*-selectivity. Using the triflate analogue **2c**, leads to an *endo*-selective reaction (entry 3). Unfortunately, this reaction was racemic. For the reaction of **3a** and **4a** in the presence of tosylate catalyst **2d**, a high conversion is obtained (entry 4). The



2a: X = Cl
2b: X = Br
2c: X = OTf
2d: X = OTs

endo-selectivity of this reaction is excellent, and this was the first example of a metal-catalysed 1,3-dipolar cycloaddition reaction between nitrones and alkenes proceeding with more than 90% ee.

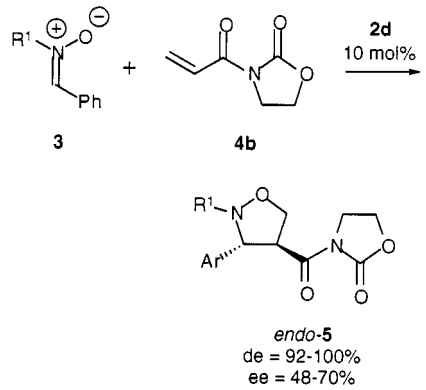
As an extension of the successful application of **2d**, this catalyst was applied in a series of reactions (Scheme 6). For all eight reactions of nitrones **3** and alkenes **4** in which **2d** was applied as the catalyst, diastereoselectivities >90% de were



Scheme 6

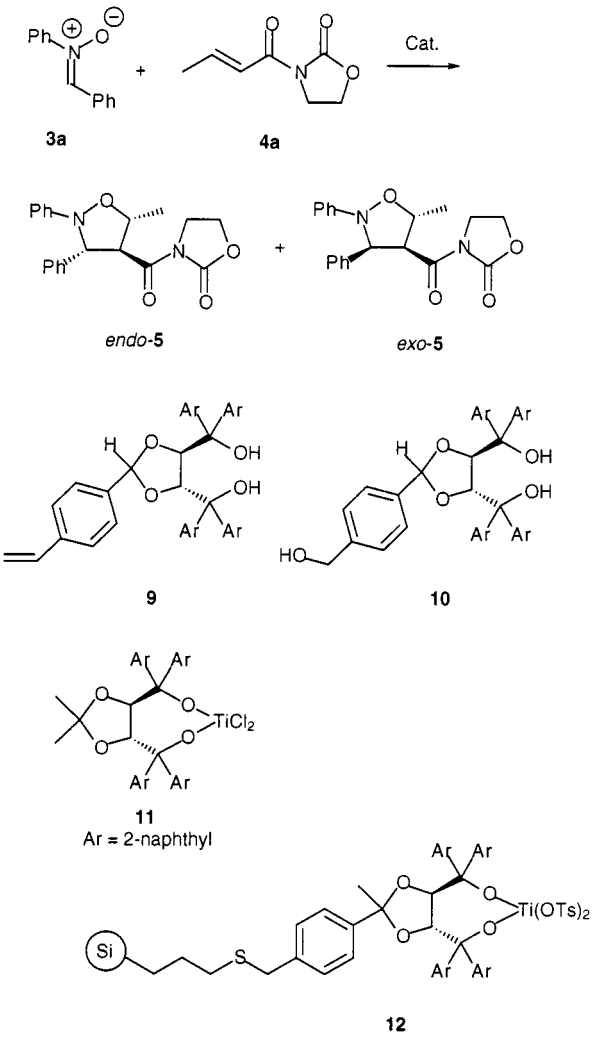
observed, and most remarkably >90% ee is obtained for all reactions involving a nitrone with an aromatic R^1 substituent, whereas reactions with *N*-benzyl and *N*-alkyl nitrones led to lower enantioselectivities.[19]

The TiX_2–TADDOLate catalysed 1,3-dipolar cycloaddition reactions were extended to include an acrylate derivative.[20] In the absence of a catalyst, the reaction between nitrone **3** and acryloyloxazolidinone **4b** proceeded to give a mixture of all eight regio-, diastereo- and enantiomers (Scheme 7). However, application of $Ti(OTs)_2$-TADDOLate **2d** (10 mol%) as catalyst for the reaction of various nitrones such as **3** with alkene **4b**, led to complete regioselectivity, high *endo*-selectivity, and the *endo*-products **5** were obtained with 48–70% ee (Scheme 7).[20]



Scheme 7

Seebach *et al.*, who first developed the TADDOL ligands,[7] have also developed a number of polymer- and dendrimer-bound $TiCl_2$–TADDOLate catalysts derived from the monomeric TADDOLs.[21] Application of 10 mol% of this type of catalyst, derived from polymers and dendrimers of **9** and **10**, respectively, in the reaction between nitrone **3a** and alkene **4a** led to *endo*:*exo* ratios between 18:82 and 8:92 and up to 56% ee (Scheme 8). The selectivities are thus slightly decreased compared to similar reactions of the homogeneous catalysts. They also made a study of the relationship between the enantiomeric purity of the ligand of the homogeneous catalyst **11**, and the products obtained in both the 1,3-dipolar cycloaddition reaction between **3a** and **4a** and in the Diels–Alder reaction of **4a** with cyclopentadiene. Surprisingly, the 1,3-dipolar cycloaddition shows a linear relationship, whereas the Diels–Alder reaction shows a positive non-linear relationship. In recent work Heckel and Seebach have studied the use and reuse of $Ti(OTs)_2$–TADDOLate catalysts immobilized on porous silica gel.[22] The selectivity obtained in the 1,3-dipolar cycloaddition reaction between nitrone **3a** and **4a** catalysed by **12**, was only slightly lower compared to the corresponding homogeneous reaction.[19] The same batch of the ligand in **12** could be



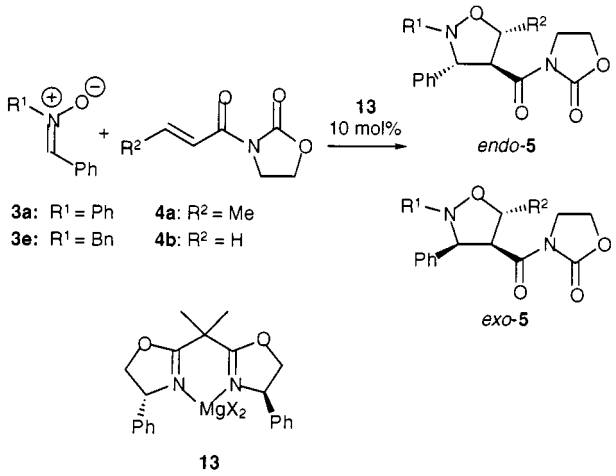
Scheme 8

used in four consecutive reactions with no significant loss of activity, when the ligand was carefully washed between the reactions.[22]

Magnesium catalysts

Prior to the first publication on chiral magnesium catalysts for 1,3-dipolar cycloaddition reactions in 1995, there had been several studies on the impact of non-chiral magnesium salts on the diastereoselectivities in cycloaddition reactions of both nitrones,[23–25] and nitrile oxides[26] with allylic alcohols.

In the first[27] and also the following[28–30] publications applying chiral magnesium catalysts, chiral bisoxazolines (BOX) were applied as the ligand for magnesium. The MgX_2–Ph-BOX catalyst **13** (X = I), proved to be a useful catalyst for the 1,3-dipolar cycloaddition between **3** and **4a**,**b** when it was activated by the addition of I_2 (Scheme 9).[27] Furthermore, the



Scheme 9

reaction had to be performed in the presence of molecular sieves (MS) 4 Å. In the presence of 10 mol% of **13** (X = I) the reaction proceeded with good to high *endo*-selectivity and the *endo*-isomer was obtained in an ee of up to 82% (Scheme 9, Table 2, entry 1).

A rather unexpected discovery was made during these investigations.[28] When the 1,3-dipolar cycloaddition reaction of **3a** with **4b** catalysed by **13** (X = I) was performed in the absence of MS 4 Å a remarkable reversal of enantioselectivity was observed, as the opposite enantiomer of *endo*-**5** was obtained in up to 73% ee (Table 2, entries 1, 2). This had not been observed for enantioselective catalytic reactions before and the role of MS cannot simply be ascribed to the removal of water by the MS, since the application of MS 4 Å that were presaturated with water, also induced the reversal of enantioselectivity (Table 2, entries 3, 4). Recently, Desimoni *et al*. found that in addition to the presence of MS in the MgX_2–Ph-BOX catalysed 1,3-dipolar cycloaddition reaction shown in Scheme 9, the counter ion for the magnesium catalyst also strongly affects the absolute stereoselectivity of the reaction.[29,30] They applied MgX_2–Ph-BOX **13** (X = ClO_4, OTf) complexes and compared the results with the MgX_2–Ph-BOX **13** (X = I) catalyst. It was observed that both in the presence and absence of MS, the catalyst **13** (X = ClO_4) gave the opposite absolute configuration of the product compared to the reaction of catalyst **13** (X = I) (Table 2, entries 5, 6). For catalyst **13** (X = OTf), the reaction was racemic in the presence of MS, whereas a high enantioselectivity of 86% ee was obtained in the absence of additives. The absolute configuration of the product of the reaction catalysed by **13** (X = OTf) in the absence of MS was similar to that obtained with **13** (X = ClO_4) catalyst and opposite to that obtained with **13** (X = I) (entries 2, 6 and 8).[29]

It should also be mentioned that in relation to the investigations on MgX_2–BOX catalysts, Desimoni *et al*. also tested a $Zn(ClO_4)_2$–BOX catalyst for the 1,3-dipolar cycloaddition of a nitrone and acryloyloxazolidinone **4b** (see Scheme 9). Contrary

Table 2 Dependence of the absolute stereoselectivity on molecular sieves (MS) and counter ion in the reaction of **3a** with **4b** catalysed by 10 mol% of MgX_2–Ph-BOX catalysts **13**

Entry	MgX_2-counter ion	Additive	*endo*:*exo* (%)	Ee *endo* (%)	Absolute induction	Ref.

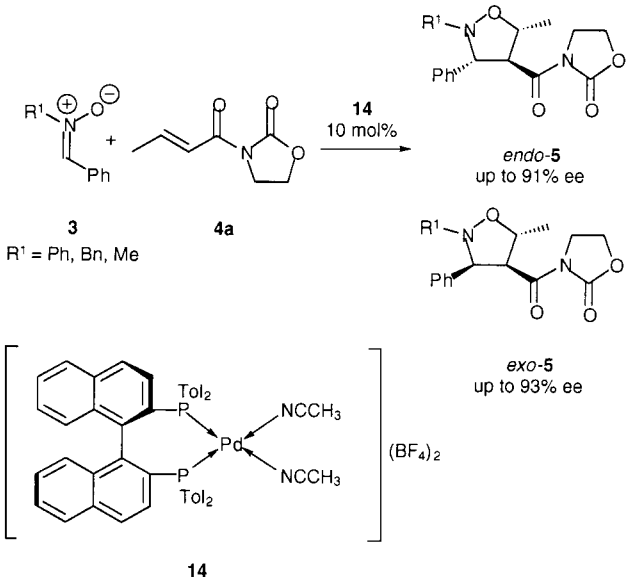
[a] Mixture of regiomers obtained.

to the magnesium catalysts, this zinc catalyst was *exo*-selective as a 27 : 73 *endo* : *exo* ratio was obtained, with 84% ee of the *exo*-isomer.[30]

Palladium catalysts

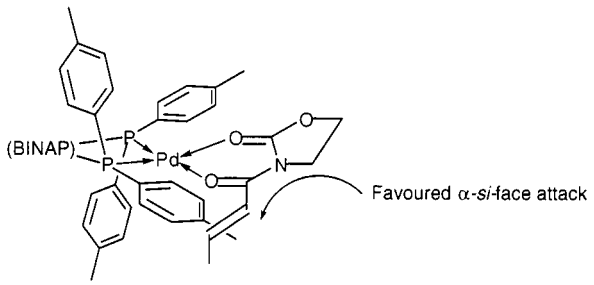
For the activation of a substrate such as **4a** *via* coordination of the two carbonyl oxygen atoms to the metal, one should expect that a hard Lewis acid would be most suitable, since the carbonyl oxygens are hard Lewis bases. Nevertheless, Furukawa *et al*. succeeded in applying the relatively soft d^{10} palladium as the catalyst for the 1,3-dipolar cycloaddition reaction between **3** and **4a** (Scheme 10).[32,33] They applied the



Scheme 10

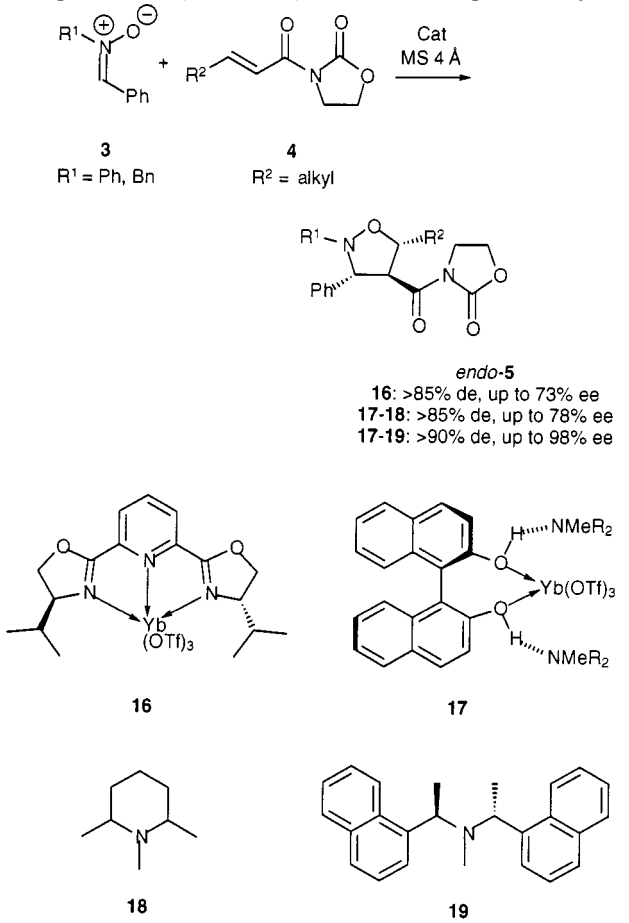
dicationic Pd–BINAP **14** as the catalyst, and whereas this type of catalytic reaction is often carried out at room temperature, the reactions catalysed by **14** required heating at 40 °C in order to proceed. In most cases mixtures of *endo*-**5** and *exo*-**5** were obtained, however, high enantioselectives of up to 93% ee were obtained for reactions of some derivatives of **3**.

A model **15** for the intermediate of the reaction was proposed to account for the high selectivities obtained for some of the substrates.[33] In **15**, the two phosphorous atoms of the Tol-BINAP ligand and the two carbonyl oxygens of the crotonoyloxazolidinone are arranged in a square planar fashion around the palladium center (note that the counter ions are omitted from this model). From the model it appears that the upper *si*-face of the alkene is sterically available for the cycloaddition reaction, while the *re*-face is shielded by one of the Tol-BINAP *p*-tolyl groups.



Lanthanide catalysts

In 1997 the application of two different chiral ytterbium catalysts, **16** and **17**, to the 1,3-dipolar cycloaddition reaction was reported almost simultaneously by two independent research groups.[34,35] In both reports, it was observed that the achiral $Yb(OTf)_3$ and $Sc(OTf)_3$ salts catalyse the 1,3-dipolar cycloaddition between nitrones **3** and alkenoyloxazolidinones **4** with *endo*-selectivity. In the first study 20 mol% of the $Yb(OTf)_3$–PyBOX complex **16** was applied as the catalyst for reactions of a number of derivatives of **3** and **4**. The reactions led to *endo*-selective 1,3-dipolar cycloadditions giving products with up to 73% ee (Scheme 11).[34] In the other report, Kobayashi

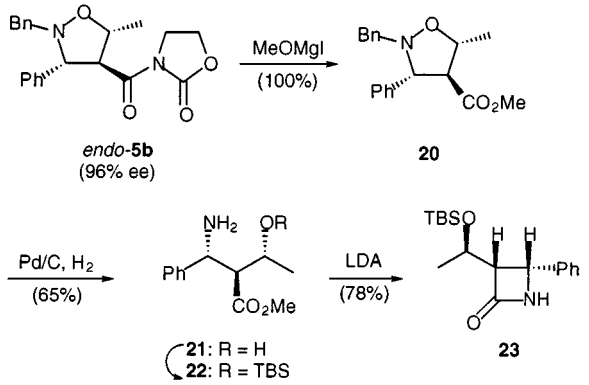


Scheme 11

et al. described a 1,3-dipolar cycloaddition catalysed by 20 mol% of the $Yb(OTf)_3$–BINOL complex **17** in the presence of the achiral tertiary amine **18**.[35] In this approach the nitrone **3** (R^1 = Bn) was formed *in situ* from the respective aldehyde and hydroxylamine. High *endo*-selectivities were observed, and for one derivative the product *endo*-**5** was obtained with 78% ee.[35] In an extension of these investigations the 1,3-dipolar cycloaddition reaction was performed in the presence of 20 mol% of the catalyst **17** and 40 mol% of the chiral amine **19**.[36] By substituting the achiral amine **18** with the chiral amine **19**, the selectivity of the reaction was improved significantly. For the reactions of some derivatives of **3** and **4**, *endo*-**5** was obtained as a single diastereomer and with up to 96% ee. Further investigation in this field by Kobayashi *et al*. led to the finding that the absolute stereoselectivity of the reaction was reversed when the reaction was performed in the absence of MS 4 Å.[37] This observation is analogous to the MgX_2–BOX catalysed reactions, where a similar incidence was observed.[28] In the reaction catalysed by **17** using **19** as the additive, *endo*-**5** (R^1 = Bn, R^2 = Me) was obtained in 96% ee in the presence of MS 4 Å. In the absence of MS 4 Å the opposite enantiomer was obtained in 50% ee. This inverse selectivity could be improved by using various *N*-oxides as a third additive.[37]

Whereas there are numerous examples of the application of the products from the diastereoselective 1,3-dipolar cycloaddition reactions in synthesis,[2,3] there are only very few examples

of the application of the products from catalytic enantioselective 1,3-dipolar cycloaddition reactions in the synthesis of potential target molecules. The reason for this may be due to the fact that most asymmetric metal-catalysed 1,3-dipolar cycloaddition reactions have been carried out on model systems that have not been optimised for further derivatisation. One exception of this is the elegant and short synthesis of a β-lactam by Kobayashi and Kawamura.[36] The isoxazolidine *endo*-**5b**, which was obtained in 96% ee from the $Yb(OTf)_3$–BINOL catalysed 1,3-dipolar cycloaddition reaction, was converted into the ester derivative **20**, quantitatively (Scheme 12). Hydrogenation over

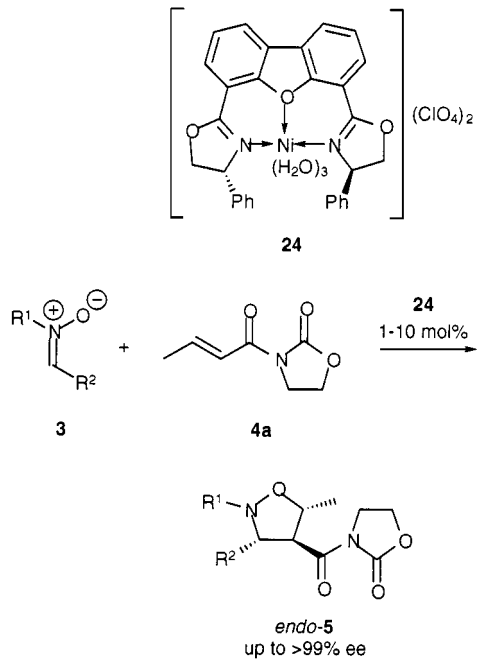


Scheme 12

palladium on carbon opens the isoxazolidine ring and cleaves the *N*-benzyl moiety to give **21**. Following a silyl protection of the hydroxy group to obtain **22**, the final ring-closure is mediated by LDA to give the β-lactam **23** in a high yield with a conserved optical purity of 96% ee.

Nickel catalysts

In 1998 Kanemasa *et al.* published the structure of dibenzofuranyl-2,2′-bisoxazoline (DBFOX) which has proved to be an excellent new ligand for a variety of Lewis acids.[38] The catalytic reactions that have been developed using this type of Lewis acid–DBFOX complex include catalytic 1,3-dipolar cycloaddition reactions of nitrones.[39] The $Ni(ClO_4)_2$–DBFOX/Ph complex **24** (Scheme 13) is a quite remarkable Lewis acid



Scheme 13

catalyst as it can be formed from the aqueous $Ni(ClO_4)_2 \cdot 6H_2O$ salt and the ligand. The water can be removed by the addition of MS 4 Å. The reaction between different nitrones **3** and crotonoyloxazolidinone **4a** proceeded in the presence of 1–10 mol% of the dicationic nickel complex **24** as the catalyst. Although long reaction times were required to obtain good yields, the reactions proceeded, in most cases, with very high *endo*-selectivities, and in several cases > 99% ee of the *endo*-products **5** was obtained. So far this catalyst is undoubtedly the most selective catalyst for the normal electron-demand 1,3-dipolar cycloaddition reaction between nitrones and alkenes, especially with respect to the enantioselectivity of the reaction.[39]

The inverse electron-demand reactions

The other catalytic approach to the 1,3-dipolar cycloaddition reaction is the 'inverse electron-demand', in which the nitrone is activated for addition to an electron-rich alkene such as, for example, a vinyl ether (Fig. 2). In this scenario the $FMO's_{alkene}$

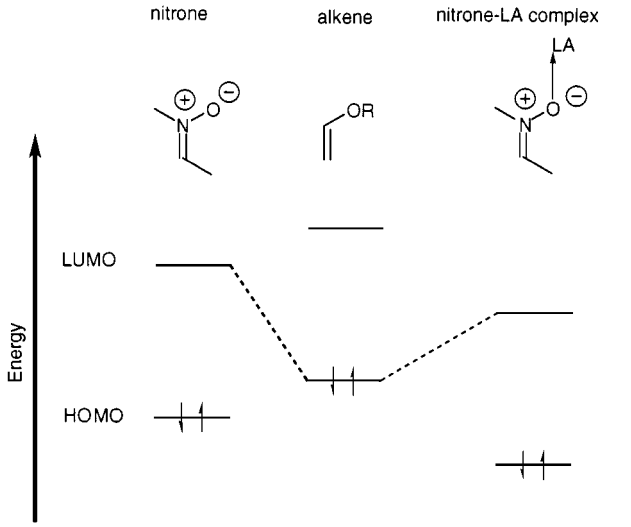


Fig. 2 The catalytic alteration of the nitrone FMO's in the inverse electron-demand 1,3-dipolar cycloaddition reaction.

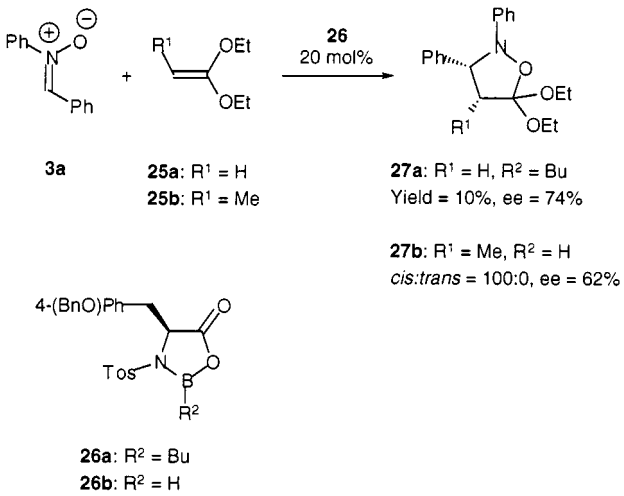
have higher energies than the $FMO's_{nitrone}$ and the dominating interaction in the reaction will be $LUMO_{nitrone}$–$HOMO_{alkene}$. The nitrone can coordinate to the Lewis acid, leading to a decrease of the $LUMO_{nitrone}$ energy. The decreased energy gap between the two FMO's responsible for the dominating interaction leads to an enhanced rate of the 1,3-dipolar cycloaddition reaction of nitrones.

Boron catalysts

Scheeren *et al.* reported the first catalytic enantioselective 1,3-dipolar cycloaddition reaction of nitrones with alkenes in 1994.[40] Their approach involved *C*,*N*-diphenylnitrone **3a** and ketene acetals **25**, and the amino acid derived oxazaborolidinones **26** were applied as the catalyst (Scheme 14). This type of boron catalyst has been used successfully for asymmetric Diels–Alder reactions.[41,42] In this reaction the nitrone is activated, according to the inverse electron-demand, for a 1,3-dipolar cycloaddition with the electron-rich alkene. They found that coordination of the nitrone to the boron Lewis acid strongly accelerated the 1,3-dipolar cycloaddition reaction with ketene acetals. The reactions of **3a** with **25a**,**b** were catalysed by 20 mol% of oxazaborolidinones such as **26a**,**b**. Fair enantioselectivities were induced and **27a** was obtained with an optical purity of 74% ee, however, in a low yield. The reaction involving **25b** gave the *C*-3,*C*-4-*cis*-isomer **27b** as the only diastereomer of the product with 62% ee.

In an extension of this work Scheeren *et al.* studied a series of derivatives of *N*-tosyl-oxazaborolidinones as catalysts for the 1,3-dipolar cycloaddition reaction of **3a** with **25b**.[43] The



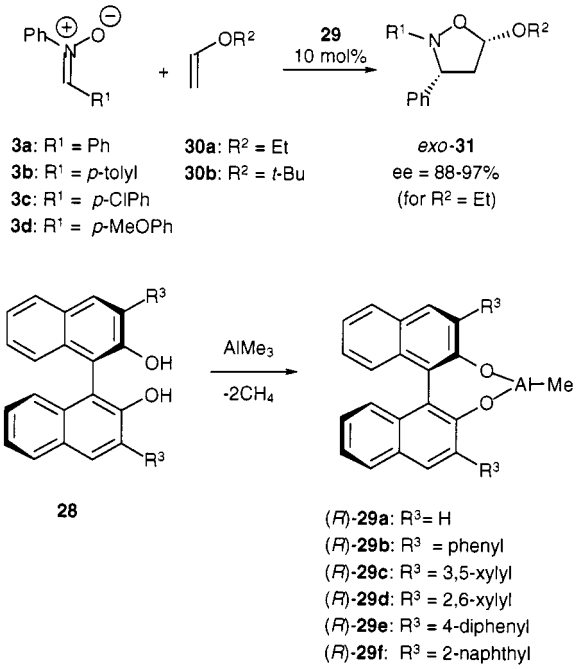
Scheme 14

addition of a co-solvent appeared to be of major importance. Catalyst **26b** was synthesized from the corresponding amino acid and BH_3·THF, hence, THF was present as a co-solvent. In this reaction (−)-**27b** was obtained with 62% ee. If the catalyst instead was synthesized from the amino acid and BH_3·SMe_2, and diphenyl ether was added, a remarkable reversal of the enantioselectivity of the reaction occurred, since (+)-**27b** was now obtained as the major isomer. Furthermore, the ee in this approach was improved to 79%. In more recent work the same research group has applied cyclic and acyclic vinyl ethers in the oxazaborolidinone catalysed 1,3-dipolar cycloaddition reaction with nitrones.[44] High diastereoselectivities were obtained, however, the highest enantioselectivity was 38% ee. In an analogous study by Meske, the impact of various oxazaborolidinone catalysts for the 1,3-dipolar cycloaddition reactions between acyclic nitrones and vinyl ethers was studied.[45] The highest enantioselectivity obtained in this work was 20% ee.

Aluminium catalysts

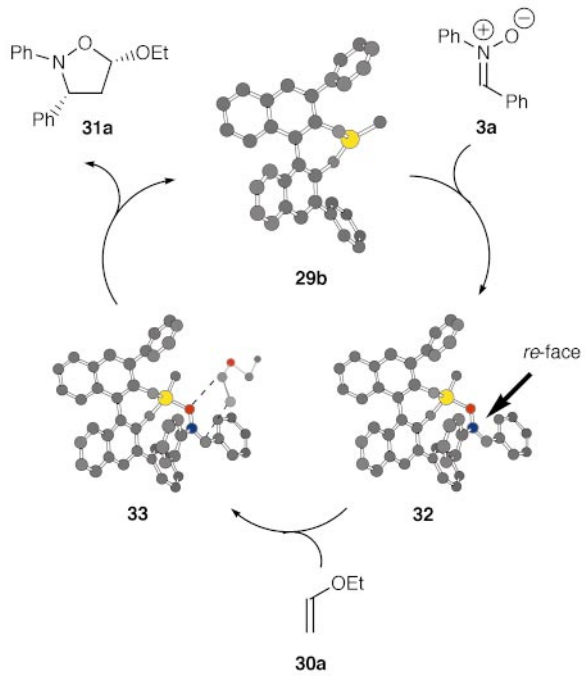
As for boron catalysts, the aluminium catalysts have exclusively been applied for the inverse electron-demand 1,3-dipolar cycloaddition between alkenes and nitrones. The first contribution to this field was published in 1999.[46] The initial catalytic experiments were performed using the AlMe–BINOL catalyst **29a**, that was simply synthesised by mixing the chiral BINOL ligand **28a** with $AlMe_3$ (Scheme 15). This catalyst was applied for the reaction between nitrone **3a** and vinyl ethers **30a**,**b**. A large rate enhancement was observed by using this catalyst, although, the selectivity of the reactions was rather disappointing. As part of these studies a new method for the synthesis of 3,3′-aryl substituted BINOL ligands **28b**–**f** was developed.[47] The introduction of substituents in the ligands 3,3′-position as in catalysts **29b-f** led to a remarkable improvement of the selectivities when these catalysts were applied in the reaction of **3a** with **30b** (Scheme 15). In particular, complex **29b** possessed the desired properties as the reaction performed in the presence of 20 mol% of this catalyst was completed within 45 min to give *exo*-**31b** (R^1 = Ph, R^2 = *t*-Bu) as the only observable diastereomer with 89% ee. The best results were achieved by applying the ethyl vinyl ether **30a** in the reaction instead of **30b**. The reactions between a series of nitrones **3a**–**d** with **30a** catalysed by 10 mol% of **29b** all proceeded to give the corresponding products **31** with excellent *exo*-selectivities and with enantioselectivities of 88–97% ee.[46]

A model for the mechanism of the highly enantioselective AlMe–BINOL-catalysed 1,3-dipolar cycloaddition reaction was proposed as illustrated in Scheme 16. In the first step nitrone **3a** coordinates to the catalyst **29b** to form intermediate **32**. In this intermediate, which is proposed to account for the absolute stereoselectivity of the reaction, it is apparent that one



Scheme 15

of the faces of the nitrone, the *si*-face, is shielded by the ligand, whereas the *re*-face remains available for reaction with ethyl vinyl ether **30a** as shown in **33**. The high *exo*-selectivity may also be explained by the model. As appears from the step in which **30a** approaches the nitrone–catalyst complex **33**, the ethoxy moiety of **30a** is pointing away from the nitrone *N*-phenyl group which leads to formation of the *exo*-isomer of the product **31a**. The assignment of the absolute configuration of the product was in full agreement with the *re*-face selectivity proposed in this model.[46]



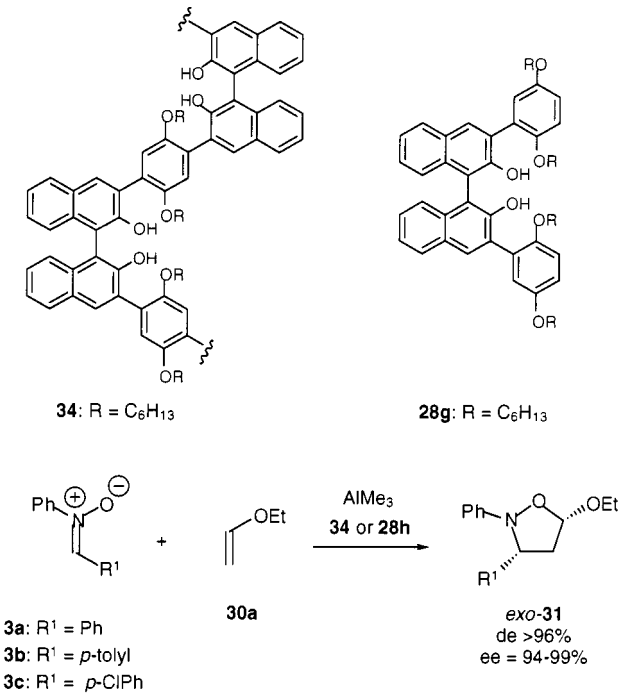
Scheme 16

Pu *et al.* have developed a new type of rigid polymer of 1,1-binaphthols.[48–50] The 3,3′-crosslinked polymeric binaphthol ligand **34** in combination with $AlMe_3$ was applied as the catalyst for the 1,3-dipolar cycloaddition (Scheme 17).[51] Very high selectivities were obtained when the aluminium catalyst of **34** (20 mol%) was applied to the 1,3-dipolar cycloaddition reaction of nitrone **3a** with alkene **30a**. The only observable

diastereomer resulting from the reactions was *exo*-**31a** (R^1 = Ph) and it was obtained with an enantioselectivity as high as 99% ee. One of the advantages of using a polymeric catalyst is the easy removal and recovery of the ligand from the reaction. Upon completion of the reaction, the catalyst was hydrolysed and the ligand precipitated by addition of methanol. After evaporation of the solvent and the excess of **30a**, the pure product *exo*-**31a** was isolated in 97% yield. Similar excellent selectivities were obtained for reactions of other nitrones.

Another important advantage of using the polymeric ligand **34** is, in addition to the easy purification of the product, that the ligand can be isolated and reused after the simple precipitation procedure. In this manner a sample of the polymeric ligand was isolated and reused in four consecutive reactions of nitrone **3a** and ethyl vinyl ether **30a**. Both yield and enantioselectivity of *exo*-**31a** showed only slight decreases after the ligand had been reused. The slight decrease was ascribed to the loss of small amounts of the ligand during the recycling procedure.[51]

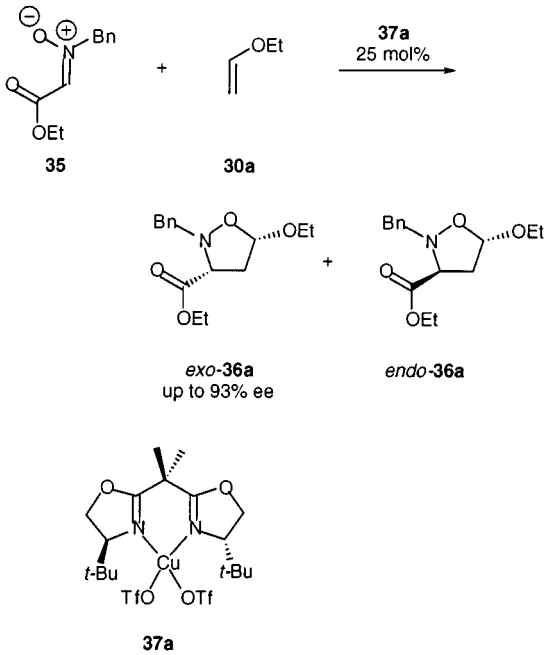
The polymeric ligand's monomeric counterpart **28g** was also synthesised and applied in the 1,3-dipolar cycloaddition reaction in order to compare the properties with the polymeric ligand (Scheme 17). When **28g** in combination with $AlMe_3$ (10 mol%) was used as the catalyst for the reactions between nitrones **3a**–**c** and ethyl vinyl ether **30a**, the reactions proceeded to give the pure *exo*-**9** in yields ranging from 76–93%. The enantioselectivities of the reactions were very high at 94–99% ee, and were thus comparable to the results obtained using the polymeric ligand.



Scheme 17

Copper catalysts

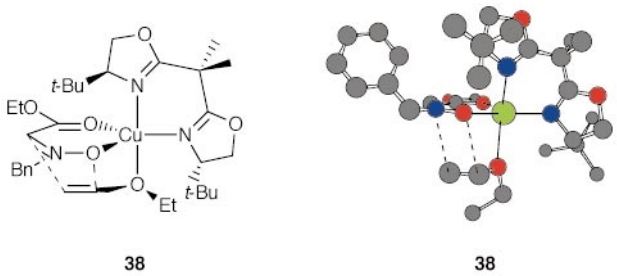
In order to control the stereochemistry in the 1,3-dipolar cycloaddition reactions the bidentate glyoxylate derived nitrone **35**, chiral copper catalysts were applied.[52] For the reaction of nitrone **35**, the electron-rich ethyl vinyl ether **30a** was chosen as the dipolarophile (Scheme 18). A series of chiral catalysts was investigated for the reaction and the $Cu(OTf)_2$–*t*-Bu-BOX complex **37a** was found to be the most suitable catalyst for this reaction. In the presence of 25 mol% of **37a** the reaction proceeded to give a conversion of 98%, an *exo*:*endo* ratio of 84:16, and as the most significant result, *exo*-**36a** was obtained with 89% ee. By changing the solvent to toluene the



Scheme 18

diastereoselectivity of the reaction was slightly lowered, but the enantioselectivity was improved to 93% ee.[52]

In order to account for the stereoselectivity observed in this reaction a model **38** for the intermediate consisting of substrates

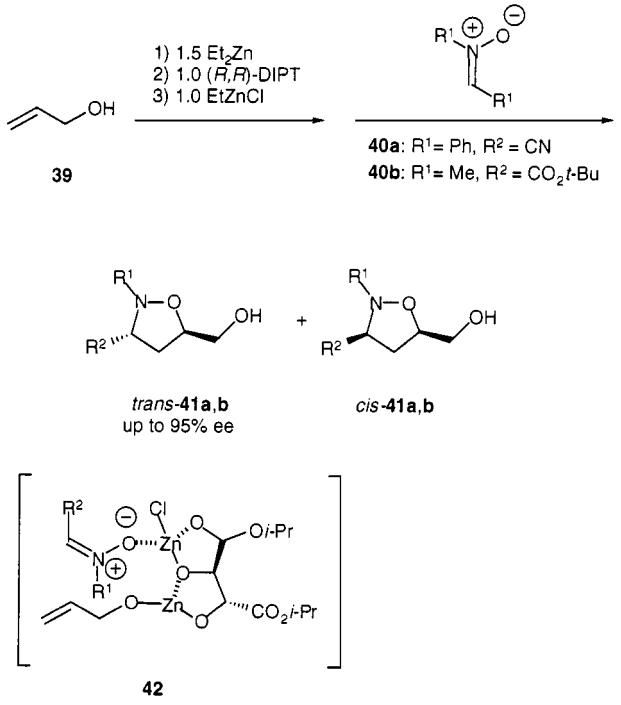


35 and ethyl vinyl ether **30a** coordinated to catalyst **37a** was proposed.[52] In the model the two triflate ligands are dissociated from copper and the ligands are arranged around the copper center as a trigonal bipyramid. It should be noted that in model **38** the oxygen atom of vinyl ether **30a** also coordinates to the metal center. However, a tetrahedral intermediate consisting of only the catalyst and the nitrone could also account for the absolute stereoselectivity of the reaction.

It should also be mentioned that Bosnich *et al.* have applied a chiral titanocene derived catalyst for the inverse electron-demand 1,3-dipolar cycloaddition reaction of nitrones with ketene acetals, however, the highest chiral induction was 14% ee.[53]

Other types of asymmetric catalysis

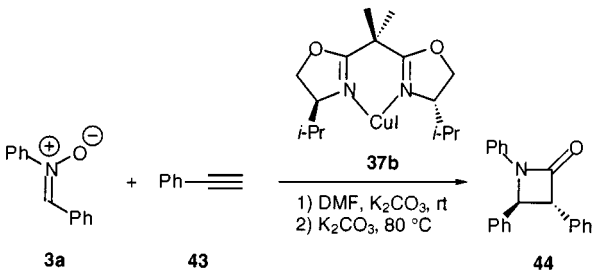
A different catalytic enantioselective approach was developed for the 1,3-dipolar cycloaddition reaction of nitrones with allyl alcohol (Scheme 19).[54] The zinc catalyst complex, which was used in a stoichiometric amount, was generated from allyl alcohol **39**, Et_2Zn, (*R*,*R*)-diisopropyltartrate (DIPT) and EtZnCl. Addition of the nitrone **40a** led to primarily *trans*-**41a**, which was obtained in a moderate yield, however, with a high ee of up to 95%. Application of **40b** as the nitrone in the reaction led to higher yields of **41b** (47–68%), high *trans*-selectivities and up to 93% ee. Compared to other asymmetric metal catalysed 1,3-dipolar cycloaddition reactions of nitrones, this reaction cannot be assigned as normal or inverse electron-demand. The reaction is controlled, rather than by altered FMO energies, instead by the chelation of the substrates to the catalyst



Scheme 19

leading to a favorable entropy of the proposed pseudo-intramolecular intermediate **42**.

Another quite different asymmetric copper catalysed reaction was published by Miura *et al*. in 1995.[55] The reaction of nitrone **3a** and phenylacetylene **43** is catalysed by CuI–*i*-Pr-BOX **37b** as outlined in Scheme 20. The product of this reaction is not a



Scheme 20

1,3-dipolar cycloaddition adduct, rather it is the azetidone **44**. The reaction proceeds, however, *via* an isoxazoline intermediate and is therefore mentioned here. By using 1 equivalent of the catalyst **37b**, the *trans*-isomer **44** is obtained in 54% yield and with 68% ee. If the catalyst loading is lowered to 10 mol% CuI and 20 mol% ligand the selectivity decreases to 57% ee.

Summary

The catalytic enantioselective 1,3-dipolar cycloaddition reaction of nitrones has reached a mature stage and there are several examples of reactions that proceed with very high enantioselectivities. For the normal electron-demand 1,3-dipolar cycloaddition reaction of nitrones with electron-deficient alkenes a number of metal complexes have been applied successfully. All of these have in common that they favor a bidentate coordination of the alkenoyloxazolidinone (or succinimide) to the metal catalyst. Most of these reactions proceeded with *endo*-selectivity. The chiral $Ni(ClO_4)_2$–DBFOX/Ph has been the most selective catalyst for the *endo*-selective normal electron-demand 1,3-dipolar cycloaddition reaction so far. Application of 1–10 mol% of this catalyst induced in general very high enantioselectivities of up to 99% ee. It has been more difficult to obtain the *exo*-isomer in the above described reaction. The application of succinimide as an auxiliary for the alkene in the $TiCl_2$–TADDOLate catalysed reaction has been the only entry to a highly *exo*-selective reaction and in this case up to 72% ee of the *exo*-isomer was obtained.

Other types of catalysts had to be applied for the inverse electron-demand 1,3-dipolar cycloaddition reaction of nitrones with electron-rich alkenes. Fair enantioselectivities of up to 79% ee were obtained with oxazaborolidinone catalysts. However, the AlMe–3,3′-Ar-BINOLate complexes proved to be superior for reactions of acyclic nitrones and more than > 99% ee has been obtained in some reactions. The CuX_2–BOX catalyst was efficient for reactions of the glyoxylate derived nitrones with vinyl ethers and enantioselectivities of up to 93% ee were obtained. A few examples of different approaches to catalyst induced control of the stereoselectivity of the reaction have also been reported, however, in these examples a stoichiometric amount of the chiral catalyst was required.

The development of catalytic enantioselective 1,3-dipolar cycloaddition is probably going to continue during the next decade and there are some problems that need to be solved. One of the major drawbacks for most of the reactions is the high catalyst loadings that are required. Another challenge is to explore new substrates that are more suitable for application in synthesis. Hopefully, some of these problems will be solved, because the catalytic enantioselective 1,3-dipolar cycloaddition reaction of nitrones is a highly valuable reaction for the control of multiple stereocenters in a single reaction step.

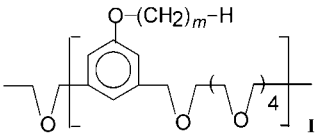
A solvent-free, low-dimensional polymer electrolyte blend is described demonstrating a novel process of 'self-tracking' along the field direction in DC polarisation between lithium electrodes and giving ambient DC and AC conductivities upto 10^{-3} S cm^{-1} with low temperature dependence of conduction.

Solvent-free polymer electrolytes have been based largely upon complexes of lithium salts in amorphous forms of poly(ethylene oxide) (PEO).[1–3] However, their application in ambient temperature batteries, requiring conductivities of *ca.* 10^{-3} S cm^{-1}, has been prohibited due to their low ambient temperature conductivities. Other amorphous systems giving conductivities between 10^{-4}–10^{-5} S cm^{-1} have been proposed.[4,5] With a view to creating low impedance pathways and inhibiting ion aggregates we have adapted the extended helical crystalline structures of PEO–alkali salt complexes[6–8] to synthesise organised low-dimensional polymer complexes[9–13] with amphiphilic polymers poly[2,5,8,11,14-pentaoxapentadecamethylene(5-alkyloxy-1,3-phenylene)] coded C*m*O5 or (**I**).



I

-[-O-(-(CH$_2$)$_4$-O-)$_x$-A-]- x = *ca.* 30 **II**

When m = 16, (C16O5), sidechains interdigitate in an hexagonal lattice layer between polyether helices into which cations are encapsulated, one per repeat unit/helical turn, in equimolar complexes denoted, *e.g.* C16O5:LiClO$_4$ (1:1). Anions lie in the interhelical spaces. (*cf.* Fig. 1) and interlamellar long spacings of 40–45 Å are observed.[9,10,11]

Here, we report enhanced ambient conduction in solvent-free LiClO$_4$ and LiClO$_4$/LiBF$_4$ complexes of C*m*O5 blended with a second copolymer of poly(tetramethylene oxide) (**II**). The *n*-alkyl side chains R in **I** are either C$_{16}$H$_{33}$ (C16O5) or a random equimolar copolymer mixture with C$_{12}$H$_{25}$ (C16C12O5). In **II** the units -A- are either -CH$_2$- (denoted **II**C1) or -CH$_2$C(=CH$_2$)CH$_2$- (denoted **II**D4). Both **I** and **II** are prepared to high molar mass ($<M_w>$ = 8 × 10^4 and 4 × 10^4 respectively) giving thin films with good mechanical properties.

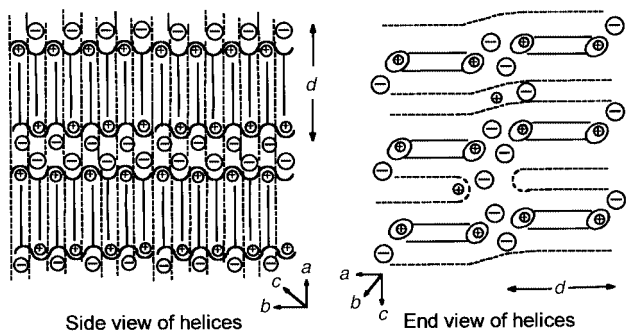


Fig. 1 Schematic molecular structure of C16O5:**II**:LiClO$_4$: Solid lines: C16O5, dashed lines: polymer **II**.

Polymers **I**[9,10] and **II** were prepared by standard Williamson condensations and complexes were prepared by mixing polymer **I** (1 mol repeating unit), polymer **II** (7 mols of (-(CH$_2$)$_4$-O-)- units) and either LiClO$_4$ (1.5 mol) or LiClO$_4$ / LiBF$_4$ (0.75/0.75) from mixed dichloromethane/acetone solvent. The heptamer segment for the stoichiometric equivalent of polymer **II** for each repeat unit of **I** is indicated by a molecular dynamics model.† The molar compositions of complexed blends are therefore denoted **I**:**II**:Li salt (1:1:1.5) where the second digit denotes the mol of heptamer segment. The schematic model (Fig. 1) and the molecular model† are consistent with small-to-wide angle X-ray analysis and with DSC which indicate that the strands of polymer **II** disrupt the alkyl sidechains of polymer **I**. Sidechain melting temperatures are reduced by *ca.* 10 °C by blending with **II**. C16O5:**II**:LiClO$_4$ melts at *ca.* 34 °C at the peak. Complexes with mixed m = 16/12 sidechains (C16C12O5) melt at *ca.* 24 °C. The pure polymers **II** melt at *ca* 20 °C.

Fig. 2 shows isothermal DC‡ conductivity *vs.* time in cells with Li electrodes (Li|**I**/**II**–LiClO$_4$|Li) for C16O5 : **II** : LiClO$_4$ (1 : 1 : 1.5) polarised with 10 mV at 30 °C, Fig. 2(*a*), and C16O5 : **II** : LiClO$_4$: LiBF$_4$ (1 : 1 : 0.75 : 0.75) polarised with 100 mV at 25 °C, Fig. 2(*b*). In a novel 'self-tracking process' the current increases stepwise over *ca.* 24 h corresponding to Li$^+$ conductivity increasing from *ca.* 10^{-6} S cm^{-1} to *ca.* 10^{-3} S cm^{-1}.

The DC data are supported by AC complex impedance measurements for C16O5:**II**:LiClO$_4$ (1:1:1.5) and C16C12O5:**II**:LiClO$_4$ (1:1:1.5) between ITO electrodes as shown in Fig. 3(*a*) and (*b*) as log σ *vs.* 1/T. From lower levels at ambient temperatures all three systems undergo similar 'transitions' on heating to *ca.* 100 °C after which ambient conductivities between 2–6 × 10^{-4} S cm^{-1} are observed. In

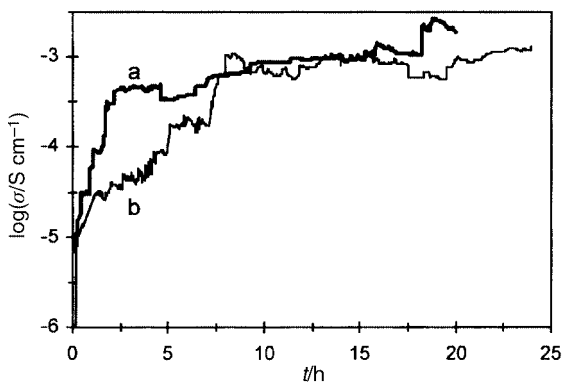

Fig. 2 DC polarisation between lithium electrodes. (*a*) C16O5:**II**D4:LiClO$_4$ (1:1:1.5), 10 mV at 30 °C, 450 μm. (*b*) C16O5:**II**C1:LiClO$_4$: LiBF$_4$ (1:1:0.75:0.75), 100 mV at 25 °C, 100 μm.

† Electronic supplementary information (ESI) available: a molecular dynamics model with coloured atoms of the C16O5:**II**:Li salt complex from Cerius[2] software. See http://www.rsc.org/suppdata/cc/b0/b004174m/

DOI: 10.1039/b004174m

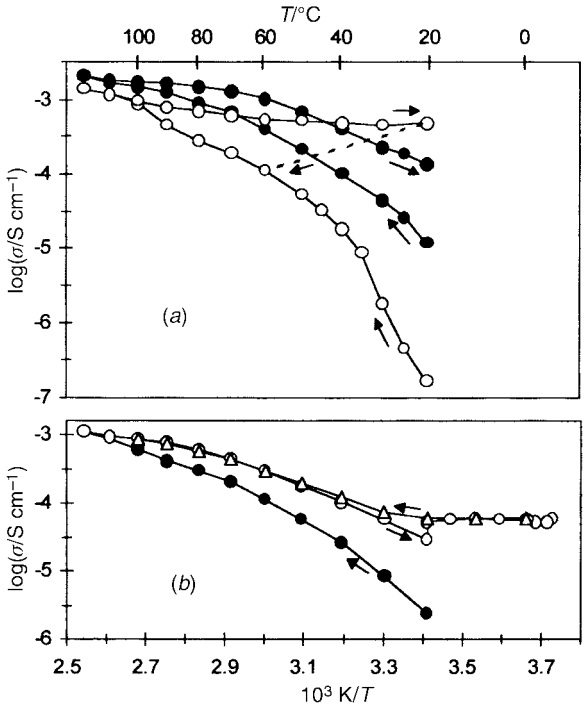

Fig. 3 Temperature dependence of AC conductivities between ITO electrodes. Arrows indicate the direction of heating. (*a*) C16O5:**II**C1:$LiClO_4$ (1:1:1.5) (—○—) and C16C12O5:**II**C1:$LiClO_4$ (1:1:2) (—●—) Cell thicknesses are 100 μm. (*b*) C16O5:**II**D4:$LiClO_4$ (1:1:1.5) Heating (—●—), cooling (—○—) and reheating (—△—). Cell thickness is 50 μm.

Fig. 3(*b*) the ambient conductivity is slightly lower at 8×10^{-5} S cm^{-1} after an isothermal increase over *ca.* 12 h at 20 °C but this level of conductivity is remarkably maintained down to −5 °C. The cooling runs of the C16O5 systems also demonstrate virtual temperature independence (temperature-independent conductivities at the level of 10^{-7}–10^{-6} S cm^{-1} have previously been observed[13] in Langmuir–Blodgett films of a variety of C16O5-Li salt complexes). However, whereas the 'cooling data' are unstable on re-heating above the sidechain melting temperature (*ca.* 35 °C), returning to the lower initial heating curve, Fig. 3(*a*), the data in Fig. 3(*b*) demonstrate that on cooling below the side chain melting endotherm (lower limit 20 °C) stable and reversible conductivities may be observed.

The possibility that Li dendrite formation has a significant influence on these and a number of other DC polarisations reproducing these results is not supported by comparisons with observed[14] dendritic growth in conventional amorphous polymer electrolyte systems. In contrast to the latter the tracking phenomenon commences almost from the outset with very low current densities (*ca.* 0.1 μA cm^{-2}) and without cycling, Furthermore, the maximum conductivities (*ca.* 10^{-3} S cm^{-1}) are reproduced over a wide range of final current densities. In Fig. 2(*b*) (100 mV and 100 μm cell thickness) the current density is 45 times greater than in Fig. 2(*a*) (10 mV and 450 μm thickness, 0.2 mA cm^{-2} maximum).

It is anticipated that polymer **II** (with the more extensive skeletal domain) will promote orientation of conducting planes *bc* in the direction normal to the electrodes when the blend is subjected to mechanical shear in the plane of the film (parallel to the electrodes). The ion current may perhaps assist such orientations by a 'melting–recrystallisation' reorganisation within the sidechain melting endotherm (20–35 °C). However, imposition of the field is expected to bring about a new steady state redistribution of ions between the channels of polymer **I** and the polymer **II** environment promoting vacancies in **I** in which ions are presumed the more mobile ($\sigma = 7 \times 10^{-7}$ S cm^{-1} for complexes of pure **II** with $LiClO_4$ at 25 °C). The relative mobilities and stabilities of ions in **I** and **II** and the identification of premelting (order–disorder) transitions which could account for the low temperature dependence of conductivity are subjects of further work.

We acknowledge financial support for this work from the Engineering and Physical Science Research Council.

1-Ethoxyvinyl 2-furoate, an efficient acyl donor for the lipase-catalyzed enantioselective desymmetrization of prochiral 2,2-disubstituted propane-1,3-diols and meso-1,2-diols†

Shuji Akai, Tadaatsu Naka, Tetsuya Fujita, Yasushi Takebe and Yasuyuki Kita*

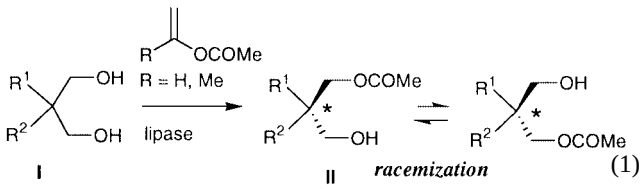
Received (in Cambridge, UK) 15th May 2000, Accepted 19th June 2000
Published on the Web 21st July 2000

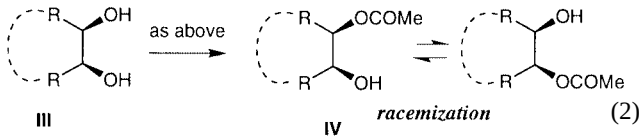
A novel acyl donor, 1-ethoxyvinyl 2-furoate, was found to produce the title reactions with high enantiotopic selectivity, high reactivity and stability of the products under various conditions.

The enzymatic transesterification of alcohols with acyl donors in organic solvents has become a widely applicable protocol to provide a variety of optically active compounds.[1] However, its application to the enantioselective desymmetrization of prochiral 2,2-disubstituted propane-1,3-diols (**I**) has rarely been reported, despite the promising potential of this approach as a powerful alternative to the well-investigated chemical syntheses of compounds bearing an optically active quaternary carbon center.[2] Recently, Fadel and Arzel reported the first practical enzymatic desymmetrization of **I** using well-known acyl donors, *i.e.* vinyl acetate and isopropenyl acetate. The reactions, however, suffered from low reactivity (it usually took several days or more to consume **I**), and racemization of the products **II** *via* acyl group migration was often observed [eqn. (1)].[3] Easy racemization of the products **IV** has also been an



(1)

annoying problem for the desymmetrization of the *meso*-1,2-diols (**III**) [eqn. (2)].[4,5] Therefore, to solve these problems



(2)

the development of an effective acyl donor which fulfills the criteria of high enantiotopic selectivity, high reactivity,[6] and production of stable products under various conditions is an urgent matter.

Very recently, we reported that 1-ethoxyvinyl acetate is similar-to-more reactive than vinyl acetate in the common enzymatic transesterifications[7] and we developed 1-ethoxyvinyl benzoate (**1a**) as an effective reagent for the desymmetrization of **I**.[8] However, this method is still unsatisfactory for sterically congested 1,3-diols in terms of the reaction time and the enantiotopic selectivity. The finding for **1a** encouraged us to find a more prominent ethoxyvinyl aromatic ester.[9] In this communication, we present 1-ethoxyvinyl 2-furoate (**1b**) as an effective reagent applicable to both diols **I** and **III**.

In the preliminary evaluation of 19 aroyl reagents **1** on the desymmetrization of the congested diol **2** under identical reaction conditions (the reaction was quenched when **2** was consumed), we observed that the 2-furoate (**1b**) was the best reagent in both reactivity and enantiotopic selectivity (Table 1, run 1). Some other reagents (**1**, Ar = *p*-tolyl, *p*-bromophenyl, 5-bromo-2-furyl, 2-thienyl) were fairly effective in producing the corresponding mono esters (75–86% ee, 46–60% isolated yields), and the rest were moderate (Ar = 2-naphthyl, *p*-

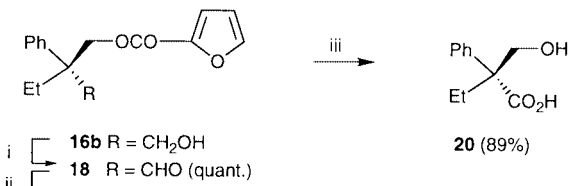
methoxyphenyl, *p*-nitrophenyl, 3-methyl-2-furyl, 3-furyl; 50–80% ee, 22–41% isolated yields) or poorly reactive (Ar = *o*-tolyl, 1-naphthyl, 1-anthryl, 1-methylpyrrol-2-yl, 4-pyridyl, 3-pyridyl, 3-quinolyl, benzofuran-2-yl, 1-methylindol-2-yl).[10] Therefore, the desymmetrization of various types of 2,2-disubstituted 1,3-diols (**3–9**) was performed using **1b** (Table 1). These results disclosed the eminent performance of **1b** as follows.

First, the reactions using **1b** were generally completed within 5 h. This is quite remarkable because all of the other aroyl donors required at least 1 day and generally more than 4 days to consume the diols. Second, the optical and the chemical yields of the products **10b**–**17b** were generally high and better than those obtained using the other aroyl reagents. Particularly, the product **15b** was obtained with > 99% ee. Third, the stability of the furoate **10b**–**17b** under acidic conditions was very much improved as noted from the following example. Thus, **16b** was inert to racemization in an acidic medium [0.1 equiv. of camphorsulfonic acid (4×10^{-4} M) in CH_2Cl_2] at room temperature after 1 d, whereas the same treatment of the corresponding benzoate resulted in gradual racemization ($t_{1/2}$ = 18 h).[8] All of these products were easily isolated by standard column chromatography on SiO_2, and the optical purity did not decrease during the chromatography.

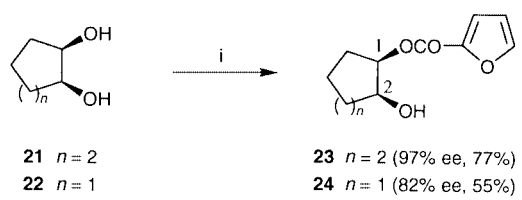
In addition, an improvement in the optical purity of the products was observed by prolonging the reaction time beyond the complete mono acylation of the substrates due to kinetic amplification (*e.g.* runs 2 and 5). Because the only side-products, *i.e.* the diesters, were quantitatively hydrolyzed to the starting diols, this method provides products with high optical purity without any loss in chemical yield.

The furoate moiety was preserved under oxidizing conditions. Neither a decrease in optical purity nor decomposition of the furan ring was observed after treatment of **16b** (88% ee) with the Dess–Martin periodinane, and the corresponding aldehyde **18** was quantitatively obtained with 87% ee as determined using a chiral HPLC column. Further treatment of **18** with $NaClO_2$ followed by methanolysis gave the known carboxylic acid (*R*)-**20** {$[\alpha]_D^{22}$ +13.4 (*c* 0.8, $CHCl_3$), lit.[11] $[\alpha]_D^{20}$ −16.5 (*c* 1.0, $CHCl_3$) for 97% ee of the (*S*)-form}. Therefore, the absolute configuration of **16b** was determined to be *S* (Scheme 1).



Scheme 1 *Reagents and conditions*: i, Dess–Martin periodinane, CH_2Cl_2, 0 °C → room temperature, 30 min; ii, $NaClO_2$, NaH_2PO_4, Bu^{t}OH–H_2O, room temperature, 10 min; iii, NaOMe, MeOH, 0 °C → room temperature, 1 h.

The reaction of the *meso*-1,2-diol **21** with **1b** using CHIRAZYME® L-9 (from *Mucor miehei*, Roche Diagnostics) provided the monofuroate (1*R*,2*S*)-**23** (97% ee, 77% yield) (Scheme 2). The optical purity did not change during purification by the standard column chromatography on SiO_2. Similarly, the desymmetrization of **22** gave (1*R*,2*S*)-**24** (82% ee, 55% yield).†[12,13]



Scheme 2 *Reagents and conditions*: i, **1b** (2.5 equiv.), CHIRAZYME® L-9, Bu^{t}OMe, 45 °C, 2 d.

In conclusion, the above-mentioned procedure using **1b** features the following advantages. (1) **1b** is readily prepared from commercially available ethoxyacetylene and 2-furoic acid in high yield and may be stored in a refrigerator for more than six months. (2) The products are obtained in high optical and chemical yields. If necessary, the only side-products, diesters, can be converted to the starting diols. (3) The products are sufficiently stable under various conditions and can serve as the key synthetic intermediates for optically active compounds having a quaternary carbon center at the benzylic position. Moreover, the high reactivity and high enantiotopic selectivity of **1b** are outstanding among a large number of acyl donors and offer an interesting topic from the mechanistic point of view.

This work was supported by Grants-in-Aid for Scientific Research (No. 09557180 and 11672102) from the Ministry of Education, Science, Sports, and Culture, Japan and the Takeda Science Foundation, Japan. 12 *Typical procedure for the enzymatic desymmetrization of the 1,3-diols using **1b***. Commercially available Pr$^i_2$O was distilled as usual, and 0.1% of water was added. After vigorous stirring at room temp. for 20 min, the mixture was allowed to settle. The upper layer (3.0 cm^3) was placed in a resealable test tube, to which were successively added **1b** (0.60 mmol), the 1,3-diol (0.20 mmol), and lipase MY (125 mg). The flask was sealed, and the reaction mixture was stirred at 30 °C during the time given in Table 1 and filtered through a Celite® pad. The filtrate was concentrated *in vacuo*, and the residue was purified by column chromatography on SiO_2 (hexane–EtOAc) to give the monoester and the diester. *Optical rotations of the products*: **10b**, 90% ee, $[\alpha]_D^{28}$ −37.0 (*c* 0.99, $CHCl_3$); **11b**, 61% ee, $[\alpha]_D^{23}$ +10.5 (*c* 0.95, $CHCl_3$); **12b**, 91% ee, $[\alpha]_D^{28}$ −16.5 (*c* 0.68, $CHCl_3$); **13b**, 85% ee, $[\alpha]_D^{23}$ +18.6 (*c* 1.4, $CHCl_3$); **14b**, 92% ee, $[\alpha]_D^{23}$ +30.8 (*c* 0.96, $CHCl_3$); **15b**, > 99% ee, $[\alpha]_D^{20}$ −4.9 (*c* 0.86, $CHCl_3$); **16b**, 89 ee, $[\alpha]_D^{20}$ −10.3 (*c* 0.93, $CHCl_3$); **17b**, 82 ee, $[\alpha]_D^{20}$ −19.3 (*c* 0.54, $CHCl_3$); **23**, 97% ee, $[\alpha]_D^{19}$ −3.0 (*c* 0.7, $CHCl_3$); **24**, 82% ee, $[\alpha]_D^{19}$ −1.9 (*c* 1.1, $CHCl_3$).

13 The absolute configurations of the products, (*S*)-**15b**, (*S*)-**17b**, (1*R*,2*S*)-**23** and (1*R*,2*S*)-**24**, were deduced by comparison of specific rotations of these or their derivatives with those of authentic samples. The details will be presented in a forthcoming full paper. The absolute configuration of the others (**10b**–**14b**) have not been established yet.

Intramolecular [2+2] photocycloadditions as an approach towards the bicyclo[2.1.1]hexane substructure of solanoeclepin A

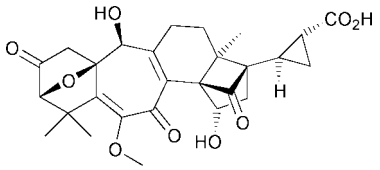
The synthesis of a tricyclic substructure of solanoeclepin A is described. The key step involves an intramolecular [2+2] photocycloaddition between a dioxinone and a tetrasubstituted bicyclic alkene providing the strained bicyclo[2.1.1]hexane moiety.

Solanoeclepin A (**1**) is the most active natural hatching agent of the potato cyst nematode.[1] Its heptacyclic structure contains all ring sizes ranging from three to seven, including a strained

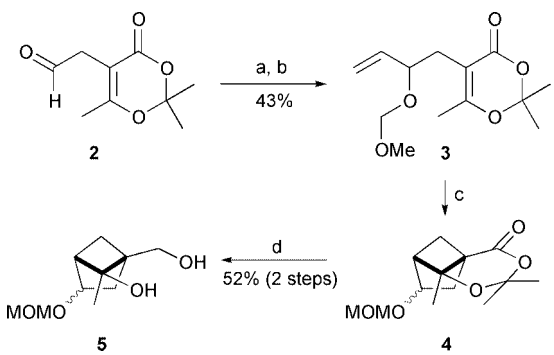


1

bicyclo[2.1.1]hexanone unit, which to the best of our knowledge is an unprecedented structural feature in natural products. The structure of **1** to a certain extent resembles that of glycinoeclepin A,[2] the hatching agent of the soybean cyst nematode. The extreme scarcity of natural material, its fascinating structure, and its potential role in the search for a benign way to control potato sickness make **1** a challenging target for total synthesis. This and the following communication[3] document our first strides towards this goal.

We have investigated intramolecular [2+2] photocycloadditions[4] between a 1,3-dioxin-4-one and variously substituted alkenes connected at C5 with a two carbon tether, to arrive at highly substituted bicyclo[2.1.1]hexanes. We wish to report herein (1) our preliminary results on these cycloadditions, which exhibit remarkably variable regioselectivities, and (2) our achievements towards the stereoselective construction of a tricyclic substructure of solanoeclepin A, containing the bicyclo[2.1.1]hexane moiety.

To investigate the viability of a photochemical approach a simple model system was selected containing the 6-methyl-1,3-dioxin-4-one moiety (see Scheme 1). This structure is known to be readily prepared and to show reliable photochemical behaviour[4] and it should eventually provide useful functionality for our total synthesis endeavour. Aldehyde **2** was prepared from commercially available *tert*-butyl acetoacetate *via* (1) alkylation with allyl bromide, (2) dioxinone formation[5] and (3) oxidative cleavage of the allyl group.[6] Subsequent alkenylation with vinylmagnesium bromide, followed by MOM protection of the allylic alcohol, afforded cyclisation precursor **3**.



2 **3** **5** **4**

Scheme 1 *Reagents*: a, vinylmagnesium bromide, THF, −78 °C; b, MOMCl, *i*-PrNEt$_2$, CH_2Cl_2, rt; c, *hν* (300 nm), MeCN–acetone (9:1 v/v), rt; d, $LiAlH_4$, THF, rt.

Upon irradiation smooth cyclisation occurred to afford the expected bicyclo[2.1.1]hexane **4** as a 1:1 mixture of diastereoisomers. This product is in accordance with the so-called 'rule of five'.[7] A close analogue has been earlier prepared by Kaneko and co-workers.[4b] Cycloadduct **4** was found to be unstable, decomposing slowly under the reaction conditions and during the subsequent work-up. However, exhaustive reduction with lithium aluminium hydride led to stable diol **5**.

Encouraged by this result, we set out to construct a more appropriately functionalised cyclisation precursor, bearing a cyclohexenyl side chain, necessary for the construction of **1**. Chromium-mediated coupling of aldehyde **2** and vinyl triflate **6**[8] (Scheme 2), followed by oxidation of the allylic alcohol and acetalisation,[9] afforded cyclisation precursor **7**. This oxidised and protected precursor was chosen to prevent diastereomeric mixtures after the cycloaddition.

Much to our surprise, cyclisation of **7** resulted in the exclusive formation of the strained bicyclo[2.2.0]hexane **8**. This cycloadduct exhibited enhanced stability compared to **4**, even to silica gel column chromatography, allowing the complete characterisation of this molecule. Ultimate proof of the structure of **8** was obtained by performing a De Mayo fragmentation, which after esterification with diazomethane gave spiro[3.4]octane **9**.[10] The structure of one of the isomers of **9** was unambiguously secured by X-ray crystallography.

We hypothesised that this remarkable regiochemical preference could be attributed to stereoelectronic effects. In an

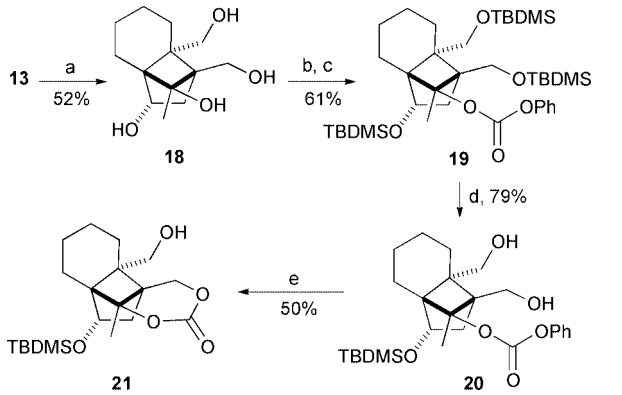
attempt to direct the cycloaddition to the desired mode of closure, aldehyde **2** was reacted with triflate **10** bearing an additional electron-withdrawing ester substituent on the alkene (Scheme 3). Not unexpectedly,[11] the product was not the hydroxy ester **11**, but lactone **12**. Gratifyingly, subjection of this latter precursor to the irradiation conditions smoothly led to bicyclo[2.1.1]hexane **13** with complete regio- and diastereoselectivity in high yield. The cycloadduct **13** appeared unstable on a silica gel column, but was readily purified by recrystallisation (mp 177–178 °C), and its structure was confirmed by X-ray crystallography‡.

To probe the generality of this cyclisation mode we also investigated the five-membered ring triflate ester **14** as starting material. Its coupling with aldehyde **2** gave hydroxy ester **15**, which did not lactonise spontaneously nor could it be forced to do so by heating. Alcohol **15** was therefore protected as the MOM ether **16**. On irradiation of **16** under the usual conditions a *ca*. 1:1 mixture of stable stereoisomeric cycloadducts **17** was obtained containing again the bicyclo[2.2.0]hexane moiety. The diastereoisomer with the OMOM group *trans* with respect to the cyclopentane ring (mp 62–64 °C) was crystalline and allowed unambiguous structural proof by X-ray diffraction.

Thus, of the four photocyclisation precursors investigated, two (**3** and **12**) cyclise in the expected crossed mode obeying the rule of five, while the other two (**7** and **16**) cyclise in the unexpected straight mode. In view of the precedent available, **3** shows normal cyclisation behaviour. However, very little is known about tri- or tetrasubstituted alkenes in photocycloadditions with 2-carbon tethered dioxinones. It is tempting to speculate that the first C–C-bond formation by radical cyclisation to a 5- or 6-membered ring is reversible,[12] depending on the feasibility of the second, irreversible C–C-bond formation. Preliminary molecular modeling studies indicate that in the case of ester **16** initial 5-membered ring formation cannot be readily followed by a second C–C-coupling due to conformational constraints. At any rate, photochemistry once again proves to be a very powerful synthesis technique, producing in one step four contiguous quaternary carbon centres, exemplified by the formation of **13** and **17,** of which the former has the desired skeleton for our total synthesis purposes.

To examine the utility of **13** in model studies towards the natural product, it was reduced with excess lithium aluminium hydride to yield the stable tetrahydroxy compound **18** (Scheme 4). Further elaboration of **18** required a differentiation of the two primary hydroxy groups. Unfortunately, all attempts to selectively mono-protect one of the primary alcohols met with



Scheme 4 *Reagents*: a, $LiAlH_4$, THF, rt; b, TBDMSOTf, 2,6-lutidine, CH_2Cl_2, 0 °C; c, KHMDS, phenyl chloroformate, THF, −78 °C; d, CSA, MeOH, 0 °C; e, NaH, THF, 0 °C.

failure. Therefore, the primary and secondary hydroxy groups were protected as their TBDMS ethers, followed by functionalisation of the tertiary alcohol with a phenyl carbonate group, affording **19**. Selective hydrolysis of the primary TBDMS ethers, yielded diol **20**. Upon treatment of this diol with sodium hydride, cyclic carbonate **21** was formed, leaving one primary hydroxy group unprotected. This compound contains appropriate substitution and stereochemistry for elaboration towards the right-hand substructure of solanoeclepin A.

These investigations are supported (in part) by the Netherlands Research Council for Chemical Sciences (CW) with financial aid from the Netherlands Technology Foundation (STW).

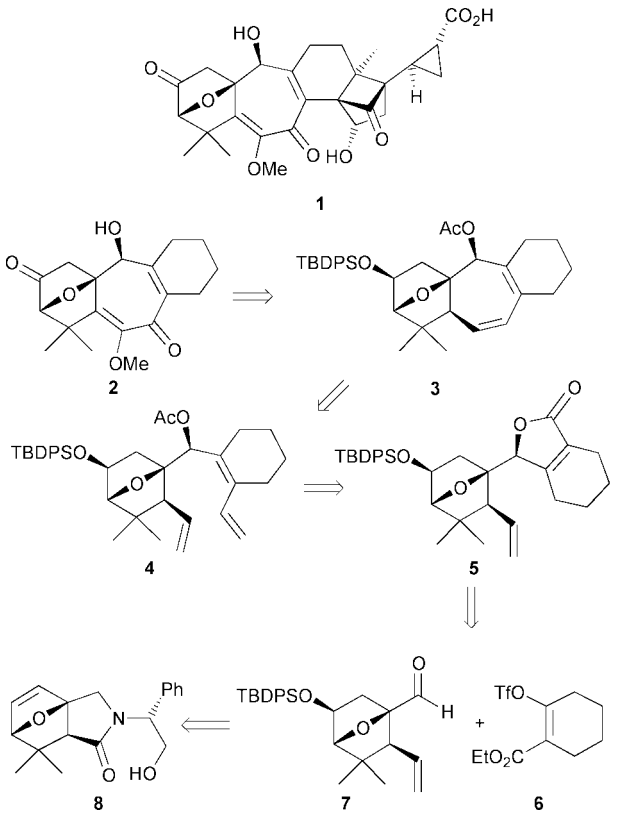
Received (in Liverpool, UK) 9th May 2000, Accepted 20th June 2000
Published on the Web 14th July 2000

The synthesis of the enantiopure left-hand substructure of solanoeclepin A is described. Key steps include a chromium-mediated coupling of an oxabicyclic aldehyde with a β-ketoester-derived enol triflate to give a lactone, and a ring-closing metathesis reaction to form the seven-membered ring.

In the preceding communication[1] we have disclosed a synthetic approach to the intricate bicyclo[2.1.1]hexane moiety of solanoeclepin A (**1**), the hatching agent of the potato cyst nematode.[2] In this paper we present the successful synthesis of the tetracyclic left-hand substructure **2** of this challenging natural product.

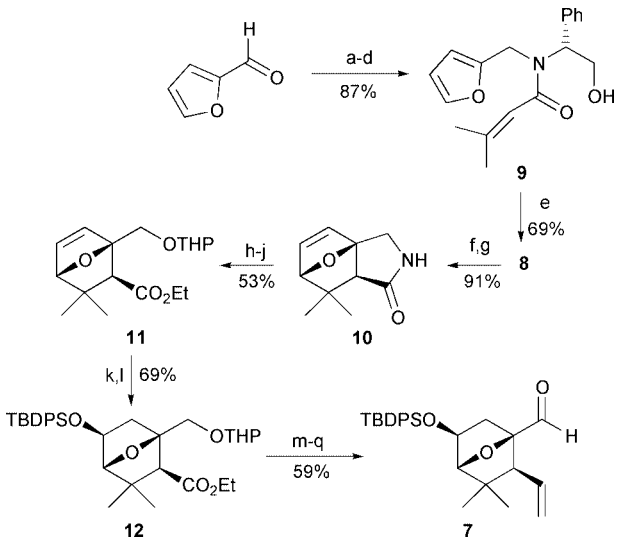
In our retrosynthetic analysis (Scheme 1) compound **2** was deemed accessible *via* oxidative functionalisation of diene **3**, which was thought to result from a ring-closing metathesis reaction of triene **4** as a key step. Compound **4** was expected to arise from lactone **5**, the product of a chromium-mediated[3] coupling of enol triflate **6** and aldehyde **7**. Diels–Alder product **8** has been previously reported by Mukaiyama and Iwasawa[4a] and seemed a suitable intermediate for the construction of aldehyde **7**.



Scheme 1 Strategy for the synthesis.

The synthesis of aldehyde **7** started with the condensation of furfural with (*R*)-(−)-2-phenylglycinol and reduction of the formed imine with sodium borohydride (Scheme 2). At this point it was not possible to selectively acylate the amine. Therefore the hydroxy group was first silylated, followed by *N*-acylation and acidic work-up to give Diels–Alder precursor **9** in 87% overall yield from furfural. The intramolecular Diels–Alder reaction following the Mukaiyama protocol[4] afforded **8** in excellent diastereoselectivity (89%) on a 50 g scale. The pure diastereomer **8** was obtained after column chromatography in 69% yield.

As chemoselective hydroboration of the alkene in **8** appeared impossible in the presence of the lactam, the latter functionality was removed as follows. First, the *N*-substituent was removed *via* a non-reductive procedure to keep the 7-oxabicycloheptene moiety intact.[5] The Diels–Alder product **8** was successively treated with tosyl chloride and DBU to give an enamine, which after hydrolysis led to lactam **10** (mp 154 °C; $[\alpha]_D^{22}$ +52.4, *c* = 0.8, $CHCl_3$) in excellent yield. Lactam **10** was then *N*-nitrosated and ring-opened to a hydroxy ester,[4] which on THP-protection gave **11** in moderate yield. Highly selective hydroboration of the double bond appeared now possible with disiamylborane[6]§ to give the desired alcohol in a 92:8 regioisomeric ratio. Separation of the isomers by column chromatography and protection of the secondary hydroxy group as a silyl ether afforded **12** in a good yield. The ester function was then

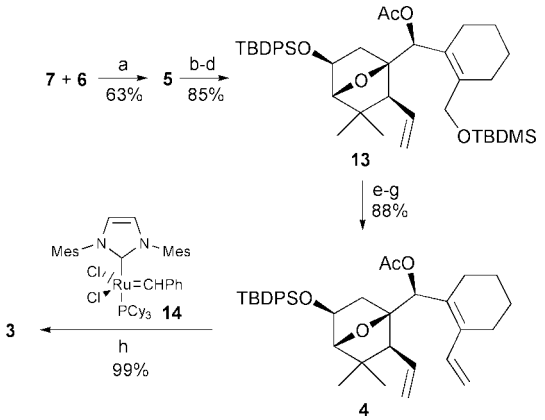


Scheme 2 *Reagents*: a, (*R*)-(−)-2-phenylglycinol, toluene, reflux; b, $NaBH_4$, *i*-PrOH; c, TMSCl, pyridine, THF; d, 3,3-dimethylacryloyl chloride then 5% HCl, H_2O; e, *n*-BuMgCl, Et_2O, −60 °C then toluene, reflux, 16 h; f, *p*-TsCl, pyridine, CH_2Cl_2; g, DBU, MeCN then 5 M HCl, H_2O; h, $NaNO_2$, AcOH, Ac_2O; i, KOH, EtOH then sat. $NaHCO_3$ (aq); j, DHP, *p*-TsOH, CH_2Cl_2; k, disiamylborane, THF then NaOH, H_2O_2; l, TDBPSCl, imidazole CH_2Cl_2; m, $LiAlH_4$, THF; n, TPAP, NMO, acetone; o, $Ph_3P{=}CH_2$, THF; p, HOAc, THF, H_2O; q, SO_3·pyridine, DMSO, Et_3N, CH_2Cl_2.

DOI: 10.1039/b003757p

transformed into a vinyl group by reduction to the alcohol, followed by TPAP[7] oxidation and Wittig olefination. After THP deprotection and oxidation,[8] aldehyde **7** was obtained.

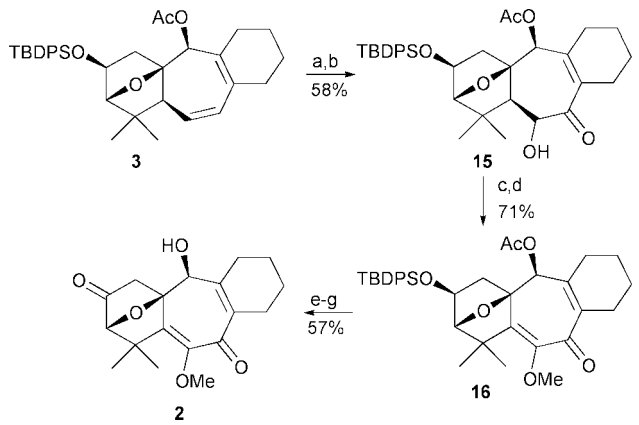
A chromium-mediated coupling of enol triflate **6** with aldehyde **7** afforded an intermediate γ-hydroxy unsaturated ester which spontaneously lactonised to α,β-unsaturated lactone **5** and its diastereomer (Scheme 3).[3] This mixture of diastereoisomers (70:30) could be easily separated by column chromatography. The major isomer was used for the rest of the synthetic sequence and its stereochemistry was later proven to be as given in **5**.



Scheme 3 *Reagents*: a, $CrCl_2$, $NiCl_2$ (cat.), DMF, 50 °C (2.3:1); b, $LiAlH_4$, Et_2O, rt; c, TBDMSCl, pyridine, CH_2Cl_2 ; d, Ac_2O, pyridine, CH_2Cl_2; e, CSA, MeOH; f, TPAP, NMO, acetone; g, $Ph_3P{=}CH_2$, THF; h, **14** (15%), toluene, reflux, 16 h.

Reduction of lactone **5** with lithium aluminium hydride resulted in a diol, which was protected with a TBDMS group on the primary hydroxy group, and an acetyl group on the secondary hydroxy group to give **13**. The primary alcohol was then selectively deprotected with CSA and subsequently oxidised with TPAP.[7] Wittig olefination of the crude aldehyde resulted in the ring-closing metathesis precursor **4**. Our first experiments to cyclise **4** were carried out with Grubbs' ruthenium benzylidene catalyst,[9] but a very slow process was observed requiring a stoichiometric amount of the catalyst for completion of the ring-closing metathesis. Gratifyingly, the use of the more stable ruthenium catalyst **14**[10] gave quantitative closure to form tetracyclic diene **3** after 16 h in refluxing toluene using only 15% of the catalyst.

With the diene **3** available we needed to functionalise the least-substituted double bond with oxygen substituents (Scheme 4). We first attempted to introduce a 1,2-diketone moiety in one step using $KMnO_4$ in Ac_2O,[11] but this reagent mixture led to complete cleavage of the C=C bond, resulting in a diacid. We then decided to introduce the 1,2-diketone *via* a milder three-step procedure. First the double bond was dihydroxylated, which was only successful by following a recent procedure of Corey and co-workers,[12] using stoichiometric osmium tetroxide activated with DMAP. Direct double oxidation of the resulting diol to the dione, using manganese dioxide, TPAP or DMSO-based reagents failed and resulted in most cases in C–C bond cleavage to give the corresponding dialdehyde. However, we then found that is was possible to selectively oxidise the allylic alcohol using 1 equiv. of Dess–Martin periodinane,[13] resulting in α-hydroxyketone **15**. Heating of **15** with cupric acetate[14] in MeOH gave the desired 1,2-diketone, which existed completely in the enol form, and was readily methylated to give methyl enol ether **16**. In the last few steps the silyl ether was cleaved and the liberated hydroxy group oxidised using a TPAP oxidation. Deprotection of the acetate group resulted in the desired **2** as a stable crystalline compound (mp 173 °C) with a high rotation ($[\alpha]_D^{24}$ +495, *c* = 0.6, $CHCl_3$). The X-ray crystal structure‡ proved its identity, including the orientation of the hydroxy function. Compound **2** has been subjected to hatching activity tests,[15] but appeared to be devoid of any activity.



Scheme 4 *Reagents*: a, OsO_4, DMAP, *t*-BuOH–H_2O 1:1 then Na_2SO_3; b, Dess–Martin, CH_2Cl_2 (19% dialdehyde); c, $Cu(OAc)_2$, MeOH, 60 °C; d, MeI, Ag_2O, DMF; e, HF·pyridine; f, TPAP, NMO, acetone; g, K_2CO_3, MeOH.

In summary, we have completed a synthesis of the tetracyclic left-hand substructure **2** of solanoeclepin A in enantiopure form. Compound **2** appeared to be quite stable so that the reported instability of **1** can probably be ascribed to the bicyclo-[2.1.1]hexanone part of the molecule. The synthesis reported herein provides important information for the eventual synthesis of **1** itself. To this end triflate **6** needs to be replaced by a more complex molecule containing the bicyclo[2.1.1]hexane moiety. Studies in this direction will be reported in due course.

These investigations are supported (in part) by the Netherlands Research Council for Chemical Sciences (CW) with financial aid from the Netherlands Technology Foundation (STW).

A polymer-supported alkyl methyl sulfide as an efficient promoter of the Khand cyclisation reaction

Published on the Web 18th July 2000

A readily prepared polymer-supported alkyl methyl sulfide has been shown to be a recyclable, practically convenient, and efficient promoter of the Khand cyclisation reaction, affording good to excellent yields of cyclopentenones.

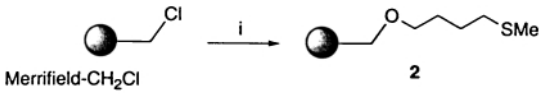
In recent years the Khand cycloaddition reaction has been developed into a highly utilisable method for generating cyclopentenone systems.[1] This cobalt carbonyl mediated annulation involving an alkyne, an alkene and carbon monoxide, was first described in 1971 and was originally conducted under thermal conditions.[2] With few exceptions, the technique of simply heating the reactants led to reaction mixtures from which the desired cyclopentenone products could only be separated in low to moderate yield after careful chromatography. Consequently, great efforts have been made to find more efficient procedures by which this valuable cycloaddition process can be carried out.[3]

Although promotion by ultrasound[4] and dry state adsorption conditions[5] have provided improvements in product yields in certain instances, it has undoubtedly been the introduction and thorough investigation of the use of amine *N*-oxides as promoters[6] that has led to the most significant advances in overall Khand reaction applicability and efficiency. More specifically, studies in our own laboratory have developed amine *N*-oxide promoted Khand techniques for use with gaseous olefins[7] and gaseous olefin equivalents,[8] and have exploited the same class of *N*-oxide promoted cyclisations within total synthesis programmes.[9] Additionally, the use of non-racemic chiral amine *N*-oxides has led to the establishment of direct asymmetric Khand cyclisation strategies.[10]

As part of an on-going optimisation of the asymmetric process, we have synthesised a novel polymer-linked amine *N*-amine *N*-oxide and shown this to be a good solid phase promoter of the Khand reaction.[11] As well as forming the basis for the construction of a potentially structurally diverse library of supported chiral amine *N*-oxides, this work also demonstrated that the widely recognised benefits associated with the technique of employing a solid phase reagent[12] could be realised within the arena of Khand cyclisation chemistry. Indeed, a major advantage offered by this resin-based *N*-oxide method is in the simplification of product isolation procedures; by routine filtration the desired cyclopentenone is removed from the (organometallic) by-products in remarkably pure form. With this knowledge, we have now gone on to further extend and widen the overall scope of this immobilised Khand reaction promoter strategy.

Sugihara has recently reported that *n*-butyl methyl sulfide was the optimum sulfide promoter of a number that were tested and provided good to excellent yields in both intra- and intermolecular Khand cyclisations.[13]† Indeed, this reaction additive is particularly notable for its ability to promote some Khand reactions which had previously failed completely or proceeded only very poorly under alternative conditions. On the other hand, we considered the use of *n*-butyl methyl sulfide to have certain drawbacks. More specifically, as a low molecular weight sulfide, the *n*-butyl methyl derivative has a very unpleasant odour and imparts a lachrymatory effect. Furthermore, it is relatively expensive and, under the developed techniques, cannot be readily recycled. Therefore, we sought to develop a reusable polymer-supported analogue of *n*-butyl methyl sulfide and examine its ability to promote the Khand annulation reaction.

To initiate this work, the supported sulfide was synthesised in a single step, using standard chemistry, from commercially available Merrified gel-type resin‡ and 4-(methylthio)butan-1-ol **1**, *via* formation of a chemically robust ether link (Scheme 1). The derivatised polymer **2** obtained was odour-free and possessed sulfide functionality which is similar to the optimum solution phase promoter. Elemental analysis and infrared spectroscopy confirmed complete displacement of all chloride atoms from the starting material and gave the expected sulfur content for the new polymer.

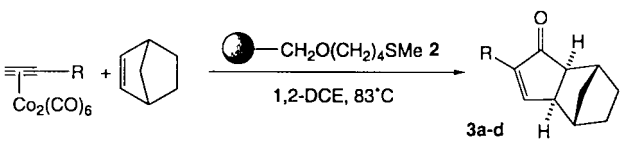


Scheme 1 *Reagents and conditions*: i, $HO(CH_2)_4SMe$ **1** (3 equiv.), NaH (6 equiv.), THF, Δ, 72 h.

Having established a simple preparation of our new solid phase reagent, we turned our attention to the study of its effectiveness as a promoter of the Khand reaction. The cyclisation of a series of alkyne substrates with norbornene was investigated and to our delight these reactions were complete in only 30 min at 83 °C in the presence of 3.5 equiv. of the supported sulfide and using 1,2-dichloroethane (1,2-DCE) as solvent.§ As shown in Table 1, very good to excellent yields of the desired cyclopentenones **3** were obtained. Furthermore, work-up of these reactions was rendered expedient by the fact that the cobalt residues produced were sequestered by the resin and merely involved filtration of the reaction mixture followed by minimal chromatographic purification. This feature of the novel promoter **2** confers a tangible practical benefit over the alternative Khand cyclisation methods.¶

In due course, using dimethylpropargyl alcohol as the alkyne substrate, we conducted several reactions using alternative alkenes. These reactions also proceeded entirely satisfactorily (Table 2); the modest yields of cyclopentenone products from the reactions of cyclopentene and 2,5-dihydrofuran reflect the lower reactivity of these olefins in Khand cyclisations.

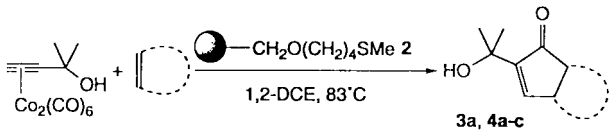
Table 1 Solid phase sulfide promoted Khand reactions



R	*t*/min	Product	Yield (%)
$Me_2(OH)C$-	30	**3a**	92
Ph-	30	**3b**	97
Me_3Si-	30	**3c**	83
t-Bu-	30	**3d**	89

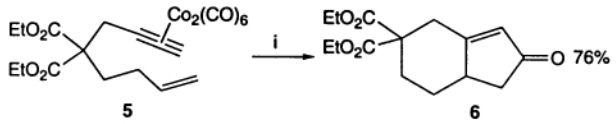
DOI: 10.1039/b004568n

Table 2 Khand reactions with a selection of alkenes



Alkene	*t*/min	Product	Yield (%)
Norbornene	30	**3a**	92
Norbornadiene	30	**4a**	91
2,5-Dihydrofuran	30	**4b**	47
Cyclopentene	90	**4c**	50

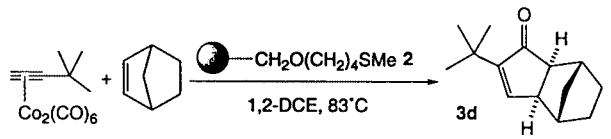
In order to further extend the substrate applicability of this new solid-phase technique, an intramolecular Khand cyclisation was examined using enyne complex **5**. This example furnished the requisite bicyclic compound **6** in 76% yield (Scheme 2).



Scheme 2 *Reagents and conditions*: i, Resin **2** (3.5 equiv.), 1,2-DCE, 83 °C, 30 min.

A further important observation from this study was that, at the conclusion of all reactions the recovered polymer resin could be cleaned very easily by washing with a THF–aqueous 2 M HCl mixture. This enabled us to investigate the potential of recycling the resin. For this study the *tert*-butylacetylene–norbornene reaction was chosen. As illustrated in Table 3, the excellent yield of **3d** and short reaction time is maintained through five cycles. This aspect of the new promoter is particularly noteworthy in that, unlike our previously disclosed supported amine *N*-oxide techniques,[11] no chemical transformation is necessary for regeneration of the active solid phase promoter. Moreover, in contrast to the solution phase analogue, expense is minimised by the recyclable nature of the immobilised sulfide.

Table 3 Khand reactions using recycled resin **2**



Run	1	2	3	4	5
t/min	30	30	30	30	30
Yield (%)	89	92	87	86	88

Finally, two additional *tert*-butylacetylene–norbornene cyclisations were carried out in which the quantity of the polymeric reagent used was reduced in order to determine if the 3.5 equiv. of sulfide (as established in the Sugihara solution phase studies[13] and employed throughout this work) were absolutely necessary. With 2 equiv. of resin **2** an 86% cyclisation yield was achieved, whereas 1 equiv. of **2** delivered cyclopentenone **3d** in 88% yield. Therefore, in both cases the product yield was not significantly lowered. However, it should be noted that with successive reduction in quantity of resin there was a stepwise drop in the efficiency of the cobalt residue retention.

In conclusion, a relatively cheap, commercially available gel-type resin was readily modified to afford an odourless, supported alkyl methyl sulfide. This novel solid phase reagent can be used to promote both intra- and intermolecular Khand cycloaddition reactions in a highly efficient and practical manner. Isolation of the cyclopentenone products is facilitated by the resin's ability to retain undesired cobalt residues and, furthermore, the resin can be easily and rapidly regenerated by a mildly acidic wash.

We thank the Carnegie Trust for a postgraduate scholarship (M. M.), Astra Zeneca Pharmaceuticals, Alderley Park for generous funding of our research endeavours *via* Strategic Research Funding, and the EPSRC Mass Spectrometry Service, University of Wales, Swansea, for analyses. We are also grateful to Mr Francesco Bernardis for helpful discussions.

Notes and references

† It should be noted that the promoting effect of suitably spaced methyl sulfide groups when tethered to the alkene[14] or alkyne[6d,15] was first discovered and reported by Krafft.

‡ The 1% cross-linked Merrifield resin was purchased from NovaBiochem with a chloride loading of 1.1 mmol g^{-1}.

§ Respresentative experimental procedure; To a solution of hexacarbonyl(3,3-dimethylbut-1-yne)dicobalt (34.0 mg, 0.092 mmol) and norbornene (56.0 mg, 0.596 mmol) in 1,2-DCE (2.5 ml) was added sulfide resin **2** (0.29 g, 0.29 mmol) and the mixture was stirred at 83 °C for 30 min. The solvent was drained and the resin washed with CH_2Cl_2 (10 × 2 ml) and THF (5 × 2 ml). The combined filtrates were evaporated *in vacuo* to afford a residue which was chromatographed on silica using 5% Et_2O in petrol as eluant. The product **3d** was obtained as a white crystalline solid (16.7 mg, 89%).

¶ 4-(Methylthio)butan-1-ol was also tested as a solution phase promoter using Sugihara's conditions in the *tert*-butylacetylene–norbornene reaction and provided an 89% yield of cyclopentenone **3d**. However, this additive suffers from an undesirable odour and lacks the potential to be readily recycled.

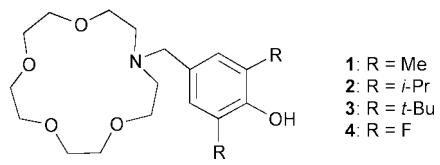
Received (in Cambridge) 2nd May 2000, Accepted 20th June 2000
Published on the Web 19th July 2000

3′,5′-Difluoro-4′-hydroxybenzyl-armed monoaza-15-crown-5 ethers which form fluorine-bridged polymer-like complexes with MSCN in the solid state and in solution are reported.

Recently, we reported the molecular structure of alkali metal complexes with armed-monoazacrown ethers having 3′,5′-dialkyl-4′-hydroxybenzyl groups (alkyl = Me, *i*-Pr and *t*-Bu).[1] The molecular structure of the RbSCN complexes with these ligands was systematically changed depending upon the size of the R groups at positions 3′ and 5′ in the side arm (**1** (R = Me), a polymer-like $(1:1)_n$ complex; **2** (R = *i*-Pr), a mixture of 1:1 and polymer-like $(1:1)_n$ complexes; **3** (R = *t*-Bu), a dimeric



1: R = Me
2: R = *i*-Pr
3: R = *t*-Bu
4: R = F

1:1 complex). To further investigate the electronic and steric effects of the substitutents next to the phenolic OH group in the side arm on the structure of the complexes, we have prepared a new armed-azacrown ether having fluorine atoms at positions 3′ and 5′ in the side arm (**4**). Computer modeling experiments suggest that the oxygen atom of the phenolic OH group cannot bind to metal cations incorporated into the crown part of the molecule so that the ligand can form polymer-like complexes with alkali metal cations.† It was also expected that the ligand would form polymer-like complexes using the electron donating properties of fluorine atoms next to the phenolic OH group.[2] Here we report the structures of polymer-like complexes of ligand **4** which are bridged by the fluorine atoms in the side arm.

New armed-azacrown ether, **4**,‡ was prepared by the Mannich reaction of *N*-methoxymethylmonoaza-15-crown-5 ether with 2,6-difluorophenol in benzene by the method previously reported.[3] Two alkali metal thiocyanate complexes, **4-KSCN** and **4-RbSCN**, were obtained (host–guest ratio = 1:1) as single crystals.§

The structures of **4-KSCN** and **4-RbSCN** complexes have been determined by X-ray analysis.¶ As shown in Fig. 1(*a*), the K^+ ion in **4-KSCN** is eight-coordinated by four ring O atoms, the ring N atom, and the O* atom of the phenolic OH group and an F* atom in the side arm of the nearest-neighbor molecule with the S atom of SCN^- as a counter ion. The complex is a polymer-like $(1:1)_n$ complex. The K(1)–O (ring), K(1)–O(5*), K(1)–N(1), K(1)–S(1) and K(1)–F(2*) bond lengths are in the range 2.757(2)–2.792(2), 3.028(2), 2.877(2), 3.253(1) and 2.783(2) Å, respectively. The K–O and K–N bond lengths are comparable with those of the potassium complex of the lariat monoaza-15-crown-5 ethers.[4] The K–F bond length is also comparable with those of complexes including CF–K^+ contacts.[5] Fig. 1(b) shows the ORTEP view of the **4-RbSCN** complex. The Rb^+ ion is also eight-coordinated by four ring O atoms, the ring N atom, the F atom in the side arm of the nearest-neighbor molecule with the two S atoms of SCN^- as counter ions. The complex is a polymer-like $(2:2)_n$ complex which is bridged by an F atom in the side arm. Interestingly, the O atom of the phenolic OH group in the side arm is not involved in the complex formation. The Rb(1)–O (ring), Rb(1)–N(1), Rb(1)–S(1), Rb(1)–S(1*) and Rb(1)–F(2*) bond lengths are in the range 2.860(7)–2.972(8), 3.087(7), 3.412(3), 3.475(3) and 3.001(6) Å, respectively. It is important to note that the F–Rb^+ bond length in **4-RbSCN** complex is classified as a short F–Rb^+ bond length which is a rare case.[5]

To investigate the complexation ability of ligand **4** in solution, stability constants *K* and thermodynamic values (ΔH and $T\Delta S$) were measured by titration calorimetry in MeOH solution (Table 1).‖ Interestingly, the log *K* values for Na^+ (log *K* = 2.96), K^+ (log *K* = 2.95), Rb^+ (log *K* = 2.79) and Cs^+ (log *K* = 2.74) were almost equal. The log *K* values suggest that ligand **4** coordinates to the alkali metal cations not only by the crown ether moiety but also by the binding sites of the side-arm,

DOI: 10.1039/b003451g

Table 1 Log K, ΔH(kJ mol^{-1}), and $T\Delta S$(kJ mol^{-1}) values for the 1:1 interaction of ligand **4** with metal cations in methanol solution at 25 °C

Cation	log K	ΔH	$T\Delta S$
Na^+	2.96 ±0.03	−16.5 ±0.2	−1.4
K^+	2.95 ±0.05	−23.1 ±0.7	−6.3
Rb^+	2.79 ±0.06	−17.5 ±0.4	−1.6
Cs^+	2.74 ±0.05	−8.2 ±0.4	7.4

because the log K value for Na^+ which fits to the hole size of the monoaza-15-crown-5 ether is not remarkable higher than that for the other alkali metal cations.[6] Inoue and Gokel reported that the slope (α) of the enthalpy-entropy compensation (plot of $T\Delta S$ *versus* ΔH) indicates conformational changes of host compounds on complex formation.[7] The α value was calculated as 0.923 (r^2 = 0.994) from the plot of $T\Delta S$ versus ΔH, which is close to the average (0.89) of typical armed-crown ethers, and indicates that significant conformational changes would occur when the ligand forms complexes. Therefore, the log K values and the α value support the supposition that ligand **4** forms complexes with alkali metal cations by both the crown moiety and the side arm.

Plenio and Diodone reported that the ^{19}F NMR chemical shift changes when fluorine atoms coordinate to metal cations in fluorine containing azacrown ethers and cryptands.[2] The ^{19}F NMR titration experiments were carried out in a CD_3CN solution (Table 2) to determine F atom participation from the side-arm. When 1.0 equiv. of NaSCN, KSCN and RbSCN were added to a CD_3CN solution of ligand **4**, the chemical shifts of the fluorine atoms next to the phenolic OH group shifted to a lower field by about 0.7–0.8 ppm. These values are much greater than the 0.1–0.2 ppm shifts observed with the addition of 1.0 equiv. of MSCN to a CD_3CN solution of 2,6-difluorophenol. These chemical-shift changes strongly suggest that one or both fluorine atoms along with the oxygen atom of the phenolic OH group coordinate to the alkali metal cations incorporated in the crown part of a second armed ligand to give polymer-like complexes in solution.

+1.0 KSCN	+0.19	+0.83
+1.0 RbSCN	+0.14	+0.78

[a] Titration experiments were carried out at 298 K by addition of 0.5, 0.75, 1.0, 1.5 and 2.0 equiv. of MSCN (NaSCN and KSCN: 0.001 mmol μL^{-1} in CD_3CN; RbSCN: 0.001 mmol μL^{-1} in CD_3CN–D_2O (95:5)) to 2,6-difluorophenol or ligand **4** (0.01 mmol, 0.65 mL in CD_3CN). Positive numbers show down field shifts. [b] α,α,α-Trifluorotoluene (δ −63.72) was used as an internal standard.

In conclusion, we have demonstrated that the fluorine atoms in the side arm of ligand **4** coordinate to alkali metal cations incorporated in a second ligand in the solid state and in solution. This first example for a fluorine-bridged polymer-like complex has potential for the design of new supramolecular systems. Further studies of the new armed-azacrown ethers are in progress.

Financial support from the Japan Securities Scholarship Foundation (Y. H.) is gratefully acknowledged.

A universal approach to web-based chemistry using XML and CML

Peter Murray-Rust,[a] Henry S. Rzepa,[b] Michael Wright[b] and Stephen Zara[b]

Received (in Cambridge, UK) 28th March 2000, Accepted 14th June 2000
Published on the Web 18th July 2000

We report the first fully operational system for managing complex chemical content entirely in interoperating XML-based markup languages.

The World-Wide-Web (WWW) was originally developed as a collaborative tool for scientists. In 1994 we proposed its use as a novel and widely applicable global model for expressing chemical information in an interlinked and re-usable form.[1] This model, based on HTML, has become widely used but suffers from a number of structural problems. Chemistry represents its message both *semantically* (*e.g.* as a machine-processable connection table) and graphically (*e.g. presentation* through human-readable arrows, boxes, diagrams). The existing use of HTML in chemistry emphasizes presentation, and provides no structured extension mechanisms. A presentational approach is too flexible to be reliably interpreted by machines, and cannot *validate* the integrity of the chemical *content*. Thus the chemical subscript and superscript conventions in *e.g.* $CH_4^{+\cdot}$ are only unambiguously interpretable by humans. This severely limits the re-usability of the rapidly growing amount of high-quality chemistry available on Web pages.

We therefore developed[2] our model to support both types of markup. Chemical Markup Language (CML) can carry molecules, crystallography and reactions in a formal manner. It forms the core of a comprehensive approach to publishing and communicating chemical information for both humans and machines. It uses the protocols of the WWW Consortium (W3C),[3] whose goal is to support such *interoperability* with the strategic aim of achieving a "semantic web" where automatic processing of information is possible. The core W3C approach is the *meta-language* XML (eXtensible Markup Language) which was formalised in 1998 and which encourages the creation of discipline-specific languages such as CML. The W3C have created a family of protocols supporting most aspects of managing Web-based information; the following are most relevant here: *XML Schemas* are a formal description of the language and can support arbitrary datatypes and or validate complex documents. *Scalable Vector Graphics (SVG)* provide a framework where presentation and content can be robustly combined. *XSLT (XSL stylesheets)* is a very powerful tool for transforming documents. *XML Query Language* and XLinking are under development. *XSL(FO)* provides high quality formatted output for any XML application.[3]

Much time is currently wasted on processing *legacy* unstructured and often binary documents and poor semantics leads to serious information loss. The 'plug-compatible' XML approach guarantees a document to be searchable, stylable, sortable, transformable, mergeable, transmittable and printable without extra cost. CML uses these developments and for the first time offers a universal platform- and application-independent infrastructure for chemical information. Ideally we see all future document and publishing systems being converted to XML and describe here an implementation of these concepts termed ChiMeraL.

Technical documents are often multidisciplinary and component-based and draw their components from several XML Schemas. Subdisciplines, *e.g.* MathML (for mathematics), CML, SVG, are identified within documents by discrete *namespaces*. To avoid *collision* their *tag names* are mapped onto globally unique URIs (Uniform Resource Identifier); http://www.xml-cml.org/ serves to uniquify any CML element. Components will often be glued together with XHTML (the XML version of HTML).[4] *Transformation/reformatting* through XSL stylesheets is a particularly important operation because it allows extraction of document sub-components such as molecules for *e.g.* redrawing in SVG (*vide infra*) or outputting in any desired format.

Besides transformation, various operations can be automatically performed, often without knowing the precise document structure. These include searching, whereby XML elements ('components') can be located by local or global context in a document or through content, re-use by fragmenting or combining XML documents, rendering/viewing in a browser window, high-quality printing, and data authentication services.[5]

'Chemical' information usually requires several other types of markup (text, numbers, tables, graphics, etc.). Such CML document components can come from many sources, either directly or after conversion from legacy formats. The sources include: instruments, databases, dictionaries and catalogues; hand-editing/authoring of chemical information; primary and secondary publications, and computational chemistry tools. To illustrate how the operation of transmitting, querying and processing compound chemical data within a Web browser can be combined, we have created a Web-based collection of XML tools termed ChiMeraL.[6] Its use involves five distinct stages (Fig. 1).

(1) Conventional HTML is used in conjunction with JavaScript in a browser to allow the user to select from an XML library containing CML components (Fig. 2). The library could be a server-based collection or could be generated by selective querying of a larger XML document held on an XML repository.

(2) The XML document is validated for integrity against a Schema. This is a major improvement over HTML, which has no validation for chemical or most other content. Validation can be server or browser-based.

(3) Selection of a suitable stylesheet for popular chemical editing and display programs, *e.g.* for 2D and 3D molecular co-ordinates and numerical information such as spectral/analytical data. The stylesheet is used to convert CML elements to legacy formats (*e.g.* MDL Molfile, Minnesota XYZ format, JCAMP DX format) for display using existing applets (*e.g.* JME, JMol, JSpec, Marvin, SDA), or it could be directed towards CML-compliant applets without the need for such legacy transformation. The XSL transform can again be server or browser based. The use of a stylesheet also provides the possibility of deriving new quantities from the original data such as *e.g.* aligning a range of pharmacophores or computing diverse molecular properties. The ChiMeraL demonstration (Fig. 2)† includes a range of XSL stylesheet fragments, XML example documents and a CML schema, together with utility programs which can generate CML documents.[6]

(4) The output from the stylesheet is displayed as a web page. The original CML components (*e.g.* < molecule > < /molecule >) are wrapped with suitable XHTML to allow appropriate display (Fig. 2).

(5) At this stage, the user could edit or add to the document

DOI: 10.1039/b002483j

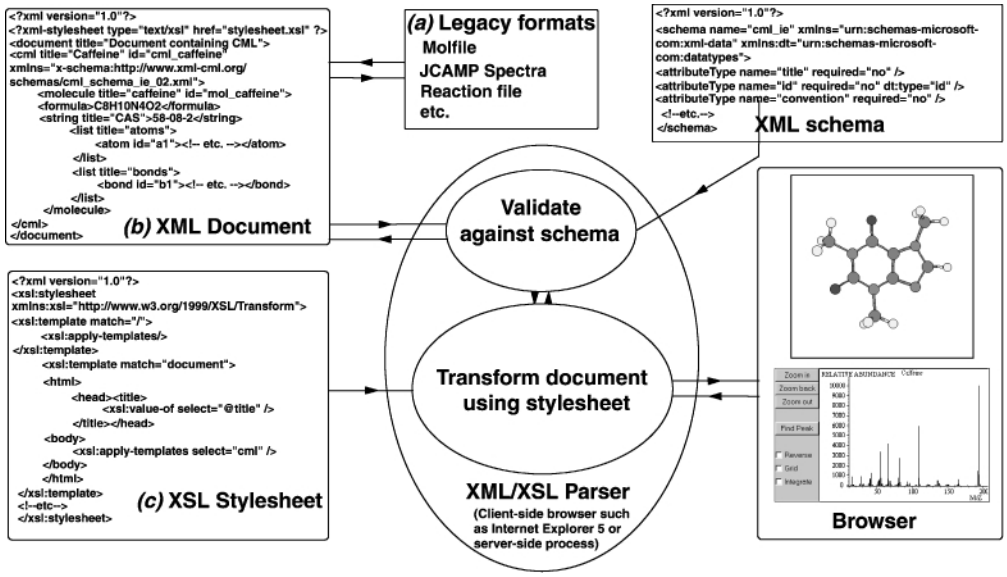

Fig. 1 Data flow between the principal components of ChiMeraL (a) The creation of a *structured document* in XML syntax from unstructured *legacy* formats (MOL, JCAMP, *etc.*). The validity of the process is checked by a CML-specific XML schema. (b) Illustrative CML document whose *root element* contains a *child molecule element*. In turn the *molecule* contains a *list* element, itself the parent of many *atom* elements (omitted for clarity); bonds are analogous. *Attributes* such as *convention* identify the usage of terms and values, while the *id* attribute identifies every element uniquely. (c) Illustrative XSL stylesheet, which transforms CML to XHTML. The *title* of the *molecule* is transformed to the XHTML document title, while the content of the *molecule* is transformed into various legacy formats (MOL, JME, *etc.*) for display by applets.

by selecting an appropriate stylesheet to invoke appropriate software tools, and with appropriate validation, create a new annotated XML document which could be returned to the original document repository. Multiple authorship of a document is possible since subsequent stylesheet transforms could *e.g.* extract either the original document, or any individual's additions to it.

Chimeral is offered as OpenSource, *i.e.* available as source code which can be used for any purpose, but especially for the development of new ideas, tools and resources in this area. XML has benefitted greatly from this movement and Chimeral uses several OpenSource components (XML tools, JMol, JSpect).[7] OpenSource is an effective means of developing high-quality robust applications very rapidly and we encourage developers to increase the volume of WWW-based collaboration in chemistry.

We have described a method for completely transparent Internet-based transfer of chemical information from creator/author to reader/user. Applications of this method might include a document such as this journal article being automatically abstracted for molecular content, and stored or used for calculations or searching. One can envisage *e.g.* laboratory robots scanning CML-based reaction schemes for starting materials and ordering them from CML-based 'dot.coms' on the WWW, and recording this in electronic notebooks. Instruments could directly output universally processable spectra and data. Databases could accept chemistry in many traditional formats and re-offer them transparently. Computational chemistry and modelling programs could be used routinely for adding information content to molecules. Finally, we note that the use of XML allows other disciplines (bioscience, pharmaceutical, materials, patents) to include semantically rich chemistry in their information.

[26]Hexaphyrin(1.1.1.1.0.0): an all-aza isomer of rubyrin with an inverted pyrrole subunit

Jonathan L. Sessler,* Daniel Seidel, Christophe Bucher and Vincent Lynch

Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, Texas 78712-1167, USA. E-mail: sessler@mail.utexas.edu

Received (in Corvallis, OR, USA) 9th May 2000, Accepted 20th June 2000
Published on the Web 19th July 2000

The synthesis, characterization and X-ray structure of an hexapyrrolic macrocycle, [26]hexaphyrin(1.1.1.1.0.0), is reported; it is characterized by a partially inverted structure.

Expanded porphyrins continue to attract attention as synthetic targets due to the fact that they often display features, such as anion binding and neutral substrate recognition, that are not seen in normal porphyrins.[1–3] Recently, a special structural feature, namely the inversion of one or two of the pyrrolic-subunits has been observed in certain expanded porphyrins. For instance, the free-base form of *meso*-tetraphenylsapphyrin exhibits such an inverted structure. Upon bis-protonation, however, this species undergoes a change in conformation adopting a 'regular' planar structure wherein all the nitrogens are pointed inward.[4,5] Similar structural features have been observed for certain heteroatom-containing *meso*-tetraphenylsapphyrins;[6–8] depending on the protonation state and the nature of the heteroatom, these latter systems can exhibit either an inverted or a planar structure. Several heterorubyrins (*e.g.* **1** with X = S or Se, respectively) have also been found to adopt bis-inverted conformations under appropriate conditions.[7] Another recent report described the isolation of a novel [26]hexaphyrin(1.1.1.1.1.1) in low yield as a side product in the Rothemund synthesis of porphyrins,[9] that exhibits a bis-inverted structure in its free-base form. In this instance, the influence of protonation has yet to be established. Interestingly, the original [26]hexaphyrin(1.1.1.1.1.1), first reported by Gossauer in 1983,[10] was found to adopt a different conformation. Rather than existing in a form wherein one or more of the pyrrolic subunits is inverted, this system, bearing substituents on the β-pyrrolic but not *meso*-carbon positions, was found to adopt a conformation wherein the two opposing *meso*-C*H* protons point inward. Upon metalation with $PdCl_2$, however, it is believed that this latter hexaphyrin, never characterized structurally, rearranges such that two of the six pyrrolic subunits point outwards.[11] The subtle nature of the conformational effects evident in hexapyrrolic macrocycles and their structural origins are currently far from understood. They thus provide an impetus for further study. In this communication we report the synthesis of the hitherto unknown hexapyrrolic macrocycle, [26]hexaphyrin(1.1.1.1.0.0) (**2**). Based on an analysis of molecular models, this particular system was expected to adopt a conformation wherein one pyrrolic subunit (only) is inverted.

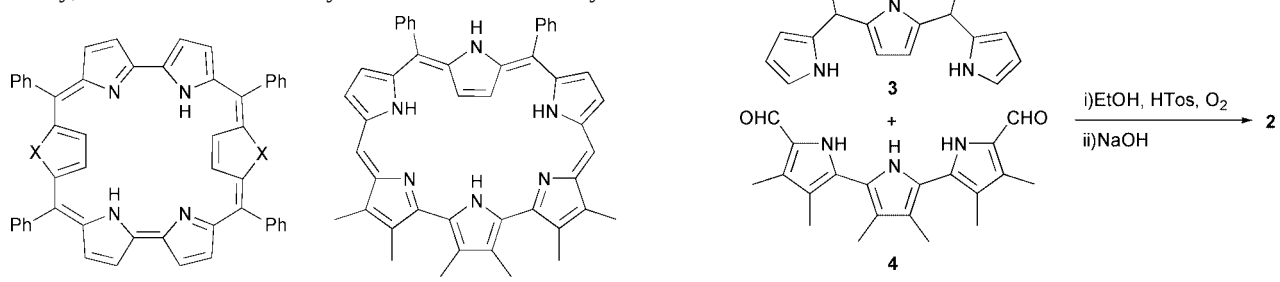
The synthesis of compound **2** is summarized in Scheme 1. Briefly, it is obtained in 46% yield from the acid catalyzed condensation of a 1 : 1 mixture of the diphenyltripyrane **3**[12] with the diformylhexamethylterpyrrole **4**.[13]

[26]Hexaphyrin(1.1.1.1.0.0) (**2**) constitutes the first true isomer of rubyrin.[14] While other porphyrin analogues bearing the same combination of four *meso*-like carbon atoms and six heterocyclic subunits are known, in particular the bronzaphyrins,[15] in all cases at least one of the six pyrrolic units present in rubyrin has been replaced by a furan or a thiophene.†

Macrocycle **2** is aromatic as judged from the ^{1}H NMR (d_6-DMSO) spectra of the protonated and free-base forms, respectively. The dihydrochloride salt, $H_2\mathbf{2}^{2+}\cdot 2Cl^-$, in particular, shows a strong magnetic ring current effect. Here, upfield shifts for the inner N*H* protons are found, with resonances observed at −0.75, −0.14 and 0.05 ppm in a 1 : 2 : 2 ratio. One more upfield resonance, namely at −2 ppm is also observed. On the basis of a two-dimensional C–H correlation experiment, this signal is ascribed to a C*H* proton. Indeed, the upfield position of this resonance is considered *prima facie* evidence for the inverted nature of $H_2\mathbf{2}^{2+}\cdot 2Cl^-$.‡

The COSY spectrum of **2** shows a correlation between the peak at −2 ppm with one at 15 ppm, a signal that was found to correspond to the outer N*H* proton. The $\Delta\delta$-value of 17 ppm between these two signals provides strong support for the aromatic nature of the inverted macrocycle. Also, the C*H* protons of the *meso*-positions were found to resonate at 11.4 ppm while two doublets at 9.2 and 9.8 ppm, respectively, were found to correspond to the two outer β-pyrrole C*H* protons. Interestingly, in the ^{1}H NMR spectrum of the free-base macrocycle **2** the $\Delta\delta$-value between the β-C*H* protons of the inverted pyrrole (δ = 3.5 ppm) and the N*H* signal (δ = 9.8 ppm) of the same pyrrole is reduced to 6.3 ppm. The C*H* protons of the *meso*-positions resonate at 8.5 and the two doublets which correspond to the two outer β-pyrrole C*H* protons are shifted to 7.3 and 8 ppm, respectively. The reduced aromatic effect for the free-base form of macrocycle **2** can be rationalized in terms of a lower number of fully conjugated π-electron peripheries (*i.e.* fewer aromatic resonance structures can be drawn). It is also possible that **2** is subject to a greater distortion from planarity than $H_2\mathbf{2}^{2+}\cdot 2Cl^-$. Nevertheless, the critical point is that **2** is still considered to be inverted; the $\Delta\delta$-value between the outer and inner β-C*H* protons amounts to 5 ppm as the result of an extant but weak ring current effect.

The NOESY spectrum supports the assignment of an inverted structure to the free-base form of **2**. A correlation is found



Scheme 1

DOI: 10.1039/b003777j

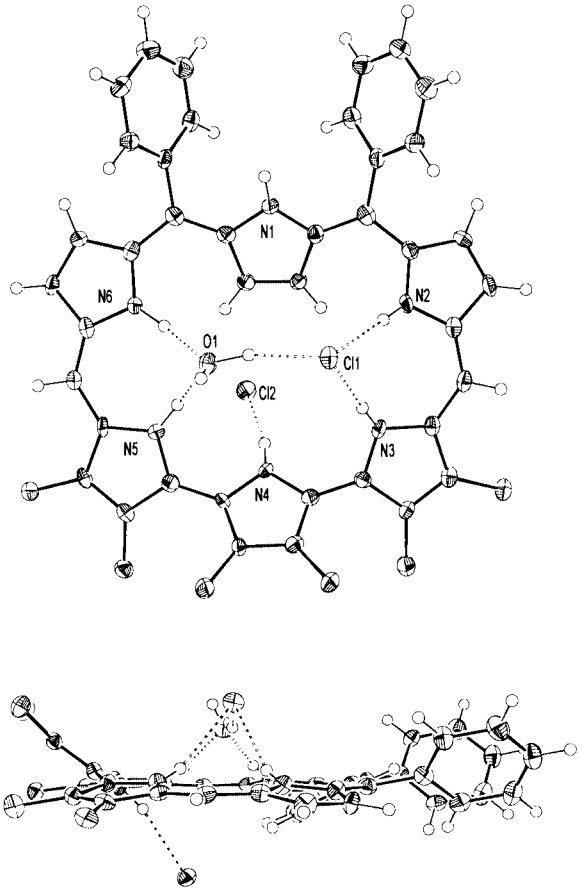


Fig. 1 Top and side views[16] of $H_2\mathbf{2}^{2+}\cdot 2Cl^-$ with a partial atom labeling scheme. Thermal ellipsoids are scaled to the 50% probability level. Hydrogen atoms shown are drawn to an arbitrary scale. Dashed lines are indicative of a hydrogen bonding interaction.

between the β-C*H* protons of the inverted pyrrole with the N*H* proton of the middle pyrrole of the terpyrrole subunit. Additionally, the outer N*H* proton clearly interacts with the *ortho-H* protons of the *meso*-phenyl substituents, findings which can only be rationalized in terms of an inverted structure. The UV-vis spectra of **2** and $H_2\mathbf{2}^{2+}\cdot 2Cl^-$ support the assumption that the free-base form of **2** is subject to a greater deviation from planarity than its bishydrochloride salt, $H_2\mathbf{2}^{2+}\cdot 2Cl^-$. In particular the extinction coefficients are found to be reduced by a factor of 2–2.5 in the case of the free-base.§

Definitive proof for the inverted nature of $H_2\mathbf{2}^{2+}\cdot 2Cl^-$ was obtained from a single crystal X-ray diffraction analysis. The resultant structure is shown in Fig. 1.¶ In addition to the two bound chloride counteranions, there is one molecule of water incorporated into the structure. Several hydrogen bonding interactions, indicated by dashed lines, are found between the pyrrolic N*H* protons and the water and the chloride anions, respectively. These might, at least to some extent, account for the partial deviation from planarity. Another hydrogen bonding interaction is found between the water and a molecule of tetrahydrofuran (not shown).¶ The middle pyrrole of the terpyrrole subunit is tilted out of the plane, minimizing the interactions between the β-methyl groups.

In summary, the approach reported here provides an easy, high-yielding access to a new class of rubyrin analogue, namely [26]hexaphyrin(1.1.1.1.0.0) (**2**). This new macrocycle differs quite dramatically from its better studied parent system. Not only is one pyrrole-unit found to be inverted in the case of **2**, this prototypical [26]hexaphyrin(1.1.1.1.0.0) is also found to be stable in both its free-base and protonated forms. Rubyrin, on the other hand, is stable only in its bisprotonated form.[14] That the middle pyrrole of the tripyrrane subunit of **2** remains inverted in both these states is interesting, especially in light of the behavior of sapphyrins. In these latter pentapyrrolic systems, the pyrrole unit may be either 'inverted' or 'normal', depending on conditions, substitution paterns and the nature of the heteroatom contained within the central heterocycle of the constituent tripyrrane-subunit. In fact, **2** can be thought of as an 'expanded sapphyrin' with the bipyrrolic subunit exchanged for a terpyrrole. In this context it is worth highlighting the fact that **2** displays a greater propensity for inversion when fully protonated than does tetraphenylsapphyrin. Indeed, this latter species is found to adopt a planar, pyrrole-in conformation when fully protonated.[4,5] These disparities underscore the richness of structural space that may be sampled through the construction of appropriately designed new expanded porphyrin systems.

This work was supported by the National Science Foundation (grant CHE-9725399 to J. L. S.).

Notes and references

† In a more systematic sense, rubyrin might be referred to as [26]hexaphyrin(1.1.0.1.1.0) while bronzaphyrin is a [26]hexaphyrin(2.0.0.2.0.0).

‡ Such behavior has been reported for N-confused porphyrins where 'inversion' is enforced.[17,18]

§ UV-vis (CH_2Cl_2) λ_{max} (nm) (ε in $mol^{-1}\cdot l^{-1}$) of **2**: 502 (61100), 531 (73400), 782 (20200); $H_2\mathbf{2}^{2+}\cdot 2Cl^-$: 533 (173000), 556 (156000), 733 (10400), 877 (30200).

¶ Crystallographic summary for $(C_{46}H_{42}N_6)^{2+}\cdot 2Cl^-\cdot 2C_4H_8O\cdot H_2O$: Crystals were grown by layering a CH_2Cl_2 solution of $H_2\mathbf{2}^{2+}\cdot 2Cl^-$ with THF. Small, very dark prisms, monoclinic, $P2_1/c$, μ = 0.189 mm^{-1}, Z = 4 in a cell of dimensions: a = 20.6415(5), b = 13.3094(4), c = 17.2658(8) Å, β = 95.591(2)°, V = 4720.8(3)Å^3, ρ_{calc} = 1.28 g cm^{-3}, $F(000)$ = 1936. A total of 8152 unique reflections were measured on a Nonius Kappa CCD using graphite monochromatized Mo-Kα radiation (λ = 0.71073Å) at −150 °C. The structure was refined on F^2 to an R_w = 0.184, with a conventional R = 0.0983 (5669 reflections with $F_o > 4[\sigma(F_o)]$), and a goodness of fit = 1.19 for 574 refined parameters using the SHELX-97 package.[19] Two molecules of THF were observed in the unit cell, one of which was severely disordered. The contribution to the data by this molecule was removed using the utility SQUEEZE, found in PLATON98.[20] CCDC 182/1704. A Schiff-base [2 + 2] macrocycle obtained by the reaction of 2,6-diformyl-4-methylphenol with 1,11-diamino-3,9-dimethyl-3,9-diazo-6-oxaundecane encapsulates three manganese ions into its cavity; EPR, UV–VIS–NIR, XPS spectroscopic data, X-ray crystallography and magnetic measurements showed that the metal ions are in a mixed valence state (II, III, II) which is rare for trimanganese systems.

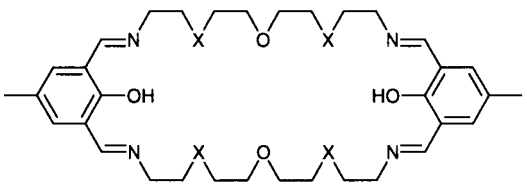
Polynuclear manganese complexes are now receiving increased attention from a wide area of science, including chemistry, biology and physics. Representative target molecules fascinating synthetic inorganic chemists are tetranuclear aggregates as models of the oxygen-evolving complex (OEC) of photosystem II[1] and 'high spin Mn-clusters'[2] potentially applicable to future molecular devices. Most commonly, these complexes are synthesized utilizing self-assembling properties of manganese ions, where the metal ions are bridged by O^{2-} units and externally capped with multidentate ligands.[3] Our approach to Mn-aggregated systems has started with specially designed polynucleating macrocycles. For example, the macrocycle $(L^1)^{2-}$ functions as a tetranucleating ligand for Zn^{II},[4] but did not



X = O : H_2L^1, X = NMe : H_2L^2

give any manganese complexes, probably owing to poor affinity of the ether oxygen towards this metal ion. Thus, we have prepared a new macrocycle H_2L^2, to enhance binding ability by substituting the ether units with tertiary amine groups. We report herein, the synthesis and characterization of a novel mixed valence $Mn^{II}Mn^{III}Mn^{II}$ trimanganese subunit formed within the macrocycle.

1,11-Diamino-3,9-dimethyl-3,9-diazo-6-oxaundecane (daud) as a precursor for H_2L^2 was prepared in a four-step synthesis with an overall yield of *ca.* 30%.† All products obtained at each step were identified by ^1H NMR spectroscopy.

The metal-templated Schiff-base condensation of 2,6-diformyl-4-methylphenol (dfmp) with the diamine in methanol was carried out in open-air using $Mn(ClO_4)_2{\cdot}6H_2O$ as the template core in the presence of triethylamine (NEt_3). The reaction using a mole ratio of dfmp:daud:Mn:NEt_3 = 2:2:4:2 gave dark-brown microcrystals formulated as $[Mn_3(L^2)(\mu\text{-}OMe)_2](ClO_4)_3$ **1**.‡ The [2 + 2] Schiff-base macrocyclization and formation of the trinuclear Mn_3 unit were supported by detection of the strongest peak in its electrospray mass spectrum (*m/z* 305.8) corresponding to the trication for an acetonitrile solution of the complex. A mixed valence state (two Mn^{II} and one Mn^{III}) expected from the formula is evident from spectroscopic data (EPR, UV–VIS-NIR and XPS). An X-band solid-state EPR spectrum of **1** at 25 °C showed two sets of overlapped six-line signals at $g \approx 2.00$ with $A \approx 0.87$ mT, suggesting the presence of two magnetically uncoupled Mn^{II} ions. The electronic spectrum of the complex in methanol showed a very broad peak centered at *ca.* 1005 nm (ε = 142 $dm^3\ mol^{-1}\ cm^{-1}$) and a shoulder at *ca.* 550 nm (ε = 280 $dm^3\ mol^{-1}\ cm^{-1}$), tentatively attributed to $^5B_{1g} \rightarrow {}^5A_{1g}$ and $^5B_{1g} \rightarrow {}^5B_{2g}$ transitions of high-spin Mn^{III} species, respectively, while no strong absorption assignable to an intervalence charge transfer was observed in the visible or near-IR region. The XPS spectrum of **1** exhibited two peaks at 641.5 and 653.3 eV, which were attributed to Mn $2p_{3/2}$ and Mn $2p_{1/2}$ core ionization potentials from each manganese. Although these values do not agree with those of Mn^{2+} or Mn^{3+} ionized states, the spectral envelope as well as the peak positions can be reproduced by superposition of corresponding spectra of $[Mn^{II}(TPP)]{\cdot}py$ and $[Mn^{III}(TPP)]Cl$ (TPP = 5,10,15,20-tetraphenylporphyrinate) with a 2:1 intensity ratio.

Recrystallization of **1** from wet methanol gave needle-like single crystals as the monohydrate (**1**·H_2O), the structure of which (Fig. 1) was determined by X-ray crystallography.§ The three manganese ions are encapsulated into the macrocycle in a bent-chain form with an angle of 129.45(6)° for Mn(1)–Mn(2)–Mn(3). Each of the two facing phenoxide moieties bridges a pair of adjacent manganese ions which are further bridged by an exogenous methoxide ion. The two terminal manganese centers, Mn(1) and Mn(3), have essentially the same coordination geometry being significantly distorted octahedral with average Mn–O,N bond distances of 2.245 and 2.230 Å, respectively, comparable with typical Mn(II)–O,N distances.[5] The central Mn(2) has an elongated octahedral geometry where its axial positions are occupied by the two phenoxide oxygen atoms [Mn(2)–O(1) 2.134(6) Å, Mn(2)–O(3) 2.137(6) Å]. These distances are significantly longer than the four basal Mn–O,N bonds [av. Mn–O,N = 1.962 Å], thus revealing a Jahn–Teller distortion expected for a high spin Mn^{III} species. Thus, we concluded that the three metal ions in the macrocycle are in a mixed valence state $Mn^{II}Mn^{III}Mn^{II}$.

The value of μ_{eff} = 9.968 μ_B at 300 K for powder sample **1** is close to the spin-only value of 9.695 μ_B expected for three spin systems of S = 5/2; S = 4/2; S = 5/2, indicating that all the

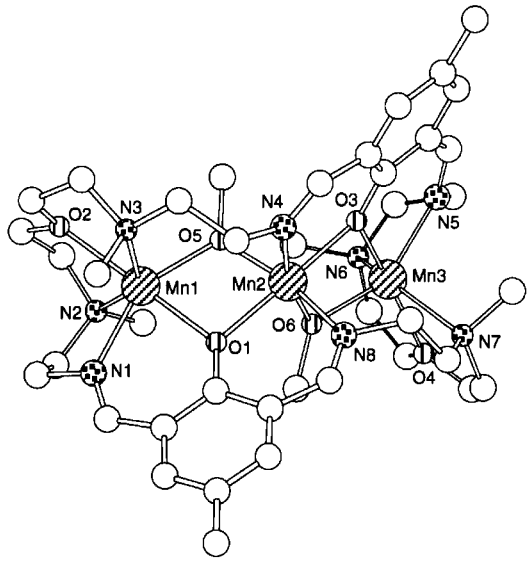

Fig. 1 Perspective view of the $[Mn_3(L^2)(\mu\text{-}OMe)_2]^{3+}$ cation; Selected distances (Å) and angles (°): Mn(1)–O(1) 2.192(6), Mn(1)–O(2) 2.217(6), Mn(1)–O(5) 2.085(5), Mn(1)–N(1) 2.178(8), Mn(1)–N(2) 2.393(8), Mn(1)–N(3) 2.403(8), Mn(2)–O(1) 2.134(6), Mn(2)–O(3) 2.137(6), Mn(2)–O(5) 1.913(5), Mn(2)–O(6) 1.899(7), Mn(2)–N(4) 2.015(7), Mn(2)–N(8) 2.022(8), Mn(3)–O(3) 2.172(6), Mn(3)–O(4) 2.200(7), Mn(3)–O(6) 2.085(7), Mn(3)–N(5) 2.16(1), Mn(3)–N(6) 2.35(1), Mn(3)–N(7) 2.41(1), Mn(1)–Mn(2) 3.235(2), Mn(2)–Mn(3) 3.218(2); Mn(1)–Mn(2)–Mn(3) 129.45(6), Mn(1)–O(1)–Mn(2) 96.8(2), Mn(1)–O(5)–Mn(2) 108.0(2), Mn(2)–O(3)–Mn(3) 96.6(2), Mn(2)–O(6)–Mn(3) 107.7(3).

metal ions are in the high-spin state. The μ_{eff} value increases with decreasing temperature up to a maximum value of 13.96 μ_B at *ca.* 6 K (Fig. 2). The drop in μ_{eff} below 6 K suggests a zero-field splitting of Mn^{II} and Mn^{III} ions or an intermolecular antiferromagnetic coupling. The magnetic data were analyzed with the Van Vleck equation including a correction term θ based on the Heisenberg model [$\mathcal{H} = -2(J_{12}S_1\cdot S_2 + J_{23}S_2\cdot S_3 + J_{13}S_1\cdot S_3)$; $S_1 = S_3 = 5/2$, $S_2 = 4/2$, $J_{12} = J_{23} = J$, $J_{13} = J'$], leading to the best-fitting parameters $g = 2.01(1)$, $J = +1.83(5)$ cm^{-1}, $J' = 0$ cm^{-1}, $\theta = -1.03(4)$ K. The result indicates that weak ferromagnetic interactions operate between the adjacent Mn^{II}–Mn^{III} pairs while interactions between the terminal ions are negligible. Structural data on oxygen-bridged $Mn^{II}Mn^{III}$ pairs showing ferromagnetic interaction remain scarce. However, observed Mn^{II}–O–Mn^{III} angles [96.8 and 108.0° for Mn(1)–Mn(2); 96.6 and 107.7° for Mn(2)–Mn(3)] are comparable to the angles (97.1 and 102.4°) reported for a mixed valence dinuclear $Mn^{II}Mn^{III}$ complex exhibiting $J = +0.89$ cm^{-1}.[6] Magnetically coupled Mn^{II} clusters with high nuclearity, *e.g.* $Mn^{II}{}_5$[7] and $Mn^{II}{}_9$,[8] often show interesting electrochemical properties. A cyclic voltammogram of **1** in methanol (1.0 mM, 0.1 M NEt_4ClO_4) indeed exhibited a quasi-reversible one-electron reduction wave at $E_{1/2} = -0.14$ V with ΔE_p = *ca.* 70 mV (glassy carbon working electrode, Pt counter electrode, Ag^+/AgCl reference electrode), which was tentatively attributed to the formation of the $Mn^{II}{}_3$ species. However, all attempts to isolate this species by chemical or electrochemical reduction were unsuccessful. Finally it should be emphasized that the metal-templated reaction in Ar atmosphere with the same stoichiometry as that for **1** yielded a yellow powder formulated as $[Mn_2(L^2)](ClO_4)_2\cdot H_2O\cdot 2MeOH$ **2**.¶

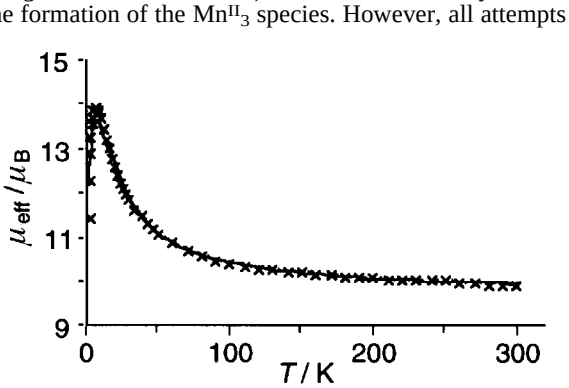

Fig. 2 Plot of μ_{eff} *vs.* *T* for a powdered sample of **1**.

In conclusion, a new Schiff-base macrocycle $(L^2)^{2-}$ obtained by the Mn-templated reaction afforded a novel $Mn^{II}Mn^{III}Mn^{II}$ complex, which is very rare[9] for mixed valence trimanganese systems in contrast to the many $Mn^{II}{}_3$[10] and $Mn^{III}Mn^{II}Mn^{III}$ [11] complexes that have been reported. In addition to EPR, UV–VIS–NIR and XPS spectroscopic evidence, the X-ray structure and the magnetic behavior finally establish that the mixed valence state is of class I type in the Robin–Day classification.[12] In principle, the macrocycle could incorporate further aggregated cores ($n > 3$), since a closely related ligand $(L^1)^{2-}$ is known to afford two types of tetrazinc complex.[4] Approaches to highly aggregated systems are now scheduled and in progress in our laboratory.

Published on the Web 18th July 2000

Three-dimensionally ordered macroporous (3DOM) metal alloys of Ni_xCo_{1-x} (a solid solution) and Mn_3Co_7 (an intermetallic compound) have been prepared by templated precipitation of mixed metal salts within colloidal crystals of poly(methyl methacrylate) spheres and subsequent chemical conversion of the inorganic precursors.

In the past three years, several chemical preparations of ordered macroporous materials based on colloidal crystal templating have been described. By using close-packed arrays of monodisperse spheres (polystyrene or silica) as templates, three-dimensionally ordered macroporous (3DOM) structures have been fabricated whose compositions include silica,[1–4] metal oxides,[3,5–8] simple metals,[9–11] metal chalcogenides,[12] carbon[13] and polymers.[14–17] Since the pore diameters (typically a few hundred nanometers) are comparable to optical wavelengths, 3DOM dielectric materials can be used to create photonic crystals, which exhibit interesting optical effects based on Bragg diffraction and the formation of optical stopbands.[6,18] In addition, applications including catalysis, sorption, and separations may benefit from the bicontinuous void and wall structures and from the well-defined pore sizes of these materials.

Recent theoretical and experimental studies have suggested that metals with well-ordered porous networks would also exhibit interesting photonic properties,[19] and that 3DOM metals provide relatively large surface areas which are uniformly accessible in electrochemical experiments.[9] Periodic macroporous metals have now been prepared by several methods, including hydrogen reduction of preformed macroporous oxides,[9] decomposition of templated metal oxalates in a non-oxidizing environment,[9] electroless deposition,[10] deposition of colloidal gold particles in colloidal crystals,[11] and infiltration of natural calcium carbonate skeletons with gold paint, followed by annealing.[20] All of these macroporous solids contain a single metal. However, most technological applications of metals employ alloys containing two or more elements, because with alloys it is possible to realize an extensive variety of physical properties by varying the composition of the alloy. Here we report a method of synthesizing 3DOM metal alloys, using a solid solution (Ni_xCo_{1-x}) and an intermetallic compound (Mn_3Co_7) as examples.

Colloidal crystals were prepared from uniformly sized poly(methyl methacrylate) (PMMA) spheres synthesized according to the literature[21] and close-packed by gravity sedimentation or centrifugation. To prepare a 3DOM Ni_xCo_{1-x} alloy, 0.008 mol nickel(II) acetate tetrahydrate and 0.008 mol cobalt(II) acetate tetrahydrate were dissolved in 20 mL methanol at 60 °C. After cooling to room temperature, any undissolved solid was removed by filtration and a clear precursor solution was obtained. Centimeter-scale PMMA colloidal crystals (*ca.* 8 g) were soaked in this solution for 3–5 min. Excess solution was removed from the impregnated colloidal crystals by vacuum filtration. The samples were dried in air at room temperature for 1 h. Then the dried composites were soaked in oxalic acid solution (*ca.* 3.6 g oxalic acid in 30 mL ethanol) for 2 min to form metal oxalate inside the PMMA colloidal crystals. After an additional vacuum filtration and drying step, the samples were processed at 400 °C in flowing H_2 (0.3 L min^{-1} in a 22 mm i.d. quartz tube) for 1 h (heating rate: 2 °C min^{-1}). Carbon (0.52 wt%) and hydrogen (0.19 wt%) analyses of a calcined sample confirmed that most of the PMMA template was removed by this treatment and that the metal oxalates had been fully decomposed.

Fig. 1(a) shows a typical SEM image of the template-free macroporous product. Open voids and interconnected walls form a pore structure that is ordered over a range of tens of unit cells in three dimensions. Average void diameters of 200 nm were obtained with 410 nm PMMA spheres. Some cracks can be observed, which arise mainly from the large volume shrinkage and sintering during the template removal/chemical conversion processes. X-Ray energy dispersive spectroscopy (EDS) covering one ordered colloidal crystal domain indicated a Ni : Co mol ratio in the walls of 0.69,[22] bulk elemental analysis by ICP a Ni:Co ratio of 0.86. The walls are composed of fused grains with typical sizes of 20–50 nm (determined by TEM). The average grain size based on PXRD line widths, calculated by the Scherrer equation, is 33 nm.

The PXRD pattern. [Fig. 2(a)] of the product shows a single phase cubic structure (space group *Fm*3*m*), which matches the phase determined by selected-area electron diffraction (SAED) of an ordered area in the TEM. The average calculated lattice constant is 3.529(4) Å, which is between that of Ni (3.5238 Å) and Co (3.5447 Å), suggesting that the Ni_xCo_{1-x} alloy is a solid solution.[23] The 3DOM Ni_xCo_{1-x} alloy exhibited a type II nitrogen adsorption isotherm with a BET surface area of 9.9 m^2 g^{-1}, which is attributed to the surface of fused, nonporous Ni_xCo_{1-x} nanocrystallites composing the wall structure. Owing

DOI: 10.1039/b003147j

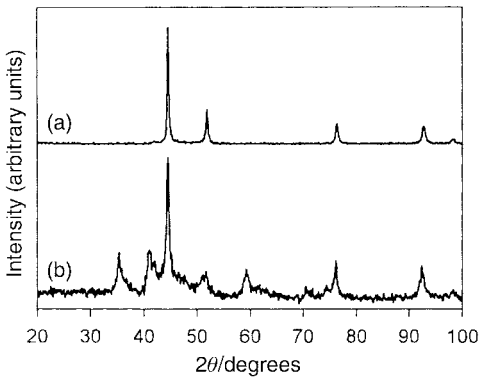

Fig. 2 Powder X-ray diffraction (PXRD) patterns of (a) 3DOM Ni_xCo_{1-x} and (b) 3DOM Mn_3Co_7.

to this large surface area, the fresh products were highly reactive, combusting upon rapid exposure to air even at room temperature. Combustion could be avoided by slow oxidation in a mixture of air (0.2 L min^{-1}) and nitrogen (1.0 L min^{-1}) for 30 min to passivate the sample surface. Passivated samples were air-stable over a period of weeks. Based on the total metals content from ICP analysis, the sample contained at most 4.8 wt% oxygen. However, no metal oxide reflections were observed in the PXRD pattern, indicating that the oxide layers were amorphous or very thin.

As another demonstration of a 3DOM alloy synthesis by the PMMA templating method, we also prepared a Mn_3Co_7 alloy from a stoichiometric mixture of manganese acetate and cobalt acetate precursors, using the same procedure as above. Mn_3Co_7 is an intermetallic compound alloy and has a crystal structure different from both Mn and Co. The PXRD pattern [Fig. 2(b)] shows reflections characteristic of the calcined Mn_3Co_7 alloy in agreement with the standard powder pattern (PDF#18-0407) and with SAED [Fig. 1(c)]. Elemental analysis of the template-free product revealed 1.79 wt% C, 0.20 wt% H and a Mn:Co mol ratio of 0.39 (expected: 0.43). The SEM [Fig. 1(b)] shows that the Mn_3Co_7 alloy has a well-ordered porous structure with average void diameters of 210 nm obtained from 290 nm diameter PMMA spheres. This more ordered structure is probably due to reduced shrinkage and smaller grain sizes [ranging from 15 to 30 nm by TEM, Fig. 1(c)], caused by slower crystal growth kinetics of Mn_3Co_7. The smaller grain size leads to a larger BET surface area of 26.4 m^2 g^{-1}.

It should be noted that the use of PMMA colloidal crystals as templates can significantly improve the periodicity and reduce the remaining carbon content of the resulting macroporous alloys/metals, relative to PS templates. The main reason for the improved performance of PMMA lies in its better thermal degradation character. PMMA decomposes by chain depolymerization, resulting in a gradual reduction in molecular weight and the production of monomer. By this mechanism, the yield of monomer can be as high as 100% in the temperature range 170–300 °C.[24] In comparison, PS degrades to *ca.* 40% of monomer in the temperature range 300–400 °C[24] and leaves a larger amount of carbon after thermal treatment of the product in a non-oxidizing atmosphere (*e.g.* in a macroporous Ni/PS sample, 39 wt% C remained after heating in nitrogen at 450 °C for 10 h, compared to 15 wt% C in a Ni/PMMA sample after 1 h of heating). As a result of the milder conditions required to remove the PMMA template, smaller framework grain sizes and larger surface areas can be obtained. An additional benefit of using PMMA over PS spheres is the better penetration of the precursor solution in the PMMA colloidal crystal owing to increased wettability. Consequently, fewer structural defects are introduced during the composite formation, if a sufficiently concentrated precursor solution is employed.[7]

The PMMA templating method can be used to synthesize 3DOM alloys containing Mn, Fe, Ni, Co and other alloy forming metals whose salt precursors are easily reducible and whose melting points exceed that of the template. Ternary or higher multicomponent alloys may also be formed. For example, we have prepared a Ni/Fe/Co 3DOM alloy by the same procedure. Besides providing a way of structuring metals on a nanometer scale and endowing them with relatively high surface areas, this technique allows one to tailor the physical properties (corrosion resistance, thermal properties, magnetic properties, *etc.*) of the 3DOM structures by changing the metallic composition of the alloy. As a result, the new class of alloys presented here may find applications as high performance catalysts, electrodes, supports and magnetic materials.

We thank 3M, Dupont, the David and Lucile Packard Foundation, the National Science Foundation (DMR-9701507 and the MRSEC Program of the NSF under Award Number DMR-9809364), and the Department of Energy (DOE/DE-FG02-93-ER14384) for support of this research.

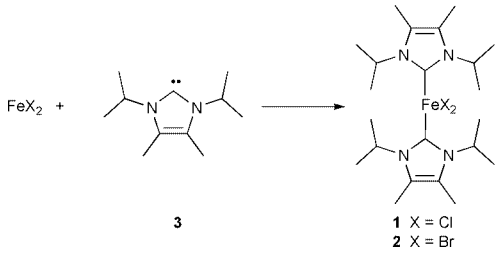
Iron(II) halides possessing highly donating imidazolylidene ligands were found to be remarkably active and efficient catalysts for the atom transfer radical polymerization of styrene and methyl methacrylate.

Atom transfer radical polymerization (ATRP), a method for controlling free radical polymerizations, has recently developed into a versatile tool in polymer chemistry. ATRP is a metal mediated halide exchange process that establishes a fast and dynamic equilibrium between growing (P_n•) and dormant (P_n–X) polymer chains. This equilibrium is dramatically shifted towards favoring the dormant species giving extremely low (*ca.*10^{-8} M) radical concentrations which effectively minimizes bimolecular termination. A fast halide exchange process ensures all polymer chains grow at the same rate giving excellent control over the radical polymerization. Most reports describe the use of a combination of copper(I) halides and amine ligands as ATRP catalysts.[1] However, the ability to conveniently tune catalyst reactivity has led to the emergence of other metal systems (Ru,[2] Rh,[3] Pd,[4] Ni[5,6]) since they are capable of coordinating a wide range of ligands. Recently, attention has shifted towards iron catalyzed ATRP owing to its lower cost and similar activity to their ruthenium analogs.[6]

A steady effort has been directed toward designing ligands that display improved activity in ATRP, yet are still cost effective. In copper based ATRP, replacement of bipyridine ligands with alkyl amines lowers the redox potential of the copper halide catalyst and accelerates the polymerizations.[7] A similar phenomenon was also observed in ruthenium and iron[6e] catalyzed ATRP when triphenylphosphine and bipyridine were replaced with tributylphosphine and tributylamine, respectively. Noels and coworkers reported the highly active ruthenium ring-opening metathesis polymerization (ROMP) catalyst, $Cl_2(PCy_3)_2Ru$=CHPh, was also active for ATRP.[8] Recently, a dramatic increase in the activity of ruthenium ROMP catalysts coordinated with imidazolylidenes was observed,[9] largely due to their higher Lewis-basicity. In addition to being excellent electron donating ligands that are less toxic than phosphines and amines, imidazolylidenes are attractive because they are easy to prepare and handle. These observations prompted us to explore the influence of imidazolylidenes in ATRP. Herein we report the synthesis of FeX_2L_2 [X = Cl, Br; L = 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene (Pr^iIm **3**)[10]] complexes and their use as catalysts in the ATRP of styrene and methyl methacrylate (MMA). The polymerization rates rival copper based systems and yield polymers with extremely low polydispersities.

Heating a toluene solution of FeX_2 and Pr^iIm **3** to 90 °C followed by slow cooling of the reaction mixture to room temperature afforded crystals of chloro-complex **1**† and its bromo- analog **2** in 70–85% yields [eqn. (1)]. The structure of **1**‡ was determined by X-ray crystallography and is shown in Fig. 1. To the best of our knowledge, complex **1** is the first monomeric iron halide possessing imidazolylidene ligands.[11] Complex **1** adopts a distorted tetrahedral geometry with angles in the range 102.05–115.62°. As expected the Fe–C(1) bond length (2.136 Å) in **1** is significantly shorter than Fe–P bond



lengths [2.429 Å in $FeBr_2(PEt_3)_2$[12] and 2.639 Å in $FeCl_3(PPh_3)_2$[13]] as well as Fe–N bond lengths [2.273 Å in $FeCl_3(NMe_3)_2$[14]] in analogous iron based ATRP catalysts.

The homogeneous ATRP of styrene (100 equiv., 50% v/v toluene) initiated with 1-phenylethyl bromide (1-PEBr) and **1** was monitored at 85 °C under inert atmosphere. The semi-logarithmic plot of $\ln([M]_0/[M])$ *vs.* time was linear, with a pseudo-first order rate constant (k_{obs}) of 3.4×10^{-5} s^{-1}, and indicated that radical concentration was constant throughout the polymerization (Fig. 2). The rate of polymerization is among the highest reported for metal catalyzed ATRP in organic solvents.[15] Molecular weight (M_n, determined by gel permeation chromatography relative to polystyrene standards) increased linearly over time and agreed with theoretical weights demonstrating good control [Fig. 3(a)]. Polydispersities (M_w/M_n) were low (*ca.* 1.1) and decreased with monomer conversion [Fig. 3(b)] as expected for a controlled polymerization. In addition, determination of molecular weight by end-group analysis (M_n = 3400) of a low molecular weight polystyrene was in agreement with the targeted molecular weight (M_n = 4000). Addition of the higher oxidation metal (M^{x+1}) to polymerizations is known to lower PDIs by shifting the equilibruim towards dormant polymer chains and lowering

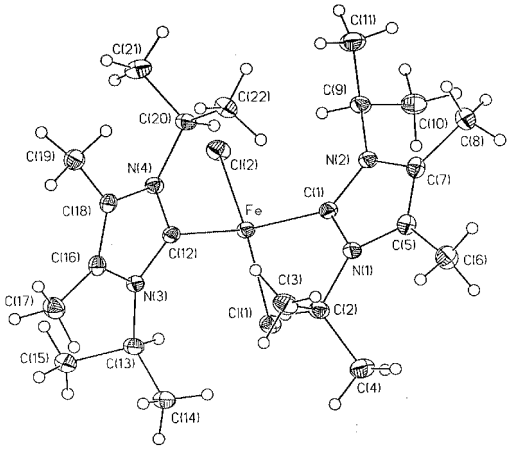


Fig. 1 Molecular structure of complex **1**. Selected bond lengths (Å) and angles (°): Fe–C(1) 2.1363(15), Fe–C1(2) 2.1298(16), Fe–Cl(1) 2.3035(4), Fe–Cl(2) 2.2976(4); C1(2)–Fe–C(1) 102.05(6), C1(2)–Fe–Cl(2) 106.85(4), C(1)–Fe–Cl(2) 114.41(4), C1(2)–Fe–Cl(1) 115.62(4), C(1)–Fe–Cl(1) 104.68(4), Cl(2)–Fe–Cl(1) 112.947(17).

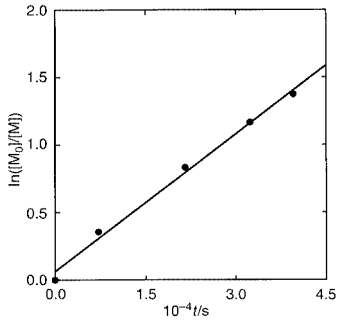

Fig. 2 First-order kinetic plot of $\ln([M]_0/[M])$ *vs.* time in the polymerization of styrene (50% v/v, toluene) at 85 °C ($[\mathbf{1}]_0$ = 44 mM, $[PEBr]_0$ = 44 mM, $[styrene]_0$ = 4.4 M).

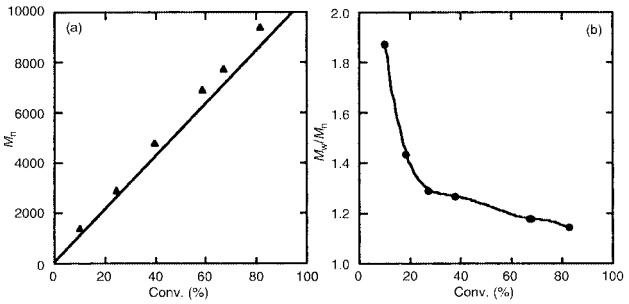

Fig. 3 Dependence of the polystyrene molecular weight (a) and polydispersity (b) on the monomer conversion at 85 °C ($[FeCl_2]_0$ = 44 mM, $[\mathbf{3}]_0$ = 90 mM, $[PEBr]_0$ = 44 mM, $[styrene]_0$ = 4.4 M).

radical concentrations. Thus, addition of 1 equiv. of $FeCl_3$ to the reaction slowed polymerization slightly (k_{obs} = 1.7 × 10^{-5} s^{-1}) but afforded polymers with lower PDIs (1.05 *vs.* 1.14). With or without additional $FeCl_3$, the PDIs of the resulting polymers rival those obtained by anionic polymerizations as well as other metal catalyzed ATRP systems.[16]

Bromo complex **2** had a higher observed rate constant (k_{obs} = 4.2 × 10^{-5} s^{-1}) than chloro complex **1** (k_{obs} = 3.4 × 10^{-5} s^{-1}) which may be related to the difference in the iron halide bond dissociation energies. A similar rate enhancement has also been observed in both copper and ruthenium based systems.[17] Although catalysts **1** and **2** are relatively simple to synthesize, iron(II) halides can be used directly in the presence of free Pr^iIm ligand **3** to generate the catalyst *in situ*. An added benefit of using Pr^iIm **3** is that it is a microcrystalline solid that is indefinitely stable under an inert atmosphere. The observed rate constant for **1** is slightly lower than when using $FeCl_2$ and Pr^iIm **3** (k_{obs} = 2.7 × 10^{-5} s^{-1}) and may be related to an induction period involving catalyst formation.

The ATRP of methyl methacrylate using complex **1,** complex **2**, and the complex formed *in situ* was also investigated. The homogeneous polymerization of MMA (100 equiv., 50% v/v benzene) was initiated with ethyl 2-bromoisobutyrate (EBIB) and monitored at 60 °C under an inert atmosphere. Results analogous to the ATRP of styrene were observed and indicated that these catalysts are also effective in controlling the polymerization of MMA. In addition, a similar trend in observed rate constants as discussed above was observed: complex **2** (k_{obs} = 1.6 × 10^{-4} s^{-1}) > complex **1** (k_{obs} = 1.2 × 10^{-4} s^{-1}) > $FeCl_2$ and Pr^iIm **3** (k_{obs} = 8.1 × 10^{-5} s^{-1}). Addition of $FeCl_3$ reduced the rate of polymerization (k_{obs} = 3.5 × 10^{-5} s^{-1}) but afforded polymers with lower PDIs (1.47 *vs.* 1.09).

Our results confirm that increased electron donacity of the ligands play an important role in the activity of ATRP catalysts. The high Lewis basicity of the imidazolylidene may lower the redox potential of the iron(II) complexes facilitating halide abstraction from dormant polymer chains. This would shift the equilibrium toward growing polymer radicals and therefore increase the rate of polymerization. Interestingly, the relatively high radical concentration does not seem to compromise the control. The increased donacity of these ligands may also stabilize the iron(III) species[18] and therefore enhance the rapid exchange of halides between dormant and active polymer chain ends.

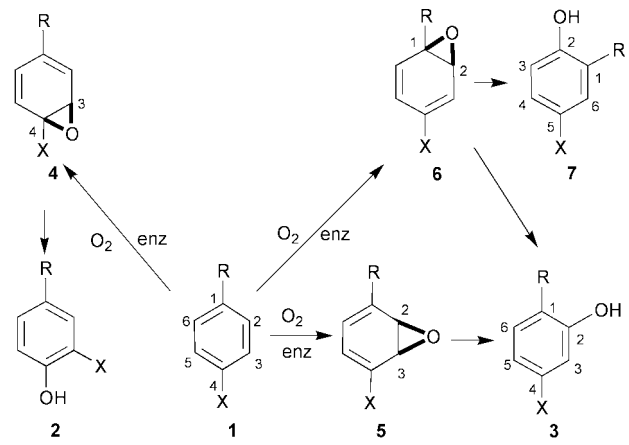
Received (in Cambridge, UK) 31st May 2000, Accepted 19th June 2000
Published on the Web 18th July 2000

Substituted methyl benzoates are biotransformed in the fungus *Phellinus ribis* by enzyme-catalysed epoxidation to yield an isolable benzene oxide and transient benzene oxides, whose presence was inferred from isomerisation to the corresponding methyl salicylates with concomitant migration of the carbomethoxy group.

Aromatic hydroxylation in eucaryotes is widely assumed to involve the monooxygenase-catalysed epoxidation of the benzene ring.[1,2] Although benzene oxides have often been proposed as intermediates in the literature,[1–4] to date none have been isolated as a metabolite. Their role as transient intermediates during aromatic hydroxylation has been inferred on the basis of hydrogen atom migration from the hydroxylation site and its retention at an adjacent carbon atom ('NIH shift').[1,2]

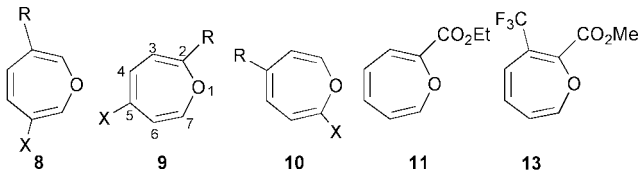
The 'NIH shift' was first observed during the *para*-hydroxylation of phenylalanine to yield tyrosine[5,6] **2** (Scheme 1, R = $CH_2CH(NH_2)CO_2H$, X = ^{3}H) and more than 100 examples have since been reported with ^{1}H, ^{2}H or ^{3}H atoms as the migrating species X. The detection of arene oxides of naphthalene[7] and quinoline[8] during liver microsomal hydroxylation of these arenes provided direct evidence of bicyclic arene epoxidation. By contrast, no unequivocal evidence of enzyme-catalysed benzene oxide formation from monocyclic arene substrates has been available and recently the role of transient arene oxide intermediates in the 'NIH shift' mechanism in biological systems has been questioned.[9–11] In earlier studies[12] we demonstrated that hydroxylation of ^{2}H-labelled halobenzenes **1A** (X = ^{2}H) and **1B** (X = ^{2}H) in fungi mainly occurs at the *ortho* position to yield phenols **3A** and **3B** (X = ^{2}H, Scheme 1) and proceeds *via* the 2,3- (**5A**, **5B**, X = ^{2}H) rather than the isomeric 1,2-benzene oxide (**6A**, **6B**, X = ^{2}H) which would yield phenols **7A** and **7B** (X = ^{2}H) after halogen migration.



R = Cl(**A**), Br(**B**), COOMe(**C**); X = ^{1}H, ^{2}H, ^{3}H, F, Cl, Me

Scheme 1

Some substituted benzene oxides are unstable, *e.g.* the 1,2-oxide of chlorobenzene **6A** (X = ^{1}H) could not be isolated after synthesis,[12] while the 2,3-oxide **5A** and 3,4-oxide **4A** (X = ^{1}H) were found to be stable.[13] Benzene oxides have been assumed to equilibrate spontaneously with the corresponding oxepine valence tautomer by a disrotatory electrocyclic rearrangement mechanism.[1,2] However, in practice, dependent on substituent position, monosubstituted benzene oxides have been found to exist almost exclusively as either the epoxide, *e.g.* 2,3-benzene oxides **5A**–**C** rather than oxepines **8A**–**C**, or the oxepine valence tautomers *e.g.* **9C** and **10A**–**C** rather than 1,2-benzene oxides **6C** or 3,4-benzene oxides **4A**–**C**.[14] The preferred benzene oxide valence tautomers containing an electron withdrawing carboalkoxy group, *e.g.* **5C** (X = ^{1}H), and the preferred oxepine tautomers, *e.g.* **9C** and **10C** are among the most stable known compounds in this arene oxide–oxepine class.[15–17] Thus oxepine tautomer **9C** could be chemically synthesized and was isolated as a fungal metabolite.[18,19]



R = Cl(**A**), Br(**B**), COOMe(**C**); X = ^{1}H

The biosynthetic origin of the secondary metabolites methyl benzoate **1C** (X = ^{1}H) and methyl salicylate **3C**/**7C** (X = ^{1}H) in *Phellinus*, a widespread genus of white rot fungi, has been the subject of ongoing investigations in these laboratories. The genus is unusual in utilising CH_3Cl as a methyl donor in the biosynthesis of methyl benzoate and methyl 2-furoate.[20–23] However, the time course study of incorporation of C^2H_3 from labelled methionine (the immediate metabolic precursor of CH_3Cl) into methyl salicylate **3C**/**7C** (X = ^{1}H) by *Phellinus pomaceus* was quite different from that of methyl benzoate **1C** (X = ^{1}H). This suggests that the compound is formed by *ortho*-hydroxylation of compound **1C** (X = ^{1}H) rather than methylation of salicylic acid,[20] a conclusion consistent with the observation that isolated mycelia cannot utilize CH_3Cl in the methylation of salicylic acid.[20] A more recent study has detected carbomethoxyoxepine **9C** (X = ^{1}H) as a natural metabolite in *Phellinus tremulae*.[18] The propensity for this oxepine to rearrange *via* the postulated,[15] but undetected, benzene oxide tautomer **6C** (X = ^{1}H) with migration of the carbomethoxy group has prompted speculation[18] that it may be an intermediate in methyl salicylate biosynthesis. This hypothesis is given strong support by the results of incorporation experiments with this fungus involving administration of α-

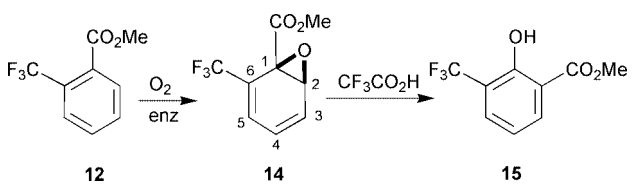
^{13}C-benzoic acid.[19] We have undertaken further biotransformation studies using *Phellinus ribis* and a range of substituted methyl benzoate substrates in the quest for the first evidence of carbomethoxy group migration *in vivo*.

P. ribis cultures were grown on 0.5% mycological peptone in shake flasks at 25 °C and the culture medium monitored for methyl esters of aromatic acids, oxepines and arene oxides by HPLC and GC/MS. As in the earlier investigations of Ayer and Cruz,[18,19] using *P. tremulae*, oxepine **9C** was detected in the medium after 12 days in addition to methyl benzoate and methyl salicylate as natural products of this fungus.[23] When cultures were supplemented after 12 days growth with 0.5 mM methyl 2,6-$^2H_2$-benzoate and examined after a further 2 days incubation, substantial incorporation of label into oxepine, 3,7-$^2H_2$-**9C** (*ca.* 70% incorporation), and methyl salicylate, 3,6-$^2H_2$-**3C** and 3-^{2}H-**7C** (*in toto* 40% incorporation) was found. GC/MS and NMR analyses of the metabolites showed that the major metabolic route involved migration of the carbomethoxy group to yield methyl salicylate **7C** (*ca.* 75% relative yield, 3-^{2}H, X = ^{1}H). A minor pathway (*ca.* 25% relative yield) involved migration and partial retention of a deuterium atom yielding methyl 3,6-$^2H_2$-salicylate **3C** (X = ^{1}H).

A series of methyl esters of monosubstitited benzoic acids were next examined as possible substrates by supplementation of the fungal growth medium as described above. Comparison of the metabolites from the methyl esters of *para*-substituted benzoic acids **1C** (X = F, Cl, Me), with authentic standard samples of the substituted methyl salicylate metabolites **7C** (X = F, Cl, Me) by GC/MS indicated that the 'NIH shift' involving migration of the carbomethoxy group had occurred during aromatic hydroxylation. Methyl esters of the corresponding *meta*-substituted benzoic acids were also examined as substrates but only the methyl *m*-fluoro- and *m*-methyl-salicylates were detected and no carbomethoxy migration was observed. Aromatic hydroxylation did not occur with the methyl esters of *ortho*-substituted benzoic acids or methyl esters of the *o*-, *m*- and *p*-trifluoromethyl benzoic acids as substrates. The only oxepine detected, other than oxepine **9C**, was oxepine **11** when ethyl benzoate was a substrate. However, GC/MS analysis of the bioextracts from metabolism of methyl 2-trifluoromethylbenzoate **12** as substrate, revealed a major bioproduct with a molecular weight identical to that of the corresponding oxepine **13.** This metabolite, purified by PLC, was obtained (*ca.* 2 mg from 300 cm^3 of culture medium) as a stable colourless liquid. ^{1}H- and ^{13}C-NMR spectra (NOE, COSY, HETCOR) of the metabolite were consistent with previously synthesised arene oxides.[13,24] It was identified as benzene oxide **14** (Scheme 2). δ_H 500 MHz, $CDCl_3$: 3.85 (s, Me), 4.23 (dd, H-2), 6.59 (ddd, H-4), 6.7 (ddd, H-3), 6.98 (dd, H-5), $J_{2,3}$ 3.7, $J_{2,4}$ = $J_{5,3}$ 1.9, $J_{3,4}$ = $J_{4,5}$ 8.6; δ_C (125 MHz, $CDCl_3$): 53.09, 61.03, 65.39, 128.02, 130.24, 130.28, 132.20, 166.55. ^{19}F-NMR, UV, IR and high resolution MS were used to confirm the identification of benzene oxide **14**.

Chemically synthesised 2,3-benzene oxides (*e.g.* **5A** and **5B** X = ^{1}H), derived from the *cis*-2,3-dihydrodiol enantiomers, were found[24] to have totally racemized *via* the oxepine tautomer in accord with predictions.[1,2] Benzene oxide **14** was similarly found to be racemic suggesting that total racemization had occurred *via* the undetected oxepine valence tautomer **13**. Addition of trifluoroacetic acid to oxide **14** resulted in aromatization to yield product **15** (Scheme 2) whose structure was confirmed by MS and NMR analysis (^{1}H-, ^{13}C-, HMBC) thus providing a further example of a carbomethoxy group migration. Interestingly phenol **15** was only detected as a trace metabolite of the methyl benzoate **12** and this appears to be a consequence of the remarkable stability of benzene oxide **14** which may be due to the presence of two strongly electron withdrawing groups, in particular the bulky CF_3 group. The location of these groups at positions C-1 and C-6 in arene oxide **14** appears to bias the equilibrium almost exclusively towards the benzene oxide valence tautomer **14**. As in other eucaryotes the enzyme is presumably a monooxygenase and attempts to isolate it are in progress.



12 **14** **15**

Scheme 2

The isolation of benzene oxide **14** as a metabolite and the identification of aforesaid metabolites in cultures of *P. ribis* provide compelling evidence that *o*-hydroxylation of the methyl benzoates proceeds *via* benzene oxide intermediates. These intermediates, in turn, provide a rationale for this first report of an 'NIH shift' of the carbomethoxy group in a biological system. The apparent carboxyl group migration reported earlier[25] may in fact involve an ester intermediate.

We thank the BBSRC (N. D. S.) and European Social Fund (J. S. H.) for funding and Dr Paul J. Stevenson for helpful discussion.

Efficient planar chiral 2′-substituted 1,1′-P,N-ferrocene ligands for the asymmetric Heck reaction: control of enantioselectivity and configuration by planar chiral substituent

Wei-Ping Deng, Xue-Long Hou,* Li-Xin Dai and Xiao-Wei Dong

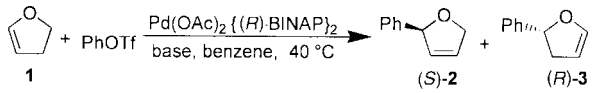
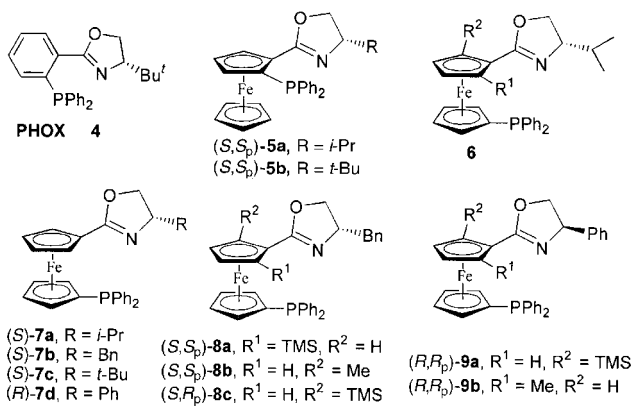
Planar chiral 1,1′P,N-2′-substituted 2′ substituted 1,1′-P,N-ferrocene derivatives were efficient ligands for the Pd-catalyzed asymmetric Heck reaction, in which 79–85% yields with high enantioselectivity (80–92%) were obtained within several hours; the enantioselectivity and the absolute configuration were controllable by changing the size of the planar chiral group and/or configuration of planar chirality.

Among palladium-catalyzed C–C bond-forming reactions, the Heck reaction enjoys considerable current popularity because of its versatility and tolerance of functionality.[1] It has only recently been exploited in the key steps of many total syntheses[2] although the first intramolecular asymmetric Heck reactions were reported, independently, by Shibasaki[3] and Overman[4] in 1989. Two years later, the intermolecular asymmetric version of the Heck reaction was reported by Hayashi,[5] with BINAP as ligand. The reaction was carried out with dihydrofuran **1** and phenyltriflate and afforded a mixture of regioisomers **2** and **3** in a 29 : 71 ratio, with the major product **3** obtained in high ee (96%) (Scheme 1).



Scheme 1

In an important extension to this work, Pfalz[6] described the application of the diphenylphosphinooxazoline **4** (PHOX) ligand to arylation and alkenylation of substrate **1**. In contrast to the regioisomer problem observed by Hayashi, the phenylation of dihydrofuran **1** produced the 2,5-dihydrofuran derivative **2** in high yield (85%) and with so far the best enantioselectivity (97% ee). Although impressive results have been achieved in asymmetric inter- and intra-molecular Heck reactions with several kinds of ligands,[6–8] there are still problems for the practical use of this asymmetric reaction, such as low reaction rates (usually several days) and high catalyst loading. Therefore, it is important and challenging to develop novel highly efficient ligands.



Ferrocene-based planar chiral ligands have been proven to be effective and highly reactive in many kinds of asymmetric catalytic reaction.[9] However, to the best of our knowledge, there is so far no report on their use in the asymmetric Heck reaction, except for the result of Guriy[8] that excellent enantioselectivity was observed with very low catalytic activity (14 days for a complete conversion) by using ferrocene-type ligands **5** in the phenylation of 2,2-dimethyl-2,3-dihydrofuran. Quite recently, as a part of the program aimed at the design and application of chiral ligands to asymmetric synthesis,[10] we synthesized a new kind of planar chiral 1,1′-P,N-ferrocene ligand **6**, which showed that the planar chirality is decisive in exerting control over both absolute configuration and enantiomeric excess in Pd-catalyzed allylic substitution reactions.[11] These encouraging results prompted us to extend the scope of these new structural-framework ligands to the asymmetric Heck reaction. Herein we report our initial findings on the phenylation of 2,3-dihydrofuran **1** by using palladium complexes derived from new ligands **7**, **8** and **9**, which were synthesized by our group.[11,12]

We initially tested the effectiveness of the structurally novel 1,1′-disubstituted P,N-ferrocene ligands **7**. At the same time, 1,2-disubstituted P,N-ferrocene ligands **5** were also used for this reaction in order to compare the catalytic activity of **5** and **7**. The results are summarized in Table 1.

With 3 mol% of catalyst, prepared *in situ* from $Pd(dba)_2$ and 1.5 equiv. of ligands **7a–d**, the corresponding 2,5-dihydrofurans **2** were formed as sole products (as shown by TLC), similar to the results Pfalz obtained.[6] The best enantioselectivity (76.5%) and also the highest catalyst activity (affording 80% of yield in 8 h) was observed with ligand **7b** (Table 1). Ligand **7d** showed the same catalytic activity as ligand **7b**, however, gave the lowest enantioselectivity (42.4%). It is noteworthy that 1,2-disubstituted P,N-ferrocene ligands **5a–b** had almost no catalytic activity in this reaction even with the reaction time prolonged to 24 h.[8] Usually, 1.5 equiv. of ligand were used in this reaction. However, when 1.0 or 2.0 equiv. of the ligand were used the resulting ee values and yields of reaction product were slightly lower. Next, a variety of solvents and bases were investigated and the results showed that the ee value was independent of the base used, which is in consistent with Pfaltz's results. However, the enantioselectivity with benzene as solvent was inferior to that with THF. For ligands **7b** and **7d**, the yields in asymmetric Heck reactions are good with higher reaction rates (several hours) using 3 mol% of catalyst compared with literature results[6] (2 to 3 days for a high conversion).

Considering the high reactivity of ligands **7b** and **7d**, we envisaged that the enantioselectivity and/or the configuration of the reaction product might be improved and/or inverted by introducing planar chirality into these two ligands according to our previous experience on the role of planar chirality in Pd-catalyzed allylic alkylation reactions.[11] Consequently, planar chiral ligands (S,S_p)-**8a**, (S,S_p)-**8b** and (S,R_p)-**8c**, (R,R_p)-**9a** and (R,R_p)-**9b**, containing a newly introduced Me or TMS group on the same Cp ring with oxazoline moiety, were synthesized and

[e] Configurations were assigned by comparison of the signs of optical rotation.

tested for this reaction. The results are summarized in Table 2.

A dramatic change in the enantioselectivity of the reaction was observed with (S,S_p)-**8a** containing a (S_p)-TMS planar chiral group. The enantiomeric excess of reaction product **2** changed from 76.5% with *R* configuration by using ligand **7b** to 83.5% with *S* configuration (entry 2 *vs.* entry 1 of Table 2). This exciting result encouraged us to probe the effect of the newly introduced group with opposite planar chirality, which might increase the ee value and with the same configuration of product **2** from that by using ligand **7b**. Therefore, (S,S_p)-**8b** containing a (S_p)-Me planar chiral group was synthesized and subjected to the same reaction. Just as expected, a remarkable improvement in the ee value (88.5%, *R* configuration) was observed. The same phenomenon was observed by using ligands (R,R_p)-**9a** and (R,R_p)-**9b** (compare entries 6 and 7 with entry 5). These results indicate that the effect of planar chirality on the stereochemical outcome is significant in this Heck reaction, which is inconsistent with our previous results with Pd-catalyzed asymmetric allylic alkylation.[11] Maybe the planar chirality has the same role in two different reaction systems, *i.e.* the planar chirality controls and tunes the ee value and absolute configuration of the reaction product by changing the ratio of rotamers of the axial chirality on coordinating with metal Pd due to its steric repulsion on the coordinating center.[12] If this is true, then increasing the steric bulkiness of the newly introduced planar chiral group may improve the ee value of product **2**. In fact, the ee value actually increased to 92% when ligand (S,R_p)-**8c** containing a bulky TMS group was used in this reaction. Thus, the ee value and absolute configuration of product **2** are controllable and tunable just by changing the configuration and/or size of the planar chiral group. In addition, a very small amount of regioisomer **3** (entries 3 and 7) in the reaction product was detected by GC but not observed by preparative TLC.

In conclusion, the above mentioned new kind of ligand is effective and attractive in the asymmetric Heck reaction not only because of the high reactivity and enantioselectivity but also because the absolute configuration of the reaction product can be controlled just by changing the configuration and/or size of the planar chiral group of these ligands. Further studies on the improvement of enantioselectivity *via* modifying these ligands and their application to other substrates are in progress.

Functional analysis of Phe605, a conserved aromatic amino acid in squalene–hopene cyclases†

Tsutomu Hoshino,* Masanori Kouda, Takamasa Abe and Tsutomu Sato

Department of Applied Biological Chemistry, Faculty of Agriculture and Graduate School of Science and Technology Niigata University, Ikarashi, Niigata 950-2181, Japan

Received (in Cambridge, UK) 23rd May 2000, Accepted 21st June 2000
Published on the Web 19th July 2000

Incubation of squalene with the site-directed mutant F605A of squalene–hopene cyclase from *Alicyclobacillus acidocaldarius* yielded many triterpenes consisting of the 6/6/5-fused tri-, 6/6/6/5-fused tetra-, and 6/6/6/6/5-fused pentacyclic skeletons, the function of F605 being assignable for facilitating the ring expansion and for stabilizing the hopanyl C22-cation, possibly *via* cation-π interactions.

Squalene–hopene cyclase (SHC) converts acyclic squalene into pentacyclic triterpenes, hopene **1** and hopanol **2**, with regio- and stereochemical specificity.[1] In the past few years, there have been remarkable advances in addressing both the cyclization mechanism and the catalytic sites by site-directed mutagenesis experiments.[2] The cyclization cascade is triggered by proton attack at the terminal double bond, which is supplied by D376 and/or D374.[2a] The carbocation intermediates of the initially cyclized A-ring and the bicyclic A/B-fused ring, progressively formed during the polycyclization reaction, are stabilized by the carboxylate anion of D377[2a] and by the π-electrons of F365[2b] *via* a cation-π interaction, respectively. The 6-membered C-ring (anti-Markovnikov adduct) is formed as a result of a ring expansion process from the 5-membered C-ring that has been previously formed under Markovnikov closure.[2c] This expansion may be facilitated by π-electrons of F601. The point mutation experiments targeted for W 169 and W 489 allowed us to propose the involvement of the ring expansion from the 5- to 6-membered D-ring.[2d] The bulk size at the 261 position is critical in directing the stereochemical destiny for the formation of the hopane skeleton.[2f] The question still remained unanswered as to how the last 5-membered E-ring is constructed. Phe605 is strictly conserved in all the known SHCs, but not in oxidosqualene cyclases. We describe here the enzymic products obtained by the mutant F605A and the functional analysis of Phe605.

With the cell-free homogenates from a 8L-culture of the transformed *E. coli* encoding F605A SHC, 400 mg of squalene was incubated for 14 h at optimum catalytic conditions (pH 6.0 and 50 °C). Ten new products were homogeneously purified with SiO_2 column chromatography (5% $AgNO_3$) eluting with hexane. The yields of **1**–**12** were estimated by GC to be 141, 133, 9.9, 6.6, 23.3, 11.5, 9.3, 20.4, 7.4, 0.5, 12.4, 12.6 mg, respectively, and to be 1.2 mg for the recovered squalene.

Scheme 1 shows the structures of all the isolated products, which were determined by the detailed analyses of EIMS and 2D NMR spectra. Products **3** and **4** (**3**:**4** = 1.5:1) had a 6/6/5-fused tricyclic skeleton. All the NMR data and the specific rotation of **3** and **4** were indistinguishable from those of the known podioda-8,17,21-triene and -7,17,21-triene,[3] respectively, but the stereochemistry at the 14-position has remained undetermined. These two products were formed from the common biosynthetic intermediate **13** (Scheme 2). The successive rearrangement reactions of 13βH to C14 and of the 26-Me to C13 on **13** gave the C8-cation (podiodatrienyl cation **13′**). The deprotonation of H9 or H7 afforded **3** or **4**, respectively. The cyclization reaction proceeds through intermediates **13**–**17**, as shown in Scheme 2. A ring expansion of **13** to form **14** and a further cyclization could produce **15**. Products **5**–**8** were produced *via* **15** by deprotonation reactions at different positions, rearrangement reactions of hydride and methyl, or nucleophilic attack of a water molecule. Intermediate

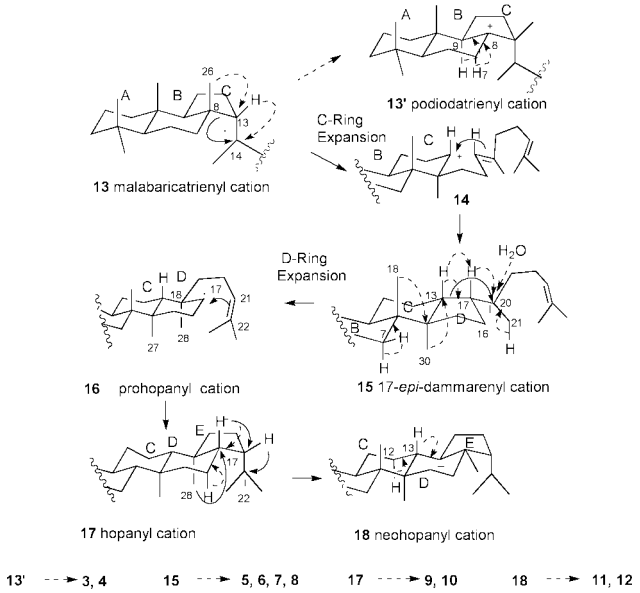
DOI: 10.1039/b004129g



Scheme 2

15 underwent ring expansion and a further cyclization to give **16**,[2f] and **17**, respectively. **9**[2f] and **10** were produced *via* **17**. The migration of 28-Me into C17 in **17** gave **18**, which was subjected to deprotonation reactions to yield **11** and **12**. The product ratio of **2**:**1** was significantly increased by this mutation (0.9:1), compared with that of the native SHC (0.2:1). This fact strongly suggests that the perturbation occurred around the E-ring, which allowed the easy access of a water molecule to the enzyme cavity and also led to the incorrect positioning of the deprotonation site for introducing the $\Delta^{22:29}$ double bond in **1**. Therefore, a larger amount of **2** and **8** could be accumulated together with the pentacyclic **9**–**12** having different double bond positions due to the improper deprotonation reactions. The significant perturbation around the E-ring may have had a greater influence on the earlier reaction steps in forming tri- and tetracyclic ring systems to afford **3**–**8**. Many different triterpene skeletons have been found from various point mutants;[2] but the high production of podiodatrienes (**3**,**4**) and neohopanes (**11**,**12**) has not previously been reported.

To identify the function of F605, we constructed the mutants of F605Y, F605W and F605H. If F605 stabilises a carbocation intermediate through a cation–π interaction, the higher π-electron density gives the faster reaction rate.[2b] Fig. 1 shows the specific activities for the formation of **1** or of both **1** and **2** against incubation temperatures. At lower temperatures, F605Y and F605W had faster reactions than the wild-type,[4] suggesting that a cation–π interaction may be involved in the cyclization cascade.[2b] The F605Y had a bell-shape, while the F605W had a steady state in the range 45–55 °C. The cyclase activities of the mutants were somewhat sensitive to the incubation temperatures. These features may have occurred due to the decreased binding (the largest K_m of F605W[5]) and/or to the occurrence of the geometrical change around the active site region by elevating the temperature, as previously discussed for the F365Y and F365W SHCs.[2b] The mutants F605Y and F605W afforded a larger amount of **2** relative to **1** than the wild-type (Fig. 1);[4] the bulky substituents make the active site region (around the E-ring) less compact, thus the water molecule has easier access to the cavity resulting in the production of a larger amount of **2**. However, the quantities of **3**–**12** produced by the Tyr and Trp mutants were negligible, strongly suggesting that the perturbation was lower compared to that of the Ala mutant and that a cation–π interaction was still effective in the active site (Fig. 1). F605H afforded **5** in a significantly higher yield (14%) than the wild-type (1%), despite the total amount of **1** and **2** being decreased (84% of the native SHC); the His moiety would have abstracted the proton from 21-Me of **15** owing to the basic function. Thus, F605 can be situated near to 21-Me in **15**. The more favourable placement of F605 on the C17 cation (the secondary cation) in **16**, though near to the C20-cation in **15** (the tertiary cation), may facilitate the ring expansion reaction to give the energetically unfavourable **16**, as is predicted from computational studies.[6]

Tetracyclic **5**–**8** were accumulated with F605A, but never with F605Y and F605W, which definitively suggests that the π-electrons of Phe605 have a crucial role for the D-ring expansion process from **15** to **16**. A nucleophilic attack of the Δ^{21} double bond to the C17 cation in **16** yields the E-ring and the last C22 cation of **17**. The E-ring formation reaction would be further accelerated if the C22 cation could be stabilized *via* a cation–π interaction. Phe605 is not conserved in oxidosqualene cyclases. For lanosterol and cycloartenol biosyntheses, the polycyclization is quenched at the tetracyclic stage without a D-ring expansion.[1] For the syntheses of pentacyclic lupeol and β-amyrin, the ring expansion is also involved to give a common intermediate of the baccharenyl cation, but the position of the carbocation is different from that of the **16** cation.[1,2d,f] The different cyclization mechanism between eukaryotic and prokaryotic cyclases further support the proposed function of Phe605 which is conserved only in SHCs.

This work was supported by a Grant-in-Aid to T. H. (No.11660104) from the Ministry of Education, Science, Sports and Culture, Japan.

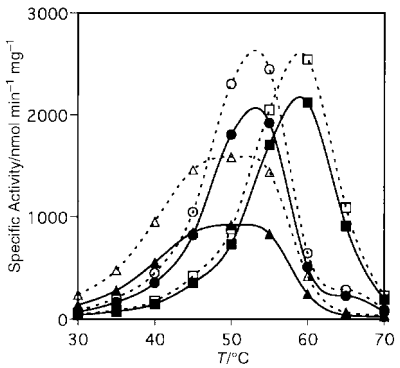


Fig. 1 Specific activities for the formation of **1** (closed symbols, solid lines) or of the both of **1** and **2** (open symbols, dotted lines) against incubation temperatures are given for the wild-type SHC (■,□), the mutants of F365Y (●,○) and F365W (▲,△). One mg of squalene was incubated with 5 μ of the homogeneously purified SHCs for 60 min at pH 6.0. The ratio of **1** to **2** can also be estimated from the difference between the solid and the dotted lines.

4 On prolonged incubation for 20 h at 45 °C and pH 6.0 with equal amounts of squalene and the enzyme, the total amounts of **1** and **2** produced were almost equal for the three different SHCs. However, the product ratio of **1** to **2** was significantly altered as follows: 5.0 for the native SHC; 3.65 for the F605Y; 1.37 for the F605W (Fig. 1).
5 Kinetic data for the total amount of **1** and **2**, produced by incubating squalene at 35 or 45 °C (in parentheses) and for 60 min, were as follows: k_{cat}s; 0.25 (1.48), 0.18, 0.92 (4.52) and 1.67 (9.11) s^{-1}, and K_ms; 17.8 (18.2), 47.9, 21.1 (69.6) and 21.1 (109) μM, respectively, for the wild-type, F605A, F605Y and F605W. The more bulky substituents gave the larger K_m (looser binding) with elevating incubation temperatures, which may result in the profile of steady state in the range of 45–55 °C (Fig. 1), despite π-electron density being enhanced.[2b]

Mesoporous dimethylsiloxane-incorporated silica materials are synthesized which exhibit high surface areas, regular mesopores, thick walls, high hydrophobicity and high mechanical strength.

Since the discovery of the M41S mesoporous silica materials in 1992 by Mobil researchers,[1] various mesoporous materials have been developed.[2] Several organic-group modified mesoporous silica materials have been synthesized by the *in situ* co-condensation of organosilane precursors and tetraethyl orthosilicate (TEOS) in the presence of surfactant self-assemblies.[3] Recently, several groups reported the synthesis of mesoporous organic–inorganic hybrid materials with organic groups directly incorporated into the silicate framework using bis(alkoxysilyl)-functionalized precursors. Here, we present the synthesis of mesoporous dimethylsiloxane-incorporated silica materials from the co-condensation of TEOS and diethoxydimethylsilane (DEDMS) in the presence of surfactant self-assemblies.

In the multi-component sol–gel processes it is important to control the hydrolysis and condensation rates of the precursors.[6] If the hydrolysis rates of the precursors were considerably different, phase-separated mixtures would be produced instead of homogeneous hybrid materials.[7] It is well-known that the hydrolysis rate of DEDMS is nearly zero in basic medium and that it hydrolyzes much faster in acidic medium. In consequence, we chose the so-called $S^+X^-I^+$ route (S^+: cationic surfactant, X^-: halide ion, and I^+: cationic silicate oligomer) to synthesize MCM-41 type mesoporous dimethylsiloxane-incorporated silicas.[8]

TEOS and DEDMS were partially pre-hydrolyzed separately in acidic medium by stirring for 30 minutes in an ice bath with molar ratios of 1 TEOS : 2 H_2O : 0.04 HCl and 1 DEDMS : 1 H_2O : 0.04 HCl respectively. The resulting two clear solutions were mixed with vigorous stirring and were poured into a surfactant solution at 60 °C. The resulting gel mixture had a molar composition of 1 (TEOS + DEDMS) : 0.13 octadecyltrimethylammonium bromide (OCTAB) : 5.4 HCl : 150 H_2O. The mixture was aged for 5 d with vigorous stirring at 60 °C. The surfactant was removed by refluxing in ethanol for 3 h followed by refluxing for 6 h in 5 mol% HCl in ethanol. The resulting mesoporous materials were designated as mesoporous $(CH_3)_2SiO$-*a*SiO_2 materials (*a* = the molar ratios of DEDMS and TEOS in the initial reaction mixtures, and were set to 2, 3 and 4). For comparison, pure mesoporous MCM-41 silica was synthesized according to a similar procedure using TEOS as a precursor. The elemental analytical results of these mesoporous materials revealed that most of the surfactant was successfully removed (typical elemental results in wt%: C, 7.68; H, 1.84; N, 0 for $(CH_3)_2SiO$-$4SiO_2$. C, 9.36; H, 2.41; N, 0 for $(CH_3)_2SiO$-$3SiO_2$. C, 11.11; H, 2.76; N, 0 for $(CH_3)_2SiO$-$2SiO_2$). Solid-state ^{13}C NMR also confirmed the successful removal of surfactant.

The ordered mesoporous structure of the materials was investigated by X-ray powder diffraction (XRD), transmission electron microscopy (TEM) and gas adsorption measurement. Powder X-ray diffraction patterns of mesoporous $(CH_3)_2SiO$-*a*SiO_2 materials and mesoporous silica are shown in Fig. 1. The XRD pattern of mesoporous silica [Fig. 1(*a*)] exhibited hexagonal MCM-41 pore arrangement, displaying one intense (100) reflection with d_{100} of 4.0 nm and smaller (110) and (200) reflections. On the other hand, the XRD patterns of dimethylsiloxane-incorporated silica materials shown in Fig. 1(*b*)–(*d*) revealed only a (100) reflection, demonstrating that they are less ordered in the long range than the pure silica material.

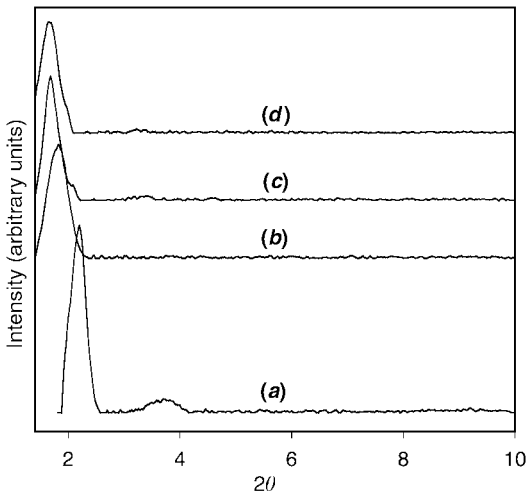

Fig. 1 X-Ray diffraction (XRD) patterns of mesoporous MCM-41 silica (trace *a*), mesoporous $(CH_3)_2SiO$-$4SiO_2$ (trace *b*), $(CH_3)_2SiO$-$3SiO_2$ (trace *c*) and $(CH_3)_2SiO$-$2SiO_2$ (trace *d*) materials. The patterns were obtained with a Rigaku D/Max-3C diffractometer equipped with a rotating anode and Cu-K_α radiation (λ = 0.15418 nm).

Table 1 shows the pore characteristics of these mesoporous materials. The BET surface areas of the dimethylsiloxane-incorporated silicas are slightly smaller than that of the pure silica material. Nitrogen adsorption/desorption isotherms of these materials exhibited type IV, which is characteristic of mesoporosity. The pore diameters of these materials were comparable to that of the pure mesoporous silica. The wall thickness was obtained by subtracting the BJH pore size from the unit cell parameter a_0 ($a_0 = 2d_{100}/\sqrt{3}$). The results revealed that the walls of these dimethylsiloxane-incorporated silicas were thicker than those of the pure silica derivative, which is very important for their future applications. A TEM image of

Table 1 Pore characteristics of mesoporous dimethylsiloxane-incorporated silicas[a]

Sample	Surface area/ $m^2\ g^{-1}$	Pore diameter/ nm	Pore volume/ $cm^3\ g^{-1}$	Wall thickness/ nm
MCM-41 SiO_2	1082	2.8	0.95	1.8
$(CH_3)_2SiO$-$4SiO_2$	1028	2.7	0.67	2.9
$(CH_3)_2SiO$-$3SiO_2$	980	2.4	0.62	3.6
$(CH_3)_2SiO$-$2SiO_2$	1029	2.3	0.73	3.8

[a] N_2 adsorption and desorption isotherms were collected on a Micromeritics ASAP2010 Gas Adsorption Analyzer after the materials were degassed at 150 °C at 30 μTorr for 5 h. The surface areas were calculated by the BET method and the pore size distributions were calculated from the adsorption branch of the nitrogen isotherm by the BJH method.

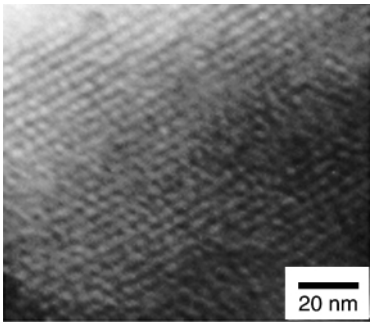

Fig. 2 Transmission electron micrograph (TEM) of mesoporous $(CH_3)_2SiO$-$4SiO_2$ material. The images were obtained with a Phillips CM-20 instrument.

the mesoporous $(CH_3)_2SiO$-$4SiO_2$ material showed a regular array of *ca*. 2.5 nm diameter holes separated by *ca*. 3 nm thick walls (Fig. 2).

One of the disadvantageous features of mesoporous silica materials for the applications is their poor mechanical stability.[9] In the present research, we have incorporated the dimethylsiloxane component into silica frameworks to increase the mechanical strength of the silica framework. The mechanical properties of these materials were evaluated by taking XRD patterns after compressing the materials. In the case of the pure silica mesoporous material, the XRD pattern after compressing at 104 MPa (15 000 psi) for 10 min showed no diffraction peak, revealing that the mesopores were completely collapsed. On the other hand, mesoporous $(CH_3)_2SiO$-$3SiO_2$ after compressing at 104 MPa exhibited a (100) reflection with slightly decreased intensity compared to the XRD pattern before the compression. The surface area and pore volume of the mesoporous material were kept nearly unchanged after compressing at 104 MPa. The results clearly demonstrated that these mesoporous dimethylsiloxane-incorporated silicas possess better mechanical stability compared to mesoporous silica materials.

The hydrophobicity of the mesoporous materials was tested by mixing with an immiscible mixture of water and methylene chloride. After shaking vigorously, the mesoporous $(CH_3)_2SiO$-$3SiO_2$ material resided exclusively in the methylene chloride layer. In contrast, the pure silica mesoporous material stayed in water layer. The same trend was observed when a mixture of diethyl ether and water was used as a partitioning medium. These results showed that these mesoporous materials are very hydrophobic. Thermogravimetric analysis (TGA) of mesoporous $(CH_3)_2SiO$-$3SiO_2$ revealed that the material decomposed around 300 °C.

The homogeneous distribution of the $(CH_3)_2Si$ moiety in the mesoporous material was investigated by FT-IR spectroscopy (Fig. 3). The successful incorporation of $(CH_3)_2Si$ groups in the silicate framework was confirmed by four peaks at *ca*. 2970, 1267, 850 and 800 cm^{-1}, which can be assigned as CH_3 asymmetric stretching, CH_3 deformation, CH_3 rocking and Si–C stretching mode, respectively. The Si–O–Si bending vibration mode was known to be sensitive to the chemical environment and was utilized as a fingerprint for the homogeneous incorporation of organic groups into the silicate framework.[10] In our samples, the Si–O–Si bending vibration mode was shifted from 467 cm^{-1} for pure silica mesoporous material to 454 cm^{-1} for $(CH_3)_2SiO$-$4SiO_2$ and $(CH_3)_2SiO$-$3SiO_2$, and 450 cm^{-1} for $(CH_3)_2SiO$-$2SiO_2$, demonstrating that the Si-$(CH_3)_2$ moieties are homogeneously distributed in the silicate framework structure.[10] The ^{13}C CP-MAS (cross polarization-magic angle spinning) NMR spectrum of mesoporous $(CH_3)_2SiO$-$3SiO_2$ material showed a single Si-$(CH_3)_2$ peak at δ −1.5. The ^{29}Si CP-MAS NMR spectrum of the material exhibited characteristic peaks attributed to $(CH_3)_2Si(OSi)_2$ (D_2 δ −15.7), $Si(OSi)_4$ (Q_4 δ −110), $(OH)Si(OSi)_3$ (Q_3 δ −103). These NMR results demonstrated that the $(CH_3)_2Si$ moiety was kept intact during the synthesis and was successfully incorporated into the silicate framework.

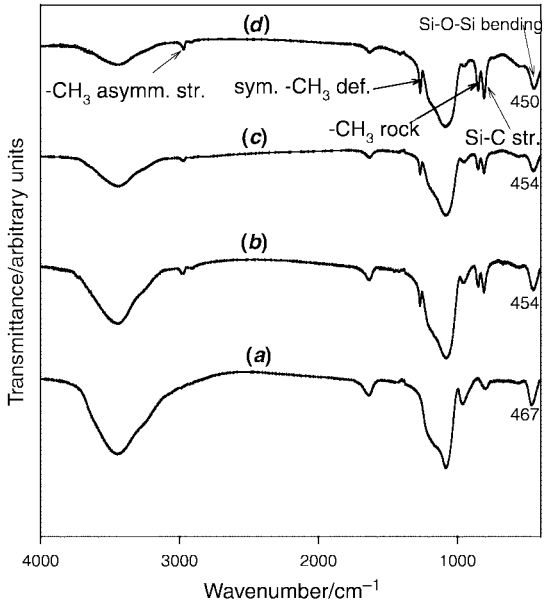

Fig. 3 FT-IR spectra of mesoporous MCM-41 silica (trace *a*), mesoporous $(CH_3)_2SiO$-$4SiO_2$ (trace *b*), $(CH_3)_2SiO$-$3SiO_2$ (trace *c*) and $(CH_3)_2SiO$-$2SiO_2$ (trace *d*) materials. The spectra were obtained with a Bomem MB-100 instrument.

These new mesoporous dimethylsiloxane-incorporated silica materials exhibit many interesting characteristics for future applications, including high surface areas, regular mesopores, thick walls, high mechanical strength and high hydrophobicity. We expect that these materials can find applications in catalysis, adsorption technology and the fabrication of low dielectric materials for ULSI (ultra large scale integration) devices.

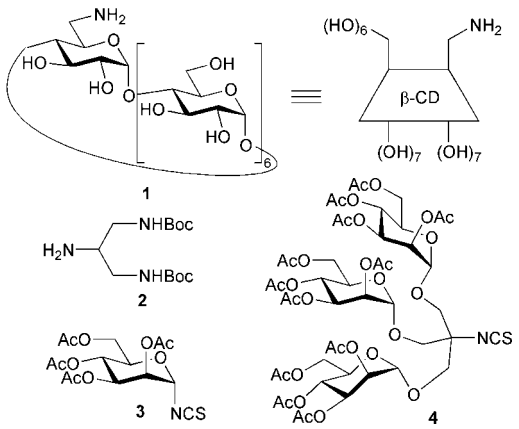
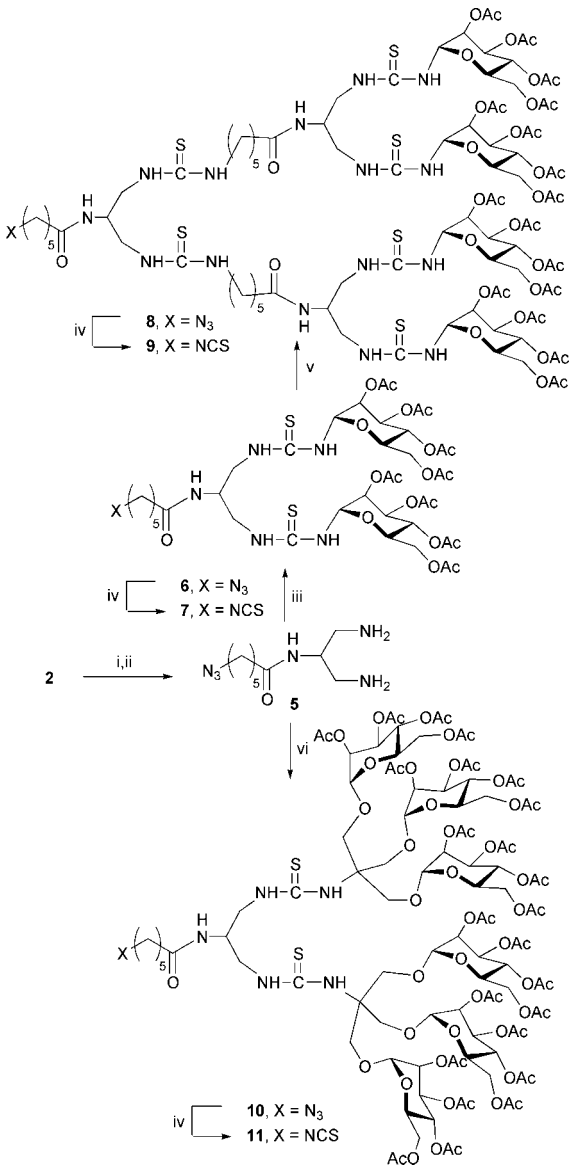
Published on the Web 19th July 2000

Targeted drug delivery systems have been built from β-cyclodextrin by monoconjugation with mannosyl-coated dendritic branches following an iterative thiourea-forming convergent strategy; the multivalent adducts showed high Concanavalin A lectin binding ability and intact inclusion capabilities.

Grafting biorecognisable saccharide epitopes onto suitable molecular carriers may provide new vectors for site-specific delivery of therapeutics. Several examples of oligosaccharide-branched cyclodextrins (CDs) have been reported in recent years for this purpose, taking advantage of the known ability of CDs to include a variety of hydrophobic compounds *via* host-guest complexation.[1] The majority of such conjugates are monosubstituted derivatives at a single primary hydroxy group position of the CDs.[2] A few per-(C-6)-substituted branched-CDs have also been synthesised to comply with the need for a multivalent presentation pattern of the saccharide markers.[2a,d,3] However, although lectin-binding capacity is substantially increased when compared with the monovalent counterparts, polysubstitution at the primary face of CDs may seriously impair inclusion and complex stabilisation of potential guests. Our own results indicated approximately a 10-fold decrease in the water solubilisation power of branched β-CDs, measured for the anticancer drug Taxotère®, upon heptafunctionalisation.[2c,d]

As an attempt to combine both high biological receptor binding ability and efficient inclusion capabilities, a series of monosubstituted multivalent β-CD carriers have now been synthesised. For this purpose, we have developed an efficient preparation of dendritic wedges suitable for sequential external carbohydrate coating and covalent attachment to the β-CD core through a convergent iterative methodology that exploits the reactivity of isothiocyanate and amine functionalised mono-





Scheme 1 *Reagents and conditions*: i, 6-azidohexanoyl chloride, 1:1 DMF–collidine, rt, 96%; ii, 1:1 TFA–water, rt, 2 h, 98%; iii, pyridine, 24 h, 87%; iv, PPh_3, CS_2, toluene, rt, 16 h, 90%; v, **7** + **5**, 1:1 water–acetone, pH 8 ($NaHCO_3$), 55%; vi, **4**, 1:1 water–acetone, pH 8 ($NaHCO_3$), 70%.

mers.[4] The key templates are 6^{I}-amino-6^{I}-deoxy-β-CD (**1**), for which an improved synthetic route has been recently elaborated,‡[5] the selectively protected 1,2,3-triaminopropane branching element **2**,[6] and the isothiocyanate functionalised α-D-mannopyranosyl derivatives **3**[4] and **4**. The latter was prepared by reaction of the known tris-α-mannopyranoside amine[7] with thiophosgene. Intercalation of a six-carbon spacer has also been considered to ensure the accessibility of the grafted bioactive components to molecular recognition events.

Mono- and trivalent mannosylated thioureido β-CDs **12** and **14** were obtained in high yield by direct coupling of **1** with **3** and **4**, respectively, followed by removal of the *O*-acetyl groups.§ Reaction of **2** with 6-azidohexanoyl chloride and further TFA-catalysed hydrolysis of the Boc N-protecting groups afforded dendron **5**, which was subsequently reacted with **3** and **4** to give the di- and hexavalent ligands **6** and **10** (Scheme 1). Aza-Wittig type isothiocyanation reaction of the terminal azido group using the triphenylphosphine–CS_2 system led to the corresponding bridging armed glycosyl clusters **7** and **11**, which were conjugated with monoamine **1** and deacetylated to yield the mannosyl labelled β-CD carriers **13** and **16**. The potential of the approach was further examined by constructing the second-generation tetravalent homologue **15** *via* nucleophilic addition of diamine **5** to the divalent isothiocyanate **7** (→**8**), isothiocyanation of the resulting adduct (→**9**), conjugation with the β-CD reagent **1** and final deacetylation.¶

Comparative protein-affinity evaluation of the mannosyl-coated thioureido β-CDs **12**–**16** towards horseradish peroxidase-labelled concanavalin A (Con A) was effected by performing the enzyme-linked lectin assay (ELLA) test.[8] The corresponding IC_{50} values for inhibition of Con A-yeast mannan binding[9] reflected the expected amplification of lectin-binding strength for the higher-valent representatives. Nonetheless, preliminary Taxotère® solubilisation experiments in water showed solubility values (*e.g.* 4.5 g L^{-1} in a 50 mM solution of **14**) that were similar to those obtained for monobranched CDs.

This research was supported by the European Comission DG XII under the FAIR programme (contract no. FAIR CT95-0300) and the DGICYT (grant no. PB 97/0747).

Notes and references

‡ A much better yield for the key precursor of **1**, namely the corresponding C-6 monotosyl derivative, was achieved by using the following procedure: To a solution of β-CD (11.35 g, 10 mmol) in water (500 mL), $CuSO_4$ (7.5 g, 30 mmol) in water (750 mL) and NaOH (10 g, 250 mmol) in water (250 mL) were successively added. After 10 min, tosyl chloride (15 g, 79 mmol) in acetonitrile (100 mL) was added dropwise within 1 h. The mixture was stirred for 4.5 h, then neutralised (1 M HCl, 50 mL), the salts were filtered off and the solution was concentrated by freeze-drying to $\frac{2}{3}$ of its original volume. The crystallised solid was washed with acetone (2 × 40 mL), ether (2 × 30 mL) and dried. After two recrystallisations from water, pure monotosyl β-CD (6.33 g, 48%) was obtained.

§ Coupling yields 45–75%. Removal of the acetyl groups was effected by a mixed transterification–saponification process (see ref. 2*d*). In the cases of compounds **12**, **13** and **15** this step was performed at 0 °C to avoid anomerization of the external mannosylthioureido subunits (see ref. 10).

¶ All new compounds gave microanalytical, mass spectral (FAB or MALDI-TOF) and ^{13}C NMR data (125.7 MHz, D_2O) in agreement with the proposed structures.

Selected data for **12**: $[\alpha]_D$ +107.1 (*c* 0.7, H_2O); ^{13}C NMR δ 182.8 (CS), 102.6–101.9 (C-1$^{I–VII}$), 82.8 (C-1′), 46.3 (C-6^{I}). For **13**: $[\alpha]_D$ +105.2 (*c* 1, H_2O); ^{13}C NMR δ 183.3 (CS), 177.3 (CO), 102.7–101.8 (C-1$^{I–VII}$), 83.0 (C-1′). The asymmetric arrangement of chloride and oxide ligands around the octahedral Nb_6 cluster core and their electrostatic interaction with Ti^{3+} counterions play an important role in the formation of a novel 2D framework with cluster connectivity unprecedented in compounds containing octahedral clusters.

Low-dimensional materials containing transition metals have significant importance due to their remarkable physical properties and a wide range of applications in catalysis, ionic transport, and redox intercalation processes.[1] Thus, extensive research efforts have been spent on the design, preparation and characterization of these materials. Investigation of early transition metal cluster materials led to development of a strategy for controlling the cluster-framework dimensionality by adjusting the number of intercluster bridging ligands.[2]

Recently, we began investigating a new approach to the design and preparation of low-dimensional materials containing octahedral metal clusters. The methodology being explored is the modification of the environment of the metal core to form building blocks with well-defined anisotropic bonding preferences using a combination of ligands that create anisotropic charge distribution. In addition, a combination of counterions with large difference in their charge-to-radius ratios and, thus, different coordination preferences, is used to enhance the effects of anisotropic ligand distribution. Our systematic investigation of niobium oxochlorides containing octahedral Nb_6 clusters recently led to the preparation of the layered material $[Tl_5(Ti_2Cl_9)][(Nb_6Cl_{12}O_4)_3(Ti_3Cl_4)_2]$ which has a unique hexagonal-bronze-type cluster connectivity.[3] Here we describe a novel layered oxochloride $Cs_2Ti_3(Nb_6Cl_{12.5}O_4)_2Cl_2$ **1** in which each octahedral Nb_6 cluster is connected to three adjacent clusters through chloride ligands to form layers with graphite-type topology.[4] The factors leading to its unusual structural properties are proposed.

Compound **1** was initially obtained as black elongated rectangular plates in a reaction designed to prepare the caesium analogue of $[Tl_5(Ti_2Cl_9)][(Nb_6Cl_{12}O_4)_3(Ti_3Cl_4)_2]$ **2**. The crystals were analyzed by energy-dispersive X-ray analysis, and the crystal structure of **1** was determined by single crystal X-ray diffraction.‡ Subsequently, **1** was obtained in high yield in the reaction of stoichiometric amounts of Nb powder, Ti foil, CsCl, Nb_2O_5 and $NbCl_5$. The mixture (handled under argon atmosphere) was placed in a silica tube, sealed under vacuum, heated for 4 d at 750 °C and cooled to 500 °C in 4 d, followed by radiative cooling to room temperature. The product purity was confirmed by X-ray powder diffraction.

The main building block of the two-dimensional structure of **1** (Fig. 1) is an octahedral cluster unit $(Nb_6Cl^i_8O^i_4)Cl^a_6$,[5] in which four oxide ligands selectively occupy 'inner' positions arranged in sets of three ('triad') and one on opposite sides of the Nb_6 octahedron (Fig. 2). The ligand arrangement results in an anisotropic chiral cluster unit with symmetry close to C_2. Octahedral niobium oxochloride clusters with four oxide ligands were also encountered in **2** and in $Ti_2Nb_6Cl_{14}O_4$ **3**,[6] however in contrast to **1**, the O^i ligands in the latter oxochlorides are arranged centrosymmetrically in two sets of two, leading to a different isomer with symmetry close to C_{2h}. A cluster unit in which the oxide ligands are arranged in a 'triad' similar to that in **1**, is found in the previously reported oxochloride $ScNb_6Cl_{13}O_3$ **4** which has three oxide ligands per cluster.[7] The bond distances in the cluster in **1** are similar to those found in compounds **2**–**4** and are consistent with the presence of 14 valence electrons per cluster.[3,6–8] Each cluster shares three of its six Cl^a ligands with three adjacent clusters to form layers with topology similar to that of graphite (Fig. 3). The connectivity formula can be written as $(Nb_6Cl^i_8O^i_4)Cl^{a\text{-}a}_{3/2}Cl^a_3$. Layered frameworks based on octahedral clusters, typically, have pseudo-square topology with connectivity formula $(M_6L^i_n)L^{a\text{-}a}_{4/2}L^a_2$ (M = Zr, Nb, n = 12; M = Mo, Re, n = 8).[9] The graphite-type connectivity found here is especially surprising for cluster units with C_2 symmetry, for which one would expect an even number of bridging ligands. This could be the result of optimizing the electrostatic interactions between the ligands and Ti^{3+} ions. In the presence of highly charged counterions, the oxide and chloride ligands tend to segregate to form aggregates of oxide ions surrounded by chlorides, as illustrated by the structures of typical ternary transition metal oxochlorides such as layered MOCl (M = Ti^{3+}, Fe^{3+}, Yb^{3+})[10] and $VOCl_2$,[11] and the 1D material $NbOCl_3$.[12] In these structures, chloride ions form the surface of the layers or chains, while oxide and metal ions are

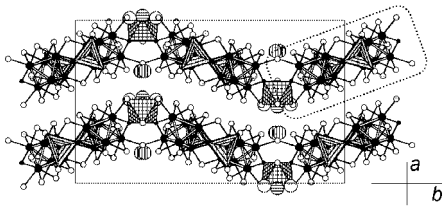

Fig. 1 A view of the crystal structure of **1** in the [001] direction. Large black, small black and small light-gray spheres represent Nb, O, and Cl, respectively. Hatched and light cross-hatched polyhedra represent $[Ti(1)Cl_2O_3]$ trigonal bipyramids and $[Ti(2)Cl_4O_2]$ octahedra, respectively. Caesium atoms are shown as large gray spheres: vertically hatched - Cs(1), horizontally hatched - Cs(2a), not hatched - Cs(2b). The dotted curve outlines the $[Ti(Nb_6Cl_{13}O_4)]$ chain running in the [001] direction.

located inside. Similar ion segregation is observed in the cluster compounds **1**–**4**. The ligand arrangement in the cluster unit of **1** favors the formation of $[Ti(Nb_6Cl_{13}O_4)]$ zig-zag chains (Fig. 4) in which the clusters are connected through Ti^{3+} ions (Ti(1)) and Cl^a ligands so that oxide ligands forming the 'triads' are shielded by chlorides. Each Ti(1) connects three clusters and has a distorted trigonal-bipyramidal environment formed by three O^i and two Cl^a ligands (bond distances: $d_{Ti–Cleq}$ = 2.411(3) and 2.423(3), $d_{Ti–Oeq}$ = 1.876(6), $d_{Ti–Oax}$ = 2.035(7) and 2.037(7) Å). Bond-valence sum calculations[13] confirm the oxidation state +3 for Ti(1). The chains connect to each other through an additional titanium (Ti(2)) and Cl^a ligands to form layers, so that the remaining oxide ligands (O(4)) are shielded by chlorides (Fig. 1). This linkage type results in the wave-like geometry of the layers and novel graphite-like cluster framework topology. The titanium Ti(2) coordinates to two O^i and two Cl^a ligands, arranged in a distorted square-planar geometry. Its coordination environment is completed to octahedral or square-pyramidal by additional chloride or oxide ligands[14] (bond distances: $d_{Ti–Cl}$ = 2.36(3)–2.570(9), $d_{Ti–O}$ = 1.84(2)–2.02(1) Å). The anion segregation argument allows us to rationalize the formation of the complex 3D cluster framework and the unusual trigonal-bipyramidal coordination of scandium ions in **4** which is based on clusters with the same 'triad' of O^i ligands as that found in **1**. The clusters and the Sc^{3+} ions form chains similar to the one shown in Fig. 4, where the O(4) atoms are substituted by chlorines. These chains are connected to each other through Cl^a ligands in a tetragonal 'woodpile'-fashion to form a chiral 3D framework.

Adjacent layers in **1** are related by an *a*-glide plane perpendicular to $\vec{c}$ (Figs. 1 and 3) and interact through caesium ions that are distributed over three independent sites (Cs(1), Cs(2a), Cs(2b)) located on the layers' surface on each side of cone-shaped openings generated by six-member cluster rings (Fig. 1). The site Cs(1) is fully occupied and is coordinated by

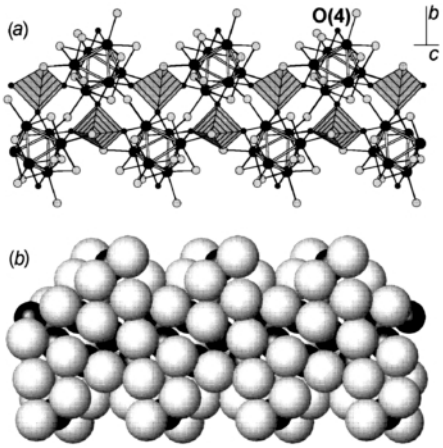

Fig. 4 (*a*) A ball-and-stick view of the $[Ti(Nb_6Cl_{13}O_4)]$ chain in **1**. For labelling, see caption to Fig. 1. (*b*) Space-filling representation of anions in the same fragment (black - O, gray - Cl).

9 chlorides within 4 Å. The Cs(2a) and Cs(2b) sites, separated by 1.29 Å, are located in the channels running between the layers in the $\vec{b}$ direction. These two sites are partially occupied (Cs(2a) 41(2)%, Cs(2b) 18.8(9)%), and are coordinated by 8 and 7 chlorines within 4 Å, respectively. The number of caesium ions per cluster was refined to 0.89(2) which agrees with the oxidation states assigned to the transition metals and the refined occupancies of Cl(14), L(15), and Cl(16) sites.

The structural properties of the new oxochloride $Cs_2Ti_3(Nb_6Cl_{12.5}O_4)_2Cl_2$ demonstrate the effectiveness of using a combination of ligands to prepare low-dimensional cluster materials. The interplay between the effects of anisotropic charge distribution around the cluster core and the trend for the anion segregation in the overall structure is conducive for the formation of diverse structural types with low-dimensional or open-framework character. These effects seem to have a greater influence on the framework dimensionality than the total number of ligands which is the primary structure-determining factor in cluster compounds with one ligand type or statistical ligand distribution.

Infrared spectroscopy has been used to characterise the folded and unfolded states of bovine ubiquitin (a small protein of 76 residues) under acidic conditions (pH ~ 1); fast time-resolved measurements of protein unfolding, initiated by a laser-induced temperature-jump of ~ 8 °C, shows rapid refolding and β-sheet secondary structure formation on a timescale of a few milliseconds.

Our understanding of the mechanism of chemical reactions has benefited greatly from time-resolved kinetic measurements to examine the order of bond breaking events and the relative strengths of covalent interactions.[1] The protein folding reaction, in which a disordered polypeptide chain can assemble into a compact 3D structure, is a highly complex process involving numerous weak co-operative non-covalent interactions.[2] Despite the complexity of the problem, many small proteins (< 100 residues) fold on a timescale of only a few milliseconds.[3] Current models suggest that folding proceeds through a hierarchical process[4] in which the lower limit to the kinetics of folding is determined by local structural events such as the formation of α-helices, β-turns and β-hairpins that nucleate the collapse and folding of the polypeptide chain.[5] Observations on the folding of these structures with submillisecond half-lives have necessitated new methods of detection.[5]

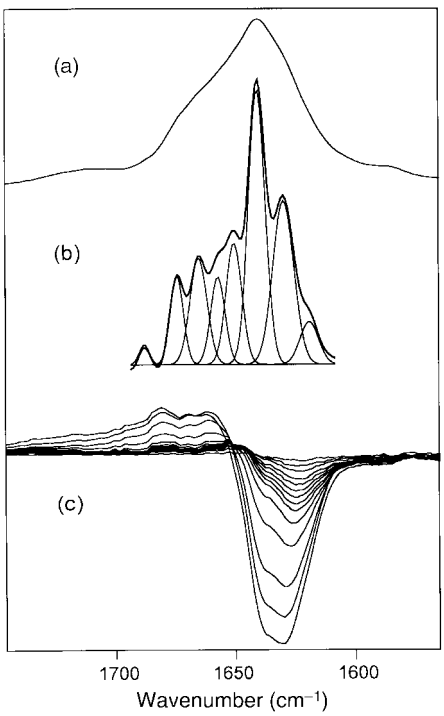

Fig. 1 (a) Conventional and (b) deconvoluted FTIR spectra of bovine ubiquitin at 25 °C pH 1.0 showing 8 principal bands.[18] (c) FTIR difference spectra, showing the change in the absorption envelope with temperature over the range 278 to 363 K. Data were collected using a Nicolet Nexus 670 FTIR spectrometer equipped with MCT detector.

Infrared spectroscopy has emerged as an important technique for studying protein structure and fast folding kinetics.[6,7] The position of the amide stretching vibration (1610–1680 cm^{-1}) has been shown to be strongly correlated with protein secondary structure because of its sensitivity to hydrogen bonding, dipole–dipole interactions and the geometry of the peptide backbone.[8,9] The possibility of detecting by IR both native, as well as transient non-native structures, on the protein folding pathway has already been demonstrated.[10] The application of vibrational spectroscopy to the study of rapid kinetic processes in chemical systems is well documented,[1] and is now being applied to biological molecules.[6,10–12] Here we examine the steady state and time-resolved folding/unfolding of a small protein by IR spectroscopy, and demonstrate rapid formation of protein secondary structure on the timescale of a few milliseconds.

We have used bovine ubiquitin (a small protein of 76 residues, free of disulfide bridges) as a model system). Ubiquitin consists of both α-helix and β-sheet, forming a highly stable, compact structure that has been shown to fold in a two-state process.[13] We have been investigating the mechanism of folding by examining the conformational propensity of protein fragments for evidence of possible nucleation sites for folding of the native structure. In particular, the N-terminal β-hairpin sequence in isolation shows evidence for a small population of native-like structure in water,[14] while hairpin analogues, with mutated β-turn sequences, have demonstrated both native and non-native conformational features.[15] The kinetics of folding of these isolated elements of secondary structure is of current interest in the context of understanding the mechanism of folding of the native protein.

Here we probe the structure of both the native and unfolded states of bovine ubiquitin, and the unfolding transition, at pD 1.0 in D_2O solution by FTIR. NMR spectra of the native protein at pH 1.0 and 7.0 are essentially identical, indicating that there are no significant changes in the structure. However, at low pH, the reduced T_m allows the thermal unfolding transition to be investigated. In Fig. 1, we illustrate conventional (a) and deconvolved (b) steady state FTIR spectra of native folded ubiquitin at 25 °C (after NH → ND exchange). Fitting the deconvolved absorption envelope enables us to identify eight principal bands which have been assigned according to literature precedent,[8–10] and on the basis of features identified in the X-ray structure.[16] The absorption profile changes significantly with temperature as the protein unfolds, resulting in a reduction of the β-sheet band at 1629 cm^{-1}. The appearance of weaker peaks in the range 1660–1680 cm^{-1} has been attributed to disordered structure or turn-type conformations.[8–10] IR difference spectra, showing the change in the absorption envelope with temperature, are shown in Fig. 1c. Monitoring thermal unfolding from the change in integrated intensity of the principal β-sheet band observed at 1629 cm^{-1} at 25 °C, demonstrates a reversible cooperative sigmoidal melting process with a T_m of ~65 °C at pH 1.0. Parallel NMR melting

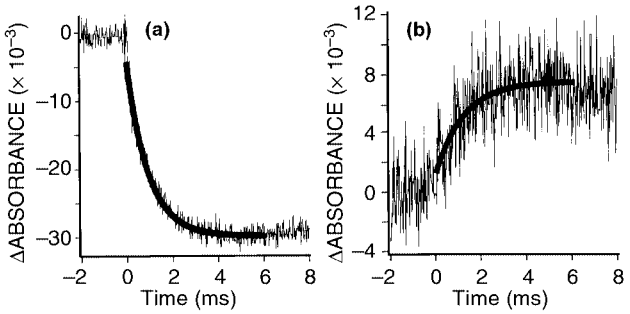

Fig. 2 Time-resolved IR spectra showing the decay/growth of the signals due to disappearance of protein secondary structure at 1635.5 cm^{-1} (a), and appearance of random coil at 1667 cm^{-1} (b) monitored as the protein unfolds following the T-jump. The line of best-fit is shown, assuming a single exponential process.

experiments under identical conditions give a very similar T_m value.

We have investigated the kinetics of folding by IR close to the mid-point of the thermal unfolding transition where the change in absorption is most temperature-sensitive. Using a 10 nanosecond-duration 1.9 μm pulse from a Raman-shifted Nd:YAG laser, we have generated effectively an instantaneous temperature-jump of ~8 °C, initiated at 67 °C. Changes in the IR spectrum, corresponding to transient perturbation of the equilibrium between folded and unfolded states, were used to measure fast folding kinetics outside the normal time-range accessible using rapid mixing techniques.[6] The transient IR spectrum obtained 4 ms after the T-jump is in good agreement with the IR difference spectrum obtained from the steady state spectra taken at 67 and 75 °C. The T-jump was calibrated from the change in absorbance of the D_2O band at 1620 cm^{-1}, providing an internal thermometer. The time-resolved change in the IR absorbance was monitored at ~1640 and ~1670 cm^{-1}, corresponding to the disappearance of bands due to ordered secondary structure, and appearance of the weak band due to random coil structure, respectively (Fig. 2). Subtraction of the solvent absorption, collected in an identical T-jump experiment in D_2O alone, reveals an exponential decay/growth curve at these wavelengths,which we are readily able to fit to a single rate process consistent with a two-state folding model (Fig. 2a, b). Despite the much lower signal-to-noise ratio at 1670 cm^{-1}, both kinetic traces yield the same observed rate constant $k_{obs} \approx 1000\ s^{-1}$. Assuming that k_{obs} is the sum of the folding and unfolding rate constants, $k_{obs} = k_F + k_U$,[5,13] and that the equilibrium constant at a given temperature is given by $K_{eq} = k_F/k_U$, then we are able to estimate a rate of folding at 75 °C (at the T_{max} of the T-jump) of ~400 s^{-1}.

We have demonstrated from equilibrium FTIR measurements of ubiquitin that the various elements of secondary structure result in a unique fingerprint. We have demonstrated that the relaxation kinetics for folding/unfolding of β-sheet structure provides a convenient handle for monitoring fast dynamic processes. Comparison with results from fluorescence and amide NH exchange experiments identified some common features.[13,17] Both methods have identified a major folding phase with a half-life of 5–10 ms at 25 °C. However, fluorescence-detected kinetics also show very rapid hydrophobic collapse (< 2 ms) within the dead-time of the stopped-flow experiment.[13] This early collapsed structure does not protect amide NHs against exchange, the latter occurring on a longer timescale (~10 ms). In the folding/unfolding studies presented in this work, we have monitored by IR spectroscopy the rapid formation of protein secondary structure with a half-life of 2–3 ms ($1/k_F$) at 75 °C. Despite the difference in folding temperature between this and earlier studies,[13,17] the rate of formation of secondary structure is in broad agreement, as far as comparisons are possible between these complementary techniques. While previous fluorescence measurements have detected very early burial of hydrophobic residues, we show that time-resolved IR, as with amide NH exchange, monitors the formation of hydrogen bonded secondary structure during a slower folding phase on the timescale of a few milliseconds.

We are grateful for access to the EPSRC-funded central Laser Facilities at the Rutherford Appleton Laboratory in Oxfordshire, and thank M. Towrie, P. Matousek and A. W. Parker for helpful discussions. We acknowledge the financial support of the EPSRC for studentships to CSC and SRG-J, and to Roche Discovery, Welwyn, UK for a CASE award to SRG-J.

A highly stable copper(I)-olefin coordination polymer with strong red fluorescent emission

Under solvothermal conditions, the reaction of 4-pyridylacrilic acid (4-hpya) and 2,2′-bipyridine (bpy) with $Cu(MeCN)_4BF_4$ gives rise to an unprecedented stable copper(I)-olefin coordination polymer $\{[(bpy)(4\text{-hpya})Cu(I)](BF_4)\}_n$ 1 which displays strong red fluorescent emission in the solid state.

Since the pioneering work of Thompson *et al.*[1] demonstrated the first stable copper(I)–olefin complexes, in which a tridentate ligand, hydrotris(3,5-dimethylpyrazol-1-yl)borate [HB(3,5-$Me_2pz)_3$], was used to stabilize the complexes, many copper(I)–olefin complexes have been reported in which bidentate ligands such as 2,2′-bipyridine(bpy) and its derivatives, di-2-pyridylamine,[2] 2,2-bipyridine[3] and 1,10-phenanthroline,[3] were used. An excellent example was shown by Doyle *et al.*[4] in which a β-diketonate was introduced to chelate the copper(I)–olefin complex. Recently, a tridentate ligand, *N*-(3-indolylethyl)-*N*,*N*′-bis(6-methyl-2-pyridylmethyl)amine (Me_2iep) and a macrocyclic ligand, *N*-[2-(1-naphthyl)ethyl]-1-aza-4,8-dithiacyclodecane, have been used to stablize copper(I)-η^2-indole[5] and copper(I)–η^2-naphthyl[5] complexes. Moreover, Hoffmann and coworkers have successfully prepared a remarkable stable (up to 108 °C) copper(I)–ethylene complex in which iminophosphanamide derivatives were used as chelating stabilizers to fix the ethylene.[6] However, it should be noted that all the above-mentioned complexes are air-sensitive and molecular in nature. More recently, Schultz and co-workers have utilized crystal engineering strategies to synthesize a unique dense monofumarate dicopper(I) metal–organic layered framework containing η^2-copper(I)–olefinic bonds.[7] They suggested that the high air stability of the copper(I)–olefin layered framework (up to 300 °C) may be due to the high concentration of bonding and exclusion of water in the lattice.

In this work we have combined the above-mentioned synthetic strategies and designed *trans*-4-pyridylacrilic acid (4-hpya) as a building block to construct a novel one-dimensional copper(I) polymer with η^2-olefin binding mode, *catena*-(2,2′-bipyridine)(*trans*-4-pyridylacrilic acid)copper(I) tetrafluoroborate $\{[bpy)(4\text{-hpya})Cu(I)](BF_4)\}_n$ **1** which, to the best of our knowledge, represents the first example of a stable copper(I)–olefin complex capable of co-existing with an organic acid (Scheme 1).

Golden yellow crystals of **1** were obtained by treating 4-hpya, bpy and $Cu(MeCN)_4(BF_4)$ under solvothermal reaction conditions.† The IR spectrum of complex **1** shows a very strong peak at 1072 cm^{-1}, indicating a typical uncoordinated BF_4^- anion. A broad peak at *ca.* 3224–3392 cm^{-1} and two peaks at 1712s and 1600m cm^{-1} suggest that the carboxylic acid group of 4-hpya in **1** is protonated.[8]

Complex **1** possesses high thermal stability, as evidenced from thermogravimetric analysis. The TGA curve of polycrystalline complex **1** showed that no weight loss occurred below *ca.* 229 °C.

The X-ray crystal analysis of complex **1**‡ revealed that Cu(I) ion in **1** is coordinated in a distorted tetrahedral geometry, which is defined by three nitrogen atoms (two from bpy and one from 4-hpya) and the C=C moiety of the olefin of 4-hpya [Fig. 1(a)]. The ligand 4-hpya acts as a neutral bidentate spacer to link two Cu(I) ions by an N atom and an olefin moiety to give rise to a 1D coordination polymer, as depicted in Fig. 1(b). The C=C bond distance [1.361(6) Å] of the coordinated olefin, is comparable to those found in $[Cu(bpy)(C_2H_4)]ClO_4$ [1.360(13)–1.346(18) Å],[3] $[Cu(phen)(C_2H_4)]\cdot ClO_4$ [1.361(22) Å],[3] $[Cu_2\{HB(3,5\text{-}Me_2pz)_3\}(C_2H_4)Cl]$ [1.347(5) Å], $[Cu(C_2H_4)$(dipyridylamine)] [1.359(7) Å],[2] $[Cu_2(O_2CCH{=}CHCO_2)]$ [1.371(14) Å][7] and $[Bu^t_2P(NSiMe_3)_2\text{-}\kappa^2N]Cu(\eta^2\text{-}C_2H_4)$ [1.362(6) Å].[6] However, it is slightly longer than those found in $[Cu\{HB(3,5\text{-}Me_2pz)_3\}(C_2H_4)]$ [1.329(9) Å][1] and $[Cu_2(cot)(hfacac)_2]$ [1.31(1)–1.33(1) Å] (cot = cycloocatatetraene, hfacac = hexafluoroacetylacetonate).[4]

Interestingly, the coordinated olefinic bond in **1** [1.361(6) Å] is longer than free ethylene [1.337(2) Å], suggesting that the coordination to copper(I) could potentially activate the olefinic bond which may be of use in catalysis.[6] The Cu–N and Cu–O bond lengths of complex **1** are normal and lie within the distances expected for Cu(I) complexes. Moreover, the Cu–C bond distances [2.058(4)–2.068(4) Å] in **1** are comparable to those found in other reported copper(I) organometallic compounds.

It is notable that in complex **1** the H atom of carboxylic acid group of 4-hpya is hydrogen-bonded to one of the fluorine atoms of BF_4^-, as shown in Fig. 1(c), while the other three fluorine atoms of BF_4^- are also weakly hydrogen-bonded to the H atoms of the pyridine ring (3.323–3.341 Å).[9] Similarly, the carbonyl oxygen is hydrogen-bonded to H atoms of pyridine ring (3.341 Å). Moreover, there are the stabilizing π–π interactions (*ca.* 3.71 Å) of adjacent strands, clearly suggesting that π–π stacking of neighboring strands plays an important role in stabilizing the copper(I)–olefin complex. Thus, overall hydrogen bonding and π–π stacking make **1** a stable 3D coordination polymer. The secondary interactions may explain why 4-hpya exists in its protonated form in complex **1**. As far as we are aware, **1** is the first example of 1D Cu(I)–olefin coordination polymer containing a protonated organic acid ligand, which is stabilized hydrogen-bonding and π–π stacking, similar to weak hydrogen bonds of the type $C\text{–}H_{aromatic}\cdots F\text{–}C$

in organic crystalline solids capable of stabilizing the secondary structure of biomolecules such as DNA.[9,10] Attempts to synthesize neutral $\{[bpy)(4\text{-pya})Cu(I)]\}_n$, were unsuccessful.

The diffuse-reflectance UV–VIS spectrum of **1** shows only a low-energy band at *ca.* 429 nm, which can be assigned to the metal-to-ligand charge transfer (MLCT) band.[11] The strong red emission spectrum of **1** in the solid state at room temperature is shown in Fig. 2, with a maximum at *ca.* 647 nm (λ_{exc} = 250 nm). A clearly bathochromic shift occurs in **1** relative to $[Cu_4I_4(py)]$ (λ_{emax} = 580 nm)[11] and [Cu(3,4-bpyBr] (λ_{emax} = 580 nm),[11] which is probably due to π–back-donation from the filled metal D_π orbital to the vacant antibonding π* orbital of the coordinated olefin.[1b]

In conclusion, the rational design of building blocks and the flexible combination of copper(I) in the supramolecular system provide a robust strategy for the construction of coordination polymers supported by metal–olefin bonds.

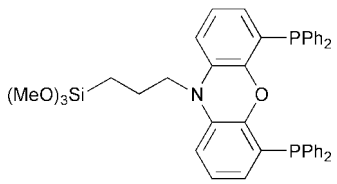
A continuous process for the selective hydroformylation of higher olefins in supercritical carbon dioxide ($scCO_2$) is presented; the catalyst shows high selectivity and activity over several hours and no decrease in performance was observed over several days.

Hydroformylation is one of the mildest and most efficient methods of producing aldehydes and it is therefore widely applied in the petrochemical industry. The cleanest, industrially important hydroformylation process is the aqueous biphasic process, developed by Ruhrchemie/Rhône-Poulenc, affording a straightforward separation of the organic products from the catalyst.[1] The applicability of this system, however, is strictly limited to substrates which are slightly water soluble, such as propene and but-1-ene. In the industrial hydroformylation of higher olefins, the catalyst is separated by either extraction, catalyst destruction or distillation. One of the major challenges in this field is the development of a continuous hydroformylation process combining a high catalytic activity and selectivity with facile product separation, in which catalyst leaching does not occur.[2] To date, no such system has been reported; often at higher CO pressures the ligand on the metal is easily exchanged for CO molecules resulting in rhodium leaching.[3] Recently Van Leeuwen and coworkers reported a promising approach based on rhodium–diphosphine hydroformylation catalysts with a large P–Rh–P bite angle in a multiphase batch process.[4,5]

The use of $scCO_2$ is becoming increasingly important as a reaction medium in metal catalysed reactions.[6–8] The absence of a gas–liquid phase boundary and the ability of $scCO_2$ to support high concentrations of dissolved gases combined with facile product and catalyst separation makes $scCO_2$ a competitive alternative to conventional solvents. However, homogeneous catalysts often require modification in order to increase their solubility in $scCO_2$,[9–12] although unmodified[13] and even insoluble catalysts[14] have demonstrated significant activity in $scCO_2$ systems. The use of an immobilised homogeneous catalyst overcomes both solubility and catalyst recovery problems. At Nottingham, continuous processing in $scCO_2$ has been successfully applied to a wide range of hydrogenations,[15,16] Friedel–Crafts alkylations[17] and etherification reactions[18] using heterogeneous catalysts supported on polysiloxane (Deloxan®, Degussa AG). Here, we show how this technique is effectively applied in the hydroformylation reaction using an immobilised rhodium–diphosphine catalyst containing a large P–Rh–P bite angle.

The catalyst used is the rhodium complex of *N*-(3-trimethoxysilyl-*n*-propyl)-4,5-bis(diphenylphosphino)phenoxazine **A**, immobilised on silica (particle size 200–500 μm).†



A

Typically, 1 g of ligand-modified silica was reacted with 4 mg of $Rh(acac)(CO)_2$ and then loaded into a 5 mL supercritical flow reactor.‡

The catalyst performed well in the hydroformylation of oct-1-ene with selective production of linear nonanal. The average linear to branched aldehyde ratio (l:b) was 40:1. Oct-1-ene conversions of up to 14% were obtained (Table 1, entries 5 and 7) and only a few percent of octene isomers and a trace amount (*ca.* 1%) of alcohol were observed as byproducts.

Table 1 Results from the hydroformylation of oct-1-ene, values shown are average numbers over a period of 3–6 h[a]

Entry	TOF[b]	Linear aldehyde[c] (%)	Branched aldehyde[c] (%)	Alkene isomers[c] (%)	Linear alcohol[c] (%)	Linear to branched ratio	Oct-1-ene conversion (%)
1[d]	39	96.1	2.4	1.5	0	40	3.6
2	87	92.9	3.0	3.8	0.3	32	9.4
3[e]	112	94.4	2.4	2.5	0.7	40	10.1
4[f]	117	92.6	3.8	2.5	1.0	24	10.3

7[i]	93	96.0	1.9	1.1	0.9	50	14.3
8[j]	96	91.3	4.1	4.3	0.3	23	4.6

[a] Ligand:Rh ratio is 10:1 and the catalysis was performed at 80 °C, 120 bar CO_2 at 0.65 L min^{-1} flow rate (at 20 °C, 1 atm), 50 bar overpressure syngas and an oct-1-ene flow rate of 0.05 mL min^{-1} (substrate:syngas = 1:10) unless otherwise stated. [b] Average turnover frequencies were calculated as mol aldehyde (mol catalyst)$^{-1}$ h^{-1}. [c] Determined by means of GC analysis using decane as an internal standard. [d] Reaction temperature is 70 °C. [e] Syngas overpressure is 25 bar (substrate:syngas = 1:5). [f] 0.3 L min^{-1} CO_2 flow rate (at 20 °C, 1 atm). [g] Reaction temperature is 90 °C. [h] 180 bar CO_2. [i] Oct-1-ene flow rate of 0.03 mL min^{-1}. [j] Oct-1-ene flow rate of 0.1 mL min^{-1}.

DOI: 10.1039/b002526g

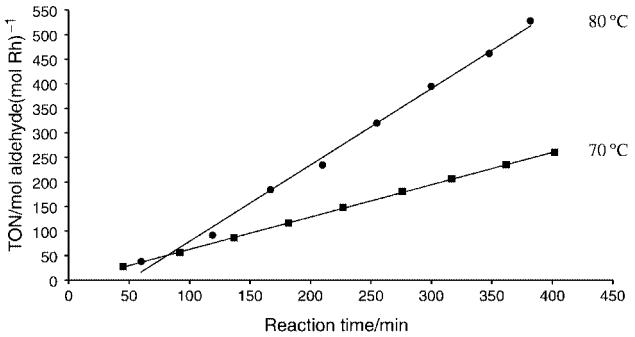

Fig. 1 Turnover number (TON) for the hydroformylation of oct-1-ene in $scCO_2$ at 70 and 80 °C.

The rate of hydroformylation is moderate (39 h^{-1}) at 70 °C with an oct-1-ene flow rate of 0.05 mL min^{-1} (Table 1, entry 1). The rate increased to 87 h^{-1} with the catalyst bed at 80 °C (Table 1, entry 2) and improved further to 112 h^{-1} on decreasing the syngas pressure from 50 to 25 bar (Table 1, entry 3). This improvement in rate is consistent with the negative order in CO pressure that is commonly observed in hydroformylation reactions.[19] A TOF of 117 h^{-1} was observed on increasing the residence time of the substrate in the reactor by decreasing the CO_2 flow rate (Table 1, entry 4). An alternative method of increasing the residence time is to increase the CO_2 pressure, however this resulted in a decrease in TOF (Table 1, entry 6). This may be explained as a higher pressure results in a higher density of CO_2 which will alter the transport properties in the reactor. The highest TOF (160 h^{-1}) was observed at 90 °C (Table 1, entry 5). Varying the oct-1-ene flow rate was found to have an effect on the l:b ratio but not on the TOF (Table 1, entries 2, 7 and 8). As the CO concentration in $scCO_2$ is relatively high, it is remarkable that the hydroformylation rate is over three times faster than the batch reaction in toluene (TOF = 35 h^{-1}) and only half the rate of the *homogeneous* analogue (TOF = 283 h^{-1}) under comparable reaction conditions (80 °C, 50 bar syngas).[5] The high rate in $scCO_2$ is probably caused by enhanced mass-transport properties and the lower viscosity of the solvent medium.[20]

It was also found that the expansion system in our apparatus facilitated the separation of the aldehyde product from the residual oct-1-ene. In our preliminary experiments, we were able to remove *ca.* 90% of oct-1-ene from the product by simply controlling the two-step depressurization of CO_2.

The catalyst appears to be very robust, as its performance is constant over at least 30 h. Fig. 1, shows a plot of the turnover number (TON) *vs.* reaction time. The TON increased linearly with time at both 70 and 80 °C. Moreover, we were able to continue using the catalyst for six non-consecutive days with no observable decrease in either activity or selectivity. Furthermore, no rhodium leaching was detected (detection limit of used technique (AES) is 0.2% of the total amount of rhodium of the catalyst). This demonstrates that the rhodium–diphosphine bond in this catalyst remains stable under hydroformylation conditions.

In conclusion, we have presented the first example of continuous selective hydroformylation of higher olefins in $scCO_2$ using an immobilised homogeneous rhodium catalyst. The process is potentially interesting in the manufacture of fine chemicals and our approach has several advantages compared to conventional homogeneously catalysed reactions. Firstly, $scCO_2$ is a clean, environmentally benign medium which can be easily separated from the organic phase. Secondly, the application of an immobilised homogeneous catalyst in the flow reactor provides a direct and quantitative separation of the products from the catalyst and avoids any solubility limitations of homogeneous catalysts. Finally, the robustness of the catalyst and absence of Rh leaching, makes this system an interesting candidate for sustainable processes.

We are grateful to Dr W. K. Gray for initiating this collaboration and thank Dr S. K. Ross for his help. We thank Thomas Swan & Co. Ltd. and the EPSRC (GR/M73644) for funding the work at Nottingham and the Innovation Oriented Research Program (IOP-katalyse) for financing the work in Amsterdam. We thank J. Elgersma for performing the Rh analyses and Dr P. A. Arnold, Dr M. Glenny, M. Guyler and K. Stanley for their assistance.

Notes and references

† *Catalyst preparation*: 100 mg (1.40×10^{-4} mol) of *N*-(3-trimethoxysilyl-*n*-propyl)-4,5-bis(diphenylphosphino)phenoxazine (Siloxantphos) was added to a suspension of 1 g silica (200–500 μm) (predried at 140 °C for several days) in 25 ml toluene and the mixture was mechanically stirred at 80 °C for 20 h. After cooling to room temperature, the liquids were removed from the residue and the silica was washed with three portions of toluene. The ligand-on-silica was dried *in vacuo* and was then suspended in a mixture of 5 mL THF and 1 mL Et_3N. The suspension was mixed for 10 min and 4 mg (1.55×10^{-5} mol) $Rh(acac)(CO)_2$ was then added. The mixture was mechanically stirred for 15 min, after which the THF was removed and the catalyst was further washed with three portions of THF. The catalyst was dried *in vacuo* and was either used directly or stored under argon at −20 °C.

‡ The substrate + internal standard, supercritical CO_2 (P_c = 73.8 bar, T_c = 31.1 °C) and CO/H_2 are brought together in a heated mixer, passed through the reactor containing catalyst, and then expanded to separate the fluid product from the process-stream. The reactor is assembled from commercially available units: $scCO_2$ pump PM101, CO/H_2 compressor CU105 and Expansion Module PE103 (all from NWA GmbH, Lörrach, Germany), a high pressure mixer (Medimix) and a Gilson 305 pump (for the organic substrate). **CAUTION**: Flow reactors have a comparatively small volume under pressure. Nevertheless, equipment with the appropriate pressure and temperature rating should always be used for high pressure experiments.

Published on the Web 19th July 2000

A synthesis of alkali-free borosilicate gel from $Si(OEt)_4$ and $(MeO)_3B_3O_3$ in non-aqueous solvents is reported; the formation of the gel proceeds *via* rapid transesterification/oxygen transfer with elimination of $B(OR)_3$; removal of volatiles from the gel, followed by drying (60 °C, 12 h) and furnacing in air (600 °C, 20 min) resulted in alkali-free borosilicate glass.

The sol–gel methodology involving hydrolysis and condensation of metal alkoxides is potentially an important low temperature route to homogeneous multicomponent oxide glass thin films and coatings.[1–3] Thus, for example, suitable coatings may be obtained by a 'dip and furnace' route without exposure to temperatures required in melt/fusion processes (> 1300 °C). The production of alkali-free borosilicate glass by sol–gel routes have generally used protic solvents and mineral acids, with the silicon source partially hydrolysed by prolonged reflux prior to addition of the boron source as either an orthoborate ester[4–8] or as boric acid.[9–10]. The susceptability of B–O–Si bonds to hydrolytic attack at boron, with subsequent leaching of borate, is a severe limitation of the aqueous sol–gel method.[9] The first synthesis of an alkali-free borosilicate gel carried out at ambient temperature in organic solvents, with exclusion of water and mineral acids and using the metaborate ester trimethoxyboroxine (TMB), has recently been reported by Varma[11] in the patent literature. Here, we report on the underlying chemistry of this new and novel 'sol–gel' route to borosilicate materials, in which the TMB functions as both a source of boron and as a non-aqueous 'oxygen transfer' reagent.

A transparent gel was obtained when TMB and tetraethoxysilane (TEOS) were dissolved in dry acetone in a 1:1 molar ratio (B:Si ratio 3:1) and left at room temperature for *ca.* 2 weeks.† We have further noted that (i) the gelation time is decreased by increasing the B:Si ratio (*e.g.* 9:1, 1 week), (ii) that gels do not form at B:Si ratios of 1:1 even after prolonged periods, and that (iii) in the absence of solvent neat TMB and TEOS (1:1) gelled within a week. The transparent gel was isolated and upon removal of all volatiles and oven-drying (60 °C) gave an opaque/glassy solid. The mass of the dried gel was *ca.* 35% of the combined masses of the added TEOS and TMB. The dried gel lost a further 30–40% of its mass upon firing to 600 °C in air and yielded a silver-grey borosilicate glass with a B:Si ratio of *ca.* 1:1.2; TGA showed that most of this mass was lost at 350–400 °C.

The solid products were characterised by elemental analysis,† IR, XRD and solid-state MAS NMR spectroscopy. Elemental analysis confirmed the presence of boron and silicon in both dried and fired samples and the mass balance of the reaction confirms that > 90% of the silicon (added as TEOS), and *ca.* 25% of the boron (added as TMB), remained in the final borosilicate glass. XRD analysis indicated that they were both non-crystalline amorphous solids. The ^{11}B MAS NMR spectrum of the furnaced glass [Fig. 1(b)] exhibited a clear residual quadrupolar 'doublet' pattern and was simulated as one signal (δ_{iso} = +14.4 ppm) indicating that the boron atoms were all in equivalent three-coordinate axially symmetrical environments

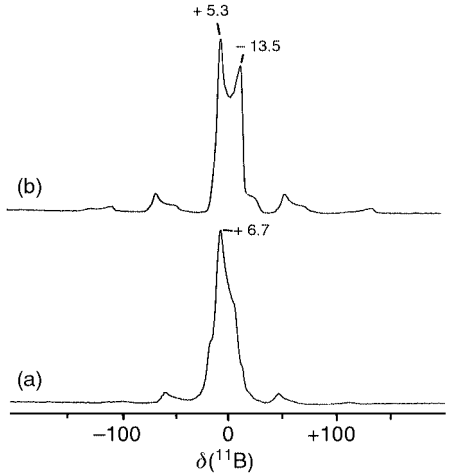

Fig. 1 Observed (96.234 MHz) MAS ^{11}B NMR spectra for (a) the dried gel and (b) the furnaced glass, spinning at 5200 and 5900 Hz, respectively. The dried gel was simulated as two signals: [δ_{iso} (ppm), rel.int, η, C_q (MHz)] 15.6, 80, 0.0, 2.38; 10.6, 20, 0.0, 1.14. The furnaced glass was simulated as a single signal: 14.4, 100, 0.0, 2.63.

and consistent with them being part of the silica network.[12–14] The dried gel gave a ^{11}B spectrum [Fig. 1(a)] simulated as an 80:20 mixture of two signals (δ_{iso} = +15.6 and +10.6 ppm), with the main species at lower field. ^{29}Si MAS NMR demonstrated that the principal species in both the dried gel and the furnaced glass was Q^4 (δ_{iso} = −109 ppm), with the furnaced glass giving an asymmetric signal which was deconvoluted as a 63:37 mixture with the lower intensity signal at δ_{iso} = −101 ppm.[14] IR spectra of both the dried and furnaced solids (Fig. 2) showed absorptions at 928 and *ca.* 670 cm^{-1} indicating that

DOI: 10.1039/b003047n

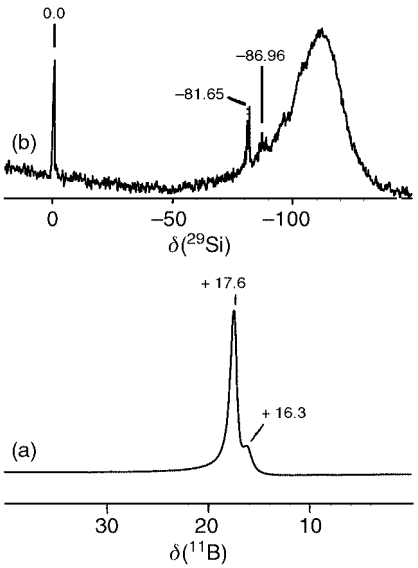

Fig. 3 Solution NMR of the sol diluted with $CDCl_3$ prior to gelling of the TMB:TEOS (1:1) reaction mixture (a) $^{11}B\{^1H\}$ spectrum (80.249 MHz) and (b) ^{29}Si spectrum (49.694 MHz) with $SiMe_4$ added as an internal standard (0.0 ppm).

both samples contain B–O–Si links.[9,15] Strong B–O (br, 1450 cm^{-1}), Si–O stretches (br,1150 cm^{-1}) and Si–O–Si (*ca.* 790 cm^{-1}) were also observed.[9,15] Heating the sample to 600 °C enhanced the relative intensity of B–O–Si bands and produced a weak shoulder (at 740 cm^{-1}) on the lower energy B–O–Si band which may indicate the formation of some B–O–B (720 cm^{-1}) upon furnacing.[15]

The volatile reaction products were investigated qualitatively by GCMS, and ^{11}B NMR and quantitatively by gravimetric boron analysis. ^{11}B NMR showed one peak (*ca.* +17.6 ppm) consistent with a trigonal boron with three oxygen substituents, and GCMS confirmed that $B(OEt)_3$ was the major species present. Gravimetric analysis showed that *ca.* 45% of boron initially added to the reaction mixture as TMB was now in the isolated volatile component.

The above observations demonstrate that orthoborate esters are produced as co-products in the gelling process and an idealised equation for the production of silica from a 2:1 B:Si stoichiometry may be written as in eqn. (1). In the preparation

$$Si(OEt)_4 + 2/3(MeO)_3B_3O_3 \rightarrow 1/n\{SiO_2\}_n + 2B(OR)_3 \ (R = Me, Et) \quad (1)$$

of the gel described above a B:Si ratio of 3:1 was used, and it was noted that gels were not formed with B:Si ratios of 1:1. The incorporation of boron in the gel, either present as B–O–Si linkages or as occluded borate, appears to be a consequence of the increased B:Si ratio. Occluded metaborate esters would disproportionate to orthoborate esters and boron oxide upon furnacing with the orthoborate esters volatilised at high temperatures.

The initial stages of the reaction (sol formation) were followed by solution ^{11}B and ^{29}Si NMR spectroscopy which show clear evidence for initial B–O–Si bond formation, and oxygen transfer and transesterification, respectively (Fig. 3). The formation of B–O–Si bonds in the sols can be seen by the appearence of a new signal in the ^{11}B spectrum at +16.3 ppm [5] in addition to that for the TMB and $B(OR)_3$ which overlap at *ca.* +17.6 ppm. ^{29}Si NMR of the sols also indicated that transesterification had occurred [Q^0 ester signals at −79.93, −80.82 and −81.65 for $Si(OMe)_2(OEt)_2$, $Si(OMe)(OEt)_3$ and TEOS[5,16]] with strong evidence for Q^1 species (centered at −87 ppm: −85.96, −86.96, −88.56 ppm) but with molecular Q^2, Q^3 and Q^4 species at *ca.* −96, −104 and −112 ppm barely discernable above the broad baseline hump due to borosilicate glass of the sample tube, and gelling sample.[5] Transesterification of orthoborates/orthosilicates has been reported in the literature but several hours at elevated temperature and acid/base catalysis were required for systems to reach equilibrium.[17] In the system described here transesterification is very rapid at room temperature and we believe this to be a consequence of the increased Lewis acidity of the metaborate ester over that of orthoborate esters.[18] It is acknowledged however, that the acetone solvent may play a non-innocent role in this reaction, by functioning as a Lewis base and as a potential catalytic proton source.

Mechanistic aspects of this unusual reaction and detailed studies of these and other multicomponent systems, including applications for the preparation of thin films by 'dip-coating' using the sols, are in progress.

We thank Dr D. Apperley (EPSRC solid-state MAS NMR service, Durham) for spectra and Pilkington plc for financial support.

Notes and references

† TMB (4.16 g; 24 mmol) and TEOS (5.0 g; 24 mmol) were disolved in dry acetone (25 cm^3) and left to stand in a dry, inert atmosphere. The transparent gel, which slowly formed over a 2 week period, was isolated as a solid (4.61 g) after removal of volatiles (25.1 g) (vacuum, RT). GCMS confirmed that $B(OEt)_3$ was the major component of the volatiles and gravimetric analysis (barium borotartrate method[19]) of a hydrolysed aliquot (1.0632 g) gave 0.9689 g of $4BaC_4H_4O_6{\cdot}Ba(BO_2)_2{\cdot}4H_2O$ (= 1.35 mmol B), and hence total B of 31.9 mmol. The gel was oven dried at 60 °C for 12 h to yield an opaque glassy solid (3.24 g) with elemental composition Si 21.7; B 10.2; C 14.3; H 3.6; (O ≈ 50.2)%. Firing a sample of the dried gel (0.51 g) to 600 °C in air for 20 min resulted in weight loss (38%) and a silvery–grey borosilicate glass (0.32 g) with elemental composition of Si 31.4 **;** B 10.1; C < 0.5; H < 0.5; (O ≈ 58.0)%.

Received (in Liverpool, UK) 19th May 2000, Accepted 21st June 2000
Published on the Web 19th July 2000

Asymmetric Pd(0) catalyzed allylic amination followed by a Ru catalyzed RCM–ROM sequence converted an easily accessible racemic cyclopentenol 2 to the functionalized tetrahydropyridine 9 which can be used for the asymmetrical synthesis of indolizidine 13.

Polyhydroxylated indolizidine alkaloids are widespread in nature and possess very diverse and important physiological properties.[1] Consequently, development of general methodologies for their construction is an important challenge.

Recently we published a paper in which ruthenium catalyzed ring-rearrangement (*i.e.* sequential ring-closing–ring-opening metathesis) is described.[2] The herein reported ring-rearrangement opens the way to converting readily accessible carbocycles into stereodefined heterocycles containing highly functionalized side chains. In order to illustrate the general applicability of this reaction it was decided to synthesize (see Scheme 1) 1,2,3,5,6,8a-hexahydroindolizine-1,2-diol **A** (R=H).

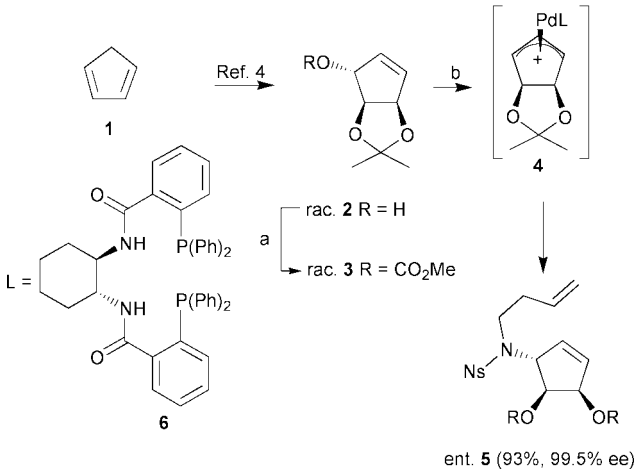
Retrosynthetic analysis reveals that the target compound **A** can be attained from functionalised tetrahydropyridine **B** which, in turn, can be obtained from cyclopentenylamine **C** *via* ruthenium catalyzed ring-rearrangement. Asymmetric Pd-catalyzed allylic amination[3] of the racemic alcohol **2**, readily accessible from cyclopentadiene **1**,[4] leads to the optically pure metathesis precursor **C**.

It was expected that palladium(0) catalyzed allylic amination of a cyclopentenyl donor derived from **2** would be an appropriate way to introduce the desired nitrogen nucleophile.

We now report an asymmetric synthesis of hexahydroindolizine **13** starting from **1** using a ring-rearrangement as the key step (see Scheme 2).

In order to provide a good leaving group for the oxidative addition event of the palladium catalyzed allylic amination, alcohol **2** was converted into its corresponding methyl carbonate **3**. In the first instance a solution of optically pure **3**† in THF–triethylamine was subjected to palladium(0) catalysis, using dppb as a ligand and *o*-nitrophenylsulfonyl[5] (Ns) protected homoallylamine as the nitrogen nucleophile. Work-up and purification gave cyclopentenylamine **5** as a racemic mixture in 95% yield.

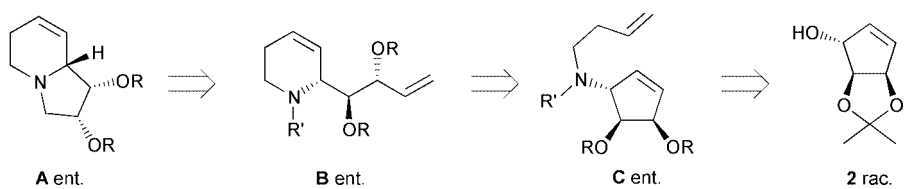
It is well established that the palladium catalyzed reaction proceeds through the symmetrical π-allyl palladium complex **4**. This indicates that the use of asymmetric ligands would open the way to the synthesis of both enantiomers of **5**. To this end ligand **6**, developed by Trost and co-workers,[6] was selected for this purpose because of its proven reliability in terms of yield and enantioselectivity. Gratifyingly, the reaction of **3** with ligand (*R*,*R*)-**6** led to the isolation of (−)-**5**‡ in good yield with > 99.5% enantiomeric excess.§



Scheme 2 *Reagents and conditions*: a $ClCO_2Me$, CH_2Cl_2, pyridine, 0 °C, 30 min, 97%; b $H_2C{=}CH(CH_2)_2NHNs$, $Pd_2dba_3{\cdot}CHCl_3$ (1 mol%), ligand **6**, Et_3N, THF, 18 h, −10 to 0 °C, 93%, 99.5% ee.

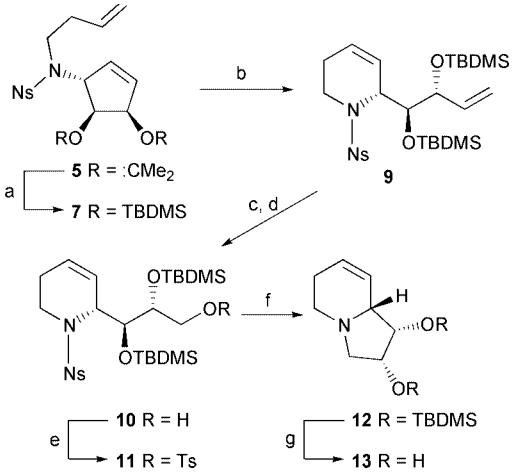
At this stage, enantiomerically pure cyclopentenylamine (−)-**5** was now subjected to ruthenium catalyzed ring-rearrangement using a catalytic amount of **8**[7] in the presence of ethylene (Scheme 3). It was established that **5** was inert under the reaction conditions, however, the corresponding TBDMS protected derivative **7** gave **9** quantitatively. It is also worth mentioning that no reaction was observed in the absence of ethylene.

It turned out that differentiation between the internal and terminal double bonds in **9** could be realized *via* regioselective dihydroxylation of the terminal double bond resulting in the corresponding diol in 80% yield as a single diastereoisomer. Periodate cleavage and *in situ* reduction of the newly generated aldehyde function gave alcohol **10**. Alcohol **10** was tosylated to provide **11**, setting the stage for an intended cyclisation–cleavage procedure. Deprotection of the Ns group was accompanied by concomitant cyclisation resulting in the 1,2,3,5,6,8a-hexahydroindolizine **12**. Removal of the TBDMS groups led to the unprotected indolizidine **13** in 87% yield based on **11**.



Scheme 1

DOI: 10.1039/b004106h



Scheme 3 *Reagents and conditions*: a, HOAc, H_2O, 80 °C, 30 min; TBDMSCl, imidazole DMF, rt, overnight, 75% (two steps); b, $Cl_2(PCy_3)_2Ru{=}CHPh$ (**8**) (4 mol%), $H_2C{=}CH_2$, CH_2Cl_2, rt, overnight, 100%; c, $K_2OsO_4{\cdot}2H_2O$ cat., NMO, acetone–H_2O, rt, 48 h, 80%; d, $NaIO_4$, MeOH/H_2O, 0 °C, 30 min, then $NaBH_4$(aq), 0 °C, 3 min, 99%; e, TsCl, pyridine, DMAP, rt, overnight, 71%; f, PhSH, $K_2C_2O_3$, DMF, 0 °C, 30 min, 100%; g, TBAF, THF, rt, overnight, 88%.

In conclusion, it has been shown that asymmetric palladium catalyzed introduction of a nitrogen nucleophile proceeds with a high degree of enantioselectivity. The resulting stereodefined platform serves as a suitable substrate for an ensuing ruthenium catalyzed ring-rearrangement leading to an azacycle carrying a highly functionalized side chain amenable to further manipulations.

Double aromaticity and anti-aromaticity in small carbon rings†

Sonsoles Martín-Santamaría and Henry S. Rzepa*

Calculated NICS indices for C_{10} and C_{14} indicate these species are doubly aromatic and that C_{12} is doubly anti-aromatic, with the π-aromaticity dominating the σ-contribution in systems such as triplet C_{10}, C_8N_2, $C_{10}B_2$ or C_{12}^{2+} all of which have opposing aromatic/anti-aromatic character.

Recent experimental studies[1] of the electronic absorption spectra of small carbon clusters have provided evidence for the first time that the fundamentally important C_{10}–C_{14} clusters are monocyclic polyalkynes or cumulenes rather than linear species.[2] Such rings were noted[1b] as being potentially doubly aromatic, *via* both conventional p_π–p_π overlaps, and *via* the novel in-plane conjugation of $4n + 2$ π-electrons described recently by Schleyer and co-workers.[3] The latter identified [10] and [14] trannulenes (all-*trans* annulenes) as having in-plane aromaticity, on the basis of calculated nucleus independent chemical shift values at the ring centroid (NICS[4] −14.0 and −17.2 ppm respectively, *cf.* benzene, −10 ppm) and the $4n$ electron [12] trannulene as being strongly anti-aromatic (NICS +35.7 ppm). We noted that the NICS aromaticities of the C_{10}–C_{14} carbon rings have not hitherto been reported. More importantly, we considered that these small carbon rings might be suitable systems for investigating the controversial suggestion[5] that the π-electrons in benzene have a distortive tendency towards bond localisation, and that the D_{6h} symmetry of benzene itself arises purely from the σ-framework. Adding or removing two electrons to the doubly aromatic C_{10} ring could give a $4n$ count for one set of p_π–p_π electrons, and a $4n + 2$ count for the orthogonal p_π–p_π set, resulting in molecules which would be simultaneously aromatic in one dimension and anti-aromatic in another. We also speculated whether the triplet[6] and higher excited states of these species might exhibit a similar effect. Finally, our recent studies[7] suggested to us that the two orthogonal $4n + 2$ sets of p_π–p_π electrons in C_{10} might be converted to a single $4n$ set by introducing a Möbius component into the ring. Here we report our theoretical findings on these various aspects.

† Electronic supplementary information (ESI) available: computed 3D coordinates as PDB files. See http://www.rsc.org/suppdata/cc/b0/b002922j/

Initial studies† of these species were at the AM1 semi-empirical level[8] followed by B3LYP/6-31G(d) geometry optimisation[9] with no symmetry constraints of the singlet states. All the rings were characterised as planar minima *via* inspection of the Hessian matrix. Of the four valence electrons available to carbon, two contribute to conventional C–C single bonds (*e.g.* sp hybridisation) and are not considered further here. The remaining two electrons occupy orthogonal p-orbitals which for C_{10} specifically, overlap cyclically to form a set of five doubly occupied in-plane σ-molecular orbitals and a set of five out of plane π-orbitals. Each set has a characteristic benzene-like double degeneracy (E) for the highest two pairs (*e.g.* the Hückel $4n + 2$, $n = 2$ electron rule, Table 1). The calculated NICS(0)-B3LYP/6-31G(d) value at the C_{10} ring centroid (D_{5h} symmetry) of −28.9 ppm implies the molecule is indeed doubly aromatic compared to benzene itself. The C_{14} homologue showed a similar pattern of orbital occupancy and even higher aromaticity (Table 1). C_{12} differs from C_{10} in having a pair of additional p_π electrons in both the σ- and π-planes, each of which occupies a single, now non-degenerate orbital. Such $4n$ occupancy ($n = 3$) results in doubly anti-aromatic character (NICS +50.0 ppm) and a Jahn–Teller distortion towards bond localisation of the geometry (Fig. 1). The degeneracy of the π HOMO can be recovered by promoting one π electron to the π LUMO to form a triplet state, calculated to be 6.7 kcal mol^{-1} higher than singlet C_{12}. This species can be described as out-of-plane π triplet aromatic[6] but remains an in-plane σ-anti-aromatic. The overall NICS value indicates the dominance of the π aromaticity over the in-plane σ-anti-aromaticity (Table 1). Further σ–σ* electron excitation to form the quintet state of C_{12} additionally removes the in-plane σ-anti-aromaticity, increasing the overall NICS aromaticity index to −31.5 ppm.

Although reliable calculations for small carbon clusters appears to require very high levels of theory,[2] we emphasize here the relative trends in the geometries and NICS values rather than the absolute values and energies. Thus the calculated B3LYP/6-31G(d) geometries of planar C_{10}, C_{12} and C_{14} differ markedly in the degree of calculated bond alternation (Fig. 1). The doubly aromatic singlet systems show no bond alternation, doubly-antiaromatic singlet C_{12} shows strong alternation (due as we note above to a Jahn–Teller distortion) but the bonds are

again symmetrised when the π-system is aromatised *via* formation of triplet state C_{12}. The additional reversal of the σ-anti-aromaticity *via* the planar σ/π doubly aromatic quintet C_{12} reveals bond relocalisation (Fig. 1), the origins of which remain to be established. These various results contrast with the proposal that π-aromaticity in benzene is bond distortive and that the symmetry is due to the σ framework alone.[5]

B_5N_5 is isoelectronic with C_{10} and also has the characteristic cumulene structure (Fig. 1) with no bond alternation and a similar orbital ordering to the carbon analogue, but a surprisingly small NICS value (Table 1) corresponding to non-aromaticity. The anomalous behaviour of B_5N_5 in a different context has been previously noted.[10] Two valence electrons added to C_{10} in the form of C_8N_2 occupy an in-plane p_π–p_π orbital, resulting in an in-plane $4n$ (n = 3) rather than $4n + 2$ occupancy. Overall, the NICS value suggests that the π $4n + 2$ aromaticity is clearly dominant over the σ $4n$ anti-aromaticity (Table 1). The reverse effect is observed with C_{12}^{2+}. This is a 12-electron ($4n$) π-antiaromatic system (NICS +32.4) associated with bond alternation, dominating a 10-electron ($4n + 2$) in-plane σ-aromatic system. A third example of this π-dominance is the isoelectronic $C_{10}B_2$ which reveals 10-electron π-aromaticity and 12-electron in-plane p_π–p_π σ-anti-aromaticity, with overall NICS aromaticity (Table 1) and only mild bond alternation (Fig. 1).

We had previously suggested[7] that replacing a two electron C=C unit in a $4n + 2$ electron annulene by a partially twisted four electron HC=C=CH unit can induce Möbius $4n$ aromaticity. Applying this analogy to replacing one four electron triple bond by this unit in C_{10} results in chiral $C_{11}H_2$, in which the in-plane p_π–p_π/σ and the out-of-plane p_π–p_π/π-systems interact to form a 20-electron Möbius $4n$ aromatic. Less effective orbital overlap reduces the NICS value compared to C_{10} and induces bond alternation (Fig. 1). Inserting the same HC=C=CH unit into the strongly anti-aromatic C_{12} to produce the 24 electron $C_{13}H_2$ reduces the anti-aromaticity substantially, but does not eliminate it (Table 1).[11] Finally, we note that two hydrogen atoms in $C_{11}H_2$ can be removed entirely by replacing them with a second carbon ring to give C_{19}, a novel form of chiral Möbius carbon (Fig. 1), again with mild NICS aromaticity indicated for each ring.

A novel hybrid network of synthetic polymer mesh and collagen sponge was prepared by forming collagen sponges with interconnected microporous structures in the interstices of the synthetic polymer mesh.

Biodegradable synthetic poly(α-hydroxy acids), such as poly(lactic acid) (PLA), poly(glycolic acid) (PGA) and their copolymer of poly(DL-lactic-co-glycolic acid) (PLGA), and collagen have been widely used for tissue engineering as temporary scaffolds to accommodate transplanted cell masses, and as materials for assisting in surgeries in clinical applications.[1–6] The synthetic polymer meshes demonstrate good biocompatibility, good mechanical properties, and are easy to handle. Their rate of degradation can also be controlled to meet the rate of new tissue formation in tissue repair. However, these synthetic polymers are relatively hydrophobic. These hydrophobic properties, together with the large mesh interstices, hinder smooth cell seeding. In contrast, collagen offers the advantage of specific cell interactions and hydrophilicity, but scaffolds constructed entirely of collagen have poor mechanical strength. Therefore, synthetic biodegradable polymers and collagen have been hybridized to combine their advantages.[7–13] In the present study, a novel hybrid biomaterial was prepared by combining synthetic biodegradable polymer mesh with collagen sponge.

The hybridization of synthetic poly(α-hydroxy acids) and collagen was achieved by forming collagen sponges between the interstices of poly(α-hydroxy acids) mesh. A Vicryl knitted mesh made of polylactin 910 (a 90 : 10 copolymer of glycolic acid and lactic acid), as shown in Fig. 1a, was immersed in a bovine collagen acidic solution (type I, pH 3.2, 0.5 wt%), and frozen at −80 °C for 12 h. It was then freeze dried under a vacuum of 0.2 Torr for 24 h to allow the formation of collagen sponge. The collagen sponge was further cross-linked by treatment with glutaraldehyde vapor saturated with 25% glutaraldehyde aqueous solution at 37 °C for 4 h. After the cross-linking, the sponge was treated with 0.1 M glycine aqueous solution to block unreacted aldehyde groups. After being washed with deionized water and freeze dried, the polymer–collagen hybrid mesh was prepared.

The hybrid mesh was coated with gold and observed by scanning electron microscopy (SEM). The SEM photomicrographs of the hybrid mesh are shown in Fig. 1. Collagen sponges with interconnected microporous structures were formed in the interstices of the synthetic polymer mesh. The polymer mesh was embedded in the collagen sponge sheet so that the fiber bundles of polymer mesh and the collagen sponges were alternately chained. The thickness of the collagen sponge sheet surrounding the polymer mesh could be manipulated by adjusting the volume of the collagen solution. A greater volume of collagen solution resulted in a thicker layer of collagen sponge. The position of the polymer mesh in the hybrid network could also be manipulated. It could be a sandwich type with the polymer mesh embedded in the middle of the collagen sponge layer, or be overlapped. The hybrid mesh could be prepared in the shape of a sheet or a cylinder by using a polymer mesh sheet or tube.

20-mM HEPES buffer-soaked hybrid mesh, polymer mesh and collagen sponge were used for static tensile mechanical tests. They were pulled to failure at a rate of 0.5 mm min^{-1}. Load–deformation curves were obtained from a chart recorder. The moduli of elasticity of the hybrid mesh, polymer mesh and collagen sponge determined from the load–deformation curves and the dimensions of each sample were 35.42 ± 1.42, 35.15 ± 1.00 and 0.02 ± 0.00 MPa, respectively. The hybrid mesh possessed almost the same mechanical property as that of the polymer mesh, much higher than that of the collagen sponge alone.

Human skin fibroblasts were subcultured in 106S serum medium supplemented with 2 (v/v)% fetal bovine serum (FBS), 10 ng mL^{-1} recombinant epidermal growth factor (rEGF), and

DOI: 10.1039/b003508o

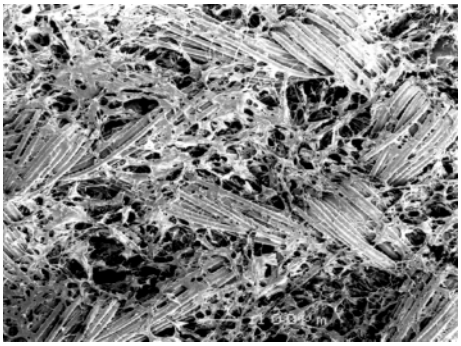

Fig. 2 SEM photomicrograph of human skin fibroblasts cultured on the hybrid mesh for 5 days at original magnification ×100.

3 ng mL^{-1} recombinant fibroblast growth factor-basic (rb-FGF). The subcultured fibroblasts were harvested and seeded on the hybrid and polymer meshes (7.64×10^4 cells/cm^2), and cultured in 106S serum medium under a 5% CO_2 atmosphere at 37 °C. The medium was replaced every 2 days. The cells adhering to the hybrid and polymer meshes after 24 h of culturing were $6.42 \pm 0.21 \times 10^4$ and $1.48 \pm 0.26 \times 10^4$ cells cm^{-2}, respectively. Many more cells adhered to the hybrid mesh than the polymer mesh. The cell morphology on the hybrid mesh was examined by SEM observation. Fig. 2 shows the appearance of the cells on the hybrid mesh after being cultured for 5 days. The fibroblasts adhered and spread well on the surfaces of the collagen sponge of the hybrid mesh after being cultured for 5 days. After 2 weeks, they proliferated to become completely connected in a layer structure. Over a longer culture period, the hybrid mesh degraded and eventually disappeared. Only cell sheet containing fibroblasts and extracellular matrices was left. These results suggest good cell interaction of the hybrid mesh.

Biodegradable synthetic poly(α-hydroxy acids) meshes have been used as temporary scaffolds for the tissue engineering of skin,[2] nerve,[9] esophagus,[10] ligament,[11] *etc*. However, the mesh interstices and their hydrophobicity hinder cell seeding. Cultured urothelial cells do not grow into a confluent layer on PGA or polyglactin mesh because of the large size of the mesh interstices.[14] To increase the cell seeding density on the PGA mesh, a method of surface hydrolysis has been used to improve the wettability of the mesh.[15] Hybridization of synthetic polymer with collagen has also been used to address these problems.[7–11] Polyglactin 910 mesh and PGA mesh have been coated with collagen solution, or embedded in collagen gels, to improve cell attachment and cell seeding. However, neither surface hydrolysis nor collagen coating changes the pore size of the interstices. The use of collagen gel produces a complete loss of pore structure. Compared to collagen gel, collagen sponge is porous enough to accommodate implanted cells, and its microporous structure facilitates cell seeding. The hybrid mesh of polylactin 910 mesh with collagen sponge exhibited a novel hybrid structure with interconnected microporous collagen sponges formed in the interstices of the synthetic polymer mesh. The polymer mesh, serving as a skeleton, reinforced the hybrid mesh and resulted in easy handling, while the collagen sponge provided the hybrid with a microporous structure and hydrophilicity, and, therefore, easy cell seeding. The hybrid mesh we developed could serve as a useful biomaterial for tissue engineering.

Triisobutylaluminium promoted reductive rearrangement of substituted vinyl ethers to homologous alcohols

Bérengère du Roizel, Matthieu Sollogoub, Alan J. Pearce and Pierre Sinaÿ*

École Normale Supérieure, Département de Chimie, associé au CNRS, 24 rue Lhomond, 75231 Paris Cedex 05, France. E-mail: Pierre.Sinay@ens.fr

Received (in Liverpool, UK) 25th April 2000, Accepted 26th June 2000
Published on the Web 19th July 2000

Substituted vinyl ethers carrying electron-donating groups in the ether moiety undergo smooth oxygen to carbon rearrangement with triisobutylaluminium to afford chain extended alcohols.

Lewis acid promoted oxygen to carbon rearrangements of vinyl acetals have received considerable attention as synthetically useful procedures.[1] For example, we have developed efficient methodology for the preparation of carbocycles by the reductive rearrangement of carbohydrate based vinyl acetals using TIBAL (triisobutylaluminium) as the Lewis acid.[2] We recently reported[3] that unsaturated *C*-aryl glycosides (hex-5-eno-pyranosides) such as **1**, also undergo the analogous TIBAL promoted rearrangement into carbocycles, provided that the aryl moiety is sufficiently electron-donating in nature in order to stabilise the carbocationic centre of the proposed intermediate **2** (Scheme 1). It is noteworthy that **1** is however no longer a vinyl acetal but a cyclic benzyl vinyl ether. Given that the Lewis acid promoted rearrangement of acyclic vinyl acetals[4] and allyl benzyl ethers[5] has been reported, we reasoned that an acyclic variant of **1** should also undergo a Lewis acid promoted rearrangement. Therefore, as part of our evaluation of the wider scope of the TIBAL promoted reductive rearrangement, we herein report the first application of this process to the rearrangement of acyclic *non-carbohydrate* based systems.

The substituted vinyl ethers **4** were readily prepared by standard acetylation of the starting alcohols **3** and methylenation using the Tebbe reagent (Scheme 2).

The substituents were chosen in order to stabilise the proposed carbocation intermediate and therefore favour rearrangement over the known competitive hydroalumination–elimination process[3] which would afford **3**. The TIBAL promoted reductive rearrangements† of **4** proceeded smoothly (64–70%) for electron-rich aromatic derivatives **4a** and **4b**

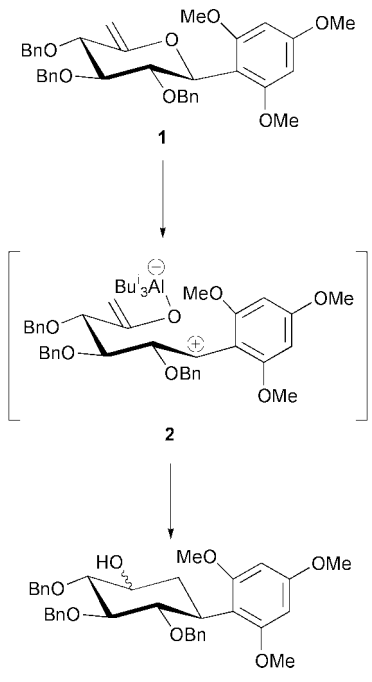

Table 1 Reaction of substituted vinyl ethers with TIBAL

Substituted vinyl ether	Product	Yield (%)
 **4a**	 **5a**	64
 **4b**	 **5b**	70
 **4c**	 **5c**	87
 **4d**	 **5d**	35[a]
 **4e**	 **5e**	60[a]

[a] **3d** (15%) and **3e** (10%)—the products of the competitive cleavage process *via* hydroalumination–elimination[3] were also isolated.

Scheme 2 *Reagents and conditions*: i, Ac_2O, pyridine (for **3a**,**b**); AcCl, Et_3N (for **3c**,**e**); AcBr, AcOH, NH_3, toluene (for **3d**); ii, 2.0 equiv. Tebbe reagent, 4.0 equiv. pyridine, THF, −45 °C to rt; iii, 5.0 equiv. TIBAL (1 M in toluene).†

(Table 1). The related non-reductive rearrangement of benzyl vinyl ethers has been reported as a side-reaction to Claisen rearrangements under radical[6] or forcing thermal conditions.[7] The TIBAL promoted rearrangement of diphenylmethyl isopropenyl ether (**4c**) proceeded in excellent yield. In the case of triphenylmethyl isopropenyl ether (**4d**), TIBAL rearrangement was indeed observed, although in only 35% yield, probably due to steric hindrance. Finally, the ferrocenylmethyl isopropenyl ether (**4e**) underwent smooth TIBAL promoted rearrangement to afford 4-ferrocenylbutan-3-ol (**5e**)‡ in 60% yield.

In summary, substituted vinyl ethers carrying electron-donating groups in the ether moiety undergo smooth TIBAL promoted rearrangement to afford chain extended alcohols. This approach constitutes a simple three step homologation procedure for benzylic alcohols, carrying electron-donating substituents in the aromatic nucleus and other alcohols bearing adjacent electron-donating groups and furthermore illustrates the more *general* nature of the TIBAL induced rearrangement.

Notes and references

† *Typical procedure*: TIBAL (1 M in toluene, 5 equiv.) was added to a stirred solution of starting material **4** in dry toluene (1 mL/100 mg), at 0 °C under argon. The cooling bath was then removed and the reaction mixture was allowed to warm to room temperature. After *ca*. 2 h (as indicated by TLC), the reaction mixture was cooled to 0 °C and distilled water was added dropwise until no further gas evolution was observed. The reaction mixture was then filtered (Celite®) and washed with EtOAc. The organic phase was then diluted with distilled water and extracted twice with EtOAc. The organic layers were then combined, dried ($MgSO_4$), filtered and the solvent was removed *in vacuo*. Purification of the residue by flash chromatography (cyclohexane–EtOAc) afforded pure **5**.

Self- and hetero-recognition in the guest-controlled assembly of Pd(II)-linked cages from two different ligands

Shuichi Hiraoka,† Yasuo Kubota and Makoto Fujita*

Department of Applied Chemistry, Graduate School of Engineering, Nagoya University, CREST, Japan Science and Technology Cooperation (JST), Chikusa, Nagoya 464-8603, Japan. E-mail: mfujita@apchem.nagoya-u.ac.jp

Received (in Cambridge, UK) 30th May 2000, Accepted 27th June 2000
Published on the Web 21st July 2000

The equilibration of cage-like receptors, $M_3(L^1)_2$ + $M_3(L^2)_2$ ⇌ 2 $M_3(L^1)(L^2)$, was efficiently controlled by appropriate guest addition: large (spherical) or small (flat) guests stabilized the homoleptic cages ($M_3(L^1)_2$ or $M_3(L^2)_2$) while medium-sized guests preferred the heteroleptic cage ($M_3(L^1)(L^2)$).

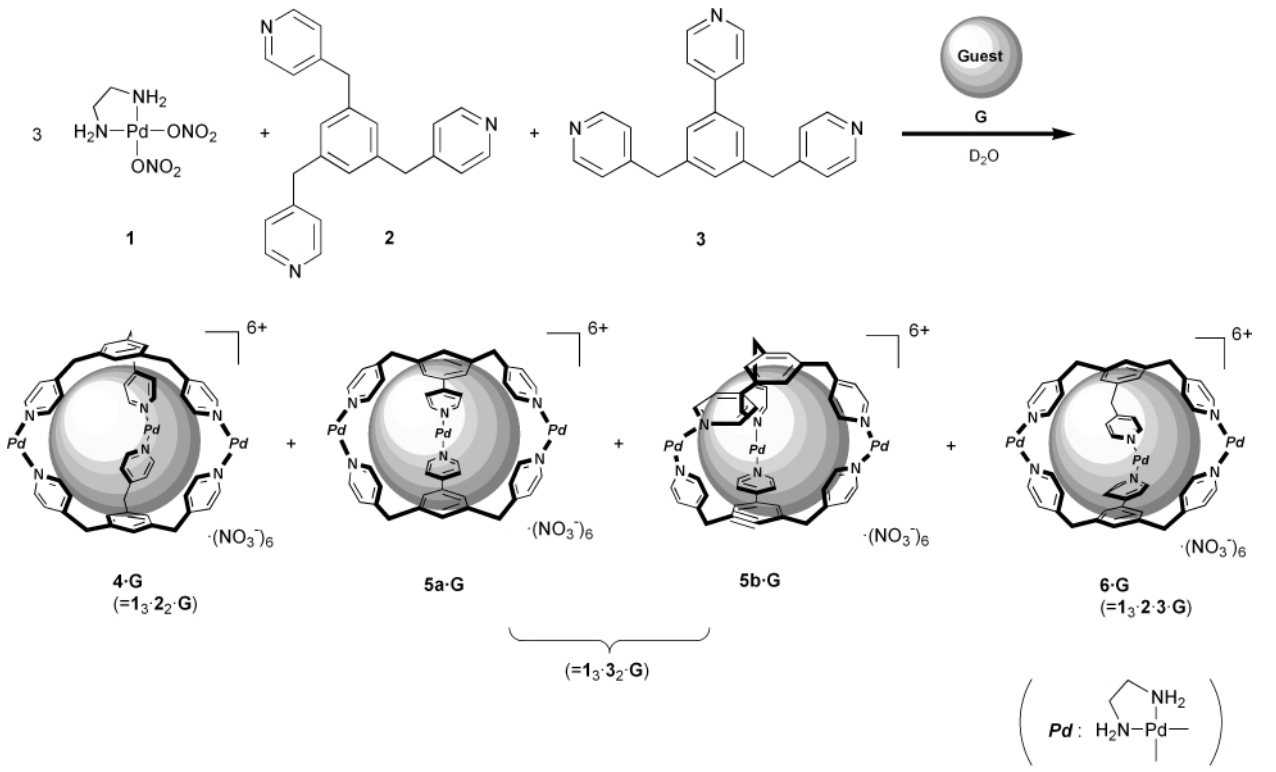
A dynamic receptor library is an equilibrium mixture of several receptors from which the appropriate one is selected by an optimal guest.[1–6] It is particularly important to study the dynamic features of guest-selected receptor formation from the library because the phenomenon is closely related to biological receptor systems.[7] Herein reported is the guest-controlled assembly of Pd(II)-linked cage-like receptors from a dynamic library generated from Pd(II) complex **1** and two different tridentate ligands **2** and **3**. As shown in Scheme 1, the library contains two classes of receptors: homoleptic (**4**, **5a** and **5b**) and heteroleptic (**6**). The homoleptic receptor contains two identical ligands and, hence, is termed a 'self-recognized' receptor while the heteroleptic receptor contains two different ligands and is termed 'hetero-recognized'.[8] We show that the equilibration between the receptors is very efficiently controlled by the addition of appropriate guests which selectively stabilize their optimal receptors.

The equilibration we deal with is represented by the following equation:

$$\underset{\text{'self - recognized'}}{\mathbf{4} + \mathbf{5}} \rightleftharpoons \underset{\text{'hetero - recognized'}}{2 \bullet \mathbf{6}}$$

Self-recognition should be dominant if only **4** and/or **5** are stabilized, while hetero-recognition is favored if **6** is selectively stabilized. Note that **5a** and **5b** are structural isomers with identical composition and the equilibration between these isomers is highly controlled by guest addition, as previously reported.[6]

When Pd(II) complex **1** (10 mM) was combined with tridentate ligands **2** and **3** (3.3 mM each) in D_2O, cages **4**–**6** and uncharacterized oligomeric products were formed with a very low self/hetero ratio‡ (**4**:**5**:**6**:oligomers = 15:35:30:20 corresponding to *ca.* 6:4 self/hetero ratio; see Table 1, run 1).[9] The product ratios were estimated by ^{1}H NMR (Fig. 1). Oligomer formation became predominant at higher concentrations and exclusive when $[\mathbf{1}]_0$ > 40 mM.



Scheme 1

DOI: 10.1039/b004271o

Table 1 Guest-selected formation of homo- and heteroleptic Pd(II)-linked receptors

Run	Guest[b]	Ratio[a] (%) **4**:**5a**:**5b**:**6**:Oligomers[c]	S/H[d]
1	None	15:0:35:30:20	6:4
2	PhCOOH	27:0:31:38:4	6:4
3	**7**	42:0:42:16:0	8:2

7	CBr_4	29:18:11:42:0	6:4
8	*c*-C_6H_{12}	19:6:13:62:0	4:6
9	*c*-C_7H_{14}	8:0:20:60:12	3:7
10	*c*-C_8H_{16}	15:0:33:34:18	6:4

[a] Determined by ^{1}H NMR ([**1**]$_0$ = 10 mM, 25 °C, D_2O). [b] Excess amounts of guests were used. [c] At 3.3 mM for each ligand, it was confirmed that only ligand **2** gives oligomeric components. Thus, the amount of the oligomers was estimated on the assumption that compound **3** does not contribute to the oligomeric fraction of complexes. [d] S/H = self/hetero ratio.

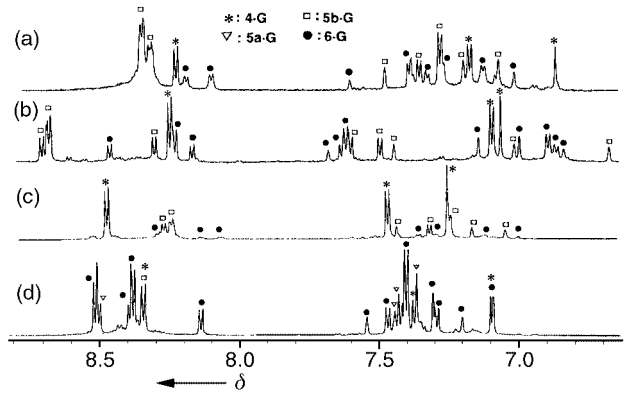

Fig. 1 ^{1}H NMR spectra (500 MHz, D_2O, aromatic region) of the mixture of complexes **4**–**6** obtained from a 3:1:1:1 mixture of **1** ([**1**]$_0$ = 10 mM), **2** ([**2**]$_0$ = 3.3 mM), **3** ([**3**]$_0$ = 3.3 mM) and various guests: (a) guest free; (b) guest = PhCOOH; (c) guest = **7**; (d) guest = $CBrCl_3$.

Upon the addition of adamantane-1-carboxylic acid (**7**), however, the oligomer formation was completely suppressed and the equilibration was significantly shifted toward the self-recognized products (**4** + **5** = 84%; run 3). The cavity size becomes larger and more spherical in the order of **5** < **6** < **4** because ligand **2** is larger than **3** by the length of a CH_2 unit. Thus the preference for the self-recognition can be ascribed to the efficient binding of the large and spherical guest by host **4**. In fact, only the signals of host **4** were downfield shifted while those of **5** and **6** were unchanged, suggesting the selective complexation of **7** and **4**.

Self-recognition should be most effective if **4** and **5** are stabilized simultaneously but not **6**. Thus, we attempted the use of two different guests adamantan-1-ol (**8**) and benzene-1,3,5-tricarboxylic acid (**9**) because the former was expected to be bound by bulky cage **4** and the latter by flat cage **5b**. When **8** and **9** were added, only self-recognized receptors **4** and **5b** were assembled exclusively as expected (**4** + **5b** = 100%; run 4). The signals of only **4** and **5b** were downfield shifted suggesting the selective formation of **4**•**8** and **5b**•**9** complexes.

In contrast, the equilibrium was markedly shifted toward hetero-recognition when $CBrCl_3$ was added as the guest: **6** was preferentially formed (68%) and the self/hetero ratio was *ca*. 3:7. This spherical and 'medium-sized' guest seems to best fit within the cavity of **6**. The formation of **6** was not exclusive because $CBrCl_3$ was also bound efficiently in the cavity of **5a**.[6] Similar spherical guests such as CCl_4 induced the preferential formation of **6** (66%) while the slightly larger CBr_4 was no longer a suitable guest for selective heteroleptic receptor formation (42%). Cyclohexane and cycloheptane were also favorable for hetero-recognition (self/hetero ratios 4:6 and 3:7, respectively), but cyclooctane, which seems too large, showed no stabilizing effects for any receptors.

Notes and references

† Present address: Department of Applied Chemistry, Kanagawa University, Kanagawa-ku, Yokohama 221-8686, Japan.

‡ Self-recognized receptors **4** and **5** have been obtained by two independent reactions: **1** + **2** → **4**;[9] **1** + **3** → **5**. Thus, from the NMR spectrum of a **4**–**6** mixture, **4** and **5** can be easily assigned. In the present reaction, the newly appeared signals, which contain the framework of both **2** and **3** in a 1:1 ratio, can be assigned as **6**. ^{1}H NMR data of **6** (from the reaction of run 6 in Table 1): ^{1}H NMR (500 MHz, D_2O, 25 °C) δ 8.51 (2H, d, *J* 6.6 Hz, PyH_α), 8.39 (4H, d, *J* 6.6 Hz, PyH_α), 8.38 (2H, d, *J* 6.6 Hz, PyH_α), 8.14 (4H, d, *J* 6.6 Hz, PyH_α), 7.54 (1H, s, Ar*H*), 7.47 (2H, d, *J* 6.8 Hz, PyH_β), 7.40 (8H, d, *J* 6.8 Hz, PyH_β), 7.31 (2H, s, Ar*H*), 7.29 (2H, d, *J* 6.8 Hz, PyH_β), 7.20 (1H, s, Ar*H*), 7.09 (2H, s, Ar*H*), 3.92–3.72 (10H, m, –CH_2–), 2.79–2.60 (12H, m, $NH_2CH_2CH_2NH_2$).

Li[$Cp_2Zr(C{\equiv}CPh)(\eta^2{:}1,2\text{-}PhC_2C{\equiv}CPh)$]: an anionic zirconium(II) intermediate for carbon–carbon coupling

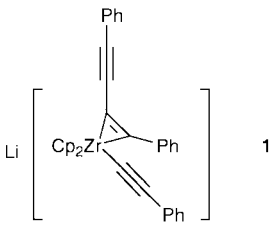
Robert Choukroun,* Jianshe Zhao, Christian Lorber, Patrick Cassoux and Bruno Donnadieu

Equipe Précurseurs Moléculaires et Matériaux, Laboratoire de Chimie de Coordination du CNRS, 205 Route de Narbonne, 31077, Toulouse Cedex, France. E-mail: choukrou@lcc-toulouse.fr

Received (in Basel, Switzerland) 5th June 2000, Accepted 5th July 2000
Published on the Web 24th July 2000

The unexpected anionic Zr^{II} complex $[Cp_2Zr(C{\equiv}CPh)(\eta^2{:}1,2\text{-}PhC_2C{\equiv}CPh)]^-$ was isolated from $LiC{\equiv}CPh$ and Cp_2ZrCl_2 in THF, giving clear evidence for a CC coupling between two alkynyl moieties, one of them being η^2-bonded to the zirconium atom.

New prospects towards non linear optical (NLO) materials have induced, in recent years, a resurgence of interest in the chemistry of acetylenic transition metals complexes.[1] Numerous studies have focused on the CC coupling of the acetylenic moieties, which underlies the synthesis of the building block of the poly-ynes.[2] We have been interested in the reaction of vanadocene with poly-ynes.[3] An unexpected heterodimetallic complex $Cp_2V(\mu{:}\eta^2{:}\eta^4\text{-}PhC{\equiv}CC{\equiv}CPh))ZrCp_2$, containing a butadiene framework with two internal planar tetracoordinate carbons was isolated from Cp_2V and $Cp'_2Zr(C{\equiv}CPh)_2$ (Cp′ = C_5H_5, C_5H_4Me, $C_5H_4Bu^t$, $C_5H_4SiMe_3$).[4,5] The chemistry of these bis(alkynyl)metallocene precursors has previously been detailed[6–8] and their synthesis, generally in diethyl ether solvent, well described.[6] On the other hand, a CC bond forming reaction was reported by Negishi *et al.*[9] as resulting from the reaction of Cp_2ZrCl_2 with 3 equiv. of $LiC{\equiv}CPh$ in THF followed by hydrolysis affording the isomerically pure (*Z*)-1,4-diphenylbut-1-ene-3-yne. In this process, Li[$Cp_2Zr(C{\equiv}CPh)_3$] was postulated as an intermediate species.[9] The authors underline the necessity of the third equiv. of $LiC{\equiv}CPh$ to $Cp_2Zr(C{\equiv}CPh)_2$ to produce the CC coupling. More recently, the $[Zr(C{\equiv}CR)_3]^-$ anion moiety was suggested as being an intermediate species in the trimerization of *tert*-butyl acetylene to 1,3,6-tri(*tert*-butyl)fulvene.[10] We report here the X-ray structure of the intermediate anion species Li[$CpZr(C{\equiv}CPh)(\eta^2{:}1,2\text{-}PhC_2C{\equiv}CPh)$] and some aspects of its formation mechanism.



1

When the reaction of Cp_2ZrCl_2 with 2 equiv. of $LiC{\equiv}CPh$ is carried out in THF, followed by slow diffusion of pentane, the unexpected Zr^{II} lithium salt species Li[$Cp_2Zr(C{\equiv}CPh)(\eta^2{:}1,2\text{-}PhC_2C{\equiv}CPh)$] **1**,† was obtained as a red crystalline complex and fully characterized by an X-ray structure determination (Fig. 1).‡ The main feature of this structure gives clear evidence for a CC coupling between two alkynyl moieties, one of them being η^2-bonded to the zirconium atom. A titanium complex related to **1**, namely $(C_5Me_5)_2Ti(\eta^2{:}1,2\text{-}RC_2C{\equiv}CR)$] was also recently isolated by Rosenthal *et al.* by Mg reduction of $(C_5Me_5)_2TiCl_2$ in the presence of $Me_3SiC_4SiMe_3$.[11*a*] Depending on the ratio of the reactants, this reaction also affords either the tweezer Ti^{III} complex $[(C_5Me_5)_2Ti(\eta^1\text{-}C{\equiv}CSiMe_3)_2][Mg(THF)Cl)]$ (A) or $[(C_5Me_5)_2Ti((\eta^3\text{-}Me_3SiC_3{=}C(C{\equiv}CSiMe_3)SiMe_3]$[11*b*] (B). The tweezer Ti^{III} complex (A) could be described as an intermediate for the formation of complex (B).

Different crossing reactions were monitored by ^1H NMR to gain an understanding of the formation of **1**.§ When the reaction of Cp_2ZrCl_2 and 2 equiv. of $LiC{\equiv}CPh$ is carried out in THF and in the absence on sunlight, $Cp_2Zr(C{\equiv}CPh)_2$ **2** was obtained as the sole product and can be kept unchanged at least one week in the dark, whereas in presence of daylight only **1** is formed.[12] Starting from **2** and the solid lithium salt $LiC{\equiv}CPh$ in THF-d_8, complete consumption of the Li salt gives **1** nearly immediately and quantitatively in absence or in presence of daylight. We checked that in the absence of daylight no reaction occurs in C_6D_6 between **2** and $LiC{\equiv}CPh$ (1 : 1) whereas still in the absence of daylight the addition of THF-d_8 in the NMR tube, which dissolves the lithium salt, immediately generates **1**.

Complementary hydrolysis experiments on complex **1** containing the preformed CC coupling were performed to ensure that the 1,4-diphenylbut-1-en-3-yne is also formed in this case. In presence of HCl and at room temperature, hydrolysis of **1** leads to the formation of *E* and *Z* isomers of the enyne $PhCH{=}CHC{\equiv}CPh$ with a high selectivity when the reaction is carried out in toluene (toluene: *Z*:*E* = 98 : 2; THF: *Z*:*E* = 30 : 70).¶ Adding $LiC{\equiv}CBu^t$ to **2** followed by HCl hydrolysis gives *Z* enynes, namely $PhCH{=}CHC{\equiv}CBu^t$, $PhC{\equiv}CCH{=}CHBu^t$ and PhCHCHC≡CPh (roughly 30, 15, 55% respectively, characterized by GC/MS and ^1H NMR).‖ This result suggests that the first step of the reaction is the formation of the

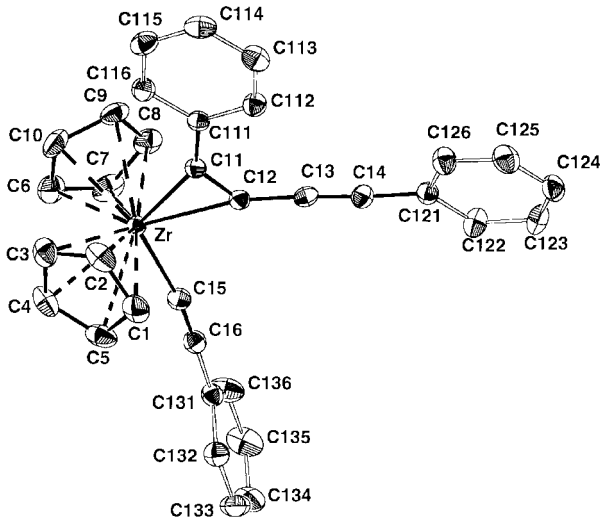


Fig. 1 Molecular structure of anionic $[\mathbf{1}]^-$ with selected bond distances (Å) and angles (°), hydrogen atoms omitted. Scheme 1

$Li[Cp_2Zr(C{\equiv}CPh)_2(C{\equiv}CBu^t)]$ intermediate which could give three possible species such as $Li[Cp_2Zr(C{\equiv}CPh)(\eta^2:1,2\text{-}PhC_2C{\equiv}CBu^t)]$, $Li[Cp_2Zr(C{\equiv}CPh)(\eta^2:1,2\text{-}Bu^tC_2C{\equiv}CPh]$ and $Li[Cp_2Zr(C{\equiv}CBu^t)(\eta^2:1,2\text{-}PhC_2C{\equiv}CPh)]$, the formation of the latter being favoured by the presence of the less steric R = Ph group on the η^2 chain.**

The CC coupling between two alkynyl moieties from $Cp'_2Zr(C{\equiv}CR)_2$ ($Cp' = C_5H_5$, R = Bu^t; $Cp' = C_5Me_5$, R = Ph, $SiMe_3$) has already been demonstrated by Rosenthal *et al.*[11,13,14] This reaction occurs under *hν* irradiation or sunlight to give the zirconacyclocumulene complex $Cp'_2Zr(\eta^4:1,2,3,4\text{-}RC{=}C{=}C{=}CR)$.†† Thus $(C_5H_5)_2Zr(\eta^4:1,2,3,4\text{-}PhC{=}C{=}C{=}CPh)$ **3** should be an excellent candidate for explaining the formation of **1**. Starting from **3**, generated by *hν* daylight in THF-d_8 from **2**,[12] addition of one equiv. of LiC≡CPh gives **1**. This experiment is indicative of an equilibrium between the zirconacyclocumulene and a ($\eta^2:1,2\text{-}PhC_2C{\equiv}CPh$) containing species (Scheme 1) as already mentioned by Rosenthal *et al.*[13] Nevertheless the formation of the zirconacumulene species must be catalysed either by daylight, or by the $B(C_6F_5)_3$ borane,[15] or by the Cp_2V vanadocene for at least one day. By contrast, the formation of the ($\eta^2:1,2\text{-}PhC_2C{\equiv}CPh$) moiety in **1** is immediate in THF when adding the third LiC≡CPh equiv. to the bis(alkynyl)zirconocene complex. No catalytic reaction from **2** to **3** with LiC≡CPh as catalyst was observed by ^1H NMR.

At this stage we are not in a position to prove the involvement of LiC≡CPh in a photoassisted reaction with **2** leading to **1**. However, it is noteworthy that when the reaction is carried out in the dark, it yields only **2**. Our results clearly suggest that the alkynyl coupling reaction is induced by a third alkynyl ligand *via* the formation of the unstable 'ate' intermediate Zr^{IV} species $Li[Cp_2Zr(C{\equiv}CPh)_3]$, or an assumed tweezer Zr species $[Cp_2Zr(C{\equiv}CPh)_2][Li(C{\equiv}CPh)]$, which may subsequently rearrange to **1**.[16]

† *Spectroscopic data* for $C_{42}H_{41}LiO_2Zr$ **1**: M = 675.9, Calc: C, 74.55; H, 6.06. Found: C, 74.72; H, 5.86%; (40% yield based on 2 equiv. LiC≡CPh; 75% yield when the reaction is performed with 3 equiv. LiC≡CPh). IR (Nujol): ν(C≡C) 2063, 2110 cm^{-1}; ^1H NMR (C_6D_6, δ/ppm) 8.26 (pseudo triplet, 2H, *o*-Ph from the η^2-PhC_2-bonded to the zirconium atom), 7.54–6.9 (m, 13H, Ph), 5.78 (s, 10H, Cp), 3.36, 0.95 (m, 16H, THF). A ^1H NMR VTP of the complex from −80 to +80 °C does not show any change in the solution structure. Assignement of the ^{13}C NMR spectrum of **1** in THF-d_8 (δ/ppm, J(Hz)) could be tentatively done with a JMOD and 2D heteronuclear correlation technique (inverse HMQC (LR), gradient selected). $Li[Cp_2Zr(C_\alpha{\equiv}C_\beta Ph)(\eta^2\text{-}PhC_a{\equiv}C_b\text{-}C_c{\equiv}C_dPh)]$, **1**: 205.9 (s, $^3J_{CH}$ = 4 Hz, C_b), 134.9, 130.4, (s, C_a/C_α), 97.6 (s, C_c), 126.4/107.4 (t, $^3J_{CH}$ = 4–5 Hz, C_β/C_d), 142.5, 127.9, 128.3 (t, ^2J = 7–8 Hz, C_{ipso}), 130.8, 129.8, 129.0, 128.4, 128.2, 128.0, 126.1, 126.0, 125.8 (d, $^1J_{CH}$ = 158–162 Hz, Ph), 105.0 (d, $^1J_{CH}$ = 171 Hz, Cp).

‡ *Crystallographic data* for **1**: $C_{34}H_{25}LiZr{\cdot}2THF$ M = 675.95, monoclinic, space group $P2_1/c$, a = 14.986(2), b = 10.4594(8), c = 22.028(2) Å, β = 102.07(1)°, V = 3376(1) Å^3, D = 1.33 g cm^{-3}, μ = 3.61 cm^{-1}, $R(Rw)$ = 0.0272 (0.0722) for 4701 unique data and 415 parameters, G.O.F. = 1.04. Data collection were performed at *ca.* 160 K on a IPDS STOE diffractometer using graphite monochromatized Mo-Kα radiation. The structure was solved by direct methods and subsequent difference Fourier maps. CCDC 182/1708. See htpp://www.rsc.org/suppdata/cc/b0/b004478o/ for crystallographic files in .cif format.

§ A suspension of Cp_2ZrCl_2 (0.900 g, 3.08 mmol) was treated with 2 equiv. solid LiC≡CPh (0.665 g, 6.16 mmol) in benzene for 4 h and species such as Cp_2ZrCl_2, $Cp_2ZrCl(C{\equiv}CPh)$ and **2** were identified by ^1H NMR (in nearly 1:4:1 ratio respectively). After 24 h stirring and work-up, **2** was obtained as a crystalline solid (0.840 g, 64% yield). With 3 equiv. LiC≡CPh for 24 h, in the same experimental conditions, a red solution is obtained with the appearance of a paramagnetic Zr^{III} species (g = 1.997, $a(^{91}Zr)$ = 37 G, 20%) which broadens the ^1H NMR signals of the solution (the main peak observed at 5.6 ppm could not be assigned). Different experiments were conducted in THF and in absence of daylight (to avoid the formation of the zirconacyclocumulene species) between $(C_5H_4R)_2Zr(C{\equiv}CPh)_2$ (R = Me, $SiMe_3$) and LiC≡CPh. ^{13}C NMR spectroscopy shows the characteristic peak of the ($\eta^2:1,2\text{-}PhC_2C{\equiv}CPh$) moiety at 208 and 205 ppm for R = Me and $SiMe_3$, respectively which suggests the *in situ* formation of $Li[(C_5H_4R)_2Zr(C{\equiv}CPh)(\eta^2:1,2\text{-}PhC_2C{\equiv}CPh)]$ (R = Me, $SiMe_3$) (for $Cp^*_2Ti(\eta^2:1,2\text{-}Me_3SiC_2C{\equiv}CSiMe_3$[11] two peaks were observed at 227 and 205 ppm). Hydrolysis of the THF mixture with HCl gives the *Z/E* enynes (30:70).

¶ It is of note that Cp_2ZrCl_2 + 3 equiv. LiC≡CPh in toluene at room temperature for 24 h selectively affords, after hydrolysis, the *Z* isomer whereas the same reaction carried out in THF gives a mixture of *Z/E* isomers (40:60). The *Z* isomer was selectively obtained in THF when the reaction is carried out at −80 °C.[9]

‖ Hydrolysis experiments with HCl on $(C_5H_4R)_2Zr(\eta^4:1,2,3,4\text{-}PhC{=}C{=}C{=}CPh)$ (R = H, Me, $SiMe_3$) give in toluene or in THF solution nearly 100% of the *E* isomer PhCH=CH-C≡CPh, in contradiction with the described results in which the η^2 coordination is involved.

** LiC≡CBu^t was added to **2** in THF; after stirring for 4 h, the solvent was evaporated to dryness and replaced by toluene. Hydrolysis with HCl (3 equiv. in solution in diethyl ether) gives Z enynes; ^1H NMR (δ/ppm, $CDCl_3$, 250 MHz), MS: PhCH=CHC≡CBu^t: 6.55, 5.69, (d, CH=CH, J = 12 Hz), 1.32 (s, Bu^t), MS: 184; PhC≡CCH=CHBu^t: 5.87, 5.60, (d, CH=CH, J = 12 Hz), 1.26 (s, Bu^t), MS: 184; PhCH=CHC≡CPh: 6.70, 5.92, (d, CH=CH, J = 12 Hz), MS: 204. When HCl hydrolysis was performed in THF, a mixture of *Z/E* enynes was observed by GC/MS but not further characterized.

†† ^1H and $^{13}C\{^1H\}$ NMR of the reaction show complex spectra in which three main cyclopentadienyl signals can be observed at 5.76, 5.71, 5.67/105.0, 104.9, 104.7 ppm; low field quaternary carbons at 228, 225.9, 208.2, 205.9, 203, 202 ppm were also observed.

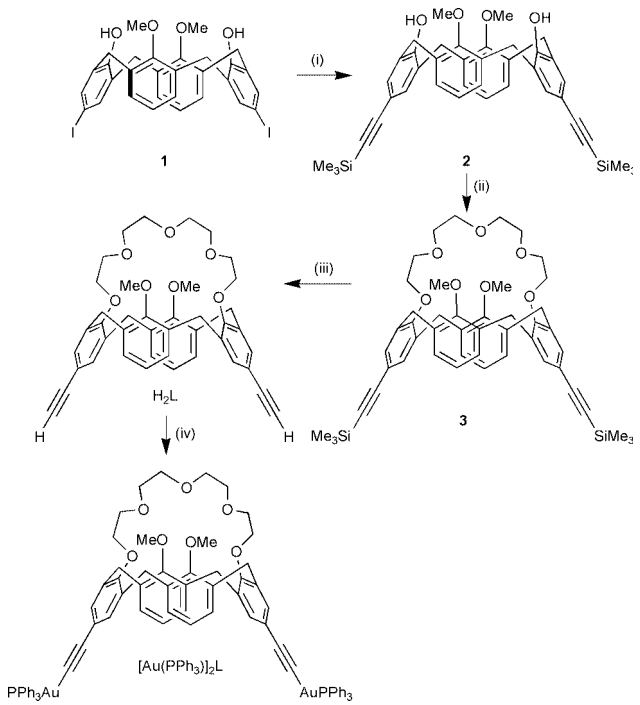
Received (in Cambridge, UK) 3rd May 2000, Accepted 21st June 2000
Published on the Web 24th July 2000

A novel dinuclear gold(I) calix[4]crown acetylide complex, $[Au(PPh_3)]_2L$, has been synthesized and structurally characterized; binding studies of the complex revealed a high K^+/Na^+ selectivity.

During the last decade, there has been a growing interest in the study of calix[*n*]arenes,[1,2] owing to their unique molecular structure and simple one-pot preparation. Indeed, calix[4]arene has proven to be a very important building block in supramolecular chemistry.[3] The easy chemical transformability of this molecule, together with its 'tunable' molecular shape and conformation, makes calix[*n*]arene an attractive candidate for molecular design strategies and has led to an increasing number of examples in the literature. In particular the calix[4]arene is the best developed of the calix[*n*]arene family as a molecular scaffold for the synthesis of more elaborate molecules, supramolecular assemblies, sensors,[4] and receptors.[5]

The recent interest in calixcrowns, which represent a class of calixarenes functionalized with crown ether moieties on the lower rim, together with our recent efforts in the utilization of crown ether-containing metal complexes in the design of selective spectrochemical and luminescence ion probes,[6] have prompted us to extend our work to the calixcrown system. Herein are reported the synthesis, structural characterization, and binding behaviour of a novel dinuclear gold(I) calix[4]-crown acetylide complex.



Scheme 1 *Reagents and conditions*: (i) $HC{\equiv}CSiMe_3$, Et_3N, $Pd(PPh_3)_2Cl_2$, CuI; (ii) tetraethylene glycol bis(toluene-*p*-sulfonate), Cs_2CO_3, CH_3CN; (iii) KF, DMF, 65 °C; (iv) NaOEt, $(PPh_3)AuCl$, EtOH.

The reaction of (**1**)[7] with (trimethylsilyl)acetylene in the presence of CuI, $Pd(PPh_3)_2Cl_2$ and triethylamine for 24 h at *ca.* 40 °C gave **2** in 50% yield (Scheme 1). Introduction of the polyether linkage into the lower rim was accomplished by reacting **2** with tetraethylene glycol bis(toluene-*p*-sulfonate) in the presence of Cs_2CO_3 in MeCN to give **3**, followed by deprotection of the trimethylsilyl groups by KF to give H_2L in moderate yield. Reaction of $Au(PPh_3)Cl$ with H_2L in the presence of NaOEt in EtOH afforded the desired complex, $[Au(PPh_3)]_2L$, as pale yellow crystals after subsequent recrystallisation using dichloromethane–*n*-hexane. The identities of **2**, **3**, H_2L and $[Au(PPh_3)]_2L$ have been confirmed by satisfactory elemental analyses, ^1H NMR, ^{31}P NMR, IR, and FAB-MS.† The structure of $[Au(PPh_3)]_2L$ has also been determined by X-ray crystallography.‡

Fig. 1 shows $[Au(PPh_3)]_2L$ with atomic numbering. The calix[4]crown in the gold(I) complex shows a cone conformation. Cone conformation is also known in 1,3-calixcrown compounds[8] although a 1,3-alternate conformation[9] is more commonly found. The two gold atoms adopt an essentially linear coordination geometry, with P–Au–C bond angles of

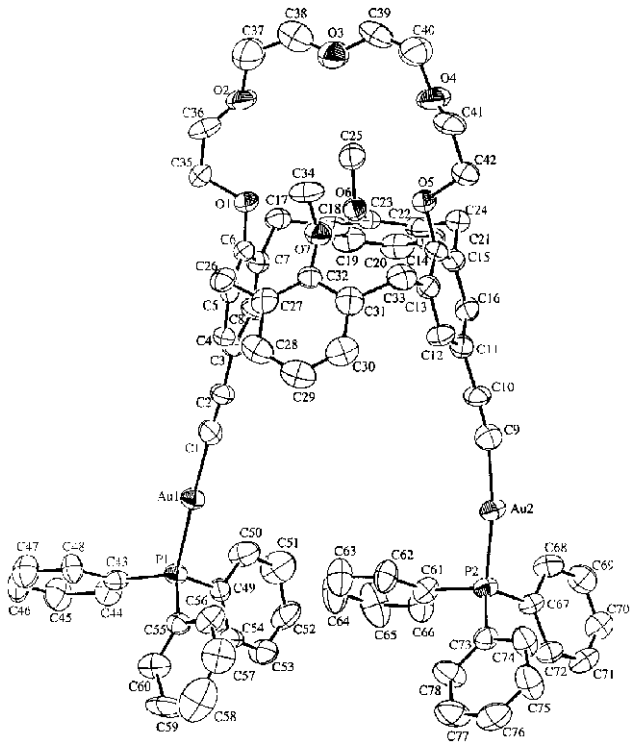


Fig. 1 Perspective drawing of $[Au(PPh_3)]_2L$ with atomic numbering. Hydrogen atoms have been omitted for clarity. Thermal ellipsoids are shown at the 40% probability level. Selected bond distances (Å) and bond angles (°): Au(1)–P(1) 2.283(3), Au(2)–P(2) 2.275(3), Au(1)–C(1) 2.04(1), Au(2)–C(9) 2.04(1), C(1)–C(2) 1.18(2), C(9)–C(10) 1.17(2); P(1)–Au(1)–C(1) 177.9(4), P(2)–Au(2)–C(9) 170.5(4), Au(1)–C(1)–C(2) 177(1), Au(2)–C(9)–C(10) 166(1).

DOI: 10.1039/b003536j

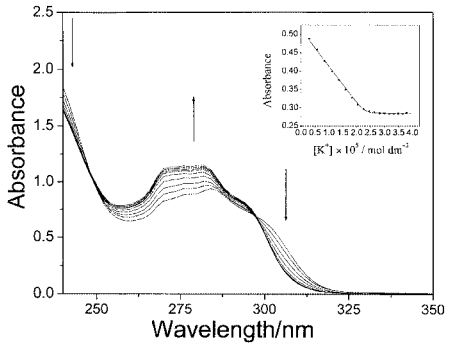

Fig. 2 UV-Vis absorption spectral changes of $[Au(PPh_3)]_2L$ (2×10^{-5} mol dm^{-3}) upon addition of various concentrations of potassium hexafluorophosphate in dichloromethane–methanol (1 : 1 v/v) containing 0.1 mol dm^{-3} tetra-*n*-butylammonium hexafluorophosphate as supporting electrolyte. The insert shows a plot of *A versus* [K^+] at 304 nm and its theoretical fit.

170.5(4) and 177.9(4)°; the slight deviation from a perfect 180° is probably a result of the steric demand of the ligands and crystal packing forces. The C≡C bond lengths of 1.18(2) and 1.17(2) Å are typical of terminal Au(I) acetylides.[10,11]

The electronic absorption spectra of $[Au(PPh_3)]_2L$ in dichloromethane–methanol (1 : 1 v/v) containing 0.1 M tetra-*n*-butylammonium hexafluorophosphate as supporting electrolyte show spectral changes upon addition of K^+ and Na^+ ions. Fig. 2 shows the UV-vis spectral traces of $[Au(PPh_3)]_2L$ upon addition of K^+ ions. Isosbestic points were observed at 244 and 298 nm which are indicative of a clean reaction. Theoretical fits of the plots of absorbance *vs.* [K^+] or [Na^+] to eqn. (1) derived for a

$$X = X_o + \frac{X_{lim} - X_o}{2C_o}[C_o + C_m + 1/K_s - [(C_o + C_m + 1/K_s)^2 - 4C_oC_m]^{\frac{1}{2}}] \quad (1)$$

1 : 1 complexation stoichiometry gave the stability constant K_s. In eqn. (1) X_o, X and X_{lim} are the initial absorbance of $[Au(PPh_3)]_2L$, the absorbance after the addition of a given amount of salt at concentration C_m, and the limiting absorbance of $[Au(PPh_3)]_2L$ in the fully complexed state, respectively; C_o is the initial concentration of $[Au(PPh_3)]_2L$ and C_m is the total salt concentration. The log K_s values of 7.24 and 2.75 were obtained for the binding of K^+ and Na^+ ions, respectively. The selective recognition of K^+ over Na^+ with a K^+/Na^+ selectivity of 3×10^5, which is higher than a related 1,3-dimethoxycalix[4]arene crown compound (K^+/Na^+ selectivity = 3×10^3),[9a] and even higher than that of the naturally occurring valinomycin,[12] may suggest that the present complex would serve as a promising candidate for application as a selective K^+ ion chemosensor.

Reaction of the lithium salt of *N*,*N*′,*N*″-triisopropylguanidinate with Fe(III) or Fe(II) halides led to isolation of the new species $[(Pr^iN)_2C(HNPr^i)]_2FeCl$ (1) and $[\mu\text{-}\eta^2\text{-}(Pr^iN)_2C(HNPr^i)]_2\{Fe[\eta^2\text{-}(Pr^iN)_2C(HNPr^i)]\}_2$ (2); attempted alkylation of 1 with 1 equiv. of a variety of reagents produced 2; the reaction of 2 with $LiCH_2SiMe_3$ resulted in a coupling reaction between the two bridging ligands to yield $[(\mu\text{-}\eta^2:\eta^2\text{-}(Pr^iN)_2C)_2NPr^i)]\{Fe[\eta^2\text{-}(PrN^i)_2C(HNPr^i)]\}_2$.

Amidinate anions are well established as versatile ligands for a variety of transition metal complexes and particularly for compounds for the early transition metals.[1,2] In contrast, the isoelectronic *N*,*N*′,*N*″-trialkylguanidinate anions have received very limited attention as ligands in organometallic and coordination chemistry (Fig. 1).[3,4] We anticipate that these species will exhibit the same flexibility in coordination properties as amidinates and that the presence of the third nitrogen center should lead to novel coordination properties. Furthermore, the added potential of generating dianionic species, by deprotonation of the second N–H function, may yield a unique, conjugated π system.

The scarcity of Fe complexes supported with anionic nitrogen-centered ligands warrants exploration of guanidinate ligands in this regard. Interestingly, the first transition metal complexes with dianionic guanidinate ligands are represented by the dinuclear iron complexes $[\mu^2\text{-}(RN)_3C][Fe(CO)_3]_2$ (R = Cy, Pr^i).[5] These species were formed by the reaction of the appropriate carbodiimide with $Fe(CO)_5$ and remain the sole examples of guanidinate anions employed in Fe chemistry.

We wish to report our initial exploration into the use of *N*,*N*′,*N*″-trisubstituted guanidinates as supporting ligands for Fe(II) and Fe(III). This necessarily requires the development of fundamental ideas regarding the introduction of these ligands into the metal coordination sphere as well as definition of the reactivity of these species.[3,4,6]

The *N*,*N*′,*N*″-tri(alkyl)guanidinatolithium $[[(RN)_2C(HNR)]Li$ (R = Pr^i, Cy) starting materials were formed by direct reaction of the guanidine with 1 equiv. of either MeLi or Bu^nLi.[4] In all cases, metathesis reactions with iron halides were carried out with freshly prepared solutions of lithium guanidinate in ether or THF (Scheme 1). Addition of 0.5 equiv. $FeCl_3$ to a solution of $[(Pr^iN)_2C(HNPr^i)]Li$ followed by recrystallization from pentane resulted in isolation of the new bis(guanidinate)iron(III) chloride complex $[(Pr^iN)_2C(HNPr^i)]_2FeCl$, **1** (Scheme 1).[7] The solid state structure of **1** revealed a monomer with two monoanionic chelating bidentate guanidinate ligands yielding planar M–N–C–N cycles as depicted in Scheme 1.[8] The coordination sphere of the metal is completed by a terminal chloride to generate a distorted pseudo-trigonal bipyramidal geometry for **1** with approximate C_2 symmetry. The average Fe–N_{ax} bond distances of 2.085(3) Å are slightly longer than the average Fe–N_{eq} distances of 2.008(3) Å. The C–N bond distances within the chelate rings (average 1.34, 1.36 Å) are consistent with partial double bond character within the NCN moiety. The central C atoms of the guanidinates, the Cl ligand and the Fe center are coplanar.

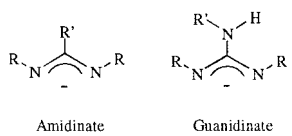

Fig. 1

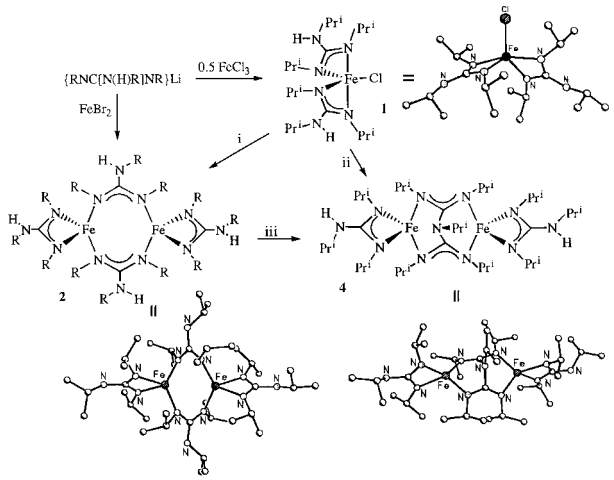

Scheme 1 Reaction scheme for the preparation of **1**, **2** and **4** and the structures of these complexes. *Reagents and conditions*: i, LiMe, $LiCH_2(SiMe_3)$, $ZnEt_2$, or BzMgCl; ii, 2 $LiCH_2(SiMe_3)$; iii, $LiCH_2(SiMe_3)$.

Attempts to exchange the chloro ligand of **1** with an alkyl group using a variety of reagents including RLi (R = Me, $CH_2(SiMe_3)$), $ZnEt_2$, and BzMgCl were examined. In all cases, reduction of the metal center from Fe(III) to Fe(II) was observed and complex **2** was isolated in 40–80% yields.[7] Single crystal X-ray analysis of this new product showed it to be a dinuclear species with two bridging guanidinate ligands and two chelating bidentate ligands with formula $Fe_2[\mu\text{-}\eta^2\text{-}(Pr^iN)_2C(HNPr^i)]_2[\eta^2\text{-}(Pr^iN)_2C(HNPr^i)]_2$ (Scheme 1).[8] Another route to the Fe(II) dinuclear species **2** was *via* direct reaction of $FeBr_2$ with 2 equiv. of $[(Pr^iN)_2C(HNPr^i)]Li$ in THF followed by recrystallization from ether. This method led to isolation of **2** in 82% yield.

The coordination sphere for each Fe center is composed of four nitrogen centers of the two different ligands. The N–Fe–N bond angles exhibit a broad range of values from 63.3 to 132.3° with an average of 106°. The Fe–N bond distances vary from 2.056(6) to 2.127(7) Å. The two chelating bidentate ligands in **2** are planar and exhibit bonding parameters reminiscent of other complexes with chelating monoanionic guanidinates such as **1**. In contrast the bridging ligands appear to be quite distorted. The central C atoms of both of these groups are planar and the four N centers deviate only slightly from planarity. The CN bond distances within the bridging groups are indicative of delocalized π-bond (av. 1.33 Å). Furthermore, the average C–N(H)Pr^i distance of 1.41 Å is consistent with a CN single bond. However, the bridging ligands coordinate to the two Fe centers with a decided twist that can be described by the dihedral angle α represented in Fig. 2. In **2** these angles are 67.2 and 70.3°.

A similarly distorted bridging ligand was observed in the case of the benzamidinate complex $Fe_2(\mu\text{-DPhBz})_2(DPhBz)_2$ (**A**).[9]

DOI: 10.1039/b003547p

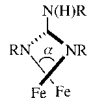

Fig. 2

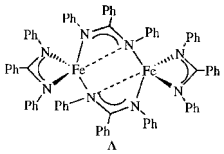
In **A** the severe distortion of the bridging ligands was attributed to a weak intramolecular Fe···N interaction at a distance of 2.477(4) Å. In the case of **2** the two closest non-coordinated N atoms to the Fe centers are at distances of 2.970 and 3.007 Å. These distances are considerably further than in **A** and seem



A

unlikely to be the result of an interaction between these atoms. The possibility of an Fe–Fe bond in **2** can be excluded based on the large iron–iron separation of 3.264 Å.

We have further evidence that the bonding features observed for **2** may be general for this ligand system. In a reaction scheme similar to that used in the preparation of **2**, $FeBr_2$ was reacted with 2 equiv. of $[(CyN)_2C(HNCy)]Li$ in ether to successfully generate the cyclohexyl analogue, $Fe_2[\mu\text{-}\eta^2\text{-}(CyN)_2C(HNCy)]_2[\eta^2\text{-}(CyN)_2C(HNCy)]$ **3**. The resemblance of the metrical parameters of **3** with those of **2** was confirmed through a structural analysis.[10] Complex **3** displayed a similar orientation for the bridging ligands with the dihedral angles α of 70.0 and 73.6°. In **3**, the closest non-coordinated N centers for each Fe were even further away than in **2** (*i.e.* 3.050 and 3.190 Å) and a long Fe–Fe separation (3.161 Å) ruled out a metal–metal bonding interaction.

It is worthwhile to note that for the molybdenum complex $Mo_2[\mu\text{-}\eta^2\text{-}(NPh)_2CNHPh]_4$, all four of the triaryl guanidinate ligands bridge the two metal centers resulting in the formation of a metal–metal bond and none of the bridging ligands demonstrate the distortion exhibited by complex **2**.[11]

Reaction of complex **1** with a variety of alkylating reagents led to reduction of the Fe(III) center and formation of the dinuclear structure **2**. When either **2** or **1** are allowed to react with additional $LiCH_2SiMe_3$ a reaction involving the guanidinate ligands was observed (Scheme 1). For example, reaction of **1** with 2 equiv. of $LiCH_2SiMe_3$ resulted in formation of the Fe(II) complex **4**. Examination of single crystals of **4** by X-ray diffraction provided the structure displayed in Scheme 1.[8]

The obvious result of the added lithium reagent is a coupling of the two bridging guanidinates to yield a bridging biguanidinate dianion. A likely pathway for the transformation of **2** to **4** begins with the deprotonation of one of the bridging ligands with the added lithium reagent to generate a nitrogen-centered anion. Subsequent attack of this nucleophilic center at the central carbon of the second bridging ligand and release an amido anion would generate the new dianionic ligand, $\{[(Pr^iN)_2C]_2NPr^i\}^{2-}$ observed for **4**.

Bonding parameters within the $\{[(Pr^iN)_2C]_2NPr^i\}^{2-}$ moiety are consistent with the resonance representation in Scheme 1. In particular, the π bonds within this species appear to be delocalized as depicted. Furthermore, the $C(NPr^i)_3$ carbon centers are planar (Σ = 360°) and the N atoms bonded to iron deviate only slightly from planarity (Σ = 357°). The two Fe atoms in **4** are separated by a distance of 4.945 Å.

The utility of *N*,*N*′,*N*″-trialkylguanidine ligands in the preparation of new Fe(II/III) complexes has been established. Attempts to alkylate bis(guanidinato)iron(III) chloride resulted in reduction of Fe(III) to Fe(II) and formation of dinuclear species. Complexes **1**–**4** demonstrate the versatility in coordination behavior for these ligands. Transformation of guanidinate ligands can be prompted by deprotonation and in the case of **2** led to the tetradentate biguanidinate dianion $\{[(Pr^iN)_2C]_2NPr^i\}^{2-}$. Our continuing efforts are directed toward understanding the details that dictate the formation of mono- *vs.* dianionic ligands and the intramolecular interactions exhibited by these ligands.

This work was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC).

7 The paramagnetic complexes **1**–**4** have been fully characterized by IR spectroscopy, magnetic susceptibility and elemental analysis. Connectivity for all of these species have been established through single crystal X-ray diffraction studies. In all cases suitable crystals were mounted in inert oil and transferred to the cold gas stream of the diffractometer. The structures were solved using direct methods and refined by full-matrix least-squared on F^2.

8 Crystals of **1** were obtained from pentane. *Crystal data* for $C_{20}H_{44}ClFeN_6$ **1**: M = 459.91 monoclinic, a = 9.631(2), b = 14.350(2), c = 19.259(3) Å, β = 98.581(3)°, U = 2631.9(7) Å^3, T = 238 K, space group $P2_1/c$, Z = 4, μ(Mo-Kα) = 0.690 mm^{-1}, reflections measured 20672 unique 3212 [R(int) = 0.1274] which were used in all calculations. Final R indices [$I > 2\sigma(I)$] $R1$ = 0.0470, $wR2$ = 0.0995. Vanadyl pyrophosphate-based VPO catalysts for butane oxidation to maleic anhydride can be completely rehydrated in the solid phase into their vanadyl hydrogenphosphate hemihydrate precursors which again can be transformed into vanadyl pyrophosphate thus enabling a reuse of spent catalysts.

Vanadyl pyrophosphate, $(VO)_2P_2O_7$, (VPP) is well known to be the active and selective component of VPO catalysts in the partial oxidation and ammoxidation of hydrocarbons. Owing to its unique catalytic properties it plays a significant role especially in the oxidation of *n*-butane to maleic anhydride (MA).[1]

VPP is formed by dehydration of vanadyl hydrogenphosphate hemihydrate, $VOHPO_4{\cdot}0.5H_2O$, (VHP) in a topotactic reaction at temperatures above 638 K according to eqn. (1):[2]

$$2\ VOHPO_4{\cdot}0.5H_2O \rightarrow (VO)_2P_2O_7 + 2\ H_2O \qquad (1)$$

Well crystallized VPP catalysts obtained by calcination at high temperatures (*e.g.* above 900 K) or after an equilibration procedure in a chemical reactor for hundreds of hours time on stream are described to be comparatively resistent against overoxidation.[3] In this state they are insoluble in boiling water and even poorly soluble in concentrated hydrochloric acid. No rehydration reaction of VPP has been mentioned until now. Experience shows that also the presence of large amounts of water vapour in the feed and effluent gases of oxidation reactions passing through the VPP catalyst bed does not lead to any detectable hydration of VPP resulting only in a loss of phosphorus[4] and influencing recrystallization processes in the catalyst particles.[5]

Therefore, it was surprising that in a well crystallized VPP sample having been kept for some years at room temperature in a laboratory atmosphere (with a typical moisture content of 2–3% water vapour) a small amount of VHP was detected by X-ray diffraction (XRD). This observation led us to study the behaviour of VPP at higher water vapour pressure to elucidate the rehydration process of this compound and to find a new advantageous route to regenerate spent catalysts. Therefore, we studied sequences of the hydrothermal transformation of VPP into VHP and of the reconversion of these VHP samples into VPP by calcination. Furthermore, the influence of these procedures was investigated on the catalytic properties of the VPP materials obtained.

The VPP samples applied in this study were prepared as follows: the precursor VHP A1 was synthesized after stepwise addition of V_2O_5 into a hot solution of oxalic acid in dilute phosphoric acid by evaporation to dryness. The precursor VHP B1 was prepared by reaction of V_2O_5 with an ethanolic solution of oxalic acid in phosphoric acid. The P:V ratio of both VHP compounds was 1:1. The precursors were pelletized, crushed, sieved (1.25–2.5 mm) and transformed into VPP A1 and VPP B1, respectively, in a N_2 stream at 770 K for 2 h. For deactivation and 'deselectivation' a sample of VHP A1 was calcined at 923 K for 6 h and then for 5 h at 1123 K yielding VPP C1. Renewed transformations of the obtained VPP A1, VPP B1 and VPP C1 samples led to the precursor samples VHP A2, VHP B2 and VHP C2, respectively, which were calcined again as described above forming the samples VPP A2, VPP B2 and VPP C2.

The rehydration experiments were performed as follows: The VPP A,B,C samples were placed together with water in an ampoule (molar ratio VPP : H_2O = 1 : 2.5) and heated at 393–413 K for 24 h. The hydration reaction led to VHP according to eqn. (2).

$$(VO)_2P_2O_7 + 2\ H_2O \rightarrow 2\ VOHPO_4{\cdot}0.5H_2O \qquad (2)$$

This change was evident by a change of colour to blue for the VHP A samples (broad distribution of particle sizes, average particle size: 6.2 μm) and to greenish for the VHP B samples (narrow distribution of particle sizes, average particle size: 1.7 μm). Another possibility to introduce water into VPP is its reaction with water-rich vanadyl hydrogenphosphate hydrates, *e.g.* according to eqn. (3).

$$3\ (VO)_2P_2O_7 + 2\ VOHPO_4{\cdot}4H_2O \rightarrow 8\ VOHPO_4{\cdot}0.5H_2O + H_2O \qquad (3)$$

Excess water was then removed from the samples by drying of the obtained solids at 400 K.

The catalytic tests were performed in a tube reactor using 3–10 cm^3 catalyst (granules 1.25–2.5 mm) after conditioning of the fresh VPP samples for 2 h at 750 K in a butane–air mixture (1.5 vol% butane). The maximum MA yields of the VPP samples from the VPP → VHP → VPP sequences were determined at constant space velocities (GHSV = 1000 h^{-1}) adjusting a butane conversion degree of 90% by variation of the reaction temperatures. For sample VPP C1 the space velocity was reduced to 500 h^{-1} to determine the MA yields at similar temperatures relative to VPP C2.

The VPO materials were characterized using XRD, BET and chemical methods.

Fig. 1 shows diffractograms for samples in the VPP B → VHP B → VPP B transformation sequence starting with the fresh sample VHP B1. The diffractogram of VHP B2 shows typical reflections of $VOHPO_4{\cdot}0.5H_2O$,[6] *i.e.* a quantitative conversion of VPP into the VHP precursor took place. This result and the sequence of the other diffractograms in Fig. 1 reveal that the dehydration and rehydration, respectively, of VHP and VPP are reversible over a number of cycles. Preliminary experiments showed that the rates of the conversions depend on the partial pressure of H_2O, the temperature and on the properties of the solids such as their crystallinity and particle size.

The FWHM of the VPP B1–3 reflections (200) decreased from 2θ = 1.13° (VPP B1) to 2θ = 1.07° (VPP B2) and 2θ = 1.02° (VPP B3). This result was mirrored by the decrease of the FWHM of the same reflections from 2θ = 0.305 to 0.231° for the VPP A1–3 samples. Both findings are interpreted to be caused by recrystallization processes occurring especially during the hydration. Simultaneously, the specific surface areas decreased from 1.8 to 1.5, 12.2 to 11.2, 13.9 to 8.8 and 14.5 to 13.0 $m^2\ g^{-1}$ for VHP A, B and VPP A, B samples, respectively. This behaviour may also be explained by recrystallization leading to an increase in crystallite sizes. The remarkable increase in the specific surface areas in the conversion of VHP to VPP samples is interpreted in terms of particle size effects.[7]

DOI: 10.1039/b003700l

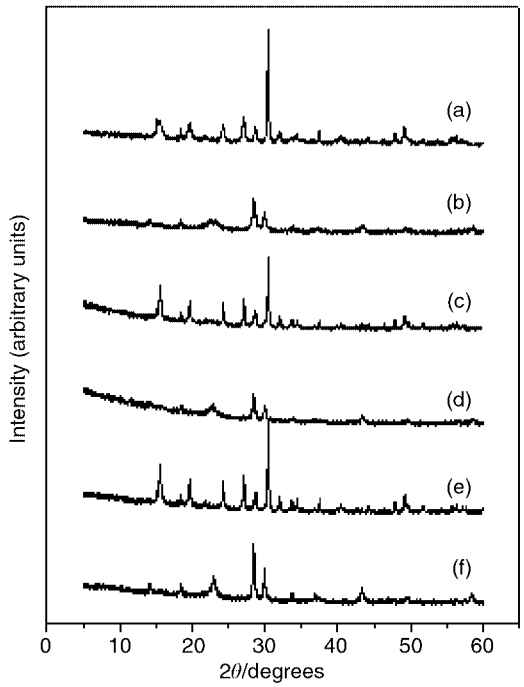

Fig. 1 Diffractograms of VHP B and VPP B samples measured during the transformation VPP B → VHP B → VPP B: (a) VHP B1, (b) VPP B1, (c) VHP B2, (d) VPP B2, (e) VHP B3, (f) VPP B3.

The fact that the colours of the different VHP samples in the sequences A1–3 and B1–3, did not change during the dehydration–rehydration transformations suggest a topotactic nature of this reaction as expected for the mild hydration conditions and the transformation rate.

The maximum MA yields of VPP A samples obtained in the course of several transformation sequences and the corresponding catalyst temperatures necessary to adjust a butane conversion degree of 90% demonstrate that the transformations can lead to both a decrease in activity and selectivity of the VPP samples: the MA yields decreased from 52 mol% MA (VPP A1) to 45 mol% MA (VPP A4 sample, obtained after the third transformation sequence) and the temperatures for 90% butane conversion increased from 690 to 707 K. This finding is interpreted to be caused by the recrystallization effect discussed above: from catalytic and EPR experiments using VPP samples of different crystallinity it is known that maximum catalytic performance requires a certain degree of disorder in the VPP lattice.[8] This is supported by recent results which showed that the catalytic performance of well crystallized VPP may be improved by tribomechanical treatment upon milling samples.[9]

Fig. 2 shows the catalytic results of the well crystallized sample VPP C1 (deactivated and 'deselectivated' by prolonged calcination at high temperatures) and of the regenerated sample VPP C2. The figure clearly shows that the transformation led to a marked increase in both the activity and the selectivity of the VPP C2 sample. This result can be explained by the increase in the low surface area from 3.2 $m^2\ g^{-1}$ of the deactivated sample to 15.9 $m^2\ g^{-1}$ of the regenerated sample and by an increase in the lattice disorder of the latter due to the transformation procedure.

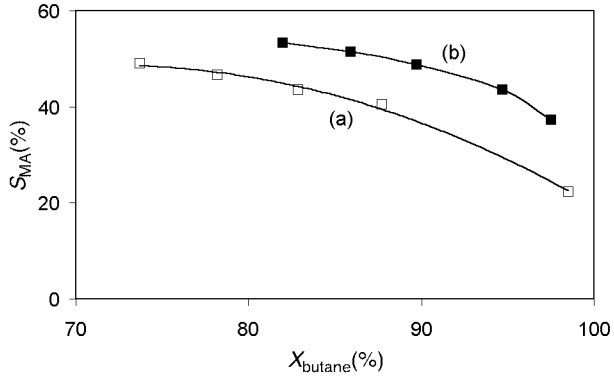

Fig. 2 MA selectivities of samples VPP C1 (a) and VPP C2 (b) as a function of the degree of conversion of butane, GHSV: 500 h^{-1} (VPP C1), 1000 h^{-1} (VPP C2), reaction temperatures: VPP C1: from 716 K ($X_{C_4H_{10}}$ = 73.7%) to 768 K ($X_{C_4H_{10}}$ = 98.5%), VPP C2: from 703 K ($X_{C_4H_{10}}$ = 82%) to 740 K ($X_{C_4H_{10}}$ = 97.5%).

The presented results illustrate that the described method is suitable for regenerating spent catalysts. Furthermore, as shown by additional experiments, it could open a way to adjust the P : V ratio in regenerated catalysts by adding the desired amount of phosphoric acid to the amount of water necessary for the transformation procedure. The new route presented here avoids chemical conversion of the spent materials by dissolution or other processes followed by separation procedures to recover the vanadium component. It could also be an alternative method of regeneration instead of treatments of catalyst beds with halide containing compounds[10] which can cause difficult technical and environmental problems.

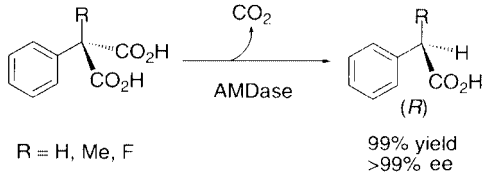
Arylmalonate decarboxylase (EC. 4. 1. 1. 76) catalysed decarboxylation followed by enantioface-differentiating protonation of [α-^{2}H]- and [α-^{1}H]phenylmalonic acid in ^1H_2O and ^2H_2O respectively, gave highly enantiomerically enriched (*R*)- and (*S*)-[α-^{2}H]phenylacetic acid in quantitative yields.

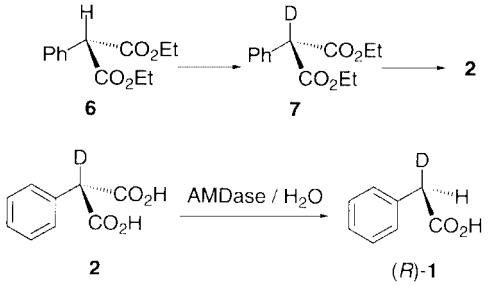
Regio- and stereospecifically [^{2}H]-labelled compounds are very useful in studying metabolic pathways and reaction mechanisms. Phenylacetic acid is the intermediary metabolite of aromatic amino acids, and also the starting material of amphetamine. For studies in this field, it will be of great use if both of the enantiomers of [α-^{2}H]phenylacetic acid **1** are available. So far, enantiomerically enriched forms of **1** have been synthesized *via* deuteriolysis of (*R*)-(−)-*N*,*N*-dimethylphenylglycine[1] and oxidative addition of optically active [α-^{2}H]benzyl halides to palladium complexes, followed by carbonyl insertion.[2] However, the products of these two methods suffer from the low enantiomeric excess (55[1], 76%[2]) and contamination of di-deuterated and non-deuterated by-products. It is practically impossible to raise the ee of the product and to separate these by-products by ordinary methods, as there are no chemical differences between the two enantiomers, and labeled and non-labeled compounds. Accordingly, high selectivity of the reaction is essential for obtaining the product in high enantiomeric excess.

Arylmalonate decarboxylase (AMDase, EC. 4. 1. 1. 76), which was found in our laboratory, catalyses decarboxylation of arylmalonate derivatives resulting in the formation of enantiomerically pure (*R*)-α-substituted phenylacetic acids (Scheme 1).[3] It is thought that enantioface-differentiating protonation to the enolate intermediate in the active site of the enzyme is the key step of this reaction. Thus, if [α-^{2}H]phenylmalonic acid was used as the substrate of this enzymatic reaction, it would give enantiomerically enriched (*R*)-[α-^{2}H]phenylacetic acid.



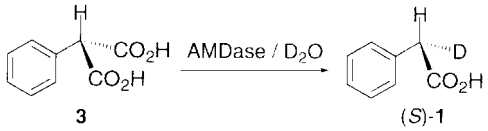
Scheme 1

[α-^{2}H]Phenylmalonic acid **2**† was prepared by deuteration of the corresponding [α-^{1}H]-diethyl ester followed by hydrolysis in ^2H_2O. The amount of non-deuterated diethyl ester was evaluated from ^{1}H-NMR to be about 3%, which was consistent with the peak intensity ratio of *m*/*z* 136 and 137 (parent ions corresponding to non- and mono-deuterated phenylacetic acids) of the enzyme-catalysed reaction product. The asymmetric decarboxylation of **2** by arylmalonate decarboxylase, which was obtained by overexpression in *E. coli* JM 109 and subsequent purification,[4] worked very well. The expected compound (*R*)-**1**‡ of over 95% ee was obtained in a quantitative yield (Scheme 2).



Scheme 2

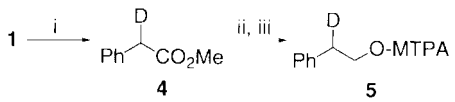
In this enzyme-catalysed reaction, it is considered that the origin of the proton source can be traced back to the solvent ^1H_2O. Consequently, when the reaction is performed in ^2H_2O, then ^{2}H will be incorporated enantioselectively into the product from the same direction as that of ^{1}H in the above case. As this enzyme is purified from the culture of *E. coli*, it is obtained as a solution in ^1H_2O. When the replacement of the solvent is incomplete, it will cause the formation of non-deuterated phenylacetic acid. Thus, we tried to replace ^1H_2O with ^2H_2O. Fortunately, as this enzyme was not inactivated by repeated lyophilization, it was possible to replace the ^1H_2O of the enzyme solution by ^2H_2O *via* successive freeze-drying and addition of ^2H_2O. When substrate **3** was added to this ^2H_2O-exchanged enzyme solution, the reaction proceeded smoothly in the same manner as for ^1H_2O, although the rate of reaction was not measured accurately. As expected, (*S*)-**1**§ in over 95% ee was obtained in a quantitative yield (Scheme 3).



Scheme 3

The absolute configuration of the product was determined by comparison of the sign of rotation with the one reported.[2] The ee of **1** was determined by ^{1}H NMR analysis of (*R*)-α-methoxy-α-trifluoromethylphenyl acetate (MTPA ester **5**¶), which was prepared by an esterification of the corresponding alcohol obtained by the reduction of methyl ester **4** (Scheme 4). The ^{1}H NMR spectra of the benzylic protons are shown in Fig. 1. The signals of the protons in question were simplified *via* decoupling by irradiation of the adjacent methylene protons.

In conclusion, an efficient method for the asymmetric synthesis of both enantiomers of [α-^{2}H]phenylacetic acid was established *via* decarboxylation of phenylmalonate catalysed by



Scheme 4

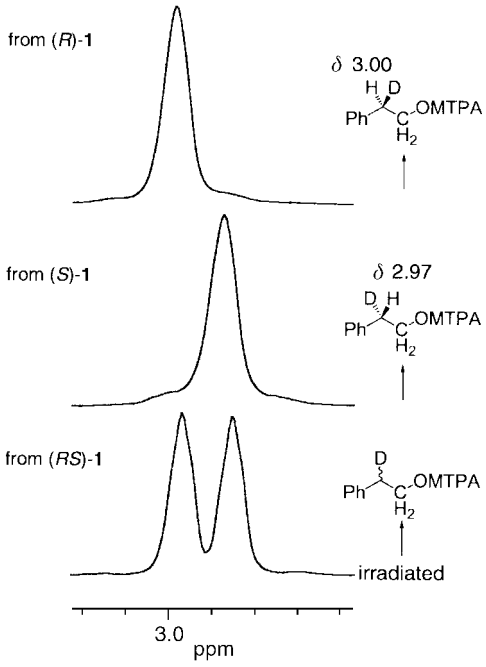

Fig. 1

arylmalonate decarboxylase. As some other analogous compounds having substituents on the aromatic ring also undergo this enzyme-catalysed reaction,[5] this procedure will be applicable to the preparation of the enantiomers of substituted [α-^{2}H]arylacetic acids.

Notes and references

† **2**: To a dispersion of NaH (12.7 mmol) in dry THF (10 ml) was added a solution of **6** (4.23 mmol) in dry THF (2 ml). The mixture was refluxed with stirring for 5 h and cooled to 0 °C. To this mixture was added D_2O (3.5 ml) and DCl (35% in D_2O, 1.4 ml). The product was extracted and purified by column chromatography on silica gel to give diethyl [α-^{2}H]phenylmalonate **7** (0.957 g, 96%). This was contaminated with **6** (3%), as judged from the signal at δ_H 4.61 [1H, s, $C_6H_5CH(CO_2CH_2CH_3)_2$]. The solution of **7** (0.747 g, 3.15 mmol) in CH_3OD (5 ml) was treated with NaOD (6.84 mmol) in D_2O (5 ml). The mixture was stirred at rt for 12 h, concentrated *in vacuo* and MeOH (15 ml) was added to the residue. The resulting precipitates were collected by suction filtration, washed with cold MeOH and ether, and then dried *in vacuo* to give the disodium salt of **2** (0.640 g, 90%) as a colorless powder. ν_{max}/cm^{-1} 3021, 1591, 1496, 1429, 1324, 1023, 910, 698; (400 MHz, D_2O) δ_H: 7.11–7.21 [m, 5H, $C_6H_5CD(CO_2Na)_2$].

‡ (*R*)-**1**: The disodium salt of **2** (0.450 g, 2.00 mmol) was added to a solution of purified arylmalonate decarboxylase (400 units) in Tris-HCl buffer (2 M, pH 8.5, 4 ml). This mixture was incubated at 35 °C for 30 min followed by acidification with 2 M HCl. The mixture was saturated with NaCl and extracted with ether. The organic layer was concentrated *in vacuo* to give (*R*)-**1** (0.279 g, quant.) as a white solid. This product was revealed to be pure by ^{1}H NMR. This was recrystallized from hexane to afford (*R*)-**1** (0.250 g, 92%) as colorless plates, mp 73.5–74.5 °C; $[\alpha]_D^{22}$ −1.1° (*c* 10.0, $CHCl_3$); ν_{max}/cm^{-1} 3033, 1700, 1412, 1263, 1224, 904, 700, 673; (400 MHz, $CDCl_3$) δ_H: 3.64 [t, 1H, *J* = 2.0 Hz, $C_6H_5CDHCO_2H$], 7.25–7.36 [m, 5H, $C_6H_5CDHCO_2H$]; MS (*m/z*, %) 92 (C_7H_6D, 100), 136 (1.2), 137 (M^+, 34.9), 138 (*M* + 1, 3.0). HRMS Found: *m/z* 137.0598. Calcd. for $C_8H_7DO_2$: 137.0586. Assuming the peak *m/z* 136 is entirely due to the presence of non-deuterated phenylacetic acid ($C_7H_8O_2$), the contamination is calculated to be about 3%. However, the peak corresponding to *M* − 1 (135) was also observed in the MS of non-deuterated phenylacetic acid. Thus the contamination of the non-deuterated compound in the enzymatic reaction product will be less than 3%.

MS of non-deuterated phenylacetic acid (*m/z*, relative intensity) 91 (C_7H_7, 100), 135 (1.2), 136 (M^+, 72), 137 (*M* + 1, 7.0), 138 (*M* + 2, 1.2).

§ (*S*)-**1**: The purified arylmalonate decarboxylase (600 units) was dissolved in a Tris-HCl buffer (2 M, pH 8.5, 5 ml) and lyophilized. The residue was dissolved in D_2O (5 ml) and incubated at 4 °C for 1 h and lyophilized again. The residue was dissolved in D_2O (5 ml) and the disodium salt of **3** (0.550 g, 2.45 mmol) was added. The mixture was incubated at 35 °C for 30 min and acidified with 2 M HCl. The mixture was saturated with NaCl and extracted with ether. The organic layer was concentrated *in vacuo* to give (*S*)-**1** (0.337 g, quant.) as a white solid. This was recrystallized from hexane to give (*S*)-**1** (0.300 g, 89%) as colorless plates, mp 74.5–75.5 °C [lit.[2] 75 °C]; $[\alpha]_D^{22}$ +1.1 (*c* 9.5, $CHCl_3$), +1.2 (*c* 25.7, $CHCl_3$) [lit.[2] for *S* enantiomer, $[\alpha]_D^{22}$ +1.5 ± 0.2 (*c* 25.7, $CHCl_3$)]; MS (*m/z*, %) 92 (C_7H_6D, 100), 136 (1.2), 137 (M^+, 34.9), 138 (*M* + 1, 3.0). HRMS Found: *m/z* 137.0566. Calcd. for $C_8H_7DO_2$: 137.0586. The IR and NMR spectra were identical with those of (*R*)-**1**. The racemic sample of **1** was prepared by the reported procedure.[6]

¶ **5** from (*R*)-**1**: (400 MHz, $CDCl_3$) δ_H: 3.00 [t, 1H, *J* = 6.3 Hz, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$], 3.47 [s, 3H, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$], 4.53 [d, 2H, *J* = 6.3 Hz, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$], 7.17–7.43 [m, 10H, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$]. **5** from (*S*)-**1**: (400 MHz, $CDCl_3$) δ_H: 2.97 [t, 1H, *J* = 7.3 Hz, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$], 3.46 [s, 3H, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$], 4.53 [d, 2H, *J* = 7.0 Hz, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$], 7.17–7.43 [m, 10H, $C_6H_5CDHCH_2OCOC(CF_3)(OCH_3)C_6H_5$].

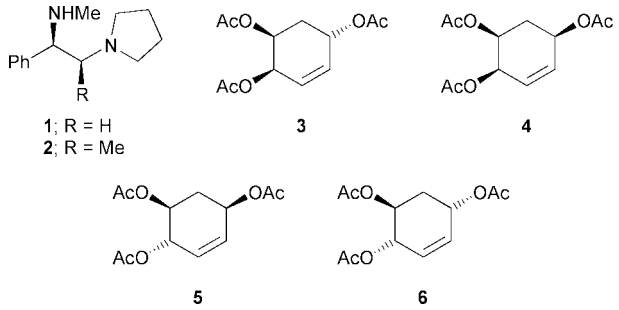
Two novel and completely diastereoselective lithium amide-mediated rearrangements of diprotected 4,5-dihydroxycyclohexene oxides and their use in the synthesis of 4-deoxyconduritols are described.

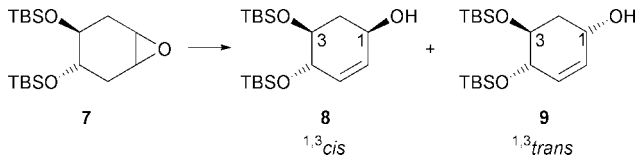
Conduritols and structurally related cyclitols possess a range of useful biological activity (including glycosidase inhibition)[1] and the stereocontrolled synthesis of such compounds continues to attract considerable attention.[2] As part of our research programme into the synthesis of polyhydroxylated cyclohexenes using chiral bases derived from **1** and **2**, we became



interested in the preparation of the triacetates of 4-deoxyconduritols **3**–**6**. Although the preparation of *racemic* **3**, **4** and **6** has been reported,[3–6] there exists no general, stereocontrolled method for the synthesis of 4-deoxyconduritols. Previously, we have described[7,8] the preparation of precursors to **3** and **4** in > 90% ee using the chiral base-mediated asymmetric desymmetrisation of *meso*-4,5-dihydroxycyclohexene oxides. In this paper, we describe a related but conceptually distinct lithium amide epoxide rearrangement approach to the synthesis of **5** and **6**.

In order to synthesise **5** and **6** with the required stereochemistry, we needed to study the rearrangement of *chiral* 4,5-dihydroxycyclohexene oxides like **7** using lithium amide bases (Scheme 1). Such a reaction is intrinsically different to our previously reported epoxide rearrangements: (i) the reaction is not a desymmetrisation; (ii) the reaction can proceed to give two possible *diastereomeric* allylic alcohol products (**8** and **9**) depending on the reacting conformation adopted by the epoxide (*vide infra*); (iii) any optical activity in the allylic alcohols produced must arise either from enantioenriched starting epoxide **7** or from a kinetic resolution of *racemic* **7** using a chiral base.

The rearrangement of cyclohexene oxides to allylic alcohols proceeds *via* lithium amide abstraction of a proton that is *cis* and



Scheme 1

pseudo-axial to the epoxide.[9] When such criteria are imposed on the two possible conformations (**A** and **B**) of **7** then it can be seen from Fig. 1 that removal of the highlighted (*cis* and pseudo-axial) proton in each conformation leads to different *diastereomers* of allylic alcohols: reaction *via* conformation **A** (diaxial silyloxy groups) generates **8** (^{1,3}*cis* stereochemistry); reaction *via* **B** (diequatorial silyloxy groups) gives **9** (^{1,3}*trans* stereochemistry). Thus, we anticipated that by controlling the reacting conformation, we would be able to synthesise allylic alcohols with either ^{1,3}*cis* or ^{1,3}*trans* relative stereochemistry. The successful implementation of this novel strategy is the subject of the present communication.

Racemic **7** was readily synthesised from cyclohexa-1,4-diene in 48% yield over three steps. The reaction of **7** with 2 equiv. of the lithium amide bases generated from *racemic* diamine **2** and diisopropylamine (Scheme 1) was studied under different conditions (Table 1). Reaction of **7** with the lithium amide base from **2** in THF, our usual solvent, generated a 32 : 68 mixture of allylic alcohols **8** and **9**† (Entry 1) which were readily separated by column chromatography. They were identified by conversion of **8** into the previously unreported 4-deoxyconduritol triacetate **5** (*vide infra*). The major product (**9**) must have arisen through reaction *via* conformation **B** (see Fig. 1).

Using *rac*-**2** and by changing the solvent to either Et_2O or cyclopentane, the coordinating ability of the solvent is reduced and only allylic alcohol **8** was formed (Entries 3 and 4). With these solvents, preferential reaction *via* conformation **A** is presumably promoted by intramolecular chelation of the silyloxy group and epoxide oxygen by the lithium cation. For

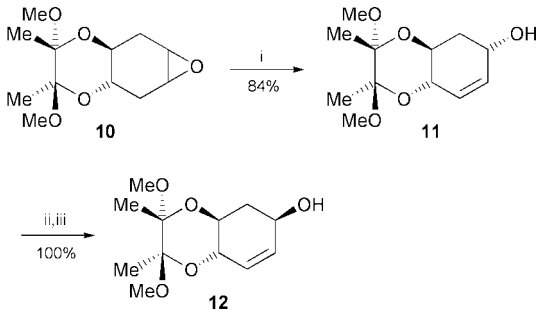

Scheme 2 *Reagents and conditions*: i, 2 equiv. *rac*-**2** + 2 equiv. BuLi, THF, 0 °C to rt over 2 h then 70 h at rt; ii, PCC, CH_2Cl_2 (100%); iii, $NaBH_4$, $CeCl_3{\cdot}7H_2O$, MeOH, 0 °C, 10 min (100%).

similar reasons, carrying out the reaction in THF with added lithium bromide led to a lowering of the ^{1,3}*trans* diastereoselectivity (Entry 2). The use of TBDPS and TES as protecting groups gave essentially the same results.

We have also investigated the use of LDA for these diastereoselective rearrangement reactions. In THF, a very good isolated yield (82%) of allylic alcohol **8** was obtained (Entry 5). The reaction must proceed preferentially *via* the chelated conformation **A** which is in stark contrast to the result obtained with diamine *rac*-**2** (Entry 1) indicating that LDA is a far better coordinator than *rac*-**2** in THF. Use of LDA in Et_2O led to a slight improvement in ^{1,3}*cis* selectivity (Entry 6) but this did not mirror the improvement in ^{1,3}*cis* selectivity observed with *rac*-**2** on moving from THF to Et_2O where none of the ^{1,3}*trans* diastereomer was observed (Entry 3).

From a synthetic viewpoint, reaction of **7** with the lithium amide derived from *rac*-**2** in cyclopentane generated **8** as the sole diastereomer which was isolated in 89% yield (Entry 4). Conversion of **8** into unknown triacetate **5**‡ was accomplished by deprotection with TBAF and subsequent acetylation (88% yield over the two steps).

Although it was possible to generate allylic alcohol **9** in 61% isolated yield (Entry 1), we wondered if it was possible to have a completely diastereoselective synthesis of an allylic alcohol with ^{1,3}*trans* stereochemistry (reaction only *via* the diequatorial conformation **B**). Thus, we used the Ley butane-2,3-diacetal protecting group[10] to lock the conformation equivalent to **B** in epoxide **10** (Scheme 2).

Racemic **10** was prepared from cyclohexa-1,4-diene in 56% yield. Reaction of **10** with the lithium amide of *rac*-**2** generated only one diastereomer of allylic alcohol in 84% yield and it was identified as the expected **11** by conversion into known[3] triacetate **6** (TFA–water deprotection followed by acetylation, 80% yield). Use of LDA produced allylic alcohol **11** in a slightly improved 89% isolated yield. In passing, we also note that it is possible to carry out a PCC oxidation–Luche reduction sequence to convert **11** into its diastereomer **12** with complete stereocontrol (axial attack of hydride in the conformationally locked intermediate enone explains the stereoselectivity). Finally, we present our preliminary findings on the kinetic resolution of **10** as a route to enantiomerically enriched allylic alcohols.[11] Reaction of *racemic* **10** with 0.7 equiv.[12] of the chiral base from (1*R*,2*S*)-**2** generated **11** in 32% yield (63% ee) and recovered *ent*-**10** in 51% yield (44% ee).

In summary, we have described two novel, completely diastereoselective and stereodivergent lithium amide-mediated epoxide rearrangement reactions (**7** → **8** and **10** → **11**). Mechanistically, our results can only be adequately explained in terms of the removal of a proton which is *cis* and pseudo-axial to the epoxide (see Fig. 1) as proposed by Rickborn and Thummel.[9] In addition, we have also reported the first example of a kinetic resolution on chiral 4,5-dihydroxycyclohexene oxides which, coupled with the oxidation–reduction sequence in Scheme 2, provides a concise approach to enantiomerically enriched 4-deoxyconduritols **5** and **6**.

A MCM-41/Nafion® composite prepared from tetraethoxysilane and Nafion gel solution with cetyltrimethylammonium surfactant, is a highly selective catalyst for α-methylstyrene dimerization to form the corresponding acyclic dimer.

The synthesis of mesoporous materials is one of the most important subjects in modern chemistry. MCM-41 obtained by the utilization of surfactant micelles[1] is actively studied for applications to catalysts. Recently organically modified MCM-41 materials using alkyl-substituted silane compounds have been prepared for use as catalysts and other applications.[2] On the other hand, DuPont has recently reported amorphous silica/Nafion composites which were effective solid acid catalysts.[3] It is thought that the combination of the new technology for fabricating mesoporous materials and Nafion resin creates a novel class of functional solid acid materials.[4] Here, we report the first preparation (to our knowledge) of a MCM-41/Nafion composite material and its applications as a solid acid catalyst.

The MCM-41/Nafion composite was obtained by the following procedure; 0.1 g of Nafion gel obtained from a 5% Nafion solution (Aldrich) in ethanol was dissolved in 1.5 mL of ethanol. This solution was added slowly to a mixture of tetramethylammonium hydroxide (8 mmol) and cetyltrimethylammonium bromide (4.5 mmol) in distilled water (15 mL) with vigorous stirring. Then, tetraethoxysilane (30 mmol) was added dropwise with stirring to the resulting mixture. Finally, the mixture was transferred to a Teflon beaker and crystallized in a stainless steel autoclave at 130 °C under autogeneous pressure for 24 h. The white solid obtained was washed twice with 200 mL of distilled water and dried at 60 °C. The removal of the template and acidification of the Nafion resin were performed by refluxing in concentrated sulfuric acid (3 mL) in ethanol (300 mL) for 18 h. After two further refluxes in ethanol (300 mL), the recovered solid was dried at 150 °C for 20 h.

Fig. 1 shows the XRD pattern of the MCM-41/Nafion composite obtained.† A clear peak at $2\theta = 2.15°$ was observed which was assigned to the (100) reflection of MCM-41 type materials.[1] The (110) and (200) reflections from MCM-41 appeared as broad peaks at $2\theta \approx 4.1°$. The BET surface area and pore volume were estimated at 619 $m^2\ g^{-1}$ or 0.64 $cm^3\ g^{-1}$, respectively. The diameter of the main pore type (*ca*. 90%) was 2.8 nm in accord with an organically modified MCM-41.[2] The minor pore type had a diameter of 3.8 nm and corresponded to MCM-41.[1] From the IR spectrum, it was confirmed that the template was removed because of the absence of alkyl adsorptions of the template around 2900 cm^{-1}. All these results indicate that the preparation of the MCM-41/Nafion composite was successful.

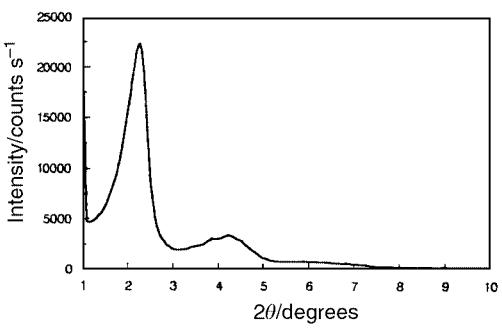

Fig. 1 X-Ray diffraction pattern of the MCM-41/Nafion composite.

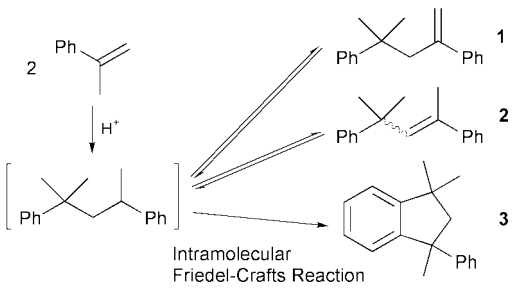
This novel composite material was applied to the dimerization of α-methylstyrene (AMS) to produce the corresponding acyclic dimer, 4-methyl-2,4-diphenylpent-1-ene **1**, which is a chain transfer agent amongst other uses.[5] Although this reaction using solid sulfuric acid has been actively studied,[5] the significant side reaction to form the cyclic dimer, 1,1,3-trimethyl-3-phenylindan **3**, often results in low production of **1** (Scheme 1). The yields of the desired dimer **1** [Fig. 2(a)] and of the undesired dimer **3** [Fig. 2(b)] as a function of time are shown using the MCM-41/Nafion composite, as well as for Nafion NR-50, Nafion SAC-13 (silica/Nafion composite),[3] Amberlyst® 15 (all obtained from Aldrich) and Al-MCM-41.[6]† Although SAC-13 and Amberlyst 15 had high activity, the yields of **1** drastically decreased with time and substantial increases of the bicyclic dimer **3** were observed. For NR-50, the reaction rate was quite slow as reported[3] and **3** was formed in considerable yield even at a low conversion of AMS. On the other hand, when the MCM-41/Nafion composite was used, the yield of **1** was about 70% and scarcely decreased with reaction time. Furthermore, the formation of **3** was low even after 1000 min. This high selectivity shown by the MCM-41/Nafion composite is not simply derived from the mesoporous channel structure since **3** was obtained in high yield using Al-MCM-41 which was reported as an acid catalyst.[6] Furthermore, other types of MCM-41/Nafion composite obtained from impregnating Nafion solution to MCM-41[7] also afforded **3** in 30% yield with a lower yield of **1** (25%) after 300 min. As expected, MCM-41 itself (silica material without Nafion resin or other metals) showed no activity for this dimerization under our conditions (no conversion of AMS even after 1500 min). Thus, the MCM-41/Nafion composite prepared in this work was an excellent catalyst to produce **1** *via* the dimerization of AMS.



Scheme 1

The low yield of **3** for our MCM-41/Nafion composite suggests poor catalytic activity for Friedel–Crafts reactions.[8] The conversion of **1** to **3** at 60 °C scarcely proceeded with the MCM-41/Nafion composite (3% after 24 h), whereas SAC-13 considerably catalyzed this reaction (17% after 6 h and 56%

DOI: 10.1039/b004842i

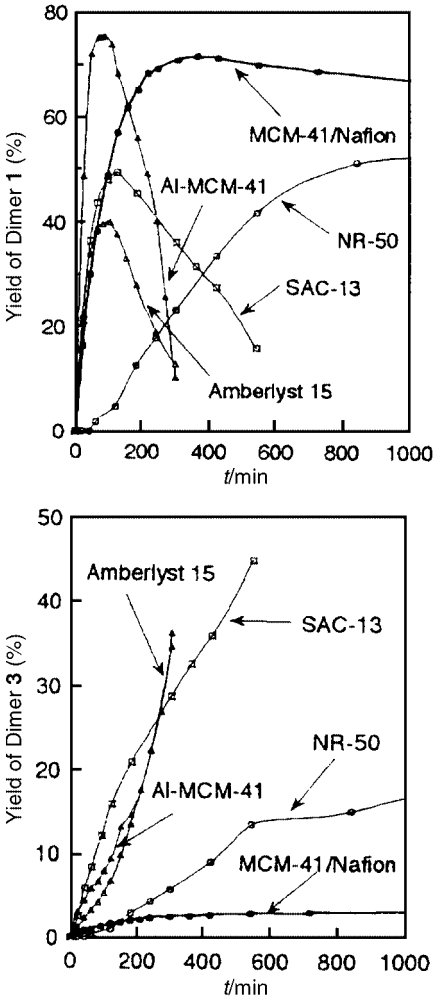


Fig. 2 Yields of **1** (a) and **3** (b) as a function of time using various catalysts.

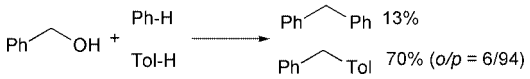
after 24 h). The clear difference of the catalytic activity between the MCM-41/Nafion composite and SAC-13 in another Friedel–Crafts type reaction was also observed.[9] While SAC-13 catalyzed the reaction of styrene with toluene to form 1-phenyl-1-tolylethane in 27% yield with complete conversion of styrene at 70 °C for 6 h, MCM-41/Nafion composite gave only a trace of the product even after 24 h (styrene conversion: 37%). Therefore, it is thought that the low activity of the MCM-41/Nafion composite to Friedel–Crafts reaction at 60 °C results in the high selectivity towards dimer **1** from AMS. However, it is noteworthy that AMS afforded **3** in 91% yield using the MCM-41/Nafion composite at 100 °C after 3 h, and that the reaction of benzyl alcohol with toluene at 100 °C for 3 h afforded 87% of phenyltolylmethane, *cf*. trace amounts at 60 °C even after 24 h. Moreover, the competitive reaction of benzene and toluene with benzyl alcohol [eqn. (1)] at 90 °C showed a



(1)

higher selectivity towards toluene (toluene/benzene = 5.4) than NR-50 (toluene/benzene = 3.6).[10] These results indicate that the catalytic properties of sulfuric acid in the MCM-41/Nafion composite are crucially influenced by the reaction temperature and the reactivity of the substrate. It is expected that some novel selective reactions can be carried out using this characteristic catalytic activity, and further studies are under investigation.

We gratefully acknowledge all the members of 'Catalysis Section' of Osaka National Research Institute, especially Dr T. Kobayashi and Dr M. Ando, for their help to the characterization study.

Notes and references

† To a solution of AMS (5 mmol) in toluene (5 mL) a solid catalyst (50 mg) was added under argon atmosphere and the resulting mixture stirred at 60 °C. Remaining AMS and all products were determined by capillary GC.

Insertion of O_2 into a Pd(I)–Pd(I) dimer and subsequent C–O bond formation by activation of a C–H bond

Víctor Durà-Vilà, D. Michael P. Mingos, Ramón Vilar,* Andrew J. P. White and David J. Williams

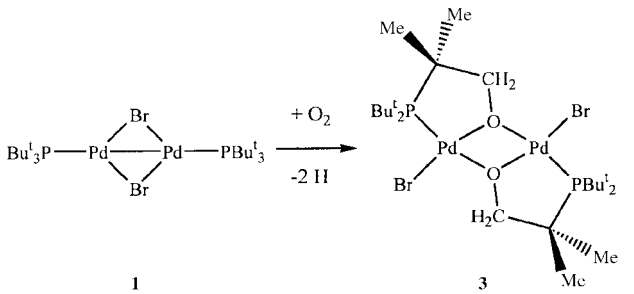
Received (in Cambridge, UK) 7th June 2000, Accepted 10th July 2000

The reaction between O_2 and the dimer $[Pd_2(\mu\text{-}Br)_2(PBu^t_3)_2]$ leads to the formation of the novel dimeric compound $[Pd(\mu\text{-}OCH_2\{CMe_2\}PBu^t_2)Br]_2$ by coordination of O_2 to the original palladium dimer and further formation of two C–O bonds by intramolecular activation of C–H bonds.

The study of transition metal dioxygen complexes has attracted substantial interest as these types of compounds are involved in the metabolism of O_2 in living organisms.[1,2] These bioinorganic natural systems have inspired chemists to search for synthetic analogues which can be used as industrial catalysts for the oxidation of C–H and C–C bonds.[3] It is believed that, in both the biological and synthetic systems, coordinated species such as O_2^-, O_2^{2-}, HO^-, RO^- and O^{2-} play important roles in the transfer of oxygen to the organic substrates.[4] This belief has led to extensive studies on the synthesis and reactivity of transition metal dioxygen complexes. Owing to their direct relevance to biological systems, nickel,[5] cobalt,[6] copper[7] and iron[8] mono- and bi-nuclear species have been those most extensively studied. By contrast, palladium dioxygen metals have received far less attention even though they have been implicated in various catalytic processes.[9]

During the past few years we have investigated extensively the reactivity of the dimers $[Pd_2(\mu\text{-}X)_2(PBu^t_3)_2]$ (X = Br, **1**; X = I, **2**).[10] These compounds contain two palladium(I) centres and have been demonstrated to react with a wide range of small molecules such as CO, CNR, H_2 and alkynes.[11] While studying these reactions, it was observed that dimer **1** exhibited a high reactivity towards aerial oxygen. The possibility of an oxidative addition of O_2 into this dimeric species, stimulated us to undertake a systematic study of the reaction between these dimers and oxygen. Here we report our preliminary results on the reaction of O_2 with the palladium dimer $[Pd_2(\mu\text{-}Br)_2(PBu^t_3)_2]$ (Scheme 1).



Scheme 1 The reaction between **1** and O_2 leads to the formation of a novel dimeric species in which new Pd–O and C–O bonds are formed. In this process an intramolecular C–H activation occurs.

Crystallographic evidence has demonstrated that in this reaction three transformations occur: coordination of O_2 and cleavage of an O=O bond, intramolecular activation of a C–H bond and formation of new C–O bonds.

When a solution of **1** in dry and deoxygenated benzene was reacted with aerial oxygen, the original dark green colour of the solution changed to orange after few seconds. The $^{31}P\{^1H\}$ NMR spectrum of this mixture showed a singlet at δ 108.0 (*cf.* δ 87.5 for the starting material) suggesting the presence of a single product. The solvent from this mixture was then evaporated under reduced pressure and the remaining dark orange material was analysed spectroscopically† and structurally‡ demonstrating it to be the novel dimer $[Pd(\mu\text{-}OCH_2\{CMe_2\}PBu^t_2)Br]_2$ **3** (Scheme 1). The ^1H NMR spectrum of this new compound showed three doublets in the range δ 1.4–1.7 with an integration ration of 1 : 3 : 9. The doublet integrating for 9 protons corresponds to the Bu^t groups in the PBu^t_3 while the other two doublets correspond to a CMe_2 and a CH_2 group, suggesting cyclometallation of the phosphine. This type of intramolecular rearrangement is well established for PBu^t_3 and the NMR spectra of the resulting compounds are well documented.[12] Signals at high field were not observed suggesting that O–H groups are not present in the new compound **3**. This was also verified by IR spectroscopy which did not show any O–H stretches. Elemental analyses were also consistent with the formulation of **3**.

The unambiguous nature of compound **3** was established by an X-ray crystallographic study. Single crystals were obtained by layering a benzene solution of the dimer with hexane.

This analysis‡ confirmed that **3** is the dimeric species $[Pd(\mu\text{-}OCH_2\{CMe_2\}PBu^t_2)Br]_2$ (Fig. 1) which results from the incorporation of aerial O_2 into the original complex **1**. The molecule **3** has non-crystallographic C_2 symmetry about an axis normal to, and passing through the centre of, the Pd_2O_2 ring. This central four-membered ring is folded 52° out of plane about the O··O vector; the non-bonded Pd··Pd and O··O distances are 2.911(1) and 2.566(6) Å. The two five-membered chelate rings both have envelope conformations, with Pd(1)P(1)C(1)O(1) and Pd(2)P(2)C(3)O(2) being planar to within *ca*. 0.04 and 0.08 Å, respectively, and with C(2) and C(4) lying 0.68 and 0.70 Å out of their respective planes with consequent axial/equatorial dispositions of their methyl sub-

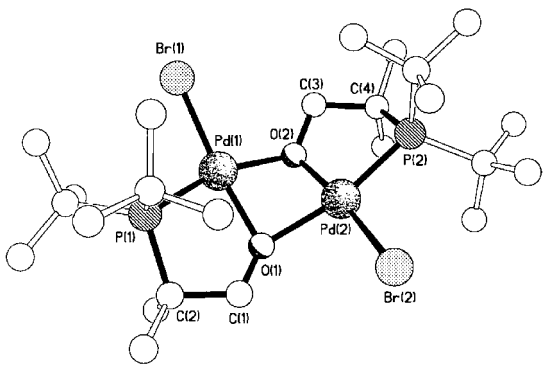


Fig. 1 The molecular structure of **3**. Selected bond lengths (Å) and angles (°): Pd(1)–O(1) 2.001(5), Pd(1)–O(2) 2.125(5), Pd(1)–P(1) 2.226(2), Pd(1)–Br(1) 2.4242(9), Pd(2)–O(1) 2.126(5), Pd(2)–O(2) 2.015(5), Pd(2)–P(2) 2.223(2), Pd(2)–Br(2) 2.4152(9), O(1)–C(1) 1.413(8), O(2)–C(3) 1.408(8), O(1)–Pd(1)–O(2) 76.9(2), O(1)–Pd(1)–P(1) 85.95(14), O(2)–Pd(2)–O(1) 76.6(2), O(2)–Pd(2)–P(2) 87.05(14), C(1)–O(1)–Pd(1) 119.1(4), C(1)–O(1)–Pd(2) 127.6(4), Pd(1)–O(1)–Pd(2) 89.7(2), C(3)–O(2)–Pd(2) 117.0(4), C(3)–O(2)–Pd(1) 127.0(5), Pd(2)–O(2)–Pd(1) 89.3(2).

DOI: 10.1039/b004537n

stituents. The geometry at each oxygen centre is distinctly pyramidal with both O(1) and O(2) lying *ca*. 0.5 Å out of the plane of their substituents. The coordination at each palladium centre is distorted square planar with *cis* angles in the range 76.9(2)–101.53(5)° and 76.6(2)–100.01(5)° at Pd(1) and Pd(2), respectively, the acute angle in each case being associated with the central Pd_2O_2 ring. The Pd–O–Pd bridges are both asymmetric, with the Pd–O bonds *trans* to bromine [2.001(5) and 2.015(5) Å] being *ca*. 0.1 Å shorter than those *trans* to phosphorus [2.125(5) and 2.126(5) Å]. These distances are comparable to those observed in the few reported examples of Pd_2O_2 rings.[13] In these literature examples the non-bonded Pd··Pd separation is in all cases longer than that we observe in **3**.

A remarkable aspect of the structure of **3** is the formation of two C–O bonds by intramolecular C–H activation of one of the Bu^t groups of each phosphine. This leads to the formation of two five-membered chelate rings, which explains the presence of the three doublets observed in the ^{1}H NMR spectrum of **3** and is also consistent with the singlet present at δ 108.0 in the ^{31}P{^{1}H} NMR spectrum.

Careful inspection of the sample from which the crystals of **3** were taken indicated the presence of very few crystals of both a different colour and morphology (the number of these crystals was negligible compared to the amount of crystals of **3**). X-Ray crystallographic analysis of one of these crystals‡ showed that the structure of this second product is the dimeric species with formula $[\overline{Pd(Bu_2^tPCMe_2CH_2}](\mu\text{-Br})]_2$ **4**. This complex is isomorphous with the already reported chloride analogue having a planar central Pd_2Br_2 ring and folded $PdPC_2$ rings (Fig. 2).[12]

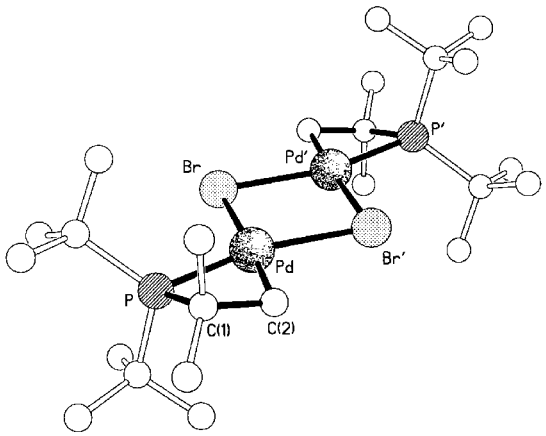

Fig. 2 The molecular structure of **4**. Selected bond lengths (Å) and angles (°): Pd–C(2) 2.048(8), Pd–P 2.215(2), Pd–Br′ 2.5497(11), Pd–Br 2.5922(12), P–Pd–C(2) 69.6(2), Br–Pd–Br′ 88.30(4), Pd–Br–Pd′ 91.70(4). There is a 25° out of plane fold about the P··C(2) vector in the $PdPC_2$ ring.

Interestingly when the oxygenation reaction was attempted with the analogous iodo-dimer $[Pd_2(\mu\text{-I})_2(PBu^t_3)_2]$, no reaction was observed. As we have reported previously, dimer **1** tends to be much more reactive than **2** towards small molecules such as CO, H_2, CNR and alkynes.[11] In the present investigation, this difference in reactivity has once again been observed.

The results presented here have demonstrated the ability of a Pd(I) dimer to react with aerial oxygen. In this process, three transformations seem to be taking place: *(i)* coordination of an O_2 molecule and cleavage on an O=O bond, *(ii)* intramolecular activation of two C–H bonds and *(iii)* formation of two new C–O bonds. To our knowledge, this is the first example of a palladium compound in which such a process has been demonstrated by crystallographic characterisation. The mechanistic aspects of this reaction are yet to be studied. For example an important question that remains to be answered is whether the two oxygen atoms come from the same O_2 molecule or from two different ones. Also important will be to establish the exact mechanism by which the reaction occurs and the fate of the two hydrogen atoms lost in the activation of the C–H bond. Experiments are currently in progress to attempt to provide answers to these questions.

6-*Endo-trig* and 5-*exo-trig* selective aryl radical cyclisations of *N*-(*o*-bromobenzyl) enamides

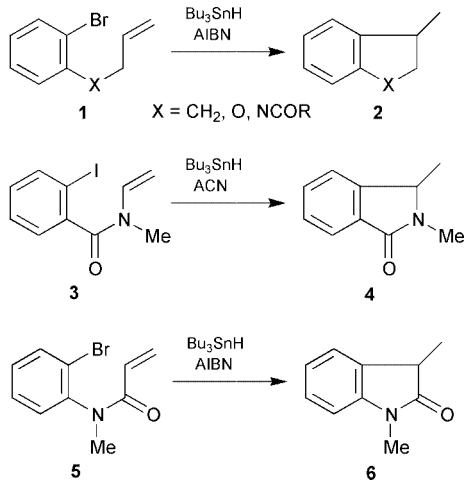
Hiroyuki Ishibashi,* Issei Kato, Yoshifumi Takeda, Momoyo Kogure and Osamu Tamura

Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920-0934, Japan. E-mail: isibasi@dbs.p.kanazawa-u.ac.jp

Received (in Cambridge, UK) 11th May 2000, Accepted 28th June 2000

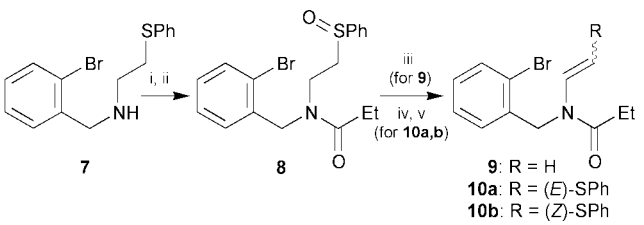
Bu_3SnH-mediated aryl radical cyclisation of enamide 9 proceeded in a 6-*endo-trig* manner to give exclusively tetrahydroisoquinoline derivative 12, whereas enamide 10b having a (*Z*)-phenylthio group at the terminus of the *N*-vinylic bond gave exclusively the 5-*exo-trig* cyclisation product 16.

Aryl radical cyclisations are now widely used in organic synthesis for the construction of fused aromatic compounds. A 5-*exo-trig* cyclisation is generally preferred over a 6-*endo-trig* ring closure in those systems having an alkenic bond at the 5-position relative to the aryl radical centre. For example, aryl bromides **1** (X = CH_2, O or NCOR), upon treatment with Bu_3SnH in the presence of AIBN, gave almost exclusively the 5-*exo* cyclisation products **2**.[1] This was also the case for the



cyclisations of enamide **3** and acryloylanilide **5**, which gave only the five-membered lactams **4**[2] and **6**,[3,4] respectively. Herein we wish to report that *N*-(*o*-bromobenzyl) enamide **9** undergoes aryl radical cyclisation in a 6-*endo-trig* manner to give exclusively tetrahydroisoquinoline derivative **12**, and that the mode of cyclisation can be shifted to a 5-*exo-trig* manner by introducing a (*Z*)-phenylthio group at the terminus of the *N*-vinylic bond.

The requisite radical precursors **9**, **10a** and **10b** were prepared as shown in Scheme 1.

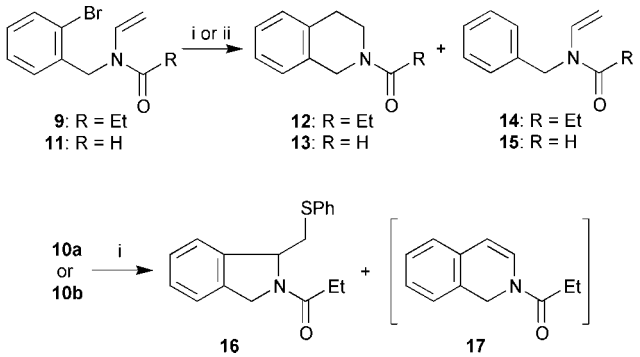


Scheme 1 *Reagents and conditions*: i, EtCOCl, Et_3N, CH_2Cl_2, rt, 90%; ii, MCPBA, CH_2Cl_2, 0 °C, 93%; iii, xylene, $NaHCO_3$, reflux, 81%; iv, $(CF_2CO)_2O$, CH_2Cl_2, rt; v, toluene, reflux, 46% for **10a**, 13% for **10b** (based on **8**).

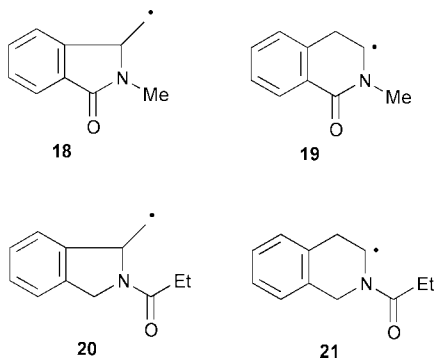
When a mixture of Bu_3SnH (2.2 eq.) and azobis(cyclohexancarbonitrile) (ACN) (0.4 eq.) in toluene was added slowly to a boiling solution of **9** in toluene over a period of 3.5 h, the 6-*endo* cyclisation product **12**[5] was obtained in 68% yield, along with the simple reduction product **14** (16% yield) (Scheme 2). Similarly, the *N*-formyl congener **11** gave **13** and **15** in 43 and 19% yields, respectively. On the other hand, treatment of the sulfur substituted (*E*)-isomer **10a** with Bu_3SnH–ACN afforded the 5-*exo* cyclisation product **16** in 40% yield, along with dihydroisoquinoline derivative **17** in 41% yield. The corresponding (*Z*)-isomer **10b** gave **16** as a sole product in 75% yield.

The exclusive formation of the 6-*endo* cyclisation product **12** from **9** is of great interest in view of previous work on radical cyclisations of the related compounds **1**, **3** and **5**, which gave the 5-*exo* cyclisation products **2**, **4** and **6**, respectively. Formation of **4** (from **3**) and **12** (from **9**) can be rationalized by an attack of Bu_3SnH on the primary radical **18** and on the secondary radical **21**, respectively. Since enamide **3** gave no 6-*endo* cyclisation product *via* the secondary radical **19**, formation of **12** from **9** could not be explained by assuming that the nitrogen-substituted secondary radical **21** might be more stable than the primary radical **20**.

One possible explanation for the formation of **12** from **9** may involve a consecutive 5-*exo* cyclisation and neophyl-like† rearrangement of the resulting radical **20**. The possibility,



Scheme 2 *Reagents and conditions*: i, Bu_3SnH, ACN, toluene, reflux; ii, Bu_3SnH, Et_3B, toluene, rt.



DOI: 10.1039/b003790g

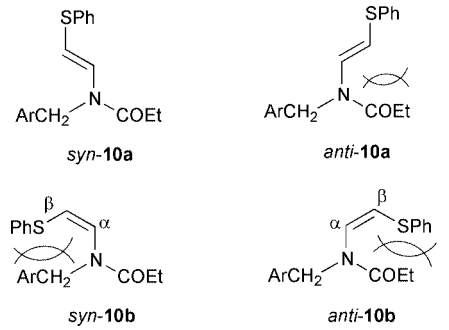


Fig. 1 Ar = *o*-BrC_6H_4.

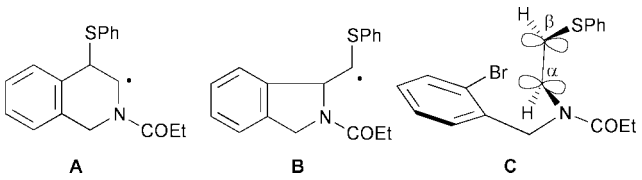

Fig. 2

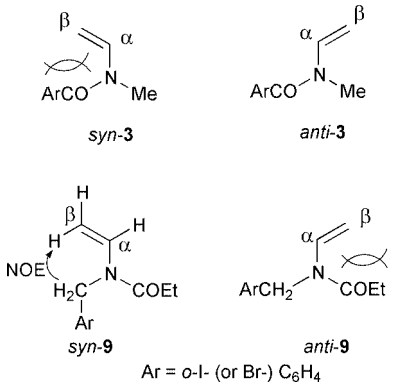
however, could be ruled out by the following work to simultaneously examine the effects of various Bu_3SnH concentrations, addition times and reaction temperatures.[6] Thus, treatment of **9** with 4 eq. of Bu_3SnH (not using the slow addition technique) in the presence of triethylborane in toluene at rt for 16 h also gave the 6-*endo* cyclisation product **12** in 51% yield, along with the reduction product **14** (23%). The most plausible explanation for the results with **3** and **9**, therefore, may be derived from the consideration of the rotation of enamide.[7] Two conformers can be considered for both radical precursors, *i.e.* *syn*-**3** and *anti*-**3** for **3** and *syn*-**9** and *anti*-**9** for **9**. In the



conformers *syn*-**3** and *anti*-**9**, severe steric repulsions between the aroyl (*o*-IC_6H_4CO) and C=C groups and between the acyl (EtCO) and C=C groups, respectively, are evident. The conformers *anti*-**3** and *syn*-**9** therefore predominate, and the resulting radicals attack on the more proximate C_α-position of *anti*-**3** and C_β-position of *syn*-**9**, to give the observed 5-*exo* cyclisation product **4** and the 6-*endo* cyclisation product **12**, respectively. The NOE difference spectroscopy also indicated that **9** exists only in the *syn*-**9** form.[8] Thus, irradiation of the signals due to the *N*-benzylic protons [δ 4.76 ($\frac{1}{3}$ × 2 H, s) and 4.94 ($\frac{2}{3}$ × 2 H, s)] of **9** caused an enhancement of the signals due to the C_β-proton *cis* to the nitrogen atom [δ 4.26 ($\frac{1}{3}$ H, d, *J* 15.6) and 4.29 ($\frac{2}{3}$ H, d, *J* 15.6)] and no enhancement of the signals due to the Cα-proton [δ 6.95 ($\frac{2}{3}$ H, dd, *J* 15.6 and 9.2) and 7.67 ($\frac{1}{3}$ H, dd, *J* 15.6 and 9.2)].[11] The preponderance of the *syn*-**9** conformer over *anti*-**9** seems to be independent of the size of the *N*-acyl group, since **11** having a sterically less demanding *N*-formyl group, also gave the 6-*endo* cyclisation product **13**.

For the sulfur substituted (*E*)-isomer **10a**, the two conformers *syn*-**10a** and *anti*-**10a** can be considered (Fig. 1). As in the case of *anti*-**9**, there is a severe steric repulsion between the EtCO and C=C groups in *anti*-**10a**, and the cyclisation might therefore proceed *via* the conformer *syn*-**10a** in a 6-*endo* manner to give **17** through an elimination of a benzenethiyl radical from the resulting intermediate radical **A** (Fig. 2). The major product of the reaction of **10a**, however, is the 5-*exo* cyclisation product **16**. This is probably because the sulfur atom of the intermediate radical **B** can strongly stabilise the neighboring radical centre.[9]

On the other hand, both conformers *syn*-**10b** and *anti*-**10b** for the (*Z*)-isomer **10b** have a more severe steric constraint between the *o*-$BrC_6H_4CH_2$ and SPh groups for the former and between the COEt and SPh groups for the latter (Fig. 1), and hence the C_α=C_β bond and amide nitrogen might not be conjugated in enamide **10b**.[10] If the C_α=C_β bond is almost perpendicular to the amide bond, as depicted in **C** (Fig. 2), the resulting radical can attack the more proximate C_α-position to give exclusively the observed 5-*exo* cyclisation product **16**.[11]

6 Careful examinations on the effects of varying Bu_3SnH concentration, addition time and reaction temperature, have frequently shown that 6-*endo* cyclisation products are formed by an initial 5-*exo* cyclisation followed by neophyl rearrangement. See: K. A. Parker, D. M. Spero and K. C. Inman, *Tetrahedron Lett.*, 1986, **27**, 2833; A. N. Abeywickrema, A. L. J. Beckwith and S. Gerba, *J. Org. Chem.*, 1987, **52**, 4072; K. Jones, S. A. Brunton and R. Gosain, *Tetrahedron Lett.*, 1999, **40**, 8935. See also ref. 2.

7 An initial conformation of a radical precursor has been suggested to play an important role in deciding the course of cyclisation. See: D. P. Curran and J. Tamine, *J. Org. Chem.*, 1991, **56**, 2746; O. M. Musa, J. H. Horner and M. Newcomb, *J. Org. Chem.*, 1999, **64**, 1022; D. P. Curran, W. Liu and C. H.-T. Chen, *J. Am. Chem. Soc.*, 1999, **121**, 11 012, and references cited therein.

8 It has been also suggested that the vinyl groups of *N*-alkyl-*N*-vinylcarbamates occupy *anti*-position to the alkoxycarbonyl groups. See: O. Tamura, M. Hashimoto, Y. Kobayashi, T. Katoh, K. Nakatani, M. Kamada, I. Hayakawa, T. Akiba and S. Terashima, *Tetrahedron*, 1994, **50**, 3889; T. Akiba, O. Tamura, M. Hashimoto, Y. Kobayashi, T. Katoh, K. Nakatani, M. Kamada, I. Hayakawa and S. Terashima, *Tetrahedron*, 1994, **50**, 3905.

9 For sulfur-controlled *exo* selective radical cyclisations, see: H. Ishibashi, T. Kobayashi and D. Takamasu, *Synlett*, 1999, 1286 and references cited therein.

10 This assumption was supported by IR spectral properties showing the carbonyl band for (*E*)-isomer **10a** in a higher frequency region (1680 cm^{-1}) compared to that (1660 cm^{-1}) for (*Z*)-isomer **10b**.

11 It seems that the size of the substituent on the nitrogen atom of **10a,b** does not influence the conformer population. Thus, treatment of the *N*-COBu^t congener of (*E*)-isomer **10a** also gave nearly equal amounts of 5-*exo* cyclisation product (42%) and 6-*endo* cyclisation product (37%), and the corresponding (*Z*)-isomer gave only the 5-*exo* cyclisation product in 70% yield (compare to the results with **10a**,**b**).

Pyridyl-thiazoles as a new class of ligand for metallosupramolecular chemistry: formation of double and triple helicates with Cu(II)

Craig R. Rice,*[a] Stefan Wörl,[b] John C. Jeffery,[b] Rowena L. Paul[b] and Michael D. Ward[b]

[a] *Department of Chemical and Biological Sciences, University of Huddersfield, Huddersfield, UK HD1 3DH. E-mail: c.r.rice@hud.ac.uk*

Received (in Cambridge, UK) 31st May 2000, Accepted 7th June 2000

Reaction of either 1,10-phenanthroline-2-thioamide or pyridine-2-thioamide with 1,4-dibromobutane-2,3-dione affords the novel thiazole-containing polydentate ligands L^1 and L^2, respectively; these ligands form dinuclear double and triple helicate architectures, respectively, with Cu^{2+}.

Studies on the assembly of double and triple helicate complexes have been a major area of supramolecular coordination chemistry for the last 15 years. Helicate complexes have elegantly illustrated how the specific formation of architecturally complex assemblies are directed by the interplay between relatively simple parameters such as the stereoelectronic preference of the metal ion and the disposition of binding sites in the ligand.[1]

Many helicates are derived from ligands which are obviously partitioned into distinct binding sites, as exemplified by (i) the bis-catecholate ligands of Albrecht which form dinuclear triple helicates with various octahedral M(IV) ions;[2] (ii) the polybipyridyl ligands of Lehn and coworkers which form multinuclear double helicates with pseudo-tetrahedral Cu(I) and Ag(I);[3] and (iii) the bisterdentate ligands of Piguet and coworkers which afford triple helicates with nine-coordinate lanthanide(III) ions.[4] In contrast to these are the well-studied linear oligopyridines, whose partition into distinct metal-ion binding domains is controlled by the preference of the metal ion.[5] Thus, 2,2′:6′,2″:6″,2‴:6‴,2⁗:6⁗,2⁗⁗-sexipyridine (spy) splits into two terdentate domains to give dinuclear double helicates with metals such as Cd(II) which are six-coordinate, but splits into three bidentate domains to give trinuclear double helicates with metals such as Cu(I) which prefer to be pseudo-tetrahedral. Similarly 2,2′:6′2″:6″,2‴-quaterpyridine (qpy) can act as a simple tetradentate chelate in many mononuclear complexes,[6,7] or split into a '3 + 1'-dentate arrangement in octahedral $[Fe(qpy)_2]^{2+}$ in which qpy behaves as a terdentate ligand,[8] or split into a '2 + 2'-dentate arrangement in dinuclear double helicates with Cu(I) and Ag(I).[7] It is clear that the versatility of these ligands arises from their ability to adopt a wide variety of different coordination modes.

Here, we describe the preparation of a new class of ligand, containing chelating pyridyl-thiazolyl fragments, for the assembly of helicates. There are two features that make these of particular interest. Firstly, they are very simple to prepare and are readily available in far higher quantities than the analogous polypyridines; in this respect they are like the pyridyl/imine chelates of Hannon *et al.*[9] The thiazole unit is particularly easy to introduce into polydentate ligands and a number of metal complexes (but no helicates) of thiazole-based ligands have been prepared.[10] Secondly, unlike their polypyridyl analogues, these ligands naturally partition themselves into distinct binding domains because of the inability of the two adjacent thiazolyl units to chelate to the same metal: thus a substantial twist arises in the backbone of the coordinated ligand at this point.

The new ligands L^1 and L^2 are easily prepared as the bishydrobromide salts in good yield by reaction of 2 equivalents of the corresponding thioamide (2-pyridylthioamide and 1,10-phenanthroline-2-thioamide, respectively) with 1,4-dibromobutane-2,3-dione in methanol (Scheme 1).† Subsequent neutralization gives the free-base ligands. Reaction of L^1 with 2 equivalents of $Cu(PF_6)_2$ in Me_2CO gives, after precipitation in an atmosphere of ethyl acetate, a green crystalline material for which electrospray mass spectrometry and elemental analysis suggested a formula of $[Cu_2(L^1)_3](PF_6)_4$ **1**. This formulation was confirmed by X-ray crystallography, which shows two Cu(II) ions co-ordinated by three bridging ligands L^1 in a triple helical arrangement (Fig. 1).‡ Each of the Cu centres has a pseudo-octahedral coordination geometry (bite angles 77.0–79.6°, Cu–N distances 2.028–2.228 Å), formed by coordination of three thiazole-pyridyl bidentate units with each

DOI: 10.1039/b004319m

ligand twisted about the bond between the two thiazole rings. Although the coordination geometry is somewhat irregular, there is no obvious Jahn–Teller distortion axis. The structure is stabilized by extensive aromatic π-stacking interactions between overlapping, near-parallel fragments of adjacent ligand, as emphasized in the space-filling picture (Fig. 2).

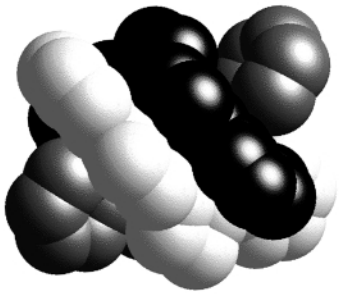

Fig. 2 Space-filling representation of the triple helicate **1**.

The formation of a triple helicate is in interesting contrast to the mononuclear complexes in which qpy acts as a simple equatorial tetradentate chelate.[6,7] In qpy this coordination mode is facilitated by the fact that each chelate ring has a bite angle appropriate for coordination to a single metal ion. In L^1, this is not the case; the two five-membered thiazolyl rings cannot chelate as the N atoms of the two five-membered rings are not sufficiently convergent, so the ligand naturally partitions into two bidentate pyridyl/thiazolyl units with a twist in the ligand backbone between them. The result is a dinuclear triple helicate instead of a simple mononuclear complex.

Reaction of L^2 with $Cu(ClO_4)_2$ in MeCN gives the double-helical complex $[Cu_2(L^2)_2](ClO_4)_4$ **2**.‡ Each of the copper centres is pseudo-octahedral, coordinated by two thiazolyl-phenanthroline tridentate units [bite angles 74.2–98.7°, Cu–N distances 1.967–2.312 Å], with each ligand again twisted about the inter-thiazole bond (Fig. 3) for the same reason as before.

In conclusion, we have demonstrated that polydentate ligands containing two central thiazolyl units are easy to prepare, and are very effective at forming double and/or triple helicates because of the way they naturally partition into two separate binding domains.[11] This method for preparing large polydentate ligands not only allows significant quantities to be produced but can also be readily extended to the preparation of a wide variety of ligands whose size, shape and functionality can be changed with ease.

We thank EPSRC for support.

Received (in Cambridge, UK) 31st May 2000, Accepted 5th July 2000

A series of polyphenylacetylene networks are modelled through force-field based simulations and are predicted to exhibit unusual mechanical properties, namely, negative Poisson's ratios (auxetic), a property which is explained through a simple model involving a network of connected rotating triangles.

Materials with a negative Poisson's ratio [auxetic, see methods section, eqn. (2)] exhibit the unexpected property of becoming wider when stretched and thinner when compressed.[1,2] Apart from the purely scientific importance of having such an unusual basic property, a negative Poisson's ratio gives a material many additional beneficial effects,[2,3] such as increased shear stiffness, increased plane strain fracture toughness and increased indentation resistance. Auxetics also have a natural ability to form synclastic doubly curved surfaces (*i.e.* dome shaped). This means that auxetic materials are superior to conventional counterparts in many practical applications. Unfortunately, although several auxetics have now been discovered or manufactured (*e.g.* foams,[3] microporous polymers[4] and silicates[5]), a negative Poisson's ratio is not a common feature in most everyday materials (*e.g.* the Poisson's ratio of most isotropic polycrystalline metals is approximately +0.3).

In recent years, considerable attention has been focused towards designing and synthesising molecular auxetics.[2,6] Such systems would offer the advantage over naturally occurring auxetics that they can be 'made to measure' to have a predefined set of mechanical properties.

In this communication we present a new class of molecular auxetics that have been predicted to exhibit negative Poisson's ratios.† They may be described as parallel 'graphite-like' layers each containing a planar polyphenylacetylene infinite network. These planar networks are a tessellation of a repeat unit having two equilateral molecular triangles at 60° to each other, an example of which is illustrated in Fig. 1(*a*). Homologues of the network in Fig. 1(*a*) may be produced by using longer or shorter acetylene chains. Since there is no simple way of naming these polytriangular networked systems, we shall henceforth refer to them as polytriangles-*n*-yne where *n* refers to the number of triple bonds per acetylene chain. Thus the network in Fig. 1(*a*) shall be referred to as polytriangles-2-yne.

Molecular mechanics simulations of these systems (aligned as in Fig. 1) using Cerius^2 V3.0 (Molecular Simulations Inc., San Diego, USA) have shown that the minimum energy separation between the different layers is approximately 3.6 Å, a distance which indicates the π–π interactions in between the different layers are being well represented. As illustrated in Table 1, it was observed that for $n \geqslant 2$, these polytriangles-*n*-yne networks exhibit negative Poisson's ratios (auxetic) in the Ox_2–Ox_3 plane (*i.e.* negative ν_{23} and ν_{32}) which tend to −1 as *n* increases. Furthermore, for $n \geqslant 2$, all the six Poisson's ratios were predicted to be negative. This is the first time that a material is predicted to simultaneously exhibit six negative mutually orthogonal Poisson's ratios.

In an attempt to understand the reason behind these very unusual properties, especially the very highly negative ν_{23} and ν_{32}, the minimum energy configurations at different loads in the Ox_2 and Ox_3 directions were obtained. From these minimum energy configurations, it was observed that for the larger triangles, the main type of deformation mechanism is through flexure of the acetylene chains. This flexure results in an overall

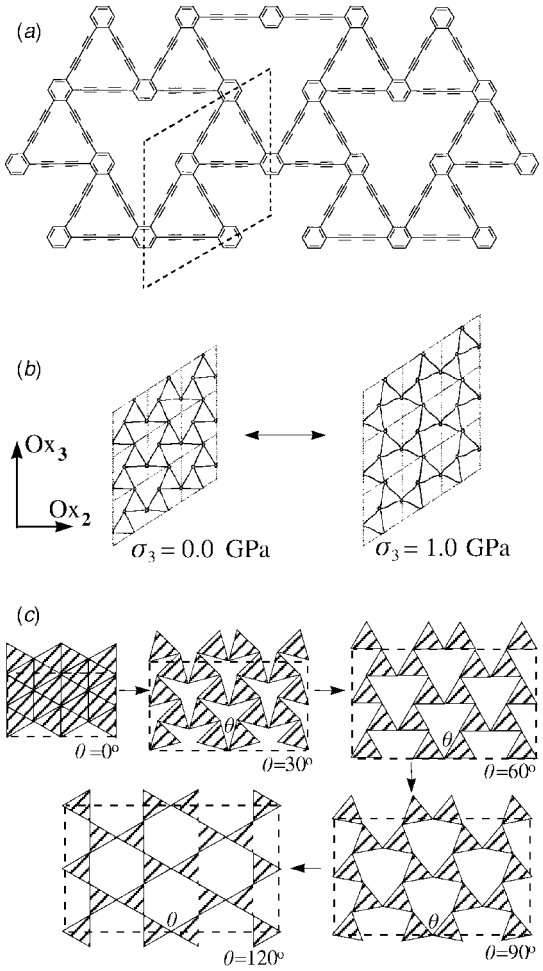

Fig. 1 (*a*) The structure of polytriangles-2-yne; (*b*) the minimum energy configurations of polytriangles-7-yne at $\sigma_3 = 0.0$ GPa and at $\sigma_3 = 1.0$ GPa; (*c*) the concept behind the design of the molecular networks: the idealised 'rotating triangles' networks. The molecular networks relate to the structure where $\theta = 60°$.

Table 1 The predicted single crystalline Poisson's ratios (ν_{ij}) of the polytriangles-*n*-yne where *n* is the number of triple bonds in the acetylene chains. The Ox_i axis are as defined in Fig. 1

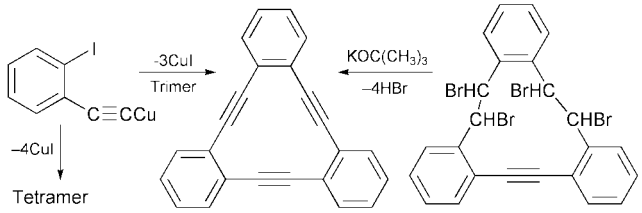
DOI: 10.1039/b004305m



Scheme 1 The synthesis of single triangles.[11]

relative rotation of the triangles as illustrated for $n = 7$ in Fig. 1(*b*).

The possibility of achieving negative Poisson's ratios *via* rotating triangles compliments the recent predictions that a number of zeolites deform though a 'rotating squares' mechanism[7,8] and hence produce negative Poisson's ratios.[7–10] As illustrated in Fig. 1(*c*), a two dimensional structure composed of rigid hinged equilateral triangles connected together through hinges is geometrically constrained to maintain its aspect ratios and hence have in-plane Poisson's ratios of -1.[8] This simple geometric model explains why for the larger networks (*i.e.* the ones where the geometry of the triangles become more conspicuous), the Poisson's ratio tends to -1. The other four negative Poisson's ratios are probably due to a variation in the amount of interactions between the different layers.

Finally, we note that other similar two-dimensional delocalised π-systems such as graphyne and graphdiyne (*i.e.* the all-carbon fully substituted versions of polytriangles-1-yne and polytriangles-2-yne respectively) have also attracted considerable attention *vis-à-vis* their unique optical and electronic properties.[10] Unfortunately, graphyne and graphdiyne do not exhibit any auxeticity as they lack the required polytriangles geometry.[8] We also note that the synthesis of single, non-networked, equilateral molecular triangles has been known for a long time[10,11] (see Scheme 1) and that several advances have been made in the synthesis of other polyphenylacetylene networks.[10]

Thus to conclude, this work has shown the potential of these simple polyphenylacetylene networks as molecular auxetics. We hope that given the many advantages of auxetics when compared to conventional materials, these predictions will encourage further research into their chemistry so as to enable the synthesis of the first purpose-built molecular auxetic material.

Notes and references

† *Methods used:* (1) Simulation of the minimum energy configurations: Molecular mechanics simulations were carried out on an array of these networks (n = 1,2, …, 8) using the Cerius² V3.0 molecular modelling package. The polyphenylacetylene layers were aligned parallel to the Ox_2–Ox_3 planes (see Fig. 1). The energy expressions E were set up using parameters from the Dreiding force-field[12] except for the atomic charges which were calculated through the charge equilibration procedure developed by Rappé and Goddard.[13] Non-bond terms were added using the Ewald summation technique.[14] (2) Simulation of the mechanical properties:[15] The 6×6 stiffness matrix **C** (and its inverse, the compliance matrix **S**) of the minimum energy single crystalline polytriangles-*n*-yne systems were calculated from the second derivative of the potential energy function since:

$$c_{ij} = \frac{1}{V}\frac{\partial^2 E}{\partial\varepsilon_i \partial\varepsilon_j} \qquad i,j = 1,2,\ldots,6 \tag{1}$$

where E is the energy expression, V is the volume of the unit cell and ε_i are strain components. Other mechanical properties were then calculated from these matrices since, for example, the Poisson's ratios in the Ox_2–Ox_3 plane for loading in the Ox_3 direction is given by:

$$\nu_{32} = -\frac{\text{transverse strain}}{\text{axial strain}} = -\frac{\varepsilon_2}{\varepsilon_3} = -\frac{s_{32}}{s_{33}} \tag{2}$$

A novel one step photocatalytic synthesis of dihydropyrazine from ethylenediamine and propylene glycol†

Received (in Cambridge, UK) 16th May 2000, Accepted 7th July 2000

Dihydropyrazine (DHP), the intermediate for pyrazine, is synthesized from ethylenediamine and propylene glycol; it is assumed that the reaction proceeds by photooxidation of propylene glycol and cyclization with ethylenediamine to give dihydromethylpyrazine, which by subsequent oxidative demethylation *via* the corresponding acid, forms dihydropyrazine; molecular oxygen, light and TiO_2/zeolite promote the reaction.

In the last few years heterogeneous photocatalysis applied to synthetic chemistry has become an exciting and rapidly growing area of research. For a multistep synthesis illuminated semiconductors offer unique features. Many studies[1a–f] have reported photocatalytic organic reactions using mild experimental conditions. To date they are mostly in the categories of oxidations and oxidative cleavage, reduction, geometric and valence isomerization, substitution, condensation and polymerization. The discovery of the photo-Kolbe reaction by Kraeutler and Bard[2] using Pt/TiO_2 as a photocatalyst for the conversion of acetic acid to methane and CO_2 has attracted much attention. However, in spite of several titanium dioxide mediated reactions, examples of inducing intermolecular C–C bonding are rather limited in the literature. A recent report demonstrated that platinized TiO_2 is a successful photocatalyst in the selective *N*-cyclization of *N*ε-carbamyl-L-lysine into virtually optically pure L-pipecolinic acid.[3] Also Nishimoto *et al.*[4] showed photocatalytic intermolecular conversion of primary diamines to cyclic secondary amines in an aqueous suspension of Pt/TiO_2. In contrast to thermal processes by homogeneous and heterogeneous catalysts, these reactions proceed at ambient temperature. Furthermore, study of the photochemistry of organic molecules adsorbed on solid surfaces such as zeolites and microporous solids to conduct phototransformations has been explored.[5a–g] Combining the photocatalytic activity of TiO_2 with the utility of zeolites for photoinduced organic synthesis[9a,b]/degradation[6] has, so far, been little exploited.

Thermal catalytic processes are available for the synthesis of pyrazine and its derivatives.[7a–e] The present photocatalytic synthesis of dihydropyrazine by the cyclization of ethylenediamine and propylene glycol using TiO_2/zeolite, to the best of our knowledge, has not been reported.

In the present work zeolites HY, HZSM-5, Hβ and HM were used to support TiO_2 (Degussa P25) or ZnO (Fluka). The SiO_2/Al_2O_3 ratios of the above zeolites are 4.4, 30, 20 and 30, respectively. The preparation method for the catalysts consisted of mechanical mixing of TiO_2 or ZnO and zeolites using a low-boiling organic solvent (ethanol), evaporation of the solvent, drying at 110 °C and finally calcination at 400 °C for 6 h. Prior to the evaluation, the catalysts were activated at 300 °C for 4 h. The photocatalytic reaction was carried out in a batch type cylindrical quartz reactor of 200 ml capacity with a refluxing condensor at the top of the reactor. The slurry, which was composed of an equimolar ratio (1:1) of ethylenediamine and propylene glycol (either of the reactants in excess did not provide any better yields) and 100 mg of photocatalyst along with 20 ml of acetonitrile solvent.‡ A provision for bubbling molecular oxygen at a rate of 20 ml h^{-1} was also provided to the reactor. The reactants were stirred magnetically with simultaneous irradiation§ from a 250 W high pressure mercury lamp (Philips India) for 15 h at ambient temperature. Parallel experiments were also carried out for the synthesis of DHP using ZnO[8] and ZnO supported zeolite but lower yields were observed compared to TiO_2/zeolite catalysts. All the experimental results are shown in Table 1.

Table 1 Results obtained after 15 h of irradiation (250 W high pressure mercury lamp) over different TiO_2/zeolite combinations for the cyclization of ethylenediamine and propylene glycol[a]

Entry	Catalyst	Surface area[b]/m^2 g^{-1}	Acidity[c]/ mmol g^{-1}	Yield of DHP[d] (%)
1	2wt% TiO_2/HZSM-5	350	0.37	13.0
2	2wt% TiO_2/HY	400	0.25	13.6
3	2wt% TiO_2/Hβ	406	0.20	20.4
4	2wt% TiO_2/HM	391	0.12	2.03
5	2wt% ZnO/HZSM-5	326	0.13	8.12
6	2wt% ZnO/HY	336	0.18	8.06
7	TiO_2	50	—	—
8	ZnO	30	—	—

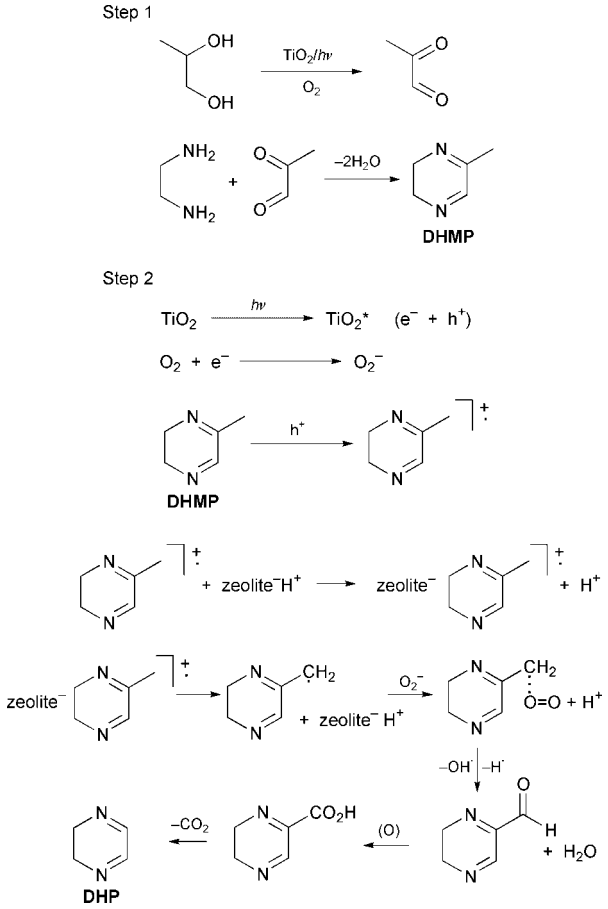
[a] All reactions were performed with an equimolar ratio (1:1) of ethylenediamine and propylene glycol in 20 ml of acetonitrile using 100 mg of catalyst under oxygen bubbling at room temperature. [b] Measured by the BET technique with liquid N_2 at 77 K. [c] Measured by STPD of NH_3. [d] Yields were calculated based on the recovery of propylene glycol.

At the end of the reaction, 20 ml of demineralized water was added to the reaction mixture which was centrifuged, which allowed recovery of the adsorbed substrates and products on the surface of the solid catalyst. The supernatant liquid was analyzed with a Chemito 3865 Gas Chromatography unit using a 6 ft, 10% SE-30 packed column. The products were further identified by ^{1}H NMR and mass spectrometry.

Further experiments were carried out to confirm whether the reaction is photocatalytic or non-photocatalytic and it was observed that no product was formed in the absence of molecular oxygen + irradiation + TiO_2/zeolite catalyst. Zeolite alone without TiO_2 did not yield any product. Irradiation in the presence of photocatalyst when carried out using conventional liquid acids such as HCl and solid acids such as silica gel did not yield the product.

Zeolite acidity seems to influence the reaction mechanism; the oxidation is dependent on the acidity of the reaction mixture[9a] and ethylenediamine is adsorbed preferentially relative to propylene glycol in the internal surface area of the zeolite pores. The preferential adsorption of ethylenediamine leads propylene glycol to undergo oxidation to the diketone (step 1, Scheme 1) at the oxidizing site of TiO_2. The diketone formed undergoes cyclization with ethylenediamine to give dihydromethylpyrazine (DHMP) with loss of 2 mol of water. The methyl group of dihydromethylpyrazine is oxidatively demethylated leading to dihydropyrazine (DHP) as shown in

† IICT Communication No 4561.



Scheme 1 Proposed reaction mechanism for the formation of DHP.

step 2 of Scheme 1. Photoexcitation of the semiconductor in step 2 would produce an electron and a hole. Oxygen serves as an electron acceptor for the conduction band electron and the dihydromethyl pyrazine supplies an electron to the photogenerated hole at the surface of the TiO_2 particle forming an adsorbed radical cation. The zeolite may assist the stability of the radical cation through proton transfer as observed by Beaune *et al*.[9b] Thus, the proposed mechanism of step 2 is enhanced by more acidic zeolites. Here, dihydropyrazine carbaldehyde undergoes further oxidation to the corresponding acid which in turn forms the dihydropyrazine after decarboxylation. The obtained dihydropyrazine was subjected to dehydrogenation[10] using a conventional method which yielded the pyrazine thereby confirming the product formation (DHP).

The reaction was then attempted with ethylene glycol instead of propylene glycol, but no cyclic product was observed. This shows that the electron donating substituent, *i.e.* the methyl group of propylene glycol, may favour the oxidation mechanism.[9c] In aerated solutions, the photogenerated electron can be trapped by adsorbed oxygen to form superoxide or other negatively charged adsorbed oxygen species.[11]

Hydrogen peroxide [eqn. (1)] thus formed by sequential

$$\begin{aligned} O_2 + e^{-} &\longrightarrow O_2^{\cdot-} \\ O_2^{\cdot-} + H^{+} &\longrightarrow HOO^{\cdot} \\ 2HOO^{\cdot} &\longrightarrow H_2O_2 + O_2 \\ H_2O_2 + O_2^{\cdot-} &\longrightarrow OH^{\cdot} + OH^{-} + O_2 \end{aligned} \qquad (1)$$

electron and proton transfer readily decomposes on illuminated TiO_2 to hydroxy radicals and oxygen. Since the recombination is inhibited by adsorbed oxygen, it is reasonable to expect that the rate of photocatalytic oxidation should be high as oxygen is continuously bubbled in a steady state. Thus the selectivity for the primary alcohol site of propylene glycol is higher in pure oxygen than in air. The secondary alcohol site is oxidized to a greater extent by the adjacent electron donating group *i.e.* methyl at the TiO_2 center. No photodegradation of compounds (formation of CO_2) was observed for lower wt% values of TiO_2 on the zeolite. The evaluation of TiO_2/zeolite catalysts in the cyclization of ethylenediamine and propylene glycol show that 2wt% TiO_2 is optimal since higher loadings lead to total oxidation.

As seen from Table 1, 2 wt% TiO_2/HZSM-5 and 2wt% TiO_2/HY show more or less the same activity and yield of dihydropyrazine. The hydrophobicity and acid site strength of zeolites influences the activity of these zeolite systems in the order Hβ > HZSM-5 = HY. This order illustrates that the cyclization is favoured by a combination of moderate hydrophobicity and acidity. However, 2wt% TiO_2/Hβ is found to be more active, leading to a high yield of dihydropyrazine which may be possibly explained by the structure of Hβ which is a combination of both HZSM-5 (channel pore system, high Si/Al ratio) and Y (12-ring pore system) zeolites.[12]

Dihydropyrazine was obtained with a yield of 20.4% over 2wt% TiO_2/Hβ during the cyclization of ethylenediamine and propylene glycol by photocatalysis *via* the proposed reaction scheme under irradiation in the presence of molecular oxygen.

One of us (K. V. S. R.) thanks the Council of Scientific and Industrial Research, New Delhi, India for the award of a Senior Research Fellowship. We thank Dr (Mrs) V. Durga Kumari for her valuable suggestions in improving the manuscript.

A new simple synthesis of *cis*- and *trans*-3,5-di-*tert*-butyl-3,5-diaryl-1,2,4-trithiolanes from ketones and tetraphosphorus decasulfide

Kentaro Okuma,*[a] Shinji Shibata,[a] Kosei Shioji[a] and Yoshinobu Yokomori[b]

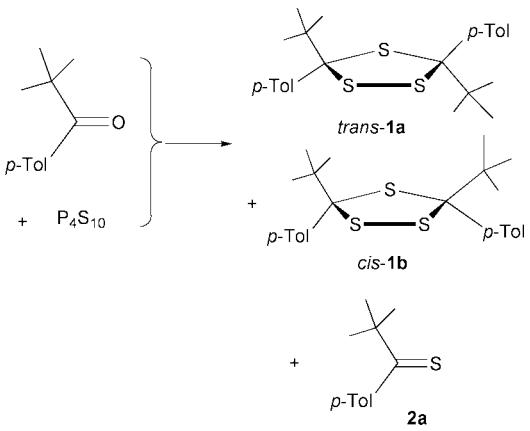
Received (in Cambridge, UK) 18th May 2000, Accepted 30th June 2000

The reaction of pivalophenones with tetraphosphorus decasulfide afforded *cis*- and *trans*-3,5-di-*tert*-butyl-3,5-diaryl-1,2,4-trithiolanes, which equilibrated to give other isomers in refluxing toluene *via* thiopivalophenones and thiopivalophenone *S*-sulfides.

1,2,4-Trithiolanes (**1**), some of which have been obtained from natural products, are well-known.[1] Methods for their synthesis include: reaction of thiobenzophenone with *o*-chloranil,[2] reaction of thiobenzophenones with 1,1-diphenylethylene sulfide,[3] reaction of thiones with Lowesson reagents,[4] reaction of dialkyl ketones with hydrogen sulfide elemental sulfur, and amines,[5] and fragmentation of 1,2,3-thiadiazoles.[6] Recently, Senning and co-workers reported that reaction of α-chlorosulfenyl disulfides with morpholine afforded the corresponding dispirotrithiolanes.[7] However, there are only a few reports on the synthesis of trithiolanes from ketones using thiation reagents although it is well known that the reaction of ketones with tetraphosphorus decasulfide (P_4S_{10}) affords the corresponding thioketones.[8] We have investigated the synthesis of trithiolanes from ketones using P_4S_{10} as a thiation reagent and report herein the isolation and X-ray crystallographic analysis of *cis*- and *trans*-**1** from P_4S_{10} and their thermal isomerization.

Treatment of 4-methylpivalophenone with P_4S_{10} in refluxing pyridine for 48 h resulted in the formation of *trans*-3,5-di-*tert*-butyl-3,5-di-*p*-tolyl-1,2,4-trithiolane (*trans*-**1a**), *cis*-3,5-di-*tert*-butyl-3,5-di-*p*-tolyl-1,2,4-trithiolane (*cis*-**1a**), and 4-methylthiopivalophenone (**2a**) in 13, 35, and 23% yields, respectively. Refluxing for 72 h resulted in the formation of *cis*-**1a** in 35 % yield along with *trans*-**1a** (24%) and **2a** (16%) (Scheme 1).

The structures *cis*-**1a** and *trans*-**1a** were confirmed by NMR and elemental analysis. Table 1 lists the ^{1}H NMR and ^{13}C NMR data for *cis*- and *trans*-**1a**. The chemical shift of the *tert*-butyl group of trans-**1a** is higher than that of *cis*-**1a**, whereas chemical shifts of the aromatic groups of trans-**1a** are lower than those of *cis*-**1a**. This observation suggests that each aromatic group of *cis*-**1a** was on the other aromatic plane whereas the *tert*-butyl group of *trans*-**1a** was on the aromatic plane.



Scheme 1

Both structures were confirmed by single crystal X-ray crystallographic analysis (Fig. 1)[9]: no unusual bond lengths or angles are observed in the 1,2,4-trithiolane rings. The trithiolane rings of both products have similar conformations to other trithiolanes. The C–S bond lengths of the trithiolane rings are between 1.796 and 1.875 Å—longer than normal (1.763–1.767 Å)[6] because the trithiolane rings are compressed by bulky *tert*-butyl groups. However, the S–S bond lengths (2.027 Å for *cis*-**1a** and 2.016 Å for *trans*-**1a**) are shorter than the one reported by Senning *et al.* (2.0345 Å).[7] As suggested by their NMR spectra, the aromatic groups of *cis*-**1a** were out of plane whereas the *tert*-butyl group of *trans*-**1a** was on the aromatic plane.

Other reactions were similarly carried out. The results are shown in Table 2.

More than three decades ago, Elam and Davis reported the synthesis of dimethylthioketene dimer by the reaction of tetramethylcyclobutane-1,3-dione with tetraphosphorus decasulfide. They isolated the corresponding trithiolane as a side product (2.8%).[8] However, they did not apply the general synthesis of **1** from ketones. The reaction of pivalophenone with P_4S_{10} generally afforded thiopivalophenone in good yield.[10] The present reaction is the first practical method on the synthesis of **1** from ketones by using P_4S_{10}.

Thiocarbonyl *S*-sulfides (thiosulfines) are well-known to exhibit high reactivity such as dienophile-like behavior, for example, and can add to a variety of thiones to give **1**. 3,3,5,5-Tetraaryl-1,2,4-trithiolanes are thermally unstable and dissociate into thiocarbonyl *S*-sulfides and thiobenzophenone in refluxing chloroform.[3] Since *cis*- and *trans*-**1** were isolated, the thermal behavior of these isomers was investigated. A solution of *cis*-**1a** in deuterated toluene was heated at 110 °C for 72 h. The ^{1}H NMR spectroscopic analysis of the solution revealed that *cis*-**1a** gradually converted to *trans*-**1a** (26%), along with **2a** (44%), whereas *cis*-**1** a was recovered in 25% yield. While *trans*-**1a** also converted to *cis*-**1a**, the rate of conversion was low. After being heated at 110 °C for 72 h, 66% of *trans*-**1a** still remained, suggesting that *trans*-**1a** is more stable than the corresponding *cis*-isomer. The most straightforward explanation for the conversion of *cis*-**1a** to *trans*-**1a** involves the isomerization of *cis*-**1a** to the thiocarbonyl *S*-sulfide (**3a**) and **2a** followed by recombination *via* 1,3-dipolar cycloaddition between **3a** and **2a** (Scheme 2).

Table 1 Spectral data of *cis*- and *trans*-**1a**

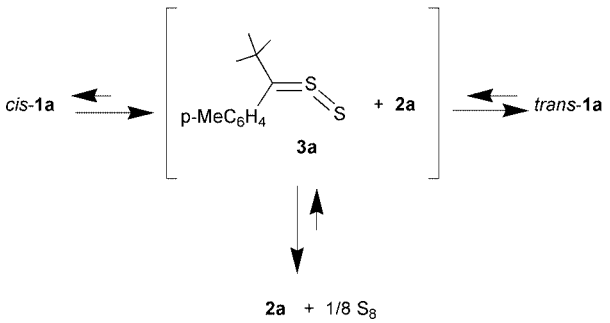
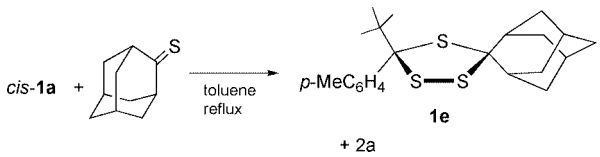
Bond angles: C1–S1–C2 102.8(4); S3–S2–C2 96.6 (3); S2–S3–C1 95.5(3); S1–C1–S3 106.4(4); S1–C2–S2 106.5(4)°.



Scheme 2

When the reaction was carried out in the presence of adamantane-2-thione (2 eq.), the corresponding cycloadduct (**1e**) was obtained in 67% yield along with recovered *cis*-**1a** (15 %) and **2a** (70%) (Scheme 3).[11]

The difference in stability between *cis*- and *trans*-**1** might be attributed to the difference in their steric hindrances. As can be



Scheme 3

seen in Figure 1, *cis*-**1a** is more crowded than the *trans* isomer. In fact, Senning *et al.* have reported that the reaction of thiosulfenyl chloride with morpholine afforded mainly the corresponding *trans*-trithiolane, suggesting that *cis*-trithiolane is generally unstable and gradually converts into the more stable *trans*-isomer.[7]

In summary, we have isolated and characterized *cis*- and *trans*-**1** by the reaction of pivalophenones with P_4S_{10}. Both isomers interconvert in refluxing toluene. The intermediate **3** was trapped by the reaction with adamantane-2-thione to afford unsymmetrical **1**.

Control of crystal polymorphs by a 'latent inductor': crystallization of calcium carbonate in conjunction with *in situ* radical polymerization of sodium acrylate in aqueous solution

Kensuke Naka,* Dong-Ki Keum, Yasuyuki Tanaka and Yoshiki Chujo*

Department of Polymer Chemistry, Graduate School of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto, 606-8501, Japan. E-mail: ken@chujo.synchem.kyoto-u.ac.jp

Received (in Cambridge, UK) 12th June 2000, Accepted 10th July 2000

Three different crystal polymorphs of $CaCO_3$ (aragonite, vaterite and calcite) have been selectively induced by changing the time of addition of a radical initiator to a calcium carbonate solution containing sodium acrylate.

In nature, biological organisms produce polymer–inorganic hybrids. In these mineralized tissues, crystal morphology, size, polymorph, and orientation are determined by local conditions and, in particular, the presence of 'matrix' proteins or other macromolecules.[1] However, there remain many unknowns as to how the matrix affects the crystallization process, especially the initial nucleation. A final crystalline phase might arise through a multistage crystallization process.[2,3] The existence of several phases would enable organisms to control mineralization through intervention with the kinetics. By selectively interacting with the mineral at different stages during the crystal forming process, the organisms may choose to manipulate both the polymorph and the orientation of the mineral to meet specific biological requirements. Although crystallization of minerals in the presence of various additives and synthetic polymers has been investigated as a model of biomineralization,[4–6] selective interaction of synthetic additives with the minerals at different stages during the nucleation process has not been examined.

Here, we report a new concept for controlling crystal polymorphs of $CaCO_3$ by addition of a synthetic additive. The key point of our method is using a 'latent inductor' for crystal nucleation as shown in Fig. 1. The latent inductor at its inactive state does not affect nucleation and growth of the crystal. After the inactive state is transferred to an active state by a stimulus, the active inductor can induce nucleation and growth of the crystal. We used sodium acrylate as a latent inductor for this purpose and a water-soluble radical initiator was used as a stimulus. While sodium acrylate does not affect nucleation and growth of crystals[7] poly(acrylate) affects crystal morphology by inhibiting the growth of particular crystal faces.[3,8] Indeed, the precipitation of $CaCO_3$ in the presence of the sodium salt of poly(acrylic acid) (PAA) (M_n = 5100) was prevented under the nucleation conditions applied here.[6] Sodium acrylate can be transformed to poly(acrylate) by adding a radical initiator. In the present system, aqueous solutions of $CaCl_2$ and $(NH_4)_2CO_3$ were initially added to an aqueous solution of sodium acrylate and then subjected to polymerization by adding the radical initiator at 30 °C after incubation for several minutes. Crystallization of calcium carbonate with *in situ* polymerization of anionic monomers in aqueous solution has not been reported.

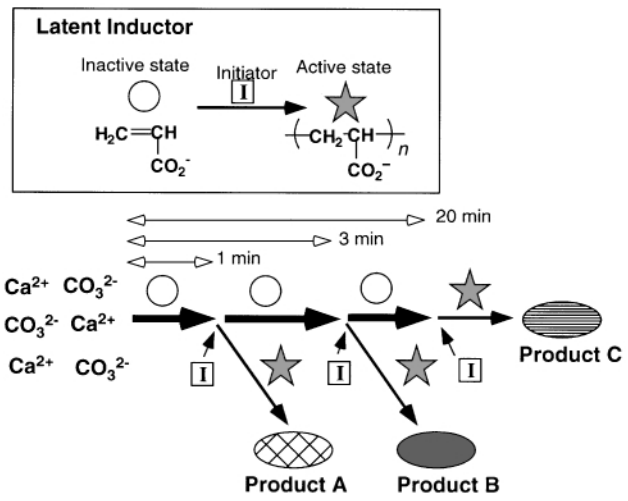

Fig. 1 Schematic depiction for the control of crystal polymorph growth by a latent inductor.

The precipitation of $CaCO_3$ was carried out under the same conditions as reported by Cölfen *et al.*[9,10] 4.95 ml of each reactant [0.1 M $CaCl_2$ and 0.1 M $(NH_4)_2CO_3$] were injected *via* syringe into 180 ml of an aqueous solution of sodium acrylate which was adjusted to pH 8.5 by NH_3(aq). The ratio of sodium acrylate to calcium ions was 0.62 : 1. After addition of the reactants was complete, an aqueous solution of $K_2S_2O_8$ as a water-soluble radical initiator was added to the reaction mixture after incubation at 30 °C for several minutes (1, 3 or 20 min). A sudden increase in the turbidity of the solution was observed after incubation for several minutes. The solutions were kept at 30 °C under N_2 for 1 day with gentle stirring. The crystalline $CaCO_3$ was collected and washed with water several times. The yields of the crystalline products obtained when the radical initiators were added to the reaction mixture after incubation for 1 min (product A), 3 min (product B) and 20 min (product C) were 33, 35 and 54%, respectively.

The crystal phases of the obtained $CaCO_3$ were characterized by FTIR analysis.[3,11,12] Product A displayed a characteristic symmetric carbonate stretching vibration at 1084 cm^{-1}, a carbonate out-of-plane bending vibration at 856 cm^{-1} and a pair of peaks at 701 and 713 cm^{-1} indicating aragonite formation. When the radical initiator was added after incubation for 3 min, product B showed several bands corresponding to a carbonate out-of-plane bending vibration. A band at 746 cm^{-1} indicated vaterite formation and bands at 877 and 713 cm^{-1} assignable to calcite were also present. The crystal phase of product C was calcite according to IR with only two bands at 877 and 713 cm^{-1} observed.

Fig. 2 shows scanning electron micrographs (SEM) of the three crystalline products. Each SEM micrograph shows different crystal modifications. The aragonite crystals (product A) were efflorescent bundles of needles [Fig. 2(a)], typical of the phase. Product B consisted of two different crystal modifications, spherical vaterite and rhombs of calcite [Fig. 2(b)]. Stable spherical vaterite crystals have already been reported in the presence of various bivalent cations,[13] double-hydrophilic block copolymers[9] and anionic PAMAM dendrimers.[6] Crystals of product C were rhombohedral [Fig. 2(c)]. The crystal phases of the obtained $CaCO_3$ samples were further confirmed by powder X-ray diffraction (XRD) analysis. The reflections of products A and C were characteristic for aragonite and calcite, respectively. The fraction of vaterite in product B

DOI: 10.1039/b004649n

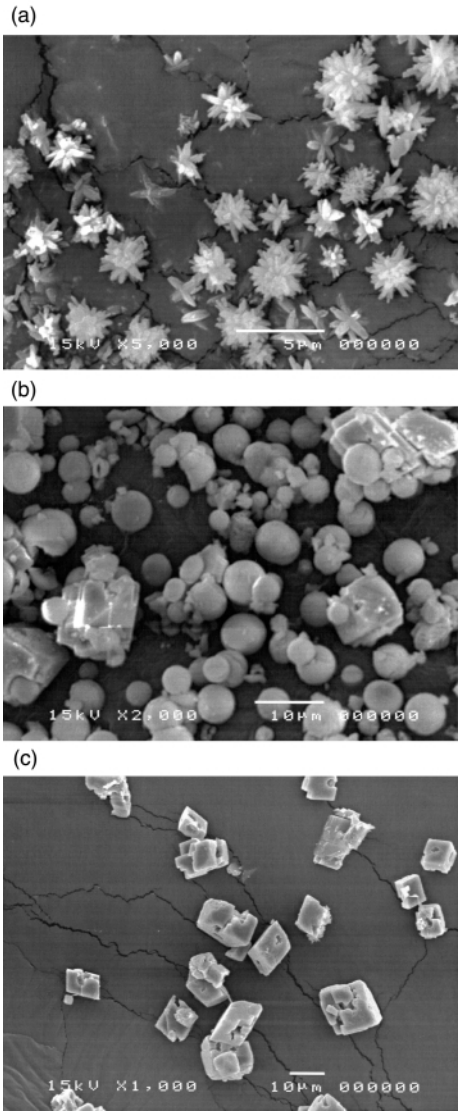

Fig. 2 Scanning electron micrographs of (a) product A, (b) product B and (c) product C.

was 63% as determined by Rao's equation.[14] These results indicate that the three different polymorphs of $CaCO_3$ were controlled simply by changing the addition time of the radical initiator to the calcium carbonate supersaturated solution containing sodium acrylate at ambient temperature. When the ratio of sodium acrylate to calcium ions was reduced to 0.37, the crystal phase obtained when the radical initiator was added after incubation for 1, 3 and 20 min was always calcite. This result suggests that the presence of the radical initiator was not the main factor for controlling the final crystal phase of $CaCO_3$.

Calcite is thermodynamically more stable than the other two crystalline modifications, aragonite and vaterite. The crystal phase of $CaCO_3$ obtained without any additives or with sodium acrylate in the absence of radical initiators was calcite under the same conditions as described above. Sodium acrylate is thus inactive for induction of metastable $CaCO_3$ crystalline phases (vaterite or aragonite). Since the crystal phase of product C was also thermodynamically stable calcite, the final crystalline phase was not affected when the polymerization of sodium acrylate was started *via* radical initiation after incubation of the reaction mixture containing calcium reactants and sodium acrylate for 20 min.

Aragonite is usually obtained at temperatures > 50 °C using a solution method of preparation.[4,11] In our present results, aragonite can be obtained at 30 °C when the radical initiator is added to the calcium ion solution with sodium acrylate after incubation for 1 min, during which time $CaCO_3$ crystal formation has not started. It is possible that aragonite is rapidly nucleated at the very beginning of the nucleation process, resulting in it being kinetically induced by the poly(acrylate). When the initiator was added to the reaction mixture after incubation for 3 min, crystals of calcite and vaterite were formed. These results indicate that the final crystalline phases are highly sensitive to the presence of the active additives at the very initial nucleation stage (first few minutes). During the phase transformation, the poly(acrylate) may kinetically and thermodynamically induce a crystal nucleation at each stage. In the absence of any additives, it is well known that vaterite transforms into stable calcite *via* a solvent-mediated process.[15] Although the crystal polymorph of product B did not change when the solution was kept for 2 days, vaterite crystals were transformed to calcite when the solution was incubated for 3 days. We speculate that the vaterite surfaces were stabilized by the resulting poly(acrylate) in aqueous solution so slowing phase transformation.

After the crystalline $CaCO_3$ was filtered off and washed with water, the combined water phase was evaporated under reduced pressure. GPC and FTIR analyses of the residue indicated the formation of poly(acrylate). Although we do not fully understand the mechanistic implication of the effect of *in situ* radical polymerization of sodium acrylate in aqueous solution for nucleation and growth of calcium carbonate, our current results have provided a new concept for controlling the crystal polymorphs of calcium carbonate. While sodium acrylate is inactive for nucleation and growth of crystals, addition of a radical initiator leads to poly(acrylate), which can influence nucleation and growth of $CaCO_3$. Sodium acrylate can be regarded as a latent active ligand for induction of crystal phases. We believe that the initial nucleation processes play an important role in controlling the final crystal modifications of $CaCO_3$ obtained. Further investigations are in progress.

We thank Dr Tetsuo Yazawa and Mr Kouji Kuraoka at Osaka National Research Institute for the SEM micrographs and XRD analysis.

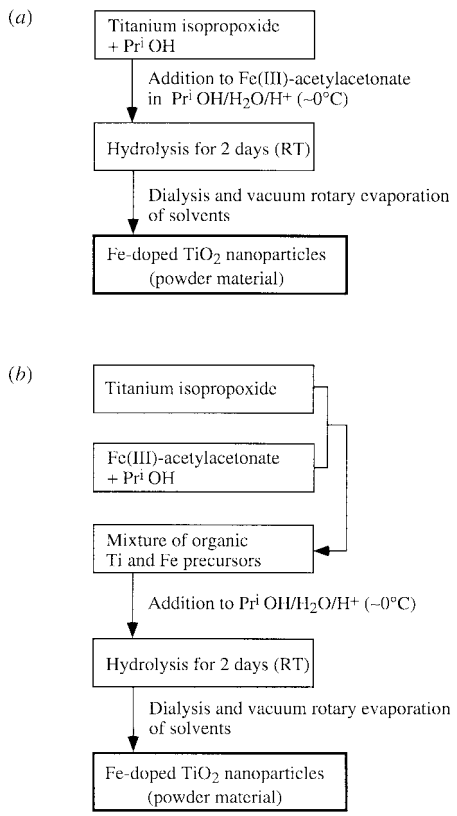
Received (in Oxford, UK) 12th April 2000, Accepted 20th June 2000

Fe^{III}-doped TiO_2 nanoparticles prepared from organic precursors (≤2.5 atom% Fe) exhibit strongly enhanced photocatalytic activity as demonstrated by the quantum yields measured for the formation of formaldehyde by photocatalyzed oxidation of methanol in aqueous solution (Φ up to *ca.* 15%).

In recent years, considerable effort has been devoted to the study of Fe^{III}-doped titanium dioxide in order to improve the photocatalytic efficiency of TiO_2.[1–4] The generally accepted mechanism to explain this improved photocatalytic performance is the formation of shallow charge trapping sites within the TiO_2 matrix as well as on the particles' surface through the replacement of Ti^{IV} by Fe^{III} ions.[3] Thus, the undesirable recombination of electron/hole pairs generated upon ultra-bandgap irradiation can be partially prevented. In most cases such photocatalysts have been prepared by hydrolysis of a Ti-precursor in the presence of a Fe^{III}-containing aqueous solution (Scheme 1*a*). Since the reaction system is fed with the Ti and Fe precursors present as different solution phases, the Fe/Ti ratio is unavoidably changed on addition of the Ti precursor to the solution of the Fe precursor, particularly so in the initial stage of particle growth. There is little doubt that this effect influences the local distribution of iron in the particles formed and hence the photocatalytic efficiency. In view of this we have developed a novel preparation in which organic Ti and Fe precursors were employed and mixed prior to hydrolysis (Scheme 1*b*). To the best of our knowledge, such a preparation has not been reported previously.



Scheme 1 Preparation of iron-doped TiO_2 nanoparticles. Previous (*a*) and present novel method (*b*).

As seen from Scheme 1*b*, the fraction of iron in the mixture and, hence, the nominal iron content of the particles can be varied as desired. As-prepared samples come as yellowish powders which can be resuspended in water, methanol or in a mixture of both solvents to obtain a colloidal suspension transparent in the visible region.

Fig. 1 shows the absorbance spectra of as-prepared samples of neat TiO_2 and of TiO_2 doped with different amounts of Fe^{III}. From Fig. 1 and by use of the procedure given by Kormann *et al.*[5] the bandgap energy, E_g, of the colloidal particles was obtained as 3.32, 3.25, 3.22 and 3.07 eV for zero, 0.25, 0.5 and 2.5 atom% iron, respectively. Clearly, E_g decreases with increasing iron content. Compared with bulk anatase TiO_2 (E_g = 3.23 eV[6]) the bandgap of the undoped TiO_2 particles (3.32 eV) is larger by *ca.* 0.1 eV. This corresponds to a mean spherical particle diameter of *ca.* 2.7 nm when the Brus equation[7] is applied.

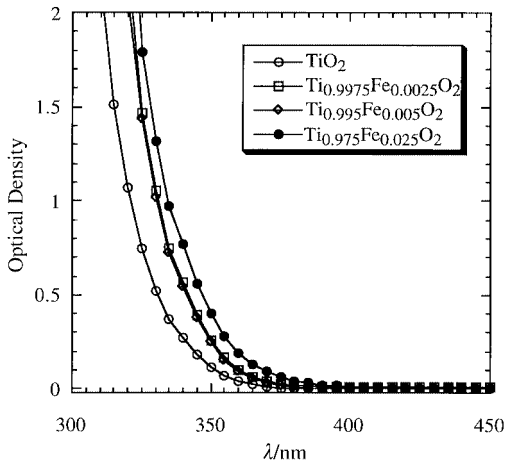


Fig. 1 Absorbance spectra of TiO_2 and iron-doped TiO_2 nanoparticles in colloidal aqueous solution (as-prepared according to Scheme 1*b*, pH ≈ 3, 1 cm cell, virtually no light scattering).

From the preparation procedures given in Scheme 1 it is expected that the distribution of iron in the TiO_2 matrix of the particles prepared by method (1*b*) is more uniform than by method (1*a*). Uniformity of doping was expected to result in enhanced photocatalytic activity. This was indeed verified by determination of the quantum yield of formaldehyde produced by photocatalytic oxidation of methanol in aerated aqueous solution[9] in the presence of the TiO_2 colloidal particles doped

DOI: 10.1039/b002988m

with iron by different methods. The photocatalytic reaction was carried out in a cylindrical cell under cw-illumination by filtered light from a xenon lamp (WG 320 + UV black filters, 60% transmission at 340 nm). The photon flux of this illumination set-up was determined by use of the Aberchrome-540 chemical actinometer.[8] The production rate of HCHO was measured by HPLC of samples taken at different time intervals[9] (total photolysis time *ca.* 30 min).

TiO_2-photocatalyzed oxidation of methanol proceeds as follows:[1,9,13]

$$TiO_2 + h\nu(\geq E_g) \xrightarrow{(fs)^1} h^+_{VB} + e^-_{CB} \quad (1)$$

$$h^+_{VB} + \equiv Ti^{IV}OH \xrightarrow{(fast)^1} \equiv Ti^{IV}OH^{\bullet +} / OH^{\bullet} \quad (2)$$

$$e^-_{CB} + \equiv Ti^{IV}OH \xrightarrow{(<100\ ps)^1} \equiv Ti^{III}OH / e^-_{tr} \quad (3)$$

$$e^-_{tr} + O_2 \xrightarrow{k_4} O_2^{\bullet -} \quad (4)$$

$$OH^{\bullet} + CH_3OH \xrightarrow{k_5} {}^{\bullet}CH_2OH + H_2O \quad (5)$$

$${}^{\bullet}CH_2OH + O_2 \xrightarrow{k_6} HCHO + HO_2^{\bullet} \quad (6)$$

$${}^{\bullet}CH_2OH + \equiv Ti^{IV}OH \xrightarrow{(fast)^{13}} HCHO + \equiv Ti^{III}OH / e^-_{tr} + H^+ \quad (7)$$

where $k_4 = 7.6 \times 10^7\ M^{-1}\ s^{-1}$ for trapped electrons,[10] $k_5 = 5 \times 10^8\ M^{-1}\ s^{-1}$ [11] and $k_6 \approx 5 \times 10^9\ M^{-1}\ s^{-1}$.[12] As detailed by Sun and Bolton[9] the quantum yield of HCHO is proportional to that of $OH^{\bullet}$ which plays a vital role in TiO_2 based photocatalytic reactions.[1,15]

Table 1 shows the values of Φ_{HCHO} determined for the TiO_2 and iron-doped TiO_2 colloidal photocatalysts prepared here by different methods. A 15 min pre-illumination of the aqueous colloidal particles was applied in the absence of CH_3OH for removal of surface flaws. Note that without pre-photolysis the concentration of HCHO was not proportional to the photolysis time but rather showed an induction-type behavior characteristic for the oxidation of residual organic material originating from the catalyst preparation. No HCHO was formed in the dark or during illumination in the absence of methanol evincing that the process was truly photocatalytic. As seen from Table 1, iron-dopant concentrations of up to 0.5 atom% increase Φ_{HCHO} dramatically. Further, Φ_{HCHO} is strongly affected by the method of photocatalyst preparation in some cases. Comparison of Φ_{HCHO} demonstrates that the novel preparation, Scheme 1*b*, is superior to that of Scheme 1*a* for the optimum dopant concentration of 0.5 atom% iron, where Φ_{HCHO} exhibits a *ca.* sixfold increase over the quantum yield measured in the presence of 2.7 nm undoped TiO_2 particles. The optimum iron-dopant concentration depends on the method of catalyst preparation (0.5 atom% for methods 1*a* and 1*b*, 0.25 atom% for the preparation from $TiCl_4$, similar to ref. 2).

Table 1 Quantum yields of formaldehyde formation by the photocatalytic oxidation of methanol in the presence of TiO_2 and iron-doped TiO_2 colloidal nanoparticles[a]

Fe/atom%	Φ_{HCHO}[b]/%	Precursor(s)	Photocatalyst preparation
0	2.3	$TiCl_4$	ref. 2
	2.8	$TiPr^iO$[c]	Scheme 1*a*
0.25	12.0	$TiCl_4 + FeCl_3$	ref. 2
	12.0	$TiPr^iO$[c] + Fe-acac[d]	Scheme 1*a*
	12.5	$TiPr^iO$ + Fe-acac	Scheme 1*b*[e]
0.50	7.2	$TiCl_4 + FeCl_3$	ref. 2
	12.7	$TiPr^iO$ + Fe-acac	Scheme 1*a*
	15.3	$TiPr^iO$ + Fe-acac	Scheme 1*b*[e]
2.50	5.2	$TiCl_4 + FeCl_3$	ref. 2
	9.2	$TiPr^iO$ + Fe-acac	Scheme 1*a*
	9.5	$TiPr^iO$ + Fe-acac	Scheme 1*b*[e]

[a] 100 mM methanol, O_2-saturated aqueous solution at pH ≈ 3, catalyst loading 0.5 g L^{-1}, reaction volume 23 mL, $I_o = 1.43 \times 10^{-6}$ Einstein L^{-1} s^{-1}, room temperature. See text for further details. [b] ±0.2. [c] Titanium tetraisopropoxide. [d] Fe^{III}-acetylacetonate. [e] Present method.

In conclusion, it has been shown that the novel preparation, Scheme 1*b*, of iron-doped TiO_2 nanoparticles yields a highly active photocatalyst for the oxidation of methanol in aqueous solution. This is tentatively attributed to conditions of particle growth more favorable than with method 1*a*. Further work on photocatalytic properties of related as-prepared materials, including structure characterization and studies by time-resolved techniques,[10,14] is under way.

Template-directed stepwise post-synthesis alumination of MCM-41 mesoporous silica

Robert Mokaya

School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD.

Received (in Cambridge, UK) 13th June 2000, Accepted 10th July 2000

Stepwise post-synthesis alumination of pure silica MCM-41 in which increasing proportions of the MCM-41 are aluminated depending on the amount of Al available in the synthesis gel is achieved during secondary synthesis (*i.e.* recrystallisation) of calcined pure silica MCM-41 in the presence of discrete amounts of Al.

The recent synthesis of MCM-41 type mesoporous silicas which possess well ordered pores of diameter 20–100 Å has expanded the range of heterogeneous catalysis into the mesoporous regime.[1–4] With regard to catalysis, purely siliceous mesoporous molecular sieves are of limited use owing to the absence of active sites in their matrices. Active sites may be generated *via* chemical modification involving the introduction of heteroatoms into the silica matrix.[2–4] The incorporation of Al (which gives rise to solid acid catalysts with acid sites associated with the presence of Al in framework positions) is a typical example. The introduction of Al into mesoporous silicas (*i.e.* alumination) normally takes place in a homogeneous form and results in uniform incorporation of Al with little control of its spatial distribution. Increasing the Al content in the synthesis gel generally results in a uniform increase in the amount of incorporated Al throughout the entire sample.[5] In a departure from this norm, this report describes preliminary work on the unusual stepwise post-synthesis alumination of pure silica MCM-41 in which increasing proportions of the MCM-41 are aluminated depending on the amount of Al available in the synthesis gel. This apparently step-wise alumination is achieved during secondary synthesis (recrystallisation) of calcined pure silica MCM-41 in the presence of discrete amounts of Al. Evidence from several characterisation techniques indicates that during recrystallisation, the proportion of aluminated MCM-41 increases with increase in the content of Al in the recrystallisation gel and that beyond a certain gel Si/Al ratio (determined by synthesis conditions) the whole sample is aluminated. The findings reported here suggest that it is possible to fully aluminate a portion of the pores of a pure silica MCM-41 before alumination of other pores has started, resulting in an apparently mixed-phase material. The ability to vary the spatial distribution of Al (or other heteroatoms) in such a manner may find use in the preparation of composite or multiphase materials and may open new opportunities for selective molecular engineering within the internal surface of mesoporous silicas.

We have recently shown that calcined pure silica MCM-41 is stable under normal MCM-41 synthesis conditions and that when used as the 'silica source' during secondary synthesis (*i.e.* recrystallisation) the calcined MCM-41 crystallites are preserved and act as seeds for further crystal enlargement.[6,7] This 'preservation' principle was used to prepare a series of recrystallised Al-MCM-41 samples by adding varying amounts of Al to the recrystallisation gel. The recrystallised samples were prepared as previously described[6,7] except that aluminium isopropoxide was added to the recrystallisation gel along with the calcined pure silica MCM-41 at gel Si/Al ratios in the range 5–80. In brief, tetramethylammonium hydroxide (TMAOH) and cetyltrimethylammonium bromide (CTAB) were dissolved in distilled water by stirring at 35 °C. Calcined pure silica MCM-41 and the required amount of Al (as aluminium isopropoxide) were then added to the template solution under stirring for 1 h. After further stirring for 1 h the resulting gel was aged for 20 h at room temperature and then transferred to a Teflon-lined autoclave and heated at 150 °C for 48 h. The solid product was obtained by filtration, washed with distilled water, dried in air at room temperature and calcined in air at 550 °C for 8 h. The samples were designated Al-MCM41-*x*, where *x* is the gel Si/Al ratio.

Powder X-ray diffraction (XRD) patterns of the parent pure silica MCM-41 and the aluminated samples are shown in Fig. 1. The XRD pattern of the parent Si-MCM-41 material exhibits a single (100) basal peak and several higher order peaks which is typical of a well ordered MCM-41. The XRD patterns of aluminated materials prepared at gel Si/Al ratios of 80, 40 and 20 exhibit two low angle peaks; the original 100 peak and a new peak which occurs at slightly higher 2θ values and progressively shifts to even higher values (*i.e.* lower basal spacing) as the gel Si/Al ratios reduced from 80 to 20. Furthermore the intensity of the new peak increases at the expense of the original basal peak. The position of the original peak does not however change despite the reduction in intensity (Table 1). At a gel Si/Al ratio of $\leqslant$10, the original basal peak is completely lost and only the new peak is observed. Our preliminary interpretation of the XRD results is that the new peak is due to aluminated MCM-41 which increases in proportion as the amount of Al in the recrystallisation gel increases and that at a gel Si/Al ratio close to 10, the whole sample is aluminated and therefore only the new peak is observed. The presence of the original peak for samples recrystallised at a Si/Al gel ratio of 80, 40 and 20 implies that a portion of these samples remains essentially non-aluminated and retains the characteristics of the parent Si-MCM-41 material. This interpretation is consistent with the fact that in the absence of Al (*i.e.* in all silica recrystallisation) only one peak (*i.e.* the original peak) is observed,[6] which supports our proposal that the new peak observed here is due to the presence of Al. Our interpretation of the XRD results is

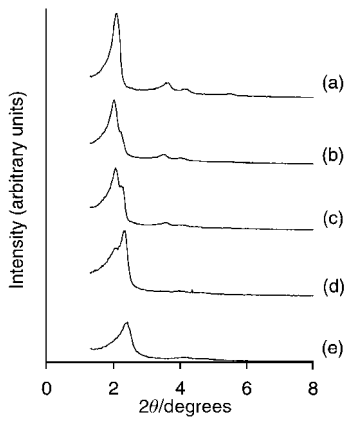

Fig. 1 Powder XRD patterns of pure silica Si-MCM-41 (a) and recrystallised Al-MCM41-80 (b), Al-MCM41-40 (c), Al-MCM41-20 (d) and Al-MCM41-10 (e) materials.

DOI: 10.1039/b004728g

Table 1 Textural properties of the studied materials

Sample	Basal (d_{100}) spacing/Å	Surface area/ $m^2\ g^{-1}$	Pore volume/ $cm^3\ g^{-1}$
Si-MCM-41	42.8	1017	0.91
Al-MCM41-80	43.2; 40.1	995	0.87
Al-MCM41-40	43.0; 39.7	922	0.78
Al-MCM41-20	42.8; 38.2	840	0.62
Al-MCM41-10	37.6	785	0.53
Al-MCM41-5	33.5	878	0.51

supported by the N_2 sorption isotherms in Fig. 2 which clearly show two capillary condensation (pore filling) steps for the 'partially' aluminated samples (Al-MCM41-80, Al-MCM41-40 and Al-MCM41-20). The first step (at lower partial pressure) is ascribed to the filling of aluminated pores and the second step to the filling of non-aluminated pores. It is noteworthy that the second pore filling step in the 'partially' aluminated samples occurs at the same partial pressure as the filling of pores in the parent Si-MCM-41. This indicates that the pore size of the channels in the parent sample remains unchanged in the 'partially' aluminated samples.

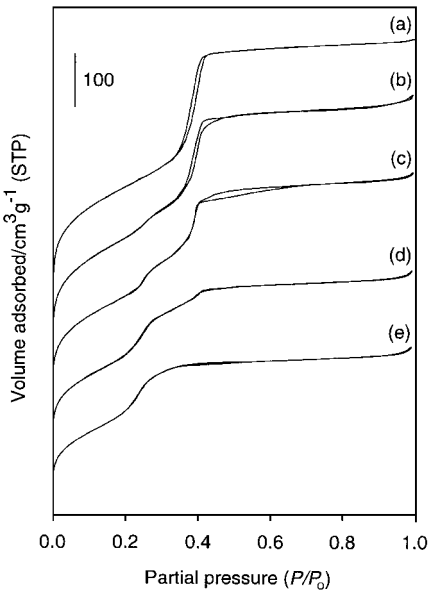

Fig. 2 Nitrogen sorption isotherms of pure silica Si-MCM-41 (a) and recrystallised Al-MCM41-80 (b), Al-MCM41-40 (c), Al-MCM41-20 (d) and Al-MCM41-10 (e) materials.

The coexistence of the two distinct pore systems within one sample implies that alumination of a portion of pores is accomplished before the start of alumination in other pores. The reduction in basal spacing and pore size (Fig. 1 and 2) and the gradual decrease in surface area and pore volume (Table 1) which accompanies the alumination is consistent with the incorporation of an aluminosilicate layer on the inner pore walls of the parent Si-MCM-41. The incorporation of Al onto the silica framework must be accompanied by charge balancing surfactant molecules since there are no inorganic ions present in the recrystallisation gel. It is likely that the strong interaction between the charge balancing surfactant molecules and the framework Al sites causes contraction of the mesoporous framework, resulting in a reduced basal spacing in the aluminated parts of the recrystallised sample. Indeed thermogravimetric analysis (TGA) of as-synthesised samples indicated the presence of strongly held surfactant molecules (associated with framework Al) whose proportion increased with the extent of alumination. Incorporation of Al onto the framework was confirmed by ^{27}Al MAS NMR of the calcined samples. More than 80% of the Al in the samples (except for Al-MCM41-5 with 65%) was found to be in tetrahedral coordination. During recrystallisation, the surfactant molecules and Al which are eventually occluded/incorporated into the recrystallised Al-MCM-41 samples must be transported into the pores of existing Si-MCM-41 particles/crystallites.[6,7] We propose that the transportation of Al into the pores is, owing to the presence of the surfactant, diffusion controlled and that the Al is therefore first incorporated into the outer region of the MCM-41 particles. Alumination then proceeds into the interior of the sample depending on the amount of Al available. If all the particles are equally accessible, then each particle is aluminated from the edges inwards until all the Al is depleted or in an aggregate of particles, the outermost particles are aluminated first while the inner particles remain untouched by the Al. In such a scenario, the proportion of aluminated MCM-41 will depend on the amount of Al available and the diffusion time. In the present study the diffusion time (*i.e.* synthesis time) was kept constant and the only variable was the amount of Al. For the partially aluminated samples, SEM with elemental analysis gave Si/Al ratios of 40.1, 28.3 and 16.9 for Al-MCM41-80, Al-MCM41-40 and Al-MCM-41-20, respectively. The implied Al content for these samples was higher than that expected from the gel Si/Al ratio which is not suprising considering that only part of the pure silica MCM-41 is aluminated. It is also evident that the Si/Al ratio approaches the expected value as the extent of alumination increases. Indeed at full alumination (gel ratio Si/Al 10 and 5) the obtained elemental composition (Si/Al = 8.8 for Al-MCM-41-10 and 5.8 for Al-MCM41-5) is very close to the expected values since the samples are essentially homogeneous with respect to spatial distribution of Al. The alumination mechanism proposed here is similar to that suggested by Anwander *et al.* for the chemisorption of trimethyaluminium into MCM-41.[8] We also note that the incorporation of Al predominantly into the outer region of MCM-41 was previously observed when Al was added to an already formed surfactant–silicate mesostructure.[9]

We have considered other scenarios that are possible during the recrystallisation; (i) the parent Si-MCM-41 can completely dissolve to generate silicate ions which then interact with the Al. This would in effect be equivalent to conventional direct mixed-gel synthesis and should yield homogeneous Al-MCM-41 materials with uniform pores and elemental compositions close to the gel Si/Al ratio irrespective of the amount of Al.[5,10] This is clearly not observed here. In any case we know that the Si-MCM-41 crystallites are stable under the recrystallisation conditions and that complete dissolution of the parent Si-MCM-41 does not occur.[6,7,11] (ii) Some silica (mainly amorphous phase) from the parent Si-MCM-41 can dissolve and interact with the Al to create a new separate Al-MCM-41 phase which coexists with the original preserved crystallites of the parent Si-MCM-41. However in such a scenario, the same amount of silica will dissolve (regardless of the recrystallisation gel Si/Al ratio) and therefore the resulting recrystallised samples should be substantially the same (irrespective of gel Si/Al ratio) with any excess Al existing as an alumina phase. This is, however, not likely since the nature of the recrystallised samples reported here is strongly dependent on the gel Si/Al ratio.

I am grateful to the EPSRC for an Advanced Fellowship.

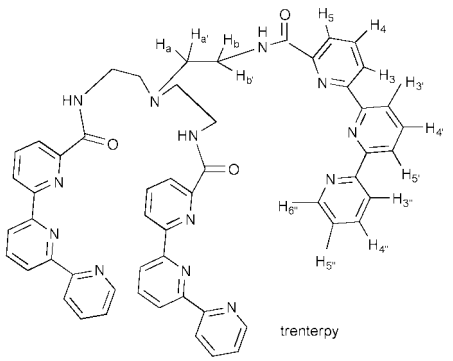
Received (in Basel, Switzerland) 24th May 2000, Accepted 11th July 2000

The new dodecadentate tripodal ligand trenterpy in the presence of lanthanide triflates leads to the self assembly of homotrinuclear lanthanide complexes.

In recent years there has been a proliferation in the coordination chemistry of lanthanide(III) ions with polydentate ligands owing to their potential applications in biology, medicine and materials science.[1] However, while the assembly of oligonuclear coordination compounds is a burgeoning field,[2] only limited research has focused on the preparation of polymetallic molecular or supramolecular lanthanide-containing complexes, in spite of the interesting magnetic and luminescence properties of Ln(III) ions.[3] Moreover the creation of highly organised polymetallic architectures is crucial for the design of lanthanide-based functional devices such as light converters[2b] or MRI contrast agents,[4] with, for example, the aggregation of Gd(III) ions in trimeric centres by non-covalent pseudo-octahedral tripods leading to an increase of the relaxivity.[5] We and others have recently shown that the assembly of three neutral bidentate binding units such as phenanthroline[6] or pyridine–carboxamide[7] to [tris(2-aminoethyl)amine] (tren) through an amide linkage yields covalent tripods which form mononuclear nine-coordinate lanthanide complexes with a rigid solution structure.

Here, we report the complexation properties of the new potentially dodecadentate tripodal ligand trenterpy‡ containing three tridentate terpyridine binding units connected to a common anchor (tren) through amide linkages. 2,2′:6′,2″-Terpyridine has been widely used as a building block in metallosupramolecular chemistry[8] and the incorporation of terpyridine or tridentate terpyridine analogues in non-covalent podating ligands has led, in the presence of lanthanide ions, to the formation of mononuclear monohelical complexes[9] or to the self-assembly of dinuclear triple-helical homo- or hetero-dinuclear[10] complexes. Nevertheless the ligand trenterpy is, to our knowledge, the first example of the incorporation of terpy in a covalent tripod.



† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b0/b004152l/

Here, we show that the high number of coordination sites and the likely presence of interstrand interactions in trenterpy prevent the formation of mononuclear 1:1 complexes and lead to the self-assembly of discrete homotrinuclear lanthanide complexes. Very recently Orvig and coworkers have reported another example of how the mismatch of ligand denticity and Ln(III) coordination number can be used to create polynuclear arrays.[11] While rigid C_3-symmetric ligands have often been used for the 'designed assembly' of oligonuclear compounds,[12] the work we present here is, to our knowledge, the first example of self-assembly directed by a flexible tripod.

The reaction of trenterpy with lanthanum triflate leads to the isolation, after addition of diethyl ether, of the crystalline M_3L_2 complex $[La_3(\mu_3\text{-trenterpy})_2(OTf)_4(H_2O)_2](OTf)_5$ **1**§ independently of the starting M:L stoichiometric ratio (1:1 or 3:2). Yellow crystals of **1** suitable for X-ray diffraction analyses were obtained by slow diffusion of diethyl ether in a solution of **1** in acetonitrile. The structure of the La complex is shown in Fig. 1 and an atomic numbering scheme of the asymmetric unit which contains 1.5 La ions is shown in Fig. 2. The $[La_3(\mu_3\text{-trenterpy})_2(OTf)_4(H_2O)_2]^{5+}$¶ cation lies on a twofold crystallographic axis passing through La(1) and between the capping nitrogens N(1) and N(1)A of the two ligands. Each trenterpy ligand is spread out such that each of its tetradentate carboxyterpyridine arms is coordinated to a different metal ion. Each La ion is coordinated by six terpyridine nitrogens and two amide oxygens provided by two different ligands. All La ions are ten-coordinate with two triflate oxygens binding La(1) and one water oxygen and one triflate oxygen binding the two symmetry related ions La(2) and La(2)A; the La–O distances are standard.[13] The average value of the La–N distance (2.748 Å) is longer than the average La–N bond distance found for a ten-coordinate mononuclear cationic complex of terpyridine $[La(NO_3)_2(terpy)_2]^+$ [13] (2.68 Å) but is similar to the La–N distances previously found in $[La(tbpa)(H_2O)(\eta^2\text{-}ClO_4)]^{2+}$ (2.728 Å)[14] and in $[La(edta)(H_2O)_3]^-$ (2.755 Å).[15] The geometry of the coordinated terpyridine arms is strongly distorted from planarity with the dihedral angles between two neighbouring pyridine rings ranging from 9.7 to 23.3°. Significant distortion from planarity had also been observed in the bisterpyridine La(III) complex[13] and for the complex $[Eu(terpy)_3](ClO_4)_3$[16] [dihedral angle between the two pyridine planes is: 4.8–28.6° for the La(III) complex and 12–26° for the Eu(III) complex].

The ^{1}H NMR spectrum of the trinuclear lanthanum complex in CD_3CN shows the presence of sharp signals with four resonances for the ethylene protons, one resonance for the amide proton and 10 overlapping signals for the terpyridine protons, in accord with an averaged D_3-symmetric structure on the NMR time-scale of the solution species. The ^{1}H NMR spectrum of a 1:1 solution of $La(OTf)_3$ and trenterpy in

acetonitrile shows the presence of broad signals resulting from intermolecular ligand exchange. The ESMS spectra of 1:1 and 3:2 solutions of $La(OTf)_3$ and trenterpy in acetonitrile show a set of peaks which are in accord with the presence in solution of the trinuclear M_3L_2 complex. The ESMS spectrum of the 1:1 solution also shows another set of prominent peaks which were assigned to a mononuclear ML complex {$[La(trenterpy)(CF_3SO_3)_2]^+$ *m/z* 1360} and a set of minor peaks which were assigned to a dinuclear M_2L complex {$[La_2(trenterpy)(CF_3SO_3)_5]^+$ *m/z* 1945.6}. The preferential formation of the trinuclear species at different stoichiometric ratios, and its rigid solution structure indicate that **1** is the thermodynamic product of a self-assembly process. The ESMS spectra of 3:2 solutions of $Ln(OTf)_3$ (Ln = Pr, Eu, Lu) and trenterpy in acetonitrile also show the presence of peaks assigned to the M_3L_2 species. The ^{1}H NMR spectra of these solutions indicate a higher fluxionality of the solution species with respect to the La(III) complex.

In conclusion, the predisposition of three terpyridine units in a covalent tripod directs the process of self-assembly toward the formation of homotrinuclear lanthanide complexes of potential interest for the study of intramolecular metal-to-metal energy transfer. This work shows that tripodal ligands can be used to predetermine the geometric arrangement of flexible polydentate binding units containing neutral N-donors around lanthanide ions, allowing an improved control over the structure of the final polymetallic array with respect to single-stranded ligands.

Received (in Cambridge, UK) 17th May 2000, Accepted 21st June 2000

Labeling experiments of mevalonolactone-d_9 were pursued for studies of the biosynthesis of the core membrane lipids from thermophilic methanogenic archaea, which revealed that unusual double-bond migration occurred during the ultimate formation of the saturated isoprenoid chains in these particular archaea.

Archaea, which have been attracting considerable attention from both biochemical and evolutionary aspects, are distinct from bacteria and eukarya.[1] Archaeal cell membrane lipids are composed of isoprenoid-chain hydrocarbons linked to a glycerol molecule at the *sn*-2 and 3-positions by an ether linkage. The isoprenoid hydrocarbon chains of lipid molecules are frequently joined at the hydrophobic end to form a macrocyclic ring as large as 36- or 72-membered as shown in Scheme 1.[2]

The biosynthesis of these macrocyclic lipids is believed to proceed in a direct manner *via* digeranylgeranylglyceryl phosphate derived *sn*-glycerol 1-phosphate and geranylgeranyl diphosphate.[3] However, nothing is known about the mechanistic details of the final carbon–carbon bond(s) formation found in macrocyclic lipids. Described here are unanticipated observations from similar feeding experiments[4] of mevalonolactone-d_9 to thermophilic methanogens, *Methanococcus jannaschii* and *Methanobacterium thermoautotrophicum*.

The cultures of *M. jannaschii* (DSM 2661) and *M. thermoautotrophicum* JCM 10044^T (DSM 1053) were carried out as previously reported.[5,6] Mevalonolactone-d_9,[4] was aseptically and anaerobically added to the culture in a final concentration of 0.25 and 1.0 g L^{-1}, respectively. After cultivation the lipids were separately purified according to the standard procedure.[7] Repetitive chromatography afforded diphytanylglycerol, a 36-membered lipid, and a 72-membered lipid from *M. jannaschii*, and diphytanylglycerol and a 72-membered lipid from *M. thermoautotrophicum*, respectively. These core lipids were further converted to their corresponding benzoates and were first analyzed by ^{1}H NMR.

Fig. 1 shows pertinent ^{1}H NMR spectra of the benzoates of diphytanylglycerol, the 36-membered lipid, and the 72-membered lipid biosynthesized from mevalonate-d_9 from *M. jannaschii* and *M. thermoautotrophicum*. Also shown is the previously reported ^{1}H NMR spectra of perdeuterated diphytanylglycerol benzoate from *Haloarcula japonica*.[4] It was initially suggested that the signals due to the two oxymethylene groups (3.50 and 3.65 ppm, Fig. 1C and 1D) of the phytanyl chains from methanogenic archaea were significantly reduced due to the corresponding glycerol signals and the deuterium being highly incorporated, *ca.* 90%. Since the spectra of biosynthesized lipids from methanogenic archaea (Fig. 1C and 1D) are similar to that of the halophile (Fig. 1B), it seems most likely that the saturation of a geranylgeranyl group in methanogen lipids take place similarly through the addition of hydrogens in a *syn*-manner. However, closer inspection of these spectra allowed us to immediately see the different proton incorporation between methanogen and halophile, which was unexpected, including the increased signal for the methyl groups (0.85 ppm) and the appearance of signals (1.05 ppm) in methanogen lipids. The latter signals at 1.05 ppm must be

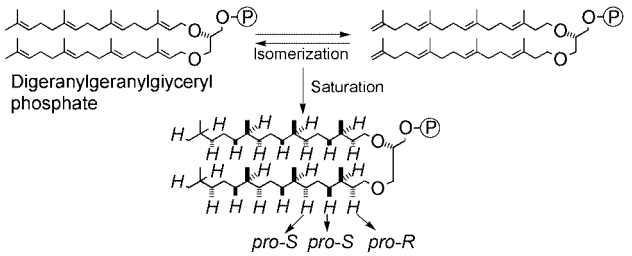
† Electronic supplementary information (ESI) available: ^{1}H NMR and ^{1}H–^{1}H COSY spectra. See http://www.rsc.org/suppdata/cc/b0/b003948i/

ascribable to those of the diastereotopic protons of methylene groups at the C-4, -8 and -12 positions of phytanyl chains.[4] According to our previous assignment and the spectroscopic studies of others,[4,8] these signals were assigned to *pro-S* protons at the C-4, -8 and -12 positions. On the other hand, the signal intensities of the other positions were quite similar to those of the halophile. It now appears that the proton incorporation at these positions occurred regio- and stereospecifically in each phytanyl chain. This protonation pattern in these methanogen lipids cannot be rationalized by the well-known isomerase reaction between isopentenyl diphosphate and dimethylallyl diphosphate, because this isomerization reaction must cause stereochemical scrambling of protonation at the methylene group at the C-4, -8, and -12 positions of the phytanyl groups. Further, the increased methyl group signal at 0.85 ppm (Fig. 1C and 1D) can simply be assigned to the methyl groups at C-16 that originated from the C-2 position of mevalonate by ^{1}H–^{1}H COSY spectrum (data not shown), this was clearly verified by the reduced methyl signals of macrocyclic lipids (Fig. 1E and 1F), because the C-16 positions of macrocyclic lipids are known to originate from the C-2 position of mevalonate. Moreover, since digeranylgeranylglyceryl phosphate is known to be involved in the biosynthesis of archaeal lipids, this protonation pattern may well suggest involvement of migration of the double bonds, and this double-bond migration must occur *after* construction of the digeranylgeranylglyceryl group.

The present study now strongly suggests that the unusual double-bond migration occurred during the biosynthesis of the core lipid in the methanogenic archaea as shown in Scheme 2. Although it has not been rigorously verified, it is worth noting that the dissimilarity of the labeling patterns between methanogenic and halophilic archaea may reflect the presence and absence of macrocyclic lipids, and further, the isomerization of the double-bonds in digeranylgeranylglyceryl phosphate could be a trigger for new carbon–carbon bond(s) formation in macrocyclic lipids.



Scheme 2 Double-bond isomerization and saturation reaction in the lipid biosynthesis of methanogenic archaea.

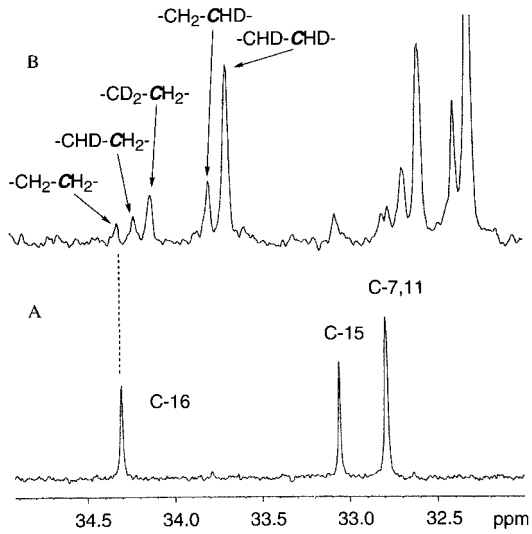


Fig. 2 Partial ^{13}C NMR spectra (125 MHz) of (A) non-labeled 72-membered lipid benzoate, and (B) multiply deuterated 72-membered lipid benzoate from *M. jannaschii* (^{1}H and ^{2}H decoupled).

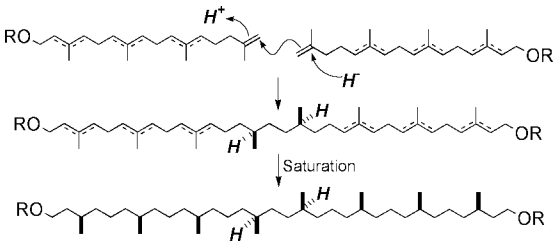
Furthermore, the labeling patterns of biosynthetically deuterated 36- and 72-membered lipids were especially crucial in determining the nature of C-16, and the cyclized lipid benzoates were analyzed by ^{13}C{^{1}H,^{2}H} NMR spectroscopy. As shown in Fig. 2, the ^{13}C signals of the C-16 were observed as a cluster due to the various degrees of deuterium shift. Although the intensities of the cluster signals are low due to the isomerase reaction described above, a ^{13}C signal with two deuterium atoms retention was clearly observed at the C-16 position, which is a key feature in excluding higher oxidized states such as an aldehyde or a carboxylate as an intermediate for C–C bond formation.

These results further support the hypothesis that the isomerized intermediate having a terminal methylene functionality is a precursor. This precursor has to be ultimately saturated in the biosynthetic sequence. Saturation of isolated double bonds in various biological systems normally involves addition of a proton to generate a carbocation which is then quenched by hydride transfer from NAD(P)H. Therefore, a plausible and mechanistically simple solution to the problem of creating a new and critical C–C bond in the macrocyclic lipid biosynthesis is that the C–C bond formation occurs at the stage of the saturation step including intermolecular acid catalyzed condensation as shown in Scheme 3. While a mechanism involving a radical trigger can not be ruled out at the moment, the validity of this hypothesis is under investigation.



Scheme 3 Proposed mechanism of the new C–C bond forming reaction in the biosynthesis of macrocyclic lipids in methanogenic archaea.

A sugar-substituted ligand allowed for the synthesis of chiral Cu(II) tetranuclear aggregates which assemble *via* H-bonding in a 3D-network containing hydrophobic helical channels.

Polynuclear complexes attract much interest. They are the subject of extensive studies regarding their magnetic properties[1–4] as well as in the field of bioinorganic chemistry.[5–7] The most common strategy to obtain these complexes involves metal self-association induced by bridging ligands like alkoxyde, thiolate or carboxylate.[8–12] Alternatively, polyfunctional ligands have been used in directing construction of polynuclear architectures.[13–16] However, little attention has been paid to the construction of supramolecular networks by the association of these polynuclear entities through non-covalent interactions between their organic ligand shells. Such a supramolecular arrangement might be desirable for controlling the bulk physical properties arising from the inorganic subunits. One way to achieve the self-assembly of discrete units into a more organised network would be to take advantage of the ability of specific functional groups (*e.g.* hydroxy groups) to link the molecular unit by H-bonding.[17,18] We report here that a sugar functionalised Schiff-base may induce polymetallic aggregation. Moreover, the resulting tetranuclear complexes associate *via* H-bonding into a 3-D network.

The ligand (H_2L, Scheme 1) was synthesised in 91% yield by the condensation of salicylaldehyde and 1-amino-1-deoxy-D-sorbitol.§ The reaction of H_2L and $Cu(MeCO_2)_2$ in hot water afforded a green complex of formula $\{Cu_4L_4\}\cdot 2H_2O$¶ which it was possible to recrystallize almost quantitatively by slow diffusion of THF to a DMF solution. X-Ray structural determination revealed a molecule consisting of an inorganic core formed by four Cu(II) ions surrounded by four ligands in a head-to-tail arrangement (Fig. 1), two water molecules being associated to the molecular unit.‖ Each $\{Cu_4L_4\}$ molecule has a central core formed by an eight-membered $\{Cu_4O_4\}$ ring folded in a boat-like conformation. The phenyl rings and the polyhydroxy chains point outward from the core in an alternate disposition in all directions, giving the molecule a globular shape. The molecule is chiral, the optically pure ligand leading to the formation of a single enantiomer of the polynuclear compound. Intracluster H-bonds stabilise the structure, notably the bond formed between H(21) and O(11) with an H··O distance of 2.13 Å. The copper atoms are five-coordinate in a distorted square-pyramidal geometry and are bridged by alkoxy groups formed by the deprotonation of the sorbitol C-2 hydroxy group. The base of each pyramid consists of the imine nitrogen, the phenolate oxygen atom and the two bridging alkolate oxygen atoms. Notably, for Cu(1) the hydroxy group bound in axial position is borne by C-3 of the sorbitol chain [O(40)], while for Cu(2) it is borne by C-4 [O(21)]. Thus alternate Cu atoms are chelated by 6/5/5 and 6/5/6 ring systems.

The $\{Cu_4L_4\}$ molecules are assembled in a 3D-network by intermolecular hydrogen bonding involving the hydroxy groups of the side chains and the two water molecules located between neighbouring $\{Cu_4L_4\}$ units. This H-bonded pattern can be described as a network of supramolecular helices interconnected by H-bonds. In the *c* direction the packing generates a three-fold screw axis and parallel channels (Fig. 2). Based upon van der Waals radii, the width of the channels is 5 Å for the smaller lobes and up to 7 Å wall to wall. These channels are

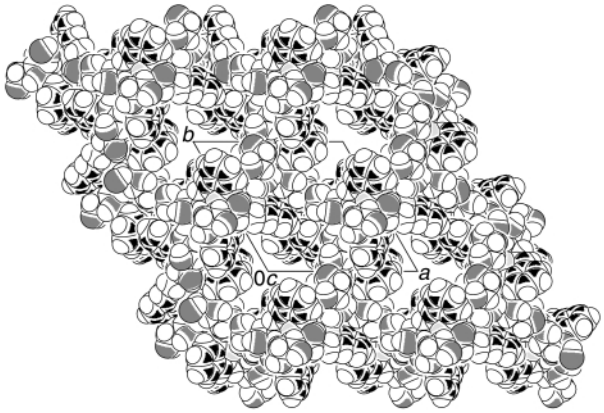

Fig. 2 CPK model view of the molecular packing along the *c* axis showing the channels (H_2O located in the channels have been omitted for clarity). H-Bonds involved in the intermolecular association (Å): OH(22)··O(42)#1 2.11, OH(40)··O(1)#3 1.99, OH(41)··O(20)#4 1.98, OH(42)··O(22)#5 2.20, OH(1B)··O(42)#4 2.45, OH(23)··H(41)#2 2.43 (Symmetry used: #1 $x - y + 1, -y + 1, -z + 2/3$; #2 $-x + 1, -x + y, -z + 1/3$; #3 $-y + 1, x - y + 1, z + 1/3$; #4 $-x + y, -x + 1, z - 1/3$; #5 $x - y, -y + 1, -z + 2/3$).

hydrophobic because the hydrogen atoms of the phenyl moieties and those in positions 2 and 3 of the sorbitol chains point towards the cavities. The X-ray structure analysis suggested that these channels are occupied by highly mobile water molecules distinct from those included in the formula $\{Cu_4L_4\}\cdot 2H_2O$.‖ However, after drying the crystalline compound *in vacuo* at room temperature, these labile water molecules are removed as found by the elemental analysis.

The magnetic interaction between the Cu(II) ions in the inorganic core was investigated, the plot of $\chi_M T$ *vs.* T being shown in Fig. 3. The observed behaviour indicates that substantial antiferromagnetic interactions among the spin carriers tend to cancel the magnetic moment of the Cu(II) cluster. It is very unlikely that they include significant intermolecular interactions, because the inorganic cores are well shielded by the organic ligands. Therefore, the magnetic data have been analysed using a model for interaction between Cu(II) ions bridged by an O-atom within the $\{Cu_4O_4\}$ ring ($H = -J(\boldsymbol{S}_1\cdot\boldsymbol{S}_2 + \boldsymbol{S}_2\cdot\boldsymbol{S}_3 + \boldsymbol{S}_3\cdot\boldsymbol{S}_4 + \boldsymbol{S}_4\cdot\boldsymbol{S}_1)$)[19] yielding an interaction parameter, $J = -87.8$ cm^{-1}.

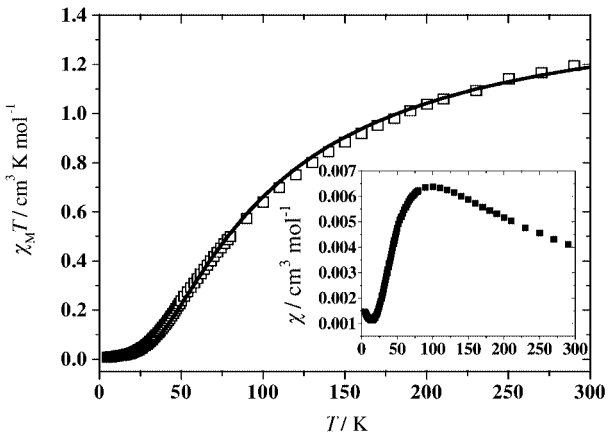

Fig. 3 Experimental (□) and calculated (—) $\chi_M T$ *vs.* T curve; χ_M *vs.* T is depicted in the insert.

The $\{Cu_4L_4\}$ compound illustrates the ability of a polyol-substituted Schiff base to induce the formation of an inorganic core. Moreover the functional groups of the ligand are able to associate the polynuclear aggregates by hydrogen bonding, so constructing a very stable network. The possibility of varying the nature of the metal ions as well as the size of the inorganic core is under investigation. The solubility of the $\{Cu_4L_4\}$ compound in hot water or alcohols suggest the possibility of trapping organic molecules in the hydrophobic cavities while still maintaining the hydrogen bond network.

ChemComm

New linked and threaded cluster compounds

Brian F. G. Johnson,*[a] Catherine M. G. Judkins,[a] Justin M. Matters,[a] Douglas S. Shephard[a] and Simon Parsons[b]

[a] *Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: bfgj1@cam.ac.uk*

[b] *Dept. of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ*

Received (in Cambridge, UK) 25th April 2000, Accepted 3rd July 2000

The linked cluster species $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_4C_{10}H_{20}O_6)]_2[H_3N(CH_2)_8NH_3][BF_4]_2$ 2 and the threaded derivative $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_4C_{12}H_{24}O_8C_6H_4)][PhCH_2NH_2CH_2Ph]PF_6$ 4 have been prepared and fully characterised by single crystal X-ray analysis; these compounds are valuable precursors in the formation of nanoparticle devices.

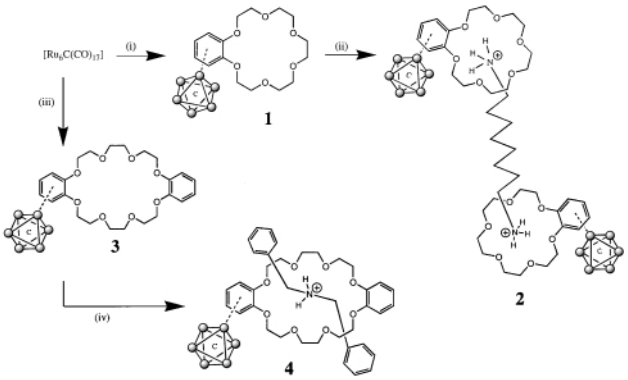
For some time we have been investigating the potential of metal clusters to act as precursors in the formation of nanoparticle arrays for use in catalysis[1] and in the production of electronic devices.[2] A primary objective of our work has been the preparation of polymer precursors which lead to materials with cluster units bonded either within the polymer backbone [Fig. 1(a)] or as pendants, suspended from a polymeric backbone [Fig. 1(b)].

In each case clear advantages have become apparent.[3,4] Recently, we have established a route to "electron-hopping" materials which permit the production of linked nanoparticle arrays such as chains or wires. In this work we report a new and valuable route to linked and threaded clusters which has enabled us to investigate the potential of adopting such methods in the formation of polymers bearing discrete cluster units.

Several years ago we demonstrated[5] that arene clusters of the type $[(\eta^6\text{-arene})Ru_6C(CO)_{14}]$ and later $[(\mu_3\text{-arene})Ru_6C(CO)_{14}]$ could easily be prepared.[6] With this knowledge in mind, attempts were made to establish a range of derivatised arenes coordinated to cluster units. More recently, we have been able to attach benzocrown ethers to hexaruthenium clusters by direct thermolysis and this has generated our interest into the potential use of such complexes as molecular sensors.[7,8] Preliminary investigations into such applications have been conducted and the compound $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{16}H_{24}O_6)]$ **1** shown to encapsulate either the NH_4^+ ion or metal ions such as K^+ and Na^+.[8]

Building on these observations, we have investigated the use of such non-covalent interactions to link two or more clusters and have developed a simple route to both linked and threaded cluster systems.

Compound **1** may be readily prepared according to the reaction sequence outlined in Scheme 1.[7] It has been fully characterised by the usual spectroscopic techniques and by single crystal X-ray analysis† (Fig. 2). The arene ring is coordinated in an η^6 fashion to a single ruthenium atom, with the average Ru–arene bond distance being 2.26 Å. In each of these cluster/crown complexes the interstitial carbon atom is displaced slightly from the centre of the cluster towards the arene ring and there is one bridging carbonyl ligand on the cluster. The oxygen atoms are tilted up at an angle to the plane of the arene ring and the undistorted cavity allows an ideal site for host–guest chemistry.



Scheme 1 Preparation of **2** and **4**: *Reagents and conditions*: (i) di-*n*-butyl ether, benzo-18-crown-6, 16 h reflux, N_2; (ii) CH_2Cl_2 + few drops MeOH, stir 24 h; (iii) di-*n*-butyl ether, dibenzo-24-crown-8, 16 h reflux, N_2; (iv) stir 24 h in CH_2Cl_2.

Treatment of **1** with the diprotonated diamine $[H_3N(CH_2)_8NH_3]^{2+}$ yields the new linked cluster system **2** (yield *ca.* 76%) in which the two quaternary ammonium units are embraced at either end by the polycyclic ether bonded to a cluster unit. This novel compound has been fully characterised by IR and NMR spectroscopy, elemental analysis and its molecular structure established by single crystal X-ray analysis. This is shown in Fig. 3, together with some relevant bond distances. As expected, the cluster units arrange themselves in a *trans*-configuration relative to the diammonium octane 'linker,' with the $-NH_3^+$ function lying *ca.* 1.3217 Å above the least squares mean plane of oxygen atoms. Two of the hydrogen atoms on each of the ammonium species interact with two of the oxygen atoms of the crown and have N–H···O bond distances of 2.970(5) and 2.967(5) Å (in each of which the N–H distances

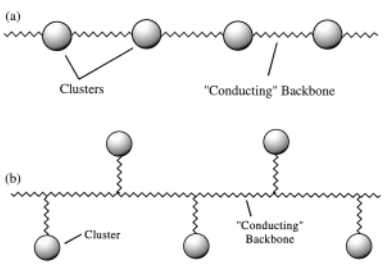


Fig. 1 (a) Polymer with cluster units within polymer backbone and (b) with cluster units as pendants.

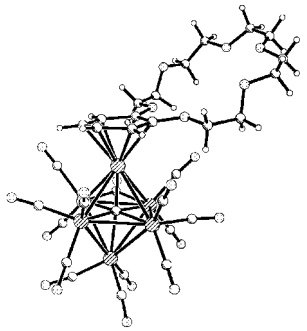

Fig. 2 Molecular structure of $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_4C_{10}H_{20}O_6)]$ **1**.

DOI: 10.1039/b003291n

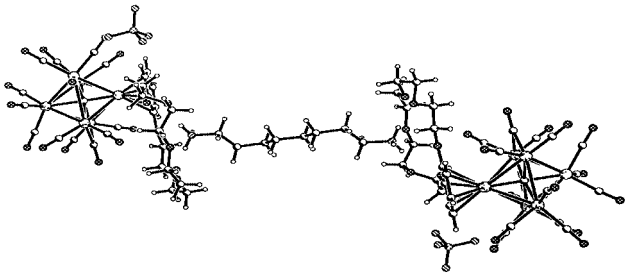

Fig. 3 Molecular structure of $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_4C_{10}H_{20}O_6)]_2\text{-}[H_3N(CH_2)_8NH_3][BF_4]_2$ **2** Average ruthenium–arene bond length = 2.26 Å; N–O distances range from 2.952(4) to 3.231(4) Å.

are 0.91 Å). The third hydrogen of the ammonium species points in the direction of one of the oxygen atoms of the crown but is aimed above the plane and displays a long range interaction of 3.205(4) Å.

In a separate experiment, compound **3**, a relative of **1** but containing the dibenzo-24-crown-8 ligand was prepared as outlined in Scheme 1 and a crystal suitable for X-ray analysis† obtained (Fig. 4). The crown is approximately planar with the mean deviation from the plane of oxygen atoms being 0.0747 Å. The larger macrocyclic cavity size which is suitable for "threading" reactions (in which the molecules are actually threaded through the hole) to yield *pseudo*rotaxanes[9] can clearly be seen.

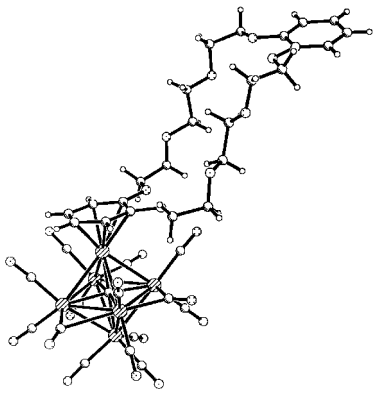

Fig. 4 Molecular structure of $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_4C_{12}H_{24}O_8C_6H_4)]$ **3**. Average ruthenium–arene bond length = 2.26 Å.

When **3** was reacted with the protonated amine $[PhCH_2NH_2CH_2Ph]^+$ in dichloromethane, the *pseudo*rotaxane **4** was produced (yield *ca*. 70%). The amine has threaded through the macrocyclic cavity attached to the cluster to generate the classic 'bead on a string configuration.' This compound has also been fully characterised by single crystal X-ray analysis† and the molecular structure is shown in Fig. 5. In contrast to analogous organic compounds[9] in which the two arene rings of the crown ether are widely separated, the macrocycle in **4** has bent to display a π-stacking arrangement between the two arene units of the crown and one of the phenyl units of the thread. The two hydrogen atoms of the ammonium group display short range interactions with two of the oxygen atoms of the crown, with approximate distances of 2.019 and 2.131 Å. They also display longer range interactions with two further oxygen atoms of the crown (distances *ca*. 2.4–2.6 Å) and there are also several long range interactions between the hydrogen atoms of the methylene group nearest to the arene involved in the π-stack and the macrocyclic oxygen atoms.

These new materials open up a new and important route to cluster polymer precursors which, in other systems, have been shown to serve as valuable intermediates in the formation of nanoparticle materials for use in electron devices.[10]

We gratefully acknowledge Dr Neil Feeder and Dr John Davies for determining the crystal structures of **1**, **2** and **3**, the EPSRC and ICI for financial support (C. M. G. J.) and Peterhouse College, Cambridge for a research fellowship (D. S. S.).

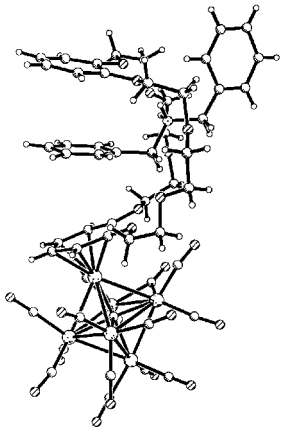

Fig. 5 Molecular structure of $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_4C_{12}H_{24}O_8C_6H_4)]\text{-}[PhCH_2NH_2CH_2Ph]PF_6$ **4**. Distance between planes 1 and 2 = 4.105 Å, distance between planes 2 and 3 = 3.820 Å. Angle between planes 1 and 2 = 22.5°, angle between planes 2 and 3 = 8.5°. Average N···O separation = 2.9595 Å, average H···O separation = 2.075 Å.

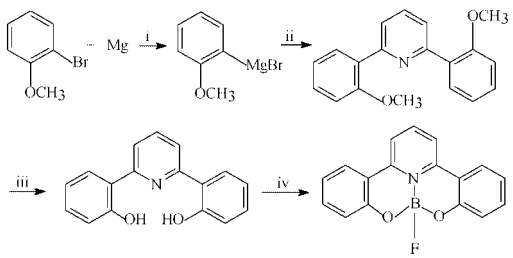
Received (in Cambridge, UK) 8th May 2000, Accepted 7th July 2000

A blue light emitting 1,6-bis(2-hydroxyphenyl)pyridine boron complex has been synthesized and used as an emitting material to fabricate electroluminescent devices.

The electroluminescence (EL) of Alq_3 (q = 8-hydroxyquinolinate) and its derivatives and also of other metal chelate complexes[1–14] have attracted a great deal of attention since the first light-emitting devices (LEDs) fabricated from Alq_3 were reported by Tang and VanSlyke.[1] This report describes the synthesis and EL properties of a 1,6-bis(2-hydroxyphenyl)pyridine boron complex.

The pyridine–phenol ligand dppy and its boron complex were prepared following the synthetic route shown in Scheme 1.† The dppy ligand was obtained by the reaction of 2-bromopyridine with the Grignard reagent from 2-bromoanisole in THF with [$NiCl_2$(dppe)] as catalyst at room temperature, followed by demethylation in molten pyridinium chloride.[15] The reaction of dppy with 1 equivalent of BF_3 in benzene at 60 °C resulted in the formation of (dppy)BF. An X-ray diffraction study shows that in the solid state (dppy)BF molecules exhibit intermolecular π···π interactions,‡ leading to columnar aromatic stacks as shown in Fig. 1. The average intermolecular π···π interaction distance is 3.28 Å. Our earlier report demonstrated that the higher electron mobility of tris(8-hydroxyquinolinato)-gallium is due to intermolecular π···π stacking interactions.[16] Munakata *et al*. confirmed that strong intermolecular interactions as well as intermolecular aromatic stacking could assist charge-transfer pathways.[17] We believe that the strong intermolecular π···π interactions in solid (dppy)BF are beneficial in terms of charge mobility.



Scheme 1 Synthetic route towards dppy and (dppy)BF. *Reagents and conditions*: i, THF, 25 °C; ii, [$NiCl_2$(dppe)], 2,6-dibromopyridine, 25 °C, 12 h, 75%; iii, py·HCl, 200 °C, 3 h, 85%; iv, BF_3, benzene, 60 °C, 5 h, 70–85%.

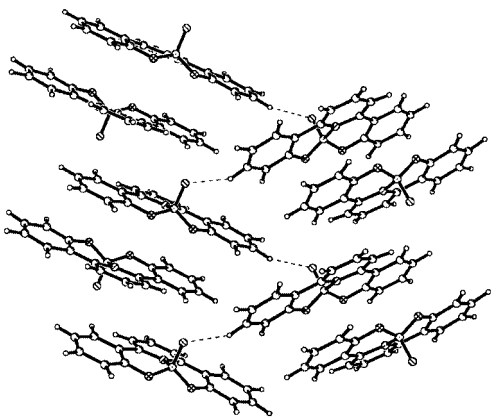


Fig. 1 Intermolecular π···π interactions in (dppy)BF.

(dppy)BF exhibits strong blue emission at *ca*. 445 nm. The PL spectra of (dppy)BF in $CHCl_3$ solution, the solid state and as an evaporated film are compared in Fig. 2 while Fig. 3 shows the PL and EL spectra of devices of structure [ITO/TPD (500 Å)/(dppy)BF (400 Å)/Al (2000 Å)].§ The EL spectrum are dramatically different from the PL spectra of pure (dppy)BF or solid TPD films, shifting to longer-wavelength (λ_{max} = 550 nm). This suggests that exciplex formation takes place at the organic solid-state interface between TPD and (dppy)BF, resulting in a yellow emission. The devices exhibit a maximum luminance (L) of 500 cd m^{-2} with an efficiency of 0.0013 lm w^{-1} and achieve a maximum efficiency of 0.01 lm W^{-1} at 18 cd m^{-2}. In order to investigate the relationship between the interface state and EL properties of boron complexes, PVK (*N*-vinylcarbazole) was employed as hole transport layer to

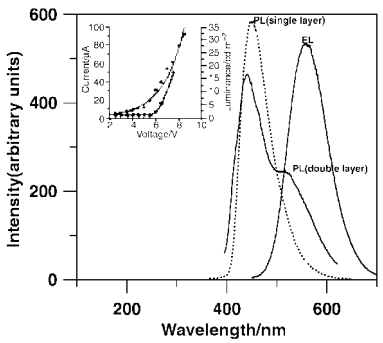

Fig. 3 EL and PL spectra for [ITO/TPD/(dppy)BF/Al] together with the PL spectrum of an evaporated single layer film of (dppy)BF; the inset shows the *I–V* (●) and *L–V* (+) characteristics for the devices.

DOI: 10.1039/b003774p

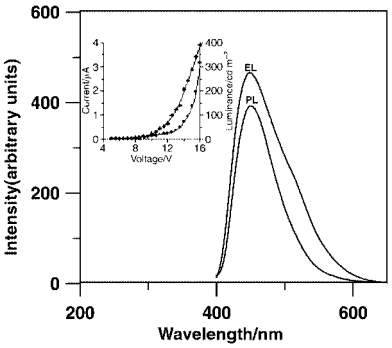

Fig. 4 The EL and PL spectra for [ITO/PVK/(dppy)BF/Al]; the inset shows the *I–V* (●) and *L–V* (+) characteristics for the devices.

fabricate emitting devices with structure [ITO/PVK (1000 Å)/(dppy)BF (500 Å)/Al (2000 Å)].§ Fig. 4 presents the EL spectrum of [ITO/PVK (1000 Å)/(dppy)BF (500 Å)/Al (2000 Å)] together with its PL spectrum. The EL spectrum exhibits a strong peak at 450 nm accompanied by a weaker shoulder at 500 nm. The above experimental results suggest that there are very little or no exciplex formation at the interface between PVK and (dppy)BF. An alternative explanation may be electroluminescence of PVK is favored by the fact that (dppy)BF acts as an electron transport material. When PVK was used as the hole transport material, the devices showed a dramatic improvement in performance. Each device exhibited a maximum luminance of 400–600 cd m^{-2} with an efficiency of 0.012 lm W^{-1} at a driving voltage of *ca*. 12.5 V and showed a maximum efficiency of 0.1 lm W^{-1} at a luminance of 26 cd m^{-2}. The devices [ITO/TPD/(dppy)BF/Al] and [ITO/PVK//(dppy)BF/Al] exhibited obviously different EL properties. Our experimental results also demonstrated that, frequently, the organic–solid interface can determine the EL properties of organic light emitting devices.[18] At present we have yet to elucidate the mechanism and further investigation is in progress.

The complexes (dppy)B(OMe) and (dppy)B(OEt) have also been synthesized and exhibited similar EL behavior as (dppy)BF. X-Ray structural studies show that there are strong intermolecular π···π interactions in the solid state of (dppy)-B(OEt) and detailed results will be reported in due course.

In conclusion, we have demonstrated that a pyridine–phenol ligand can be used as to synthesize strong blue phtoluminescent boron complexes. The pyridine–phenol boron complexes show novel electroluminescent properties. We also found that the interface state determines the EL color of the devices based on the boron complexes.

Ferrocene and ruthenocene have been incorporated into a range of conjugated systems. The interaction of these metallocene donor moieties with conjugated substituents is more complex than that of organic donors; both metal-based and ligand-based orbitals of the metallocene interact with the orbitals of the π-system. Here we review the rôle of these interactions in giving rise to a variety of interesting properties including non-linear optical activity in donor–acceptor systems, mixed-valence behaviour in bis(ferrocenyl) compounds, and structural distortions in polymethines.

Introduction

While derivatives of ferrocene and, to a lesser extent, ruthenocene are one of the most widely studied classes of organometallic compounds (work on osmocene derivatives has been much more limited), a detailed understanding of the electronic structure of conjugated metallocene derivatives has only recently emerged. Here we survey some the electronic and optical properties of conjugated metallocene derivatives, illustrating how similarities in the electronic structure can be used to draw parallels between what may appear to be somewhat disparate sets of observations. We hope to highlight aspects of the structure–property relationships for metallocene derivatives which are unique and are not found in conjugated organic materials.

Steve Barlow was born and raised in Hampshire and Dorset. He obtained BA and DPhil degrees in Chemistry in 1992 and 1996 respectively, both from the University of Oxford. After postdoctoral work with Seth Marder at the California Institute of Technology, he returned to Oxford in 1998 as a temporary lecturer in the Inorganic Chemistry Laboratory and a tutorial fellow at Lady Margaret Hall. His research interests include optical, electronic and magentic properties of organometallic and unsaturated organic systems, and understanding how these properties are related to electronic structure.

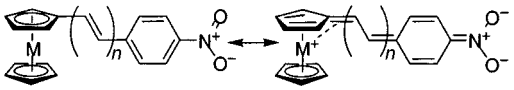
Seth Marder was born and raised in New York city. He obtained his Bachelors of Science in Chemistry from Massachusetts Institute of Technology in 1981 and his Doctorate, in Chemistry, from the University of Wisconsin-Madison in 1985. After postdoctoral studies at Oxford and at the California Institute of Technology and the Jet Propulsion Laboratory, he become a Member of the Technical Staff at the Jet Propulsion Laboratory and a Member of the Beckman Institute at the California Institute of Technology. In 1998 he moved to the University of Arizona, where he is a Professor of Chemistry and Optical Science. His research interests include liquid crystals, transport phenomena, multiphoton processes in organic and organometallic materials, and labels for biological imaging.

Electronic structure of metallocenes and their conjugated derivatives

Firstly we will briefly review the electronic structure of metallocenes, and the perturbation to this structure induced by substitution with an electron-withdrawing conjugated system. The three highest filled levels of ferrocene are derived from the d_{xy}, $d_{x^2-y^2}$ (e_{2g} in staggered {D_{5d}} geometry) and the d_{z^2} (a_{1g}) orbitals (the HOMO of the neutral molecule is a_{1g}, whilst the SOMO of the cation is e_{2g}). The e_{2g} orbitals are somewhat δ-back-bonding, through interaction with combinations of the cyclopentadienyl (Cp) anion LUMOs, whilst the a_{1g} has some interaction with the metal s orbital and with the Cp rings. Nonetheless, these orbitals may be regarded as essentially metal-based. The next highest orbitals (e_{1u}) of the metallocene are principally ligand-based, possibly with some contribution from the p_x and p_y metal orbitals. The lower energy orbitals involve bonding combinations of Cp orbitals with the metal d_{yz}, d_{xz}, s and p_z orbitals and do not concern us further. The LUMO of ferrocene has symmetry e_{1g} (in D_{5d}) and is derived from an out-of-phase π interaction between the d_{xz}/d_{yz}, and Cp orbitals.

The bonding in ruthenocene (and osmocene) is qualitatively the same, but UV-photoelectron spectra reveal substantial differences in metal-based orbital energies. The first vertical ionisation potentials (IPs) for ferrocene and ruthenocene are 6.86/6.89 and 7.45 eV, respectively,[1,2] whilst the highest ligand-based levels lie at rather similar energies with e_{1u} vertical ionisations at 8.72/8.77 and 8.47/8.51 eV, respectively. Thus, ferrocene is clearly the stronger donor in an electron-transfer sense. Methylation of the cyclopentadienyl rings raises the energy of both the filled d-orbitals (the first IP of decamethylferrocene is 5.88 eV) and the highest ligand-based orbitals (lowest ligand ionisation of decamethylferrocene is 7.31 eV). For comparison, the first IPs of *N*,*N*-dimethylaniline and anisole are 7.45 and 8.42 eV, respectively,[3] indicating that these compounds are weaker electron-transfer donors than ferrocene. However, it does not necessarily follow that a stronger electron-transfer donor will lead to a greater perturbation of an attached π-conjugated system, since the detail of the electronic coupling between the donor and the π-system is also critical (*vide infra*).

When a conjugated system is attached to a metallocene the most significant perturbation is *not* to the metal-based HOMOs. Consider a ferrocene derivative with a moderately electron-withdrawing conjugated substituent, such as **1** (Fig. 1). The first IP (6.97 eV) and electrochemical oxidation potential (+25 mV *vs.* ferrocenium/ferrocene in THF) of **1** are close to those of ferrocene.[4] Similar electrochemical results have been found in related systems.[5,6] The highest *ligand* level of the metallocene



1, M = Fe, *n* = 1
2, M = Fe, *n* = 2
3, M = Ru, *n* = 1

Fig. 1 Neutral and charged resonance structures for nitrostyrene-substituted metallocenes.

(e_{1u}) shows a much greater perturbation; in **1** an ionisation is found at 8.36 eV, *i.e.* lower in energy than that e_{1u} ionisation of ferrocene, or the first ionisation of nitrostyrene. We attribute this ionisation to an orbital ('π') formed by an out-of-phase combination of one of the e_{1u} pair with the HOMO of the nitrostyrene fragment (as shown in Fig. 2).

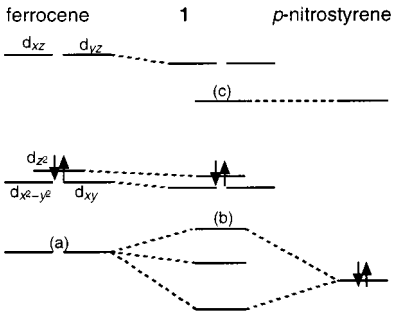


Fig. 2 Qualitative partial MO diagram showing interaction between the frontier orbitals of ferrocene and *p*-nitrostyrene fragments in **1**. The paired electrons indicate the HOMO for each compound. Orbital (a) is the highest filled Cp-based orbital of the metallocene (e_{1u} in D_{5d}), whilst (b) is the highest ligand-based orbital ('π') of **1** and (c) is the acceptor-based LUMO of **1**.

Compound **1** exhibits a molecular reduction at the same potential as *p*-nitrostyrene (−1670 mV *vs.* ferrocenium/ferrocene according to cyclic voltammetry in THF). The extended analogue **2** is reduced at −1635 mV, whilst nitrobenzene is reduced at −1730 mV. A similar chain length dependence of reduction potential was found for $[Mc(CH{=}CH)_nC_7H_6]^+$ (*n* = 0, 1, 2, 3; Mc = Fc {ferrocenyl}, Rc {ruthenocenyl}).[7] These results suggest that the LUMO is centred on the acceptor moiety, with some delocalisation onto the π-bridge (the empty d_{xz} and d_{yz} orbitals of the metallocene are at relatively high energy). An EPR study of $[\mathbf{1}]^{\bullet-}$ shows the unpaired electron to be largely localised on the nitrophenyl ring,[8] consistent with electrochemical data.

The orbital picture deduced from PES, electrochemical and EPR data above is consistent with that derived from extended-Hückel[9] and DF[4] calculations (see Fig. 3). This model can be successfully extended to other donor–acceptor metallocene derivatives (so long as the acceptor is sufficiently strong that the empty acceptor orbital lies below the metal d_{xz} and d_{yz} orbitals in energy). However, as the acceptor gets very strong it is necessary to further refine the simple model described above. Crystallographic and NMR data indicate that with electron-acceptors of moderate strength, the structure is well approximated by the neutral valence-bond picture (Fig. 1, left-hand structure). However, as the acceptor (or donor) is strengthened the zwitterionic resonance form gains in importance. This results in a reduction in the bond-length alternation (BLA) of the alkene bridge. Although there are apparently no crystallographically characterised examples of metallocene derivatives with a strong acceptor such as that in compounds **4**–**9**, the effect is manifested in NMR spectra. For example, in compound **4** (strong acceptor) the polyene protons show coupling constants of *ca.* 13 Hz over both formally double and formally single bonds, whilst in Fc″(CH = CH)$_2$CHO {Fc″ = 2,3,4,5,1′,2′,3′,3′-octamethylferrocen-1-yl, (C_5Me_4H)Fe(C_5Me_4)} (weak acceptor) coupling constants alternate between *ca.* 15 Hz across

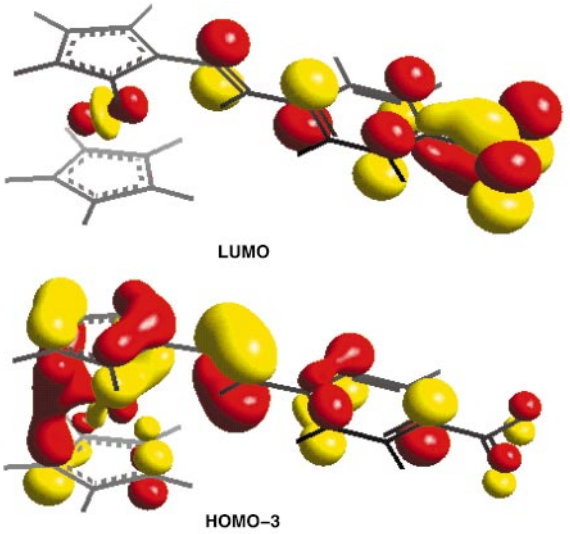

Fig. 3 The LUMO and the highest filled ligand-based π-level of **1** according to DF calculations; the three highest-filled levels are all principally metal d in character.[4]

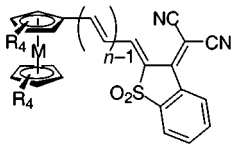
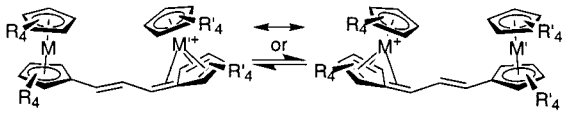


4, M = Fe, R = Me, *n* = 3
5, M = Fe, R = H, *n* = 1
6, M = Fe, R = H, *n* = 2
7, M = Fe, R = H, *n* = 3
8, M = Fe, R = H, *n* = 4
9, M = Ru, R = H, *n* = 3

formally double bonds and *ca.* 10 Hz across formally single bonds. More evidence for the increased importance of the charge-transferred resonance form in strong-acceptor compounds comes from electrochemistry: **5** is oxidised at +325 mV *vs.* ferrocenium/ferrocene in THF, suggesting a much more severe effect of the acceptor on the metal than in the nitrophenyl analogue, **1**. Moreover, the effect is strongly chain-length dependent; the potentials for **6** and **7** are +200 and +110 mV, respectively, indicating a decrease in donor–acceptor coupling as the chain length increases.[4]

A broadly similar picture is revealed by DF calculations for the bis(metallocenyl)allylium cations ([**10**]$^+$–[**14**]$^+$); here the



[10]$^+$, M = M′ = Fe, R = R′ = H
[11]$^+$, M = M′ = Fe, R = R′ = Me
[12]$^+$, M = M′ = Ru, R = R′ = H
[13]$^+$, M = M′ = Fe, R = H, R′ = Me
[14]$^+$, M = Fe, M′ = Ru, R = R′ = H

LUMO is the π* orbital of the unsaturated bridge (Fig. 9).[10] A similar picture of filled d-orbitals above an extended π-level presumably applies to bis(metallocenyl)polyenes, polyynes and arylenes, although, where the π-system is not particularly electron-poor, the LUMO may be the empty d_{xz}/d_{yz} orbitals rather than π*.

In many donor–acceptor systems there is little evidence to distinguish between the donor strengths of ferrocene and ruthenocene. For example, **7** and **9** are reduced at experimentally identical potential (−880 mV *vs.* ferrocenium/ferrocene in THF), indicating comparable contributions of the charge-transferred resonance form in each case (the octamethylferrocenyl group is clearly a stronger donor; the reduction potential of **4** is −960 mV).[4] However, comparison of the dipole moments of **1** (4.5×10^{-18} esu) and **3** (5.3×10^{-18} esu)[9] does suggest a slightly larger zwitterionic contribution in the ruthenium case. Systems with even stronger acceptors, such as 1,3-bis(metallocenyl)allylium cations, provide electrochemical evidence that, despite having a lower energy HOMO than ferrocene, rutheno-

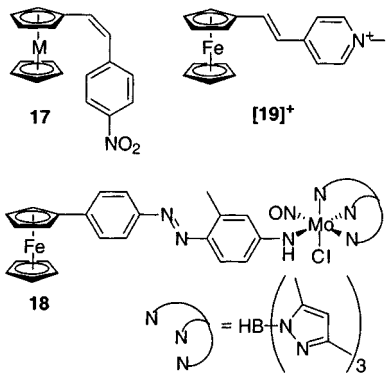
cene is the stronger donor in conjugated systems. Thus, [**10**]$^+$ is reduced at −670 mV (*vs.* ferrocenium/ferrocene in THF), whilst [**12**]$^+$ is reduced at −715 mV ([**11**]$^+$ is reduced at −930 mV).[10] Crystal structures of [FcCHRc]$^+$[PF_6]$^-$ [11] and [**14**]$^+$[PF_6]$^-$ [10] show ruthenium coordination well approximated as η^6-fulvene : η^5-cyclopentadienyl, whilst the ferrocene centres are 'normal'. Thus, the superior donor properties of ruthenocene in this type of system can be attributed to the more extensive d-orbitals of ruthenium and its consequent tendency to shift towards η^6-fulvene coordination. It seems the difference in donor strength between ferrocene and ruthenocene are most evident when η^6-fulvene is an important resonance structure.

Linear and non-linear optical properties of conjugated metallocene–bridge–acceptor compounds

Much of the work on donor–acceptor conjugated metallocenes has been directed towards maximising and understanding their second-order NLO properties. Second-order NLO phenomena include frequency doubling and the linear electrooptic effect (*i.e.* electric-field-dependence of refractive index). For these properties to be observed, a non-centrosymmetric array of non-centrosymmetric molecules is required. The relevant molecular parameter is the first hyperpolarisability, β. The perturbation-theory-derived two-level model relates the static hyperpolarisability $\beta(0)$ to the characteristics of low-lying electronic excited states through eqn. (1):

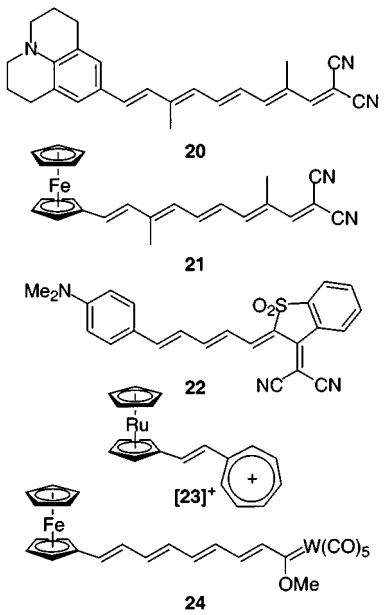
$$\beta(0) \propto (\mu_{ee} - \mu_{gg})\frac{\mu_{ge}^2}{E_{ge}^2} \quad (1)$$

where μ_{ee} and μ_{gg} are excited and ground-state dipole moments respectively, μ_{ge} is the transition dipole linking ground and excited states, and E_{ge} is the energy difference between the two states.[12] The two-level model does not apply to all classes of chromophore; for example, the non-linearity of octopolar molecules, where $\mu_{ee} = \mu_{gg} = 0$, depends on three-level terms.[13] Eqn. (1) indicates that intense low-energy charge-transfer transitions should lead to large β. The prototypical chromophore is the 'push–pull' donor–(conjugated bridge)–acceptor; good examples are (*E*)-4-(methoxy)-4′-nitrostilbene **15** and (*E*)-4-(dimethylamino)-4′-nitrostilbene **16**. In analogy, ferrocene was used to replace the organic donors of **15** and **16**;



17 was found to have a powder second-harmonic generation (SHG) efficiency 62× that of urea,[14] and even larger values of 123× and 200× urea have been reported for **18**[15] and [**19**]$^+$[I]$^-$[16] respectively. Much other early work relied on powder SHG data. However, results are inherently subject to the vagaries of crystallisation; a large β chromophore will give zero SHG if it crystallises in a centrosymmetric space group. Resolved chiral chromophores have also been used;[17] these *must* crystallise in non-centrosymmetric space groups, but the molecules may still pack in such a manner that the hyperpolarisabilities of neighbouring molecules still largely cancel each other out, leading to low SHG responses. To understand relationships between molecular structure and molecular NLO properties, values of β are more useful. For non-ionic polar chromophores in solution, electric field-induced second-harmonic generation (EFISH)[18] can be used to measure $\mu\beta_\mu$, the scalar product of the permanent dipole moment (μ) and the vectorial part of the β tensor. Combined with a determination of μ, values of β_μ, the projection of the vectorial part of β onto the axis of μ, can be determined. $\mu\beta_\mu$ itself is also a figure-of-merit for the second-order NLO activity of a material where non-centrosymmetry is achieved *via* electric-field poling of a polymer matrix. Poling is carried out above the glass-transition temperature of the polymer, and the resulting polar order is 'frozen' in by cooling back below the glass transition. This means of achieving polar order is currently the most widely used approach for fabricating non-centrosymmetric materials for second-order NLO applications. More recently hyper-Raleigh scattering (HRS)[19] has also been used to measure β; the technique can be applied to ionic or octopolar chromophores, but great care must be taken to correctly account for the other non-linear optical effects which can contribute to the observed signal.

A wide variety of metallocene–donor–acceptor compounds have been synthesised; in addition to traditional organic acceptors, main group moieties,[20] transition-metal coordination complexes,[6,21–23] and organometallic groups[24–28] have been used as acceptors. The second-order NLO properties of a selection of these compounds are summarised in Table 1, along with absorption maxima.



Comparison of β or $\mu\beta$ values between chromophores is complicated by the fact that eqn. (1) relates to the static (dispersion-free) hyperpolarisability. The hyperpolarisability is greater (dispersion-enhanced) if the fundamental radiation employed in the measurement, or the frequency-doubled radiation generated, is close in energy to the energy of the excited state(s) responsible for the NLO behaviour. In the case of metallocene compounds, the contributions of more than one excited state to the non-linearity means that correction for dispersion cannot be made according to the two-level model (nevertheless, estimates have been made for some compounds and are included in Table 1).

To understand the origin of the NLO properties of a class of compounds it is necessary to understand the characteristics of the excited state or states contributing to the hyperpolarisability *via* eqn. (1). The quantities in eqn. (1) can be probed by optical

Table 1 Comparison of second-order NLO properties of some metallocene and organic molecules

[a] EFISH values are β_μ; HRS values are $\langle\beta\rangle$. [b] For long-chain lengths, the highest π-level may approach the metal-based HOMO in energy and the two transitions may overlap; clearly this will happen at shorter chain length for ruthenocene compounds. [c] 640 × 10^{-30} esu in $MeNO_2$. [d] 2420 × 10^{-30} esu in acetonitrile.

spectroscopy. The most striking characteristic of the metallocene compounds, in contrast to their all organic analogues, is the presence of *two* relatively low-energy bands (Fig. 4). In most of the metallocene compounds both bands show positive solvatochromism (red shifts with increasing solvent polarity), suggesting that the corresponding transitions are both associated with increases in dipole moment.[34]

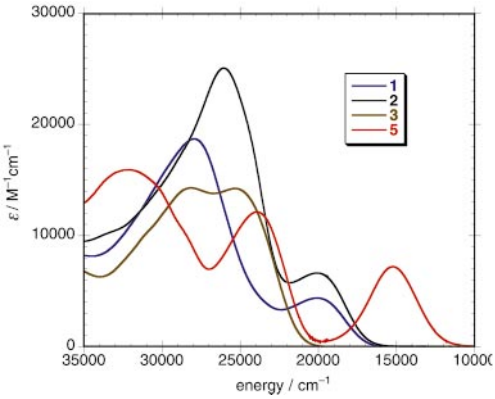

Fig. 4 UV–VIS–NIR spectra of several metallocenyl second-order NLO chromophores showing the effects on the spectra of chain length (**1** *vs*. **2**), replacing Fe with Ru (**1** *vs*. **3**), and acceptor strength (**1** *vs*. **5**).

Recently, Stark spectroscopy has been used to confirm that both transitions are indeed associated with dipole moment changes; in both **2** and **4** the lower energy (LE) band was found to have the larger $|\Delta\mu|$. Combining the observed ratio of $|\Delta\mu|$ with the transition energies and oscillator strengths, the relative contributions of the two excited states to the second-order NLO response can be estimated according to eqn. (1). In **2** the higher energy (HE) transition dominates β (63% of the two-level contributions). In the strong-acceptor compound **4** the relative importance of the two transitions is reversed (75% from LE transition).[4]

If one wishes to predict the effect of changes in molecular structure upon the optical spectrum, and hence upon the NLO behaviour, it is important to assign the two bands. We have recently suggested an assignment based on the orbital scheme described for **1** in the previous section, *i.e.* that the LE transition is metal-to-acceptor (HOMO-to-LUMO), whilst the HE transition is π-to-acceptor.[4] In contrast to previous assignments,[9,35] this model is consistent with *both* the larger $|\Delta\mu|$ of the LE transition, and with the changes in the spectra seen as the structure of the molecule is modified. The relatively high absorptivities observed for the LE band, despite poor metal–acceptor interaction, can be rationalised in terms of intensity stealing from the HE band. This intensity stealing should be most pronounced when the energy differences between the two excited states and between the ground and second excited state are minimised. This is seen experimentally; for example, the oscillator strengths of the LE and HE transitions of **1** are *ca*. 0.60 and 0.10 respectively, whilst for **5** (where the stronger acceptor leads to a smaller second excited state/ground state separation) the relevant values are 0.40 and 0.18.[36]

Many studies show the same factors used in organic chromophore design are operative in metallocene chromphores; Table 1 gives some examples of the effects of acceptor strength and chain length, as well as of changing ferrocene for ruthenocene. It should be noted, however, that in analogy with organic compounds,[37] if the donor and/or acceptor strength is increased sufficiently, a point of optimised β will be obtained, corresponding to an optimised BLA, *i.e.* optimised mixture of neutral and charge-transferred resonance forms. The data in Table 1 show that metallocene chromophores can exhibit large β and $\mu\beta$ values of similar magnitude to the best all-organic chromophores. However, metallocene derivatives with high β or $\mu\beta$ absorb at very low energies; both the energies and broadness of the absorptions are factors which would limit the utility of metallocene chromphores in devices designed for use at the telecommunications wavelengths of 1.3 and 1.55 μm. Nonetheless, films obtained by poling **1** and **2** in polymethylmethacrylate at 120 °C, showed electro-optic coefficients in excellent agreement with the values predicted from the EFISH-derived $\mu\beta$ values using an oriented gas model. The results indicate that the more three-dimensional shapes and lower oxidation potentials of ferrocene chromophores relative to traditional all-organic chromophores do not lead to any special complications.[38] Metallocene chromophores have also been covalently incorporated into a variety of polymers; the long-term orientational stability of these polymers after poling has been monitered by SHG measurements.[38–40]

We have seen that metallocene chromophores can exhibit large β and $\mu\beta$ values, but do metallocene chromophores offer any significant advantages over organic compounds for NLO applications? Comparing **1** and **15**, which have similar $\mu\beta$ and β, we find the ferrocene compound shows distinct disadvantages owing to the decreased transparency arising from its lower energy absorption band, as mentioned above. The ruthenocene analogue **3** shows superior transparency, but lower β. For the same bridge/acceptor motif, it seems that the ferrocenyl donor gives poorer β and $\mu\beta$ than *p*-dimethylaminophenyl (**1** *vs*. **16**; **7** *vs*. **22**). The LE excited state of **1** is lower in energy than the excited state of **16** (since ferrocene is a stronger electron-transfer donor), but the corresponding transition is much less intense (due to poor metal–acceptor interaction); as in **2**, the HE state is presumably the major contributor to β in **1**. In the stronger acceptor compound **7** the LE ferrocene band is much more important for β; however, it is no longer significantly lower in energy than that of its organic analogue **22**. Both **7** and

22 will show more contribution from the zwitterionic resonance form than **1** and **16**; we suggest this effect is more important for **22** (dimethylaminophenyl is a more effective donor for perturbing the electron density of a π-system than ferrocenyl), leading to larger μ and low energy absorption in the all-organic case. It is, however, possible that with even stronger acceptors, where dimethylaminophenyl compounds will have passed the point of optimal BLA, the ferrocene compound may actually give larger β.

We know of no reports of a bulk material based on a metallocene chromophore with non-linear optical properties rivalling those of the best all-organic materials. In addition, organometallic chromophores have not yet been shown to exhibit thermal[41,42] and photochemical[43] stabilities comparable to the some of the better all-organic systems; these factors are crucial to the fabrication of long-term performance devices. Thus, there is still a clear challenege to the organometallic chemist to demonstrate a specific advantage for using metallocene chromophores in second-order NLO applications.

In addition to the NLO-related studies described above, several other studies have focussed on other aspects of the spectroscopy of metallocene–(π-bridge)–acceptor compounds. Toma *et al*.[44] found the low-energy bands of (*E*)-FcCH=CHAr (Ar = aryl) were similar to those of ferrocene, with some dependence upon the Hammett coefficients of the substituent, except where Ar bore a strongly mesomerically electron-withdrawing substituent (*p*-CHO, *p*-CN, *p*-NO_2). These observations are consistent with our assignment of the spectra of **1**; presumably, in the former class of compounds the d–d transition is lowest in energy, whereas in the latter class the LUMO is acceptor-based. The complexes [(ferrocenylpyridine)$Ru(NH_3)$]$^{3+}$ could also be regarded as metallocene–donor–acceptor complexes, the LUMO here being the part-filled t_{2g}-like orbitals of Ru^{III}. The low-energy band has accordingly been assigned to a $Fe^{II} \rightarrow Ru^{III}$ transfer, and analysed to show much stronger metal–metal coupling in the [(4-FcC_5H_4N)$Ru(NH_3)$]$^{3+}$ than in [(3-FcC_5H_4N)$Ru(NH_3)$]$^{3+}$.[45] Derivatives of [**19**]$^+$ have been used as indicators in rapid screening of hydrogenation catalysis.[46]

Electronic and optical properties of bis(metallocenyl)polyenes and related compounds

In this section we consider systems where two (or more) metallocene units are linked by alkene, alkyne or arene bridges. Ferrocene systems have been attractive candidates for studying mixed-valence behaviour,[48] since ferrocene has a well-developed organic chemistry, allowing attachment to a wide variety of bridges, and since both ferrocene and the ferrocenium ion are relatively stable. When linked conjugated ferrocenes undergo one-electron oxidation, a hole is introduced into the e_{2g} d-orbitals of one of the ferrocene moieties. The lowest energy band in the UV–VIS–NIR spectra is thus a transition from the highest filled d-orbital of the Fe^{II} moiety to the partially occupied orbital of the Fe^{III} moiety. In cases where the electronic coupling, *V*, between the Fe^{II}/Fe^{III} wavefunction (Φ_A) and the Fe^{III}/Fe^{II} wavefunction (Φ_B) is small compared to the reorganisation energy, λ, the strength of this intervalence charge-transfer (IVCT) band can be analysed to afford *V* and the interaction parameter, α.[48] according to eqn. (2) where Ψ is the

$$\Psi = (1 - \alpha^2)^{0.5}\Phi_A + \alpha\Phi_B \quad (2)$$

ground state wavefunction. In bis(ferrocenyl) conjugated systems it generally seems that the assumption of small coupling is valid. The values of α and *V* in Table 2 allow one to compare the efficacies of various bridges at mediating electronic coupling. Electrochemical data are also included in Table 2; interpretation of $\Delta E_{1/2}$ data is less straightforward than that of IVCT data ($\Delta E_{1/2}$ depends on stabilising factors in the Fe^{II}/Fe^{II}, Fe^{II}/Fe^{III} and Fe^{III}/Fe^{III} species, and on through-space electrostatic effects), but the value can provide a useful rough indication of the strength of metal–metal interaction.

Both optical and electrochemical data show more interaction for alkenes than alkynes. This result is consistent with linear and non-linear optical results on analogous ferrocene–bridge–acceptors with alkene and alkyne bridges [the LE absorption of (*E*)-FcCH=CHB(mes)$_2$ {mes = 2,4,6-trimethylphenyl} is lower in energy and more intense than that of FcC≡CB(mes)$_2$ and β_μ is larger[20]] and with calculations for all-organic mixed-valence compounds.[49] Arenes are rather poor at mediating metal–metal interactions; this is consistent with the disruption of donor–acceptor coupling effected by the introduction of aromatic moieties into organic second-order NLO chromophores.[50]

Bis(ruthenocenyl) compounds have been much less studied, presumably partly due to the irreversible redox chemistry of ruthenocene itself. Recently, however, it has been found that RcCH=CHRc, and a number of substituted derivatives, undergo chemically (though not electrochemically) reversible two-electron oxidations to diamagnetic bis(η^5-cyclopentadienyl-

ruthenium)(μ-η⁶:η⁶-pentafulvadiene) dications (Fig. 5).[60,61] These formally ligand-based oxidations can be contrasted to the metal-based oxidations of iron analogues; presumably the small differences in energy between the highest π-orbital and the

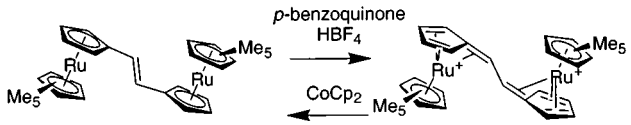

Fig. 5 Chemically reversible two-electron oxidation of a bis(ruthenocenyl) ethene.[58]

ruthenium d-orbitals is important (although di-Ru^{III} intermediates are postulated[61]), along with the greater tendency of ruthenium to adopt η⁶ coordination and to retain an 18 electron configuration. Similar two-electron oxidations involving structural rearrangemnt of a ruthenocene to η⁶-fulvene geometry, have been observed in RcC≡CRuCp(PPh$_3$)$_2$ and related compounds.[62,63] Even biruthenocene can be oxidised to the diamagnetic bis(η⁵-cyclopentadienylruthenium)(μ-η⁶:η⁶-fulvalene) dication under certain conditions.[64] In this respect, ruthenocene resembles an organic fragment more than does ferrocene. For example, the dication of *N*,*N*,*N*′,*N*′-tetramethylbenzidine has a quinoidal, and presumably diamagnetic, structure,[65] due to good mediation of N–N interaction by the π-system. By contrast, the dications of dinuclear bis(ferrocenyl) complexes typically behave as two more-or-less non-interacting spin 1/2 centres; the biferrocene dication has no significant exchange interactions between the two Fe^{III} centres.[66,67]

The metal–metal interactions possible in conjugated linked metallocenes have been exploited in poly(ferrocenylenevinylene)[68] and poly(ferrocenylenedivinylene)s;[69] when partially oxidised poly(ferrocenylenedivinylene) shows superior conductivity to similar polymers with more 'insulating' bridges.[69]

Electronic and optical properties of bis(metallocenyl)polymethines

In this class of compounds, two metallocenes are linked with an odd number of CH groups and there is an overall positive charge stabilised by contributions from (η⁶-fulvene)(η⁵-cyclopentadienyl)metal cation resonance structures. We have been studying symmetrical and unsymmetrical termethine {*n* = 3} examples with Fc, Rc and Fc″ end groups.[10,70,71] We have determined crystal structures for a number of these compounds. Whilst [**10**]$^+$[PF$_6$]$^-$ and [**11**]$^+$[PF$_6$]$^-$ showed symmetrical cations (as do a close trimetallic analogue,[72] and [FcCHFc]$^+$[BF$_4$]$^-$[73]), the crystal structure of [**12**]$^+$[PF$_6$]$^-$ showed a cation best described as a (η⁶-fulvene)(η⁵-cyclopentadienyl)ruthenium cation bridged by a vinylene moiety to a 'normal' ruthenocene, with BLA between formally single and double bonds of some 0.100(6) Å (Fig. 6). Moreover, the similarity of the IR and

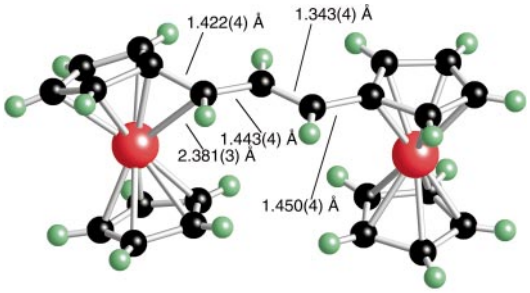

Fig. 6 The [**12**]$^+$ cation in the crystal stucture of its hexafluorophosphate salt.[10,70]

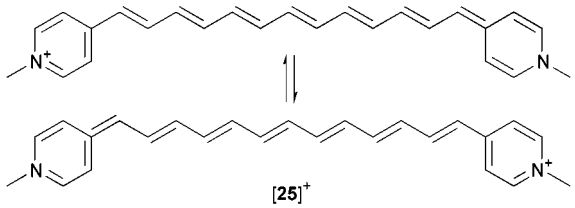
Raman spectra of [**12**]$^+$[PF$_6$]$^-$ in the solid state and in solution suggests the origin of this distortion is an intramolecular effect. The only previous report of such a distortion is that reported by Tolbert and Zhao, who showed [**25**]$^+$ to be unsymmetrical in



[**25**]$^+$

solution by comparing IR and UV–VIS spectra with those of lower homologues.[74,75] Such distortions afford bistable systems, which could form the basis for a switchable device, where a change in external electric field leads to a dramatic change in polarisation.

Unsymmetrical intramolecular localisation effects have been predicted to occur in long-chain (*ca*. 13 methine groups where the end group can stabilise the positive charge) all-organic polymethines,[74,76] and can be understood in analogy to the Peierls distortion,[76] or by analogy with mixed-valence chemistry.[49,74] We attribute the observation of localisation at low chain length for [**12**]$^+$ to the high reorganisation energy associated with the ruthenocene/(η⁶-fulvene)(η⁵-cyclopentadienyl)ruthenium system.

The electronic spectra of bis(metallocenyl)polymethines are strongly reminiscent of those of the metallocene donor–acceptor NLO dyes discussed earlier; *i.e.* there are two prominent transitions. Tolbert has synthesised the series [Fc(CH)$_n$Fc]$^+$[BF$_4$]$^-$ {*n* = 1, 3, 5, 9, 13}, and found the energy of the LE band to be inversely proportional to the conjugation length (N_{eff} = *n* + 6).[58] Fig. 7 shows this dependence, along

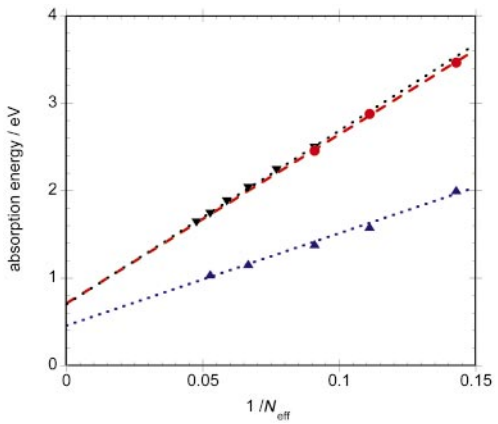


Fig. 7 Conjugation-length dependence of the absorption maxima of α,ω-bis(phenyl)polymethine cations (black; data from ref. 58), the LE (blue; data from ref. 58) and HE (red; data from refs. 10, 59 and 77) bands of α,ω-bis(ferrocenyl)polymethine cations. N_{eff} is defined as *n* + 8 for the phenyl compounds, and *n* + 6 for the ferrocenyl species.

with the stronger chain-length dependence of the HE band, which closely resembles that of the absorption of [Ph(CH)$_n$Ph]$^+$ cations. Thus, we assign the HE band as a π → π* transition. This is, of course, consistent with the assignment of the HE of metallocene–bridge–acceptor compounds as π → (acceptor), and with the orbital scheme. Assignment of the LE band as M → π* is consistent with the weaker chain-length dependence of this band, with the greater blue shift compared to that in the HE band seen on replacing iron with ruthenium (Fig. 8), with the analogous metallocene–bridge–acceptor compounds, and with the calculated orbital structure (Fig. 9). As shown in the calculated orbitals for the distorted [**12**]$^+$ cation, the highest π-level of unsymmetrical species is mainly from the cyclopentadienyl orbitals of the'normal' metallocene, whilst the π* LUMO is correspondingly displaced towards to the (η⁶-

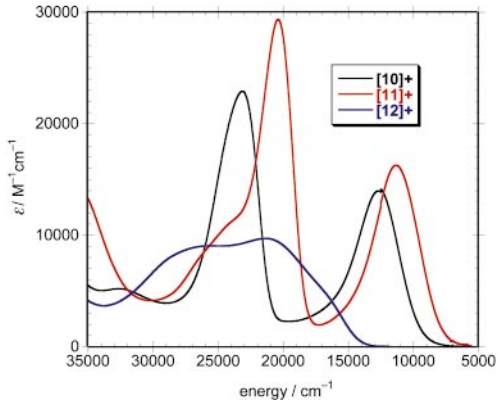

Fig. 8 UV–VIS–NIR spectra of three bis(metallocenyl)termethines, showing the effect of metallocene methylation ([**10**]$^+$ *vs.* [**11**]$^+$), and changing Fe for Ru ([**10**]$^+$ *vs.* [**12**]$^+$).

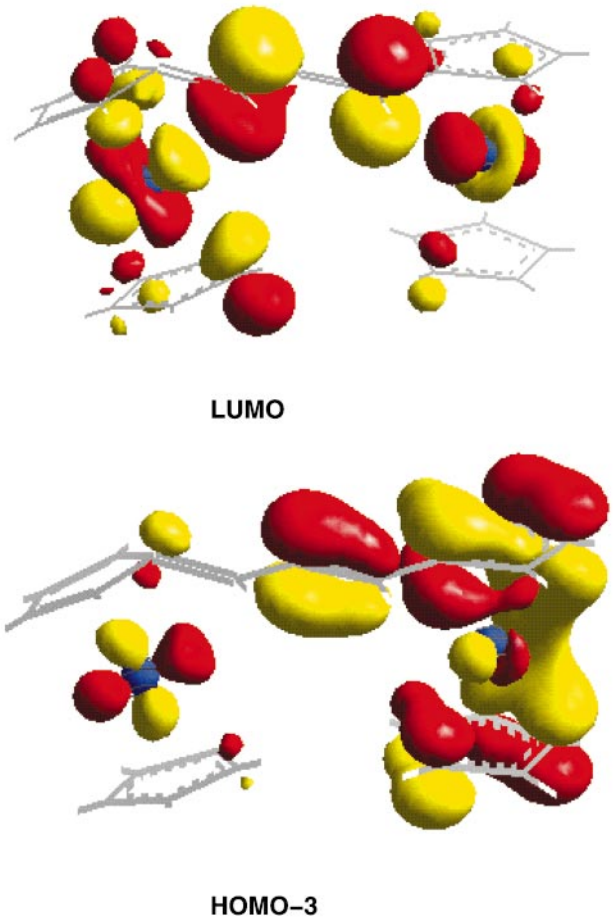

Fig. 9 The LUMO and the highest filled ligand-based π-levels of [**12**]$^+$ according to DF calculations; the three highest-filled levels are all principally metal d in character.[10]

fulvene)(η^5-cyclopentadienyl)metal end of the molecule. The HOMO is located on the 'normal' metallocene. Nevertheless, the orbitals of symmetrical and unsymmetrical bis(metallocenyl)termethines are broadly similar. The bis(metallocenyl)termethine series holds completely symmetrical species ([**10**]$^+$, [**11**]$^+$), somewhat unsymmetrical species ([**13**]$^+$, in which the octamethylferrocenyl group undergoes more distortion than the ferrocene, but the BLA is small), and fully bond-alternated structures ([**12**]$^+$, [**14**]$^+$). This variation is analogous to that found in donor–acceptor compounds, where one can tune between bond-equalised and fully bond-alternated structures through donor and acceptor strength.[37]

Summary

The work of numerous groups has demonstrated that conjugated group 8 metallocenes have a variety of interesting optical and electronic properties. Over the past several years it has become more clear that the metallocenes are different in their behaviour as π-electron donors from simple organic groups, such as those derived from anisole or aniline. In particular, a metallocene interacts with a conjugated π-system both through the cyclopentadienyl group and through the metal-based orbital. These various interactions create opportunities to control the coupling of the metal orbital with the π-system and to control the interaction between metal centres. While interesting non-linear optical and electronic properties have been reported, conjugated metallocenes have yet to find use in device applications. Perhaps, as our understanding of the electronic of this class of molecules become more complete, novel applications of these materials will be identified.

The sorption of biphenyl (BP) in dehydrated M-ZSM-5 (M = H^+, Cu^{2+}) zeolites through solid–gas exchange spontaneously causes ionisation of BP molecules; the radical cation and trapped electron disappear slowly *via* two different electron transfer mechanisms.

Spontaneous generation of long-lived organic cation radicals in porous crystalline aluminosilicates (zeolites) has been known for over three decades.[1–3] The tight fit between the radical cation and the pore size is considered to be the main factor responsible for this stabilisation and it is now accepted that the acid sites of the porous materials are related to their electron acceptor ability.[3,4] The Brönsted acid sites can impart to zeolites a dual behaviour as acid and oxidant. Earlier work has showed that persistent carbocations are formed more readily than radical cations.[5] However, the electron and proton transfer mechanisms are not yet completely understood, particularly the fate of the ejected electron.[3,4,6,7] This gap prompted this work relating to unusual biphenyl sorption behaviour in M-ZSM-5 zeolites with H^+ and Cu^{2+} as counterbalancing cations.

UV–VIS, IR, Raman, EPR spectra as well as chemical analysis of calcined zeolites $M_{m/n}(SiO_2)_{96-m}(AlO_2)_m$ (m = 3, 6; M = H^+, Na^+) (24 h, 773 K, O_2, Ar) do not exhibit any detectable impurity (Fig. 1) with X-ray diffraction patterns exhibiting the characteristics of well-crystallised ZSM-5 solids while ^{29}Si MAS NMR spectroscopy revealed the absence of abnormal defect groups. The ^{27}Al MAS NMR spectrum of hydrated H_6ZSM-5 shows only a low amount of six-coordinated non-framework Al.

Exposure under argon or helium atmosphere at room temperature of freshly dehydrated $H_m(SiO_2)_{96-m}(AlO_2)_m$ (m = 3, 6) powdered solids to dry biphenyl, turned the powder immediately from white to blue and after one week the solids turned pink. Numerous diffuse reflectance UV–VIS absorption spectra were recorded at different times, immediately after the exposure and until the reaction went to completion over one month at 330 K. The processing data for all the spectra of each sample (Fig. 2), provided evidence of three independent spectra of occluded species in H_m-ZSM-5.[8] The extracted spectrum with main bands around 380 and 666 nm reached a maximum intensity within several minutes and then decreased slowly, and was assigned to the radical cation $BP^{\cdot+}$. It should be noted that this maximum corresponds to *ca.* 10% of $BP^{\cdot+}$ with respect of the BP loading. The extracted spectrum with two prominent features at 468 and 491 nm reached maximum intensity within 20 h and then decreased slowly and was attributed straightforwardly to trapped electrons. The spectrum with two maxima at 250 (sharp) and 505 nm (broad) increased slowly with diffusion of BP in the porous void and reached a maximum within one month and was assigned to non-bonding electronic interactions of BP with protons of the Si–OH–Al framework groups. The EPR spectra recorded immediately after the exposure of H_mZSM-5 samples to BP solid exhibited the sharp features of $BP^{\cdot+}$ at 300 and 77 K. After annealing the sample at 320 K for one week, these sharp features disappeared to give a broad intense signal (77 K) corresponding to both trapped electrons and positive holes. After annealing the sample at 320 K for a month no paramagnetic species were detected. Zeolite samples with loading values from 0.2 to 1 BP per unit cell (m = 3, 6) exhibited similar behaviour.

The exposure of dehydrated $M_m(SiO_2)_{96-m}(AlO_2)_m$ (m = 3, 6, M = Li^+, Na^+, K^+, Rb^+, Cs^+) to solid BP led to no colour change and BP was found to be sorbed as an intact molecule.[9]

Photolysis at 248 nm of BP occluded in M-ZSM-5 (M = Li^+, Na^+, K^+, Rb^+, Cs^+) generated persistent UV–VIS spectra analogous to that generated spontaneously through BP sorption in $H_m(SiO_2)_{96-m}(AlO_2)_m$ without photolysis.[9] EPR spectroscopy provided evidence of paramagnetic species, namely trapped electrons and positive holes, after the disappearance of $BP^{\cdot+}$.[9] Exposure of dehydrated $M_{m/2}(SiO_2)_{96-m}(AlO_2)_m$ (m = 6, M = Zn^{2+}, Cd^{2+}) to solid BP also led to no colour change and BP was found to be sorbed without any ionisation.

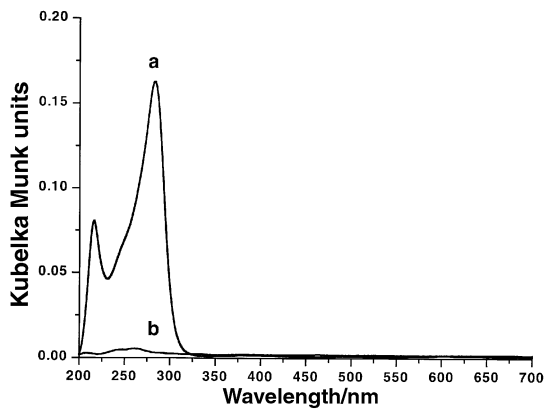

Fig. 1 Diffuse reflectance UV–VIS absorption spectra (Kubelka-Munk units) recorded (a) before thermal treatment of $(NH_4)_6$ZSM-5 zeolite $(NH_4)_6(SiO_2)_{90}(AlO_2)_6$ and (b) after thermal treatment (24 h, 773 K, O_2).

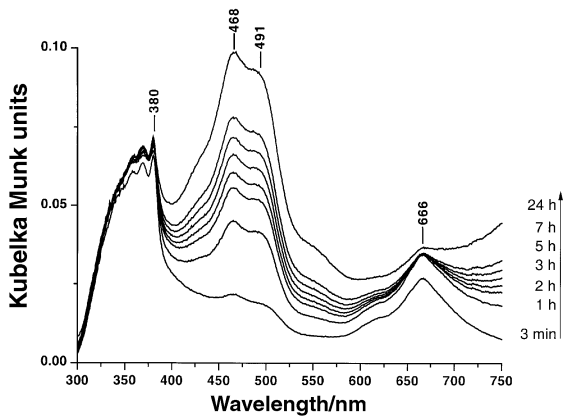

Fig. 2 Diffuse reflectance UV–VIS absorption spectra (Kubelka-Munk units) recorded during the sorption of biphenyl into H_6ZSM-5 zeolite [1BP/$H_6(SiO_2)_{90}(AlO_2)_6$]. The spectra were recorded at room temperature at different times.

DOI: 10.1039/b001307m

Exposure of $Cu_3(SiO_2)_{90}(AlO_2)_6$ after thermal treatment (24 h, 773 K, O_2) to solid BP under argon generated persistent $BP^{\cdot+}$ and trapped electrons as evidenced through data processing of the UV–VIS spectra. Surprisingly, Cu(II) does not appear to be a preferred electron trapping site.

Diffuse reflectance IR absorption spectra of dehydrated $H_m(SiO_2)_{96-m}(AlO_2)_m$ samples (m = 3, 6) exhibited two sharp OH stretching bands at 3611 and 3745 cm^{-1}. These bands were assigned to acidic (Si–OH–Al) hydroxy groups and (Si–OH) silanol groups, respectively.[10] After BP sorption was complete, the 3611 cm^{-1} band decreased in intensity and a new broad band appeared at 3300 cm^{-1}. The dehydrated $M_{m/n}$ZSM-5 (M = Li^+, Na^+, K^+, Rb^+, Cs^+, Zn^{2+}, Cd^{2+}) exchanged zeolites (24 h, 773 K, O_2) did not exhibit any intense OH stretching band at 3611 cm^{-1}. In contrast, the O_2-calcined Cu_3-ZSM-5 sample DRIFT spectrum showed an intense band at 3661 cm^{-1}.[11] It is tempting to attribute the spontaneous BP ionisation to the acidic properties of the O_2-calcined Cu_3-ZSM-5 sample. The most prominent mid-IR absorption bands (1485, 1432 cm^{-1}) of BP occluded in H_mZSM-5 do not differ from those recorded for Na_mZSM-5 (1485, 1432 cm^{-1}) or for the bulk solid (1480, 1430 cm^{-1}). ^{13}C CP-MS NMR spectra of BP occluded in H_mZSM-5 and Na_mZSM-5 were found to be very similar. Thus, in spite of the high basicity of BP (proton affinity = 814 kJ mol^{-1}), proton transfer from H-ZSM-5 to BP does not occur at room temperature.

The FT-Raman spectra (1.06 μm excitation) of occluded BP in M_mZSM-5 (M = Li^+, Na^+, K^+, Rb^+, Cs^+) were found to be similar in frequencies and relative intensities with the Raman spectrum of BP in solution. However, the relative intensities of the Raman bands of occluded BP in $M_{m/n}$ZSM-5 (M = H^+, Zn^{2+}, Cd^{2+}, Cu^{2+}) differed markedly from BP in solution and provided significant evidence of local BP symmetry lowering and electrostatic interactions between BP and the extraframework cations M^{n+}.

Spontaneous ionisation phenomena upon sorption into H_mZSM-5 has been observed for several aromatics such as biphenyl, naphthalene and anthracene which have relatively low ionisation energies (*ca.* 8 eV in the gas phase). The formation of radical cations occurs by electron detachment mediated by the combined effects of radical cation stabilisation and the electron trapping ability of the host. It should be noted that for BP, the ratio $BP^{\cdot+}$/BP is < 0.1, but for anthracene, the ionisation yield approaches unity. It appears that acid sites, either Brönsted or Lewis in nature, are necessary for this reaction to occur at room temperature. The zeolites behave both as electron acceptors to electron donor aromatics and as electron donors to electron deficient radical cations. The role of possible undetectable impurities, such as low extraframework Al content, may be ruled out, since the Na^+ exchanged ZSM-5 sample did not exhibit any spontaneous charge separation; however, the role of defect groups cannot be excluded.[6] The exact chemical nature of the electron trapping sites as well as the positive holes within the ZSM-5 zeolites is not unequivocally identified from the present spectroscopic data. Evidence for charge separation arises from electronic and EPR spectra. In addition, it is possible that the ionisation occurs at the pore openings of the zeolite microcrystals.[12] From the relationship between the zeolite Al content and the stabilisation of the charge separation, it appears that Al is directly involved in the electron trapping sites. However, the presence of nearest Si–OH–Al Brönsted sites appears to be necessary to induce the spontaneous phenomenon at room temperature since H^+–Na^+ exchange of samples with analogous Lewis sites inhibited this effect.[13] A recent model of the interaction of trapped electrons in sodalite cage sheds some light on the possible environment of the trapped electron.[14] The frame atoms for the electron can be provided by five-member ringed containing Al and bridging OH. The radical cation or the positive hole ($R^{\cdot+}$) counterbalances the negative charge in $[H(AlO_2)(SiO_2)_4$ **e**$]$ $R^{\cdot+}$. A concerted mechanism in the void space of ZSM-5 zeolites between the occluded aromatic, the proton interactions and the nearest efficient trapping site can lower the ionisation activation energy and can lead to thermally durable charge separation.

Received (in Cambridge, UK) 5th June 2000, Accepted 4th July 2000
Published on the Web 31st July 2000

An enzyme involved in the biosynthesis of the 4-*epi*-vancosamine substituents of a vancomycin group antibiotic has been expressed and its role as a TDP-4-keto-6-deoxyglucose-3,5-epimerase demonstrated.

The glycopeptide antibiotics vancomycin (**1**, Fig. 1) and teicoplanin are currently the drugs of choice for treatment of infections due to methicillin-resistant *Staphylococcus aureus*.[1] The continued rise of vancomycin-resistant bacteria has heightened the need for new therapeutic agents. Manipulation of the biosynthetic gene cluster for the glycopeptide chloroeremomycin (**2**, Fig. 1) may be a potential route to new antibiotics.[2–5] This approach will require further understanding of the biosynthetic pathway.

Chloroeremomycin consists of a crosslinked heptapeptide backbone, adorned with the unusual deoxy-sugar 4-*epi*-vancosamine (4-*e*-V) on residue 6, and the disaccharide glucosyl-4-*e*-V on residue 4. These substituents enhance antibacterial efficacy by promoting antibiotic dimerisation, which is important in the mode of action of this group of compounds.[6,7] Analysis of sequence data from the chloroeremomycin gene cluster revealed five putative proteins, ORFs 23–26 and ORF14, that had significant homologies (30–70% identity) with sugar biosynthesis enzymes in other antibiotic gene clusters, in particular those for erythromycin and daunomycin.[2,8–11] Given the ubiquitous deoxy-sugar precursor TDP-4-keto-6-deoxyglucose, homologies to enzymes identified in the biosynthetic pathways for daunosamine and mycarose allowed a probable route to 4-*e*-V to be deduced (Fig. 2).[2] This paper describes the expression of EvsA (previously referred to as ORF26) and demonstration of its role as the TDP-4-keto-6-deoxyglucose-3,5-epimerase in the 4-*e*-V biosynthetic pathway.

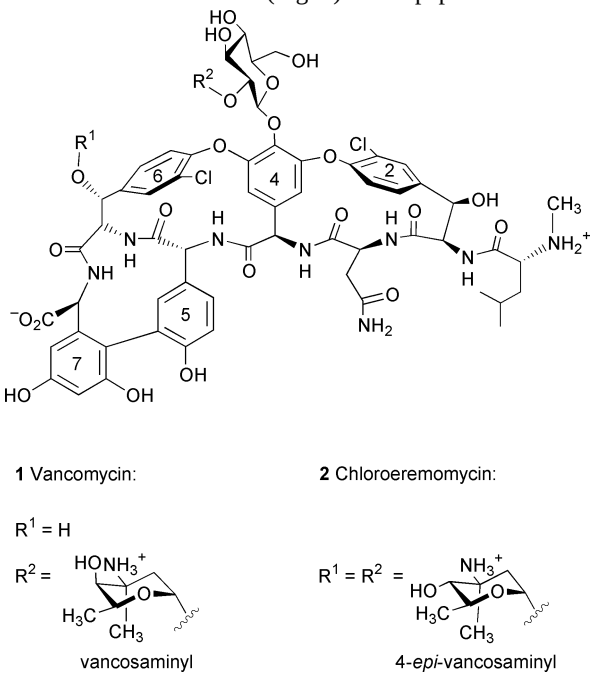

Fig. 1 Structures of vancomcyin (**1**) and chloroeremomcyin (**2**).

EvsA consists of 205 amino acids and shows strong homology (~60% identity) with putative sugar 3,5-epimerase enzymes from the gene clusters of several antibiotics containing L-sugars, including those involved in the daunosamine pathway of *S. peucetius* (DnmU) and the mycarose pathway of *S. erythraea* (EryBVII).[8–11] It is also closely related to the enzyme RmlC from the rhamnose pathway of *E. coli*, *M. tuberculosis* and *S. enterica*, which has been shown to be a TDP-4-keto-6-deoxyglucose-3,5-epimerase.[12,13] The crystal structure of RmlC from *S. enterica* has been determined and the potential active site located, but as yet the residues responsible for catalysis have not been identified.[14] All the highly conserved residues present in this region are also present in EvsA. Although epimerisation at C-3 is not required in the biosynthesis of 4-*e*-V, it seems plausible that all these enzymes have evolved from a common ancestor capable of catalysing epimerisation at both positions 3 and 5, and thus EvsA is suggested to be the first enzyme in the 4-*e*-V pathway.

In order to confirm the proposed role of EvsA, the *evs*A gene was amplified by polymerase chain reaction (PCR) and cloned into the expression vector pET28a(+) (Novagen). The resulting plasmid was used to transform *E. coli* BL21(DE3) and the cells grown at 37 °C in LB medium with induction by isopropyl β-D-thiogalactoside (IPTG, 1 mM) to produce *N*-terminal His_6-tagged EvsA. The enzyme was purified using Novagen His-Bind Quick 900 cartridges and transferred to 50 mM HEPES, pH 7.6 using Millipore centrifugal filters. The relative molecular mass of the purified protein (which gave rise to a single band on an SDS-PAGE gel) was found to be 24.52 kDa (using ESI-MS) which was in excellent agreement with that calculated from the protein sequence (24.521 kDa).

The proposed substrate for EvsA, TDP-4-keto-6-deoxyglucose, was prepared enzymatically from TDP-glucose using RmlB (also known as RfbB), the TDP-glucose-4,6-dehydratase

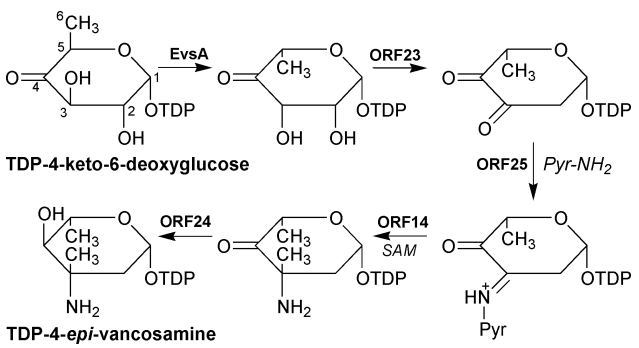

Fig. 2 Proposed route for the biosynthesis of TDP-4-*epi*-vancosamine from TDP-4-keto-6-deoxyglucose. Putative enzymes involved in each step are indicated. Cofactors thought to be required are shown in italics. Abbreviations: Pyr-NH_2, pyridoxamine-5′-phosphate; SAM, S-adenosyl-methionine.

DOI: 10.1039/b004463f

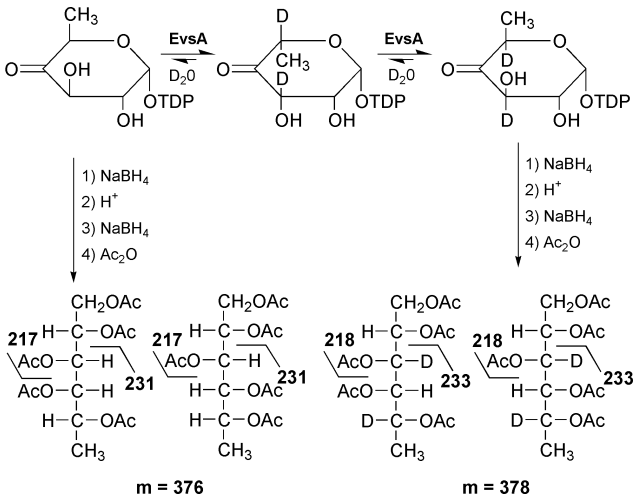

Fig. 3 The equilibrium catalysed by EvsA and the products of the subsequent derivatisation reactions (with the masses of the molecular ions and their fragments).

from the rhamnose pathway.[15] Incubation of TDP-glucose (5 mg) with RmlB (1.6 mg) at 25 °C for 3 h resulted in essentially complete conversion to TDP-4-keto-6-deoxyglucose (monitored by observing the intensity of the UV absorption band of the product at 320 nm).

The potential epimerase activity of EvsA was assayed using a technique based on that described by Stern *et al.* when investigating RmlC, the 3,5-epimerase of the rhamnose pathway.[12] This study demonstrated that incubation of the enzyme with TDP-4-keto-6-deoxyglucose in D_2O allowed for the incorporation of two deuterium atoms from the solvent at positions 3 and 5, and thus that RmlC was capable of catalysing the expected epimerisations.

Consequently, EvsA (10 μg in 50 mM HEPES, pH 7.6) was incubated with TDP-4-keto-6-deoxyglucose (10 μg) in D_2O at

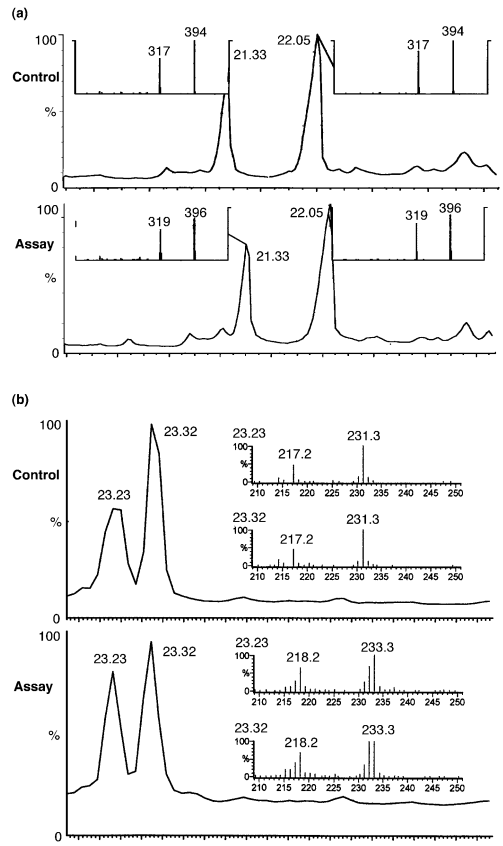

Fig. 4 GC-MS traces [(a) chemical ionisation, (b) electron impact] of the alditol acetates produced from the assay with EvsA and the control without EvsA.

37 °C for 90 min in a total volume of 100 μl. Due to $[^1H]_2O$ in the enzyme and substrate solutions, the resulting concentration of $[^2H]_2O$ was about 80%. A reaction in which protein was replaced by buffer was used as a control. The reactions were stopped by addition of EtOH and the protein removed by centrifugation. The resulting 4-keto-sugar nucleotides were then reduced with $NaBH_4$, hydrolysed with trifluoroacetic acid, reduced again, and then acetylated for analysis by GC-MS as described by Stern *et al.* (Fig. 3).[12] The alditol acetates produced were dissolved in MeOH and analysed by ammonia chemical ionisation GC-MS. The traces for the GC-MS of the EvsA and control reactions are shown in Fig. 4(*a*). Mass analysis of the two peaks revealed that the molecular ions (MNH_4^+) present in the EvsA reaction are two mass units higher (*m*/*z* 396) than those in the control reaction (*m*/*z* 394).[16] The same difference is observed in the masses of the major fragment ion, which corresponds to loss of acetic acid and ammonia. Thus two deuterium atoms have been incorporated into TDP-4-keto-6-deoxyglucose from the solvent by the action of EvsA. In order to establish the positions of incorporation, the samples were also analysed using electron impact GC-MS, which gives fragments rather than the molecular ions (Fig. 3 and Fig. 4(*b*)). No deuterium incorporation was seen in the control but incorporation at both positions 3 and 5 occurred in the presence of EvsA.[17] These results confirm that EvsA is indeed an epimerase involved in the biosynthesis of 4-*e*-V at the stage suggested (Fig. 2) and that epimerisation is catalysed at both C-5 and C-3.

We thank Samantha Barton and Oliver Choroba for valuable assistance and the BBSRC and EPSRC (P. K.) for funding. H.-w. Liu thanks the National Institutes of Health for funding.

15 The enzyme RmlB was originally derived from *Salmonella enterica* LT2 and was overexpressed and purified from *E. coli* HB101/pYLR1 cells in the laboratory of H.-w. Liu.
16 The presence of just two major peaks (rather than four) corresponding to the expected masses of the ammoniated molecular ions is presumably due to the previously observed equilibrium position of the reaction catalysed by 3,5-epimerases, which lies strongly on the side of the *gluco*-configuration.[12]
17 This incorporation was not total as there are ions observed at 217 and 232 in the EvsA assay. This will be in part due to the presence of some $[^1H]_2O$ in the reaction mixture, but it is also possible that reaction of the substrate was not complete.

Photochromic heteroaromatic thiofulgides and dimethoxybutanoic acid lactones

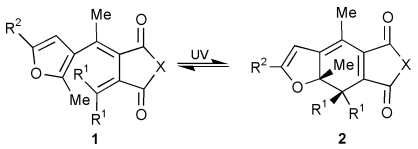
Matthew Badland, Alison Cleeves, Harry G. Heller,* David S. Hughes and Michael B. Hursthouse

Chemistry Department, Cardiff University, PO Box 912, Cardiff, UK CF1 3TP

Received (in Cambridge, UK) 13th March 2000, Accepted 3rd July 2000
Published on the Web 3rd August 2000

Thiofulgides 1, (X = S) cyclise on irradiation with UV light to form thermally stable photochromes 2, (X = S) that absorb at much longer wavelengths than photochromes 2, (X = O), formed from corresponding fulgides 1, (X = O), reverse reactions occur on exposure to white light; photochromic thiofulgides are prepared by reaction of fulgides with sodium hydrosulfide in hot toluene and photochromic lactones 9 and 12 are prepared by reaction of fulgides with sodium hydrosulfide in cold methanol followed by cyclisation with a carbodiimide.

Photochromic heteroaromatic thiofulgides **1**, (X = S) are of special interest because their coloured forms **2**, (X = S) have the potential to show large bathochromic shifts of their long wavelength absorption bands compared to the coloured forms **2**, (X = O) from corresponding fulgides **1**, (X = O). (The effect of replacement of oxygen by sulfur can be seen in the ultraviolet spectra of thiomaleic anhydride[2] which shows λ_{max} 230 nm compared to λ_{max} 198 nm for maleic anhydride[3].)



Previous attempts to synthesise photochromic heteroaromatic thiofulgides by methods used for the preparation of acetic,[4] succinic,[5] phthalic,[6] and dibenzylidenesuccinic thioanhydrides[7] were unsuccessful.

We find that (*Z*)-thiofulgides, (*Z*)-4-dicyclopropylmethylene[1-(2,5-dimethyl-3-furyl) and (2-methyl-5-phenyl-3-furyl)-ethylidene]thiosuccinic anhydrides **6a** and **6b** can be prepared

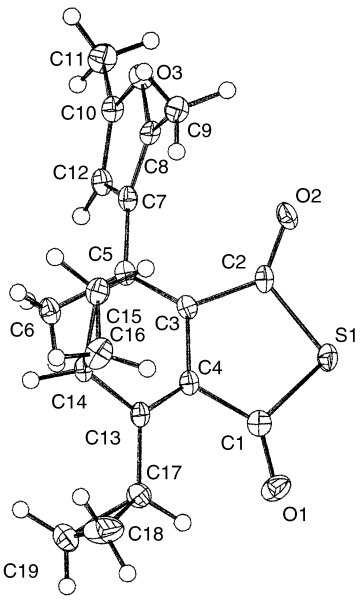


Fig. 1 The X-ray structure of (*Z*)-thiofulgide **6a**.

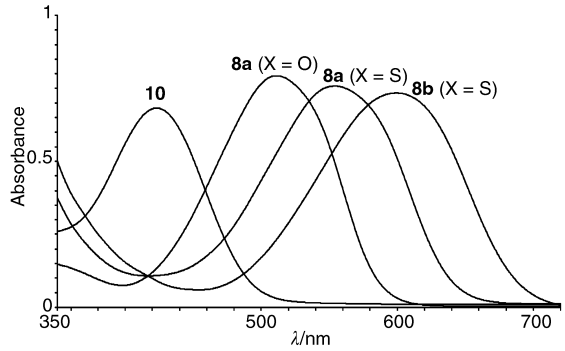

Fig. 2 The spectra of compounds **10**, **8a** (X = O), **8a** (X = S), and **8b** (X = S) (λ_{max} 424, 511, 544, and 599 nm respectively) obtained after irradiation at 366 nm of compounds **9**, **4a**, **6a** (X = S) and **6b** (X = S) (1 $\times 10^{-4}$ molar solutions in toluene) to the photostationary state, illustrating the major colour changes which can be achieved by molecular tailoring.

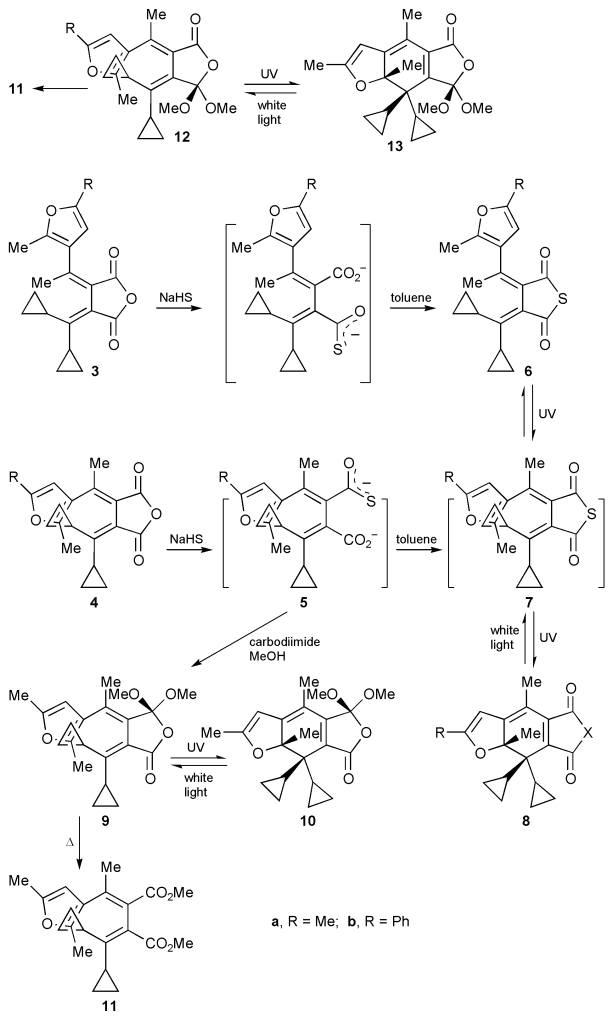

DOI: 10.1039/b002033h

by boiling (4 h) (*Z*)-fulgides **3a** and **3b** (1 g) in toluene with 2–3 eq. of yellow sodium hydrosulfide (Aldrich). They were obtained as yellow crystals, mp 133 and 147–8 °C respectively, after purification by column chromatography and crystallisation from dichloromethane and petroleum. Seven photochromic thiofulgides have been prepared in yields of *ca.* 35% by this general method. Yields depend on the quality of sodium hydrosulfide, which deteriorates with time.

The structure and stereochemistry of (*Z*)-thiofulgide **6a** was established by X-ray crystallographic analysis† (Fig. 1).

On irradiation (366 nm), (*Z*)-thiofulgides **6a** and **6b** in toluene isomerised to (*E*)-thiofulgides **7a** and **7b** which cyclised to thermally stable purple and blue photochromes **8a** (X = S) and **8b** (X = S), showing bathochromic shifts (40 and 60 nm) of the maxima of their long wavelength absorption bands compared to the red and magenta photochromes **8a** (X = O) and **8b** (X = O) (Fig. 2). On exposure to white light, photochromes **8a** (X = S) and **8b** (X = S) ring opened to pale yellow (*E*)-thiofulgides **7a** and **7b**. Quantum efficiencies for colouring ($\emptyset$c) at 366 nm for (*E*)-thiofulgides in toluene were less than for corresponding (*E*)-fulgides. $\emptyset$c for thiofulgide **1** ($R^1 = R^2$ = Me, X = S) was 9% compared to 20% for fulgide **1** ($R^1 = R^2$ = Me, X = O). Preliminary studies indicate that bleaching efficiencies and photochemical fatigue of the photochromes of thiofulgides were comparable to those of photochromes of the corresponding fulgides.

When (*E*)-fulgide **4a** was stirred with sodium hydrosulfide in MeOH at room temperature, the salt of thioacid **5** was formed which after treatment with 1-ethyl-3-(dimethylamino)propyl-carbodiimide HCl, reacted with methanol to give **9** (colourless crystals, mp 168–9 °C, 33% yield). On irradiation (366 nm), lactone **9** in toluene cyclised to the thermally stable bright intensely coloured yellow photochrome **10** which underwent the reverse reaction on exposure to white light.

(*Z*)-Fulgide **3** gave the colourless lactone **12** in 31% yield in an analogous reaction which cyclised to the pale yellow photochrome **13** on irradiation at 366 nm.

Lactones **9** and **12** were converted quantitatively into **11** on boiling with sodium hydrosulfide in MeOH, exemplifying a convenient method of preparing dimethyl esters from anhydrides. All new compounds were fully characterised.

We thank PPG Industries, Pittsburgh, USA and the Brite Euram Syladec programme for grants to MB and AC respectively and financial support for this programme, and EPSRC for support for the X-ray crystallographic work.

Chiral organolithium species: determination of the rate of cyclization and extent of racemization

Iain Coldham* and Graham P. Vennall

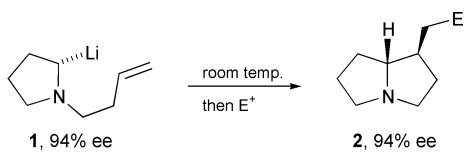
School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD. E-mail: I.Coldham@exeter.ac.uk

Received (in Cambridge, UK) 6th June 2000, Accepted 10th July 2000
Published on the Web 2nd August 2000

The rate of intramolecular carbolithiation onto an unactivated alkene to give a six-membered ring has been determined and follows first order kinetics with a half life of ~ 90 min at 23 °C; this allows significant racemization using a chiral organolithium species, although good levels of optical purity are obtained with a phenylthio-substituted alkene.

The ability to use enantiomerically enriched organometallic species in asymmetric synthesis hinges on the configurational stability at the chiral centre. Since Still and Sreekumar showed that chiral organolithium species could be generated from α-alkoxyorganostannanes and reacted stereospecifically,[1] the reactions of chiral α-hetero-substituted organolithium species have been the subject of extensive studies.[2] The majority of these studies focus on the intermolecular quench, which occurs with retention, inversion or racemization of configuration. We and others have demonstrated that intramolecular (anionic) cyclization occurs with complete retention of configuration at the carbanion centre and provides enantiomerically enriched heterocyclic and carbocyclic compounds.[3–5] For example, we have found that cyclization using the α-aminoorganolithium species **1** (formed from the corresponding organostannane, 94% ee) gives (Scheme 1) the hexahydro-1*H*-pyrrolizine alkaloid (+)-pseudoheliotridane† **2**, E = H with complete diastereoselectivity and enantiospecificity.[3] Unusually, the organolithium species **1** is formed at rt, yet no racemization takes place.[6] Such cyclizations from chiral organolithium species have, so far, been restricted to the formation of five-membered rings, and must occur at rates that are significantly greater than the rate of racemization. Bailey and co-workers have determined the rate of anionic cyclization to generate a cyclopentane ring and found that $t_{1/2} \approx 5.5$ min at 23 °C.[7] We were intrigued to determine the effect of ring size on the stereochemical integrity of the chiral organolithium species. In this paper, we report the first determination of the rate of anionic cyclization to give a six-membered ring and its comparison with the rate of racemization of the chiral organolithium species.

Stannane **3** was prepared by treatment of *N*-Boc-2-tributylstannylpyrrolidine[8] with *B*-bromocatecholborane, followed by acylation with pent-4-enoyl chloride and reduction with $LiAlH_4$.[3] Transmetallation of amine **3** in hexane–Et_2O (4:1) with ^{n}BuLi (3 molar equiv. in hexanes) at rt gave the enantiomerically enriched organolithium species **4** (Scheme 2) which cyclized to give, after quenching with MeOH, the diastereomeric octahydroindolizines **5** and **6** in high yield (80–87%) and diastereoselectivity (95:5, **5**:**6**).[9] Remarkably, the use of the solvent system hexane–Et_2O–TMEDA (4:1:1, equating to 15 molar equiv. of TMEDA) completely reversed the diastereoselectivity, giving predominantly **6** (10:90, **5**:**6**).

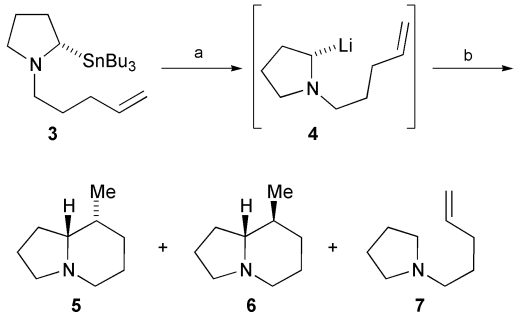


Scheme 1

In each case a small amount of proto-destannylated material **7** was formed. Intramolecular carbolithiation in hexane–Et_2O gave, after 6 h or more, **5** with 13% ee.[10] The presence of TMEDA caused complete racemization. By quenching the reaction mixture (in the absence of TMEDA) at shorter time intervals (*e.g.* 30 min), **5** and **6** (95:5) were obtained in low yield (22%) but enhanced enantiomeric excess (**5**, 62% ee). By taking aliquots of a reaction at different reaction times, it was possible to measure the rate of the cyclization. This followed first order kinetics with a rate constant, $k \approx 1.2 \times 10^{-4}$ s^{-1}, corresponding to a half-life for cyclization of approximately 90 min at 23 °C (complete transmetallation requires 20–30 min). This is significantly slower than the corresponding five-membered ring. Racemization can compete with cyclization, thereby accounting for the loss in enantiopurity. This is in stark contrast to the completely enantiospecific and diastereoselective cyclization of organolithium species **1**. The data reveal that the organolithium species **4** is racemic within approximately 30 min at rt in hexane–Et_2O and therefore the half-life for racemization of the organolithium species **4** must be less than 30 min.

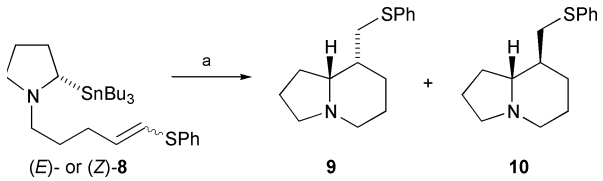
In order to improve the optical purity of the indolizidine products, a method to slow the rate of racemization or to increase the rate of cyclization must be found. Alkenes substituted with an anion stabilising group have been shown to increase the rate of anionic cyclization reactions.[11] Thus the *E*- and *Z*-stannanes **8**, in which a phenylthio substituent is located at the terminus of the alkene, were prepared. The synthesis of the stannanes **8** was achieved by reductive amination.[12,13]

Stannanes **8** were treated with ^{n}BuLi in either hexane–Et_2O (4:1) or hexane–Et_2O–TMEDA (4:1:1), to give the diastereomeric cyclized products **9** and **10** (Scheme 3).‡ In the former solvent system, the organolithium species derived from stannane (*E*)-**8** gave predominantly **9** (77%, 70:30, **9**:**10**) in good ee (**9**, 75% ee; **10**, 72% ee). The organolithium species derived from the stannane *Z*-**8** cyclized to give a mixture of octahydroindolizines **9** and **10** (79%, 50:50, **9**:**10**) in slightly lower ee (**9**, 55% ee; **10**, 53% ee). In the presence of TMEDA, the organolithium species derived from stannane (*E*)- or (*Z*)-**8** cyclized to give racemic **10** exclusively in good yield (71–73%). The addition of TMEDA therefore appears to increase the rate



Scheme 2 *Reagents and conditions*: (a) 2.5 equiv. ^{n}BuLi, hexane–Et_2O (4:1) or hexane–Et_2O–TMEDA (4:1:1), 22 °C; (b) 6 h then MeOH, **5** and **6** (95:5, 80%), **5** (13% ee) and **7** 13%; or **5** and **6** (10:90, 76%), **6** (0% ee) and **7**, 21%.

DOI: 10.1039/b004519p



Scheme 3 *Reagents and conditions*: (a) 2.5 equiv. ^{n}BuLi, hexane–Et_2O (4:1) or hexane–Et_2O–TMEDA (4:1:1), 22 °C, 2 h then MeOH; see text for yields and selectivities.

of racemization, presumably *via* co-ordination of TMEDA to the lithium atom.[14] In the presence or absence of TMEDA, the cyclization is complete within approximately the same time as the substrate takes for complete tin–lithium exchange (≈30 min). The half-life for cyclization is therefore reduced considerably in comparison with the substrate **3**, in which no anion-stabilising phenylthio substituent is present at the terminus of the alkene.

The Leverhulme Trust is thanked for support of this work (G. P. V.). We are grateful to Zeneca Pharmaceuticals (Strategic Research Fund) and Pfizer for unrestricted grants. We acknowledge the use of the EPSRC mass spectrometry service at the University of Wales, Swansea.

Notes and references

† The IUPAC name for heliotridane is 1-methylhexahydro-1*H*-pyrrolizine.

‡ *Cyclization of the stannane E*-**8**: The stannane *E*-**8** (1.16 g, 2.16 mmol) in hexane–Et_2O (25 cm^3, 4:1) was treated with *n*-butyllithium (2.6 cm^3, 6.50 mmol, 2.5 M in hexanes) at rt. After 2 h, MeOH (2 cm^3) was added, the solvent was removed under reduced pressure and the residue was purified by column chromatography on basic alumina, eluting with light petroleum (bp 40–60 °C)–EtOAc (1:0 to 4:1) to give the amines **9** and **10** (409 mg, 77%) as a 7:3 ratio of diastereomers as an oil; ν_{max}(neat)/cm^{-1} 3020 and 2935 (C-H); δ_H(400 MHz, $CDCl_3$) 1.25–2.21 (12H, m), 2.46–2.50 (0.3H, m), 2.62 (0.3H, dd, *J* 12.2 and 8.6), 2.93–3.03 (1.7H, m), 3.05 (0.3H, dd, *J* 12.2 and 3.7), 3.19 (0.7H, dd, *J* 12.3 and 9.0), 3.32 (0.7H, dd, *J* 12.3 and 4.5), 6.98–7.04 (1H, m), 7.09–7.14 (2H, m), 7.38–7.43 (2H, m); δ_C(100 MHz, $CDCl_3$) 20.8, 21.1, 25.7, 26.3, 28.5, 29.3, 31.4, 35.4, 37.7, 41.9, 52.5, 53.8, 54.4, 54.7, 66.6, 68.3, 125.3, 125.5, 127.7, 127.8, 128.8, 138.2, 138.3 (Found: M+H 248.1468. $C_{15}H_{22}NS$ requires M + H, 248.1473); *m/z* (CI) 248 (100%, M + H), 140 (62, $C_9H_{18}N$), 138 (60, M − C_6H_5S). The enantioselectivity of the cyclization was determined by treating the mixture of amines **9** and **10** with Raney® nickel in EtOH (60 °C, 30 min, 90%) to give the amines **5** and **6**.[10]

The nitration of halogenobenzenes using zeolite Hβ or zeolite HY as a solid inorganic catalyst and a combination of liquid nitrogen dioxide and gaseous oxygen as the nitrating reagent leads to high yields and significant *para*-selectivities in a relatively clean process for aromatic nitration.

Electrophilic aromatic substitution reactions are of considerable importance in the production of fine chemicals. However, the traditional processes suffer a number of disadvantages, such as low selectivity towards the desired product and the requirement for large quantities of mineral or Lewis acids as activators. In turn these acids are responsible for corrosion problems within the plant and the generation of large volumes of spent reagents, which, given the current environmentally conscious climate, are increasingly unacceptable. Major efforts are therefore being made towards developing processes that can reduce the volumes of spent liquors produced. Inorganic solids can offer significant benefits for these processes by providing both effective catalysis and, in some cases, enhanced selectivity. Additionally they are easily removed from reaction mixtures and in some cases recycling is possible. For example, we have utilised zeolites to enhance the *para*-selectivity in chlorination,[1] bromination,[2] acylation[3] and methanesulfonylation[4] reactions of simple aromatic substrates.

Aromatic nitro compounds represent particularly versatile chemical feedstocks for a wide range of industrial products, such as pharmaceuticals, agrochemicals, dyestuffs and explosives. Traditionally, nitration has been performed by a mixture of nitric and sulfuric acids (mixed acid method).[5] However, the method is notoriously unselective for nitration of substituted aromatic compounds and the disposal of the spent acid reagents presents a serious environmental issue. In order to address these problems several alternative methods for aromatic nitration have been developed recently. For example, lanthanide triflates have been used to catalyse nitration with nitric acid, which avoids the use of large volumes of sulfuric acid in the process.[6] However, this provides no enhancement of selectivity. Selectivity of the nitration process can be enhanced by solid catalysts such as clays, but primarily zeolites, which can improve selectivity using alkyl nitrates,[7] acyl nitrates,[8] or even nitric acid itself.[9,10] We have reported the use of zeolite Hβ in conjunction with a mixture of acetic anhydride and nitric acid, which currently offers the best combination of yield and *para*-selectivity for nitration of simple aromatic compounds.[11] None of these methods, however, are totally devoid of disadvantages.

Another approach towards clean nitration involves the use of dinitrogen tetroxide in combination with oxygen or ozone as an oxidant.[12] The method where ozone is employed most likely involves dinitrogen pentoxide, as this is known to be a highly active nitrating agent. The method utilising oxygen is less clear cut and requires the use of tris(pentane-2,4-dionato)iron(III) ($Fe(acac)_3$) as a catalyst in an organic solvent.[13] In principle, this could lead to a highly atom-efficient process [eqn. (1)], but it is not regioselective. Therefore, we decided to study the use of dinitrogen tetroxide as a nitrating agent in the presence of zeolites, in order to determine if they were able to catalyse the process and impart *para*-selectivity.

$$4ArH + 2N_2O_4 + O_2 \xrightarrow{\text{Catalyst}} 4ArNO_2 + 2H_2O \qquad (1)$$

Zeolites have been used before in the vapour phase nitration of aromatic compounds using nitrogen dioxide. However, this process did not involve oxygen, was complicated, required a high flow rate for the carrier gas (N_2, 880 ml min^{-1}) and showed poor *para*-selectivity.[14] We now report that certain zeolites can indeed catalyse the process of nitration, as shown in eqn. (1), whilst simultaneously providing enhanced *para*-selectivity.

Initially, an attempt was made to reproduce approximately the conditions of Suzuki for nitration of chlorobenzene. Liquid N_2O_4 (approx. 10 ml) was condensed into a trap at −78 °C and was then warmed to 0 °C. $Fe(acac)_3$ (0.355 g) and chlorobenzene (10 mmol) were then added, the system was flushed with oxygen and the mixture was stirred at 0 °C for 48 h. The product thus obtained contained nitrochlorobenzenes in proportions (2-:3-:4-nitrochlorobenzene proportions of 32: < 1:67) that approximated to those reported by Suzuki, but also showed significant quantities of a product based upon nitration of acetylacetone.

We then carried out similar reactions in which various zeolites were used as catalysts instead of $Fe(acac)_3$ in an attempt to determine which zeolite, if any, would be the most applicable to *para*-selective aromatic nitration. Zeolite β and zeolite Y have three dimensional channels and large pore sizes and were selected on this basis. Mordenite, which has linear large pores, and ZSM-5, which has a medium pore size, were chosen for comparison. Additionally, variation of the cation type was undertaken, with H^+, Na^+, K^+ and NH_4^+ being used in the case of zeolite β, and H^+ and Na^+ in the case of zeolite Y. Finally, zeolite ZSM-5 was tested with two specific Si/Al ratios. Thus, the effects of pore size, channel structure, acidity, cation size and Si/Al ratio could all be assessed. A reaction in the presence of chromatographic silica was also included for comparison. The results are shown in Table 1.

As shown in Table 1, reaction occurred in the presence of all of the zeolites, and all of the reactions gave higher yields than in the absence of any catalyst. The large, three-dimensional-pore zeolites gave higher yields, comparable with those achieved with $Fe(acac)_3$ as catalyst, but the medium pore zeolites and the linear large pore zeolite gave lower yields, as did the silica. All of the zeolites demonstrated higher *para*-selectivity than that obtained with $Fe(acac)_3$, except for NH_4β. This last result may reflect the fact that this was the only zeolite not calcined (heated in air to a high temperature), since this would have caused loss of ammonia and formation of Hβ.

Mordenite and ZSM-5 gave lower *para*-selectivities as well as lower yields, which probably reflects more restricted diffusion through the pores and competition from reaction at the external surface of the solid. The selectivity was also low for the reaction in the presence of silica. The ZSM-5 sample with the higher Si/Al ratio gave a higher *para*-selectivity than that with the lower ratio, possibly because of the process of dealumination, which would have opened up the pore structure of

HZSM-5	150	72	48	32	20	< 1	79

[a] All reactions were carried out with zeolite (1.0 g), chlorobenzene (10.0 mmol), 1,2-dichloroethane (30 ml) and nitrogen dioxide (*ca.* 10 ml) at 0 °C. [b] Calculated by quantitative GC. [c] For comparison.

the zeolite, causing it somewhat to resemble the larger pore systems. However, the yield with the higher Si/Al ratio sample was less, possibly because of the lower density of effective catalytic sites. Interestingly, the nature of the cation present appeared to have a negligible effect on the reactions, the H^+, Na^+ and K^+ forms of the zeolites giving very similar results for each reaction where comparison was possible. Evidently, the process does not rely upon strong acid catalysis and does not depend significantly on cation size. Perhaps the role of the active site is merely to bring together the reagents and substrates within the confines of the pores by simple co-adsorption. Alternatively, perhaps the active site facilitates cleavage of dinitrogen tetroxide to give monomeric nitrogen dioxide, which has been suggested as the active reagent in vapour phase reactions.[15]

Zeolites Hβ and Naβ produced the greatest selectivity for *para*-chloronitrobenzene (85%) and the highest yields (90 and 96%). Therefore, zeolite Hβ was tested with a range of other substrates. The results are shown in Table 2.

Table 2 The nitration of toluene, benzene and halogenobenzenes with nitrogen dioxide and zeolite Hβ in 1,2-dichloroethane[a]

Substrate	*t*/h	Conversion (%)[b]	Yield (%)[b]	Proportions[b]		
				ortho	*meta*	*para*
Toluene	24	100	85	53	2	45
Benzene	45	55	50	—	—	—
Fluorobenzene	48	100	95	7	0	93
Chlorobenzene	48	98	95	14	< 1	85
Bromobenzene	48	> 99	94	22	< 1	77
Iodobenzene	48	99	95	37	1	62

[a] All reactions were carried out with zeolite (1.0 g), substrate (10.0 mmol), 1,2-dichloroethane (30 ml) and nitrogen dioxide (*ca.* 10 ml) at 0 °C. [b] Calculated by quantitative GC.

After 24 h toluene had been completely consumed and produced a reasonable yield of mononitrotoluenes (85%). The *para*-selectivity was fairly low, though greater than for mixed acid nitrations. The reaction with benzene was slow, being only *ca.* 50% complete after 48 h. However, all the halogenobenzenes gave good yields and reasonable *para*-selectivities. This work therefore demonstrates that zeolites β and Y, with H^+, Na^+ or K^+ cations, can be efficient inorganic catalysts for the nitration of halogenobenzenes with dinitrogen tetroxide and oxygen and produce high *para*-selectivities and yields compared to classical nitration methods.

Furthermore, this method represents a low energy and potentially clean synthesis of halonitrobenzenes using an easily recycled solvent and catalyst system. However, at this preliminary point the reactions involve a large excess of dinitrogen tetroxide, long reaction times and the use of an undesirable chlorinated solvent. Therefore, our future efforts in this area will be concentrated on minimising these factors.

The reaction of chlorobenzene illustrates the general procedure for the nitration process. In an ice-water cooling bath was placed a 100 ml round-bottom flask containing a mixture of chlorobenzene (10 mmol), zeolite (1.0 g), and 1,2-dichloroethane (30 ml). The flask was flushed with oxygen gas for 20 min at 0 °C. Liquid nitrogen dioxide (*ca.* 10 ml, *ca.* 280 mmol) was added quickly all at once to the stirred mixture, and the flask was connected to an oxygen gas balloon. After 50 h at 0 °C, the mixture was filtered through a medium porosity sintered glass funnel, and the filtrate was diluted with water. 1,2-Dichloroethane was added and the organic phase was separated and dried over magnesium sulfate. The isomer distribution was determined by gas chromatography (PU 4400) (octadecane was added as an internal standard).

Friedel–Crafts alkenylation of arenes using alkynes catalysed by metal trifluoromethanesulfonates

Teruhisa Tsuchimoto, Takeshi Maeda, Eiji Shirakawa* and Yusuke Kawakami

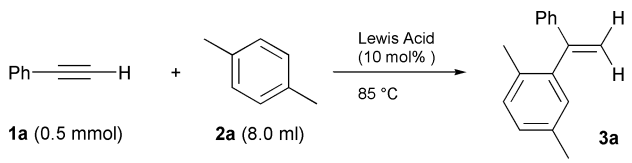
Graduate School of Materials Science, Japan Advanced Institute of Science and Technology, 1-1 Asahidai, Tatsunokuchi, Ishikawa 923-1292, Japan. E-mail: shira@jaist.ac.jp

Received (in Cambridge, UK) 9th May 2000, Accepted 3rd July 2000
Published on the Web 3rd August 2000

Metal trifluoromethanesulfonates [M(OTf)$_n$; M = Sc, Zr, In] catalyse the Friedel–Crafts alkenylation of arenes using alkynes, including internal alkynes, to give, through an alkenyl cation intermediate, 1,1-diarylalkenes in high to excellent yields.

Friedel–Crafts alkylation reactions have been extensively studied and have established a prominent historical position in organic synthesis including industrial applications.[1] In contrast, little has been known about the corresponding Friedel–Crafts alkenylation reaction with either an alkenyl halide or an alkyne. With an alkenyl halide, a substituent such as a phenylthio[2] or an aryl[3] group that stabilizes an alkenyl cation intermediate is required to attain a good yield. The reaction using an alkyne, where a C–H bond of the arene adds to the triple bond of an alkyne, is environmentally friendly without being accompanied by formation of by-products like hydrogen halide. However, the reaction often brings about the polymerization of alkynes and results in the formation of undesired side products.[1b,4] Zeolite HSZ-360 as a heterogeneous acid was found to be efficient especially for *ortho*-selective monoalkenylation of phenol, but only phenylethyne had been examined as a substrate.[5] Recently, alkenylation of arenes with trimethylsilylethyne promoted by an excess amount of $GaCl_3$ was also reported.[6] To the best of our knowledge, the Friedel–Crafts alkenylation reaction with internal alkynes has yet to be explored. We found that metal triflates [M(OTf)$_n$; M = Sc, Zr, In] are effective catalysts for the Friedel–Crafts alkenylation reaction with internal alkynes as well as terminal ones.[7]

The reaction of phenylethyne (**1a**) (0.5 mmol) with *p*-xylene (**2a**) (8.0 ml) at 85 °C for 19 h in the presence of 10 mol% of In(OTf)$_3$ proceeded smoothly to give the corresponding alkenylation product, 1-phenyl-1-(*p*-xylyl)ethene (**3a**), in 80% yield (Scheme 1). Although the reaction using Sc(OTf)$_3$[8] or Zr(OTf)$_4$ required a longer reaction time, **3a** was obtained in 92 or 53% yield, respectively. On the other hand, metal chlorides such as $ZrCl_4$ and $AlCl_3$ gave **3a** only in low yields.



In(OTf)$_3$	Sc(OTf)$_3$[a]	Zr(OTf)$_4$	$ZrCl_4$	$AlCl_3$
80% (19 h)	92% (96 h)	53% (39 h)	1% (100 h)	6% (100 h)

[a] 0.1 ml of $MeNO_2$ was used as an additive.

Scheme 1

These results prompted us to survey the scope of the reaction. The results are summarized in Scheme 2 and Table 1. Arenes except for *p*-dimethoxybenzene were used not only as the substrates but also as solvents. Phenylethyne was successfully reacted with benzene in the presence of Sc(OTf)$_3$ to afford 1,1-diphenylethene in 73% yield (entry 2). A phenylethyne bearing an electron-donating group (–OMe) at the *para* position was also reacted with *p*-xylene using Sc(OTf)$_3$ to give **3** in 62% yield (entry 3). Although Sc(OTf)$_3$ was totally inactive for more electron-deficient alkynes than phenylethyne, In(OTf)$_3$ was effective for the reaction of phenylethyne having a *p*-Cl or *p*-CF_3 group and the products were obtained in high yields (entries 4 and 5). Internal alkynes can obviously participate in this protocol. 1-Phenylprop-1-yne satisfactorily reacted with benzene, toluene, *p*-xylene or anisole using In(OTf)$_3$ to produce the corresponding products (entries 6–11). Zr(OTf)$_4$ was especially effective for the reaction of *p*-dimethoxybenzene to furnish **3** in

[a] The reaction was carried out at 85 °C using an alkyne (0.5 mmol) and an arene (4–10 ml) in the presence of 10 mol% of a Lewis acid. Nitromethane (0.1 ml) was used as an additive in entries 1, 2, 3 and 10. [b] Isolated yield based on alkyne. [c] GC yield. [d] The reaction was carried out at 130 °C. [e] The reaction gave a mixture of 6 isomers which consist of *o*-, *m*- and *p*-regioisomers including the corresponding *cis*/*trans* isomers determined by GC–MS. The isomer ratios are as follows; 30:4:3:2:31:30 (entry 7); 3.0:34.4:0.1:0.3:32.0:30.2 (entry 11); 2:29:1:1:32:35 (entry 13); 2:31:1:1:22:43 (entry 14). [f] Isomer ratios of stereoisomers were determined by GC as follows; 91:9 (entry 8); 91:9 (entry 9); 91:9 (entry 10); 90:10 (entry 12); 93:7 (entry 15). [g] The reaction was carried out with *p*-dimethoxybenzene (2.5 mmol) in chlorobenzene (4 ml) as a solvent.

DOI: 10.1039/b003702h

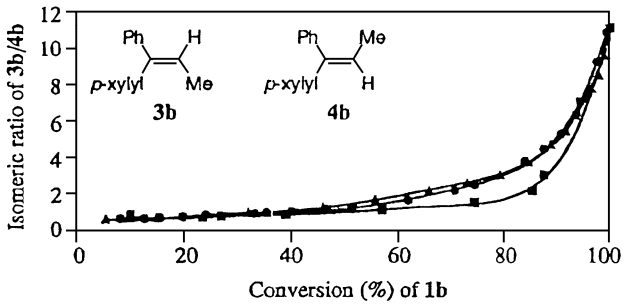

Fig. 1 Plots of isomeric ratio of **3b**:**4b** *versus* conversion (%) of **1b** for $In(OTf)_3$ (-●-), $Zr(OTf)_4$ (-■-), and $Sc(OTf)_3$ (-▲-).

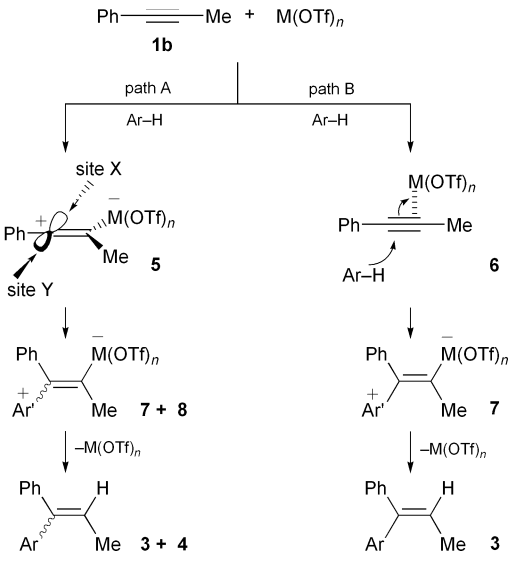
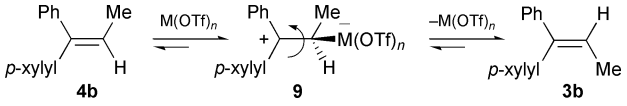
70% yield, whereas $In(OTf)_3$ did not catalyse the reaction (entry 12). Treatment of halobenzenes, which can be used as a solvent in the Friedel–Crafts alkylation, with 1-phenylprop-1-yne gave the products in somewhat lower yields (entries 13 and 14). Arenes attacked these alkynes exclusively at the carbon having the aryl group. The reaction of 1,2-diphenylethyne with *p*-xylene using $In(OTf)_3$ as a catalyst also gave **3** in 79% yield (entry 15). In all cases, the triarylalkane that would be produced by the reaction of **3** and **4** with an arene was not observed.

Dependence of the isomer ratio between alkenylated products **3b** and **4b** on the conversion of 1-phenylprop-1-yne (**1b**) in the reaction with *p*-xylene is illustrated in Fig. 1.[9] Fig. 1 indicates that (1) both stereoisomers **3b** and **4b** already exist in almost a 1:1 ratio at the early stage of the reaction, and (2) there is a drastic change of the isomer ratio at the late stage of the reaction.

Two routes (path A and path B) are possible for this alkenylation reaction (Scheme 3). In path A, the attack of an arene to initially formed zwitterionic intermediate **5** from both X and Y sites affords a mixture of **7** and **8**, which are transformed by protonation to **3** and **4**, respectively. As regards path B, the activation of an alkyne by a metal triflate and the attack of an arene to the alkyne proceeds through a concerted mechanism. Therefore, an arene attacks **1b** stereoselectively from the side opposite to the metal triflate to furnish **7** and subsequent protonation of **7** gives **3** as the sole stereoisomer. The existence of both **3b** and **4b** at the early stage of the reaction



Scheme 3



Scheme 4

strongly suggests that path A works in the reaction. The predominance of **3b** at the end of the reaction should be due to an equilibrium between **3b** and **4b** under the reaction conditions (Scheme 4). Thus, formation of alkyl cation **9** by the reaction of **4b** with a metal triflate and subsequent bond rotation followed by elimination of the metal triflate would induce the isomerization from **4b** to thermodynamically favored **3b**. Prolonged reaction time (100 h) showed no further change in the isomer ratio.

The drastic change in the isomer ratio around the point over 80% conversion of **1b**, *i.e.*, almost consumption of **1b**, may show that metal triflates prefer an alkyne rather than an alkene for complexation under the reaction conditions. Actually, in the absence of **1b**, the isomerization catalysed by 10 mol% of $In(OTf)_3$ in *p*-xylene at 85 °C was completed within 20 min to give a 91:9 ratio of **3b** and **4b** from a mixture of **3b** and **4b** in a ratio of 45:55. Such salient character of metal triflates should be ideal for the Friedel–Crafts alkenylation with alkynes to reduce the possibility of side reactions through alkyl cation **9**.

In summary, we disclose here the preliminary results on the use of some metal triflates as efficient catalysts for the Friedel–Crafts alkenylation of arenes with alkynes including internal ones. Further investigation on the reaction of alkynes with nucleophiles other than arenes is currently in progress.

The detection of all of the aluminium present in steamed zeolite H-Y catalysts by ^{27}Al MAS NMR at high field (18.8 T, 800 MHz for ^{1}H) is reported; further, it is shown that it is possible by ^{27}Al MAS and MQMAS measurements to clearly identify four separate aluminium environments characteristic of these materials and to unambiguously assign their coordinations.

The acid form of faujasite (zeolite H-Y) is converted to a very stable material by steam treatment at elevated temperatures, producing the universally used cracking catalyst 'ultrastable-Y' (USY). Early ^{29}Si MAS NMR studies documented the increase in the framework Si/Al ratio brought about by steaming.[1–4] ^{27}Al MAS NMR indicated that six-coordinate aluminium (Al^{OCT}) is produced even during mild calcination and that substantial amounts of amorphous material can be generated by steaming,[1–8] characterised by a broad ^{27}Al resonance between those of the four-coordinate aluminium (Al^{TET}, at ≈ 60 ppm) and Al^{OCT} (at ≈ 0 ppm). The nature of the species responsible for this signal intensity has been a matter of dispute for almost twenty years. Some workers have assigned the broad signal to a second, distorted tetrahedral species.[4,5*a*,8,9] More recently, various authors have shown that the chemical shift of the intensity maximum of the broad resonance corresponded to five-coordinate aluminium (Al^{PENT}) and the broad resonance was attributed to this species.[5*b*,6,10,11] Despite considerable ongoing effort, there remains little overall agreement in the interpretation of ^{27}Al NMR data. Early studies also suffered from the problem of quantification of the ^{27}Al spectra:[3,4,7,9] Even using small pulse angles, some 30% of the aluminium known to be present could not be observed (the so-called 'invisible aluminium'). Therefore the nature of the aluminium and the related catalytic sites in USY are still poorly understood at the present time.

In the present work, we present preliminary results of an ultra-high field ^{27}Al MAS and MQMAS NMR investigation of a USY sample prepared from Na-Y by the conventional method of ammonium exchange followed by steam treatment at 600 °C, repeated twice. ^{27}Al NMR spectra were obtained at 208.43 MHz (18.8 T, 800 MHz ^{1}H) using a Varian INOVA Spectrometer. In this work we have been able to quantitatively observe all of the aluminium present and to identify four well defined aluminium environments.

The integrated intensities of the ^{27}Al single pulse MAS [Fig. 1(a) and (d)] and 90–180° spin–echo MAS NMR spectra of weighed samples were calibrated at both 104.26 MHz (9.4 T, 400 MHz for ^{1}H) and 208.43 MHz against spectra of weighed Na-Y and Na-A samples acquired under identical conditions. In line with previous work,[3,4,7,9] the data at 104.26 MHz not only fail to account for all of the aluminium present, but show considerable differences in intensity distributions between single pulse and echo experiments; the echo experiments detecting larger contributions from the broader resonances. However, there are no significant differences between the single pulse [Fig. 1(a)] and echo spectra at 18.8 T, where the integrated intensities of both spectra indicate that signal is observed from 100% of the aluminium present.

The MQMAS experiment introduced by Frydman and Harwood[12] (Fig. 2) correlates peaks in the MAS dimension (F2) to signals in the isotropic dimension (F1), with shifts in this dimension being a linear combination of isotropic chemical and

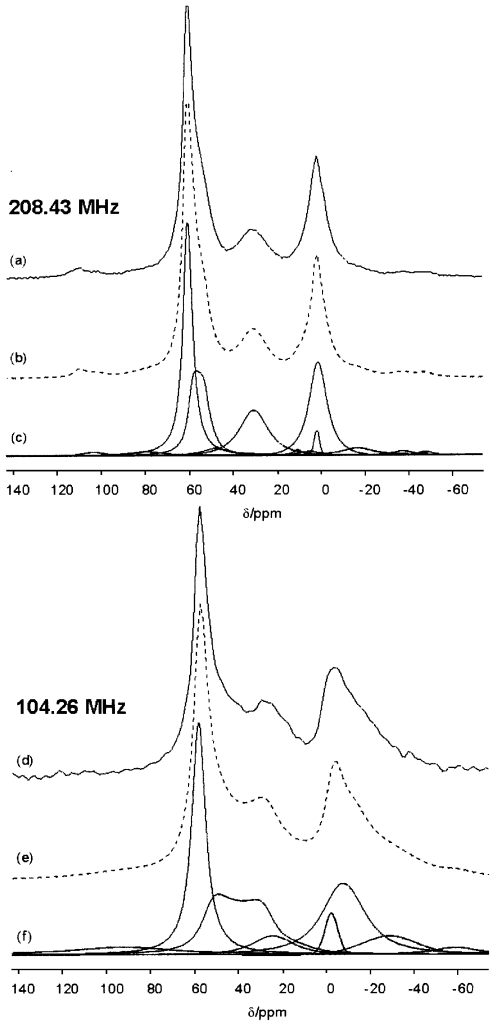

Fig. 1 (a) ^{27}Al single pulse MAS spectrum of USY at 208.43 MHz, recorded at a spinning speed of 10.2 kHz. (b) Simulation of (a). (c) Deconvolution of (b). (d) ^{27}Al single pulse MAS spectrum of USY at 104.26 MHz, recorded at a spinning speed of 9.8 kHz. (e) Simulation of (d). (f) Deconvolution of (e). Chemical shift is referenced to 1 M $Al(NO_3)_3$ aqueous solution. Spectral simulations and deconvolutions were made using 'Dmfit 98'.[15] Isotropic peaks are simulated by half-integer spin quadrupolar lineshapes (parameters given in Table 1) with superimposed exponential broadenings. Spinning sideband intensity is approximated by peaks with mixed Lorentzian and Gaussian character.

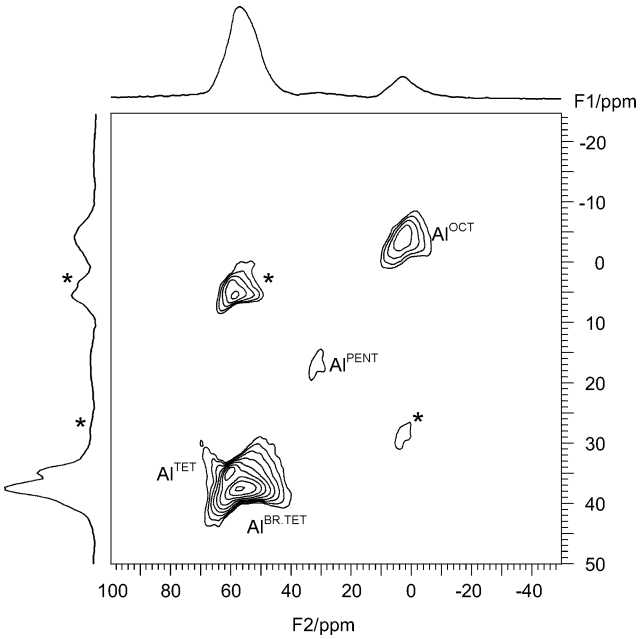

Fig. 2 ^{27}Al MQMAS spectrum of USY at 208.43 MHz, recorded at a spinning speed of 10.2 kHz. Chemical shift is referenced to 1 M $Al(NO_3)_3$ aqueous solution. Coherences were generated using a three-pulse, Rotationally Induced Adiabatic Transfer pulse sequence and selected with a 24-step phase cycle. A shearing transformation was performed after the first Fourier transform. Skyline projections along both axes are shown. * indicates spinning sidebands.

second order quadrupolar shifts. Using this technique, many of the problems caused by peak overlap in the MAS experiment are alleviated, allowing the coordinations to be clearly established.

Fig. 2 clearly shows four aluminium environments. At 61 ppm in F2 there is a sharp Al^{TET} resonance, whose F2 shift closely matches the sharp peak from the framework aluminium in Na-Y spectra. In addition there is clearly a separate and much broader $Al^{BR.TET}$ resonance with an intensity maximum at 57 ppm in F2. Upfield of the four-coordinate resonances are similarly broad Al^{PENT} and Al^{OCT} peaks, with intensity maxima in F2 at shifts typical of five- and six-coordinate aluminium species previously reported.[6,13,14]

Fig. 1(b) and (c) shows a simulation of the single pulse MAS spectrum [Fig. 1(a)] using the program 'Dmfit 98'.[15] The complete intensity profile is based on only the intensity from four peaks (and their spinning sidebands) corresponding to the signals observed in the MQMAS spectrum (Fig. 2). A small, sharp resonance in the octahedral region due to monomeric octahedral aluminium has been observed in the ^{27}Al NMR spectra of USY samples of lower Si/Al. For completeness, a similar peak is included in the simulated spectra of the sample used in this study [Fig. 1(c)], although it has no significant influence on the proportions of the different coordinations calculated to be present (Table 1).

The same parameters (Table 1) yield simulations of similar quality for the ^{27}Al MAS spectra of the same sample taken at 104.26 MHz [Fig. 1(d), (e)] and 156.38 MHz (14.4 T, 600 MHz for ^{1}H). They also reproduce the observed MQMAS isotropic (F1) shifts to within ±5 ppm at both 104.26 and 208.43 MHz, with the positions of the two tetrahedral peaks being predicted to within an accuracy of ±1 ppm. From these data it is apparent that the broad peak at ≈ 30 ppm observed in the spectrum at 104.26 MHz [Fig. 1(d)] has contributions from both broad tetrahedral and five-coordinate aluminium. Spectra at the two higher fields show that each of these account for ≈ 20% of the total spectral intensity.

Framework Si/Al ratios of the Na-Y starting material (calculated from ^{29}Si MAS NMR) and of the USY sample (calculated both by ^{29}Si NMR and IR) suggest that 33% of the aluminium remains in the USY framework following steaming.

Table 1 Summary of USY single pulse ^{27}Al MAS spectral simulation parameters[a]

	δ_{CS}[b]/ppm	Average C_Q[c]/kHz	η_Q	% of total intensity[d]
Al^{TET}	60.7	360	0.53	33
$Al^{BR.TET}$	60.4	940	0.1	21
Al^{PENT}	32.2	578	0.1[e]	20
Al^{OCT}	3.2	492	0.1[e]	26

[a] Chemical shift and quadrupolar coupling distributions are accounted for by an exponential broadening function with a chemical shift component proportional to the magnetic field strength and a quadrupolar coupling component inversely proportional to the magnetic field. [b] Isotropic chemical shift. [c] Calculated to ±3% for 208.43 MHz spectrum using spinning sideband intensities approximated by lineshapes with mixed Lorenzian and Gaussian character. [d] $C_Q = 3e^2qQ/2I(2I - 1)\hbar$. [e] The parameter η_Q has a minimal effect on the simulated MAS spectrum [Fig. 1(b)].

This is in good agreement with the intensity ratios of the simulated spectrum [Fig. 1(c)] in which 33% of the overall intensity is contained within the Al^{TET} peak (Table 1) suggesting that all of the aluminium contained within the fully intact framework could be represented by the Al^{TET} peak at 61 ppm.

In summary, this study shows that high magnetic field strengths solve the problem of the "invisible aluminium" associated with USY materials and that these quantitative ^{27}Al MAS spectra consist of intensity from four distinct aluminium environments. A complete account of this work and its extension to related systems is currently in preparation. We believe that this represents the most complete and self-consistent investigation of the aluminium species present in USY materials to date. Further investigations of the exact nature of the framework and non-framework aluminium species in these steamed zeolite systems is also being carried out.

This research was performed in the Environmental Molecular Sciences Laboratory (a national scientific user facility sponsored by the U.S. DoE Office of Biological and Environmental Research) located at the Pacific Northwest National Laboratory, operated by Battelle for the DoE. We thank Dr David Hoyt and the EMSL staff for their kind assistance and for access to their facility, without which this work would not have been possible. C. A. F. acknowledges the financial assistance of the NSERC of Canada in the form of operating and equipment grants.

An efficient synthesis of heterocyclic *N*-oxides over molecular sieve catalysts†

M. Ramakrishna Prasad, G. Kamalakar, G. Madhavi, S. J. Kulkarni* and K. V. Raghavan

Catalysis and Physical Chemistry Division, Indian Institute of Chemical Technology, Hyderabad-500 007, India. E-mail: root@csiict.ren.nic.in

Received (in Cambridge, UK) 16th May 2000, Accepted 3rd July 2000
Published on the Web 2nd August 2000

Heterocyclic *N*-oxides have been synthesized in very high yields over redox molecular sieve catalyts in the presence of H_2O_2.

N-Oxides hold a key position in the chemistry of heterocyclics in that they offer functional group manipulation and structural modification possibilities, which are not accessible by other methods. Recently the synthesis of heterocyclic *N*-oxides using oxides of rhenium ($MeReO_3$) have been reported by Sharpless *et al.*[1,2] The catalysts/reagents used were methyltrioxyrhenium (MTO), ReO_3, Re_2O_7, $HOReO_3$,Me ReO_3. These rhenium oxide reagents are water sensitive and undergo changes in the presence of water and so cannot be reused. The compounds are often obtained by the oxidation of heterocycles with acetic acid and hydrogen peroxide[3] ($AcOH/H_2O_2$), *m*-chloroperbenzoic acid (MCPBA),[4] monoperoxyphthalic acid,[5] dioxiranes,[6] hydrogen peroxide[7] and more recently Caro's acid (H_2SO_5).[8] Dilute hydrogen peroxide is a poor oxidizing agent but an inexpensive and readily available oxidant and gives H_2O only as a by-product. Recently titanium-containing molecular sieves like TS-1, TiZSM-5 (prepared by post-synthetic modification) with MFI topologies and mesoporous materials like TiMCM-41 have been found to possess very good redox properties in catalyzing many oxidation reactions[9–12] *e.g.* olefin epoxidation, hydroxylation, oxidation of alkanes and conversion of carbonyl compounds to oximes. TiMCM-41, by virtue of its bigger pore diameter and redox property, overcomes the barrier of spatial limitation and has been used to oxidize bigger molecules like 2,6-di-*tert*-butylphenol and cinnamyl alcohol. The preparation of *N*-oxides of mono binuclear heterocycles suffers mainly from the disadvantage of very low yields of product formation in spite of using very costly and stoichiometric amounts of reagents.[13] Titanium-containing redox molecular sieves in the presence of an oxidant like H_2O_2 have the advantage of reusability, no catalyst separation problems, and no environmental disposal problems. In order to overcome problems associated with homogenous reactions, heterogeneous catalysts like molecular sieve materials were employed for the oxidation of heterocycles.

Titanium silicalite (TS-1), TiZSM-5(30) and TiMCM-41 are prepared[14,12,15] in our laboratory by the procedures reported earlier. All these catalysts were characterized using XRD and FTIR analyses and the results are in accordance with the reported literature. Oxidation of substituted pyridines and quinolines and, substituted isoquinolines have been carried out and the results are presented in Table 1. In our studies it is observed that pyridines having electron donating substituent groups such as $–CH_3$, –OH or vinyl are oxidized rapidly in a single step to yield the corresponding *N*-oxides as the exclusive oxidation product when the substrate is treated with 5% wt/wt catalyst and 2 equiv. of 30% H_2O_2. However, pyridines containing electron withdrawing substituent groups like –CN, $-NO_2$ or $–CONH_2$ take comparatively longer to reach the quantitative reaction yield of the product. It can be understood that a peroxo species like Ti(μ-O_2) oxidizes the nitrogen of the heterocycle which results in the corresponding heterocyclic *N*-oxide. TiMCM-41 was used as catalyst for the oxidation of quinolines, isoquinolines and *N*,*N*-dimethylaniline and the products were obtained in quantitative yields. The effect of varying the solvent was also studied for this reaction and the results are presented in Table 2. Methanol, acetone and acetonitrile were found to be better solvents than dichloromethane and chloroform with TS-1 as catalyst. The performance of the catalysts was also studied for 3-cyanopyridine and the results are presented in Table 3. TS-1 and TiZSM-5(30) gave better yields of the product, indicating the better redox system of the materials reported. The effect of varying the reaction temperature for the oxidation of 3-cyanopyridine was studied and the results are presented in Table 4. Methanol at a reaction temperature of 60 °C gave the optimum yield of the product.

All the starting materials and solvents were obtained commercially. A typical oxidation of a substituted pyridine was

TiMCM-41	53.0	25

Reaction temp. 60 °C; substrate: oxidant = ½, solvent methanol.

† Communication No. 4553.

DOI: 10.1039/b003926h

Table 4 Oxidation of 3-cyanopyridine: variation of reaction temperature

Reaction temp. °C	Isolated yield(%) of *N*-oxide	Reaction time (h)
Room temp.	22.7	23
40	38.8	24
50	52.9	24
60	97.0	25

Substrate: oxidant = $\frac{1}{2}$, solvent methanol; catalyst TS-1.

carried out as follows. A mixture of 4-cyanopyridine (10.0 g, 0.096 mol) and TS-1 (500 mg) in 40 ml of methanol as solvent was refluxed in the presence of 30% aq. H_2O_2 (19.8 ml, 0.192 mol) for 24 h. The progress of the reaction was monitored by TLC. Once the reaction was complete the catalyst was removed by filtration and the product isolated from the solvent by vacuum evaporation. The isolated product by this procedure, contained exclusively the corresponding *N*-oxide as observed from the ^{1}HNMR and mass spectra. 4-Cyanopyridine gave 9.6 g of corresponding *N*-oxide without any trace of the by-product. The products were also confirmed by mass and ^{1}H NMR techniques.

Asymmetric Diels–Alder chemistry based on a new chiral auxiliary for 1-hydroxy substituted dienes

Philip Garner,* James T. Anderson and Regis A. Turske

Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106-7078, USA.

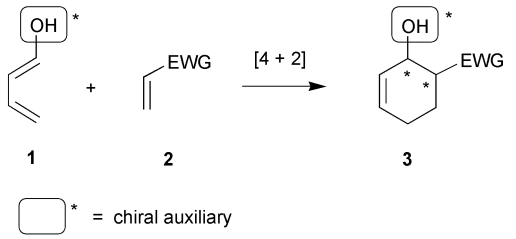
Received (in Corvallis, USA) 8th May 2000, Accepted 23rd June 2000
Published on the Web 2nd August 2000

A rationally designed chiral auxiliary for hydroxylated dienes results in stereocontrolled Diels–Alder cycloadditions under purely thermal conditions.

The Diels–Alder reaction is arguably one of the most powerful synthetic transformations in the modern organic chemist's arsenal. The stereospecific creation of 2 sigma bonds and up to 4 stereocenters in a single step allows for an unsurpassed increase in the level of molecular complexity.[1] Not surprisingly, the development of asymmetric variants of the Diels–Alder reaction to yield enantiomerically-enriched products has taken center stage. Both stoichiometric (chiral auxiliaries) and catalytic (chiral Lewis acids) approaches to asymmetric Diels–Alder reactions have been investigated. The bulk of these investigations have been concerned with chiral auxiliary modified dienophiles[2] and the development of chiral (dienophile-activating) catalysts.[3] Fewer studies have dealt with chiral auxiliary modified dienes.[4] We now disclose a new THP based chiral auxiliary system for 1-hydroxylated dienes[5] that should be of general utility for a variety of thermal Diels–Alder reactions.



The germ for this idea came from earlier work in our laboratories which found that chiral acetaloxyalkyl radicals such as **4** were trapped preferentially on the *si*-face as a result of steric congestion by the *tert*-butyl substituent at C-6 (Fig. 1).[6] Diastereofacial bias in this TS was rationalized in terms of a radical conformation which maintained an *exo*-anomeric effect[7] and minimized steric repulsion between the acyclic side-chain and THP ring. We surmised that the same stereoelectronic control elements might be extended to the reactive *s-cis* conformation of a 1-oxygenated diene partner in a Diels–Alder reaction as well (*cf.* TS **5**). Our original design also incorporated a potential π-stacking interaction between the reactive *s-cis* diene and a properly disposed naphthalene moiety in the Diels–Alder TS. The prototype 'α-diene' **6** was synthesized along with the chromatographically separable 'β-diene' **7** from 2-naphthylisobutyraldehyde by first making the auxiliary-lactol according to ref. 6 and then incorporating it into McDougal's synthetic approach to 1-alkoxybuta-1,3-dienes.[8] α-Diene **6** was actually used as an inseparable 85:15 mixture of *E*- and *Z*-isomers, the latter being unreactive under our cycloaddition conditions.

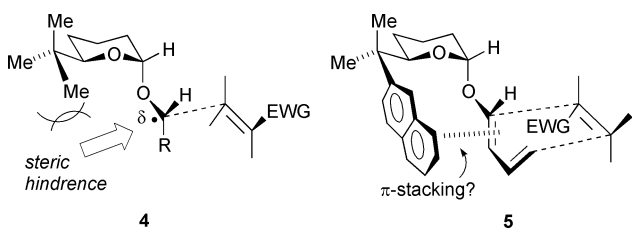


Fig. 1

Chiral dienes **6** and **7** (Fig. 2) were subjected to a battery of Diels–Alder reactions with a variety of electron-deficient dienophiles (Table 1). A number of conclusions can be drawn from these collected data. First, thermal Diels–Alder reactions proceed cleanly with these chiral dienes to give good yields of cycloadducts. As expected for the 1-alkoxy-substituted diene system, higher reaction temperatures are required with the less reactive dienophiles. The observed diastereoselectivities for reactions of the α-diene with *N*-phenyl maleimide (**6** + **8** → **9**), dimethyl maleate (**6** + **11** → **12**), and methacryaldehyde (**6** + **13** → **14**) were found to be quite high (entries 1, 3, and 4) in spite of this potential limitation. Interestingly, reaction of the β-diene with *N*-phenyl maleimide (**7** + **8** → **10**) proceeded about 5 times faster than its α counterpart but with slightly lower (and opposite!)[9] facial selectivity (entry 2). Thus, complementary stereodirection is possible starting from a single antipodal form of the auxiliary. Increasing the Diels–Alder reactivity by reducing the FMO gap between the diene HOMO and dienophile LUMO had the predicted effect of enhancing the diastereoselectivity: diene **6** reacted with the reactive quinoid dienophiles **15**[10] and **17**[11] to give the respective adducts **16** and **18** almost exclusively (entries 5 and 6).[10] On the other hand, the combination of a less sterically encumbered acetylenic dienophile **19** and higher reaction temperatures resulted in a somewhat lower facial selectivity (entry 7).[12]

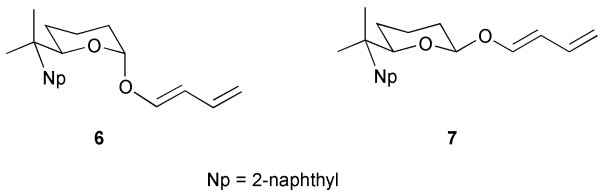

Fig. 2

Chiral dienes such as **6** offer the advantages of high and predictable facial selectivity without the need for Lewis acid activation along with the option of recovering the auxiliary while leaving the synthetically versatile cyclohexen-3-ol substructure intact. The ability to control the diastereoselectivity to the extent shown in purely thermal Diels–Alder reactions (some conducted at temperatures above 100 °C!) is quite remarkable. Although the goal of these initial studies was hypothesis validation, further optimization of the auxiliary design as well as an improved diene synthesis (*via* cross-coupling methodology as described in reference 5*g*) can certainly be envisioned. The incorporation of these chiral auxiliaries into more reactive dienes (for example, a Danishefsky-like system) is also possible. These preliminary results auger well for the further development of this asymmetric Diels–Alder variant as well as

Table 1 Auxiliary-controlled Diels–Alder reactions

Entry	Diene	Dienophile (equiv.)	Reaction conditions	Major product	Yield (%)	Ds
1	**6**	 **8** (1.5)	PhH, 80 °C (sealed tube) 12 h	 **9**	76	9/1

The application of stereoselective antibodies in an enzyme immunoassay enables the quantitative determination of enantiomeric impurities beyond the outer limits of currently available methods; thus, using an antibody raised against a derivative of D-phenylalanine, the D-enantiomer of the free amino acid can be detected in a 100 000 fold excess of the L-enantiomer (ee 99.998%).

The determination of low ees is exceedingly important in wide-ranging chemical studies, such as, asymmetric synthesis,[1] dating of material of biological origin,[2] and the analysis of material of extraterrestrial origin.[3] In experiments where the ee may be very low, *e.g.*, those based upon non-conservation of parity,[4] ultra-sensitive assays are essential. The increasing understanding of the stereoselectivity of drug actions is causing regulatory agencies to define guidelines for the development of stereoisomeric drugs and to demand the specification of their stereochemical purity.[5] In some cases, even minor enantiomeric impurities may cause severe pharmacological and toxicological side effects.[6] Commonly used methods for the determination of enantiopurity include polarimetry, NMR spectroscopy and chromatography, which may allow detection of 0.1% enantiomeric impurity (99.8% ee).[7] More sensitive analytical tools are desirable, and may be vital for health safety, with regard to the production and investigation of therapeutic or nutritional chiral compounds. Improved techniques require the development of highly selective chiral hosts that specifically bind to one enantiomer present in a large excess of the opposite enantiomer. Stereoselective interaction between enantiomers and biological macromolecules such as antibodies, enzymes and receptor proteins is well known and has found various applications in stereochemistry.[8] Recently, we have shown that enantiomeric impurities can be determined by a chiral immunosensor utilizing the exquisite stereoselectivity of antibodies.[9] Here, we demonstrate the determination of enantiomeric impurities at an unprecedented level of detectability using an enzyme immunoassay.

Stereoselective antibodies sensitive to the chiral center of α-amino acids[10] were used to detect D-phenylalanine in non-racemic mixtures by a competitive enzyme-linked immunosorbent assay (ELISA, Fig. 1).[11] Rabbit antibodies, raised against a conjugate, prepared by diazotization of *p*-amino-D-phenylalanine and coupling to the protein keyhole limpet hemocyanin (KLH), stereoselectively bind to D-phenylalanine, but not to L-phenylalanine (Fig. 2). Typical sigmoidal inhibition curves were obtained with D-phenylalanine diluted in phosphate buffered saline (PBS) in the concentration range between 0.01 μM and 500 μM, while no inhibition was observed using L-phenylalanine even at much higher concentrations (up to 50 mM). Antibody binding to D-phenylalanine in the presence of a large excess of L-phenylalanine was shown using the D-enantiomer diluted in a solution of 10 mM L-enantiomer in PBS (Fig. 2). The inhibition curves obtained with D-phenylalanine in the presence and absence of L-phenylalanine are virtually identical, indicating that the stereoselective interaction between the antibody and D-phenylalanine is not affected by the presence of the L-enantiomer. As seen in Fig. 2, D-phenylalanine concentrations as low as 0.1 μM can be detected in the presence of 10 mM L-phenylalanine. This is equivalent to one part of D-phenylalanine in 100 000 parts of L-phenylalanine, corresponding to an ee of 99.998%. The limit of detection is dependent primarily on the affinity of the antibody and the sensitivity of the assay.

The suitability of this antibody for the quantitative determination of enantiomeric impurities was demonstrated in com-

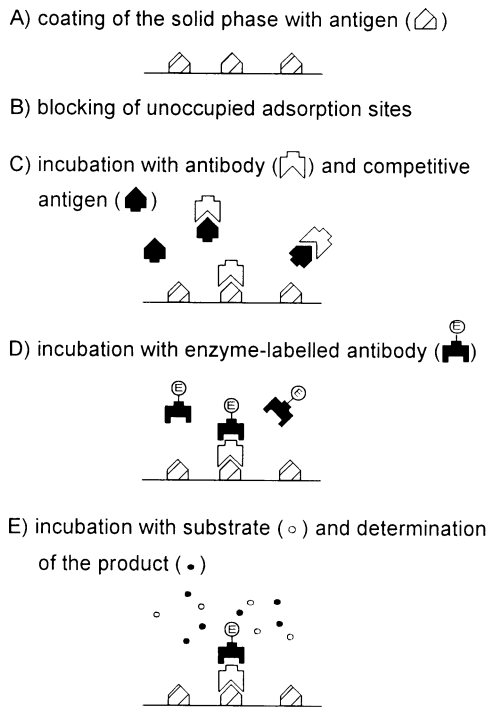

Fig. 1 Schematic depiction of the competitive ELISA procedure.[11] The antigen, in this case *p*-amino-D-phenylalanine, is bound to the wells of a polystyrene microtiter plate (A). After blocking of unoccupied adsorption sites on the plastic surface (B), antibody specific to D-amino acids is added to the wells along with the test sample (competitive antigen) (C). Enzyme-labelled antibody specific for the first antibody is added (D), and a chromogenic enzyme substrate is dispensed (E). The colored product which indicates the amount of the first antibody bound to the solid-phase immobilized antigen is determined photometrically. Between steps A–E, excess reagents are removed by washing.

† This paper is dedicated to Prof. Guenter Wulff on the occasion of his 65th birthday.

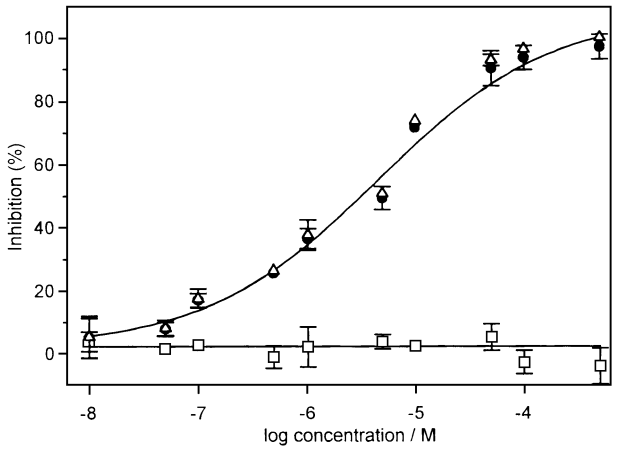

Fig. 2 Inhibition of antibody binding to solid-phase immobilized *p*-amino-D-phenylalanine by increasing concentrations of D-phenylalanine (■); by D-phenylalanine in the presence of 10 mM L-phenylalanine (△); by L-phenylalanine (□). Absorbance values were converted to % inhibition by: % inhibition = $(1 - (A/A_0)) \times 100$; A represents values in the presence of competitor, while A_0 is the absorbance without competitor. Here and in Fig. 3 error bars indicate standard deviations of triple determinations (missing error bars are obscured by the symbols).

petitive assays employing non-racemic mixtures of phenylalanine. Enantiomeric impurities of 0.1% and 0.01% were simulated by the addition of D-phenylalanine (2 μl of a 100 mM stock solution in PBS) to L-phenylalanine (1998 μl and 19 998 μl, respectively, of a 100 mM stock solution in PBS). Fig. 3 shows the inhibition curves obtained with these mixtures. The concentrations of total phenylalanine necessary to cause 50% inhibition of binding (I_{50}) were determined to be 3.12 ± 0.25 mM and 29.12 ± 2.26 mM, respectively. These results are in good accord with the I_{50} value of 3.1 ± 0.3 μM obtained from the calibration curve using enantiomerically pure D-phenylalanine in PBS (Fig. 2), and indicate that, within the accuracy of the method, the test mixtures indeed contain one part D-enantiomer in 1000 parts and 10 000 parts, respectively, of the L-enantiomer.

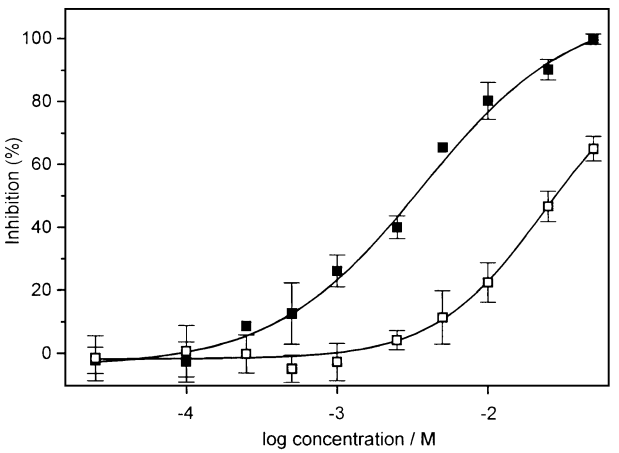

Fig. 3 Inhibition of antibody binding to solid-phase immobilized *p*-amino-D-phenylalanine by increasing concentrations of test mixtures containing 1 part of D-phenylalanine in 1000 parts of L-phenylalanine (■), and 1 part of D-phenylalanine in 10 000 parts of L-phenylalanine (□).

We have demonstrated the value of stereoselective antibodies for the detection of trace enantiomeric impurities and the determination of ee for the α-amino acid phenylalanine. Stereoselective antibodies have been raised for a variety of purposes, including the measurement of degree of racemization.[12] Enzymes have been used to determine enantiopurity[13] but their use is confined to natural substrates and suitable analogs, and is restricted by the number of appropriate enzymes. In contrast, antibodies can be raised against virtually any compound of interest[14] and can be selected and engineered according to one's needs.[15] Their use is routine and they are suitable for automated assays. Thus, the use of antibodies for the determination of enantiomeric impurities at extremely low levels may be extended to other compounds. This approach should be particularly valuable in chemical or pharmaceutical studies where the highest enantiopurity is essential.

The fullerene cross-dimer C_{130}: synthesis and properties

Koichi Komatsu,* Koichi Fujiwara and Yasujiro Murata

The fullerene C_{60}–C_{70} cross-dimer C_{130} was synthesized by the mechanochemical solid-state reaction using a high-speed vibration milling technique, and was characterized by UV-vis and ^{13}C NMR spectroscopy as well as electrochemical methods.

The multiple [2 + 2] cycloadditions of C_{60} molecules afford the all-carbon C_{60} polymers by photo-irradiation[1] or high-pressure/high-temperature treatment of C_{60}.[2] However, it is rather difficult to control these reactions to give selectively the dimers and/or trimers. In contrast, it was demonstrated in our previous work that the fullerene dimer C_{120}[3] and trimer C_{180}[4] were successfully produced by the mechanochemical solid-state reaction using a high-speed vibration milling (HSVM) technique. So far there has been no report concerning the oligomerization of C_{70}.† In this paper we report the formation of a C_{60}–C_{70} cross-dimer, C_{130}, by the use of the solid-state HSVM reaction in the presence of 4-aminopyridine which proved to be an effective catalyst for the synthesis of C_{120}[3] and C_{180}.[4]

The reaction was conducted by placing C_{60} (23 mg, 0.032 mmol) and C_{70} (27 mg, 0.032 mmol) in a mixing capsule made of stainless steel, together with 4-aminopyridine (6.5 mg, 0.069 mmol) and a mixing ball, and treating them by HSVM for 30 min. The mixture was examined by HPLC on a Buckyprep column eluted with toluene. Although most of the mixture was found to be the starting materials, the formation of a small amount of what was possibly C_{130} was observed with a retention time of 24 min (HPLC peak area, 1.5%) in addition to C_{120} at 14.5 min (6%), unchanged C_{60} at 7.5 min (46%), and C_{70} at 12 min (44%).

The portion with an HPLC peak at the retention time of 24 min on a Buckyprep column was isolated by the use of a 5PBB column eluted with *o*-dichlorobenzene (ODCB). The analytical HPLC on a Buckyprep column showed that this is composed of a single isomer, and this was confirmed by the ^{13}C NMR spectrum (*vide infra*). The isolated fraction was found to undergo slow dissociation into C_{60} and C_{70} under room light with a half life of about 2 days, suggesting that this peak actually corresponds to C_{130}, which is the [2 + 2] cycloaddition product of C_{60} and C_{70}. The isolated yield of C_{130} was 3.0% (1.5 mg).

After treating this fraction with NaCN in ODCB–*N*,*N*-dimethylformamide, atmospheric pressure chemical ionization mass spectroscopy operated in the negative ion mode exhibited peaks at *m*/*z* 1586 and 1613 corresponding to the mono- and biscyanated C_{130}, *i.e.* $C_{130}(CN)^-$ and $C_{130}H(CN)_2^-$, respectively, thus proving the presence of C_{130} in this fraction.

The UV-vis spectrum‡ of C_{130} has the characteristic absorptions for C_{120} and also for the 1,2-dihydro[70]fullerene[5] as shown in Fig. 1. The ^{13}C NMR spectrum† of C_{130} (Fig. 2) clearly exhibits four signals for sp^3 carbons at 78.03, 75.75 (C_{60} carbons), 69.96, and 68.90 ppm (C_{70} carbons) and partially overlapped > 52 signals for the sp^2 carbons at 156.42–131.93 ppm, which corresponds to a structure with C_{60} and C_{70} connected by a shared cyclobutane ring with C_s symmetry. From these results, the most plausible structure of C_{130} is the one with a C_{60} cage attached at a 6–6 bond to a C_{70} cage at a 1,2-junction bond in a [2 + 2] fashion (Fig. 3). In fact, this isomer has been predicted to be more stable than the 3,4-isomer, in which the C_{70} cage is connected at the 3,4-junction bond.[6]

The redox behavior of C_{130} was examined by cyclic voltammetry and differential pulse voltammetry to give the voltammograms shown in Fig. 4. The curve with a dotted line is the voltammogram of a 1:1 mixture of C_{60} and C_{70}. It is clearly seen that the first reduction occurs at the same potential as the reduction potential of both C_{60} and C_{70}. The following three reduction waves are also identical to those of C_{60} and C_{70}. Therefore, it is quite likely that, as in the case of the C_{60} dimer,[3]

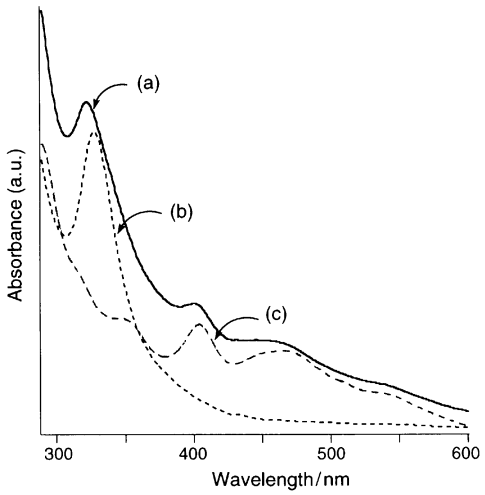

Fig. 1 UV-vis spectra of (a) C_{130} and (b) C_{120} in ODCB and (c) 1,2-H_2C_{70} in toluene–hexane (3:2).

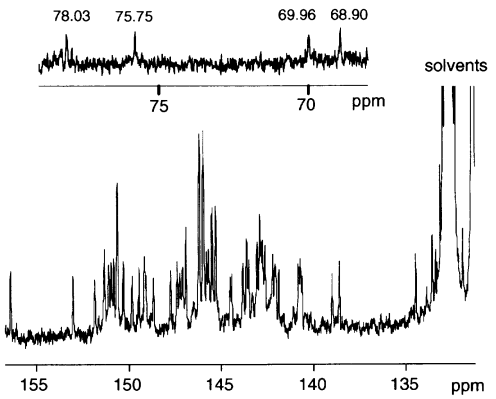

Fig. 2 ^{13}C NMR spectrum of C_{130} (100 MHz, ODCB–C_6D_6 (5:1)).

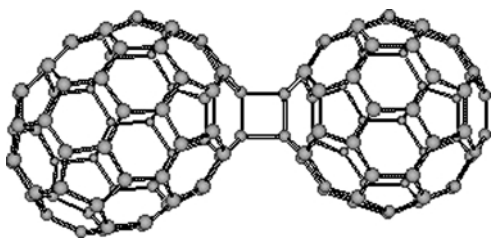

Fig. 3 PM3 calculated structure of C_{130}.

DOI: 10.1039/b003719m

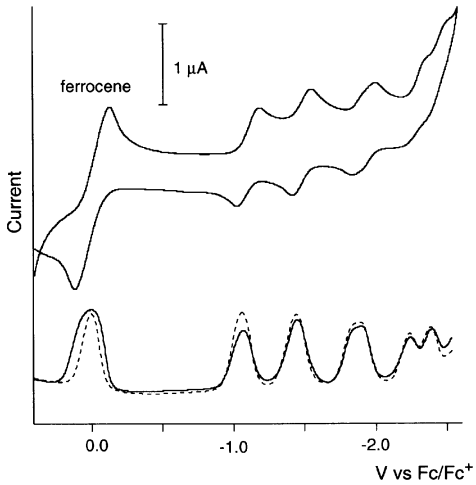

Fig. 4 Cyclic voltammogram (upper) and differential pulse voltammogram (lower) for C_{130} (a solid line) and a 1:1 mixture of C_{60} and C_{70} (a dotted line) measured in ODCB with 0.1 M $Bu_4N^+BF_4^-$: scan rate, 0.02 V s^{-1}.

the central intercage bonds are weak and are readily cleaved off to give radical anions of C_{60} and C_{70} upon obtaining extra negative charge.

Finally an attempt was made to dimerize C_{70} under the solid-state reaction conditions used to dimerize C_{60}, but absolutely no indication for such dimerization was observed. It is known that the most reactive 6–6 junction bond in a C_{70} molecule is the one at the '1,2' position.[7] The possibility of this bond in each C_{70} molecule encountering another is geometrically much lower than in the case of C_{60}, and this would be the reason for the poor reactivity of C_{70} towards dimerization.

The use of hydrazones for efficient mannich type coupling with aldehydes and secondary amines

Valérie Atlan, Hugues Bienaymé, Laurent El Kaim* and Adinath Majee

The Mannich reaction of hydrazones originally limited to the coupling of hydrazones with formaldehyde has been extended to a large variety of aldehydes through appropriate selection of experimental conditions; in conjunction with the Japp–Klingmann reaction, this process provides an efficient synthetic tool for the formation of carbon–carbon bonds.

The Mannich reaction is one of the most widely used reactions for the formation of carbon–carbon bonds. In its initial form, it implied the addition of aldehydes to ketones in the presence of amines.[1] The scope of the Mannich reaction was then extended to the addition of different carbon nucleophiles such as nitro compounds.[2] The ease of deprotonation of monosubstituted hydrazones **1** under basic conditions is dependent upon the attached substituents. The resulting salt can be viewed as an aza-substituted carbanion and as such may interact in a Mannich reaction leading to carbon–carbon bond formation (Scheme 1). Indeed in 1957, Keil and Ried[3] reported such behavior but their study revealed only modest synthetic potential as moderate to good yields were only obtained with formaldehyde; furthermore the hydrazones needed an electron withdrawing group (R^1) tethered to the carbonyl function. The potential of this reaction has led us to perform a more extensive study and we were delighted to find that different experimental conditions and the appropriate selection of the amine permit the condensation of hydrazones **1** with many different aldehydes **2** (Table 1, Scheme 1) giving the new aminohydrazones **4** in good yields. Most noteworthy are the good yields obtained with several aliphatic aldehydes possessing α-hydrogens. For the latter, competing aldol type reactions usually preclude their efficient use in Mannich reactions.[4] The first indication of success probably came from the choice of *N*-benzylpiperazine as the amine partner in this reaction. A net increase in yield is observed in going from aliphatic amine to morpholine and finally to *N*-benzylpiperazine. The reaction is best performed in a concentrated toluene solution (2 M) at 80 °C with nearly equimolar amounts of aldehyde (1.1 eq.) and amine (1.1 eq.).

The main drawback of this reaction is, as observed by Reid and Keil,[3] the need for an electron withdrawing group tethered to the hydrazone functionality. This limitation on the starting hydrazones is however deeply counter-balanced by their easy access *via* the Japp–Klingmann reaction between β-ketoacids and diazonium salts (Scheme 2).

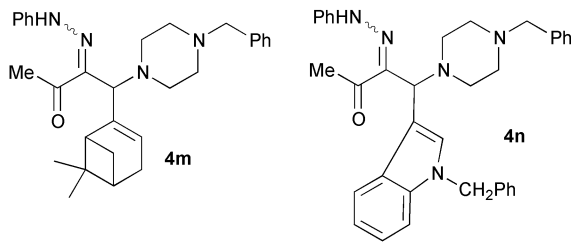
4h	OMe	O	Ph
4i	OMe	O	$(CH_2)_2Ph$
4j	OMe	NCH_2Ph	4-(OMe)Ph



Since the use of *N*-benzylpiperazine leads to good yields of product, a clean way to displace this group becomes crucial for the synthetic potential of this reaction. The chemistry of azoalkenes brings us a possible answer to this problem: treatment of hydrazone **4g** in various alcohols with two equivalents of 1,2-dibromoethane under reflux generates the new ether **5** probably *via* an azoalkene trapping by the alcohol (Scheme 3); hydrazone **4b** behaves similarly. This substitution process needs an alcohol with a rather high boiling point (at

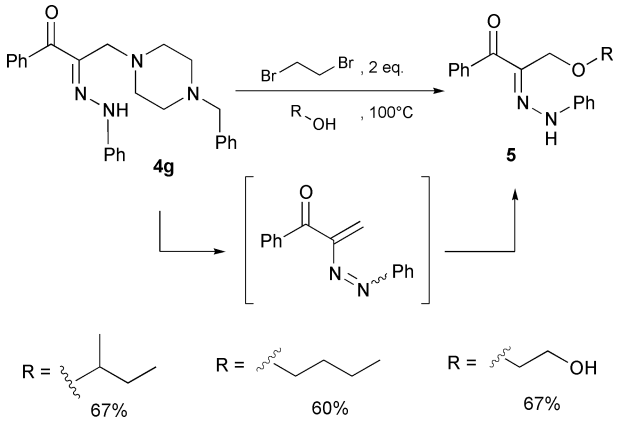
least 100 °C) as no reaction is observed in MeOH or EtOH. The use of 1,2-dibromoethane seems to be important for elimination of the piperazine unit; MeI reacts cleanly with hydrazone **4b** in ethanol giving a salt that does not react in refluxing EtOH or



Scheme 3

reacts sluggishly in higher boiling alcohols (the regiochemistry of the alkylation step could be invoked to explain these results).

This 1,2-dibromoethane assisted elimination procedure further emphasises the potential of the preceding Mannich reaction as many fruitful applications of transient azoalkenes (cycloadditions to give various heterocycles, Michael additions, *etc*.) have been reported in the literature[5] and could be applied to the Mannich addition products. These features and the selectivity of the 1,2-dibromoethane alkylation are currently being studied in our research group and will be reported soon.

We thank Rhône-Poulenc Industrialisation for financial support.

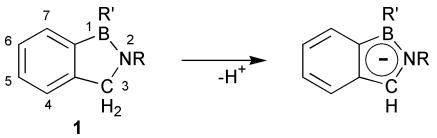
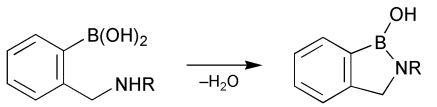
It has been found that 1*H*-2,1-benzazaboroles can be prepared by the interaction of substituted benzylaminochloroboranes with Al_2Cl_6 in CH_2Cl_2 at 0 °C, the ^{13}C NMR spectroscopy data obtained being in favour of an electrophilic substitution mechanism involving formation of cationic complexes as reactive intermediates.

The π-delocalized anions accessible through deprotonation of 1*H*-2,1-benzazaboroles (**1**) are isoelectronic with indenyl anions (Scheme 1), making them attractive precursors for single site olefin polymerization catalysts based on heterocyclic analogues of metallocenes[1] (*cf.* ref. 2).

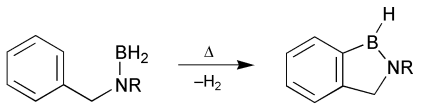


Scheme 1

The two well known approaches towards benzazaborole derivatives involve intramolecular condensation of *o*-(aminomethyl)benzene boronic acids[3] (Scheme 2) and intramolecular cyclization of benzylaminoboranes[4] (Scheme 3). The first method is applicable for preparation of derivatives with B–OH or B–O–B fragments only, while the second route requires high process temperatures and is not applicable to compounds in which there is no B–H bond.

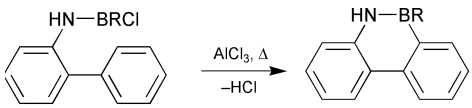


Scheme 2

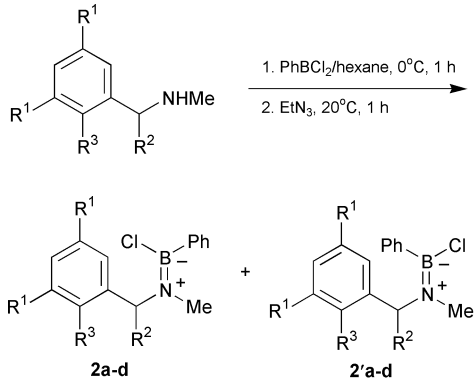


Scheme 3

As part of our program to develop synthetically attractive approaches towards precursors for heterocyclic analogues of cyclopentadienyl ligands, we studied the utility of Lewis acid catalysed borylation reactions for the preparation of benzoborazoles **1**. To the best of our knowledge there have been no data on their preparation by this reaction, the closest related data being those of M. J. S. Dewar on the $AlCl_3$ catalysed preparation of (10*R*)-9-aza-10-boraphenanthrene and related heteroaromatics at high temperature and without solvent[5] (Scheme 4).



Scheme 4

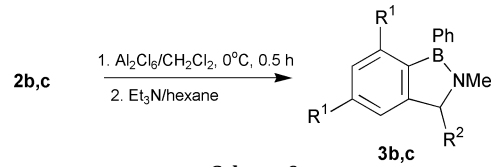


Scheme 5

The starting materials, halogen substituted aminoboranes **2a**–**d**,† have been prepared by the procedures analogous to those described in refs. 6 and 7 (Scheme 5). There are two sets of signals in the ^1H and ^{13}C NMR spectra of each of these compounds indicating the presence of mixtures of *cis*- and *trans*-isomers, obviously due to partially double bond character of the B–N bond‡ (*cf.* ref. 6).

Aminoboranes **2a** and **2b**, when treated with $AlCl_3$ under Dewar's conditions[5] (without solvent, 150 °C) yielded polymeric products only.

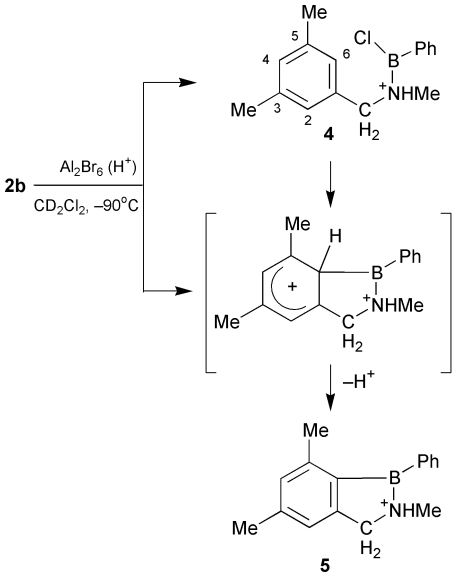
It has been found that the interaction of compounds **2b** and **2c** with equimolar amounts of Al_2Cl_6 in CH_2Cl_2 at 0 °C results in formation of the target products, **3b** and **3c**, respectively, the yields being 75% (Scheme 6).§ In contrast, the compounds **2a** and **2d** do not react at 0 °C, while at rt they give multicomponent mixtures of unidentified products.



Scheme 6

The mechanism of the cyclization reaction has been studied by NMR using **2b** as starting material, CD_2Cl_2 solvent and Al_2Br_6 as a Lewis acid which is more soluble in this solvent than Al_2Cl_6.¶ These experiments indicate that upon the interaction of **2b** with Al_2Br_6 at −90 °C a mixture of **4** and **5** is formed, their ratio being approximately 1:1 (Scheme 7).‖ When the temperature rises to 0 °C, the structure **4** transforms entirely into **5**.

The results reported here suggest that intramolecular electrophilic borylation is a viable approach toward 1*H*-2,1-benzaza-



Scheme 7

boroles, starting from readily available and inexpensive chemicals.

Notes and references

† Satisfactory spectral data have been obtained for all the new compounds. The signals of the carbon atoms bearing B-centred fragments were not observed in the ^{13}C NMR spectra.

Published on the Web 3rd August 2000

An easily prepared porphyrin with pendant arms is shown to form a stable complex with bismuth(III) ion; the complex is eight coordinate with a square antiprismatic coordination geometry; the solid-state structure exhibits the formation of a dimer assembled *via* mutual coordination of a terminal ester group.

The chemistry of bismuth has been somewhat neglected until recently when bismuth complexes have become of interest in the treatment of gastric ulcers[1] and cancer therapy.[2] In this context, the coordination of bismuth with several types of ligands has been developed in the last ten years. The synthesis of bismuth(III) complexes with nitrogen-donor macrocycles[3,4] has been investigated and it appears that the bismuth(III) ion has a high affinity for these ligands. The promising interest of ^{212}Bi as an α-emitter for radioimmunotherapy has induced studies concerning the complexation[5,6] of this ion with polyaminoacid ligands derived from diethylenetriaminepentaacetic acid, in these types of complexes, the metal exhibits a coordination with carboxylate groups and nitrogen atoms. This background about the coordination of the Bi(III) ion has led us to consider with a new point of view our studies with porphyrins acting as ligands. The literature concerning the metallation of porphyrin with bismuth salts is not very widespread.[7,8] In a recent publication,[9] we have described the structure of (OEP)Bi(SO_3CF_3) as a dimer with a seven coordination geometry in which the bismuth lies 1.07 Å from the plane formed by the four nitrogen of the porphyrin. To quote Brechbiel,[10] 'An important ligand property that increases metal complex stability is preorganization, the tendency of the free ligand to assume the conformation necessary for metal ion complexation'.[11] On the basis of this particular structural feature, we have designed porphyrins with pendant arms as potentially oxygen-atom donors. It is worth noting that in our case, and in contrast with tetraazamacrocycles such as DOTA, the four pickets are not coplanar with the four-nitrogen macrocycle but pre-oriented in a perpendicular direction, as a result of their grafting to *ortho* positions of the meso phenyl ring. Ligand $4ESH_2$ **1**† (the free-base analogue of **2**) was synthesized by reaction of *meso*(tetra-*o*-aminophenyl)porphyrin (atropisomer αααα, TAPP)[12] with ethylsuccinyl chloride (Scheme 1) and isolated in high yield (93%). The Bi(III) complex was prepared under mild conditions with metallation occurring in pyridine at 50 °C during 2 h. The yield of the reaction was almost quantitative (85%) and no demetallation was observed during the purification of the product. Indeed, in contrast to unfunctionalized porphyrins such as (OEP)Bi(SO_3CF_3), chromatography of coumpound **2** does not afford any free base analogue. Crystals‡ suitable for X-ray study were obtained by a slow diffusion of H_2O–MeOH onto a saturated THF solution of **2**. The ORTEP[13] plot of the X-ray structure is shown in Fig. 1. As depicted in Fig. 2, the Bi(III) is eight coordinate with an approximate square antiprismatic geometry. The four nitrogen atoms of the macrocycle form a square, the other distorted square being formed by four oxygen atoms described as follows: two oxygen atoms of the nitrate anion, the oxygen atom of a water molecule and a carbonyl oxygen atom of the terminal ester group belonging to an arm attached to a

DOI: 10.1039/b004394j

symmetrically related macrocycle, thus forming a centrosymmetric dimer in the solid state (Fig. 1). The Bi atom lies 1.125 Å above the N_4 plane and the mean Bi–N bond length is 2.34(2) Å, similar to those observed in (OEP)Bi(SO_3CF_3)[9] which also adopts a centrosymmetric dimeric form [ΔN_4 = 1.07 Å and < Bi–N > = 2.31(1) Å]. The Bi–O bond lengths [2.706(5) and 2.789(4) Å] are larger than the sum of their ionic radii (1.13 + 1.40 = 2.53 Å)[14] for the bonds with the nitrate anion O13 and O15, respectively), 2.816(5) Å with the oxygen of the water molecule (Ow1) and 3.018(5) Å with the oxygen atom of the carbonyl group (O8#). This later value is large but, to the best of our knowledge, this type of bond between a Bi atom and an ethoxycarbonyl group is unprecedented, however such a large distance is observed in the (OEP)Bi(SO_3CF_3) dimer[9] where a Bi–O distance of 2.98(2) Å was found between the Bi atom and a triflate oxygen atom. A second water molecule (Ow2) is present in the cage and as shown in Fig. 1, both water molecules are engaged in an intra- and inter-molecular hydrogen bond net, contributing to the stability of the dimer. One arm of the molecule does not participate in any interaction and thus exhibits a regular conformation. As reported above, one arm participates to the coordination sphere of the Bi atom, belonging to the second molecule of the dimer, and the two remaining arms involved in the hydrogen bond net with Ow1 and Ow2, adopt folded conformations.

As it is of interest to know if this particular structure is also plausible in solution, the complex **2** has been studied by NMR spectroscopy. A previous variable temperature ^{1}H NMR study[8] has been made on the compound [Bi(TTP)]NO_3 investigating the aromatic protons of the tolyl groups. The slow rotation of aryl groups of this complex induced broadened signals at room temperature, whereas at low temperature the signal of the tolyl protons were split. In our complex, at 300 K, the methylene protons of the ester groups appear at δ 3.37 as a broad singlet whereas at 290 K, these protons become magnetically non-equivalent, as two singlets at δ 3.31 and 3.39, the same observation being made for the methyl group. It is of note that a 1 : 3 intensity ratio is observed instead of the 1 : 2 : 1 expected. When the temperature decreases, we can clearly see that the pendant arm of the porphyrin is not in the same magnetic environment as the three others, as shown by the integration of the signal. The same temperature dependence is observed for the aromatic protons of the phenyl rings, with the exception of the apparent triplet at δ 7.90 ppm.[15] These observations suggest an unsymmetrical geometry around the Bi(III) ion involving one arm of the porphyrin, which is plausible with the radiocrystallographic structure of 4ESBi(NO_3) **2**. However, the geometry of the molecule is not exactly the same in solution as in the solid state. It seems that the dimer is broken in solution. Indeed, the protons of the pendant arm if bonded to the bismuth *via* the carbonyl, would be strongly upfield shifted because of their localization in the anisotropic current of the porphyrin. As all the aliphatic protons are normally shifted between 0.5 and 3.5 ppm, the ^{1}H NMR spectrum is in accord with a monomer complex in which one of the 'picket' groups is able to interact with the metal.

In conclusion, this new bismuth(III) porphyrin demonstrates that the metal can be stabilized by the presence of a suitable coordination sphere, and particularly by oxygen-donor groups. Indeed, in the reported complex, even if the ethoxycarbonyl groups are not ideal in stabilizing the complex, their spatial arrangement seem to be sufficient to increase the rate of metallation and the stability of the complex. Work is now in progress to characterize corresponding analogues with carboxylate picket groups and to study their coordination around Bi(III).

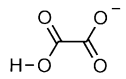
A recent study which addressed the nature of the association between hydrogenoxalate anions in the solid state came to the conclusion that short OH···O contacts between these species did not constitute an attractive interaction, but one which simply minimized inter-anion repulsion; in the light of new crystallographic evidence and a solution study, some issues raised in this work need to be re-evaluated.

It was recently put forward that an interaction which had the physical appearance of a short, charge-assisted hydrogen bond was, in fact, not a hydrogen bond. The case of the hydrogenoxalate anion **1** was examined in detail by Braga *et al.*[1] using



1

computational methods, where the conclusion was reached that charge delocalization over the whole species meant that no attractive force of interaction could be present between these anions, despite the fact that they organize into chains in the solid state connected through close, interanionic OH···O contacts. This then led to the reassignment of these contacts as the 'least repulsive' orientation of the two species, rather than a bond. This, finally, was cited as a breakdown of the widely accepted length–strength inverse analogy of hydrogen bonding, since, despite its shortness, the H-bond was not strong, indeed not even a bond but a repulsive interaction held in place by a stronger cation–anion network.

One problem with the above assertions is contextual. To be sure, in a vacuum and in the absence of counterions, the isolated OH···O interaction is not sufficient to keep the interanionic complex associated.[2] Under such circumstances, as was claimed, the relationship could not be characterized as 'bonding', since energy would be required to maintain it, rather than dissociate it. This view, however, does not take into account that the association of any two species consists of a combination of interaction energies, the totality of which must result in a net force of attraction. In salts of **1**, four primary interactions are present: (+)–(−), (+)–(+), (−)–(−) and OH···O. These interactions can be modeled and evaluated individually, but the report in question isolated two of the interactions and compared them to each other, *i.e.* (−)–(−) to OH···O, found the former dominant, and came to the conclusion the latter was therefore not enthalpically favorable.[1]

Perhaps the most significant feature of this work was however the remarkable and counterintuitive finding that the absence of positive regions in the molecular electrostatic potential map calculated for **1** indicated that, 'irrespective of the relative orientation, two $HC_2O_4^-$ anions repel each other electrostatically.'[1] This suggested that, under *no* circumstances could the OH···O interaction in question ever be considered 'bonding'.

We first confronted this issue by doing a study of the behavior of soluble salts of **1** in chloroform solution by ^{1}H NMR spectroscopy. We chose as counter ion the large, non-coordinating tetrapropylammonium cation. Systematic variation of the concentration [Pr_4N^+**1**$^-$] produced a classic H-bonding isotherm for the acidic proton in the NMR (Fig. 1), to which a curve could be fit modeled either on linear oligomers or on a combination of cyclic H-bonded dimers plus linear oligomers to give association constants K_a = 294 or 226, respectively.[3] Parallel control studies of acetic acid and the tetrapropylammonium acetate–acetic acid (1 : 1) complex under the same experimental conditions gave association constants for these species of 89 and 861, respectively, the latter value reflecting the charge-assisted nature of the bond.[4] No noteworthy change in chemical shift for the protons of the counterion was observed in any case. If acetic acid and its acetate complex can be taken as reasonable models for the hydrogen bonding between hydrogenoxalates, the **1**···**1** association can not be accounted for by cyclic dimers alone, but requires a substantial contribution from charge-assisted linear interactions. Clearly, however, the repulsion term (−)–(−) leads to less effective hydrogen bonding in **1**···**1** than for AcO^-···HOAc, although its influence is greatly diminished relative to vacuum by the dynamic charge-screening effects of the solvent and counterions.

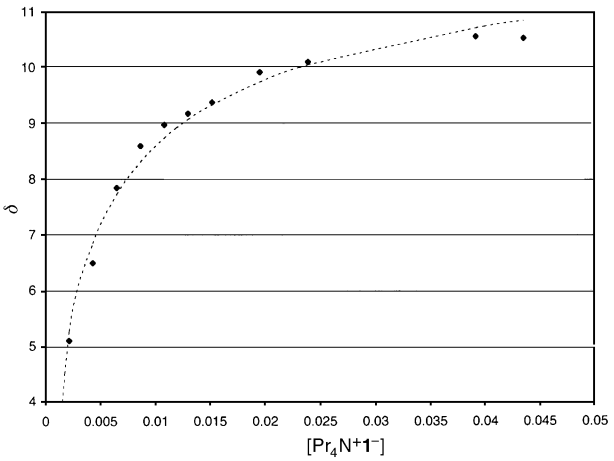


Fig. 1 Plot of the variation in chemical shift of the acidic proton in [Pr_4N^+**1**$^-$] with increasing concentration; (●) experimental, (----) best fit curve.

Our second approach to examining the nature of the OH···O interactions in **1** was crystallographic. If it is indeed the case that this interaction is actually repulsive, despite the very short O···O contact distance of 2.52 Å in potassium hydrogenoxalate (the example used in ref. 1), then distancing the cationic centers from hydrogenoxalate chain would be likely to disrupt this 'explosive' motif. In any case, the tremendous electrostatic compression which would be experienced by two *repulsive* functions (O^- and OH) being forced into such close proximity should be relaxed as less effective cations lose influence over the anions. We chose to test this concept by preparing the tetramethyl- and tetraethyl-ammonium hydrogenoxalate salts and determining their X-ray crystal structures.† Although the tetrapropylammonium salt is also a solid, X-ray quality crystals could not be not obtained, and the higher alkylammonium hydrogenoxalates are oils. As shown in Fig. 2, the hydrogen bonded chain is preserved in the Me_4N^+ and Et_4N^+ salts, thus no

DOI: 10.1039/b002361m

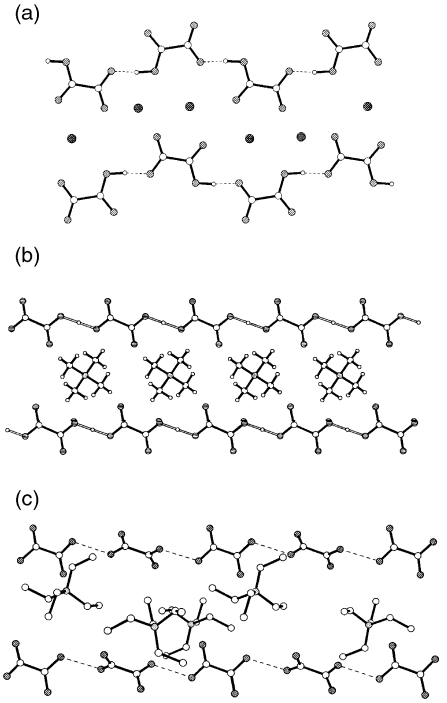

Fig. 2 (*a*) X-Ray crystal structure of [K$^+$**1**$^-$] (ref. 5). (*b*) X-Ray crystal structure of [Me$_4$N$^+$**1**$^-$]. The hydrogen bond appears to be symmetric with the hydrogen atom located equidistant between two oxygen atoms. Note, however, that it is not always possible to distinguish between an ordered H atom on a symmetry element from two disordered H atoms close to that symmetry element. Although the electron density contour maps gave no sign of disorder, the assignment of this hydrogen as an ordered atom in the center of the H-bond is not conclusive. (*c*) X-Ray crystal structure of [Et$_4$N$^+$**1**$^-$].

disruption of the motif occurs. Furthermore, the O···O distances in both the Me$_4$N$^+$ (2.476 Å) and Et$_4$N$^+$ (2.485 Å) derivatives are actually shorter than for the K$^+$ salt (2.518 Å),[5] even though the separation between the charged center of these cations and the H-bonded chain is considerably greater than for the K$^+$ ion.

In conclusion, if no hydrogen bonding were possible between hydrogenoxalate anions, as suggested,[1] we would expect no **1**···**1** interaction in solution; we would anticipate the lengthening of the OH···O contact and the eventual disruption of the chain motif in the solid as more weakly coordinating counterions are used; and in any case, very short O···O distances, typically diagnostic of strong or very strong hydrogen bonds,[6] would not be expected. In fact, all of the experimental observations suggest the contrary, *i.e.* a case is clearly made for hydrogen bonding between hydrogenoxalates in solution, and the O···O distances actually decrease in the solid state on association with more diffuse cations.

Indeed, one must consider the overall picture of **1**···**1** and its counterions in terms of a balance of interactions, two 'associative' [(+)–(−), and OH···O] and two dissociative [(+)–(+), (−)–(−)], with the net effect, both in solution and the solid state, being the assembly of hydrogenoxalate anions into aggregates of some description, depending on the medium. The assertion that a breakdown in the H-bonding length–strength analogy has been observed (based on the hypothesis that interanionic OH···O contacts are not hydrogen bonds) must herewith be revised: although no direct measurement of the quality of these interactions has been made, the experimental evidence supports their characterization as hydrogen bonds, and there is at present no argument to suggest that the length–strength analogy should not apply in this or related cases.

We also note that in the course of this study, Steiner[7] produced statistical evidence that the O–H and H···O distances in $^-$[O–H]···O$^-$ hydrogen bonds were consistent with those in undisputed hydrogen bonded systems, as well as citing the key example of dimethylammonium hydrogenoxalate, whose counterions do not bridge the hydrogenoxalates and thus can not be responsible for the assembly of the '*pseudo*-hydrogen bonded' chain, as implied by Braga *et al.* for [K$^+$**1**].[1] We feel our spectroscopic and crystallographic studies are complementary with the results of Steiner, and that the weight of experimental evidence now strongly implies that the computational model of the electron density in **1** used by Braga *et al.* is not an ideal representation, since it does not predict the observed association.

We thank the Leverhulme Trust for a Research Grant (C. E. M.) and the RSC for a Journals Grant For International Authors (M. M.). Dario Braga, Juan J. Novoa and Fabrizia Grepioni are thanked for discussions concerning this work on a number of occasions.

2 The measured hydrogen bond enthalpy in KHC_2O_4 is 51.4 kJ mol^{-1} (M. S. Rozenberg, *Spectrochim. Acta, Part A*, 1996, **52**, 1559), whereas the simple point charge model $q_aq_b/4\pi\varepsilon\varepsilon_0 r$ gives a value of 270 kJ mol^{-1} for the interanionic repulsion in vacuum.

3 A least-squares fitting procedure was used to obtain K_a from the expression for the calculated chemical shift values. An expression for hydrogenoxalate where equilibria between a cyclic dimer, linear dimer, linear trimer and linear tetramer are taken into account is:

$$\delta_{calc} = \delta_{dimer}\frac{2K_d[O\times H]^2}{[O\times H]_i} + \delta_{end}\frac{\Sigma_n K_a^{n-1}[O\times H]^n}{[O\times H]_i} + \delta_{complex}\frac{\Sigma_n (n-1)K_a^{n-1}[O\times H]^n}{[O\times H]_i}$$

where K_d is the association constant for the cyclic dimer and is given the value 89 as determined for acetic acid in deuterochloroform under strictly anhydrous conditions, and δ_{dimer} is the associated chemical shift for this dimer. K_a is the association constant for the equilibria between monomeric **1** and the **1**···**1** linear dimer and each n-mer up to n = 4. The values of δ_{end} and $\delta_{complex}$ represent the chemical shifts of the non-associated protons at the end of the chain and the hydrogen bonded protons present in these oligomers, respectively. The value $[OxH]_i$ is the total concentration of hydrogenoxalate and [OxH] is the concentration of non-hydrogen bonded hydrogenoxalate present at equilibrium. The equilibria present in the (Pr$_4$N$^+$AcO$^-$)(AcOH) system can be modeled on a similar expression.

4 The K_a value for acetic acid dimerization in chloroform is consistent with those in the same concentration range as determined by IR spectroscopy: G. M. Barrow and E. A. Yerger, *J. Am. Chem. Soc.*, 1954, **76**, 5248.

By incorporating palladium into oxidative dehydrogenation catalysts, a key step in the usual Mars–van Krevelen redox cycle has been by-passed, resulting in a decrease in operating temperature of around 200 °C.

In the partial oxidation of hydrocarbons by gas-phase oxygen, the desired reaction (*i.e.* oxidative dehydrogenation, oxygen insertion, or ammoxidation) has to compete with total combustion. In general, chemisorbed oxygen will react with adsorbed hydrocarbons to generate waste products, unless it can first form lattice oxide ions—the species implicated in selective partial oxidation.[1] By definition, therefore, metals usually catalyse total combustion, while metal oxides have the potential to generate added-value products. This potential is realised when hydrocarbon molecules are adsorbed near available oxide ions, which in turn can be replenished as soon as they are consumed in the selective reaction.

The parent materials used in this study, iron(III) oxide and bismuth molybdate, both belong to a category of catalysts that function by a cyclic redox mechanism, first described by Mars and van Krevelen.[2] In this cycle, the mobility of oxygen through the lattice is crucial to the overall process of replenishing oxide ions close to the hydrocarbon adsorption sites. Since the mobility of lattice oxygen is strongly dependent on temperature, it can become rate limiting when the operating temperature is lowered.[3] Eventually, a threshold is reached (usually at about 300 °C), below which the mobility is so low that the oxide has negligible catalytic activity. However, we have been able to induce partial oxidation activity at operating temperatures within the range 100–200 °C and even lower, by incorporating palladium into Fe_2O_3 and Bi_2MoO_6. This dramatic reduction in temperature is brought about by a change in the prevailing reaction mechanism.

The method by which Pd is introduced into the metal oxide is critical to inducing low temperature activity. We have found that controlled precipitation is the optimum route, resulting in reproducible catalysts that do not require any special activation procedures. The incorporation of Pd into iron(III) oxide (Pd–Fe–O) and bismuth molybdate (Pd–Bi–Mo–O) is described in detail in a family of patent filings.[4]

XPS of freshly dried precipitate of Pd–Fe–O (as used in activity tests) showed Pd in the +2 state (Pd $3d_{5/2}$ E_b = 337.3 eV) and Fe in the +3 state (Fe $2p_{3/2}$, E_b = 710.6 eV). XRD revealed the material to be amorphous, which was also the case when the precipitation was carried out in the absence of Pd.

As bismuth molybdate catalysts require calcination in order to form the active binary phases,[5] our precipitate of Pd–Bi–Mo–O was also subjected to the same thermal treatment, before characterisation and testing. XRD of the calcined Pd–Bi–Mo–O showed it to be a mixture of α-bismuth molybdate (monoclinic $Bi_2Mo_3O_{12}$) and β-bismuth molybdate (monoclinic $Bi_2Mo_2O_9$), with no evidence of a crystalline Pd-phase. Without Pd, the bismuth molybdate catalyst was also a mixture of two allotropes, but these were the β- and γ-(orthorhombic Bi_2MoO_6) forms.

In common with other metal oxides, conventional catalysts derived from iron oxide are not active for butene oxidation below 300 °C.[6] However, when fresh samples of Pd–Fe–O made by coprecipitation were exposed to a feed of 14% but-1-ene in air at 100 °C, there was a delay (2–10 min, depending on Pd content) and then reaction began. Starting temperatures as low as 80 °C (for a catalyst containing 4% Pd by mass) and 60 °C (10% Pd) were recorded. In order to assess whether this low temperature activity was due to a synergy between the palladium and iron oxide phases or was primarily a result of the preparative method, we also tested palladium oxide and iron oxide prepared by essentially the same precipitation method. Neither showed any activity at such low temperatures. However, some reduction in operating temperature could be induced by impregnating Fe_2O_3 with Pd (4% by mass). This material was capable of achieving 50% butene conversion with 35% selectivity to butadiene at a feed temperature of 200 °C, but showed no activity below 150 °C.

Initial butadiene yield of the coprecipitated Pd–Fe–O catalysts was poor (*ca.* 10%), and their sensitivity to the butene/air feed ratio was high. During the first few hours on line, the yield improved and the sensitivity declined, before stabilising. For example, after 5 h on line, 4%Pd–Fe–O converted 50% of the hydrocarbon in a 20% butene/air feed with 70% butadiene selectivity; after the same time in a 14% butene/air feed, it converted 55% with 60% selectivity. The on-line improvement in yield appeared to be closely related to the blocking of non-selective (combustion and isomerisation) sites by carbon. As shown in Table 1, the catalysts could be 'regenerated' by heat treatment in flowing air (550 °C), during which the retained carbon was displaced as CO_2.

Pd–Bi–Mo–O required a higher operating temperature and a leaner hydrocarbon feed (12.5% butene/air) than Pd–Fe–O. After no activity was observed at 150 °C, the bed temperature was raised to 200 °C, whereupon reaction began as soon as the gas feed was introduced. The initial conversion of butene was 55%, with 45% selectivity to butadiene. Again, the performance improved with time, before stabilising after 30 min at 60% conversion and 60% butadiene selectivity. By contrast, unmodified bismuth molybdate showed only short-term activity under the same conditions (Fig. 1). Its temperature had to be raised to 350 °C before activity could be sustained (80% conversion; 70% selectivity). The fact that the selectivity of Pd–Bi–Mo–O (at 200 °C) was not as high as that of the unmodified bismuth molybdate (at 350 °C) may reflect the change in phase composition caused by the presence of Pd.

Both Pd–Fe–O and Pd–Bi–Mo–O are derived from catalysts that conform to a redox mechanism, in which the movement of

[a] Feed: 14% butene/air; contact time: 0.6 s; feed temperature: 100 °C.

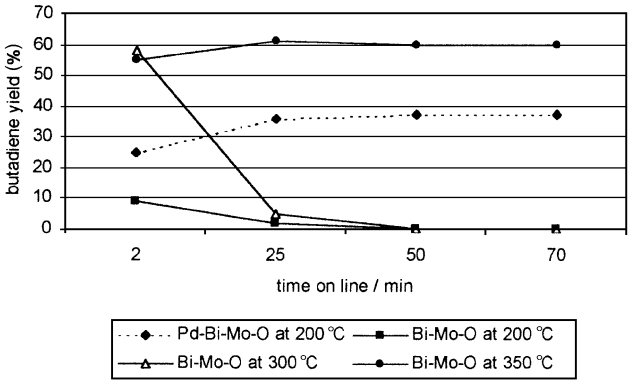

Fig. 1 Yield of butadiene as a function of time, over unmodified and Pd-modified bismuth molybdate, at operating temperatures of between 200 and 350 °C (feed: 12.5% butene/air; contact time: 0.6 s).

lattice oxygen is a key step in the selective partial oxidation of hydrocarbons.[7] The performance (preferred feed-composition; product distribution; activity/selectivity correlation) of the Pd-containing materials is similar to that of the unmodified catalysts, except in terms of operating temperature. Our working model, therefore, is one in which the same alkene adsorption sites are present in both forms, but the role of Pd is to supply selective oxygen at lower temperatures, by-passing the need for transport through the lattice.

A TAP study of the initial steps in the butene to butadiene reaction over 4%Pd–Fe–O, compared to a conventional α-Fe_2O_3 catalyst, provides support for this model.[8] Even at 150 °C, unmodified Fe_2O_3 is capable of converting butene/O_2 to butadiene, but only for a short time. At this temperature, it only forms butadiene, while it is consuming O_2. Although the same applies to Pd–Fe–O, it continues to consume O_2 indefinitely. The presence of the Pd enables the catalyst to activate gas-phase oxygen into selective species at low temperatures, leading to sustainable oxidative dehydrogenation under conditions where Fe_2O_3 does not usually function.[6] This mechanistic short cut enables low-temperature activity to be achieved by redox catalysts in which oxygen mobility would normally be the limiting factor. It cannot, however, overcome some of the other factors (such as product desorption) that can prevent low-temperature activity—as we have found to be the case for the conversion of propene to acrolein over Pd–Fe–O and Pd–Bi–Mo–O.

During the past thirty years, there have been a number of reported examples of heterogeneously catalysed oxidation reactions at unexpectedly low temperatures. In most cases, the reaction has been the total oxidation of a simple molecule.[9–13] Furthermore, these instances of low-temperature activity have appeared to be isolated and exceptional effects, associated with very specific compositions, preparations or interactions. We believe that our studies of Pd-incorporation into metal oxides illustrate a more general phenomenon that can allow the normal activity of a redox catalyst to be achieved at temperatures much lower than previously expected. Indeed, the Pd–Fe–O family of catalysts is particularly versatile, exhibiting catalytic activity at exceptionally low temperatures for CO oxidation[14] and the water–gas shift reaction,[4] as well as for the partial oxidation of hydrocarbons described here. For each reaction, the minimum operating temperature is about 250 °C below that observed for unmodified iron(III) oxide.

Carborane–fullerene hybrids as a seemingly attractive–attractive dyad with high hyperpolarizability†

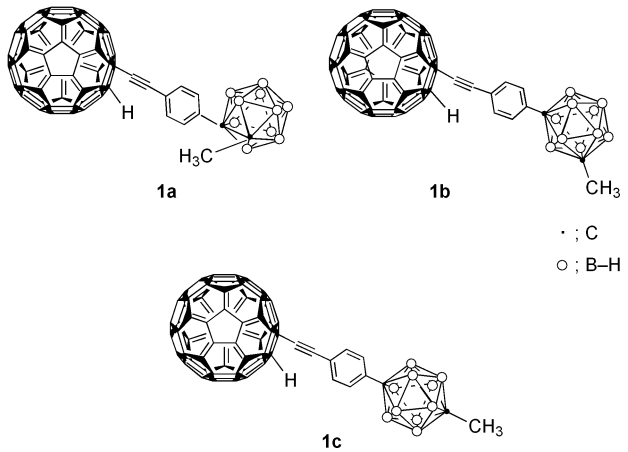
A combination between seemingly attractive carboranes and fullerene through an ethynyl π-system (compounds 1a–c) gives unexpectedly high β-values, thereby providing a guideline that in certain cases a seemingly A–A system becomes a promising complementary combination for obtaining high hyperpolarizability; the β values of 1a, 1b and 1c were 346, 483, and 1189 × 10^{-30} esu, respectively.

Quadratic nonlinear optical (NLO) materials have increasingly attracted attention owing to their direct application in the development of efficient optical telecommunication networks lacking electrical-to-optical, and *vice versa*, signal conversion.[1] Such application requires thermally robust materials with highly nonlinear optical (NLO) response (first hyperpolarizability β). The use of organic materials may offer significant advantages over conventional inorganic crystals. Typical organic NLO compounds include Donor (D) and Acceptor (A) moieties bridged by a π-conjugated linker. Until now, most efforts to obtain better hyperpolarizability (β) have been directed to finding both the right combination of D and A species and the right length of the conjugated bridge between D and A.[2] It has been known for many years that *closo*-carboranes are *electron deficient boron clusters* having highly polarizable σ-aromatic character.[3] Previously carboranes (A) containing certain donor (D) groups were synthesized, but their hyperpolarizable properties were not satisfactory.[4] More recently it has been recognized that fullerenes are *electron attracting carbon clusters* having highly delocalizable π-electrons.[5] Actually, fullerenes (A) containing electron donor (D) moieties have been reported,[6] but there are no NLO studies on those compounds at all, to the best of our knowledge. It occurred to us that carborane–fullerene dyads bridged by an appropriate linker might exhibit an interesting NLO response, in spite of the fact that both groups are electron attracting clusters, since both clusters have highly polarizable electrons. We wish to report that a combination between seemingly attractive carboranes and fullerene through an ethynyl π-system (compounds **1a**–**c**) gives unexpectedly high β-values, thereby providing a guideline that in certain cases a seemingly A–A system becomes a promising complementary combination for obtaining high hyperpolarizability.

The synthetic procedure for **1a** is shown in Scheme 1 (see ESI.†) The *meta*- and *para*-carborane analogues, **1b** and **1c**, were prepared in a similar manner.[7]

For clarity, the cyclic voltammetries of only **1a** and C_{60} are shown in Fig. 1 (see ESI†). Those of the phenylethynyl analogue **7** are similar. The redox potentials of **1a**–**c**, **6**, **7** and C_{60} are summarized in Table 1. Only E_1^{red}/E_2^{ox} values are shown for simplicity, although three quasireversible reduction–oxidation peaks were observed. The one-electron reduction of the non-charged molecules **1** (E_1^{red}) and the one-electron oxidation to **1** (E_1^{ox}) are more important than the further



reductions of the charged molecules (E_2^{red} and E_3^{red}) and the oxidations to the charged molecules (E_2^{ox} and E_3^{ox}), when we discuss the electrochemical property of the C_{60} end group. The three quasireversible reduction peaks of **1a** are similar to those found for C_{60}, **6** and **7** under the same experimental conditions. One additional irreversible oxidation wave at −187 mV (E^{ox}) most probably corresponds to the oxidation peak of the conjugated spacer fragment, since authentic samples of **6** and **7** also exhibited similar peaks at −122.5 and −286 mV, respectively. The three reduction potentials of **1a** were remarkably shifted to more negative values in comparison with those of the parent C_{60}, presumably due both to the saturation of a double bond of C_{60} and the electron donating character of the ethynylphenyl group. Consequently, it is clear that the C_{60} framework of **1a** behaves as an A group.

Similar observations were made for the *meta*- and *para*-derivatives **1b** and **1c**. An important question was whether the

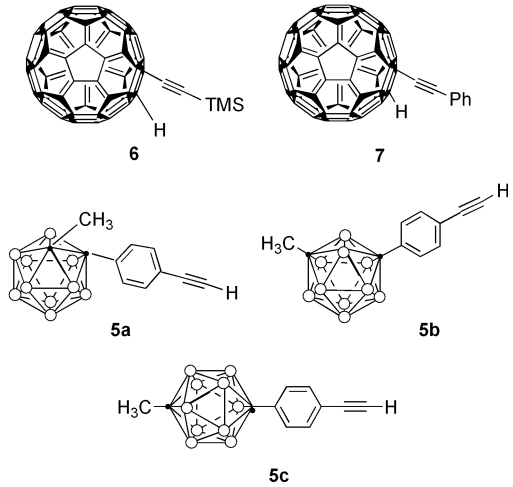
[a] Potentials in mV *vs.* ferrocene/ferrocenium measured in *o*-dichlorobenzene (see Fig. 1) (see ESI†). [b] Among three quasireversible redox peaks, only the first peaks E_1^{red}/E_1^{ox} are shown and the other peaks are shown in the ESI†. [c] Irreversible oxidation peak most probably due to the ethynyl spacer units. [d] The compound did not exhibit electroactivities within the potential range we investigated.



carborane framework acted as a donor or (as usual) an attractor. We synthesized the reference compounds **5a–c** in order to help clarify this point, but those compounds did not exhibit electroactivities within the potential range we investigated. The E^{ox} value of **7** was −286 mV, which was the most negative value among those observed in Table 1, indicating that the electron density of the ethynyl group of **7** was higher than that of **1a–c**. Accordingly, we assume at present that the carborane end group acts as an attractor, as well established previously.[8]

Absorption spectra of **1a–c**/$CHCl_3$ in the UV-vis range showed two large absorption bands at 258 and 328 nm; **1a**, λ_{max} 258 (log ε 5.10), 328 (4.77); **1b**, 258 (5.05), 328 (4.58); **1c**, 258 (5.32), 328 nm (4.71). Absorption spectra of **5a–c** in $CHCl_3$ showed absorption bands at 260 (log $\varepsilon \approx$ 4.66–4.49) and 283 nm (3.83–4.36), and those of C_{60} in $CHCl_3$ showed two strong bands at 259 (4.85) and 329 nm (4.28). These data in addition to those for **6** and **7**[9] clearly indicate that the two strong bands of **1a–c** are due to the phenylethynyl–C_{60} chromophore and the influence of the carborane groups to the UV absorption is very small (see ESI†). Very weak absorption bands between 400–440 nm (log $e \approx$ 4.00–3.50) were observed for **1b** and **1c**, which were presumably due to a forbidden transition (see ESI†). In $CHCl_3$ solution of **1a–c**, no absorption was observed after 450 nm, although C_{60} itself, **6** and **7** in cyclohexane exhibited very weak absorption bands between 470–700 nm with log ε 2.3–3.2.[9]

The fluorescence spectra of **1a–c** in $CHCl_3$ following excitation at 258 and 328 nm showed broad band emission in the range 350–390 nm, which was attributed to Raman scattering of the $CHCl_3$ (see ESI†). Fullerene fluorescence is usually observed around 700 nm; this was in general measured in cyclohexane.[10] We attempted to dissolve **1a–c** in cyclohexane, THF and CH_3CN, but they were soluble only in $CHCl_3$. The emission spectra of **6** and **7** in $CHCl_3$ also exhibited Raman scattering of $CHCl_3$. In conclusion, no significant spectroscopic absorption or/and emission was observed for the $CHCl_3$ solution of **1a–c** (10^{-6} M) in the range of the double frequency value 532 nm, allowing us to get the necessary measurements to deduce the β coefficients of **1a–c**.[11]

The quadratic dependence of the second-harmonic signal intensity to the harmonic intensity for **1a**, for example, is demonstrated in Fig. 2 (see ESI†). The laser wavelength of 1064 nm was used. The molar absorption coefficients (ε) of **1a–c** at 532 nm were below *ca.* 1000 $dm^3\ mol^{-1}\ cm^{-1}$, so that the influence of resonance effects were very small.[12] The β values of **1a–c** were 346, 483 and 1189 × 10^{-30} esu, respectively (Table 1). It should be noted especially that *the para-derivative* ***1c*** *exhibited a large* β *value*. As expected, the β value of C_{60} itself was zero under the same experimental conditions owing to its centrosymmetric structure. For comparison, the β values of **6** and **7**, which are typical D–A systems, were measured: the β of **6** was 87 × 10^{-30} and that of **7** 139 × 10^{-30} esu. The β-values of **5a–c** were 7, 28 and 48 × 10^{-30} esu, respectively. It is clear that the reference compounds exhibit ordinary level of β-values, although the values of **6** and **7** (~100 × 10^{-30} esu) are still higher than that for a standard *para*-nitroaniline, which showed 23 × 10^{-30} esu under the same experimental conditions. By attaching the carboranes, the β value increased up to 1189 × 10^{-30} esu confirming the strong electronic polarizable influence of the boron clusters.

Very high hyperpolarizability of **1c**, which constitutes the first example of its kind, is quite fascinating since it has often been surmised[13] that, by forming charge-transfer complexes with appropriate donors, the center of symmetry of C_{60} is broken. In our case the hybride **1** do not form any charged complex but present high β values. Further investigation on boron–carbon cluster hybrids is being pursued actively in our laboratories.

8 For a recent example on the strong electron-withdrawing nature of *closo*-carboranes, see Y. Endo and Y. Taoda, *Tetrahedron Lett.*, 1999, **40**, 9073. One referee posed a question concerning the electron-withdrawing character of the carborane groups of **1a–c**: whether the observed E^{ox} values of the phenylethynyl groups should be similar to those for **5a–c** if the carborane groups act as electron-withdrawing groups. However, the CVs of **5a–c** did not show any signals in the voltammograms. A possible explanation might be that C_{60} is a very strong EWG group, but that the carboranes are weaker EWG moieties.

Huge enhancement of the quadratic nonlinear optical susceptibility in push–pull chromophores based on bridged dithienylethylene spacers

Received (in Cambridge, UK) 1st March 2000, Accepted 11th July 2000
Published on the Web 4th August 2000

Replacement of the open chain dithienylethylene π-conjugating spacer by its bridged analog in push–pull NLO-phores produces a dramatic increase of the quadratic hyperpolarisability.

Chromophores for 2nd order nonlinear optics consist of electron-donor and electron-acceptor groups interacting through a π-conjugating spacer.[1] Whereas the optimization of the donor[2] and acceptor[3] groups has led to considerable progress in the synthesis of stable and efficient systems, the relationship between the structure of the conjugating spacer and 2nd order nonlinearity are less clearly understood. Push–pull polyenes can reach huge nonlinearities,[2a,4] but their practical use might be limited by stability problems.

As shown in recent work, thiophene-based spacers lead to stable NLO-phores with second order hyperpolarisabilities sometimes exceeding $10\,000 \times 10^{-48}$ esu.[2b–d,3] These high performances can be related to the moderate resonance energy of thiophene which allows a better π-electron delocalization than *e.g.* benzene-containing spacers.

It has been shown that the static hyperpolarizability is correlated with the ground state polarization which is in turn reflected by bond length alternation (BLA).[5] Optimal β values, predicted for BLA intermediate between those for unsubstituted polyenes (~0.10 Å) and the cyanine limit (0.00 Å), have been approached by selecting appropriate combinations of donor and acceptor groups in order to tune the balance between the neutral and charge-separated limiting resonance forms.[4,5]

Previous theoretical and experimental work has shown that the covalent bridging of dithienylethylene (DTE) results in a 0.40 eV decrease of the HOMO–LUMO gap due to a reduction of BLA.[6] On this basis, replacement of DTE by a bridged analog with inherently reduced BLA, can be expected to improve the quadratic hyperpolarizability of the derived push–pull chromophores. In this context, we report here preliminary results on two series of NLO-phores derived from open chain (**1c**–**e**) and bridged (**2**,**3**) DTE spacers, used in conjunction with *N*,*N*-dialkylaniline donors, and various acceptors.

All NLO-phores have been prepared according to the general procedure shown in Scheme 1. DTE **1f** and its bridged analog **2f**[6c] were converted into aldehydes **1g** and **2g** by Vilsmeier formylation. Wittig olefination of **1g** and **2g** with phosphonium iodides bearing the *N*,*N*-dialkylaniline group led to compounds **1h**–**3h** as a mixture of *E* and *Z* isomers. After separation of the *Z*-isomer, a second formylation led to aldehydes **1i**–**3i** and the target molecules were obtained by Knoevenagel condensation between **1i**, **2i** and **3i** and various acceptors with active methylene groups. All final compounds have been fully characterized by ^{1}H and ^{13}C NMR, mass spectroscopy and elemental analysis.

Table 1 lists the UV-vis absorption maxima (λ_{max}), second order nonlinear hyperpolarizabilities ($\beta\mu$), and decomposition temperatures (*T*d) of the NLO-phores. Comparison of the data for the open chain and bridged compounds containing similar donor–acceptor pairs shows that the bridging of the spacer produces a considerable red shift of λ_{max}, (up to 100 nm between **1d** and **2d**), indicating an enhancement of the effective conjugation. Preliminary tests on **1e** and **2d** gave anomalously low μβ values which were attributed to the poor solubility of the

compounds. This problem was resolved by replacing methyl by hexyl groups in compounds **3c** and **3d**.

Comparison of the data for the two series of compounds shows that, for a given acceptor, the bridging of the DTE spacer produces a huge enhancement of μβ which increases from 2720 to 10 400 × 10^{-48} esu for the **1c**/**3c** pair, while for the **1d**/**3d** one, μβ increases by a factor of three and reaches a value of 19 400 × 10^{-48} esu. To the best of our knowledge, this value is the largest ever reported for a NLO-phore based on an heteroaromatic spacer.

Improved thermal stability has already been reported for NLO-phores based on configuration-locked olefinic spacers,[7] or for bridged dithienyl hexatrienes.[8] While the various acceptor groups used here make it difficult to evaluate the specific effect of the spacer on the stability, the similarity of the Td values for open chain and bridged compounds bearing the same acceptor *e.g.* **1d** and **2d** suggests that, in that case, the stability is limited by that of the acceptor. Further support for this hypothesis is provided by the identical *T*d values (235 °C) found for **3c**, **1c** and its analog containing the more stable diphenylamino substituted thiophene donor.[2d] On the other hand, the high Td values for **2a** and **2b** (⩾ 300 °C) definitively show that thermally stable chromophores can be synthesized from bridged DTE spacers.

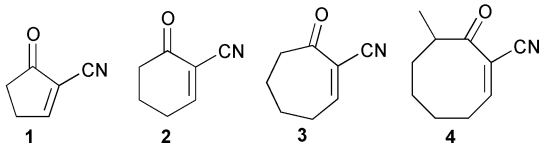
Under zinc chloride catalysis, a number of 2-cyanoalk-2-enones representing various ring sizes were found to undergo facile cycloaddition with several selected conjugated dienes; sequential treatment of the adducts with lithium naphthalenide and an alkylating agent resulted in the direct replacement of the angular cyano group with an alkyl group, providing easy access to angularly substituted polycyclic systems.

The Diels–Alder reaction has long played an important role in synthetic organic chemistry. One of the most important features of its application is to build fused polycyclic skeletons, a process requiring only a straightforward addition of a cyclic dienophile to an appropriately substituted buta-1,3-diene. However, early investigations have demonstrated that under thermal conditions, the cycloaddition of dienes to cyclic dienophiles, such as cyclohex-2-enone is a poor process, often resulting in low yields of products.[1] Over the years, there have been extensive studies directed towards the enhancement of the dienophilicity of cycloalkenones, resulting in the development of two general solutions. One makes use of Lewis acid catalysis and the other involves the incorporation of an additional electron-withdrawing group to the dienophilic carbon–carbon double bond. In l977, we showed that the introduction of a methoxycarbonyl group to C-2 of 4,4-dimethylcyclohexa-2,5-dien-1-one vastly improved the Diels–Alder reactivity of an otherwise poor dienophile.[2] This strategy proved to be useful for the activation of the dienophilic double bond in systems where the conjugated enone functionality could not undergo enolization towards the C-4 carbon and has been successfully applied in facilitating the total synthesis of various polycyclic natural products.[3] This strategy, however, was found to be less effective when the cycloalk-2-enone contains an enolizable hydrogen at C-4, as the placement of an ester group onto the C-2 carbon makes the compound extremely labile. For instance, although 2-methoxycarbonylcyclohex-2-enone can be applied as a dienophile,[4] the efficiency of its Diels–Alder reaction is much lower than that of its 4,4-dimethyl derivative because of the poor stability associated with the former compound. Another drawback of using an ester as an activating group is the multi-step operation required for its subsequent conversion to an alkyl group, which is often necessary in natural product synthesis. In continuation of our investigations on the activation of cycloalk-2-enones as dienophiles, we have observed that the placement of a cyano group at C-2 induces a high degree of enhancement of the dienophilicity of the parent molecule. Interestingly, the enolizable 2-cyanocyclohex-2-enones, unlike the corresponding 2-alkoxycarbonyl compounds, are rather stable.† Also the cyano group in the adducts can be directly replaced by an alkyl group *via* a reductive alkylation process.

Four 2-cyanocycloalk-2-enones **1**–**4** representing various ring sizes were examined. Compound **4** was readily prepared from 2-methylcyclooctanone *via* a four-step synthetic sequence (Scheme 1), involving formylation,[6] isoxazole formation and its subsequent rearrangement,[7] and phenylselenenylation–oxidative elimination.[8] Compounds **1**–**3** were easily accessible by



Thorpe–Ziegler condensation of the corresponding alkanedinitriles followed by phenylselenenylation–oxidative elimination. In sharp contrast to the instability associated with the corresponding 2-alkoxycarbonylcycloalk-2-enones, cyano compounds **1**–**4**‡ were shown to be rather stable and could be distilled, chromatographed and stored at 0 °C over a long period of time without apparent decomposition. Under Lewis acid catalysis, zinc chloride in particular, the Diels–Alder reaction of these compounds occurred readily at room temperature with a variety of dienes to give adducts in high yields.§ As shown in Table 1, which summarizes the results obtained for the present studies, the regioselectivity strictly follows the general rules governing the Diels–Alder reaction; 1-substituted and 2-substituted buta-1,3-dienes gave *ortho*- and *para*-adducts, respectively. In terms of stereochemistry, all of the reactions, where applicable (Entries 3, 6 and 7), gave the *endo*-to-ketone addition products. Interestingly, the addition of 2-cyano-8-methylcyclooct-2-enone (**4**) to two selected dienes (Entries 6 and 7) occurred with a complete face-selectivity from what appears to be the sterically less hindered face to give adducts **10** and **11**, respectively.

The cyano group present in each of the adducts could be readily replaced by a proton or an alkyl group *via* reductive removal of the cyano group using lithium naphthalenide (LN) followed by trapping of the ensuing enolate ion with a proton source or an appropriate electrophile.[9] As an example, treatment of adduct **6** with a stock solution of LN (6 eq.) in THF[10] at −25 °C for 30 min resulted in the reductive elimination of the cyano group. Protonation of the enolate thus formed with MeOH gave ketone **12** (80% yield), whereas treatment with allyl bromide (20 °C, 20 h) gave the angularly substituted ketone **13** (75% yield). The reductive alkylation process is apparently general and highly stereoselective. In all of the cases examined (Table 2), only the *cis*-fused alkylation product was observed.

In conclusion, 2-cyanoalk-2-enones, which are surprisingly stable, have proved to be useful dienophiles. Their Diels–Alder reaction coupled with the ease of replacement of the cyano

group with an alkyl group provides convenient access to various angularly substituted, *cis*-fused bicyclic systems. This newly developed process is expected to have broad synthetic utility, particularly towards polycyclic natural products of structural complexity. For instance, the complete carbon framework of neolemnane (**14**)[11]¶ could be rapidly constructed by two simple operations. Addition of cyano enone **4** to 2-*tert*-butyldimethylsilyloxypenta-1,3-diene (Table 1, Entry 7) gave adduct **11**. Sequential treatment of **11** with LN and methyl iodide (Table 2, Entry 11) completed the carbon skeleton of neolemnane (**14**). Modification of the existing functionalities to effect the total synthesis of **14** is under active investigation.

From the fluorination of [60]fullerene with K_2PtF_6 at 470 °C under *ca.* 0.01 bar we have isolated (HPLC) 1,2-F_2C_{60}, the structure of which is confirmed by ^{13}C NMR and a single ^{19}F NMR line at −148.3 ppm.

As synthons, halogenofullerenes containing very few halogen atoms are desirable, but thus far they have been unattainable. Both chlorination and bromination involve a radical cascade process which necessitates, for steric reasons, contiguous *para* (1,4) halogenation. This is terminated by *ortho* (1,2) halogenation only as a necessity for the formation of a non-radical product such as $C_{60}X_6$ (X = Br, Cl)[1,2] or $C_{70}Cl_{10}$.[3] The adjacency of the bulky halogens creates instability, and these are preferentially lost for example either in subsequent reactions[4,5] or through rearrangement *e.g.* the conversion of $C_{60}Br_6$ to $C_{60}Br_8$ on standing.[1] In $C_{60}Br_8$ (and also in $C_{60}Br_{24}$)[6] all of the bromines are in either a 1,4- or a 1,3-relationship. Thus no 1,2-dibromo- or 1,2-dichlorofullerene has been either isolated or inferred from subsequent substitutions.

By contrast, the lack of steric hindrance in fluorination permits 1,2-addition which results in contiguous activation of adjacent double bonds (through increased bond localisation). The ensuing halogenation cascade tends to cease only when a product is obtained of enhanced aromaticity (such as $C_{60}F_{18}$ or $C_{60}F_{36}$)[7,8] *i.e.* containing delocalised benzenoid rings.

Characterisation of bromo- and chlorofullerenes is rendered difficult by their instability towards mass spectrometry, which becomes greater the fewer halogens that are present; so far, only a FAB spectrum of $C_{60}Cl_{24}$ has been obtained.[9] Fluorofullerenes are more stable towards mass spectrometry and the existence of $C_{60}F_n$ (n = 18, 36 or 48)[8–10] shows that fluorines can be attached to adjacent carbon atoms without introducing undue strain. Nevertheless, as with the other halogenofullerenes noted above, *the stability decreases the fewer the number of attached fluorines*, seen for example by the appearance of lower fluorinated species (through fragmentation) in the EI mass spectrum of $C_{60}F_{18}$.[8] In fluorination by fluorine gas, the EI mass spectrum showed a continuous spectrum of derivatives from $C_{60}F_2$ up to *ca.* $C_{60}F_{42}$ (and numerous oxygenated derivatives).[11–13] However, it was unclear if the lower fluorinated species were compounds or merely fragmentation ions.

We now report the successful isolation and characterisation of $C_{60}F_2$.

[60]Fullerene (240 mg) was fluorinated with K_2PtF_6 (575 mg) and a toluene solution of the product (280 mg after prepurification by sublimation) was filtered with precautions to minimise interaction with atmospheric moisture, all as described previously.[14] HPLC separation of the product was carried out using a 10 mm × 250 mm Cosmosil Buckyprep column with elution by toluene at 4.7 ml min^{-1}. This yielded mainly $C_{60}F_{18}$[8] (elution time 37 min) together with a large number of other components, most of which are ethers. A fraction (*ca.* 1.5 mg) which eluted at 10.5 min (*cf.* 7 min for [60]fullerene) was shown by the mass spectrum (Fig. 1) to contain $C_{60}F_2$ (758 amu). The spectrum also gave peaks at 858 [$C_{60}(CF_3)_2$], 840 ($C_{60}C_2F_5H$), and 790 amu ($C_{60}CF_3H$). [Formation of CF_3 radicals by fragmentation is well-known to accompany fluorination of [60]fullerene,[13,15] and is especially marked when using K_2PtF_6; the radicals then attack other [60]fullerene molecules.] The mass spectrum is however very misleading (as the ^{13}C and ^{19}F spectra show) because it *greatly* underestimates the concentration of $C_{60}F_2$ in the sample due to fragmentation (as described above), and which is severe at this fluorination level. This is shown (Fig. 1) by the peak at 720 amu being 960 × the intensity of the 758 amu peak, *yet no [60]fullerene was present in the sample*. The same effect was evident in the spectra of $C_{60}F_nO$, (n = 8,6,4) which due to increasing fragmentation with lower addend level, showed increased amount of [60]fullerene relative to the parent ion, along this series.[14]

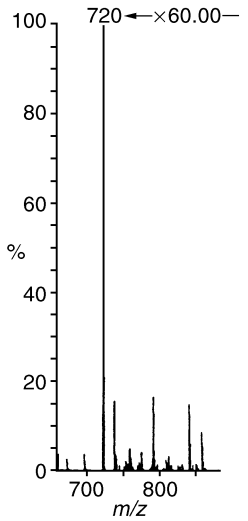

Fig. 1 EI mass spectrum (70 eV) for $C_{60}F_2$.

The IR spectrum (KBr, Fig. 2) shows two sharp peaks at 1070 and 1035 cm^{-1} in the C–F stretching region, and also sharp bands at 770, 724, 648, 594, 527 and 500 cm^{-1}. The very simple spectrum is consistent with a highly symmetrical structure, and the strong band at 527 cm^{-1} is characteristic of unaddended [60]fullerene,[16] which the present structure closely resembles.

The ^{19}F NMR spectrum (Fig. 3, 338.9 MHz, $CDCl_3$) showed a singlet at −148.3 ppm together with two very small peaks at −67.9 and −69.7 ppm, which are typical of CF_3-containing [60]fullerenes. The peak area intensities indicate that these derivatives constitute *ca.* 6% of the total fluorinated fullerene present, which further emphasises the misleading nature of the EI mass spectrum (see above).

This singlet thus falls in the range obtained for fluorinated [60]fullerenes, *e.g.* −(132–158) for $C_{60}F_{18}$ and −(130–166) ppm for $C_{60}F_{36}$. 1,2-Isomers of [60]fullerene are more stable than 1,4-isomers, since the latter contain a destabilising double bond in a pentagon and are obtained only when the addend is large. Thus due to the difference in addend size, methylation gives a mixture of 1,2- and 1,4-dimethyl derivatives, whereas benzylation gives 1,4-addition.[17] Since fluorine is smaller than

DOI: 10.1039/b004467i

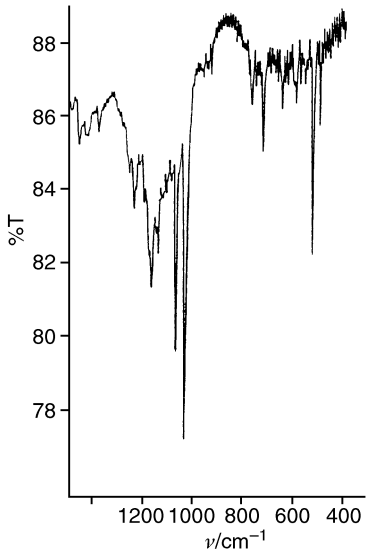

Fig. 2 IR spectrum (KBr) for $C_{60}F_2$.

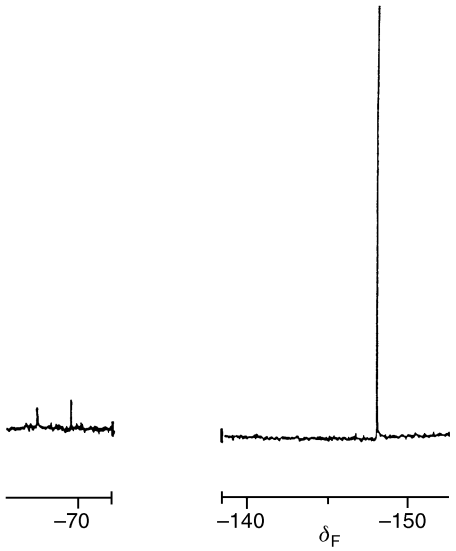

Fig. 3 ^{19}F NMR spectrum (338.9 MHz) for $C_{60}F_2$.

carbon, there is no advantage, either thermodynamic or kinetic, in forming the 1,4-isomer.

The location of the ^{19}F NMR peak is also consistent with a 1,2- rather than the 1,4-isomer. In the latter, each sp^3-hybridised carbon bearing the fluorine is surrounded by *three* sp^2-hybridised carbons (which are more electron withdrawing than sp^3), whereas there are only *two* in the 1,2-isomer. This differential effect is clearly seen in the $C_{60}F_{18}$ peak positions which are −132, −140 (av.) and −158 ppm for C–F bonds having 2, 1, and 0 sp^2 neighbours,[9] or in *T* $C_{60}F_{36}$ where they are −138 (av.) and −155 ppm for C–F bonds having 1 and 0 sp^2 neighbours.[18] Thus for the 1,4-isomer the peak would be expected to appear more downfield, the above data suggesting a value of −(120–130) ppm.

Final proof that we have isolated the 1,2-isomer comes from the ^{13}C NMR spectrum (Fig. 4). Obtaining such spectra for F-containing compounds requires F-decoupling which is unavailable, nevertheless for $C_{60}F_{18}$ we obtained a spectrum showing singlets for γ-carbons (and those more remote) relative to the

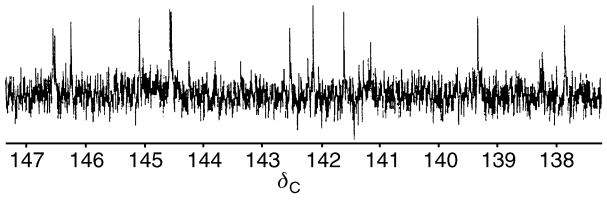

Fig. 4 ^{13}C NMR spectrum for $C_{60}F_2$.

(F)C_α carbons. Whereas 1,4-F_2C_{60} (C_s symmetry) requires in the sp^2 region (29–3) = (26 × 2 C lines, 1,2-F_2C_{60} (C_{2v} symmetry) requires 3 × 2 C and (13 − 1) = 12 × 4 C lines. Our spectrum (which required 90 h acquisition time) shows 12 × 2 C lines at 146.54, 146.50, 146.24, 145.08, 145.01, 144.54 (two coincident), 142.53, 142.23, 142.14, 141.62, 139.32, 137.85. Lines of 2 C intensity appeared at 141.16 and 138.35. Other lower intensity lines at δ_C 144.23, 143.79, 143.36, 141.29 and 141.20 were barely above background and may not be real. The compound is thus fully confirmed as the 1,2-isomer. No peak is seen in the sp^3 region due to coupling with fluorine.

In early work with F_2-fluorinated [60]fullerene, treatment of the crude product with either acetone or THF gave a product showing a single ^{19}F NMR line at *ca.* −150.5 ppm, and two sharp IR bands at 1067 and 1035 cm^{-1}; a single line NMR was also obtained by treatment of $C_{60}F_{48}$ with diethyl ether.[10] We conjectured that this line could be due to $C_{60}F_{60}$,[11] but later work showed this to be unlikely.[19] Since both the NMR line and especially the IR peaks for $C_{60}F_2$ are remarkably similar to those described above, $C_{60}F_2$ could conceivably be the species responsible in the earlier work. However, the availability now of a defined HPLC retention time for $C_{60}F_2$ means that repetition of the earlier work and separation of the products may provide an answer. We plan to undertake this work.

We thank the Royal Society for a Joint Project grant, NATO for additional support, and Dr Anthony Avent for the ^{13}C NMR spectrum.

Homogeneously catalyzed, chelate assisted hydrogenolysis of an amine C–N bond

Mark Gandelman and David Milstein*

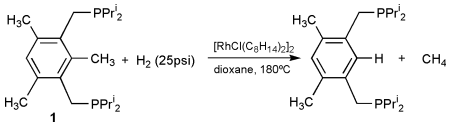
Department of Organic Chemistry, The Weizmann Institute of Science, Rehovot, Israel, 76100

Received (in Cambridge, UK) 15th June 2000, Accepted 12th July 2000
Published on the Web 4th August 2000

Reaction of $[RhCl(COE)_2]_2$ with an excess of the aromatic aminophosphine 1-(diethylaminomethyl)-3-(di-*tert*-butylphosphinomethyl)-2,4,6-trimethylbenzene (2) in dioxane under mild H_2 pressure results in selective catalytic activation of an unstrained C–N single bond.

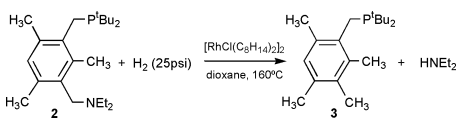
The design of homogeneous processes for selective activation and catalytic functionalization of strong single bonds by transition metal complexes is a highly desirable goal.[1] The catalytic C–N bond activation is of considerable current interest, as it is a key step in hydrodenitrogenation (HDN)—an important part of the hydrotreating process whereby crude oil or coal-derived liquids are upgraded to fuels.[2] Relatively few clear examples of metal-complex promoted C–N cleavage of amines are known, most of them being stoichiometric.[3–6] Catalytic reactions of this type are scarce.[7] We report here a remarkable example of *homogeneous catalytic* hydrogenolysis of an unstrained sp^3 C–N bond. This chelate-assisted rhodium catalyzed process occurs under homogeneous reaction conditions and is highly selective.

We have recently reported that the PCP-based ligand **1** undergoes selective catalytic C–C bond activation by Rh under H_2 pressure at 180 °C (Scheme 1).[8]



Scheme 1

In order to extend the scope of this process to other systems, we tried this reaction with the PCN-based ligand **2**. As we have recently shown, the stoichiometric reaction of **2** with $[RhCl(COE)_2]_2$ (COE = cyclooctene) results in exclusive C–C activation of the Ar–CH_3 bond situated in between the phosphine and amine 'arms'.[9] Surprisingly, when the reaction is performed in a catalytic manner C–N rather than C–C bond activation takes place. Thus, reaction of $[RhCl(COE)_2]_2$ with 10 eq. of **2** under mild H_2 pressure (25 psi) in dioxane at 160 °C for 24 h leads to quantitative formation of the hydrodenitrogenated phosphine **3** and diethylamine (Scheme 2, 10 turnovers based on Rh and 100% yield). The catalysis can be continued by adding more of substrate **2**, demonstrating that the catalyst remains active. The yield was lower when larger quantities of **2** were used. 13 turnovers (93%) were observed when 15 eq. of compound **2** were reacted, and 21 turnovers (47% yield) for 45 eq. of the starting material.



Scheme 2

The product diethylamine was identified and quantified by GC-MS and GC analysis, respectively. It was also detected by ^{1}H-NMR, when the reaction was performed in dioxane-d_8. The phosphine **3** was isolated by evaporation of diethylamine and subsequent extraction of the residue with pentane and was fully characterized by $^{31}P\{^1H\}$, ^{1}H, $^{13}C\{^1H\}$, ^{13}C-DEPT NMR and MS techniques. The structure of **3** was confirmed by comparison with an authentic sample, which was independently prepared by phosphination of bromomethylisodurene.† Formation of **3** is highly selective, no other organic products being catalytically formed (*vide infra*). Control experiments showed that substrate **2** does not undergo catalytic C–N activation under the reaction conditions in the absence of Rh or H_2.

A postulated catalytic cycle is presented in Scheme 3. Initially, selective insertion of Rh(I) into the aryl-CH_3 bond resulting in complex **4** most probably takes place. As reported, the stoichiometric reaction of **2** with $[RhCl(COE)_2]_2$ leads to **4**.[9] Subsequently, **4** reacts with H_2 to yield the hydrido chloride complex **5** and CH_4. Indeed, when the reaction was performed with a small excess of **2** (5–7 eq.), a stoichiometric amount of **5** was detected by NMR spectroscopy. Also, a stoichiometric amount of CH_4 (based on Rh) was regularly observed by GC analysis in the catalytic reaction. Compound **5** and CH_4 were independently obtained by the reaction of **4** with H_2 (25 psi) at 80 °C for 3 d. The products were analyzed by $^{31}P\{^1H\}$, ^{1}H, $^{13}C\{1H\}$, ^{13}C-DEPT NMR‡ and by GC. This reaction may proceed through a Rh(V) intermediate or *via* σ-bond metathesis. Complex **5** is part of the catalytic cycle and can also be used as catalyst under the same reaction conditions.

The exchange of the amine 'arm' of **5** by the phosphine moiety of **2** most probably proceeds *via* intermediates **A** and **B**. Replacement of a pincer-type amino ligand of Ru(II) by a phosphine analog was reported recently.[10] The exchange of the phosphine group in **5** by the amine 'arm' of **2** is impeded, since an amine is, in general, a poorer ligand for low valent late transition metals than a phosphine.[11] At this stage, most probably, C–N bond activation and hydrogenolysis by the unsaturated Rh center takes place, giving the phosphine-coordinated product **C** and diethylamine. Following replacement of **3** by the amine 'arm', **5** is regenerated, this process being assisted by the generation of two stable five-membered chelating rings. The liberated **3** most probably competes with **2**, slowing down the catalytic process as its concentration increases.

An alternative mechanism involving phosphine displacement by the amine group in **B** can be excluded, as we have observed that Ar-CH_3 bond activation occurs immediately even under very mild conditions, when both P and N ligands are coordinated.[12]

In summary, catalytic hydrogenolysis of an unstrained C–N bond has been presented. The phosphinoamine mixed system **3** undergoes selective stoichiometric C–C and catalytic C–N bond activation by Rh. In addition to the general interest in catalytic C–N activation, the reactivity of pincer-type complexes is the focus of much current research.[13]

Notes and references

† *Independent synthesis of 1-(di-tert-butylphosphinomethyl)-2,3,4,6-tetramethylbenzene* (**3**). 1-Bromomethyl-2,3,4,6-tetramethylbenzene was prepared by bromomethylation of isodurene (1,2,3,5-tetramethylbenzene) according to a literature procedure.[14] The resulting bromomethylisodurene (2 g, 8.81 mmol) and di-*tert*-butylphosphine[15] (1.29 g, 8.81 mmol) in acetone (20 ml) were heated under reflux with stirring for 2 h.[16] The mixture was cooled to rt, the white precipitate that formed was filtered off and washed with hexane to remove unreacted starting material. The obtained phosphonium salt was dissolved in water and treated with a 10-fold excess (based on starting bromide) of sodium carbonate. The organic product was extracted with ether (3 × 20 ml). The ether fractions were combined, and the solvent was evaporated, giving the clean phosphine **3** in 86% yield (2.21 g). Selected NMR data for **3**: ^{31}P{^{1}H} NMR ($CDCl_3$): 26.86 (s); δ_H($CDCl_3$): 6.82 (s, 1H, Ar-*H*), 2.91 (d, J_{PH} = 1.9 Hz, 2H, Ar-CH_2-P), 2.49 (s, 3H, Ar-CH_3), 2.47 (s, 3H, Ar-CH_3), 2.13 (s, 3H, Ar-CH_3), 2.03 (s, 3H, Ar-CH_3), 1.10 (d, J_{PH} = 10.3 Hz, 18H, 2 P-C(CH_3)$_3$; δ_H($CDCl_3$): 32.05 (d, J_{PC} = 26.4 Hz, 2 (CH$_3$)$_3$*C*-P), 29.71 (d, J_{PC} = 13.4 Hz, 2 (*C*H$_3$)$_3$C-P), 24.15 (d, J_{PC} = 29.5 Hz, Ar-*C*H$_2$-P), 21.89 (d, J_{PC} = 6.8 Hz, Ar-*C*H$_3$), 20.38 (s, Ar-*C*H$_3$), 18.17 (d, J_{PC} = 10.9 Hz, Ar-*C*H$_3$), 15.87 (s, Ar-*C*H$_3$). Published on the Web 4th August 2000

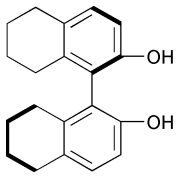
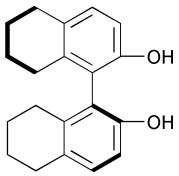
The asymmetric hetero-Diels–Alder reaction of Danishefsky's diene and an aldehyde catalyzed by 20 mol% chiral H_8-BINOL–Ti(IV) affords the corresponding 2-substitutent-2,3-dihydro-4*H*-pyran-4-one with ees of up to 99% under mild reaction conditions.

The formal hetero-Diels–Alder reaction between 1-methoxy-3-(trimethylsilyloxy)buta-1,3-diene and aldehydes provides useful access to dihydropyrones, a class of compounds with extensive utility in organic synthesis.[1] Asymmetric catalysis of this reaction has been previously reported by a number of investigators.[2] Corey *et al.* found that the tryptophan-derived oxazaborolidine catalyst gave good yields and moderate enantioselectivities for the reaction of Danishefsky's diene with representative aldehydes.[2a] Keck *et al.* reported that catalysts generated using 2 : 1 BINOL–Ti(O-i-Pr)$_4$ in the presence of 4 Å



(*R*)-H_8-BINOL



(*S*)-H_8-BINOL

MS and 0.0003 equiv. of CF_3CO_2H led to dihydropyrones in Et_2O with good to excellent ee.[2b] Jacobsen and co-workers developed some chiral (Salen)Cr(III) catalysts which afforded cycloadducts with good enantioselectivity.[2c] However, progress in the area of asymmetric hetero-Diels–Alder reactions has been limited. A catalyst that can be used with a wide range of substrates will be pursued.

5,5′,6,6′,7,7′,8,8′-octahydro-1,1′-bi-2-naphthol (H_8-BINOL) is a new atropisomeric diol ligand, which possesses a unique structure compared to conventional BINOLs.[3] Chan *et al.* reported its outstanding asymmetric induction ability in the asymmetric alkylation of aromatic aldehydes with triethylaluminium.[4] Herein, we wish to describe that chiral H_8-BINOL–Ti(O-i-Pr)$_4$ complexes are more effective catalysts than BINOL–Ti(O-i-Pr)$_4$ and others for the asymmetric hetero-Diels–Alder reactions.

Our studies started with benzaldehyde as a test substrate. A H_8-BINOL–Ti(O-i-Pr)$_4$–4 Å MS system was found to be the most promising catalyst for this reaction. In toluene solvent and at 0 °C, benzaldehyde gave (*R*)-2-phenyl-2,3-dihydro-4*H*-pyran-4-one in 92% isolated yield with 97% ee (Table 1, entry 1). Further studies showed that several parameters were important for both the reactivity and enantioselectivity of the cycloaddition reaction. The best results were obtained when 1.1 equiv. of (*R*)-H_8-BINOL were used per Ti. A solvent study showed that toluene provided the best overall results.[5] The yield and enantioselectivity were also found to be dependent on temperature. When the reaction was carried out below 0 °C, dihydropyrone was obtained in lower conversion and enantioselectivity. The optimal temperature ranged between 0 and 14 °C depending on the aldehydes used. At rt, high yield (92%) and enantioselectivity (93% ee) were also obtained (Table 1, entry 3). It should be noted that the ee of 93% was particularly high at rt, since most precedent catalytic asymmetric hetero-Diels–Alder reactions require a rather low temperature (−78 to −30 °C) to attain a good level of enantioselectivity. The amount of the catalyst was also revealed to be an important parameter for the attainment of high enantioselectivity. When the amount of catalyst was reduced to 10 mol%, the enantioselectivity of the reaction was decreased considerably (Table 1, entries 1 and 2).

Encouraged by the result obtained for benzaldehyde (Table 1, entry 1), we investigated a number of other aldehydes to probe their behavior under the current catalyst conditions. As shown in Table 1, the aromatic, heteroaromatic, conjugated and aliphatic aldehydes afforded the corresponding product in moderate to high isolated yield with quite high ee. A comparison of the experimental results (Table 1, entries 1, 4–11) revealed the effect on enantioselectivity by *ortho*-substitutents on benzaldehyde. This was probably due to the

[a] All reactions were carried out using 20 mol% of catalyst as detail in the experimental procedure,[6] unless otherwise mentioned. [b] All yields are isolated yields. Satisfactory spectral data (^{1}H NMR, ^{13}C NMR, IR) and C, H, N combustion analyses were obtained for the new compounds. [c] In all cases ee was determined by HPLC using a chiral column (chiracel OD), unless otherwise mentioned. [d] Determined by GC using a chiral column (Cyclodex-β). Absolute configurations were *R*, which were determined by comparison of optical rotations with literature values.[2c,e] The reactions were carried out using 10 mol% of catalyst as detail in the experimental procedure.[7] [f] Determined by HPLC using a chiral column (chiracel AD). [g] Absolute configurations were *R*, which were determined by comparison of optical rotations with literature values.[2c]

DOI: 10.1039/b004813p

strong steric hindrance effect of the *ortho*-substitutents, which weakened the coordination of the aldehyde and consequently lowered the enantioselectivity of reaction. These results are consistent with Chan *et al's* report about asymmetric alkylation of aromatic aldehydes with triethylaluminium.[4] The precise structure of the catalyst is not clear at present. An investigation of the mechanism is underway.

In conclusion, we have developed a new, highly efficient method for the synthesis of chiral 2-substitutent-2,3-dihydro-4*H*-pyran-4-one from aldehydes and Danishefsky's diene using chiral H_8-BINOL-Ti(IV).[3] High levels of enantioselectivity in the synthesis of 2-substitutent-2,3-dihydro-4*H*-pyran-4-one with wide substrate generality were obtained according to this reaction.

5 A series of solvents was screened including toluene, TBME, CH_2Cl_2, DMF, Et_2O and THF.

6 A typical experimental procedure is given for the synthesis of (*R*)-2-phenyl-2,3-dihydro-4*H*-pyran-4-one: a mixture of (*R*)-H_8-BINOL (16.2 mg, 0.055 mmol), 1 M Ti(O-i-Pr)$_4$ in CH_2Cl_2 (50 μl, 0.05 mmol), and activated powdered 4 Å molecular sieves (120 mg) in toluene (1 ml) was heated at 35 °C for 1 h. The yellow mixture was cooled to rt, and benzaldehyde (26 μl, 0.25 mmol) was added. The mixture was stirred for 10 min and cooled to 0 °C. Danishefsky's diene (60 μl, 0.30 mmol) was added. The mixture was stirred at 0 °C for 24 h, then it was treated with 5 drops of TFA. After the mixture was stirred for 15 min at 0 °C, saturated $NaHCO_3$ (1.5 ml) was added, the mixture was then stirred for 10 min and filtered through a plug of Celite. The organic layer was separated, and the aqueous layer was extracted with ether (5 × 3 ml), the combined organic layers were dried over Na_2SO_4 and concentrated. The crude residue was purified by flash chromatography (petroleum ether–ethyl acetate, 4 : 1) to yield (*R*)-2-phenyl-2,3-dihydro-4*H*-pyran-4-one (40 mg, 0.23 mmol, 92% yield) as a clear oil. The isolated material was determined to be in 97% ee by chiral GC analysis (cyclodex-β, 159 °C, 20 min, isothermal, t_S(minor) = 14.43 min, t_R(major) = 14.66 min).

7 1-Methoxy-3-(trimethylsilyloxy)buta-1,3-diene was purchased from Lancaster with 95% content.

Novel diphosphite derived from D-*gluco*-furanose provides high regio- and enantioselectivity in Rh-catalysed hydroformylation of vinyl arenes

Both high enantioselectivity (91%) and high regioselectivity (98.8%) are achieved under mild reaction conditions in the Rh-catalysed hydroformylation of vinyl arenes with a new chiral diphosphite ligand derived from the readily available D-(+)-glucose.

Asymmetric hydroformylation has attracted much attention as a potential tool for preparing enantiomerically pure aldehydes. These are important as precursors for synthesising biologically active compounds, biodegradable polymers and liquid crystals.[1] In the last ten years, several studies have reported a remarkable improvement in the rhodium-catalysed asymmetric hydroformylation based on the use of diphosphite[2] or phosphine–phosphite[3] (Binaphos) ligands. At the moment, Binaphos is the only ligand with a wide scope in asymmetric hydroformylation, although its difficult preparation limits its application. Furthermore, its regioselectivy in 2-phenylpropanal is not completely satisfactory even under carefully optimised conditions.[3] More recently, perfluoroalkyl substituents at the aryl group of the Binaphos increased the regioselectivity, in the best case up to 96%, but high pressures and an excess of ligand were still needed for good enantioselectivities.[4] In this context, much research still needs to be done to find ligands that are readily available and provide both good regio- and enantioselectivities in asymmetric hydroformylation.

In the last few decades carbohydrates have been widely used in asymmetric synthesis.[5] Nevertheless their full potential in providing chiral ligands has scarcely been exploited[6] despite the accessibility and low cost of the carbohydrate synthons. In previous work on diphosphite ligands with a furanose backbone moderate results (up to 60% ee) in asymmetric hydroformylation of styrene have been reported.[7] Since these ligands had a phosphorus moiety bonded to a nonstereogenic center (C-5), we tested whether further modifying the ligand would improve enantioselectivities. With this purpose and following from our interest in using carbohydrates as a chiral source for preparing ligands,[7b,8] we designed a new diphosphite ligand **4** which was easily prepared from D-(+)-glucose. This ligand has the two phosphite moieties bonded to two stereogenic centers (C-3 and C-5) and has proven to be highly enantioselective and regioselective in the asymmetric hydroformylation of vinylarenes (Scheme 1).

Diphosphite **4**[9] was synthesised in 3 steps from 1,2-*O*-isopropylidene-3-*O*-acetyl-α-D-glucofuranose **5** as shown in Scheme 2. Diol **5** is easily prepared from D-(+)-glucose on a large scale by previously described highly effective methods.[10] Tosylation of **5** produced a good yield of the expected 5-tosyl derivative (88%).[11] Treatment with NaOMe at rt followed by reduction with lithium aluminium hydride produced crystalline 6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose **7** in 92% yield.[12]

Reacting diol **7** with two equiv. of 3,3′-di-*tert*-butyl-5,5′-dimethoxy-1,1′-biphenyl-2,2′-diyl phosphorochloridite[13] *in situ* formed in the presence of pyridine produced the desired diphosphite **4** in good overall yield.

Scheme 1

Ligand **4** was used in the rhodium-catalysed asymmetric hydroformylation of styrene and other vinylarenes.[14] Results are given in Table 1. In no cases were hydrogenated or polymerised products observed.

Varying the ligand-to-rhodium ratio shows that it is not necessary to have excess ligand to obtain good regio- and enantioselectivities (entries 1–2). This contrasts with Rh–Binaphos systems, for which a large excess of ligand is needed.[3,4] Moreover, activities were best at low P_{CO}–P_{H2} ratios

(entry 3). This is in line with detailed kinetic studies on rhodium-catalysed hydroformylation with bulky phosphites reported by van Leeuwen *et al.*, who showed that the rate-determining step is the oxidative addition of H_2 to the acyl–rhodium complex.[15] Comparing entries 1 and 3 also shows that regio- and enantioselectivities are not affected by varying the partial pressure of CO. A remarkable increase in enantioselectivities (up to 91%, entries 4–6) combined with excellent regioselectivities (up to 98.8%) were found by lowering the reaction temperature. There were no changes in the enantioselectivities over time, which indicates that no decomposition of the catalyst took place.

Results were similar when **4** was used in the asymmetric hydroformylation of the substituted vinylarenes **1b** and **1c**. The presence of different substituents in the *para* position does not seem to affect the conversion or the regio- and enantioselectivities of the hydroformylation.

In conclusion, a novel chiral diphosphite **4**, derived from readily available D-(+)-glucose, is a highly efficient ligand for the asymmetric rhodium-catalysed hydroformylation of vinyl arenes under mild reaction conditions and without an excess of ligand. The combination of excellent regio- and enantioselectivities (up to 98.8 and 91% respectively) in simple unoptimised reactions and the low cost of the ligand make this catalyst system attractive for further investigation of its potential use for the industrial preparation of biologically active compounds in asymmetric hydroformylation. Studies of the scope and mechanistic aspects of the catalytic process are currently in progress.

Received (in Cambridge, UK) 18th May 2000, Accepted 11th July 2000
Published on the Web 4th August 2000

Zeolites P1 and SUZ-4 with enhanced Si/Al ratios (*ca.* 4.9 and 8.2) compared to previously reported isostructural materials have been synthesized in the presence of *N,N,N,N′,N′,N′*-hexaethylpentanediammonium together with Na^+ and K^+ ions, respectively.

The use of the doubly charged cation *N,N,N,N′,N′,N′*-hexaethylpentanediammonium (Et_6-diquat-5) as an organic structure-directing agent (SDA) in the synthesis of zeolites was first attempted by Valyocsik and Page in 1986.[1] It has been shown that this diquarternary cation can direct the crystallization of ZSM-57 (MFS topology) with the intersecting 10- and 8-ring channel system when used together with Na^+ ions.[2] Very recently, we have studied zeolite synthesis related to the use of a series of diquarternary cations with different chain lengths and found that the type and amount of alkali metal cations added to the synthesis mixture may play a major role in determining the phase selectivity of the crystallization.[3]

Zeolite P1 is the synthetic analogue of the GIS-type zeolites and contains a two-dimensional pore system with two intersecting 8-ring channels.[4] On the other hand, SUZ-4,[5,6] a new zeolite closely related to ferrierite and ZSM-57, has been considered to have a topology that corresponds to the hypothetical model 5b described by Gramlich-Meier.[7] To our knowledge, the only organic SDA leading to the successful SUZ-4 formation is the tetraethylammonium cation.[8] Here, we report for the first time, the synthesis of zeolites P1 and SUZ-4 from sodium- and potassium-containing aluminosilicate gels in the presence of Et_6-diquat-5, a new organic SDA for these structure-types of materials.

In a typical synthesis of zeolite P1, 0.48 g of $Al(NO_3)_3{\cdot}9H_2O$ (98%, Junsei) and 2.20 g of NaOH (50% aqueous solution, Aldrich) were dissolved into 22.01 g of H_2O. To this clear solution, 5.63 g of colloidal silica (Ludox AS-40, DuPont) and 2.48 g of Et_6-diquat-5 dibromide prepared according to the procedure described elsewhere[1] were added. The oxide composition of the resulting gel was $4.5Et_6$-diquat-5 : $11.0Na_2O$: 1.0-Al_2O_3 : $30SiO_2$: $1200H_2O$. For the crystallization of SUZ-4, NaOH was replaced by an equivalent amount of KOH (45% aqueous solution, Aldrich) under the conditions described above. After stirring at room temperature for 1 day, the final synthesis mixture was transferred to Teflon-lined 45 mL autoclaves and heated at 160 °C under slow rotation (60 rpm) for 8 days. The white solid products were recovered by filtration, washed repeatedly water, and then dried overnight at room temperature.

Fig. 1 shows the typical powder X-ray diffraction patterns (Rigaku Miniflex, Cu-Ka radiation) of P1 and SUZ-4 prepared here. Comparison of the patterns in Fig. 1 with those in the literature[6,9] reveals that both materials are highly crystalline and no reflections other than those from the corresponding zeolites are observed. This can be further supported by the N_2 adsorption data (Micromeritics ASAP 2410) of P1 and SUZ-4 calcined at 500 °C for 6 h to remove the occluded organic species, from which the BET surface areas of 124 and 370 $m^2\ g^{-1}$ were derived, respectively. SEM photographs (JEOL JSM-6300) show that zeolite P1 appears as agglomerates of small (1.5–2.0 μm), heavily overlapped cuboids, while SUZ-4 consists of needle-like crystals that are *ca.* 1 μm in length and 0.2 μm in diameter. On the other hand, it can be seen from the ^{13}C-^1H CP/MAS NMR spectra (Fig. SI 1, ESI†) of as-synthesized P1 and SUZ-4 that both samples exhibit three main resonances around δ 54, 21 and 8, which can be assigned to the methylene carbons bonded to the nitrogen, the methylene carbons in the pentyl chain and the methyl carbons in the ethyl groups of Et_6-diquat-5, respectively. This indicates that the organic SDA remains intact upon its occlusion in the P1 and SUZ-4 pores. A combination of elemental and thermal analyses reveals, within experimental error, that as-synthesized P1 and SUZ-4 zeolites have the chemical compositions (Et_6-diquat-5)$_{0.6}Na_{1.8}Al_{2.7}$-$Si_{13.3}O_{32}{\cdot}2.0H_2O$ and (Et_6-diquat-5)$_{1.2}K_{2.0}Al_{3.9}Si_{32.1}$-$O_{72}{\cdot}4.8H_2O$, respectively. Thus, there is a small but non-negligible dissimilarity between the amount of Al and the sum of Et_6-diquat-5 and alkali metal cations for the unit cell formula of each material. This suggests that a portion of the organic occluded is present in either bromide or hydroxide form to act as a space-filling species. Also, it should be noted that the Si/Al ratios (4.9 and 8.2) of P1 and SUZ-4 zeolites prepared here are higher than those of previously known isostructural materials. The Si/Al ratios for all the natural and synthetic GIS-type zeolites reported so far are always in the range 1.0–3.2,[4,10] while SUZ-4 materials are known to have a narrow Si/Al ratio range of 6.2–7.1.[5,6,8] The enhanced Si/Al ratios of our P1 and SUZ-4 zeolites can be rationalized by considering that the length (*ca.* 15 Å) of the Et_6-diquat-5 used as an organic SDA here is much larger than that of the already known SDAs (*e.g.* tetramethylammonium and tetraethylammonium cations) for these materials.

DOI: 10.1039/b004004p

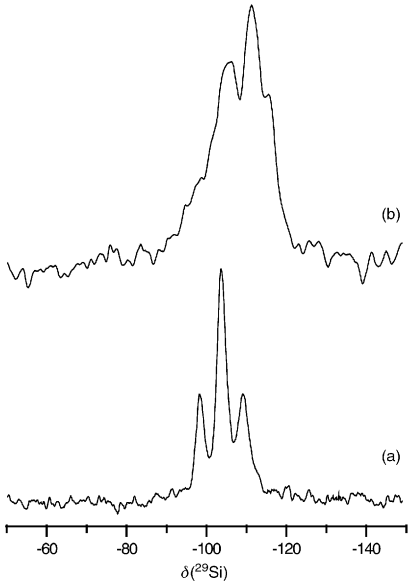

Fig. 2 ^{29}Si MAS NMR spectra of as-synthesized (a) P1 and (b) SUZ-4 zeolites. Spectra recorded on a Bruker DSX 400 at 12 kHz spinning rate, 60 s recycle delay, 79.459 MHz, π/5 rad, 2 μs pulse length, 1200 scans.

The ^{27}Al MAS NMR measurements (Bruker DSX 400, 13.0 kHz spinning rate) show that as synthesized P1 and SUZ-4 exhibit only one line at δ 58.2 and 52.7, respectively, typical of tetrahedral Al sites in zeolites (Fig. SI 2, ESI†). The ^{29}Si MAS NMR spectra of these phases are shown in Fig. 2. The spectrum of zeolite P1 is characterized by three ^{9}Si resonances at δ −109.8, −104.1 and −98.6, assigned to Si(*n*Al) species with *n* = 0, 1 and 2, respectively. Deconvolution of this spectrum allowed us to calculate a Si/Al ratio of 4.5 for our P1 that is in good agreement with the value determined from elemental analysis. On the other hand, the ^{29}Si MAS NMR spectrum of SUZ-4 shows three main resonances at −115.1, −111.3 and −106.8. We note here that the high-field resonance has not been clearly found in the reported spectrum of an SUZ-4 material with Si/Al = 6.4.[9] This again confirms the enhanced Si/Al ratio of SUZ-4 prepared here, although the existence of multiple T-sites in the proposed framework of SUZ-4 makes it impossible to determine accurately the framework Si/Al ratio from its ^{29}Si MAS NMR spectrum at this time. Further details on the physicochemical properties of our P1 and SUZ-4 will be given elsewhere.[11]

The overall synthetic results of this study reveal that the crystallization conditions and the oxide composition of synthesis mixtures yielding pure P1 or SUZ-4 in the presence of Et_6-diquat-5 are restricted within narrow limits, which is quite similar to the trend found in the synthesis of ZSM-57 using the same organic SDA.[3] When trying to reproduce the synthesis of zeolite P1 under static conditions, for example, the synthesis mixture remains amorphous even after heating at 160 °C for 2 weeks. By contrast, a MOR zeolite is the phase that crystallizes from the synthesis mixture with Si/Al = 20 under stirring in conditions described above. Thus, it appears that the structure-directing ability of the organic Et_6-diquat-5 itself is not strong enough to govern the crystallization of P1 and SUZ-4. This suggests that the synergy of alkali metal cations and a particular organic Et_6-diquat-5 may be a critical factor affecting the phase selectivity of the crystallization, although the exact role of alkali cations in the Et_6-diquat-5-mediated synthesis of P1, SUZ-4, and ZSM-57 remains to be elucidated. In order to follow a more rigorous study on this issue, extensive investigations of the host–guest interactions in these zeolites are currently underway in our laboratory.

A neutral dicopper(III) bis(μ-oxo) complex from a copper(I) ethylene iminophosphanamide and O_2†

Bernd F. Straub, Frank Rominger and Peter Hofmann*

Published on the Web 4th August 2000

The copper(I) ethylene complex [$Bu^t_2P(NSiMe_3)_2$-κ^2N]Cu(η^2-C_2H_4) reacts with O_2, yielding an uncharged dinuclear copper(III) bis(μ-oxo) species, which has been fully characterized, *e.g.* by single-crystal X-ray diffraction.

Tyrosinase, the longest known monooxygenase, activates dioxygen for transforming phenols to catechols and quinones.[1] Similar to hemocyanin, the oxygen transport protein of invertebrates, tyrosinase contains a dinuclear copper site, where each copper atom is coordinated by three histidine imidazole ligands.[2] A great number of model complexes have been synthesized to realize different coordination modes of dioxygen in dinuclear copper complexes and to understand their reactivity.[3] Amine, pyridine, imidazole and pyrazole derivatives have been utilized as ligands. The coordination number at copper, the steric demand of ligands as well as counter ions, temperature and solvent have been varied in order to correlate ligand features with spectroscopic, structural, kinetic and thermodynamic data of the resulting (μ-η^2:η^2)peroxo,[3,4] μ-1,2-peroxo[5] and bis(μ-oxo)[6] dicopper complexes. Despite intense research directed towards ligand effects in copper dioxygen chemistry, neither extremely electron-rich and basic ligands nor four-membered chelate systems have been investigated.

We have introduced the anionic iminophosphanamide ligand $[Bu^t_2P(NSiMe_3)_2]^-$ into copper(I) coordination chemistry.[7] Its basicity is many orders of magnitude higher than that of any ligand used in copper dioxygen chemistry so far. In addition, the small N–Cu–N bite angle of the neutral d^{10} fragment [Bu^t_2P(N-$SiMe_3)_2$-κ^2N]Cu of *ca.* 78° leads to increased Lewis acidity of the copper center, provides better back-bonding capability and stabilizes the copper(III) oxidation state.[7,8]

The copper(I) ethylene complex **1**[7] is oxidized by O_2, yielding a brown crystalline precipitate of bis(μ-oxo) complex **2** (Scheme1).‡ The reaction is irreversible; no ethylene complex **1** could be detected upon addition of C_2H_4 to a solution of **2**.

The low solubility of **2** in various solvents is in contrast to the extremely high solubility of the precursor complex **1**. A 444 nm absorption maximum of **2** is characteristic for a bis(μ-oxo) dicopper chromophore.[3,6] Formation of a butterfly (μ-η^2:η^2)peroxo dicopper(II) complex, which also would show an absorption band at 420–490 nm,[9] is hampered by the bulky trimethylsilyl groups (*viz.* Fig. 1) and so far an out-of-plane distortion could only be enforced by linkers between the ligand units. Even in concentrated solutions, no absorption bands at 340–370 nm 500–600 nm, indicative of the presence of a (μ-η^2:η^2)peroxo complex, could be observed. Thus, a nearly thermoneutral equilibrium of **2** with its (μ-η^2:η^2)peroxo isomer, as reported for some dicationic analogues,[3,6a] can be ruled out.[3,4] $^{29}Si\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra of **2** at room temperature are in accordance with a diamagnetic low-spin d^8-ML_4 copper(III) species. The respective low-field shifts, unprecedented among all other derivatives synthesized so far, indicate a distinct net charge transfer from the [Bu^t_2P-$(NSiMe_3)_2$-κ^2N]Cu fragment to the oxygen atoms.[7,10] An antiferromagnetically coupled bis(μ-hydroxo) dicopper(II) complex is ruled out for **2** by IR spectroscopy and LT-FAB[11] mass spectrometry, which reveals stepwise fragmentation of the bis(μ-oxo) complex **2**.† At ambient temperature, complex **2** decomposes within minutes in solution and within days in the solid state. This decomposition occurs independently of the solvent (pentane, toluene or $CDCl_3$), leading to a copper(II) species (λ_{max} = 640 nm, $\varepsilon \approx 10^2$ M^{-1} cm^{-1}), which possibly results from an intramolecular process. The product remains unidentified so far.

The solid-state structure of **2** reveals a perfectly planar bis(μ-oxo) dicopper unit (Fig. 1).§ Compound **2** represents the first neutral bis(μ-oxo) dicopper complex, that has been structurally characterized; all other bis(μ-oxo) dicopper complexes are dicationic.[3,6] The Cu–Cu distance of 2.906(1) Å has no precedent and is distinctly longer than Cu–Cu distances reported for bis(μ-oxo) dicopper cores so far.[6] The O–O

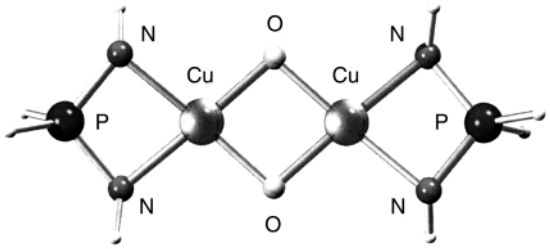

Fig. 2 Ball-and-stick plot of the model complex $[\{H_2P(NH)_2\text{-}\kappa^2N\}_2Cu_2(\mu\text{-}O)_2]$ **3** [B3LYP/6–311+G(2d,p), NIMAG = 0].§ Distances and bond lengths (Å): O–O 2.330, Cu–Cu 2.739, Cu–N 1.969, Cu–O 1.798, P–N 1.613. Bond angles (°): N–P–N 99.55, P–N–Cu 91.52, N–Cu–N 77.41, O–Cu–O 80.77, Cu–O–Cu 99.23. Dihedral angles (°): Cu–O–Cu′–O′ 0.0, N–Cu–O–O′ 174.2. NBO charges: Cu +1.40, O –0.93, N –1.32, P +1.55.

distance of 2.338(6) Å is unexceptional.[6] The Cu–N bond lengths of 1.980(4) and 1.976(4) Å underline the presence of copper(III), consistent with all spectroscopic data even in the absence of K-edge X-ray absorption investigations.[12] The minimally elongated Si–N bonds compared to ethylene complex **1** can be attributed to the reduced negative partial charge of the nitrogen atoms in **2**. For the first time, the neutral species **2** offers an opportunity to compare theoretical and experimental geometries without Coulomb repulsion artifacts, which are a problem for calculations of gas-phase dications.

Full B3LYP 6-311+G(2d,p) geometry optimization of the simplified model complex $[\{H_2P(NH)_2\text{-}\kappa^2N\}_2Cu_2(\mu\text{-}O)_2]$ **3** accurately reproduces the PN_2Cu geometry.¶ The Cu_2O_2 core is similar to that of the dicationic bis(μ-oxo) dicopper(III) complexes,[3,6] however, the calculation underestimates the Cu–O bond length by 0.066 Å and the Cu–Cu distance by 0.167 Å compared to the solid-state structure of **2** (Fig. 2).

From CASSCF and DFT calculations as well as from orbital arguments for the dicationic model $[\{(H_3N)_3Cu\}_2(\mu\text{-}O)_2]^{2+}$, Tolman and coworkers have rationalized that the energy surface for elongating the Cu_2O_2 core of bis(μ-oxo) copper complexes in the Cu–Cu direction, with concomitant decrease of the O–O distance, is flat.[13] This is corroborated by a single-point calculation for model **3** with the experimental Cu_2O_2 geometry of **2**, leading to an increase in energy of only 19.4 kJ mol^{-1}. Thus steric interactions in the solid-state structure of real system **2** and the need for a still higher level of theory may explain the discrepancy between the Cu_2O_2 cores of the computed model **3** and of **2**. By contrast, accurate $[(H_3N)_6Cu_2O_2]^{2+}$ geometries were obtained even with modest basis sets.[13] However, such studies on dications may benefit from a mutual cancellation of errors due to an underestimation of bond lengths by small basis sets§ and bond enlargement by repulsive Coulomb forces, respectively.

Related to the well documented small isomerization barrier between dicationic bis(μ-oxo) copper(III) and (μ-η^2:η^2)peroxo copper(II) complexes,[3,6a] a relative stabilization of the bis(μ-oxo) core in **2** can be expected from the electronic stabilization of high copper oxidation states by the iminophosphanamide ligand and the lack of intramolecular Coulomb repulsion, which would favor the peroxo isomer.[11] We expect compound **2** to allow further interesting model studies.

Polypyrrole films possessing regular macropores interconnected through size-controlled holes have been prepared by electrochemical oxidation in the presence of ordered arrays of silica spheres as templates.

Ordered porous ceramics, metals and polymers have attracted much attention currently because of their applications in catalysis, separation films, porous electrodes and photonic crystals. For synthesis of these materials, useful methods using emulsions[1] or colloidal crystals, which are comprised of submicron-sized monodisperse lateces[2–8] or silica particles,[9–12] as templates have been successfully developed. The advantages of the template-directed methods are mainly due to their size tunability and the simple procedure involving impregnation of the interstitial channels of templates with the desired precursors, reactions and subsequent removal of the templates.

Thus obtained macroporous materials generally possess two types of characteristic void closely related to the applications mentioned above. One is a macropore that is well controlled by the size of the particles that constitute the templates. The other is a smaller hole, which forms at each contact point between the nearest neighbor particles of templates and three-dimensionally connects each macropore. The size of these holes as well as the macropores strongly influence the mass transportation in the bulk of the porous materials. Therefore, the size control of these holes is the critical issue in the fields that require easy access to the high internal surface area of the materials and designed diffusion pathways. However, its control is more difficult than that of the macropores. This is because their size is sensitive to the degree of filling of the channels of the original templates which depends on the viscosity and concentration of precursors and shrinkage of materials when the precursors react. Consequently, there have been only a few reports in which the control of the interconnecting hole size has been achieved through changing the viscosity of the precursor which depends on temperature,[11] repetitions of the filling process[3] or sintering of templates to give larger contact areas between original particles.[9,10]

Recently, electrodeposition has been applied to colloidal template-directed synthesis toward complete impregnation of interstitial channels with group II–VI semiconductors.[13] The electrochemical technique should be an effective route not only for complete filling but also for governing the growth and volumes of materials being deposited in the complex channels *via* parameters such as potential and current that are easy to vary and monitor.

Here we describe the size control of the small interconnecting holes as well as the macropores in template-directed electrochemical synthesis of macroporous polypyrrole. This new material should be of practical value for electrochemical capacitor and battery material applications.

According to a convective self-assembly technique by Jiang *et al.*[14] which relies on capillary forces, we prepared silica colloidal crystals supported on F-doped SnO_2 coated glasses (OTE). An OTE was dipped into ethanol containing monodisperse silica spheres with a mean diameter of 238 nm. Because rapid ethanol evaporation led to poor uniformity of the thickness of the colloidal crystals, the OTE dipped into silica/ethanol dispersion was covered by a 200 mL beaker to slow the evaporation rate. After ethanol was evaporated for 5 days, opalescent colloidal crystals of 3.0 μm average thickness were deposited on the conducting surface. These colloidal crystals used as templates were hydrothermally treated at 473 K for 3 h at a heating rate of 2 K min^{-1} leading to slight necking between silica particles which mechanically stabilizes the templates.[9,10] The necking also resulted in a shrinkage of *ca.* 2% of the thickness compared to the as-grown crystals. Finally, the templates were washed with ethanol several times and kept in a vacuum desiccator until use. The electropolymerization was potentiostatically performed using 0.1 M pyrrole and 0.1 M $LiClO_4$ in acetonitrile solutions with a BAS 100W apparatus (Bioanalytical Systems, Inc.). The counter electrode was Pt wire and the reference electrode was Ag/Ag^+. After electropolymerization of pyrrole, the templates were dissolved by immersing in 20% HF aqueous solutions for 48 h. The polypyrrole films which were peeled off from the OTE were washed with deionized water and characterized by SEM (Hitachi S-800) without the requirement for deposition of metal because of the conductivity of polypyrrole.

Fig. 1 shows chronoamperometric responses of pyrrole polymerization at applied potentials of 0.55, 0.75 and 0.85 V *vs.* Ag/Ag^+. Transition points (marked by the arrows), where the current rapidly increased were observed and shifted toward shorter times at higher potentials. Similar transition points have been observed in template synthesis using membranes with topologically simple cylindrical pores.[15] These rapidly increased currents were suggested to be mainly caused by a rapid increase of the electrochemical reaction area when the growing surface of materials reached the membrane/bulk solution interface. In our case, the surfaces of the colloidal crystals were almost fully covered with cauliflower-like polypyrrole at

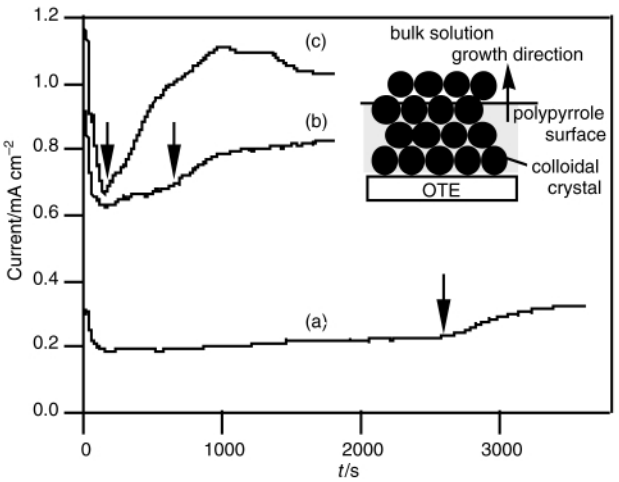

Fig. 1 Chronoamperometric responses of pyrrole electropolymerization in channels of silica colloidal crystals by applying (a) 0.55 V, (b) 0.75 V and (c) 0.85 V. The inset shows a schematic represetation of colloidal crystals and the growth direction of polypyrrole.

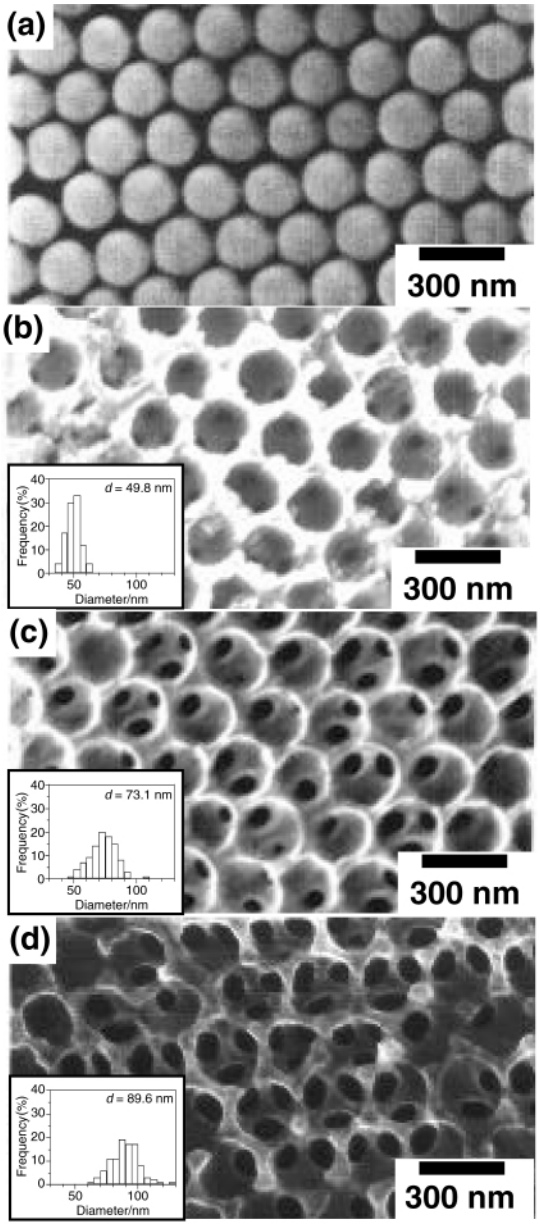

Fig. 2 SEM imges of (a) the original templates and the macroporous polypyrrole films prepared by applying (b) 0.55 V, (c) 0.75 V and (d) 0.85 V. The insets show the hole size distributions corresponding to each SEM image. The size distributions were determined by counting more than 200 holes.

deposition times beyond the transition points (data not shown). Hence, in the present colloidal template synthesis, the transition points are considered to appear according to a similar phenomenon as above. These transition points also should enable us to avoid covering the pores of the top surface of the films with excess polypyrrole.

Fig. 2 shows typical SEM images of the original templates and the macroporous polypyrrole prepared at various potential with electropolymerization stopped before each transition point. Fig. 2(b), (c) and (d) demonstrate that the polypyrrole films had honeycomb macroporous structures mirroring the ordered channels of the original templates [Fig. 2(a)] and smaller holes inside each macropore were clearly observed. As shown in the insets of Fig. 2, their average size increased with increasing polymerization potential from 49.8(5.68) to 73.1(10.6) to 89.6(11.2) nm (esds in parentheses) at 0.55, 0.75 and 0.85 V. These results demonstrated that simple potential change should allow the hole size to be controlled. At 0.55, 0.75 and 0.85 V, the center-to-center distances between the macropores were smaller by 0.1, 0.2 and 3% than the diameters of the original silica spheres, respectively. Taking into account the low shrinkage, the hole size is likely determined rather by incomplete filling during the electropolymerization process than by shrinkage of polypyrrole. The charges passed at each transition time were 0.8, 0.6 and 0.2 C at 0.55, 0.75 V and 0.85 V, respectively implying that smaller quantities of polypyrrole were deposited within the channels at higher potentials, which would decrease the degree of filling.

In conclusion, we have electrochemically prepared macroporous polypyrrole films using colloidal templates. Furthermore, we found that their smaller hole size could be controlled by changing the polymerization potentials. Preliminary experiments showed that this electrochemical control of the hole size can be extended to other templates with different diameters of silica spheres. More detailed mechanisms of the variation of the hole size and the growth of materials in three-dimensionally complex channels are under investigation by experiments with other conducting polymers and metals.

The present study was supported in part by the Japan Society for the Promotion of Science as part of the ‘Reserch for the Future Program’ and also by a Grant-in-Aid for Scientific Reserch from the Ministry of Education, Science, Sports and Culture of Japan.

The designed α-helical coiled-coil peptides, which contain nucleobase moieties at the amino acid side chains, were found to take a stable α-helical form owing to the base-pair interaction.

α-Helical coiled-coil, found in many natural proteins, is one of the well-studied motifs aiming to understand protein sequence–structure relationships,[1] and also to develop novel proteins with functional properties by *de novo* protein design.[2] The initial studies have focused on the usage of hydrophobic and electrostatic interactions between amino acid side chains to assemble α-helical peptide chains.[3] In this study we, for the first time, provide another example utilizing hydrogen bonds between nucleobases at amino acid side chains to form an α-helical coiled-coil. In nature, DNA and RNA take advantage of hydrogen bonds in their structures and functions. Sequence-complementarity of antiparallel strands and high-fidelity information transfer including transcription, translation, and replication are performed owing to the nucleobase-molecular complementarity through hydrogen bonds. Thus, peptides equipped with the nucleobase-molecular complementarity should gain new useful characters in their structure and function. In order to explore the applicability of nucleobase-complementarity in a peptide structure, we have introduced nucleobase amino acids (NBAs)[4] in a two-stranded α-helix with the coiled-coil motif (Fig. 1), and examined the effects on the peptide secondary structure.

We designed an antiparallel, two-stranded coiled coil QQ as a basic framework, based on the peptide designed by Zhou *et al*.[5] QQ consists of two amphiphilic α-helices, each containing a two-heptad repeat unit with the amino acid sequence $A_cL_dQ_eK_fQ_gL_aA_b$. In the design of the peptide, Leu residues at the a and d positions are expected to form a hydrophobic face, which drives coiled-coil formation through its burial in the interface. Gln residues are selected at the e and g positions to prevent induction of inter- or intrahelical electrostatic interactions. To produce a disulfide-bridged coiled-coil in an antiparallel fashion, the sequence Cys-Gly-Gly- is added to the N-terminus of one helix, and the sequence -Gly-Gly-Cys is placed at the C-terminus of the other helix. Since the Cα-Cβ vectors of amino acid at the g and g′ positions are pointed toward each other in antiparallel coiled-coils in the wheel diagram (Fig. 1c), NBAs were incorporated at the g and g′ heptad positions instead of Gln. Thereby, we expected the specific interaction between thymine NBA (T_{NBA}) and adenine NBA (A_{NBA}) in the two-stranded α-helix. We designed three peptides with T–A pair(s) at the g and g′ heptad positions; TA-1 has the pair apart from the disulfide-bridged end, TA-2 has the pair near the disulfide linker, and TA-1·2 contains pairs at both positions (Fig. 1).

TA-1·2	T_{NBA}	T_{NBA}	A_{NBA}	A_{NBA}

Fig. 1 (a) Structures of nucleobase amino acids (NBAs); (b) amino acid sequences; (c) helix wheel drawing of the designed peptides.

The designed peptides were synthesized manually by the solid-phase method using the Fmoc-strategy.[6] To introduce A_{NBA} and T_{NBA} to the Fmoc chemistry protocols, *N*-Fmoc-*L*-α-amino-γ-(6-*N*-benzyloxycarbonyl)adenine butanoic acid [Fmoc-A_{NBA}(Z)-OH] and *N*-Fmoc-L-α-amino-γ-thymine butanoic acid [Fmoc-T_{NBA}-OH] were prepared according to literature methods with some modifications.[7] All peptides were acetylated at the N-terminus and amidated at the C-terminus to avoid unfavorable helix–dipole interactions. To build an antiparallel heterodimer, an asymmetric disulfide bond formation between two peptides was performed *via* activation of the thiol function of one peptide by pyridinesulfenylation, and the reaction with the second peptide with the free thiol.[8] The peptides were purified by reversed-phase HPLC, and identified by matrix-assisted laser desorption time-of-flight mass spectrometry and amino acid analysis.[9] The concentrations of the peptides were determined by quantitative amino acid analysis using valine as an internal standard.

The circular dichroism (CD) spectra of the designed peptides in a buffer (pH 7.4) at 25 °C are shown in Fig. 2. All peptides showed spectra characteristic of an α-helical conformation with negative maxima near 208 and 222 nm and a positive maximum at 195 nm. The ratio of the molar ellipticities at 222 and 208 nm, $[\theta]_{222}/[\theta]_{208}$, was reduced in a solution containing trifluoroethanol, known as a solvent enhancing an α-helix form but isolating a helix-dimer, indicating two-stranded α-helical formation in the buffer. The $[\theta]_{222}$ values of TA-1 and TA-2, both having a T–A pair, were −20500 and −22100 deg cm^2 dmol^{-1}, respectively, showing their higher helical contents than the content of QQ ($[\theta]_{222}$ = −15100 deg cm^2 dmol^{-1}). Furthermore, TA-1·2 having two T–A pairs showed a higher α-helicity ($[\theta]_{222}$ = −23800 deg cm^2 dmol^{-1}) than TA-1 and TA-2. We assumed that this helix-inducing effect was not the result of the peptide aggregation, judged from the concentration independence of the $[\theta]_{222}$ values of designed peptides (ranging

DOI: 10.1039/b004318o

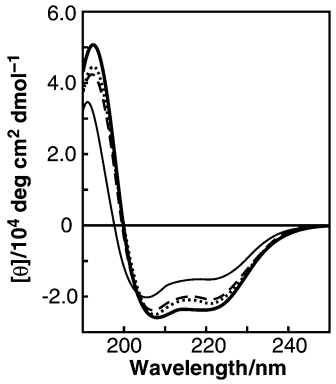

Fig. 2 CD spectra for the designed peptides in 2.0×10^{-2} mol dm^{-3} Tris·HCl buffer (pH 7.4) at 25 °C. [Peptide] = 1.0×10^{-5} mol dm^{-3}. QQ, (——); TA-1, (– – –); TA-2, (-----); TA-1·2, (▬).

from 7.5×10^{-7} to 1.0×10^{-4} mol dm^{-3}). The addition of an excess amount of exogenous adenine reduced the α-helical contents in the cases of peptides possessing T–A pair(s) ($\Delta[\theta]_{222}$ = 6500 deg cm^2 dmol^{-1} in TA-1·2), whereas no change occurred in the case of QQ.[10] This demonstration implied that the added interaction between A and T increases the α-helical content.

Denaturation studies were carried out to determine the stabilities of the peptides. With increasing temperature of the peptide solution, the bimodal spectra were gradually converted into those of a random conformation, indicating the decrease of the fraction of α-helix structure. The presence of an isodichroic point at *ca*. 202 nm was consistent with the helix-coil transition. From the temperature dependence of $[\theta]_{222}$ shown in Fig. 3, it was apparent that the thermal stabilities of the nucleobase-containing species, especially TA-1·2, were noticeably increased as compared to the stability of QQ. Furthermore, the guanidine hydrochloride (GuHCl) denaturation study also provided the observation of the stabilizing effect in nucleobase-containing peptides (Table 1). The incorporation of one T–A pair in the two-stranded α-helix (TA-1 and TA-2) made peptides with a higher stability than QQ, and the additional incorporation (TA-1·2) afforded further stability to the peptide. TA-2 is slightly more stable than TA-1, which is consistent with the α-helicity. An explanation may be the difference of the position of a T–A pair (Fig. 1). In TA-2 the pair was located near the disulfide-linker so that T and A might configure to interact at g–g′ positions, whereas in TA-1 the pair was at the end leading to fluctuation of T and A. Moreover, the effect of nucleobase-incorporation on the helix stability was not additive. The incorporation of one T–A pair into QQ increased ΔGu^{H_2O} by 0.56 (TA-1) and 0.90 kcal mol^{-1} (TA-2), whereas two T–A pairs increased greatly by 1.88 kcal mol^{-1}.

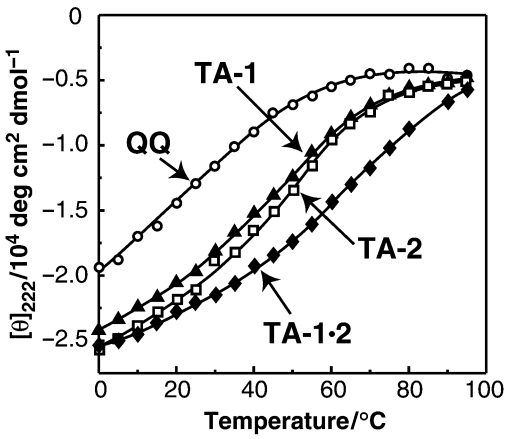

Fig. 3 Temperature dependence of the CD signal at 222 nm for QQ, TA-1, TA-2, and TA-1·2 in 2.0×10^{-2} mol dm^{-3} Tris·HCl buffer (pH 7.4).

Table 1 Stabilities of the designed peptides estimated by GuHCl denaturation

Peptide	QQ	TA-1	TA-2	TA-1·2
ΔGu^{H_2O}[a]/kcal mol^{-1}	0.74	1.30	1.64	2.62
$\Delta\Delta Gu^{H_2O}$[a]/kcal mol^{-1}	0	0.56	0.90	1.88
$[GuHCl]_{1/2}$[b]/mol dm^{-3}	1.7	2.0	2.3	3.2
$\Delta[GuHCl]_{1/2}$[b]/mol dm^{-3}	0	0.3	0.6	1.5

[a] ΔGu^{H_2O} is the free energy of unfolding in the absence of GuHCl at 25 °C, estimated according to the equation: $\Delta Gu = \Delta Gu^{H_2O} - m[GuHCl]$, where m is the slope term. ΔGu is calculated from the equation: $\Delta Gu = -RT\ln[(1 - fn)/fn]$.[11] [b] The $[GuHCl]_{1/2}$ values represent the concentration of GuHCl at which 50% of the peptide is unfolded.

We also examined the peptides having two T–T pairs (TT-1·2) or two A–A pairs (AA-1·2) at the g–g′ positions in the two-stranded α-helix. However, these mismatch pairs did not significantly improve the α-helical form unlike T–A pairs (TT-1·2, $[\theta]_{222}$ = −17800; AA-1·2, $[\theta]_{222}$ = −18100 deg cm^2 dmol^{-1}). These results strongly suggest that the specific interaction between the T–A pair is important in promoting the α-helical formation. In such a case of the specific pair(s), T and A in the two-α-helix might orient and interact in the appropriate fashion. One possible interaction might be base stacking (hydrophobic interaction), and another might be hydrogen-bonding. The former does not contribute greatly to the helix formation, because the α-helical content of AA-1·2, containing two A–A mismatch pairs, is not as large as that of TA-1 or TA-2. In respect to the latter interaction, the pH dependence of $[\theta]_{222}$ revealed that T–A-containing peptides took a higher helical form under neutral conditions than under acidic or basic conditions. The protonation of nucleobases had an influence on the interaction between T and A, suggesting a large contribution of the hydrogen-bonding interaction. Although detailed inspection is necessary to answer how these bases interact and induce the helical structure, the specific interaction, including the hydrogen-bonds, were successful at stabilizing two-stranded α-helix structures.

In conclusion, peptides containing NBAs at the g–g′ positions in the coiled-coil structure were synthesized, and the incorporated A–T nucleobase pairs were found to make an effective contribution to the formation of stable α-helical structures. The base-pair interaction can be utilized as a new tool for designing secondary or tertiary peptide structure, and also applied to development of novel functions based on the complementarity.

Published on the Web 8th August 2000

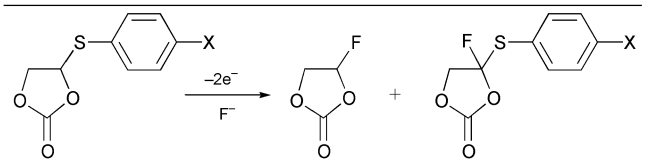
This is the first example of a solvent effect on fluorinated product selectivity; anodic fluorination of 4-arylthio-1,3-dioxolan-2-ones in CH_2Cl_2 containing a fluoride supporting electrolyte using an undivided cell provided the fluorodesulfurization product, 4-fluoro-1,3-dioxolan-2-one preferentially while anodic fluorination in DME resulted in α-fluorination, without desulfurization, selectively.

Fluorinated ethylene carbonates seem to be promising organic electrolytic solvents or additives for rechargeable Li batteries since introduction of fluorine atom(s) into ethylene carbonate is expected to increase its electrochemical stability and decrease its melting point. We have studied selective anodic fluorination of various organic compounds.[1,2] The selective anodic fluorination has many advantages since the fluorination can be carried out in one step under safe conditions and the use of hazardous reagents is not required. So far, limited examples of selective anodic fluorination of oxygen-containing heterocycles have been reported.[3] With these facts in mind, we have attempted anodic fluorination of ethylene carbonates having an arylthio group **1** using various supporting fluoride salts and solvents.

At first, we investigated anodic fluorination of 4-phenylthio derivative **1a** under various conditions. Constant current electrolysis was carried out at platinum plate electrodes in an undivided cell at rt until **1a** was completely consumed. The results are summarized in Table 1.

As shown in Table 1, anodic fluorodesulfurization of **1a** proceeded selectively in $Et_4NF{\cdot}4HF$–CH_2Cl_2 and $Et_3N{\cdot}5HF$–CH_2Cl_2 to provide monofluorinated product **2**[4] in moderate to good yields (runs 3 and 5). In sharp contrast, α-fluorination of **1a** took place preferentially in $Et_4NF{\cdot}4HF$–DME to give **3a**[5] (run 4). In this case, difluorinated products such as **4** (Scheme 2) were not formed. This can be explained in terms of the oxidation potential of **3a** (E_p^{ox}: 2.2 V *vs.* SCE) being 0.3 V higher than that of **1a** (E_p^{ox}: 1.9 V *vs.* SCE).

Table 1 Anodic fluorination of 4-arylthio-1,3-dioxolan-2-ones



1a : X = H
1b : X = Cl
2 **3**

Run	Substrate **1**	Supporting electrolyte	Solvent	Electricity/ F mol^{-1}	Yield (%)[a] **2**	**3**
1	**1a**	$Et_4NF{\cdot}3HF$	CH_2Cl_2	3.1	29	16
2	**1a**	$Et_4NF{\cdot}3HF$	DME	7.2	5	40
3	**1a**	$Et_4NF{\cdot}4HF$	CH_2Cl_2	5.2	53	Trace
4	**1a**	$Et_4NF{\cdot}4HF$	DME	3.4	28	54
5	**1a**	$Et_4NF{\cdot}5HF$	CH_2Cl_2	5.5	67	Trace
6	**1b**	$Et_4NF{\cdot}4HF$	DME	3.1	20	80
7	**1b**	$Et_4NF{\cdot}5HF$	CH_2Cl_2	4.2	96	0

[a] Determined by ^{19}F-NMR spectroscopy.

Next, we extended this anodic fluorination to the 4-(4-chlorophenylthio) derivative **1b**. Similarly, the use of $Et_3N{\cdot}5HF$–CH_2Cl_2 provided **2** exclusively in almost quantitative yield (run 7) while the use of $Et_4NF{\cdot}4HF$–DME afforded **3b**[6] selectively in good yield (run 6). Thus, it was found that electrolytic conditions, particularly electrolytic solvents, greatly affected the fluorinated product selectivity. Such marked product selectivity depending on electrolytic solvents has not been previously reported for anodic fluorination.

In order to clarify the solvent effects, we investigated anodic fluorination of **1b** in a mixed solvent of DME and CH_2Cl_2 containing $Et_4NF{\cdot}4HF$. As shown in Fig. 1, the product ratio of **2** to **3b** increased with an increase in the ratio of CH_2Cl_2 to DME. Notably, addition of only 25% CH_2Cl_2 to DME caused a dramatic change in the product ratio and **2** was mainly formed in *ca.* 60% yield.

This interesting phenomenon can be explained as follows. The fluorination can be rationalised by postulating a radical cation intermediate **A** as shown in Scheme 1.

CH_2Cl_2 has a poor ability to solvate carbocations, therefore, **A** seems to be unstable in CH_2Cl_2. Consequently it is reasonable to assume that desulfurization followed by fluorination mainly takes place prior to α-fluorination of **A**.[7] On the other hand, DME is known to strongly coordinate cations.[8] Therefore, DME should stabilize the intermediate **A** and DME also enhances the fluoride ion nucleophilicity.[9] Then, the deprotonation of **A** with fluoride ions takes place prior to desulfurization followed by further oxidation to generate cation **B** and this cation reacts with a fluoride ion to provide the α-fluorinated product.

Furthermore, we examined anodic fluorodesulfurization of **3a**. As shown in Scheme 2, anodic fluorodesulfurization of **3a** in $Et_4NF{\cdot}4HF$–CH_2Cl_2 and $Et_3N{\cdot}5HF$–CH_2Cl_2 proceeded to give desired difluorinated product **4**[10] in reasonable yield. However, anodic fluorodesulfurization of **3a** did not take place at all in $Et_4NF{\cdot}4HF$–DME and **3a** was almost recovered.

Finally, we also examined chemical fluorination of **1a**. However, treatment of **1a** with various *N*-fluoropyridinium

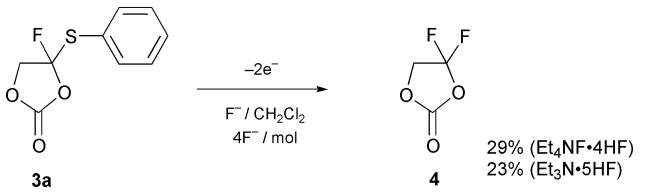
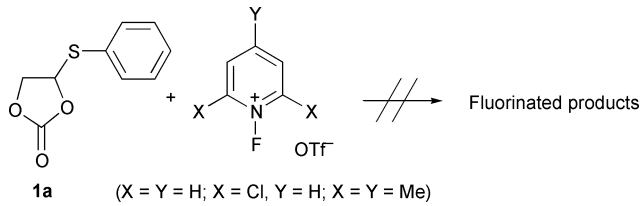


Scheme 2



Scheme 3

triflates in CH_2Cl_2 resulted in the formation of none of the desired fluorinated products, as shown in Scheme 3. Therefore, electrochemical fluorination is more advantageous than conventional chemical methods for such heterocyclic sulfides.

In summary, we have developed a novel synthesis of fluorinated ethylene carbonates using anodic fluorination and we also found a unique marked solvent effect on fluorinated product selectivity.

We thank the Kato Foundation and the Ministry of Education, Science, Sports and Culture of Japan for Financial support (Grant-in-Aid for Scientific Research, No. 12555252).

High yield olefination of a wide scope of aryl chlorides catalyzed by the phosphinito palladium PCP pincer complex: [PdCl{$C_6H_3(OPPr^i_2)_2$-2,6}]

David Morales-Morales, Rocío Redón, Cathleen Yung and Craig M. Jensen*

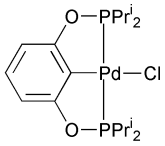
Published on the Web 9th August 2000

[PdCl{$C_6H_3(OPPr^i_2)_2$-2,6}] efficiently catalyzes the olefination of a broad scope of aryl chlorides; as a result of the high thermal stability of the catalyst, the coupled products are obtained in excellent and in many cases nearly quantitative yields.

The formation of vinylic C–C bonds from the palladium catalyzed coupling of aryl bromides, iodides and triflates with alkenes (the Heck reaction) is one of the "true power tools of contemporary organic synthesis".[1] However, the industrial application of the reaction has been very limited owing to the instability of the palladium catalysts and the high cost of the aryl starting materials. Recently a great deal of progress has been made toward overcoming these limitations.[2–9] In a pioneering study, Milstein and coworkers found that the olefination of relatively inexpensive aryl chlorides is catalyzed by [$Pd(OAc)_2$] in the presence of 1,3-bis(diisopropylphosphino)propane.[2] Higher turnovers and yields have recently been achieved with activated aryl chlorides using palladacycle,[3] carbene–palladium[4] and palladium–phosphite[5] catalysts. It has also been discovered that the activity of more traditional Heck coupling systems is enhanced by the addition of [PPh_4]Cl[6] or PBu^t_3[7] such that the chloro substrates can be utilized in the reaction. Notably, Littke and Fu found that in the presence of PBu^t_3, $Pd_2(dba)_3$ catalyzes the olefination of a broad scope of aryl chlorides.[7]

A key feature of several of these systems is the stabilization of the active catalysts by either ligand chelation or steric shielding of the metal center. Both of these stabilizing effects can be realized with mixed donor polydentate ligands. This combination has been used to good advantage in catalytic aliphatic dehydrogenation reactions by iridium PCP pincer complexes, [$IrH_2\{C_6H_3(CH_2PR_2)_2$-2,6}]. The pincer ligand confers high stability on the complexes at the temperatures required for oxidative additions of aliphatic C–H bonds.[10] Similarly, the palladium PCP pincer complexes, [Pd{O-C(O)CF_3}{$C_6H_3(CH_2PPr^i_2)_2$-2,6}], [Pd{OC(O)CF_3}{C_6CH_2-1-$(CH_2PR_2)_2$-2,6-$(CH_2)_2$-3,5-H-4}] (R = Pr^i, Bu^t) have been found to be an extraordinarily active catalyst for the Heck couplings with iodo- and bromo-arenes.[11] However, the phosphino pincer complexes were found to be almost inactive with chloroarenes. Beller[5] and Zapf van Leeuwen and coworkers[9] have recently reported cases in which the catalytic activity of palladium complexes are remarkably enhanced upon substitution of phosphine ligands by alternative phosphorus ligands containing electron withdrawing groups.[5,9] We have found that unlike 1,3-bis(phos*phino*)benzenes, 1,3-bis(phos*phinito*)benzene, can be conveniently prepared in 95% yield from the reaction of inexpensive precursors.[12] It was therefore of interest to examine the activity of the phosphinito palladium complex, [PdCl{$C_6H_3(OPPr^i_2)_2$-2,6}] **1**, as a catalyst for Heck couplings of aryl chlorides. We report here that **1** is an efficient catalyst for this reaction, giving olefinated products in excellent, and in many cases nearly quantitative yields.

The results of our studies of the catalytic activity of **1** are presented in Table 1. In order to optimize the efficiency of the catalytic system, we initially examined the coupling of



1

chlorobenzene and styrene by **1** under a variety of reaction conditions† and analyzed the product mixtures through gas chromatography. Unlike most previously reported systems for Heck couplings of aryl chlorides, additional cocatalyst such as excess LiBr,[3] PBu^t_3,[7] [NBu_4][Br][3–5] or [PPh_4]Cl,[6] are not required to achieve high catalytic activity. We found that > 99% isolated yield of *trans*-stilbene is obtained when the reaction is carried in dioxane solvent and caesium acetate is used as base. Employing this same combination of reagents in a preparative scale experiment, we were able to isolate the coupled product in nearly quantitative yield. At 120 °C, a reaction time of 5 days is required to achieve this high conversion. We found, however, that the catalyst can withstand prolonged heating to 180 °C and thus the request reaction time can be reduced to 24 h.

The reactivities of a variety of aryl chlorides were examined under the optimized conditions and uniformly showed > 99% selective for the *trans* configured product. The system is also one of the few reported systems to show high reactivity with electron-rich[2,7] and sterically hindered[7] aryl chlorides. The practical utility of this catalytic system was probed by carrying out preparative scale couplings of 4-chloroacetophenone and 4-chloroanisole with styrene. We obtained the corresponding *E*-

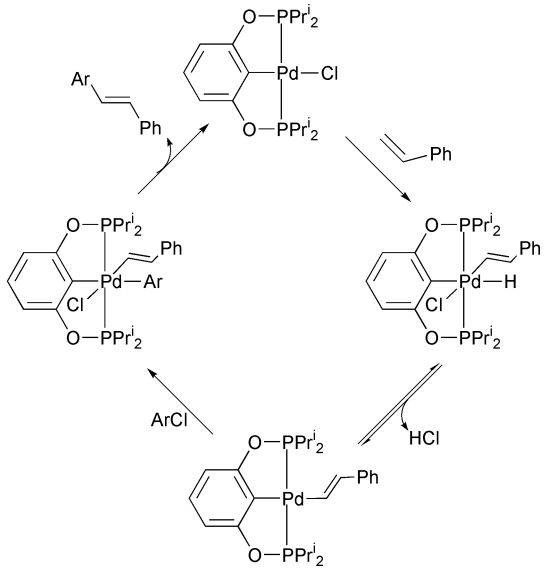

Scheme 1 Proposed mechanism for the catalytic olefination of aryl chlorides by [PdCl{C_6H_3($OPPr^i_2$)$_2$-2,6}].

stilbenes in > 95% and 85% isolated yields respectively. To our knowledge, these yields are the highest that have been achieved to date for the Heck coupling of these aryl chlorides with styrene.

In order to verify that the high catalytic activity of **1** requires the presence of phosphinito rather than a phosphino PCP ligand, we examined the catalytic activity of, [PdCl{C_6H_3($CH_2PPr^i_2$)$_2$-2,6}] **2**† under the conditions that were optimized for **1**. The chloro complex **2**, like [Pd{OC(O)CF_3}{C_6H_3($CH_2PPr^i_2$)$_2$-2,6}],[11] showed only a very low level of activity with aryl chlorides.

It has been suggested that Heck couplings catalyzed by PCP complexes proceed through Pd(II) and Pd(IV) rather than Pd(0) and Pd(II) intermediates.[11,13] Additionally, it seems unlikely that catalytic sequence in our system could be initiated by the oxidative addition of aryl chlorides to **1** as the resulting 18-electron complex would not be expected to undergo further reaction. We therefore conclude that the mechanism of the catalytic olefination of aryl chlorides by **1** is fundamentally different from those commonly considered for palladium catalyzed Heck couplings[1c] and operates through a mechanism like that seen in Scheme 1. Our suggestion is that the catalytic process is initiated by the oxidative addition of a vinyl C–H bond of the alkene reactant. This hypothesis is supported by the recent observation that the reaction of the palladium PCP pincer complex, with tributylstannyl furan results in the substitution of the triflate by an η^1-vinyl ligand.[14] Also the deuterium labeling studies of the reaction of *tert*-butylethylene with the related PCP pincer complex, [IrH_2{C_6H_3-($CH_2PBu^t_2$)$_2$}-2,6] have shown that activation of vinyl C–H bonds at the metal center occurs rapidly at room temperature.[15] The Pd(IV) intermediate resulting from the vinyl C–H oxidative addition would be expected to undergo a reductive elimination of HCl. It is well established that reductive elimination is promoted by decreasing ligand donor strengths.[16] Thus the finding that the phosphinito PCP complex has markedly higher activity than its phosphino analog suggests that this step is rate determining. The catalytic cycle is completed by oxidative addition of the aryl chloride followed by reductive elimination of the coupled product. Similar mechanistic considerations may explain the extraordinary high catalytic activities that Beller and Zapf[5] and van Leeuwen and coworkers[9] have observed respectively for palladium phosphite and phosphorus amidite complexes.

In summary, the relatively inexpensive, phosphinito PCP pincer complex **1** catalyzes the high yield olefination of broad scope of aryl chlorides. It should be noted, that while most of the reactions reported here were expedited by heating to 180 °C, high yields of coupled products can be obtained at longer times at temperatures as low as 120 °C. Thus it should be possible to apply this catalytic system to the synthesis of commercially important, structurally complex fine chemicals containing thermally sensitive groups.

† *General procedure* for the olefination of aryl chlorides. Under an atmosphere of nitrogen, a solution of 0.924 mmol of aryl chloride, 1.83 mmol of olefin, 3.0 mg of **2** (0.0062 mmol) and 202 mg (0.924 mmol) of diethylene glycol di-*n*-butyl ether (internal standard) in 1.0 mL of dioxane, was introduced into a Schlenk tube containing a magnetic stir bar and charged with 1.01 mmol of base. The tube was sealed and fully immersed in a 180 (120) °C silicon oil bath. After 24 (120) h, the reaction mixture was cooled to room temperature and, the organic phase analyzed by gas chromatography (GC/FID, GC–MS). For quantitative analysis a gas chromatograph GC HP 5980A with flame ionization detector (FID), and a HP-1 capillary column (25.0 m) from Hewlett Packard was used.

An aluminosilicate gel barrier as a zeolite precursor is first incorporated in the pores of an alumina support tube and then subjected to hydrothermal crystallization, leading to ZSM-5 zeolite membranes with high compactness at the molecular level.

The potential industrial applications of zeolite membranes in continuous separation and reaction–separation processes on the basis of molecular sieving have recently motivated many attempts and efforts in zeolite membrane preparation. The last ten years have witnessed significant progress in the demonstration of the potential of zeolite membranes to separate hydrocarbon gas mixtures and organic/aqueous mixtures using MFI and A type zeolite membranes.[1,2] *In situ* hydrothermal crystallization in solution or the vapor phase is mainly applied in zeolite membrane synthesis.[3–5] However, presently good quality zeolite membranes are obtained in plate form rather than in tube form though the latter is preferable for industrial applications owing to its large volume/area ratio. It appears to be difficult to adapt a synthesis method applied to plate-form zeolite membranes for tubular zeolite membranes since the membrane quality is sensitive to the geometry of a substrate (plate *vs*. tube) and the manner of contacting a substrate with a zeolite synthesis mixture. Therefore, synthesis of tubular zeolite membranes is still a subject of importance and remains to be addressed.

We note in the literature[6–10] that the separation performance of zeolite membranes is strongly related to the degree that zeolite crystallites are incorporated in the pores of the substrate during hydrothermal crystallization. In addition, in view of the methodology for zeolite membrane preparation it seems that plugging pores of a substrate with inter-grown zeolite crystals is easier to achieve than growing a continuous defect-free zeolite layer on top of a substrate. Therefore, based on the concept of pore plugging, we anticipated developing a novel synthesis method for tubular zeolite membranes.

Here we outline such a method by the synthesis of ZSM-5 zeolite membranes using a tubular substrate. Our synthetic strategy was to incorporate a highly dense aluminosilicate gel barrier in the substrate pores followed by hydrothermal crystallization. The method can generate a compact zeolite barrier and appears to be reproducible.

In our synthesis, a commercial porous alumina tube of 10 mm outside diameter and 7 mm inside diameter and *ca*. 50 mm length was employed as the substrate. The tube has a multilayer structure with a 0.1 μm porous outer layer. One end of the tube was sealed and the other end was connected with a dense alumina tube *via* a high-temperature glaze. The synthesis procedure consisted of two sequential processes. The first was to incorporate an aluminosilicate gel barrier in the outer layer pores by the urea technique. The substrate was first impregnated *in vacuo* with an alcohol-based solution containing $Si(OEt)_4$, $Al(NO_3)_3$, $CO(NH_2)_2$, H_2O (EtOH as balance). The impregnated substrate was dried at *ca*. 50 °C to such an extent that all the solution was sucked by and further concentrated in the outer layer pores by capillary action. The sample was then placed in a closed glass vessel at 90 °C. Thus, precipitation of $Si(OEt)_4$ and $Al(NO_3)_3$ occurred exclusively in the pores by homogeneous alkalinization from decomposition of $CO(NH_2)_2$ [$CO(NH_2)_2 + 3H_2O \rightarrow 2OH^- + 2NH_4^+ + CO_2$]. The above steps were repeated until the N_2 gas flow of the sample was below 10^{-9} mol m^{-2} s^{-1} Pa^{-1} at room temperature. The second process was to convert the aluminosilciate gel barrier to a desired zeolite barrier by hydrothermal treatment. The modified substrate tube was filled with $Si(OPr)_4$ (bp 225 °C) and then placed into a solution of composition $0.005NaAlO_2 : 0.55TPABr : 0.42NaOH : 100H_2O$ in a Teflon vessel. In this arrangement, a reactive interface at the incorporated gel barrier was developed between the two separate liquids. Thus, during hydrothermal treatment, hydrolysis of $Si(OPr)_4$ supplied an additional silica source to the crystallization front while the gel barrier was being converted to zeolitic materials. Hydrothermal treatment was performed in a stainless steel autoclave at 190 °C for 10 days. When the hydrothermal treatment was complete, the sample was thoroughly washed with H_2O and dried at 50 °C overnight and then carefully calcined at 400 °C for 12 h to remove the TPA occluded within the zeolite channels.

In each synthesis experiment, the membranes were shown by XRD to be highly crystalline, pure zeolite ZSM-5. Fig. 1 shows SEM micrographs of the cross-section of a representative ZSM-5 zeolite membrane. From the micrographs, the following two points can be made. (a) As seen in Fig. 1A, the substrate outer layer displays an SEM contrast comparable to those of the ZSM-5 zeolite films indicating that some zeolitic materials were formed from the aluminosilicate gel barrier incorporated in the pores. (b) It was observed that 10 and 100 μm ZSM-5 zeolite films grew on the inner and outer surface, respectively (Fig. 1B and C). These films showed significant morphological differences. The crystals of the inner zeolite film were essentially parallelepipeds of size *ca*. 30 μm and well intergrown. In contrast, those of the outer zeolite film were coffin-shaped and much larger being *ca*. 80 μm along the *c*-axis. It was also observed that few non-zeolitic pathways existed in both the inner and outer zeolite film, which act as defects for gas separation.

A dead-end method was applied for gas permeation measurements with pure He, N_2, CO_2, *n*-butane and isobutane. The permeation measurements were performed at room temperature with the permeation side set at an atmospheric pressure. The gas flow rates were measured with a mass flow meter. The flow rates were plotted *vs*. the kinetic diameters of gas molecules in Fig. 2. As seen, the permeance of all the gases showed a good correlation with their kinetic diameters except for *n*-butane and isobutane. Noble's group reported that an MFI zeolite membrane on a 5 nm γ–alumina tubular substrate showed a *n*-butane/isobutane perm-selectivity of 3–20 and a *n*-butane permeance of

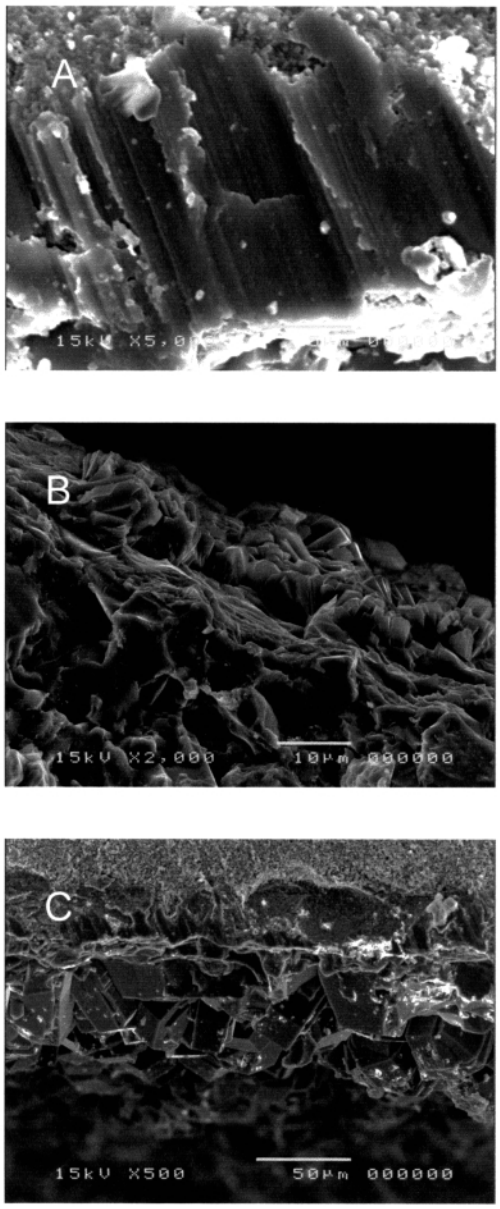

Fig. 1 SEM micrographs of a cross-section of the ZSM-5 zeolite membrane: (a) the 0.1 μm porous outer layer, (b) the inner layer and (c) the outer layer.

ca. 10^{-9} mol m^{-2} s^{-1} Pa^{-1}. The ZSM-5 zeolite membrane in the present study showed a comparable permeance although it exhibited no *n*-butane/isobutane perm-selectivity.

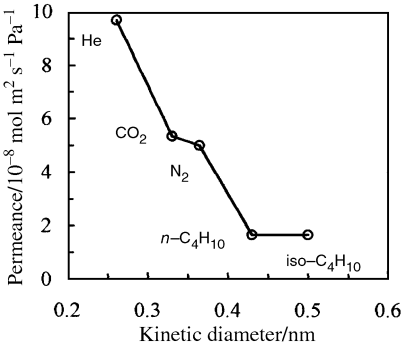

Fig. 2 Permeance of pure gases through the ZSM-5 zeolite membrane *vs*. their kinetic diameters.

Accordingly, a highly compact zeolite barrier with few defects has been formed within and on the substrate. Further, on the basis of SEM observations, zeolite barriers, mainly that in the pores, led to a significant contribution to gas separation. The reason for the formation of defects could be that the reactive interface has insufficient additional aluminosilicate at the crystallization front during crystallization and contracting of the gel barrier, or/and the gel barrier was partially dissolved during hydrothermal treatment.

In summary, the present study has explored a new route for the preparation of tubular zeolite membranes. The resulting ZSM-5 zeolite membrane shows the potential of the novel preparation method. However, improvement of the membrane integrity with regard to separation performance is underway by studying the process kinetics of the preparation method.

The EPR silent acetated 54-member crown-shaped polyoxomolybdate $Na_{26}[\{Na(H_2O)_2\}_6(\{\mu_3\text{-}OH)_4Mo^V_{20}Mo^{VI}_{34}O_{164}(\mu_2\text{-}CH_3COO)_4\}]\cdot\approx 120H_2O$ (1), constructed from two different but related building blocks in a new mode, is synthesized in high yield by reducing an acidified aqueous solution of $Na_2MoO_4\cdot 2H_2O$ and $CH_3COONa\cdot 3H_2O$.

Ever since interest was sparked by the biological activity of the sodium cryptate $[NaW_{21}Sb_9O_{86}]^{18-}$, a species that has been subsequently applied as HAP23 in AIDS therapy,[1,2] there has been an enormous growth in the area of inorganic 'host–guest' polyoxometalates, partly motivated by their potential applications in catalysis, biology, medicine and materials science.[3,4] Generally, the guests are linked to the *endo* oxygen atoms of the host shells *via* valence bonds or intermolecular interactions such as hydrogen bonding.[5–7] One among many examples is that the N_3^- or NO_3^- anion is encapsulated within an approximately spherical $\{H_{12}V_{18}O_{44}\}^{n-}$ polyoxovanadate 'host' cage.[8]

Octamolybdates exhibit various structural patterns in the solid-state and these isomers can interconvert with each other by 'bond-making/breaking' in solution.[9,10] Although a number of corresponding oxide-based composite solid-state materials were synthesized in the presence of structure-directing organic ligands such as diamines, few nanometered polyoxomolybdates constructed from these octamolybdates have been reported. We report here the synthesis and characterization of a novel acetated 54-member crown-shaped polyoxomolybdate, which contains unprecedented building blocks, and exhibits interesting structural features.

$$Na_{26}[\{Na(H_2O)_2\}_6(\{(\mu_3\text{-}OH)_4Mo^V_{20}Mo^{VI}_{34}O_{164}\text{-}(\mu_2\text{-}CH_3COO)_4\}]\cdot\approx 120H_2O \quad (1)$$

Compound **1** was synthesized in high yield by reducing an acidified aqueous solution of Na_2MoO_4,† and characterized by elemental analysis, cerimetric titration (to determine the number of Mo^V), thermogravimetric analysis (to determine the amount of crystallized water), bond valence sum (BVS) calculations[11,12] (to determine the number and the positions of OH groups, as well as the number of Mo^V centers), spectroscopic methods (IR, Raman and UV–VIS)‡ and single-crystal X-ray structure analysis.§

The structure of **1** consists of a discrete 54-member crown-shaped $[\{Na(H_2O)_2\}_6(\{\mu_3\text{-}OH)_4Mo^V_{20}Mo^{VI}_{34}O_{164}(\mu_2\text{-}CH_3COO)_4\}]^{26-}$ **1a** nanoanion (containing four bridging acetate groups and six encapsulated seven-coordinated sodium cations as 'guests'), and 26 Na^+ cations. As shown in Figs. 1 and 2, two different but related building blocks have been found in **1a**. The first building block is the centrosymmetric octamolybdate $\{Mo_8O_{28}\}$ ($\equiv[Mo^V_2Mo^{VI}_6O_{28}]^{10-}$) moiety, which consists of eight distorted edge-shared molybdenum–oxygen octahedra. The structure of this centrosymmetric octamolybdate is very similar to other reported octamolybdate anions, which can be described as $[Mo_8O_{26}(X)_2]^{2n-4}$, for example, $[(HO)_2Mo_8O_{26}]^{6-}$, where *n* is the normal charge of coordinated base X.[12–14] However, in addition to long interblock distances existing within this octamolybdate unit, rather short metal–metal bonds are also found between two neighboring $\{Mo_8O_{28}\}$ units (Mo(7)–Mo(27), 2.58216(18), Mo(19)–Mo(20), 2.5985(16) Å). To the best of our knowledge, such short Mo–Mo distances have rarely been observed in other polyoxomolybdates, particularly in nano-size systems. The second feature is the unprecedented asymmetric $\{Mo_9O_{30}(X)_2\}$ ($\equiv[(\mu_3\text{-}OH)_2Mo^V_4Mo^{VI}_5\text{-}O_{28}(CH_3COO)_2]^{10-}$) unit, which is constructed by nine molybdenum atoms (four Mo^V and five Mo^{VI} centers). Each molybdenum is coordinated by six oxygen atoms in distorted octahedral arrangement with one short Mo=O bond for Mo^V and two for Mo^{VI}. Again, long Mo–Mo distances (around 3.21 Å) and short Mo–Mo bonds (shorter than 2.6 Å) are also formed within the new $\{Mo_9O_{30}(X)_2\}$ unit. In summary, each crown-shaped anion **1a** contains ten short Mo–Mo bonds and eight long interblock Mo–Mo distances, which are listed in the caption to Fig. 1.

The two building blocks are connected to each other into a spiral $[(HO)_4Mo^V_{16}Mo^{VI}_{34}\text{-}O_{160}(CH_3COO)_4]^{44-}$ ring, in which the linkage between the two neighboring $\{Mo_8O_{28}\}$ units is edge-shared, while that between $\{Mo_8O_{28}\}$ and $\{Mo_9O_{30}(X)_2\}$ is corner-shared (Fig. 2). Four additional $\{Mo_1\}$ ($\equiv[Mo^VO]^{3+}$) groups, which cap the linking Mo atoms between $\{Mo_8O_{28}\}$ and $\{Mo_9O_{30}(X)_2\}$ units, are bridged by four acetate ligands to complete the crown-shaped 'host' nanoanion. Six seven-coordinated Na^+ cations with (distorted) pentagonal-

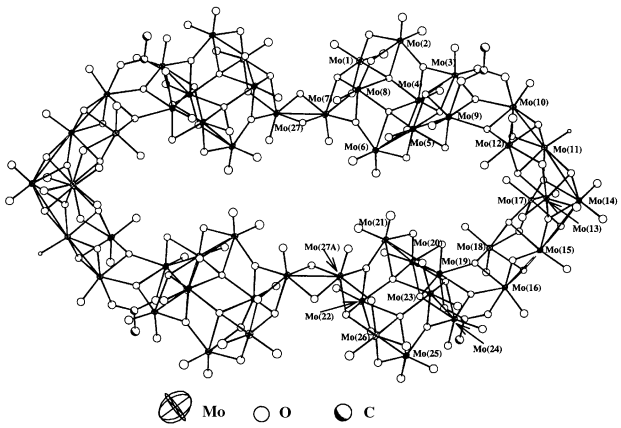

Fig. 1 (*a*) Perspective drawing of **1a** constructed by two different building blocks: $\{Mo_8O_{28}\}$ ($\equiv[Mo^V_2Mo^{VI}_6O_{28}]^{10-}$) and novel unprecedented $\{Mo_9O_{30}(X)_2\}$ ($\equiv[(\mu_3\text{-}OH)_2Mo^V_4Mo^{VI}_5O_{28}[(CH_3COO)_{2/2}]_2]^{10-}$) moieties. According to BVS calculations, the following molybdenum centers are Mo^V: Mo(5), Mo(7), Mo(9), Mo(10), Mo(11), Mo(15), Mo(16), Mo(19), Mo(20) and Mo(27). Selected Mo–Mo distances: Mo(5)–Mo(9) 2.5974(18), Mo(5)–Mo(6) 3.2146(18), Mo(7)–Mo(27) 2.5816(18), Mo(10)–Mo(11) 2.5962(17), Mo(11)–Mo(14) 3.2185(17), Mo(14)–Mo(15) 3.2143(18), Mo(15)–Mo(16) 2.5933(18), Mo(19)–Mo(20) 2.5985(16), Mo(20)–Mo(21) 3.2096(17) Å.

DOI: 10.1039/b004948o

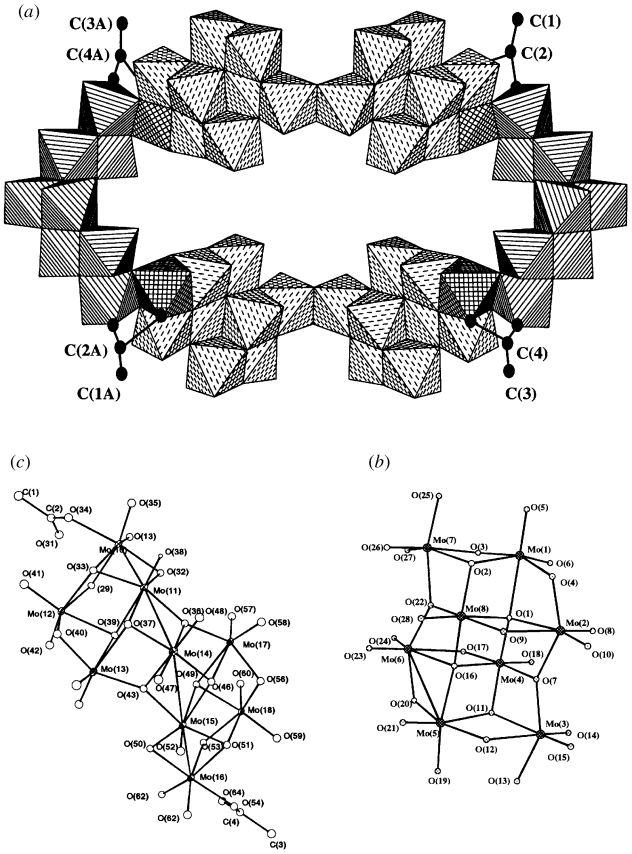

Fig. 2 (*a*) Polyhedral representation of **1a** (all encapsulated Na^+ cations are deleted for clarity). The linkage between two neighboring $\{Mo_8O_{28}\}$ moieties (having a pattern of dashed lines) is edge-shared, while that between $\{Mo_8O_{28}\}$ and $\{Mo_9O_{30}(X)_2\}$ units (marked with parallel lines) are corner-shared. $\{Mo^{V}O\}^{3+}$ units are cross-hatched; (*b*) the $\{Mo_8O_{28}\}$ unit in **1a**; (*c*) the $\{Mo_9O_{30}(X)_2\}$ (X=CH_3COO) moiety in **1a**.

bipyramid environments are held inside the 'host' nanoanion by linking to five *endo* oxygen atoms with Na–O distances of 2.264–3.010 Å. These encapsulated Na^+ cations are located near Mo atoms (Na(1)–Mo(10), 3.691, Na(2)–Mo(16), 3.697, and Na(3)–Mo(6), 3.989 Å), and may play an important template role in the formation of the crown-shaped anion **1a**.

The silent EPR spectrum of compound **1** indicates that the unpaired electrons of the two neighboring Mo^{V} atoms are completely coupled, which is consistent with structural analysis. The IR spectrum of **1** exhibits strong bands at 962 (s), 947 (s) and 901 (s) attributed to ν(Mo=O), and a series of characteristic bands for bridging acetate groups in the range 1550–1200 cm^{-1}.

The positions of OH^- and Mo^{V} sites are assigned on the basis of the *s* values, in which *s* is the bond strength derived from the expression $s = (R/1.882)^{-6.0}$ (R = Mo–O distances).[11] According to this procedure, the O(39), O(39A), O(49) and O(49A) ascribed to OH^- sites, have *s* values (0.9875–0.9927) are significant smaller than that of the others (1.5707–2.0930) which are normal for the O^{2-} sites.

In summary, a novel 54-member crown-shaped polyoxomolybdate has been synthesized and characterized crystallographically. It seems that there exists various building blocks in solution, and it is possible to link those building blocks to a variety of crown-shaped polyoxomolybdates. This has been confirmed recently by our preliminary experiments.

We thank the Chinese Academy of Sciences, the State Education Ministry and the State Personnel Ministry for financial support.

† *Synthesis of* **1**: to a solution of $Na_2MoO_4{\cdot}2H_2O$ (40 mmol, 9.68 g) and $CH_3COONa{\cdot}3H_2O$ (50 mmol) in H_2O (55 ml) acidified by 8.5 ml of 17% HCl (pH = 4.15), $NH_2NH_2{\cdot}2HCl$ (4.8 mmol, 0.5 g) was added under continuous stirring for 5 min. The resulting reaction mixture was then kept at room temperature in a wide-necked Erlenmeyer-flask for ten days (color changed from green to dark brown). Black–red columnar crystals of **1** were filtrated from the mother liquor, washed with cooled propan-2-ol, and finally dried in air (4.95 g, yield 59.54%). Anal. calcd. for $C_8H_{280}Mo_{54}Na_{32}O_{308}$: Mo, 46.16, Na, 6.56, C, 0.86, H, 2.51. Found: Mo, 46.62, Na, 6.59 (atomic absorption method), C, 0.79, H, 2.71% (determination was carried out on EA1110 (CHNS-0 CE instruments). Cerimetric titration was carried out to determine the number of Mo^{V} ($\sim 20 \pm 2$ electrons), which is consistent with the results of BVS calculations.

‡ Characteristic IR bands for **1** (KBr pellet, ν/cm^{-1}): 1630 (s, $\delta(H_2O)$), 1541 (s-m, ν_{as}(COO)), 1444 (m, ν_s(COO)), 962 (s), 947 (s), 901 (s) (ν(Mo=O)), 862(s), 721 (s), 727 (s), 494 (m): Characteristic FT-Raman bands (λ_e = 1064 nm, ν/cm^{-1}): 969 (vs), 940 (s), 927 (m), 912 (w) (ν(Mo=O)), 875 (w), 796 (w), 472 (m), 352 (m), 323 (m), 281 (m). Characteristic UV/VIS bands (λ/nm): 308.00 ($\varepsilon = 6.71 \times 10^4$ M^{-1} cm^{-1}) and 209.50 ($\varepsilon = 3.59 \times 10^5$ M^{-1} cm^{-1}).

§ *Crystal data*: $C_8H_{280}Mo_{54}Na_{32}O_{308}$, 11222.76, triclinic, $P\bar{1}$, a = 17.6814(6), b = 19.8620(7), c = 23.4663(8) Å, α = 90.0210(10), β = 102.6740(10), γ = 100.41°, V = 7902.0(5) $Å^3$ and Z = 1. The diffraction data were collected on a Simens SMART CCD diffractometer with graphite monochromated Mo-Kα radiation (λ = 0.71073 Å) at room temperature. A total of 41201 reflections (0.89 to 25.02°) were collected, of which 27539 independent reflections [R(int) = 0.0507] were used. The coordinates of molybdenum atoms were determined by direct methods, and the remaining non-hydrogen atoms were located and refined by a usual procedure of a combination of the difference Fourier synthesis and least-squares technique. All molybdenum atoms and partial other non-hydrogen atoms were refined with anisotropic thermal parameters giving rise to convergence with R_1 = 0.0718 and wR_2 = 0.1969 ($I > 2(I)$). CCDC182/1725. The phenanthridinium-linked terbium complex [4Tb.5] serves as a novel probe for DNA duplexes.

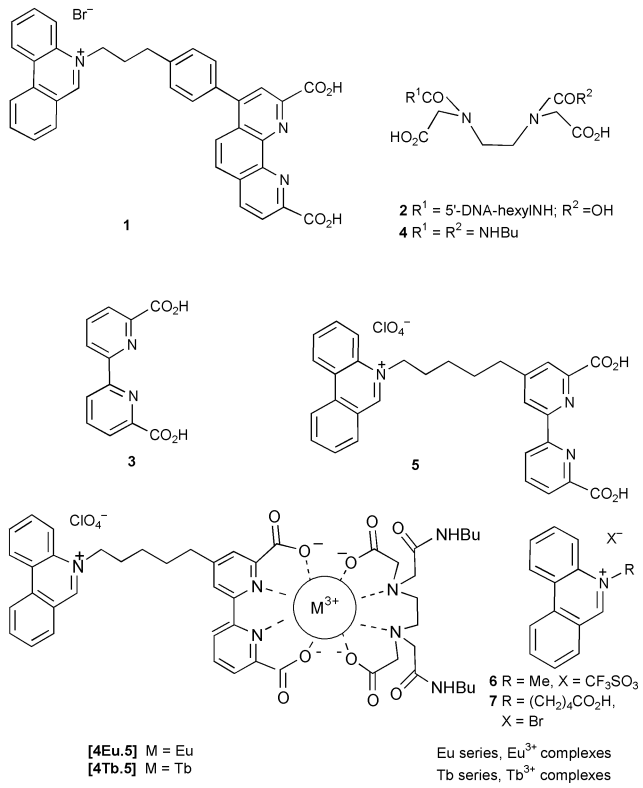
In recent work[1] we have demonstrated a cooperative procedure for the detection of DNA sequences. In this procedure, the phenanthridinium group of the sensitiser **1** intercalates in the locality of the duplex DNA formed between a probe DNA strand, to which is attached an EDTA complexing group **2**, for a europium ion, and a target sequence of DNA. Under appropriate conditions, the sensitiser **1** can also bind to the europium complex of **2** to form a 1 : 1 : 1 complex [**2Eu.1**][2] that,



when irradiated, exhibits a strong luminescence signal from the europium ion. The system thus signals the presence of a target strand of DNA since, in its absence, the complex dissociates and only a very weak signal is observed.

In attempting to develop a two-colour signalling system suitable for discriminating between normal and point mutated target DNA strands, a sensitiser system was required that would work for both europium and a second luminescent lanthanide ion, such as terbium. Thus, for example, a 'normal' DNA sequence could be matched by a europium probe (red emission) and a mutated sequence by the corresponding terbium probe (green emission). The phenanthroline sensitiser, such as **1**, was not suitable for use with terbium, presumably because terbium requires a higher energy triplet sensitiser than europium.[3]

Examination of several alternative systems revealed that the 2,2′-dipyridyl-6,6′-dicarboxylic acid system, **3** is suitable, giving excitation of both europium and terbium chelated with EDTA bisbutylamide **4**, as complexes [**4Eu.3**] and [**4Tb.3**] respectively, although the optimal excitation wavelength with this system was shorter (λ_{ex} = *ca.* 320 nm) compared to that possible with the phenanthroline sensitiser **1** (λ_{ex} = 340 nm). In addition, luminescence intensities were temperature dependent and measurements were therefore conducted within a narrow ambient range (around 23 °C).

The dipyridyl dicarboxylic acid unit was then incorporated into the probe **5**.† Examination of the properties of this probe revealed that the complex with the Eu^{3+}·EDTA bisbutylamide, chelate [**4Eu.5**] exhibited a strong luminescence signal on irradiation at 318 nm (Table 1). However, on standing, the intensity of the luminescence dropped with time. After exploring several possible explanations for this fading of the signal it was discovered that the effect could be countered by the addition of a surfactant, such as the cationic CTAB (cetyl trimethylammonium bromide), whereupon a stable signal was observed. Independent experiments showed that the complex [**4Eu.5**] has a strong tendency to adhere to the surface of the cuvette, thus removing it from solution.

The corresponding Tb^{3+} complex, [**4Tb.5**], only exhibited a very weak signal (Table 1), which was not enhanced by the addition of CTAB. This inefficiency with the terbium complex is in contrast with the behaviour of the simpler complexes described above, *e.g.* [**4Tb.3**], and is ascribed to an intramolecular quenching process from the attached phenanthridinium group. Since only the terbium complex was affected but not the europium complex, this quenching process was not of the sensitising dipyridyl species, common to both systems, but of the excited lanthanide ion.

It is known[4] that the triplet level of the phenanthridinium group (*ca.* 21 300 cm^{-1}) is near in energy to that of the excited $^5D_4$ state of the terbium ion (*ca.* 20 500 cm^{-1}) and is capable of quenching the latter. In order to confirm this triplet quenching mechanism an experiment involving the intermolecular quenching of the terbium complex [**4Tb.3**] with the phenanthridinium salts **6** and **7** was carried out. The results followed Stern–Volmer plots (Fig. 1). Of note was the observation that the carboxylic acid derivative **7** was a less efficient quencher than the *N*-methyl salt **6**. Presumably, electrostatic effects play a part

Table 1 Luminescence signals for various chelates

Ln^{3+}	Complex	I_{max}[a]	Notes
Eu^{3+}	[**4Eu.3**]	500	
Tb^{3+}	[**4Tb.3**]	350	
Eu^{3+}	[**4Eu.5**]	170[b]	
Eu^{3+}	[**4Eu.5**]	150	calf thymus DNA added[c]
Tb^{3+}	[**4Tb.5**]	1	
Tb^{3+}	[**4Tb.5**]	300	calf thymus DNA added[c]
Tb^{3+}	[**4Tb.5**]	210	SDS added[d]

[a] I_{max} in arbitrary units. Measurements all with same instrument settings using a PE LS50B spectrofluorimeter; slit widths 10 nm; delay time 0.1 ms; gate time 1.0 s. Measurements at 23 °C, pH 7.5 in buffer; complex concentrations at 1×10^{-6} mol dm^{-3}. For Eu^{3+} I_{max} for the band at *ca.* 614 nm was measured; for Tb^{3+} I_{max} for the emission at *ca.* 545 nm was measured. [b] Initial intensity in the absence of CTAB. [c] Intensity measured at a ratio of DNA base pair : complex of > 10 : 1. [d] Intensity measured at a concentration of SDS of 2×10^{-4} mol dm^{-3}.

DOI: 10.1039/b003970p

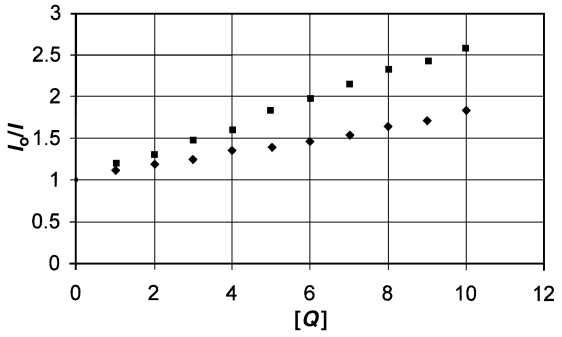


Fig. 1 Stern–Volmer plots: Tb^{3+} signal at λ_{em} = 545 nm, delay time 0.1 ms; [**4Tb.3**] at 1×10^{-6} mol dm^{-3}, buffered at pH 7.5 at 23 °C; ◆ addition of **6** as quencher; ■ addition of **7** as quencher; no degassing. [Q] in molar equivalents of quencher to complex.

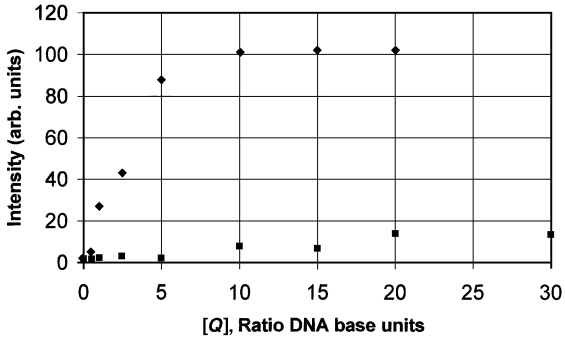

Fig. 2 Enhancement of Tb^{3+} signal at λ_{em} = 545 nm, delay time 0.1 ms; [**4Tb.5**] at 1×10^{-6} mol dm^{-3}, buffered at pH 7.5 at 23 °C; ◆ addition of calf thymus duplex DNA; ■ addition of synthetic 15-mer DNA single strand oligomer. [Q] in molar DNA base equivalents to the probe.

and the latter, net positively charged species, can approach the net negatively charged complex [**4Tb.3**] more easily than the former, which is net neutral under the quenching conditions utilised.

The possible involvement of oxygen, as a known quenching agent for the excited phenanthridinium species[5] was also examined but deoxygenation of the system by a number of freeze–thaw cycles had little effect on the overall levels of emission from the europium [**4Eu.5**] complex, whilst, as anticipated there was a small increase for the terbium [**4Tb.5**] complex. This indicates that, although the *N*-substituted phenanthridinium species can act as a sensitiser for the terbium ions, under our conditions the dominant sensitiser is the dipyridyl chromophore, the phenanthridinium ion acting as a net triplet energy sink.

Triplet quenching requires close contact of the interacting species in order to operate. Quenching would not be expected to occur if the terbium ion could be held apart from the phenanthridinium unit. Since the phenanthridinium ion has a propensity to intercalate with duplex DNA,[6] it was of interest to test whether or not quenching was observed in the presence of such DNA. Thus to a solution of the terbium complex [**4Tb.5**] in HEPES buffer, was added a solution of duplex DNA (calf thymus); the onset of the terbium signal appeared within seconds and approached a maximum at DNA base to complex concentration ratios > 10 : 1 (Fig. 2). Thus intercalation of the phenanthridinium group is sufficient to prevent its intramolecular approach to the complexed terbium ion. In contrast, the luminescent properties of the corresponding europium complex, [**4Eu.5**] were only slightly altered by the addition of calf thymus DNA, a slight reduction in the europium emission being observed. In both cases no substantial changes in the patterns of lanthanide emissions were observed upon the addition of the DNA.

Further experiments have shown that these effects could be reproduced using synthetic DNA hybrids. Addition of the complex [**4Tb.5**] to single stranded DNA showed only a small increase in the terbium signal (Fig. 2).

The triggering of the terbium signal thus serves as a useful 'switch' for the detection of duplex DNA in solution and complements the behaviour of the dipyridophenazine–ruthenium complexes described by Barton *et al.*[7]

Since we believe the onset of the terbium signal was caused by a physical barrier to approach of the phenanthridinium ion to the chelated terbium species and hence quenching, we subsequently tried use of the anionic surfactant, SDS (sodium dodecyl sulfate). No effect was observed at low concentrations but at molar equivalents > 10 : 1 SDS: [**4Tb.5**] a typical terbium emission signal appeared, reaching a maximum at molar concentrations > 100 : 1. We ascribe this to a micellar effect, the phenanthridinium group being surrounded by SDS molecules as micellation occurs thus effectively restricting approach by these groups to the hydrophilic and net anionic, dipyridyl lanthanide segment of the complex. Thus the complex [**4Tb.5**] can also act as a probe for anionic micellation.

We thank the EPSRC and the BBSRC for support of this work.

Applying the probe molecule strategy, surface-enhanced Raman spectroscopy has been used, for the first time, as a diagnostic tool of the electronic properties of metal nanorods; the vibrational frequency of the probe molecule SCN^- at Cu nanorods is shown to critically depend on the nanorod's diameter in the range from 50 to 15 nm; the upshifting of the Fermi level with a decrease of the nanorod's diameter is interpreted based on the change of cohesive energy owing to the high ratio of surface to bulk atoms.

Metal nano-rods (-wires) have aroused tremendous interest recently because of their novel properties and potential applications in a wide variety of fields.[1–5] So far many techniques have been employed to characterize the novel optical, electronic and magnetic properties of such materials.[2–5] UV–VIS absorption and fluorescence spectroscopies are two of the most widely used methods.[3–5] Raman spectroscopy has, however, only been applied to characterize semiconductor nanowires and carbon nanotubes.[6–9] Important and meaningful information can be obtained in these cases, as some forbidden Raman modes in the bulk materials become Raman active.[6,7] Raman spectroscopic study on metal nanowires can only detect the mechanical vibration bands (also denoted inelastic Mie scattering or acoustic modes) located in the extremely low frequency region (typically 2–10 cm^{-1}).[10] Consequently, an alternative way has to be established to study metal nano-wires (-rods) with Raman spectroscopy.

It is well known that for a molecule which interacts strongly with a surface, its vibrational band frequency and shape are very sensitive to the electronic property, the chemical environment and the morphology of the surface. Hence Raman spectroscopy has long been used to analyze the atomic structures and the electronic properties of surfaces indirectly through assessing carefully the spectral changes of the adsorbate, the so called probe molecule.[11] On that account, it is of great interest to diagnose the electronic structures of metal nanorods *via* the vibrational spectrum of a probe molecule. In the present work, surface-enhanced Raman spectroscopy (SERS) has been used because of its extremely high sensitivity in characterizing the surface species on metals. In order to examine the changes in the electronic properties of nanorods by analysis of the spectral changes of the probe molecule, a typical SERS system of SCN^-/Cu was employed in the present study. SERS measurements were performed on a confocal microprobe Raman system (LabRam I).[12]

The arrays of Cu nanorods were fabricated using anodic aluminum oxide (AAO) templates as described in ref. 13. By controlling the electrochemical conditions during AAO formation and/or metal deposition processes, one can prepare nanorod arrays with different diameters from *ca.* 15 to 70 nm. As the SERS intensity depends critically on the nanorods' length exposed at the surface,[14] the length was varied between several tens to several thousands of nanometers, which was controlled by chemically etching off the AAO template to the desired extent in an aqueous solution of phosphoric acid or sodium hydroxide. SERS intensities from these ordered nanorod arrays are higher than those from the electrochemically or chemically roughened electrodes even with the best surface preparation.[14]

Fig. 1 shows the wavenumber–diameter profile of SCN^- adsorbed at Cu nanorod arrays with lengths of *ca.* 100 nm but with variation of the diameter from 15 to 70 nm. The vibrational frequency of ν_{CN} is shown to critically depend on the nanorods' diameter when the diameter is < 50 nm. It is essential to compare this interesting vibrational property to that of a normal Cu electrode in the same solution. The wavenumber–potential profile of SCN^- adsorbed at an electrochemically roughened Cu electrode is also displayed in Fig. 1. The wavenumber shows a linear downshift as the applied electrode potential is made more negative, showing a similar trend to the size effect of decreasing the diameters of the metal nanorods. It can be seen that the effect on the wavenumber upon changing the diameter from 50 to 15 nm is equivalent to that of decreasing the applied potential by *ca.* 200 mV. Similar results have also been obtained from Au and Ag nanorods. Therefore, it is of importance to reveal the reason for the wavenumber–size dependence of the metal nanorods.

The Fermi energy level is well known as one of the most important parameters, with which to characterize a metal. The Fermi level determines many of the gross electronic properties that could consequently influence the intermolecular bonding and the relevant vibrational frequency of an adsorbate. The more negative the applied electrode potential, the more upshifted the Fermi level, and so the greater tendency to supply electrons from the electrode to the adsorbate. This leads to a down-shift of ν_{CN} as found for SCN^-/Ag.[15] It is well known that if a bulk metal is cut into very small pieces whose characteristic size is about or smaller than the electron mean free path, many physical properties will be changed substantially.[1,2] At present, we think the surface effect and small

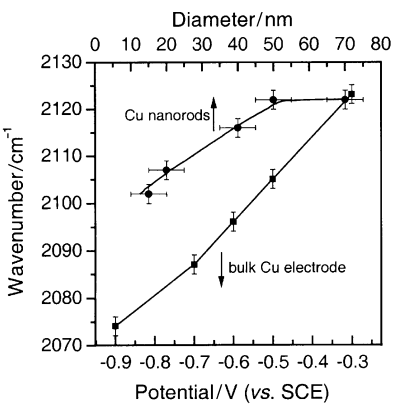

Fig. 1 The wavenumber–diameter profile of SCN^- adsorbed at Cu nanorod arrays and the wavenumber–potential profile of SCN^- adsorbed at a bulk Cu electrode.

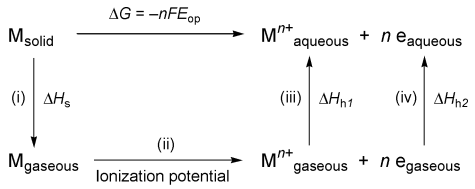
DOI: 10.1039/b002717k

size effect may play an important role on the considerable change of the Fermi energy.

The Fermi level of a metal nanorod can be estimated in a simple way by considering free electrons confined to a cylindrical rod of length l and radius r. The energy level in atomic units is given by:

$$E = \frac{n^2\pi^2}{l^2} + \frac{C_m^2}{r^2} \qquad n = 1, 2, 3, \ldots; m = 0, \pm 2, \ldots$$

where C_m is a parameter determined by the Bessel function. This equation indicates, at least qualitatively, that the Fermi level of a metal nanorod would increase as the diameter decreases. Since the present study on the Cu nanorods was performed in electrolyte solution, the electrode potential should be calculated under open circuit conditions, where E_{op} corresponds to the Fermi level of a metal nanorod (M_{solid}) in solution. In general, several factors affect the value of E_{op}. These are (i) sublimation of a solid metal, (ii) ionization of a gaseous metal atom, (iii) hydration of a gaseous ion, (iv) hydration of n gaseous electrons; which could be best considered in a Born–Haber type of cycle (Scheme 1).



Scheme 1

For a set of nanorods of the same metal with different diameters, the energy changes for processes of (ii)–(iv) are all the same. Therefore, the differences of the electrode potential E_{op} of a set of nanorods should depend only on the differences of the sublimation energies, ΔH_s. The value of ΔH_s is related directly to the cohesive energy, which is determined by the metal–metal bonding. It is reasonable to assume that the metal–metal bonds are the same in the bulk phase for all the nanorods studied here. However, one has to consider the fact that a surface atom possesses a lower coordinate number as compared to a bulk atom. This implies that the change of the cohesive energy might depend substantially on the ratio of the surface atoms to bulk atoms for nanorods of different size. Based on this, we have carried out the relevant calculations on the potential difference ΔE of a set of nanorods with respect to the bulk electrode potential. Fig. 2 shows the dependence of the potential difference on the diameter ($d = 2r$) of the Cu nanorods. It is clearly seen that the potential difference significantly depends on the nanorod's diameter when the diameter is < 50 nm, and small nanorods show a larger potential difference, indicating an up-shift of the Fermi level. This trend is in general agreement with our experimental results. If we consider the additional influence of the sublayer atoms, the calculated values are even closer to the experimental data. Although more sophistical theoretical investigation on this aspect is required, it has shown that Raman spectroscopy can be developed into a diagnostic tool for measuring the electronic properties of metal nanorods by applying the probe molecule strategy.

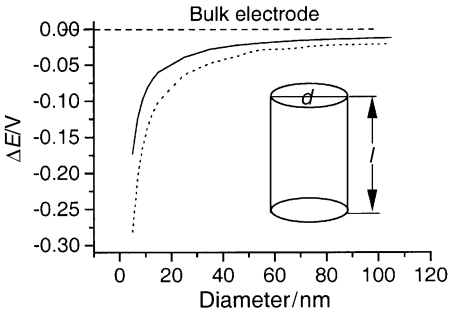


Fig. 2 Dependence with diameter of the difference potential of Cu nanorods ($l \approx 100$ nm) with respect to the bulk Cu electrode after consideration of the surface effect (—) and surface and subsurface effect (····), see text.

Alcohol induced stereospecific P–C bond cleavage to afford Ru–phenyl derivatives containing three different types of stereogenicity: novel and unprecedented complexes of P(OH)(OR)Ph

Tilmann J. Geldbach, Daniela Drago and Paul S. Pregosin*

Laboratory of Inorganic Chemistry, ETHZ, Universitätstr. 6, CH-8092 Zurich, Switzerland.

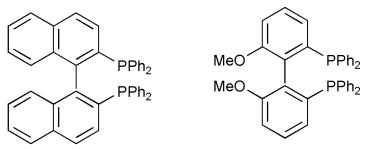
Received (in Basel, Switzerland) 31st May 2000, Accepted 19th July 2000
Published on the Web 10th August 2000

Alcohol induced stereospecific P–C bond cleavage in a Ru–P(OH)Ph_2 fragment affords new chiral-Binap and MeO-Biphep based complexes containing three different forms of stereogenicity: ligand atropisomerism plus stereogenic Ru and P atoms; these represent the first reported transition metal complexes of the ligands P(OH)(OR)Ph.

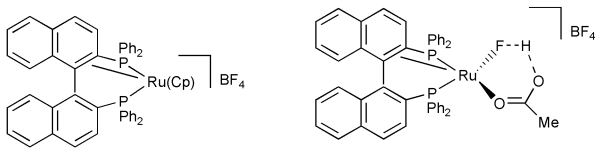
The atropisomeric chelating phosphines, Binap **1** and MeO-Biphep **2** are well known to be excellent chiral auxiliaries



1 **2**

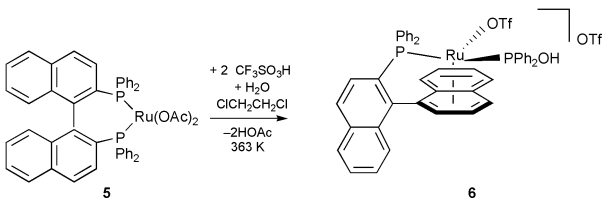
though there is relatively little known with respect to their Ru-organometallic chemistry.[1–5]

It is now known[6,7] that both of these bidentate ligands are capable of acting as six-electron donors to Ru(II), in that one of the biaryl double bonds, immediately adjacent to one of the two P-donors, can complex the metal, *e.g.* **3** and **4**.



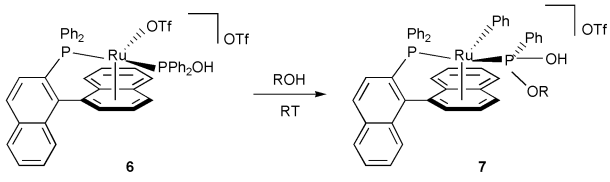
3 **4**

Once the proximate double bond complexes to Ru(II), it is relatively easy to cleave a P–C bond,[7] with the metal attaining an 18e configuration by sliding from the η^2 mode to the η^6 arene form, *e.g.* complex **6** of eqn. (1).



5 **6** (1)

We report here an extension of the chemistry of eqn. (1) in which compound **6** reacts with aliphatic alcohols to afford the Ru–phenyl products, **7** [eqn. (2)]. These arise from a stereospecific P–C bond splitting and P–O bond making reaction of the P(OH)Ph_2 ligand to afford P(OH)(OR)Ph complexes.



6 **7** (2)

a, R = Me, **b** R = Et, **c** R = Pr^i

The Binap complexes **7** and the MeO-Biphep analogues **8** have been prepared using MeOH, EtOH and Pr^{i}OH, by simply stirring the starting materials **6** in the appropriate alcohol[8] [eqn. (2)] The new phenyl complexes **7** and **8** are unique in that (a) they are produced in only *one* diastereomeric form, *i.e.* the phenyl migration and P–O bond formation are specific, (b) they contain *three* different forms of stereogenicity: atropisomerism, from the biaryl moiety,[9] a chiral transition metal and the newly formed stereogenic P atom and (c) these are the first reported transition metal complexes of the ligands P(OH)(OR)Ph. We know of only one example in which a marginally related species arises through P–C bond protonation, *i.e.* a Mo–P(OH)PhMe moiety can be formed by protonation of one of the two P–C phenyl bonds of a $PMePh_2$.[10] In this chemistry the $PMePh_2$ is complexed as an η^6-arene and not as a tertiary phosphine.

In solution the formation of **7a** from **6** is conveniently followed by ^{31}P NMR spectroscopy in that the disappearance of the signal for the complexed P(OH)Ph_2 ligand of **6**, δ = 114.5, is accompanied by the appearance of a new signal for the Ru–P(OH)(OMe)Ph moiety at δ = 144.7. The presence of the new P(OR) fragment was confirmed by a ^{31}P–^{1}H-correlation, *e.g.* see Fig. 1 for the ethanol analogue **7b**. This NMR spectrum shows cross-peaks for the P(OH), at high frequency, and the two non-equivalent (diastereotopic) methylene protons as multiplets (one of which is almost completely covered by the OCH_2 of the solvent, THF-d_8) all correlated to the new ^{31}P signal at δ 142.4. In addition cross-peaks are observed from the *ortho* (intense) and *meta* (weaker) P–phenyl aromatic protons. The *ipso* ^{13}C resonance of the new η^1 phenyl ligand is found at δ 150.3.

The solid-state structure of the Binap Pr^{i}OH analog **7c**, was determined by X-ray diffraction methods (Fig. 2).[12] The immediate coordination sphere consists of the two phosphorus atoms, the π-arene and the η^1-phenyl ligand. Whereas four of the Ru–C(arene) separations are normal,[11] the remaining two distances, from the bridgehead carbons C2 and C3, are quite long (see **9**) and suggest little or no bonding to the metal. Selected bond lengths and bond angles are given in the caption to Fig. 2.[13]

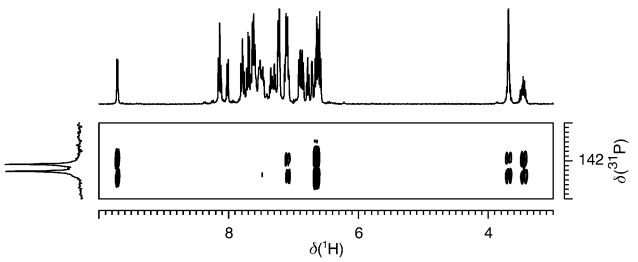


Fig. 1 Slice through the ^{31}P–^{1}H correlation (δ 142.4) showing the cross-peaks arising from the hydroxy P(OH), at high frequency, and the two non-equivalent methylene protons of the EtO moiety as multiplets (one of which is almost completely covered by the OCH_2 of the solvent, THF-d_8). There are also cross-peaks from the *ortho* and *meta* protons of the remaining P–phenyl ring.

12 *Crystal data* for **7c**: $C_{60}H_{41}F_3O_5P_2RuS$, M = 1094.00, monoclinic, space group $P2_1/n$, a = 11.415(2), b = 35.057(5), c = 13.524(2) Å, β = 100.54°, V = 5320.7(14) Å^3, Z = 4, D_c = 1.381 Mg m^{-3}, μ = 0.453 mm^{-1}, F(000) = 2232, Crystal size = 0.54 × 0.40 × 0.32 mm. Data were collected on a Siemens SMART platform diffractometer equipped with a CCD detector using graphite monochromated Mo-Kα radiation (λ = 0.71069 Å). Total number of reflections was 33233 of which 10942 were independent. The structure was solved by direct methods and refined on F^2, $R1$ = 0.0772, $wR2$ = 0.1751. The CF_3SO_3 molecule is disordered and was refined as a rigid group. Further, two molecules of disordered benzene solvent were found and refined in two different orientations. CCDC 182/1723.

13 There is no doubt as to the structure of the molecule; however, owing to disorder in several molecules of benzene, which co-crystallise, and some disorder in the triflate anion, the *R* factor is rather large. This does not interfere with a reasonable determination of the various Ru–(ligand atom) bond lengths.

The synthesis and characterization of an efficient green electroluminescent conjugated polymer: poly[2,7-bis(4-hexylthienyl)-9,9-dihexylfluorene]

A novel soluble electroluminescent (EL) material, poly[(4-hexylthiophene-2,5-diyl)(9,9-dihexyl-9*H*-fluoren-2,7-ylene)(4-hexylthiophene-2,5-diyl)] (PHTDHFHT), with high absolute photoluminescence (PL) quantum efficiency (32 ± 3%) compared with other polythiophene derivatives, was synthesized and a green EL is observed.

During the past decade, design and synthesis of novel conjugated polymers as low-cost materials with high potential for electronic and optoelectronic applications have received considerable attention.[1–3] The development of novel highly efficient materials that emit primary color lights is particularly attractive due to the requirement for full-color displays. Among conjugated polymers, polythiophene (PT) and its processable derivatives are an important class of representatives as electrically conductive and optoelectronic materials because of their high electrical conductivity and environmental and thermal stability in both neutral and doped states, as well as their interesting electronic and optical properties.[4–6] However, the low PL quantum efficiency of PTs in solid films, typically 1–3%, has limited the application of PTs in polymer light-emitting diodes (PLEDs).[7] In our previous reports, a significant increase in PL efficiency of PTs by modifying the backbone structure with phenylene groups was demonstrated.[8,9] Recent progress made in our group demonstrates that 9,9-disubstituted polyfluorene copolymers with arylene groups, such as a phenylene ring, may exhibit relatively high PL and EL efficiencies as well as good EL performances.[10,11] Here we present a novel conjugated polymer, PHTDHFHT, in which thiophene moieties are introduced into the backbone of poly(9,9-dihexyl-9*H*-fluoren-2,7-ylene) in place of phenylene units. The resultant polymer emits green PL and EL with high quantum efficiencies.

The synthetic approach towards PHTDHFHT is outlined in Scheme 1. Compound **2** is synthesized through the coupling reaction between thienylzinc chloride and 2,7-dibromo-9,9-dihexylfluorene catalyzed by $Pd(PPh_3)_4$ in a high yield (89%). The bromination of compound **2** with NBS produces monomer **3**, 2,7-bis(5-bromo-4-hexylthienyl)-9,9-dihexyl-9*H*-fluorene. The polymer, PHTDHFHT, was obtained through a nickel-catalyzed reductive polymerization. Usually the preparation of PFs and PTs can also employ direct oxidative polymerization using ferric chloride as an oxidant. It was found that residual iron in the polymers was difficult to remove completely, which could affect the performance of devices.[12] Metal-catalyzed coupling reactions of dihalo compounds in place of the oxidative polymerization by ferric chloride was employed in our synthesis. The reductive polymerization also avoids irregular coupling or branching that easily happens in conventional electrochemical and oxidative polymerization. After careful purification,† the polymer was obtained as a light-yellow solid in a yield of 60%.

PHTDHFHT is highly soluble in common organic solvents, *e.g.*, THF, toluene, xylene, and $CHCl_3$. Uniform and transparent films on substrates, such as ITO-coated glasses and microslides, can be obtained by spin-casting the solutions. The molecular structure and purity of the polymer are verified by ^1H and ^{13}C NMR, FT-IR, and elemental analysis.‡ The molecular weights of the polymer determined by gel permeation chromatography (GPC) against the polystyrene standards in THF are M_w = 2.1 × 10^4, M_n = 1.3 × 10^4 (polydispersity, 1.67). Thermal gravimetry analyses (TGA) (heating at 10 °C min^{-1} in nitrogen) indicate that the polymer is stable up to 300 °C. Differential scanning calorimetry (DSC) reveals an exothermic phase transition around 70 °C, which is higher than those of our previously reported poly[bi(thienyl)phenylene] derivatives.

The absorption and photoluminescence (PL) spectra of the polymer as film (spun-cast from a solution in xylene at the concentration of 30 mg ml^{-1}) on microslides are shown in Fig. 1. The absorption onsets at 490 nm and gives a broad spectrum with the maximum at 396 nm. From the onset wavelength, the optical band gap of the polymer can be estimated to be 2.53 eV. The film emits intensive green light when it is exposed to UV light. The PL spectrum exhibits a peak at 493 nm with a shoulder at 515 nm, corresponding to green emission (CIE: x = 0.24, y = 0.51). The absolute PL quantum yield of the neat polymer film was measured to be 32 ± 3% in an integrated sphere at rt in air using an argon ion laser line of 358 nm as the excitation source according to the procedure described by Greenham *et al.*[13] The PL efficiency is quite high compared with conventional PTs, and is also higher than those of our previously reported polythiophene derivatives modified by the phenylene group in their backbones, although it is still lower than those measured from 9,9-disubstituted polyfluorenes which are highly efficient blue light-emitting polymers.[14] The photochemical stability of PHTDHFHT is also high. The fluorescence intensity of the thin film shows negligible degradation in 5 h under irradiation of UV light (367 nm) in air. This is similar to other polyfluorene and polythiophene

derivatives. These results indicate that PHTDHFHT is an efficient and stable green emissive material.

Cyclic voltammetry (CV) was performed on a thin polymer film of PHTDHFHT coated onto a glassy carbon disc electrode in a 0.1 mol L^{-1} tetrabutylammonium hexylfluorophosphate (*n*-Bu_4NPF_6) solution in acetonitrile by using platinum wire as a counter electrode and a silver wire as a quasi-reference electrode. All the experiments were performed in a glove-box under an argon atmosphere at rt. As shown in Fig. 2, in the anodic scan, the oxidation started at about 0.90 V and gave a sharp oxidation peak at 1.21 V. The re-reduction peak appeared at 1.15 V. On sweeping the polymer cathodically, the reduction (*n*-doping) began at −1.60 V and then the cathodic current increased quickly and produced a cathodic peak at −1.81 V, and a corresponding re-oxidation peak occurred at −1.75. The oxidation and reduction reactions are reversible. The clear redox behavior and the good doping reversibility prove that the polymer may be a good candidate of EL materials for applications in polymer light emitting diodes and polymer light-emitting electrochemical cells (LECs).[15] The electrochemically measured band gap is 2.5 V, which agrees well with the HOMO–LUMO energy gap of 2.53 eV as determined from the absorption onset. The HOMO and LUMO energy levels of this polymer were estimated from the oxidation and reduction onset potentials to be −5.30 and −2.85 eV, respectively.

The fabrication of LED devices was carried out in a glove box under a nitrogen atmosphere. The thickness of the PHTDHFHT film was about 100 nm and the thickness of the calcium electrode, which was thermally evaporated onto the polymer film under 10^{-6} Torr, as about 200 nm. First, the single devices

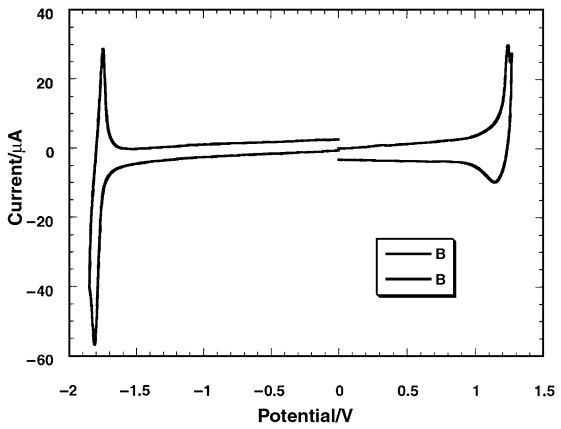

Fig. 2 Cyclic voltammograms of PHTDHFHT recorded in a solution of TBAPF6 (0.1 M) in acetonitrile at rt.

with the configuration ITO–PHTDHFHT–Ca were fabricated. In forward bias, the single-layer devices turned on at about 20 V for current and emitted green light at about 21 V. Considering the energy barrier for hole injection at the anode, double-layer devices with the configuration ITO–PVK–PHTDHFHT–Ca were also fabricated. By employing a PVK layer (90 nm) between the ITO and the polymer film the turn-on voltage for light output was reduced to about 8 V, and the maximum external quantum efficiency was increased from 0.05 to 0.6%. It indicates that PVK as hole-transporting layer can reduce the turn-on voltage of the devices and improve their efficiency.

In conclusion, a novel poly(fluorene-*co*-bithiophene) conjugated polymer, PHTDHFHT, was prepared through metal-catalyzed coupling polymerization in place of ferric chloride oxidative reaction. This polymer shows good thermal stability and photostability. Efficient green PL and EL are demonstrated with the polymer.

Notes and references

† The polymer was precipitated from the reaction mixture by pouring it into MeOH. The precipitate was washed with MeOH and was then re-dissolved in THF. The THF solution was vigorously stirred together with the 50% aqueous solution of hydrazine monohydrate (v:v 1:1) at rt for 24 h. The THF solution was separated and filtered. The solution was then poured into MeOH to precipitate the polymer. The polymer was collected by filtration and was washed with MeOH. Finally, the polymer was washed with acetone in a Soxhlet apparatus for 24 h and then dried under vacuum at rt.

Degradation of an antitumour bicyclic hexapeptide, RA-VII 1, produced protected cycloisodityrosines in an efficient manner through bis(thioamide) intermediate 6.

RA-VII **1**[1] and bouvardin (NSC 259968) **2**[2] are a class of peptides originating from Rubiaceous plants. They show potent antitumour activity, and their mode of action is considered to be inhibition of protein synthesis through interaction with eukaryotic 80 S ribosomes.[3] While the cycloisodityrosine moiety is proposed to be the pharmacophore for this type of peptide,[4] the role of the 18-membered ring moiety for the activity is still an outstanding issue. Although several approaches towards the synthesis of cycloisodityrosines have been reported,[5–7] their multi-step synthesis inevitably requires construction of a strained diphenyl ether linkage, which is not easily accessible, using unusual amino acids. Also, the easily epimerisable properties of cycloisodityrosines[6d–f,7b] hamper ready access to the cycloisodityrosine unit needed for the synthesis of 18-membered ring modified analogues. We report herein an alternative practical approach towards cycloisodityrosines from RA-VII **1** which is the most abundant congener of RAs obtained from commercially available Rubiae Radix.[8]

To obtain cycloisodityrosines from peptide **1**, selective cleavage of the peptide bonds at specific positions was required. Previously, we reported that when RA-VII **1** was treated with 2,4-bis(methylthio)-1,3,2λ^5,4λ^5-dithiadiphosphetane-2,4-dithione **3** at rt, [Tyr-3-Ψ(CS-NH)-Ala-4; Tyr-6-Ψ(CS-NH)-D-Ala-1]RA-VII **4**, with accompanying monothioamides and other bis(thioamides), was obtained in 38% yield.[9] We deemed that bis(thioamide) **4** would be a suitable substrate for such degradation. Although some enhancement of the yield (~50%) of **4** has been made by modifying the reaction conditions, we found that when [*N*-methyl-Ala-2]RA-VII **5**, which is readily prepared from peptide **1** in 97% yield,[10] was thionated using the same reagent, bis(thioamide) **6** possessing thioamide bonds at the same positions as **4** was produced in 91% yield (Scheme 1). Compound **6** was converted into bis(imidothioate) **7** using

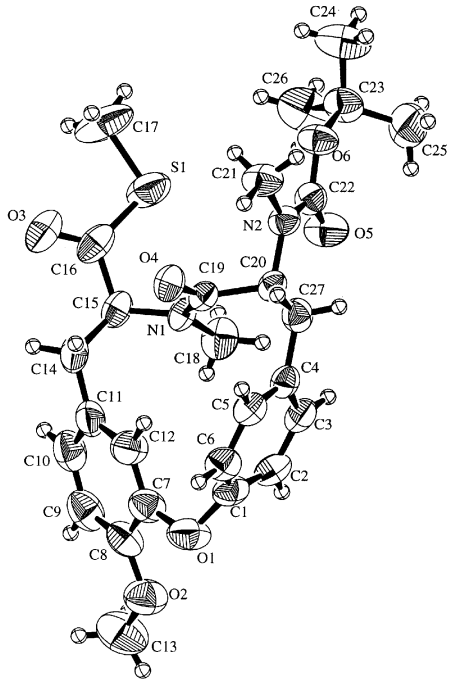

Fig. 1 The crystal structure of compound **10**.

iodomethane and potassium carbonate, and successive treatment with 6 M HCl in acetonitrile resulted in the cleavage of two imidothioate linkages to produce a mixture of two tripeptide segments **8** and **9** (Scheme 2). This mixture, without separation, was then subjected to Edman degradation, and *N*-protection using di-*tert*-butyl dicarbonate afforded cycloisodityrosine thioester **10** in 78% yield from bis(thioamide) **6**.† The structure of compound **10** was confirmed by X-ray crystallography (Fig. 1).‡ Compound **10** was converted into benzyl ester **11** and known methyl ester **12**[6f,7b] in yields of 90 and 97%, respectively.§ The spectroscopic data of **12** were in good agreement with those of **12** previously reported. The chemical conversion described here proceeds in an efficient manner; the overall yields of cycloisodityrosines **11** and **12** from RA-VII **1** were 62 and 67%, respectively. We are currently engaged in the design and synthesis of 18-membered ring modified analogues of RA-VII using **11** and **12**, and the results will be disclosed in due course.

Notes and references

† This key transformation (**6** → **10**) was most effectively carried out on a 0.15–0.2 mmol scale.

Methylation of (2-methylethanethiol-bis-3,5-dimethylpyrazolyl)methane zinc complexes and coordination of the resulting thioether: relevance to zinc-containing alkyl transfer enzymes

Brian S. Hammes and Carl J. Carrano*

Methylation of the coordinated thiolate in pseudotetrahedral Zn complexes of the form [(L3S)ZnX] by a variety of alkylating agents appears to occur *via* a nondissociative route and the resulting thioether can remain coordinated to the metal center as it does in zinc dependent alkyl transfer enzymes such as the DNA repair protein, Ada, from *Escherichia coli.*

The role of zinc metalloproteins in enzymatic alkyl group transfer is an emerging area of bioinorganic chemistry.[1] Examples of such enzymes include the DNA repair protein Ada from *E. coli*, the cobalamin dependent and independent methionine synthases, farnasyl transferase, and others.[2–6] In all of these proteins the zinc ion is in a thiol rich coordination environment with multiple cysteine residues as ligands. Zinc in the Ada protein, for example, is surrounded by four such cysteine residues (designated a CCCC site) although systems in which one or two of the cysteine residues have been replaced by histidines (CCHC and CCHH) are also known.[2–6] Interestingly, these same motifs also characterize the non-enzymatic zinc-finger proteins.[1]

A major question, which has been addressed by several model compound studies, has been: what is the role of the zinc in modulating the reactivity of cysteine residues toward methyl group transfer? In seminal mechanistic work, Wilker and Lippard have shown that in reactions of $Zn(SPh)_4^{2-}$ and its derivatives with trimethylphosphate as the methyl donor, methyl group transfer from the model substrate did not require the presence of zinc.[7] Thiolate anions were actually more readily alkylated although no transfer was seen when thiols were the acceptors. Methylation also occurred in the presence of $Zn(SPh)_4^{2-}$ but since all of its reactivity could be attributed to dissociated thiolate anion, doubts existed regarding the reactivity of a true zinc bound thiolate. More recently however, both we and Vahrenkamp and associates, have presented evidence for a nondissociative mechanism in the alkylation of [(L)ZnSR] (where L is a trispyrazolylborate or other scorpionate ligand) complexes by a variety of methylating agents.[8,9] Evidence has been accumulating that zinc-bound thiolates are in fact the active nucleophiles in the enzymatic reactions as well.[10]

One aspect of the enzymatic reactions not mimicked in any model system studied thus far is the fact that in many of the former, the thioether produced in the alkyl transfer remains coordinated to the zinc. Thioether coordination has been unequivocally demonstrated for the Ada protein and spectroscopic evidence consistent with this has been presented in several other cases as well.[11–13] In all of the model studies conducted to date the thioether has never been found in the zinc coordination sphere after alkylation.[7–9] This observation has prompted Vahrenkamp to propose that the apparently very poor donor capabilities of the thioether group toward zinc may contribute significantly to the overall reactivity in these systems.[9] Using a new N_2S heteroscorpionate ligand that is isostructural and isoelectronic with the well known N_3 trispyrazolylborates, we report here a system where a zinc-bound thiolate appears to be the active nucleophile[8b] and the thioether resulting from methyl group transfer reaction remains in the coordination sphere of the zinc in the absence of superior anionic ligands.

The ligand L3SH is prepared in reasonable yield using the same approach used to prepare previous members of this family.[8a] Thus bis(3,5-dimethylpyrazolyl)ketone reacts with 2-methyldithioisobutyraldehyde as a melt at 80 °C in the presence of $CoCl_2$ as a catalyst. The thio-protected intermediate, L3SSMe, was cleanly reduced with $LiAlH_4$ to yield the desired product. Pseudotetrahedral zinc complexes such as [(L3S)ZnI] **1**, or [(L3S)ZnOAc] **2**, were readily prepared by either direct reaction of deprotonated $(L3S)^-$ (methoxide ion) with the appropriate zinc salt or protonation of the $[(L3S)ZnCH_3]$ derivative with HX. Methylation of the coordinated thiolate in these complexes was achieved using methyl iodide, trimethyloxonium tetrafloroborate, or *p*-nitrobenzene sulfonic acid methyl ester as methyl donors.

Reaction of **1** with an equivalent of methyl iodide in dichloromethane yields the complex $[(L3SCH_3)ZnI_2]$, **3**, where the thioether is uncoordinated as has been previously found in related systems. Reasoning that the neutral thioether could not compete with the anionic iodide ion released in the methylation reaction, we removed one iodide by treatment of **3** with an equivalent of $AgBF_4$. Isolation of the product after filtration of precipitated AgI yielded the pseudotetrahedral complex **4**, $[(L3SCH_3)ZnI][BF_4]$ where the thioether is now bound to the zinc (Fig. 1).† These transformations are summarized in Scheme 1. The same reaction sequence starting with **2** leads to $[(L3SCH_3)ZnOAc][BF_4]$ which in the solid state dimerizes to the acetato bridged complex **5**, $[(L3SCH_3)Zn(\mu\text{-}OAc)_2(\mu\text{-}OH)Zn(L3SCH_3)][BF_4]$ containing octahedral zinc with coordinated thioethers (Fig. 2).† These reactions show clearly,

that in the absence of superior anionic ligands such as iodide, neutral thioethers can bind to a zinc center in either a tetrahedral or octahedral geometry.

Although coordinated thioether complexes could be prepared by removal of iodide by treatment with silver salts, the question remained, would a thioether formed by methylation of a zinc-bound thiolate remain coordinated without the addition of outside intervention? Trimethyloxonium tetrafloroborate and *p*-nitrobenzenesulfonic acid methyl ester are methyl donors used extensively to modify cysteine residues in proteins and are expected to produce only the weakly coordinating CH_3OCH_3 or *p*-nitrobenzene sulfonate as byproducts. Reaction of [(L3S)ZnX] where X = I^- or OAc^- with either of the above gave the expected $[(L3SCH_3)ZnX]^+$ directly as determined by NMR and electrospray-MS.‡ Thus the system reported herein mimics the known chemistry of the relevant zinc enzymes such as Ada.

Although the chelate effect is clearly important helping the thioethers produced here remain coordinated, it is not decisive. Thus while complexes of zinc with coordinated thioethers incorporated into anionic ligands are known,[14–16] numerous neutral chelates containing thioethers have been examined and invariably the thioethers are uncoordinated.[17–21] Thus we can envision zinc enzymes of this type being divided into two groups: the first where the sulfur to be methylated is part of the protein backbone *i.e.* one of the cysteine donors in the zinc coordination sphere as in the Ada protein. Under these conditions the resulting thioether can be expected to remain coordinated to the zinc due the macromolecular chelate effect. In the case where the thiol to be methylated represents an exogenous substrate, as in the cobalamin independent methionine synthases, the resulting neutral monodentate coordinated thioether is expected to be easily displaced by other ligands such as water (hydroxide). Such a process would yield free product and zinc enzyme with an open coordination site ready to repeat the catalytic cycle.

1-Triphenylphosphoniobenzo[*c*]phospholide 2 which is accessible *via* $NaBH_4$ reduction of 1,3-bis(triphenylphosphonio)benzophospholide 1 displays an ambident coordination ability similar to a phosphinine; this is shown by its reactions with (cyclooctene)$Cr(CO)_5$ and (naphthalene)$Cr(CO)_3$ which gave (σ(*P*)-2)$Cr(CO)_5$ and (η⁵-2)$Cr(CO)_3$, the first π-complex of a 10π-aromatic phosphorus heterocycle with a d-block metal.

Phosphinines **I** and phospholides **II** are aromatic phosphorus heterocycles whose use as ligands in transition metal complexes receives substantial current interest,[1] in particular in connection with possible applications in catalysis.[2] As compared to their organic analogues, *viz.* arenes and cyclopentadienides, **I**, **II** are more versatile ligands which may bind to metals not only *via* the π-electron system (η⁵/η⁶-coordination) but also *via* the phosphorus lone-pair (σ(*P*)-coordination), or a combination of both.[1] For phosphinines, formation of σ(*P*)-complexes in which the ligand displays σ-donor/π-acceptor-properties similar as a phosphane or phosphite is generally more favourable with metals in low oxidation states, although complexes with η⁶-coordinated phosphinines are also accessible for various metal centres.[1] Phospholides prefer, in contrast, π-coordination and the vast majority of complexes feature η⁵-bound ligands; pure σ(*P*)-phospholide complexes are known,[3] but remain rare.

We have recently established that cationic 1,3-bis-triphenylphosphonio-benzophospholide **1** binds to various transition metals in a σ(*P*)- or μ_2(*P*)-coordination mode.[4,5] The donor ability of the π-electron system in **1** was found to be inferior to that of the phosphorus lone-pair, and on the whole the structural features of the complexes resembled more closely those of topologically related phosphinine complexes rather than genuine phospholide complexes.[4] These findings suggested that the reduction of π-nucleophilicity and enhancement of π-electrophilicity induced by the phosphonio groups is of pivotal importance for the complexation regioselectivity and lead us to conclude that mono-phosphonio-substituted benzophospholides might display a balanced ligand behaviour with prospects for both σ(*P*)- and π-coordination, similar to the case of phosphinines. Here, we report on the synthesis and coordination studies of the phosphonio-benzophospholide **2** which lead to the isolation and structural characterisation of the first π-complex of a 10π-aromatic phosphaarene with a d-block transition metal.[6]

During our studies of reductive fragmentation reactions of the cation **1**[7] we discovered that **1**[Cl] reacts selectively with excess $NaBH_4$ *via* cleavage of PPh_3 to form neutral species **2** (Scheme 1). The latter was isolated in satisfactory yield after recrystallisation from THF–isopropyl alcohol and its constitution established by analytical and spectroscopic data.† Interestingly, the first UV–VIS absorption band of **2** [λ_{max} (CH_2Cl_2) = 352 nm] which is attributable to a π–π* transition of the benzophospholide chromophore occurs at nearly the same wavelength as for **1** [λ_{max} (CH_2Cl_2) = 354 nm[5]], thus indicating similar frontier orbital gaps in both molecules. As the effect of the positive charge in **1** should shift all orbitals to more negative energies,[8] neutral **2** is thus expected to behave as a better π-donor but less effective π-acceptor than **1**.

To survey the coordination behaviour of **2**, we explored reactions with equimolar amounts of [(cyclooctene)$Cr(CO)_5$] and [(naphthalene)$Cr(CO)_3$], respectively. Both reactions proceeded according to an ^{31}P NMR spectroscopic assay with quantitative formation of a single phosphorus containing species. The products were isolated after precipitation with hexane and recrystallisation from toluene, and their nature as the complexes **3**, **4** was established by microanalytical and spectroscopic data and single crystal X-ray diffraction studies.[9]

Complex **3** displays a moderate negative coordination shift for the endocyclic phosphorus atom [δ^{coord} = δ(ligand) − δ(complex) = −29] while coordination shifts for the benzophospholide carbon atoms are insignificant (δ^{coord} < ± 3) and the proton at C3 is slightly deshielded (δ^{coord} = 0.3). All these features are characteristic for complexes featuring σ(*P*)-coordinated low valent phosphorus species.[1] The carbonyl region of the IR spectrum of **3** displays the expected pattern of a $M(CO)_5$ moiety with the band at highest energy (ν = 2064 cm^{-1}) appearing at slightly lower wavenumbers than in [$(Ph_3P)Cr(CO)_5$] ($\tilde{\nu}$ = 2070 cm^{-1}) or the phosphinine complex [σ-(2,4,6-triphenylphosphinine)$Cr(CO)_5$] **5** ($\tilde{\nu}$ = 2071 cm^{-1} [10]). Although comparison of this vibrational frequency in $LM(CO)_5$ complexes has been used to relate the π-acceptor qualities of L,[2] a more common and quantitative approach is provided by evaluation of Tolman's electronic parameter χ which can be obtained from vibrational spectra of $LNi(CO)_3$ complexes.[11] We have therefore recorded IR spectral data of the $Ni(CO)_3$ complex of **2** (prepared *in situ* from equimolar amounts of **2** and $Ni(CO)_4$) and determined a value of χ = 13 indicating that the π-acceptor ability of **2** should match that of PPh_3 (χ = 13[11]) but is lower than that of $P(OMe)_3$ (χ = 23[11]) or 2,4,6-triphenylphosphinine (χ = 23[2]).

The ^1H, ^{13}C and ^{31}P NMR spectra of complex **4** reveal large negative coordination shifts for the endocyclic phosphorus (δ^{coord} = −158), the hydrogen at C3 (δ^{coord} = −2.6) and the carbon atoms in the five membered ring (δ^{coord} = −17 to −24) whereas the remaining nuclei in the benzophospholide unit exhibit similar chemical shifts as in free **2**. Altogether, these

† Electronic supplementary information (ESI) available: analytical and spectroscopic data for **2**-**4**. See http://www.rsc.org/suppdata/cc/b0/b005130f/

DOI: 10.1039/b005130f

data indicate π-coordination of **2** *via* the five-membered ring which has likewise been observed for indenyl complexes such as $[(\eta^5\text{-indenyl})Cr(CO)_3]^-$ **6**.[12] The carbonyl stretching vibrations in the IR spectrum of **4** ($\tilde{\nu}$ = 1925, 1835, 1826 cm^{-1}) appear at higher wavenumbers than in both **6** ($\tilde{\nu}$ = 1895, 1791 cm^{-1} [12] and $[\eta^5\text{-}(C_5H_4PPh_3)Cr(CO)_3]$ **7** ($\tilde{\nu}$ = 1900, 1805, 1785 cm^{-1} [13]), indicating that the amount of π-electron density transferred to the metal is lower for **2** than for the carbocyclic ligands $C_9H_7^-$ and $C_5H_4PPh_3$, respectively.

The results of the X-ray structure analysis of complex **3** [Fig. 1(a)] confirms the presence of a σ(*P*)-coordinated benzophospholide ligand with a planar annulated ring system. Unlike as in known complexes of σ(*P*)-coordinated phospholides,[3] the metal-bound phosphorus atom lacks any evidence for pyramidalisation (sum of bond angles 360°). The exocyclic P–C bond [P2–C2 1.744(1) Å] is similar as in complexes of **1** (1.75 ± 1 Å[4]) whereas of the endocyclic P–C distances the one to the protonated carbon atom is shortened [P1–C9 1.691(2) Å] and the other lengthened [P1–C2 1.767(2) Å]. The P1–Cr1 bond [2.376(5) Å] matches that in the phosphinine complex **5** [2.372(15) Å[4]]. The Cr–C distances in **3** [$Cr–C_{trans}$ 1.862(4) Å, $Cr–C_{cis}$ 1.895–1.912, av. 1.902 Å] are generally longer than those in **5** [$Cr–C_{trans}$ 1.822(12) Å, $Cr–C_{cis}$ 1.825–1.865, av. 1.843 Å[10]]. Although interpretation of these data in terms of electronic effects is difficult in view of sterically induced distortions in both structures, the more pronounced shortening of the *trans*-relative to the *cis*-Cr–C bonds in **3** agrees with a lower π-acceptor ability of **2** as compared to 2,4,6-$Ph_3H_2C_5P$ which was predicted on grounds of the spectroscopic data.

The molecular structure of **4** [Fig. 1(b)] displays a three-legged piano-stool geometry with the coordinated five membered ring featuring a flat twist conformation. The Cr–C distances range between 2.229(2) and 2.341(3) Å with the closest distances observed for the carbons atoms C2, C9 adjacent to P1 which are presumably the centres of highest π-electron density,[8] and the Cr–P distance amounts to 2.407(4) Å. The distances between the metal and the carbonyl C-atoms [1.806(3)–1.837(3) Å] and the centroid of the phospholide ring [1.874(3) Å], respectively, compare well with the corresponding values of $[\eta^5\text{-}(C_5H_4PPh_3)Cr(CO)_3]$ **7** (Cr–CO 1.77–1.83, Cr–Cent. 1.862 Å[13]) and [(η⁶-2,4,6-triphenylphosphinine)$Cr(CO)_3$] (Cr–CO 1.80–1.82, Cr–Cent. 1.686 Å[14]). The exocyclic P2–C2 bond in **4** [1.755(3) Å] is similar than in **3** but the endocyclic P–C [1.744(2), 1.805(2) Å] and adjacent C–C bonds [1.426(3), 1.460(3) Å] are lengthened as expected for a π-complex. The extent of this lengthening is somewhat more pronounced for the P–C than for the C–C bonds which agrees with the finding that the largest coefficients in the frontier orbitals of benzo[*c*]phospholides are found at the phosphorus and the two adjacent carbon atoms.[8]

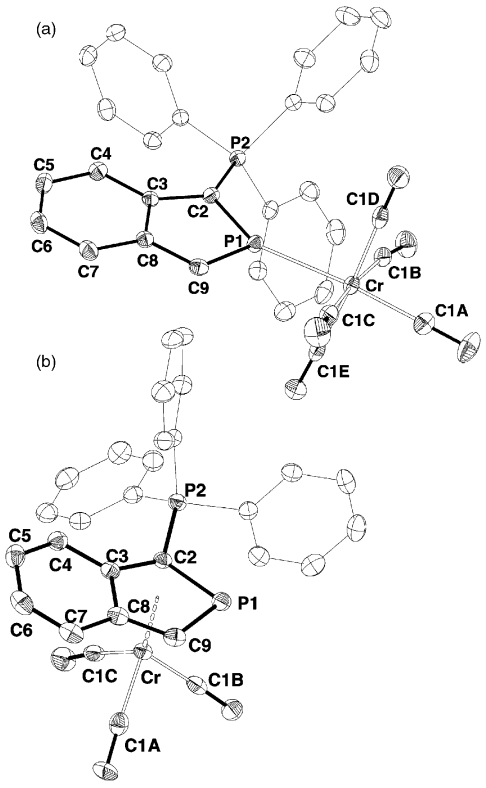

Fig. 1 Molecular structures of **3** (a) and **4** (b). Thermal ellipsoids are drawn at 50% probability level, and H atoms have been omitted for clarity. Selected bond lengths (Å); for **3**, Cr–P1 2.3760(5), P1–C9 1.6910(17), C9–C8 1.414(2), C–C7 1.422(2), C7–C6 1.370(3), C6–C5 1.398(3), C5–C4 1.379(2), C4–C3 1.417(2), C3–C8 1.430(2), C3–C2 1.456(2), C2–P1 1.7670(18), C2–P2 1.7438(17), Cr1–C1D 1.9030(19), Cr–C1B 1.912(2), Cr–C1E 1.8953(19), Cr–C1A 1.862(2). For **4**: P1–C9 1.744(4), C9–C8 1.426(0), C8–C7 1.429(3), C7–C6 1.354(0), C6–C5 1.418(1), C5–C4 1.367(3), C4–C3 1.419(0), C3–C8 1.436(1), C3–C2 1.460(2), C2–P1 1.805(0), C2–P2 1.755(3), Cr–C1A 1.826(2), Cr–C1B 1.806(1), Cr–C1C 1.837(1).

Preliminary studies indicate that analogous complexes as **3**, **4** are likewise accessible with molybdenum and tungsten. In conclusion, our reported findings strongly suggest that the electron withdrawing effect of the PPh_3 group induces a balanced coordination behaviour which enables the benzophospholide **2** to act both as a phosphine-like σ-donor/π-acceptor ligand in σ(*P*)-complexes and a phosphaarene like ligand in π-complexes. A similar switching between different coordination modes was previously known for phosphinines,[1] but scarcely for phospholide type species. Further exploration of this feature as well as the possible exploitation of the chiral nature of **4** are currently under investigation and may possibly add new facets to the coordination chemistry of phospholide ligands.

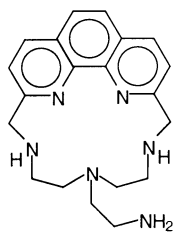
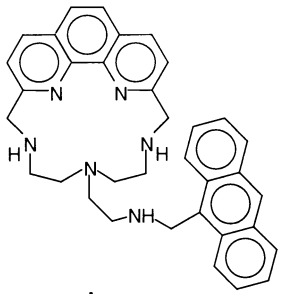
Coordination/detachment of a pendent functionality in the Zn(II) complex with a macrocyclic ligand L gives rise to on/off switching of exciplex emission, defining an elementary molecular machine whose movements are driven by both pH and light.

Chemical systems capable of performing controlled movements at the molecular level are a topic of great interest. In particular great attention is paid to molecular systems whose movements can be controlled by external inputs (pH, temperature, light, redox potential, metal ions).[1–6]

In the present work we describe a Zn(II) complex behaving as an elementary molecular machine driven by pH and light. The mechanical function of this machine consists in the movement of a ligand moiety determined by pH-controlled coordination–detachment of a donor atom leading to the formation of an exciplex emitter. The ligand used, **L**, was obtained by reaction



1



L

of anthracene-9-carbaldehyde (EtOH, room temperature, 48 h) with the macrocyclic precursor **1**, followed by reduction *in situ* of the resulting imine with $NaBH_4$, according to a reported procedure.[7] **1** was synthesized by condensation of 2,9-bis-(bromomethyl)-1,10-phenanthroline with tris(2-tosylaminoethyl)amine by using the Richman and Atkins procedure.[8]

The absorption spectrum of the free ligand presents the characteristic band of the anthracene moiety (λ_{max} = 352 nm), and is only slightly dependent on the pH. The most intense absorption band occurs at 252 nm, a region where both the first singlet of phenanthroline, and the second singlet of anthracene absorb. However, the fluorescence emission exciting at 352 or 252 nm is the same, as expected from the Kasha–Vavilov's rule.[9]

The most interesting feature of the fluorescence emission concerns its dramatic dependence on the protonation state of the compound.† A total quenching of the emission is observed for the species **L**, $H\mathbf{L}^+$ and $H_2\mathbf{L}^{2+}$, while the $H_3\mathbf{L}^{3+}$ form exhibits an intense emission. As observed for many other similar molecules possessing the anthracene fluorophore attached to a polyamine chain, the quenching effect can be explained by an electron transfer process from unprotonated amine groups to the excited anthracene.[10,11] On the other hand protonation of amines rises their oxidation potential to > 2.5 V changing the photoinduced electron transfer reaction from exoergonic to endoergonic, thus precluding the quenching effect.[12] ^{1}H NMR titrations performed at different pH values showed that in $H_3\mathbf{L}^{3+}$ all three benzylic nitrogens are protonated. Only the N2 amine remains unprotonated, although, according to the emission spectra, this would not be an efficient site for photo-induced electron transfer quenching, probably because of involvement in hydrogen bonding to adjacent protonated nitrogens. The species $H_2\mathbf{L}^{2+}$, $H\mathbf{L}^+$ and **L** have two, three and four unprotonated nitrogens, respectively, accounting for the observed quenching effect.

Potentiometric measurements performed in water–MeCN (1 : 1, v/v) solutions, containing Zn(II) and **L** in 1 : 1 molar ratios, showed the formation of stable complexes ($[Zn\mathbf{L}]^{2+}$, $[ZnH\mathbf{L}]^{3+}$, $[ZnH_2\mathbf{L}]^{4+}$, $[Zn\mathbf{L}(OH)]^+$, $[Zn\mathbf{L}(OH)_2]$) over the entire pH region investigated.† The formation of these Zn(II) complexes has also been followed by recording ^{1}H NMR spectra at different pH values, indicating that deprotonation of $[ZnH_2\mathbf{L}]^{4+}$ to form $[ZnH\mathbf{L}]^{3+}$ (pH 3–5) takes place at the amine nitrogen of the pendant arm. At the same time, remarkable shifts for the signals of anthracene and phenanthroline protons evidence the formation of a π-stacking interaction between the two aromatic moieties in the $[ZnH\mathbf{L}]^{3+}$ complex. In other words, metal coordination by the deprotonated amine group of the pendant arm enables the two aromatic moieties to interact *via* π-stacking. Such stacking interaction is maintained in the $[Zn\mathbf{L}]^{2+}$ and $[Zn\mathbf{L}(OH)]^+$ species, as shown by the fact that the spectra do not bear significant changes at neutral or slightly alkaline pH. By contrast, NMR data obtained in very alkaline media (pH 10–13), where $[Zn\mathbf{L}(OH)_2]^{2+}$ is formed, suggest that binding of the second OH^- ion causes the detachment of the amine group of the pendant arm and consequent loss of the π-stacking interaction.

Like many other Zn(II) complexes bearing polyamine chains attached to a fluorophore, the fluorescence emission spectra of the Zn(II) complexes with **L** (λ_{max} = 418 nm) are quite similar to those of the protonated ligand (Fig. 1). This is explained by the fact that coordination of Zn(II) to the amine groups (like protonation) precludes the electron transfer quenching effect.[10–12] On this basis, the quenching effect occurs only at pH values that permit the existence of nitrogens which are neither attached to the metal nor protonated (Fig. 1). This clearly occurs for all the complexes species except $[ZnH_2\mathbf{L}]^{4+}$ which still exhibits an intense emission with a maximum at 418 nm. The most intersting feature of this system, however, is the formation of a non-structured and red shifted emission band (Fig. 1), occurring for all metal complexes with the exception of $[Zn\mathbf{L}OH)_2]$. The excitation spectrum at pH = 6.4, collected at 418 nm is coincident with the absorption spectrum. However the excitation spectrum collected at 600 nm is slightly red shifted, as expected from a ground state association. This exciplex type emission can thus be ascribed to an intramolecular

DOI: 10.1039/b004506n

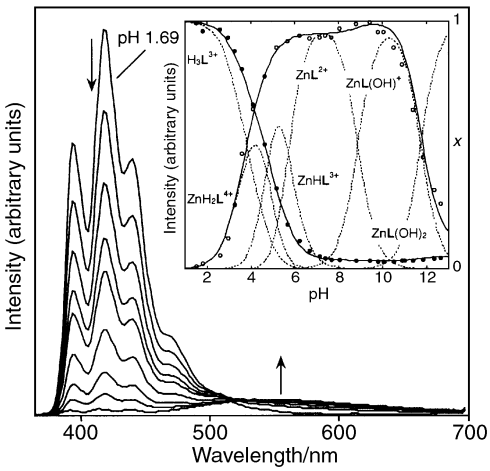


Fig. 1 Fluorescence emission spectra of the Zn(II)–**L** (1 : 1) system in 0.15 M NaCl MeCN–H_2O (1 : 1, v.v) at different pH values: 1.69; 3.73; 4.4; 4.87; 5.1; 5.57; 6.05; 6.55, 10.37 (λ_{exc} = 352 nm). Inset: fluorimetric titration of the same system: (●) emission followed at 418 nm, (○) exciplex emission followed at 600 nm. Species distribution curves (inset) represent mol fractions.

π-stacking complex in the excited state, involving phenanthroline and anthracene. As described above, the π-stacking complex is already formed in the ground state for the species $[ZnH\mathbf{L}]^{3+}$, $[Zn\mathbf{L}]^{2+}$ and $[Zn\mathbf{L}(OH)]^{+}$, but not for $[ZnH_2\mathbf{L}]^{4+}$ and $[Zn\mathbf{L}(OH)_2]$. As a consequence, for $[ZnH_2\mathbf{L}]^{4+}$ the π-stacking complex must be formed during the excited state lifetime. The π stacking complex in the ground state and the *exciplex* emission from the excited state can be explained as a consequence of coordination of the nitrogen of the pendent arm to the metal, since this leads to a geometry where phenanthroline and anthracene are forced to stay close to each other in a sandwich-like mode. This structure is maintained upon coordination of a single OH^- ion to the metal, probably because the binding occurs at the opposite side of the pendent arm, while the exciplex emission, as well as the π-stacking complex, disappear at more basic pH values, in agreement with the detachment of the amine nitrogen of the pendent arm caused by coordination of the second OH^- ion.

Time-resolved fluorescence measurements collected at 419 and 550 nm reveal that, independently of the pH value considered, the decays are always fitted with sums of two or three exponentials. The fluorescence decay of the parent compound, 9-(methylaminomethyl)anthracene, measured at pH = 2 is however single exponential with a lifetime of 10.5 ns. Within the pH range studied (1.6–12.0), two lifetimes with values of 2–2.9 and 5.2–10.5 ns are observed. For lower pH values the contribution of the shorter lifetime is largely predominant at 419 nm (99%), but not so much at 550 nm (70%). As the pH increases the contribution of the second lifetime increases with a concomitant decrease of the shorter component. A third lifetime, attributed to the emissive exciplex species of 21–25 ns, begins to appear at pH = 5. For pH = 8.7 the contribution of this new species is predominant at λ_{em} = 550 nm (45% of the overall decay) but almost negligible at λ_{em} = 419 nm. This means that the back reaction from the exciplex to the monomer(s) is almost non-existent. Although always present for pH > 5, the emission contribution of the exciplex seems to reach a maximum at pH *ca.* 8, slowly decreasing at higher pH values.

We interpret the existence of the two first lifetimes to the presence of two opened structures (monomers) in equilibrium, one clearly ascribable to the free $[H_3\mathbf{L}]^{3+}$ species and the other probably to the $[ZnH_2\mathbf{L}]^{4+}$ complex. In conjunction with steady-state data it is clear that these two monomer species emit in the same region and can only be distinguished by time-resolved fluorescence. In cases where exciplex emission occurs, no negative pre-exponential, *i.e.* a rise-time, is observed as a result of two factors: the first is related to previous findings that

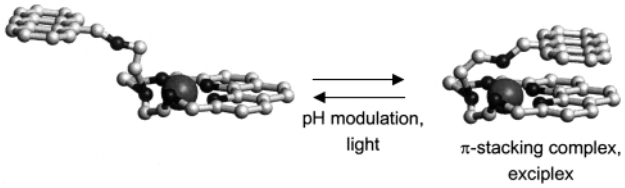

Fig. 2 Modulated formation of the π-stacking complex (exciplex).

a pre-formed exciplex is already present in the ground-state, and the second is a consequence of the fact that the fluorescence emission of the monomer(s) extends to the emission region where the exciplex emits.

The system here reported exhibits a significant advantage, in comparison with other similar compounds, because coordination of the pendent arm to the metal can be easily monitored by the appearance of the *exciplex* emission. The system defines an elementary molecular machine whose movements are driven by pH, and also by light around pH 4 (Fig. 2). Additionally, it can operate in acidic media switching from the species $H_3\mathbf{L}^{3+}$ to $[ZnH_2\mathbf{L}]^{4+}$ or in alkaline media between $[Zn\mathbf{L}(OH)]^{+}$ and $[Zn\mathbf{L}(OH)_2]$.

Interestingly the exciplex emission occurs not only in MeCN–water mixtures but also in pure water, in contrast with other exciplexes or excimers reported in literature which are only stable in non-polar solvents.[9]

A new photochromic cross-linked copolymer composed of PMMA and fluorescing 2-indolylfulgimide is synthesized which can be converted photochemically into two forms which are found to be thermally stable; the spectroscopic properties and quantum yields of photochemistry and fluorescence are also measured.

The increasing fast developments in new technologies associated with optoelectronics, waveguides, molecular switches, optical computer memories among others, require the design and synthesis of novel materials with properties which satisfy the specific needs of each new device.[1] Organic photochromic materials have attracted significant attention, in recent years, because of their potential application to optical devices, and in particular to switches and 3D optical storage.[2] One of the most promising classes of photochromic materials are fulgides because they possess excellent fatigue resistance and thermal stability in both isomeric forms.[3]

In previous papers we have reported the synthesis, photochromic and spectroscopic properties of several new thermally stable fluorescing photochromic 2-indolylfulgides and fulgimides which may be potential materials for use as media in rewritable 3D optical memory devices.[4–6] Here we describe the synthesis and properties of a new fluorescing photochromic 2-indolylfulgimide which is attached to methyl methacrylate monomer, to form a cross-linked photochromic fluorescing polymer.

Photochromic molecules must be uniformly dispersed in a polymer matrix at relatively high concentration to be suitable for use in optical devices. The photochromic materials which have been used in 3D optical memory devices, based on two-photon absorption, require concentrations of 10^{-1} M and higher in order to record a sufficient number of bits of information.[2] The photochromic cross-linked copolymer described here is formed by attaching the photochromic molecule to the polymer chain by copolymerization with the corresponding monomer. We were able to copolymerize the methyl methacrylate monomer and the photochromic 2-indolylfulgimide (*E*-**8**), which we synthesized, to form an optically clear photochromic cross-linked copolymer.

Fulgimide *E*-**8** was readily prepared by the process shown in Scheme 1. Commercially available 3-methylindole (**1**) was converted to **2** by reacting it with vinyl benzyl chloride in potassium hydroxide DMSO solution (78% yield). Product **2** was then converted to **3** using the Vilsmeier-Haack formylation reaction (42% yield).[7] Diethyl isopropylidenesuccinate (**6**) was prepared by Stobbe condensation (86% yield).[8] Stobbe condensation of indole-2-carbaldehyde (**3**) with diethyl isopropylidenesuccinate (**6**) followed by hydrolysis and intramolecular acid anhydride formation yields 2-indolylfulgide (*E*-**7** and *Z*-**7**) with 23% yield from **3** to **7**, where *E*-**7** was separated as the main product. Fulgimide *E*-**8** was synthesized from *E*-**7** by Lewis acid and hexamethyldisilazane-promoted one pot reaction (42% yield).[9,10]

The fulgimide *E*-**8** was subsequently dissolved in methyl methacrylate and the initiator (AIBN) was added forming a homogenous mixture. This mixture was transferred to a glass cell and sealed under vacuum. After 24 h of polymerization, at 50 °C, a rigid optically clear polymer was formed. The structure of this copolymer was determined by immersing it into 1,2-dichloroethane solvent for one month, in which both PMMA and fulgimide *E*-**8** are very soluble. We found, as expected, for cross-linked copolymers, that this immersed material was not dissolved, at all, in 1,2-dichloroethane. This indicates, strongly, that this material is a cross-linked copolymer of MMA and *E*-**8**. After the solid, nondissolved polymer was removed from the solution, the absorption spectra of the remaining phase were measured. The spectra showed that not

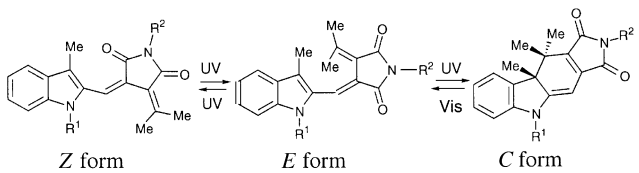
even traces of fulgimide *E*-**8** were present in the solution and only the spectrum of 1,2-dichloroethane solvent was recorded. To the best of our knowledge, this is the first cross-linked photochromic fulgimide copolymer ever synthesized.

The copolymer was found to possess photochromism, *i.e.* can be reversibly colored and bleached by irradiation with light of the appropriate wavelength. In addition the colored form (*C*) also fluoresces when excited with visible light which is rather seldom found in fulgimides. This is, also, the first time that a copolymer of this class has been observed. Fig. 1 shows the absorption spectra of the copolymer in its colorless and colored forms and the fluorescence spectrum of the colored form. The colored form was photoinduced by irradiating the copolymer with 400 nm light. When irradiated with visible light, λ = 530 nm, the colored form can be easily bleached back to the original colorless form, as shown in Scheme 2. The quantum efficiency of the coloration and bleaching processes were measured to be 0.13 and 0.17 respectively. These numbers are the same as the quantum efficiencies measured for pure *E*-**8** in ethyl acetate solution. We thought, previously, that in rigid cross-linked copolymer matrices, where the moieties of the fulgimide molecule are attached to the polymer chains, the efficiency of *E*–*Z* isomerization would be decreased, because of stereo constrains. In addition we had expected that because the *E*–*Z* isomerization competes with the ring-closure reaction, the cyclization reaction yield will increase. However, our data show that in a copolymer composed of fulgimide *E*-**8** and methyl methacrylate the efficiency of cyclization yield does not change. This suggests that the *E*–*Z* isomerization be not significantly reduced compared to the solution, probably due to segment rotation of the polymer chain.



Scheme 2

The colored form of the fulgimide–MMA copolymer emits red fluorescence when promoted to its first excited state. The fluorescence spectra observed are similar to the colored forms of the pure fulgimides in solution. To confirm that the recorded fluorescence is due to the colored forms of the organic photochrome rather than any impurities or other species, we measured the excitation spectra and fluorescence emission spectra intensity change as a function of bleaching/coloration cycles. The data show that the fluorescence intensity and the excitation spectra of the colored from decrease proportionally with the decrease of the absorption of the fulgimide colored form. When the material was completely bleached, *i.e.* the absorption band of the *C* form disappeared no fluorescence was detected. When the fluorescence spectrum appeared again, its intensity increased with the same rate as the rate of growth of the *C* form concentration. The fluorescence quantum yield of the colored form was found to be 5%. The method that we have used to measure the quantum efficiencies of these forms has been described previously by us.[5]

Asymmetric synthesis of febrifugine and isofebrifugine using yeast reduction

Yasuo Takeuchi,* Kumiko Azuma, Kentaro Takakura, Hitoshi Abe and Takashi Harayama

Faculty of Pharmaceutical Sciences, Okayama University, Tsushima-naka 1-1-1, Okayama 700-8530, Japan. E-mail: take@pharm.okayama-u.ac.jp

Received (in Cambridge, UK) 22nd June 2000, Accepted 21st July 2000
Published on the Web 11th August 2000

The antimalarial agents febrifugine ((+)-1) and isofebrifugine ((+)-2) were asymmetrically synthesized from chiral piperidin-3-ol ((+)-4), which was prepared by the reductive dynamic optical resolution of the 3-piperidone derivatives ((±)-3) using baker's yeast.

Febrifugine ((+)-**1**) is an antimalarial agent that was isolated from *Dichroa febrifuga* and *Hydrangea umbellata* along with isofebrifugine ((+)-**2**).[1a–c] The plane structure[2a] of (+)-**1** and (+)-**2** was first proposed in 1950. Subsequently, the relative[2b] and absolute[2c] structures were proposed on the basis of Baker's synthetic work.[3a–c] The relative configuration[2d] of (+)-**1** was corrected in 1973 and then the absolute structures[2e,f] of (+)-**1** and (+)-**2** were corrected in 1999 (Fig. 1). We previously synthesized the racemates of (+)-**1** and (+)-**2** *via* the unusual Claisen rearrangement and highly diastereoselective reduction.[4a,b] In this paper, we describe the asymmetric synthesis of (+)-**1** and (+)-**2** based on our synthetic method.

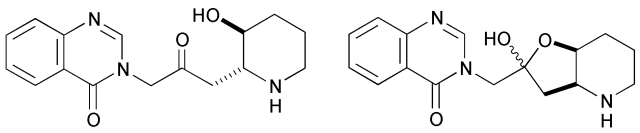

Fig. 1 Structures of febrifugine and isofebrifugine

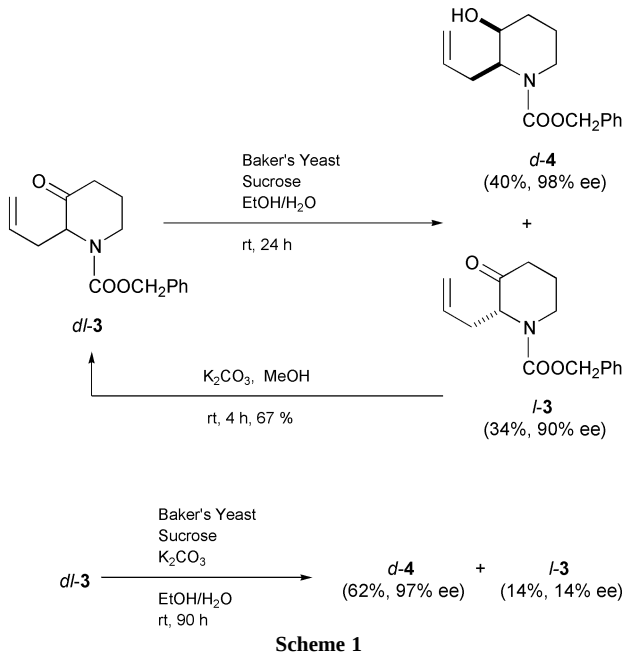
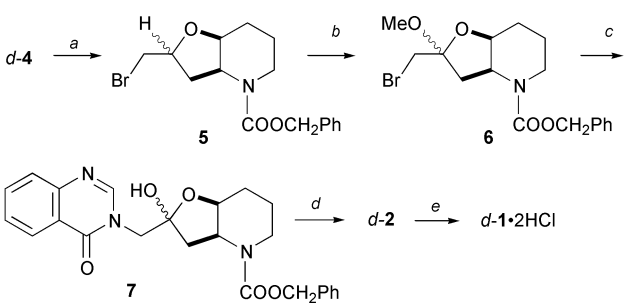
As a key asymmetric reaction, we selected the yeast reduction of 3-piperidone derivatives ((±)-**3**)[4a,b] protected by a benzyloxycarbonyl (*Z*) group (Scheme 1). The reaction of (±)-**3** with baker's yeast and sucrose in EtOH and water at rt for 24 h afforded chiral piperidin-3-ol ((±)-**4**), for which the ^{1}H-NMR data agreed with reported values[4b] for (±)**4**, in high yield (40%) and enantiomeric purity (98% ee).[5] The remaining piperidone ((−)-**3**, 34%) also had high enantiomeric purity (90% ee). Since epimerization of (−)-**3** with K_2CO_3 for 4 h gave (±)-**3** in 67% yield, we could be sure of the possibility of reductive dynamic optical resolution. Epimerization that maintained the reductive activity of the yeast was examined under a variety of concentrations of K_2CO_3 and EtOH in water. Stirring a mixture of (±)-**3**, baker's yeast, sucrose, and K_2CO_3 in EtOH and water at rt for 90 h afforded (+)-**4** in 62% yield (97% ee) along with (−)-**3** in 14% yield (14% ee).[6]



Scheme 1

Isofebrifugine ((+)-**2**) was prepared by improving our previous method (Scheme 2). The intramolecular bromoetherification of (+)-**4** using NBS afforded octahydrofuro[3,2-*b*]-pyridine (**5**) in 87% yield. The HPLC data indicated that this was a 3:1 mixture of the diastereomeric isomers. To improve the yield and reproductivity of preparing *Z*-protected isofebrifugine (**7**) from **5**, we designed a 2-methoxy derivative **6**. The new intermediate **6** could be prepared by a 2-step reaction in high yield (90%) as a 4 : 1 mixture of the diastereomeric isomers. The steps were dehydrobromination using potassium *tert*-butoxide and bromoetherification using NBS and MeOH. Deacetalization of **6** followed by a coupling reaction with 4(3*H*)-quinazolinone afforded **7** in 69% yield. The hydrogenolysis of **7** gave isofebrifugine ((+)-**2**) in 62% yield as a crystalline solid. The melting point,[1b] ^{1}H-NMR data,[7a,b] and optical rotation[1b] for (+)-**2** agreed with reported values for the natural product.[8] It was clear that the yeast reduction of (±)-**3** followed the Prelog rule[9] with high enantio- and diastereoselectivity to give (+)-**4** having the absolute configuration of 2*S*,3*S*.

In our previous method for synthesizing (±)-febrifugine ((±)-**1**), the large differences[4b] in the melting point and solubility of (±)-**1** and (±)-**2** played a convenient role for the isolation of (±)-**1**. However, we could not isolate pure (+)-**1** by refluxing (+)-**2** in EtOH. Although it is known that isomerization of the congeners of (+)-**2** run under the reversible Michael reactions,[7a,10] there are no reports of (+)-**2** itself. We examined the isomerization of (+)-**2** to (+)-**1** in various solvents, including toluene, DMF, pyridine, EtOH, water, and 10% HCl aq. Heating (+)-**2** at 80 °C for 30 min in water resulted in the largest ratio (2 : 1) of (+)-**1** to (+)-**2** among these solvents. On the other hand, the epimerization of (+)-**2** in 10% HCl aq. was not observed under the same conditions. Based on these results, we isolated pure (+)-**1**[11] as the hydrochloride salt and its physicochemical



Scheme 2 *Reagents and conditions*: *a*, NBS, MeCN, rt, 0.5 h, 87%; *b*, (i) ^{t}BuOK, THF, 0 °C, 0.5 h; (ii) NBS, MeOH, rt, 1 h, 90%; *c*, (i) H^+, MeCN, rt, 1 h; (ii) 4(3*H*)-quinazolinone, K_2CO_3, DMF, rt, 2 h, 69%; *d*, H_2, 20%-Pd(OH)$_2$/C, MeOH, rt, 3.5 h, 62%; *e*, (i) H_2O, 80 °C, 15 min; (ii) H^+, 73%.

DOI: 10.1039/b005028h

properties[1c] and spectral data[7a,b] were identical with those reported for the natural product.

We were able to prepare febrifugine ((+)-**1**) in 15.2% yield and 6 isolated steps from (±)-**3** without using compounds that were very expensive, toxic, or dangerous. We think that our method is widely applicable to the synthesis of the derivatives needed to study the structure–activity relationship of febrifugine.

We are grateful to the SC-NMR Laboratory of Okayama University for the use of the facilities.

Received (in Irvine, CA, USA) 8th June 2000, Accepted 12th July 2000

The complex tris[1(*N*- ethylcarbazolyl)(3′,5′-hexyloxybenzoyl)methane](phenanthroline)europium 1 incorporates a phenanthroline ligand for electron transport and a carbazole fragment in the diketonate ligand for hole transport; furthermore, the six hexyloxy groups prevent crystallization and allow for the formation of transparent clear films directly from solution; the photoluminescence from films of 1 is nearly monochromatic, characteristic of the europium ion and proceeds with an efficiency of 50(3)%; light emitting diodes(LEDs) were fabricated using the simplest possible device architecture comprising an anode (ITO), a layer of 1 and a cathode (Ca); a second LED configuration with a PVK layer on top of the ITO was also investigated; the performance of the two types of devices is discussed.

Europium tris(β-diketonate) complexes are finding innovative applications as the electroluminescent layer in molecular light emitting diodes (LEDs).[1] Since the emission from these complexes stems from transitions between f levels that are well protected from environmental perturbations by the filled $5s^2$ and $5d^{10}$ orbitals, the resulting emission bands (585 nm, $^5D_0 \rightarrow {}^7F_1$ and 617 nm $^5D_0 \rightarrow {}^7F_2$) are nearly monochromatic.[2] Color purity of this type is required for full color displays. Pure red, green and blue light can be obtained by the use of filters, albeit with a decrease in light output.[3]

Typically, LEDs using lanthanide-based materials are fabricated by vacuum deposition of the complex onto a suitable charge injection layer. To optimize charge balance, the best devices take advantage of a multilayer architecture.[4] We recently reported polymeric light-emitting diodes that emit pure red light with a 3.5 nm linewidth by making use of energy transfer from poly[2-(6′-cyano-6″-methylheptyloxy)-1,4-pheneylene] (CN-PPP) to europium complexes with β-diketonate and phenanthroline ligands.[5] In this approach, a film containing the polymer and the complex can be cast directly from solution thereby facilitating fabrication. Efficient excitation transfer from CN-PPP results in complete quenching of the broad emission of the polymer and pure red Eu-based emission.

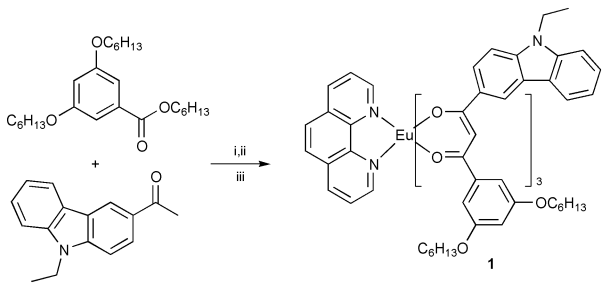
It occurred to us that it should be possible to design a ligand for europium that contained structural features for optimizing charge transport across the bulk and that gave the complex topological attributes which would discourage crystallization. The latter requirement was incorporated so as to obtain stable glasses and uniform optical quality thin films directly from solution. As our target, we chose the complex tris[(*N*-ethylcarbazolyl)(3′,5′-hexyloxybenzoyl)methane](phenanthroline)europium **1** (Scheme 1). The phenanthroline ligand was included since it is thought to enhance the electron transport of the material.[6] A carbazole fragment was appended to the diketonate ligand with the intention of improving hole transport.[7] Finally the hexyloxy groups were introduced to prevent crystallization and to increase solubility in common organic solvents.

As shown in Scheme 1, the diketonate ligand is prepared by Claisen condensation of 3-acetyl-9-ethylcarbazole[8] and hexyl-3,5-hexyloxybenzoate in the presence of NaH. After refluxing in dimethoxyethane for 24 h, followed by acetic work-up and purification by chromatography, (*N*-ethylcarbazolyl)(3,5-hexyloxybenzoyl)methane is obtained in 24% yield. The europium complex **1** is prepared by taking advantage of well established protocols.[9] Deprotonation of three equivalents of (*N*-ethylcarbazolyl)(3,5-hexyloxybenzoyl)methane with an excess of NaOH, followed by treatment with $EuCl_3(H_2O)_6$ and finally phenanthroline affords **1** in 50% yield. Purification can be accomplished by precipitation from concentrated acetone solutions.

Compound **1** is a pale yellow powder, which by differential scanning calorimetry (DSC) shows a glass transition temperature at 65 °C. Powder diffraction experiments show no evidence of crystalline regions. The morphological properties of compound **1** make it possible to spin-cast clear transparent films directly from solution.

Fig. 1 shows the absorption and photoluminescence spectra of a thin film of **1**. The absorption onset at *ca.* 458 nm corresponds to a HOMO–LUMO energy difference of 2.71 eV. This value is also observed in the spectrum of the sodium salt of the diketonate ligand. Light absorption is therefore controlled by the ligand framework. The sharp emission at 612 nm is characteristic of the europium ion within a tris(β-diketonate)-phenanthroline environment. Therefore, the triplet level of the ligand is sufficiently high to allow energy transfer to the ion.[10] Use of an integrating sphere revealed that the solid state photoluminescence efficiency from films of **1** is 50(3)%. These measurements were made using the 351 nm line from an argon laser (intensity of 2.5 mW cm^{-2}), an integrating sphere, a high pass filter that blocks the laser line, and a silicon diode.[11]

The resistance to crystallization and exceptionally low self quenching of **1** prompted us to examine its electroluminescent properties. Two types of LED structures were fabricated.[12] In



Scheme 1 *Reagents and conditions*: i, NaH/dimethoxyethane; ii, NaOH, $EuCl_3(H_2O)_6$, ethanol; iii, phenanthroline, toluene.

† Complete details for the synthesis of **1** (PDF). The material is available free of charge *via* the Internet at http://pubs.acs.org.

DOI: 10.1039/b004739m

the first device, a film of **1** (600 Å) was spin-cast directly onto the indium tin oxide (ITO) anode. The spin-casting solution was 1 wt% in toluene and was filtered through a 5 micron Nylon filter. The layer of **1** was subsequently dried under vacuum at ambient temperature for *ca.* 1 h. The calcium cathode layer was deposited as described previously and subsequently overcoated with aluminium.[12] This device has only a single layer and only one molecular component between the electrodes; *i.e.* the simplest architecture possible.

Fig. 2 shows the current–voltage curve of the single-layer device. Light emitted from this device is identical to the PL spectrum shown in Fig. 1. The turn-on voltage for current and luminance, is observed at *ca.* 5.3 V (8.8 mV $Å^{-1}$) and is similar in magnitude to many polymer LEDs and lower than many multilayer organic LEDs (OLEDs) prepared by sublimation. These characteristics demonstrate that the ligand design was successful in facilitating electron and hole injection and transport into and across the europium layer. At 15 mA cm^{-2}, the light output is 9 cd m^{-2} with an external EL quantum efficiency of 0.08%.

A second device architecture was fabricated in an effort to improve the device efficiency, and to gain insight into the mechanism of europium electroluminescence. In this archetecture, a layer of polyvinylcarbazole (PVK) (30 nm) was first spin-cast from a 2% solution of PVK in 1,1,2,2-tetrachloroethane on top of the ITO-glass substrate and, after drying at 60 °C for 1 h, a 700 Å layer of **1** was spin-cast as before. The cathode layer is the same as in type 1. Only emission from Eu was observed, *i.e.* identical to Fig. 1. Fig. 3 shows the current–voltage relationship for this device. Compared to the single layer device, the turn-on voltage is higher, *ca.* 8.7V (8.75 mV $Å^{-1}$), owing to the extra thickness introduced by the PVK layer; but both devices operate at equivalent field strengths. The device efficiency was improved considerably (50 cd m^{-2} at 15 mA cm^{-2})[13] with an external quantum efficiency of 0.3%. It is thought that the PVK layer acts both as a hole injection and an electron blocking layer[14] facilitating more balanced carrier injection from the anode and cathode.

In summary, it is possible to introduce structural attributes to the ligand framework of an europium complex that allow its use as the electroluminescent layer in a single component LED. The key design components include the use of hole and electron transport fragments, together with aliphatic sidegroups that lead to a stable amorphous phase. The film forming properties of **1** play an important role in device fabrication.

We thank Dr Vojislav Srdanov and Dr Troy Bergstedt for helpful discussions. This work was supported in part by the MRL Program of the NSF under Award No. DMR 96-32716 and the AFOSR under Contract No. FQ8671-9901244 STTR-TX.

Nickel bromide as a hydrogen transfer catalyst

Matthew D. Le Page and Brian R. James*

Department of Chemistry, University of British Columbia, Vancouver, British Columbia, Canada V6T 1Z1

Received (in Corvallis, OR, USA) 30th June 2000, Accepted 21st July 2000

Catalysed transfer hydrogenation of a range of organics is achieved using $NiBr_2$ in alkaline ^{i}PrOH

During our studies on $NiX_2(PPh_{3-n}py_n)_2$ complexes (X = halogen, py = 2-pyridyl, n = 1–3), some of which are water-soluble,[1] a report appeared on the use of a $NiCl_2(PPh_3)_2$–NaOH–^{i}PrOH system for transfer hydrogenation of ketones and aldehydes.[2] Our Ni(II) pyridylphosphines, under corresponding conditions, were of comparable activity, but some 'blank tests' soon revealed that $NiCl_2{\cdot}6H_2O$ had similar activity, while anhydrous $NiBr_2$ or $NiI_2{\cdot}6H_2O$ had much higher activity. For example, 90% conversion of cyclohexanone to cyclohexanol was attained after 1 h of refluxing in an alkaline ^{i}PrOH solution containing $NiBr_2$, whereas conversions of only 14 and 24%, respectively, were achieved with $NiCl_2(PPh_3)_2$ and $NiBr_2(PPh_3)_2$, under comparable conditions (0.4 mM Ni, 35 mM NaOH, 100 mM ketone in 3.0 cm^3 ^{i}PrOH). More optimised reaction conditions for a practical scale synthesis (5 mM $NiBr_2$, 0.5 M NaOH, 1.5 M cyclohexanone) resulted in 100% conversion after 30 min refluxing. The use of $CoBr_2$ and CoI_2 under corresponding conditions resulted in conversions of ~60%. The simplicity of the system using commercially available $NiBr_2$ makes it attractive for laboratory hydrogenations without the need for H_2, especially as it is applicable to a wide range of organic substrates (see below). A further advantage is that the system operates under aerobic conditions, while the often used platinum metal, phosphine-containing complexes are usually air-sensitive in solution.[3]

$$\text{substrate (A)} + {}^i\text{PrOH} \xrightarrow[\text{reflux}]{NiBr_2,\ NaOH} A(H)_2 + \text{acetone} \qquad (1)$$

The $NiBr_2$–NaOH–^{i}PrOH system† (eqn. 1) can be effective for catalytic hydrogen transfer of saturated ketones, aldehydes, alk-1-enes, cyclohex-2-en-1-one, nitrobenzene and 4-nitrobenzaldehyde (Table 1). For cyclohexanone, butan-2-one and oct-1-ene, the conversion activity is generally comparable with, or greater than, that reported by others for transfer hydrogenation using more 'exotic' catalysts.[2–6] The extremely efficient hydrogenation of a terminal olefin such as oct-1-ene using ^{i}PrOH is unusual; more commonly, 'hydrogenated aromatics' like 1,2-dihydronaphthalene and indoline have been used as hydrogen donors with either homogeneous or heterogeneous-based platinum metal systems,[6] but the systems are much less efficient than the $NiBr_2$ system. Internal olefins and cod are not hydrogenated; of note, the system effects selective hydrogenation of oct-1-ene in a 1 : 1 mixture with (*t*) oct-2-ene, but at a lower rate (27% conversion in 0.5 h) than with oct-1-ene alone. With α,β-unsaturated ketones, cyclohex-2-en-1-one is converted initially to cyclohexanone but this saturated ketone is subsequently reduced at a rate comparable to the rate of appearance of the cyclohexanol; *e.g.* after 0.5 h, there is 40% reduction of the enone to equal amounts of the saturated ketone and alcohol, while after 48 h there is 73% conversion of enone to essentially just cyclohexanol (Table 1)—no cyclohexen-1-ol is detected. The non-reduction of but-3-en-2-one may be due to its coordination to the Ni as a chelate, which could block coordination of the propoxide (the usually postulated steps for a homogeneously catalysed process are: propoxide coordination, hydride abstraction, and transfer to coordinated substrate[3,7]). Nitrobenzene is reduced selectively to aniline, but the conversion is only ~20% after 48 h, and there is a significant 'base-only' contribution (Table 1); correspondingly, 4-nitrobenzaldehyde undergoes Ni-promoted hydrogenation (38% in 24 h), but non-selectively to mainly the nitrobenzyl alcohol and smaller amounts of aminobenzyl alcohol and the aminobenzaldehyde.

Of interest, although the use of base co-catalysts for metal complex catalysed hydrogen transfer is common,[2–4,7–11] data on the 'base-only' systems are rarely reported.[8,9] In the strongly basic medium employed in our work, acetophenone and heptan-1-al are effectively reduced to the respective alcohols even in the absence of the $NiBr_2$ (Table 1). The basic conditions used preclude reduction of pentane-2,4-dione and hexane-2,5-dione because these were converted, respectively, to sodium acetylacetonate and a self-condensation product (probably 5-methylundec-5-ene-2,7,10-trione); in a related manner, benzaldehyde undergoes the Cannizzaro reaction to yield the alcohol and sodium benzoate. Nitriles were not reduced and, to our knowledge, there are no reports on transfer hydrogenation of nitriles.

The $NiBr_2$ system appears to be homogeneous, at least for cyclohexanone. For all the substrate systems, the initially light-coloured solutions gradually darken through yellow to orange with reaction time but, after filtration through a 0.22 μm pore, the orange filtrate showed no loss of activity, for example, for

Table 1 $NiBr_2$ catalysed transfer hydrogenation of organics[a]

Substrate	% Conversion (time, h)	% Conversion (time, h)[b]	Product(s)
Cyclohexanone	99.9 (0.5)	29.1 (0.5)	Cyclohexanol
Acetophenone	60.1 (4), 99.4 (24)	65.4 (4), 98.8 (24)	1-Phenylethanol
Butan-2-one	55.2 (2), 97.2 (24)	8.4 (2), 18.5 (24)	Butan-2-ol
Pentan-2-one	31.0 (24), 99.9 (48)	12.2 (24), 27.8 (48)	Pentan-2-ol
Oct-1-ene	99.9 (0.5)	0.0 (0.5)	*n*-Octane
Cyclohex-2-en-1-one	73.0 (48)[c]	20.0 (48)[d]	Cyclohexanone Cyclohexanol
Heptan-1-al	92.2 (4)	83.0 (4)	Heptan-1-ol
Nitrobenzene	14.1 (0.5), 19.2 (48)	4.0 (0.5), 14.0 (48)	Aniline
4-Nitrobenzaldehyde	38.0 (24)[e]	12.5 (24)[f]	ABA, NBA, AB[e]

[a] In 24 h, no conversion for: (*t*) oct-2-ene, but-3-en-2-one, pentane-2,4-dione, hexane-2,5-dione, 2-propionic acid, MeCN, PhCN and benzene, and < 5% for cyclooctene and cod. [b] In presence of base only, no $NiBr_2$. [c] 2% ketone, 71% alcohol. [d] 4% ketone, 16% alcohol. [e] 10.5% 4-aminobenzyl alcohol (ABA), 21.9% 4-nitrobenzyl alcohol (NBA), 5.6% 4-aminobenzaldehyde (AB). [f] 3.6% ABA, 7.4% NBA, 1.5% AB.

DOI: 10.1039/b005338o

cyclohexanone hydrogenation; also the addition of Hg(0), an inhibitor for colloidal activity,[12] to a 'fresh' system gave only a 7% decrease in conversion (*cf*. Table 1). Further, the solid inorganic residue obtained after a hydrogenation of cyclohexanone was re-used three more times for repeat conversions, when only slow deactivation of the catalyst was noted: 1st run, 99.9% conversion after 0.5 h; 2nd, 95% (3 h); 3rd, 92% (7 h); 4th, 63% (3 h).

Of interest, addition of up to 4 equiv. of PPh_3 to the $NiBr_2$ system has no effect on the rate of hydrogenation of cyclohexanone, and also $NiBr_2(PPh_3)_2$ is unstable in the alkaline medium (with dissociation of the phosphine), implying that in the earlier work on the $NiCl_2(PPh_3)_2$ system[2] the precursor catalyst may be simply $NiCl_2$.

We thank the NSERC of Canada for financial support.

† A glass vessel (35 mL) equipped with a Teflon-coated magnetic stirrer was charged in air with $NiBr_2$, NaOH and ^{i}PrOH, and the mixture heated at 95 °C to yield a pale-green solution. After this was cooled to rt, the vessel was fitted with a condenser and charged with substrate; the mixture was then refluxed, and samples were withdrawn for GC and NMR analysis (Table 1). The $NiBr_2$: NaOH : substrate ratios were 1 : 85 : 250 in all cases, with [$NiBr_2$] between 1–6 mM.

ChemComm

A new phthalocyanine derivative having peripheral 2-thienyl substituents

Tsuyoshi Muto, Tetsuji Temma, Mutsumi Kimura, Kenji Hanabusa and Hirofusa Shirai*

Department of Functional Polymer Science, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386-8567, Japan. E-mail: hshirai@giptc.shinshu-u.ac.jp

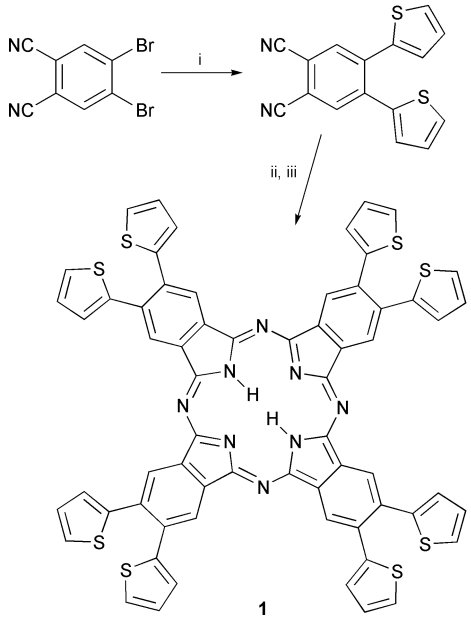
Received (in Cambridge, UK) 9th June 2000, Accepted 24th July 2000

A phthalocyanine derivative having eight 2-thienyl substituents at the β-position was synthesized and electrochemical oxidation of the phthalocyanine gave an insoluble polymer film on the electrode surface.

π-Conjugated polymers such as polythiophenes or polyphenylenes have been the subject of intensive studies.[1] Due to the high stability of the polymers, they are readily characterized by chemical or physical methods, making them good candidates for electronic or photonic devices. Polythiophenes are the type most frequently investigated because they are easily obtained from chemical reactions[2] or electrochemical couplings of thiophene derivatives,[3] and the monomers or precursors are readily derived by conventional synthetic methods from thiophene.[4] Recently, several groups reported the design of novel conducting polymer architectures which alternatively contain functional moieties and αα′-coupled oligothiophene moieties.[5] The wide range of these studies contributed towards the application of the polymers as organic semiconductors, sensory materials or electrocatalysts.[6] Our current interest in this class of materials is motivated by the property of the attractive characteristics, endowed by functional molecules embedded in the polymer backbone, for the development of electronic devices. Phthalocyanines or phthalocyanine metal complexes are known to have a diversity of functions such as electrocatalysts or organic electronic devices.[7] Therefore, introduction of phthalocyanine moieties to the new polymer architectures imparts a variety of functions to the polymers. In this communication we demonstrate the synthesis, photo- and electrochemical properties of a new phthalocyanine (pc) derivative which has thiophene moieties as substituents, and the electrochemical construction of a pc-based polymer film deposited on the electrode surface.

The synthetic route to **1** used 4,5-dibromophthalonitrile[8] as starting material which was converted into 4,5-di-2-thienylphthalonitrile with thiophene-2-boronic acid[9] in the presence of $Pd(0)(PPh_3)_4$ under basic conditions (Scheme 1). Refluxing of 4,5-di-2-thienylphthalonitrile with NaOMe in MeOH gave 5,6-di-2-thienyl-2,3-dihydro-1,3-diiminoisoindole, and the reaction of this compound in *N*,*N*-dimethylaminoethanol at 140 °C gave **1** as a dark-green solid. Analytically pure **1** was obtained by column chromatography of the crude product on silica gel by eluting with CH_2Cl_2–*n*-hexane (2/1 v/v). This new pc derivative **1** was characterized by ^1H NMR and MALDI-TOF mass spectrometry.†

The pc derivative **1** was soluble in common organic solvents such as CH_2Cl_2, $CHCl_3$, THF and DMF but not in hexane, toluene or acetonitrile. The shape of absorption and emission spectra of **1** in $CHCl_3$ were similar to that of tetrakis(*tert*-butyl)phthalocyanine (^{t}Bupc) except for a broad absorption around 430 nm and a weak, structureless emission peak centered around 500 nm. The position of both absorption and emission bands of **1** were red-shifted about 20 nm from that of the corresponding ^{t}Bupc. These results obtained from the photophysical measurements are consistent with the presence of electronic interaction between the pc ring and 2-thienyl substituents in a molecule of **1** at their ground and excited states.



Scheme 1 (i) Thiophene-2-boronic acid, $Pd(0)(PPh)_4$, toluene, THF, EtOH, 2 M Na_2CO_3 aq., reflux under N_2, 18 h, 62%; (ii) NaOMe, MeOH, reflux under NH_3 gas, 5 h, 95%; (iii) *N*,*N*-dimethylaminoethanol, reflux under N_2, 36 h, 32%.

The pc derivative **1** was oxidatively polymerized when the potential of the electrode was swept between 0.0 and +1.1 V *vs.* Ag/Ag^+ at a scan rate of 100 mV s^{-1}. [Working electrode, indium/tin oxide coated glass (ITO) electrode; Counter electrode, Pt wire; Reference electrode, Ag/Ag^+; Solvent, 0.1 M tetra-*n*-butylammonium hexafluorophosphate ($TBAPF_6$)–CH_2Cl_2]. An anodic polymerization trace of **1** is shown in Fig. 1. The first oxidative scan is characterized by monomer

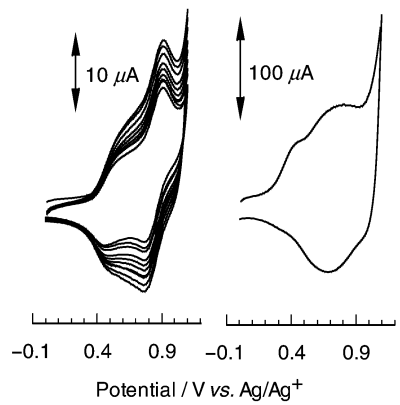


Fig. 1 Trace of oxidative scan of **1** ([**1**] = 2×10^{-4} M) in 0.1 M $TBAPF_6$–CH_2Cl_2 with ITO glass electrode (left) and cyclic voltammogram of poly(**1**) film deposited on ITO glass electrode in 0.1 M $TBAPF_6$–CH_3CN (right). Conditions: 0.1 V s^{-1}, Pt wire counter electrode; Ag/Ag^+ reference electrode.

DOI: 10.1039/b004694i

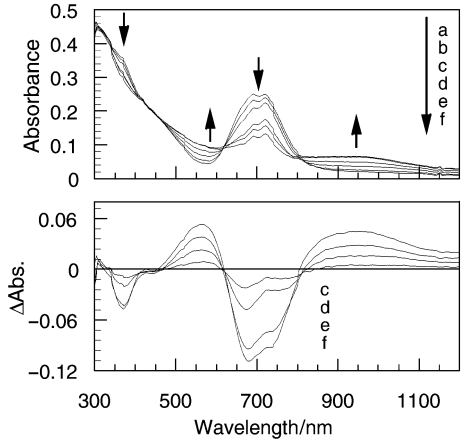

Fig. 2 *In situ* UV-Vis-NIR absorption spectra of poly(**1**) on ITO electrode upon applied potential (top): (a) 0.0 V *vs*. Ag/Ag^+; (b) +0.3 V; (c) +0.5 V; (d) +0.6 V; (e) +0.7 V; (f) + 0.8 V. Difference spectra obtained from the data of the *in situ* spectra (bottom). The neutral-point spectrum (V = 0.0 V) was used as the reference.

oxidation at +0.60 and +0.90 V followed by associated reduction at +0.45 and +0.75 V in the return process. The first oxidation wave observed in the oxidative trace of **1** is attributed to the oxidation of free-base pc[10] and the second could be attributed to the oxidation of 2-thienyl substituents at the β-position. In subsequent potential sweeps, an oxidation wave grows in around +0.70 V. Applied potential cycling results in further increased electroactivity of the electrode, indicative of insoluble polymer deposition on the electrode surface.[5] The cyclic voltammogram (CV) of the electrochemical deposited polymer (poly(**1**)) in monomer-free 0.1 M $TBAPF_6$–CH_3CN is shown in Fig. 1. The CV is characterized by the appearance of an oxidation wave at +0.4 V and a redox couple at +0.70 V. The observed difference between the redox potentials of monomer **1** and poly(**1**) is in agreement with the difference in π-conjugation length elongated in the polymerization and oxidation processes.

The *in situ* electronic absorption measurement of poly(**1**) film deposited on the ITO electrode recorded at various doping levels shows that the transition around 360 nm and pc Q-band absorption (λ_{max} = 634, 662, 692, 724 nm) decreases continuously as doping proceeds while two new absorption bands appear around 560 and 950 nm (Fig. 2). In the absorption of poly(**1**) film at high doping levels, the new lower energy π–π* transition[11] around 950 nm was promoted and grew as shown in Fig. 2. The optoelectrochemical behavior observed in our system is assigned to formation of oxidized states of poly(**1**) and the effective conjugation paths include a pc ring system and αα′-bithienyl bridges have been formed. The position of the lower energy π–π* absorption maximum is close to that reported for cation radicals of oligothiophenes, but the shape of the band is broader than that of oligothiophene cation radicals.[12] From these observations, we assume that poly(**1**) in the oxidized state has intermediary effective conjugation length of oxidized oligothiphenes and oxidized polythiophenes.

In conclusion, we have synthesized a new pc derivative **1** and constructed a π-conjugated polymer film by electrochemical oxidation of **1**. The π-conjugation length of the polymer was switched between pc-like and oligothiophene-like by application of the appropriate voltage. Since this switching is accompanied by a color change at the applied potential between 0 and +0.8 V *vs*. Ag/Ag^+, the polymer has potential electrochromic material applications.[11]

Superior ion-exchanged ZSM-5 catalysts for selective catalytic oxidation of ammonia to nitrogen

Richard Q. Long and Ralph T. Yang*

Department of Chemical Engineering, University of Michigan, Ann Arbor, MI 48109-2136, USA. E-mail: yang@umich.edu

Received (in Cambridge, UK) 20th June 2000, Accepted 21st July 2000

Fe-ZSM-5 showed the best catalytic performance (nearly 100% N_2 yield) and resistance to water vapor for selective catalytic oxidation of NH_3 to N_2 at a high gas hourly space velocity (2.3×10^5 h^{-1}) among transition-metal (Cr, Mn, Fe, Co, Ni and Cu) ion-exchanged ZSM-5 catalysts.

The removal of ammonia from waste streams is becoming an increasingly important issue due to environmental reasons. Many chemical processes use reactants containing ammonia or produce ammonia as a by-product. They are all plagued with the ammonia slip problem. Selective catalytic oxidation (SCO) of ammonia to nitrogen is potentially an ideal technology for removing ammonia from oxygen-containing waste gases and consequently it is of increasing interest in recent years.[1–12] The SCO process could also be applied to the selective catalytic reduction (SCR) of NO by ammonia where ammonia slip has been a serious problem,[2] as well as to the combustion of biomass-derived gases for removing the NH_3 impurity.[3-5]

Early results[1] on ammonia oxidation showed that noble metals (*e.g.* Pt and Pd) were active for oxidation of NH_3 to NO and N_2O, while transition metal oxides such as V_2O_5 could selectively convert NH_3 to N_2, but were much less active than the noble metals. Li and Armor[2] reported that Pt, Rh and Pd exchanged to ZSM-5 or supported on Al_2O_3 showed good SCO performance in a wet stream, which were more active than V_2O_5/TiO_2 and Co-ZSM-5. More recently, Burch and Southward found that 12-tungstophosphoric acid[4] and Ni, Fe and Mn oxides supported on γ-Al_2O_3[5] were active for the reaction. A number of other catalysts were also investigated, such as $CuMoO_4$,[6] CuO/Al_2O_3,[7,8] Cu, Co and Ni oxides doped on SiO_2,[9] Cu–Mn/TiO_2,[10] V_2O_5/TiO_2, CuO/TiO_2 and Cu-ZSM-5,[11] as well as V_2O_5, MoO_3 and WO_3 on various supports.[12] They all exhited activities for N_2 formation under different conditions. However, the aforementioned work was normally performed at low space velocities ($< 10^5$ h^{-1}) and in the absence of H_2O or SO_2. Here, we report a series of transition metal (*i.e.* Cr, Mn, Fe, Co, Ni and Cu) ion-exchanged ZSM-5 samples that have excellent catalytic performance (both activity and product selectivity) for the SCO reaction at a high space velocity. The effects of H_2O and/or SO_2 are also studied.

Transition metal ion-exchanged ZSM-5 samples were prepared using the conventional ion exchange procedure. NH_4-ZSM-5 (Si/Al $\approx$ 10) was obtained from Alsi-Penta Zeolithe Gmbh (Germany). In each experiment, 2 g NH_4-ZSM-5 was added to 200 ml of 0.05 M $Cr(MeCO_2)_3$, $Mn(MeCO_2)_2$, $FeCl_2$, $Co(MeCO_2)_2$, $Ni(MeCO_2)_2$ or $Cu(MeCO_2)_2$ solution with constant stirring at room temperature. After 24 h, the particles were filtered off and washed with deionized water. Pd-ZSM-5 was prepared by exchanging NH_4-ZSM-5 with 100 ml 0.015 M $Pd(NO_3)_2$ solution at room temperature for 24 h.[2] The obtained samples were first dried at 120 °C in air for 12 h, then calcined at 500 °C for 6 h. H-ZSM-5 was prepared by calcining NH_4-ZSM-5 at 500 °C for 3 h. The metal contents measured by neutron activation analysis in the Cr, Mn, Fe, Co, Ni, Cu and Pd ion-exchanged ZSM-5 samples were 0,13, 1.03, 1.59, 1.24, 0.85, 4.35 and 5.51% by weight, respectively.

The SCO performance tests were carried out in a fixed-bed quartz reactor described elsewhere.[13] The typical reaction conditions were as follows: 0.1 g (0.13 ml) catalyst, 1000 ppm NH_3, 2% O_2, 500 ppm SO_2 (when used), 4% water vapor (when used) and balance He. The total flow rate was 500 ml min^{-1} (ambient conditions) and thus a high gas hourly space velocity (GHSV = 2.3×10^5 h^{-1}) was obtained. Premixed gases (1.05% NH_3 in He and 0.99% SO_2 in He) were supplied by Matheson. Water vapor was generated by passing He through a heated gas-wash bottle containing deionized water. The tubings of the reactor system were heat traced with heating tapes to prevent formation and deposition of ammonium sulfate/hydrogensulfate. A magnetic deflection type mass spectrometer (AERO VAC™, Vacuum Technology Inc.) was used to monitor continuously the effluent gas from the reactor. The concentrations of unreacted NH_3 and formed NO_x (NO + NO_2) were also continually monitored by a chemiluminescent NO/NO_x analyzer (Thermo Electro Corporation, Model 10), where a high temperature converter oxidized NH_3 to NO_x by the reaction $NH_3 + O_2 \rightarrow NO_x + H_2O$.

The catalytic performances of different ion-exchanged ZSM-5 catalysts are summarized in Table 1. H-ZSM-5 showed a good activity for NH_3 oxidation at 350–450 °C, with 62–74% selectivity for N_2 and 23–37% selectivity for NO. N_2 selectivity increased slightly with temperature. It is noted that a moderate

DOI: 10.1039/b004957n

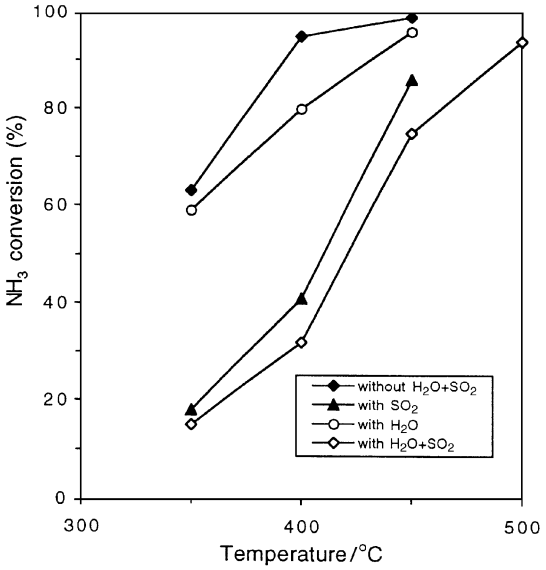

Fig. 1 Effect of H_2O and SO_2 on NH_3 conversion for Fe-ZSM-5. *Reaction conditions*: 0.1 g catalyst, $[NH_3]$ = 1000 ppm, $[O_2]$ = 2%, 500 ppm SO_2 (when used), 4% water vapor (when used), He = balance, total flow rate = 500 ml min^{-1} and GHSV = 2.3×10^5 h^{-1}.

activity was also observed on the empty reactor under the same conditions, resulting from homogeneous NH_3 oxidation, but the major product was NO (Table 1). When transition metal ions were exchanged to ZSM-5, Cr-ZSM-5, Fe-ZSM-5 and Cu-ZSM-5 showed very high activities for oxidation of NH_3 to N_2. Only small amounts of N_2O and NO were produced by Fe-ZSM-5 and Cu-ZSM-5 catalysts. Both NH_3 oxidation activity and N_2 selectivity increased with temperature. Near 100% N_2 yield was obtained on Fe-ZSM-5 at 450 °C. In comparison, a lower activity was observed on Mn-ZSM-5, Co-ZSM-5 and Ni-ZSM-5, with large amounts of NO formation. These results suggest that metal cations in the ZSM-5 play an important role in the SCO of NH_3 to N_2. Pd-ZSM-5, a good SCO catalyst reported by Li and Armor,[2] also showed high NH_3 conversions under our reaction conditions, *i.e.* a higher space velocity (2.3×10^5 h^{-1} *vs.* 4.6×10^4 h^{-1} in ref. 2), but the selectivity for N_2 was lower than that on Fe-ZSM-5 and Cu-ZSM-5. The maximum N_2 yield on the above catalysts increased in the sequence of Co-ZSM-5 ≈ Ni-ZSM-5 < Mn-ZSM-5 < H-ZSM-5 < Pd-ZSM-5 < Cr-ZSM-5 < Cu-ZSM-5 < Fe-ZSM-5. This rank order is similar to the previous results obtained on the metal ion-exchanged Y zeolites, except for Fe.[1] The nitrogen balance was above 95% in this work.

It is known that the waste streams usually contain water vapor and small amounts of SO_2. We further studied the effects of H_2O and SO_2 on the catalytic performance of Cr-ZSM-5, Fe-ZSM-5 and Cu-ZSM-5. For Cr-ZSM-5, when 500 ppm SO_2 and/or 4% H_2O were added to the reactants, NH_3 conversion decreased significantly. Only 50% NH_3 conversion was obtained at 450 °C in the presence of both H_2O and SO_2. Comparatively, NH_3 conversion was decreased only slightly by H_2O on Fe-ZSM-5 (Fig. 1). SO_2 and $H_2O + SO_2$ decreased NH_3 conversion at 350–450 °C, but the decrease was less significant at high temperatures. For example, 94% NH_3 conversion could be obtained at 500 °C. H_2O and SO_2 also inhibited NH_3 conversion over Cu-ZSM-5. Only 65% NH_3 conversion was observed at 450 °C in the presence of H_2O and SO_2. Increasing the temperature to 500 °C resulted in 73% NH_3 conversion. N_2 was the dominant product for NH_3 oxidation in the presence of H_2O and/or SO_2.

The above results indicate that Fe, Cu and Cr ion-exchanged ZSM-5 are very active for selective catalytic oxidation of NH_3 to N_2. Our previous results showed that, although iron cations were exchanged with NH_4-ZSM-5 as Fe^{2+}, most iron cations in the Fe-ZSM-5 are present as Fe^{3+} ions after calcination, leaving only a small amount of Fe^{2+}.[14] An equilibration between Fe^{2+} and Fe^{3+} exists in the Fe-ZSM-5. It has also been reported that both Cu^+ and Cu^{2+} ions are present in Cu-ZSM-5[15] and the ratio of Cu^+/Cu^{2+} depends on the Cu content and the preparation procedure. The variable valence of metal cations in these two catalysts may be beneficial to oxygen adsorption and activation. Therefore, a high activity for the SCO reaction is expected. Relatively lower activities were observed on Mn, Co, and Ni ion-exchanged ZSM-5. This may be attributed to their stabilized valence in zeolites,[1] which is not favorable for oxygen activation. H_2O and SO_2 have strong negative effects on NH_3 conversion for Cr-ZSM-5 and Cu-ZSM-5, whereas H_2O decreased NH_3 conversion slightly for Fe-ZSM-5. Although SO_2 decreased NH_3 conversion at low temperatures for Fe-ZSM-5, a high NH_3 conversion (94%) was obtained at 500 °C in the presence of H_2O and SO_2 at such a high space velocity (GHSV = 2.3×10^5 h^{-1}). Fe-ZSM-5 may be suitable as a practical catalyst for oxidation of NH_3 to N_2 in a wet stream. In addition, the effects of the ammonia concentration on activity and other Fe-exchanged zeolites were also studied for the SCO reaction. The initial results showed that NH_3 conversion over Fe-ZSM-5 increased with a decrease in NH_3 concentration. For example, 99% NH_3 conversion was obtained at 350 °C when the NH_3 concentration was decreased to 10 ppm (*vs.* 63% at 1000 ppm). Also, the SCO performance was found to follow the trend Fe-ZSM-5 ≈ Fe-mordenite ≈ Fe-clinoptilolite > Fe-Y ≈ Fe-beta > Fe-ferrierite ≈ Fe-chabazite. More details will be presented in a future paper. Moreover, Fe-ZSM-5 is also a good catalyst for the selective catalytic reduction (SCR) of NO with ammonia.[13] In the SCR reaction, the reactions of NH_3 with NO/O_2 and that with O_2 are known as two competitive reactions. A decrease in reactivity of NH_3 with O_2 by $H_2O + SO_2$ will be beneficial to NO reduction, which has indeed been observed in our previous results that $H_2O + SO_2$ increased the SCR activity at high temperatures on Fe-ZSM-5.[13]

We gratefully acknowledge Dr Ramsay Chang of EPRI for discussions.

First oxidative cyclization of 1,3-bis(trimethylsilyloxy)buta-1,3-dienes

Peter Langer* and Valentin Köhler

Institut für Organische Chemie der Georg-August-Universität Göttingen, Tammannstrasse 2, 37077 Göttingen, Germany. E-mail: planger@uni-goettingen.de

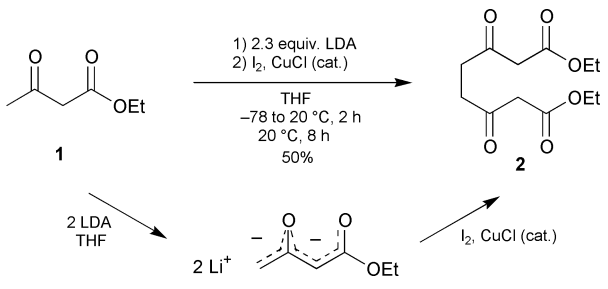
Received (in Cambridge, UK) 1st June 2000, Accepted 26th July 2000

The first oxidative cyclizations of 1,3-bis(trimethylsilyloxy)-buta-1,3-dienes, electroneutral 1,3-dicarbonyl dianion synthons, result in regioselective formation of functionalized 1,4-dihydroquinones.

The development of new, preparatively useful single-electron-transfer (SET) reactions is of considerable current interest. Although SET-oxidations of monoanions have been extensively studied,[1] little is known about dianion oxidations.[2] Herein, we wish to report, to the best of our knowledge, the first oxidative cyclizations of 1,3-bis(trimethylsilyloxy)buta-1,3-dienes which represent electroneutral 1,3-dicarbonyl dianion synthons.[3] This methodology provides a direct, mild and regioselective synthesis of 2,3-acceptor-substituted 1,4-dihydroquinones which can be regarded as products of a formal oxidative cyclization of 1,3-dicarbonyl dianions.[4] These products, which have been previously prepared by multi-step syntheses under drastic conditions,[5] represent useful intermediates in organic synthesis. 2,3-Acceptor-substituted 1,4-dihydroquinones are present in a variety of polyketide-derived natural products, such as *dericamycin A* and the related *fredericamycin A*,[5a] or prominent enediynes, such as *calicheamicin*, *esperamicin*, *neocarzinostatin* chromophore or *dynemicin A*.[6a] Simple 1,4-dihydroquinone-2,3-dicarbonyl derivatives have proven biologically active against murine tumors.[6b]

Oxidation of the dianion[7,8] of ethyl acetoacetate with iodine or bromine in the presence of catalytic amounts of copper(I) chloride has been reported to afford the open-chain dimerization product **2** rather than a cyclization product (Scheme 1).[9] The use of 1,2-dibromoethane, $CuCl_2$ and $Cu(OTf)_2$ as the oxidizing agents resulted in formation of complex mixtures. The main problem associated with the oxidative cyclization of dianions is the fact that, due to electrostatic repulsion, dimerization of the radical anionic intermediates is slow and many side-reactions, such as deprotonation of the solvent (THF), can occur.

Our concept to overcome these problems was to study the oxidative dimerization of 1,3-bis(trimethylsilyloxy)buta-1,3-dienes **3**.[10] Slow addition of an acetonitrile solution of CAN to an acetonitrile solution of $NaHCO_3$ and diene **3a**[3c] resulted in formation of the ester-substituted 1,4-dihydroquinone **4a**, however, in only low yield. Much to our satisfaction, employment of an inverse addition protocol resulted in an increase of the yield. Optimal yields (up to 56%) were obtained when an acetonitrile solution of **3a** (2 eq.) was slowly added to a solution of CAN (6 eq.) and $NaHCO_3$ (12 eq.) at −45 °C.†



Scheme 1

Formation of **4a** can be explained by the following working hypothesis (Scheme 2): SET-oxidation of **3a** affords the radical-cation **A**. Formation of a ceric enolate, supported by the chelating nature of the two oxygen atoms, can not be excluded.[11] Cleavage of the Si–O bond and $NaHCO_3$-assisted extrusion of a silyl-cation results in formation of radical **B** which subsequently attacks the terminal carbon atom of a second molecule of **3a** to give intermediate **C**. Radical **B** should be more stable than the isomeric, cross-conjugated radical **B′**. Oxidation and extrusion of the second silyl group affords intermediate **D**. Oxidation of the latter and extrusion of the third silyl group results in formation of intermediate **E**. Cyclization, oxidation and extrusion of the fourth silyl group affords intermediate **F** which is subsequently oxidized to give the final product **4a**.

The 'head–head' regioselectivity may be rationalized by considering that attack at the γ-position of radical **B** leads to the most stabilized carbonyl conjugated α-silyloxy radical **C**. Radical **C** is probably formed through a transition state less

[a] Isolated yields.

energetic than that leading to the respective unconjugated α-silyloxy radical (by attack of the central carbon atom of intermediate **B** onto **3a**), assuming the addition step possesses a substantial product-like character. This suggestion is supported by the regioselectivity observed for the alkoxy radical catalyzed auto-oxidation of 1,4-dienes.[12] It is noteworthy, that the open-chain dimer **2** was isolated as a side-product in low yield. This result supports the assumption that bis-silyl enol ether **D** represents an intermediate of the reaction.

In order to study the preparative scope of our new cyclization reaction, the substituents of the 1,3-bis(trimethylsilyloxy)buta-1,3-dienes were systematically varied (Table 1). Oxidation of the dienes derived from ethyl-, methyl-, iso-propyl-, methoxy-ethyl-, iso-butyl-, *tert*-butyl- and benzyl acetoacetate afforded the corresponding ester-substituted 1,4-dihydroquinones **4a**–**g** with very good regioselectivities. Dimerization of the diene derived from acetylacetone afforded 2,3-diacetyl-1,4-dihydroquinone (**4h**). Oxidation of the 1,3-bis(trimethylsilyloxy)buta-1,3-dienes derived from methyl 3-oxopentanoate and ethyl 3-oxohexanoate afforded the 1,4-dihydroquinones **4i**–**j** containing two ester groups at carbons C-2 and C-3 and two alkyl groups at carbons C-5 and C-6. Oxidation of the 1,3-bis-(trimethylsilyloxy)buta-1,3-diene derived from methyl 4-methoxyacetoacetate resulted in formation of the highly functionalized 1,4-dihydroquinone **4k**. Reaction of the diene derived from methyl 3,5-dioxohexanoate afforded the highly functionalized 1,4-dihydroquinone **4l**.

In summary, we have developed the first oxidative cyclizations of 1,3-bis(trimethylsilyloxy)buta-1,3-dienes which represent electroneutral 1,3-dicarbonyl dianion synthons. Currently, we are studying the mechanism and preparative scope of the new transformation.

† *Preparation of 1,4-dihydroquinone* **4a**. To a thoroughly degassed CH_3CN solution (25 ml) of $NaHCO_3$ (15.3 mmol, 12 eq., 1.29 g) and CAN (7.65 mmol, 6 eq., 4.20 g) was slowly added a CH_3CN solution (2 ml) of 1,3-bis(trimethylsilyloxy)buta-1,3-diene **3a** (2.55 mmol, 2 eq., 0.7 g) at −45 °C. The temperature of the reaction mixture was allowed to rise to 20 °C during 2 h. After stirring for 1 h at 20 °C a saturated aqueous solution of brine was added, the organic layer was separated and the aqueous layer was repeatedly extracted with ether. The combined organic extracts were dried ($MgSO_4$), filtered and the solvent of the filtrate was removed *in vacuo*. The residue was purified by column chromatography (silica gel, ether–petrol ether = 1:1; ($CDCl_3$, 250 MHz) δ_H 1.34 (t, 6 H, J = 7, CH_3), 4.34 (q, 4 H, J = 7, OCH_2), 7.07 (s, 2 H, CH), 8.85 (s, 2 H, OH; ($CDCl_3$, 62.5 MHz) δ_C 13.98, 62.01, 112.66, 123.83, 152.29, 168.98; MS (70 eV) 254 (22, M^+), 208 (40), 180 (100), 162 (58); *Anal*. calcd. for $C_{12}H_{14}O_6$: C, 56.69; H, 5.55. Found: C, 56.42; H, 5.68. All compounds were characterized by spectroscopic methods and gave correct elemental analyses and/or high resolution mass spectra.

Entropy–enthalpy compensation and anticompensation: solvation and ligand binding

Otto Exner

Received (in Cambridge, UK) 6th April 2000, Accepted 21st July 2000

Plots of $\Delta H°$ *versus* $T\Delta S°$ are misleading and can suggest an apparent linear relationship (compensation) with a slope near to unity when $\Delta S°$ has been obtained from experimental $\Delta G°$ and $\Delta H°$; recently reported relationships with a slope of -1 in the fields of enzyme complexes and hydration processes are still more misleading and have arisen only by deliberately selecting the input data.

Linear dependences between enthalpy and entropy in a series of related reactions (isokinetic relationship) have been observed in various fields and have been the subject of many theoretical considerations.[1,2] However, a regression or plot according to eqn. (1) presents non-trivial statistical problems. Neglecting these often leads to results[2,3] which are totally at variance with the original experimental data.[4]

$$\delta\Delta H = \beta\delta\Delta S \quad (1)$$

In the notation used here, the symbol δ is the difference between a given reaction and the reaction used as reference and Δ is the difference between the products and reactants as usual. Both ΔH and ΔS may refer either to thermodynamics ($\Delta H°$ and $\Delta S°$) or to kinetics ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$). The slope β has dimension of temperature (isokinetic temperature). The problems and their solution depend on how ΔH and ΔS have been obtained.[1,5] When the original experimental quantities are $\Delta H°$ (obtained for instance by calorimetry) and $\Delta G°$ (from equilibrium measurements),[6] a plot according to eqn. (1) may yield a slope β near to the experimental temperature. One speaks about compensation[2,4] since the contributions of $\Delta H°$ and of $\Delta S°$ to the resulting $\Delta G°$ are opposite. In a formal modification, eqn. (1a), the dimensionless slope (β/T) is near to unity.

$$\delta\Delta H = (\beta/T)\, T\, \delta\Delta S \quad (1a)$$

However, dependence with this slope means only that ΔG is nearly constant, a plot according to eqn. (1) or (1a) expresses in fact the dependence of ΔH on itself. A plot of ΔH *vs.* ΔG was recommended in these cases.[7]

In a recent communication,[8] plots of $\delta\Delta H°$ *versus* $T\delta\Delta S°$ according to eqn. (1a) were reported for two series of reactions. In both, a regression line of a slope near to -1 was found. The conclusions were drawn[8] that (a) there is a linear relation between enthalpy and entropy in both sets and (b) that a compensation of enthalpy and entropy[2,4] is not a general feature since the present case is just an example of anti-compensation. The purpose of the present work is to prove that these conclusions are not right: (a) any plot of ΔH *versus* ΔS cannot be recommended when these two variables are *a priori* dependent by the procedure of their estimation and (b) the slope (β/T) equal to -1 is not a result of any natural law but has arisen by an arbitrary choice of data.

The first example, complex formation of various peptides with an enzyme, was thoroughly investigated[9,10] by thermometric titration.[11] In this method, one obtains $\Delta G°$ and $\Delta H°$ simultaneously from a non-linear regression.[12] One can assume with a good approximation that their estimates are not intercorrelated, *i.e.* not statistically dependent from the procedure of their calculation.[12] Fig. 1(a) shows all data from one experimental study,[9] concerning seven compounds at five temperatures. No dependence is evident: $\Delta H°$ are more variable than $\Delta G°$ and depend rather more on temperature, still more strongly than on the reactant. In any case, it is evident that the choice of data into the correlation,[8] eqn.(1a), was arbitrary. One has always withdrawn two data and plotted their difference. Four such pairs are shown by arrows in Fig. 1(a). Their position is suitable to obtain the slope $\beta/T = -1$ in eqn. (1a) but other points would yield different slopes. For instance, it would be sufficient to choose the same pair of compounds as in the uppermost example in Fig. 1(a) (points ○→△) but at a different temperature (dashed arrow): instead of -1 a slope of +0.61 would be obtained in eqn. (1a).

The picture changes when one goes from the plot $\Delta H°/\Delta G°$ to the plot $\Delta H°/T\Delta S°$ [Fig. 1(b)]. Plots of this type may be misleading[5,7] when $\Delta G°$ is almost constant, since they express mainly the dependence of $\Delta H°$ on itself. This is also the case in Fig. 1(b). The apparent correlation coefficient $R = 0.975$ expresses only this dependence. The slope $b = \beta/T$ is not significantly different from unity. In terms of eqn. (1), this means that the isokinetic temperature β is equal to the experimental temperature T. This was commonly assumed[1] as a proof that the isokinetic relationship is only apparent, although it is not a deciding proof in all cases.[14] In the paper under criticism,[8] the picture represented by Fig. 1(b) was not accepted as an (apparent or actual) dependence with unity slope but several particular pairs of points were taken off, yielding an opposite slope of -1. As shown already in Fig. 1(a), selection of these points was arbitrary if not biased, and there is no physical reason for choosing just these points. The whole procedure[8] of treating eqn. (1) is unique. The operator δ means commonly comparison with a reference object, reaction, or substrate but this reference is always common for all objects. Introducing this operator means shifting the origin of coordinates and has no effect on the statistics. In ref. 8, a particular

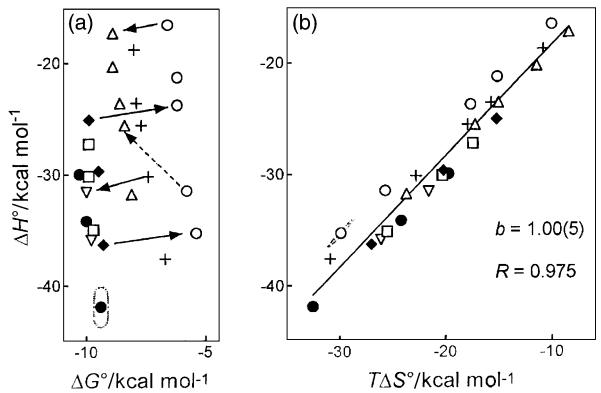

Fig. 1 (a) Experimental (ref. 9) enthalpy $\Delta H°$ *versus* Gibbs energy $\Delta G°$ of binding in a series of peptides with ribonuclease S: (○) peptide M13A, (△) M13ANB, (▽) M13V, (□) M13I, (◆) M13L, (●) S15, (+) M13F. The arrows show the pairs of peptides selected in ref. 1; the broken arrow is an alternative possibility. (b) Plot of $\Delta H°$ *versus* $T\Delta S°$ for the same set of data. The experimental uncertainty is shown as an ellipse corresponding to $\pm 3\sigma$ at one point in each graph.

DOI: 10.1039/b002758h

reference object is chosen in each case: one does not deal with the objects but with the arbitrarily selected pairs of objects.

The conclusion for this set of data is that there is no relationship between experimental[9] $\Delta G°$ and $\Delta H°$. The values of $\Delta H°$ are strongly dependent on temperature and it seems that their experimental uncertainty was somewhat underestimated.[9] When one chooses arbitrarily two compounds, one can observe various slopes, even the reported[8] value of -1.

The second case[8] concerns hydration enthalpies $\Delta H°_h$ and Gibbs energies $\Delta G°_h$ of simple organic compounds and is different in character. The two quantities have been obtained from independent experiments. From some 160 compounds listed in a review,[15] 33 pairs were selected,[8] again rather arbitrarily: some compounds were even chosen several times. In all pairs the first compound is simpler, the second may be considered as its derivative or analogue. However, the relation is not always evident. In Fig. 2(a) only these selected[8] compounds are shown. In the whole set, there is no stochastic dependence of $\Delta H°_h$ and $\Delta G°_h$ but relationships are evident when one divides the compounds into classes; most evident is a group of O- and N-derivatives with large negative values of both $\Delta H°_h$ and $\Delta G°_h$. Pairs of compounds compared were selected intentionally to obtain an increase in the two quantities in a ratio approximately $\delta\Delta G°_h/\delta\Delta H°_h = 2$; two such pairs are shown in Fig. 2(a) by arrows. Some of these choices were quite artificial and certain alternatives seem more natural (broken arrows) which would not produce the desired result. For instance, one cannot understand why cyclohexane should be compared with toluene (arrow ⊙→□) instead of with benzene (broken arrow ⊙→□) or cyclopropane with but-1-yne (arrow ⊙→▽) and not with prop-1-ene (broken arrow ⊙→△). When the plot is transformed into a plot $\Delta H°_h/T\Delta S°_h$ [Fig. 2(b)], the groups of compounds are represented by approximate linear relationships which can be considered as a dependence of $\Delta H°_h$ on itself (slope near to +1). Arbitrary pairs of near points can be selected in this graph, giving a slope -1, similarly one can select pairs with any other slope.

The conclusion concerning the hydration process is that there is a stochastic, not a linear dependence between $\Delta H°_h$ and $\Delta G°_h$: compounds can be divided into groups, in which greater negative values belong particularly to hydrophilic compounds. Values of $\Delta G°_h$ within each subset are nearly constant while $\Delta H°_h$ are more sensitive to small structural changes. For a given pair of compounds, any arbitrary slope can be found.

Examples analyzed here confirm the previous statement[1,4,5] that the plots of $\Delta H°$ *versus* $T\Delta S°$ are misleading and can suggest an apparent dependence without a physical meaning when $\Delta S°$ was obtained from $\Delta H°$ and $\Delta G°$. Still more misleading may be comparing only pairs of reactions.[8] Then even a slope of -1 can be obtained for selected pairs. Nevertheless, anti-compensation with a negative slope, not exactly -1, exists and was detected in kinetics by exact statistical methods.[14]

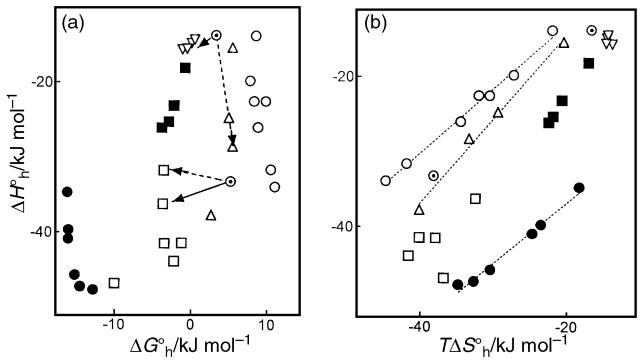

Fig. 2 (a) Experimental (ref. 15) hydration enthalpy $\Delta H°_h$ *versus* hydration Gibbs energy $\Delta G°_h$: (○) alkanes, (⊙) cycloalkanes, (△) alkenes, (▽) alkynes, (□) aromatic hydrocarbons, (■) monohalogenomethanes, (●) oxygen and nitrogen derivatives. The arrows show some of the pairs selected in ref. 8, broken arrows indicate physically more justified choices. (b) The plot of $\Delta H°_h$ *versus* $T\Delta S°_h$ for the same set of data. Dotted lines are regression lines for some subgroups.

12 Estimates of $\Delta G°$ and $\Delta H°$ from a common set of data can be considered as nearly independent. Two cases were analyzed in detail, ref. 13: in one $\Delta G°$ and $\Delta H°$ were independent, in the other the greater estimate of $\Delta G°$ was weakly correlated with greater $\Delta H°$.

Cycloaddition reaction of *tert*-butyl isocyanate and a tellurium diimide dimer: extended helical structure of the ureato telluroxide $\{[OC(\mu\text{-}NBu^t)_2TeO]_2(thf)\}_\infty$

Gabriele Schatte, Tristram Chivers,* Cory Jaska and Nicole Sandblom

Published on the Web 11th August 2000

The reaction of $Bu^tNTe(\mu\text{-}NBu^t)_2TeNBu^t$ with Bu^tNCO in a 1:4 molar ratio in thf produces *N,N′*-bis(*tert*-butyl)ureato telluroxide dimers $[OC(\mu\text{-}NBu^t)_2TeO]_2$, which form an extended helical network *via* weak >C=O···Te interactions.

Reactions of transition-metal imido compounds with heteroallenes have been investigated extensively.[1] The M=NR linkage reacts with isocyanates RNCO *via* cycloaddition of the N=C double bond to give *N,N′*-ureato complexes which, in some cases, can be isolated.[2] The *N,N′*-ureato ligand may also be generated by interaction of oxo complexes of Ru or Os with Bu^tNCO, presumably through the formation of an M=NR intermediate.[3] *N,O*-ureato complexes have been implicated in reactions of isocyanates with some transition-metal complexes, but none of the products of C=O cycloaddition to the M = NR bond have been isolated.[4–6] Iminophosphoranes Ph_3P=NR normally react with isocyanates by an Aza-Wittig process to generate carbodiimides and Ph_3PO.[7] By contrast, sulfur diimides, *e.g.* Bu^tN=S=NBu^t undergo exchange reactions with certain isocyanates RNCO (R = R′SO_2, R′CO or Ar) to form Bu^tNCO and Bu^tNSNR.[8] In the context of this divergent behaviour, we have investigated the reactions of the tellurium(IV) diimide dimer $Bu^tNTe(\mu\text{-}NBu^t)_2TeNBu^t$ **1**, which contains two highly reactive terminal Te=NBu^t groups,[9] with isocyanates. We describe here, the facile reaction between **1** and Bu^tNCO, which yields the *N,N′*-ureato telluroxide **3** *via* the corresponding ureato tellurium imide **2** (Scheme 1). In the solid state **3** forms an extended helical network *via* weak >C=O···Te interactions.

Treatment of the dimer **1** with 2 equiv. of Bu^tNCO in toluene at 23 °C produces an extremely moisture-sensitive yellow solid, which was identified as the *N,N′*-ureato tellurium(IV) imide $O{=}C(\mu\text{-}NBu^t)_2Te{=}NBu^t$ **2** on the basis of CHN analysis, IR and NMR spectroscopic data.† The ^1H NMR spectrum of **2** in C_6D_6 exhibits two singlets at δ 1.46 and 1.35 in the intensity ratio 1:2. An IR absorption attributed to the CO stretch is observed at 1653 cm^{-1}, and the carbonyl carbon appears in the $^{13}C\{^1H\}$ NMR spectrum at δ 160.7. Hydrolysis of **2** by atmospheric moisture produces *N,N′*-bis(*tert*-butyl)urea $OC[N(H)Bu^t]_2$ (δ_H 1.24 in d_8-thf). Complex **2** can be viewed as the product of the cycloaddition reaction of the monomeric tellurium(IV) diimide $Bu^tN{=}Te{=}NBu^t$ and Bu^tNCO. By contrast, the reaction of **1** with Bu^tNCS (1:2 molar ratio) in *n*-hexane at 65 °C produces the cyclic tellurium(II) imide $[Te(NBu^t)]_3$[9a] (95% yield) and no cycloaddition intermediate could be isolated.

When a solution of **1** in *n*-hexane is added to a solution of Bu^tNCO in thf (1:4 molar ratio) a white solid identified by X-ray crystallography‡ as $\{[OC(\mu\text{-}NBu^t)_2TeO]_2(thf)\}_\infty$ (**3**·thf)$_\infty$ is obtained in essentially quantitative yield.† The carbodiimide Bu^tN=C=NBu^t was detected as a by-product of this reaction by ^1H NMR (δ_H 1.17). This observation implies that an unstable tellurium(IV) complex involving both *N,N′* and *N,O*-bound ureato ligands is an intermediate in the formation of **3**. As indicated in Fig. 1 the asymmetric unit in **3** is *N,N′*-bis(*tert*-butyl)ureato telluroxide [*d*(Te=O) = 1.9040(17) Å] which, in common with other telluroxides, dimerizes *via* O→Te [2.0723(18) Å] interactions, *cf.* *d*(TeO) = 1.885(7) and 2.170(7) Å in metal complexes of the related dimer $[Bu^tNTe(\mu\text{-}NBu^t)_2(\mu\text{-}O)]_2$.[10] The ureato ligands in **3** adopt a *cis* arrangement with respect to the Te_2O_2 ring which is essentially planar (torsion angle −2.6°). The CNTeN rings are slightly puckered (torsion angle −7.2°). In the parent urea $OC(NHBu^t)_2$[11] and in ureato complexes of Ru and Os[3] the NCN unit is symmetrical [|*d*(CN)| = 1.352 and 1.380 Å, respectively]. By contrast, the CN bonds in **3** are unsymmetrical [*d*(CN) = 1.345(4) and 1.420(3) Å] as are the TeN bonds [*d*(TeN) = 2.034(2) and 2.087(2) Å]. The C=O bond length is 1.227(3) Å, *cf.* 1.252(3) Å in $OC(NHBu^t)_2$[11] and 1.22–1.26 Å in ureato complexes of Ru[3], Os[3] and W.[12] Complex **3** is readily hydrolyzed by traces of moisture to give the urea $OC[N(H)Bu^t]_2$ and TeO_2.

The presence of a two-fold screw axis (2_1) at the centre and corners of the unit cell and a four-fold (4_1) axis at the mid-points of the cell axes results in two different channels parallel to the *ab* plane involving weak >C=O···Te contacts [3.020(2) Å, *cf.* sum of van der Waals radii for Te and O = 3.58 Å][13] as depicted in Fig. 2. The first type involves a lantern-shaped arrangement of four dimers. Two disordered thf molecules located in the middle of the lantern also engage in weak Te···O interactions [2.961(6) Å]. The second type of >C=O···Te interaction involves only one Te atom of four dimeric units and gives rise

DOI: 10.1039/b004137h

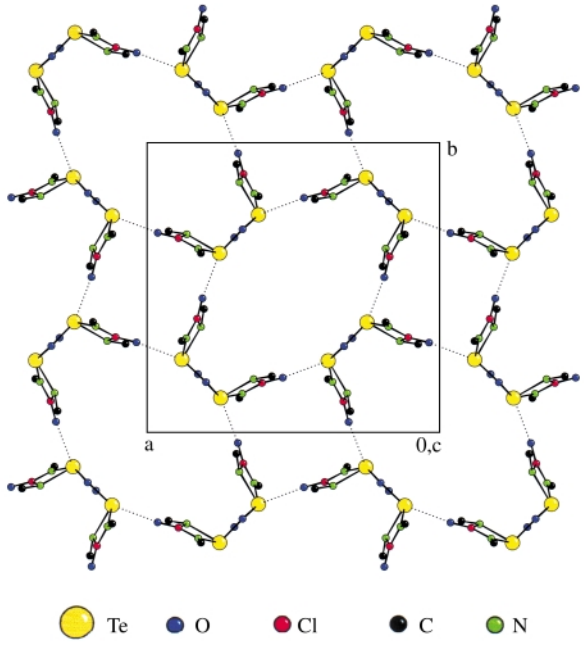

Fig. 2 Unit cell of $\{[OC(\mu\text{-}NBu^t)_2TeO]_2(thf)\}_\infty$ viewed down the *c*-axis. Disordered thf molecules are omitted.

to a square-shaped arrangement. In both of these structural motifs one of the >C=O···Te interactions links dimeric units in adjacent planes of the unit cell to give a helical arrangement, which is apparent when viewed down the *c* axis. The Te···Te distance in both cases is 12.4867(8) Å, *i.e.* the length of the *c* axis. Although weak intermolecular E···Te (E = O, N, S) interactions are a well known feature of tellurium complexes,[14] an extended network involving carbonyl–tellurium contacts is unique.

In summary, the presence of *two* Te=NBu^t linkages in **1** presents a unique opportunity for the study of double cycloadditions with heteroallenes. The reaction of **1** with Bu^{t}NCO generates a *N,N′*-ureato ligand *and* converts a tellurium imide (TeNBu^t) to a telluroxide (TeO) linkage, presumably *via* an unstable *N,O*-ureato complex. Thus it combines features of the reactions of both transition-metal imides and iminophosphoranes with isocyanates.

We thank the NSERC (Canada) for financial support, Dr R. MacDonald (University of Alberta) for assistance with the data collection, and Dr M. Parvez for helpful discussions of the disorder problem.

Notes and references

† *Experimental procedure*: all manipulations were performed under an inert atmosphere of dry argon using standard Schlenk techniques. All solvents were dried prior to use.

2: a colourless solution of Bu^{t}NCO (0.120 mL, 1.112 mmol) in toluene (10 mL) was added to an orange solution of **1**[9c] (0.30 g, 0.556 mmol) in toluene (5 mL) at room temperature. The addition of a small amount of Bu^{t}NCNBu^t prevents the formation of **3**. A yellow precipitate of **2** was formed after 3 min. The pale orange solution was stirred for 2 h, cooled to −10 °C and then the supernatant was decanted *via* cannula. The solid product was washed with cold *n*-pentane (3 mL) to give **2** (0.185 g, 0.501 mmol, 45%) as a yellow solid. ^{1}H NMR (400.13 MHz, C_6D_6, 25 °C) δ 1.46 (9 H), 1.35 (18 H). ^{13}C NMR (100.62 MHz, C_6D_6, 25 °C) δ 160.70 (CO), 64.17 [$C(CH_3)_3$], 54.83 [$C(CH_3)_3$], 34.69 [$C(CH_3)_3$], 31.86 [$C(CH_3)_3$]. ^{125}Te NMR (126.20 MHz, C_6D_6, 25 °C) δ 1225. IR:1653 [ν(CO)] cm^{-1}.

3: an orange solution of **1** (0.30 g, 0.556 mmol) in *n*-hexane (10 mL) was added to a colourless solution of Bu^{t}NCO (0.257 mL, 2.223 mmol) in thf (10 mL) at 23 °C. The pale yellow solution was stirred for 1.5 h and then volatile materials were removed under vacuum and **3**·2 thf (0.423 g, 0.549 mmol, 99%) was obtained as a white solid. Colourless crystals of **3**·thf suitable for X-ray diffraction were obtained after two days at 23 °C by layering an orange–red solution of **3** in *n*-hexane (3 mL) over a solution of Bu^{t}NCO in thf (3 mL). ^{1}H NMR (400.13 MHz, C_6D_6, 25 °C) δ 3.55 (thf), 1.45 (Bu^t, 18H), 1.41 (thf). ^{13}C NMR (100.62 MHz, C_6D_6, 25 °C) δ 160.39 (CO), 68.15 (thf), 54.97 [$C(CH_3)_3$], 31.27 [$C(CH_3)_3$], 26.15 (thf). ^{125}Te NMR (126.20 MHz, C_6D_6, 25 °C) δ 1090. IR: 1669 [ν(CO)], 663 [ν(TeO)] cm^{-1}.

‡ *Crystal data* for $(\mathbf{3}\cdot thf)_\infty$: $C_{22}H_{44}N_4O_5Te_2$, M = 699.81, tetragonal, space group $P4_12_12$ (no. 92), a = b = 15.5941(7), c = 12.4867(8) Å, V = 3036.5(3) Å^3, Z = 4, D_c = 1.531 g cm^{-3}, μ(Mo-Kα) = 19.55 cm^{-1}. Crystal dimensions 0.26 × 0.23 × 0.15 mm. Data were collected on a Bruker AXS P4/RA/SMART 1000 CCD diffractometer with graphite-monochromated Mo-Ka radiation using ϕ and ω scans. The structure was solved using direct methods (SIR-97) and refined by full-matrix least squares on F^2 (SHELXL-97). The thf molecule was disordered around the two-fold screw axis with partial occupancy factors of 0.5. Of the 2593 unique reflections 2410 had $I \geqslant 2.00\sigma(I)$. The final agreement factors were R_1 = 0.0164 and wR_2 = 0.041.

Received (in Cambridge, UK) 13th June 2000, Accepted 21st July 2000

The first examples of complexes containing the novel 1,2,5-azadiphosphole and 1,2,3-azadiphosphole ring systems are presented, together with the molecular structure of $[Ir(\eta^5\text{-}C_5Me_5)(\eta^4\text{-}(Bu^tCPNBu^tPCBu^t)]$ as established by a single crystal X-ray diffraction study.

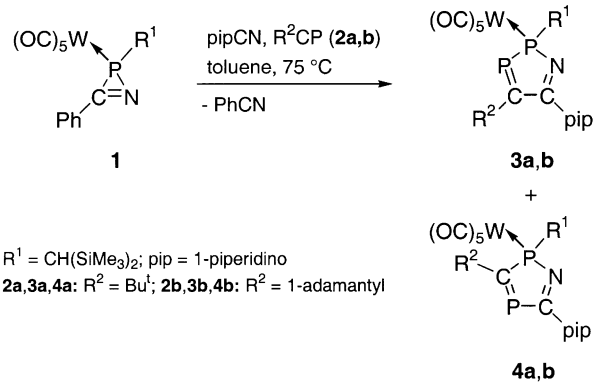
Transition metal-promoted syntheses of unsaturated P-heterocycles has received considerable attention in recent years in the quest for sophisticated ligands containing sp^2- and/or sp^3-hybridised phosphorus atoms in heterocyclic rings.[1] Tungsten complexes of 2*H*-1,2-azaphosphole,[2] 2*H*-1,3,2-diazaphosphole[3] and 2*H*-1,4,2-diazaphosphole[3,4] rings can be obtained using the dual precursor potential of 2*H*-azaphosphirene complexes *via* intermediate terminal phosphanediyl and nitrilium phosphane-ylide complexes, the former giving rise to 3- and 4-membered and the latter to 5-membered P-heterocycles. The planar, aromatic 1,2,4-azadiphosphole ring systems, $P_2C_2Bu^t_2NR$[5] (R = Pr^i, Et, Ph, Tol, Pr^n, Cy, Bu^tCH_2) on the otherhand, have recently been reported *via* coupling reactions involving the phospha-alkyne, $PCBu^t$, with the imido fragment of $[TiCl_2(NR)(py)_3]$ (R = Pr^i, Et, Ph, Tol) or $[VCl_3(NR)]$ (R = Pr^i, Pr^n, Cy, Bu^tCH_2) complexes.[5] We now describe the syntheses of complexes containing the previously unknown 1,2,3-azadiphosphole and 1,2,5-azadiphosphole ring systems; we also provide first evidence for 1,2,4-azadiphosphole complexes.

Extending our three-component reaction concept[3] towards phospha-alkynes, we have now observed that 2*H*-azaphosphirene complex **1**[6] react with 1-piperidinonitrile (2 equiv.) and an excess of Bu^tCP[7] **2a** or 1-AdCP[8] **2b** (Ad = adamantyl) in toluene at elevated temperature to give the 1,2,3-azadiphosphole complexes **3a**,**b** and 1,2,4-azadiphosphole complexes **4a**,**b**. Based on observations made earlier, *cf.* ref. 3 we assume that a transiently formed *C*-1-piperidino-substituted nitrilium phosphane-ylide complex react with the phospha-alkynes in [4 + 2] cycloaddition reactions to yield the two regioisomers, which were formed in ratios of 8:1 (**3a**:**4a**) and 3:1 (**3b**:**4b**) respectively. Unfortunately, even using low-temperature column chromatography, only complex **3b** could be separated by extraction and subsequent crystallisation (Scheme 1).

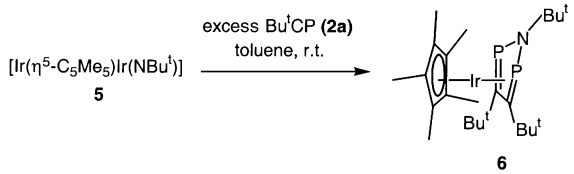
Bergman and co-workers,[9] synthesised the monomeric imido complex $[Ir(\eta^5\text{-}C_5Me_5)(NBu^t)]$ from $[\{Ir(\eta^5\text{-}C_5Me_5)Cl_2\}_2]$ and 4 equiv. of $LiNHBu^t$ in THF and described its cycloaddition reaction with dimethyl acetylenedicarboxylate to afford the structurally characterised compound $[Ir(\eta^5\text{-}C_5Me_5)\{NBu^t\text{-}(MeO_2CCCCO_2Me)_2\}]$, which contains an η^4-coordinated pyrrole ring. Since phospha-alkynes, PCR, are known to behave very like alkynes,[1] we have extended this type of cyclisation reaction and find that $[Ir(\eta^5\text{-}C_5Me_5)(NBu^t)]$ **5** on treatment with an excess of $PCBu^t$ **2a** in toluene at ambient temperature afforded the η^4-ligated 1,2,5-azadiphosphole ring complex **6**.¶

The E.I. mass spectra† exhibited the molecular ions of **3b** and **6**, which are consistent with the proposed formulations. The molecular structures of **3b** and **6** were deduced by NMR spectroscopy‡ (^{13}C, ^{31}P) (*vide infra*) and confirmed by a single crystal X-ray diffraction study§ in the case of **6** (Fig. 1). The $^{31}P\{^1H\}$ NMR spectra of complexes **3** and **4** displayed the expected AB-type spectra with low-field resonances for the two-coordinated phosphorus centers and with typical magnitudes of phosphorus–phosphorus coupling constants (for **3** *ca.* 294 Hz; for **4** *ca.* 34 Hz). Additionally, complex **3b** shows signals in its $^{13}C\{^1H\}$ NMR spectrum at δ 180.3 (m) and 196.5 (dd, $^1J_{(PC)}$ 61.1 Hz, $^2J_{(PC)}$ 9.7, *C*=P), which were readily assigned to the imino- and the phosphaalkene-carbon atoms respectively. The $^{31}P\{^1H\}$ NMR spectrum of **6** displayed a singlet (δ 0.26) implying a symmetrical environment for the two P atoms. The three signals (δ 1.92, 1.48, 1.07) observed in the ^1H NMR spectrum were readily assigned to C_5Me_5, $PCBu^t$ and NBu^t respectively. Further insight into the structure of this molecule was gained from the $^{13}C\{^1H\}$ NMR spectrum which showed two pseudo triples (δ 34.7 $^3J_{(PC)}$ 6.51 Hz, 28.7 $^3J_{(PC)}$ 7.28 Hz) in an intensity ratio of 2:1 which were assigned to the methyl resonances of the two sets of non-equivalent *tert*-butyl groups, thereby establishing the connectivity of both phosphorus nuclei with nitrogen.

The molecular structure of complex **6** which was confirmed by a single crystal X-ray analysis of crystals grown from a saturated pentane solution (−50 °C), is shown in Fig. 1 together



Scheme 1 Reaction of complex **1** with 1-piperidinonitrile and phospha-alkynes **2a**,**b**§



Scheme 2 Reaction of $[Ir(\eta^5\text{-}C_5Me_5)(NBu^t)]$ **5** with the phospha-alkyne $PCBu^t$ **2a**.¶

DOI: 10.1039/b004692m

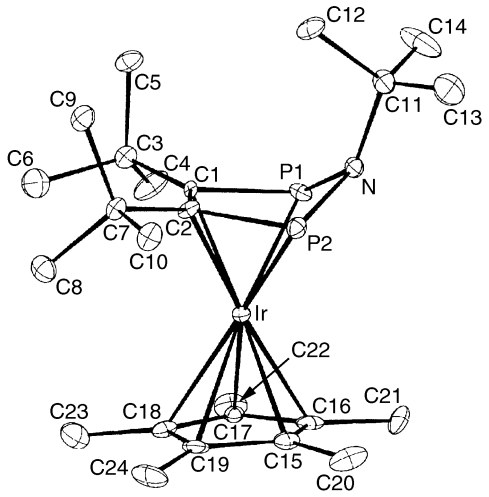


Fig. 1 Molecular structure of [Ir(η^5-C_5Me_5)(η^4-(Bu^{t}CPNBu^{t}PCBu^t)] **6**. Selected distances (Å) and angles (°): P(1)–C(1) 1.846(7), C(2)–P(2) 1.837(11), P(1)–N 1.718(7), P(2)–N 1.733(6), C(2)–C(1) 1.427(12), Ir–C(2) 2.161(11), Ir–C(1) 2.173(5), Ir–P(2) 2.333(2), Ir–P(1) 2.338(3), C(18)–C(19) 1.433(14) Å. N–P(2)–C(2) 101.3(4), N–P(1)–C(1) 101.2(3), P(1)–N–P(2) 98.9(3), C(2)–C(1)–P(1) 108.8(5), C(1)–C(2)–P(2) 109.1(7), P(2)–N–C(11) 121.8(4), P(2)–C(2)–C(7) 118.6(7), C(1)–C(2)–C(7) 132.0(8)°. Hydrogen atoms are omitted for clarity. Displacement ellipsoids are shown at the 50% probability level.

with principal bond lengths and angles. The IrC_5Me_5 fragment is η^4-ligated to the 1,2,5-azadiphosphole ring resulting in the nitrogen atom becoming pyramidalised and it lies out of the plane formed by P(2)–C(2)–C(1)–P(1), (dihedral angle between P(2)–C(2)–C(1)–P(1) and P(1)–N–P(2), 44.2(3)°). The longer Ir–P(1)/Ir–P(2) (av. 2.335 Å) bond lengths compared with Ir–C(2)/Ir–C(1) (av. 2.167 Å) causes the P(2)–C(2)–C(1)–P(1) fragment to tilt away from the plane of the C_5Me_5 ring (dihedral angle between P(1)–C(1)–C(2)–P(2) and C(15)–C(16)–C(17)–C(18)–C(19), 7.7°). The C(1)–C(2) bond distance (1.427(12) Å) lies within the range expected for η^4-bonded systems, whereas the P(1)–C(1) and P(2)–C(2) distances (1.846(7), 1.837(11) Å) are considerably longer than anticipated for P=C double bonds. This is the first structurally characterised metal complex containing a 1,2,5-azadiphosphole derivative.
