Some years ago,[4] protonation of *trans*-[Mo(N$_2$)(NCPr^n)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] was found to occur at dinitrogen, forming the corresponding hydrazide (top line). However recently, the analogous *trans*-[Mo(N$_2$)(NCPh)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] was shown to protonate at the nitrile carbon[5] (bottom line). This observation is rather unexpected since earlier investigations[6,7] showed that protonation of end-on coordinated dinitrogen is rapid (probably diffusion-controlled), whereas protonation at carbon sites is usually several orders of magnitude slower, even when bound to electron-rich metal centres[2,3,8] indicating that hydrazides would always be formed in such reactions. Given that in *trans*-[Mo(N$_2$)(NCPh)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] both dinitrogen and nitrile are bound to the same centre it is difficult to reconcile why carbon should be the preferred protonation site. Herein, we report kinetic studies on the family of reactions represented in eqn. (1) (R = MeO, Me, H, Cl, MeCO or NO$_2$),[9] and show that R affects the protonation chemistry of the dinitrogen and nitrile ligands in quite different ways.

trans-[Mo(N$_2$)(NCC$_6$H$_4$R-4)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] + HCl ⟶
trans-[MoCl(NCH$_2$C$_6$H$_4$R-4)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$]$^+$ + Cl$^-$ (1)

When the reaction between *trans*-[Mo(N$_2$)(NCPh)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] and an excess of anhydrous HCl is studied in thf, using stopped-flow spectrophotometry, a single exponential absorbance–time curve is observed. Under all conditions, the initial absorbance corresponds to the reactant and final absorbance† to *trans*-[MoCl(NCH$_2$Ph)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$]$^+$. The kinetics of this reaction exhibit a first order dependence on the concentration of *trans*-[Mo(N$_2$)(NCPh)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] but the dependence on the concentration of HCl is markedly non-linear, such that at high concentrations of HCl the rate is independent of the concentration of acid (Fig. 2).

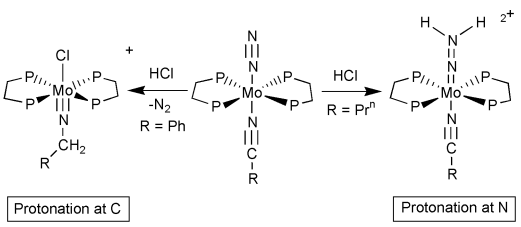

Fig. 1 Protonation of dinitrogen *vs.* nitrile in *trans*-[Mo(N$_2$)(NCR)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$].

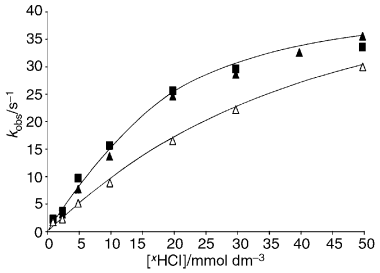

Fig. 2 Dependence on the concentration of ^{x}HCl for the reaction with *trans*-[Mo(N$_2$)(NCPh)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] in thf at 25.0 °C. The data points correspond to: [Mo] = 0.2 mmol dm^{-3} (■) and [Mo] = 0.4 mmol dm^{-3} (▲). Data collected in the reaction with ^{2}HCl (△) are also shown. The data were analysed by plotting $1/k_{obs}$ *vs.* 1/[HCl], from the straight line the intercept = $1/k_2$ and gradient = $1/k_1$.

These observations are consistent with the mechanism shown in Fig. 3. Initial protonation of the nitrile carbon (k_1) generates [Mo(N$_2$)(NCHPh)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$]$^+$. Protonation of the nitrile diminishes the electron density at the metal, and because dinitrogen is a strong π-acceptor ligand, this has two effects on its reactivity: (i) decreasing the basicity of dinitrogen thus suppressing protonation and (ii) increasing the lability of dinitrogen. Dissociation of dinitrogen (k_2) and subsequent rapid binding of chloride facilitates further protonation of carbon to form *trans*-[MoCl(NCH$_2$Ph)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$]$^+$. An analogous mechanism has been proposed for the reactions of acid with *trans*-[Mo(N$_2$)$_2$(R$_2$PCH$_2$CH$_2$PR$_2$)$_2$][6,7] (R = Ph or Et), involving rapid protonation of one dinitrogen followed by rate-limiting dissociation of the other. The important difference in the two systems is that for *trans*-[Mo(N$_2$)(NCPh)(Ph$_2$PCH$_2$-

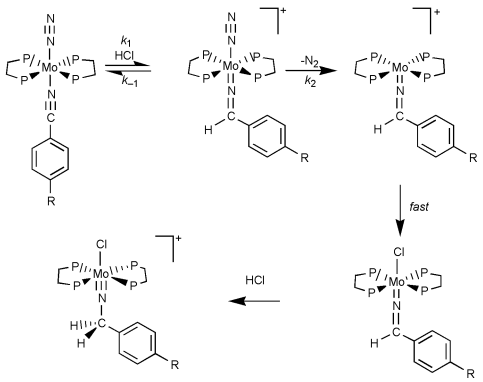

Fig. 3 Mechanism for the formation of *trans*-[MoCl(NCH$_2$C$_6$H$_4$R-4)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] in the reactions of anhydrous HCl with *trans*-[Mo(N$_2$)(NCC$_6$H$_4$R-4)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$].

DOI: 10.1039/b006302i

$CH_2PPh_2)_2$] the protonation at carbon is rate-limiting at low concentrations of HCl, and consequently the reaction with DCl is associated with a primary isotope effect (k_1^H/k_1^D = 1.8; Fig. 2). Only at high concentrations of acid does the unimolecular dissociation of dinitrogen become rate-limiting, and under these conditions there is no isotope effect (k_2^H/k_2^D = 1.0).

Studies on *trans*-[Mo(N_2)(NCC_6H_4R-4)($Ph_2PCH_2CH_2PPh_2)_2$] (R = MeO, Me, Cl, MeCO or NO_2) show analogous behaviour to that of *trans*-[Mo(N_2)(NCPh)($Ph_2PCH_2CH_2PPh_2)_2$] and allow investigation into how k_1 and k_2 are affected by the electronic influences of R (Fig. 4).

The effect of R on the lability of dinitrogen (k_2) is not unexpected. As R is varied and becomes more electron-releasing, the dinitrogen becomes less labile. This is in line with the labilities of dinitrogen previously observed in the reactions of *trans*-[Mo(N_2)$_2${(4-RC_6H_4)$_2PCH_2CH_2P(C_6H_4$R-4)$_2$}$_2$] (R = CF_3, Cl, H, Me or MeO).[10] The effect of R on the rate of protonation at the nitrile carbon is less straightforward. It is anticipated that k_1 would be affected by both the electron density at the carbon and the barrier to structural rearrangement (rehybridisation).[11] Certainly, there is a general increase in the rate of protonation as R becomes more electron-releasing but the trend is markedly non-linear, and with the most strongly electron-releasing substituents the rate of protonation is essentially independent of the nature of R. The reason R affects protonation of the nitrile and dinitrogen ligands so differently becomes clearer after considering the effect R has on the IR stretching frequencies, $\upsilon(N_2)$ and υ(CN) (Fig. 4, insert).[9] It is evident that R affects $\upsilon(N_2)$ and υ(CN) in a manner which parallels the rates of dinitrogen dissociation and protonation of carbon, respectively. The values of $\upsilon(N_2)$ and υ(CN) reflect the bond orders in these groups, which are affected by the backbonding from {Mo($Ph_2PCH_2CH_2PPh_2)_2$} to each of the π-acceptor ligands. The substituent R will modulate this effect, but because it is sited on the nitrile, R affects the backbonding to dinitrogen and nitrile differently.

For the *trans*-dinitrogen, as R is varied and made more electron-releasing the backbonding from Mo to dinitrogen is reinforced resulting in a decrease in $\upsilon(N_2)$ and dinitrogen lability (k_2) (and, as noted above, an increase in basicity). In contrast, the effect of an electron-releasing R will oppose the backbonding from Mo to nitrile. This counterbalance of the electron-releasing effect of R and the backbonding from Mo results in the increasing insensitivity of υ(CN) and the rate of protonation of the nitrile carbon as R becomes more electron-releasing ($k_1^{max} \approx 1 \times 10^4$ dm^3 mol^{-1} s^{-1}). Understanding the electronic origins of these effects allows us to appreciate that it is a combination of kinetic and thermodynamic factors which control product-selectivity in the reactions of acid with *trans*-[Mo(N_2)(NCR)($Ph_2PCH_2CH_2PPh_2)_2$] (Fig. 1).

As noted above, the π-backbonding from the {Mo($Ph_2PCH_2CH_2PPh_2)_2$} site affects both the lability and the basicity of dinitrogen.[12] In *trans*-[Mo(N_2)(NCC_6H_4R-4)($Ph_2PCH_2CH_2PPh_2)_2$], the aryl group is poorly electron-releasing and consequently the *trans*-dinitrogen is only weakly basic. Indeed, we can estimate an upper limit for the proton-affinity of the dinitrogen in these systems [eqn. (2)]. Even at the highest concentration of HCl (50 mmol dm^{-3}), there is no spectroscopic or kinetic evidence for dinitrogen being protonated, and hence $K_3^{Ph} \leqslant 4 \times 10^{-5}$. Since $K_3^{Ph} = k_3^{Ph}/k_{-3}^{Ph}$ and assuming the thermodynamically favourable k_{-3}^{Ph} step is diffusion controlled, we can estimate $k_3^{Ph} \leqslant 4 \times 10^5$ dm^3 mol^{-1} s^{-1}. Hence in these systems, the rates of protonation of dinitrogen and the nitrile carbon are not necessarily appreciably different. Since the exclusive product is always *trans*-[MoCl(NCC_6H_4R-4)($Ph_2PCH_2CH_2PPh_2)_2$] thermodynamic factors must be controlling the outcome of the reaction.

$$Mo{-}N{\equiv}N + HCl \underset{}{\overset{K_3}{\rightleftharpoons}} Mo{=}N{=}\overset{+}{N}\overset{H}{\diagdown} + Cl^- \qquad (2)$$

As indicated above, a natural consequence of the mutually *trans* dinitrogen and nitrile both being π-acceptor ligands is that protonation at one suppresses protonation at the other. However, the unfavourable value of K_3^{Ph} means that the parent dinitrogen complex is the major component of the protolytic equilibrium mixture and is able to react by the irreversible, protonation of the nitrile carbon, resulting in the ultimate formation of *trans*-[MoCl($NCH_2C_6H_4$R-4)($Ph_2PCH_2CH_2PPh_2)_2$]$^+$.

Consider now the situation where the nitrile is *very* electron-releasing, as is the case in *trans*-[Mo(N_2)(NCPr^n)($Ph_2PCH_2CH_2PPh_2)_2$]. The Pr^{n}CN ligand is sufficiently electron-releasing[4] that dinitrogen binds two protons even with [HCl] = 10 mmol dm^{-3}, giving $K_3^{Pr} \geqslant 0.36$ and hence $k_3^{Pr} \geqslant 3.6 \times 10^9$ dm^3 mol^{-1} s^{-1} (*i.e.* close to the diffusion-controlled limit). However, the data in Fig. 4 indicate that protonation of carbon will not exceed $k_1 \approx 1 \times 10^4$ dm^3 mol^{-1} s^{-1}. Consequently both the kinetics and thermodynamics favour protonation at dinitrogen, and *trans*-[Mo(NNH_2)(NCPr^n)($Ph_2PCH_2CH_2PPh_2)_2$]$^{2+}$ is formed (Fig. 1).

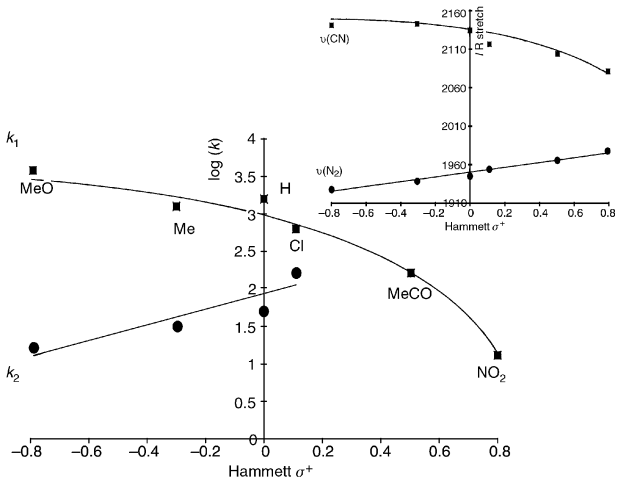

Fig. 4 Correlation of log(k) with Hammett σ^+ for the protonation of the nitrile carbon, k_1 (■) and dissociation of dinitrogen, k_2 (●) in the reactions of HCl with *trans*-[Mo(N_2)(NCC_6H_4R-4)($Ph_2PCH_2CH_2PPh_2)_2$] (R = NO_2, MeCO, Cl, H, Me or MeO) in thf at 25.0 °C. Insert: correlation of Hammett σ^+ with υ(CN) (■) and $\upsilon(N_2)$ (●).

First published as an Advance Article on the web 27th September 2000

Carbon nanotubes can be efficiently separated from impurity material in carbon soot using a conjugated polymer filtration system as monitored by EPR, allowing the calculation of purity of the crude carbon soot.

Carbon nanotubes have generated interest in all areas of science owing to their novel structural, mechanical and electronic properties. In the physical sciences nanodevices have already been demonstrated including transistors[1] and rectifying heterojunctions.[2] In microbiology they have been used as probes to study the structure of biomolecules[3,4] and as templates for the self assembly of proteins.[5] However, at present, as-produced carbon soot remains low in nanotube content.[6] Furthermore, neither quantitative techniques to analyse soot content nor methods to measure nanotube content exist. This work presents the first measurement of nanotube content in impure carbon soot. Using a conjugated polymer as a nanotube 'filter', carbon nanotubes are separated from all other soot components. An absolute value for the nanotube content can then be calculated for the first time using electron paramagnetic resonance and thermogravimetric measurements. This is a vital step towards making nanotubes a practical material for novel scientific developments.

The necessity for a technique to measure nanotube content in carbon soot is apparent when the present fabrication and purification methods are examined. During nanotube production unwanted carbon species such as turbostratic graphite (TSG) and carbon onions are invariably formed. Purification by oxidation[7] destroys many nanotubes and alters the electronic properties of the remaining tubes. Chromatographic techniques[8] have succeeded in purifying carbon soot but no quantitative measure of purity has been obtained. Furthermore, scale-up of these processes is problematic. The process outlined in this work approaches these issues in a novel manner *via* the production of a polymer nanotube composite. Thus a quantifiable purification method for carbon soot is presented which leads logically to a measurement of the purity of that soot.

In order to produce the polymer nanotube composites used in this work 80 mg of poly(*m*-phenylene-*co*-2,5-dioctyloxy-*p*-phenylenevinylene) (PmPV) were mixed with 25.5 mg of multiwall nanotube (MWNT) containing arc-generated carbon soot in 4 ml of toluene. The PmPV was synthesised using a standard polycondensation reaction,[9] while the carbon soot was generated in a Krätschmer generator.[10] The mixture was sonicated for 2 min using a high power sonic tip and then for 2 h in a low power sonic bath to ensure complete dispersion of the Krätschmer generated carbon soot. This was carried out for seven composite solutions with identical constituents. These solutions were then allowed to stand undisturbed for various amounts of time, from 30 min to 90 h. At the end of its settling time each solution was carefully decanted into a new sample bottle, leaving a black sediment at the bottom of the old bottle. These sediments were then dried and weighed.

To determine the natures of the sediment and remaining solute, EPR spectroscopy was used. This technique measures microwave-induced transitions between electron spin energy levels in the presence of a magnetic field. Unpaired electrons in different environments may be distinguished using this technique by differences in their resonance spectra. To prepare samples for EPR, *ca.* 0.3 ml of each of the separated solutions was drop cast onto spin free quartz plates, giving *ca.* 7 mg of solute after the solvent had evaporated. In addition all the recovered sediments were carefully weighed and *ca.* 7 mg of each placed in spin free quartz tubes. EPR spectra were recorded for all samples and carbon soot. The carbon soot was dispersed in toluene in a spin free glass tube to reduce the interaction of the spins within neighbouring particles, and to match more closely the environment of the spins in a polymer host.

Fig. 1 shows EPR derivative spectra for the dispersed carbon soot, the sediment and solute samples for both the shortest and longest settling times. In all cases these spectra could well be fitted to the superposition of two symmetric absorption lines of Lorentzian shape. In the case of the dispersed carbon soot and the various sediments, *g* values determined from the line positions, of *ca.* 2.011 and 2.020 and peak-to-peak line widths, ΔB_{pp}, of close to 11 and 12 G, respectively, were observed. Similar results were obtained for the solute spectra which could be fitted to two lines with *g* values of *ca.* 2.011 and 2.020 and widths of 7 and 18 G, respectively. This demonstrates that the carbon soot consists of the same two components as are in the solutes and sediments. The variation in linewidth between sediment and solute is probably due to small environmental variations between the two phases. Two such components have been observed by other authors who attribute them to paramagnetic centers in nanotubes[6,11] and TSG.

In addition to *g* values and linewidths, signal intensities can be measured for both the MWNT and TSG. In each case the signal intensity of the MWNT or TSG line is proportional to the mass of the MWNT or TSG present in the measured sample. Assuming that the measured fraction is representative of the whole mass of sediment or solute, the signal intensities can be normalized to represent all the unpaired spins in the total mass of sediment or solute. This normalized signal intensity (*NSI*) is achieved by multiplying the measured signal intensity by a

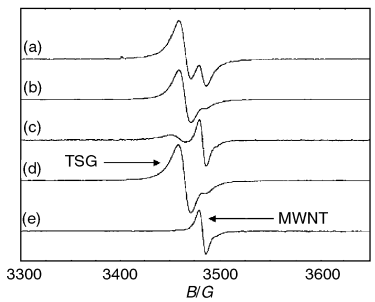

Fig. 1 EPR derivative spectra for some of the samples studied in this work. EPR spectra of (a) carbon soot dispersed in toluene, (b) the sediment formed after 30 min settling time, (c) the solute remaining after 30 min settling time, (d) the sediment formed after 90 h settling time and (e) the solute remaining after 90 h settling time. Note that in all spectra except E two components, TSG and MWNT (denoted by arrows), are clearly present. For spectrum E the sole component present is that of the MWNT.

DOI: 10.1039/b006164f

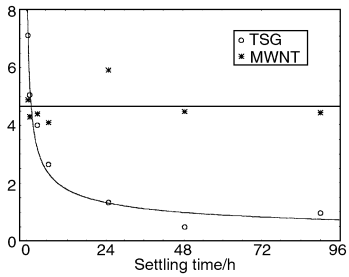

Fig. 2 Normalised signal intensities (*NSI*) for the nanotube and TSG components of the solute formed for various settling times. The *NSI* values are proportional to the entire mass of each component for each solute. Note that while the nanotube component remains approximately constant the turbostratic graphite component decreases as the TSG falls out of solution.

factor of M_T/M_{EPR} where M_T is the total sediment or solute mass and M_{EPR} is the mass of the sample measured.

These normalized signal intensities, for both nanotube and TSG components of the solute are shown in Fig. 2 as a function of sample settling time. It is clear from this diagram that the nanotube component of the various solutes is approximately constant for all the settling times. The TSG component however shows a sharp decrease. After 48 h settling time there is virtually no TSG present in the solute. Therefore the PmPV holds carbon nanotubes in solution while the TSG gradually settles out to give solutions rich in nanotubes. Thus nanotubes can be effectively separated from other unwanted forms of carbon present in carbon soot.

For the 48 h settling time we can calculate the percentages of both MWNT and TSG that have remained in solution. This can be calculated for a given species from

$$\% = 100 \times \frac{NSI_{solution}}{NSI_{solution} + NSI_{sediment}} \quad (1)$$

where % is the percentage of the given species (MWNT or TSG) in solution, $NSI_{solution}$ and $NSI_{sediment}$ are the normalized signal intensities for the same species in solution and sediment, respectively. For the 48 h settling sample $NSI_{solution}$(MWNT) = 4.5 while $NSI_{sediment}$(MWNT) = 2.6 (in arbitrary units). By comparison for the same sample $NSI_{solution}$(TSG) = 0.5 while $NSI_{sediment}$(TSG) = 26.5. Using this we can calculate that 63% of the added nanotubes go into solution while only 1.9% of the added TSG remains in solution.

While this allows us to make relative comparisons of amounts of nanotubes present in a given sample using the *NSI* values, EPR alone does not give us enough information to make absolute measurements of nanotube content. In order to do this we need to be able to calculate a nanotube signal intensity per unit mass, *k*, such that we can write an equation of the form

$$S_i = k_i m_i \quad (2)$$

where S_i is a signal intensity for a given mass m_i of a given species (MWNT or TSG) *i*. This will allow us to calculate the mass of nanotubes in a given sample from the EPR spectrum provided we know *k*.

In order to calculate the mass of nanotubes present in a purified composite sample with only trace amounts of TSG we use thermogravimetric analysis (TGA). In this technique the sample is heated in air and the sample mass monitored as it is oxidised. This was carried out for the carbon soot, PmPV and a highly separated solute sample (settling time 48 h). The TGA traces for these samples are shown in Fig. 3. By 650 °C the PmPV sample is almost completely oxidised (except for some impurities), while the carbon soot only begins to burn at *ca.* 700 °C. For the composite sample, between these two temperatures, no oxidisation occurs as demonstrated from the horizontal part of the trace in this region. Thus the stable mass in this temperature region represents nanotubes and some polymer impurities. It is possible to account for the polymer impurities and hence calculate the mass of nanotubes present in the composite using these data. For the composite solute

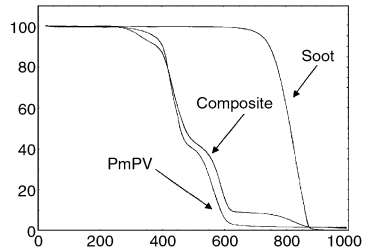

Fig. 3 Thermogravitational analysis trace for PmPV, a highly separated composite film and carbon soot. Note that PmPV stops burning at *ca.* 600 °C while the carbon soot only begins to burn at 750 °C. For the composite sample there is no oxidation between these temperatures. This allows us to calculate the mass of nanotubes in this sample.

measured here the nanotube mass was calculated at 5.1% of the total composite mass. This allows us to calculate the actual mass of nanotubes present in the (same) sample measured by EPR. As we know the nanotube EPR signal intensity (S_n) for this sample we can calculate a signal intensity per mass of nanotubes, k_n. This works out to be 1.04 per mg in our system of units.

From this it is possible to calculate the nanotube content in the carbon soot. As described above we can obtain a *NSI* for the nanotube component in the carbon soot. This was measured as 0.53 for the 1.5 mg of carbon soot dispersed in toluene, giving a nanotube component in this sample of carbon soot a mass of $m_n = S_n/k_n = 0.53/1.04\ mg^{-1} = 0.51$ mg. This allows us to calculate the nanotube content of the carbon soot as 34%. This value is consistent with estimates of nanotube content in various carbon soots from scanning electron microscopy and transmission electron microscopy.

In conclusion we have demonstrated a preparation method which allows us to isolate nanotubes from unwanted carbon components with a high nanotube yield. This allows us to use EPR and TGA to calculate the nanotube content (purity) of the soot. For the carbon soot used in this study, the nanotube content was 34% by mass.

While calculation of carbon soot purity is the most obvious benefit of this technique many other potential advantages exist. To date no technique exists which can give quantitative measurements of nanotube content in any environment. In the past nanotube researchers in all fields have relied on purely qualitative methods such as measuring ratios of ill-defined Raman peaks or counting nanotubes in SEM or TEM micrographs. This present technique will eradicate these issues and finally solve the fundamental problem of high yield nanotube extraction. Furthermore we believe that this work is the first step toward the ability to design specific polymer architectures to select tubes of given chirality or diameter. This is considered to be one of the most important potential developments needed to make nanoelectronics using nanotubes a reality.

The authors wish to thank the Irish Higher Educational Authority for partly funding this work.

Intramolecular benzylic C–H activation: palladium-catalyzed synthesis of hexahydromethanofluorenes†

Marta Catellani,*[a] Elena Motti[a] and Stefano Ghelli[b]

[a] *Dipartimento di Chimica Organica e Industriale dell'Università, Parco Area delle Scienze, 17/A, I-43100 Parma, Italy. E-mail: catell@unipr.it*

Received (in Cambridge, UK) 28th June 2000, Accepted 5th September 2000
First published as an Advance Article on the web 27th September 2000

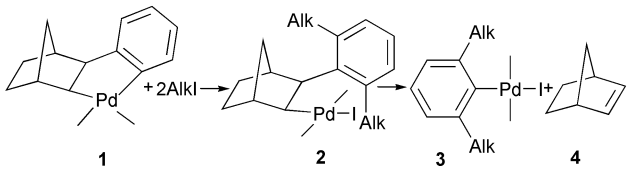
C–H activation of benzylic methyl groups has been realized catalytically under mild conditions through intramolecular reaction on a palladium complex.

Aromatic and aliphatic C–H activation catalyzed by transition metal complexes is an area of increasing interest in view of the elaboration of selective methodologies for the functionalisation of arenes and alkanes.[1] Cyclometallation and, in particular, cyclopalladation reactions are valuable tools to achieve intramolecular C–H bond cleavage.[1f–h]

We previously reported[2] a new methodology for selective aromatic substitution which implies C–H activation and *o*,*o*′-dialkylation of the hexahydropalladafluorene **1**. As shown in the simplified Scheme 1, the reaction proceeds through oxidative addition of alkyl halides, alkyl group migration on the aryl site of the palladacycle **1** and spontaneous expulsion of norbornene **4** to give the *o*,*o*′-dialkylated arylpalladium species **3**.

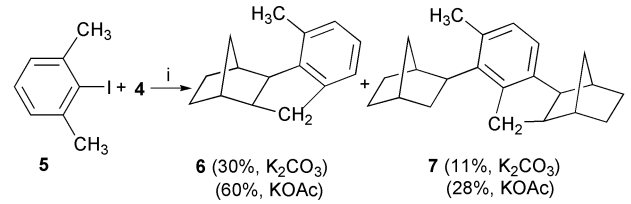
The reaction could be made catalytic by causing the final complex **3** to undergo further reaction so that palladium(0) could be formed.[3] An example is shown by the reaction of iodobenzene, *n*-propyl bromide, norbornene and phenylboronic acid to form 2,6-di-*n*-propyl-1,1′-biphenyl in 90% isolated yield.[3c]

We have now found that in the presence of a methyl group the reaction can take a completely different course, norbornene no longer being expelled as in Scheme 1, but instead undergoing ring closure on the methyl group.



Scheme 1

Compounds **6** and **7** (Scheme 2) are formed by heating an *N*,*N*-dimethylformamide (DMF, 5 mL) solution of norbornene (49 mg, 0.52 mmol) and *o*,*o*′-dimethyliodobenzene (103 mg, 0.44 mmol) at 105 °C for 18 h under nitrogen in the presence of $Pd(OAc)_2$ (10 mg, 0.044 mmol) as the catalyst and K_2CO_3 (61 mg, 0.44 mmol) as the base. *cis*,*exo*-Hexahydromethanofluorenes **6** (30%) and **7** (two diastereoisomers, 11%) correspond to palladium-catalyzed C–H activation of a benzylic methyl group. Yields of **6** and **7** could be raised to 60 and 28%, respectively, by using KOAc instead of K_2CO_3 as a base.



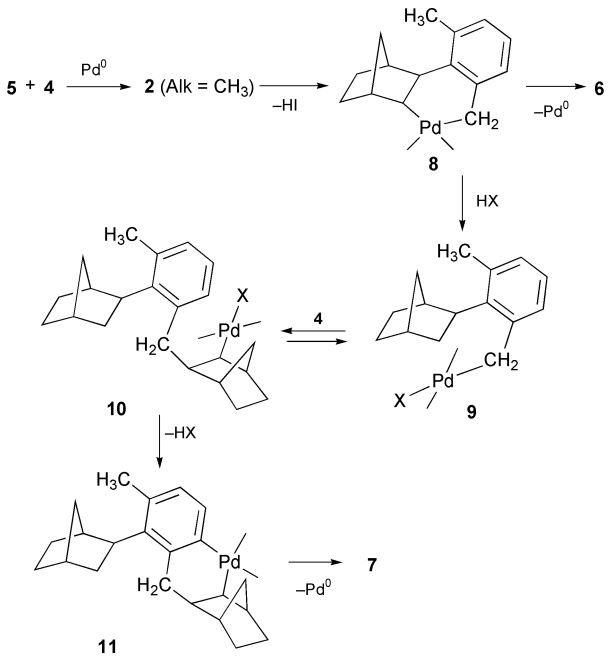
Scheme 2 *Reagents and conditions*: i, 10% mol $Pd(OAc)_2$, KOAc, DMF, N_2, 18 h, 105 °C, 91% conversion.

† Electronic supplementary information (ESI) available: selected spectroscopic data for compounds **6**, **7**, **15** and **16**. See http://www.rsc.org/suppdata/cc/b0/b005182i/

The positive influence of KOAc on the conversion of the disubstituted aryl iodide **5** could be ascribed to the favourable action exerted by the acetate anion on norbornene insertion,[4] this step being adversely affected by the steric hindrance of the two *ortho* methyl groups. The proposed course of the reaction leading to compounds **6** and **7** is shown in Scheme 3.

Complex **2** (Alk = CH_3) instead of undergoing norbornene deinsertion as previously observed (see Scheme 1), prefers to activate the methyl group to give the palladacyclohexene complex **8**. This means that the tendency of palladium to react with a suitably positioned methyl group, possibly through agostic interaction,[1h,5] is strong enough relative to C–C bond cleavage so preventing norbornene deinsertion. Complex **8** can either undergo $C(sp^3)$–$C(sp^3)$ coupling to give compound **6** or ring opening catalyzed by protonic species HX in the manner previously described[6] and thoroughly investigated by Carmona's group in a recent study.[7] Norbornene then inserts into the new alkylpalladium complex **9** to form **10**; the latter gives the new disubstituted *cis*,*exo*-hexahydromethanofluorene **7** through the intermediacy of a six-membered palladacycle of type **11**.

Since compound **7** must originate from a benzylpalladium complex of type **9**, which in turn requires the palladacyclohex-



Scheme 3 Proposed mechanism for the palladium-catalyzed synthesis of **6** and **7**. Solvent or reagent molecules as ligands are omitted for simplicity.

DOI: 10.1039/b005182i

ene **8** as precursor, its presence unequivocally confirms the proposed mechanism.

The reaction shows some analogy with those of *o*-*tert*-butyliodobenzene and *o*-iodoanisole described by Dyker[8] which, however, imply palladium-catalyzed C–H activation at a *tert*-butyl group and at a methoxy group, respectively, and end up with a $C(sp^3)$–$C(sp^2)$ ring closure.

To further support these results we carried out the stoichiometric reaction of the dimeric *o*-tolylnorbornylpalladium chloride complex **2** (one Alk = CH_3, the other being H)[9] (52 mg, 0.08 mmol) with methyl iodide (23 mg, 0.16 mmol) in the presence of K_2CO_3 (33 mg, 0.24 mmol) in DMF (5 mL) at room temperature for 5 h under nitrogen. The cyclopentene derivative **6** was obtained in 73% yield.

At this point we wondered whether a catalytic reaction involving benzylic activation could be possible also using *o*-iodotoluene in place of *o*,*o*′-dimethyliodobenzene. Poor results were obtained with KOAc while using K_2CO_3 led to the formation of four products. Thus compounds **15**–**18** (Scheme 4) were obtained by heating a DMF (25 mL) solution of norbornene (57 mg, 0.6 mmol) and *o*-iodotoluene (109 mg, 0.5 mmol) in the presence of $Pd(OAc)_2$ (11 mg, 0.05 mmol) as catalyst and K_2CO_3 (70 mg, 0.5 mmol) as the base under the conditions previously reported. The formation of products **15** (63%) and **16** (two diastereoisomers, 5%) implies the same type of C–H activation of a benzylic methyl group as observed for **6** and **7**.

The reaction pathway involves the intermediacy of palladacycle **13** and its further reaction with a second molecule of *o*-iodotoluene to form eventually **14**.[9c] Once the *o*,*o*′-disubstituted aromatic is formed the reaction proceeds as shown in Scheme 3 for *o*,*o*′-dimethyliodobenzene.

Although the cyclisation reaction leading to **15** could be expected to occur between one molecule of iodotoluene and one of norbornene, it surprisingly takes place only after a second tolyl unit has been introduced into the free *ortho* position. This fact can be explained considering that, as long as one *ortho* methyl group only is present, coordination with the aromatic ring is preferred. This point has been recently highlighted by Crabtree and coworkers.[1g,10]

The formation of **17** (10%)[11] and **18** (two diastereoisomers, 4%) does not involve benzylic C–H activation. However, since it can readily be explained according to a pathway previously described,[11] it will not be examined further. Yields are strongly influenced by reaction conditions (such as temperature, concentration, solvent) as well as by the base used and the addition of ligands and salts. For example by adding tetrabutylammonium bromide to the reaction mixture, compound **16** becomes the main product, being obtained in 37% yield together with compounds **15**, **17** and **18** in 23, 6 and 14% yield, respectively.

Compounds **6**, **7**, **15** and **16** were fully characterised by spectroscopic methods and by elemental analysis (ESI).†

In conclusion we have shown that C–H bonds of benzylic methyl groups can be activated catalytically with formation of cyclopentene rings. The use of the appropriate organometallic precursors allows the reaction to occur stoichiometrically even at room temperature. The generality of the reaction is being investigated.

A novel C–C bond formation by Baylis–Hillman type reaction mediated by SmI_2: an effective approach to α-hydroxyalkylacrylamide synthesis

So Won Youn, Heui Sul Park and Yong Hae Kim*

Center for Molecular Design & Synthesis and Department of Chemistry, Korea Advanced Institute of Science and Technology, 373-1, Kusong Dong, Yusong Gu, Taejon, 305-701, Korea. E-mail: kimyh@sorak.kaist.ac.kr

Received (in Cambridge, UK) 15th August 2000, Accepted 5th September 2000
First published as an Advance Article on the web 28th September 2000

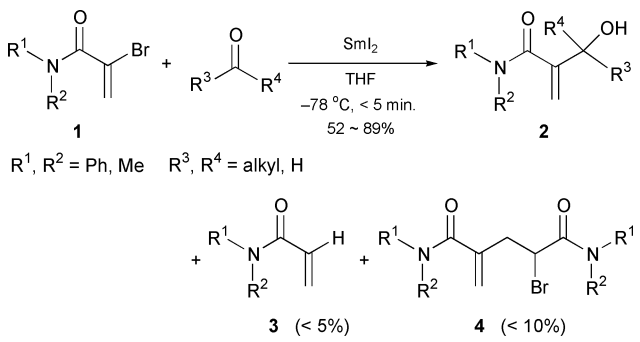
α-Bromoacrylamides (1) reacted with aldehydes or ketones, in the presence of SmI_2 at −78 °C in THF, within 5 min to produce Baylis–Hillman type reaction products (2) through an anionic process using vinylsamarium Grignard species in good yields (52–89%).

The construction of C–C bonds has been one of the most fundamental reactions in organic synthesis. The Baylis–Hillman reaction[1] produces multifunctional molecules that can be used for the synthesis of natural and unnatural products[2] through C–C bond formation between the α-position of activated alkene and carbon electrophiles having an electron-deficient sp^2 carbon atom under a basic catalyst, in particular a tertiary amine. But the reaction suffers from being inconveniently slow.[1] Furthermore, under normal circumstances acrylamides, crotonic derivatives, and ketones are inert substrates for the Baylis–Hillman reaction.[1,3] Therefore a number of attempts[2g,4,5] have been made to provide the corresponding adduct including the use of microwave irradiation and high pressure.[6]

Samarium diiodide has become a useful reagent for various organic reactions.[7] Especially, SmI_2 can be used to generate radicals and to reduce alkyl radicals to alkylsamarium reagents that can be trapped by a variety of electrophiles to form a new C–C bond.[7–9] However, there have been arguments that in general, vinyl- and aryl radicals do not usually undergo further reduction to vinyl- or arylsamarium reagents.[9] We report here the first example of reactions *via* vinylsamarium species.

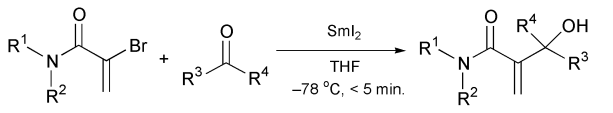
It has been found that α-bromoacrylamides (**1**) reacted with a variety of aldehydes or ketones in the presence of SmI_2 to give α-hydroxyalkylacrylamides (Baylis–Hillman adducts, **2**) within 5 min at −78 °C in THF in good yields (Scheme 1).

The reaction works best when 1 eq. of aldehyde and 3 eq. of SmI_2 are used in THF (run 2–5, Table 1). The crotonic derivative gave only the (*Z*)-isomer which was readily confirmed by ^1H NMR spectroscopy[5a,b,d,f] and a variety of aldehydes and enolizable ketones also proceeded successfully in good yields. The results obtained are summarized in Table 1. Benzaldehyde and α,β-unsaturated carbonyl compounds are reduced to the corresponding alcohols without undergoing Baylis–Hillman type reaction: reduction of carbonyl groups must be faster than Baylis–Hillman type reaction.



Scheme 1

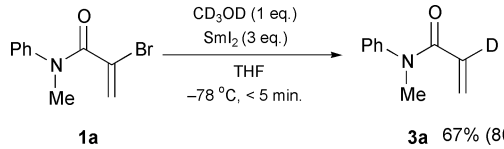
Table 1 The reactions of acrylamides with various aldehydes and ketones[a]



Run	Acrylamide	R^3	R^4	Product	Yield[b] (%)
1		Me	H	**2a**	81
2		Et	H	**2b**	19[c]
3		Et	H	**2b**	43[d]
4		Et	H	**2b**	51[c]
5	**1a**	Et	H	**2b**	62
6		$PhCH_2CH_2$	H	**2c**	70
7		c-Hex	H	**2d**	88
8		t-Bu	H	**2e**	63
9		Me	Et	**2f**	89
10		Me	CH_2CO_2Me	**2g**	52
11		Me	CH_2Ph	**2b**	62
12		$-(CH_2)_4-$		**2i**	63
13		Et	H	**2j**	76
14		c-Hex	H	**2k**	77
15		t-Bu	H	**2l**	77
16	**1b**	Me	Et	**2m**	73
17		Et	H	**2n**	81
18	**1c**	c-Hex	H	**2o**	53

[a] All reactions were performed with SmI_2 (3 eq.) and aldehyde or ketone (1 eq.) in THF at −78 °C, unless otherwise noted. [b] Isolated Yields. [c] Performed with SmI_2 (1 eq.). [d] Performed with SmI_2 (2 eq.). [e] Performed with SmI_2 (2.5 eq.).

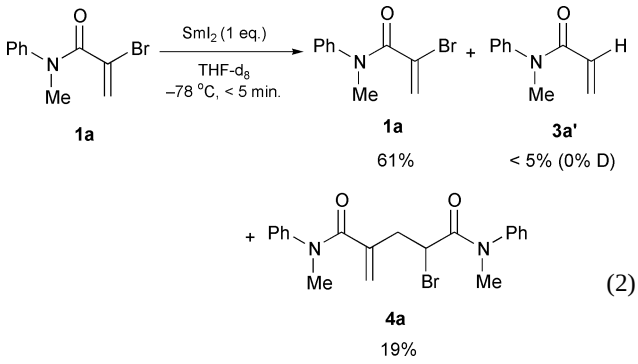
Here a question is raised as to whether the reaction proceeds *via* anionic or radical species. Treatment of **1a** with SmI_2 (3 eq.)–CD_3OD (1 eq.) in THF afforded **3a** (67%, 80% deuterated product) as the main product as shown in eqn. 1. The amount of



(1)

deuterium incorporation was determined by ^1H NMR and mass spectroscopy. On the other hand, when **1a** was treated with SmI_2 (1 eq.) and THF-d_8 as a solvent, no deuterated acrylamide was detected, whereas α-bromoacrylamides acted as an electrophile to form **4a** (eqn. 2).[7a,10] If the vinyl radical species (**A**) exists for long time it should abstract one D from THF-d_8. If the reaction undergoes samarium Grignard type reaction, it should require more than 2 eq. of SmI_2 to consume the starting acrylamide.

DOI: 10.1039/b006495p



Judging from the three observations, an anion species (**B**) appears to be involved in the reaction (Fig. 1). The reaction might proceed *via* an allenoate intermediate (**C**).[5,11] Ethyl α-bromoacrylate or 2-bromocyclohex-2-en-1-one did not give the desired products. A phenyl group in the amide seems to enable the formation of the vinylsamarium intermediate (**B**). The α-carbon of the acrylamide bearing phenyl group is more electron-deficient than other moieties bearing alkyl or hydrogen. Therefore, the vinyl radical can undergo further reduction to vinylsamarium reagent **B** by a further mole of SmI_2. These results imply that the reduction of the vinyl radical should be faster than hydrogen abstraction from THF. To our knowledge, *this is the first example of the generation of the vinyl samarium intermediate by means of the reduction of bromovinyl compounds!* It is noteworthy that the reaction with enolizable ketones also affords the Baylis–Hillman products.

In summary, it has been demonstrated that the reaction of α-bromoacrylamides with aldehydes or ketones in the presence of SmI_2 can provide Baylis–Hillman adducts through an anionic process, solving several problems of Baylis–Hillman reaction. Baylis–Hillman reactions require long reaction times and a tertiary amine as a catalyst and its scope is limited to aldehydes as acrylamides, crotonic derivatives and ketones are not reactive. However, a Baylis–Hillman type reaction mediated by SmI_2 is available for both aldehydes and ketones under mild reaction conditions and with short reaction times.

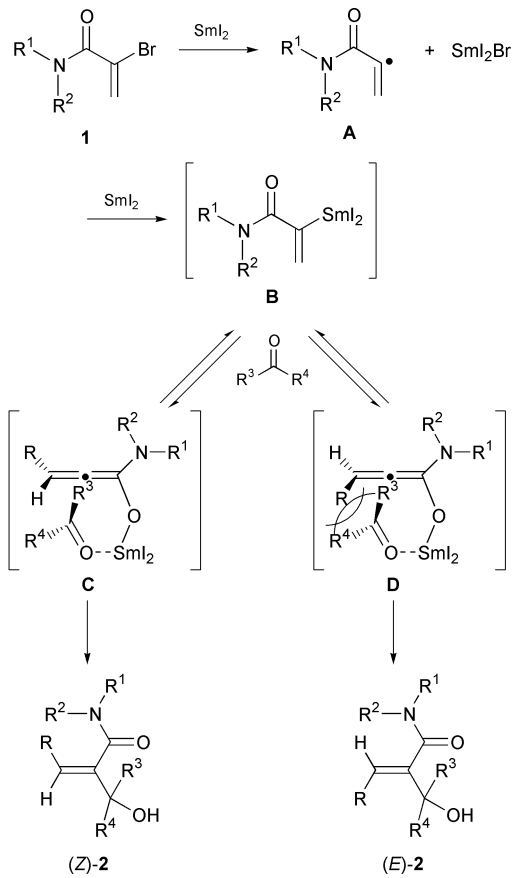


Fig. 1 Possible mechanism.

Enantiomerically-enriched organic reagents *via* polymer synthesis: enantioselective copolymerization of cycloalkene oxides and CO_2 using homogeneous, zinc-based catalysts†

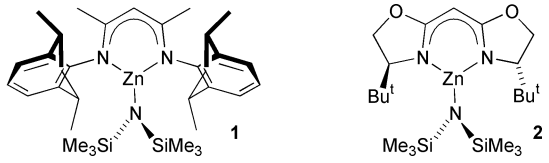
Ming Cheng, Nicholas A. Darling, Emil B. Lobkovsky and Geoffrey W. Coates*

Department of Chemistry and Chemical Biology, Baker Laboratory, Cornell University, Ithaca, NY 14853, USA. E-mail: gc39@cornell.edu

Received (in Irvine, CA, USA) 3rd July 2000, Accepted 18th August 2000
First published as an Advance Article on the web

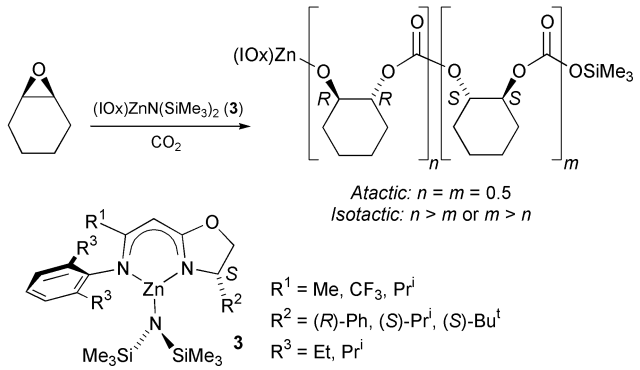
Enantiomerically pure zinc complexes have been designed and synthesized for the enantioselective copolymerization of cycloalkene oxides and CO_2.

The desymmetrization of *meso* molecules with chiral catalysts or reagents is rapidly emerging as valuable strategy for the synthesis of enantiomerically-enriched products.[1,2] *Meso* epoxides are particularly attractive substrates for desymmetrization reactions: ring-opening with a variety of nucleophiles yields a range of valuable synthetic intermediates.[3] Remarkable advances in the development of chiral catalysts have yielded highly enantioselective systems for the delivery of halide, azide, alcohol, thiol, cyano and carboxylic acid nucleophiles to epoxides. Despite the recent intense interest in developing enantioselective catalysts for the synthesis of optically-active polymers,[4,5] there are few examples of *meso*-desymmetrization in polymerization reactions.[6,7] We have recently developed a new class of single-site catalysts (**1**, Scheme 1)[8] for the



Scheme 1

copolymerization of CO_2 and cyclohexene oxide (CHO); (Scheme 2).[9,10] Following reaction of the amido ligand with CO_2, extrusion of trimethylsilyl isocyanate and reinsertion of CO_2,[11–13] the ring-opening of the epoxide monomer in this system occurs with inversion of stereochemistry thus producing stereogenic centers in the polymer backbone. We reasoned that a chiral ligand set would have the potential to control the



Scheme 2

† Electronic supplementary information (ESI) available: experimental procedures, X-ray data for and molecular structure of **3e**, and characterization data of CHO/CO_2 polymers. See http://www.rsc.org/suppdata/cc/b0/b005537i/

absolute stereochemistry of the ring-opening process, and that hydrolysis of the resultant polycarbonate[14] would yield valuable enantiomerically-enriched diols.[8] During the course of our research Nozaki and coworkers reported a chiral catalyst system for the enantioselective copolymerization of CO_2 and CHO,[15] prompting us to communicate our preliminary results. Herein we report a chiral, homogeneous catalyst system which exhibits unprecedented activity, stereoselectivity and molecular weight control for the polymerization of CO_2 with both cyclopentene and cyclohexene oxide, even under mild reaction conditions.

Owing to the well-defined nature of β-diiminate zinc complexes (**1**) for the synthesis of aliphatic polycarbonates, we first decided to investigate structurally-related bisoxazoline-derived zinc complexes (**2**) to attempt stereochemical control. Complex **2** was readily formed in quantitative yield from the reaction of the bisoxazoline ligand with $Zn[N(SiMe_3)_2]_2$. Despite the structural similarity of the diimine and bisoxazoline ligands, complex **2** is inactive for the copolymerization of CO_2 and CHO at 20 °C. Although the cause of inactivity is currently unknown, we believe that either decomposition to a bis-ligated zinc species or irreversible aggregation of the catalytic species occurs early in the polymerization reaction. To impede such deleterious processes we designed a hybrid imine–oxazoline ligand (IOx) that is sterically incapable of forming strongly aggregated or bis-ligated complexes (**3**, Scheme 2). Despite lacking the high symmetry which is often the hallmark of highly selective catalysts, these ligands have the advantage that efficient synthetic strategies allow the systematic variation of the ligand structure to optimize catalyst behavior. The ligands are formed by the nucleophilic attack of imidoyl chlorides with chiral, deprotonated 2-methyloxazolines.[16–18] Reaction of the ligand with $Zn[N(SiMe_3)_2]_2$ gives **3** in quantitative yield.

Complexes of type **3** are active catalysts for the copolymerization of cycloalkene oxides and CO_2 (Table 1). In general, the reaction of a 2.5 M solution of CHO in toluene under 100 psi of CO_2 at 20 °C using 1 mol% **3** yields an alternated polycarbonate (ether linkages cannot be detected by ^{1}H NMR) with narrow molecular weight distribution (M_w/M_n is significantly less than 2). To optimize this class of catalysts with respect to stereoselectivity, we employed a condensed version of an improvement strategy earlier described by Snapper and Hoveyda.[19,20] By investigating the variation of substituent R^1 (**3a** Me; **3b** CF_3; **3c** Pr^i) while keeping the structures of R^2 (*R*-Ph) and R^3 (Pr^i) constant, we found that the methyl and isopropyl substituents had the best enantioselectivities. Owing to the higher activity of **3c**, we selected the isopropyl group as the substituent to fix at R^1. To probe the effect of R^2 on stereoselectivity, we examined ligands whose chirality was derived from phenylglycine (**3c**), valine (**3d**), and *tert*-leucine (**3e**). Interestingly, complex **3e** exhibits both the highest activity and stereoselectivity, producing a quantitative yield of polymer with an *RR*:*SS* ratio of 86:14. With R^1 fixed as isopropyl and R^2 set as *tert*-butyl, we investigated the effect of varying R^3. Unfortunately, modification of the *ortho*-aryl with the less bulky ethyl group significantly diminishes the activity and slightly decreases the stereoselectivity of the catalyst. Owing to

Table 1 Enantioselective copolymerization of cycloalkene oxides and CO_2 using **3**[a]

[a] All reactions performed in 2.5 M epoxide solution (toluene) at 20 °C and 100 psi CO_2 using 1 mol % catalyst. [b] CHO = cyclohexene oxide; CPO = cyclopentene oxide. [c] Measured using gel-permeation chromatography *versus* polystyrene standards. [d] Measured by hydrolyzing the polymer and analyzing the resultant diol by chiral GC.

the high activity of the CF_3-substituted complex **3b**, we decided to investigate the related complex **3g** with the substituents at R^2/R^3 presumably optimized as *tert*-butyl/isopropyl. Although the high activity of the complex was retained, the stereoselectivity of the complex was inferior to that of **3e** (*RR*:*SS* ratio 82:18). Complex **3e** was also investigated for the copolymerization of cyclopentene oxide and CO_2: the polymer formed contained 88% *RR*-units in the main chain. This result represents not only the first successful asymmetric polymerization of this monomer, but also the highest degree of asymmetric induction achieved to date in a CO_2/epoxide copolymerization.

With complex **3e** identified as the most selective catalyst for the copolymerization we obtained a molecular structure of this catalyst precursor using X-ray diffraction.†,‡ Complex **3e** is a rare example of a three-coordinate zinc complex; the steric bulk of the IOx and the amido ligands precludes dimerization or coordination of Lewis-basic solvents. In agreement with other zinc diimine and bisoxazoline complexes, the aryl group is perpendicular to the nearly planar IOx–Zn chelate,[8] and the *tert*-butyl group adopts a staggered conformation. The origins of asymmetric induction are not understood at the current time, although we anticipate that mechanistic studies currently underway on complexes of type **1** will facilitate the more rational design of improved variants of **3**.

We have studied the chemical structure and physical properties of the CHO/CO_2 polymer derived from **3e** in detail. The carbonyl region (δ_C 152–154) of the ^{13}C NMR spectrum of the polymer appears to exhibit partial tetrad resolution based on comparison of experimental and predicted intensities assuming an enantiomorphic-site control mechanism.§ The large peak at δ_C 153.8 is assigned to the chemical shift equivalent m-centered tetrads ([mmm], [mmr] and [rmr]),[15] while the small shifts at δ_C 153.3 and 153.2 are assigned to the [mrm]/[rrr] tetrads (they cannot be unambiguously determined due to their statistical equivalence in the polymer). Finally, the peak at δ_C 153.1 is assigned to the [mrr] tetrad. The T_g and T_m of the polycarbonate are 120 and 220 °C, respectively. The application of these complexes for other asymmetric transformations, as well as the development of improved catalysts for CHO/CO_2 polymerization, is currently underway in our laboratory.

Received (in Cambridge, UK) 14th August 2000, Accepted 5th September 2000
First published as an Advance Article on the web 28th September 2000

1-Substituted prop-2-ynyl mesylates cause propargylation of aldehydes with tin(II) iodide, tetrabutylammonium iodide and sodium iodide in 1,3-dimethylimidazolidin-2-one to produce 2-substituted but-3-yn-1-ols, while 3-substituted prop-2-ynyl mesylates cause allenylation of aldehydes under the same conditions as those of the propargylation by 1-substituted prop-2-ynyl mesylates to produce 2-substituted buta-2,3-dien-1-ols.

Table 1 Allenylation by prop-2-ynyl mesylate with SnI_2 and TBAI[a]

R^3	Time/h	Yield (%)[b] **2** + **3**	**2**:**3**[c]
C_6H_5	45	85	78:22
ClC_6H_4	48	80	75:25
$CH_3OC_6H_4$	70	74	78:22
$CH_3(CH_2)_5$	71	66	66:34
c-C_6H_{11}	72	68	81:19

[a] The reaction of prop-2-ynyl mesylate (1.5 mmol) with aldehydes (1.0 mmol) was carried out using SnI_2 (1.5 mmol), TBAI (0.10 mmol) and NaI (1.5 mmol) in DMI (3 ml) at 10 °C. [b] Yields of a mixture of **2** and **3**. [c] The ratio was determined by ^{1}H NMR analysis (JEOL Λ-500).

Alkynes and allenes have formed an attractive chemistry for high reactivities with metal complexes or reagents.[1] Thus, the preparation of alkynes and allenes becomes an important theme. Barbier-type carbonyl propargylation or allenylation with propargylic halides is one of the most convenient methods for the introduction of propargyl or allenyl functions.[2–7] However, it is not easy to control selectivity between Barbier-type propargylation and allenylation with propargylic halides. We have established both selective propargylation and allenylation by 1-haloprop-2-yne with tin(II) halide and tetrabutylammonium halide (TBAX) through choice of reaction conditions: carbonyl propargylation occurs with 1-bromoprop-2-yne, $SnCl_2$ and TBABr at 50 °C in water, while carbonyl allenylation occurs with 1-chloroprop-2-yne, SnI_2 and TBAI at 25 °C in 1,3-dimethylimidazolidin-2-one (DMI).[8] ^{1}H NMR observations (JEOL Λ-500) have confirmed that prop-2-ynyltriiodotin (propargyltin), derived from 1-chloroprop-2-yne with SnI_2 and NaI at 25 °C in DMF-d_7, does not isomerize to propa-1,2-dienyltriiodotin (allenyltin) at 25 °C but does so at 50 °C.[8,9] We thus hoped that this kind of isomerization of propargyltin to allenyltin would be prohibited by the steric effect of a 3-substituent in 1-haloprop-2-ynes and be promoted by the steric effect of a 1-substituent in 1-haloprop-2-ynes.[10] We here

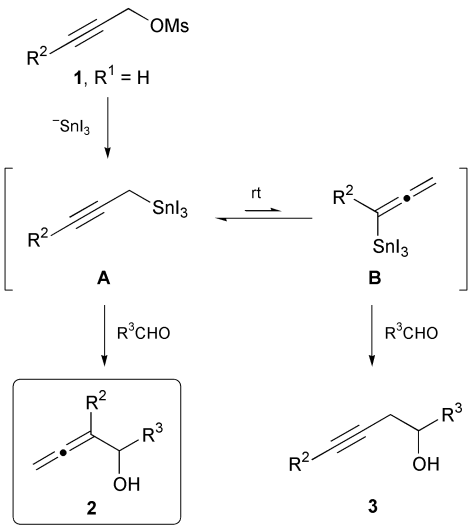
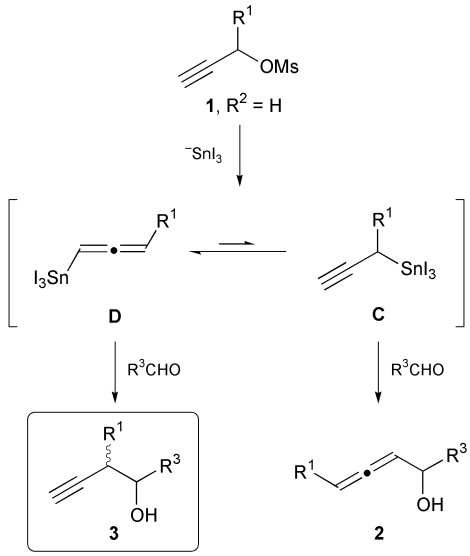
[a] The reaction of 1- or 3-substituted prop-2-ynyl mesylates (1.5 mmol) with aldehydes (1.0 mmol) was carried out using SnI_2 (2.0 mmol), TBAI (0.20 mmol) and NaI (2.0 mmol) in DMI (3 ml) at rt. [b] Yields of a mixture of **2** and **3**. [c] The ratios were determined by ^{1}H NMR analysis (JEOL Λ-500). For the ratio of *syn* to *anti*, see ref. 8. [d] The reaction was carried out in the presence of MS 4Å in THF. [e] The ratio was not confirmed.



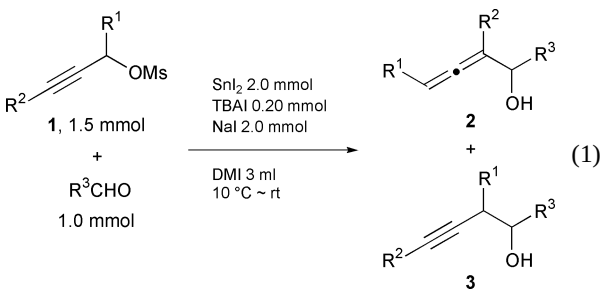
Scheme 1 Allenylation.



Scheme 2 Propargylation.

report on selective Barbier-type carbonyl propargylation and allenylation mediated by steric effects, using the 1- or 3-substituted prop-2-ynyl mesylates‡ as Barbier-type propargylating or allenylating reagents, rather than the more usual corresponding halides (1-haloprop-2-ynes), because the mesylates are superior to the halides for ease of preparation and the stability of propargylic substrates.[11]

The reaction of prop-2-ynyl mesylate (**1**; R^1, R^2 = H) with some aldehydes was carried out using SnI_2, TBAI and NaI under the same conditions as those reported for the carbonyl allenylation by 1-chloroprop-2-yne [eqn. (1)].[8] The results are



(1)

summarized in Table 1. Prop-2-ynyl mesylate (**1**; R^1, R^2 = H) proved to be as available as 1-chloroprop-2-yne for the selective carbonyl allenylation with SnI_2 and TBAI. Thus, we investigated whether the 1- or 3-substituents of prop-2-ynyl mesylates affect the selectivity between propargylation and allenylation under the same conditions as those of prop-2-ynyl mesylate (**1**; R^1, R^2 = H) [eqn. (1)]. The results are summarized in Table 2. 3-Substituted prop-2-ynyl mesylates (**1**; R^1 = H, R^2 = CH_3 and R^1 = H, R^2 = C_6H_5) caused the same allenylation of various aldehydes as that of **1** (R^1, R^2 = H). In particular, with aromatic aldehydes, only allenyl carbinols **2** were obtained. The reaction of cinnamaldehyde in DMI afforded 1-phenylhexa-1,3-dien-5-one derivatives that were probably formed by the hydration of the corresponding allenyl carbinols **2** (R^2 = CH_3, C_6H_5) followed by dehydration.[4,8] 1-Substituted prop-2-ynyl mesylate (**1**; R^1 = CH_3, R^2 = H and R^1 = Pr, R^2 = H) caused the preferential propargylation of various aldehydes. The selectivity for this propargylation was enhanced by the use of THF–H_2O (1 : 1) as a solvent instead of DMI: R^1 = CH_3, R^2 = H, R^3 = C_6H_5; rt, 72 h; 92%, **2** : **3** = 0 : ~100, *syn*:*anti* = 46:54.

A plausible mechanism for the allenylation is illustrated in Scheme 1. 3-Substituent R^2 (CH_3 or C_6H_5), being bulkier than H, probably prohibits propargyltin intermediate **A** from isomerizing to allenyltin intermediate **B**. Thus allenyl carbinols **2** are produced more selectively than in the allenylation by prop-2-ynyl mesylate (**1**; R^1, R^2 = H), *via* nucleophilic addition of the propargyltin **A** at the γ-position.[8] A plausible mechanism for the propargylation is illustrated in Scheme 2. 1-Substituent R^1 (CH_3 or Pr) probably promotes the isomerization of the initially prepared propargyltin **C** to allenyltin **D**, even at room temperature, or mediates a direct preparation of allenyltin **D**.§ The allenyltin **D** then undergoes nucleophilic addition to aldehydes at the γ-position to afford homopropargyl alcohols **3**.

Unusual *tri*substitutions on (η⁶-arene)tricarbonylchromium(0) complexes and evidence for the formation of a *tri*anion

Susan E. Gibson (née Thomas), Sandra A. Saladin and Surojit Sur*

Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS

Received (in Liverpool, UK) 25th July 2000, Accepted 4th September 2000
First published as an Advance Article on the web 28th September 2000

A one-pot *tri*substitution on a representative range of (η⁶-arene)tricarbonylchromium(0) complexes is described and evidence for the formation of a *tri*anion is presented.

(η⁶-Arene)tricarbonylchromium(0) complexes have been studied extensively[1] and have a wide range of applications from their use in total synthesis[2] through their growing importance as chiral building blocks[3] to their current involvement in ligand design for asymmetric catalysis.[4] The characteristic enhanced kinetic acidity of the ring protons has been utilised regularly in the introduction of a single substituent *via* a deprotonation/electrophilic quench sequence and has been the subject of numerous synthetic and mechanistic studies.[1b] In contrast, reports regarding the introduction of two new substituents employing a similar sequence are relatively few.[5] Although such double functionalisation has been mentioned in the literature, this reactivity has never been the target of a systematic study. Furthermore, to the best of our knowledge, there exist only two examples of *tri*substitution.† In the first, chlorination of (η⁶-chlorobenzene)tricarbonylchromium(0) afforded a tetrasubstituted complex as a side product in poor yield.[5g] In the second report, we observed a *tri*substitution reaction as part of a wide ranging study on the reactivity of an electron-deficient sulfone complex.[5e] We wish to report here the results of a recent study which indicate (a) this reaction involves the formation of a rare *tri*anionic species, and (b) this extraordinary reactivity is not limited to a single, electron deficient substrate and may be viewed as an inherent feature of (η⁶-arene)tricarbonylchromium(0) complexes.

Initially, the sulfone complex **1a**,[5e] was examined. Treatment of **1a** with 3.0 eq. of 2,2,6,6-tetramethylpiperidine (LiTMP) in THF (−78 °C for 2 h) was followed by a Me_3SiCl quench. The reaction mixture was allowed to warm up to rt and worked up. Column chromatography yielded the *tri*silylated complex **2a** in 50% yield (Table 1, entry 1). In order to gain insight into the species involved in this *tri*substitution, we subsequently performed a reaction under identical conditions using deuteroacetic acid as the electrophilic quench. The mass spectrum of the product mixture showed four molecular ion peaks corresponding to unreacted **1a** and its mono-, di- and trideuterated analogues in the ratio 14 : 38 : 35 : 13.‡ It can thus be concluded that a *tri*anionic species is a significant component (13%) of the reaction mixture prior to quenching.

We next decided to study the electron rich complex (η⁶-anisole)tricarbonylchromium(0), **1b**, in order to start to define the scope of the trisubstitution reaction. Treatment of **1b** with 3.0 eq. of LiTMP in THF (−78 °C for 2 h) was followed by a Me_3SiCl quench. Column chromatography yielded the novel *tri*silylated complex **2b**[6] in 42% yield along with a 9% yield of **3b** (Table 1, entry 2).[5f] A deuteration experiment under identical conditions was once again performed. Analysis of the mass spectrum revealed the presence of unreacted **1b**, and its mono-, di- and trideuterated analogues in a 24 : 45 : 25 : 6 ratio.‡

Encouraged by the *tri*substitution of electron rich **1b**, we then progressed to the electronically neutral complex **1c**. In this case, reaction with LiTMP followed by an electrophilic quench with Me_3SiCl afforded almost equal amounts of the *tri*-substituted complexes **2c** and 2,5-disubstituted complex **3c**, both previously unknown compounds (Table 1, entry 3).

The prospect of C_{3v}-symmetric arenes being accessible through this route encouraged us to attempt the reaction on unsubstituted (η⁶-benzene)tricarbonylchromium(0) which led to novel **5a** and **6a**.[7] Optimisation experiments demonstrated that use of LDA at −40 °C afforded the desired C_{3v}-symmetric product **5a** in the highest yield (Table 2, entry 1). A control experiment was then performed on uncomplexed benzene under identical conditions. This resulted in recovery of unreacted starting material (≥ 95%), confirming beyond doubt that the *tri*substitution reaction requires the presence of the tricarbonylchromium(0) moiety.

Having established that the one-pot *tri*substitution is not limited to electron deficient arene complexes, we decided to further test the scope of this reaction by using other electrophiles. Considering the utility of tin containing compounds in coupling reactions we chose Me_3SnCl as the electrophile: pleasingly, *tri*substitution afforded the novel complex **5b** in good yield with **6b**[8] as the minor product (Table 2, entry 2). The possibility of gaining access to C_{3v}-symmetric phosphine ligands led us to use PPh_2Cl as the next electrophile. The novel

*tri*substituted complex **5c** was isolated by fractional crystallisation, fully characterised and its structure confirmed by X-ray crystallography.[9]

In summary, we have presented evidence for the formation of a *tri*anionic species in an unusual one-pot *tri*substitution reaction. Furthermore, we have broadened the scope of this reaction sufficiently to demonstrate for the first time that it is an inherent feature of the reactivity of (η^6-arene)tricarbonylchromium complexes.

Notes and references

† An example of trisubstitution in two discrete steps has also been reported: see ref. 5*d*.

‡ The product mixture was also analyzed using ^{1}H and ^{2}H NMR spectroscopy; these gave results consistent with the mass spectral data.

1,2-Hopobactin: a hydroxamate analog of enterobactin

Haim Weizman,† and Abraham Shanzer*

Received (in Cambridge, UK) 20th June 2000, Accepted 1st September 2000
First published as an Advance Article on the web 28th September 2000

Hopobactin is a 1-hydroxy-2-oxopyridine-6-carboximide analog of enterobactin that forms isostructural complexes.

Enterobactin is a catechol-based siderophore that is one of the strongest ferric iron binders.[1] The remarkable binding properties of enterobactin are attributed to a unique binding cavity that stabilizes the metal complex.[2] This hexacoordinate cavity is composed of a trislactone ring where three 2,3-dihydroxybenzamide units are attached to the L-serine α-amino groups (Fig 1). Upon Fe^{3+} binding, the lactone ring allows for coplanarity of the amide bond and the coordinated catecholate moiety. The conjugation with the amide increases the acidity of the phenol groups and results in an inter-chain hydrogen bond between the amide NH and the 2-catecholate oxygen. As a consequence of the trislactone chirality and the hydrogen bonds, the natural enterobactin iron complex preferentially adopts a Δ configuration. Synthetic analogs of enterobactin have demonstrated that deviations from the enterobactin structure result in less profound properties.[3] Here we present the synthesis of a hydroxamic acid analog of enterobactin, 1,2-hopobactin (HOPO = 1-hydroxy-2-oxopyridine-6-carboximide, Fig. 1). The HOPO ligand and its anion have resonance forms that are isoelectronic with pyrocatechol and have a similar structure. Attaching the HOPO moiety through an amide linkage to the trislactone results in a perfect structural analog of enterobactin that forms neutral complexes.

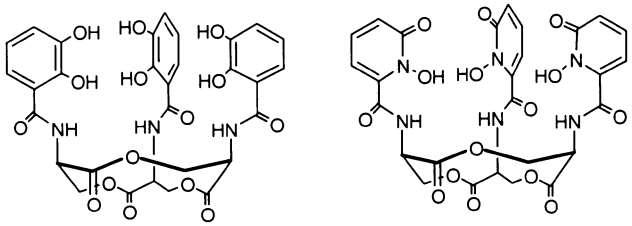

Fig. 1 Enterobactin (left) and its hydroxamic acid analog (right).

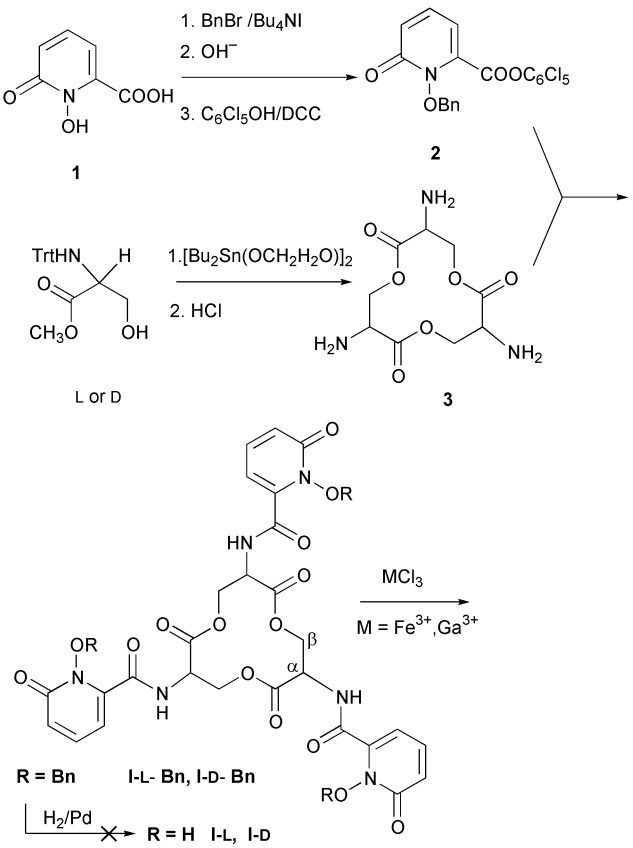
Two enantiomeric trilactones were prepared from L and D-serine (Scheme 1).[4a] 1,2-dihydro-1-hydroxy-2-oxopyridine-6-carboxylic acid [4b] was protected with benzyl groups, activated and coupled with the trislactone. Hydrogenolysis of the protected product gave a mixture of products and the desired compound could not be isolated.[5] Yet, by addition of ferric or gallium acetylacetonates to the mixture, the corresponding complexes could be purified by preparative TLC in very low yields. The complexes were characterized by NMR (for Ga), IR and MS.[6] Removal of the benzyl protecting groups was accomplished quantitatively using Lewis acids like $FeCl_3$ or $GaCl_3$. After the reaction was complete, the pH was adjusted to 8 and the complexes were purified by chromatography. The spectroscopic data for the ferric and gallium complexes were identical to those of the complexes isolated by addition of ferric and gallium acetylacetonate as described above.

Both gallium complexes I-D-Ga and I-L-Ga were characterized by NMR (Table 1). Since Ga^{3+} has the same charge as Fe^{3+} and a similar radius, it is a good diamagnetic equivalent of iron.[7] I-L-Ga displays one set of signals in the NMR time scale. Due to the homochirality of the trislactone, the formation of the diasteromeric complexes (L,L,L-Δ and L,L,L-Λ) would be expected to form two sets of NMR signals. The observance of only one set indicates the formation of only one diastereoisomer (within the limits of detection of NMR). The possibility of fast exchange between the two isomers can be disregarded, as isomerization reactions of hydroxamates are slow enough to allow detection of two geometrical isomers.



Scheme 1 Synthetic scheme for the preparation of 1,2-hopobactin (I-L) and enantioenterobactin (I-D).

I-D-Ga gave an NMR spectrum identical to that of I-L-Ga. Because the two compounds are based on enantiomeric trislactones, the identical spectra reveal that the complexes are

enantiomers and that the D,D,D trislactone is directing the formation of a complex with opposite helicity. Therefore, the NMR indicates that the enterobactin skeleton serves as a stereospecific template for the formation of exclusively one stereoisomer depending on the chirality of the serine units.

For I-Ga, the vicinal proton–proton coupling constants for the $C_\alpha H$-$C_{\beta 1}H$ and $C_\alpha H$-$C_{\beta 2}H$ were both small (J = 1.1 and 1.7 Hz). These values indicate equatorial–equatorial and axial–equatorial relationships between the vicinal protons and, therefore, an axial arrangement of the HOPO ring. The pronounced shift of the amide proton to a lower field upon Ga^{3+} complexation compared to the protected I-D is compatible with hydrogen-bonding. A similar shift was previously observed in enterobactin and several triscatecholamides as well. In enterobactin the shift was attributed to a hydrogen bond between the amide NH and the 2-catecholate oxygen in the complex. This suggestion was supported by theoretical calculations, and it was shown experimentally that replacement of the NH with *N*-Me results in a lower binding affinity. It is suggested that a similar stabilization occurs in I-Ga between the amide proton and the HOPO N-oxygen.

The isolated iron complexes exhibit two absorption maxima at 321 nm (ε = 16430 M^{-1} cm^{-1}) and 398 nm (ε = 6375 M^{-1} cm^{-1}) in chloroform (Fig. 2). The LMCT band has an additional shoulder at 450 nm (ε = 5575 M^{-1} cm^{-1}). The CD spectra of I-L-Fe and I-D-Fe showed opposite Cotton effects. The fact that the spectra are mirror images confirms that the enantiomeric trislactone skeleton induced opposite helicity around the iron center.

The determination of metal center chirality of the metal complex in solution is possible through comparison of the solution CD spectra. However, the correlation of the rotary power with left or right-handed helical stereochemistry requires an absolute assignment based on crystal structure data. As this data is not available, the ferric enterobactin CD spectrum was used as a reference.[9a] This comparison is based on the high structural and electronic similarity between the HOPO and enterobactin complexes together with the resemblance in their CD spectral shape.[9b] This correlation suggests that I-L induces the formation of the Δ iron complex while the I-D ligand induces the formation of the Λ isomer. This chiral induction is compatible with the one observed for enterobactin.

These results indicate that the unique structure of the enterobactin complex is preserved in the HOPO analog. This work demonstrates that careful design of ligands allows for the mimicking of the unique features of enterobactin while changing only desired properties. While the enterobactin complex is negatively charged and, therefore, water-soluble, hopobactin forms neutral M^{3+} complexes that are soluble in non polar organic solvents. Therefore, hopobactin is a potential ligand for liquid-membrane separations. The evaluation of these complexes as siderophore mimics is underway.

Unusual addition reactions of lithium alkoxides to 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene†

M. Krein, U. Bergsträßer, C. Peters, S. G. Ruf and M. Regitz*

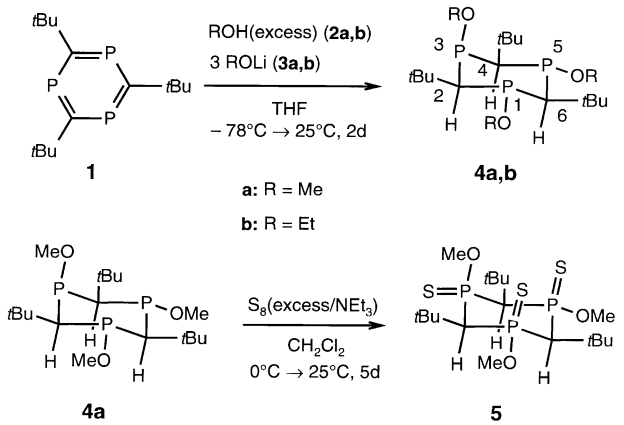
Fachbereich Chemie der Universität Kaiserslautern, Erwin-Schrödinger-Straße, D-67663 Kaiserslautern, Germany. E-mail: regitz@rhrk.uni-kl.de

Received (in Cambridge, UK) 21st January 2000, revised manuscript received 18th August 2000, Accepted 21st August 2000
First published as an Advance Article on the web

2,4,6-Tri-*tert*-butyl-1,3,5-triphosphabenzene (1) reacts selectively with a mixture of the primary lithium alkoxides 2a,b and the corresponding alcohols 3a,b to afford the novel 2,4,6-tri-*tert*-butyl-1,3,5-alkoxy-1,3,5-triphosphacyclohexane derivatives 4a,b; treatment of 4a with sulfur results in oxidation of all phosphorus atoms to furnish the triphosphane sulfide 5.

The polarity of the P/C double bond resulting from the electronegativity difference between phosphorus and carbon generally favours the addition of H-acidic compounds.[1] In this process, the proton is added to the carbon atom of the phosphaalkene unit while the nucleophilic part is attached to the positively polarised phosphorus atom.[2,3] It has recently been shown that the addition of alcohols to isolated P/C double bonds is particularly successful when a mixture of a lithium alkoxide with at least an equimolar amount of the corresponding alcohol in THF as solvent is used.[4] In the course of these studies we posed the question of whether this reagent system would be able to undergo addition to phosphaalkene units incorporated in a delocalised, heteroaromatic[5] bonding system. For this purpose, we have chosen 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene[6] (**1**) as a reaction partner. To date, only the unusual addition of water to a η^1-bonded 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene platinum(II) complex has been reported.[7]

When the triphosphabenzene **1** was allowed to react with three equivalents of the lithium alkoxides **3a**,**b** and an excess of the respective alcohol **2a**,**b**, a highly regio- and stereoselective, three-fold addition of alcohol to all three P/C double bonds of **1** was indeed observed. The products are the 1,3,5-trialkoxy-1,3,5-triphosphabenzenes **4a**‡ (84%, mp 51 °C) and **4b** (72%, 74 °C) obtained as microcrystalline solids (Scheme 1). For the reaction of **1** + **2a**/**3a** we found that the use of merely 10% of the stoichiometric amount of lithium ethoxide can also result in the same product yield when a longer reaction time is allowed. The rate-determining step is most certainly the 1,2- or 1,4-addition of the first equivalent of the alcohol which destroys the aromaticity of **1**.[5] The thus-formed 1,3,5-triphosphacyclohexa-1,3(or 1,4)-diene then reacts much more rapidly so that intermediates cannot be detected by ^{31}P NMR spectroscopic monitoring of the reaction.



Scheme 1

The ^{31}P and ^{13}C NMR spectra of **4a** and **4b** are in accord with the assumed saturation of the double bonds of the heteroarene **1** (^{31}P: δ = 232.6 , ^{13}C: δ = 211.8). The ^{31}P NMR signals of **4a** are shifted to higher field in comparison to those of **1** and appear at δ = 162.8 (d, P-1/P-5) and δ = 162.4 (t, P-3) with $^2J_{P,P}$ coupling constants of 3.1 Hz. The corresponding signals for **4b** show the same splitting pattern but are slightly diagmagnetically shifted (δ = 156.3 and δ = 155.5, respectively). Also noteworthy are the high-field shifts of the signals of the ring carbon atoms of **4a** and **4b** appearing at δ = 57.2 and 56.9 (C-2/C-4) and δ = 60.7 and 59.9 (C-6), respectively.

For the structural elucidation of the 1,3,5-triphosphacyclohexanes **4a**,**b** it is justifiable to assume that the framework prefers the chair form in analogy to the cyclohexane system. The sterically demanding *tert*-butyl substituents should adopt an equatorial arrangement for energetic reasons. However, a conclusive assignment of the configurations of the three phosphorus atoms is not possible at this stage.

The final structure elucidation was established by an X-ray crystallographic analysis of **4a** (Fig. 1).§ The highly distorted, chair conformation of the ring skeleton with equatorial linked *tert*-butyl substituents is clearly apparent.

In the crystal the two methoxy substituents at P-1 and P-5 occupy approximately equatorial positions while that at P-3 is in an axial position. The P/C bond lengths measured in the ring range from 1.824(3) Å to 1.874(3) Å and thus exhibit only minor deviations from the average literature value.[8] Other characteristic features in the crystal structure of compound **4a**

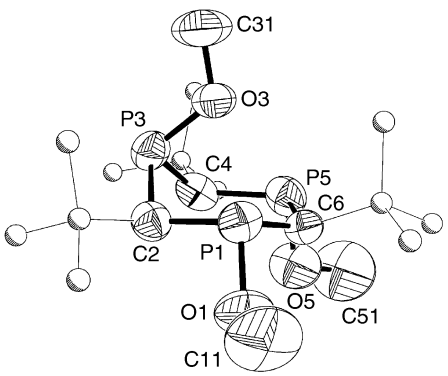


Fig. 1 Crystal structure of **4a**. Selected bond lengths (Å) and angles (°): P(1)–C(2) 1.843(3), P(1)–C(6) 1.870(3), P(3)–C(2) 1.840(3), P(3)–C(4) 1.824(3), P(5)–C(4) 1.834(3), P(5)–C(6) 1.874(3), P(1)–O(1) 1.660(2), P(3)–O(3) 1.653(2), P(5)–O(5) 1.656(2); C(2)–P(1)–C(6) 104.34(11), C(4)–P(3)–C(2) 99.10(12), C(4)–P(5)–C(6) 107.51(12), P(1)–C(2)–P(3) 109.93(14), P(3)–C(4)–P(5) 112.33(14), P(1)–C(6)–P(5) 126.15(14).

† Part 152 of the series of papers in Organophosphorus Compounds. For part 151, see: S. G. Ruf, J. Dietz and M. Regitz, *Tetrahedron*, 2000, **56**, 6259.

DOI: 10.1039/b006795o

are the widely differing folding angles between the planes defined by the atoms P-1/C-6/P-5 and C-2/P-3/C-4 to that defined by the atoms C-2/P-1/P-5/C-4 (23.9 and 112.8°, respectively). The widely opened endocyclic bonding angle at C-6 [126.15(14)°] is comparable to that of a 1,3-diphosphorinane described in the literature.[9]

Since the novel products **4a**,**b** represent the first members of a new class of compounds we have also investigated their functionalisation reactions with chalcogens. The reaction of **4a** with an excess of sulfur in the presence of triethylamine proceeded with coordination increases at all phosphorus atoms to furnish the triphosphane trisulfide **5** (74%, colourless solid, mp 84 °C).¶ The ^{13}C NMR data for compound **5** confirm the retention of the cyclic structure while the absorption at ν = 1261 cm^{-1} in the IR spectrum is characteristic for the newly introduced P/S double bonds. We also assume that the configurations at the phosphorus atoms remain unchanged by this reaction. The oxidation of **4a** with bis(trimethylsilyl) peroxide proceeded analogously to furnish **5** (O in place of S) but this product still contains traces of impurities (^{31}P NMR).

We thank the Fonds der Chemischen Industrie for graduate grants (to C. P. and S. R.) and the Deutsche Forschungsgemeinschaft (Graduate College Phosphorus as Connecting Link between Various Chemical Disciplines) for generous financial support.

Recombinant human α(1→3/4)-fucosyltransferases (FucT-III) expressed in CHO cells or baculovirus-infected insect cells, immobilized on Ni^{2+}-agarose through a 6His tag, exhibit a marked stability, which was exploited in the synthesis of Lewis a and Lewis x trisaccharides.

Glycosyltransferases have become widely used over the past decade as efficient tools for glycosylation because they catalyze sugar unit transfer with complete regio- and stereoselectivity. Early work in this area suffered from the low availability of these membrane-bound enzymes isolated from natural sources, but nowadays, thanks to genetic engineering, the expression of secreted forms of recombinant glycosyltransferases offers the opportunity of producing active enzymes in large quantities. Fucosyltransferases comprise a family of enzymes that catalyze the transfer of a fucose residue from GDP-fucose, the sugar-nucleotide donor, to a disaccharide acceptor. Among this family, α(1→3/4)-fucosyltransferase (FucT-III), is responsible for both the synthesis of the Lewis a trisaccharide Gal*p*-(1→3)-[α-L-Fuc*p*-(1→4)]-β-D-GlcNAc*p* from β-D-Gal*p*-(1→3)-β-D-GlcNAc*p* (type 1 disaccharide), and to a smaller extent the synthesis of the Lewis x trisaccharide Gal*p*-(1→4)-[α-L-Fuc*p*-(1→3)]-β-D-GlcNAc*p* from β-D-Gal*p*-(1→4)-β-D-GlcNAc*p* (type 2 disaccharide). FucT-III, consist of a short NH_2-terminal cytoplasmic tail, a transmembrane domain and a stem region followed by a large globular COOH-terminal catalytic domain. Previous works have reported cloning of the human FucT-III, expression of a soluble form in COS cells and in BHK-21 cell lines.[1] Besides, another construct of recombinant FucT-III turned out to be very efficient to produce sialyl Lewis a libraries.[2]

Within a French network devoted to the production and studies of recombinant glycosyltransferases, the cDNA coding for the human FucT-III gene[1] deleted of the part corresponding to the transmembrane domain was again expressed in three different expression systems: *Pichia pastoris* yeast,[3] Chinese Hamster Ovary (CHO) cells and baculovirus-infected insect cells. In CHO and baculovirus-infected insect cells, a 6His tag was added to the sequence, at the *C*-terminal end in the first case, at the *N*-terminal end in the latter case.[4]

We wish to report here an efficient procedure for concentration, immobilization and stabilization of FucT-III, relying on the His tag of the recombinant enzymes.

In each expression system, CHO and baculovirus-infected insect cells, a functional soluble form of FucT-III was produced. The specificities of both recombinant enzymes were compared (see Table 1). The highest activity was noticed when type 1 disaccharide was substituted by a galactose residue. Activity with the type 2 acceptor increased when concentration changed from 10 to 20 mM, which clearly showed evidence of the low affinity for β-D-Gal*p*-(1→4)-β-D-GlcNAc*p* and β-D-Gal*p*-(1→4)-β-D-Glc*p* disaccharides. No significant difference in substrate specificity has been observed between both FucT-III. Furthermore, a novel fluorescent assay was developed as an alternative to radioactive assays routinely used for glycosyltransferases. For this purpose, new disaccharide derivatives **3**

Table 3 Immobilization of recombinant FucT-IIIs on Ni^{2+}-NTA-agarose. Culture supernatant (23 mL) was immobilized on 1 mL of gel

	Initial soluble enzyme activity mU mL^{-1}[a]	Gel-bound enzyme activity mU mL^{-1}[a]	Immob. yield %[b]
CHO	1.3	28	92
Baculovirus	2.1	41	87

[a] U represents the enzyme unit number defined as the quantity of enzyme that catalyzes transformation of 1 μmole of substrate per min. [b] Immobilization yield is expressed as the ratio of immobilized activity to that initially present in the solution.

and **4** bearing, an aminohexyl chain substituted by a dansyl group at the anomeric center were prepared. Kinetic parameters for these substrates are reported for both enzymes in Table 2.

Recombinant FucT-III were tagged with a polyhistidine tail: indeed a stretch of six His is now commonly appended to the primary sequence of recombinant proteins, in order to facilitate their purification by Ni^{2+} affinity chromatography, according to strong interactions between Ni^{2+} immobilized on agarose through ligands such as nitriloacetic (NTA) and the polyhistidine tag.[5] Thus the 6His-tagged FucT-IIIs were immobilized on Ni^{2+}-NTA-agarose at 4 °C according to a batch procedure. Prior to the binding step, the culture media must be dialyzed, in order to adjust the pH and remove any interfering components. Irrespective of the position of the His tag, the *N*-terminal and *C*-terminal tagged FucT-IIIs were immobilized in quantitative yield (see Table 3). However it is worth noting that attempts to elute enzymes from the gel were troublesome and unsuccessful; imidazole turned out to be a strong inhibitor of FucT-III, and less than 5% of enzyme activity was recovered in the dialyzed eluate. On the contrary, the immobilisation of FucT-III on Ni^{2+}-agarose presented two major advantages. First it turned out to be a very efficient procedure for concentrating enzyme activity (by a 15–20 factor), much better than ultrafiltration bringing about some protein denaturation. Secondly immobilized FucT-III exhibited an outstanding stability under enzymatic incubation conditions at 37 °C with an half-life of three weeks (Fig. 1). On the other hand, CHO culture supernatant incubated in the same conditions proved to be very unstable (Fig. 1).

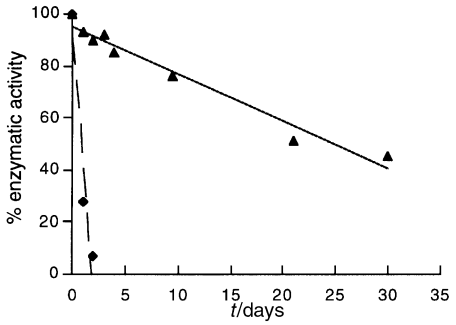

Fig. 1 Percentage of remaining enzymatic activity as a function of incubation time, expressed in days, for FucT-III immobilized on Ni^{2+}-NTA-agarose (▲) and crude CHO culture supernatant (◆) both incubated at 37 °C in 0.1 M sodium cacodylate buffer pH 7.4.

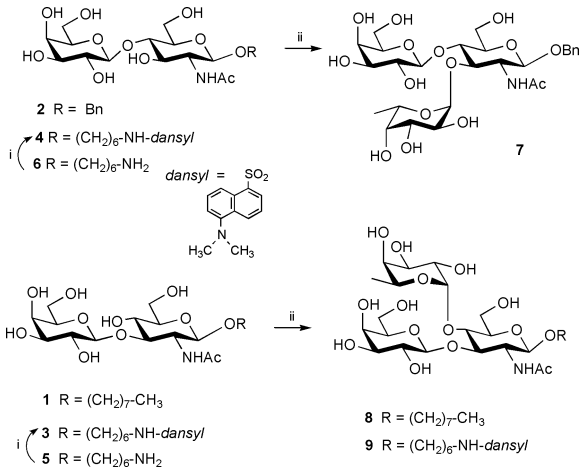
Disaccharide **2** was incubated with GDP-fucose and Mn^{2+} in the presence of the recombinant CHO FucT-III adsorbed on Ni^{2+}-agarose to afford the Lewis x trisaccharide **7** (Scheme 1). Fucosylation of this disaccharide required a long incubation time (10 d) because of its low affinity, but could finally be achieved in 80% yield. At the end of the incubation almost 50% of enzyme activity still remained. Then the same immobilized enzyme could be used two more times for the synthesis of Lewis a trisaccharides **8** and **9** in quantitative yields from the best disaccharide substrates **1** and **3** (Scheme 1).‡

To our knowledge there was one previous report on the use of a recombinant mannosyltransferase immobilized on Ni^{2+}-agarose for synthesis on a microscale, but the increased stability of the immobilized biocatalyst was not highlighted.[6]



Scheme 1 *Reagents*: i, dansyl chloride, Na_2CO_3, acetone; ii, FucT-III adsorbed on Ni^{2+}–agarose, GDP-Fuc, 5 mM $MnCl_2$.

Work is now in progress to extend immobilisation on Ni^{2+} to other His-tagged recombinant glycosyltransferases and to apply such immobilized enzymes to the supported enzymatic synthesis of oligosaccharides.

This work has been achieved in the frame of the French GTrec Network, supported by MENRT (ACC SV n° 951411) and CNRS (Programmes Interdisciplinaires PCV Génie des et Procédés).

Non-covalent ternary systems (DNA-acridine hybrid/DNA/lanthanide(III)) for efficient and site-selective RNA scission†

Akinori Kuzuya and Makoto Komiyama*

Research Center for Advanced Science and Technology, The University of Tokyo, 4-6-1 Komaba, Meguro, Tokyo, 153-8904 Japan. E-mail: komiyama@mkomi.rcast.u-tokyo.ac.jp

Received (in Cambridge, UK) 17th August 2000, Accepted 30th August 2000
First published as an Advance Article on the web 2nd October 2000

The target phosphodiester linkage in RNA is activated by the combination of acridine-attached DNA and unmodified DNA, so that the RNA is site-selectively hydrolysed at this linkage by free Lu^{III} ion.

Interests in sequence-selective RNA hydrolysis have been rapidly growing.[1] The most common strategy is to tether chemical scissors (either organic or inorganic) to DNA oligomers.[2] However, non-covalent systems, which involve no tethering and are obtainable without complicated organic synthesis, are also valuable for practical applications.[3] Here we show that non-covalent systems, composed of (i) DNA oligomer bearing an acridine residue, (ii) unmodified DNA, and (iii) free lanthanide(III) ion, selectively and efficiently hydrolyse RNA at the target site. The corresponding phosphodiester linkage is notably activated by non-covalent interactions with the DNAs ((i) and (ii)), and thus the site-selective scission by the metal ion promptly proceeds under physiological conditions. The predominant role of the acridine residue is evidenced.

The substrate RNA (36-mer: ^{32}P-labeled at its 5′-end) and the DNA oligomers are presented in Fig. 1a. When the DNA bears an acridine at the 5′-end (DNA_1-Acr), another DNA (DNA_2), and $LuCl_3$ are combined, the RNA is efficiently and site-selectively hydrolysed (lane 3 in Fig. 2).[4] Here, all the ribonucleotides in the RNA, except for U-19, are forming Watson–Crick base-pairs with either DNA_1-Acr or DNA_2. The selective scission occurs at the 3′-sides of C-18 and U-19 (Fig. 1b). The C-18/U-19 ratio is around 3. When the position of unpaired ribonucleotide in the RNA is moved from U-19 to C-18 by using appropriate DNAs, the site of selective scission accordingly shifts to the 3′-sides of U-17 and C-18 (Electronic Supplementary Information (ESI) Fig. 1a). In the absence of these DNA oligomers, however, RNA scission by Lu^{III} (and by other lanthanide(III) ions also) takes place almost randomly (lane 1 in Fig. 2).

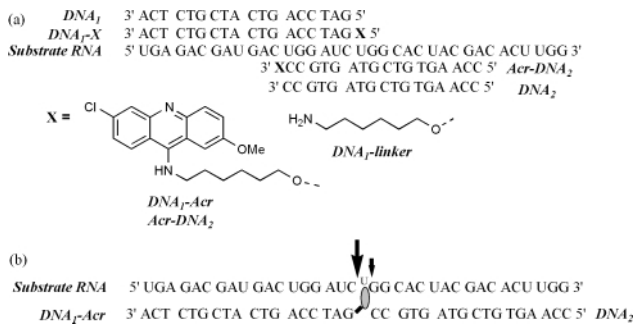

Fig. 1 Structures of the substrate RNA and the DNA oligomers used in the present study (a), and the scission pattern by the DNA_1-Acr/DNA_2/Lu^{III} system (b). The hatched ellipse shows the acridine residue, and the length of arrow corresponds to the scission efficiency.

† Electronic supplementary information (ESI) is available: supplementary Figs. 1–3 and Scheme 1. See http://www.rsc.org/suppdata/cc/b0/b006772p/

Quite significantly, the site-selective RNA scission is far more (> 30 fold)[5] efficient than that by the DNA_1/DNA_2/Lu^{III} system (compare lane 3 in Fig. 2 with lane 2). Furthermore, this selective scission is faster than the scission (at the corresponding site) in the absence of the DNAs (lane 3 *vs.* lane 1). Apparently, the target phosphodiester linkage is significantly activated by the acridine moiety of DNA_1-Acr. A similar site-selective scission is achieved, when Acr-DNA_2 bearing an acridine at the 3′-end is combined with DNA_1 (lane 4). The scission by the DNA_1-Acr/Acr-DNA_2/Lu^{III} system is also selective, but less efficient (lane 5).

Both DNA_1-Acr and DNA_2 (as well as the relevant combinations) are essential for prompt and site-selective scission. When only one of them is used, the whole single-stranded portion in RNA is hydrolysed without any specific selectivity (lanes 2 and 3 in Fig. 3). The DNA bearing only the linker moiety (DNA_1-linker) is also poor in the activity (lane 5), further substantiating the necessary role of the acridine. In the absence of the lanthanide ions, no scission occurs. Site-selective scission is also successful, when two ribonucleotides in the RNA are unpaired (lane 3 in ESI Fig. 1b). Without any unpaired ribonucleotide, however, no scission takes place (lane 1).[6]

One of the most important characteristics of the present non-covalent ternary systems is that the RNA hydrolysis comes up near to completion under physiological conditions. At pH 8.0 and 37 °C ($[LuCl_3]_0$ = 100 μmol dm^{-3}), more than half of the

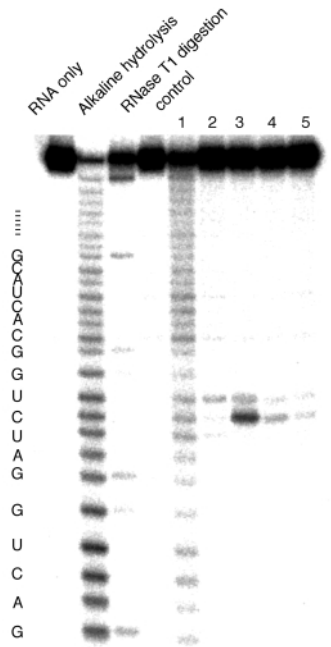

Fig. 2 RNA scission by the ternary systems composed of two DNAs and Lu^{III}. Lane 1, Lu^{III} only; lane 2, DNA_1/DNA_2/Lu^{III}; lane 3, DNA_1-Acr/DNA_2/Lu^{III}; lane 4, DNA_1-Acr/DNA_2/Lu^{III}; lane 5, DNA_1-Acr/Acr-DNA_2/Lu^{III}. At pH 8.0 and 37 °C for 2 h; $[RNA]_0$ = 1, [each of modified or unmodified DNAs]$_0$ = 10, and $[LuCl_3]_0$ = 100 μmol dm^{-3}; $[NaCl]_0$ = 200 mmol dm^{-3}.

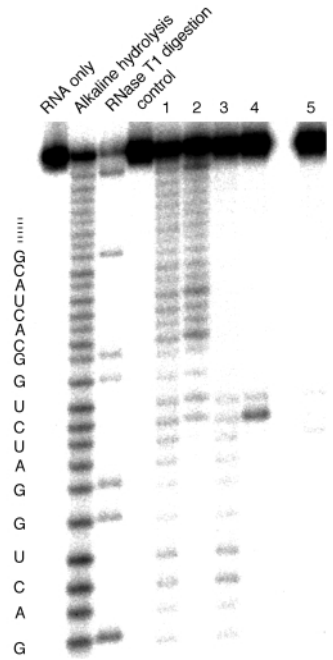

Fig. 3 RNA scission by various non-covalent systems. Lane 1, Lu^{III} only; lane 2, DNA_1-Acr/Lu^{III}; lane 3, DNA_2/Lu^{III}; lane 4, DNA_1-Acr/DNA_2/Lu^{III}; lane 5, DNA_1-linker/DNA_2/Lu^{III}. The reaction conditions are presented in the legend for Fig. 2.

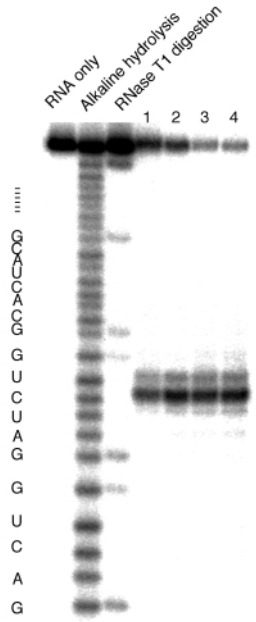

Fig. 4 Time-course of the sequence-selective RNA scission by the DNA_1-Acr/DNA_2/Lu^{III} system: lane 1, 13 h; lane 2, 23 h; lane 3, 40 h; lane 4, 48 h.

RNA is hydrolysed in 13 h by the DNA_1-Acr/DNA_2/Lu^{III} system (lane 1 in Fig. 4). The conversion is nearly 90 mol% at 48 h (lane 4).[7]

In the DNA_1-Acr/DNA_2/RNA system, the UV-visible absorption band of acridine (380–480 nm) shows a clear-cut hypochromicity. In the DNA_1-Acr/RNA system, however, hypochromicity is marginal. These results indicate that the acridine (bound to the 5′-end of DNA_1) is sandwiched by the DNA–RNA base-pair (G–C) at the 5′-terminus of DNA_1 and the C–G base-pair at the 3′-terminus of DNA_2 (see Fig. 1b). Consistently, the fluorescence from the acridine is significantly quenched (ESI Fig. 3).[8] Assumedly, the conformation of the RNA near the sandwiching site is perturbed, and the attacking 2′-OH is brought closer to the P-atom for facile nucleophilic attack. These arguments fairly agree with the fact that neither DNA_1-Acr nor DNA_2 alone activates the RNA (note that the scission efficiencies at C-18 and U-19 in lanes 2 and 3 in Fig. 3 are almost the same as those in lane 1). Only by combining both of them is the target phosphodiester linkage efficiently activated (lane 4). Applications of the present findings are currently under way.

Bashkin, *Chem. Commun.*, 2000, 767.

3 Non-covalent systems for site-selective RNA scission were previously reported: D. Hüsken, G. Goodall, M. J. J. Blommers, W. Jahnke, J. Hall, R. Häner and H. E. Moser, *Biochemistry*, 1996, **35**, 16 591; A. Kuzuya, M. Akai and M. Komiyama, *Chem. Lett.*, 1999, 1035.

4 The RNA cleavage was achieved at pH 8.0 (10 mmol dm^{-3} Tris buffer: [NaCl] = 200 mmol dm^{-3}) and 37 °C, and analysed by denaturing polyacrylamide gel electrophoresis. The melting temperatures of the RNA–DNA hetero-duplexes are significantly higher than the reaction temperature, so that they are almost completely formed in the reaction mixtures. The phosphoramidite monomer bearing an acridine was synthesized according to ESI Scheme 1.

5 This value is evaluated from the ratio of band intensities at C-18 and U-19 in lane 3 to those in lane 2. The weak scission in lane 2 is mainly at U-19.

6 When bulge structures were formed in the RNA by using appropriate DNAs (without an acridine residue), the RNA was cleaved at several positions around near the bulge (see ESI Fig. 2).

7 The RNA is hydrolysed mostly at C-18 and U-19, although a minor scission occurs at U-17.

8 The G-20 and G-21 of RNA and the 5′-terminal G of DNA_1-Acr are fixed near the acridine residue, and their guanine residues quench the fluorescence.

Received (in Cambridge, UK) 26th June 2000, Accepted 7th September 2000
First published as an Advance Article on the web 29th September 2000

Self-assembled monolayers of stearic acid, (*R*,*S*) and (*S*)-16-methyloctadecanoic acid ion-paired with 4,4′-bipyridine have been observed on a solution–graphite interface by a scanning tunneling microscope (STM) and the observed macro-scale molecular patterns have been interpreted in terms of absolute chirality of the constituent molecule.

Scanning tunneling microscopy (STM) has provided molecular images of self-assembled molecules at atomic resolution.[1] Monolayers of self-assembled amphiphiles including fatty acids, alkylated amines, amides and alcohols have been directly imaged at solution–solid interfaces.[2] Recently, determination of absolute configuration of chiral molecules from the STM and AFM images has attracted considerable attention.[3] Determination of the absolute stereochemistry is very important for accessing the biological and toxicological properties of enantiomers. Walba and his group have obtained the STM images of several chiral mesogens aligned on a graphite surface.[4] In this case, the macro-scale chiral structure of the domain has been controlled by the molecular chirality of individual molecules. Flynn's group has observed STM images of (*R*,*S*)-2-bromodecanoic acid aligned on graphite.[5] Although they used a racemic mixture, it was possible to assign the absolute configuration of right handed and left handed molecules from the relative location of the bromine atom, long alkyl chain and hydrogen bonded carboxylic acid. These functional groups provided relative contrast in the image and therefore acted as 'chemical markers'.

In the present paper we have attempted to observe directly the molecular patterns of a chiral and racemic 16-methyloctadecanoic acid (16MeC18) which was synthesized from 2-methylbutanol of known absolute configuration.[6] Such branched fatty acids are found in mammalian tissues and play biologically important roles.[7] In order to confirm the relative position of fatty acid in the observed images, we have attempted to insert 4,4′-bipyridine (bpy) between the carboxy groups as a marker. The observed molecular pattern in the macro-scale order has been correlated with the chirality of the constituent molecule.

For the measurement of STM, sample crystals were dissolved in phenyloctane to near saturation and a drop of solution was applied on the surface of freshly cleaved highly oriented pyrolytic graphite (HOPG). The STM images were obtained in both constant current mode and constant height mode using NanoScope IIIa STM (Digital Instruments). The tunneling tip was a Pt–Ir purchased from Digital Instruments or a tungsten wire which was sharpened by electrochemical etching prior to use. Edges of multilayers were not observed in any STM images, indicating that the observed images are those of monolayers.

Fig. 1 shows the STM image of (*S*)-16MeC18 over a scan area of 12 × 12 nm. Unlike stearic acid, these molecules appear to orient parallel to each other forming a centro-symmetric molecular pattern. An interdigitated geometry, in which the head groups alternately point in opposite directions, has been observed for the molecular alignment of stearic acid and other *n*-alkanoic acids.[8] Steric repulsion between the carboxy group and the branched end group may prevent the molecules from aligning interdigitally. Although a small change in the carbon number of *n*-alkanes and straight chain fatty acids has little effect on the molecular pattern, introduction of a single methyl group on the chain dramatically influences the self-assembled molecular pattern. In Fig. 1, the dark area corresponds to hydrogen bonded carboxy groups associated head-to-head,[8] whereas bright bands can be attributed to the branched alkyl ends. Since most unsubstituted fatty acids do not show such marked contrast in the methylene chain, the alkyl end group in this molecule may locate away from the graphite basal plane.

Stearic acid as well as (*S*)-16MeC18 readily formed 2 : 1 ion pairs with 4,4′-bipyridine (bpy) in octylbenzene solution and generated a stable monolayer on HOPG. Their STM images are given in Figs. 2 and 3, along with their possible molecular alignments. The remarkably bright areas in the image correspond to bpy moieties since areas of higher electronic conductance tend to give brighter images.[9] Therefore a conjugate system like bpy can act as a marker, which provides unusual contrast in the obtained image. Obviously, the bpy moiety is sandwiched by two molecules of fatty acid, as depicted in Figs. 2(b) and 3(b). The molecular axis of the stearic acid appears to incline at an angle of 70° with respect to the bpy array, and that of (*S*)-16MeC18 is inclined as well. It is of note that the bpy salt of stearic acid generates two enantiomeric domains in the macro-scale molecular pattern (Fig. 2(a)). Some achiral molecules are known to form mirror image domains in long-range order when assembled on substrate.[3,4] Thus, sponta-

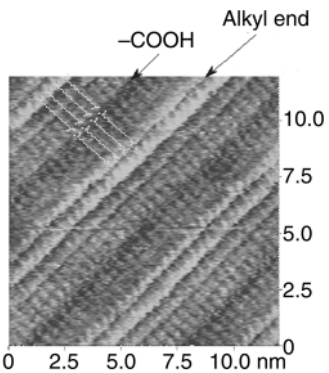

Fig. 1 The STM image of (*S*)-16MeC18 at an interface of phenyloctane and graphite over a scan area of 12 × 12 nm (bias voltage and tunneling current were 1.85 V (tip positive) and 247 pA, respectively).

† Electronic supplementary information (ESI) is available: colour versions of Figs. 1–4. See http://www.rsc.org/suppdata/cc/b0/b005112h/

DOI: 10.1039/b005112h

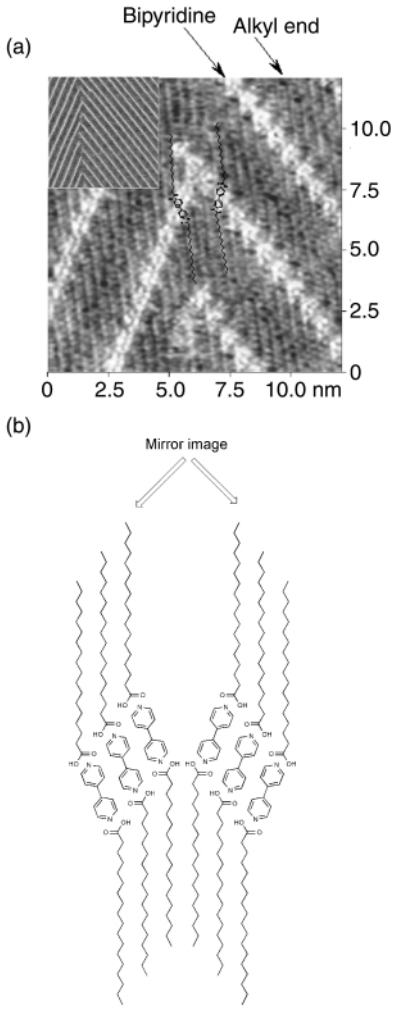

Fig. 2 (a) The STM image of an ion pair composed of stearic acid and 4,4′-bipyridine (2 : 1) over a scan area of 12 × 12 nm (bias voltage and tunneling current were 1.32 V (tip positive) and 234 pA, respectively). A 50 × 50 nm image is inserted in the corner. (b) The schematic drawing of the possible geometry.

neous segregation of achiral bpy salt has taken place upon self-assembly. However, under repeated experiments only a single domain was observed for (*S*)-16MeC18/bpy, as given in Fig.

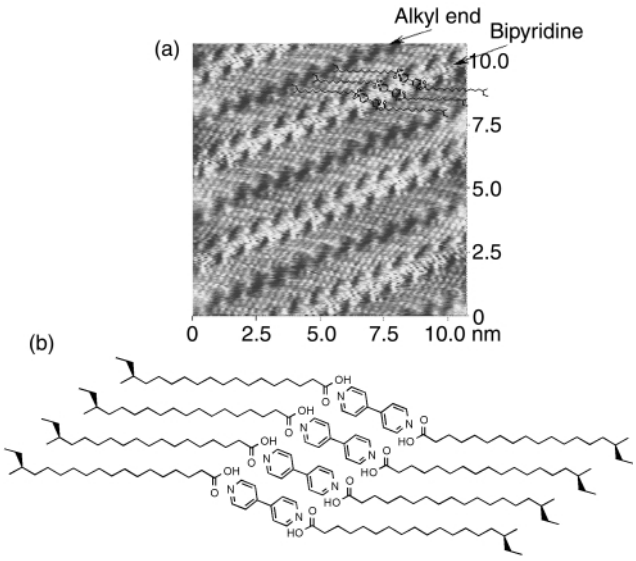

Fig. 3 (a) High resolution STM image of an ion pair composed of (*S*)-16MeC18 and 4,4′-bipyridine (2 : 1) over a scan area of 10.5 × 10.5 nm (bias voltage and tunneling current were 1.85 V (tip positive) and 243 pA, respectively). (b) Proposed molecular alignment of the (*S*)-16MeC18/bpy.

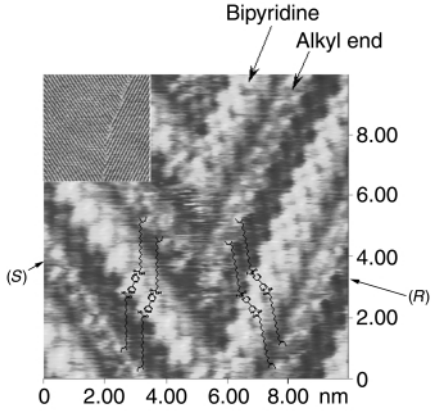

Fig. 4 The STM image of an ion pair composed of (*R*,*S*)-16MeC18 and 4,4′-bipyridine (2 : 1) over a scan area of 10 × 10 nm (bias voltage and tunneling current were 1.80 V (tip positive) and 318 pA, respectively).

3(a). We can clearly see the alkyl chains of the fatty acid as brighter spots. Under careful observation, the alkyl terminal appears to locate out of the straightly stretched alkyl chain. The obtained image is consistent with an (*S*) configuration provided that the bright spot at the alkyl terminal is assigned to the ethyl group, as depicted in Fig. 3(b). Fig. 4 shows the STM image of (*R*,*S*)-16MeC18–bpy over a scan area of 10 × 10 nm, where the racemate mixture appears to segregate into two domains. Thus two different domains of pure enantiomers have grown on the graphite surface from the racemate solution. Since macro-scale morphology of the aligned molecule has been defined by the handedness of the constituent molecule, we can assign the configuration of molecules in each domain by comparison with the macro molecular pattern of (*S*)-16MeC18.

Received (in Corvallis, OR, USA) 31st July 2000, Accepted 29th August 2000
First published as an Advance Article on the web 28th September 2000

Direct chirality measurement of tartaric and other α-hydroxy acids at very low enantiomeric excess (ee) using a fast new mass spectrometric method.

Tartaric acid is a special molecule in the history of chirality. As the first compound resolved[1] it triggered the concept of molecular chirality and for more than 150 years it has been used to explore new chiral technologies. For instance, tartaric acid has recently been absorbed on a copper surface to study heterogeneous enantioselectivity.[2] Herein, tartaric acid, along with other α-hydroxy acids, is employed as a model compound to study chiral analysis by mass spectrometry. Previously, ester derivatives of tartaric acid, although not the acid itself, were extensively studied for gas-phase chiral recognition.[3–5] These studies, along with most other mass spectrometric experiments attempting to achieve gas-phase chiral recognition,[6,7] were qualitative. We report the first enantiomeric quantification of tartaric acid and other α-hydroxy acids in the gas phase, on the basis of a newly developed method[8,9] that employs cluster ions comprised of the analyte, a chiral reference and a transition metal. Chiral discrimination is achieved in the dissociation of these cluster ions and evaluated by the kinetic method[10,11] that is sensitive to small energy differences between diastereomers. Two independent parallel reactions are used to monitor the chiral distinction and measurements of the ratio of product ion abundances allow the quantification of enantiomeric mixtures, even at low enantiomeric excess (ee). This simple chiral analysis method employs a standard commercial instrument.[12]

Electrospray ionization (ESI) was performed on an aqueous methanol solution containing a mixture of an analyte (α-hydroxy acid, A, as an enantiomeric mixture A_R and A_S, 100 μM), a chiral reference compound (chiral amino acid, ref*,100 μM), and a transition metal ion (Co(II), 25 μM). The electrosprayed solution formed abundant singly-charged cluster ions $[Co^{II}(ref^*)_2(A) - H]^+$ which were mass-selected and dissociated in a quadrupole ion trap to competitively form the dimeric complexes $[Co^{II}(A)(ref^*) - H]^+$ and $[Co^{II}(ref^*)_2 - H]^+$ by the loss of neutral reference compound, ref*, and analyte, A, respectively. The difference in stability of the diastereomeric ions $[Co^{II}(A)(ref^*) - H]^+$ due to the two configurations of the analyte A, results in different abundances, relative to the abundance of the $[Co^{II}(ref^*)_2 - H]^+$ ion. The relative abundance ratio R (eqn. 1) depends on the enantiomeric composition of the analyte, A:

$$R = [Co^{II}(A)(ref^*) - H]^+ / [Co^{II}(ref^*)_2 - H]^+ \quad (1)$$

When the analyte is enantiomerically pure, R equals R_R or R_S. Therefore, the ratio of R_R to R_S, defined as R_{chiral}, measures the degree of chiral distinction:[13]

$$R_{chiral} = R_R / R_S = \frac{[Co^{II}(A_R)(ref^*) - H]^+ / [Co^{II}(ref^*)_2 - H]^+}{[Co^{II}(A_S)(ref^*) - H]^+ / [Co^{II}(ref^*)_2 - H]^+} \quad (2)$$

Tartaric and four other α-hydroxy acids (malic acid, mandelic acid, 3-phenyllactic acid, citramalic acid) were selected for chiral analysis. Chiral references were chosen for their capability to produce large steric interactions and for structural similarity to the analyte. Such similarity allows the complexes to form easily and it also allows accurate relative abundance ratios to be measured, otherwise dissociation proceeds overwhelmingly to form the more stable product. Amino acids (α-aminocarboxylic acids) having similar structures to the analyte (α-hydroxy acid) and the nineteen natural chiral α-amino acids, plus numerous other amino acids, provide an array of choices. Aromatic amino acids were observed to provide the greatest chiral distinction.[8,9] The use of Co(II) ion as the central ion rather than Cu(II) or Ni(II) previously used for chiral recognition of amino acids[8,9] is because of its ready binding to hydroxy groups. By contrast, Cu(II) and Ni(II) bind to amino groups so strongly that loss of the hydroxy acid is the only observed dissociation channel.

Typical spectra showing the distinction of D- and L-malic acid, using L-tyrosine as the chiral reference, are shown in Fig. 1. The chiral recognition of five α-hydroxy acids is summarized in Table 1. Abundance ratios showed standard deviations of 2%. Chiral selectivity (R_{chiral})[13] values for the five α-hydroxy acids ranged from 0.67 to 1.43. Among them, tartaric acid shows moderate chiral selectivity (R_{chiral} = 1.29). Mandelic acid shows a low affinity for Co(II) and there is no chiral distinction between *R* and *S*-mandelic acids with L-alanine as reference. However, when a chiral aromatic compound, L-3-phenyllactic acid, is used as reference, chiral distinction is observed with an

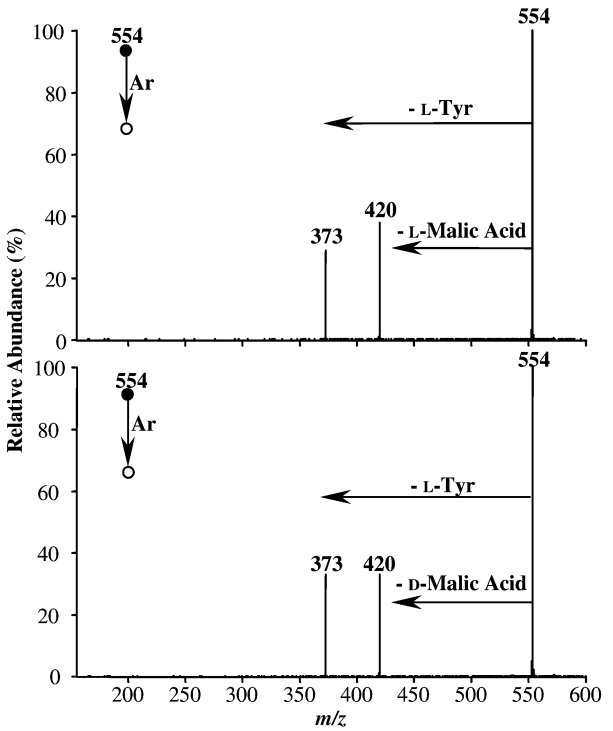

Fig. 1 MS/MS product ion spectra of (a) $[Co^{II}$(L-malic acid)$(L\text{-Tyr})_2 - H]^+$ (*m/z* 554); (b) $[Co^{II}$(D-malic acid)$(L\text{-Trp})_2 - H]^+$ (*m/z* 554). The CID activation level is chosen as 11%, corresponding to approximately 275 mV AC.

DOI: 10.1039/b006277o

Table 1 Chiral recognition of α-hydroxy acids.[a,b]

A	Ref*	$[Co^{II}(ref^*)(A) - H]^{+\cdot}/[Co^{II}(ref^*)_2 - H]^{+\cdot}$	R_{chiral}
D-Tartaric acid	L-Tyr	0.823	1.29
L-Tartaric acid		0.640	
D-Malic acid	L-Tyr	1.11	1.43
L-Malic acid		0.775	
R-Mandelic acid	L-Ala	1.00	1.00
S-Mandelic acid		1.02	
R-Mandelic acid	L-3-Phenyllactic acid	0.175	0.81
S-Mandelic acid		0.216	
D-3-Phenyllactic acid	L-Pro	0.168	1.29
L-3-Phenyllactic acid		0.130	
D-3-Phenyllactic acid	L-Phe-d_5	0.0226	0.67
L-3-Phenyllactic acid		0.0337	
R-Citramalic acid	L-Tyr	5.81	1.35
S-Citramalic acid		4.30	

[a] R_{chiral} is defined in eqn. 2. [b] CID activation level is optimized in each experiment and then kept constant for the measurement of enantiomers.

R_{chiral} value of 0.81. Chiral recognition of D- and L-3-phenyllactic acids shows the largest chiral effect using L-phenylalanine-d_5 as the reference (an isotopically labelled compound was used for convenience, since there is only one-dalton mass difference between phenylalanine and 3-phenyllactic acid). As expected,[8,9] when a non-aromatic compound, for example L-proline, is used as reference the chiral selectivity is smaller.

Quantification of tartaric acid was performed using an enantiomerically pure chiral reference (L-tyrosine) and tartaric acid in various ee. The experiments focused on mixtures with extreme ee values, since these are particularly difficult to analyze accurately and yet combinatorial syntheses frequently yield such samples. The ratio (*R*) of the two fragment ions was measured in a single tandem (MS/MS) spectrum as a function of the ee of the tartaric acid. A linear relationship of ln (*R*) *versus* ee was obtained (Fig. 2) with a correlation coefficient (r^2) of 0.9945. Such a linear correlation between the logarithm of the fragment ion abundance ratio and the ee is intrinsic to the kinetic method[10,11] and is the result of the logarithmic relationship between relative ion abundance and energy that characterizes this method.[14] On the basis of such an experimentally established semi-log plot, two-point calibrations can be performed using a racemic sample and a sample of known ee and quantitative chiral analysis carried out by measuring the ratio of two fragment ions in a single spectrum, within a time of about 1 min.

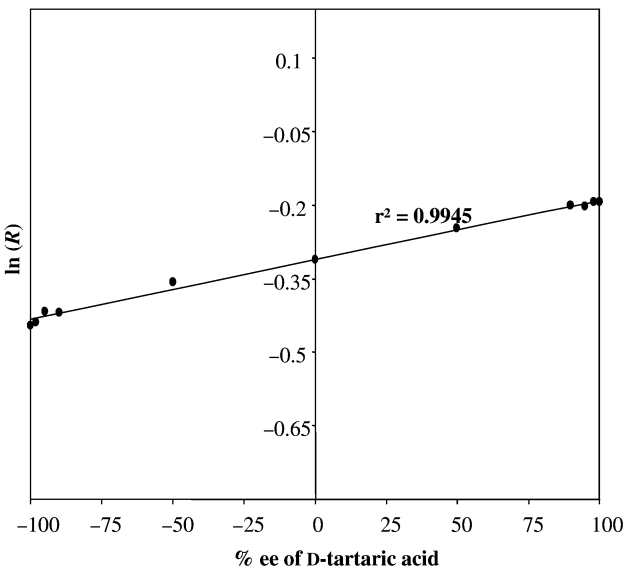

Fig. 2 Calibration curve for chiral analysis of tartaric acid using L-tyrosine as the reference.

The present study has described a novel method for rapid enantiomeric determination. At low %ee values, where the error is greatest, tartaric acid samples whose ee values differ by 2% (3 and 5%) can be distinguished at the σ confidence level in the current experiments.[15] When applying the method to real mixtures, matrix effects may influence its accuracy. Note that the chiral resolution (R_{chiral}) achieved for tartaric acid is only 1.29, and further improvement in chiral selectivity will further improve the method. The experiment, along with the previous observation of chiral analysis of other types of chiral compounds, represents a general mass spectrometric method for gas-phase chiral analysis. The measurements are simple, rapid, and only require very small amounts of sample for analysis. Further extension of this work to the study of other chiral compounds, such as chiral drugs is in progress.

12 All experiments were performed using a commercial LCQ ion trap mass spectrometer (Finnigan, San Jose, CA), equipped with an ESI source and operated in the positive ion mode. Spectra shown represent the average of about 50 scans, each requiring 0.2 s. The sample was infused *via* a syringe pump at a flow rate of 1–2 μL min^{-1}. The collision-induced dissociation (CID) conditions were optimized for each analyte.
13 R_{chiral} is equivalently defined as the ratio of R_D to R_L (nomenclature commonly used for chiral acids). The further the R_{chiral} value is from unity, the higher the degree of chiral recognition. $R_{chiral} = 1$ indicates no chiral discrimination, which means that the particular combination of Co(II) ion and reference ligand fails to create stereochemically-distinctive interactions with the enantiomers under the observation conditions employed.
14 From the kinetic method, ln (*R*) is linearly proportional to the energy change $\Delta Co^{II}BDE\{(A)(ref^*)\}$, where $\Delta Co^{II}BDE\{(A)(ref^*)\}$ is defined as energy of the reaction $[Co^{II}(ref^*)_2 - H]^+ + A \rightarrow [Co^{II}(ref^*)(A) - H]^+ + ref^*$, and the designation $\Delta Co^{II}BDE\{(A)(ref^*)\}$ is used to recognize that the energy term involves both deprotonation and binding to Co. The quantity $\Delta Co^{II}BDE\{(A)(ref^*)\}$ is linearly proportional to the ee of the analyte A, therefore ln (*R*) changes linearly with ee. Detailed derivation is available in ref. 9.
15 Multiple injections were used to determine these values which refer to standard deviation σ.

Natural bond orbital dissection of fluorine–fluorine through-space NMR coupling ($J_{F,F}$) in polycyclic organic molecules

A new approach to deconvolute DFT and *ab initio* Fermi contact-derived NMR coupling constants into conceptually familiar localized orbital contributions (NJC analysis) is exemplified by analysis of through-space *J*(F,F) couplings in a few illustrative cases.

Large NMR spin–spin coupling between two proximate atoms that are otherwise separated by a considerable number of formal bonds, through-space coupling, has been observed for many years. Very early, the idea that spin polarization associated with the Fermi contact coupling mechanism can be transmitted between such atoms was advanced.[1] Since that time, both experimental and theoretical evaluations of through-space coupling has stimulated useful insights on how such a mechanism operates.[2–6] Most known theoretical approaches are semiempirical in nature. They partition the total coupling according to the electronic mechanisms involved in spin polarization transmission.[7–9] One attempt to extend the IPPP[9] method to the *ab initio* level proved to be intractable for systematic study of practical problems.[10]

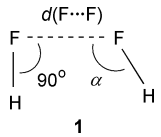
Recently, very efficient and reliable implementations of Finite Perturbation Theory[11] within the Gaussian suite of programs[12] permit calculation of the Fermi contact contribution to spin–spin couplings, J^{FC}(A,B). Both single (FPT-1) and double perturbation (FPT-2) approaches have been reported and reviewed.[13,14] For calculating J^{FC}(A,B) within the FPT-1 method, the Fermi contact operator is introduced as a perturbation placed at only one of the two coupled nuclei, *e.g.* A. The resulting interaction spin-polarizes the electronic environment to define a spin density at nucleus B proportional to J^{FC}(A,B).

Ordinarily, the spin density is written in terms of canonical molecular orbitals. However, if localized molecular orbitals are employed instead, then each localized orbital contribution to J^{FC}(A,B) can be rationalized in terms of familiar chemical concepts. In this way, a practical and intuitive theoretical approach to dissecting J^{FC}(A,B) couplings into different transmission mechanisms is achieved.

In the present work, natural localized molecular orbitals (NLMO) provided by natural bond orbital analysis, NBO,[15] are utilized to express the spin density. The latter and, consequently, J^{FC}(A,B) can then be rewritten as a sum of contributions in terms of core orbitals, CR, non-bonding electron pairs, LP, and bonding orbitals, BD, as in eqn. (1). We refer to the method as natural *J*-coupling (NJC) analysis and consider it a complement to natural chemical shielding analysis (NCS).[16] All calculations of Fermi contact terms reported here were carried out with the Gaussian 98 suite of programs[12] at the DFT B3LYP/6-311G** level.

$$J^{FC}(A,B) = J_{CR}(A,B) + J_{LP}(A,B) + J_{BD}(A,B) \qquad (1)$$

Eqn. (1) is particularly suited to the study of through-space *J*-coupling originating from lone-pair overlap between atoms which are proximate in space, a problem of considerable current interest.[6,17] Three examples illustrate mechanistic insights obtained from the approach. The first case concerns the hydrogen fluoride dimer as a model for pure intermolecular F–F coupling. In this very simple system evaluated for different planar configurations (**1**), the coupling mechanisms can be



1

understood on intuitive grounds. Fig. 1 displays the total J^{FC}(F,F) coupling and the J_{LP}(F,F), J_{CR}(F,F) and J_{BD}(F,F) contributions as a function of F···F distance for α = 90°. Several features of the plots are noteworthy. The total J^{FC}(F,F) coupling decreases rapidly with increasing *d*(F···F) following the same trend as the absolute values for the different components. The J_{LP}(F,F) and J_{CR}(F,F) contributions correspond to positive decrements, while J_{BD}(F,F) is negative. In agreement, several experimental reports on *J*(H,H) and *J*(F,H) couplings offer evidence that through-space transmission as a result of direct overlap between two bonds elicits a negative contribution.[3,18] With respect to different lone pairs within the HF dimer, the J_{LP}(F,F) breakdown suggests that (a) the lone pairs of both fluorine atoms whose NLMOs are of π-symmetry do not participate in through-space transmission; (b) the NLMOs of lowest energy yield the largest and positive contribution to J^{FC}(F,F); and (c) the *J*-contribution of the lone pairs of highest energy are negative but of notably smaller absolute value than that described in (b). However, actual values of each component depend strongly on α for a given *d*(F···F) distance. Thus, for *d*(F···F) = 2.3 Å and α = 90°, J^{FC}(F,F), J_{LP}(F,F), J_{CR}(F,F) and J_{BD}(F,F) are calculated to be 245, 210, 53 and −18 Hz, respectively. On the other hand, for α = 120° at the same distance, the values are 351, 330, 90 and −70 Hz, respectively. These NJC variations call for caution when *J*(F,F) couplings dominated by a through-space mechanism are correlated with only the *d*(F···F) parameter.

Our second example is taken from compound **2**, in which $^4J(F_a,F_b)$ and $^4J(F_a,F_c)$ were reported to be 37 and 24 Hz, respectively.[19] In order to study the behavior of the through-

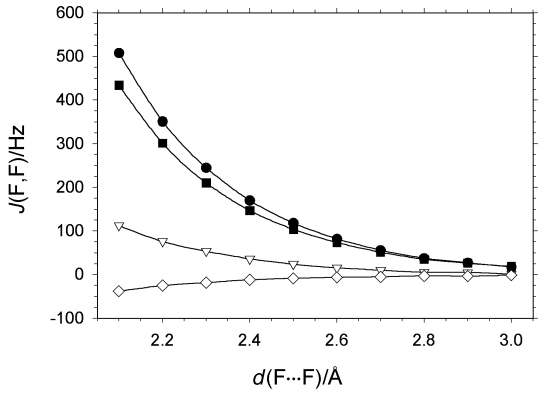


Fig. 1 Plots of J^{FC}(F,F), ●, in the hydrogen fluoride dimer **1** and its J_{LP}(F,F), ■, J_{CR}(F,F), ▽, and J_{BD}(F,F), ◇, contributions as a function of *d*(F···F); α = 90°.

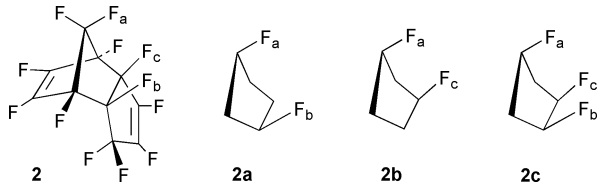
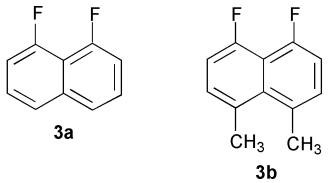
DOI: 10.1039/b006283i



space components of the two couplings for fluorine atoms with the same configuration, the structure of **2** was first optimized with the MM3*/MacroModel.[20] The five-membered ring structures **2a**–**c** were then constructed from optimized **2** by preserving local heavy atom geometries; that is, both distance and angular relationships between the fluorine atoms are unchanged. The lone pair contributions to $^4J^{FC}(F_a,F_b)$ and $^4J^{FC}(F_a,F_c)$ in **2a**–**c** are compared with their respective total $^4J^{FC}(F,F)$ couplings in Table 1. While the latter calculated values do not accurately reproduce the corresponding experimental values in **2**, a number of qualitative trends are evident. $^4J_{LP}(F,F)$ and $^4J_{CR}(F,F)$ are positive and correspond to contributions transmitted through-space. On the other hand, the negative term $\Delta^4J(F,F)$ is composed of both through-space and through-bond contributions, the former originating in the direct superposition of two C–F bonds. Not surprisingly, the absolute value of $\Delta^4J(F_a,F_b)$ (16–20 Hz) is considerably larger than that for $\Delta^4J(F_a,F_c)$ (3–5 Hz) (Table 1). To interpret the difference, we note that the fluorine pairs F_a/F_b and F_a/F_c are linked by four bonds, while the fluorine atoms in each pair are separated by 2.56 and 2.92 Å, respectively. A reasonable assumption is that the −3 to −5 Hz exhibited by $\Delta^4J(F_a,F_c)$ is an upper limit for through-bond coupling. Thus, the −16 to −20 Hz calculated for $\Delta^4J(F_a,F_b)$ can be viewed primarily as a C–F bond through-space effect, a result in harmony with the HF dimer model calculations.

In the final example, we perform an NJC analysis for the *peri*-$^4J^{FC}(F,F)$ coupling in compounds **3a** and **3b**. The total $J^{FC}(F,F)$



coupling and the $J_{LP}(F,F)$, $J_{CR}(F,F)$ and $J_{BD}(F,F)$ contributions to these *peri*-$^4J^{FC}(F,F)$ couplings are compared in Table 2. While the total $J^{FC}(F,F)$ couplings are underestimated by 12–15%, they follow experiment nicely. All contributions are in agreement with expections based on molecular geometry. For instance, the larger absolute values of $^4J_{LP}(F,F)$, $^4J_{CR}(F,F)$ and $\Delta^4J(F,F)$ in **3b** with the smaller $d(F\cdots F)$ (Table 2), parallel the trends described above for the FH dimer (Fig. 1). Similar to **2a**–**c**, the combined and negative through-bond and through-space term, $\Delta^4J(F,F)$, is larger for the shorter distance. As before, we assume a similar ^4J through-bond coupling (both σ and π) for **3a** and **3b**. The calculated difference of −11.8 Hz can thus be attributed to the C–F bonds contribution to coupling in the latter compound.

Table 1 Becke3LYP/6-311G**/NBO values for $^4J^{FC}(F,F)$ (Hz) and component couplings in **2a**–**c**

Coupling	**2a**		**2b**	**2c**
	$^4J(F_a,F_b)$	$^4J(F_a,F_c)$	$^4J(F_a,F_b)$	$^4J(F_a,F_c)$
$^4J^{FC}(F,F)$	68.0	7.6	67.7	9.0
$^4J_{LP}(F,F)$	72.9	11.8	71.1	12.6
$^4J_{CR}(F,F)$	14.5	0.4	13.0	0.2
Δ^4J $(F,F)^a$	−19.4	−4.6	−16.4	−3.8
$d(F\cdots F)^b$	2.56	2.92	2.56	2.92

[a] $\Delta^4J(F,F) = {}^4J^{FC}(F,F) - [{}^4J_{LP}(F,F) + {}^4J_{CR}(F,F)]$. [b] From MM3*/MacroModel[19] optimized **2**(Å).

Table 2 Becke3LYP/6-311G**/NBO and experimental values for $^4J^{FC}(F,F)$ (Hz) and component couplings in **3a** and **3b**

Coupling	**3a**	**3b**
$^4J^{FC}(F,F)$	52.1	73.2
$^4J_{LP}(F,F)$	58.2	86.4
$^4J_{CR}(F,F)$	10.8	15.5
Δ^4J $(F,F)^a$	−16.9	−28.7
Jexp[b]	59.0	85.2
$d(F\cdots F)^c$	2.580	2.508

[a] $\Delta^4J(F,F) = {}^4J^{FC}(F,F) - [{}^4J_{LP}(F,F) + {}^4J_{CR}(F,F)]$. [b] Taken from F. B. Mallory, *et al*.[17] [c] MM3*/MacroModel optimized **3a** and **3b** (Å). X-ray of 1,8-difluoronaphthalene, $d(F\cdots F)$ = 2.584 Å; P. A. Meresse, C. Courseille, F. Leroy and N. B. Chanh, *Acta Crytallogr. B*, 1975, **31**, 1236.

In summary, the main features of dissection of $J(F,F)$ couplings transmitted through-space in compounds such as **2**–**3** are in good agreement with currently accepted mechanisms, especially the lone-pair overlap proposal of Mallory and co-workers.[17] However, in addition to presenting a novel tool for *J*-analysis, we also highlight the previously unrecognized importance of angular effects and X–F bond–bond coupling contributions. Future NJC analyses will explore these phenomena in detail.

Synthesis and structural characterisation of the first hexaphosphastrontocene $[Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2]$ and its pyrazine adduct

Matthew D. Francis, Peter B. Hitchcock and John F. Nixon*

School of Chemistry, Physics and Environmental Sciences, University of Sussex, Falmer, Brighton, UK BN1 9QJ. E-mail: j.nixon@sussex.ac.uk

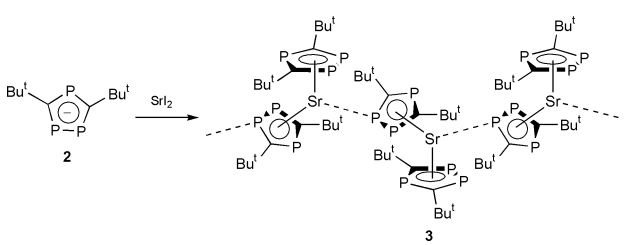
Received (in Cambridge, UK) 20th July 2000, Accepted 1st September 2000
First published as an Advance Article on the web 28th September 2000

Treatment of SrI_2 with 2 equivalents of $K[P_3C_2Bu^t_2]$ affords the hexaphosphastrontocene $[\{Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2\}_\infty]$ which is polymeric in the solid state; treatment of this complex with an excess of pyrazine leads to the corresponding Lewis base adduct $[\{Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2(\mu\text{-}C_4H_4N_2)\}_\infty]$ which is also polymeric in the solid state.

There has been increasing interest in the structure and bonding in metallocene complexes of the heavier alkaline earth elements (Ca, Sr, Ba) in recent years and several reviews have appeared.[1–3] With the exception of $[Ca(\eta^5\text{-}C_5H_5)_2]$ which is a three-dimensional polymer, these compounds are generally monomeric in the solid state or weakly associated, the degree of association depending on both the steric bulk of the cyclopentadienyl ligand and size of the central metal. Moreover, where the cyclopentadienyl ligands are not excessively bulky (typified by encapsulated metallocenes), additional coordination of Lewis bases may occur.

In contrast, however, sandwich compounds of the alkaline earth metals with heteroatom substituted cyclopentadienyl ligands are extremely rare. To the best of our knowledge only two structurally characterised examples, incorporating the 2,5-di-*tert*-butylpyrrolyl ligand and coordinated THF have been reported[4] namely $[M(\eta^5\text{-}NC_4H_2Bu^t_2)_2(THF)]$ **1** (M = Ca, Sr). Westerhausen and co-workers[5,6] showed that the 2,5-diphenyl-3,4-bis(trimethylsilyl)phospholyl ligand coordinates in an η^1-fashion to the metal dications $[M(THF)_4]^{2+}$ (M = Ca, Sr), however unpublished calculations by the same authors on the solvent free systems favour an η^5-ligating mode. Motivated by our recent observation[7] that the complex $[In(\eta^5\text{-}P_3C_2Bu^t_2)]$, containing the aromatic 3,5-di-*tert*-butyl-1,2,4-triphospholyl anion **2**, is a source of pure InP by chemical vapour deposition, we decided to react **2** with alkaline earth metal halides. We now report the first synthesis and structural characterisation of the hexaphosphastrontocene, $[\{Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2\}_\infty]$ **3** and its pyrazine adduct $[\{Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2(N_2C_4H_4)\}_\infty]$ **4**.

Thus, treatment of a THF solution of SrI_2 with two equivalents of **2** (Scheme 1) leads to the formation of air and moisture sensitive, but thermally stable, $[\{Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2\}_\infty]$ **3** (*ca.* 50% yield). Complex **3**, which is a pale yellow solid, can be extracted from the initial reaction residue with toluene but sublimation or prolonged evacuation of the extracted residue renders it insoluble in all but donor solvents. We believe the initially formed complex is a THF solvated monomeric species $[Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2(THF)_n]$ which readily loses THF to afford polymeric strands of **3** (*vide infra*). This behaviour also occurs in the case of strontocenes such as $[Sr(\eta^5\text{-}C_5H_4Bu^t)(THF)_2]$ and $[Sr\{\eta^5\text{-}C_5H_3(SiMe_3)_2\}_2(THF)]$ which both readily desolvate on sublimation, although they remain monomeric.[8,9]



Scheme 1

The $^{31}P\{^1H\}$ NMR spectrum of **3**† is consistent with η^5 ligated triphospholyl rings and the chemical shifts are similar to those of $[K(\eta^5\text{-}P_3C_2Bu^t_2)]$ (δ 252.8 and 244.8). This is in contrast to the generally observed *upfield* shift in the ^{31}P resonances of **2** upon coordination to transition metals {*e.g.* AB_2 pattern at δ 65 in $[Ru(\eta^5\text{-}P_3C_2Bu^t_2)_2]$}[10] and this may indicate a significant degree of ionic character in the metal–ligand bonding in **3** in solution. The EI mass spectrum of **3** exhibits a strong molecular ion (*m/z* 550, 58%) but no higher peaks, suggesting that in the gas phase **3** exists primarily as a monomeric species.

A single crystal X-ray diffraction study‡ reveals that in the solid state, **3** consists of bent sandwich units linked in chains along the crystallographic *c*-glide plane (Fig. 1). Each unit bears one solely η^5 bound triphospholyl ligand and a second η^5 ligand which also acts as a bridge linking the molecules into extended chains *via* a further η^1 interaction involving one of the two adjacent phosphorus ring atoms. This strontium–phosphorus bond distance [3.2200(7) Å] is only marginally longer than the average strontium–phosphorus distances within the sandwich unit (3.1837 Å) and all lie within the sum of the van der Waals radii for the two elements. The centroid–metal–centroid angle of 141.50(7)° in **3** is larger than that observed in analogous strontocenes bearing substituted cyclopentadienyl ligands of comparable steric bulk {*e.g.* 122 and 124° in **1**[4] and 134° in $[Sr\{\eta^5\text{-}C_5H_3(SiMe_3)_2\text{-}1,3\}_2]$ **5**).[8] Similarly, the metal–centroid distances of 2.692(3) and 2.788(3) Å in **3** are somewhat larger than those in **1** (2.525 Å) and **5** (2.551 Å), which probably results from replacement of three ring carbon atoms with the

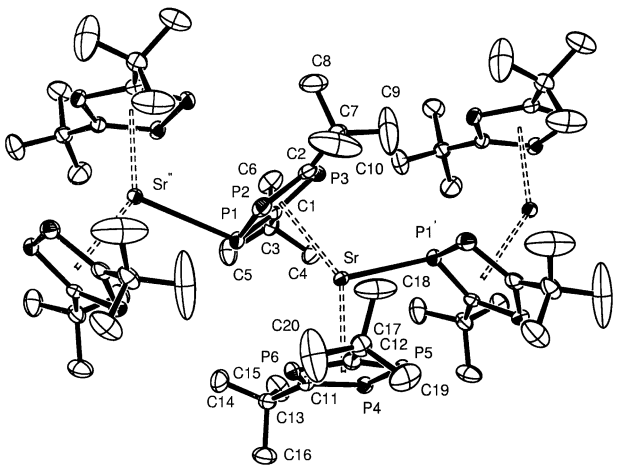


Fig. 1 Solid state structure of **3**. Selected bond distances (Å) and angles (°): M(1)–Sr–M(2) 141.50(7); Sr–M(1) 2.788(3), Sr–M(2) 2.692(3), P(1)–P(2) 2.1150(11), P(2)–C(2) 1.749(3), C(2)–P(3) 1.745(3), P(3)–C(1) 1.749(3), C(1)–P(1) 1.753(3), P(4)–P(5) 2.1069(11), P(5)–C(12) 1.756(3), C(12)–P(6) 1.755(3), P(6)–C(11) 1.751(3), C(11)–P(4) 1.759(3). M(1) and M(2) are the centroids of the rings defined by C(1), C(2), P(1), P(2), P(3) and C(11), C(12), P(4), P(5), P(6), respectively.

DOI: 10.1039/b005855f

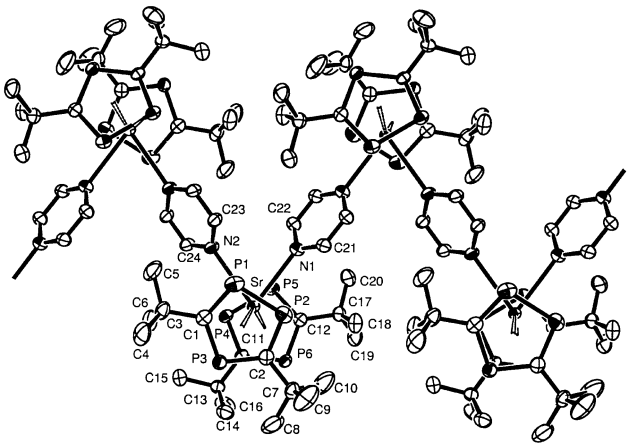

Fig. 2 Solid state structure of **4**. Selected bond distances (Å) and angles (°): M(1)–Sr–M(2) 146.73(6); Sr–M(1) 2.794(2), Sr–M(2) 2.791(2), P(1)–P(2) 2.1073(10), P(2)–C(2) 1.751(3), C(2)–P(3) 1.748(2), P(3)–C(1) 1.754(2), C(1)–P(1) 1.746(3), P(4)–P(5) 2.1101(9), P(5)–C(12) 1.748(2), C(12)–P(6) 1.755(2), P(6)–C(11) 1.750(2), C(11)–P(4) 1.749(2). M(1) and M(2) are the centroids of the rings defined by C(1), C(2), P(1), P(2), P(3) and C(11), C(12), P(4), P(5), respectively.

larger phosphorus atoms. The bridging strontium–phosphorus interaction in **3**, not possible in the related strontocenes, obviates the need for any additional ligation to THF or other donor solvent molecules.

However, treatment of **3** with an excess of pyrazine in refluxing toluene leads *quantitatively* to $[\{Sr(\eta^5\text{-}P_3C_2Bu^t_2)_2(\mu\text{-}C_4H_4N_2)\}_\infty]$ **4** in which the strontium–phosphorus bridges of **3** have been broken and replaced with pyrazine units. Complex **4**, which is an orange solid, is insoluble in all but donor solvents but could be recrystallised from a hot saturated toluene solution. The room temperature mass spectrum of **4**† indicates a ready loss of pyrazine and at higher temperature the spectrum is essentially that of the parent complex **3**. Furthermore, the NMR spectroscopic data for **3** and **4** are essentially identical, suggesting that **4** undergoes complete dissociation into **3** and free pyrazine in solution.†

The solid state, polymeric structure of **4** determined by a single crystal X-ray diffraction study‡ is shown in Fig. 2. The pyrazine units act as bridges linking the hexaphosphastrontocene molecules into zigzag chains, each sandwich unit being related to the next by a crystallographic inversion centre lying at the middle of the pyrazine ring. The *intra*ring parameters of **4** do not differ significantly from those in **3**: the average phosphorus–carbon (1.750 Å) and phosphorus–phosphorus (2.1087 Å) distances within the strontium hexaphosphametallocene unit in **4** are very similar to those observed in **3** (1.752 and 2.1109 Å, respectively). Moreover, the centroid–metal–centroid angle in **4** is 146.73(6)° compared with 141.50(7)° in **3** and the two individual metal–centroid distances of 2.791(2) and 2.794(2) Å are similar to those in **3** [2.692(3) and 2.788(3) Å].

First published as an Advance Article on the web 28th September 2000

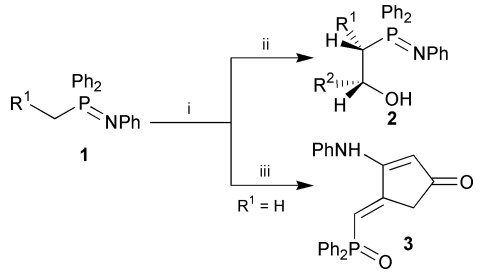
The first synthesis of di-, tri- and tetrasubstituted alkenes through reaction of lithium *P*-diphenyl(alkyl)(*N*-carboxymethyl)phosphazenes with aldehydes and ketones is reported.

Phosphorus-stabilized carbanions are very important reactive intermediates in the stereoselective synthesis of olefins. Since the breakthrough of the Wittig reaction between phosphorus ylides and carbonyl compounds[1] in carbon–carbon double bond forming reactions, the usefulness of other phosphorus derivatives in this type of process has been demonstrated. The most relevant members of this class of compounds are phosphonates,[2] phosphonamides[3] and phosphine oxides.[4]

Phosphazenes are isoelectronic with phosphorus ylides and phosphine oxides. They are well known for the large number of synthetic applications of the P–N bond,[5] particularly in the preparation of heterocycles[6] based on the aza-Wittig reaction. However, the chemistry of their α-carbanions has received much less attention.[7] We have shown that lithiated *P*-diphenyl(alkyl)(*N*-phenyl)phosphazenes **1** add to aldehydes with a high diastereoselectivity yielding the corresponding β-hydroxy derivatives (Scheme 1).[8] These compounds are easily isolated and no trace of olefins were observed in the reaction even when forcing conditions were used.

Recently, in a synthesis of cyclopentenones **3** obtained by reaction of lithium *P*-diphenyl(alkyl)(*N*-phenyl)phosphazenes with dimethylacetylene dicarboxylate (DMAD) (Scheme 1) we proposed a reaction mechanism in which one intermediate phosphazene participated in an olefination step similar to the Horner carbon–carbon double bond synthesis using phosphine oxides.[9] No experimental evidence could be obtained regarding the structure of any reactive intermediate involved in the synthesis.

Here we report the first application of phosphazenes to the synthesis of di-, tri- and tetrasubstituted alkenes. The phosphazenes **4** used in this study are readily obtained, either by alkylation of the anion Ph_2P^- (generated by reaction of Ph_3P with lithium) followed by *in situ* addition of N_3CO_2Me, or through alkylation of simpler lithiated phosphazenes (Scheme 2). *P*-diphenyl(alkyl)(*N*-carboxymethyl)phosphazenes **4** were metallated with *n*-BuLi in THF at −35 °C over a 30 min period. The appropriate aldehyde or ketone was then added and the mixture was stirred for 4–20 h at rt. Aqueous work-up followed by distillation or filtration through a short path silica-gel chromatography column afforded the olefins **8**(*Z*)/**9**(*E*)



Scheme 1 *Reagents and conditions*: i, *n*-BuLi, −30 °C, THF; ii, R^2CHO, −70 °C; iii, DMAD, −70 °C.

(Scheme 3).† The diphenylphosphinamide **11** by-product was completely eliminated in the aqueous layer.

A list of the compounds obtained, as well as the isolated yields and the diastereomeric ratios observed are given in Table 1.[10] The stereochemistry of the tri-substituted alkenes was easily assigned through 2D NOESY spectra measured from the mixture of isomers. For the di-substituted derivatives the geometry of the double bond was deduced from the magnitude of the vicinal coupling constants or chemical shifts of the olefinic protons.

Reaction yields were higher than 90% in all cases except for the phosphazene having R^1 = Me and R^2 = ^{n}Bu. In this case only a 16% yield of the *E*/*Z* alkenes was obtained under the standard conditions. However, this yield increased to 70% without changes in the isomeric ratio when a large excess of aldehyde (10 equiv.) was used. Worthy of note is the high yield obtained when benzophenone is used as electrophile giving rise to the tetrasubstituted alkene **8j**. The olefin *E* predominates in all cases except for phosphazenes bearing a benzyl group where the *Z* alkene is favoured (Table 1, entries 7, and 8). Good to excellent stereoselectivies are obtained for phosphazenes with R^1 = Ph, CO_2Me and R^2 = H (Table 1, entries 1–5). Using the synthesis of alkenes **8/9d** as reference, under the same reaction conditions the appropriate phosphazene, phosphine oxide, phosphonate, and phosphonium salt afforded essentially the *E* isomer (*Z*:*E* 1:99) in similar yields. Curiously, the stereoselectivity of the Wittig reaction showed a slight decrease (*Z*:*E* 4:96) when the olefination was carried out with the isolated phosphorus ylide. However, the reported reactions of Ph_3P=CHPh with benzaldehyde using BuLi or PhLi as a base

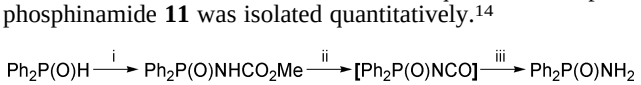
[a] Determined from the integrals of the olefinic protons and/or the methyl signals in the ^{1}H NMR spectrum of the mixture. [b] When a large excess of aldehyde is used.

are clearly less stereoselective (*Z*:*E* 34:66 and 30:70, respectively)[1b,11] than the analogous synthesis of stilbene through phosphazenes (Table 1, entry 1). The olefination reported here is sensitive to the degree of substitution in the carbanion and modest *Z*/*E* ratios are obtained when α,α-disubstituted phosphazenes are used (*cf*. entries 6–9 in Table 1). This is a known characteristic of Horner olefination.[5]

A reaction mechanism explaining the formation of **8**, **9**, and **11** is shown in Scheme 3. First, one carbon–carbon bond is formed by addition of the C_α-metallated phosphazene to the carbonylic carbon of the electrophile affording the alkoxy intermediate **5a**. The nucleophilic oxygen of this adduct attacks the electrophilic phosphorus intramolecularly to yield an oxaphosphetane heterocycle **6** as proposed for the Wittig[1] and Horner[12] reactions. In this particular case, the oxaphosphetane **6** may break down to the alkenes **8**/**9** (route a) or may eliminate lithium methoxide affording the isocyanate derivative **7**. Ring opening of **7** would yield the alkenes **8**/**9** and diphenylphosphinoyl isocyanate **10** (route b), which by reaction with water would produce the diphenylphosphinamide **11**. Alternatively the isocyanate **10** may be formed by elimination of lithium methoxide from the lithium phosphinamide **12** (route a).

The intermediate adducts **5b** can be isolated as the corresponding (β-hydroxy)phosphazenes when the carbonyl compound is added at −70 °C and the reaction is stirred for 2 h at this temperature. Aqueous work-up yields a mixture of diastereomeric compounds **5b** in the same ratio as observed for the respective olefins. Therefore, the diastereoselectivity of the synthesis is determined by the addition step and no interconversion occurs between the two isomers. The (β-hydroxy)-phosphazenes **5b** are converted quantitatively into the corresponding olefins by lithiation under the same reactions conditions used in the one-pot process.

Support for the participation of phosphinoyl isocyanates as intermediates in the formation of phosphinamides in the olefination reaction described above has been obtained from phosphinamide **13** synthesized by reaction of methoxycarbonyl azide with diphenylphosphine oxide. Compound **13** was treated with one equiv. of *n*-BuLi in THF at −30 °C (Scheme 4) and the reaction was stirred for 4 h at rt.[13] After aqueous work-up the phosphinamide **11** was isolated quantitatively.[14]



Scheme 4 *Reagents and conditions*: i, N_3CO_2Me, THF, rt; ii, *n*-BuLi, THF, −35 °C to rt; iii, H_2O.

In conclusion, the application of phosphazenes to the synthesis of alkenes through reaction with carbonyl compounds is described for the first time. The phosphazenes are readily available through conventional reactions, analogous to the preparation of phosphine oxides. High yields of di-, tri and tetrasubstituted olefins are obtained. The stereoselectivity depends on the substituents on the alkyl group bonded to phosphorus and for α-substituted phosphazenes the stereocontrol achieved is comparable to that obtained in the Wittig, Horner, and Wadsworth–Emmons reactions. A reaction mechanism is proposed which involves the sequential formation of an isolable (β-hydroxy)phosphazene and an oxaphosphetane intermediate.

The first vanadium-catalyzed oxidation of aryl allylic selenides with *in situ* [2,3] sigmatropic rearrangement†

Rich G. Carter* and T. Campbell Bourland

Department of Chemistry and Biochemistry, University of Mississippi, Oxford, MS 38677 USA. E-mail: rgcarter@olemiss.edu

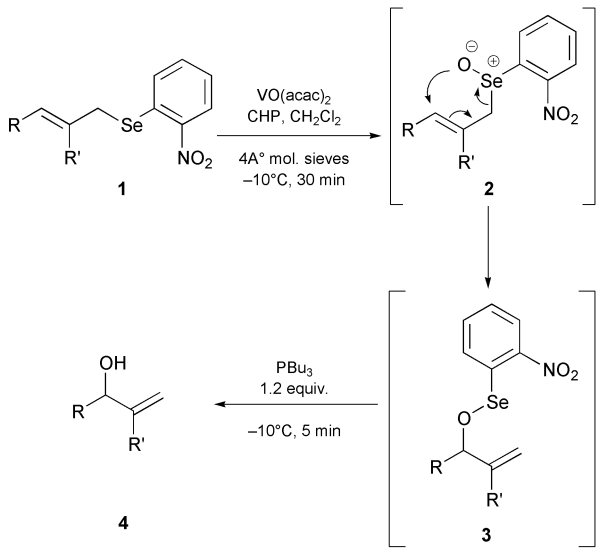
Received (in Corvallis, OR, USA) 28th July 2000, Accepted 1st September 2000
First published as an Advance Article on the web 28th September 2000

The efficient synthesis of a series of 2° allylic alcohols from a vanadium-catalyzed oxidation of suitably disposed allylic selenides with tandem [2,3] sigmatropic rearrangement is outlined.

The rapid growth of metal-catalyzed transformations in recent decades has contributed to the construction of evermore complex synthetic targets. For example, the catalytic oxidation of sulfides is well documented using several transition metal catalysts.[1] This methodology has proven useful in both racemic and enantioselective pathways. Recently, Bolm and co-workers showcased the use of vanadium for the enantioselective oxidation of prochiral sulfides.[2] In addition, the Ellman laboratory has reported an elegant use of a similar catalytic system for the enantioselective oxidation of alkyl disulfides.[3] Despite these encouraging results, relatively little attention has been paid to the corresponding oxidation of selenium. In particular, the tandem oxidation of suitably disposed allylic selenides with *in situ* [2,3] sigmatropic rearrangement has been limited to stoichiometric oxidants such as oxaziridines, peracids or peroxides.[4] Scattered asymmetric methods have also been developed for these transformations utilizing primarily stoichiometric titanium–tartrate complexes[5] or chiral oxaziridines.[6] In addition, several groups have studied the effect of a chiral auxiliary on selenium.[7] None of these systems, however, have been exploited in a sub-stoichiometric sense for this transformation.[8] We herein report the first catalytic method for oxidation of allylic selenides with tandem *in situ* [2,3] sigmatropic rearrangement.

Our initial exploits in this area were directed toward the use of titanium-mediated oxidation based on previously described conditions;[9] however, this proved to be ineffective in our hands due to lack of generality, slow reaction times, and the need for stoichiometric amounts of the metal catalyst. Our interest then turned to the use of vanadyl(IV) acetylacetonate as a potential candidate for the desired transformation. Synthesis of the selenide precursors was readily accomplished from the corresponding alcohol using tributylphosphine and *o*-nitrophenyl selenocyanate in high yield.[10]

The standard reaction conditions involved a 0.3 M solution of the selenide **1** in methylene chloride with vanadyl(IV) acetylacetonate (10 mol%) in the presence of powdered 4 Å molecular sieves (Scheme 1). This green solution was then cooled to −10 °C in an ice–acetone bath and cumene hydroperoxide (1.8 equiv.) was added to the stirred solution. After the reaction was judged to be complete, tributylphosphine (1.2 equiv.) was added to convert the intermediate selenenate **3** to the desired allylic alcohol **4**. This efficient and rapid method for cleavage of the selenenate species **3** is noteworthy because of its tolerance for sterically demanding systems such as the adamantyl selenide **1c**. Previous described methods for selenenate cleavage (such as pyridine and water) proved to be slow and capricious in our hands. The vanadium metal catalyst is



Scheme 1 Selenide oxidation, sigmatropic rearrangement and selenenate cleavage sequence.

critical for the dual reaction sequence to proceed; the blank experiment without $VO(acac)_2$ resulted in no conversion of the selenide under the prescribed reaction conditions.[11] It has been previously reported that phenyl selenides can be oxidized using *tert*-butyl hydroperoxide in the absence of a metal catalyst;[12] however, the decreased reactivity of the selenium to oxidation that is observed may be due to the electron withdrawing nature of the *o*-nitro substituent.

A variety of substituents on the alkene were studied in order to investigate the utility of this methodology as shown in Table 1. These results suggest that the oxidation and rearrangement occur rapidly, regardless of the steric environment located at the allylic position. In addition, the vanadium-mediated conditions occur equally effectively with conjugated and non-conjugated olefins. These results are in contrast to preliminary studies in our laboratory with titanium-mediated reactions in which substitution on the alkene function had a dramatic impact on the efficiency of the reaction. Furthermore, the rearrangement does not seem to be influenced by a stereogenic center located in the allylic position. For example, treatment of selenides **1f** and **5c** yielded the resultant allylic alcohol in nearly 1:1 selectivity. This result is in good agreement with Davis and co-workers who have shown that the stereochemical outcome of the resultant alcohol in acyclic substrates appears to be determined by the oxidation of the selenide.[6] Finally, the results in Table 2 demonstrate that this methodology is equally effective for the *cis* olefin geometry.

In conclusion, the first vanadium-catalyzed method for oxidation of selenides is reported with tandem [2,3] sigmatropic rearrangement. This methodology is effective on a broad range of substrates, regardless of steric environment, thereby expanding the scope and utility of selenoxide rearrangements. Furthermore, tributylphosphine is shown to be a rapid and

general method for selenenate cleavage and a viable alternative to traditional methods. In addition, it should be possible to effect catalytic asymmetric oxidation of selenium with tandem sigmatropic rearrangement using the appropriate multidentate ligand–vanadium system. We are actively pursuing this area and will report our results in due course.

The authors wish to thank the University of Mississippi for their generous support of this work.

Tandem 1,3-azaprotio cyclotransfer–cycloaddition reactions between aldoximes and divinyl ketone. The effect of oxime *E*/*Z*-isomerism on cycloaddition stereoselectivity

Peter J. Dunn,[b] Alison B. Graham,[a] Ronald Grigg,*[a] Paul Higginson[b] and Imaad S. Saba[a]

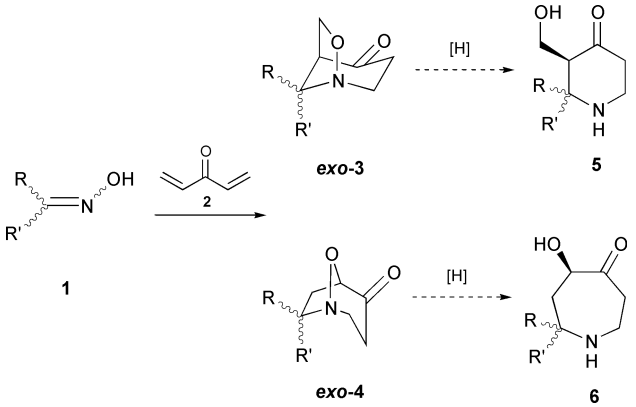
[a] *Molecular Innovation, Diversity and Automated Synthesis (MIDAS) Centre, School of Chemistry, The University of Leeds, Leeds, UK LS2 9JT. E-mail: R.Grigg@chem.leeds.ac.uk*

[b] *Pfizer Global Research & Development (UK), Sandwich, Kent, UK CT13 9NJ*

Received (in Cambridge, UK) 5th July 2000, Accepted 11th September 2000
First published as an Advance Article on the web 2nd October 2000

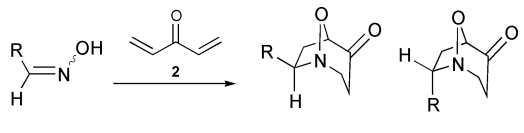
The tandem 1,3-azaprotiocyclotransfer–cycloaddition reaction between aldoximes and divinyl ketone affords mixtures of *exo*- and *endo*-isomers of substituted 1-aza-8-oxabicyclo[3.2.1]octan-4-ones, the ratio of which is dependent on the *E*/*Z* geometry of the starting oxime and its ability to isomerise under the thermal reaction conditions.

We recently reported that the tandem 1,3-azaprotio cyclotransfer–cycloaddition reaction between symmetrical ketoximes (R′ = R) and divinyl ketone **2** (or its equivalents) is selective for cycloadducts **3** or **4**, depending on solvent or additive.[1] Reductive cleavage of **3** and **4** can afford *piperidones* **5** and *perhydroazepinones* **6**, potentially making these Class 2 cascades viable routes to various alkaloids and other related natural products (Scheme 1).[2] We have been exploring the



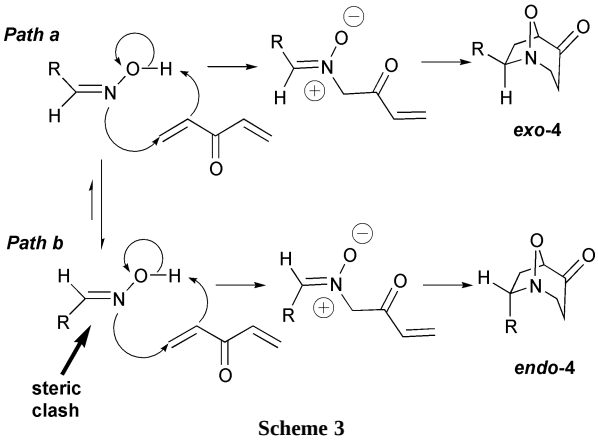
Scheme 1

scope of this reaction with aldoximes **1** (R or R′ = H). Under thermal reaction conditions (81 °C, acetonitrile) symmetrical ketoximes (R = R′) afford mixtures of **3** and **4**, whereas aldoximes (R or R′ = H) afford **4** only (as a mixture of *exo*- and *endo*-isomers) (Scheme 2).



Scheme 2

Under thermal reaction conditions aldoximes isomerise to a mixture of *E*- and *Z*-isomers. The rate of *E*/*Z* equilibration is dependent on temperature and the nature of the aldoxime R group. The desired 1,3-azaprotiocyclotransfer process (herein referred to as 1,3-APT) (Scheme 3) can occur between either *E*- or *Z*-oxime isomer and **2** to form respective *E*- and *Z*-nitrones. Nitrones are not expected to isomerise under the reaction conditions.[3] Intramolecular 1,3-dipolar cycloaddition then proceeds completely regioselectively from the *Z*-nitrone affording *exo*-**4** (*path a*) or the *E*-nitrone affording *endo*-**4** (*path b*).[4] A survey of aldoximes **1a**–**f** showed that the diastereoselectivity of the reaction is dependent on the size of the aldoxime R group (Table 1). Increasing the size of the R group (aldoximes **1b**–**d**) resulted in a decrease in *exo*-selectivity. However, the case of **1e** perturbed this trend, affording *exo*-**4e** as the sole product.



Scheme 3

It is proposed that *path a* and *path b* can have different rate determining steps. In *path a*, oxime isomerism can become the rate determining step when the steric clash resulting from the *cis*-relationship of the R and hydroxy moieties in the *Z*-oxime is severe or due to the electronic properties of R (*vide infra*). In contrast, 1,3-APT is rate determining in *path b* because the R group impedes the reactivity of the lone pair. The ratio of *exo*- and *endo*-products is determined by the relative rates of these steps and this is determined by the nature of R. Predominant formation of *exo*-**4** (*e.g.* for aldoximes **1a**,**b**) indicates that oxime *E*/*Z*-isomerism is faster than *E*-oxime 1,3-APT.

Though an increase in the size of the R group will decrease both the rate of oxime isomerism and *E*-oxime 1,3-APT, we propose that the effect is more pronounced on the oxime isomerism step due to the increased steric clash between the R and hydroxy moieties. The *E*-oxime 1,3-APT step can occur

provided the oxime R substituent contains an α-hydrogen (as in **1a**–**d**). This allows conformations where a C–H bond, as opposed to a C–R′ bond, impedes the reactivity of the lone pair. As the size of R increases, the increasingly sluggish nature of the *E*-oxime 1,3-APT step is reflected in the lower yields and conversions (Table 1). Where the oxime contains no α-hydrogens (**1e**) severe impediment of the lone pair's reactivity is unavoidable and 1,3-APT can only proceed *via* the *Z*-oxime (*path a*). The sluggish nature of the oxime isomerism step for **1e** is reflected in the low conversion (25% after 48 h) and yield (11%).

Unlike aliphatic oximes (*E*)-benzaldoxime **1f** does not isomerise at 81 °C. Both *E*- and *Z*-isomers can be prepared and stored separately.[5,6] The observation that (*E*)-**1f** forms *endo*-**4f** exclusively while (*Z*)-**1f** affords *exo*-**4f** exclusively (Table 2) supports our hypothesis. In order to determine the effect of the electronic nature of the aryl ring on oxime isomerism we carried out the cascade with both *E*- and *Z*-isomers of *para*-substituted benzaldoximes (Table 2). We observed that the presence of electron donating groups promotes oxime isomerism, affording mixtures of *exo*- and *endo*-isomers. The presence of electron withdrawing groups in the aromatic ring does not promote oxime isomerism and instead 'switches off' the 1,3-APT step for *E*-oxime isomers. Switching to the *Z*-isomers in the case of these electron deficient benzaldoximes allows the reactions to proceed, leading to *exo*-**4** exclusively.

Increasing the reaction temperature from 80 to 95 °C (closed system) resulted in an increase in the propensity of aliphatic aldoximes to form the *exo*-isomer (Table 3). We were able to utilise this effect in the case of phenyl acetaldehyde oxime (**1a**), attaining *exo*-selectivity of 8 : 1 (81%) when the reaction temperature was 120 °C (closed system) (Table 3). Similarly, **1b** afforded an 8 : 1 ratio of *exo*-**4b** and *endo*-**4b** (65%). Increasing the temperature of the system further (150 °C) resulted in identical *exo*-selectivity, however. It is proposed that high temperatures facilitate higher rates of *E*/*Z*-oxime equilibration, leading to enhanced *exo*-selectivity.[7]

In conclusion we have demonstrated that this tandem 1,3-APT-cycloaddition cascade between aldoximes and divinyl ketone can afford single diastereomers with predictable *exo*- or *endo*-stereochemistry by a correct choice of conditions: high temperatures for aliphatic aldoximes and correct choice of starting oxime for aromatic aldoximes.

Received (in Cambridge, UK) 5th July 2000, Accepted 11th September 2000
First published as an Advance Article on the web 2nd October 2000

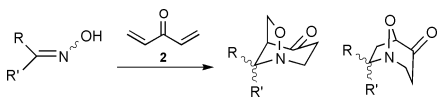
The tandem 1,3-azaprotiocyclotransfer–cycloaddition reaction between aldoximes and divinyl ketone affords the *exo*-isomers of substituted 1-aza-8-oxabicyclo[3.2.1]octan-4-ones when a substoichiometric amount of hafnium(IV) chloride is added.

As part of our continuing interest in cascade cycloaddition reactions of oximes we recently outlined our efforts to incorporate divinyl ketone **2** as a bifunctional azaprotiophile/dipolarophile component[1] in Class 2 processes.[2] The reaction between **2** and symmetrical ketoximes **1** (R′ = R) proceeds smoothly to afford a regioisomeric mixture of isoxazolidinones **3** and **4**, where **4** is the major product (Scheme 1). We were able to obtain **3** (R = R′) as the major product by the addition of a stoichiometric amount of zinc bromide and to bias the cascade in favour of **4** (R = R′) by a judicious choice of solvent. Preliminary investigations of aldoxime **1** (R′ or R = H)-**2** cascades gave **4** as the major product and **3** was rarely detected.[3] The *exo*-:*endo*-ratio was shown to be dependent on the geometry of the starting oxime and its propensity to isomerise under thermal conditions. The addition of zinc bromide was found to be much less effective for aldoxime cascades than for symmetrical ketoxime cascades, prompting us to seek an alternative Lewis acid. We now report a regio- and stereoselective hafnium(IV) chloride catalysed aldoxime-**2** cascade.

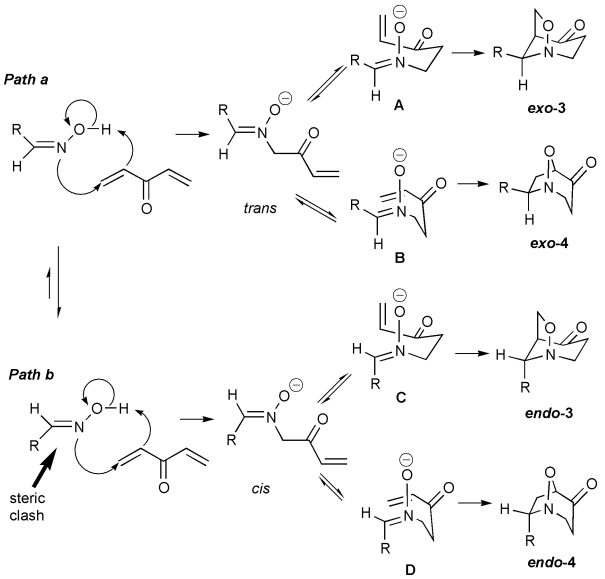
The reaction between an achiral aldoxime **1** (R or R′ = H) and **2** can in principle occur *via* a number of pathways, including the synthetically less useful *O*-Michael addition. Polymerization of **2** is also a potential problem. Generally both *E*- and *Z*-aldoxime isomers can undergo 1,3-azaprotiocyclotransfer (herein referred to as 1,3-APT) to afford *E*- and *Z*-nitrones respectively.[3] Subsequent cycloaddition of each nitrone can afford four possible diastereomeric products *exo*-**3**, *exo*-**4**, *endo*-**3** and *endo*-**4** (Scheme 2). Under thermal conditions (81 °C, acetonitrile) *exo*-**4** and *endo*-**4** are the exclusive products.

Amongst the Lewis acids tested were salts of lanthanides, titanium, indium and magnesium. These have been reported to catalyze 1,3-dipolar cycloaddtions.[4] The majority of these salts directed the regioselectivity of the cascade towards *exo*-**3** but the results were capricious in terms of yield. Hafnium(IV) chloride appeared to be the least detrimental and was selected for further optimisation. The mode 2 conditions outlined in Table 1 afford reproducible results.[5]

Thus treatment of aryl and aliphatic aldoximes **1a**–**j** with hafnium(IV) chloride resulted in complete reversal of the



Scheme 1



Scheme 2

selectivity of the thermally controlled cascade, giving exclusive formation of *exo*-**3a**–**j** (Table 1). The scope of the reaction includes aliphatic aldoximes (entries **a**–**c**), electron deficient aryl aldoximes (entries **f, g, h**) and electron rich aryl aldoximes (entry **i**). In many cases the addition of hafnium(IV) chloride was necessary for a reaction to occur (entries **f**, **g**, **h**).

Both *E*- and *Z*-isomers of benzaldoxime (**1d**,**e**) afford the same product under the hafnium(IV) chloride catalysed conditions. In the absence of hafnium(IV) chloride **1d** and **e** each afford different *exo*- and *endo*-diastereomers of **4**, due to the inability of these oxime isomers to equilibrate at 81 °C.[2,3] Thus hafnium(IV) chloride promotes oxime isomerism. This may be by co-ordination of hafnium to the oxime *via* the hydroxy moiety and the subsequent lowering of its pK_a or the release of a catalytic amount of HCl from hafnium(IV) chloride and traces of water.[6,7] Only a small equilibrium concentration of the *Z*-oxime is required for exclusive formation of the *Z*-nitrone.[8] Though we have evidence to suggest that hafnium(IV) chloride enhances the rate of the 1,3-APT step, it's precise role is a matter of conjecture at this time.[9]

The regiochemistry, which is dictated by the relative magnitudes of the interacting orbital coefficients, is completely reversed by the addition of hafnium(IV) chloride. This particular cycloaddition is expected to be $HOMO_{nitrone}$–$LUMO_{alkene}$ controlled and is predicted to result in bond formation between the oxygen and the terminal alkene carbon as in **A**, ultimately leading to **3**.[10] However, Gandolfi and co-workers have shown experimentally that only strongly electron withdrawing alkenes (*e.g.* nitroethylene) and electron rich nitrones (*e.g.* triphenyl nitrones) react in this way.[11] Otherwise, mixtures of regio-

isomers are formed. Co-ordination of the hafnium to the ketone as depicted in Fig. 1 will alter the relative magnitudes of the atomic coefficients favouring **A** (leading to *exo*-**3**) over **B** (leading to *exo*-**4**).

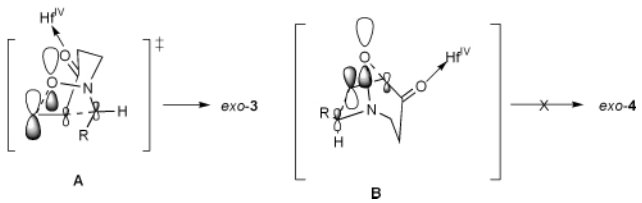

Fig. 1

Hafnium(IV) chloride is a highly effective catalyst for aldoxime–divinyl ketone cascades. There are only a few reports[12] of the use of hafnium salts in organic synthesis. To the best of our knowledge this is the first example of a hafnium promoted 1,3-dipolar cycloaddition.

An ultimate species in the substrate oxidation process by cytochrome P-450

Masayuki Hata,* Tyuji Hoshino and Minoru Tsuda

Laboratory of Physical Chemistry, Faculty of Pharmaceutical Sciences, Chiba University, Chiba 263-8522, Japan. E-mail: hata@pn120.p.chiba-u.ac.jp

Received (in Cambridge, UK) 3rd August 2000, Accepted 31st August 2000
First published as an Advance Article on the web 2nd October 2000

We propose a structure for the ultimate species which gives a straightforward explanation of the major results in the oxidation of hydrocarbons by cytochrome P-450 where the stereochemistry is retained and the isotope effect is small.

In the substrate oxidation process by cytochrome P-450 it was believed that the ultimate species is compound **I** [(heme)Fe=O] (Fig. 1).[1] Recently, Harris and Loew[2] showed that the spin-density of compound **I** in the spin doublet state (the ground state of this compound) is localized at the oxygen atom that is bound to the Fe atom of the heme, *i.e.* the spin-density is 0.92, indicating that the oxygen atom has the character of a free radical. The summation of the spin-densities shared by the heme and the fifth ligand gives a value of 0.08. We re-confirmed this spin-density distribution of compound **I** by performing similar calculations using density functional theory (DFT).[3]

It is well known that a free radical abstracts a hydrogen atom from hydrocarbons.[7] We found that compound **I** abstracts a hydrogen atom from hydrocarbons and produces Fe–OH with an activation energy of 15.5 kcal mol^{-1}. The hydrogen abstraction from hydrocarbons has been considered to be one of the plausible mechanisms caused by the ultimate species, compound **I**, and the substrate oxidation process by cytochrome P-450 should be as in the two-step mechanism shown in Fig. 1(a).[1,8] This two-step mechanism has the characteristics that (*i*) the stereochemistry is lost, and (*ii*) an isotope effect is clearly observed.[1,8]

The hydroxylation of a hydrocarbon by cytochrome P-450, however, generally occurs with retention of stereochemistry and a small isotope effect.[1,8] The concerted insertion of an oxygen atom into a hydrocarbon C–H bond [Fig. 1(b)] is therefore, favorable from this viewpoint. In order to examine the possibility of the one-step mechanism [Fig. 1(b)], a theoretical study has been preformed.

Firstly, we carried out the molecular dynamics (MD) simulations for 300 ps at 310 K on oxy-ferrous P-450cam in water, and showed that the substrate–oxygen molecule interaction is maintained in the heme pocket of cytochrome P-450cam, *i.e.* the distance between the C5 atom of d-camphor and the oxygen atom which is not directly bound to the Fe atom of the heme (the distal oxygen atom, O2) is *ca.* 3.0–3.5 Å (3.22 Å in Fig. 2). It is considered that the interaction between the substrate and the oxygen molecule bound to the Fe atom of the heme is always effective throughout the substrate oxidation process by cytochrome P-450. Experiments by Tuckey and Kamin[14] support the existence of the substrate–oxygen molecule interaction in the heme pocket, *i.e.* the 1-electron-reduced–oxygenated complex of cytochrome P-450 is kinetically stabilized by the binding of the substrate.

From Fig. 2 it is natural to consider that the distal oxygen atom is inserted into the C5–H bond of d-camphor. From this the revised ultimate species shown in Fig. 3 is proposed. Because it exists at a minimum in the potential energy hypersurface, the structure of this compound is stable. The potential energy of the structure is 59.8 kcal mol^{-1} higher than the sum of the potential energies of compound **I** and H_2O. However, it is considered that formation of the revised ultimate species could occur, because reduced oxy-ferrous heme is stabilized by > 700 kcal mol^{-1} upon binding of two protons to form each ultimate species. For the revised ultimate species

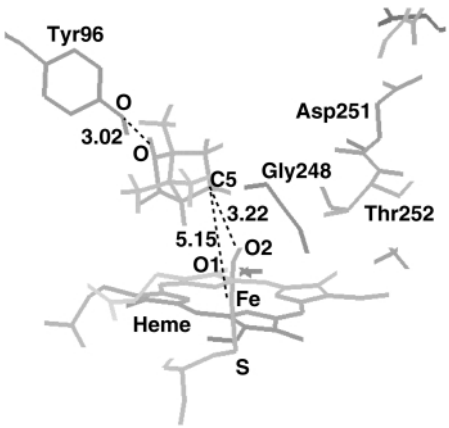

Fig. 2 Schematic of oxy-ferrous P-450cam obtained by 300-ps MD simulation at 310 K. Numerals are inter-atomic distances in Å. Computational program is AMBER 4.1.[9] A united-atom force field[10] was applied except for d-camphor, for which an all-atom force field[11] was used. Calculations of the non-bonded term were accelerated by the use of a hardware accelerator (MD Engine).[12] A cutoff distance (8 Å) was applied for computation of van der Waals forces (r^{-6} and r^{-12}). The electrostatic term (r^{-1}) was calculated with no cutoff, taking full advantage of the MD Engine. The SHAKE constraint,[13] where all of the bonds are kept at equilibrium distances, was used.

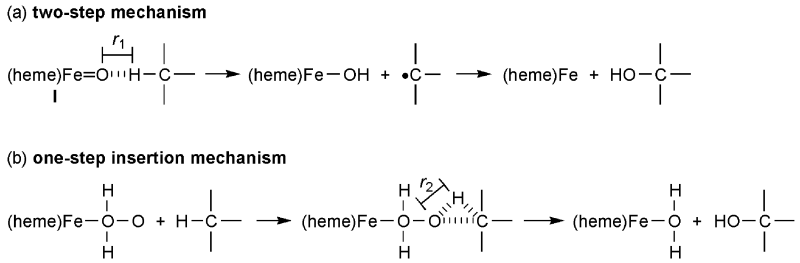

Fig. 1 Two processes in the substrate oxidation by cytochrome P-450: (a) two-step mechanism by the currently believed ultimate species, compound **I**, which has an active oxygen atom in the spin doublet state; (b) one-step insertion mechanism by the newly proposed ultimate species which has an active oxygen atom in the spin singlet state. The existence of these two processes gives complicated results in the oxidation products by cytochrome P-450.

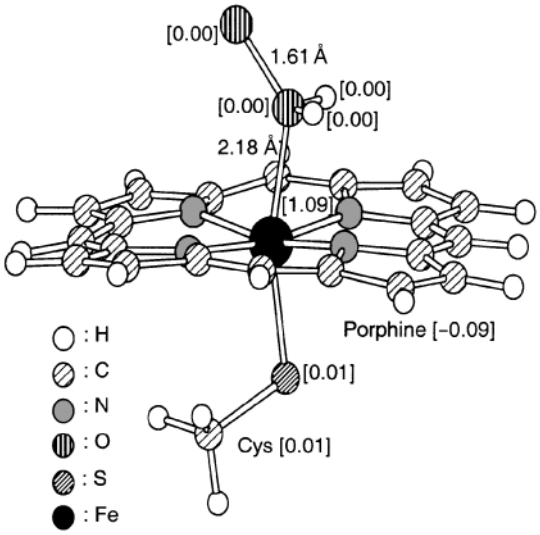

Fig. 3 Spin-density distribution of the stable structure of the newly proposed ultimate species for the mono-oxygenation reaction by cytochrome P-450. Numerals in parentheses are the spin-densities. The total electronic charge of the model compound is neutral and the total spin multiplicity is that of a doublet.

(Fig. 3) it should be noted in the spin-density distribution that the distal oxygen atom is in the spin singlet state, and it has already been suggested that a spin singlet state oxygen atom ^{1}D operates a one-step insertion mechanism.[15] The activation energy of the insertion reaction of this singlet oxygen atom to the C5–H bond of d-camphor was calculated to be 4.2 kcal mol^{-1}. This value is very small, compared with the activation energy (13 kcal mol^{-1}) of singlet oxygen atom ^{1}D insertions into hydrocarbons,[15] suggesting the important role of the heme-protein in the substrate oxidation. It is clear that this revised ultimate species gives a straightforward explanation of the major results in the oxidation of hydrocarbons by cytochrome P-450, where the stereochemistry is retained and the isotope effect is small. The formation process of the ultimate species may be followed by the same experiment which support the formation of compound **I** except in the final process, where the conventional mechanism postulates the formation of the compound **I** and a free water molecule, but the new mechanism considers the oxygenated hydrocarbon and a water molecule which binds to the Fe atom of the heme. Provided that the interaction between a substrate and the distal oxygen in the heme pocket is weak enough that the interaction is not maintained throughout the substrate oxidation process, the conventional ultimate species (compound **I**) may be produced. It is well known that compound **I** is produced in the substrate oxidation process by peroxidase where the isotope effect is clearly observed.[16]

The mechanism shown in Fig. 1 is clearly explained by the existence of these two ultimate species. The two kinds of the ultimate species generated in the substrate oxidation process by cytochrome P-450 explains in a straightforward manner the reasons why a variety of products have been reported in the literature.[1,8]

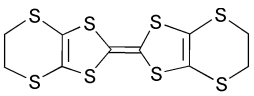
First published as an Advance Article on the web 2nd October 2000

Syntheses of fully unsaturated 5,6-diphenyl[1,3]dithiolo[4,5-*b*][1,4]dithiine-2-thione and its coupling product, a fully unsaturated analogue of BEDT-TTF, have been achieved by a 1,8-diketone ring formation reaction.

There has been wide interest in the synthesis of derivatives of bis(ethylenedithio)tetrathiafulvalene, BEDT-TTF (or ET) **1**.

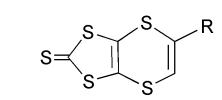


1

This is due to its electron donating ability, which makes it exhibit conducting and superconducting properties as charge transfer salts with electron acceptors such as TCNQ and mono anions.[1] The highest superconducting critical temperature, T_c, observed to date for an organic superconductor is 12.8 K with K-(BEDT-TTF)Cu[$N(CN)_2Br$].[2]

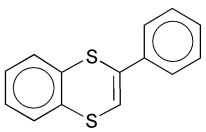
One of the important features, which has been the subject of efforts by various research groups, is the introduction of an increased conjugation, which would allow the system to have an extended π-electron delocalisation. So far, such an extension has been achieved in the middle of the molecule.[1b] However, there are limited examples of introduction of conjugation at the peripheral ethylene groups.[3]

Recently, we have reported a convenient method of synthesising fused 1,4-dithiin systems with various functional groups (**2**, **3**).[4] This method has allowed us to introduce four phenyl



R = Ph, 4-CH_3OPh, 4-NO_2Ph, CH_3, [7] 4-BrPh[7]

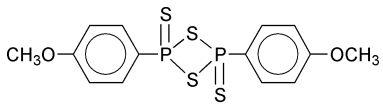
2



3

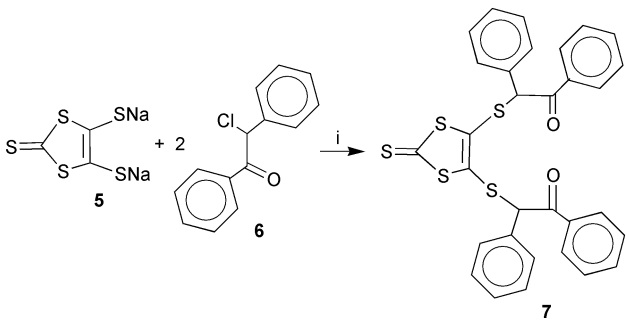
groups on to the peripheral ethylene bridges of BEDT-TTF, that is the synthesis of a tetra-phenyl substituted and fully unsaturated analogue, 5,5′,6,6′-tetraphenyl-2,2′bi([1,3]dithiolo[4,5-*b*][1,4]dithiinylidene) **11**, which has been the subject of research by other groups.[5] Unfortunately, their attempts have been unsuccessful so far, although trace amount of 5,6-diphenyl[1,3]dithiolo[4,5-*b*][1,4]dithiine-2-thione **10** was claimed to have been obtained.[5c] We report here that our 1,8-diketone ring-closure reaction smoothly gives the precursor **10** in a relatively high yield, 65%, which proves that this reaction may be an important tool in the formation of fused and fully substituted 1,4-dithiin rings.

In our previous report,[4] we disclosed that refluxing the 1,8-diketones in toluene with Lawesson's Reagent (LR) **4**



4

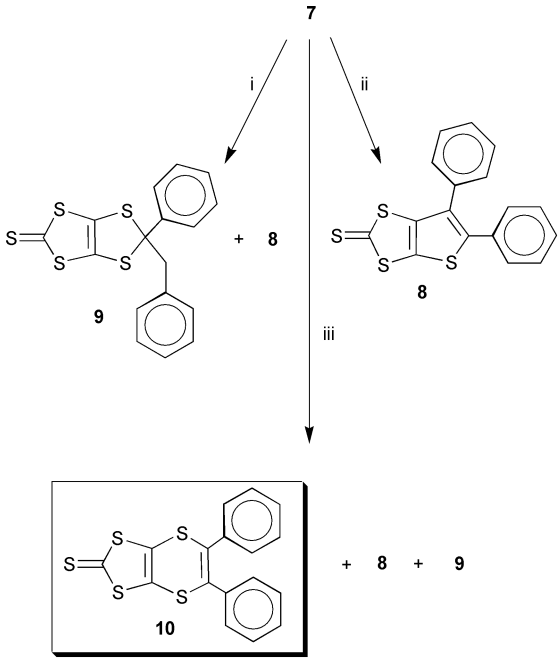
yielded fused thiophenes and 1,4-dithiins. The precursor **7**, which is the subject of the cyclisation reaction in this study, was easily obtained from the reaction of readily available dianion **5**[6] and desyl chloride† **6** in dry ethanol at rt in 90% yield (Scheme 1). Following the previous reaction conditions, the 1,8-diketone **7** was allowed to react with LR in boiling toluene overnight (Scheme 2). In agreement with the result reported by Noh *et al.*,[5b] fused thiophene rather than dithiin was isolated. Considering our preliminary results that such a ring formation reaction could be carried out with P_4S_{10} and tended to give 1,4-dithiin in a shorter reaction time, in another experiment, we treated **7** with P_4S_{10} in refluxing toluene.[7] Interestingly, this reaction, after 3 h reflux, gave **9** as one of the products, possessing a benzylphenyldithiole ring, along with the thiophene **8**, in 25 and 30% yields, respectively. This result suggested that, since there was no loss of sulfur, the initially *in situ* formed 1,4-dithiin derivative **10** rearranged radically to give benzylphenyldithiole **9**. Obviously, in the presence of sulfur as a source of radicals such a mechanism is likely. In view of all these experiences, cyclisation was performed with P_4S_{10} in refluxing toluene in the dark. After the consumption of starting material **7**, which took *ca*. 3 h, column chromatography of the crude reaction product (3 : 1, hexane–CH_2Cl_2) gave three compounds, thiophene **8** (20%), benzylphenyldithiole **9** (trace) and 1,4-dithiin **10**[8] (65%). The structures of **8**, **9** and **10** were confirmed by X-ray single-crystal diffraction analysis and the results will be published elsewhere.



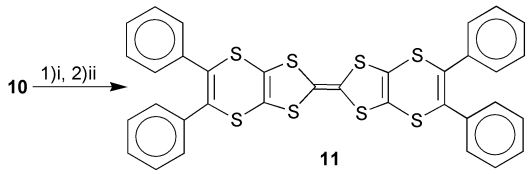
5 **6** **7**

Scheme 1 *Reagents and conditions*: i, EtOH (dry), N_2, rt, overnight.

With this fully unsaturated compound **10** in hand, which does not require storage under nitrogen, coupling product **11** was prepared following the well-established reaction scheme (Scheme 3). The thione sulfur atom in **10** was converted to oxygen with mercury acetate in a quantitative yield. Subsequent heating of the reaction product in neat triethylphosphite



Scheme 2 *Reagents and conditions*: i, P_4S_{10}, toluene, reflux, 3 h; ii, LR, toluene, reflux, overnight; iii, P_4S_{10}, toluene, reflux, dark, 3 h.



Scheme 3 *Reagents and conditions*: i, $Hg(OAc)_2$–AcOH, $CHCl_3$, 3 h, rt; ii, $(EtO)_3P$, 110 °C, N_2, 2 h.

(110 °C) for 2 h resulted a yellow precipitate of **11**,[9] which was collected in 90% yield. Contrary to the result reported for the coupling of the saturated analogue **12**, which gave tetrakis(ethylthio)tetrathiafulvalene **13** rather than its self-coupled product **14**,[5a,c] the fully unsaturated **10** yielded **11** smoothly in a high yield. This result further suggests that unsaturated dithiin ring contributes to the stability of the molecule through conjugation.

In conclusion, we have demonstrated that a fully substituted and fused 1,4-dithiin derivative can easily be prepared by a 1,8-diketone ring-formation reaction, using P_4S_{10}, and also a fully unsaturated analogue of BEDT-TTF has been prepared in an efficient procedure and in a good yield. The precursor **10** and the analogue **11** themselves could prove useful as electronic materials.

Received (in Cambridge, UK) 31st July 2000, Accepted 7th September 2000
First published as an Advance Article on the web 2nd October 2000

Microporous aluminosilicates have been synthesized in the presence of organic surfactants according to a procedure based on a two-step sol–gel process at room temperature; varying the surfactant chain length and/or the Si/Al ratio, materials with pore diameters adjustable in the range 1.0–2.5 nm have been obtained; the Al atoms in the as-synthesized samples present tetrahedral coordination, even for materials with high Al content (Si/Al = 6).

The M41S family of surfactant-templated mesoporous silicates and aluminosilicates was discovered and characterized in 1992 by Mobil Oil researchers.[1] The presence of Al atoms incorporated into the walls and large pores provide these materials with interesting properties for the catalytic conversion of bulky molecules.[2–4] In past years, a number of studies have been published aimed to the synthesis of mesoporous materials with increasing pore size by incorporation of swelling agents to the synthesis medium or by using block copolymer surfactants.[5–8] Accordingly, micelle-templated silicates and aluminosilicates have been prepared with uniform pore sizes in the range 2–10 nm.[9–13] However, less attention has been devoted to the synthesis of surfactant-templated materials with pore diameters below 2.0 nm. This is an interesting goal as it would contribute to fill the pore size gap existing between microporous zeolitic materials (D_p < 1 nm) and surfactant-templated mesoporous solids (D_p > 2 nm). Moreover, materials with uniform pore size in the range 1.0–2.0 nm are expected to exhibit interesting shape-selectivity properties in the conversion of large substrates.

Several papers have recently appeared with the aim of obtaining surfactant templated materials with small pore diameters. Thus, a novel method for tailoring the pore opening size of MCM-41 materials has been reported,[14] although based on a complex post-synthesis treatment with three steps. A completely different approach has been developed by Bagshaw and Haymann,[15] which has led to silicates with pore sizes in the range 1.4–2.0 nm through the use of a new family of ω-hydroxy-bolaform surfactants. However, at present it is not clear whether this last alternative would also allow microporous aluminosilicates to be synthesized.

In a recent work,[16] we have reported a new method for the preparation of Al-containing micelle-templated silica (Al-MTS) based on a sol–gel process at room temperature. We have found that when increasing the aluminium content, materials with pore sizes in the range 1.5–2.0 nm are obtained. In the present work we show that this method is also useful for the synthesis of Al-MTS solids with pore sizes that can be tailored in the range 1.0–2.0 nm through the variation of both surfactant alkyl chain length and Al content.

The materials were synthesized at room temperature according to the following procedure. The silica and aluminium sources (tetraethyl orthosilicate, TEOS, and aluminium isopropoxide, IPA) were first hydrolyzed under acidic conditions (aqueous HCl), the starting Si/Al ratio being varied within the range 5–30. The surfactant was added and the mixture obtained was stirred and kept under acidic conditions for 1 h (TEOS/Surf. molar ratio = 0.3). Both cetyltrimethylammonium chloride (CTMACl) and dodecyltrimethylammonium bromide (DTMABr) were employed as surfactants. In a second step, condensation reactions were promoted by dropwise addition of 2 wt% aqueous NH_3 until the gel point is reached. The solid material so obtained was filtered off, washed with deionized water and dried at 110 °C overnight. Finally, it was calcined in N_2 flow at a heating rate of 1 °C min^{-1} up to 550 °C and then kept in air flow at this temperature for 5 h.

Table 1 summarizes the physicochemical properties of different Al-MTS materials prepared. Although in general the samples obtained show Al contents lower than those of the synthesis mixture, a close correspondence is observed among them, even for the synthesis with the lowest Si/Al ratios. TG analysis of the as-synthesized samples show the presence of the surfactant molecules occluded in the pores with weight losses in the range 40–55 wt%, confirming that they can be regarded as micelle-templated materials. Fig. 1 illustrates the XRD spectra of samples prepared with surfactants of different chain length, a sharp diffraction peak at low angle being observed, which is

Table 1 Synthesis conditions and physicochemical properties of the synthesized materials

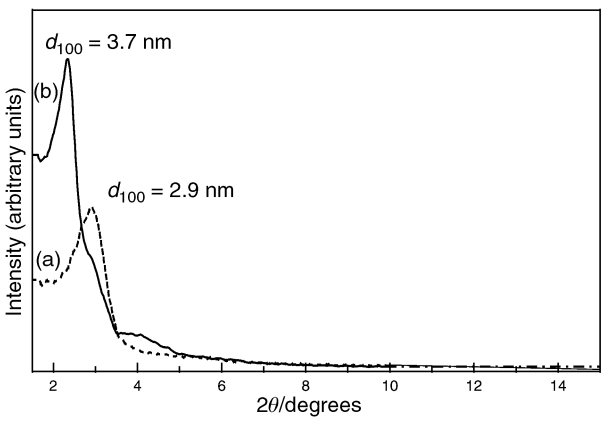

Fig. 1 XRD spectra of calcined samples: (a) DTMABr, Si/Al = 6.3 and (b) CTMACl, Si/Al = 45.2.

DOI: 10.1039/b006186g

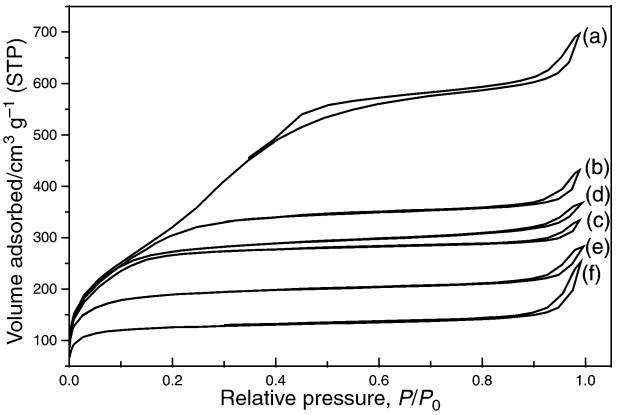

Fig. 2 N_2 adsorption–desorption isotherms: (a) CTMACl, Si/Al = 45.2; (b) CTMACl, Si/Al = 31.5; (c) CTMACl, Si/Al = 8.3; (d) DTMABr, Si/Al = 42.4; (e) DTMABr, Si/Al = 18.9; (f) DTMABr, Si/Al = 6.3.

characteristic of M41S amorphous structured materials. The *d*-spacings of the calcined samples prepared with DTMABr are higher than those obtained with CTMACl, which shows that a lower chain length of the surfactant leads to a reduction in the unit cell size.

Fig. 2 compares the N_2 adsorption–desorption isotherms at 77 K of a number of samples synthesized varying both the surfactant and the starting Si/Al ratio. A type IV isotherm is obtained for the sample prepared using CTMACl and Si/Al = 45.2, which is typical of a mesoporous material. This sample shows a pore diameter of 2.5 nm, calculated by the BJH method. However, increasing the Al content and/or reducing the alkyl chain length of the surfactant leads to type I isotherms, typical of microporous solids, which is accompanied by a decrease in both surface area and pore volume. Fig. 3 shows the variation in the pore size of these samples *vs.* the Al content. For both surfactants, the pore diameter is progressively reduced as the Al content is increased, showing that the presence of aluminium species during the synthesis process strongly affects the ionic surfactant-templated mechanism. For the samples prepared using CTMACl, the lowest pore diameter obtained is 1.5 nm, clearly within the micropore region. Interestingly, this limit can be reduced using DTMABr as surfactant, which leads to the synthesis of materials with pore sizes in the range 1.0–1.7 nm.

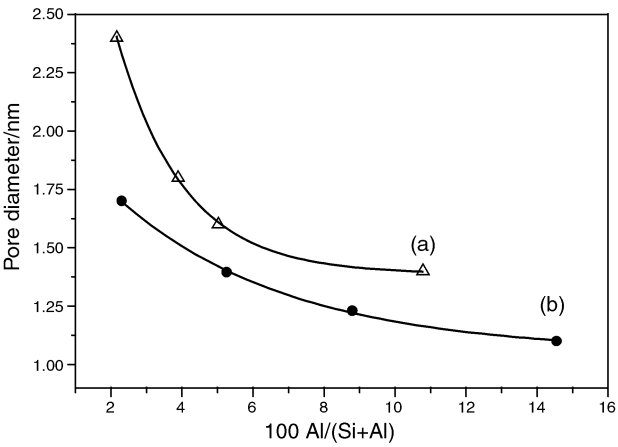

Fig. 3 Relationship between the pore diameter and the aluminium content of the samples: (a) CTMACl (pore diameters calculated according to the BJH method) and (b) DTMABr (pore diameters calculated according to the Saito–Foley method).

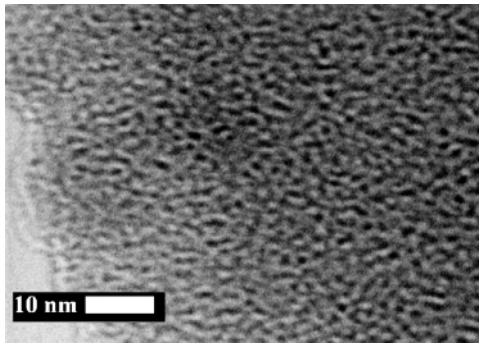

Fig. 4 TEM micrograph of the sample with Si/Al = 6.3 synthesized using DTMABr as surfactant.

These results are further confirmed by TEM micrographs of the samples (see Fig. 4). The pore diameters measured in these micrographs agree well with those derived from the N_2 adsorption measurements. Moreover, from XRD spacings and pore diameters, a large wall thickness (1.5–2.0 nm) is obtained. This result may be also important in terms of the stability of these materials.

In order to study the Al environment in the samples, ^{27}Al MAS NMR spectra were measured, which show that in the as-synthesized materials all the Al atoms present tetrahedral coordination. This result indicates that even for samples with high aluminium content (Si/Al = 6), most of the Al species are effectively incorporated into the pore walls.

In summary, it can be concluded that using this new synthesis method, and through a suitable combination of surfactant chain length and Al content, Al-MTS materials with pore size adjustable in the range 1.0 - 2.5 nm can be prepared.

This work was funded by the Spanish Comisión Interministerial de Ciencia y Tecnología (CICYT), project number AMB-97/0530, and by Comunidad de Madrid, Strategic Group Project.

Two photoluminescent two- and three-dimensional coordination polymers consisting of Zn_4O [or $Zn_4(OH)_2$] cores, dicarboxylate (isophthalate or fumarate) and 4,4′-bipyridine ligands as building blocks have been hydrothermally synthesized and structurally characterized.

The construction of supramolecular architectures are currently of great interest owing to their intriguing network topologies and potential functions as new classes of materials.[1] Polynuclear d^{10} metal (Cu^I, Ag^I, Au^I, Zn^{II} or Cd^{II}) complexes have been found to exhibit intriguing structural and photoluminescent properties.[2–5] We have been pursuing synthetic strategies for non-interpenetrating open frameworks with variable cavities or channels using simple units as building blocks.[6] We now extend to work towards extended networks based on metal clusters as building blocks, and report here the preparation and crystal structures of two novel coordination polymers constructed by zinc cluster cores, 4,4′-bipyridine (4,4′-bpy) and dicarboxylate ligands, namely $[Zn_4O(ip)_3(4,4'\text{-bpy})]$ (ip = isophthalate) **1** and $[Zn_4(OH)_2(fa)_3(4,4'\text{-bpy})_2]$ (fa = fumarate) **2**.

The hydrothermal reactions of zinc salts with the dicarboxylates and 4,4′-bpy in molar ratio 1 : 1 : 1 at 180 °C (7 days) and 140 °C (60 h) led to the formation of colourless **1** and **2**, respectively. Elemental analysis confirmed the formulae of **1** and **2**.‡ Thermogravimetric analysis (TGA) performed on the polycrystalline samples indicate that they are thermally stable up to 380 °C, in accord with the fact that hydrothermal products are usually stable.

X-Ray single-crystal analysis§ has revealed that **1** contains two-dimensional polymeric grids with supertetranuclear Zn_4O cores as building units, in which each zinc atom is coordinated by the central μ_4-oxo atom, two oxygen atoms from two μ-carboxylate, and a monodentate carboxylate or 4,4′-bpy groups to furnish tetrahedral coordination, as shown in Fig. 1. The average Zn–O length (1.971 Å) is somewhat longer than that (av. 1.939 Å) found in $[Zn_4O(O_2CPh)_6]$.[5] The ip ligands in **1** act in both bisbidentate and bismonodentate modes, though the Zn(2)–O(4) distance of 2.547(2) Å suggests a non-negligible interaction, or semi-chelate coordination mode for the bismonodentate tp ligand.[7] The different coordination environments around two crystallographically independent zinc atoms may be attributed to the different Zn–O(oxo) distances, the Zn(2)–O(5) bond (1.993 Å) is much longer than that (1.931 Å) of Zn(1)–O(5).

The most striking feature of **1** is the connection of Zn_4O cores *via* organic ligands to form infinite two-dimensional networks with two different types of cavities (8.7 × 8.7 and 8.7 × 10.4 Å), as shown in Fig. 2. The Zn_4O cores are bridged by bismonodentate and bisbidentate ip ligands into infinite one-dimensional ladder-like $[Zn_4O(ip)_3]$ chains, and adjacent ladders are interlinked through μ-4,4′-bpy spacers, resulting in a novel two-dimensional grid. It is noteworthy that the topology of **1** can be simplified to (4,4) if we connect only the core (O5) of the supertetrahedra.

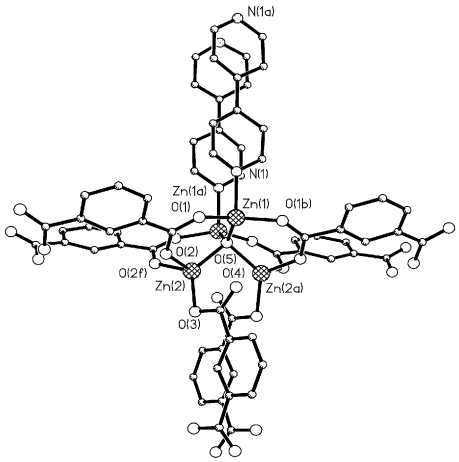

Fig. 1 The coordination environments of zinc atoms in **1**. Selected bond distances (Å) and angles (°): Zn(1)–O(1) 1.970(2), Zn(1)–O(5) 1.931(1), Zn(2)–O(2) 1.989(2), Zn(2)–O(3) 1.969(3), Zn(2)–O(5) 1.993(2), Zn(1)–N(1) 2.076(3); O(1)–Zn(1)–N(1) 96.4(1), O(1)–Zn(1)–O(5) 113.1(1), O(5)–Zn(1)–N(1) 117.0(1), O(2)–Zn(2)–O(3) 94.0(1), O(2)–Zn(2)–O(5) 108.3(1), O(3)–Zn(2)–O(5) 128.8(1).

Complex **2** is made up of an infinite interpenetrating three-dimensional framework with $Zn_4(\mu_3\text{-}OH)_2$ cores and organic bridges. Unlike **1**, the tetranuclear core in **2** is unprecedented in zinc coordination chemistry, and similar to the butterfly-like tetranuclear manganese complexes.[8] Atom Zn(1) is in a distorted octahedral geometry, coordinated by two μ_3-OH groups, one 4,4′-bpy group, and three oxygen atoms from one chelate and one monodentate carboxylate groups (Fig. 3). The Zn–O(hydroxo) distances are compatible to those documented

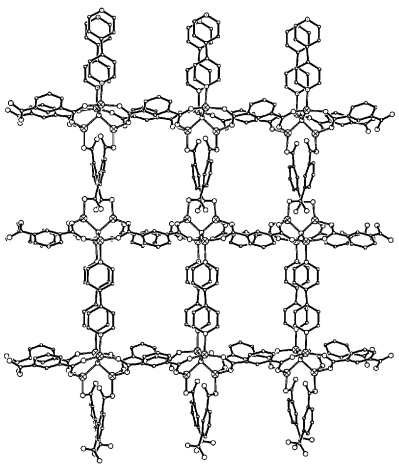

Fig. 2 Perspective view of the two-dimensional framework of **1**.

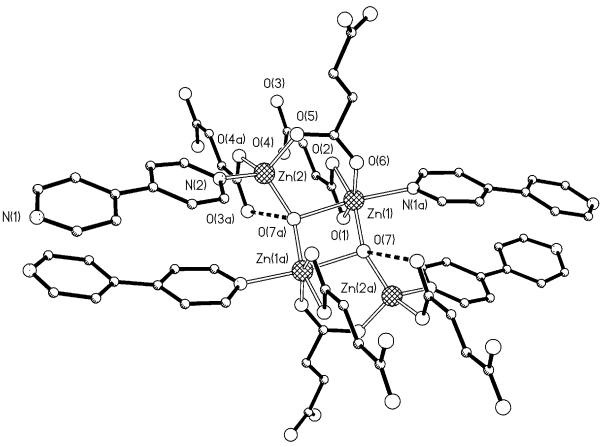

Fig. 3 The coordination environments of zinc atoms in **2**. Selected bond distances (Å) and angles (°): Zn(1)–O(1) 2.367(4), Zn(1)–O(2) 2.089(4), Zn(1)–O(6) 2.054(4), Zn(1)–O(7) 2.015(3), Zn(1)–N(1a) 2.192(4), Zn(2)–O(4a) 1.973(4), Zn(2)–O(5) 1.955(3), Zn(2)–O(7a) 1.950(3), Zn(2)–N(2) 2.054(4), O(7a)···O(3a) 2.755(5); O(1)–Zn(1)-O(2) 58.8(1), O(6)–Zn(1)–O(7) 95.0(1), O(7)–Zn(1)–N(1a) 95.5(1), O(4a)–Zn(2)-O(7a) 109.4(1), O(5)–Zn(2)–O(7a) 110.9(1), O(7a)–Zn(2)–N(2) 116.8(2), O(4a)–Zn(2)–N(2) 105.0(1), O(5)–Zn(2)–N(2) 100.0(2).

in the literature.[9] The μ_3-OH group is also hydrogen-bonded to the monodentate carboxylate [O(7a)···O(3a) 2.755(5)Å]. Zn(2) atom is tetrahedrally coordinated by μ_3-OH, one 4,4′-bpy group and two oxygen atoms from two fa ligands. The $Zn_4(OH)_2$ cores are interlinked by the carboxylate groups of six fa ligands in both bisbidentate and chelate-monodentate fashions, resulting in infinite two-dimensional $[Zn_4(OH)_2(fa)_3]$ sheets [Fig. 4(a)], which are pillared by the 4,4′-bpy ligands to generate an infinite three-dimensional prismatic-like framework [Fig. 4(b)]. The actual crystal structure has two such 3D frameworks that interpenetrate each other. The topology of **2** can be related to the simple cubic α-Po two-fold interpenetrated lattice.

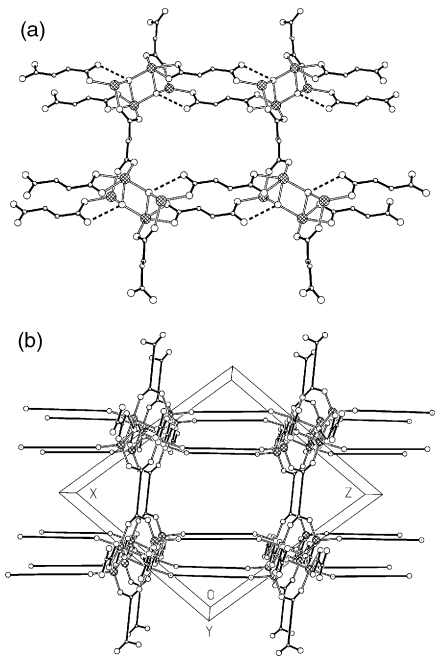

Fig. 4 Perspective views of the two-dimensional framework of $[Zn_4(OH)_2(fa)_3]$ (a) and the building unit of three-dimensional framework (b) of **2**. For clarity, both the 4,4′-bpy ligands and the ethylene groups of fa ligands in (b) are shown as solid lines.

It is noteworthy that **1** and **2** are the first examples of coordination polymers constructed by oxo or hydroxo metal clusters with mixed bridging organic ligands, though the first three-dimensional framework constructed by Zn_4O cores and dicarboxylates has recently been documented in $[Zn_4O(BDC)_3](DMF)_8(C_6H_5Cl)$ (BDC = 1,4-benzenedicarboxylate).[10]

In the solid state **1** and **2** exhibit intense photoluminescence upon photoexcitation at 320 and 398 nm, respectively. The emissions of **1** (λ_{max} = 432 nm) and **2** (λ_{max} = 453 nm) may be assigned as ligand-to-metal charge transfer (LMCT).[11] They may be good candidates for blue-light emitting diode devices, since these condensed materials are highly thermally stable and insoluble in common polar and non-polar solvents.

In conclusion, we have synthesised two stable polynuclear zinc polymers under hydrothermal conditions, providing a new synthetic route for metal coordination polymers with promising photoelectronic properties.

The structure of the phosphinyl radical, $\dot{P}R_2$ [R = $CH(SiMe_3)_2$], has been determined by gas-phase electron diffraction (GED) together with *ab initio* molecular orbital calculations, and that of the corresponding diphosphine, $(PR_2)_2$, has been established by X-ray crystallography; the diphosphine behaves as an energy storage reservoir.

In considering the homolytic cleavage of the E–E single bond of molecules of the general type $R'_nEER'_n$, the formation of the corresponding $R'_nE\cdot$ radicals is expected to be favoured by increased steric bulk of the substituents, R′. The conventional view is that such increases of steric strain would be manifested primarily in elongation of the E–E bond and that beyond a critical point of steric loading this bond would rupture. Herein we describe the X-ray crystal structure of the sterically encumbered diphosphine, $(PR_2)_2$ (**1**) (R = $CH(SiMe_3)_2$), and the gas-phase electron diffraction (GED) structure of the corresponding homolysis product, PR_2 (**2**), the exclusive species found in both solution and in the gas phase.[1] In conjunction with *ab initio* calculations on **2**, comparisons of the structural features of the radical with those of the cognate dimer **1** provide new insights into the origins of the stabilisation of **2** and related species.

Diphosphine **1** was prepared by the reduction of a hexane solution of $ClPR_2$ (**3**) as described previously[1] or by variations thereof.[2] Slow cooling of the filtered reaction mixture afforded both yellow crystals of **1** and colourless crystals of **3**, which were separated manually. Phosphinyl radical **2** was produced by melting or vaporising **1**.

One of the most interesting features of the crystal structure of **1**‡ (Fig. 1) is the P–P bond length [2.3103(7) Å]. While this is the longest such bond yet reported for a diphosphine, it is only ~0.1 Å longer than those reported for other diphosphines. Moreover, this modest lengthening amounts to a diminution of only ~4 kJ mol^{-1} in terms of the P–P bond dissociation energy. Previously reported distances for uncoordinated diphosphines $(PR'_2)_2$ include 2.260(1) Å (R′ = Mes),[3a] 2.246(2) Å (R′ = CF_3),[3b] 2.215(3) Å (R′ = Cy),[3c] 2.211(2) and 2.206(2) Å (R′ = Ph,C(O)Bu^t),[3d] 2.212(1) Å (R′ = Me)[3e] and 2.2051(11) Å (R′ = C_4Ph_4).[3f] Another noteworthy feature of the structure of **1** is the *syn,anti* orientation of the R ligands on each PR_2 fragment, which allows for a more efficient packing of the ligands around the P–P core than does the corresponding *syn,syn* orientation.

GED data†§ in conjunction with *ab initio* theoretical results revealed that **2** exists as a single *syn,syn* conformer of symmetry

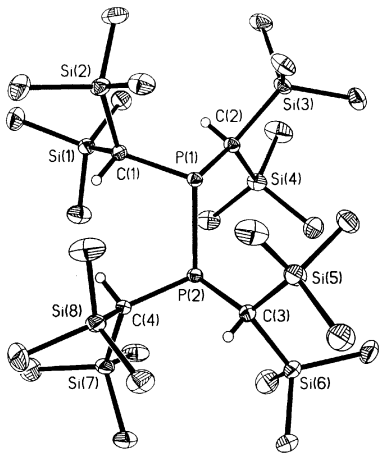

Fig. 1 Thermal ellipsoid plot (30% probability level) of $(PR_2)_2$ (**1**; R = $CH(SiMe_3)_2$). Selected bond lengths (Å), bond angles (°) and dihedral angles (°): P(1)–P(2) 2.3103(7), P(1)–C(1) 1.892(2), P(1)–C(2) 1.896(2), P(2)–C(4) 1.892(2), P(2)–C(3) 1.893(2), Si(1)–C(1) 1.905(2), Si(2)–C(1) 1.915(2), Si(3)–C(2) 1.918(2), Si(4)–C(2) 1.894(2), Si(5)–C(3) 1.892(2), Si(6)–C(3) 1.926(2), Si(7)–C(4) 1.921(2), Si(8)–C(4) 1.896(2), C(1)–P(1)–C(2) 103.57(9), C(1)–P(1)–P(2) 107.92(7), C(2)–P(1)–P(2) 104.83(6), C(4)–P(2)–C(3) 103.00(9), C(4)–P(2)–P(1) 106.98(6), C(3)–P(2)–P(1) 105.27(7), C(1)–P(1)–P(2)–C(4) 32.0(1), C(2)–P(1)–P(2)–C(3) 109.0(1), H(111)–C(11)–P(1)–C(12) 124.6, H(112)–C(12)–P(1)–C(11) 7.8, H(113)–C(13)–P(2)–C(14) −4.6, H(114)–C(14)–P(2)–C(13) 122.9.

C_2 in the gas phase [*cf.* the *syn,anti* found for $(PR_2)_2$]. The electron diffraction data for **2** in the C_2 geometry were fitted by use of the SARACEN method.[4] The final experimental structure (Fig. 2) is in reasonable agreement with that calculated by the Density Functional Theory (DFT) method at the UB3LYP/DZP level. The computed bond lengths generally exceed the experimental values by ~0.01–0.02 Å and the calculated angles within 1–2° of the GED values.

The change from the *syn,syn* to the *syn,anti* conformation represents the most obvious difference between the local geometries of the PR_2 fragments in **1** and **2**, and is a consequence of the packing requirements of the ligands about the P–P core of **1**. However, the price of this packing is that there is substantial steric strain, (a) within each R group, *i.e.* between the two $SiMe_3$ groups, (b) between the two R groups attached to each P atom, and (c) between the R groups on the two halves of the molecule. The steric strain is considerably greater in the diphosphine than in the radical, as evidenced by the distortions of the metrical parameters of **1** compared with those of **2**. For example, in **2** the root-mean-square variances from the means of the angles at carbon and silicon are 3.9 and

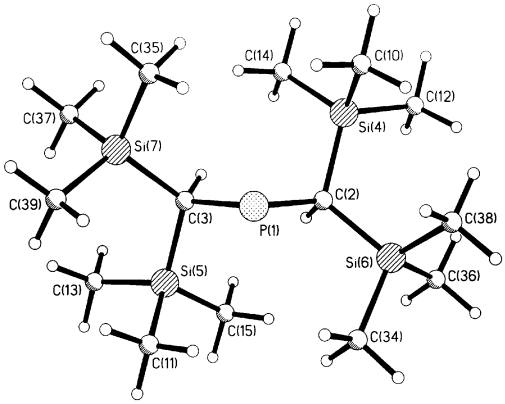

Fig. 2 Gas-phase electron diffraction structure of $\dot{P}R_2$ (**2**; R = $CH(SiMe_3)_2$). Selected bond lengths (Å), bond angles (°) and dihedral angles (°): P(1)–C(2) 1.856(9), C(2)–Si(6) 1.902(2), C(2)–Si(4) 1.905(2), Si(4)–C(10) 1.878(2), Si(4)–C(12) 1.878(2), Si(4)–C(14) 1.876(2), Si(6)–C(34) 1.880(2), Si(6)–C(36) 1.879(2), Si(6)–C(38) 1.875(2), C(2)–P(1)–C(2a) 103.9(10), P(1)–C(2)–H(8) 108.1(13), avg. P(1)–C(2)–Si 109.4(4), avg. Si(4)–C–Si(6) 117.5(5), H(8)–C(2)–P(1)–C(3) −26.4(8).

2.4° respectively, whereas in **1** they are significantly larger (15.3 and 4.1°). There are also increases in many of the bond lengths of the R ligands in **1**, the largest of which are close to the P–P core. In general, there is an attenuation of such bond length increases towards the molecular periphery.

In essence, the whole structure of **1** represents an energy storage reservoir, somewhat like a compressed spring, which, upon dissolution, melting or evaporation, is used to effect cleavage of the P–P bond. In sharp contrast, other diphosphines $P_2R'_4$ with sterically demanding substituents retain their P–P bonding in both solution and the gas phase. To gain further insights, we estimated the magnitude of steric relaxation in the dissociation process using DFT calculations, summarised in Fig. 3 (see ESI† for details). Single-point calculations on **1** (C–H bond lengths fixed at 1.08 Å) and the two fragments formed by breaking the P–P bond, $\mathbf{1A_1}$ and $\mathbf{1A_2}$, predict a P–P homolysis energy of 95 kJ mol^{-1}. The hydrogen atom positions in $\mathbf{1B_2}$ were then optimised. This energy change, which reflects the correction for unrefined placement of hydrogen atoms in the crystal, was 239 kJ mol^{-1}. The remaining atom positions in $\mathbf{1B_2}$ were then relaxed, to give structure $\mathbf{1C_2}$ releasing 52 kJ mol^{-1}. Finally, rotation of one of the R ligands around the P–C bond to form the optimised *syn,syn* conformation (**2**), analogous to that observed experimentally, releases a further 33 kJ mol^{-1} per radical. Thus, while the initial step in the homolysis reaction is endothermic, the relaxation and rotation of the R ligands releases at least 135 kJ mol^{-1}, more than sufficient to render the overall process exothermic.

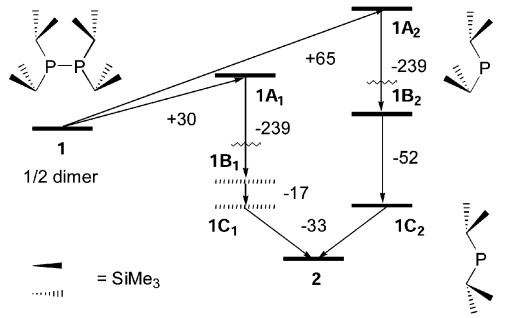

Fig. 3 Summary of DFT calculation results for diphosphine **1** in the solid-state geometry, the *syn,anti* phosphinyl radicals with solid-state geometries $\mathbf{1A_1}$ and $\mathbf{1A_2}$, with hydrogen atom positions relaxed ($\mathbf{1B_1}$ and $\mathbf{1B_2}$), the *syn,anti* phosphinyl radical in the optimised geometry **1C** (the same for both radical fragments), and the *syn,syn* phosphinyl radical in the optimised geometry **2**. Energies in kJ mol^{-1}.

An informative comparison can be made with some closely-related group 14 species. Analogous *syn,anti* to *syn,syn* conformational changes and similar dissociation energies are observed in the cleavage of $(MR_2)_2$ (M = Ge, Sn) into the MR_2 carbenoid fragments.[5] Again, the M–M distances in the solid are very similar to those in sterically less encumbered $M_2R'_4$ molecules. In contrast, the related $\{M[N(SiMe_3)_2]_2\}$ (M = Ge, Sn, Pb) species, while remaining monomeric in both the gas and the solid, change their conformations.[6]

In conclusion, the homolytic behaviour of **1** permits a new understanding concerning the functioning of bulky substituents. The shape and flexibility of the $CH(SiMe_3)_2$ ligands allows for the formation of the P–P bond in **1**. However, in the process of bond formation (and crystallisation) the molecule accumulates a large store of potential energy and is primed to spring apart upon release from the solid state. The potential energy of steric repulsion is not manifested in an elongated P–P bond, but is evidenced primarily by the deformation of the ligands. In this sense, the malleable R substituents act as the springs in a molecular jack-in-the-box.

We thank the EPSRC (UK), the National Science Foundation (USA) and the Robert A. Welch Foundation (UT) for financial support. We also thank R. Seip (Oslo) for collection of electron diffraction data, Dr. V. Typke of the University of Ulm for the variable-array version of ASYM40, and the UK Computational Chemistry Facility (admin: Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS) for the computing time on Columbus.

An *in situ* ATR (attenuated total reflectance)-IR study of CO_2 dissolved in two ionic liquids at high pressures has demonstrated the effects of the anionic species of the ionic liquids on the molecular state of the dissolved CO_2.

In the search for alternatives to conventional solvents partly driven by the need for 'green' chemistry and sustainable technology, but primarily because of the potential for novel synthetic routes, a number of media have been explored recently. These include supercritical fluids (SCF) and room-temperature ionic liquids (IL).[1] One of the challenges that exist in the use of ionic liquids is that it is often difficult to separate products from reactants, catalyst or solvent. Distillation of the solvent cannot be applied for separation because of the low vapour pressure of ionic liquids. The possibility of combining chemical reactions in IL with separations using SCF is of potential value.

Very recent work has demonstrated that supercritical (sc) CO_2 is highly soluble in certain ionic liquids while these ionic liquids are not measurably soluble in the $scCO_2$ phase.[2] This observation indicates that there is a potentially useful opportunity to separate $scCO_2$-soluble products from ionic liquids using SCF/liquid extraction. The 'tunable' solvent power of the supercritical fluid, owing to its variable (with pressure or temperature) solvent density may be utilised for extraction and separation of the products of chemical processing in ionic liquids (without, for example, removing catalyst from IL). Synthetic procedures and catalytic processes using IL media have been recently summarised[3] and the applications of SCF solvents for extraction, and in particular the role of spectroscopy in monitoring these processes, have also been reviewed.[4] The preliminary data showed that naphthalene could be extracted from an ionic liquid into $scCO_2$ phase.[2] However, the same authors later indicated that the presence of water in the IL had a significant effect on CO_2 solubility.[5] In this work the authors also speculated about the origins of the high solubility of CO_2 in ionic liquids, and the role of different anions.

A molecular-level insight into the state of CO_2 dissolved in IL is needed to elucidate the fundamental origin of this phenomenon. Here, we report an *in situ* ATR-IR study of CO_2 dissolved in two ionic liquids at high pressures. The advantage of a very shallow penetration (few microns) of the IR light in ATR-IR spectroscopy has been utilised to measure the spectrum of CO_2 dissolved in two ionic liquids. Ionic liquids based on the 1-alkyl-3-methylimidazolium cation in conjunction with either $[PF_6]^-$ or $[BF_4]^-$ {[bmim][PF_6] **I** and [bmim][BF_4] **II**}, were synthesised by established procedures.[3] ATR-IR spectroscopy overcomes some of the limitations inherent to other techniques when the objective is to gain spectra of molecules dissolved in highly absorbing media. It would be very difficult, if not impossible, to measure the IR spectrum of the bending mode of CO_2 dissolved in ionic liquids using transmission spectroscopy because of the strong absorbance of these ionic liquids in the important region of the bending mode of CO_2. The current ATR-IR method uses a modified commercial diamond ATR accessory (Specac, Ltd., UK) and a miniature high-pressure flow cell.[6] Diamond's ability to withstand high pressure was used to measure the spectra of CO_2 dissolved in IL at various pressures and temperatures. IR spectra were measured using an Equinox-55 FTIR spectrometer (Bruker) with DTGS and MCT detectors; resolution was 2 cm^{-1}. The cell was pressurised with CO_2 up to 200 bar at room temperature, equilibrated for periods from several hours to a few days, and the spectra were measured. The temperature of the cell could readily be varied from room temperature to 200 °C (for a schematic view of the cell see ESI†).

The IR spectrum of CO_2 dissolved in two ILs shows the bands corresponding to antisymmetric (not illustrated) and bending modes of CO_2. There was no difference in position of the bands corresponding to the ν_3 antisymmetric stretching modes of CO_2 dissolved in **I** and **II**. Both bands appear with the peak maximum at *ca*. 2338 cm^{-1} with the shoulder on the low-wavenumber side of the band. The position of this band of CO_2 dissolved in IL is very close to that of CO_2 dissolved in glassy polymers, such as PMMA[7] rather than the CO_2 incorporated in halogen salts of alkali metals[8] where the bands are observed in the region of 2150–2200 cm^{-1}. The absorbance of the ν_3 band is 0.35 for CO_2 dissolved in **I** at 68 bar and 40 °C. *In situ* ATR-IR spectroscopy provides a direct but approximate measurement of the solubility of CO_2 in IL; the effective pathlength for this band is *ca*. 1.5 μm, and using the same molar absorptivity for CO_2 as for CO_2 dissolved in water at high pressures[9] the solubility of CO_2 in **I** at these conditions is *ca*. 0.6 mol fraction (2 M). The absorbance of the ν_3 band of CO_2 dissolved in **II** is approximately 40% lower indicating the lower solubility of CO_2 in **II**.

Fig. 1 shows the normalised spectra of CO_2 in the ν_2 region in **I** and **II** at 68 bar and 40 °C. There are two important

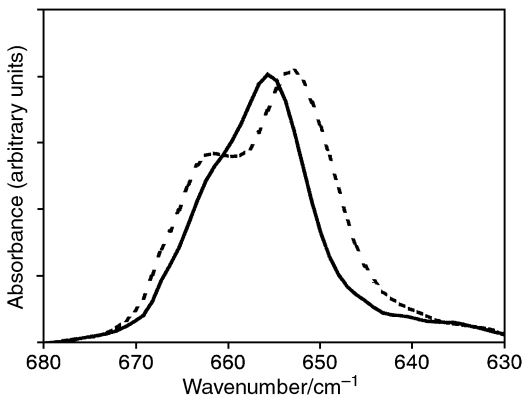

Fig. 1 ATR-IR spectra of CO_2 in the ν_2 mode region: spectrum of CO_2 dissolved in **II** (- - - -) and **I** (———). The absorbance scales of these spectra have been normalized to the absorbance of the stronger band (the maximum absorbance for **I** was *ca*. 0.2).

† Electronic supplementary information (ESI) available: schematic view of the miniature high-pressure flow cell. See http://www.rsc.org/suppdata/cc/b0/b005514j/

DOI: 10.1039/b005514j

observations: (i) the band is split into a doublet comprising of two bands; (ii) the magnitude of the splitting is different for CO_2 dissolved in **I** compared with **II**; the bands are strongly overlapped in **I** while the bands are distinct in **II**. The splitting of the bending mode of CO_2 indicates that the double degeneracy has been removed. This occurs due to a small bending of the CO_2 molecule. The angle of the bending is, probably, just a few degrees since we did not detect the appearance of the band corresponding to the symmetric stretching mode of CO_2. By analogy with the reported specific interaction between CO_2 and Lewis bases, which also results in the splitting of the bending mode,[7] it is reasonable to speculate that the splitting of the bending mode of CO_2 dissolved in ionic liquids indicates an interaction of CO_2 with a negatively charged fluorinated anion in **I** and **II**. These anions could act as weak Lewis bases, and CO_2 appears to be a useful probe to sense the extent of their basicity. The width of the ν_2 mode, measured as an effective average width of the split band (the average width represents the width of the doublet at the half-maximum of the absorbance) is an estimate of the strength of the interaction of CO_2 with the Lewis bases: the width increases with the increase of the strength of the interaction.[7] The observation of the striking differences in the band widths for CO_2 dissolved in **I** and **II** suggests that $[BF_4]^-$ is a stronger Lewis base in its interaction with CO_2 than $[PF_6]^-$. The average width of ν_2 for CO_2 dissolved in **II** reaches 19 cm^{-1}, the ν_2 width of CO_2 in **I** is just 15 cm^{-1}. The degree of the splitting also indicates that CO_2 molecules are more strongly bent and interactive with **II** than with **I** as was observed previously for CO_2 dissolved in organic solvents and supported by *ab initio* calculations.[10] Thus $[BF_4]^-$ acts as a stronger Lewis base towards CO_2 than $[PF_6]^-$. This conclusion contradicts the proposal by Brennecke and coworkers[5] that the strength of the interaction between CO_2 with $[PF_6]^-$, in ionic liquids, should be stronger than with $[BF_4]^-$. The current spectroscopic data provide strong evidence that the trend is the opposite, the $[BF_4]^-$ anion interacting more strongly with CO_2 than $[PF_6]^-$. This could also be a result of the strength of interaction decreasing with the increase of anion size. Thus, the strength of these interactions cannot be solely responsible for the solubility of CO_2 in these ionic liquids, and, presumably, a free volume contribution in the IL plays a significant role.[5] The strength of anion–cation interaction in the IL affects the available free volume, and one would anticipate that a weaker interacting anion leads to more free volume being available.

The spectroscopic ATR-IR method also facilitates the estimation of the swelling of ionic liquids subjected to high-pressure CO_2. The bands corresponding to the vibrations of the ionic liquids decrease in intensity as the pressure of CO_2 increases which would indicate that the evanescent wave in ATR spectroscopy probes a smaller number of ions in the vicinity of the ATR crystal due to the swelling of the liquid. This indicates that the interaction of CO_2 molecules with anions in ionic liquids facilitates swelling by decreasing anion–cation interactions for ions that are already largely mobile at room temperature in ionic liquids compared to other salts. The swelling of **I** is greater than of **II** presumably due to the weaker anion–cation interactions in **I**; it was noted earlier that the estimated solubility of CO_2 in **II** was *ca*. 40% less than for **I**, consistent with the differences in swelling. We have also observed a small (a few cm^{-1}) shift to the high-frequency region of the some of the bands corresponding to the stretching ν_3 modes of anions in **I** and **II** (relative to the bands of these ionic liquids in absence of dissolved CO_2) which also indicates that CO_2 interacts with the anions in these ILs. This shift also indicates a weakening of the interactions of the anions with their environment as CO_2 molecules weakly interact with the anions and act as a 'shield' reducing stronger interactions. The interactions between the CO_2 molecule and anion are probably of Lewis acid–base type, with the axis of the O=C=O molecule orienting towards the anion in perpendicular arrangement to P–F or B–F bonds. If the interaction of the CO_2 molecule with the cation in IL was *via* the CO_2 oxygen atom one would expect the ν_3 band to appear in a higher frequency range (2345–2360 cm^{-1}), the appearance of the ν_1 band and no splitting of the bending mode ν_2. This was observed in a number of studies on CO_2 adsorption in zeolites.[11] The influence of the negative charge density of the oxygen atoms in some zeolite networks reduces the ν_3 frequency,[11] which is consistent with the current proposal for the origin of the CO_2/anion interactions. The variation of the temperature of the **I**/CO_2 system in the range 40–60 °C shows that the absorbance bands of CO_2 dissolved in IL decrease in intensity as temperature increases; the interaction between CO_2 and **I** is exothermic which is typical for Lewis acid–base type interactions.

These data for the CO_2 interactions with IL is remarkably similar to those observed for CO_2 interactions with polymers.[7] There it was shown that the bending mode ν_2 of dissolved CO_2 is a very informative probe in elucidating its interactions with electron-donating functional groups in polymers. It is significant that the splitting of the bending mode of CO_2 in **II** exceeded any of the corresponding splittings observed for CO_2 in the polymers,[7] and the splitting for both **I** and **II** is significantly larger than that observed in fluorine-containing polymers indicative of the role of the negative charge in IL. There is a report implying that $[BF_4]^-$ is a stronger Lewis base than $[PF_6]^-$ based on the measurements of the coordinating ability of these anions.[12] Our spectroscopic assignment of the strength of interaction between CO_2 and anions in the two ionic liquids is also consistent with recent work[13] on the interactions between methanol and various anions where it was shown that $[BF_4]^-$ is a stronger proton acceptor relative to $[PF_6]^-$. Preliminary results for ionic liquids containing anions that are stronger bases, compared to [bmim][PF_6] and [bmim][BF_4], *e.g.* $[CF_3CO_2]^-$, has shown that the bending mode of CO_2 dissolved in this ionic liquid is split even further reflecting the greater basicity of this anion.

In summary, these spectroscopic data provide a first direct indication of the effect of an anion in the weak Lewis acid–base interactions with CO_2 molecules, and also provides a way to study phase partition behaviour of supercritical CO_2/IL systems, and hence to facilitate the design and optimisation of IL/SCF synthetic and separation routes.

We are particularly grateful to the RSC for a Journals Grant for International Authors in 1997. We thank EPSRC for support, Dr P. Turner (Bruker), Dr D. Coombs (Specac, Ltd.), Dr L. Lancaster, Dr C. J. Lawrence and Mr N. M. B. Flichy (Imperial College) for their support.

A convenient, one-step, synthesis of β-*C*-glycosidic ketones in aqueous media

Filipe Rodrigues, Yves Canac* and André Lubineau*

Laboratoire de Chimie Organique Multifonctionnelle, Associé au CNRS, Institut de Chimie Moléculaire d'Orsay, Université Paris Sud, 91405 Orsay, France. E-mail: yvescanac@icmo.u-psud.fr; lubin@icmo.u-psud.fr

Received (in Liverpool, UK) 9th August 2000, Accepted 13th September 2000
First published as an Advance Article on the web 2nd October 2000

Condensation of pentane-2,4-dione with different unprotected sugars in alkaline aqueous media gave quantitatively in one step β-*C*-glycosidic ketones.

C-Glycosides are becoming useful as building blocks for the synthesis of various types of natural products and as potential enzyme inhibitors.[1] In addition, they are used as a model in enzymatic and metabolic studies, indeed it has been shown that the conformational differences between the *O*- (or *N*-) glycosides and the *C*-linked analogue are minimal.[2] Moreover, *C*-glycosides are essentially inert to degradation because the natural anomeric centre has been transformed from a hydrolytically labile O or N acetal link to an ether. As a result, significant attention has been focused in the last decade on the development of new routes for their syntheses.

The most common method for C–C bond formation at the anomeric centre involves nucleophilic attack on this naturally electrophilic carbon atom.[3] A wide variety of electrophilic sugars have been employed such as reducing sugars, alkyl glycosides, anomeric esters, anomeric trichloroacetimidates, or glycosyl halides. The carbon nucleophiles that have been used include cyanides, allyl- and propargylsilanes, silyl enol ethers, silyl ketenes, enamines and organometallics such as Grignard reagents, organolithiums, cuprates, or aluminates.[4] In most cases, these procedures require specific, awkward reaction conditions and generally suffer from low yields.

Recently, there have been several advances in C–C bond formation in aqueous media. These milder methods include the coupling of unprotected sugars with malonate-derived nucleophiles such as barbituric derivatives[5] or Meldrum acid,[6] with Wittig-type reagents,[7] or with allyl bromides promoted by tin or indium in Barbier-type reactions.[8] In fact, water is now recognised as an attractive medium for many organic reactions[9] but curiously, for the most part, sugar chemistry stays away from this development of organic synthesis in water. Yet, the use of water-soluble unprotected reducing carbohydrates would allow syntheses without the tedious protection–deprotection protocol.

The Knoevenagel condensation,[10] a century-old reaction, consists of the condensation of aldehydes with active methylene-containing derivatives such as malonic acid or its ester. Despite the Knoevenagel reaction being a net dehydration, this reaction was surprisingly in some cases favoured in aqueous media.[11]

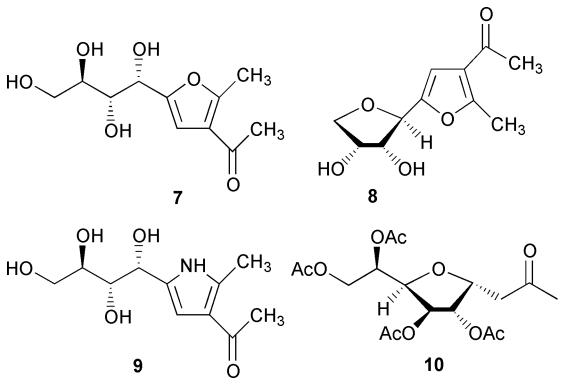
In this communication, we describe the very efficient one-step synthesis of β-*C*-glycosidic ketones in alkaline aqueous media from unprotected carbohydrates *via* the Knoevenagel condensation.

C-Glycosidic ketones are normally prepared in anhydrous conditions from an activated protected sugar by addition of a suitable nucleophile such as silyl enol ether[12] or enamines[13] to give generally the α-*C*-glycoside anomers as the major stereoisomer. Alternatively they can be obtained through multistep chemical transformations of allyl *C*-glycosides or using Wittig-type reaction on reducing sugars.[14]

We describe here the reaction in water of pentane-2,4-dione with D-glucose (**1**), D-mannose **(2)** or D-cellobiose (**3**) in the presence of sodium bicarbonate, which gave quantitatively in one step the β-*C*-glycosidic ketones (**4**–**6**).† The results and conditions are summarised in Table 1.

It is worth pointing out that compound **4** derived from D-glucose and **6** derived from D-cellobiose have been prepared only recently, respectively in six and seven steps in overall low yields from commercial 2,3,4,6-tetrabenzylglucopyranose.[15] In the case of the still unknown compound **5**, the structure and particularly the configuration at the anomeric centre was determined through ^{1}H, ^{13}C and NOESY NMR spectra.‡ Indeed a strong correlation between H-1 with both H-3 and H-5 in the NOESY spectrum along with a small coupling constant $J_{1,2}$ of 1 Hz indicates a β-configuration.

In fact, the reaction of pentane-2,4-dione with reducing sugars had already been studied in acidic medium ($ZnCl_2$, MeOH) and was shown[16] to give in the case of glucose the furan derivative (**7**) which further cyclises to **8** (32% overall yield), or, in aqueous acetone in the presence of sodium carbonate with reducing amino sugars such as glucosamine, the pyrrole derivative (**9**).[17]



In our case, the formation of compounds (**4**–**6**) results from the initial condensation of the carbanion of the β-diketone with the starting sugar (**1**–**3**), β-elimination of water and then cyclisation to the intermediate *C*-glycoside which undergoes a retro-Claisen aldolisation under the basic conditions with concomitant sodium acetate elimination, as shown in Scheme 1.

The exclusive formation of the β-pyranoside stereoisomer in the reaction at 90 °C came from thermodynamic control in the

Table 1 Addition of pentane-2,4-dione onto unprotected carbohydrates in water

Substrates	Conditions	Products and stereoselectivity[b]	Total yields (%)[a]

presence of sodium bicarbonate. Effectively, at rt after 24 h we get a mixture of the four possible α,β-furanosides and α,β-pyranosides stereoisomers in which the α-furanoside predominates.§ Indeed, it has been shown that equilibration under basic conditions of protected α,β-*C*-glucofuranoside analogues having an activated methylene group adjacent to the anomeric carbon favored the α-anomer through an α,β-unsaturated keto-intermediate.[18] By contrast, in the case of a mixture of α,β-glucopyranosides, equilibration led to the practically exclusive formation of the β-glucopyranoside.[19] In our case, the reaction with D-glucose, including the equilibration towards the pure β-*C*-glucopyranoside, is complete after 6 h at 90 °C whereas for the reaction with D-mannose a longer reaction time is required (12 h at 90 °C) as a result of a slower equilibration process. In the case of cellobiose, pure β-*C*-glycoside was obtained along with a trace of starting cellobiose (< 4%) which still existed after 12 h at 90 °C and which was removed after crystallisation of the β-*C*-glycosidic ketone.

Recently, ytterbium trifluoromethanesulfonate was shown to promote acid-catalysed reactions in water under rather smooth conditions. This encouraged us to try the reaction of pentane-2,4-dione with D-glucose in water in the presence of $Yb(OTf)_3$ at neutral pH. Indeed, after 20 h at 60 °C, we obtained a 1.5 : 1 mixture of compounds **7** and **8**, formerly prepared under rather drastic conditions,[16] in near quantitative yield which could be further separated by flash chromatography into pure **7** (58%) and **8** (39%).

In summary, the Knoevenagel condensation under aqueous conditions presented in this paper represents a very convenient method for the preparation of pure β-*C*-glycosidic ketones in one step directly from the unprotected sugar. Application of this method to other bi-functional compounds as well as the use of these compounds in the preparation of more elaborate *C*-glycosides are at present under investigation in our laboratory.

Notes and references

† *General procedure for the condensation of pentane-2,4-dione with unprotected sugars*: to a solution of D-glucose, D-mannose or D-cellobiose (1 mmol) in water (4 ml) were added sodium bicarbonate (1.5 mmol) and pentane-2,4-dione (1.2 mmol). After stirring at 90 °C for the given time, the reaction mixture was washed with CH_2Cl_2 (5 ml) and treated with Dowex resin (50X8-200, H^+ form). After concentrating the aq. mixture, the residues looked pure by NMR spectroscopy except for **6** which still contained 4% of unreacted cellobiose. Analytical samples were obtained after flash chromatography (AcOEt–iPrOH–H_2O 8 : 1 : 1) or crystallization (MeOH–Et_2O) for **5** and **6**. Compounds **4** and **6** were found identical with those described in literature,[15] except that in our hands **6** crystallized from MeOH–ether mp, 88–89 °C.

§ After 24 h at rt the mixture contained four stereoisomers in a 2 : 1 : 1 : 1 ratio in *ca*. 35% total yield from which the major stereoisomer could be separated by flash chromatography (AcOEt–iPrOH 8 : 2). It was fully characterized after peracetylation (Ac_2O, pyridine, 16 h at rt) and shown to be the α-*C*-glucofuranoside (**10**) by ^{1}H NMR. Indeed, we found H-4 at 4.29 ppm while H-5 moves downfield to 5.17 ppm showing clearly the presence of an acetate at OH-5. Moreover, NOESY experiment shows strong correlations between H-1 and H-5 and between H-1 and H-2 but not between H-1 and H-3, indicating an α configuration.

New fluorous ionic liquids function as surfactants in conventional room-temperature ionic liquids

First published as an Advance Article on the web 2nd October 2000

Ionic liquids formulated from imidazole cations with appended fluorous tails function as surfactants when added to conventional ionic liquids, facilitating the emulsification of fluoroalkanes with IL phases.

The development of less-polluting, 'neoteric' solvents is a key element in an emerging agenda for sustainable industrial development.[1] The alternatives receiving the most attention as neoteric solvents are ionic liquids (ILs), supercritical CO_2 (sc-CO_2), supercritical/near-critical H_2O, and perfluorocarbons.[2] Despite the intense interest in them, much of the basic chemistry of ionic liquids remains to be explored. Indeed, an understanding of this basic chemistry is of vital importance to the development of ionic liquids for 'green' applications.[1,3]

The thrust of our work with ionic liquids is the design and synthesis of salts composed of ions that incorporate structural or functional features that imbue them with particular properties.[1d,4] In a recent paper, we reported the synthesis of the first imidazolium ion with a long fluorous 'ponytail', with which we formulated a low-melting salt, *cf.*, a fluorous ionic liquid.[5,6] Our observation of the formation of a liquid crystalline phase by this structurally complex, fluorinated IL led us to speculate that the fluorocarbon tails of such ionic-liquid component cations associate. We subsequently reasoned that this property might be exploited to address a question of fundamental importance with regard to ionic liquid chemistry—the capacity of a designed, IL-based surfactant to alter the properties of a more conventional IL phase. Further, we deemed it feasible to capitalize upon such compounds to achieve a result of potential utility in biphasic systems—the use of the surfactant to promote and stabilize dispersions of a fluorous phase into an ionic liquid, two ordinarily immiscible neoteric solvent types. Note that Brennecke, Johnson and Rogers have all recently demonstrated the potential importance of biphasic systems in which both solvent components were neoteric materials.[7]

Here, we report the synthesis of four new fluorinated ionic liquids. The new compounds, **1**–**4**, differ substantially from the handful of known fluorine-containing ionic liquids in that the cation head-group structure is conventional and the fluorous appendage long (Fig. 1).[8,9] All of the new compounds are surfactants that promote the formation and stabilization of dispersions of perfluorocarbons in a conventional ionic liquid, 1-hexyl-3-methylimidazolium hexafluorophosphate, [6-mim]PF_6. Ours is the first report of the action of a fluorous surfactant on an ionic liquid, and only the second report of any surfactant action on or in an ionic liquid solvent.[10,11]

2 R = n-Bu, *x* = 5
3 R = Me, *x* = 7
4 R = n-Bu, *x* = 7

Fig. 1 General structure of the new fluorous ionic liquids.

The new fluorous ionic liquids are readily prepared from commercially available starting materials. Using an approach similar to that used to prepare our earlier fluorous IL, the imidazole cores 1-methyl- and 1-butylimidazole are dissolved in toluene, treated with a slight molar deficiency of 1,1,1,2,2,3,3,4,4,5,5,6,6-tridecafluoro-8-iodooctane or 1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8-heptadecafluoro-10-iododecane and heated under reflux overnight. Cooling to rt followed by removal of the solvent *in vacuo* leaves soft, off-white waxes. These iodide salts are readily metathesized in acetone using $AgPF_6$, giving ILs **1**–**4** in good yields.[12]

Compounds **1**–**4** manifest several behaviors common to surfactants. Simple capillary-rise measurements reveal that the surface tensions of saturated solutions (0.3 mass percent, ~ 1–4 mmolar) of **1**–**4** in [6-mim]PF_6 range from 10 to 15% less than the surface tensions of the conventional ionic liquid alone. Further, Ostwald viscosimetry establishes that increases in the viscosity of [6-mim]PF_6 occur upon addition of compounds **1**–**4**, a behavior common to known surfactants.[13] Still, the most dramatic surfactant behavior manifested by the new ILs is their capacity to act as agents to promote and stabilize dispersions of perfluorohexane in the 'conventional' IL [6-mim]PF_6. In the absence of the new fluorous ILs, the IL and perfluorohexane phases remain well defined. Controlled, timed mechanical agitation of the two-phase system results in the dispersal of droplets of the fluorous phase into the IL, but the droplets are quite large and individually distinguishable. They visibly begin to coalesce back into a bulk phase upon cessation of agitation. When this experiment is repeated using saturated solutions of **1**–**4** dissolved in [6-mim]PF_6, the dispersions that are formed persist for weeks without visible change.

Transmittance spectroscopy of the dispersions of perfluorohexane in the fluorous/conventional ionic liquid solution *versus* time graphically demonstrates the enhanced stability of those systems (Fig. 2).[14] Without fluorous IL, the initial turbidity of the system as determined by transmittance is slightly more than 40%. When any of the compounds **1**–**4** is dissolved in the bulk IL phase, the initial transmittance values are all near 10%. The rapid coalescence of the dispersed perfluorohexane droplets is apparent in the system without any

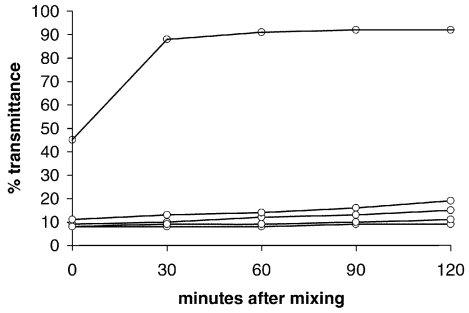

Fig. 2 Transmittance of perfluorohexane dispersions in [6-mim]PF_6 as a function of time with *(top to bottom)* no added fluorous IL; added **2**; added **1**; added **4**; added **3**. The enhanced stability of the dispersions in the presence of the fluorous ILs is apparent.

DOI: 10.1039/b005418f

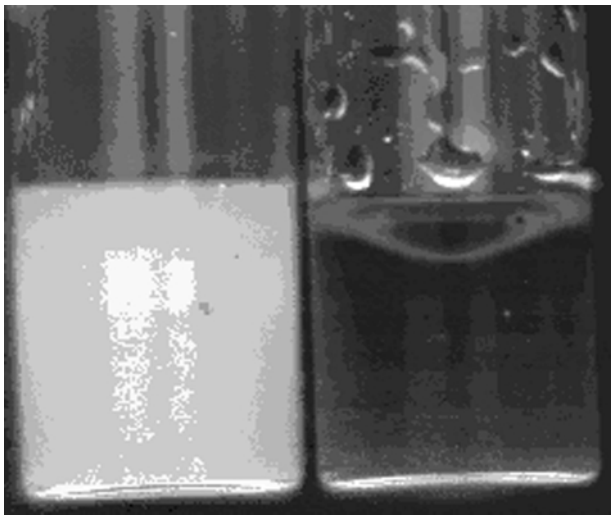

Fig. 3 Solution of **3**/[6-mim]PF_6 with emulsified perfluorohexane *(left)* and a mixture of [6-mim]PF_6–perfluorohexane *(right)*, both with added thymol blue. Note the turbidity of the stabilized emulsion, which has been aged one week, in contrast to the phase separation apparent in the system without FIL, aged five minutes. Also note the more efficient wetting of the container surface by the system containing fluorous IL.

fluorous IL, the transmittance of the system rising to 85% after 30 minutes. After similar time intervals, all four dispersions with added fluorous IL remain below 15% transmittance. This marked disparity persists with time. Over a four-hour interval, the transmittance of the IL–perfluorohexane mixture rises to 92%, while the transmittance values of the dispersions containing fluorous ILs range between 12 and 28%. This stability persists for extended time periods, dispersions of perfluorohexane and [6-mim]PF_6 with added **3** enduring for several weeks. Over periods of time greater than a month, the dispersions gradually decay with the formation of flocs.

In an effort to explore putative changes in the solvent environment arising from the presence of dissolved fluorous salt, we exploited a recent discovery by Rogers that, dissolved in conventional IL phases, thymol blue functions as an effective visual probe of such differences.[15] Systems containing [6-mim]PF_6–perfluorohexane and **3**–[6-mim]PF_6–perfluorohexane were prepared in identical fashion, solid thymol blue being added to each after the initial IL phases had been pre-equilibrated with pH 7.2 buffer. The mixtures were mechanically agitated for 15 min during which time the thymol blue dissolved. Upon dissolution of the thymol blue, the [6-mim]PF_6–perfluorohexane suspension became red, the color remaining in the IL phase as the two component liquids coalesced back into bulk phases. In the case of the **3**–[6-mim]PF_6–perfluorohexane mixture, a persistent suspension was formed which was brilliant yellow (Fig. 3). The yellow coloration was also observed in a mixture of **3** and [6-mim]PF_6 in the absence of perfluorohexane, indicating that the presence of the fluorous IL solute in the conventional IL phase is responsible for the observed difference in color. The effect does not appear to be linked to an electron-withdrawing effect of the fluorous appendage upon the imidazolium ion. Proton NMR spectra of **1**–**4** reveal that the chemical shifts of the imidazole ring C-2 protons—the most acidic within the cation structure—are similar to those of non-fluorinated ILs, suggesting that they are not rendered more acidic by the fluorous appendage.[16]† However, the presence of the fluorous appendage is likely to alter the capacity of the conventional IL to hold trace quantities of water, and the effect of such variations in water content within the IL phase on the behavior of the dye is unknown. Consequently, the basis of the difference in the color, whether pH based, solvatochromic, *etc*. is unclear. Studies to address this issue and other facets of the chemistry of fluorous ionic liquids are in progress, and will be reported in due course.

J. H. D. wishes to thank the Research Corporation for support of this work. We also wish to thank Dr Joseph Serafin for helpful advice and consultation with the turbidimetric and surface tension measurements, and Mr Michael Laurila for acquiring NMR spectra for us. Finally, we wish to thank Dr Ray Hoobler for providing the photograph appearing in this paper.

Received (in Cambridge, UK) 1st August 2000, Accepted 11th September 2000
First published as an Advance Article on the web 2nd October 2000

Cyclopalladated phosphine free pyrazole complexes 1 and benzothiazole complexes 2 are excellent catalysts for the Heck vinylation of aryl iodides and termolecular queuing cascades, leading to turnover numbers of $>10^6$ in some cases, at moderate temperatures; these catalysts show high thermal stability and are not sensitive to moisture and air.

Palladium salts/complexes are exceptionally versatile and robust catalysts for the construction of carbon–carbon and carbon–heteroatom bonds. Recently a number of novel phosphapalladacycles[1–7] as well as cyclometallated imine complexes[8] have been used in the Heck coupling of aryl halides and acrylates with TONs (turnover numbers) of 10^5–10^6. Suzuki[1,5,8,9] and Stille cross couplings[1,5] have also been performed using some of these palladacycle catalysts with varying TONs of 10^2–10^6. These catalysts exhibit higher air and thermal stability compared with conventional Pd(0) catalysts *e.g.* $Pd(PPh_3)_4$.

The use of phosphine free, nitrogen based ligands in the Heck reaction is a neglected area. We report here that palladacycles **1** and **2**[10] are outstanding catalysts for the Heck reaction and

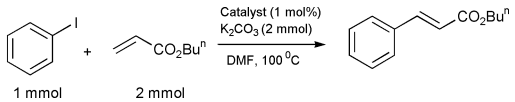
TONs of $>10^6$ can be achieved at 70–110 °C. Palladium complexes **1** and **2** are easily prepared, show high thermal stability and are not sensitive to moisture or air. Recently Milstein and coworkers reported non-phosphine cyclopalladated imine complexes for Heck reactions.[8]

Initially we explored the Heck reaction between iodobenzene and *n*-butyl acrylate (Scheme 1) in the presence of 1 mol% catalyst in DMF at 100 °C (Table 1).

Introducing fluorine (−I and π donor) substituents in the heterocyclic ligand *para* and/or *ortho* to the C–Pd bond increases the rate of the reaction (Table 1, entries 1, 4 and 9). Dual *o*- and *p*-fluoro substituents enhance this trend (Table 1,



Scheme 1

[a] Conversion estimated by NMR spectroscopy.

entries 4 and 9). Exchanging the R^1 and R^2 methyl groups for an electron withdrawing trifluoromethyl group in **1** also perturbs the rate. Thus replacing the C(3) methyl group in **1a** by CF_3 results in a more active catalyst (Table 1, entries 1 and 2; entries 4 and 5) whilst replacing the C(5) methyl group does not produce rate acceleration (Table 1, entries 1 and 3; entries 4 and 6). The role of the fluoro and trifluoromethyl substituents is to perturb the C–Pd covalent bond, and N–Pd dative bond. When these substituents are optimally located they facilitate a controlled breakdown of the Pd(II) complexes **1** and **2** furnishing the active catalytic species. These palladacycles could operate *via* a Pd(II)/Pd(IV)[12] or Pd(0)/Pd(II) catalytic cycle. It appears probable, on our current evidence that the active species are Pd(0) nanoparticles.[13,14]

Next we briefly studied the effects of base in the Heck reaction employing milder conditions. These results are summarised in Table 2.

Although in some cases competitive reduction of the aryl iodide bond was observed, the use of sodium and potassium formate was found to accelerate the rate of the reaction. When potassium carbonate was employed as the base, the product was furnished in 80% isolated yield (entry 5) after 2 h. However lower isolated yields of product (65–70%) were obtained after

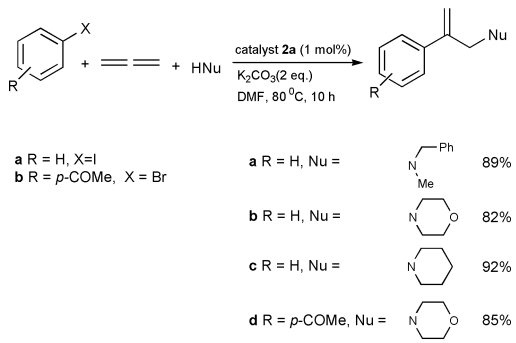
[a] Conversion estimated by NMR spectroscopy. [b] TON based on consumption of iodobenzene. [c] Isolated yields.

1 h when either sodium or potassium formate were used (entries 1, 3, 6 and 7). Sodium acetate was the least effective of the bases evaluated (entry 4), with only 29% conversion after 1 h.

Turnover numbers are summarised in Table 3 for the Heck reaction of iodobenzene (1 mmol) and *n*-butyl acrylate (2 mmol) using either HCO_2Na (2 mmol) or K_2CO_3 (2 mmol) as base in DMF at 90–110 °C for 48 h.

Although TONs of up to 2×10^6 can be achieved when employing sodium formate as base (entry 6) competitive reduction of the aryl iodide bond results in lower isolated yield of Heck product (50%). Employing potassium carbonate as base resulted in a TON of 2×10^6 (entry 7) and 78% isolated yield.

Finally we have briefly explored the scope of these catalysts in a three-component cascade process.[15] Typical examples are shown in Scheme 2.



Scheme 2

In conclusion, we have developed a range of non-phosphine palladacycles which are efficient catalysts with high TONs for Heck reactions under mild conditions and with relatively short reaction times. Studies on other Heck substrates and the mechanism are in progress.

We thank Leeds University, the ORS (X. G.) and Johnson Matthey for support.

At ambient pressure, a series of cadmium phosphosilicate glasses has been prepared in which, at certain phosphorus concentrations, the coexistence of four-, five- and six-coordinated silicon has been observed by ^{29}Si MAS solid state NMR spectroscopy.

In 1932 Zachariasen postulated that four coordinated silicon (Si^{iv}) is the building block of silicate glasses.[1] Indeed, several unsuccessful attempts were made subsequently to show that higher silicon coordination numbers would impose periodic long range order and consequent crystallinity.[2,3] However, in 1987 a peak −213 ppm (characteristic of Si^{vi}) was first observed in the ^{29}Si NMR spectrum of a 1 : 2 alkali metal silicate glass containing > 30 mol% P_2O_5 and prepared at ambient pressure.[4] Other reports of higher coordination numbers (Si^{v} and Si^{vi}) occurring in alkali and alkaline-earth silicate glasses have appeared subsequently.[5–8] Such knowledge of the local order of network forming silicon is needed to understand the physicochemical behaviour of silicate melts, magmas and plasmas at both ambient and high pressures.[8–10] Generally, the transition of Si^{iv} to Si^{v} and to Si^{vi} is favoured at high pressures. We now report the first evidence of the coexistence of Si^{iv}, Si^{v}, and Si^{vi} in a series of cadmium phosphosilicate single phase glasses prepared at *ambient* pressure and which were wholly vitreous within the detection limit of X-ray diffraction.

The cadmium phosphosilicate single phase glasses were made using appropriate amounts of analytical grade $CdCO_3$, SiO_2 and P_2O_5. A 20 g batch of nominal composition for xCdO·$(1-x-z)$$SiO_2$·$zP_2O_5$ was mixed together in a glass bottle and shaken for 8 h to achieve a homogeneous mixture. Powder batches in an alumina crucible were heated to 1250 °C by an electric furnace for 2.5 h. In order to maintain ambient pressure the crucibles in the furnace were open to the atmosphere. The glass melt was splat cooled using two steel plates at room temperature to give xCdO·$(1-x-z)$$SiO_2$·$zP_2O_5$ as a transparent homogeneous glass which was wholly vitreous within the detection limit of X-ray diffraction and, on optical inspection, did not show any evidence of phase separation. The ratio x:$(1-x-z)$ was kept constant at 1.5 while the value of z was varied between 0.50 and 0.70. The detailed composition of the samples and their nomenclature are given in Table 1.

All magic angle spinning (MAS) NMR spectra were obtained using a Chemagnetics AMX 300 Lite spectrometer operating at 59.61 MHz for ^{29}Si and 121.46 MHz for ^{31}P. Pulses of 5 μs (π/4) followed by a delay of 120 s were employed for the investigation of the ^{29}Si nuclei; 1 μs (π/4) with a 20 s delay for ^{31}P. The delays between pulses were chosen to ensure unsaturated signals. The samples were spun in 7.5 mm o.d. zirconia rotors at 6.5 kHz for ^{29}Si to put the spinning sidebands outside the −110 ppm to −215 ppm range. A higher rotational rate of *ca*. 14 kHz in 4.0 mm o.d. zirconia rotors was used for ^{31}P nuclei. The chemical shifts and peak positions were measured with respect to TMS for ^{29}Si and 85% H_3PO_4 for ^{31}P. The powdered samples were kept in a desiccator prior to spectral acquisition.

Fig. 1 shows the ^{29}Si spectra of CdSP1–CdSP4 and the NMR spectral parameters are presented in Table 1. Incorporation of phosphorus at > 30 mol% is known to rupture Si–O–Si bonds in some alkali metal silicate glasses, leading to Si^{iv}–O–P and Si^{vi}–O–P bonds characterised by ^{29}Si resonances at −120 ppm and −213 ppm, respectively.[3–7] The spectrum of CdSP1 (z = 0.50) glass showed an asymmetry on the high field side of the peak at −120 ppm suggesting the presence of a very small amount of a different species resonating at *ca*. −127.0 ± 1.0 ppm. This shift corresponds to an environment in which two adjacent silicon atoms are replaced by two phosphorus atoms while preserving the tetrahedral network.[11]

The ^{29}Si NMR spectra obtained for the glasses of composition $0.55 \leqslant z \leqslant 0.70$ differed significantly from those glasses with both lower and higher values of z. For z = 0.55 a new resonance of low intensity at −165.0 ± 0.5 ppm, characteristic of Si^{v}, along with a Si^{vi} resonance at −213.0 ± 0.5 ppm were observed. Both of these resonances increased in relative intensity with further addition of P_2O_5 up to z = 0.60. The coexistence of four-, five- and six-coordinated silicon in glasses at atmospheric pressure is unprecedented. Moreover, in contrast

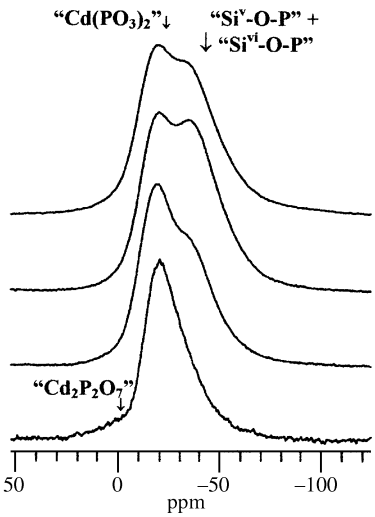

Fig. 2 ^{31}P spectra of xCdO·(1−x−z)SiO$_2$·zP$_2$O$_5$ for z = (a) 0.50, (b) 0.55, (c) 0.60 and (d) 0.70. Only the isotropic band is shown for clarity.

to alkali-metal phosphosilicate glasses, in the CdO–SiO$_2$–P$_2$O$_5$ system increasing z beyond 0.70 led to a *decrease* in the concentrations of the higher coordination number silicon environments. Integration of the unsaturated ^{29}Si NMR signals gave accurate measures of the Si^{iv}:Si^{v}:Si^{vi} ratios in the splat cooled base samples (Table 1). The Si^{v}:Si^{vi} ratio remained constant at 0.42 ± 0.03 for those samples in which higher coordinated silicon could be detected.

The reported shift of −150 ppm for Si^{v} in a K$_2$Si$_4$O$_9$ glass[8] is lower than that assigned to this environment in the cadmium phosphosilicate single phase glasses. We attribute this upfield shift to the silicon being surrounded by five oxygen atoms that are in turn bonded to phosphate species, phosphorus being of higher electronegativity.[4] The Si^{vi} chemical shift, −213 ppm, observed for the cadmium phosphosilicate glasses corresponds almost exactly to that reported for SiP$_2$O$_7$ species.[4–7]

Although the glass melt had been maintained at ambient pressure, quenching *via* splat cooling might have led to the metastable retention of a coordination multiplicity which was appropriate only to high temperatures. As CdSP3 had the highest concentrations of Si^{v} and Si^{vi}, this sample was chosen to observe the effects of slow cooling of the melt. There was a successive diminution of the higher coordination number species with slower cooling rates, corresponding to the removal of structural defects in the glass on annealing. The decrease in Si^{v} abundance is consistent with similar observations for K$_2$Si$_4$O$_9$ glass.[8] However, the decrease in the abundance of Si^{vi} contrasts with the situation for both phosphosilicate[3] and alkali metal phosphosilicate systems where annealing leads to the transformation of Si^{iv} into Si^{vi}. This suggests that the cadmium phosphosilicate system has different thermodynamic properties to those of the alkali metal-based glasses. This could lead to different optical properties for the CdO–SiO$_2$–P$_2$O$_5$ glasses.

Fig. 2 illustrates the ^{31}P NMR spectra of the glasses and the corresponding spectral parameters are given in Table 1. The sample CdSP1 (z = 0.50) showed only one resonance at −18.0 ppm, characteristic of cadmium metaphosphate species, accompanied by asymmetry on both the low and high field sides of the peak. That at lower field is due to the presence of cadmium pyrophosphate, whereas that at higher field may be due to a small amount of phosphosilicate species in which the silicon is four-coordinated. This could be the same species causing the asymmetry in the Si^{iv} peak of the ^{29}Si spectrum. With increasing P$_2$O$_5$ concentration another distinct resonance at −35.0 ppm, characteristic of phosphosilicate species with higher Si coordination numbers,[4] and a metaphosphate peak at *ca*. −16.0 ppm were observed. Relative to the metaphosphate peak, the former increased in intensity for CdSP2 and CdSP3 but then decreased for CdSP4. This change in intensity is consistent with that observed for the ^{29}Si resonances of the phosphosilicate species.

In general, we would expect two ^{31}P resonances corresponding to Si^{v}–O–P and Si^{vi}–O–P environments, but such was not observed. However, the linewidth of the resonance at −35.0 ppm (FWHM *ca*. 30.0 ppm) was far greater than that reported for Si^{vi}–O–P species (17.0 ppm) in alkali metal phosphosilicate systems.[4] This substantiated the presence of peaks attributable to Si^{v}–O–P species within the envelope of the resonance at −35.0 ppm. The unresolved spectral data suggest that the chemical shift difference between the two ^{31}P local orders is smaller than the difference in the linewidth of the resonances.

Further experiments are being performed to determine the variation of Si^{v} and Si^{vi} concentrations with CdO content. The thermodynamical and optical properties of the glasses are also being investigated and will be presented elsewhere.

We thank the Association of Commonwealth Universities in the United Kingdom for the award of a Commonwealth Fellowship (M. G. M).

Synthesis of amorphous, microporous silica with adamantanamine as a templating agent

Tao Sun,† Michael S. Wong and Jackie Y. Ying*

Received (in Irvine, CA, USA) 7th February 2000, Accepted 31st August 2000
First published as an Advance Article on the web 2nd October 2000

Amorphous, microporous silica with a spherical particle morphology has been prepared with adamantanamine, and its unusual structural properties suggest a non-zeolitic templating synthesis pathway.

Templating agents have been widely used in directing the formation of porous inorganic structures.[1,2] Traditionally, small organic molecules have been used as individual *molecular* templates in constructing the pore openings and cage-like cavities in microporous zeolites (pores < 20 Å).[2] In contrast, long-chained surfactant molecules are used as *supramolecular* templating agents in the preparation of amorphous mesoporous M41S-type silicates (pores > 20 Å).[3–6] The amphiphilic molecules interact with inorganic precursors and organize into micellar domains to form mesostructured metal oxide/surfactant composites. Mesoporous materials are produced after removal of the organic templating agents. Microporous transition metal oxide analogues prepared with short-chain surfactant-like molecules[7] and bifunctional surfactants[8] have recently been reported.

Here, we describe the formation of amorphous microporous silica using adamantanamine. Adamantanamine is a small, bulky molecule (axial length of *ca.* 5.9 Å) used as a molecular template in the preparation of zeolites, *e.g.* deca-dodecasil 3R (DD3R).[9]

In the synthesis of silicate/adamantanamine composites, 120 mol equivalents of water were added to an ethanolic solution consisting of 4 g of tetraethylorthosilicate and adamantanamine with an adamantanamine/Si molar ratio of 0.4. After stirring the reaction mixture at room temperature for 48 h, the white precipitate obtained was collected by filtration and washed with water. The resulting solid powder, designated as Si-TMS7, gave the X-ray diffraction (XRD) pattern shown in Fig. 1(a). Upon calcination at 540 °C for 3 h in air to remove the adamantanamine from the inorganic/organic composite, Si-TMS7 retained its XRD pattern [Fig. 1(b)]. The resulting silicate has an effective BET surface area of 737 $m^2\ g^{-1}$ and a pore volume of 0.35 $cm^3\ g^{-1}$. The type I nitrogen adsorption isotherm in Fig. 2 clearly illustrates the microporous nature of Si-TMS7.

The XRD patterns of Si-TMS7 (Fig. 1) have an intense low-angle diffraction peak, with *d*-spacings of 21.5 and 20.4 Å before and after calcination at 540 °C, respectively. The patterns resemble more closely those of surfactant-templated mesoporous materials than those of any zeolites. The lack of higher-order diffraction peaks indicates the absence of long-range pore ordering. The lone diffraction peak represents a common distance between the pore walls, as is usually observed in supramolecular-templated mesoporous materials with local pore ordering, *e.g.* KIT-1,[10] MSU-1[6] and L_3-phase silica gels.[11]

The particle morphology of calcined Si-TMS7 is predominated by *ca.* 1 μm spheres, as shown by transmission electron microscopy (TEM) [Fig. 3(a)]. These spheres are very monodisperse in size, as also confirmed by scanning electron microscopy. The morphology of Si-TMS7 is similar to the 200–500 μm spherical particles of MCM-41 prepared through surfactant–templating within butanol-in-water emulsions.[12] An emulsion-like system of adamantanamine, ethanol and water could be responsible for the spherical shapes of Si-TMS7 particles.

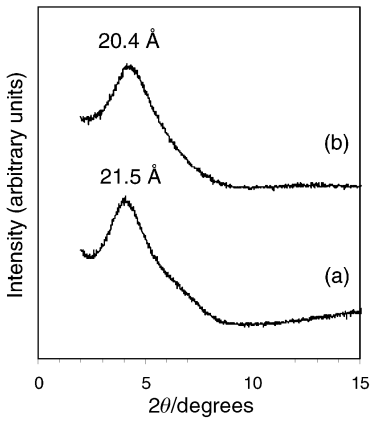

Fig. 1 XRD patterns of Si-TMS7 synthesized with adamantanamine templates at room temperature: (a) as-synthesized and (b) after calcination at 540 °C. The XRD patterns were obtained with a Siemens D5000 θ–θ diffractometer with Cu-Kα radiation (λ = 1.5406 Å).

The Si-TMS7 spheres were microtomed to reveal their amorphous, microporous structure [Fig. 3(b)]. Highly packed, randomly ordered pores appear throughout the particle. The pore size is estimated to be in the 13–17 Å range, more than twice the size of a single adamantanamine molecule (*ca.* 5.9 Å). We speculate that aggregates of adamantanamine may be directing the formation of the pores, distinct from the surfactant micellar domains prominent in mesoporous materials synthesis.

The temperature was found to be a very important parameter in the synthesis of Si-TMS7. Mesostructured Si-TMS7 could only be derived under ambient conditions; hydrothermal treatment at elevated temperatures resulted in amorphous, non-

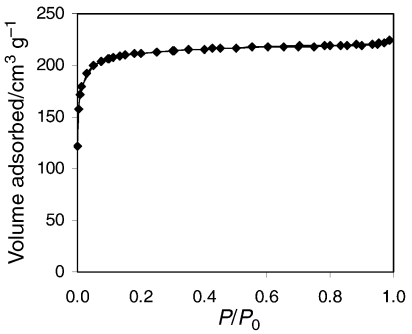

Fig. 2 N_2 adsorption isotherm of Si-TMS7 after adamantanamine removal by calcination at 540 °C in air. The isotherm was collected on a Micromeritics 2010 Gas Adsorption Analyzer after degassing the sample at 150 °C and 10^{-3} mmHg for 6 h.

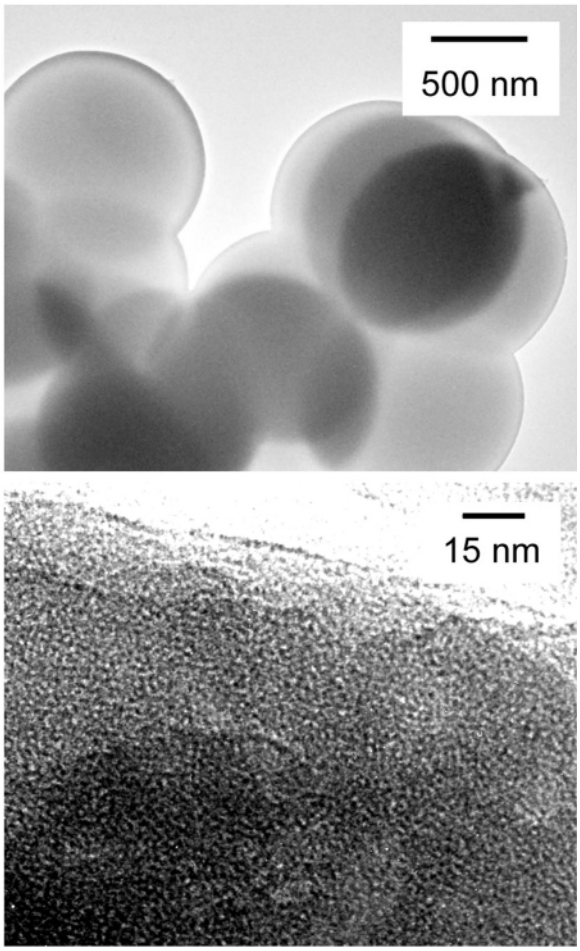

Fig. 3 TEM images of calcined Si–TMS7 (a) before and (b) after microtoming. The thinned sections were prepared by setting the calcined powder in acrylic resin. The microscopy was performed on a JEOL 2010 operating at 200 kV with a LaB_6 gun.

mesostructured materials. The interaction between the adamantanamine and the silicon alkoxide is most likely characterized by hydrogen bonding, which would be too weak to be sustained at high temperatures.[5,13] Other important factors that determine the templated inorganic structure are solubility and hydrophobicity of the templates, as shown by the fact that linear amines with only hydrocarbon chain length of > 6 are capable of leading to porous silicas with self-assembled templating structures.[13]

In conclusion, adamantanamine was used to prepare silicate/organic composites and was successfully removed without structural collapse of the resulting microporous silica. The unique structure and large 13–17 Å micropores provide evidence for collective templating of the small rigid adamantanamine molecules. Through such a synthesis pathway, other non-zeolitic microporous metal oxides can be attained.

N-Sulfonylimines as an excellent acceptor for intermolecular radical reactions

Hideto Miyabe, Masafumi Ueda and Takeaki Naito*

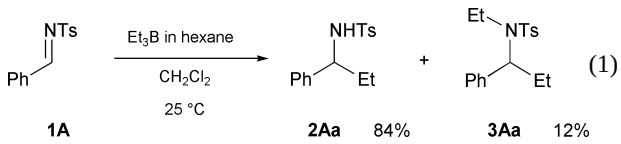
First published as an Advance Article on the web

The intermolecular carbon radical addition to *N*-sulfonylimines proceeded effectively under either iodine atom-transfer reaction conditions or zinc-mediated aqueous-medium reaction conditions.

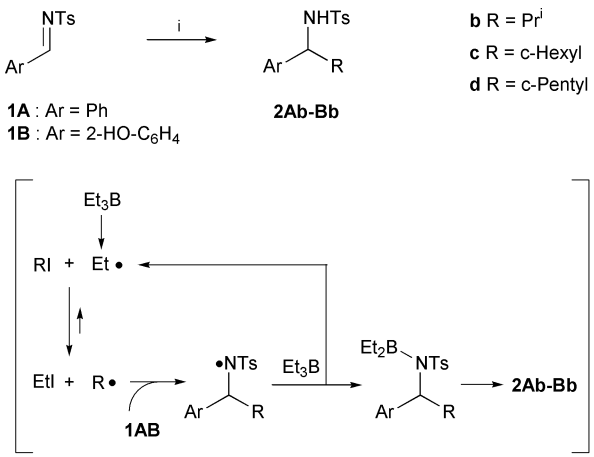
The carbon–nitrogen double bond of imine derivatives has emerged as a radical acceptor and, thus, numerous synthetically useful intramolecular carbon–carbon bond-forming reactions are available.[1] However, the intermolecular radical reaction of imine derivatives has not been widely investigated except for a few examples.[2] We reported recently that the intermolecular carbon radical addition to unactivated oxime ethers proceeded smoothly in the presence of $BF_3{\cdot}OEt_2$;[3] subsequently, the screening of more reactive imino radical acceptors has been the focus of our efforts. We now report an intermolecular radical reaction of electron deficient *N*-sulfonylimines which exhibit excellent reactivity toward nucleophilic alkyl radicals even in the absence of strong Lewis acids.

As a preliminary experiment, we investigated a simple intermolecular addition of an ethyl radical to *N*-sulfonylimine **1A** [eqn. (1)]. The reaction was run in dichloromethane at 25 °C



(1)

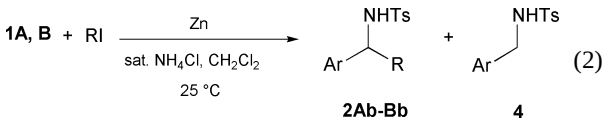
by using Et_3B as an ethyl radical source to give the desired ethylated product **2Aa** in 84% yield accompanied with a small amount of the diethylated product **3Aa**. It is important to note that the radical addition to benzaldehyde *O*-benzyloxime did not proceed under similar reaction conditions.[3] Good chemical yields were also observed in the radical addition using different radical precursors such as isopropyl, cyclohexyl, and cyclopentyl iodides under the iodine atom-transfer reaction conditions in the absence of tin hydride (Scheme 1). We also examined the stannyl radical-mediated radical reaction of **1A**;



Scheme 1 *Reagents and conditions*: i, RI (30 equiv.), Et_3B 5 equiv. 3 times), CH_2Cl_2, 25 °C; **2Ab**: R = Pr^i (80%), **2Ac**: R = c-Hexyl (55%), **2Ad**: R = c-Pentyl (54%), **2Bb**: R = Pr^i (89%).

however, the use of Bu_3SnH effected tin hydride-mediated reduction of the carbon–nitrogen double bond to give a significant amount of the corresponding *N*-sulfonylbenzylamine. Thus, the iodine atom-transfer reaction using RI and Et_3B in the absence of toxic tin hydride is an effective method for using *N*-sulfonylimine as a radical acceptor. Moreover, the reaction with more nucleophilic secondary alkyl radicals proceeded selectively and did not give the diethylated products, in contrast with the reaction with a primary ethyl radical. In this reaction, Et_3B would act as a reagent for trapping the intermediate aminyl radicals to regenerate an ethyl radical, and therefore more than a stoichiometric amount of Et_3B is required. As expected, *N*-sulfonylimine **1B**, which is activated by the intramolecular hydrogen bond by a 2-hydroxy group, was more reactive than *N*-sulfonylimine **1A** and therefore the isopropyl radical addition to **1B** proceeded effectively to give the desired product **2Bb** in 89% yield.

The use of water as a solvent has generated considerable interest from both economic and environmental points of view.[4] We recently have demonstrated that radical reactions of imine derivatives such as oxime ethers, hydrazones, and nitrones proceed in aqueous media using Et_3B.[5] In the case of *N*-sulfonylimine **1A**, a similar reaction procedure did not give good results in the radical addition reaction because of the competitive hydrolysis to $TsNH_2$. On the other hand, we have now found that the formation of the desired alkylated products **2Ab**–**Af** was observed in the zinc-mediated radical reaction of **1A** in aqueous media [eqn. (2)].[6] To a micro tube containing



(2)

N-sulfonylimine **1A**, Pr^{i}I, zinc, and dichloromethane as a co-solvent was added dropwise saturated aq. NH_4Cl over 15 min at 25 °C (Table 1, entry 1). The isopropylated product **2Ab** was obtained in 73% yield along with the reductive product **4** as a by-product. Not only a secondary alkyl but also the bulky *tert*-

Table 1 Zinc-mediated radical addition to **1A**, **B** in aq. media[a]

			Yield (%)[b]		
Entry	Sulfonylimine	RI	**2**		**4**
1	**1A**	Pr^{i}I	**2Ab**	73	8
2	**1A**	c-Hexyl I	**2Ac**	71	12
3	**1A**	c-Pentyl I	**2Ad**	64	18
4	**1A**	Bu^{s}I	**2Ae**	56	10
5	**1A**	Bu^{t}I	**2Af**	66	20
6[c]	**1A**	MeI	**2Ag**	—	16
7	**1B**	Pr^{i}I	**2Bb**	64	8
8[d]	**1A**	Pr^{i}I	No reaction		

[a] Reactions of **1A** or **1B** (50 mg) were carried out with Zn (7 equiv.), RI (5 equiv.), and sat. NH_4Cl (1 cm^3) in CH_2Cl_2 (0.1 cm^3) at 25 °C. [b] Isolated yields. [c] $TolSO_2NH_2$ was obtained in 65% yield. [d] Reactions of **1A** (50 mg) were carried out with Zn (7 equiv.) and Pr^{i}I (5 equiv.) in CH_2Cl_2 (1 cm^3) at 25 °C.

DOI: 10.1039/b006574i

butyl radical worked well under similar reaction conditions (entries 1–5). The methylated product **2Ag** was not obtained in the reaction using a less reactive methyl radical because of the competitive hydrolysis and reduction (entry 6). The isopropyl radical addition to another *N*-sulfonylimine **1B** also proceeded smoothly (entry 7). However, the reaction of **1A** using zinc in dichloromethane in the absence of aq. NH_4Cl did not proceed (entry 8). The known examples of metal-mediated carbon–carbon bond-forming reactions in aqueous media are mainly limited to allylation of carbonyl compounds;[7] thus, it is noteworthy that this reaction involves the alkylation of imine derivatives. The alkylation and reduction reactions would proceed as indicated in Scheme 2.

In conclusion, we have demonstrated the utility of *N*-sulfonylimines as radical acceptors under two different reaction conditions. These are the first examples of the reaction of *N*-sulfonylimines with carbon radicals and are a convenient method for preparing a wide range of amine derivatives.

First published as an Advance Article on the web

A novel 8-fold interpenetration diamondoid-like chiral condensed neutral coordination polymer, bis{4-[2-(4-pyridyl)ethenyl]benzoato}zinc [Zn(PEBA)$_2$] 1, synthesized by the hydrothermal reaction between $Zn(ClO_4)_2{\cdot}6H_2O$ and 4-[2-(4-pyridylethenyl)]benzenecarbonitrile (PEBC), displays very strong blue fluorescent emission and SHG response (*ca.* 1.5 × that of urea) as well as high thermal stability (up to *ca.* 430 °C).

Within the family of blue-luminescent compounds previously used in EL devices or light-emitting diodes (LED), most of them are aromatic organic molecules,[1] conjugated organic polymers,[2] organometallic compounds[3] or metal–chelate compounds such as metal complexes based on 8-hydroxyquinoline, 2-methylquinolin-8-ol, azomethine, azaindole, oxadiazole and bipyridyl derivatives.[4] More recently, boron complexes with 8-hydroxyquinoline derivatives have been shown to display very highly efficient blue-light emission.[5] However, blue-luminescent emission coordination polymers with high thermal stability (up to 400 °C) are, as far as we are aware, relatively rare. Condensed coordination polymers could play a key role in the development of LED materials because one can tune the emission color and stability of the complex readily by manipulating the ligand and the coordination environment around the central atom. Recently, the crystal engineering strategy has been utilized in the construction of acentric diamondoid metal–organic coordination polymers by using asymmetric bridging ligands as building blocks since the utilization of asymmetric ligands can introduce electronic asymmetry (push–pull effect) which is essential for a second harmonic generation (SHG) response.[6,7] However, coordination polymers which display both very strong blue fluorescent emission and SHG response in the solid state still remain, to the best of our knowledge, unexplored. The condensed neutral diamondoid-like coordination polymer, bis{4-[2-(4-pyridyl)-ethenyl]benzoato}zinc (**1**)‡ represents the first example of such materials with strong blue-lumienscent emission and an SGH response (1.5× as that of urea), as well as high stability up to 430 °C.

The three-dimensional polymeric structure of **1** was revealed by an X-ray single crystal diffraction investigation.§ The local coordination environment around Zn1 and Zn2 ions in **1** can best be described as distorted octahedral and tetrahedral, respectively, as shown in Fig. 1. Each asymmetric unit of **1** contains two Zn atom centers in which the Zn1 center coordinates to four oxygen atoms from two different PEBA groups in bidentate chelating mode and to two pyridine nitrogen atoms of two other PEBA groups, resulting in the formation of a distorted octahedral geometry. In contrast to the octahedral coordination of Zn1 centers, the Zn2 center coordinates to two pyridine nitrogen atoms of two PEBA groups and to two carboxylate oxygen atoms of two other PEBA groups in a monodentate fashion. If the chelating carboxylates are treated as one connecting point, Zn1 centers also have a pseudotetrahedral environment. Thus, both Zn1 and Zn2 centers are connected to four Zn centers through PEBA bridges to form a diamondoid-like net (Fig. 1). The crystal contains eight independent interpenetrating diamondoid networks with Zn···Zn separations in each network in the range 15.36–15.49 Å while[6,7] Zn···Zn···Zn angles are in the range 91.7–128.8° which represents a significant distortion from the ideal tetrahedral angle of 109.5° found in diamond. Thus, although the connectivity of the network is the same as diamond, the symmetry is lower. Two schematic representations of the 3D diamond-like network and the eight interpenetrating nets are shown in Fig. 2(a) and (b), respectively. As a result of the unsymmetrical nature of PEBA, **1** crystallizes in a chiral space group *C*2, which belongs to the crystal class 2 where optical activity can occur as specific physical effects.[8] Preliminary experimental results show that **1** displays strong powder SHG efficiencies, *ca.* 1.5× that of urea (see ESI†), probably due to its diamondoid structural type which is similar to that of potassium dideuterophosphate (KDP), the only known nonlinear optical (NLO)-active diamondoid network.[9] On the other hand, the protonated free ligand HPEBA also finds wide applications in second-order NLO films using organic molecular beam deposition techniques. However, because of the absence of strong donor/acceptor substituents in HPEBA, it is unlikely to display a high nonlinearity or substantial SHG response.[10] Thus, **1** combines the advantages of both pure organic and inorganic

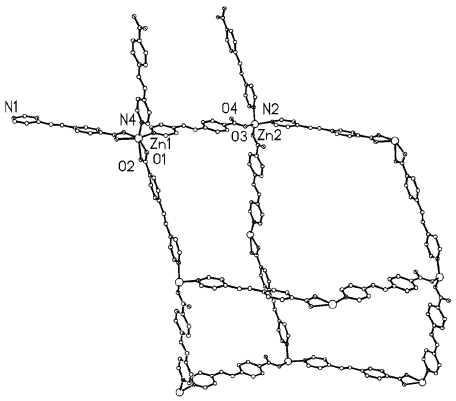

Fig. 1 A chiral diamondoid-like net representation of the coordination polymer [Zn(PEBA)$_2$] **1**. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) Zn(1)–O(1) 2.088(5), Zn(1)–O(2) 2.297(6), Zn(1)–N(4) 2.085(6), Zn(2)–O(3) 1.953(5), Zn(2)–N(2) 2.077(5).

† Electronic supplementary information (ESI) available: schematic representation of the 8-fold interpenetrating diamondoid-like network and second harmonic generation (SHG) measurements for **1**. See http://www.rsc.org/suppdata/cc/b0/b004980h/

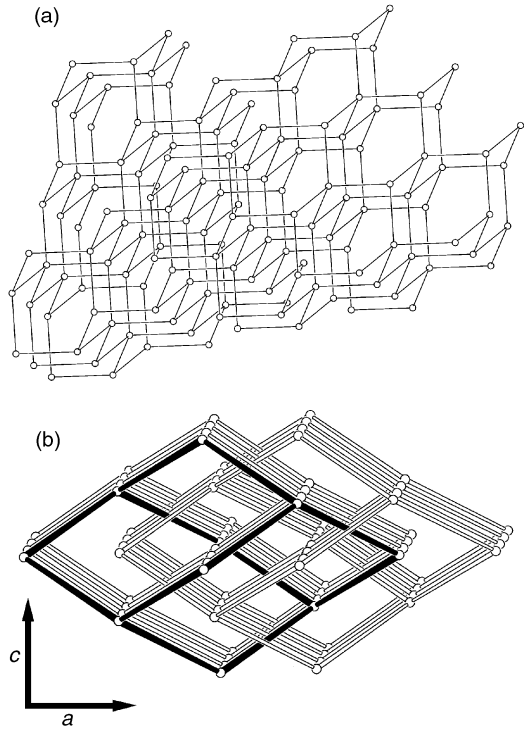

Fig. 2 (a) 3D diamond-like network representation (circles and straight lines denote Zn atoms and PEBA ligands, respectively). The other seven interpenetrating diamandoid nets are omitted for clarity. (b) A schematic representation of the eight interpenetrating diamond nets, with one net highlighted. Three other nets are related by unit cell translations in the *b*-direction. A second set of four nets is related by a translation of 1/2 + *x*, 1/2 + *y*, *z* (see also ESI).

NLO materials and such hybrid inorganic–organic NLO materials have recently been widely investigated as NLO materials.[11]

To study the thermal stability of the compound **1** thermogravimetric analysis (TGA) was performed on a polycrystalline sample, indicating that no strikingly clean weight loss step occurred below 430 °C, indicating that **1** is stable up to this temperature while HPEBA only remains intact up to 350 °C. The most important feature of the structure of **1** is that its three-dimensionally condensed polymeric structure leads to significant enhancement of fluorescent intensity, which is larger than that of free ligand (HPEBA) by a factor of *ca.* 10 (Fig. 3), probably due to the enhanced rigidity of **1**, compared to the free ligand. This phenomenon is similar to that found in Cd(TPT)(PY) (TPT = terephthalato, PY = pyridine).[4] The emission of **1** with λ_{max} = 460 nm is neither MLCT (metal-to-ligand charge transfer) nor LMCT (ligand-to-metal charge transfer) in nature, and can be probably assigned to intraligand fluorescent emission since a weakly similar emission with λ_{max} at 466 nm

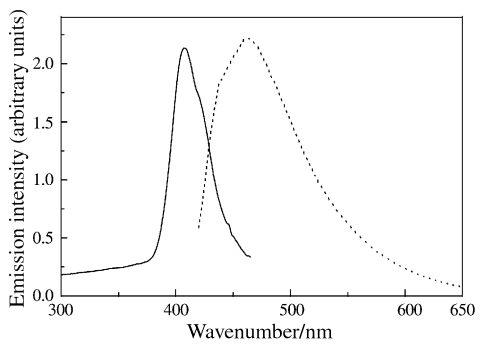

Fig. 3 Fluorescent emission spectrum of **1** in the solid state at room temperature.

is also observed for HPEBA. On the other hand, the diffuse reflectance spectrum of **1** is dominated by an intraligand π–π* transition at 423 nm. The blue fluorescent emission of **1** suggests that it may be used as an advanced material for blue LED devices. Condensed coordination polymer **1** appears to be an excellent candidate since, in addition to its high thermal stability and SHG response, it is virtually insoluble in most solvents such as ethanol, chloroform, ethyl acetate, acetone, acetonitrile, benzene and water.

Highly efficient sensitization of nanocrystalline TiO_2 films with styryl benzothiazolium propylsulfonate

Zhong-Sheng Wang, Fu-You Li and Chun-Hui Huang*

State Key Laboratory of Rare Earth Materials Chemistry and Applications, Peking University–The University of Hong Kong Joint Laboratory in Rare Earth Materials and Bioinorganic Chemistry, Peking University, Beijing 100871, P. R. China. E-mail: hch@chemms.chem.pku.edu.cn

Received (in Cambridge, UK) 7th August 2000, Accepted 18th September 2000
First published as an Advance Article on the web

Near 100% of maximum incident photon-to-electron conversion efficiency (IPCE) and > 15 mA cm^{-2} of short-circuit photocurrent under 94.6 mW cm^{-2} simulated solar light from a xenon lamp were obtained from a thin layer sandwich-type solar cell based on a 2-[4-bis(methyl)aminostyryl]benzothiazolium propylsulfonate (BTS) sensitized nanocrystalline TiO_2 film.

Dye-sensitized nanocrystalline TiO_2 is a promising material for solar cell applications since it is expected to be fabricated at a relatively low cost and can generate efficiencies of up to 10%.[1–3] The most efficient charge transfer sensitizers employed so far are polypyridyl-type complexes of ruthenium[2–4] that have been widely studied in the past ten years.[5,6] Pure organic dyes, owing to their small size, large extinction coefficients and much lower cost, are also promising sensitizers. However, with poor solar energy conversion efficiency (η) below 1%, they are insufficient for solar cell applications.[7,8] Recently Arakawa and coworkers reported that some efficient merocyanine dyes generated 4.2% overall yield on a porous TiO_2 electrode,[9] which suggests good application prospects of these organic dyes on Grätzel cells. Our previous work centered on the photoelectric conversion of hemicyanine derivatives with a π-conjugation bridge between the donor and acceptor groups (D-π-A), and some promising dyes have been selected by molecular design and use of the Langmuir-Blodgett technique.[10–12] In order to advance the development of the Grätzel cell, it is worthwhile to investigate the sensitization of nanocrystalline TiO_2 with pure organic dyes, such as hemicyanine derivatives. Here, we report an outstanding organic sensitizer for nanocrystalline TiO_2 films. A thin layer sandwich-type solar cell fabricated with this dye-modified nanocrystalline TiO_2 film generated an exceptional, high IPCE near unity between 480 and 500 nm and 15.1 mA cm^{-2} of short-circuit photocurrent, amongst the highest values reported so far.[1–3,7–9]

2-[4-Bis(methyl)aminostyryl]benzothiazolium propylsulfonate (BTS) (Fig. 1) was synthesized[12,13] by condensing its methyl azolium propylsulfonate precursor with 4-[bis(methyl)-amino]benzaldehyde. [Elemental analysis: found (calc. for $C_{20}H_{22}N_2S_2O_3{\cdot}H_2O$): C, 56.73 (57.12); H, 5.86 (5.75); N, 6.54 (6.66)%]. The absorption and fluorescence emission spectra of BTS were measured in chloroform solution. While the absorption peak in the visible region is at 557 nm, the maximum of the fluorescence is located at 590 nm. Interestingly, the emission is entirely quenched when BTS is adsorbed onto a nanocrystalline TiO_2 film, indicating efficient electron injection from the excited singlet state of the dye into the conduction band (CB) of TiO_2. Cyclic voltammetry of BTS in MeCN was measured using $LiClO_4$ as supporting electrolyte. The oxidation and reduction potentials are 0.87 and 0.80 V (*vs.* SCE), respectively, from which $E_{1/2}$ is derived to be 0.84 V (*vs.* SCE). When BTS is adsorbed onto a TiO_2 film, the absorption threshold is extended to *ca.* 700 nm. Combining the redox potential with the absorption threshold of BTS, the first excited state level of BTS is estimated to be −0.93 V (*vs.* SCE), above the flat band potential (−0.90 V *vs.* SCE) of nanocrystalline TiO_2 film in aprotic solvent containing no less than 0.1 M Li^+ ion.[14] Therefore, one can conclude that electron injection from the excited dye molecules to the CB of TiO_2 is thermodynamically possible. A 7 μm-thick nanocrystalline TiO_2 film,[2] coated onto conducting glass (fluorine doped SnO_2 sheet, resistance 20 Ω per square), was protonated by soaking for 2 h in a HCl solution at pH 2 and dried in a hot air flow before dipping it in a 1×10^{-4} M solution in chloroform for 4 h. The visible band in the absorption spectrum of BTS on TiO_2 film is red shifted by 12 nm with the half width increased from 55 to 90 nm upon previous treatment of the TiO_2 film with HCl solution, as seen in Fig. 2(a) and (b). These changes are favorable to photoelectric conversion. It is of note that HCl treatment does not significantly affect the adsorbed quantity of BTS on the TiO_2 [Fig. 2(a) and (b)]; the height of the absorption peak remains almost the same while the shape of spectrum changes drastically upon treating the TiO_2 film with HCl solution.

The photocurrent action spectra are shown in Fig. 2(c) and (d) where IPCE is plotted as a function of wavelength. After HCl treatment, IPCE values are increased by more than 50% between 400 and 700 nm with respect to the untreated TiO_2 film, but remain almost unchanged above 700 nm. Obviously, IPCE is improved remarkably upon HCl pretreatment of the TiO_2 film. The surface of nanocrystalline TiO_2 is hydroxylated

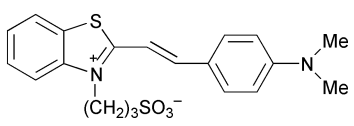

Fig. 1 Schematic structure of BTS.

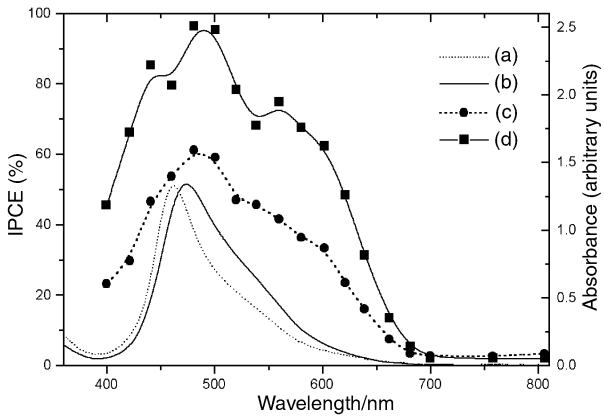

Fig. 2 Absorption spectra of BTS on nanocrystalline TiO_2 film (2 μm), corrected for the absorption of TiO_2 film and the conducting glass support: (a) untreated TiO_2 film and (b) HCl pretreated TiO_2 film. Photocurrent action spectra for BTS-coated nanocrystalline TiO_2 film (7 μm): (c) untreated TiO_2 film and (d) HCl pretreated TiO_2 film. A sandwich-type cell configuration was used to measure the action spectra. The redox electrolyte was 0.5 M LiI–0.05 M I_2 in propylene carbonate solvent. IPCE data were corrected for the absorption of the conducting glass.

DOI: 10.1039/b006427k

under preparation conditions.[15] BTS, which is adsorbed onto TiO_2 *via* coordination bonds between RSO_3^- and Ti^{4+},[2] may show a weakened interaction due to the repulsive force between RSO_3^- and deprotonated hydroxyl groups on neutral TiO_2. However, after pretreatment of the nanocrystalline TiO_2 film with HCl solution, the surface of nanocrystalline TiO_2 is protonated which enables BTS to adsorb onto the TiO_2 surface more strongly, which is consequently favorable for electron injection.[15] Another reason for the improvement in performance is that the decrease of flat band potential of nanocrystalline TiO_2 film due to the adsorption of H^+ ion can increase the driving force for electron injection.[14] Under illumination of simulated solar light from a 500 W Xe lamp (Ushio Electric, Japan), while a sandwich-type solar cell fabricated with this dye-sensitized nanocrystalline TiO_2 film in conjunction with a 0.5 M LiI–0.05 M I_2 redox electrolyte in propylene carbonate (PC) generated 9.0 mA cm^{-2} of short-circuit photocurrent (I_{sc}), 413 mV open-circuit photovoltage (V_{oc}) and 0.410 for the fill factor (FF) with an overall yield (η) of 1.6%, a value of 2.1% for η (15.1 mA cm^{-2} I_{sc}, 410 mV V_{oc} and 0.315 FF) was obtained from a HCl treated film under the same conditions. It is interesting that while V_{oc} remains almost unchanged, I_{sc} is increased by 68% upon HCl pretreatment of the nanocrystalline TiO_2 film. It is believed that the overall yield will be greatly improved after optimization of FF and V_{oc}.[2] The maximum IPCE and short-circuit photocurrent are the highest values among pure organic sensitizers so far studied.[9] For stability examination, this solar cell was illuminated with 94.6 mW cm^{-2} white light from a xenon lamp for 10 h, and the short-circuit photocurrent was almost unchanged after this period. Longer-term tests will be studied in detail.

Our results indicate that hemicyanine derivatives are promising sensitizers for solar cell applications. The notable improvement of photoelectric properties upon treating nanocrystalline TiO_2 film with HCl solution indicates that surface treatment is very important in photoelectric conversion. Preliminary experimental results show that this method for surface treatment of TiO_2 can also improve performance parameters for other hemicyanine dyes containing SO_3^- groups. Therefore, these findings open up a new pathway for designing new efficient sensitizers and aid the development of the Grätzel cell. As the cost of hemicyanine-group dye is much lower than that of ruthenium polypyridine complexes, the overall cost of dye-sensitized solar cells could be further reduced. Detailed study of BTS is now in progress.

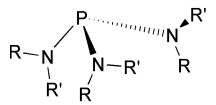
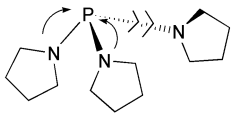
First published as an Advance Article on the web

Phosphines containing two N-bound pyrrolidine groups and one alkyl or aryl group are unusually electron rich σ-donor ligands when compared to either tris(*N*-pyrrolidinyl)phosphine or trialkyl- and triaryl-phosphines.

One of the many attractive features of phosphine ligands is their wide range of electronic properties.[1,2] Metal complexes of strongly electron donating alkyl phosphines undergo many reactions which are not possible with aryl phosphines,[3] and these types of metal complexes have recently found important applications in homogenous catalysis.[4–6] Tris(alkylamino)-phosphines are strongly electron donating phosphine ligands. The high basicity (σ-donor strength) of the P atom is thought to arise from donation towards the P from the N lone pair. X-Ray crystal structures of tris(alkylamino)phosphines and their metal complexes[2,7] show these ligands to contain two short P–N bonds with planar N, and one long P–N bond with a non-planar N atom (**1** and **2**). This suggested to us that only two of the N lone pairs could donate electron density towards P, while the third N substituent acts merely as an electronegative atom bound to the P, and therefore reduces the overall basicity of the phosphine.



1

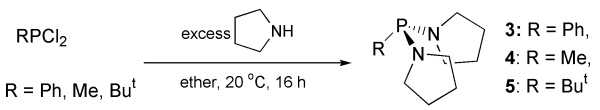


2

If this were the case, a 'hybrid' ligand that contains one electron donating alkyl group and two electron donating amino groups might be an extremely electron rich phosphine ligand, and have numerous applications in catalysis. Here, we describe the preparation of these new di(*N*-pyrrolidinyl)alkylphosphines and preliminary experiments which suggest that the new phosphine ligands are amongst the most electron rich phosphines known.

The aminophosphines described in this study were prepared by the addition of an excess of pyrrolidine to the appropriate phosphine dichloride (pyrrolidine was chosen as it is a very basic secondary amine) (Scheme 1).

^{31}P and ^{1}H NMR spectra of the air and moisture sensitive phosphine products showed them to be 90–98% pure, and they were therefore purified no further. They were further characterised by their conversion to the metal complexes described below. Molloy and Petersen have previously prepared tris(*N*-pyrrolidinyl)phosphine and shown it to be a highly electron rich ligand, in contrast to tris(*N*-pyrrolyl)phosphine which has exceptional π-acceptor character. The method they used to gauge the electronic characteristics of their ligands was measurement of ν_{CO} in the IR spectrum of the *trans*-$(R_3P)_2Rh(CO)Cl$ complexes. These are readily formed in high purity from $[Rh(CO)_2Cl]_2$ and an excess of ligand.[8] As the position of ν_{CO} in these complexes is known for a huge variety



Scheme 1

of phosphines (and is always in agreement with the expected σ-donor strength of the phosphine) this does seem to be an excellent spot test to gauge the donor characteristics of a particular phosphine.

As can be seen from Table 1, the position of ν_{CO} for $PhMe_2P$ is, as expected, in between electron rich Me_3P and the less basic Ph_3P. PhP(*N*-pyrr)$_2$, however, has ν_{CO} at lower wavenumber than P(*N*-pyrr)$_3$, and therefore can be assumed to be a more electron rich ligand. This is evidence [along with the properties of MeP(*N*-pyrr)$_2$ and Bu^{t}P(*N*-pyrr)$_2$] that only two pyrrolidinyl groups can contribute towards the strong donor strength of *N*-pyrrolidinyl phosphines. The values of ν_{CO} for MeP(*N*-pyrr)$_2$ and Bu^{t}P(*N*-pyrr)$_2$ are significantly lower than those of most other highly electron rich alkylphosphines (compare entries 11 and 12 to 5 and 6) which are often applied in catalysis. Tri-*tert*-butylphosphine, which is generally thought of as the most electron donating phosphine, actually forms a tetrahedral $(R_3P)_2Rh(CO)Cl$ complex and cannot be directly compared.[13] The new ligands may be of particular use as they deliver a donor strength that is normally reserved for very bulky ligands, as defined by their large cone angle. It is expected that the ligands **3**–**5** (especially **4**) will have relatively small cone angles. We also note here that iron(II) complexes of type $CpFe(CO)I(PR_3)$ can also be prepared from the four *N*-pyrrolidinyl phosphines by the method of Colville *et al.*[14] The position of ν_{CO} in the IR spectrum of these four compounds is less informative than the Rh compounds, but is at significantly lower wavenumber than the iron complexes of Ph_3P, $PhMe_2P$ or Bz_3P.

Finally, we have also characterised the dichloroplatinum complexes, $(R_3P)_2PtCl_2$, of the four *N*-pyrrolidinyl phosphines $[(pyrr)_3P]_2PtCl_2$ **6**, $[(pyrr)_2PhP]_2PtCl_2$ **7**, $[(pyrr)_2MeP]_2PtCl_2$ **8** and $[(pyrr)_2Bu^tP]_2PtCl_2$ **9**. These are formed quantitatively from $Pt(cod)Cl_2$ and 2 equivalents of phosphine. The sizes of $^1J_{PPt}$ reflect the reduction in coupling constant observed when a phenyl group is replaced by an alkyl group, and the increased size of $^1J_{PPt}$ observed for compounds containing P–N or P–O bonds.[8] The molecular structures[15] (determined by X-ray crystallography) of $[P(N\text{-pyrr})_3]_2PtCl_2$ and $[MeP(N\text{-pyrr})_2]_2PtCl_2$ are shown in Fig. 1 and 2, respectively.

Table 1 Comparison of ν_{CO} of *trans*-$L_2Rh(CO)Cl$ complexes for pyrrolidine based ligands with other phosphines

Entry	L	υ_{CO}[a] [$L_2Rh(CO)Cl$]	Ref.
1	$(PhO)_3P$	(2016)	9
2	$(p\text{-}CF_3C_6H_4)_3P$	(1990)	2
3	Ph_3P	1965 (1966)	2[b]
4	$PhMe_2P$	(1965)	10
5	Me_3P	(1960)	2
6	Et_3P	(1956)	11
7	Cy_3P	1943 (1942)	12[b]
8	$P(NMe_2)_3$	(1959)	2
9	P(*N*-pyrr)$_3$[c]	1951 (1952)	[b,d]2

12	Bu^{t}P(*N*-pyrr)$_2$	1942	[b,d]

[a] To ensure the accuracy and validity of our values, we have reprepared *trans*-$(R_3P)_2Rh(CO)Cl$ complexes of (*N*-pyrr)$_3$P, Ph_3P and Cy_3P. The values quoted above are those found on our spectrometer (lit. values in parentheses). [b] IR spectra recorded as KBr discs. [c] pyrr = pyrrolidinyl. [d] This work.

DOI: 10.1039/b004893n

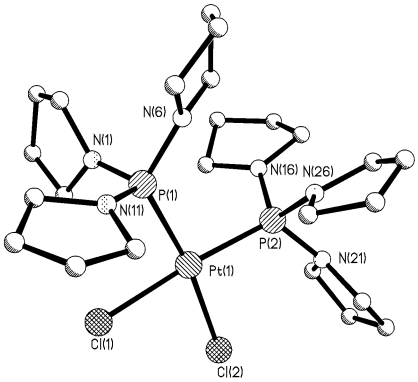

Fig. 1 Ball and stick representation of $[P(N\text{-pyrr})_3]_2PtCl_2$ **6**. Selected bond lengths (Å) and angles (°): Pt–P(1) 2.246(3), Pt–P(2) 2.270(3), Pt–Cl(1) 2.398(3), Pt–Cl(2) 2.371(3); P(2)–Pt–P(1) 98.24(10), Cl(2)–Pt–Cl(1) 85.08(11).

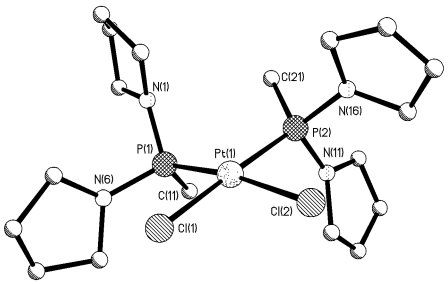

Fig. 2 Ball and stick representation of $[MeP(N\text{-pyrr})_2]_2PtCl_2$ **8**. Selected bond lengths (Å) and angles (°): Pt–P(1) 2.226(2), Pt–P(2) 2.255(2), Pt–Cl(1) 2.372(2), Pt–Cl(2) 2.391(2); P(2)–Pt–P(1) 93.37(7), Cl(1)–Pt–Cl(2) 86.14(8).

The X-ray structure of *trans*-$[P(N\text{-pyrr})_3]_2Rh(CO)Cl$ [2] shows two of the pyrrolidine rings in a given $P(N\text{-pyrr})_3$ fragment to have planar N atoms (sum of angles around N = 354–360°) and one tetrahedral N atom (sum of angles around N = 347, 350°) with a 0.02 Å longer P–N bond length [av. 1.667(3) *vs*. 1.688(3) Å]. We therefore expected the crystal structure of $[P(N\text{-pyrr})_3]_2PtCl_2$ to show this phenomenon. The crystal structure of $[P(N\text{-pyrr})_3]_2PtCl_2$ shows the expected *cis* square planar Pt complex, but to our surprise, the sum of angles around each N was similar (356–360°) and planar. The P–N bond lengths [1.628(10), 1.721(11), 1.642(11), 1.659(10), 1.678(12) and 1.678(9) Å] do not show any particular pattern.

The crystal structure of $[MeP(N\text{-pyrr})_2]_2PtCl_2$ **8** has two independent molecules in each unit cell, but there are no drastic differences between the two molecules. Complex **8** shows a similar coordination environment to complex **6**, with fairly similar Pt–Cl and Pt–P bond lengths. The angle P(1)–Pt(1)–P(2) between the phosphines is considerably smaller than in complex **6** [93.90(8), 93.37(7) *vs*. 98.24(10)°], and indicates that $MeP(N\text{-pyrr})_2$ is less sterically demanding than $P(N\text{-pyrr})_3$. As a result of this, the angle between the Cl ligands is slightly larger in complex **8** [87.01(9), 86.14(8) *vs*. 85.08(11)°]. The bond lengths and angles about the N atoms are again somewhat surprising. Each phosphine has one planar N (sum of angles from the four phosphine ligands in the two independent molecules: 356.6, 359.5, 359.5, 356.4°), and in each of the four phosphine molecules present, the other N atom shows a slight tetragonal distortion (sum of angles: 353.3, 353.5, 354.0, 351.8°), and slightly longer P–N bond length [average bond lengths: 1.683(6) *vs*. 1.643(7) Å].

The crystallographically determined cone angles of $P(pyrr)_3$ and $MeP(pyrr)_2$ are 122 and 110°, respectively. These values refer to 2/3 of the sum of the largest possible angle observed between the Pt centre and the centre H atoms on the phosphine substituents. This value differs from the Tolman cone angle (determined by molecular modelling) by using the centre of the H atom and the real Pt–P bond length. It is also likely to differ due to the volume of space occupied by the phosphine being partly determined by the coordination environment provided by the Pt. The values obtained clearly confirm the smaller size of ligand **4** with respect to ligand **2**. It has been estimated that the Tolman cone angle of **2** is 145°.[2]

The crystal structure of **6** reveals different structural features to the other crystal structure studies of tris(dialkylamino)phosphines. This may suggest that the bonding observed in these compounds is slightly more subtle than we originally supposed, and could also be related to the exact coordination environment of the ligand. The coordination environment provided by the Pt complex is also likely to have an effect on the ligand structure observed within that of complex **8**. In conclusion, we have prepared three new phosphine ligands and shown them to be especially strong donor ligands. Studies to evaluate the potential uses of these ligands in catalysis are now underway.

We are grateful to the EPRSC for financial support, and the Joint Research Equipment Initiative for an equipment grant.

First published as an Advance Article on the web

Electrochemical oxidation of the acridine ester 2′,6′-difluorophenyl 10-methyl-9,10-dihydroacridine-9-carboxylate yields the corresponding acridinium ester which reacts with H_2O_2 to generate intense chemiluminescence.

Electrochemiluminescence (ECL) has received widespread attention during the previous decade, especially in the field of chemical analysis.[1] It combines the well known sensitivity of chemiluminescence (CL) with the precise control over the time and position of light emitting reactions afforded by electrochemistry. As an alternative approach for conducting immunoassays and nucleotide assays it offers advantages such as increased sensitivity and precision, reduction in time and labor, and the elimination of radioisotopes.[2] In order to exploit the full potential of this technology there is a requirement for new CL compounds which can be initiated electrochemically. In this communication we show for the first time how acridinium ester CL can be triggered by electrochemical oxidation of 2′,6′-difluorophenyl 10-methyl-9,10-dihydroacridine-9-carboxylate (DMC).

Prior to the present communication ruthenium chelates[3] and luminol† derivatives[4] are the only compounds that have been used in a significant number of analytical applications involving ECL. Ruthenium chelates have been used for enzyme assays,[5] but their most significant impact has been as labels for immunoassays[6] and nucleotide assays.[7] Luminol has also been used for enzyme assays[8] and immunoassays.[9] Light is emitted when electrochemically oxidized luminol reacts with H_2O_2, which allows the reaction to be coupled to oxidase enzymes such as glucose oxidase.[10] The latter enzyme has been used as an antibody label in ECL enzyme immunoassays which constitute a further consolidation of existing technology.[9] The chemiluminescence reaction of luminol is also catalyzed by electrochemically oxidized ferrocenes[11] suggesting that these compounds could be used as labels in an ECL system resembling the one based on ruthenium chelates.

Acridinium esters have been used as labels in chemiluminescence immunoassays for many years.[12] The CL reaction of these compounds does not require a catalyst and is usually triggered by addition of an acidic solution of H_2O_2 followed by a NaOH solution. The acidic solution ensures that inactive pseudo-base is converted to the active acridinium ester and the alkali triggers the CL oxidation of the ester by a H_2O_2.[13] Two advantages of these compounds which do not appear to have been fully exploited are freedom from interference in matrices such as whole blood[14] and their ability to intercalate into the double helix of polynucleotides.[12] Intercalation of an acridinium ester into an oligonucleotide duplex shields it from attack by hydroxide and forms the basis of homogenous hybridization protection assays for RNA.[15]

Recently a large number of esters derived from 9,10-dihydroacridines (reduced acridinium esters and thioesters) based on the *N*-alkyldihydroacridinecarboxylate nucleus, including DMC, have been made at Lumigen.[16] These dihydroacridine compounds are stable in the presence of H_2O_2 and do not form an inactive pseudo-base. Light emission can be triggered by oxidising the acridan with horseradish peroxidase (HRP) in the presence of H_2O_2 and an enhancer such as *p*-iodophenol. HRP oxidizes the 9,10-dihydroacridine to the corresponding acridinium ester, which is immediately subject to nucleophillic attack by the peroxide anion (OOH^-) at the 9 position of the acridinium nucleus; the possibility of pseudo-base formation does not arise because peroxide is several orders of magnitude more nucleophillic than hydroxide.[13] Nucleophillic attack results in the formation of a dioxetanone which decomposes to form the singlet excited state of *N*-methylacridone. This relaxes to the ground state accompanied by the emission of intense blue light with a maximum wavelength of 430 nm. By using these compounds as a substrate for HRP it has been possible to detect as little as 0.1 amol of this enzyme in a 15 min assay.[16]

Although there have been several reports of ECL in aqueous solutions involving acridinium esters[17] and the related compound lucigenin[18] they are all based on the reduction of dissolved oxygen to H_2O_2; this has two disadvantages: reliance on dissolved oxygen concentration and the susceptibility of the acridinium ester to pseudo-base formation.[13] These drawbacks are avoided when DMC is used because the acridinium ester is produced *in situ* from a passive precursor.

Cyclic voltammetry and linear sweep voltammetry with luminometric detection were carried out using an experimental arrangement described previously;[11] all potentials *vs.* Ag/AgCl. The concentrations of DMC and the corresponding acridinium ester were 50 and 5 μM respectively. The second cyclic voltammogram (CV) of DMC shown in Fig. 1 has three peaks located at 0.76 V (peak A), −0.25 (peak B) and −0.11 V (peak C). A plot of light intensity at 430 nm against applied potential for DMC in the presence of H_2O_2 (Fig. 2) has a single peak at 0.75 V corresponding closely to the position of peak A in Fig. 1. This suggests that peak A represents the two electron oxidation of DMC to the corresponding acridinium ester as shown in Scheme 1a, which then reacts with H_2O_2 to generate chemiluminescence as shown in Scheme 1b. Peaks B and C in

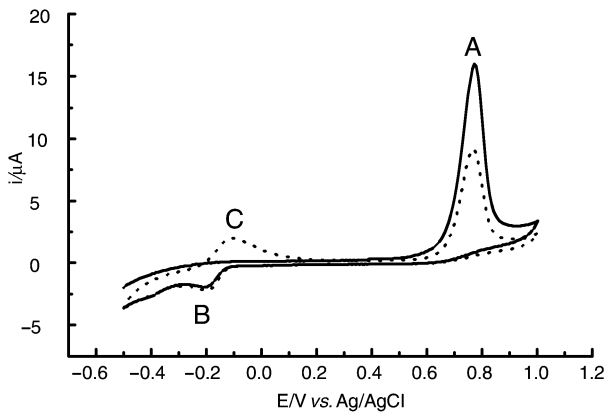

Fig. 1 Two successive cyclic voltammograms of 50 μM DMC in 10 mM Tris buffer with 0.1 M NaCl, 10 mM H_2O_2, and 0.025% Tween-20. Scan rate 100 mV s^{-1}, 1st scan (solid line); 2nd scan (dashed line).

DOI: 10.1039/b003158p

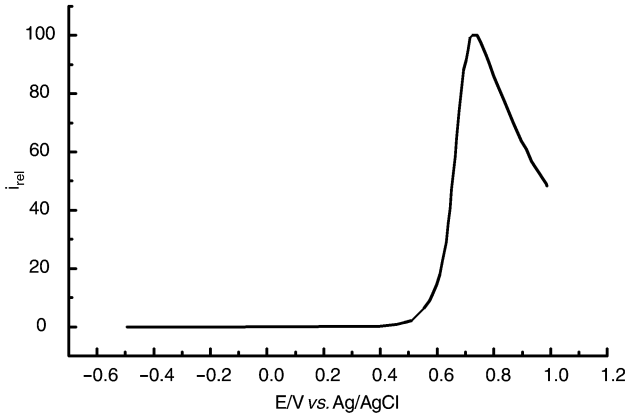

Fig. 2 Dependence of electrochemiluminescence on potential for 50 μM DMC at pH 8.0, in 10 mM Tris buffer with 0.1 M NaCl, 10 mM H_2O_2, 1 mM EDTA and 0.025% Tween-20. Scan rate 10 mV s^{-1}.

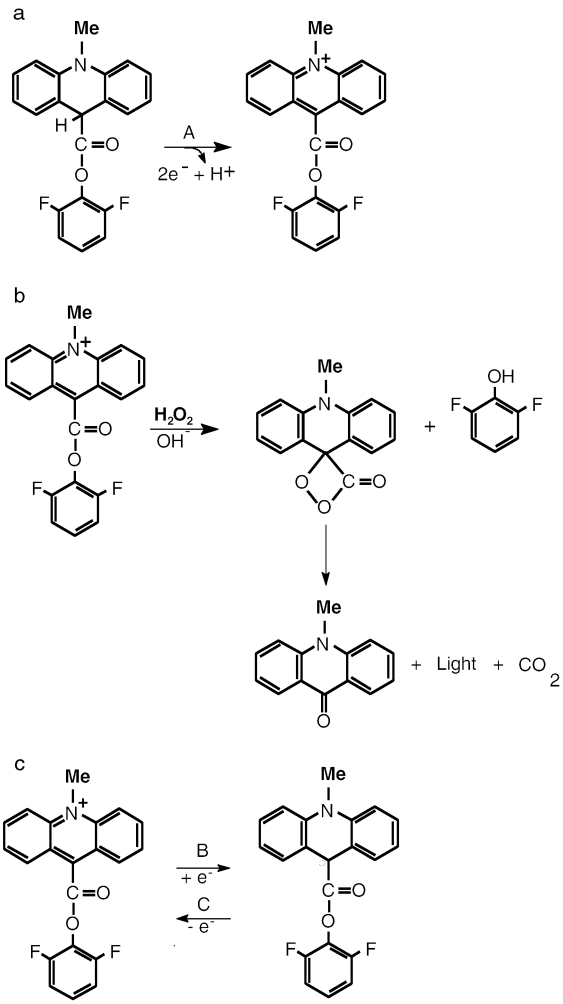

Scheme 1 Large capital letters refer to peaks in CV. (a) Two-electron oxidation of DMC to acridinium ester; (b) CL reaction of acridinium ester with H_2O_2; (c) one-electron redox reactions of acridinium ester/radical couple.

Fig. 1 only appear in the CV after oxidation of DMC and therefore peak B must represent the reduction of an oxidation product. Light emission in the presence of H_2O_2 indicates that an acridinium ester is produced when DMC is oxidized and the simplest explanation for peak B is that it represents reduction of this product as shown in Scheme 1c. This is supported by the observation that peak B is almost absent when a CV is obtained in the presence of H_2O_2, as would be expected if the compound responsible reacts with peroxide. Further investigation of this hypothesis with an authentic sample of the acridinium ester corresponding to DMC[16] gave a CV with two peaks identical to B and C in Fig. 1.

Enzymatic oxidation of DMC by HRP has been reported to occur in two one-electron oxidation steps separated by a non-enzymatic deprotonation.[16] The corresponding electrochemical pathway would be a classic ECE mechanism[19] in which the two enzymatic steps are replaced by electrochemical oxidations. Previous work on acridans, however, has suggested an alternative mechanism in which the second oxidation step occurs in solution as a result of disproportionation between protonated and unprotonated radical intermediates.[20] Further work is required to reveal which mechanism applies to DMC.

We have shown for the first time that CL of the dihydroacridine ester DMC can be triggered by electrochemical oxidation in the presence of H_2O_2. Presently work is in progress to extend this investigation to other 9,10-dihydroacridine esters in order to build up a detailed picture of the mechanism, and the relationship between electrochemiluminescence and molecular structure. ECL of 9,10-dihydroacridines in matrices where light emission from compounds such as luminol is quenched[14] will also be investigated as will the effect of nucleotide duplexes on ECL. The latter investigation is based on the assumption that if intercalation of an acridinium ester into a nucleotide double helix can shield it from hydrolysis it may also shield a 9,10-dihydroacridine ester from oxidation by an electrode.

Notes and references

† The IUPAC name for luminol is 5-amino-2,3-dihydrophthalazine-1,4-dione.

Received (in Liverpool, UK) 1st August 2000, Accepted 16th August 2000
First published as an Advance Article on the web 18th September 2000

Liquid crystalline organic solutions of poly-γ-benzyl-L-glutamate generate a sufficient differential ordering effect to visualize enantiomers using multinuclear high-resolution NMR spectroscopy at natural isotopic abundance levels. Chiral discrimination can be observed through a difference in the order-sensitive NMR observables, namely: proton–proton, carbon–proton and carbon–carbon residual internuclear dipolar couplings, carbon chemical shift anisotropies, and deuterium quadrupolar splittings. In most cases, the enantiodifferentiation is large enough to allow determation of the enantiomeric excesses satisfactorily. All theoretical considerations and significant experimental parameters that affect the efficiency of this methodology are presented and discussed. The various possible anisotropic NMR techniques provide a very reliable and powerful alternative to the current analytical techniques which operate in the isotropic phase.

Muriel Sarfati was born in Saint Denis, France, in 1974. She received her degree in chemistry in 1998 and is now doing a Ph.D at the University of Paris XI with Dr. P. Lesot and Professor J. Courtieu on natural abundance deuterium NMR spectroscopy in oriented solvents.

Philippe Lesot has been a scientific researcher at the CNRS since 1998. He was born in Paris, France, in 1967. He did his Ph.D at the University of Paris XI under the supervision of Professor J. Courtieu (1992–95). He then received a postdoctoral grant from the Royal Society of Chemistry and joined the Professor J. W. Emsley's NMR group at the Chemistry Department of the University of Southampton (1995–96). In 1997–98 he was appointed as lecturer in Chemistry at the University of Paris XI.

Denis Merlet was born in Etampes, France, in 1970. He received his Ph.D from the University of Paris VII in 1998 (Professor J. Courtieu). He was a postdoctoral fellow of the French Foreign Office and spent one year with the NMR group of Professor J.W. Emsley at Southampton (1998–99). In 1999 he returned to the University of Paris XI to take up his present position as a lecturer in Chemistry.

Jacques Courtieu is Professor of Chemistry at the University of Paris XI since 1983. He was born in Saint-Marcellin, France, in 1944. He sustained a Ph.D thesis at the University of Paris XI (Professor J. Jullien), and subsequently was a postdoctoral fellow of the University of Utah, Salt Lake City, for two years with Professor D. M. Grant's NMR team (1976–78). He is currently Chairman of the Orsay Institute for Molecular Chemistry (I.C.M.O.). In 1999, he has received the Grammaticakis-Neuman award from the French Academy of Sciences.

The research interests of the authors focus mainly on the design and the development of new NMR methodologies using oriented solvents with applications in structural chemistry. Their current work includes the enantiodifferentiation of chiral molecules using 1 D and 2 D NMR spectroscopy in chiral liquid-crystalline media.

Introduction

The sustained interest in enantioselective synthesis and the necessity of providing reliable quality control tests for marketed or new candidate synthetic chiral drugs in the pharmaceutical industry, have strongly stimulated the development of novel, convenient and efficient techniques for enantiomeric purity analysis. Among them NMR spectroscopy is widely used. Various NMR methods using isotropic solvents, nicely reviewed by Parker,[1,2] are available for determining enantiomeric excesses (ee's), but all suffer of a lack of generality. For instance, derivatization of chiral molecules using chiral derivatizing agents requires the presence of a reactive function and great care is required to ensure that neither kinetic resolution nor racemization occur during the derivatization. The preparation of specific complexing agents is needed when using chiral solvating agents dependent on the functional groups in the chiral molecule under study. Also the use of chiral lanthanide shift reagents works only when the enantiomers may complex the paramagnetic center in equilibrium at the NMR timescale. Last, but not least, the final result is not always satisfactory as in almost all cases, only the variation of a chemical shift is utilised for discrimining between isomers.

To provide an alternative when usual isotropic NMR methods fail and to avoid some of their main disadvantages, we have developed an analytical approach based on the use of chiral liquid crystals (CLC). The best results, to date, have been obtained with a chiral anisotropic solvent comprised of a synthetic polypeptide, poly-γ-benzyl-L-glutamate (PBLG), dissolved in various organic solvents such as chloroform, dichloromethane, dimethyl formamide, *etc.*[3–6]

NMR spectra of chiral solutes in this liquid crystalline medium are extremely rich in their information because they are affected not only by the usual scalar couplings and chemical shifts, but also by anisotropic interactions such as dipolar couplings, chemical shift anisotropy (CSA) and if the nuclei have a spin $I > 1/2$, by quadrupolar interactions. It is differences in these anisotropic interactions which provide the chiral discrimination. We have shown that this effect originates from the fact that enantiomers are not oriented in the same manner in this chiral anisotropic medium. The great advantage that this new NMR analytical method has over the more established techniques, which use isotropic solvents, is that

chiral discrimination can be achieved for a very wide range of compounds, including those in which there are no functional groups, such as saturated hydrocarbons. A second important advantage is that there are a number of NMR nuclei which can be exploited, and for a specific molecule there are usually many NMR parameters which can be measured, with varying sensitivities to chirality. In this review, we will illustrate this point through the investigation of a single chiral compound, (±)-1-chloropropan-2-ol [(±)-CP] for which we will show that it is possible to discriminate its *S* and *R* isomers using proton, carbon-13 and deuterium NMR spectroscopy, the enantiodifferentiation being based on a difference in their ^{1}H–^{1}H, ^{1}H–^{13}C residual dipolar couplings, carbon-13 CSA or ^{2}H residual quadrupolar splittings. In addition we will report the first successful enantiomeric discrimination based on differences of ^{13}C–^{13}C residual dipolar couplings.

To introduce chemists to this non-conventional area of NMR spectroscopy, all essential theoretical and practical aspects of NMR in chiral anisotropic solvents, particularly when using the PBLG system, are reviewed. Consequently, this article is not a comprehensive survey of successful results already obtained using this methodology, but is rather intended to describe and assess the respective pratical interests of various 1D and 2D multinuclear NMR tools in natural isotopic abundance systems that have been used or specifically developed to visualize enantiomers dissolved in the PBLG phase. Thus, all experimental parameters or useful details that can affect the efficiency of each of the NMR tools proposed will be examined and discussed. It is important to emphasise that all NMR spectra of (±)-CP reported in this work were obtained in natural isotopic abundance.

NMR in chiral oriented solvents: background

Since the pioneering work of Snyder and coworkers, it is known that enantiomers may give different NMR spectra when dissolved in a chiral anisotropic material.[7,8] This situation arises because the difference in the enantioselective interactions between the *S* and *R* isomers and the CLC generally generates a sufficient differential ordering effect (DOE) to discriminate between them using order-sensitive NMR observables.[9,10] These various observables, which are averaged to zero due to the isotropic motion of solutes in the liquid state, are the chemical shift anisotropy, ($\Delta\sigma_i$), the spin–spin coupling anisotropy (ΔT_{ij}) and the quadrupolar splitting for spin $I > 1/2$ nuclei ($\Delta\nu_{Q_i}$).[11] It should be noted that (ΔT_{ij}) is due to the purely anisotropic dipolar couplings (D_{ij}) and to the anisotropy of the scalar coupling, (ΔJ_{ij}), the latter being generally considered small in comparison to D_{ij}. In the following, we will assume that ΔJ_{ij} is negligible, thus reducing ΔT_{ij} to D_{ij}. A rough classification of the sensitivity of these anisotropic interactions towards the DOE of enantiomers indicates that $|\Delta\nu_{Q_i}| > |\Delta T_{ij}| > |\Delta\sigma_i|$.[11]

The analysis of NMR spectra obtained in CLC differs from their isotropic analogues, but the numerous anisotropic interactions provide interesting tools as far as enantiodiscrimination is concerned. Regarding the various active NMR nuclei intrinsically included in any chiral organic compounds and their natural magnetic properties, namely, ^{1}H ($I = 1/2$, 99.985%), ^{13}C ($I = 1/2$, 1.108%) and ^{2}H ($I = 1$, 0.015%), it appears that, theoretically, there are ten possible NMR observables for detecting the DOE, namely $\Delta\sigma_H$, $\Delta\sigma_C$, $\Delta\sigma_D$, ΔT_{HH}, ΔT_{HD}, ΔT_{DD}, ΔT_{CC}, ΔT_{CH}, ΔT_{CD} and $\Delta\nu_{QD}$. However, some of these will not provide an efficient tool for our purpose because the weakness of the natural isotopic abundance of the involved nuclei. For instance, the present sensitivities of routine spectrometers do not permit the observation of ΔT_{CD} or ΔT_{DD}, in natural abundance NMR. In contrast, when enantiomers under investigation exhibit other X-active nuclei of spin $I = 1/2$ (fluorine-19, phosphorus-31,…) or $I > 1/2$ (boron-10, boron-11,…), additional NMR observables such as $\Delta\sigma_X$, ΔT_{HX}, ΔT_{CX} or $\Delta\nu_{QX}$ are available and therefore increase the probability to reveal an enantiomeric discrimination.[12,13] Finally, as all these anisotropic NMR interactions are order-sensitive and therefore temperature-, concentration- and solvent-dependent, we have three further variables at our disposal to control the DOE, thus enhancing the probability to detect a chiral differentiation. Consequently, this analytical strategy offers undoubtfully better possibilities for discriminating between enantiomers compared with current isotropic NMR techniques in which only the variation of a chemical shift is used.[1,2] As we will show throughout this work, the two main features of this non-conventional approach generally involving a single NMR sample preparation are, therefore, both its analytical potentialities and high adaptability from the NMR point of view.

Description of the chiral liquid crystalline solvent

The chiral recognition principle in the liquid crystalline state is based on the ability for the chiral phase to orientate differently the two enantiomers as schematically depicted in Fig. 1, and so the choice of the solvent is crucial.[8,9,14,15] As a consequence, we need to have a system able to interact enantioselectively with almost all enantiomers (functionalized or not) and give sufficiently large orientational differences which can be revealed using NMR spectroscopy. This condition supposes therefore that the enantioselective electrostatic interactions as well as geometric shape recognition play an important role in the discrimination mechanisms. Actually, this situation is very similar to that involved for enzymatic enantioselectivity in biological systems.

From the NMR point of view, the liquid crystal should ideally solubilize almost all organic compounds, provide a very homogeneous anisotropic mesophase with low viscosity at about room temperature, and its NMR spectrum should not interfere with that of the dissolved molecules. In addition, the DOE is not directly related with the magnitude of orientational order parameters and in fact it is advantageous to use an anisotropic solvent exhibiting low molecular ordering for solutes. This is firstly because in the majority of cases the proton and proton-coupled X spectra can be easily analysed in a similar way as for isotropic spectra. Second, the contribution to NMR linewidths of order inhomogeneities in the sample is rather small, hence a higher signal-to-noise (*S/N*) ratio may be achieved. This is a key point to observe chiral discriminations for very low-sensitive quadrupolar nuclei such as deuterons at natural abundance level.[16–18]

Among the CLC examined up to now, the most valuable mesophase satisfying all criteria mentioned above is the lyotropic system poly-γ-benzyl-L-glutamate (PBLG) or its enantiomer poly-γ-benzyl-D-glutamate (PBDG), in solution with various organic helicogenic co-solvents.[19–22] In such co-solvents, the main chain of the synthetic homo-polypeptide adopts a rigid α-helical conformation similar to that observed for some naturally occuring polypeptides[23] while the glutamate side chains, which branch from the main helix, also form a secondary molecular helix.[22,24–26]

Within a certain concentration range, organic solutions of PBLG are liquid crystals. Spontaneously, the PBLG chiral fibers orientate to form a macroscopic, supramolecular helical structure of directors in the mesophase, typical of that exhibited by cholesteric liquid crystals. However, when submitted to a routine NMR magnetic field, the supramolecular helix unwinds, and the system behaves like a chiral nematic phase with positive anisotropy of the molecular diamagnetic susceptibility ($\Delta\chi_m > 0$), with the director, $\boldsymbol{n}$, homogeneously aligned parallel to the static magnetic field $\boldsymbol{B}_o$ (Fig. 1).[27,28] Various possible co-organic solvents may be used. Chloroform, dichloromethane, dioxane, DMF and THF are among the most convenient to dissolve a wide variety of organic materials.[24,29,30] However,

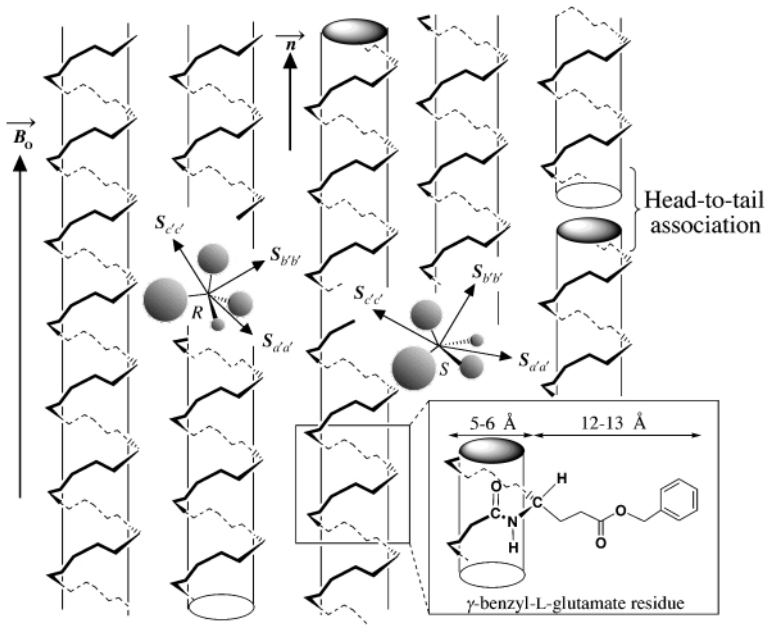

Fig. 1 Schematic illustration of the differential ordering effect for two enantiomers dissolved in the PBLG phase. To clarify the drawing, the glutamate side chains of the polypeptide and the co-solvent molecules were not displayed. The assignments *S* and *R* and the space representation of the orientational principal axis system (a',b',c') of enantiomers should be regarded as arbitrary. The PBLG and chiral solutes are not plotted to scale. Note the head-to-tail associations between two PBLG fibers.

for DMF or dioxane, it is necessary to heat the mixture in order to dissolve the polymer during the sample preparation. In all cases the organic co-solvent employed has to homogeneously dissolve the polypeptide and preserve the α-helical structure of the polymer. For instance, trifluoroacetic acid and DMSO are not suitable co-solvents since they form strong intermolecular hydrogen bonds with the polypeptide chain, giving rise to a random coil conformation for the PBLG, and consequently, the liquid crystalline properties of the solvent disappear.[24] Studies for the optimisation of the ternary mixture, 'PBLG/co-solvent/chiral material', have established that the best NMR results are generally obtained for samples prepared with a concentration in PBLG which varies between 12 and 25% by weight. Except for molecules that are able to precipitate the PBLG fibers, the addition of a reasonable amount of solute (1–20%) in PBLG/co-solvent mixtures does not disrupt the liquid crystalline properties of the solvent. The average molecular weight of PBLG is another important factor for the quality of the enantiodiscrimination. Indeed, this parameter as well as the concentration of the polymer and the nature of the organic co-solvent determine the sample viscosity. Using the same co-solvent and keeping the PBLG concentration constant, the viscosity of the phase significantly decreases when the molecular weight of the polymer is reduced. Generally, a greater fluidity of the liquid crystalline phase provides longer apparent transversal relaxation times for solutes (T_2*), and hence a better spectral resolution and *S/N* ratio. Therefore, we suggest using a PBLG whose degree of polymerisation (DP) is in the range 350–600.[4,5] Under these conditions, the sample temperature can be optimized between 285 and 340 K depending on both the organic co-solvent used and the solute under investigation. Finally we note that a DP below 200 is not convenient for our purpose because the liquid crystal range of the sample is either too small or non-existent.

Theoretical considerations

Analysis of the order-dependent NMR observables involved in chiral differentiation

When embedded in a liquid crystal, solute molecules are partially ordered.[11] This situation arises also using chiral liquid crystals, but in this case, the difference of interactions between the enantiomers and the PBLG molecules generally produces a measurable difference in their orientational ordering.[8,9,31] Consequently, the molecular order of *S* and *R* isomers must be described by two distinct second-rank order tensors, $\boldsymbol{S}^S$ and $\boldsymbol{S}^R$, denoted Saupe matrices, whose elements can be expressed as:[11]

$$S_{\alpha\beta}^{S\text{ or }R} = \frac{1}{2}\left\langle 3\cos\theta_{\alpha_z}^{S\text{ or }R}\cos\theta_{\beta_z}^{S\text{ or }R} - \delta_{\alpha\beta}^{S\text{ or }R}\right\rangle \qquad (1)$$

In this equation, $\alpha,\beta = a,b,c$ are the axes of the molecular fixed reference frame, $\theta_{\alpha_z}^{S\text{ or }R}$ is the angle between the magnetic field and the molecule fixed α axis in the *S* or *R* isomers (the *z* laboratory axis is assumed parallel to the $\boldsymbol{B}_o$ axis). $\delta_{\alpha\beta}$ is the Kronecker symbol (unity if $\alpha = \beta$ and zero otherwise). The angular brackets denote a statistical average over all orientations of the molecule as well as over all intramolecular motions. From the components of $\boldsymbol{S}^{S\text{ or }R}$, we can derive the order parameter, $S_{ij}^{S\text{ or }R}$, of any direction along a vector $\boldsymbol{v}_{ij}$ in the molecular axis system (a,b,c):

$$\begin{aligned} S_{ij}^{S\text{ or }R} &= \sum_{\alpha,\beta=a,b,c}\cos\theta_{ij\alpha}^{S\text{ or }R}\cos\theta_{ij\beta}^{S\text{ or }R}S_{\alpha\beta}^{S\text{ or }R} \\ &= \frac{1}{2}\left(3\cos^2\theta_{ija}^{S\text{ or }R}-1\right)S_{aa}^{S\text{ or }R} \\ &+ \frac{1}{2}\left(\cos^2\theta_{ijb}^{S\text{ or }R}-\cos^2\theta_{ijc}^{S\text{ or }R}\right)\left(S_{bb}^{S\text{ or }R}-S_{cc}^{S\text{ or }R}\right) \\ &+ 2\left(\cos\theta_{ija}^{S\text{ or }R}\cos\theta_{ijb}^{S\text{ or }R}\right)S_{ab}^{S\text{ or }R} \\ &+ 2\left(\cos\theta_{ija}^{S\text{ or }R}\cos\theta_{ijc}^{S\text{ or }R}\right)S_{ac}^{S\text{ or }R} \\ &+ 2\left(\cos\theta_{ijb}^{S\text{ or }R}\cos\theta_{ijc}^{S\text{ or }R}\right)S_{bc}^{S\text{ or }R} \end{aligned} \qquad (2)$$

where the $\cos\theta_{ij\alpha}^{S\text{ or }R}$ are the director cosines of the vector $\boldsymbol{v}_{ij}$ in the molecular fixed frame. All the order-dependent NMR interactions are related to these order parameters as we will see in the next sections.

As a consequence of the DOE and of the non-zero averaging of order-dependent NMR interactions, the total static spin-Hamiltonian which describes the NMR spectra of each diamagnetic enantiomer in CLC must be written as the sum of four distinct terms:

$$\mathcal{H}_{\text{tot}}^{S\text{ or }R} = \mathcal{H}_{\text{cs}}^{S\text{ or }R} + \mathcal{H}_{\text{J}}^{S\text{ or }R} + \mathcal{H}_{\text{D}}^{S\text{ or }R} + \mathcal{H}_{\text{Q}}^{S\text{ or }R} \quad (3)$$

where $\mathcal{H}_{\text{cs}}^{S\text{ or }R}$ is the Zeeman term including the electronic shielding contribution, $\mathcal{H}_{\text{J}}^{S\text{ or }R}$ and $\mathcal{H}_{\text{D}}^{S\text{ or }R}$ are the indirect electron-coupled and direct through-space spin–spin interactions and $\mathcal{H}_{\text{Q}}^{S\text{ or }R}$ is the quadrupolar interaction caused by electric field gradients acting on quadrupolar nuclei ($I > 1/2$). In this respect, magnetic interactions for liquid crystalline solutions are not different from those of solid state NMR, except that molecules are free to diffuse and tumble, leading to line narrowing, and hence high resolution spectra.

Let us now treat in detail the various order-dependent NMR observables involved in the analysis of NMR spectra of enantiomers in chiral anisotropic media.

Chiral discrimination arising from chemical shift anisotropy

In a chiral anisotropic solvent, the resonance frequency ν_i of a nucleus i contains both an isotropic, σ_i^{iso}, and an anisotropic, $\Delta\sigma_i$, contribution to the electronic shielding and may be written for two enantiomers such as:[11]

$$\nu_i^{R\text{ or }S} = \frac{\gamma}{2\pi}\left[1 - \sigma_i^{\text{iso}} - \Delta\sigma_i^{S\text{ or }R}\right] B_{\text{o}} \quad (4)$$

Expressed in a molecular frame (a,b,c), the terms σ_i^{iso} and $\Delta\sigma_i$ at the ith site are defined as:

$$\sigma_i^{\text{iso}} = \frac{1}{3}\left(\sigma_{iaa} + \sigma_{ibb} + \sigma_{icc}\right) \text{ and}$$

$$\Delta\sigma_i^{S\text{ or }R} = \frac{2}{3}\sum_{\alpha,\beta=a,b,c}\sigma_{i\alpha\beta}S_{\alpha\beta}^{S\text{ or }R} \quad (5)$$

Eqn. (4) indicates clearly that chiral discrimination is detected in NMR spectra when $\nu_i^S - \nu_i^R \neq 0$ as depicted in Fig. 2(a), *i.e.* when Δs_i^S significantly differs from $\Delta\sigma_i^R$. However, the quantity

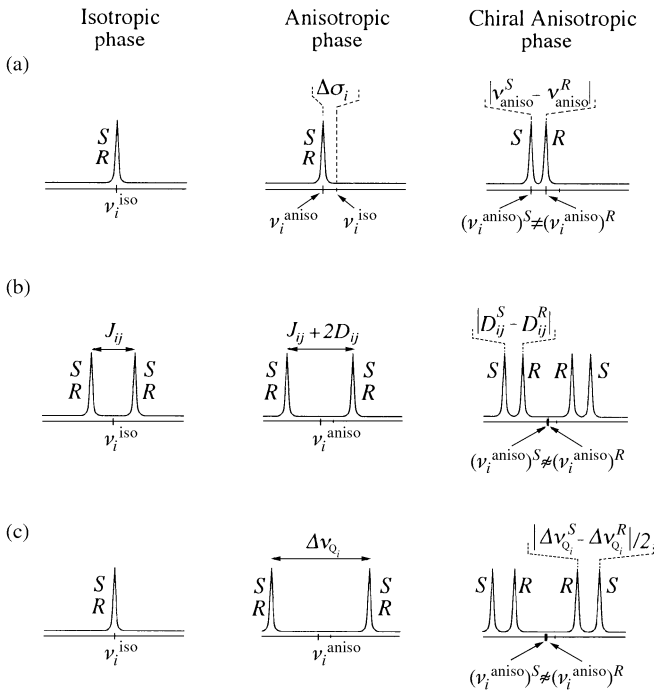

Fig. 2 Principle of the enantiomeric discrimination in CLC based on (a) a difference of chemical shift anisotropies, $\Delta\sigma_i$, (b), residual dipolar couplings, D_{ij}, and (c) residual quadrupolar splittings, $\Delta\nu_{\text{Q}_i}$, for $I = 1$ nuclei (deuterium). For all examples, we have assumed that $\Delta\sigma_i$, was negative. In addition (b) and (c) are depicted assuming the CSA difference ($\Delta\sigma_i^S - \Delta_i^R$) between the enantiomers in the chiral anisotropic phase was negligible. D_{ij}^S and D_{ij}^R were chosen to be smaller than J_{ij}, and having a positive and negative sign, respectively. $\Delta\nu_{\text{Q}_i}$ can be positive or negative. The various spectra are not plotted to scale. The assignments S and R given in all spectra are arbitrary.

$\Delta\sigma_i^{S\text{ or }R}$ is not trivial to analyse as from eqn. (5) it depends both on the elements of the shielding tensor and on the orientational order parameters, $S_{\alpha\beta}^{S\text{ or }R}$, in the same reference frame. In order to consider the various factors governing this quantity, it is more convenient to recast the previous equation into:

$$\begin{aligned}\Delta\sigma_i^{S\text{ or }R} = {} & \frac{2}{3}\left[\sigma_{iaa} - \frac{1}{2}\left(\sigma_{ibb} + \sigma_{icc}\right)\right]S_{aa}^{S\text{ or }R} \\ & + \frac{1}{3}\left(\sigma_{ibb} - \sigma_{icc}\right)\left(S_{bb}^{S\text{ or }R} - S_{cc}^{S\text{ or }R}\right) \\ & + \frac{4}{3}\left(\sigma_{iab}S_{ab}^{S\text{ or }R} + \sigma_{iac}S_{ac}^{S\text{ or }R} + \sigma_{ibc}S_{bc}^{S\text{ or }R}\right)\end{aligned} \quad (6)$$

For each nucleus i of both enantiomers, there exists a principal frame (a'_i, b'_i, c'_i), where the chemical shift tensor is diagonal. Consequently the relationship (6) can be rewritten as:

$$\begin{aligned}\Delta\sigma_i^{S\text{ or }R} = {} & \frac{2}{3}\left[\sigma_{ia'a'} - \frac{1}{2}\left(\sigma_{ib'b'} + \sigma_{ic'c'}\right)\right]S_{ia'a'}^{S\text{ or }R} \\ & + \frac{1}{3}\left(\sigma_{ib'b'} - \sigma_{ic'c'}\right)\left(S_{ib'b'}^{S\text{ or }R} - S_{ic'c'}^{S\text{ or }R}\right)\end{aligned} \quad (7)$$

with

$$S_{ia'a'}^{S\text{ or }R} = \sum_{\alpha,\beta=a,b,c}\cos\theta_{ia'\alpha}^{S\text{ or }R}\cos\theta_{ia'\beta}^{S\text{ or }R}S_{\alpha\beta}^{S\text{ or }R}$$

where $\theta_{ia'\alpha}$ are the angles between the principal axis system of the chemical shift tensor of a nucleus i and the molecular frame.

In eqn. (7), the quantity $\sigma_{ia'a'} - (\sigma_{ib'b'} + \sigma_{ic'c'})/2$ corresponds to the anisotropy of the electronic shielding of atom i, σ_i^{aniso}, while ($\sigma_{ib'b'} - \sigma_{ic'c'}$) may be seen as the asymmetry of the electronic shielding, σ_i^{asym}. An examination of the relationship (7) shows clearly that σ_i^{aniso} and σ_i^{asym} as well as the order parameter differences ($S_{ia'a'}^S - S_{ia'a'}^R$) and [($S_{ib'b'}^S - S_{ic'c'}^S$) − ($S_{ib'b'}^R - S_{ic'c'}^R$)], should both be large in order to detect any frequency difference, $|\nu_i^S - \nu_i^R|$, between the NMR signals of nucleus i for each enantiomer. Consequently, all factors which would increase either the difference in order parameters between enantiomers or the electronic shielding anisotropy of nucleus i (such as the nature of the substituents bonded to nucleus i or its hybridization state) will increase the magnitude of $\Delta\sigma_i$. As the magnitude of the shielding anisotropy, however, is rather small for almost all nuclei involved in classical organic molecules compared with other NMR interactions, only nuclei having the largest CSAs such as sp or sp^2 carbon atoms or fluorine atoms may provide appropriate spy nuclei allowing enantiomers to be differentiated on the basis of a CSA difference.[11,32,33] In contrast, deuterium, proton or sp^3 carbon atoms are rather poor in regard to CSA.

Chiral discrimination using the internuclear dipolar coupling interactions

In the spectra of enantiomers dissolved in chiral liquid crystalline solutions, dipolar interactions between atoms are not averaged to zero. In this case each pair of interacting nuclei i and j for both isomers may produce a direct dipolar coupling defined in Hz as:[11]

$$D_{ij}^{S\text{ or }R} = -k_{ij}\left\langle\frac{S_{ij}^{S\text{ or }R}}{r_{ij}^3}\right\rangle \text{ with } k_{ij} = \frac{\mu_{\text{o}}}{4\pi}\frac{h\gamma_i\gamma_j}{4\pi^2} \quad (8)$$

In this equation, γ_i and γ_j are the magnetogyric ratios of nuclei i and j, and μ_{o} is the permeability constant of a vacuum. The angular brackets denote an (ensemble or time) average over molecular tumbling and internal motions (vibrational motions,

conformational changes…), r_{ij} is the internuclear distance between nuclei i and j and $S_{ij}^{S\text{ or }R}$ is the order parameter for the internuclear vector $\boldsymbol{r}_{ij}$. Note that the magnitude of k_{ij} depends on the nuclear isotopes involved. For intance, the k_{ij} values are 7.59, 28.4, 30.19, 112.96, 120.07 kHz Å^{-3} for ^{13}C–^{13}C, ^{19}F–^{13}C, ^{1}H–^{13}C, ^{19}F–^{1}H, ^{1}H–^{1}H, interacting pairs, respectively.

Disregarding any discrepancies in the molecular geometry between two enantiomers, eqn. (8) shows that the chiral discrimination between enantiomers occurs when the internuclear order parameters, $S_{ij}^{S\text{ or }R}$, are different for the S and R isomers [Fig. 2(b)]. Although $S_{ij}^{S\text{ or }R}$ can be related to the molecular order matrix elements, $S_{\alpha\beta}^{S\text{ or }R}$, using eqn. (2), it is also convenient and often easier to express this parameter relative to the $\boldsymbol{B}_o$ axis as:

$$S_{ij}^{S\text{ or }R} = \frac{1}{2}\left\langle 3\cos^2\theta_{ij}^{S\text{ or }R} - 1\right\rangle \qquad (9)$$

where $\theta_{ij}^{S\text{ or }R}$ is now the angle between the internuclear vector $\boldsymbol{r}_{ij}$ and $\boldsymbol{B}_o$. It must be emphasised that the dipolar coupling difference, $D_{ij}^S - D_{ij}^R$, measured from spectra varies with the relative position of the internuclear vectors $\boldsymbol{r}_{ij}^S$ and $\boldsymbol{r}_{ij}^R$ with respect to $\boldsymbol{B}_o$. This point will be discussed in detail for the quadrupolar interaction.

Finally as underlined in the Introduction, the presence of internuclear dipolar interactions has a profound impact on the spectrum of a molecule dissolved in liquid crystals (chiral or not). As a consequence, the analysis of dipolar spectra may appear rather puzzling compared to those recorded in an isotropic medium. For instance, a first order splitting, denoted T_{ij}, observed between two coupled anisochronous nuclei i and j, is now equal to $J_{ij} + 2\Delta T_{ij}$, where J_{ij} is the isotropic part of the scalar coupling and ΔT_{ij} is the anisotropic part of the total coupling that we limit to the dipolar contribution, D_{ij} [see Fig. 2(b)]. Consequently, as the sign of D_{ij} can be negative or positive, the first order splitting between two non-equivalent nuclei may be zero when $J_{ij} = -2D_{ij}$, producing a fortuitous decoupling. This situation is often encountered for weakly ordered liquid crystals such as organic solutions of PBLG because in this case dipolar and scalar couplings are of the same order of magnitude. Furthermore, dipolar couplings are observable between magnetically equivalent nuclei, contrary to scalar couplings. Thus, in proton liquid crystal NMR, the nuclei of an isolated methyl group produce a 1:2:1 triplet, while a methylene group produces a 1:1 doublet. In both cases the splittings are equal to $3D_{HH}$. Actually, in an anisotropic medium, the spectrum of any n-fully equivalent $I = 1/2$ nuclei consists of an n-multiplet with line spacing $3D$ and a binomial distribution of intensities.

Chiral discrimination using the quadrupolar coupling interaction

NMR spectra of quadrupolar nuclei (spin $I > 1/2$) in oriented solvents are dominated by the nuclear quadrupole–electric field gradient interaction. Disregarding spin–spin couplings, the spectrum, to first order, consists of equally spaced $2I$ peaks corresponding to the various $m \leftrightarrow m + 1$ transitions. The separation between the lines, denoted, $\Delta\nu_{Q_i}$, is referred to as the quadrupolar splitting as shown in Fig. 2(c). For two enantiomers oriented differently in a chiral ordered environment and assuming that the quadrupole term is much smaller than the Zeeman term, the quadrupolar Hamiltonian can be written in frequency units as:[11]

$$\mathcal{H}_Q^{S\text{ or }R} = \frac{1}{h}\sum_i \frac{e^2 Q_i q_{izz}^{S\text{ or }R}}{4I_i(2I_i-1)}\left[3I_{zi}I_{zi} - I_i(I_i+1)\right] \qquad (10)$$

where eQ_i is the nuclear electric quadrupole moment of nucleus i, $eq_{izz}^{S\text{ or }R}$ is the component of the electric field gradient (EFG) tensor along the magnetic field (z axis) at the nucleus i for each enantiomer. In this equation, eq_{izz}, is related to the elements of the EFG tensor in the molecular frame, $eq_{i\alpha\beta}$, using:

$$eq_{izz}^{S\text{ or }R} = \frac{2}{3}\sum_{\alpha,\beta=a,b,c} eq_{i\alpha\beta} S_{\alpha\beta}^{S\text{ or }R} \qquad (11)$$

For most quadrupolar nuclei, the relaxation induced by the purely anisotropic quadrupolar interaction broadens the signals so strongly that the analytical potential produced by the DOE in a chiral mesophase is lost. However, the relaxation behaviour for some nuclei, such as boron-10 ($I = 3$), boron-11 ($I = 3/2$) or deuterium atoms ($I = 1$), resembles that of spin-1/2 nuclei in small molecules owing to their small quadrupole moment, and produces high-resolution quadrupolar NMR spectra.[13] In the case of deuterons, which are monovalent atoms, the EFG is usually assumed to lie along the C–D bond direction and to be axially symmetric. Choosing one of the principal axes along the C–D bond, and safely neglecting any asymmetry parameter the quadrupolar splitting between the two lines [Fig. 2(c)] can be written as:

$$\Delta\nu_{Q_i}^{S\text{ or }R} = \frac{3}{2}K_{C-D_i}\, S_{C-D_i}^{S\text{ or }R} \text{ with } K_{C-D_i} = \frac{e^2 Q_{D_i} q_{C-D_i}}{h} \qquad (12)$$

where $S_{C-D_i}^{S\text{ or }R}$ is the order parameter of the C–D$_i$ axis for the R or S enantiomers and K_{C-D_i} is the deuterium quadrupolar coupling constant. Note that K_{C-D_i} varies depending on the hybridization state of the carbon bonded to a given deuteron. Thus K_{C-D_i} is approximately equal to 170 ± 5 kHz, 185 ± 5 kHz and 210 ± 5 kHz, for sp^3, sp^2 and sp carbons, respectively.[11,34]

Similarly to eqn. (9), the order parameter associated with the EFG for a C–D bond can be related to the molecular order parameters through eqn. (2) and is expressed relative to $\boldsymbol{B}_o$ as:

$$S_{C-D_i}^{S\text{ or }R} = \frac{1}{2}\left\langle 3\cos^2\theta_{C-D_i}^{S\text{ or }R} - 1\right\rangle \qquad (13)$$

As already described for the dipolar interaction, eqn. (12) shows that chiral differentiation $|\Delta\nu_{Q_i}^S - \Delta\nu_{Q_i}^R| \neq 0$ occurs when $|S_{C-D_i}^S - S_{C-D_i}^R| \neq 0$. Eqn. (13) indicates, however, that order parameters, $S_{C-D_i}^{S\text{ or }R}$, are composite quantities as they depend both on the angle $\theta_{C-D_i}^{S\text{ or }R}$ and on the motional averaging ($\langle \ldots \rangle$). Consequently whenever two-order parameters are different between enantiomers, we generally do not know if this happens from a purely geometrical reason, $\theta_{C-D_i}^S \neq \theta_{C-D_i}^R$, or from a difference involving motional averaging, or both. However assuming that the motional averaging for enantiomers is more or less the same, it appears that the magnitude of the differentiation should depend strongly on the relative position of the EFG direction for both isomers with respect to $\boldsymbol{B}_o$ (Fig. 3). These variations occur because the trigonometric function, $(3\cos^2\theta - 1)/2$, is very steep for angles around the magic angle, $\theta_m = 54.7°$ (for which the function is null, and hence $S_{C-D_i}^{S\text{ or }R} = 0$), and rather flat in the angular ranges of [−5, +5°] and [+85, +95°]. Analyzing the evolution of the calculated quadrupolar splitting difference, assuming $\theta_{C-D_i}^S = \theta_{C-D_i}^R + 10°$, and the corresponding spectra plotted in Fig. 3, we can easily see that larger chiral discriminations are obtained when θ_{ij}^S and θ_{ij}^R vary in the interval $\theta_m \pm 20°$. This range of angles corresponds also to the smallest values for $S_{C-D_i}^{S\text{ or }R}$ and subsequently to the smallest magnitudes of quadrupolar splittings. As shown in Fig. 3, there exist several particular spectral situations corresponding to either the cancellation of quadrupolar splitting for one of the enantiomers ($\theta_{ij}^S = \theta_m$ or $\theta_{ij}^R = \theta_m$) or the disappearance of the chiral discrimination ($S_{ij}^S = S_{ij}^R$). Note that the various spectral situations simulated here in the case of spins-1 could be also observed for two dipolar coupled magnetically equivalent spins-1/2. The great efficiency of deuterium NMR in the discrimination of enantiomers in PBLG mainly originates from the relatively large magnitude of the deuterium quadrupolar coupling constants, K_{C-D}, compared with almost all k_{ij},

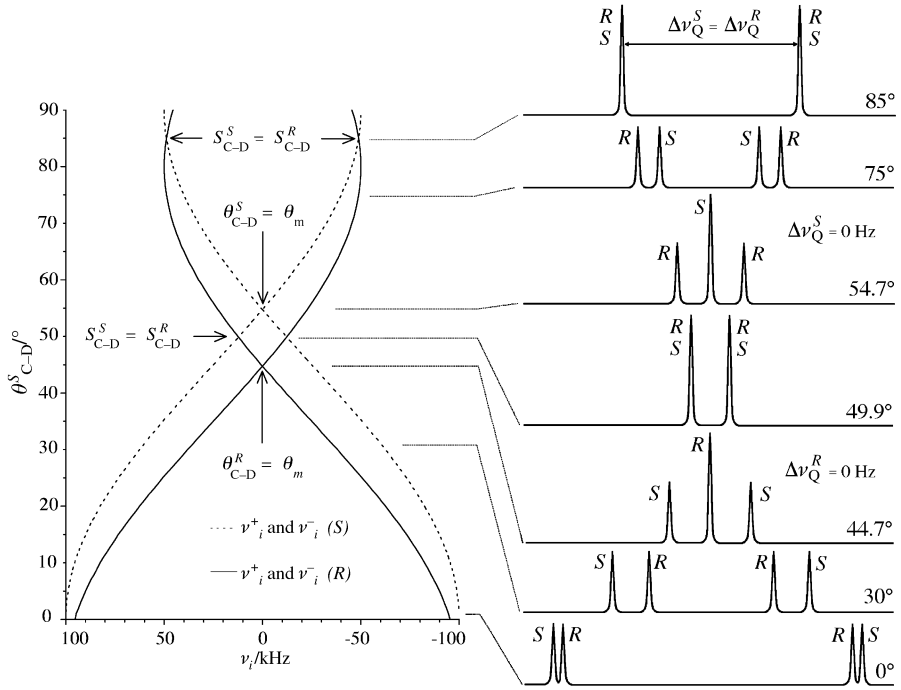

Fig. 3 Theoretical evolution of the two components (ν_i^- and ν_i^+) of a quadrupolar doublet associated with two enantiomers, versus the angle θ_{C-D}^S. We have assumed that K_{C-D} = 133 kHz and the difference $\theta_{C-D}^S - \theta_{C-D}^R$ = +10° for all values. On the right of the figure, the expected spectra for various angles θ_{ij} are shown. Note the four particular situations corresponding to $\theta_{C-D}^R = \theta_m$, $S_{C-D}^S = S_{C-D}^R$ when $\theta_{C-D}^S < \theta_m$, $\theta_{C-D}^S = \theta_m$ and $S_{C-D}^S = S_{C-D}^R$ when $\theta_{C-D}^S > \theta_m$, respectively. The *S* and *R* assignment given for the initial spectrum is arbitrary.

involved in the dipolar interaction. Indeed, even when the DOE between two enantiomers is rather small, the magnitude of the deuterium quadrupolar coupling constant for a C–D bond can make the difference in their residual quadrupolar splittings, $|\Delta\nu_{Q_i}^S - \Delta\nu_{Q_i}^R|$, measurable.

Experimental and NMR technical considerations

In this technique, PBLG sample preparation is very important because it may affect strongly the quality of NMR spectra, in particular the linewidths. The typical procedure to prepare a PBLG sample consists of directly weighing 2–100 mg of racemic material, 80–100 mg of PBLG and adding about 350–500 mg of co-solvent into a 5 mm NMR tube. Note that the viscosity of the mixture and the evaporation of the co-solvent preclude the possibility of preparing and handling the sample outside the NMR tube. Under these conditions, the total volume of the sample is optimal compared to the length of the coil of a 5 mm diameter dual probe-head. In this study we have added 100 mg of PBLG (DP = 562, MW ≈ 120 000), 100 mg of 1-chloropropan-2-ol (CP) in racemic mixture and 350 mg of dry chloroform. The polymer was purchased from Sigma and used with no further purification, however numerous preparative methods of PBLG are possible and have been described in the literature.[24,35–37] It is recommended to wait for slow dissolution of the compounds in the NMR tube (which was sealed to prevent any co-solvent evaporation) and then to centrifuge the sample in both directions until an optically homogeneous birefringent phase is obtained. Finally, before measuring the NMR spectra, the sample was kept for about 15 min in the magnetic field in order to achieve a good thermal equilibration and the complete unwinding of the cholesteric pitch prior to starting the shimming procedure.

NMR experiments in PBLG can be performed on any routine spectrometer and no special hardware equipment is required. Nevertheless, using a high magnetic field is a strong advantage to increase the chemical shift dispersion and to record low sensitivity nuclei at natural abundance level such as deuterium. In this work, all NMR spectra were obtained on a Bruker DRX-400 high-resolution NMR spectrometer equipped with an inverse 5 mm multinuclear probe, the operating frequencies being 400.1, 100.6 and 61.4 MHz for ^{1}H, ^{13}C and ^{2}H, respectively. The NMR probehead was tuned and matched very carefully to minimize losses in probe efficiency. This is of importance for detecting nuclei of very low natural isotopic abundance such as deuterons. The NMR tube was not spun in the magnet and the temperature of the sample was regulated carefully at 298.0 ± 0.1 K by the Bruker BVT 3000 temperature unit in order to prevent substantial temperature fluctuations. Note here that the sample rotation does not produce a significant improvement in the spectral resolution when the magnetic field homogeneity is good whereas a good long term thermal stability ensures an optimal spectral resolution. The field-frequency lock was not used, but the field drift of our magnet is small enough to allow for a long time accumulation without significant line broadening. When long term field stability is poor, field-frequency lock on a deuterium signal is possible, one component of the quadrupolar doublet of the deuterated solvent providing the lock signal for instance. The recording of natural abundance deuterium spectra of solutes is, however, not possible in this case. One solution consists of using a fluorine-19 signal as lock signal. Thus a few drops of $CFCl_3$ can be added to the co-solvent without perturbing the PBLG phase, but this technical solution requires a fluorine-19 lock device and a suitable probe. In order to avoid possible sample heating which can produce some line broadening, proton-decoupled carbon or deuterium spectra are recorded applying broadband proton decoupling using the WALTZ-16 composite pulse sequence (≈ 0.5 W of rf power).[38] Note here that the proton decoupling in PBLG does not necessitate more power than for isotropic samples because of the rather small amplitude of the residual heteronuclear dipolar interactions. Other specific experimental details for each technique will be given in the figure captions.

Description and analysis of various anisotropic NMR tools in PBLG

Proton NMR spectroscopy

Proton spectra of oriented molecules in classical thermotropic LCs are dominated by the residual dipolar couplings and yield

usually non-trivial second order spectra. The reason for this is that the magnitude of partially averaged ^{1}H–^{1}H dipolar couplings are often much larger than the chemical shift differences.[11] Actually, this analytical circumstance is less often encountered using organic solutions of PBLG because of the weak degree of molecular orientation in PBLG. The value of order parameters are in the range 10^{-3} to 10^{-5}, and consequently the dipolar couplings are often small (negative or positive) values compared to Larmor frequency differences.[9,10] Consequently, the analysis of proton spectra in PBLG may often be carried out at first order and allows detection of a possible chiral discrimination.

To illustrate our purpose, Fig. 4 shows the proton signals of the methyl group in (±)-CP where two different spectral

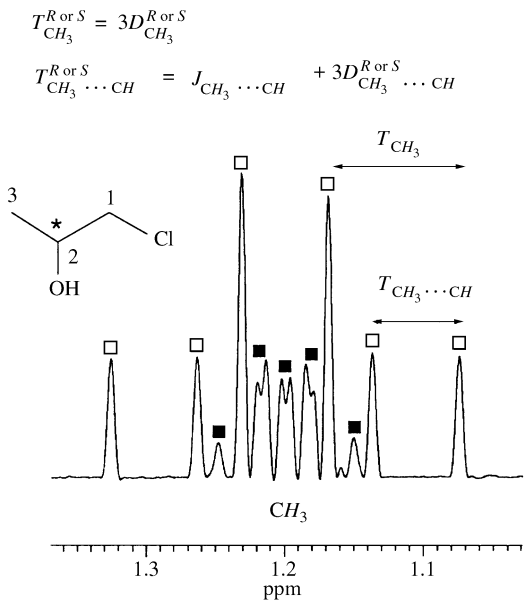

Fig. 4 Proton signal of the methyl group of (±)-CP. The spectrum was Fourier transformed after adding 256 scans. The peaks due to each enantiomer are labelled by (□) and (■). Zero filling, digital gaussian filtering (GB = 40% and LB = −9 Hz) and a baseline correction were applied to increase the digital resolution and enhance the spectral aspect.

patterns, centred on the same chemical shift, may be observed, one for each enantiomer. As already suggested in the theoretical section, this situation illustrates perfectly that the very weak sensitivity of proton CSA toward the DOE does not generally allow a chemical shift difference between enantiomers to be measured on the ^{1}H spectra (even at 400 MHz). In contrast, the superposition of two spectral patterns for the methyl shows the chiral separation of enantiomers through a difference in the residual ^{1}H–^{1}H dipolar couplings. Thus, for one of the enantiomers (labelled using white squares) we obtain a doublet of triplets due to the dipolar couplings between the three equivalent protons of the methyl group and to the coupling with the proton directly attached to the asymmetric carbon. From the values T_{CH_3} and $T_{CH_3\cdots CH}$, measured directly from the spectrum, we can determine the ^{1}H–^{1}H residual dipolar constants. We find here $|D_{CH_3}| = 12.4$ Hz and $|D_{CH_3\cdots CH}| = 9.1$ Hz. The spectral pattern associated to methyl group of the other enantiomer (labelled using black squares) is more complicated than the first because the dipolar couplings between the protons of CH_3 and the diastereotopic protons of the CH_2 group are not averaged to zero as previously. This perfectly emphasises the variation of dipolar couplings between the *S* and the *R* isomers and shows the influence of the DOE on the spectral analysis in chiral liquid crystals. However as the order parameters and subsequently the D_{ij} values are temperature-sensitive, we can modify the spectral patterns by changing the sample temperature and, hopefully, simplify the analysis. The determination of all dipolar couplings is not trivial and requires the use of spectral simulation programs such as PANIC.[39] For the *R* enantiomer of CP, we have measured $|D_{CH_3}| = 4.2$ Hz, $|D_{CH_3\cdots CH}| = 3.2$ Hz and $|D_{CH_3\cdots CH_2}| = 3.3$ Hz. Finally, it is noteworthy that the chiral discrimination may also be seen on the NMR signal of the methylene and methine groups through ^{1}H–^{1}H dipolar coupling differences, but they are not shown here.

Although chiral differentiation was visualized in this example using ^{1}H NMR, it is clear that when the number of interacting protons in the molecules becomes larger, the analysis of the ^{1}H spectra becomes very difficult. In this case, the chiral discrimination between enantiomers cannot always be unambiguously established because doubling of peaks may arise, for instance, from the long distance dipolar couplings. Two solutions can be suggested to check if a chiral discrimination occurs or not. First, it is always convenient to apply a selective decoupling of protons which are susceptible to interact with the signal suspected to give a chiral discrimination. When doubt still arises, the spectra in a racemic mixture of PBLG and its enantiomer, PBDG, dissolved in $CHCl_3$ may then be recorded.[22,31] Indeed in such a mixture, the fast exchange between chiral solutes and the vicinity of PBLG and PBDG eliminates the chiral discrimination, and hence results in a significant simplification of spectra, which can give valuable information with regard to chiral discrimination.[31] This latter solution can be also successfully applied using the other NMR spectroscopies described below such as carbon-13 or deuterium NMR. However in proton NMR, these alternatives will remain limited for large, chiral molecules because the numerous long distance dipolar couplings together with the superposition of the ^{1}H spectra for each enantiomer can yield either significant line broadening of the resonances or an excessive peak overlap which totally prevents their analysis. We reach, then, the limits of the applicability of the proton NMR spectroscopy in PBLG solvent. In such cases, carbon-13 NMR spectroscopy can offer a first and reliable alternative.

Carbon-13 NMR spectroscopy in natural abundance

In spite of the lower natural isotopic abundance of carbon-13 atoms, the advantages of using carbon-13 NMR in PBLG are obvious compared with proton NMR.[5,32] In the first place, the spectral analysis of rare spins in anisotropic medium is considerably simplified due to the absence of coupling between two dilute spins. Second, the magnetic fields used in routine NMR are sufficiently strong to reach a satisfying *S/N* ratio with a relatively small amount of material and short experimental times. Moreover because of its high molecular weight and liquid crystalline nature, the broad carbon-13 NMR resonances arising from PBLG do not interfere with the analysis of the solute signals. Consequently in a second approach, we have demonstrated that natural abundance carbon-13 NMR may be successfully applied to visualize enantiomeric discrimination, through a difference of ^{13}C–^{1}H dipolar interactions and/or C-13 chemical shift anisotropies when proton NMR gives rather poor or unconvincing results.[5]

1D proton-coupled carbon-13 experiments. Fig. 5(a), shows the proton-coupled carbon-13 signal of the methyl group of (±)-CP. Here again, we distinguish two spectral patterns, namely a doublet of quartets for each enantiomer, clearly indicating chiral differentiation. To check this analysis, we have recorded the carbon-13 signal of the methyl carbon applying a selective decoupling of the proton attached on the asymmetric carbon. In this case, we eliminate the dipolar splitting, $T_{CH_3\cdots H}$, and we observe only two distinct quartets, corroborating unambiguously the discrimination of enantiomers. Note that recording the proton-coupled carbon-13 signal of the methyl in a racemic mixture of PBLG and PBDG would give a single dedoubled quartet, showing that chiral discrimination occurred in the PBLG phase. From the values of $^nT_{CH}$ (*n* is the number of

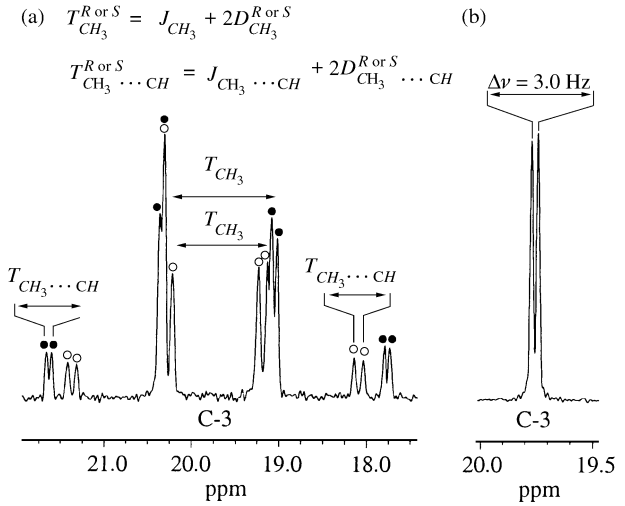

Fig. 5 (a) Carbon-13 and (b) ^{13}C-{^{1}H} signal of the methyl group of (±)-CP. The spectra were obtained after adding 2000 and 1000 scans of 16 K data points, respectively. The recycling delay was 2 s. For spectrum (a), proton decoupling was applied during the relaxation delay period in order to gain a nuclear Overhauser effect. The peaks arising from each enantiomer are labelled (○) and (●).

bonds separating the two coupled nuclei in the molecular skeleton), measured directly from the spectrum, we can calculate the residual dipolar coupling constants, $^nD_{CH}$. As the sign of $^1J_{CH}$ and $^3J_{CH}$ are known to be positive[33] and considering that $^1J_{CH}$ and $^3J_{CH}$ are larger than $^1D_{CH}$ and $^3D_{CH}$, in the PBLG phase,[9,10] we are able to determine the absolute sign of those dipolar couplings. In contrast, the sign of $^2J_{CH}$ can be positive or negative, consequently the sign of $^2D_{CH}$ cannot be ascertained directly. In this example, the four corresponding residual dipolar couplings derived from the spectrum analysis are D_{CH_3} = −8.5 Hz and $D_{CH_3\cdots CH}$ = +3.8 Hz (○) and D_{CH_3} = +1.5 Hz and $D_{CH_3\cdots CH}$ = +1.7 Hz (●) assuming that $J_{CH_3\cdots CH}$ and $T_{CH_3\cdots CH}$ are positive. Note here that at 298 K, we are not able to measure the dipolar couplings between the methyl group and the diastereotopic protons on the methylene group. Disregarding the fortuitous elimination of dipolar splittings (J + 2D = 0 Hz) and lack of spectral resolution, we may assume that the large internuclear distance ($r_{CH_3\cdots CH_2}$ > 2.8 Å) and the small magnitude of order parameters in PBLG give a negligible dipolar interaction between those protons and the methyl carbon. Consequently no further splittings are visible in the spectral pattern. We can also remark that the spectral patterns are not perfectly centered on the same chemical shift owing to a small but measurable difference of carbon-13 CSA. As we will see in the next section, this small difference is more clearly visible on the proton-decoupled carbon-13 spectrum. Finally it can be stated that a chiral discrimination has also been detected on the other two carbons on the basis of a difference in dipolar couplings, but they are not presented here.

In this example, we were able to clearly visualize a chiral discrimination based on a difference of ^{13}C–^{1}H residual dipolar couplings. It is clear, however, that such well-resolved spectra will not always be obtained when the molecule under study possesses a large number of interacting nuclei. Actually for medium to large sized molecules, we may reach again the limits of the applicability of the proton-coupled carbon-13 NMR similar to the situation which is encountered in overcrowded proton NMR spectra. For chiral compounds exhibiting an isolated group (such as a methyl group) far removed from other protons in the molecule, it may be convenient to record the proton-coupled carbon-13 spectrum in order to detect the separation of enantiomers through a difference in the ^{13}C–^{1}H dipolar couplings. When proton-coupled carbon-13 spectra cannot be conveniently resolved it becomes necessary to cancel out all dipolar interactions. By recording the proton-decoupled carbon-13 spectrum, we can, therefore, expect to distinguish between enantiomers through a difference in their carbon-13 CSA.

1D proton-decoupled carbon-13 experiments. The major advantage of proton-decoupled carbon-13 NMR (^{13}C-{^{1}H}) in PBLG is the simplicity of the spectral analysis. First, with broadband proton decoupling, carbon-13 spectra of solutes usually show resolved peaks which can be assigned to all non-equivalent individual carbon atoms in the molecule, similar to that for an isotropic sample. When the difference in C-13 chemical shift anisotropy between the *S* and *R* isomers for a given carbon *i* is large enough, then we observe two distinct resonance lines located at ν_i^S and ν_i^R as depicted in Fig. 2(a). Second, as the carbon-13 CSAs are rather small in PBLG, the chemical shifts of each carbon are very close to those observed in the isotropic solvent. Consequently the assignment of the C-13 resonances in PBLG is often trivial and comparison with the isotropic spectrum readily reveals the carbons of the chiral molecule which are discriminated.

Although the carbon-13 chemical shift anisotropies are much greater than for the proton, the chemical shift differences measured in almost all spectra are typically just a few Hz (typically 3–15 Hz), except for some sp carbon atoms for which chiral discriminations of up to 40 Hz have already been measured.[5] Nevertheless these small differences allow the visualization and the measurement of enantiomeric excess using classical numerical integration or iterative curve-fitting. As for overcrowded ^{1}H and ^{13}C spectra, it is clear that a good homogeneity of both sample and magnetic field is required to reach an optimal enantiomeric discrimination. Under the experimental conditions described above, the linewidths at half-height commonly observed in ^{13}C-{^{1}H} spectra are *ca.* 2–4 Hz. Note that when this spectral resolution is not reached, it can be useful to slightly increase the sample temperature. Indeed a greater fluidity of the phase may give an important improvement in the spectral resolution. When no significant effect is obtained, it is recommended to heat the sample for a few hours prior to centrifuging the sample in both directions again. In fact this latter procedure can produce a more homogenous distribution of each component in the mixture, thus avoiding possible concentration gradients in the sample.

Finally, compared with proton-coupled carbon-13 NMR, ^{13}C-{^{1}H} NMR offers an important advantage in terms of sensitivity and *S/N* ratio, since all signals are concentrated in only one resonance for each carbon. This situation enhances considerably the quantitative aspects of this approach through the greater precision that can be reached in measuring the ee values. Usually a sufficient *S/N* ratio is obtained after an experimental time varying between 1 and 5 h depending on the available amount of solute and its molecular weight. The experimental enantiomeric excess determined on such spectra by integration can be within 2% of the true value.[6] Generally, we estimate that the accuracy on the enantiomeric excess measurements is about 5% of the true value when the spectrum is recorded and processed using standard conditions.[40,41]

Fig. 5(b), shows a small but visible chiral discrimination ($|\nu_i^S - \nu_i^R|$ = 3 Hz) on the signal of the methyl group for (±)-CP. Although the probability for detecting a chiral discrimination is generally greater for carbons having an sp and sp^2 hybridization state, the discrimination on sp^3 carbons is also possible as seen in this example. However, we must note that none of the carbons bonded to the heteroatoms in the molecule displays a line separation. The result is rather surprising if we consider that the strength of the carbon-13 CSA increases with the electronegativity of the substituents.[33] However, as already emphasised in the theoretical section, the electronic shielding anisotropy and the asymmetry term are not the only parameters involved in the chiral discrimination, and the order parameter differences ($S^S_{ia'a'} - S^R_{ia'a'}$) and [($S^S_{ib'b'} - S^S_{ic'c'}$) − ($S^R_{ib'b'} - S^R_{ic'c'}$)],

may have a large effect on the frequency difference of both isomers for a given carbon. In this particular example, we may suppose that the angle, θ, between the magnetic field and one of the principal axes of the CSA tensor for the methylene and methine carbon are located in the region where the function $(3\cos^2\theta - 1)/2$ is rather flat and produces a negligible DOE, thus leading to absence of chiral discrimination.

In contrast with the homo- and hetero-nuclear spin–spin coupling interactions that are independant of magnetic field magnitude, eqn. (4) shows that the sensitivity of CSA to the DOE increases with $\boldsymbol{B}_o$. Consequently, the use of NMR spectrometers operating at higher magnetic fields enhances considerably the possibility to detect enantiomeric discriminations on all non-equivalent carbons of the chiral molecule. Thus, when recording the ^{13}C-{^1H} spectra of (±)-CP at 201.2 MHz (18.4 T), the chemical shift difference of 3.0 Hz measured for the methyl carbon would become around 6 Hz under the same experimental conditions. Such a difference would offer a very comfortable separation between these signals which are associated with an sp^3 carbon. In addition, we may expect to observe a chemical shift difference for the two other carbon signals of the molecule, thus increasing the probability to detect a chiral discrimination.

2D ^{13}C–^{13}C INADEQUATE experiments. The detection of coupled dilute spin systems such as two carbon-13 nuclei in a CLC solvent is not trivial to achieve for three reasons. First, the probability for observing chiral isotopomers possessing two carbon-13 nuclei is only 1/10000 and the intensity of the corresponding resonances will be a factor 200 lower than the intensity of signals from the isolated carbon-13 nuclei. Second, the k_{CC} parameter for two interacting carbon-13 nuclei is small ($\gamma_C\gamma_C/\gamma_C\gamma_H \approx 0.25$) and the larger internuclear distances between adjacent carbon-13 atoms (1.20–1.54 Å *cf.* 1.09 Å for a ^{13}C–^1H bond) significantly reduces the sensitivity of ^{13}C–^{13}C dipolar interaction to the DOE compared with that of the ^{13}C–^1H dipolar interaction. Finally the detection of two coupled carbon-13 spins is not simple, and hence requires usually the creation of double quantum coherences using the well-known 2D INADEQUATE experiment, the basic pulse sequence of which is shown in Fig. 6(a).[42–44] The condition for optimum transfer of one quantum into double-quantum coherence is satisfied with the delay $\tau = (2n + 1)/(4T_{CC})$ where n is an integer, and consequently the choice of the τ value is important. In the PBLG phase, the very small magnitude of one-bond ^{13}C–^{13}C dipolar couplings (a few Hz) compared with the range of one-bond ^{13}C–^{13}C scalar couplings (20–200 Hz, depending on hybridization state of coupled carbons)[33] allows the assumption that $^1T_{CC} \approx {}^1J_{CC}$. Consequently, despite the fact that the exact values of $^1D_{CC}$ are unknown, the loss of signal during the single-to-double quantum transfer, due to a non-ideal value of τ is weak and the detection of double quantum remains possible. Note here that the magnitude of long-distance ^{13}C–^{13}C dipolar couplings is generally too small to be experimentally detected. Finally the α read pulse (α = 90, 120 or 135°) depends on the phase cycling employed and allows either optimization of the double quantum coherence or suppression of the quadrature images in the F_1 dimension.[43,45]

Related to such 2D experiments, Levitt and coworkers were the first to report the measurements of ^{13}C–^{13}C dipolar couplings of liquid crystalline molecules using the 2D INADEQUATE sequence.[46] In our case, the low concentration of chiral solutes in the PBLG phase reduces further the sensitivity of this experiment, thus raising another difficulty. In other words, the visualization of enantiomeric discrimination based on a difference of ^{13}C–^{13}C dipolar couplings is a difficult but challenging task.

Fig. 6(b) displays part of the 2D INADEQUATE experiment of (±)-CP recorded in PBLG after 15 h of experimental time

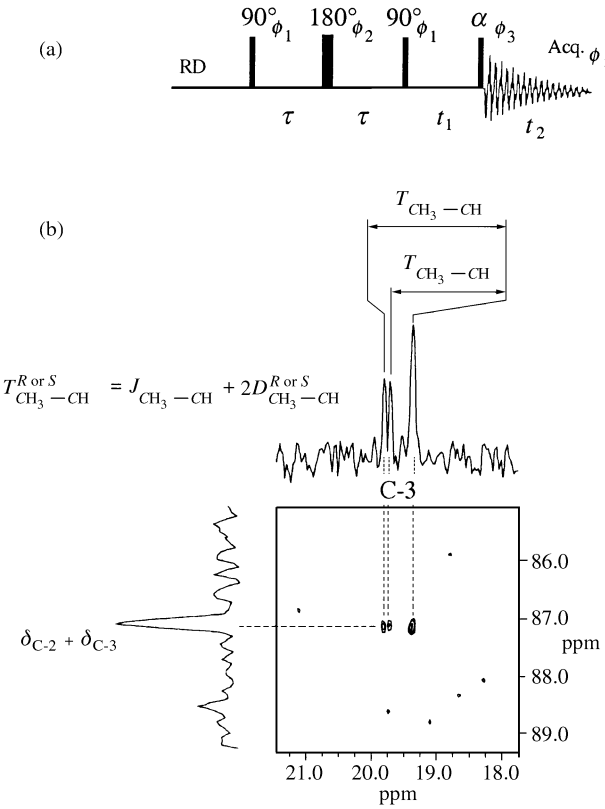

Fig. 6 (a) Basic INADEQUATE pulse scheme for carbon-13 2D NMR spectroscopy. (b) 100.6 MHz INADEQUATE 2D spectrum of (±)-CP in PBLG. The spectrum was recorded with data matrix of 384 (t_1) × 2048 (t_2) data points. The recycle delay and the preparation time τ were set to 2 s and 6.3 ms, respectively. The number of free induction decays added for each t_1 increment was 256. No apodization was applied. The 2D contour plot is presented in magnitude mode.

(overnight). As in an isotropic solvent, all dipolar coupled two-spin systems straddle the skew diagonal of slope 2, each being located at the sum of their Larmor frequency, $\nu_i + \nu_j$, in the F_1 double-quantum dimension. Two slices parallel to the ω_2 axis were observed in the 2D contour plot and permit the unambiguous identification of each ^{13}C–^{13}C doublet, and assignment of each of them on the basis of chemical shifts. On the 2D contour plot, we can observe two partially overlapping dipolar doublets associated with the carbon-13 atom of the methyl group, thus showing two different ^{13}C–^{13}C dipolar couplings between the C-2 and C-3 carbons, one for each enantiomer. This situation occurs when the two dipolar doublets are not centered on the same chemical shift due to a CSA difference between enantiomers (here *ca.* 3 Hz). This part of the 2D spectrum unambiguously evidences chiral discrimination. This result was also confirmed by recording the 2D INADEQUATE spectrum of (±)-CP in the isotropic state at 298 K because in this instance, only a single doublet was detected between this pair of adjacent carbons. The residual dipolar constant D_{CH_3-CH} measured on the 2D spectrum is +2.6 and −1.1 Hz for one enantiomer and the other, the scalar coupling measured in isotropic solution, J_{CH_3-CH}, between the two components being equal to +38.9 Hz ($^1J_{CC}$ is always positive).

It is of note that this is the first enantiomeric discrimination of a chiral molecule using ^{13}C–^{13}C dipolar interaction since no successful results using this NMR technique have, up to now, been recorded. Even though the natural sensitivity of the 2D INADEQUATE experiment is rather poor, this result establishes that enantiomeric discrimination based on a difference of ^{13}C–^{13}C dipolar coupling is possible and should not be neglected. However, it is clear that the analytical potential of this tool is rather limited because the condition for optimum transfer into double-quantum coherence subtantially restricts its

use for accurate quantitative measurements of enantiomeric excess.

Deuterium NMR spectroscopy in natural abundance

As already mentioned in the theoretical section, the deuterium quadrupolar interaction is the most sensitive interaction to the DOE of enantiomers. Consequently, in the earliest studies, we have focused on chiral discrimination using labelled materials.[14,47] Among successful results already reported, the great sensitivity of this approach allowed us to visualize the chirality of almost all investigated chiral molecules.[4,5,48,49] Among the compounds known to be very difficult to analyse, but showing a chiral discrimination in PBLG, are ethers, monohalogenated hydrocarbons and non-functionalised cycloalkenes.[4] Also we have reported the discrimination of molecules that are chiral by virtue of isotopic substitution.[3] Although synthetic methods for selectively introducing deuterium in chiral molecules are numerous and well documented, it is clear that this is not always possible or easy to do, and may be time-consuming.[4,5] Consequently, isotopic labelling may be a serious limitation to this investigation technique.

To eliminate the synthetic step, we have recently demonstrated that isotopic enrichment of chiral solutes was not necessary to yield observable deuterium resonances in PBLG, despite its very low sensitivity (1.45×10^{-6} with respect to proton).[16] Actually, calculations indicate that NAD-NMR experiments have sensitivities comparable with those of the above 2D INADEQUATE experiments. However for the same experimental time, NAD-NMR experiments are more advantageous in terms of *S/N* ratio because the deuterium T_1 relaxation values of solutes dissolved in PBLG ($\approx$ 0.8–1 s) are generally much shorter than the T_1 values of carbon-13, allowing a faster repetition rate of the pulsing. Consequently, enantiomeric differentiation of chiral compounds using natural abundance deuterium (NAD) NMR is perfectly possible using standard NMR equipments, and provides, therefore, a second and interesting alternative to other previous techniques.[6,16,50]

Assuming that the detection of a rare spin such as deuterium in natural abundance is not an insurmountable obstacle in terms of signal sensitivity, site-specific labelling of the molecules would, therefore, not be required. Furthermore, it would permit the simultaneous probing of all possible deuterated sites of the molecule, thus increasing the probability to visualize a chiral differentiation between enantiomers. At natural abundance level, ^{2}H–^{2}H spin–spin couplings are not detected (owing to the very low probability of observing two interacting deuterons in the same isotopomer). Consequently, as all the couplings with protons are eliminated through decoupling, the natural abundance ^{2}H-{^{1}H} spectra in organic solutions of PBLG consist of the superposition of independent quadrupolar doublets corresponding to all non-equivalent deuterons in each of the enantiomers.[6,16,50] Thus, disregarding the doublets originating from organic co-solvent, we can expect 2*n* doublets (4*n* peaks) to be observed in the NAD spectrum for a racemic mixture of enantiomers possessing *n* non-equivalent deuterons, assuming that all deuterated chiral isotopomers are discriminated and neither line overlaps nor null quadrupolar splittings occur. This evaluation can be, however, reduced to $2n - 1$ doublets for molecules possessing an –OD or –ND group, since no chiral discrimination has (until now) been detected for such groups, owing to the fast exchange of their deuteron. In the case of (±)-CP and disregarding solvent quadrupolar doublets (one doublet for $CDCl_3$), eight different chiral isotopomers exist in the mixture and a maximum of eight quadrupolar doublets are expected to be detected if all deuterated sites show chiral differentiation. This is because (±)-CP contains two diastereotopic nuclei associated with deuterons of the methylene group. For this group, four quadrupolar doublets corresponding to the (*S*, pro-*S*), (*S*, pro-*R*), (*R*, pro-*S*), (*R*, pro-*R*) deuterons of the *S* and *R* isomers can be expected to be seen in the NAD-NMR spectrum (when all isomers are discriminated and without peak overlapping). Traditionally we use the term '*semi-isotopic*' diastereoisomers for all deuterated isotopomers bearing a classical asymmetric carbon and an asymmetric carbon by virtue of isotopic substitution.

It must be clear that for larger molecules, the correlation between the two components for each quadrupolar doublet will not always be simple to achieve, mainly due to overlapping of peaks, and will require the use of proton-decoupled deuterium 2D-NMR experiments.[6,50,51] Consequently, we have developed several two-dimensional autocorrelation deuterium NMR experiments referred to as QUOSY (for QUadrupole Ordered SpectroscopY), which facilitate the analysis of overcrowded NAD spectra. Among them, the Q-COSY and Q-resolved experiments and their composite pulse variants were found to be the most useful 2D sequences for applications in NAD-NMR or when the problem of sensitivity is crucial (very low degree of deuteration). The optimised sequences using pulse composites and the corresponding full phase cycling are described in refs. 6 and 51.

Fig. 7 shows the 2D NAD Q-COSY spectrum of (±)-CP recorded over 14 h (overnight) with digital filtering and oversampling in order to enhance the dynamic range of the analogue-to-digital converter (ADC).[52,53] The 2D contour plot is symmetrized prior to the tilt procedure and is displayed in

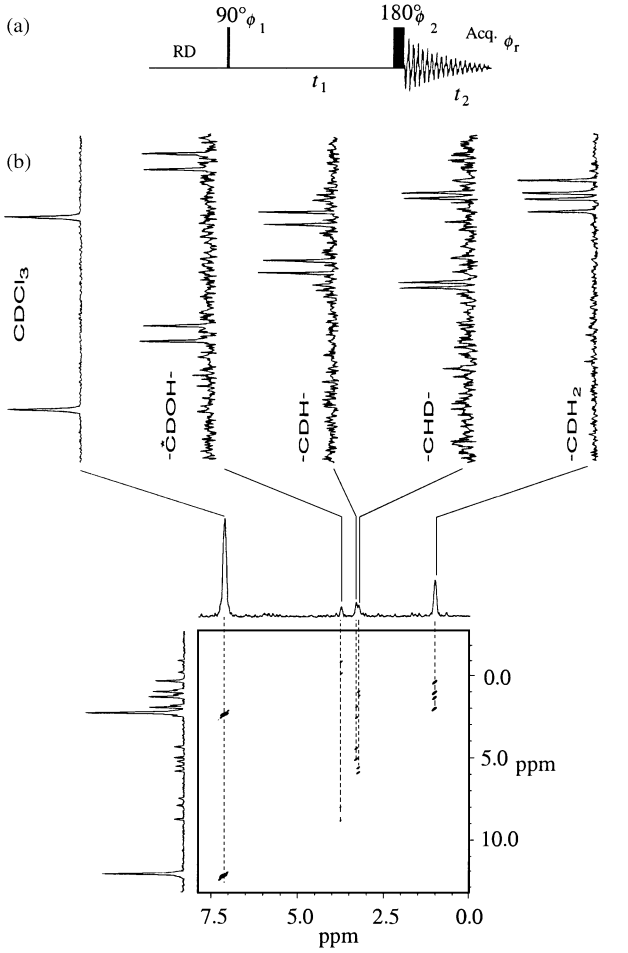

Fig. 7 (a) Basic Q-COSY pulse scheme for deuterium 2D NMR spectroscopy in partially ordered solvents. (b) 61.4 MHz tilted NAD Q-COSY 2D spectrum of the (±)-CP in PBLG and slices parallel to the ω_1 axis corresponding to the deuterium spectrum of each monodeuterated isotopomer in the mixture. The number of free induction decays added for each t_1 increment is 384. The recycling delay was 0.5 s and the spectral width in both dimensions was 2500 Hz. The data matrix of 300 (t_1) $\times$ 1400 (t_2) was weighted with a gaussian window (GB_1 = 50%, LB_1 = −2.0 Hz and GB_2 = 45%, LB_2 = −1.5 Hz) in t_1 and t_2 dimensions, respectively, and zero-filled to 512 (t_1) $\times$ 2048 (t_2) prior to 2D FT.

magnitude mode in order to cancel out the phase-twist lineshapes.[6] In this 2D spectrum, the chemical shift of each non-equivalent deuteron appears in the F_2 dimension. From each of them, we can observe the deuterium signals of the corresponding isotopomers in the mixture, the most unshielded trace (7.3 ppm) being the chloroform quadrupolar doublet. The analysis of each slice indicates that all deuterons in the molecule exhibit two quadrupolar doublets, one for each enantiomer. In particular the two diastereotopic deuterons of the methylene group distinctly show two pairs of quadrupolar doublets which are not centered on the same chemical shift. Strong differences of *S/N* ratio for each extracted slice are observed. This situation reflects that the number of equivalent deuterons (magnetic equivalence) for the various possible isotopomers is different. Thus, the signals associated with the deuteron attached to the asymmetric carbon are three times smaller than the signal of the methyl group, and hence the strong reduction of *S/N* ratio observed on the corresponding trace. The precision of the enantiomeric measurement for (±)-CP was not investigated here, but previous results have shown that such determination is possible within an accuracy of *ca.* 10% for reasonable *S/N* ratio, thus already giving a valuable estimation of the enantiomeric excess.[6]

Finally it should be noted that chloroform is the most efficient solvent for NAD NMR in PBLG. Apart from the fact that it dissolves a wide range of organic compounds, the linewidths at half-height of solutes measured on the ^{2}H-{^{1}H} spectra are usually low (2–8 Hz). Second, this solvent contains a single deuterated isotopomer giving rise only to a single additional quadrupolar doublet in the NAD spectrum. Third, the number of deuterons per unit volume is not excessively large relative to those of the chiral solutes, thus minimizing the digitization problems associated with the dynamic range of the ADC. Fourth, the deuterium signal of chlorofom can be used as an internal reference for the NAD spectra.

With this last analytical approach, we show that the enantiomeric discrimination of (±)-CP in 2D NAD-NMR using a 9.4 T field and standard NMR equipment is possible. These present results confirm the feasibility, potential and usefulness of NAD NMR spectroscopy, thus providing a further practical solution to DOE measurements in PBLG without site-specific isotopic labelling. In spite of the natural low sensitivity of deuterium, there is no doubt that, by taking advantage of higher magnetic field NMR spectrometers, it should be possible to acquire NAD spectra with shorter experimental times or determine enantiomeric excesses to a higher precision.[6] Indeed the *S/N* ratio is proportional to $(B_o)^{3/2}$ for a given experimental time t_{exptl} while t_{exptl} is proportional to $(B_o)^3$ for a given *S/N* ratio. To illustrate this, Fig. 8 shows the relationship between the total experimental time t_{exptl} and the *S/N* ratio with respect to values calculated with our 9.4 T spectrometer. Thus, when recording the NAD spectra of (±)-CP at 122.8 MHz (18.8 T), the *S/N* ratios would be increased by a factor of 2.8 for the same t_{exptl}. Conversely, the t_{exptl} would be reduced by a factor of 8 to obtain the same *S/N* ratio that is obtained at 400 MHz. This, incidently, means that the *S/N* ratio of 20 measured here for the methyl group on the NAD spectra of (±)-CP would become *ca.* 60 at 18.4 T under the same experimental conditions. Such a *S/N* ratio would then result in an acceptable error in the determination of enantiomeric excesses. Another and probably cheaper solution to improve the *S/N* ratio of NAD spectra would consist in using selective, deuterium cryogenic probes. Indeed the present developments and studies of such cryoprobes have shown a very significant gain of the signal sensitivity (a factor 3 to 4) compared with standard high resolution probes.[54] Consequently the use of both higher field and deuterium cryoprobes should quickly establish that NAD 2D NMR spectroscopy is the most general and powerful technique for analysing chiral molecules in PBLG.

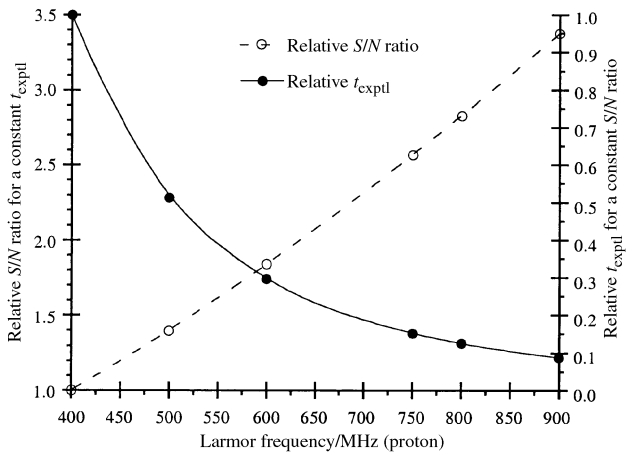

Fig. 8 Evolution of the relative *S/N* ratio and the relative t_{exptl} as a function of the Larmor frequency with respect to a 9.4 T (400 MHz for proton) spectrometer. The reference value at 400 MHz is 1.

Comparison of the various analytical potentialities of each technique

To compare and discuss the analytical potentialities of these various natural abundance NMR approaches, we have reported their respective features in terms of NMR and enantiomeric analysis in Table 1. Each of these NMR tools possesses advantages and drawbacks in terms of resolution, signal sensitivity, data presentation, complexity of spectral analysis, quality of chiral discrimination and accuracy in enantiomeric measurements. The choice of the technique to be used depends therefore on both chemical as well as NMR features of the chiral molecule (size of the molecule, functional groups, isolated group of nuclei, hybridization state of carbons, equivalent nuclei in deuterated isotopomers,…) and the available amount of material under investigation in comparison with its molecular weight.

Although too large a number of interacting protons in the molecule yields generally unresolved, overcrowded ^{1}H spectra in PBLG and prevents their analysis, it is always worthwhile to record such spectra to detect any separation of enantiomers through a difference in the residual ^{1}H–^{1}H dipolar couplings for small, chiral, functionalized molecules (which are usually precursors of larger target molecules) or compounds having isolated groups far removed from other protons in the molecule. Indeed for such compounds, we may expect well resolved spectral patterns for both enantiomers, allowing the ee to be measured to a high accuracy.

For larger molecules, proton-decoupled carbon-13 NMR spectroscopy is an excellent alternative to ^{1}H NMR since it prevents overcrowded carbon-13 NMR spectra. The spectra are relatively easy to analyse and the measurement of ee values is possible and reliable[40,41] with a reasonable amount of compound. However when ^{13}C-{^{1}H} NMR fails by a lack of spectral resolution or negligible DOEs, the proton-coupled carbon-13 NMR can provide a useful alternative, in particular, for chiral derivatives exhibiting an isolated group (such as a methyl group) in the molecule. Finally, whilst noting the problem of deuterium sensitivity, NAD 2D NMR spectroscopy seems particularly well adapted for medium to large, functionalised or non-functionalised, chiral molecules because of the strong sensitivity of the quadrupolar interaction toward the DOE and the relatively simple analysis of 2D Q-COSY spectra.

Pragmatically, it is clear that chiral molecules possessing sp^2 or sp carbons have a strong probability to be differentiated using ^{13}C-{^{1}H} NMR with a satisfactory accuracy (*ca.* 5%) on the measurement of enantiomeric excess while no significant chiral discrimination would be expected to occur for chiral, non-functionalised molecules such as alkanes or cycloalkanes; conversely, NAD 1D and 2D NMR spectroscopy seems to be

Table 1 Comparative table of various natural abundance NMR experiments for the chiral analysis in PBLG phases using a high resolution 400 MHz spectrometer

Nuclei observed	Natural isotopic abundance (%)	NMR sequence used	Useful anisotropic observables	Spectral analysis	Sensitivity to chiral differentiation	Signal sensitivity	Required amount for a racemic mixture[c]/mg	Average experimental time[c]/h	Estimated error on ee (%)

more adapted for such compounds for which ^{13}C-{^{1}H} NMR is of less value. Indeed we may assume that the difference in the interactions between *S* and *R* isomers and the polypeptide will generate a rather small DOE and consequently only a very sensitive order-dependent NMR interaction such as the quadrupolar interaction may reveal an enantiomeric discrimination.[55] In addition, if the chiral molecule possesses magnetically equivalent deuterons (a methyl group), we may reach an adequate *S/N* ratio using a reasonable quantity of chiral material after an overnight acquisition. Although to date the accuracy on the measurements of enantiomeric excesses for reasonable signal-to-noise ratios are not better than 10%, the obtained experimental results already provide a very valuable estimation of ee values. In addition this technique allows a rapid and simple determination of the best site of chiral discrimination in the molecule and subsequently, may aid in selection of the most suitable synthetic strategy for introducing a deuteron in the molecule.

For all possible anisotropic natural abundance NMR techniques in PBLG the advantages of using higher magnetic field and/or a cryoprobe are obvious both in terms of chemical shift dispersion and *S/N*, the main benefit resulting in the higher precision in the calculation of ee values. We may expect that the approaches described here provide a very reliable alternative to current analytical techniques in the isotropic phase.

Conclusion

The differentiation and the study of enantiomers is a challenging task. In this field, multinuclear NMR spectroscopy in the PBLG phase provides an efficient and convenient analytical tool to differentiate almost all possible enantiomers. The major interest of this methodology is that the polypeptide helices are able to interact enantioselectively with almost all enantiomers and give sufficiently large orientational differences to be revealed by almost all the routine NMR tools. In addition, the advent of routine high magnetic fields has made possible the observation of nuclei with very low sensitivity with acceptable *S/N* ratios such as deuterium at the natural abundance level. Here, we have shown, as illustrative examples, that it is possible to discriminate the *S* and *R* isomers of (±)-1-chloropropan-2-ol using proton, carbon-13 and deuterium spectroscopy on a single NMR sample. For almost all of the NMR methods reviewed, quantitative determination of enantiomeric purity is possible with a sufficient accuracy from simple peak integration. Nevertheless, each technique described here possesses both advantages and drawbacks in terms of signal sensitivity, complexity of spectral analysis, quality of chiral discrimination and accuracy in measurements of ee values. The choice of the best NMR technique for a given compound will depend on both the chemical and NMR features of the chiral molecule and obviously the available amount of material. This choice, however, does not exclude the examination of other possible NMR techniques in PBLG when the results obtained are not convincing. In comparison to other NMR methods for chiral discrimination, the use of this emerging methodology offers therefore important advantages in terms of flexibility and versatility and provides a useful new NMR analytical tool. Besides, it has the valuable advantage that no labelling or any chemical modification of the chiral material is needed and the NMR requirements are not different compared to those for other isotropic methods.

This analytical method, characterized by its simplicity and adequate sensitivity, should certainly be considered as a powerful alternative to classical chiroptical, chromatographic or other NMR techniques. In this review, we have attempted to point out that this non-familiar tool for organic chemists is probably the most general method for the purpose of enantiomeric analysis. Finally, there is no doubt that by routinely taking advantage of higher magnetic field NMR spectrometers and/or using double tuned (carbon-13 and deuterium) cryogenic probe systems, the present potentialities of all these techniques should become evident and definitely establish the significant advantages of this strategy in the very near future.

In order to further evaluate the applicability, advantages and limitations of this methodological approach, additional work is still required and is currently being undertaken.

Copper(I) mediated radical polymerisation is used to polymerise uridine and adenosine substituted methacrylates onto a silica surface giving supported polymers with potential as re-usable templates and for interaction with nucleic acids.

The immobilisation of polymers on solid supports and surfaces is of considerable interest for a number of applications. For example, derivatisation of surfaces for biocompatibility[1] and the production of sensors[2] is of interest to the biotechnology industry and new resins are being sought for application to solid supported organic synthesis.[3] Automated synthesis of oligonucleotides on solid supports is performed routinely for the production of short strands of DNA and RNA or their synthetic analogues.[4] Solid supported oligonucleotides are finding applications in medical diagnostics[5] and hence numerous methods have appeared in the literature for derivatising solid supports for oligonucleotide synthesis and attaching oligonucleotides to support media.[6] Having placed an oligonucleotide onto a solid support it has been shown to be possible to employ this as a re-usable template to synthesise complementary strands of DNA. Ashley and MacDonald[7] attached a naturally occurring segment of DNA directly to diazobenzyloxymethyl-cellulose and then used this to synthesise complementary strands of DNA which could be washed away and the template re-used repeatedly. This work involved using enzymes and primers however, and the solid supported template was only made on a very small scale. We have recently shown that it is possible to carry out the templated polymerisation of an unnatural backbone polyacryloylnucleoside by using non-polar solvents to maximise interactions between complementary base pairs.[8] This communication describes the synthesis of a re-usable template prepared on a silica support for use in such a polymerisation reaction.

Transition metal mediated living radical polymerisation[9] is an efficacious method for the preparation of narrow polydispersity (PDI) methacrylic and styrenic polymers, as it allows controlled synthesis of structurally diverse polymers due to its living or pseudo-living nature.[10] Such polymerisations can be performed in the presence of many functional groups and solvents which other living polymerisation methods, such as ionic or group transfer polymerisations cannot tolerate.[11] Metal mediated radical polymerisation on solid supports has been the subject of a number of recent reports. Tsujii and co-workers modified the surface properties of silica by immobilising a chlorosulfonyl phenyl moiety on silica wafers and using this for living polymerisation of MMA.[12] Matyjaszewski and co-workers carried out atom transfer radical polymerisation of styrene and acrylates on silica wafers to give homopolymers and block co-polymers.[13] Nitroxide mediated polymerisation has been utilized on Merrifield resin to produce 'designer resins' with functional properties.[14] This present work describes the application of copper(I) mediated radical polymerisation to the biologically significant nucleoside derivatives 5′-methacryloyluridine **1** and 5′-methacryloyladenosine **2** on silica gel functionalised with a bromoisobutyrate initiator (**3** or **4**) to give surfaces of considerable potential (Fig. 1).

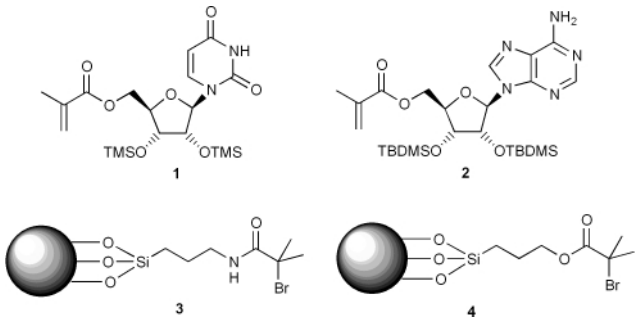

Fig. 1 Monomers and silica supported initiators used in this study.

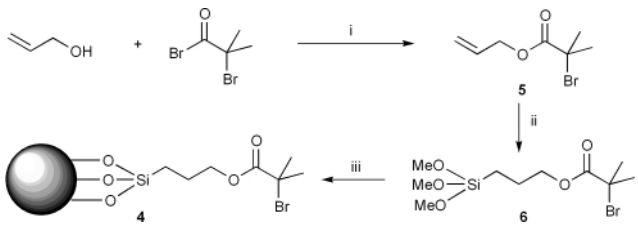
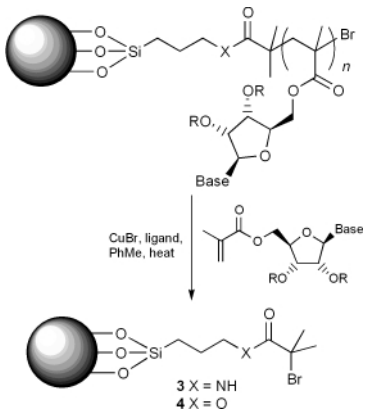
The 5′-methacryloyluridine **1** and 5′-methacryloyladenosine **2** were synthesised using a modified procedure of Moris and Gotor,[15] using the enzyme *Candida antarctica lipase* 435 (CAL 435) with an activated acetoneoxime ester.[16] In order to make these monomers soluble in suitable polymerisation solvents and to aid polymer characterisation the 2′- and 3′-hydroxy groups were protected as silyl ethers. The adenosine monomer, being more polar, required the larger *tert*-butyldimethylsilyl (TBDMS) protecting groups. The amidic initiator **3** was synthesised using commercially available 3-aminopropylsilica and bromoisobutyroyl bromide in the presence of triethylamine base and THF solvent. The ester initiator **4** was synthesised as follows (Scheme 1). Firstly bromoisobutyroyl bromide was reacted with allyl alcohol in the presence of triethylamine to give **5** in 98% yield.[17] This was then treated with trimethoxysilane in the presence of a catalytic amount of hexachloroplatinic acid[18] to give the trimethoxysilyl bromoisobutyrate initiator **6** in 62% yield. The derivatised silica was then prepared by refluxing trimethoxysilyl bromoisobutyrate **6** with TLC grade silica gel in toluene for 22 h (Scheme 1). TLC grade silica gel was used because of its larger surface area and it has been shown previously that attachment of a trimethoxysilyl group to silica gel gives better loading than powdered silica due to the former having porous particles.[19] This was found to have a loading of 0.61 mmol g^{-1} as determined by Thermal Gravimetric Analysis (TGA).



Scheme 1 *Reagents and conditions*: i, Et_3N, THF (98%); ii, $(MeO)_3SiH$, H_2PtCl_6 (98%); iii, silica gel, PhMe, reflux.

Copper(I) mediated radical polymerisation of uridine monomer **1** with the amidic solid supported initiator **3** was attempted using *N*-(*n*-pentyl)-2-pyridylmethanimine (NPMI) as a ligand in conjunction with copper(I) bromide (Scheme 2). However, this initiator was found to give a loading of only 0.87 mmol g^{-1} (Table 1). Changing the ligand to Me_6Tren[20] gave a slightly

DOI: 10.1039/b005832g



Scheme 2 Copper(I) mediated radical polymerisation of 5'-methacryloylnucleosides.

Table 1 Monomer loading for initiators **3** and **4**

Initiator	Monomer	Ligand	Loading (mmol g^{-1})	Increase in initiator weight(%)
3	**1**	NPMI	0.87	53
3	**1**	Me_6Tren	0.80	48
4	**1**	NPMI	1.51	188
4	**2**	NPMI	1.11	117
4	**1**/**2**	NPMI	1.04	105

lower loading of 0.80 mmol g^{-1}. It has been suggested by Matyjaszewski that amidic initiators are prone to intramolecular reactions in the early stages of living radical polymerisation caused by the nitrogen lone pair.[21] The non-amidic solid supported initiator **4** was therefore synthesised. Use of this initiator for polymerisation of **1** almost doubled the loading to 1.51 mmol g^{-1} using NPMI as the ligand. Fig. 2 shows the FT-IR of the immobilised polymer clearly demonstrating the broad N–H signal from 3700–2900 cm^{-1} and the carbonyl stretch at 1683 cm^{-1}. Polymerisation of 5′-methacryloyladenosine **2** using initiator **4** gave a lower loading of 0.96 mmol g^{-1}. This reflects the lower yields obtained with this functionally more complex monomer during solution phase copper(I) mediated radical polymerisations (see ref. 16). Statistical co-polymerisation of **1** and **2** was also successful giving a loading of 1.04 mmol g^{-1}. This was calculated by taking into account the ^{1}H NMR of the unreacted monomers in the filtrate which showed a 15:85 ratio of **1**:**2**, indicating that the co-polymer is rich in uridine.

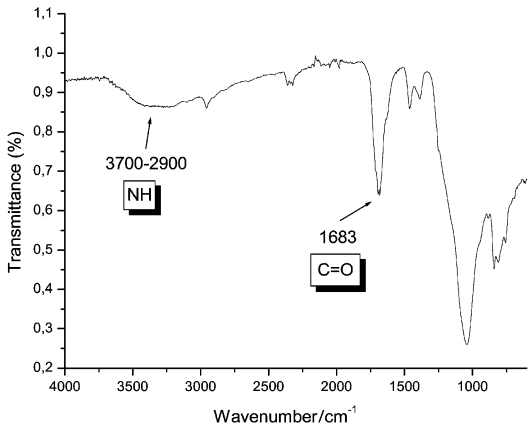


Fig. 2 IR of poly(5′-methacryloyluridine) on silica.

In summary it has been shown that copper(I) mediated radical polymerisation of the multifunctional nucleosides uridine and adenosine methacrylates is possible using a bromoisobutyrate initiator bound to silica giving surface attached homopolymers and statistical co-polymers with good loading. Although we cannot unequivocably describe this polymerisation as *living* from these experiments, we know that similar conditions bring about a controlled polymerisation. Other work has shown[22] that these conditions favour narrow polydispersity products, indicative of a living radical polymerisation.[23] To our knowledge this is the first time controlled radical polymerisation has been used to immobilise biologically important nucleosides to a solid support. Investigations into the use of these immobilised biopolymers as re-usable templates for polymerisations and their interaction with nucleic acids are under way.

We are grateful to the University of Warwick for a postdoctoral fellowship (A. K.), the EPSRC for a Fast Stream Studentship (M.G.; GR/L71933) and Novo Nordisk for a generous donation of CAL 435. We also thank Dr Stefan Bon for supplying the amidic solid supported initiator **3**.

Metallacyclophanes formed by a tetrapyrazolyl ligand and copper(II) cation

Abdelaziz Jouaiti, Marielle Loï, Mir Wais Hosseini* and André De Cian

Laboratoire de Chimie de Coordinaiton Organique, Université Louis Pasteur, F-67000 Strasbourg, France, UMR CNRS 7513. E-mail: hasseini@chimie.u-strasbg.fr

Received (in Cambridge, UK) 15th August 2000, Accepted 18th September 2000
First published as an Advance Article on the web 19th October 2000

Using a tetrakis(pyrazolyl)benzene ligand and $CuCl_2$ or $Cu(CF_3SO_3)_2$ salts, binuclear metallamacrocycles of cyclophane type have been exclusively obtained; structural characterisation by X-ray on single-crystal reveals that in both cases, chloride or triflate anions are coordinated to Cu metal centres adopting a square pyramial coordination geometry.

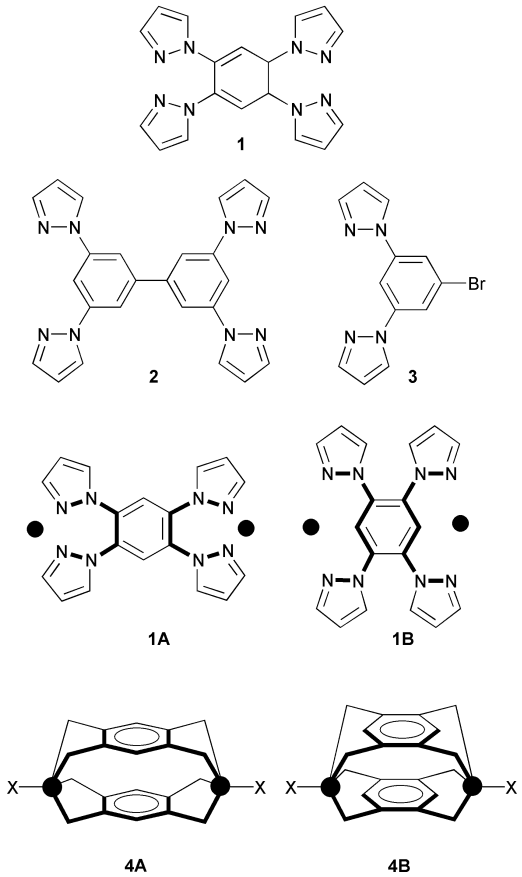
Metallamarocycles, macrocyclic frameworks based on interconnection of organic ligands by metal cations, have been attracting much attention over the past decade. Although the first examples were reported by Saalfrank *et al.*[1] and Fujita,[2] many other groups are now active in the design and synthesis of metallamacrocyles.[3] However, as connecting metallic centres the majority of examples reported so far are based on the use of diamagnetic transition metals such as Pd(II) and Pt(II) requiring square coordination geometry. Thus, using these metals, a variety of metallamacrocycles has been reported using ligands such as 4,4′-bipyridine, pyrimidine, bipyrazine, 4,7-phenanthroline or bis-pyridines interconnected by rigid or flexible spacers.[4] Using pyrazolyl based ligands, we have previously reported the formation of metallamacrocycles and metallatubulanes.[5]

Here, we report the design of new ligands based on pyrazolyl units as coordination sites and its self-assembly into binuclear metallamacrocycles using pentacoordinated paramagnetic Cu(II) cation.

Ligands **1** and **2** (Scheme 1), both based on aromatic cores (benzene or biphenyl) and bearing four pyrazolyl units, are designed to act as tetradentate ligands. For ligand **1**, two different arrangements of the coordination sites may be envisaged leading to either a seven (**1A**) or an eight membered ring cyclic system (**1B**) upon chelating to metal cations (Scheme 1). In both cases, owing to the disposition of the coordination sites ligand **1** may form metallamacrocyles in the presence of metals requiring square, octahedral or square pyramidal coordination geometry. For the latter case, the two possibilities (**4A** and **4B**) are shown (Scheme 1). Ligand **2** was designed as an extended analogue of ligand **1** thus allowing an increase in the size of the metallamacrocycle.

Ligand **1** was first prepared in 8% yield by reacting 1,2,4,5-tetrachlorobenzene with sodium pyrazolate in DMF at 95 ° C for 3 d. The yield could be increased to 68% by using 1,2,4,5-tetrabromobenzene and under reflux for 72 h. Pure compound **1** was obtained as a colourless solid after chromatography (SiO_2, CH_2Cl_2–MeOH) and was characterised by X-ray crystallography† (Fig. 1) which revealed the following relevant bond distances and angles (d_{NN} = 1.37 Å, $d_{C(Ph)N}$ = 1.42 Å; NNCC dihedral angles of −25.8 and −77.2°). Ligand **2** was prepared by a nickel coupling reaction using $NiBr_2(PPh_3)_2$[6] in the presence of Zn and NEt_4I in THF using compound **3** as the starting material. The latter was obtained upon treatment of 1,3,5-benzene by sodium pyrazolate in DMF at 95 °C for 4 d in 22% yield after chromatography [Al_2O_3, CH_2Cl_2–hexane (8/2)].

Cu(II) was selected as the metal ion because of its paramagnetic nature and the fact that it forms pentacoordinated complexes. Both the chloride and triflate Cu(II) complexes have been obtained as single-crystals upon slow diffusion of a MeOH solution of $CuCl_2$ or $Cu(OTf)_2$ (5 mg) into a $CHCl_3$ solution of ligand **1** (2 mg). For both complexes, their structure was investigated in the cystalline state by X-ray crystallography.



Scheme 1

The reaction of **1** and $CuCl_2$ in $CHCl_3$–MeOH afforded a green crystalline material which was structurally characterised by X-ray diffraction (Fig. 2).† The solid contains the complex unit [$\mathbf{1}_2Cu_2(Cl_2(CuCl_4)_2)$] and two MeOH and $CHCl_3$ solvent molecules with no specific interactions with the complex. The cationic part of the complex is indeed a metallamacrocycle composed of two ligands **1**, two Cu(II) cations and two Cl^-

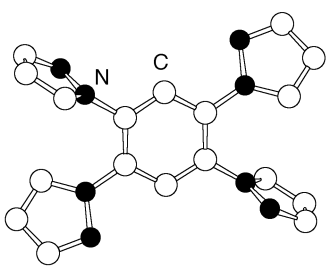


Fig. 1 The X-ray structure of free ligand **1**. H atoms are omitted for clarity, for bond length and distances see text.

DOI: 10.1039/b006665f

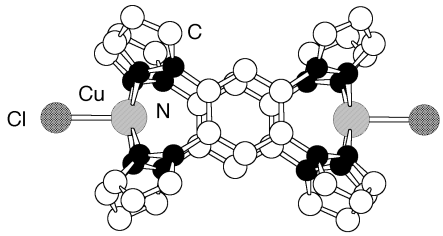

Fig. 2 The X-ray structure of the metalloamacrocycle $[\mathbf{1}_2Cu_2Cl_2]^{2+}$ obtained between **1** and $CuCl_2$. H atoms, anions and solvent molecules are omitted for clarity.

anions. Owing to the parallel orientation of the two phenyl rings, the binuclear metallamacrocycle is of the cyclophane type with an internal cavity of 4.29 × 7.42 Å (Scheme 1). The coordination sphere around the pentacoordinated Cu(II) cations is composed of four nitrogen atoms belonging to two ligands **1** and one chloride anion with a slightly distorted square pyramidal geometry. The two poles of the ligand **1**, composed each of two pyrazolyl moieties (d_{NN} = 1.37 Å, $d_{C(Ph)N}$ = 1.42 Å; NNCC dihedral angle of 57.8°) and occupying the square base in the coordination sphere around the metal, act as bidentate units and form two seven membered metallarings of type **4A** (Scheme 1) with Cu–N distances of *ca*. 2.01 Å and NCuN angles of 86.9–91.4° (Scheme 1). The axial position is occupied by a Cl anion with Cu–Cl distance of 2.44 Å. The two positive charges on the $[\mathbf{1}_2Cu_2Cl_2]^{2+}$ complex are neutralised by a $[CuCl_4]^{2-}$ anion with d_{CuCl} = 2.283 Å and ClCuCl angle of 90° (Fig. 3).

The $[\mathbf{1}_2Cu_2(CF_3SO_3)_2(CF_3SO_3)_2]$ complex was obtained as a blue-violet crystalline solid upon reaction of **1** and $Cu(CF_3SO_3)_2$ in $CHCl_3$–MeOH. The latter complex was also structurally characterised by X-ray diffraction (Fig. 4).† The solid contains the complex unit $[\mathbf{1}_2Cu_2(CF_3SO_3)_2(CF_3SO_3)_2]$ and two CH_2Cl_2 solvent molecules with no specific interactions with the complex. The triflate anions are disordered. The cationic part of the complex of type **4A** (Scheme 1) shows almost identical structural features as the above chloride complex (Scheme 1). Again a metallamacrocycle (internal cavity of 4.16 Å × 7.29 Å) composed of two ligands **1**, two Cu(II) cations and two triflate anions is observed. The coordination sphere around the pentacoordinated Cu(II) cations is, as in the chloride case, comprised of four nitrogen atoms belonging to two ligands **1** and one triflate anion (d_{NN} = 1.38 Å $d_{C(Ph)N}$ = 1.42 Å; NNCC dihedral angles of −59.6 and 58.9°, Cu–N distances of *ca*. 1.99 Å and NCuN angles of 87.4–92.6°. Interestingly, the axial position is occupied by a triflate anion with Cu–O distance of 2.20 Å. The two positive charges on the $[\mathbf{1}_2Cu_2(CF_3SO_3)_2]^{2+}$ complex are neutralised by two external triflate anions (Fig. 4).

We have previously reported examples of metallatubulanes based on interconnection of metallamacrocyles into infinite 1-D

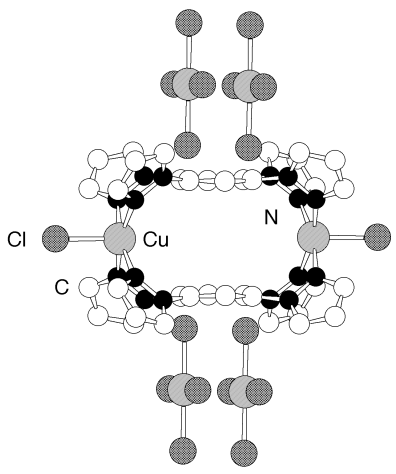

Fig. 3 The packing of the dicationic metallamacrocycle $[\mathbf{1}_2Cu_2Cl_2]$ and $CuCl_4^{2-}$ anions. H atoms and solvent molecules are not presented for clarity.

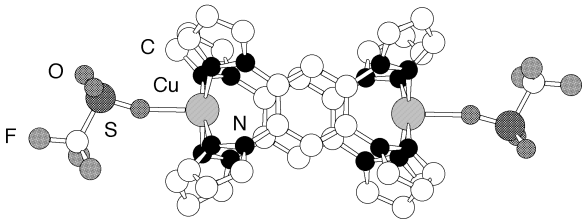

Fig. 4 The X-ray structure of the metallamacrocycle $[\mathbf{1}_2Cu_2(CF_3SO_3)_2]^{2+}$ obtained between **1** and $Cu(CF_3SO_3)_2$. Then triflate anions are disordered. H atoms, anions and solvent molecules are omitted for clarity.

coordination networks with tubular topology.[5,7,8] In relation to this, it may be of interest that, since the two anions occupying the summit of the square pyramid on each Cu centre are oriented in a divergent fashion, by interconnecting the metalloacyclophanes new types of coordination polymers may be obtained using bridging bidentate anionic ligands such as azido or isocyanato anions.

In conclusion, the synthesis of paramagnetic binuclear copper metallacyclophanes has been achieved and their solid state structural elucidation revealed that the Cu(II) cation adopts a slightly distorted square pyramidal geometry with the axial position occupied either by chloride or triflate anion. The formation of extended metallacyclophanes using ligand **2** is being currently pursued. Furthermore, the interconnection of the obtained metallamacrocyles leading to paramagnetic coordination networks through the substitution of monodentate coordinated anions by bidentate anions is currently under investigation.

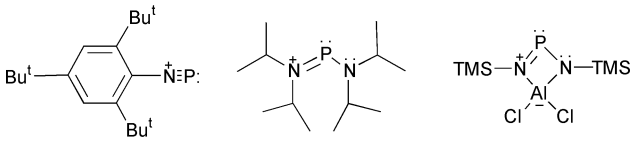
Received (in Irvine, CA, USA) 28th June 2000, Accepted 12th September 2000
First published as an Advance Article on the web 9th October 2000

In the context of the developing coordination chemistry of lone pair bearing phosphinic centers as acceptors, synthesis and characterisation for new complexes of the phosphadiazonium cation with nitrogen donors are described, including the first dipyridyl chelate.

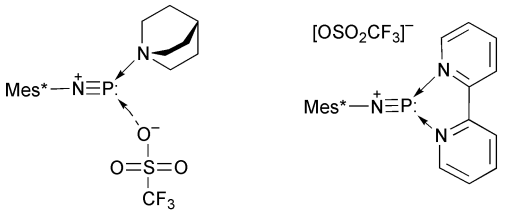
The coordination chemistry of phosphorus(V) as an acceptor is well established[1,2] and is highlighted by hexacoordinated centers such as PF_6^- and the pyridine complex of PF_5.[3] The Lewis acidity of phosphines represents a more recent and developing area and demonstrates interesting bonding properties by virtue of the non-bonding electron pair at the acceptor site. Systems **1**, **2** and **3**, containing coordinatively unsaturated



1 **2** **3**

phosphinic centers form complexes with amines,[4–7] phosphines,[8] carbenes[9] and arenes,[10] and an example of a bis-ligand complex has been mentioned.[11] We have now developed the coordination chemistry of the phosphadiazonium cation **1** with nitrogen donors, and have isolated the first chelate complex.

Reactions of [**1**][OSO_2CF_3][12] with equimolar amounts of quinuclidine (1-azabicyclo[2.2.2]octane, quin) or 2,2′-dipyridyl (dipyr) proceed almost instantaneously and quantitatively at RT as shown by ^{31}P NMR spectra of reaction mixtures, which are consistent with those for solutions of isolated crystalline products.†‡ Comprehensive characterisation, including X-ray crystallographic analysis, confirm 1:1 association of the reagents and the compounds are best represented as coordination complexes [**1**·quin][OSO_2CF_3] and [**1**·dipyr][OSO_2CF_3] involving phosphorus as an acceptor. Selected structural features for **1**·quin and **1**·dipyr are presented in Table 1 in comparison with analogous parameters for related complexes.



[**1**•quin][OSO_2CF_3] [**1**•dipyr][OSO_2CF_3]

Mes* = 2,4,6-tri-*tert*-butylphenyl

The N→P interactions are weak and variable in distance (*cf.* N–P single bond distance 1.800(4) Å),[13] but effect extension of the P–O(triflate) cation–anion interaction, which is most pronounced for the ionic material [**1**·dipyr][OSO_2CF_3]. The chelate complexation of **1** by dipyr, illustrated in Fig. 1, is

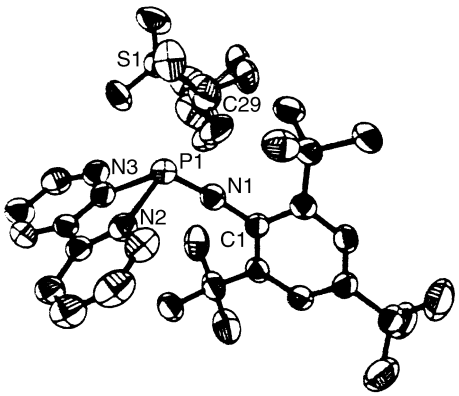


Fig. 1 Crystallographic view of [**1**·dipyr][OSO_2CF_3] with 50% probability displacement ellipsoids. The hydrogen atoms and dichloromethane solvate have been omitted. The CF_3 group of the triflate anion is disordered.

Table 1 Selected structural parameters for complexes of **1**, **2** and **3** with nitrogen donors (pyr = pyridine, DBN = 1,5-diazabicyclo[4.3.0]non-5-ene, tmeda = tetramethylethylenediamine)

defined by two indistinguishable N→P interactions, contrasting the asymmetric chelate-like cation–anion contact reported for the diselenophosphinate salt of **1**,[14] and complementing the established series of 2,2′-dipyridyl complexes of $AsCl_3$,[15] $SbCl_3$,[16] and $BiCl_3$[17] that could not be extended to PCl_3.[18]

A pyramidal geometry for phosphorus in **1**·dipyr accommodates the non-bonding electron pair and offers interesting comparisons with the hexafluorophosphate salt of phosphonium **4**,[2] which involves a distorted octahedral site. The 'bite' (N–P–N) angle in **1**·dipyr (75.1(2)°) is substantially less than in **4** (81.7(2)°), due to significantly longer N→P bond distances (*cf.* **4**, 1.896(4) and 1.898(4) Å). Coordinate interactions are demonstrated in both complexes by the small N–C–C(bridge) angles (**1**·dipyr, 111.9(4), 113.6(4)°; **4**, 112.0(4), 112.2(4)°).

Complexes of nitrogen ligands on phosphinic centers provide access to new bonding environments for phosphorus in that [**1**·quin]$^+$ represents a novel structural isomer **5** of a diaminophosphenium cation **6** and **1**·dipyr represents a cationic iminophosphide[9] bonding environment **7**, both of which are synthetically accessible only *via* the coordination chemistry of phosphorus as an acceptor.

Received (in Cambridge, UK) 15th August 2000, Accepted 19th September 2000
First published as an Advance Article on the web 9th October 2000

Chemical fixation of carbon dioxide to styrene carbonate proceeds effectively under supercritical conditions with DMF even in the absence of any additional catalysts, giving a maximum yield of 85% in the near-critical region.

From the standpoint of the protection of environment, the development of an environmentally benign process utilizing carbon dioxide, which is one of the greenhouse-effect gases, has drawn current interest in industrial chemistry and biotechnology. Chemical fixation of carbon dioxide is one of the most attractive methods for the development of a truly environmentally benign process since there are many possibilities for carbon dioxide to be used as a safe and cheap C_1 component to produce useful organic compounds. The conversion of carbon dioxide into carbonates has been carried out in conventional organic solvents using catalysts such as dialkyltin methoxide,[1] organoantimony halide,[2] alkali metal salts[3] and Mg–Al mixed metal oxide.[4] In particular, the conversion of epoxides into five-membered cyclic carbonates is industrially of great importance. However, these reactions using metallic catalysts have disadvantages, such as poor solubility of the catalyst[3] and difficulties in catalyst recycling,[2] whereas $scCO_2$ has advantageous features such as the disappearance of a gas–liquid phase boundary and easily tunable properties with pressure and temperature which make $scCO_2$ an alternative to conventional solvents.[5] The reactions of epoxides with CO_2 under supercritical CO_2 conditions have been studied in the presence of zinc catalysts; however, they give a biphasic mode of operation leading to poor reaction rates.[6] It has recently been found that the reaction with epoxide and CO_2 proceeds in DMF alone without any catalysts at temperatures around 135 °C and atmospheric CO_2 pressure, but the yield of styrene carbonate still remains low.[4,7] This low reactivity may be due to a much lower mass transfer of epoxide in DMF solution, although DMF is considered to catalyze the reaction in a manner similar to the Mg–Al mixed catalysts.[4] Thus, our conception of using a co-solvent such as DMF both as a catalyst as well as a solvent in $scCO_2$ has emerged to improve the poor reaction rates, which are due to limitations in liquid–liquid mass transfer and/or low solubility of reactants.[5] DMF itself catalyzes the reactions of CO_2 with epoxides dissolved in DMF–$scCO_2$ which allows to advantage a reduction in viscosity and an increase in diffusion rate as compared with the DMF liquid phase.[8] Here we demonstrate integration of $scCO_2$ and DMF to accelerate the reaction of styrene oxide with CO_2 and to be a very powerful tool in the chemical fixation of CO_2 (Scheme 1).†

Carboxylation of styrene oxide with CO_2 has been conducted without additional catalysts under various conditions (see Table 1). Under these conditions, carbonate was the main product with trace amounts of a few by-products.‡ In acetone and acetonitrile, styrene oxide did not react with CO_2 and styrene carbonate was not obtained (runs 2 and 3). It is noteworthy that the conversion proceeds successfully even in the absence of the metallic catalysts used so far when DMF is used in the place of acetone and acetonitrile (run 1). This is believed to be due to catalysis by DMF itself because the substrates, styrene oxide and CO_2, have similarly finite solubilities in acetone and acetonitrile as well as DMF. When $scCO_2$ alone was used as medium instead of DMF, a very poor reaction was obtained (run 7), and the catalytic action of $scCO_2$ for this reaction was found to be negligibly small. In the case of the CO_2–DMF system at lower pressures such as 2.0 MPa (run 1), the yield of styrene

Scheme 1

Table 1 Carboxylation of epoxides with carbon dioxide in different reaction systems

Run	Reaction type	Substrate	Catalyst	Solvent system	Pressure/ MPa	Temperature/°C	Yield of carbonate (%)[a]
1	Biphasic		None	DMF–CO_2	2.0	135	29
2[b]	Biphasic		None	Acetone–CO_2	2.0	135	0
3[b]	Biphasic		None	Acetonitrile–CO_2	2.0	135	0

7	Homogeneous		None	$scCO_2$	7.9	120	3.2
8[c]	Biphasic		MgO	DMF–CO_2	2.0	135	60
9	Homogeneous		None	DMF–$scCO_2$	7.9	120	83
10[d]	Biphasic		Mg–Al mixed oxide	DMF–CO_2	0.5	100	90(86)[e]

[a] The yields are determined by GC analysis based on the area ratio of tridecane or tetradecane as the internal references. [b] Reaction conditions: acetonitrile 5 mmol or acetone 5 mmol; styrene oxide 5 mmol; reaction time 15 h. [c] Ref. 7. [d] Ref. 4. [e] K. Yamaguchi *et al*. reported similar yields of the carbonate.

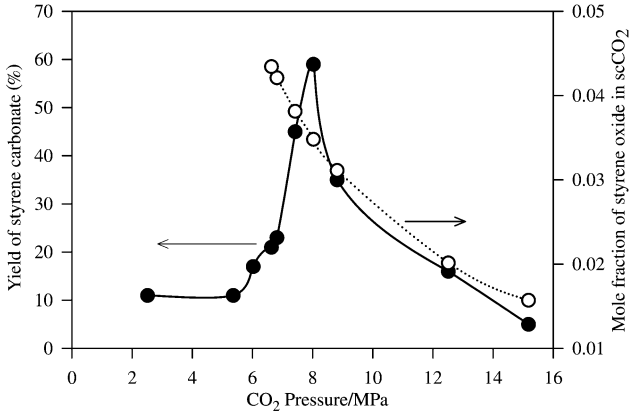

Fig. 1 Pressure dependence of the yield of styrene carbonate in CO_2 in the presence of DMF at 120 °C, and mole fraction of styrene oxide in $scCO_2$. Reaction time is 15 h. Mole fraction of styrene oxide was calculated using PROPATH Ver.10.2.

carbonate remains as low as 29%, whereas $scCO_2$–DMF (run 6) provides a much better yield compared with the CO_2–DMF system (29 to 85%) and the DMF–MgO system (60 to 85%). Furthermore, it was found that in the $scCO_2$–DMF system (run 5) styrene carbonate can be successfully synthesized even at lower temperatures around 100 °C, giving a better yield than that in the CO_2–DMF system (run 4) at 107 °C (0 to 20%). Gas–liquid–liquid mass transfer together with liquid–liquid mass transfer (solubility of substrate in catalyst or solvent phase) are important parameters for controlling the reaction yield. Visual observation through a sapphire window confirms that this $scCO_2$–DMF system forms a homogeneous reaction system, resulting in complete elimination of gas–liquid mass transfer, so that transport to and from the DMF phase is no longer a limiting factor. This is considered to be one of the most effective factors that cause the significant increase in yield as observed in Table 1.§ We have further attempted the conversion into another epoxide, 1,2-epoxy-3-phenoxypropane, using the $scCO_2$–DMF system at 7.9 MPa and 120 °C (run 9). This $scCO_2$–DMF system gives a good conversion to 3-phenoxy-1,2-propylcarbonate, the yield being comparable to that of the DMF–Mg/Al mixed oxide system (run 10). So this system can be available for acceleration of conversion from epoxides to carbonates.

Fig. 1 shows the pressure dependence of the yield of styrene carbonate in CO_2 in the presence of DMF at 120 °C. One can see an interesting pressure dependence in which the yield significantly increases, reaching a maximum yield at 7.9 MPa near the critical pressure of CO_2, and then sharply decreases with increasing pressure. In the lower pressure range below about 7 MPa, the yields are very small; DMF remains insoluble (by visual observation), leading to a much lower transfer of the epoxide. However, approach to the critical pressure with increasing pressure, which can dissolve DMF, significantly increases the rate of reaction and a higher yield is observed. On the other hand, the remarkable decrease in yield observed at higher pressures beyond 7.9 MPa near the critical pressure cannot be fully explained by the thermodynamic pressure effect, in which an increase in pressure is predicted to cause an enhancement in the reaction rate.[9] All experiments in the higher pressure range were confirmed by visual observation to take place in a single phase. To explain the decrease in yield with increasing pressure, we have attempted to introduce the mole fraction of styrene oxide in $scCO_2$ as shown in Fig. 1. It is evident that the extent of the decrease in yield of styrene carbonate is in agreement with that in mole fraction of styrene oxide except at 7.9 MPa near the critical pressure. If the reaction of styrene oxide with CO_2 is to take place by the catalysis of DMF, the molecules of styrene oxide and DMF must come into contact or very nearly so. Consequently, the decrease in mole fraction of styrene oxide in the higher pressure region prevents contact with DMF and reduces the yield of styrene carbonate. However, in the near-critical region the yield at 7.9 MPa is significantly higher than that expected from the relationship in Fig. 1, which cannot be accounted for only by the change in mole fraction of styrene oxide. It is likely that the increased local concentration[10,11] of the styrene oxide and/or CO_2 around the DMF is influencing the reaction, which becomes more pronounced at lower pressures in the near-critical region.[12,13] Thus, in the present conversion to styrene carbonate, the local concentration of reactants would be very large at 7.9 MPa near the critical pressure, resulting in the significant increase of the yield as seen in Fig. 1.

In conclusion, $scCO_2$–DMF was shown to be a good alternative catalytic system for conventional biphasic catalytic systems. It was further demonstrated that the yield of carbonates can be enhanced just by pressure manipulation of the $scCO_2$–DMF system.

Notes and references

† Typical experimental procedure is as follows: styrene oxide (5 mmol) was dissolved in DMF (5 mmol) in a 50 cm^3 reactor at rt, and then the mixture was heated up to the desired temperature and CO_2 (7.9 MPa) was introduced into the reactor. In the case of the $scCO_2$–DMF system, liquid CO_2 was subsequently charged into the reactor using a high-pressure liquid pump and compressed to the desired pressure. Pressure control was achieved by a back-pressure regulator. The reactions in both the CO_2–DMF and $scCO_2$–DMF systems were started by stirring the mixture and continued for 15 h. After the reaction, the pressure was released and the crude product was analyzed by NMR and GC-MS spectroscopy. The yields of carbonates were determined by GC-MS using tridecane or tetradecane as an internal standard.

‡ The total amount of these minor products is less than 1% from the GC analyses.

§ Another factor is thought to be solvation effect of CO_2, and studies on the solvation effect by IR and NMR are now in progress.

Self-assembled organogels formed by monoalkyl derivatives of oxamide

Xuzhong Luo, Chun Li and Yingqiu Liang*

Institute of Mesoscopic Solid State Chemistry and State Key Laboratory of Coordination Chemistry, Nanjing University, Nanjing 210093, Peoples Republic of China

Received (in Cambridge, UK) 26th July 2000, Accepted 21st September 2000
First published as an Advance Article on the web 9th October 2000

The monoalkyloxamide amphiphiles self-assemble to form ordered bilayer aggregates in a number of organic liquids and gelatinize the liquids.

In recent years the study on the gelation of organic solvents by low molecular weight organic compounds has been growing into a challenging research field.[1–4] Some attempts have been made to correlate the properties of the gels and the structures of the gelators.[5–7] Nevertheless, to date, only a limited number of small molecular gelators have been found and it is impossible to select a molecule that will definitively gel a selected liquid.[1–7] It has been known that some amphiphiles containing amide groups and chiral centers can gel a number of organic liquids even at a very low concentration, while those lacking chiral centers or racemic compounds usually exhibit no gelling ability.[2] Herein, we report simple diamide amphiphiles, monoalkyloxamide containing no chiral centers, which can form ordered bilayer aggregates in a number of organic liquids and gelatinize the liquids.

The oxamide derivatives, **1**–**7**,† used here were prepared in our laboratory. A typical procedure for studying gel formation

1 $R^1 = C_{14}H_{29}$, $R^2 = H$ **5** $R^1 = C_{14}H_{29}$, $R^2 = C_4H_9$
2 $R^1 = C_{18}H_{37}$, $R^2 = H$ **6** $R^1 = R^2 = C_{12}H_{25}$
3 $R^1 = C_{12}H_{25}$, $R^2 = H$ **7** $R^1 = R^2 = C_4H_9$
4 $R^1 = C_4H_9$, $R^2 = H$

ability is as follows: a weighed sample was mixed with an organic liquid (1 mL) in a sealed test tube and the mixture was heated until the solid dissolved. The resulting solution was cooled at 25 °C for 2 h and then the gelation was studied. Upon formation the organogel is stable and the tube can be inverted without any change of shape of the organogel.

The minimum gel concentrations of **1** necessary for gelation are summarized in Table 1. From Table 1, it is clear that **1** can form stable physical organogels and gelatinize a number of organic fluids even at a very low concentration. For example, the amounts of **1** necessary to gel one litre of carbon tetrachloride, benzene, toluene, *o*-xylene and dichloromethane are 3, 3, 3, 4 and 6 g, respectively.

The FT-IR spectrum of the KBr pellet of **1** is similar to that of the toluene gel, suggesting that the pattern of hydrogen bonding in the gel is close to that in the crystal. The FT-IR spectrum of the toluene gel of **1** is characterized by bands near 3386 (ν_{asNH2}), 3214 (ν_{sNH2}) and 1692 cm^{-1} ($\nu_{C=O}$ of primary amide) which are close to those of solid oxamide.[8,9] It has been known that the oxamide crystal has triclinic layer structure and the molecules within the layers are linked together by hydrogen bonds.[10] Therefore, it suggests that in the gel the primary amide groups (-$CONH_2$) of the amphiphiles are connected with each other by hydrogen bonds in the same way as in solid oxamide. FT-IR measurement also reveals a shift of NH stretching and secondary amide I ($\nu_{C=O}$) bands from 3440, 1680 cm^{-1} for a free secondary amide group (-NHCO-) to 3315, 1648 cm^{-1}, respectively.[11] These changes demonstrate that hydrogen bonds have formed between neighboring secondary amides. The above FT-IR results indicate that in the gel three self-complement intermolecular hydrogen bonds have been formed between an oxamido-group and its neighboring ones, and thus they form a hydrogen bond network.

The TEM image of a toluene gel of **1** is shown in Fig. 1. It reveals a number of fibers, juxtaposed and intertwined by several long slender aggregations with widths of *ca.* 30–100 nm. The X-ray diffraction patterns (Fig. 2) of the gel cast film show periodical diffraction peaks, indicating that **1** indeed assembles into an ordered structure. The long spacing (D) of the aggregate obtained by the XRD method is about 3.27 nm, which is smaller than twice the evaluated molecular length of **1** (2.35 nm, by the CPK model) but larger than the length of one molecule of **1**. According to the XRD and FT-IR results, it can be deduced that the gel aggregates consist of a repeating bilayer unit, which bears the head-to-head packing model and highly tilted alkyl chains relative to the bilayer

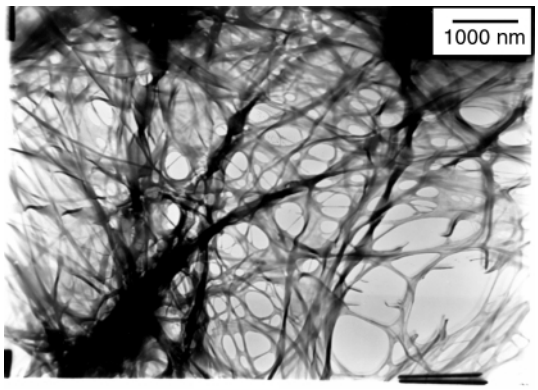

Fig. 1 TEM image of a toluene gel of **1** (4 g L^{-1}). The sample was prepared by picking up the gel on a carbon grid.

Table 1 Minimum gel concentration, *c*, of **1** (g L^{-1} solvent) necessary for gelation at 25 °C

Solvent	*c*	Stable period[a]	Solvent	*c*	Stable period[a]
Carbon tetrachloride	3	> 3 Months	Benzene	3	> 3 Months

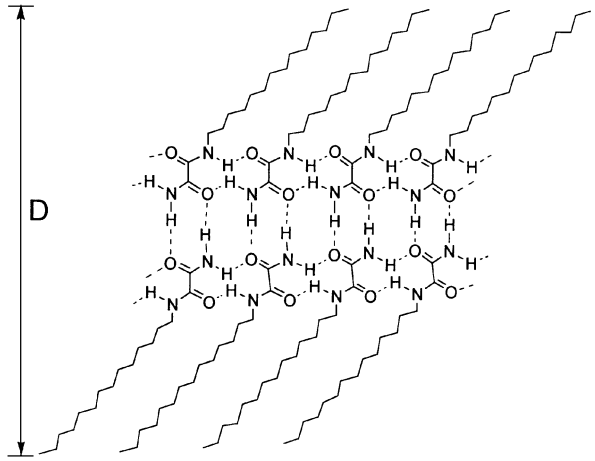

Fig. 3 Local microstructure of the bilayer aggregates of **1** in organogel.

normal (Fig. 3). Within the bilayer unit, the amphiphiles are connected with intra- and inter-layer hydrogen bonds.

The gelling abilities of some structurally related compounds, **2**, **3** (gel-forming) and **4**–**7** (non-gel-forming), have been inspected. None of the related compounds involving *N*,*N*′-disubstituted oxamide exhibit gelling ability. It may be due to the fact that after substituting one of the two hydrogen atoms of the primary amide by an alkyl group, no interlayer hydrogen bonds between the head-to-head arrangements can be formed and the amphiphiles fail to self-assemble to form ordered bilayer aggregates. Therefore the intermolecular hydrogen bonding is unable to meet the need for gelation. Furthermore, the introduction of a long lypophilic chain is essential for gelation, since organogels fail to form when the tail chain is shortened to four carbon atoms. From these observations and analyses, it can be concluded that: (i) gelling ability strongly depends on the oxamido-group; (ii) the hydrophile–lypophile balance is a significant factor for gelation; (iii) the formation of the ordered bilayer aggregates plays an important role in gel-forming.

In conclusion, this paper has shown that simple diamide amphiphiles, monoalkyloxamide, can form ordered bilayer aggregates, through intermolecular hydrogen bonding in a number of organic liquids, which are juxtaposed and interlocked by van der Waals interaction, and finally gelatinize the organic liquids.

New, efficient and chemoselective method of thioacylation, starting from carboxylic acids†

Leszek Doszczak and Janusz Rachon*

Department of Organic Chemistry, Chemical Faculty, Technical University of Gdansk, ul. Narutowicza 11/12, 80-952 Gdansk, Poland

Received (in Liverpool, UK) 19th July 2000, Accepted 19th September 2000
First published as an Advance Article on the web 9th October 2000

_S_-Acylation of dithiophosphoric acids yields mixed anhydrides 3; they readily isomerize to _O_-thioacyl 4 and _S_-thioacyl monothiophosphates 5, which treated with the excess of dithiophosphoric acid 2 can be easily converted into thioacyl dithiophosphates 6, excellent thioacylating reagents.

Thioacyl derivatives are mainly obtained by treating acyl derivatives with a thionating agent such as phosphorus pentasulfide or Lawesson's reagent.[1,2] Numerous other examples of sulfurating reagents have been reported (*e.g.* R_3OBF_4–NaHS,[3] R_2PSX,[4] $POCl_3$–$(Me_3Si)_2S$,[5] $(Et_2Al)_2S$,[1] B_2S_3[1] or SiS_2[1]) but are less well-known. Another strategy is to thioacylate nucleophiles with active derivatives of thiocarboxylic acids. Unfortunately, the known thioacylating agents (*e.g.* thioacyl halides,[1] thioacyl benzimidazolones,[6] thioacyl imidazoles, triazoles or tetrazoles,[1] thioacyloxybenzotriazoles,[7] thioacyl trifluorosulfonyl sulfides,[8] phenylmercury dithiocarboxylates[9] or bis(thioacyl) sulfides[10] *etc*.) show many disadvantages. They are generally unstable, expensive or their synthesis is complicated. In the case of less reactive reagents (like thioesters) reaction times are very long or the product cannot be obtained at all.[1] Most of the described reagents can only be prepared from dithiocarboxylic acids, which are scarcely obtainable commercially and are not easy to synthesise in high yield or to handle in pure form.

Here we report a new procedure for thioacylation with *S*-thioacyldithiophosphates, starting from carboxylic acids and dithiophosphoric acid. The usefulness of those kinds of reagents (namely thioacyl diphenylthiophosphinic sulfides) have been described by Kato *et al*.[11] but only derivatives of aromatic dithioacids were prepared by his group and the method of synthesis required cesium (or piperidinium) salts of dithiocarboxylic acids (general drawback). Moreover thioacyl diphenyldithiophosphinates are less reactive than dithiophosphates. We would like to describe a new and efficient method of synthesis of corresponding species and expand the scope of their applications (Scheme 1).‡

Acylation of dithiophosphoric acids (at the moment our best choice is 5,5-dimethyl-2-thiolo-2-thiono-1,3,2-dioxaphosphorinane[12] (**2**)) yields mixed anhydrides of type **3** almost quantitatively (see Table 1). These compounds in solution isomerize to *O*-thioacylmonothiophosphates **4** and *S*-thioacylmonothiophosphates **5** (as we have proved, potential thioacylating reagents) but in an equilibrium mixture compounds **3** generally predominate.§ However, we have found that treatment of that mixture with excess of dithiophosphoric acid leads to the formation of mixed anhydrides of type **6** in high yields (see Table 2). Compounds of type **6** are relatively inert towards water and oxygen and are very good thioacylating agents. They react immediately with nitrogen and sulfur nucleophiles at rt. Thioacyl derivative **7** can be easily separated from water-soluble salts of thiophosphoric acids. Anhydrides **6** chemoselectively thioacylate nitrogen or sulfur nucleophiles in the presence of hydroxy groups. This property allows us to obtain *e.g.* hydroxythioamides (Table 3, **7g**, **7l**) or hydroxydithioesters (**7m**) or thiohydroxamic acids (**7e**, **7f**, **7k**) as well, from substrates with an unprotected oxygen atom. It is worth mentioning that these kinds of compound are not available *via* thionation of unprotected hydroxyamides, hydroxythiolesters or hydroxamic acids with Lawesson's reagent.[13]

In summary we have developed a new strategy of thioacylation, starting from carboxylic acids. In one pot the exchange of C=O into C=S occurs and at the same time activation of the thiocarboxyl function is performed. The method is simple and efficient and cheap reagents are used. The thioacylating agents formed are stable and can be stored for months without noticeable changes. Even thioanhydrides derived from aliphatic acids can be handled without special precautions. The reaction with *N*- or *S*-nucleophiles is very fast under ambient conditions and isolation of the product is very simple.

Our efforts to apply the isomerization of anhydrides of type **3** for the synthesis of thioacylating reagents are focused on a search for dithiophosphoric acids better suited for the described procedure. Our results will be published in a full paper soon.

We gratefully acknowledge the Polish State Committee for Scientific Research for financial support (Grant No. 3 T09A 061 16).

Notes and references

‡ *Acyl dithiophosphates* **3**, *typical procedure*: acyl chloride (5 mmol) is added to a solution of 5,5-dimethyl-2-thiolo-2-thiono-1,3,2-dioxaphosphorinane (**2**) (5 mmol) in 15 ml of benzene. The solution is cooled with iced water and subsequently pyridine or triethylamine (5 mmol) is added dropwise. Immediately, ammonium chloride precipitates. After 15 minutes the reaction mixture is filtered through a short layer of silica gel. Following solvent evaporation a pure enough product is obtained.

Thioacyl dithiophosphates **6**, *typical procedure*: A solution of 5 mmol of acyl 2-(5,5-dimethyl-2-thiono-1,3,2-dioxaphosphorinanyl) sulfide (**3**) and 5,5-dimethyl-2-thiolo-2-thiono-1,3,2-dioxaphosphorinane (**2**) (10 mmol) in 35 ml of benzene is heated under reflux for 2–6 h. Subsequently phosphoric thioacids **2** and **8** are removed by washing with an aq. solution of sodium carbonate and then water. The organic layer is then dried with magnesium sulfate and the benzene is evaporated. The crude product is used for thioacylation without further purification, or if necessary is purified by means of silica gel chromatography or crystallization.

Thioacylation with thioacyl dithiophosphates **6**, *typical procedure A:* A solution of amine or thiol (5 mmol) and pyridine or triethylamine (5.5 mmol) in benzene is added dropwise to a solution of thioacyl 2-(5,5-dimethyl-2-thiono-1,3,2-dioxaphosphorinanyl) sulfide (**6**). Triethylammonium (or pyridinium) dithiophosphate precipitates and can be removed by means of filtration or washing with water and aq. sodium carbonate. Drying and evaporation of the solvent generally yields pure enough product. If necessary, the thioacyl derivative can be purified by means of chromatography or crystallisation.

Typical procedure B: A solution of acyl 2-(5,5-dimethyl-2-thiono-1,3,2-dioxaphosphorinanyl) sulfide (**3**) (5 mmol) and 5,5-dimethyl-2-thiolo-2-thiono-1,3,2-dioxaphosphorinane (**2**) (10 mmol) in 35 ml of benzene is heated under reflux for 2–6 h. A solution of amine or thiol (5 mmol) and pyridine or triethyl amine (16.5 mmol) in benzene is then added. The resulting mixture is worked up as above.

§ On the basis of our ^{31}P NMR experiments we were able to estimate the composition of the equilibrium mixtures and additionally we managed to isolate a few examples of *S*- and *O*-thioacylmonothiophosphates (*e.g.* **4b**, **5a**,**b**,**i**) and to fully characterize them. Reactivity and the mechanism of formation of the species are under investigation. We would like to emphasize that apart from not well proven reports[14] of isomerization of anhydrides of type **3** to **4**, formation of compounds type **5** from **3** (or a mixture of **3** and **4**) have not been previously reported in the literature (excluding the speculations of Cherkasov,[15] which however do not agree with our results).

Mesoporous SnO_2–SiO_2 composite stable up to 600 °C with a BET surface area of 350 m^2 g^{-1} and an average pore size of 3.4 nm is successfully prepared, which exhibits promising cycling properties as anodes for lithium batteries.

Following the discovery of the M41S family of mesoporous silicates using supramolecular templating approach,[1,2] mesoporous materials have attracted considerable attention because of their tunable pore size, narrow pore size distribution, and remarkably large surface areas, which make them ideal candidates for catalysts, molecular sieves, and electrodes for solid-state ionic devices. The ordering in these materials is a consequence of a self-assembly process in an aqueous solution containing organic surfactants (anionic, cathodic, or neutral) and inorganic cations or anions. To date, a wide range of mesoporous materials have been prepared using the structure-directing functions of electrostatic, hydrogen-bonding, covalent bonding and van der Waals interactions associated with amphiphilic surfactant molecules.[3–10]

Tin-based composite oxides are promising candidates for anodes in lithium batteries because of their much larger reversible capacity compared to carbonaceous materials. In this study, mesoporous SiO_2 stable up to 600 °C has been prepared using Brij 56 as a structure-directing agent and TEOS as precursor in an aqueous solution.† Further, a tin compound is introduced into porous SiO_2 using a sol-gel technique to form SnO_2–SiO_2 composite. The objective of our study is to create a nano-structured SnO_2–SiO_2 electrodes for lithium batteries. The structural stability of the tin-based materials during cycling is a major barrier to the successful application of this material as anodes in Li-batteries.[11] Our approach to improving the structural stability is to incorporate a tin compound into a mesoporous SiO_2 matrix, which is structurally stable and hence offers structural stability to the nanocomposite electrode. The mesoporous SnO_2–SiO_2 structure will facilitate the penetration of the liquid electrolyte into the electrodes and hence increase the rate of charge and discharge.

Shown in Fig. 1 are XRD patterns of mesoporous SiO_2 powder samples before and after calcination at 600 °C for 2 h prepared using Brij 56 as surfactant. The XRD pattern of the as-synthesized powders indicates that the surfactant molecules were organized into a hexagonal structure when aged at room temperature for 2 d. The peak at about 1.2° corresponds to the (100) reflection, which has a *d*-spacing of 6.8 nm. Thermogravimetric analysis shows that Brij 56 surfactant is completely removed upon calcination in air at 400 °C for 1 h. The appearance of a low-angle diffraction peak of the SiO_2 powder calcined at 600 °C for 2 h indicates that mesoscopic order is preserved upon removal of the surfactant by calcination, although the structure contracted slightly as evidenced from a slight shift of the XRD peak to a higher angle. The corresponding *d*-spacing is reduced to about 6.3 nm. The increased intensity of the XRD peak of the calcined SiO_2 indicates that the ordering of the mesostructure is improved during calcination. Shown in Fig. 1(*c*) is the XRD pattern of a SnO_2–SiO_2 composite. The peak is broader than that of pure SiO_2, suggesting that either the degree of ordering was reduced or the size distribution of the mesopores was broadened. However, the position of the peak did not change, implying that the *d*-spacing remained the same upon incorporating tin species into the pores of the mesoporous SiO_2. Further, the wide-angle XRD pattern shown in the inset in Fig. 1 indicates that the SnO_2 incorporated into the mesoporous SiO_2 is crystalline, rather than amorphous.

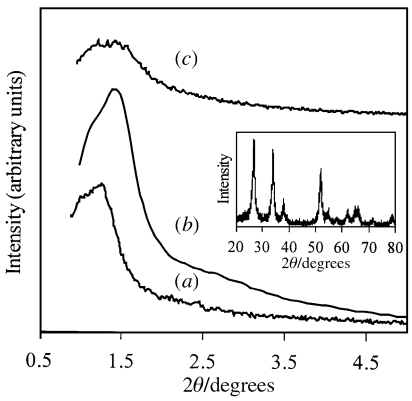

Fig. 1 Representative small-angle X-ray powder diffraction patterns of (*a*) as-synthesized SiO_2, (*b*) SiO_2 calcined at 600 °C for 2 h, and (*c*) SnO_2–SiO_2 composite calcined at 600 °C for 2 h. The wide-angle X-ray diffraction pattern of SnO_2–SiO_2 composite is shown in the inset.

Shown in Fig. 2 are representative TEM images of SiO_2 and SnO_2–SiO_2 samples after calcination at 600 °C for 2 h. Mesostructures with short-range hexagonal order can be seen and the corresponding *d*-spacings are 6.3 nm for both SiO_2 and SnO_2–SiO_2 composite, which are close to those determined from the XRD patterns. The nitrogen adsorption isotherms of the SiO_2 and SnO_2–SiO_2 samples after calcination at 600 °C for 2 h are shown in Fig. 3 and the calculated Brunauer–Emmett–Teller (BET) surface areas are 1100 m^2 g^{-1} for SiO_2 and 350 m^2 g^{-1} for SnO_2–SiO_2 composite, respectively. The gas-accessible surface area of the mesoporous SnO_2–SiO_2 composite was greatly reduced due to partial occupation of the pores by

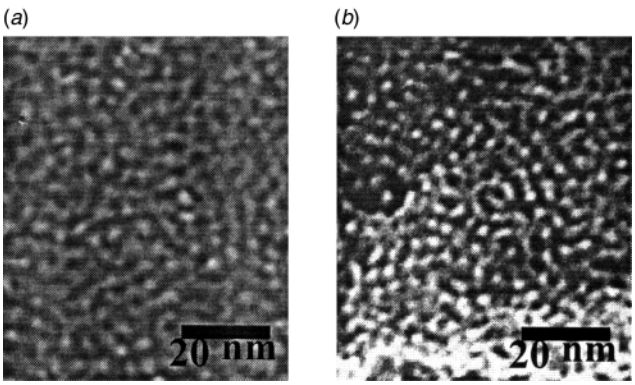

Fig. 2 TEM micrographs of (*a*) 600 °C calcined mesoporous SiO_2 and (*b*) mesoporous SnO_2–SiO_2 composite.

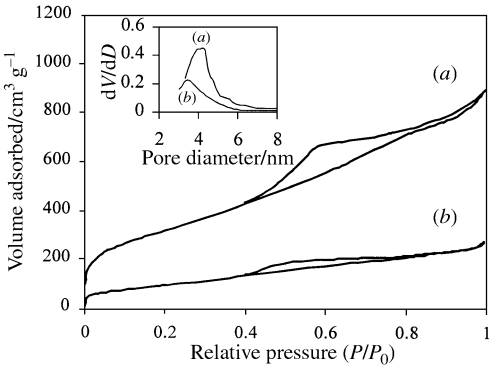

Fig. 3 Representative nitrogen adsorption and desorption isotherms for (*a*) SiO_2 and (*b*) SnO_2–SiO_2 composite after calcination at 600 °C for 2 h. Corresponding BJH pore size distributions are shown in the inset.

the tin species incorporated into the mesoporous SiO_2. Both nitogren isotherm curves have a well-defined step for the relative pressure P/P_0 ranging from 0.4 to 0.8, a characteristic of the filling of the framework-confined mesopores,[12] suggesting that both SiO_2 and SnO_2–SiO_2 samples are mesoporous after calcination at 600 °C for 2 h. As shown in the inset in Fig. 3, the average pore size in the SiO_2 structure is 4.0 nm while that in the SnO_2–SiO_2 composite is 3.4 nm, implying that a thin SnO_2 layer has been incorporated into the channel surface of the mesoporous SiO_2.

The electrochemical behavior of the obtained SnO_2–SiO_2 composite oxide is further studied using cyclic voltammetry. Shown in Fig. 4 are the cyclic voltammograms (CVs) of a mesoporous SnO_2–SiO_2 composite, as studied using a powder microelectrode in the potential range between 2.0 and 0 V (*vs.* Li^+/Li) with a scan rate of 0.2 mV s^{-1}. The potential was swept from 2.0 V in the cathodic direction down to the set limit (0 V) and then in the anodic direction. Two very small irreversible reduction peaks appeared near 0.6 and 0.9 V, respectively, in the CV of the first cycle. This is quite different from the CVs observed for tin-based composite electrodes in the literature,[13,14] in which there is only one large irreversible reduction peak around 0.9 V in the first sweep. It is well known that this large irreversible reduction peak is due to the *in situ* electrochemical reduction of SnO or SnO_2 by lithium to metallic tin and Li_2O,[15] representing a large irreversible capacity loss for tin-based composite materials in the first cycle, which is still a major barrier to the successful application of these materials as anodes in Li-batteries.[14] In this work, even though it is still not

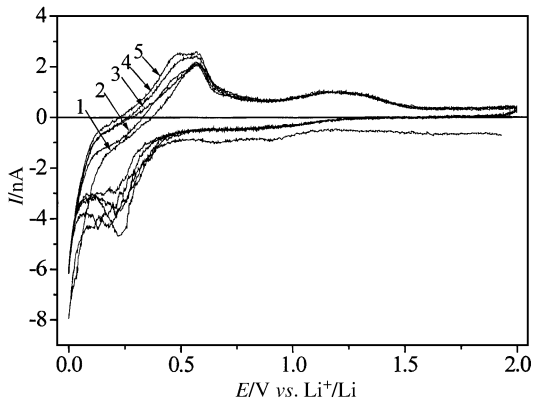

Fig. 4 Cyclic voltammograms (CVs) of a mesoporous SnO_2–SiO_2 composite as studied electrode using a powder microelectrode technique. The number adjacent to each CV represents the order of the cycles.

clear what the two tiny irreversible reduction peaks (observed for the mesoporous SnO_2–SiO_2 composite) correspond to, it is anticipated that the mesoporous SnO_2–SiO_2 composite as an anode for a lithium battery would display much less irreversible capacity loss during the first cycle. Further, the reversible redox peaks in the range of 0.1–0.7 V in the first five cycles of the CVs show very little change, an indication of good cyclability of such a mesoporous SnO_2–SiO_2 composite electrode. The electrochemical behavior of SnO_2 in mesoporous SnO_2–SiO_2 composites as well as the long-term charge–discharge cycling behavior of the composite electrodes in a lithium cell are still under investigation and will be reported in subsequent communications.

Notes and references

† In a typical preparation using Brij 56 as the structure-directing agent, 1.093 g Brij 56 was dissolved in 80 ml H_2O by stirring at room temperature. 2.667 g tetraethyl orthosilicate (TEOS) was added to the Brij 56 solution and the solution was stirred at room temperature for 2 h. Subsequently, 1.333 ml 0.2 M NaF was added to the above solution and the solution was stirred at room temperature for 2 h while a milky sol was obtained. The milky sol was placed at room temperature for 2 d and a white precipitate formed progressively. The precipitate was finally filtered off, washed 5 times using distilled H_2O, dried at 60 °C in a vacuum oven and finally calcined in air at 600 °C for 2 h to remove the surfactant. Incorporation of tin compound into the pores of SiO_2 was achieved by immersing mesoporous SiO_2 powder into tin nitrate solution and then drying at 40 °C under vacuum. Mesoporous SnO_2–SiO_2 composite was obtained by calcining the dried tin nitrate–SiO_2 powder at 600 °C for 2 h in air. A powder microelectrode was used to study the electrochemical performance of mesoporous SnO_2–SiO_2 composite in 1 M $LiN(SO_2CF_3)_2$/EC+DMC electrolyte solution.

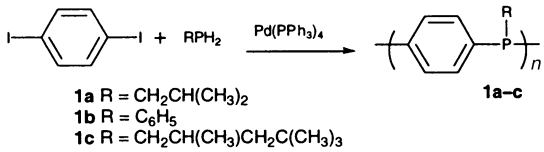
***P*-Substituted poly(*p*-phenylenephosphine)s were prepared *via* palladium catalyzed carbon–phosphorus bond formation.**

There has been substantial recent interest in the synthesis and properties of π-conjugated polymers. These polymers have found important uses for a variety of optoelectric applications such as rechargeable battery electrodes, light-emitting diodes, and chemical sensors.[1] While many conjugated polymers contain only sp and sp^2 hybridized carbon atoms along the polymer backbone, two of the most important and widely investigated conjugated polymers, polyaniline[2] and polythiophene,[3] contain heteroatoms as a vital component of the conjugation path (Scheme 1). Other interesting conjugated polymers have been prepared which contain heteroatoms in the backbone including poly(*p*-phenyleneborane)s,[4] poly(*p*-phenyleneselenide)s,[5] and poly(*p*-phenylenesulfide).[6] The presence and properties of the heteroatom have a profound impact on the optoelectronic properties of the polymer. A substantial increase in the doped conductivity is observed upon moving from poly(*p*-phenyl-eneoxide) to poly(*p*-phenylenesulfide).[6] While phosphorous containing polymers have found a variety of important uses including flame retardants, ionic conduting materials, and easily separable supports for metal catalysts,[7] the incorporation of phosphorus into the backbone of a conjugated polymer has been limited. The few cases include poly(ferrocenylphosphine),[8] oligophospholes,[9] and the trace incorporation of phosphorus into soluble poly(*p*-phenylene)s *via* catalyst ligand decomposition.[10]

Palladium catalysis has been used extensively in organic chemistry for the formation of new sp^2–sp^2 and sp^2–sp hybridized carbon–carbon bonds with high yields and is useful for the preparation of π-conjugated polymers.[11] Recent investigations by Buchwald[12] and Hartwig[13] have expanded the utility of palladium mediated cross coupling to include carbon–nitrogen bond formation. The new synthetic method couples arylhalides or aryltosylates with amines and has generated considerable interest for the preparation of arylamine containing materials such as polyanilines, oligoanilines, and arylamine dendrimers.[14] Analogous nickel[15] and palladium[16] mediated carbon–phosphorus bond forming reactions have been reported and recently utilized for the synthesis of phosphorus containing polymers.[7e] We report the synthesis and optoelectric investigation of the phosphorus analog to *N*-substituted polyanilines, *P*-substituted poly(*p*-phenylenephosphine)s, *via* palladium catalyzed carbon–carbon phosphorus bond formation.

In this paper, we describe the palladium catalyzed condensation polymerization of monoalkyl and monoaryl phosphines with 1,4-diiodobenzene (Scheme 2). A typical experiment is conducted as follows. Palladium tetrakis(triphenylphosphine) (0.310, 0.27 mmol) and diiodobenzene (1.77 g, 5.37 mmol) were dissolved in 1 : 1 dry oxygen free THF–toluene (10 ml). To this solution was added isobutylphosphine (0.63 ml, 5.37 mmol) followed by triethylamine (2.0 ml). Upon the addition of the triethylamine a white precipitate was observed indicating the formation of $Et_3N{\cdot}HI$. The reaction mixture was heated at 70 °C for 72 h and turned burnt orange. The reaction mixture was poured into rapidly stirring 5 : 1 MeOH–aq. NH_3 (500 ml) to precipitate the polymer, which was collected by filtration. The polymer was redissolved in THF, reprecipitated in MeOH, filtered, washed with MeOH, and dried under high vacuum for 8 h to yield polymer **1a** as a light pink solid (0.73 g, 83% yield).



Scheme 2 Synthesis of poly(*p*-phenylenephosphine)s.

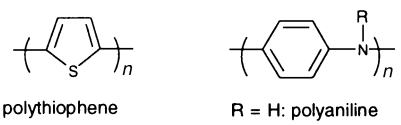
The structures of polymers **1a**–**c** are supported by ^1H, ^{13}C, and ^{31}P NMR and IR spectroscopy and the molecular weights are estimated by gel permeation chromatography (Table 1).† The ^1H NMR spectra of **1a** contain four broad resonances with appropriate chemical shifts and integrated intensities. The ^{31}P NMR spectra contain a single broad resonance at −19.81 ppm suggesting that the environment is similar for most of the P nuclei. The ^{13}C NMR spectra contain five resonances each with scalar coupling to ^{31}P. The resonance at 132.66 ppm is coupled to two different ^{31}P nuclei characteristic of ^2J (^{31}P–^{13}C, 19.1 Hz) and ^3J(^{31}P–^{13}C, 6.1 Hz) as expected for the C nuclei not directly bound to P.[17] The IR spectra include absorptions characteristic of aromatic ring stretches but contain no observable P=O absorptions. Polymers **1a** and **c** are entirely soluble in THF, toluene, and $CHCl_3$ while **1b** is only partially soluble.

The UV-visible spectra of polymers **1a**–**c** in $CHCl_3$ suggest significant π-conjugation along the polymer backbone *via* the lone pair on P. A red shift of the optical absorption upon increasing the number of phenyl phosphine units is observed, as evidenced by the shift of the absorbance maximum for the π–π* transition for the following series of phosphines: triphenylphosphine (λ_{max} = 263 nm), 1,4-bis(diphenylphosphino)benzene (**2**) (λ_{max} = 275 nm), and polymer **1b** (λ_{max} = 291 nm). In addition, polymer **1b** has a second small absorption maximum at 434 nm (Fig. 1). We suspect that this lower energy absorption results from an n–π* transition. The absorption is observed due to an increase in intensity resulting from electron delocalization in the polymer.

Table 1 Optical and molecular weight data for polymers **1a**–**c**

Polymer	R	M_n[a]	n[b]	PDI	λ_{max} Abs
1a	Isobutyl	1,700	10	1.3	278, 415
1b	Phenyl	1,300	7	1.4	291, 434
1c	2,4,4-Trimethylpentyl	3,100	14	1.5	276, 422

[a] Molecular weights were determined by GPC *vs*. polystyrene standards in THF. [b] The value *n* corresponds to the average number of repeat unit in the polymer.



Scheme 1 Heteroatom containing conjugated polymers.

DOI: 10.1039/b003989f

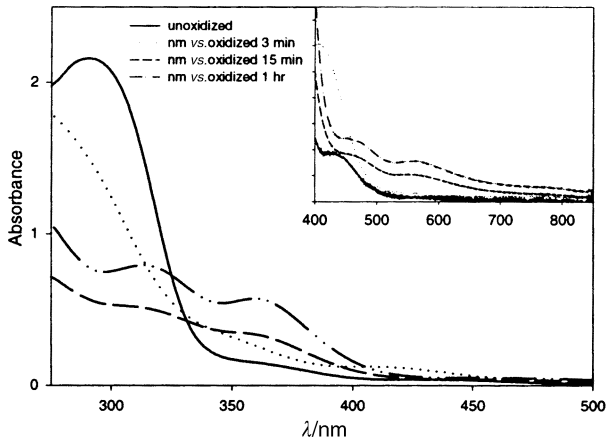


Fig. 1 UV-visible spectra of the oxidation of polymer **1b** with $FeCl_3$ in $CHCl_3$.

Chemical oxidation provides additional support for the electronic delocalization of poly(*p*-phenylenephosphine)s. Oxidation of polymer **1b** with $FeCl_3$ in the absence of O_2 and H_2O results in the formation of several new absorption bands and a shift of the band edge past 800 nm (Fig. 1). The spectral properties of these polymers are related to poly(*N*-arylaniline)s.[14a] The NMR spectra of polymers **1a**–**c** are also altered upon oxidation with $FeCl_3$. We are unable to observe ^{31}P or ^{1}H NMR spectra for oxidized polymers **1a**–**c**. The lack or severe broadening of NMR resonances is consistent with paramagnetism resulting from declocalized electrons along the polymer chain. The oxidized polymer is stable in solution for several hours in the absence of O_2 and H_2O. While we do not fully understand the spectroscopic properties of these polymers, the data support an extension of the conjugation path through P and electronic delocalization along the polymer chain.

Since phosphines are well known to undergo rapid oxidation to phosphine oxides, we investigated the oxidation of the polymers by hydrogen peroxide (Scheme 3). Addition of (30%) H_2O_2 to $CHCl_3$ solutions of **1b** resulted in a color change to deep red along with a dramatic change of the UV-visible spectroscopic properties, the primary absorption (291 nm) is blue shifted while the low energy band (434 nm) is red shifted to 550 nm and severely broadened. A change in the structure of the polymer is supported by NMR and IR spectroscopy. The ^{31}P NMR absorption for polymer **1b** cleanly shifts from −5.2 ppm to 28.6 ppm suggesting near quantitative conversion of **3b**.‡ IR spectra of polymer **3b** contain two strong absorptions at 1120 and 1188 cm^{-1} characteristic of phosphine oxides.[18] Polymers **1a**–**c** are mildly sensitive to atmospheric oxygen and are converted to **3a**–**c** over 4–6 days in solution ($CHCl_3$) and 4–6 months in the solid state.

We have described the synthesis and spectroscopic investigation of a series of poly(*p*-phenylenephosphine)s. Polymers **1a**–**c** were synthesized *via* palladium catalyzed cross coupling of diiodobenzene with primary phosphines. The investigations suggest significant electronic delocalization through P along the backbone of the polymer. We are currently further evaluating the properties of these interesting polymers and investigating additional routes to incorporate P into conjugated polymers.

The authors of this paper would like to thank the University of Rhode Island for financial support of this research, Professor William Euler for valuable help obtaining UV-visible spectra data and for thoughtful discussions, and Cytec Canada Inc. for a generous donation of primary phosphines.

Control of metal/ligand stoichiometry and structure in aminopyridinato complexes of zirconium: *N*-alkyl is better than trimethylsilyl†

Colin Morton, Paul O'Shaughnessy and Peter Scott*

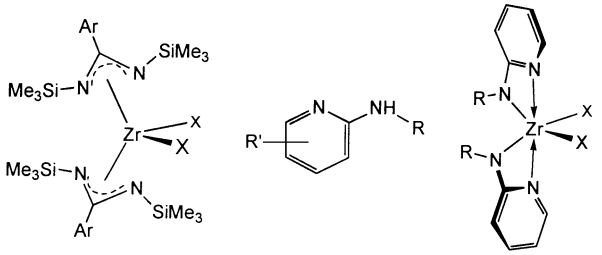
_N_-Adamantyl-2-aminopyridines (HL) readily form C_2-symmetric aminopyridinato complexes with zirconium [ZrL_2X_2] (X = Cl, NMe_2, CH_2Ph, CH_2Bu^t) which are stable with respect to ligand redistribution and lead to catalysts for ethylene polymerisation with similar productivity to the related [Zr(benzamidinate)$_2X_2$] system.

Of the many ligand sets that may provide an alternative to cyclopentadienyl,[1] the amidinates have been among the most productive in terms of both new stoichiometric chemistry and catalytic activity.[2] Of particular note recently are reports that complexes such as **I** support an impressive range of ancillary



I **II** **III**

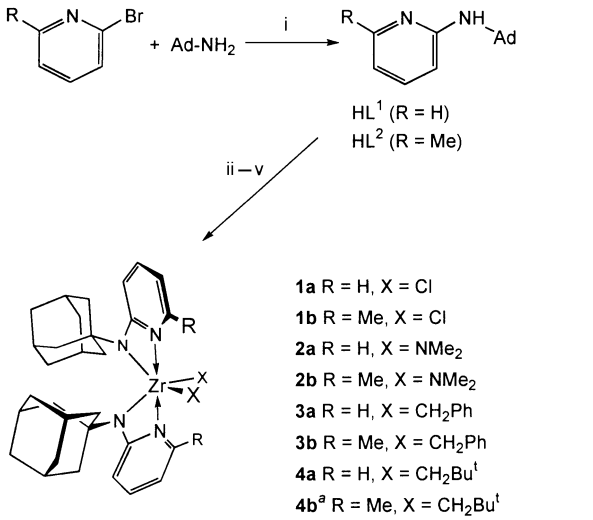
ligand- and metal-centred reactivity,[3] and are catalysts for alkene oligomerisation[4] and the synthesis of isotactic poly(propylene).[5] For the closely related aminopyridinato complexes of zirconium,[6] most commonly based on **II** (R = $SiMe_3$),[7] control of the number of such ligands about each metal centre is challenging. For example, treatment of [$Zr(NEt_2)_2Cl_2$] with aminopyridines **II** (R = $SiMe_3$) gave complexes with one or three (but not two) aminopyridinato ligands, depending on substitution at pyridine R′. Complexes of the type **III** analogous to **I** have thus never been isolated, although for the lighter congener titanium unsymmetric complexes [Ti(2-PyNR)$_2$(N-Me_2)Cl] (Py = 2-C_5H_3N; R = Me, Ph) have been crystallographically characterised.[8]

Inspired by the success of alkylanilide ligands in early transition and actinide chemistry,[9] we began to investigate the coordination chemistry of aminopyridines with sterically demanding alkyl (as opposed to trialkylsilyl) substituents R. We report here our initial findings, and in particular that control of metal/ligand stoichiometry and synthesis of catalytically competent species can be achieved.

The Buchwald arylation of amines[10] is particularly successful in the case where arene = pyridine, and we were able to synthesise the 1-adamantyl-2-pyridyl amines HL^1 and HL^2 in good yield from commercially available bromopyridines and 1-adamantylamine using this methodology (Scheme 1).‡

The lithium amide LiL^1 generated *in situ* from HL^1 and lithium butyl§ gave the complex [$L^1{}_2ZrCl_2$] **1a** on reaction with $ZrCl_4$ in diethyl ether. The free amine HL^1 reacted smoothly with [$Zr(NMe_2)_4$], [$Zr(CH_2Ph)_4$] and [$Zr(CH_2Bu^t)_4$] in toluene to give the target complexes [$L^1{}_2Zr(NMe_2)_2$] **2a**,

† Electronic supplementary information (ESI) available: characterisation data. See http://www.rsc.org/suppdata/cc/b0/b006603f/



Scheme 1 Synthesis of proligands and complexes **1**–**4**. *Reagents and isolated yields*: i, [$Pd_2(dba)_3$], dppp, $NaOBu^t$, toluene, 60% (L^1), 52% (L^2); ii, Bu^nLi, $ZrCl_4$, diethyl ether, 56% (**1a**), 49% (**1b**); iii, [$Zr(NMe_2)_4$], toluene, 70% (**2a**), pentane, 78% (**2b**); iv, [$Zr(CH_2Ph)_4$], toluene, 86% (**3a**), pentane, 59% (**3b**); v, [$Zr(CH_2Bu^t)_4$], toluene, 63% (**4a**). [a] **4b** not isolated (see text).

[$L^1{}_2Zr(CH_2Ph)_2$] **3a** and [$L^1{}_2Zr(CH_2Bu^t)_2$] **4a**, respectively. NMR tube scale experiments showed that these reactions are essentially quantitative. The analogous complexes **1b**–**3b** of L^2 were prepared similarly. In no instance was a complex of the type [L_3ZrX][6a] detected, although an intermediate [$\{L^1Zr(CH_2Bu^t)_3\}_n$] was observed by NMR spectroscopy when the synthesis of **4a** was conducted in d^8-toluene. The reaction of HL^2 with [$Zr(CH_2Bu^t)_4$] gives a similar monosubstituted intermediate which is converted slowly to **4b**. 2-Methyl substitution on the pyridine ring in L^2 thus appears to have a profound steric effect in the complex, as further evidenced by the broadness of the ^1H NMR spectrum of **4b** in the aliphatic (adamantyl) region. Steric compression in the auxiliary ligand sphere is probably also responsible for the slow thermal decomposition of this compound with elimination of neopentane. In contrast, **4a** and the other alkyls did not decompose in solution over a period of several days at room temperature.

The molecular structure of the six-coordinate neopentyl complex **4a** is shown in Fig. 1.¶ The neopentyl methylene groups and amido N atoms occupy mutually *cis* positions with C(31)–Zr(1)–C(36) and N(2)–Zr(1)–N(4) angles of 98.18(15) and 99.82(11)°, respectively. The two pyridine N atoms are mutually *trans* [N(3)–Zr–N(1) 174.85(11)°]. The overall structure is thus closely related to the bis(benzamidinate)dichlorozirconium complex[3b,5c] but is very different from the *ansa*-bis(aminopyridonato) complexes of titanium in which the quadridentate ligand adopts a planar disposition.[11]

The C_2-symmetry of **4a** is apparent from Fig. 2. The angle between the planes formed by C(36), Zr(1), C(31) and N(2), Zr(1), N(4) is *ca.* 61.85°. It is clear from space-filling models that the conformation of the neopentyl ligands serves to minimise steric interactions between their *tert*-butyl groups and

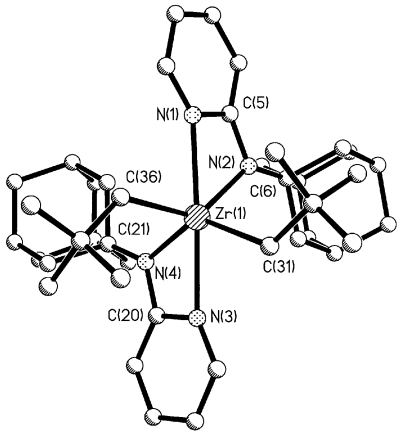

Fig. 2 Molecular structure of **4a** viewed along the approximate C_2 axis.

the pyridine rings. As we suggested above, a methyl group in the 1-position of the ring (as in L[2]) would lead to excessive steric compression in these positions, at least for a ligand as large as neopentyl.

The structures of the complexes in solution are similar to that observed in the solid state for **4a** as judged from NMR spectra. In all instances only one set of resonances for the aminopyridinato ligands is observed at accessible temperatures, and the metal-bound methylene groups in both sets of complexes **3** and **4** appear as pairs of AB doublets in the ^{1}H spectra at room temperature. At elevated temperatures these latter signals coalesce indicating that the complexes racemise, presumably through rotation of the aminopyridinato ligands. From lineshape analysis of the spectra of **3a** a value $\Delta G^{\ddagger}_{298}$ = 60(1) kJ mol^{-1} was extracted. The related amidinate complexes have much lower barriers to inversion, and for example [Zr{CyNC(Me)NCy}$_2$Cl$_2$] has spectroscopically equivalent cyclohexyl groups.[12]

The new complexes are moderately active[1] procatalysts for the polymerisation of ethene. For example, **1a**/MAO in toluene at 25 °C exposed to *ca.* 1 atm. of ethylene gave a reproducible productivity of 20 kg mol^{-1} h^{-1} bar^{-1} for a 1 h run. This exceeds significantly that obtained with previously reported aminopyridinates,[11] and compares favourably with that for the comprehensively studied benzamidinates.[5c] Although the nature of the catalytic system for ethene polymerisation produced from **1a** is as yet unknown it is likely to be of similar nature to the 'alkyl cation' [ZrCp$_2$R]$^+$ implicated in metallocene based catalysis.[13] The reactions of **3a** and **3b** with B(C$_6$F$_5$)$_3$ give species which ^{1}H NMR spectra indicate are the cations [ZrL$_2$(CH$_2$Ph)][B(C$_6$F$_5$)$_3$(CH$_2$Ph)] or ionisation isomers thereof.

We have thus shown that control of ligand stoichiometry and structure can be achieved in aminopyridinato chemistry of zirconium by careful choice of amido *N*-substituent; in this respect alkyl is better than trialkylsilyl. Given that the adamantyl group is close in steric demand to the commonly used SiMe$_3$ the dramatic disparity in the properties of the two systems is likely to arise from the electronic influence of the Si atom on the amido N–Zr bonds in the latter.[14] We note Jordan's comments to the effect that control of ligand stoichiometry in pyridine(alkoxide) complexes of zirconium depends on the proton acidity of the ligand as much as its steric demand.[15] The bis(alkylaminopyridinato) unit is thus established as a robust ligand set for the stabilisation of zirconium complexes with halide, amide and alkyl ligands. We will report further chemistry of these versatile ligands and more detailed catalysis studies in due course.

P.S. wishes to thank EPSRC for postdoctoral fellowships (to C.M. and P.O.'S.).

Notes and references

‡ We have synthesised several related ligands from sterically demanding alkyl and aryl amines and we will report their chemistry in due course.

§ The aminopyridines are also rapidly deprotonated with sodium and potassium hydrides.

Received (in Cambridge, UK) 1st August 2000, Accepted 21st September 2000
First published as an Advance Article on the web 9th October 2000

The calculated pK_{Enol} values for the enols of amides $Me_2CHCON(Me)Ph$ and $XCH_2CH(NH_2)CONHMe$ (X = H,OH) are lower by only 1.1–2.7 units than that of acetamide, and therefore these enols should not display unusual stability.

Although 'simple' enols (*i.e.* those lacking a β-electron-withdrawing substituent)[1] of aldehydes and ketones are much less stable than their aldehyde or ketone tautomers unless the enols are specially stabilised, they play an important role in several reactions.[2] Simple enols of carboxylic acid derivatives such as esters and amides are even much more unstable compared with the acid derivatives than the corresponding carbonyl/enol pair, owing to the stabilisation of the acid derivative by the alkoxy or amino substituent.[3] Recent calculations had shown that the equilibrium constant for the parent pair $MeCONH_2/CH_2{=}C(OH)NH_2$ expressed as pK_{Enol} (= $-\log K_{Enol}$; K_{Enol} = [Enol]/[Amide] at equilibrium) is 21.3 in the gas phase.[4] It is therefore not surprising that, from what we presently know, the role of enols of amides as reaction intermediates is limited.

A process in which enols of amides may play a role is peptide racemisation, since ketonisation of an intermediate planar enol of amide will give both *R* and *S* species of the amide. D-Serine and D-aspartate are observed in significant amount in mammalian tissues[5] and the enzyme responsible for serine isomerisation was recently isolated[5a] so that *in vivo* racemisation is possible.

Hegarty *et al.* reported recently experimental results which suggest that the enol 1-*N*-methylanilino-2-methylpropen-1-ol **2** of the amide *N*-methylanilino-2-methylpropionamide **1** exists in observable concentration in water-containing media and underwent tautomerisation to **1** at measurable rates.[6] Enols of amides as simple as **2** were not hitherto observed and, based on the shorter life times for related enols of acids,[7] they are not expected to have such a long lifetime. Since **2** resembles the intermediate enols expected in peptide racemisation we performed theoretical calculations for **1** and **2** as well as for two simple pairs of amides/enols of serine and alanine amides in order to find out if the enols are unusually thermodynamically stable, so that this may be reflected in their kinetic stability.

The relative stabilities of the amide **1** and the enol **2** as well as that of the other compounds in Table 1 were computationally determined by means of density functional theory at the B3LYP/6-31G** level.[8,9] This method has been extensively used in recent calculations of enols of carboxylic acid derivatives, and the calculated pK_{Enol} values were shown to be within *ca.* 2 pK_{Enol} units of the values measured in water.[4,10]

Several conformational isomers were examined for **1** and **2** and the most stable ones are shown in Fig. 1. with others given as ESI.† The phenyl ring of amide **1** is *anti* to the C=O bond and is perpendicular to the amide moiety, facing the isopropyl group. Another conformation with the phenyl ring coplanar to the amide moiety is not on a local minimum and converges to the structure shown in Fig. 1. The conformer with the carbonyl group and the phenyl ring *syn* to each other is 12.7 kJ mol^{-1} higher in energy than **1**. In enol **2**, the ethenol and the anilino moieties are twisted (O–C–N–Ph dihedral angle of 64°) and the enolic hydrogen is directed toward the Ph ring. Attempted optimisation of a planar conformation gave the twisted structure. Another conformer with the OH pointing away from the Ph ring is 4.0 kJ mol^{-1} less stable.

Table 1 Amide–enol isomerisation free energies ΔG (kJ mol^{-1}), electronic energies (ΔE) (kJ mol^{-1}) (in parentheses) and pK_{Enol} of amides calculated at the B3LYP/6-31G** level at 25 °C

Amide/enol	$\Delta G(\Delta E)$	pK_{Enol}
$Me_2CHCON(Me)Ph$ **(1)**/$Me_2C{=}C(OH)$-N(Me)Ph (**2**)	105.3 (103.2)	18.5
$MeCONH_2$ **(3)**/$CH_2{=}C(OH)NH_2$ **(6)**	121.2 (114.5)	21.3[4]
$HOCH_2CH(NH_2)CONHMe$ **(4)**/$HOCH_2C(NH_2){=}$C(OH)NHMe (**7**)	119.1 (123.7)	20.1
$MeCH(NH_2)CONHMe$ (**5**)/$MeC(NH_2){=}C(OH)NHMe$ (**8**)	112.7 (113.3)	19.8

The calculated energy difference between **1** and **2** is 103.2 kJ mol^{-1} in electronic energy and 105.3 kJ mol^{-1} in free energy, which corresponds to a pK_{Enol} value of 18.5 at 25 °C. This value is 2.8 pK_{Enol} units lower than that calculated for the parent acetamide system.[4] The pK_{Enol} value is much higher than those of enols of acids which were observed by flash photolysis, but had shorter lifetimes owing to a faster decomposition to the corresponding acids.[7] Clearly the unexpectedly long lifetime of enol **2**[6] does not reflect an unusual thermodynamic stability of the enol. The calculated gas phase K_{Enol} value for **1**, taking into account that the calculated solvent effects on pK_{Enol} values are small[4,11] suggests that **2** will not be observable in aqueous organic media at room temperature, based on data of pK_{Enol} values and the lifetimes of simple enols.[12] Indeed, the other observable simple enols of amides having two bulky β-Tip (Tip = 2,4,6-$Pr^i_3C_6H_2$) groups, *i.e.* $Tip_2C{=}C(OH)NR_2$[13] should have pK_{Enol} values of *ca.* 8, based on the calculated K_{Enol} of 9.3

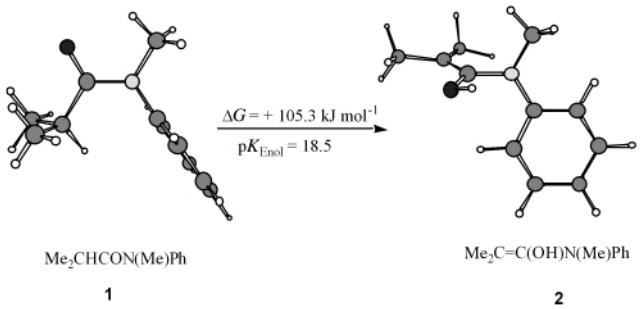

Fig. 1 Most stable conformational isomers for **1** and **2**.

† Electronic supplementary information (ESI) available: optimised structures of various conformers. See http://www.rsc.org/suppdata/cc/b0/b006216m/

for ditipylacetic acid[10] and the lower pK_{Enol} for acetamide than for AcOH.[4] The $t_{1/2}$ for the tautomerisation of diTip *N*,*N*-dimethylacetamide is *ca.* 20 min in 5:1 CD_3CN–THF-d_8 at 273 K.[13a]

Table 1 summarises the keto–enol isomerisation energies for the amide/enol pairs of the *N*-methyl amides of serine and alanine. Again, several conformations were found for each species (these are given in the ESI†) and the energy differences and the derived pK_{Enol} values in Table 1 are based on the most stable conformation of both species. For the two *N*-methylamides the pK_{Enol} values are *ca.* 1 unit lower than for the parent acetamide system but the 1,2-diaminoenols are still so unstable compared with the corresponding amide forms, that if a correlation between thermodynamic and kinetic stability exists in these cases, the isomerisation of peptides including serine and aspartic acid *via* the enol route is inferred to be very slow.[14]

Dissection of the overall effect of the C_β and nitrogen substituents to their individual effects on the amide and the enol is obtained by using the isodesmic reactions (1) and (2). All

reactions were found to be endothermic indicating that the interaction of the amino groups with either the carbonyl or the enol function stabilises the system and more so for the amide form. For the amino acid amides the amide forms (**4** and **5**) are more stabilised than acetamide by 9–14 kJ mol^{-1}, whereas the higher stabilisation of the enol forms (**7** and **8**) by *ca.* 17 kJ mol^{-1} result in lower pK_{Enol} values for the amino acid amides. The stabilisation of enol **2** is small, being only 9.1 kJ mol^{-1}, but the amide form **1** is less stabilised by 6.9 kJ mol^{-1} compared with acetamide and this destabilising interaction is responsible for the lower pK_{Enol} for **1**.

Numerical calculations were in part carried out at the Research Center for Computational Science, Okazaki, Japan. Z. R. is indebted to the Israel Science Foundation for support, to Professors A. J. Kresge, M. Goodman and R. Mechoulam for discussions and to Professor A. F. Hegarty for correspondence.

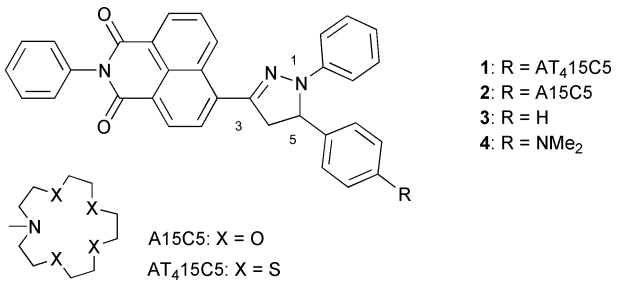
Fluorophore–spacer–receptor ionophores 1 and 2 show a strong cation-induced enhancement of the fluorescence at λ > 650 nm in the presence of Hg^{II} and Ag^{I} (1) or Pb^{II}, alkaline-earth and alkali metal ions (2).

Molecular signaling systems relying on drastic changes in fluorescence intensity and/or band position upon binding to an inorganic/organic substance have lately received much attention as photonic molecular devices.[1] As functionalized hosts for inorganic guests such as main group, heavy, and transition metal ions or anions, ionophores that consist of an ion-responsive receptor and a (potentially, *i.e.* in the 'switched on' state) highly emissive chromophore, separated by a short alkyl spacer thus preventing pronounced electronic interaction in the ground state, are of particular interest.[2] This molecular constitution allows to combine an electron-donating receptor with a reducable chromophore to invoke fast signaling processes such as intramolecular electron transfer (ET).[3] Among composite ET fluoroionophores, dyes containing a small and rigid spacer are especially advantageous in terms of minimally separated molecular subunits with efficient transduction capability. Recently, such probe molecules based on the Δ^2-pyrazoline chromophore were introduced, showing a cation-induced 'switching on' of the fluorescence upon binding to main group[4] and/or heavy metal ions.[4b] In these substituted 1,3,5-triaryl-Δ^2-pyrazolines, not only does the spacer-separated receptor at the 5-position acts as an electron donor but the main chromophore itself (including the ring fragment C(3)=N(2)–N(1)) consists of a donor (D: N(1) and 1-substituent) and an acceptor (A: C(3) = N(2) and 3-substituent) subunit, and thus the intramolecular ET reaction from the 5-donor does not quench a chromophore-localized state (as, for instance in donor–alkyl-substituted anthracenes or pyrenes)[5] but rather a highly emissive charge transfer (CT) excited state.[4b] This constitution harbors two important advantages for rational probe design: (i) rigidized D–A-fluorophores with allowed CT transtitions (*e.g.* the basic 1,3-diaryl-Δ^2-pyrazoline chromophore)[4b] usually show broad and largely Stokes-shifted absorption and emission bands often accompanied by high fluorescence quantum yields and (ii) the tuning of composite D–A-chromophores by combining specific D and A units is synthetically well feasible. Here, we extended this design concept to the red/near infra-red (NIR) region by the introduction of the strong *N*-phenyl-1,8-naphthalimide (PhNI) acceptor to the 3-position of the Δ^2-pyrazoline ring yielding **1**–**4**. **1** and **2** are equipped with cation-sensitive anilino crown units showing strongly different ion binding preferences and **3** and **4** act as model compounds.

The efficient separation of the electron donating 5-*p*-receptor unit and the main 1,3-diaryl-Δ^2-pyrazoline chromophore by the rigid spacer is suggested from the nearly identical positions of



the absorption and emission bands of **1**–**4** in acetonitrile, the solvent we used for the complexation studies (Table 1). The broad, structureless and largely Stokes-shifted absorption and emission bands underline the CT character of the optical transitions in the 1,3-chromophore. In accordance with results obtained for their 3-benzothiazol-2-yl-substituted analogues,[4b] both, the intensive low energy absorption band ($\varepsilon \approx 2 \times 10^4$ M^{-1} cm^{-1} for all the dyes) and the considerably high fluorescence quantum yield of the reference compound **3** reveal that allowed CT transitions determine the spectroscopic properties of the 3-PhNI-Δ^2-pyrazolines. When comparing the fluorescence quantum yield and lifetime data of **3** with those of **1**, **2** and **4**, the quenching electron transfer interaction (virtually no changes in spectral band position, see above) of a 5-*p*-anilino donor is evident. Since the radiative rate constants $k_f = \phi_f/\tau_f$ of **1**–**4** are very similar ($k_f \approx 0.9 \times 10^8$ s^{-1}), the rate constant of the ET quenching process in **1**, **2** and **4** can be calculated from

Table 1 Spectroscopic data of **1** and its Hg^{II} and Ag^{I} complexes, **2** and its Li^{I}, Na^{I}, K^{I}, Mg^{II}, Ca^{II}, Sr^{II}, Ba^{II} and Pb^{II} complexes, **3** and **4** in acetonitrile at room temperature[a]

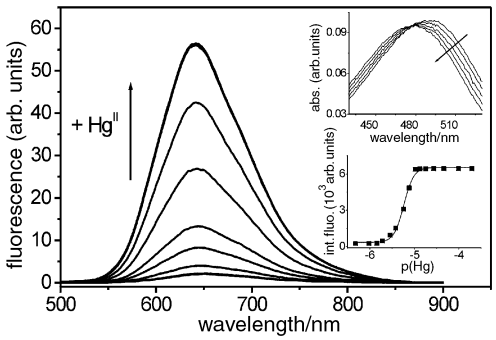

Fig. 1 Fluorescence titration spectra (λ_{exc} = 478 nm) of **1** (5×10^{-6} M) with $Hg(ClO_4)_2$ (concentration range: 5×10^{-7} to 2×10^{-3} M) in acetonitrile. Upper inset: selected absorption titration spectra (isosbestic point: 478 nm; arrow indicates the direction of change upon Hg^{II} addition). Lower inset: fit (——) of the integrated intensity (■) of the fluoroescence titration.

the measured fluorescence lifetime according to $k_{ET} = \tau_f^{(X)-1} - \tau_f^{(3)-1}$ with X = **1**, **2**, **4** by using that of **3** as a reference (Table 1). This yields k_{ET} of 12, 34 and 58 ns^{-1} for **1**, **2** and **4**, respectively. These rate constants are rather small and are thus not related to the solvent relaxation time (the longitudinal solvent relaxation time in acetonitrile was determined to 0.2 ps)[6] suggesting a nonadiabatic electron transfer process.

Upon cation addition to **1** and **2**, the changes in spectral band position are comparatively small (Table 1 and, as an example, the titration of **1** with $Hg(ClO_4)_2$ shown in Fig. 1) as is expected for an ET signaling mechanism. Accordingly, binding of a cation to the electron donating 5-*p*-receptor strongly alters its redox potential and weakens its donor strength thus decelerting the ET quenching process. As is evident from Table 1, the cation-induced changes in fluorescence quantum yield and lifetime are drastic and are directly related to the charge density of the metal ion, *i.e.* the inhibition of the ET reaction being stronger for Hg^{II} than for Ag^{I} (for **1**) and for alkaline-earth metal ions relative to alkali metal ions (for **2**). For the complexes with divalent Hg^{II}, Ca^{II} and Pb^{II}, all of them tightly binding to the fluorescent sensor molecules, even a complete 'switching off' of the ET process is manifested by rate constants of radiative and non-radiative deactivation which are nearly identical to those of the reference compound **3**, lacking a 5-*p*-anilino donor. In all the cases, the fit of the spectrofluorometric titration data[4b,7] yielded a 1 : 1 complex stoichiometry.

Besides the favorable fluorescence enhancement characteristics, the cation selectivity can easily be directed by tuning of the 5-*p*-receptor. Whereas **1**, containing four 'soft'[8] sulfur donor atoms in the 15-crown-5 receptor, only binds to the thiophilic heavy and transition metal ions Hg^{II} and Ag^{I} (for a detailed discussion of ion selectivities and preferences, see refs 4(*b*) and 9), **2** with a monoaza-tetraoxa-15-crown-5 unit shows changes in its spectroscopic properties in the presence of the 'hard'[8] group I and II metal ions as well as Pb^{II}. The power of the present design concept, especially for Hg^{II} (**1**) and Pb^{II} (**2**) commonly known as fluorescence quenchers[10] and for sensing applications in the red/NIR, is apparent.[11]

In summary, we have shown that upon combining intramolecular charge and electron transfer processes in a simple fluorophore–spacer–receptor ionophore with a small but rigid spacer, an efficient cation-triggered 'switching on' of the intramolecular charge transfer fluorescence can selectively be achieved even with advantageous emission features such as broad and largely Stokes shifted bands and considerably high fluorescence quantum yields in the red/NIR spectral region.

11 It is interesting that the corresponding substituted chalcone-type dyes (PhNI–CO–CH=CH–C_6H_4R with R = H, NMe_2 or crowns), which were obtained as intermediates within the Δ^2-pyrazoline synthesis (see ESI†), do not fluoresce ($\phi_f < 1 \times 10^{-5}$) and thus cannot be exploited for sensing purposes as, for instance their benzothiazole derivatives.[9] This is most probably due to the close neighborhood of the carbonyl and the PhNI group, since electron acceptors at the 4-position of the naphthalimide chromophore are known to quench its fluorescence.[13]

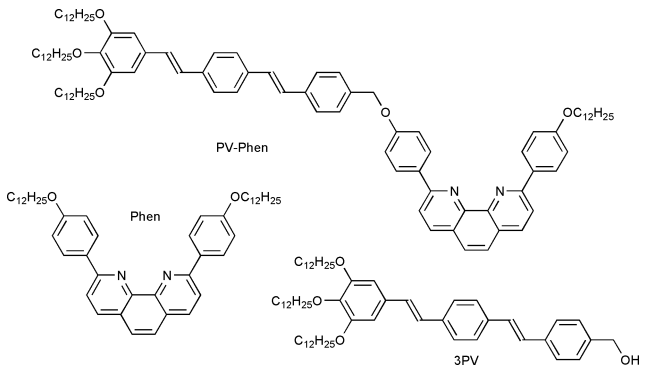
Received (in Cambridge, UK) 31st July 2000, Accepted 20th September 2000
First published as an Advance Article on the web 11th October 2000

In a two-component system combining an oligophenylenevinylene (OPV) group with a protonable phenanthroline unit, the direction of intercomponent photoinduced energy transfer can be tuned by proton input, thus allowing on/off switching of the luminescence of the OPV moiety.

A molecular switching device exists in two (or more) different states that can be reversibly interconverted and present different characteristic properties.[1–4] Typically, the switching work is carried out by photons, electrons, or external chemical species.[3] Of course it is crucial to be able to distinguish between the different states, and one of the most powerful tools is fluorescence spectroscopy.[2] For instance, a large variety of molecular recognition events taking place on molecular receptors has been revealed by switching or tuning the luminescence of nearby signaling moieties.[2,3,5]

Oligophenylenevinylenes (OPVs) are strongly fluorescent molecules widely used in materials science for the preparation of light emitting devices (LEDs), field-effect transistors (FETs) or photovoltaic cells.[6,7] Such compounds appear also to be attractive functional building blocks for the construction of new molecular and supramolecular photoactive devices. Here, we describe the preparation and the electronic properties in CH_2Cl_2 solution of the two-component array 3PV-Phen, combining an OPV unit with a protonable phenanthroline group. The related compounds 3PV[8] and Phen have been used as reference compounds for the photophysical studies.



Interestingly, 3PV-Phen can act as a proton triggered molecular switch. Effectively, the intense fluorescence of the 3PV-type moiety can be quenched (*off* state) by protonation of the phenanthroline unit upon addition of acid, whereas the starting emission can be restored (*on* state) by adding a base. The functioning of the 3PV-Phen switch is schematically represented in Fig. 1.

The synthesis of 3PV-Phen is depicted in Scheme 1. Treatment of *p*-bromododecyloxyphenyl with Bu^{t}Li in THF at −78 °C followed by quenching with 1,10-phenanthroline, hydrolysis and oxidation with MnO_2 gave **1** (85% yield). Reaction of **1** with *p*-lithio[(*tert*-butyldimethylsilyl)oxy]-phenyl[9] followed by hydrolysis and oxidation (MnO_2) yielded **2**

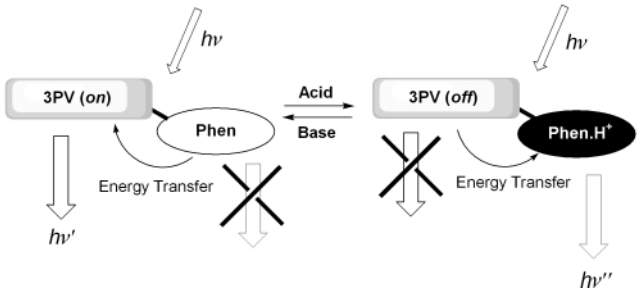


Fig. 1 Schematic representation showing the functioning of the 3PV-Phen molecular switch.

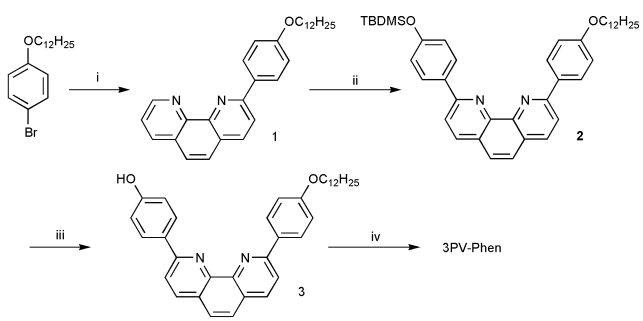
which after deprotection (TBAF) gave **3** in an overall yield of 33%. The reaction of **3** with 3PV under Mitsunobu conditions afforded 3PV-Phen in 71% yield. All of the spectroscopic studies and elemental analysis results were consistent with the proposed molecular structures.

The electronic absorption and emission properties of the model compounds 3PV and Phen [Fig. 2(a)] are very similar to those of previously investigated OPVs[7] and substituted phenanthrolines.[10] Both molecules are strongly fluorescent in the VIS spectral region; 3PV exhibits a band with λ_{max} = 460 nm, τ = 1.3 ns and Φ_{fl} = 0.77, whereas Phen displays λ_{max} = 398 nm, τ = 2.1 ns and Φ_{fl} = 0.35.†

Addition of increasing amounts of trifluoroacetic acid (TFA) to a 1.5×10^{-5} M solution of Phen causes dramatic changes in the absorption spectrum, that are leveled off at *ca.* 10 equivalents of acid added. Isosbestic points are maintained at 296, 314 and 356 nm indicating that a single chemical process occurs, *i.e.* protonation of the phenanthroline;[10] interestingly, the initially transparent solution becomes yellow at the end of the titration. In parallel with the changes in the absorption spectra, remarkable variation in the fluorescence properties are recorded. The intense luminescence band of Phen progressively disappears while a new band characteristic of $PhenH^+$ grows at



Scheme 1 *Reagents and conditions*: i, Bu^{t}Li, THF, −78 °C, 1 h, then 1,10-phenanthroline, −78 to 0 °C, 3 h, then H_2O, then MnO_2, room temp., 1 h; ii, *p*-lithio[(*tert*-butyldimethylsilyl)oxy]phenyl, THF, 0 °C, 4 h, then H_2O, then MnO_2, room temp., 1 h; iii, TBAF, THF, 0 °C, 2 h; iv, 3PV, DEAD, PPh_3, THF, reflux, 72 h.

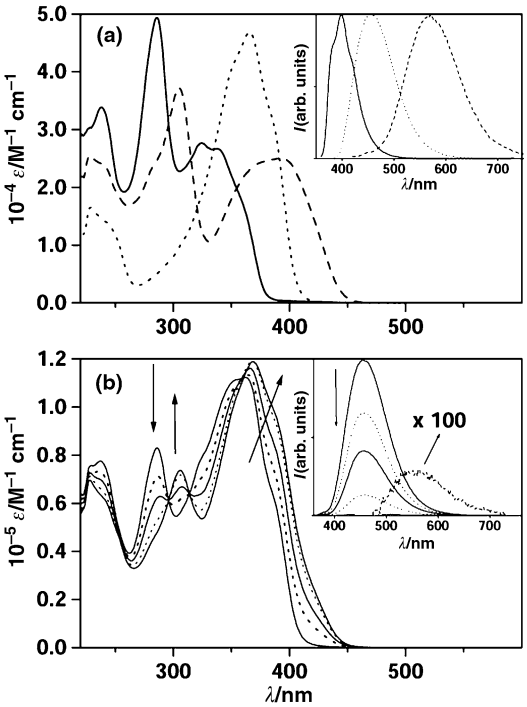


Fig. 2 (a) Absorption and (inset) fluorescence spectra of 3PV (·····), Phen (——), and $PhenH^+$ (– – –). (b) Absorption and (inset) fluorescence (λ_{exc} = 314 nm, isosbestic point) spectra of a 1.5×10^{-5} M CH_2Cl_2 solution of 3PV-Phen containing 0, 1, 2, 4 or 20 equivalents of trifluoroacetic acid. The weak red-shifted band is obtained for the solution containing 20 equiv., after subtraction of the residual 3PV luminescence (see text).

570 nm, with τ = 12.2 ns and Φ_{fl} = 0.048; the luminescence color switches from purple (Phen) to yellow ($PhenH^+$). Addition of an organic base [diazabicyclo[4.3.0]non-5-ene (DBN)] restores the initial absorption and luminescence properties. Importantly, no changes of such properties are observed upon addition of a large excess of TFA or DBN to 3PV solutions.

The absorption spectrum of 3PV-Phen matches the sum of the spectra of the reference compounds within ±10% error, showing one diagnostic band for each component unit with maxima at 286 (Phen) and 360 nm (3PV). Only the typical fluorescence band of the 3PV fragment is observed (λ_{max} = 460 nm, τ = 1.3 ns, Φ_{fl} = 0.70); the excitation spectrum (λ_{em} = 460 nm) matches the absorption profile, indicating that excitation of the Phen moiety is followed by quantitative energy transfer to the 3PV unit. One can thus conclude that, in 3PV-Phen, only the OPV luminescence is *on* since a photoinduced quenching process featuring a Phen → 3PV direction is active (Fig. 1).

Addition of increasing amounts of (TFA) to a 1.5×10^{-5} M solution of 3PV-Phen causes dramatic changes in the absorption spectrum [Fig. 2(b)]. A clear analogy with the protonation reaction of Phen is found: the same amount of acid is required to complete the reaction, isosbestic points are located at 296, 314 and 359 nm. Importantly, the final spectrum matches the sum of the spectra of 3PV and Phen.H^+ within ±10% error, and the reaction is reversible upon addition of DBN. These findings suggest that the 3PV-$PhenH^+$ species is formed.

The addition of acid also leads to dramatic changes in the emission properties (λ_{exc} = 359 nm, isosbestic point): the characteristic blue 3PV luminescence is progressively suppressed and a much weaker green-yellow emission (λ_{max} = 556 nm, τ = 12.7 ns‡) is detected, attributable to the $PhenH^+$ moiety (see above). The luminescence quenching of 3PV, observed also in a rigid matrix at 77 K, is attributable to energy transfer to the $PhenH^+$ moiety. The energy transfer efficiency is difficult to estimate, since some residual 3PV fluorescence (< 0.5%, relative to the initial value) is present, even when a large excess of acid is added. Such residual emission, likely arising from unprotonated 3PV-Phen in the acid–base equilibrium, overlaps the much weaker $PhenH^+$ emission, thus making difficult clean excitation spectroscopy. In any case one can conclude that, in an acid environment, the OPV luminescence of 3PV-Phen is *off* due to an intercomponent quenching process displaying a 3PV → Phen direction [Fig. 1].

In terms of electronic energy levels our bipartite system has been designed in order to achieve the following: in one component (3PV) the energy of the fluorescent level (E_1) is insensitive to protons; by contrast, in the other component (Phen), a proton input tunes the fluorescent levels between two energy values (E_2 and E_3). The key feature is that the energy of E_1 is intermediate between that of E_2 and E_3, thus enabling an energy transfer in the desired direction *via* the chemical (proton) input. The energy scaling ($E_2 > E_1 > E_3$) is reflected in the spectral position of the corresponding fluorescence bands [Fig. 2(a), inset].

In conclusion, we have shown a simple way to reversibly switch *on* and *off* the widely exploited fluorescence of OPVs. Also, it is worth pointing out that this is one of the rare cases of multicomponent systems where the direction of the photo-induced energy transfer can be controlled.[11–12] To the best of our knowledge, this is the first example where such control can be reversibly accomplished by chemical inputs.

This work was supported by the Italian CNR and the French CNRS. We thank L. Oswald for technical help and Professor J.-F. Nicoud for his interest and support.

Notes and references

† Fluorescence spectra, lifetimes (time resolution 0.5 ns), and quantum yields were obtained as described in detail in ref. 7; experimental uncertainties are ±2 nm, ±8% and ±20%, respectively. For emission quantum yields anthracene in cyclohexane (Φ = 0.34) and quinine sulfate in 0.05 M H_2SO_4 (Φ = 0.546) were used as standards.

‡ In this case the decay is biexponential and 12.6 ns refers to the longest component. A shorter component (1.3 ns) accounts for the residual 3PV fluorescence (see text).

Hydrothermal crystal engineering using hard and soft acids and bases: synthesis and X-ray crystal structures of the metal hydroxide-based phases $M_3M'_2(OH)_2[NC_5H_3(CO_2)_2$-2,4$]_4(H_2O)_4$ (M = Co, Ni, Zn; M′ = Pd, Pt)†

Solvothermal reaction of $K_2M'Cl_4$ (M′ = Pd, Pt) with pyridine dicarboxylate and excess base produces isostructural coordination solids in which 'complex ligands' containing palladium or platinum coordinate to metal hydroxide chains.

The use of solvothermal techniques to prepare hybrid organic–inorganic materials inaccessible by other means is a rapidly expanding area.[1,2] One current challenge is to prepare materials of increasing compositional complexity in which the individual components confer different physical properties or have different structural influences. This goal is exemplified by hydrolytic phases containing oxide or hydroxide moieties in addition to metal ions and ligands.[2] We are particularly interested in this area as judicious choice of ligands can lead to important target materials such as porous solids and low-dimensional magnets. The size of the organic ligand plays an important role in our approach to both of these classes of material as it controls both the size of the pores and the separation between low-dimensional magnetic structures. A logical choice of ligand type to fulfil the role of large 'spacer' would be polycyclic aromatic carboxylates such as 4,4′-biphenyl dicarboxylic acid or 3,4,9,10-perylene tetracarboxylic acid, however, these have proved unsuccessful in our hands,[3] possibly owing to their solubility characteristics. Subsequently we have investigated a strategy based on 'metal complex ligands' which we report here.

A multi-component ligand equivalent in size to those suggested above can be constructed by relying on the principle that hard and soft bases will coordinate to like acids.[4] By coordinating ligands with both hard and soft donor sites to a soft metal we can generate a large but soluble anionic ligand which is terminated by hard (carboxylate) donor groups and as such is analogous to the ligands we have already found to be successful in simpler reactions. Pyridine-2,*x*-dicarboxylates are known to be stable to solvothermal conditions[2] and also to form stable complexes with soft metals *via* N-coordination.[5] The existence of three isomers also presents the opportunity to study the effect of substitution pattern on product structure. This is actually a very important variable with the 2,4 isomer yielding much more straightforward chemistry hence it is this ligand on which we concentrate here.

The method we have previously developed for preparing hydrolytic phases of the 3d transition metals involves the reaction of a carboxylate salt with $M(OH)_2$ prepared *in situ*, a variation of this technique is used here. Three aqueous solutions are first prepared containing (i) K_2PtCl_4 (0.1 mmol) in H_2O (2.5 ml); (ii) pyridine-2,4-dicarboxylic acid (0.2 mmol) and 1 M KOH (0.7 mmol) in H_2O (5 ml); (iii) MCl_2 hydrate (0.2 mmol) in H_2O (2.5 ml). Solutions (i) and (ii) are first mixed, followed by (iii) which results in formation of $M(OH)_2$. Hydroxide formation is evident for cobalt-containing solutions from the slight blue colour produced which we have previously observed to be indicative of the onset of Co(II) hydrolysis.[3] This gives a Pt:metal:ligand:base ratio of 1:2:2:7. The mixture was placed in a 23 cm^3 Teflon-lined autoclave and heated at 200 °C for 15 h, followed by slow cooling to room temperature over a period of 8 h. The solid was filtered off and purified by brief ultrasonic treatment of an aqueous slurry followed by decanting. The material was then filtered off, washed with water and air dried. The palladium-containing materials are made in analogous fashion from K_2PdCl_4 on a 0.12 mmol scale with a Pd:metal:ligand:base ratio of 1:2:2:6.

These methods produce $M_3M'_2(OH)_2[NC_5H_3(CO_2)_2$-2,4$]_4(H_2O)_4$ as crystalline solids in good yields; **1a**, Co/Pd, pale pink (62 mg, 89%); **1b**, Co/Pt, orange–pink (52 mg, 78%); **2a**, Ni/Pd, pale green (52 mg, 75%); **2b**, Ni/Pt, green (44 mg, 66%); **3a**, Zn/Pd, yellow (57 mg, 82%); **3b**, Zn/Pt, yellow (49 mg, 72%). Satisfactory microanalytical data were obtained for all compounds (ESI†).

IR spectra for the six compounds are essentially superimposable showing only the slight shifts in frequency expected on isomorphous substitution (ESI†). The band which is indicative of the formation of these materials is the sharp, medium intensity O–H stretch due to the bridging hydroxide ligand: ν_{max}(KBr) = 3598, 3604, 3606, cm^{-1} for Co, Ni and Zn, respectively. The position of the band is insensitive to the presence of Pd or Pt.

The X-ray crystal structures‡ of a representative sample of the compounds (**1a** and **3a**) along with the unit cell dimensions for **1b**, **2a**, **2b** and **3b**, were determined showing that the materials are indeed isostructural (ESI†). The secondary building unit (SBU) is the $M'M_2L_2$ fragment (Fig. 1) which has two environments for the hard (octahedral) metal. The SBUs are held together by two different types of linkage, the overall effect of which is to produce layers lying parallel to [0 1 −1]. The first type of linkage consists of infinite chains with a –MLM′LMLM′– repeat unit running parallel to the *bc* bisector. The second type is a series of metal hydroxide strips containing chains of edge- and vertex-sharing $M_3(\mu_3$-OH) triangles which run parallel to the *a* axis (Fig. 2). Each individual layer has metal hydroxide 'ribs' which are linked to their nearest neighbours by a row of LM′L moieties. The ligands form the upper and lower faces of the layer (Fig. 3) with an average intra-

layer distance of 3.42(1) Å. There is a second π-stacking interaction between the sheets with an average separation of 3.56(1) Å. The π stacks and metal hydroxide strips run along orthogonal axes, this leads to the formation of a tightly packed three-dimensional structure. We believe that the stacking interaction hampers the formation of pores within these materials. It is also noteworthy that when porous materials have been prepared[3] the ligands bridge in the plane of the metal triangles, rather than above and below as seen here. All bond lengths and angles are normal with the metal–ligand distances showing small deviations from ideal square and octahedral geometry (ESI†). For example the palladium square planar angles range from 82.5(2) to 100.1(2)°. The two octahedral zinc geometries show a greater distortion for the metal that is not on an inversion centre, Zn(1). The angles range from 82.2(2) to 96.9(2)° and 172.1(2) to 176.8(2)° for Zn(1) in comparison with 86.6(1) to 93.2(1)° and exactly 180° for Zn(2). The formation of the particularly stable five-membered chelate ring for the soft metal helps to stabilise it against decomposition to intractable material, which we believe to be oxide, at the relatively high pH required for hydrolysis of the divalent 3d metal ions.

This material can be synthesised using a range of metal : metal′ : ligand : base ratios provided that the pH is kept relatively high. The optimum reaction conditions found for the platinum compounds require a ratio of 1 : 2 : 2 : 7 resulting in a pH in the range 7.7–8.8 depending on the metal. The palladium compounds can be obtained in pure form from a ratio of 1:2:2:6 which gives pH values in the range 6.7–7.8. In general the production of the platinum compounds requires more base than is needed for the palladium-containing materials. Hydrolysis of the metal salts occurs prior to heating and therefore the pH values measured for the reaction mixtures are lower than expected considering the excess base used. Accurate control of hydroxide content is essential as there is a very narrow range in which these materials may be formed. There is little overlap between the conditions required for the formation of M(OH)-containing materials and those required for stabilisation of the soft metal complex.

The reactions are also sensitive to temperature and duration. To obtain an optimum yield of pure product the reactions should be performed at temperatures in the range 180–220 °C for 15 h. Lower temperatures result in contamination by other products whilst higher temperatures result in decomposition. We have also investigated the chemistry of isomeric ligands under similar conditions. Reactions with pyridine-2,3-dicarboxylate yield only decomposition products whilst pyridine-2,5-dicarboxylate gives a range of highly complex products with structures sensitive to both the hard and soft metal.

We have shown that hard and soft donor sites on a metal can preferentially bind hard and soft metal ions from a binary mixture. This provides another tool in our armoury for engineering materials with specific properties such as magnetism and porosity.

We wish to thank Johnson-Matthey for the generous loan of precious metal salts and the University of East Anglia for funding.

Received (in Cambridge, UK) 12th July 2000, Accepted 9th August 2000
First published as an Advance Article on the web 11th October 2000

We describe the synthesis, characterization and properties of the first optically-active 1,3-unsymmetrically disubstituted ferrocene derivative which is to exhibit smectic C* and smectic A* phases.

Symmetry breaking operations and chirality have held centre stage in the fundamental investigations and applications of liquid crystals.[1,2] Furthermore, recent studies on mesogens with banana-shaped molecular structures have shown that chiral induction in self-organizing systems is possible even though the materials are themselves achiral.[3,4] The search for new chiral effects in mesomorphic systems prompted us to synthesize unsymmetrically 1,3-disubstituted ferrocene-containing liquid crystals,[5] where the different substituents at the 1- and 3-positions generate structures with planar chirality (Fig. 1). A representative example is illustrated by compound **1** (see Scheme 1); the two substituents are differentiated by the length of the alkyl chains and the orientation of the outer ester groups. Homologues of this material were prepared in racemic form from (±)-**2**[5] (see Scheme 1). Over the entire range of the compounds studied, smectic C (SmC) and smectic A (SmA) phases were observed, and in some cases an additional nematic phase was detected.

The presence of the SmC phase in this family of compounds provided a unique challenge to make the materials optically active (SmC*) and thereby ferroelectric. Of course symmetrically 1,3-disubstituted ferrocene derivatives have the potential to exhibit ferro- or antiferro-electricity if the packing constraints of the molecules within the layers induce a restricted rotation of the molecules about their long axes. Within this packing constraint, the V-shaped molecules will pack together to give a non-symmetric arrangement thereby leading to the induction of non-linear properties.

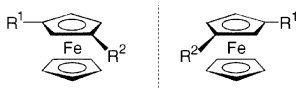

Fig. 1 Planar chirality in unsymmetrically 1,3-disubstituted Fc derivatives. Planar chirality: chirality resulting from the arrangement of out-of-plane groups with respect to a reference plane, called the 'chiral plane'.[6]

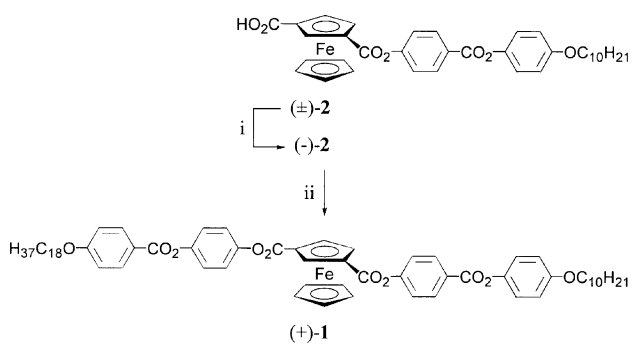


Scheme 1 *Reagents and conditions*: i, (+)-phenylethylamine [(+)-PEA], CH_2Cl_2; ii, (a) oxalyl chloride, pyridine, CH_2Cl_2, reflux, 3 h; (b) 4-hydroxyphenyl 4-(octadecyloxy)benzoate,[10] triethylamine, CH_2Cl_2, reflux, 3 h.

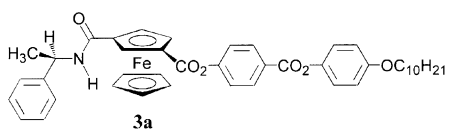
Ferroelectric liquid crystals are of considerable interest in switchable, half-wave plate, bistable light-valves. For ferrocenyl liquid crystals, SmC* phases have been reported only for two mono-substituted derivatives.[7,8] Chirality was introduced into the peripheral side-chain by means of asymmetric carbon atoms, but for the two materials no ferroelectric behavior was described.

In addition to the investigation of the dependency of ferroelectricity on planar chirality, this study allowed us to probe the influence of the chiral unit, which is embedded in the central region of the molecular structure, on the self-organization process and mesophase formation. In metallomesogens, planar chirality was elegantly exploited by Malthête and coworkers who reported optically-active butadiene–tricarbonyliron liquid crystal complexes.[9] The spontaneous polarization of one of the complexes was determined, and a value of 32 nC cm^{-2} was obtained (response time: 9 ms).[9b]

We report, herein, the synthesis, mesomorphic behavior and ferroelectric properties of the liquid-crystalline Fc derivative (+)-**1** (Scheme 1). The latter structure was selected because the corresponding racemic analogue gave the broadest SmC range among the family of homologues studied.[5]

The preparation of (+)-**1** is shown in Scheme 1. Optical resolution of acid (±)-**2** with (+)-phenylethylamine [(+)-PEA] gave (−)-**2**.† Treatment of (−)-**2** with oxalyl chloride gave the corresponding acid chloride derivative, which was condensed with 4-hydroxyphenyl 4-(octadecyloxy)benzoate[10] to furnish (+)-**1**.‡

Derivatization of the acid (−)-**2** with (+)-PEA gave the amide **3a**,§ which served for the determination of the enantiomeric excess (ee) of (−)-**2** by ^{1}H NMR and HPLC techniques. We assumed that the reactions used to prepare **3a** and (+)-**1** did not alter the optical purity of (−)-**2**. Therefore, the determination of the diastereomeric excess (de) of **3a** is a measure of the ee of (−)-**2** and, consequently, of (+)-**1**. The 1:1 diastereomeric mixture of **3a**:**3b** synthesized from (±)-**2** and (+)-PEA was used to fix the analytical conditions. The ^{1}H NMR and HPLC characteristics of diastereoisomer **3b** [from (+)-**2** and (+)-PEA] were deduced by comparing the data of the 1:1 diastereomeric mixture with that of **3a**.



3a

In the ^{1}H NMR spectrum of the 1:1 diastereomeric mixture, each diastereoisomer gave well separated signals for the five protons of the unsubstituted cyclopentadienyl (Cp) ring (**3a**:

4.28 ppm; **3b**: 4.33 ppm) and the two Cp protons *ortho* to the amide function (**3a**: 5.70 and 5.19 ppm; **3b**: 5.65 and 5.24 ppm). For these signals, the five Cp protons gave two sharp singlets with baseline resolution, and appeared to be suitable for the determination of the de of **3a**. HPLC analysis (column Nucleosil 120 RP-C_{18} (250 × 4 mm) equipped with a precolumn Nucleosil 120 RP—C_{18} (30 × 4 mm); solvent, acetonitrile–water (80:20); elution rate, 1.5 ml min^{-1}) of the 1:1 diastereomeric mixture furnished two peaks (**3a**: 40.2 min; **3b**: 38.0 min) with almost baseline resolution. Both techniques led to reliable and reproducible results.

Optical resolution of (±)-**2** by (+)-PEA proved to be efficient: ^{1}H NMR and HPLC methods gave a de of 98% for **3a**, leading to an ee value of 98% for (+)-**1**.

The absolute configuration of the Fc in (+)-**1**, (−)-**2** and **3a** is shown arbitrarily. So far, crystallization of the salt (+)-PEA/(−)-**2** and amide **3a** failed to give crystals suitable for X-ray analysis.

The liquid-crystalline properties were investigated by differential scanning calorimetry (DSC, 10 °C min^{-1}, under N_2) and polarized optical microscopy.¶ Ferrocene (+)-**1** gave enantiotropic SmC* and SmA* phases (Cr → SmC*: 170 °C; SmC* → SmA*: 198 °C; SmA* → I: 202 °C; onset point, first heating run). The SmC* to SmA* phase transition was not detected by DSC (second order transition). No decomposition or racemization was observed for (+)-**1**. Similar transition temperatures were obtained for racemic (±)-**1** (Cr → SmC: 166 °C; SmC → SmA: 198 °C; SmA → I: 200 °C).[5] No mesomorphic behavior was observed for the acid (−)-**2** and amide **3a**.

Fig. 2 shows the value of the spontaneous polarization as a function of temperature.‖ At the Curie point, the spontaneous polarization increased rapidly to a value of *ca*. 1.36 nC cm^{-2}, at which point it increased almost linearly as the temperature was lowered. At a temperature of 30 °C below the Curie point, a value of only 2.8 nC cm^{-2} was reached (response time: *ca*. 200 ms).

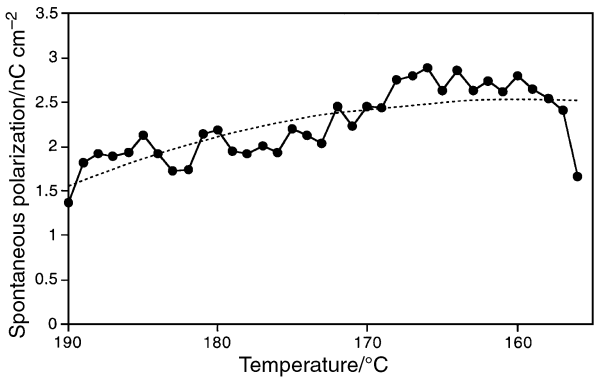


Fig. 2 The spontaneous polarization measured as a function of temperature from the Curie point for (+)-**1**.

An appreciable scatter in the data was observed because of the weak ferroelectric properties. The results obtained indicate firstly that planar chirality can induce ferroelectric properties, and secondly the induced effects are weak, revealing a poor coupling between the chirality associated with the Fc moiety at the centre of the molecular structure, the strongly polar functional groups in the material, and the liquid-crystalline environment. The weak ferroelectric properties are probably linked to the fact that the two arms attached to the Fc unit are not greatly different in length or polarity.

Notes and references

† *Optical resolution* of (±)-**2**[5] (1.45 g, 2.31 mmol) in dry CH_2Cl_2 (130 ml), was added a solution of (+)-PEA (140 mg, 1.16 mmol) in dry CH_2Cl_2 (15 ml). The solution was allowed to stand overnight at room temperature. The salt was recovered by filtration, dried (743 mg), and crystallized in a 1:1 mixture of dry CH_2Cl_2–acetone (75 ml); yield: 554 mg. A mixture of the salt (554 mg), CH_2Cl_2 (40 ml) and 5 M HCl (40 ml) was vigorously shaken and the layers were separated. The organic layer was washed (water), dried ($MgSO_4$), and evaporated to dryness. Crystallization (CH_2Cl_2–hexane) of the solid residue gave (−)-**2** (327 mg, 45% with respect to the desired enantiomer) of ee = 98%. Mp 170 °C. $[\alpha]_D$ −18 (*c* 0.45, CH_2Cl_2). δ_H(200 MHz, acetone-d_6) 8.27 (d, 2 H, arom.), 7.52 (d, 2 H, arom.), 7.22 (d, 2 H, arom.), 7.01 (d, 2 H, arom.), 5.52 (t, 1 H, Cp), 5.19 (dd, 1 H, Cp), 5.14 (dd, 1 H, Cp), 4.44 (s, 5 H, Cp), 4.03 (t, 2 H, OCH_2), 1.80 (m, 2 H, OCH_2CH_2), 1.60–1.20 [m, 14 H, $O(CH_2)_2(CH_2)_7$], 0.89 (t, 3 H, CH_3). Anal. Calc. for $C_{35}H_{38}O_7Fe$ (626.53): C, 67.10; H, 6.11. Found: C, 67.08; H, 6.27%.

‡ *Synthesis* of (+)-**1**: *first step*: a mixture of (−)-**2** (250 mg, 0.441 mmol), oxalyl chloride (670 mg, 5.29 mmol), pyridine (5 drops) and dry CH_2Cl_2 (15 ml) was heated under reflux for 3 h, and evaporated to dryness. The solid residue was extracted with hot light petroleum (bp 60–90 °C) until the extracts remained colorless. Evaporation of the solvent gave the acid chloride derivative (273 mg, 96%), which was used in the next step without further purification. δ_H(400 MHz, $CDCl_3$) 8.29 (d, 2 H, arom.), 7.33 (d, 2 H, arom.), 7.13 (d, 2 H, arom.), 6.94 (d, 2 H, arom.), 5.74 (t, 1 H, Cp), 5.34 (dd, 1 H, Cp), 5.21 (dd, 1 H, Cp), 4.50 (s, 5 H, Cp), 3.97 (t, 2 H, OCH_2), 1.79 (m, 2 H, OCH_2CH_2), 1.60–1.20 [m, 14 H, $O(CH_2)_2(CH_2)_7$], 0.89 (t, 3 H, CH_3). *Second step*: a solution of the above acid chloride derivative (250 mg, 0.39 mmol), 4-hydroxyphenyl 4-(octadecyloxy)benzoate[10] (188 mg, 0.39 mmol), triethylamine (40 mg, 0.39 mmol) in dry CH_2Cl_2 (15 ml) was heated under reflux for 3 h, cooled to room temperature, and evaporated to dryness. Purification of the solid residue twice by column chromatography (CC) [first CC: silica gel, CH_2Cl_2–AcOEt (50:1); second CC: silica gel, CH_2Cl_2–AcOEt (100:1)], and crystallization (CH_2Cl_2–EtOH) gave (+)-**1** (232 mg, 54%) of ee = 98%. $[\alpha]_D$ +3 (*c* 0.42, CH_2Cl_2). δ_H(200 MHz, $CDCl_3$) 8.29 (d, 2 H, arom.), 8.15 (d, 2 H, arom.), 7.35 (d, 2 H, arom.), 7.27 (d, 4 H, arom.), 7.12 (d, 2 H, arom.), 6.98 (d, 2 H, arom.), 6.94 (d, 2 H, arom.), 5.79 (t, 1 H, Cp), 5.27 (br s, 2 H, Cp), 4.47 (s, 5 H, Cp), 4.06 (t, 2 H, OCH_2), 3.97 (t, 2 H, OCH_2), 1.80 (m, 4 H, OCH_2CH_2), 1.60–1.20 (m, 44 H, aliph.), 0.89 (2 × t, 6 H, CH_3). Anal. Calc. for $C_{66}H_{82}O_{10}Fe$ (1091.21): C, 72.65; H, 7.57. Found: C, 72.79; H, 7.77%.

§ **3a**: prepared analogously to the synthesis of (+)-**1**, from (−)-**2** (3.00 mg) and (+)-PEA. Purification by column chromatography [silica gel, CH_2Cl_2–AcOEt (98:2)] gave the desired product of de = 98%. δ_H(200 MHz, acetone-d_6) 8.26 (d, 2 H, arom.), 7.74 (d, 1 H, NH), 7.56–7.27 (m, 5 H, arom.), 7.48 (d, 2 H, arom.), 7.21 (d, 2 H, arom.), 7.01 (d, 2 H, arom.), 5.70 (t, 1 H, Cp), 5.28 (qut., 1 H, $CHCH_3$), 5.19 (dd, 1 H, Cp), 5.10 (dd, 1 H, Cp), 4.28 (s, 5 H, Cp), 4.03 (t, 2 H, OCH_2), 1.84-1.73 (m, 2 H, OCH_2CH_2), 1.57 (d, 3 H, $CHCH_3$), 1.55–1.25 [m, 14 H, $O(CH_2)_3(CH_2)_7$], 0.89 (t, 3 H, CH_3). Anal. Calc. for $C_{43}H_{47}NO_6Fe$ (729.69): C, 70.78; H, 6.49, N, 1.92. Found: C, 70.60; H, 6.61, N, 1.90%.

¶ For instrumentation, see: B. Dardel, R. Deschenaux, M. Even and E. Serrano, *Macromolecules*, 1999, **32**, 5193.

‖ Electro-optic studies on the ferroelectric properties were carried out using homogeneously aligned cells (Linkam) which were constructed from ITO coated glass, treated with antiparallel-buffed polyimide (PI) coated layers so as to give sites for planar, homogeneous growth of the liquid-crystalline state. The cell gap (*ca*. 5 μm) maintained by glass spacers was verified by UV–VIS interferometry. The effective electrode areas of the cells used were 0.9 cm^2. The cells were filled by capillary action at atmospheric pressure with (+)-**1** in the isotropic phase. Good alignment was achieved by cooling slowly (< 0.1 °C min^{-1}) from the isotropic liquid into the liquid-crystalline state. The spontaneous polarization was determined using the triangular wave method.

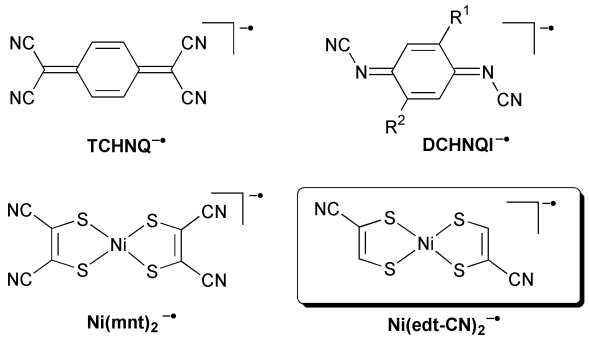
First published as an Advance Article on the web 12th October 2000

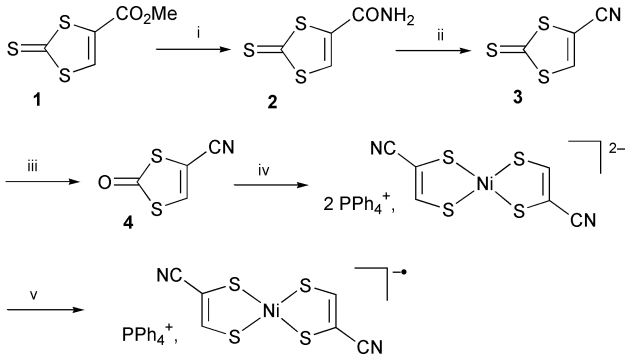
The preparation, X-ray crystal structures and electrochemical properties of bis(2-cyano-1,2-ethanedithiolate)-nickelate $[Ni(edt\text{-}CN)_2]^{2-/-\cdot}$ are described for both oxidation states together with the singlet–triplet behaviour of the PPh_4^+ salt of the paramagnetic $[Ni(edt\text{–}CN)_2]^{-\cdot}$ complex.

The construction of conducting or magnetic solids from the assembling of transition metal centers and organonitrile anion radical molecules[1] such as $TCNE^{-\cdot}$, $DCNQI^{-\cdot}$ or $TCNQ^{-\cdot}$ has



revealed extraordinary materials such as the metallic $Cu(DCNQI)_2$,[2] the electrically bistable[3] Cu(TCNQ) or a bulk ferromagnet from V with TCNE (TCNE = tetracyanoethylene).[4] By comparison and most surprisingly, the parallel coordination chemistry of the corresponding nickel dithiolene complexes with the maleonitriledithiolate ligand (mnt^{2-}) is virtually untouched and only a few salts of the diamagnetic $Ni(mnt)_2^{2-}$ have been reported with $Ag(PPh_3)_2^+$ and CuI.[5,6] The crystalline salts derived from DCNQI anions incorporating only two nitrile groups as well as the rich chemistry of the mnt^{2-} complexes[7] prompted us to investigate the numerous possibilities that would be offered by the unknown corresponding nickel dithiolene complex bearing only two cyano groups, *viz.* bis(2-cyano-1,2-ethanedithiolate)nickelate $[Ni(edt\text{-}CN)_2]^{n-}$ (n = 1 or 2). We describe here the synthesis of this novel complex system together with its electrochemical properties and report and analyse the X-ray crystal structures of the PPh_4^+ salts of both the diamagnetic $[Ni(edt\text{-}CN)_2]^{2-}$ dianion and the paramagnetic radical anion $[Ni(edt\text{-}CN)_2]^{-\cdot}$. This complex offers extensive possibilities for the elaboration of promising materials with conducting or magnetic properties by varying the nature of the counter cation, closed-shell inorganic (Na^+, Cu^+, Ag^+ or NH_4^+) or organic (R_4N^+, PyH^+, ...) cations as well as open shell organic ($TTF^{+\cdot}$, $BEDT\text{-}TTF^{+\cdot}$) or organometallic ($Cp^*{}_2Fe^{+\cdot}$) cations.

The dithiocarbonate **4**† precursor of the dithiolene ligand was prepared by a novel route (Scheme 1) which avoids the use of cyanoacetylene[8] in the reported preparation of **3** or that of activated Zn complexes in the reported preparation of **4**.[9] The easily available ester **1**[10] was successively converted into the corresponding amide **2** with NH_3 in MeOH in 72% yield, into the nitrile **3** by $POCl_3$ dehydration[11] in 75% yield before oxymercuration to the dithiocarbonate **4** in 84% yield. Treatment of **4** with 2 equiv. of MeONa followed by addition of 0.5 equiv. $NiCl_2{\cdot}6H_2O$ and PPh_4Cl afforded the air-stable dianionic



Scheme 1 *Reagents and conditions*: i, NH_3/MeOH; ii, 1 equiv. $POCl_3$, tetramethylene sulfone, 100 °C, 7 h; iii, $Hg(OAc)_2$, $CHCl_3$–AcOH, 2 h; iv, 2 equiv. MeONa, MeOH, 0.5 $NiCl_2{\cdot}6H_2O$, PPh_4Cl/H_2O; v, 0.5 I_2.

diamagnetic $[PPh_4^+]_2[Ni(edt\text{-}CN)_2{}^{2-}]$ salt. The corresponding one-electron oxidation product, $[PPh_4^+][Ni(edt\text{-}CN)_2{}^{-\cdot}]$, was obtained by iodine oxidation and recrystallisation from methanol. Cyclic voltammetry of the dianionic $Ni(edt\text{-}CN)_2{}^{2-}$ salt (Fig. 1) shows that it oxidises reversibly to the monoanionic $Ni(edt\text{-}CN)_2{}^{-\cdot}$ at −0.31 V *vs.* SCE while an irreversible process is observed at +0.65 V, a behaviour also observed for $Ni(mnt)_2{}^{n-}$ (0.226 V for $Ni(mnt)_2{}^{2-/-}$ with an ill-defined oxidation wave around 1 V)[12] but with a cathodic shift attributable to the presence of only two cyano groups. Single crystal X-ray structures‡ of both salts show that the nickel complexes adopt the same square-planar structure in the two different oxidation states (Fig. 2) with a *trans* orientation of the two cyano groups. It is likely that both *cis* and *trans* orientations are in equilibrium in solution while the most symmetrical *trans* isomer exhibits a lower solubility. The observed shortening of the Ni–S and C–S bonds upon oxidation of the dianion to the monoanion is in accordance with the antibonding character of

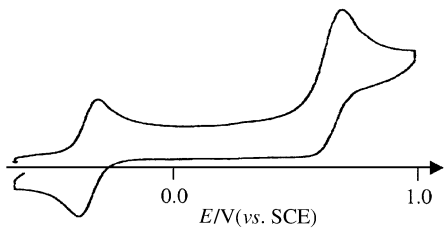


Fig. 1 Cyclic voltammetry of $[PPh_4]_2[Ni(edt\text{-}CN)_2]$, in MeCN with 0.5 M $NBu^n_4PF_6$ as electrolyte at a scan rate of 100 mV s^{-1}.

DOI: 10.1039/b006440h

Table 1 Important bond distances (Å) in $[Ni(edt\text{-}CN)_2]^{2-/-\cdot}$ together with a representation of the π-type HOMO of $[Ni(edt\text{-}CN)_2]^{2-}$

	$[Ni(edt\text{-}CN)_2]^{2-}$	$[Ni(edt\text{-}CN)_2]^{-\cdot}$
Ni–S	2.188(2)	2.148(3)
S–C (bond a)	1.756(5)	1.736(3)
S–C (bond b)	1.720(5)	1.706(4)
C=C (bond c)	1.342(7)	1.341(4)
C–C (bond d)	1.426(8)	1.427(4)
C≡N	1.148(7)	1.141(3)

those bonds in the dianion HOMO shown in Table 1. Similarly the antibonding character of the C≡N bonds is reflected by an increase in ν(C≡N), from 2180 cm^{-1} in the dianion to 2205 cm^{-1} in the monoanion. In the 2:1 $[PPh_4^+]_2[Ni(edt\text{-}CN)_2^{2-}]$ salt, two crystallographically independent dianions, each of them on an inversion centre, are fully isolated from each other by the bulky PPh_4^+ cations. On the other hand, in the 1:1 $[PPh_4^+][Ni(edt\text{-}CN)_2^{-\cdot}]$ salt, the open-shell anions, in general positions in the unit cell, associate into inversion-centered diads with a unusual overlap (Fig. 3) and a short plane-to-plane distance of 3.519(3) Å. The temperature dependence of the SQUID magnetic susceptibility for this salt (Fig. 4) exhibits a maximum at 23 K and is satisfactorily fitted with the Bleaney–Bowers[13] expression of the susceptibility[14] of singlet–triplet behaviour with $|J/k| = 37.5(2)$ K, in accordance with the diad structure. Preliminary metathesis experiments show that a highly insoluble precipitate is obtained upon addition of $AgBF_4$ to $[PPh_4^+][Ni(edt\text{-}CN)_2^{-\cdot}]$ solutions while the Cu^+ salt obtained from $Cu(MeCN)_4BF_4$ is much more soluble. Charge-transfer salts are also being investigated with organic ($TTF^{+\cdot}$) and organometallic ($Cp^*_2Fe^{+\cdot}$) radical cations as well as with functionalized TTF molecules bearing hydrogen bonding groups or halogen atoms able to interact in the solid state with the cyano group.

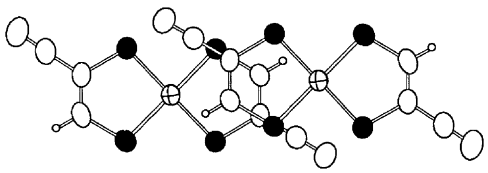

Fig. 3 The peculiar overlap between two $[Ni(edt\text{-}CN)_2]^{-\cdot}$ radical anions in the 1:1 $[PPh_4][Ni(edt\text{-}CN)_2]$ salt.

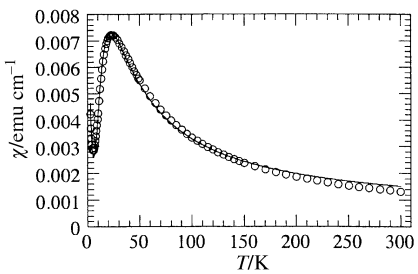

Fig. 4 Temperature dependence of the magnetic susceptibility of the 1:1 $[PPh_4][Ni(edt\text{-}CN)_2]$ salt. The solid line is a fit to the Bleaney–Bowers equation (see text) together with a low-temperature Curie tail encompassing 2.7% magnetic defects.

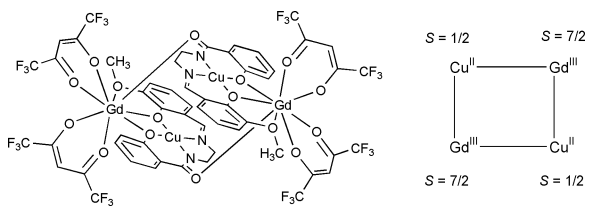
Received (in Cambridge, UK) 7th August 2000, Accepted 27th September 2000
First published as an Advance Article on the web 12th October 2000

A cyclic tetranuclear $Cu^{II}_2Gd^{III}_2$ complex, in which Cu^{II} and Gd^{III} ions are arrayed alternately, has an $S = 8$ spin ground state, due to the ferromagnetic spin coupling between $S_{Gd} = 7/2$ and $S_{Cu} = 1/2$.

The field of molecular-based magnetic compounds has shown spectacular advances in the last two decades, especially in the metal-complex based magnetic materials.[1] Hetero-metal assembly complexes with multi-dimensional extended structures and versatile magnetic behavior[1] as well as single molecule magnets derived from large ground spin state and large magnetic anisotropy[2] have attracted special attention. These interesting magnetic materials consist of a d-transition metal ion, and the magnetic chemistry of d–f and f–f transition metal complexes is the forthcoming target in this field. Since ferromagnetic coupling between Cu^{II} and Gd^{III} ions was first observed in 1985 in a trinuclear complex,[3] several polynuclear Cu_2Gd_2, Cu_2Gd and other d–f complexes have been reported.[4] However, the coexisting antiferromagnetic coupling such as within a Cu_2 pair often concealed the weak ferromagnetic coupling and resulted in net antiferromagnetic behavior. Thus, recent efforts have been focused on strictly binuclear d–f complexes,[5] in order to obtain accurate information on the magnetic properties. If a d–f cluster compound without the d–d and the f–f magnetic interactions was synthesized, it could be a single molecule with a large spin state.[6] If a d–f extended multi-dimensional compound without d–d and the f–f magnetic interactions was synthesized, it would be a magnetic material exhibiting spontaneous magnetization.[7] Here we report a cyclic tetranuclear Cu_2Gd_2 complex $[CuLGd(hfac)_2]_2$, where H_3L = 1-(2-hydroxybenzamido)-2-(2-hydroxy-3-methoxybenzylideneamino)ethane[8] and Hhfac = hexafluoroacetylacetone. The tetranuclear Cu_2Gd_2 complex assumes an $S = 8$ ground state derived from ferromagnetic spin-coupling between Cu^{II} and Gd^{III} ions arrayed alternately, in which the Cu^{II}–Cu^{II} and Gd^{III}–Gd^{III} magnetic interactions are weak.

The copper(II) complex K[CuL] was used as a '*ligand complex*' in order to construct an alternate array of Cu^{II} and Gd^{III} ions, because it is well-known that phenoxo-, methoxy- and amido-oxygen atoms can coordinate to a lanthanide ion,[9] and further it is expected that the amido oxygen atom at the opposite side serves as a bridge to provide an alternate array of the d–f metal ions.[10] As a counterpart, the gadolinium(III) complex $[Gd(hfac)_3(H_2O)_2]$ was used, because the hexafluoroacetylacetonato (hfac) ion can be easily substituted with external donor atoms and can also function as a capping or terminal ligand. The reaction of K[CuL] with an equimolar amount of $[Gd(hfac)_3(H_2O)_2]$ in methanol at ambient temperature produced dark reddish purple crystals of $[CuLGd(hfac)_2]$.[11]



Scheme 1

The structure was determined by a single-crystal X-ray diffraction analysis.[12] Fig. 1 shows an ORTEP drawing of the cyclic Cu_2Gd_2 tetranuclear structure, in which the Cu^{II} and Gd^{III} ions are arrayed alternately and the molecule has an inversion center. The Cu^{II} ion has square planar coordination geometry with the N_2O_2 donor atoms of the unequivalent tetradentate ligand (see chemical structure). The Cu–N and Cu–O distances of the 2-oxybenzamido moiety (Cu–N1 = 1.913(4), Cu–O2 = 1.903(4) Å) are considerably shorter than the corresponding values of the 2-oxy-3-methoxybenzaldehyde moiety (Cu–N2 = 1.931(4), Cu–O3 = 1.952(3) Å). In the cyclic structure, the Cu(II) complex functions as a '*ligand complex*' with the two Gd^{III} ions. The two phenoxo (O2 and O3) and the methoxy (O4) atoms at the one side of the planar Cu(II) complex coordinate to a Gd^{III} ion as a tridentate ligand with the distances of Gd–O2 = 2.468(3), Gd–O3 = 2.350(3), Gd–O4 = 2.550(3) Å, and Cu–Gd = 3.433(1) Å. The amido oxygen atom (O1) at the opposite side of the Cu(II) complex coordinates to another Gd ion as a monodenate ligand with the distance of Gd–O1 = 2.274(3) and Cu–Gd = 5.618(2) Å. Including the coordination of the two hfac ions as a bidentate chelate ligand (Gd–O = 2.347(4)–2.405(4) Å), the Gd^{III} ion has an octacoordinate geometry with the O_8 oxygen atoms. It should be noted that the Gd–O bond distance with the amido oxygen is the shortest among the eight Gd–O bonds. In a cyclic structure, there is no bridging ligand between the two Cu^{II} ions or between the two Gd^{III} ions. The Cu–Cu and Gd–Gd distances in the cyclic structure are 4.952(2) and 7.885(3) Å, respectively, indicating that each metal ion pair is well separated.

The magnetic susceptibilities were measured under a 1 T applied magnetic field in the 2–300 K temperature range.[13] The

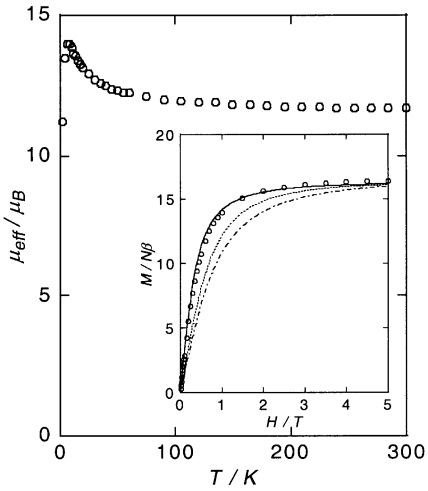

Fig. 2 Plot of the effective magnetic moment (μ_{eff}) per Cu_2Gd_2 *vs.* temperature. The inserted figure shows the field dependence of the magnetization at 2 K. The solid line represents the theoretical curve for g = 2.02 and S = 8 spin state produced by ferromagnetic coupling of the spin system (1/2, 7/2, 1/2, 7/2). The dotted and broken lines represent the theoretical curves for two isolated S = 4 spin states and for an isolated spin state of (1/2, 7/2, 1/2, 7/2).

magnetic behavior is shown in Fig. 2, as the μ_{eff} *vs.* T plot, where μ_{eff} is the effective magnetic moment per Cu_2Gd_2. The μ_{eff} at 300 K is 11.61 μ_B, which is slightly larger than the spin-only value of 11.49 μ_B expected for independently existing two Cu^{II} (S = 1/2) and two Gd^{III} (S = 7/2) ions and g = 2.00. On lowering the temperature, the μ_{eff} increases gradually to reach a maximum value, 13.98 μ_B, at 8.0 K and then decreases abruptly. The increase at the higher temperature region indicates the operation of ferromagnetic interaction between the Cu^{II} and Gd^{III} ions. The maximum value of the μ_{eff} is larger than the spin-only value, 12.65 μ_B, expected for two isolated S = 4 spins resulting from ferromagnetic coupling between the Cu^{II} and Gd^{III} ions of the binuclear complex, although the value is smaller than the spin-only value, 16.97 μ_B, expected for an S = 8 spin. The abrupt decrease in the μ_{eff} at the lower temperature region can be ascribed to weak intermolecular antiferromagnetic interaction.

To confirm the spin ground state of the cyclic tetranuclear complex, the field dependence of the magnetization was measured up to 5 T at several temperatures. The inserted plots in Fig. 2 show the experimental values of $M/N\beta$ *vs.* H at 2 K, together with the theoretical curves for the sum of the Brillouin functions of isolated two Cu^{II} (S = 1/2) and two Gd^{III} (S = 7/2) ions, for sum of two S = 4 spins, and for an S = 8 spin derived from the ferromagnetic coupling of the spin-system (1/2, 7/2, 1/2, 7/2), respectively. The magnetization data are larger than those for two independent S = 4 spins and for a magnetically isolated (1/2, 7/2, 1/2, 7/2) system. The magnetization data are well reproduced by the Brillouin function with S = 8 and g = 2.02. The slight difference is due to an incomplete population of the S = 8 state.

This study revealed that a discrete molecule with a large spin could be easily synthesized even in a d–f transition metal complex. The analogous synthetic approach should produce single molecules with larger spin states and with magnetic anisotropy. Magnets with an extended multidimensional structure can be obtained by substitution of the terminal ligand.

We are grateful to Dr J.-P. Costes for fruitful discussion and to Dr M. Nakamura for help in synthesis.

13 Magnetic susceptibilities were measured with a MPMS5 SQUID susceptometer (Quantum Design, Inc.) in the 2–300 K temperature range under an external magnetic field of 1 T. The calibrations were done with palladium. Corrections for diamagnetism were applied using Pascal's constants. Effective magnetic moments were calculated with the equation μ_{eff} = $2.828(\chi_M T)^{1/2}$, where χ_M is the magnetic susceptibility per tetrameric molecule.

Synthesis of a novel triphosphate analogue: nucleoside α-*P*-borano, α-*P*-thiotriphosphate

First published as an Advance Article on the web 11th October 2000

The first boranothiotriphosphate compound, thymidine 5′-[α-*P*-borano, α-*P*-thio]triphosphate, in which borane and sulfur replace the two non-bridging oxygens of the α-phosphate in natural nucleoside triphosphates (NTPs), has been synthesized; some chemical properties of this borane–sulfur disubstituted nucleoside triphosphate analogue have been investigated. The synthetic approach reported here should be applicable for preparation of any α-borano, α-thio modified NTP or deoxy NTP; potential applications are discussed.

Modifications of nucleoside triphosphates (NTPs) [Fig. 1a] have received much attention in searches for potential diagnostic and therapeutic agents and as probes in a multitude of biological processes.[1,2] Of these modified NTPs, only the nucleoside 5′-[α-thio]triphosphates[1] [Fig. 1b] and nucleoside 5′-[α-borano]triphosphates[2] [Fig. 1c] can substitute for normal NTP and be readily incorporated into DNA and RNA by DNA or RNA polymerases.[1,2] Yet once in DNA or RNA, the phosphorothioate[3] and boranophosphate[4] linkages are more resistant to *exo*- and *endo*-nucleases than normal phosphate diesters. By structurally combining the phosphorothioate [S–P=O]$^-$ and boranophosphate [O=P–BH_3]$^-$, we recently reported the first example of a boranothiophosphate moiety [S=P–BH_3]$^-$, dithymidine boranphosphorothioate,[5] which is stable from pH 3 to 11 and is a more nuclease resistant and highly lipophilic phosphodiester analogue of DNA. We expected that the corresponding NTP analogue, nucleoside [α-borano, α-thio]triphosphate (Fig. 1d), wherein one of the two non-bridging oxygen atoms of the α-phosphate group is replaced by a sulfur atom and the other is replaced by a borane group, should be more lipophilic than the parent NTP and have other useful properties. The borano-, thio-disubstitution of nucleoside triphosphate could greatly increase the stability of the molecule against enzymatic cleavage, thus facilitating studies of enzymes which utilize NTPs and enabling studies of the nature of phosphate ester bond formation and cleavage.

Here, we report the first example of a novel boranothiotriphosphate compound, specifically the thymidine 5′-[α-*P*-borano, α-*P*-thio]triphosphate **5**, its synthesis and properties.

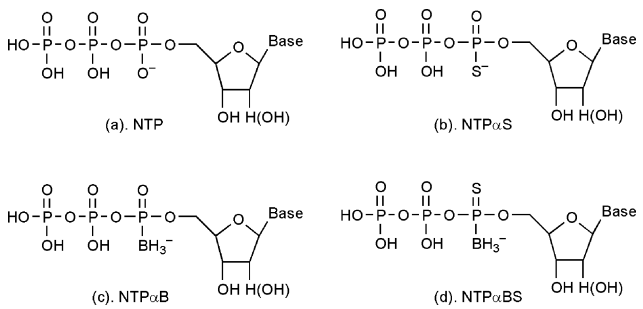

Fig. 1 Nucleoside triphosphate analogue structures and abbreviations. (a) Nucleoside triphosphates (NTP). (b) Nucleoside [α-thio]triphosphates (NTPαS). (c) Nucleoside [α-borano]triphosphates (NTPαB). (d) Nucleoside [α-borano, α-thio]triphosphates (NTPαBS).

The general procedure[6] for the one-pot synthesis of nucleoside 5′-[α-borano, α-thio]triphosphates shown in Scheme 1 is an extension of a method reported by us[2c,d] for the synthesis of boranotriphosphates and by Ludwig and Eckstein[1c] for the synthesis of thiotriphosphates. The overall yield of thymidine 5′-[α-*P*-borano, α-*P*-thio]triphosphate **5** (TTPαBS) was about 26%. The chemical structure of **5** (^{31}P NMR, δ: 153.1 ppm(br) for disubstituted α-*P*) was established *via* spectroscopic methods.[7] Successful separation of the two diastereomers (*R*p and *S*p) of **5** was achieved by reverse-phase HPLC.[7b] The first eluted isomer TTPαBS I (**5a**) and second eluted isomer TTPαBS II (**5b**) were characterized by ^{31}P NMR and ^{1}H NMR.[7c] The method here should be applicable for the synthesis of any deoxy- or ribonucleoside [α-borano, α-thio]triphosphate.

The [S=P–BH_3]$^-$ α-triphosphate is the only known non-bridging-disubstituted chiral α-triphosphate with a negative charge.[8] The borano-, thio-disubstitution in a nucleotidic linkage will result in changes in polarity of the phosphate, as well as its interactions with metal ions.[2f,g] These properties coupled with ready synthesis of isotopic [NTPα^{35}S=P–BH_3] compounds from Li_2S^* (S^* = ^{35}S) could make this modification useful as a probe for nucleotide binding sites in enzymes, for elucidating the stereochemical course and role of metal ions of phosphoryl and nucleotidyl transfer reactions, and for probing whether a non-bridging oxygen is absolutely necessary in these reactions.

To summarize, the synthesis of a new type of doubly modified nucleoside triphosphate analogue, the first [S=P–BH_3]$^-$ triphosphate, opens the possibility of preparing an entirely new and intriguing class of borane–sulfur modified phosphate analogues. Their potential utility as substrates, cofactors, or inhibitors of polymerases and nucleotide binding and metabolizing enzymes, as molecular probes, and as carriers of ^{35}S for radiolabeling and radiation therapy,[9] make the

6 The following procedure for the preparation of nucleoside [α-borano, α-thio]triphosphates is representative: 3′-*O*-acetylthymidine (0.5 mmol, 142 mg) was phosphitylated with 2-chloro-4*H*-1,3,2-benzodioxaphosphorin-4-one (0.55 mmol, 112 mg in 0.8 ml anhydrous DMF) at 0 °C for 10 min to yield two diastereomers of **1**. They were identified by the appearance of a doublet around 127 ppm in the ^{31}P NMR spectra. Instead of introducing the borane group at this stage, **1** was treated with tributylammonium pyrophosphate (240 mg in 1.0 ml anhydrous DMF) and 0.15 ml triethylamine at rt for 1 h to form a cyclic intermediate **2**. The upfield shift from around 127 to 107 ppm for trivalent phosphorus P^{III} together with a doublet around −18 ppm for pentavalent phosphorus P^{V} in ^{31}P NMR confirmed the formation of **2**. The borane group was introduced by the reaction of **2** with excess borane–diisopropylethylamine complex (1 ml) at rt for 2 h to afford **3**. The critical step in the synthesis is ring-opening of the cyclic boronated triphosphate **3** by the treatment with 2 eq. lithium sulfide at 55 °C for 1 h to yield **4**, which was converted to compound **5** with NH_3–H_2O–CH_3OH (aq. NH_3–CH_3OH = 1 : 1, v/v) at rt for 4 h. The low boiling point solvents were removed under reduced pressure and the residue was extracted with ethyl acetate (16 ml) and water (10 ml). The organic layer was washed twice with 2 ml water. The water portions were combined and concentrated to 2 ml. The resulting crude mixture was applied to ion-exchange chromatography on a QA-Cellulose (HCO_3^-) column eluted with a linear gradient of 0.005–0.20 M NH_4HCO_3 (pH = 9.56, 700 ml each) and appropriate portions were collected to give **5** as the ammonium salt. Further purification of **5** (one-sixth of total amount) by HPLC using a linear gradient of 50 mM triethylammonium acetate (TEAA, pH 7.0) and CH_3CN (from 0 to 18% in 40 min) gave pure **5**, R_t = 21.4 min (HPLC conditions: Sphereclone 5 μ ODS(2), 10 × 250 mm column; flow rate, 3.0 ml min^{-1}). The desired fraction was dried by lyophilization, and excess salt was removed by repeated lyophilization with deionized water to yield the triethylammonium salt of **5** (13 mg).

Decomposition of [PPN][Rh(CO)$_4$] [PPN$^+$ = (PPh$_3$)$_2$N$^+$] at 200 °C under CO pressure affords [Rh$_{10}$P(CO)$_{22}$]$^{3-}$, featuring the first decomposition reaction of PPN$^+$ and explaining the reason for the deactivation of [PPN][Rh(CO)$_4$]-based catalytic systems.

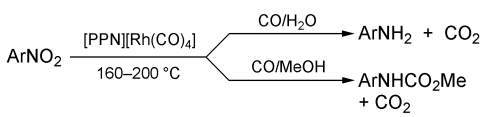
Tetraalkyl and aryl ammonium and phosphonium cations are widely used to improve isolability and solubility of anionic organometallic complexes in organic solvents. However, they usually suffer from limited chemical stability, especially in basic media. In contrast, the PPN$^+$ cation [PPN$^+$ = (PPh$_3$)$_2$N$^+$], first isolated by Appel,[1] is generally considered as a chemically very stable and little interacting counter cation. For these reasons, it has found an increasingly important use in organometallic chemistry and homogeneous catalysis. Although the 'non-interacting' character of PPN$^+$ has later been questioned,[2] to the best of our knowledge its chemical stability is still undisputed.

In recent years, some of us have been involved in the use of [PPN][Rh(CO)$_4$] as a catalyst for the reduction reactions of nitroarenes by CO/MeOH[3] or CO/H$_2$O[4] to afford respectively methyl arylcarbamates (ArNHCO$_2$Me) or anilines (Scheme 1).

Despite the high catalytic activity of [PPN][Rh(CO)$_4$] in these reactions, deactivation of the catalytic system was observed upon prolonged use. We thus decided to investigate the fate of rhodium in these reactions. Since the products of reduction and carbonylation of nitroarenes are difficult to separate from the small amounts of catalyst-derived complexes, we examined the behaviour of [PPN][Rh(CO)$_4$] under similar experimental conditions, but in the absence of any nitroarene.

Heating [PPN][Rh(CO)$_4$] in acetone–water (instead of nitrobenzene–water) at 200 °C and under 60 bar CO for 4 h afforded a brown precipitate. Only very weak carbonyl bands were observed in the IR spectrum of the solution. The IR spectrum of the residue dissolved in CH$_2$Cl$_2$ showed a strong band at 1990 cm^{-1} (in CH$_2$Cl$_2$), with several shoulders, and a series of overlapping bands between 1840 and 1775 cm^{-1}. No [Rh(CO)$_4$]$^-$ was detected either in solution or in the solid residue.

When this last residue was used in place of [PPN][Rh(CO)$_4$] as catalyst for the reduction of nitrobenzene to aniline,[4] only trace amounts of the amine were obtained, indicating that the formed compound(s) is catalytically inactive.



Scheme 1

Recrystallisation of the residue from acetonitrile + acetone (1 : 1)–diisopropyl ether afforded crystals of a cluster that was identified by single-crystal X-ray diffraction as [PPN]$_3$[Rh$_{10}$P(CO)$_{22}$],‡ having an interstitial phosphorus atom. [PPN]$_3$[Rh$_{10}$P(CO)$_{22}$] crystallises in the centrosymmetric triclinic space group $P\bar{1}$ with two independent (half) [Rh$_{10}$P(CO)$_{22}$]$^{3-}$ anions disordered about two distinct centres of symmetry. Two independent PPN cations are in general position while the third one consists of two (ordered, independent) halves lying about two distinct centres of symmetry. The [Rh$_{10}$P(CO)$_{22}$]$^{3-}$ anion which has a bicapped square antiprismatic metal core (see Fig. 1) has been previously structurally characterised as a triethylbenzylammonium salt[5] but, owing to the intrinsic centrosymmetric nature of its ligand envelope (all the external oxygen atoms were actually ordered), suffered of a similar disorder. The present, more accurate, structure determination confirms most of the previous stereochemical observations but also shows the marked effect of different packing environments by comparing the actual values of the distances, and their averages, in the three independent anions (Table 1, ESI†).

The identification of a cluster species having an interstitial phosphorus atom is very informative, since this atom can only derive from decomposition of the PPN$^+$ counter cation. The

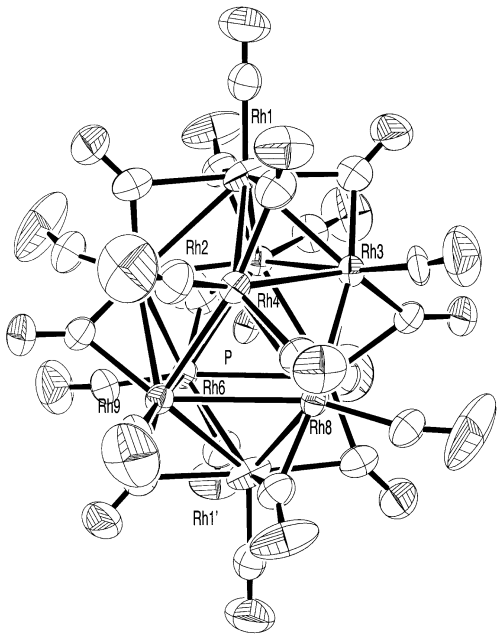


Fig. 1 ORTEP drawing of the [Rh$_{10}$P(CO)$_{22}$]$^{3-}$ anion (B). Thermal ellipsoids are drawn at the 50% probability level.

† Electronic supplementary information (ESI) available: Table 1: selected bond lengths (Å) for [PPN][Rh$_{10}$P(CO)$_{22}$]. See http://www.rsc.org/suppdata/cc/b0/b006135m/

decomposition must be initiated by a rhodium complex, since no acids or bases are present in the reaction mixture. To the best of our knowledge, this is the first time a decomposition product of PPN^+ is identified. The formation of $[Rh_{10}P(CO)_{22}]^{3-}$ also explains the loss of activity of the catalytic system. Indeed, whereas many rhodium clusters are known to convert to mononuclear species under high CO or CO/H_2 pressures,[6] this phosphido cluster has been shown to be remarkably stable even under CO/H_2 pressures much higher than that used both in our studies and in most of those from other laboratories.[5] The formation of $[Rh_{10}P(CO)_{22}]^{3-}$ must thus be considered as irreversible in most if not all catalytic systems and represents a warning against the use of PPN^+ as a counter cation when very long catalyst lives are required, as in industrial applications.

High quality MCM-41 silica with thick walls and a very narrow distribution of mesopore size has been synthesized in a relatively short time *via* ultrasound radiation.

Recently, great efforts have been dedicated to improving the synthesis of mesoporous MCM-41 silica[1] by lowering the temperature, shortening the crystallization time as well as controlling the particle size.[2] However, due to the amorphous nature within the pore wall,[3,4] the products synthesized in alkaline media at low temperature have been much less stable than those obtained at higher temperatures,[5] which imposes a strict limitation on their applications. To achieve highly stable MCM-41 silica, a number of papers have focused on thickening the pore wall in order to obtain a more condensed and longer range ordered framework, either by modifying the assembly pathways[6] or by post-synthesis treatments.[7] The drawbacks of these procedures obviously lie within the time-consuming and complicated processing strategies. Therefore it is more desirable to synthesize stable MCM-41 silica by a quick and direct way.

Ultrasound has been introduced to a variety of material syntheses[8,9] owing to its sonochemical effects based on acoustic cavitation, a property which results from the continuous formation, growth and implosive collapse of bubbles within a liquid.[10] We have found it possible, for the first time, to quickly synthesize MCM-41 silica with small particle size and enhanced pore wall thickness by a sonochemical process.

To synthesize all-silica MCM-41 in the present work, a mixture with initial molar ratio of 1.0 Na_2SiO_3:0.33 CTAB:1.86 EtAc:450 H_2O was first prepared in the following manner; CTAB and EtAc are cetyltrimethylammonium bromide and ethyl acetate, respectively. Typically, to an aqueous solution containing 4.90 g CTAB, 11.65 g $Na_2SiO_3{\cdot}9H_2O$ and 325 mL distilled water, 6.70 g EtAc was quickly injected under either vigorous stirring or sonication. A white precipitate appeared after *ca*. 1 min. The slurry was then divided into six parts for further treatment, the synthesis conditions of which are summarized in Table 1.

Powder X-ray diffraction (PXRD) shows differences among the as-synthesized as well as the calcined products. Except for the calcined sample A, all samples exhibit at least three well resolved reflections in the 2θ range between 2 and 10°. The patterns can be indexed to an ordered hexagonal lattice typical of MCM-41.[1] Interestingly, the full width at half maximum height (FWHM) of the (100) reflections of the samples synthesized with ultrasound is slightly narrower than those obtained without ultrasound (Table 2). It is well known that both structural disorder and a decrease in particle size may result in diffraction line broadening. In fact, under TEM the particles of samples A and F are much smaller and poorly

[a] Full width at half maximum height of (100) reflection. [b] Unit cell constant, $a_0 = 2d_{100}/\sqrt{3}$, where d_{100} is the *d*-spacing of (100) reflection. [c] BET surface area, calculated from the linear part of the BET plot (p/p_0 = 0.1–0.2). [d] Total pore volume, taken from the volume of N_2 adsorbed at p/p_0 = 0.995. [e] Framework pore volume, derived from the volume of N_2 adsorbed at p/p_0 = 0.54. [f] Textural pore volume, obtained from the difference ($V_T - V_F$). [g] Average pore diameter, estimated using the adsorption branch of the isotherm and the Barrett–Joyner–Halenda (BJH) formula. [h] Pore wall thickness, estimated from the difference ($a_0 - D$).

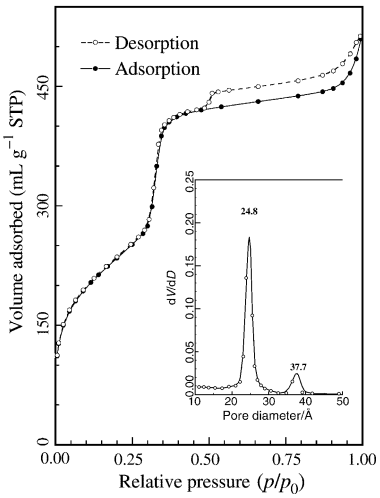

Fig. 1 N_2 adsorption–desorption isotherms of calcined sample B. *Inset*: the pore size distribution calculated by the use of the adsorption data.

aggregated than those of samples B–E, though samples A and F are more uniform in size. Moreover, all samples suffer a framework contraction upon calcination as indicated by the d_{100}-spacings' diminution, except for sample A whose framework collapses. This implies that the samples synthesized without ultrasound are less ordered and of lower stability than those synthesized with ultrasound.

The results from liquid N_2 adsorption–desorption measurements shed more light on the sonochemical effect upon the synthesis. Fig. 1 shows the N_2 adsorption–desorption isotherm as well as the pore size distribution of calcined sample B, and the structural features of the products are detailed in Table 2. The results indicate that samples B–F retain their hexagonal mesophase and exhibit narrow pore size distributions after removal of the organic templates. Though the BJH method may systematically underestimate the pore size by up to 1.0 nm,[11] and although many recent papers have developed more accurate methods for pore size calculation,[12] we think that the data obtained by applying the same method are comparable, and therefore the quantitative results based on these data are credible. It is quite obvious that the ultrasonic processing favors a thicker wall formation. Though acoustic cavitation etched the particles, resulting in a coarse outer surface whereas the inside channels retained the hexagonal arrangement, the electron diffraction pattern shows higher order spots, which provide evidence that both the pore array and pore walls are highly ordered. The processing time of sample B is relatively short; however, a highly ordered, stable mesostructure was fabricated. It was previously reported that MCM-41 can be prepared in a few hours under ambient conditions but, unfortunately, no data regarding the stability have been presented.[13] In our case, the pore wall thicknesses of samples B–D are larger than those of samples E and F. This is quite promising since high quality MCM-41 can be synthesized by a simpler procedure as well as in a shorter time than by the conventional methods. The unit cell constants of the samples decrease in the order B > C > D ≈ E > F after calcination *vs*. C ≈ D ≈ E ≈ F > B before calcination, which means that the frameworks of samples B–D suffer less shrinkage than those of samples E and F. This implies that the pore walls of the sonochemically prepared samples are more condensed or ordered than those of the conventionally prepared ones. The ^{29}Si MAS NMR of calcined sample D is measured and reveals that the framework consists primarily of a fully cross-linked Q^4 unit and a smaller fraction of Q^3 sites. The calculated Q^4:Q^3 ratio is 6.7:1; normally, calcined silica mesostructures prepared by conventional methods have Q^4:Q^3 values near 3.[1] The Q^4:Q^3 ratio of calcined sample D is much higher than those prepared with special treatment,[7c] and is comparable to those of MSG silicas with ratios in the range 6.2–7.4.[6d] In fact, when sample D was refluxed for 6 h in boiling water its crystallinity changed very little. It decreased by *ca*. 35% after refluxing for 12 h, while in the literature[14] the MCM-41 prepared using conventional hydrothermal methods became amorphous after refluxing for 12 h. This can be an advantage of the sonochemical effects. During the formation of the framework, despite the agitation of the ultrasound which helps to disperse the small silica oligomers more homogeneously in the mixture, the formation of hot spots within the surfactant–silicate interface may accelerate the silica polymerization which is slow and rate-limited under normal conditions. Thus the fabrication of the mesostructure can be achieved more efficiently. On the one hand, acoustic cavitation etches the surface of surfactant–silicate micelles which results in a coarse outer surface. On the other hand, hot spots accelerate the condensation of surface silanol groups among micelles, and by this way ultrasound radiation accelerates the formation of the MCM-41 framework and the growth of particles. This two-fold function of ultrasound radiation results in the particles of samples B–E being bigger and more aggregated than those of samples A and F, though samples A and F are more uniform in size.

In conclusion, a novel synthesis route has been developed to prepare high quality MCM-41 within a relatively short time by involving ultrasound. The as-prepared material, whose mesopore size shows a very narrow distribution, possesses thick and condensed wall and is therefore thermally stable.

Microporosity within the pore walls of ordered mesoporous silica SBA-15 was confirmed by physisorption; the micropore volume could be systematically controlled by varying the synthesis temperature and the TEOS/surfactant ratio.

Mesoporous molecular sieves, such as MCM-41[1] and FSM-16,[2] have attracted much attention as catalysts and adsorbents owing to their large pore dimensions compared to microporous zeolites. It is, however, difficult to obtain mesoporous materials exhibiting specific catalysis and adsorption properties such as the uniform acidity and the strong adsorption properties characteistic of zeolites, owing to the amorphous pore walls and large pore dimensions. Although some efforts have been made to crystallize the pore walls of mesoporous materials in order to endow them with a specific functionality,[3–5] it is well known that crystallization of thin pore walls (1–6 nm) is not easy. The generation of microporosity within the amorphous pore walls of mesoporous materials is a promising strategy for endowing them with a specific functionality. Such a material possessing a bimodal pore system, *i.e*. one in which micropores exist within the walls of mesopores, is an ideal porous material for catalysts and adsorbents, because molecules are first transported through mesopore channels and then strongly adsorbed in the micropores. The synthesis of a material with micro- and meso-porous properties would be of great interest. Although there have been some reports suggesting microporosity within the pore walls of MCM-41[6,7] and SBA-15,[8,9] a systematic study for confirmation and control of the microporosity within the pore walls of an ordered mesoporous material has not been reported. Here, we report that the micropore volume of SBA-15 can be controlled systematically by the synthesis temperature and the Si/surfactant ratio in the starting mixture, and micropores are certainly established within the pore wall of SBA-15 material.

A triblock copolymer, Pluronic P104 (BASF), EO_{17}-$PO_{58}EO_{17}$ (EO = $–CH_2CH_2O–$, PO = $–CH_2CH(CH_3)O–$), was used as a structure-directing agent for the synthesis of mesoporous materials. In a typical preparation, 0.8 g of P104 was dissolved in 53 cm^3 of deionized water at 45 °C, and then 10 cm^3 of an aqueous 36% HCl solution was added to the solution. After 2.1–5.6 g of TEOS had been added to the solution, the mixtures was maintained at 45 °C for 8 h with vigorous stirring, followed by heating at 80–100 °C for 8 h under static conditions. The solid products were filtered off and then washed with deionized water repeatedly. After drying at 45 °C overnight, the powders were calcined at 550 °C for 6 h in air. The chemical composition of the reaction mixtures was 0.18 mmol P104: 0.010–0.027 mol TEOS: 0.12 mol HCl: 3.3 mol H_2O. The SBA-15 materials reported previously[10,11] were synthesized with a higher concentration of a surfactant (33.7 g L^{-1}) than the concentration (15.2 g L^{-1}) used in this study. Triblock copolymer P104 has not been previously used for the synthesis of an SBA-15 material. The X-ray diffraction patterns of the products had 2–4 peaks in the low angle region (2θ(Cu-Kα) = 0.7–3.5°) indicating the formation of ordered mesoporous materials with hexagonal (*p*6*mm*) symmetry. Table 1 lists the lattice constants, BJH pore diameters, BET surface areas and pore wall thicknesses of the mesoporous products prepared with different TEOS/P104 ratios and synthesis temperatures.

The adsorption isotherms of the mesoporous materials synthesized under various conditions using the triblock copolymer surfactant exhibited sharp increases in adsorption at $P/P_0 <$ 0.1 and P/P_0 = 0.4–0.7 as shown in Fig. 1(a) and (b). The MS-1 material (Fig. 1(a)) showed a type IV isotherm according to the IUPAC classification,[12] which is typically observed for conventional mesoporous materials such as MCM-41[1] and SBA-15.[10] The first increase in adsorption at $P/P_o < 0.1$ is due to multilayer adsorption on the surface while the second increase at P/P_0 = 0.5–0.7 arises from capillary condensation in the mesopores with nitrogen multilayers adsorbed on the inner surface.[12] The ratio of the first to second feature is higher for MS-6 (Fig. 1(b)) than for MS-1. This suggests that the MS-6 material not only has mesopores but also micropores, since a microporous material shows a type I isotherm,[12] which exhibits a sharp increase in adsorption at $P/P_0 < 0.1$ and a plateau at $P/P_0 > 0.1$.

A comparative plot of the nitrogen adsorption isotherm[7,12] was used to confirm the microporosity and to estimate the micropore volume in the mesoporous materials, similarly to previous reports.[8,9] The t-plots were obtained by using a

Table 1 Physical properties of ordered mesoporous silicas prepared using different TEOS/P104 ratios and temperatures

Sample	TEOS/P104 molar ratio	Synthesis temperature/°C	Lattice constant[a]/nm	Pore diameter[b]/nm	Surface area[c]/m^2 g^{-1}	Pore-wall thickness[d]/nm	Micropore volume[e]/cm^3 g^{-1}

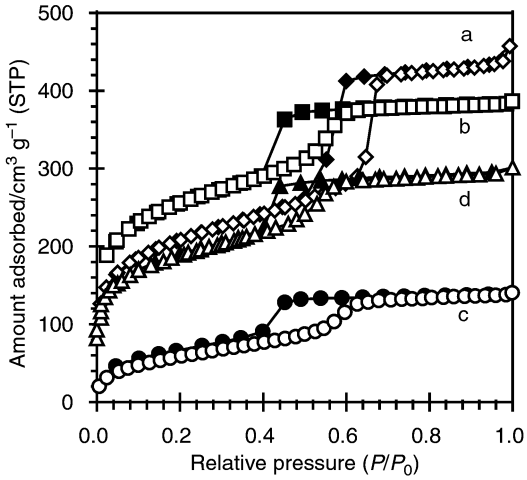

Fig. 1 Nitrogen adsorption–desorption isotherms for mesoporous materials prepared under different conditions: (a) MS-1, (b) MS-6, (c) as-synthesized form of MS-6 and (d) surfactant-depleted MS-6 material after solvent extraction.

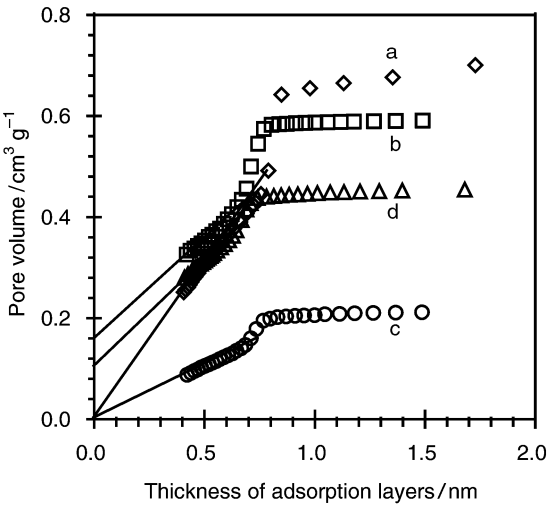

Fig. 2 t-Plots of nitrogen adsorption isotherms for mesoporous materials: (a) MS-1, (b) MS-6, (c) as-synthesized form of MS-6 and (d) surfactant-depleted MS-6 material after solvent extraction.

reference isotherm obtained for a non-porous silica described in a previous report.[13] The t-plots for MS-1 and MS-6 are shown in Fig. 2(a) and (b).

The t-plot for MS-1 gave a straight line at t = 0.40–0.75 nm (t = thickness of adsorbed layer) and the extrapolation line went through the origin, indicating that the MS-1 material has no micropores. Although the MS-6 material also showed a straight line in the same t-value region in the t-plot, the extrapolation line cut the y-axis at 0.15 cm^3 g^{-1}. This indicates that the MS-6 material has a micropore volume of 0.15 cm^3 g^{-1} with a pore radius of < 0.4 nm. A t-plot calculation with the same reference isotherm as for the nitrogen adsorption isotherm of the SBA-15 described in the previous report[10] revealed the absence of microporosity.

The microporosity in the mesoporous materials changed systematically with variation of the synthesis temperature and the TEOS/P104 ratio, as shown in Table 1. Microporosity was not observed for the mesoporous material (MS-1) prepared with a TEOS/P104 molar ratio of 60 and a temperature of 100 °C. A decrease in the temperature from 100 to 80 °C with a constant TEOS/P104 molar ratio of 120 increased the micropore volume from 0.08 to 0.15 cm^3 g^{-1}. An increase in the TEOS/P104 molar ratio from 60 to 150 with a constant temperature of 80 °C also increased the micropore volume from 0.10 to 0.19 cm^3 g^{-1}. These are the first results on the systematic control of microporosity for SBA-15. The increase in microporosity was accompanied by enlargement of the pore-wall thickness (Table 1). The density of micropores in the walls, obtained by dividing the micropore volume by the pore-wall volume, increased with enlargement of the pore walls. The generation of microporosity can be explained by penetration of hydrophilic poly(ethylene oxide) chains of triblock coplymer in the silica wall, as reported by Kruk *et al*.[9] who also suggested that the micropore volume should decrease at elevated temperatures, owing to dehydration of ethylene oxide blocks.[9] The result obtained in this study clearly shows this relationship between the micropore volume and the synthesis temperature. An increase in TEOS/surfactant ratio in the starting mixture is also found to be an effective method to increase the micropore volume of SBA-15. The TEOS/surfactant ratio affects the siloxane network structure in the pore walls, and thereby results in changes of microporosity. There are many variations in the siloxane network structure in a silica gel, which give different pore sizes and porosity.[14] The systematic change of the micropore volume and pore-wall thickness of the mesoporous materials also indicates the existence of micropores within the mesopore walls.

The nitrogen adsorption isotherm and t-plot for the as-synthesized MS-6 material are shown in Fig. 1(c) and Fig. 2(c), respectively. They indicate that the as-synthesized MS-6 material contains surfactant in the mesopore spaces (73% occupation of the mesopore space) with no microporosity. The as-synthesized MS-6 material (1 g) was treated with an ethanol solution (30 cm^3) at room temperature three times to remove the surfactant. The treated MS-6 material showed a micropore volume of 0.11 cm^3 g^{-1}, which was confirmed by the t-plot (Fig. 2(d)) of the nitrogen adsorption isotherm (Fig. 1(d)). The removal of the surfactant from the mesopore spaces made it possible for nitrogen molecules to gain access to the micropores within the mesopore walls. This strongly suggests that micropores exist within the mesopore walls, and that MS-6 is not a physical mixture of mesoporous and microporous materials.

In conclusion, t-plot analysis of nitrogen adsorption isotherms strongly suggests the formation of micropores within the mesopore walls of mesoporous materials. The microporosity can be controlled *via* the synthesis conditions. A novel porous material possessing an ideal bimodal pore system should exhibit high performance catalysis and adsorption properties.

Amperometric biosensor for inert organic solvents based on a sol–gel hybrid material

Bingquan Wang, Jingzhong Zhang, Guangjin Cheng and Shaojun Dong*

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, 130022, P. R. China. E-mail; dongsj@ns.ciac.jl.cn

Received (in Cambridge, UK) 21st June 2000, Accepted 25th September 2000
First published as an Advance Article on the web 11th October 2000

A unique sol–gel enzyme electrode for inert organic solvents is developed that is based on the partition equilibrium of the substrate between water–organic solvent media and the enzyme membrane.

Since the introduction of the first enzyme electrode over 30 years ago, growing interest in biosensors has resulted in increasingly widespread development. The development direction of biosensors can be divided into two aspects: First, the scope of the detection medium was expanded. In order to meet specific requirements, biosensors were developed from the aqueous phase, then to organic solvents saturated with water,[1] then to pure organic solvents,[2] and finally to a universal organic solvent.[3] Second, the scope of the determinable substance was expanded. Enzyme electrodes were first used to detect various substrates,[4,5] later inhibitors could be quantified due to their inhibition of enzyme activity.[6] Recently, Wang[7] applied biosensors to water determination based on the effect of water content on enzyme activity in organic solvents. In this study, we further expand the application of biosensors to inert organic solvent determination.

Recently the use of sol–gel glass as a biosensor encapsulation matrix has recieved much interest because of its high stability.[8] We have fabricated a sol–gel/hydrogel hybrid material, which retained the high activity of enzymes and exhibited negligible swelling.[9] In order to eliminate the influence of matrix swelling on the response, a tyrosinase enzyme electrode based on this hybrid material was chosen to demonstrate the feasibility of the biosensor for the determination of polar organic solvents. The preparations of fresh sol-gel solution and the enzyme electrode have been described elsewhere.[9]†

Steady-state amperometry was used to characterize the enzyme electrode, and Fig. 1(A) shows the typical steady-state current–time responses for successive addition of 50 μl acetonitrile in the presence of catechol. The first 'jump' in the current resulted from the response of catechol to the enzyme electrode, after the steady-state current reached a plateau, injection of acetonitrile caused a current drop. The current decrease is proportional to the content of the organic solvents added [Fig. 1(B)], therefore, electrochemically inert organic solvents can be amperometrically quantified by the enzyme electrode. Fig. 1(B) also shows the effect of enzyme loading upon the response for acetonitrile. Obviously, the response for acetonitrile increases upon increasing the enzyme loading between 266 and 400 units. Therefore, the increase in the enzyme loading can improve detection sensitivity, consequently decreasing the detection limit.

The dilution effect on the substrate in the solution can be ruled out by the control experiments because the injection of the same volume of buffer into the solution did not produce obvious current changes.[11] Thus the mechanism can be ascribed to the change of the sol–gel enzyme membrane due to the addition of organic solvent. Sol–gel encapsulation provides a sufficiently hydrophilic microenvironment that would both retain the essential hydration layer and exclude potentially denatured solvent components,[2,4,8] so it has a stabilization function on the enzyme system. Moreover, the content of organic solvent in this system is considerably lower than that in non-aqueous media,[1–3] so the addition of small amounts of organic solvent will not greatly influence the activity of the sol–gel encapsulated enzyme.[10] If the addition of organic solvent will inhibit the enzyme activity to a large degree, then after the 12th injection of polar organic solvents, the biosensor should exhibit a small current response to the same concentration of catechol. This was not the case. Hupp also found the sol–gel-encapsulated enzyme could retain its catalytic activity when alcohol and aldehyde were successively added into the enzyme monolith.[4]

To accurately demonstrate the response mechanism, we did steady-state QCM experiments at sol–gel modified gold electrodes. Fig. 2 shows the frequency changes following the injection of catechol and acetonitrile when the solution was under rapid stirring. When no enzyme was added into the sol–gel film, the injection of organic solvent did not produce noticeable changes in the frequency (curve *a*). Therefore, the nature of the sol–gel/electrode interface does not change on addition of solvent, which further proves the high stability of the sol–gel hybrid material.[8,9] The responses of the enzyme electrode are shown in curve *b*. With a constant frequency established at time T1, injection of catechol caused a frequency decrease. This can be explained by the fact that catechol diffuses

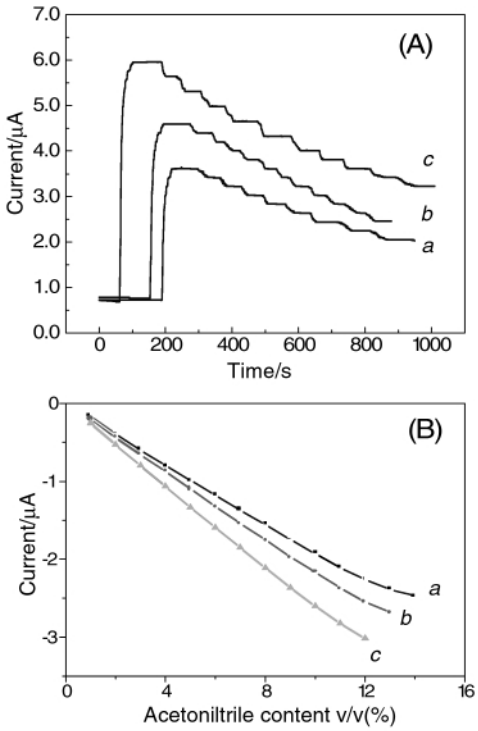

Fig. 1 (A) Amperometric responses of biosensors with different enzyme loadings to addition of 60 μM catechol, followed by successive additions of 50 μl acetonitrile to 5 ml PBS. (B) Corresponding calibration curve for acetonitrile. Enzyme loading, (a) 266 units, (b) 320 units, (c) 400 units; potential, −100 mV *vs* Ag/AgCl (sat. KCl).

DOI: 10.1039/b004967k

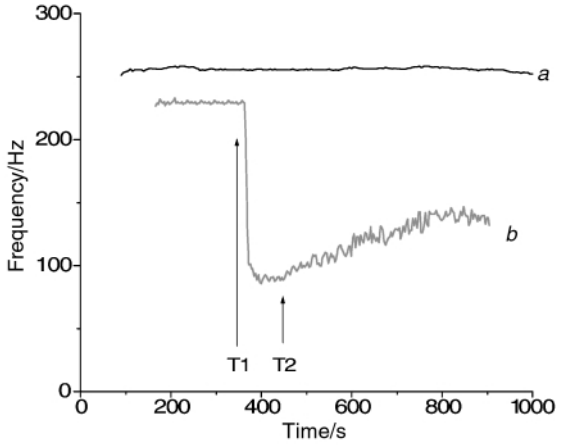

Fig. 2 Frequency–time response curves at the sol-gel-modified gold electrodes with 0 (a) and 320 units tyrosinase (b). At time T1, injections of 60 μM catechol; at time T2, injection of 1% (*v*/*v*) acetonitrile.

into the enzyme membrane and causes an increase in mass, accordingly the frequency decreases. When the response reached a steady state at time T2, injection of acetonitrile caused a frequency increase, which illustrates that the mass of the enzyme membrane does not increase but decreases. If the addition of organic solvent mainly inhibits the enzyme activity, then the mass of the enzyme membrane would not decrease. Therefore, this phenomenon further proves that organic solvent will not greatly inhibit the enzyme activity. In the enzyme membrane, only the amount of catechol may change; therefore, we attribute the current decrease to the extraction effect of organic solvent on the catechol in the enzyme membrane.[11] The solubility of catechol in organic solvents is much greater than in water, and the injected polar organic solvent quickly hydrates and concentrates catechol in the solution, which causes a decrease of the substrate concentration in the solution. Because of the dynamic distribution balance of the substrate between membrane and solution, the catechol in the membrane diffuses toward the solution; this brings about the substrate decrease in the enzyme membrane, accordingly, the response of the biosensor decreases. This mechanism is consistent with our previous report.[11] Both the working electrode and the configuration of the electrochemical cell in QCM experiments are different from those used in Fig. 1, so the response is relatively slower in Fig. 2. Moreover, because of the high sensitivity of QCM (~ng), the noise in Fig. 2 is larger than that in Fig. 1(A).

The sensitivity of the enzyme electrode to organic solvent is solvent dependent. The dielectric constant (ε) and the viscosity (λ) of organic solvents influence the response of the biosensor. The higher the $1/\varepsilon\lambda$, the lower the frictional resistance forces of the solvents on the substrate. This will bring about a higher diffusion of the substrate through the sol–gel film, therefore resulting in a greater sensitivity.[12] In addition, the hydrophobicity of the organic solvent plays an important role in the sensitivity of the biosensor. Methanol, *n*-propanol and *n*-butanol were selected to study the relationship between the sensitivity and the hydrophobicity of organic solvents, because they have similar molecular structures. The biosensor showed a sensitivity sequence as *n*-butanol > *n*-propanol > methanol. log *P* values for *n*-butanol, *n*-propanol and methanol are 0.88, −0.16 and −0.76, respectively. log *P* is a measure of the hydrophobicity of an organic solvent (*P* is the partition coefficient of a solvent in a standard octanol–water two-phase system[13]). The higher the log *P* value is, the more hydrophobic the organic solvent.[14] Obviously, the sensitivity sequence for the three organic solvents conforms to the hydrophobicity sequence. This is because the solubilities of catechol in the three solvents are in the sequence: *n*-butanol > *n*-propanol > methanol.

The biosensor proposed here determines organic solvents well. The response time for acetonitrile is about 40 s, and the detection limit of 1,4-dioxane, an explosive compound, is 0.023% *v*/*v* (*S*/*N* = 3). Moreover, the biosensor can be used to determine some organic solvents such as acetone, dimethylformamide, tetrahydrofuran *etc*., for which no specific enzyme has been found to fabricate a specific biosensor.

We acknowledge the National Natural Science Foundation (China) for financial support.

Notes and references

† The enzyme electrodes were prepared as follows: a suitable amount of tyrosinase (E.C.1.14.18.1) was dissolved in 30 μl of phosphate buffer solution (PBS, pH 7.0), and then 20 μl of hydrogel and 10 μl of silica sol were added. After complete mixing, 10 μl of the mixture was dropped on a glassy carbon electrode (diameter 4 mm). The film was allowed to dry at 4 °C for 16 h and then washed thoroughly with PBS.

Mesoporous Sn–TiO_2 composite electrodes for lithium batteries

Zuoyan Peng, Zhong Shi and Meilin Liu*

School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, GA, 30332-0245SA. E-mail: meilin.liu@mse.gatech.edu

Received (in Irvine, CA, USA) 9th May 2000, Accepted 12th September 2000
First published as an Advance Article on the web 11th October 2000

Mesoporous TiO_2 is prepared stable up to 500 °C with BET surface area of 603 m^2 g^{-1} and pore size 6.9 nm, and Sn–TiO_2 composites based on the mesoporous TiO_2 show good potential as an electrode for lithium batteries with large capacity and structural integrity.

Since mesoporous materials (*e.g.* MCM-41) were first prepared in 1992,[1,2] surfactant-templated synthesis procedures have been widely used for the preparation of highly-ordered mesoporous or nanostructured materials which would be difficult to prepare otherwise. The ordering in these materials is a consequence of a self-assembly process in an aqueous solution containing organic surfactants (anionic, cationic or neutral) and inorganic (oligo-) cations or anions. A wide range of mesoporous materials have been prepared using the structure-directing functions of electrostatic, hydrogen-bonding, and van der Waals interactions associated with amphiphilic molecules.[3–14] Mesoporous TiO_2 was first prepared using a phosphate surfactant through a modified sol–gel process.[13] Since a significant amount of phosphorus still remained in these materials, they are not pure titanium oxides. Recently, mesoporous TiO_2 has been prepared using amphiphilic poly(alkylene oxide) block copolymers as structure-directing agents and titanium inorganic salts as precursors in a non-aqueous solution.[15] The mesoporous structure was stable up to 400 °C with BET (Brunauer–Emmett–Teller) surface area of about 200 m^2 g^{-1}. The use of amine surfactants resulted in mesoporous TiO_2 with BET surface area about 700 m^2 g^{-1} (for as-synthesized powders) while heat treatment of the obtained materials in dry air at 300 °C led to loss of surface area and disappearance of the low angle diffraction peak in X-ray diffraction (XRD) patterns.[16] In this study, mesoporous TiO_2 stable up to 500 °C has been successfully prepared using tri-block copolymers, $(EO)_n$–$(PO)_m$–$(EO)_n$, as directing agents and titanium butoxide as precursor in an aqueous solution. Further, tin oxide was introduced into the mesoporous TiO_2 using a sol–gel process and then reduced in an atmosphere containing hydrogen to form a Sn–TiO_2 composite electrode for lithium ion batteries. The objective of our study is to create a nano-structured Sn–TiO_2 electrode for lithium ion batteries because tin-based compounds may offer much larger capacity than a lithiated carbon electrode. The structural stability of the tin-based materials during cycling is a major concern.[17] Our approach to improve the structural stability was to incorporate tin compound into a mesoporous TiO_2 matrix, which is structurally stable and hence offers structural stability to the nanocomposite electrode.

Shown in Fig. 1 are small-angle XRD patterns of TiO_2 powder samples prepared using a tri-block polymer surfactant (Pluronic 103). The XRD pattern of the as-synthesized sample, Fig. 1(*a*), implies that the surfactant molecules were organized into a hexagonal superstructure after being aged at 50 °C for one week. In addition to the major peak at about 1° due to the (100) reflection, which corresponds to a *d*-spacing of 8.4 nm, small peaks due to the (110) and (200) reflections are also observable. The XRD pattern of the as-calcined sample, Fig. 1(*b*), indicates that the mesoporous structure was retained during the removal of the surfactant by calcination at 500 °C in air for 1 h, although the superstructure had contracted slightly as evidenced by a slight shift of the XRD peaks toward larger angle. The

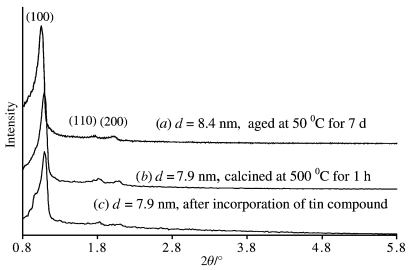

Fig. 1 XRD patterns of (*a*) as-synthesized (aged at 50 °C for 1 week) and (*b*) as-calcined (at 500 °C in air for 1 h) TiO_2 samples prepared using Pluronic 103 as surfactant and (*c*) XRD pattern of a Sn–TiO_2 sample.

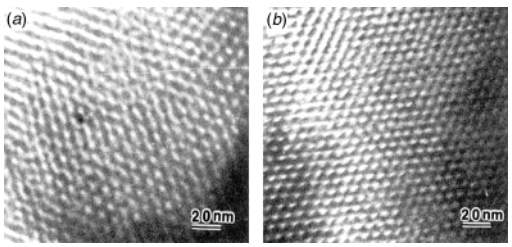

Fig. 2 TEM images of (*a*) as-synthesized (aged at 50 °C for 1 week) and (*b*) as-calcined (at 500 °C in air for 1 h) TiO_2 samples prepared using Pluronic 103 as surfactant.

corresponding *d*-spacing was reduced from 8.4 nm for the as-synthesized sample to about 7.9 nm for the as-calcined sample. Shown in Fig. 1(*c*) is a small-angle XRD pattern of a Sn–TiO_2 sample, which is nearly identical to the XRD pattern of the as-synthesized TiO_2 shown in Fig. 1(*b*), implying that the periodicity of the mesoporous TiO_2 remain unchanged during the incorporation of tin compounds into the mesoporous TiO_2 and the reduction of tin oxide to tin metal.

Shown in Fig. 2 are TEM images of the as-synthesized and as-calcined samples. The periodicities of the mesoporous superstructure as determined from the TEM images are consistent with those determined from XRD analysis. The corresponding pore sizes are about 7.6 and 6.9 nm, respectively. The N_2 adsorption isotherms of the as-synthesized and as-calcined TiO_2 powder are shown in Fig. 3(*a*). Both adsorption isotherm curves have a well-defined step for the relative pressure P_s/P_0 ranging from 0.6 to 0.8, a characteristic of the filling of the framework-confined mesoporous, suggesting that both as-synthesized and as-calcined samples are mesoporous. However, the calculated BET surface area was increased from 203 m^2 g^{-1} for the as-synthesized sample to 603 m^2 g^{-1} for the as-calcined sample, indicating that the gas-accessible surface area was dramatically increased after the surfactant was removed. Further, the average pore size in the as-calcined mesoporous superstructure is about 6.9 nm with a narrow size distribution, as shown in the insert in Fig. 3(*a*).

After the incorporation of tin compound into the pores of the mesoporous TiO_2, the surface area and pore size were reduced to 441 m^2 g^{-1} and 6 nm, respectively, as determined from the absorption isotherm and pore size distribution data shown in Fig. 3(*b*). This implies that the tin compound was formed inside the pores of the mesoporous TiO_2, an ideal configuration of a

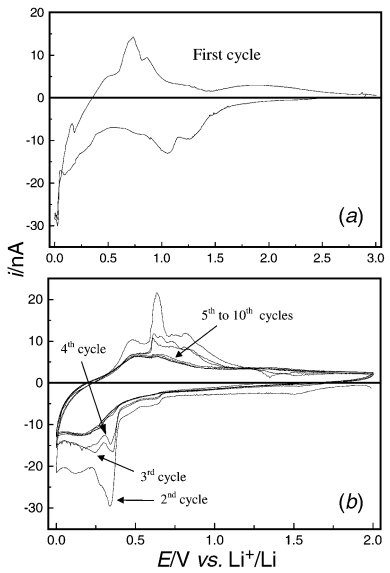

Fig. 4 Cyclic voltammograms of a mesoporous Sn–TiO_2 composite as studied using a powder microelectrode: (*a*) the cycle 1; (*b*) the 2 to 10 cycles. The potential sweep rate was 0.5 mV s^{-1}.

composite electrode for lithium batteries with desired structural stability.

Shown in Fig. 4 are the first several cyclic voltammograms of a mesoporous Sn–TiO_2 composite electrode as studied using a powder microelectrode. Clearly, the CV curve for the first cycle is very different from those commonly observed for most tin-based composite electrodes.[18] It is noted that there is no cathodic peak at 0.85 V (or 2.6 V), corresponding to electrochemical reduction of SnO or SnO_2,[18] indicating that most tin oxides had been chemically reduced to tin metal in the mesocomposite during the exposure to hydrogen. However, there are two small reduction peaks between 1 and 1.5 V in the first cycle, which disappeared after the first cycle. Several pairs of redox peaks appear in the voltammograms after the second cycle. The peak currents decreased during the first few cycles but remained relatively constant later on, as shown in Fig. 4(*b*). There was little change from 5th to 10th cycle, implying that the composite electrode may have good cycleability. Long-term cycling behavior of the composite electrode is still under investigation using constant current charge–discharge cycling test and will be reported in the near future.

In a typical preparation, 10 g titanium butoxide was dissolved in 20 ml absolute ethanol and 2.92 ml acetylacetone at room temperature before 10 ml distilled water was added, followed by stirring for another 2–3 h. In a separate beaker, 5 g Pluronic 103 was dissolved in 20 ml ethanol and 100 ml 2 M HCl solution. This surfactant solution was then slowly added to the titanium butoxide solution. The resulting solution was subsequently kept at 50 °C with continuous stirring for one week. The obtained solid product was washed and centrifuged three times using distilled water and then dried at 60 °C for 24 h and 120 °C for 5 d. The dried powder was fired at 500 °C for 1 h in air using an alumina boat to remove the surfactant.

To incorporate Sn into the pores of the mesoporous TiO_2, $SnCl_4$ was dissolved in water, to which NH_3(aq) was added to ensure all Sn^{4+} was hydrolyzed and precipitated. The solid product was washed and centrifuged three times using distilled water and was then dissolved in nitric acid to obtain a solution containing Sn^{4+}. The mesoporous TiO_2 powder was then immersed in the solution containing Sn^{4+} for a few days. The resulting powder was obtained after drying at 80 °C for one day and at 120 °C for another day, followed by reduction at 300 °C for 24 h in a hydrogen atmosphere.

The electrochemical properties of the mesoporous Sn–SiO_2 electrode were studied in 1 M $LiN(SO_2CF_3)_2$/EC+DMC electrolyte solution using a powder microelectrode[19] technique.

We gratefully acknowledge the support of this research by the National Science Foundation (under Grant No. CTS-9819850) and the Caleb Corporation.

Synthesis of aza-*C*-disaccharides using cycloaddition reactions of a functionalized cyclic nitrone

Fraser J. Duff, Vincent Vivien and Richard H. Wightman*

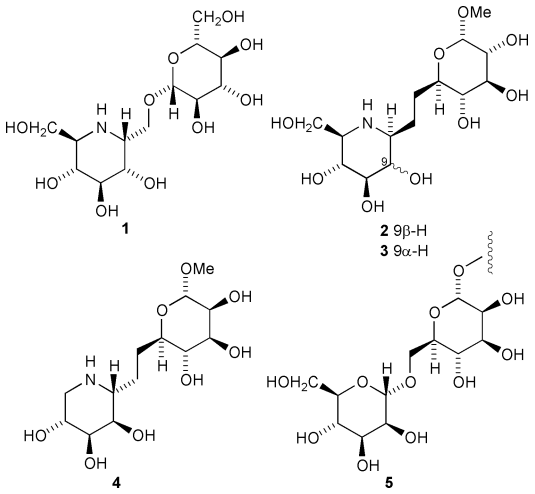
Received (in Liverpool, UK) 18th July 2000, Accepted 14th September 2000
First published as an Advance Article on the web

Cycloaddition reactions of a functionalized nitrone with sugar alkenes gives stereoselective access to aza-*C*-disaccharide analogues of α-D-Lyx(1→6)-α-D-Man and α-D-Lyx(1→6)-D-Gal.

Iminosugars have attracted much attention in recent years[1] due to their ability to act as inhibitors of glycosidases, and hence to have potential application in the treatment of a number of disparate disease states such as viral infections,[2] diabetes[3] and tumour metastasis.[4] It has been theorised that glycosidase inhibitors which permit interaction with the aglycon binding site should be more potent than those which lack this ability,[5] and the validity of this concept has been demonstrated.[6] The attachment of a second aglycone-mimicking sugar unit to an iminosugar has been done in a number of ways, as for example in the α,β-trehalose analogue **1**[6a] or by attachment *via*



nitrogen,[6c,7] but the aza-analogues of disaccharides which can be regarded as being closest in structure to the natural sequences are those with an all-carbon link, namely the aza-*C*-disaccharides prepared in the laboratories of Johnson[8] and of Vogel and van Boom,[9] such as **2**[8a,9] and **3**.[8c,9]

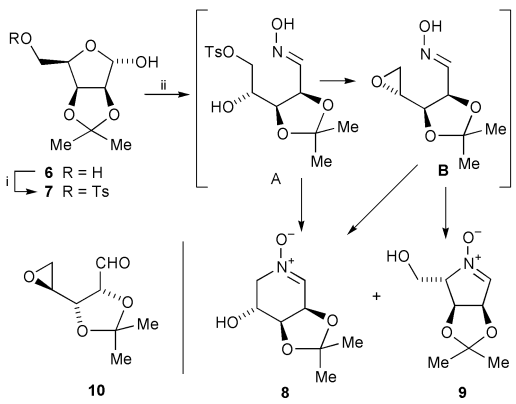
In this communication we describe our preliminary results on the synthesis of aza-*C*-disaccharides by a different synthetic approach to those previously employed,[8,9] and in which stereoselective cycloaddition reactions between functionalized cyclic nitrones and sugar alkenes are employed to establish the disaccharide analogue; our approach is illustrated by the synthesis of **4**, related to the sequence α-D-Man(1→6)-α-D-Man **5**, which is hydrolysed by Golgi α-mannosidase II during the processing of *N*-linked glycans of glycoproteins,[10] and of a related aza-*C*-disaccharide **20**.[11]

Treatment of 2,3-*O*-isopropylidene-D-lyxose **6**[12] with TsCl-pyridine (Scheme 1) gave in high yield the solid but somewhat unstable tosylate **7**, which was directly treated with excess hydroxylamine to give predominantly (44–47%) the nitrone **8**,† together with smaller amounts (3–8%) of the nitrone **9** with a five-membered ring. We consider that **9** is formed *via* intermediates **A** and **B** (Scheme 1), whilst **8** is derived predominantly by direct cyclisation of **A**,[13] but also to a lesser extent by 6-*endo*- ring closure of **B**.‡ In support of this, we have shown that epoxide **10**, on treatment with hydroxylamine, gives (54%) a mixture of the enantiomers of **8** and **9** in a 1 : 1 ratio.

Methyl α-D-mannopyranoside was converted routinely (66% overall) into **11** (see Scheme 2), which was oxidised and converted to alkene **12**. Reaction of **12** and nitrone **8** in toluene at reflux led to the isolation of a crystalline cycloadduct **13** in 84% yield. The stereostructure of **13**, which corresponds to reaction on the face of **8** *anti*- to the isopropylidenedioxy group, and *via* an *exo*-transition state,§ was indicated by NOESY data, which were obtained at high temperature (120 °C) since at lower temperatures signal-broadening was found, presumably due to slow inversion at nitrogen. Strong interactions were observed between 6-H and 7β-H, and between 7α-H and both 5-H and 8-H. The structure of **13** was subsequently confirmed by X-ray crystallography.¶ The stereoselectivity of this cycloaddition is enhanced (double stereodifferentiation) by the known facial preference of chiral allylic ethers in cycloadditions, such that an *erythro*-relationship between the stereocentres at C-5′ and C-8 will be preferred.[14]

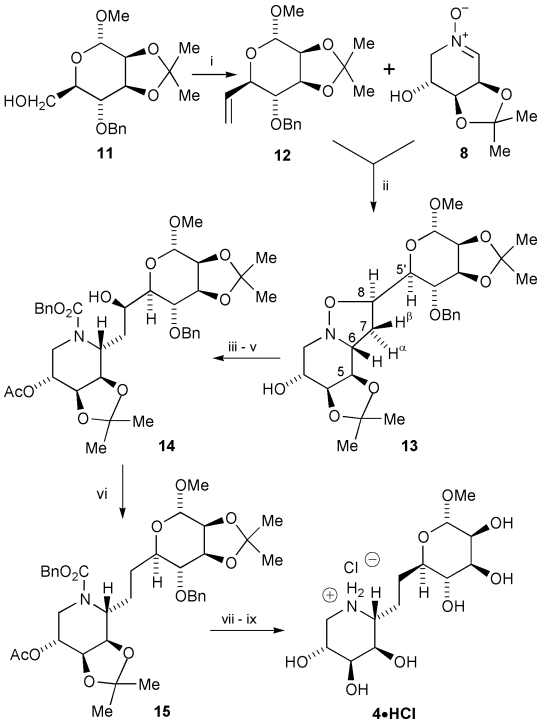
The cycloadduct **13** was acetylated, whereupon reductive cleavage of the N–O bond was carried out using $Mo(CO)_6$ in aqueous acetonitrile,[15] to give after protection of the amine the benzyloxycarbonyl derivative **14**. Deoxygenation to give **15** was carried out through the intermediacy of the imidazolyl-thiocarbonyl derivative, but we observed that it was necessary to carry out the reaction of **14** with thiocarbonyldiimidazole at high concentrations and with excess of reagent in order to obtain a high yield, an observation recently reported by others during the synthesis of *C*-disaccharides.[16] Routine deprotection of **15** then led to the aza-*C*-disaccharide **4**, isolated as its hydrochloride (44% overall from **13**).†

As a further example of this approach to aza-*C*-disaccharides, reaction of nitrone **8** with the D-galactopyranosyl alkene **16**[17] gave in 88% yield the *anti*-, *exo*-cycloadduct **17**† (Scheme 3), together with 1% of the *syn*-, *exo*-isomer. The stereochemistry of **17** again followed from NOESY spectra run at elevated temperatures, with strong interactions being observed between

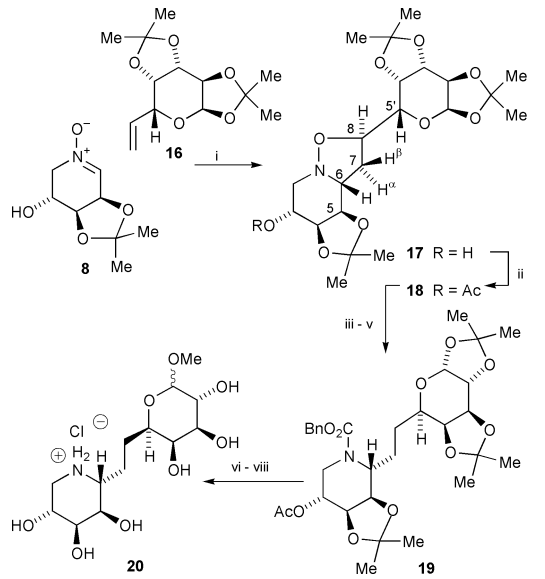


Scheme 1 *Reagents and conditions*: i, TsCl, pyridine–$CHCl_3$, 5 h (76%); ii, $NH_2OH{\cdot}HCl$, $NaHCO_3$, MeOH–H_2O, rt, 20h (44–47% **8**, 3–8% **9**).

DOI: 10.1039/b005984f



Scheme 2 *Reagents and conditions*: i, PCC, DCM, then $Ph_3PMe{\cdot}Br$, KHMDS, −78 °C to rt; ii, toluene, reflux (84%); iii, Ac_2O, DMAP, pyridine; iv, $Mo(CO)_6$, MeCN–H_2O, reflux; v, BnOCOCl, Na_2CO_3, acetone (67% from **13**); vi, excess $(Im)_2C{=}S$, $(CH_2Cl)_2$, reflux, 2 h, then Bu_3SnH, AIBN, toluene, reflux (81% from **14**); vii, NaOMe, MeOH; viii, H_2, Degussa Pd/C, MeOH; ix, HCl, MeOH (80% from **15**).



Scheme 3 *Reagents and conditions*: i, toluene, reflux (88%); ii, Ac_2O, DMAP, pyridine (82%); iii, $Mo(CO)_6$, MeCN–H_2O, reflux; iv, BnOCOCl, Na_2CO_3, acetone; v, excess $(Im)_2C{=}S$, $(CH_2Cl)_2$, reflux, then Bu_3SnH, AIBN, toluene, reflux; vi, NaOMe, MeOH, rt, 1.5 h; vii, H_2, Pd/C, MeOH; viii, HCl, MeOH, rt, 24h (48% overall from **18**).

6-H and 7β-H, between 7α-H and both 5-H and 8-H, and between 5′-H and both 6-H and 7β-H; these last interactions, and the observed value of 7.4 Hz for $J_{5',8}$ imply a preferred rotamer about the C-8–C-5′ bond as indicated in **17** (for **13**, $J_{5',8}$ = 2.4 Hz). This, and the configuration of **17**, was confirmed by X-ray crystallography of the crystalline *O*-acetyl derivative **18**. Reduction of **18**, followed by *N*-protection and deoxygenation under conditions of high concentration, gave **19**, deprotected as indicated in Scheme 3 to give the aza-*C*-disaccharide **20**, as an anomeric mixture (α:β, 5:2), in 48% overall yield from **18**.

We thank EPSRC for financial support (GR/K97301) and for access to facilities at the National Mass Spectrometry Service Centre, and Dr Georgina Rosair for X-ray crystallography.

The synthesis and structure of a new oxide fluoride, $LaSrMnO_4F$, with staged fluorine insertion

L. D. Aikens, R. K. Li and C. Greaves*

School of Chemistry, University of Birmingham, Birmingham, UK B15 2TT. E-mail: c.greaves@bham.ac.uk

Received (in Cambridge, UK) 30th August 2000, Accepted 21st September 2000
First published as an Advance Article on the web 13th October 2000

$LaSrMnO_4F$ has been synthesised and shown to have a staged structure in which the insertion of F atoms into the parent $LaSrMnO_4$ structure has occurred only in alternate (La,Sr)O rocksalt blocks.

In recent years the synthesis of materials which are superconducting or exhibit high magnetoresistance behaviour has been the focus of much attention from solid state chemists. Interestingly, although the detailed mechanistic principles for both classes of materials remain incomplete, the structural and electronic requirements are sufficiently clear to allow the design and synthesis of new materials. The two-dimensional structural features and mixed valence (generally Cu^{2+}/Cu^{3+}) observed in high temperature superconductors are now well known, and similar criteria appear to be important for some oxides which show high magnetoresistance at fairly low magnetic fields. The importance of such materials was illustrated in the $n = 2$ Ruddlesden–Popper phase $La_{1.2}Sr_{1.8}Mn_2O_7$,[1] which contains Mn^{3+}/Mn^{4+} and double layers of MnO_6 octahedra linked through corners. We have previously shown that for both superconductors and layered manganese oxides, low temperature fluorine insertion reactions provide not only the means for achieving controlled increases in cation oxidation states (associated with reduction of F atoms to F^- ions), but also new low dimensional oxide–fluoride structures. This is exemplified by the reactions of F_2 gas with Sr_2CuO_3 or $La_{1.2}Sr_{1.8}Mn_2O_7$ to form, respectively, superconducting $Sr_2CuO_2F_{2.3}$ and ferromagnetic $La_{1.2}Sr_{1.8}Mn_2O_7F_2$.[2,3] In both reactions, fluorine inserts between two adjacent AO rocksalt layers (these rocksalt 'bilayers' exist in both precursor oxides, with A = Sr for the former compound and A = Sr/La for the latter). The insertions cause increases in transition metal oxidation states, from Cu^{2+} to $Cu^{2.3+}$ and $Mn^{3.4+}$ to $Mn^{4.4+}$.

Here, we report the structure and basic magnetic properties of a new phase, $LaSrMnO_4F$, in which fluorine is inserted between *alternate* rocksalt bilayers. This is an example of a staged insertion reaction for which the product contains layers with fully occupied interstitial sites, regularly spaced between completely empty layers, rather than a random distribution of inserted species in all layers. Although staging occurs for the intercalation of alkali metal and halogen atoms into graphite,[4] and has also been reported for other layered materials, *e.g.* Ag_xTiS_2,[5] we believe $LaSrMnO_4F$ provides the first example relating to fluorine insertion in oxides. Synthetically the observation could be significant, especially for magnetic systems such as manganese oxides. For example, the successful synthesis of a series of staged manganese oxide–fluorides with different fluorine contents would produce materials with not only a gradual change in Mn oxidation state, but also a gradation of magnetic exchange interactions perpendicular to the 'MnO_2' layers.

The precursor oxide $LaSrMnO_4$ was prepared as described in previous reports,[6,7] and fluorination was achieved by exposing the sample to a $10\%F_2/90\%N_2$ gas mixture for 2 h at 200 °C. Chemical analysis of the fluorinated phase (mass change on fluorination, Mn oxidation state *via* titrimetry and F content *via* thermogravimetric decomposition in $10\%H_2/90\%N_2$) suggested the approximate composition $LaSrMnO_4F_{1.7}$, which is indicative of incomplete filling of the interstitial sites between the rocksalt layers, since full occupancy would correspond to $LaSrMnO_4F_2$. In order to prepare $LaSrMnO_4F$, the original fluorinated sample was mixed with an appropriate amount of the precursor oxide (mole ratio 1.2 : 0.8) followed by heating the mixture in air at 300 °C for 12 h. Iodometric titration indicated a manganese oxidation state of 3.93(3)+, in satisfactory agreement with the value of 4.0 expected for stoichiometric $LaSrMnO_4F$. Thermogravimetric analysis (to 600 °C, $10\%H_2/90\%N_2$) revealed a 3.5% weight loss during decomposition to give a multi-phase product consisting of SrF_2, $La_{2-x}Sr_xMnO_4$ and MnO according to X-ray powder diffraction (XRPD) analysis. The weight loss is sensitive to the F content and agrees well with that expected (3.3%) for 1 mol of $LaSrMnO_4F$ producing $\frac{1}{2}SrF_2 + \frac{3}{4}La_{1.333}Sr_{0.667}MnO_4 + \frac{1}{4}MnO$. In addition, phase analysis of the product using Rietveld refinement procedures[8] indicated a $SrF_2 : La_{1-x}Sr_xMnO_4$ ratio of 0.72, slightly higher than the 0.67 ratio expected for $LaSrMnO_4F$. The analytical data support a composition close to stoichiometric $LaSrMnO_4F$, although a small amount of F substitution at O sites may have occurred ($LaSrMnO_{3.93}F_{1.07}$ would correspond to $Mn^{3.93+}$ and produce a $SrF_2 : La_{1-x}Sr_xMnO_4$ ratio of 0.73).

In order to obtain an insight into the structural characteristics of $LaSrMnO_4F$, XRPD data were collected (Siemens D5000, primary Ge monochromator, PSD). It was clear that a fairly close structural relationship existed between $LaSrMnO_4F$ and its parent oxide $LaSrMnO_4$, and the pattern was satisfactorily indexed on a tetragonal unit cell (*P*4/*nmm*, $a = 3.7749(1)$ Å, $c = 14.1049(3)$ Å). Fluorination results in a symmetry reduction and a significant expansion of *ca.* 7.3% along *c* compared to the precursor oxide $LaSrMnO_4$ (*I*4/*mmm*, $a = 3.7952(1)$ Å, $c = 13.1410(9)$ Å). Structure refinement, using the program FULLPROF[8] was performed. Several structural models were examined including those with F atoms statistically occupying interstitial sites between all the (La/Sr)O rocksalt layers and those where occupancy is confined to alternate layers only. Only the latter model provided a basis to achieve satisfactory agreement between the calculated and experimental XRPD patterns. The F^- ions are located in the ideal interstitial positions between one of the two (La/Sr)O bilayers in the unit cell, and are tetrahedrally coordinated to 4 La/Sr sites. The fitted profile is shown in Fig. 1 and Table 1 gives the refined atomic coordinates and selected interatomic bond distances. In the refinement, all sites occupied by a given ion were constrained to have equal thermal parameters. The refined structure (Fig. 2) clearly displays the staged arrangement of guest F^- ions within the $LaSrMnO_4$ host structural framework. Although O and F atoms cannot be differentiated by XRPD, the anion assignments in Table 1, which restrict F to only one of the two interstitial positions, are supported by Madelung energy calculations.[9] This analysis, based purely on electrostatic arguments, indicates that the Madelung energy for the proposed anion distribution (24 110 kJ mol^{-1}) is the highest of all possible arrangements; the next highest (22 880 kJ mol^{-1}) corresponds to F occupying the neighbouring O2 apical site. Bond valence sum calculations[10] for the Mn–O bonds using r_o for Mn(IV) yields a value of 4.2 at the Mn site indicating that the Mn coordination is consistent with Mn^{4+}. The structure refinement clearly indicates that fluorine insertion has occurred between alternate rocksalt layers only. As a result, two quite different Mn–O apical bonds

are present (Table 1 and Fig. 2): Mn–O2 bonds, which point towards the F-containing layers, are significantly shorter than the *trans*-Mn–O3 bonds owing to the influence of F–O2 repulsions.

Studies of the magnetic properties of this material (Cryogenics S100 SQUID, Fig. 3) revealed paramagnetic behaviour

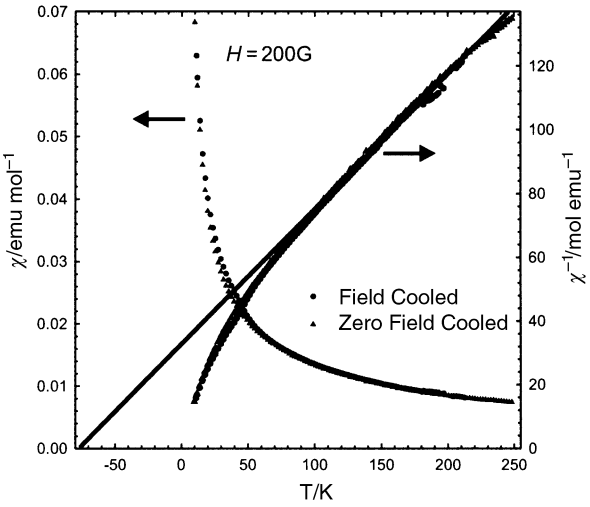

Fig. 3 Variation of magnetic susceptibility (χ) and χ^{-1} with temperature (T).

above 10 K. Above 95 K, application of the Curie–Weiss law [$\chi = C/(T - \theta)$], provides a negative value of the Curie–Weiss constant ($\theta = -80$ K), suggesting antiferromagnetic interactions are taking place. The effective moment, $\mu_{eff} = 4.3\ \mu_B$, estimated from the linear part of the $1/\chi$ *vs.* T plot (Fig. 3), is slightly higher than that expected for Mn^{4+} (spin-only moment $3.9\ \mu_B$), and is consistent with the presence of some Mn^{3+}. At temperatures below 95 K we see the appearance of a ferromagnetic component to the magnetic interactions. Further studies are required to establish whether these are intrinsic or extrinsic to the bulk $LaSrMnO_4F$ phase.

$LaSrMnO_4F$ has been synthesised and the most important structural characteristics determined by XRPD. For the first time, staged insertion of fluorine has been demonstrated such that only alternate rocksalt regions of the parent structure have been subject to intercalation. This is the first example of this type of fluorinated oxide and suggests that other staged products may be possible, not only for $n = 1$ Ruddlesden–Popper phases such as $LaSrMnO_4$ studied here, but for family members with higher n. Such possibilities are currently under investigation.

We thank EPSRC for financial support including the provision of a studentship to L. D. A.

_N_-(2-Iodoethyl) and _N_-(3-iodopropyl)pyrimidines and purines undergo stereoselective conjugate radical addition with an optically active oxazolidinone acceptor to give _syn_-adducts that can be converted into pyrimidine and purine amino acids.

Peptide-based nucleic acid analogues (PNAs) have attracted much attention as molecules with the potential to interact with nucleic acid chains.[1] Suggested applications include antisense properties.[2] Nielsen's PNA has been shown to form duplexes with the complementary DNAs.[1] DNA recognition using analogues with a 'real' peptide backbone has, however, proved more elusive. Substituted alanine oligomers **1** (B = pyrimidine or purine base) and homologues **2** (termed α-PNA[3]) do not demonstrate hybridisation with DNA and insufficient flexibility of the polypeptide chain has been suggested as the cause,[4] whereas triplex formation between tetrapeptides of type **2** and poly(dT) or poly(dU) has been reported.[5] Our interest in unusual amino acids led us to propose the homologous amino acids **4** carrying the nucleic acid bases with a 3- or 4-methylene tether to the peptide backbone, as components for PNA variant **3**. Residues **4** are also analogues of natural pyrimidine and purine amino acids.[6] We report here our flexible methodology based on stereospecific radical chemistry.[7]

In contrast to published routes to residues with C_2 tethers,[3,5,8] we determined to link preformed heterocycles with the peptide backbone by forming a *carbon–carbon* bond in the tether, and proposed to generate the C(β)–C(γ) bond by conjugate radical addition to chiral acceptor **7** (Scheme 1).[9] The (*S*)-acceptor **8** was prepared from *S*-methyl-(*R*)-cysteine (Scheme 2) by adaptation of a published sequence to the *N*-benzoyl analogue.[10] *syn*-Sulfone **7** was formed as a 10:1 mixture with its *anti*-diastereoisomer **6** [57% overall from *S*-methyl-(*R*)-cysteine] and easily separated by column chromatography.[10] The *syn*-configuration was supported *inter alia* by mutual NOE enhancements between C-2(H) and C-4(H). Base treatment afforded (*S*)-oxazolidinone **8** as a crystalline solid.

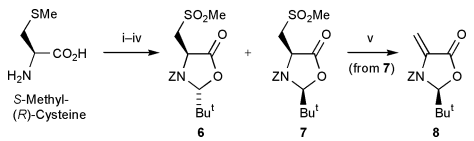
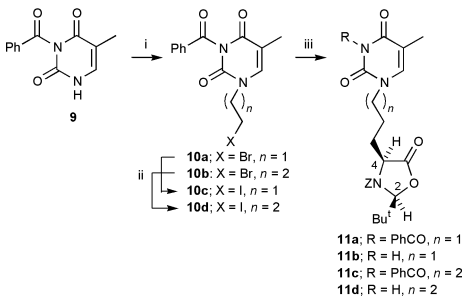


Scheme 2 *Reagents*: i, NaOH aq.; Bu^{t}CHO, Dean-Stark; iii, $PhCH_2OCOCl$ (ZCl); iv, oxone®, MeCN–H_2O; v, DBU.

† Current address: Department of Chemistry, Loughborough University, Leicestershire, UK LE11 3TU; e-mail r.c.f.jones@lboro.ac.uk

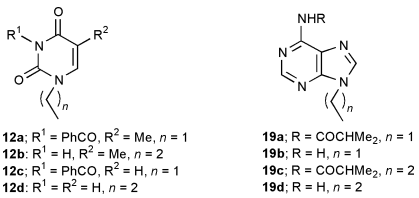
The radical precursors were haloalkyl pyrimidines and purines, prepared from the appropriately protected heterocyclic base and an ω-haloalcohol.[11] Thus 3-benzoylthymine **9**[12] was coupled with 2-bromoethanol or 3-bromopropanol (DIAD, Ph_3P) to afford the 1-(ω-bromoalkyl) derivatives **10a,b**, respectively (Scheme 3). Attempts to generate radicals from these bromides proved fruitless, so they were converted directly to the iodoalkyl compounds **10c,d**, respectively (NaI, propanone reflux; 85, 87% from **9**).

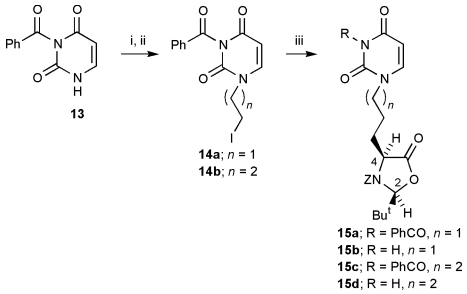


Scheme 3 *Reagents*: i, $HO(CH_2)_{n+1}Br$, $Pr^iO_2CN{=}NCO_2Pr^i$, Ph_3P; ii, NaI, Me_2CO reflux; iii, Method A: **10** (1 mol equiv.), Bu_3SnH (1 mol equiv.), AIBN (0.1 mol equiv.), toluene reflux; Method b: **8** (2 mol equiv.), Bu_3SnCl (0.3 mol equiv.), $NaBH_3CN$ (2 mol equiv.), AIBN (0.1 mol equiv.).

Iodide **10c** was treated under two protocols differing in the method for radical generation;[9] method A: with oxazolidinone **8** (1 mol equiv.) in toluene at reflux containing AIBN (0.1 mol equiv.) and dropwise addition of Bu_3SnH (1 mol equiv.); or method B: with oxazolidinone **8** (2 mol equiv.), Bu_3SnCl (0.3 mol equiv.), $NaBH_3CN$ (2 mol equiv.) and AIBN (0.1 mol equiv.) in *tert*-BuOH at reflux. Method A afforded the conjugate addition product **11a** (26%) and reduction product **12a** (24%), whereas method B after 16 h afforded 54% of conjugate addition products consisting of the adduct **11a** (24%) and the 3-debenzoylated derivative **11b** (30%), with no reduced material. The extent of debenzoylation was time dependent; a reaction time of 40 h led to **11b** as the sole addition product (47%). This suggests the deacylation may be *via* hydride-mediated reduction of the out-of-plane benzoyl carbonyl group, a possibility supported by an observed decrease in debenzoylation when less $NaBH_3CN$ is used in method B, and that debenzoylation of **10** occurs in the presence of $NaBH_3CN$ alone.[13] When 1-iodopropylthymine derivative **10d** was treated under method B, adduct **11c** was not found and deacylated adduct **11d** was isolated (25%) along with reduction product **12b** (75%).

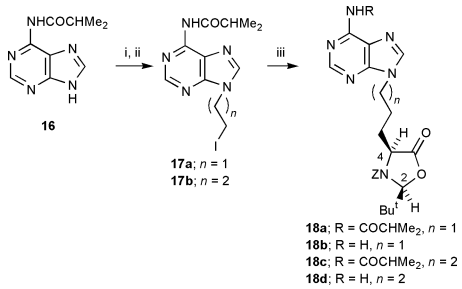
We elected to extend these standard protocols (method B preferred) to other pyrimidines and purines rather than optimise each conjugate addition. Thus 3-benzoyluracil **13**[12] was



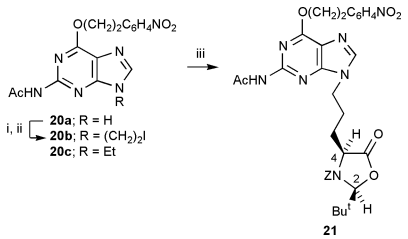


Scheme 4 *Reagents*: i, ii as Scheme 3; iii, Method B.

converted into the 1-(iodoalkyl) derivatives **14a,b** (Scheme 4). Method B applied to **14a** afforded addition product **15a** (41%) and reduction product **12c** (46%); when the reaction was left for 2 days, deacylated addition product **15b** (51%) was isolated. Homologue **14b** gave debenzoylated adduct **15d** (44%) with reduced material **12d** (51%).‡ In the purine series, the 9-(iodoalkyl)adenines **17a,b** were prepared from (2-methylpropionyl)adenine **16**[14] (Scheme 5). Using method B, iodoethyl compound **17a** led to the expected mixture of conjugate addition [40%; acylated **18a** (26%) and deacylated **18b** (14%)] and reduction [36%; acylated **19a** (17%) and deacylated **19b** (19%)]. Iodopropyl derivative **17b** likewise gave adducts [22%; acylated **18c** (12%) and deacylated **18d (**10%)] and reduced compounds [34%; acylated **19c** (11%) and deacylated **19d** (23%)]. Finally, a protected guanine **20a**[15] was converted into the 9-iodoethyl derivative **20b** (Scheme 6) and method A led to adduct **21** (21%) and reduction to **20c** (20%).

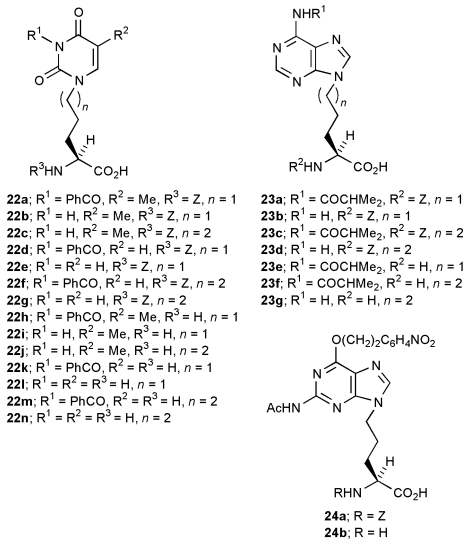


Scheme 5 *Reagents*: i, ii as Scheme 3; iii, Method B.



Scheme 6 *Reagents*: i, ii as Scheme 3; iii, Method A.

The illustrated conjugate radical addition products were all *syn*-adducts, as determined by NOE studies [enhancements between C-2(H) and C-4(H)]. Only one diastereoisomer was visible in the ^{1}H NMR spectra at 300 MHz. All of these *syn*-oxazolidinones could be easily and efficiently converted into *N*-benzyloxycarbonyl-(*S*)-amino acids (suitable for peptide coupling) by base hydrolysis (LiOH, aq. THF, 0 °C, 30–60 min; 70–98%). Thus the three thymine-substituted Z-amino acids **22a–c** (having 3- or 4-carbon tethers for the pyrimidine) were prepared from the adducts **11a**,**b**,**d**, respectively. The uracil Z-amino acids **22d–g** were likewise prepared from adducts **15a–d**, respectively, as were adenine derivatives **23a–d** (from **18a–d**, respectively) and guanine Z-amino acid **24a** (from **21**). To monitor optical purity, the Z group was removed by hydrogenolysis (Pd–C, EtOH–H_2O; 60–80%) to afford the amino



acids **22h–n**, **23e–g** and **24b**, analysed by esterification (AcCl, EtOH, reflux) and subsequent conversion to the Mosher amides (*R*-3,3,3-trifluoro-2-methoxy-2-phenylpropanoyl chloride, pyridine);[16] ^{19}F NMR spectroscopy revealed, *e.g.* 86–91% e.e. for the amino acids **22i**,**j**,**l**,**m**, and **23f**.

We have thus made available a range of novel pyrimidinyl and purinyl amino acids for application, for example, in PNA variants.

We thank the Open University for financial support (competitive studentship to D. J. C. B.) and the EPSRC National Mass Spectrometry Service Centre (Swansea) for some MS data.

Notes and references

‡ The yield of **15d** could be increased to 62% by using 5 mol equiv. of acceptor **8** in method B, but we more usually used 2 mol equiv. of this valuable optically active intermediate. When less than 2 mol equiv. $NaBH_3CN$ was used, some of the benzoylated adduct **15c** was isolated.

Conformationally stressed phthalocyanines: the non-planarity of the 1,4,8,11,15,18,22,25-octaisopentyl derivative

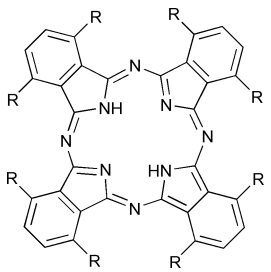
Isabelle Chambrier, Michael J. Cook* and Paul T. Wood

School of Chemical Sciences, University of East Anglia, Norwich, UK NR4 7TJ

Received (in Cambridge, UK) 25th August 2000, Accepted 21st September 2000
First published as an Advance Article on the web

An X-ray crystal structure determination reveals that 1,4,8,11,15,18,22,25-octaisopentylphthalocyanine adopts a saddle conformation, a geometry which shows modified spectroscopic properties and reduced photostability relative to planar ring structures.

Phthalocyanines (Pcs) are important commercial dyes and pigments[1] but their interesting photophysical and conducting properties[2] also render them suitable for a number of 'high-tech' applications. Examples are used as charge carriers in photocopiers, as dyes in laser/LED printing[3] and as laser light absorbers for optical data storage systems.[4] Others are promising candidates for exploitation in devices such as solar cells,[5] gas sensors[6] and optical limiters[7] and, in medicine, as singlet oxygen photosensitizers for photodynamic therapy (PDT)[8] and as a therapy for transmissible spongiform encephalopathies.[9] Such developments have benefited from the ease of tuning or modifying the properties of the ring system. Principal strategies involve ring substitution and incorporation of a metal ion or metalloid element at the centre of the ring. However, the effect of ring conformation on properties has not been adequately addressed, a situation in marked contrast with studies of ring distortion of the related porphyrin[10] and tetrabenzoporphyrin[11] systems. X-Ray structure determinations[12] show that **1** is essentially planar, allowing maximum delocalisation of the π electron system. Analogues of **1** metallated with first row transition metal ions are similar but larger metal ions, *e.g.* Pb and Sn, distort the geometry.[12] The present paper is concerned with the use of substituents alone to distort ring geometry through conformational stress. Previous X-ray studies on substituted Pcs, though few,[12] include those for two non-peripherally substituted metal-free derivatives, **2**[13] and **3**.[14] The macrocyclic cores show some limited distortion from planarity, *vide infra*, but potential conformational stress involving substituents is largely relieved through the location of some of them orthogonal to the ring. Here we report results for **4**,[15] an octaalkyl derivative in which the point of branching of the chain is one bond closer to the core than in **3**. The greater steric congestion leads to a saddle shaped conformation of the ring without precedent in the published literature on non-metallated Pc derivatives.[16] Solution phase spectroscopic properties and photostability of **4** are compared with those of **2** and the straight chain isomer of **4**, *viz.*, **5**.



1 R = H
2 R = $(CH_2)_5CH_3$
3 R = $O(CH_2)_2CH(CH_3)_2$
4 R = $(CH_2)_2CH(CH_3)_2$
5 R = $(CH_2)_4CH_3$

DSC analysis of **4**, recrystallised from THF–MeOH, indicated there is a crystal to crystal transition at 263 K. The X-ray crystal structure of **4**† at rt shows that the compound crystallises in the centrosymmetric space group *C*2/*c*. The asymmetric unit consists of half a molecule with the other half being generated by a 2-fold rotation axis. However, there is disorder in the positions of some of the atoms in the alkyl chains and evidence of considerable thermal motion. An attempt to model the disorder better by determining the crystal structure at low temperature was thwarted by the structural phase transition at 263 K. On approaching this temperature the crystal began to lose integrity as shown by smearing out of the diffraction spots into arcs.

The rt data reveal unambiguously that the central core of the molecule deviates markedly from planarity forming a saddle shape, Fig. 1a and 1b. The dihedral angles between the pair of planes formed by the isoindole units on either side of the core are both 32.0°. The two crystallographically distinct five membered rings make angles at 18.0 and 11.3° with the mean plane generated by the four pyrrole type nitrogens. The calculated positions of the hydrogen atoms attached to nitrogen are therefore out of this plane. The molecules pack together to form stacks, Fig. 1b, which run along the crystallographic *c* axis. This involves a number of π-stacking interactions, the shortest of which is 3.686 Å. The ring conformation of **4** differs significantly from that adopted by **2**,[13] shown in Fig. 1c for comparison. Here isoindole units on opposite sides of the ring are located in parallel planes. The distances between one pair of planes is 0.3 Å, for the other it is 0.15 Å.

Table 1 includes spectroscopic data for **2**, **4** and **5**. Comparison of those for **2** and **4**, the two compounds for which crystal structure data are now available, shows there are clear differences. In particular, the visible region absorption bands, Q_x and Q_y, of **4** show a bathochromic shift and lowering of the extinction coefficient relative to those of **2.** This is consistent with the trend detected upon distortion from planarity of the 18 π electron system of porphyrins[10] and indicates that the non-planar structure of **4** persists in the solution phase.

^{1}H-NMR spectral data obtained from dilute solutions at 50 °C, conditions devised to limit aggregation, show that the N-*H* signal of **4** is to lower field than for **2**. This may point to differences in the degree of aggregation for the two compounds and/or indicate a weaker ring current in **4** attributable to the greater departure of the cyclic π electron system from planarity. ^{1}H-NMR spectra of **4** recorded down to −70 °C in THF-d_8 solution showed broadening and separation of two sets of signals for the benzylic protons. However, there is no coupling between them and we therefore assign the phenomenon to slowing of N–H tautomerism rather than slowing of conformational inversion of a saddle structure for the ring itself. The latter would render the CH_2 protons diastereotopic.

Spectral data for **5** are more similar to those of **2** than **4**. The Q-band extinction coefficient and shielding of the N–H protons is highest for **5** and offers an indication that the core of **5** may be the least distorted of all three compounds. The data highlight the potential for using spectroscopic parameters for assessing Pc ring conformation in the solution phase.

Phthalocyanines are known to undergo photooxidative cleavage, particularly in the solution phase, leading to phthalimide derivatives.[17] Though a potential problem for the use of these compounds in devices, photobleaching of Pc photosensitizers in PDT treatment may provide a means of facilitating their removal from patients. Photobleaching of **2**, **4** and **5** as solutions

DOI: 10.1039/b006935n

Table 1 Comparative spectroscopic and photodecomposition data for compounds **2**, **4** and **5**.

Solvent or medium	Parameter	Compound **2**	Compound **4**	Compound **5**
THF	λ_{max} Q$_x$ ($\varepsilon \times 10^{-5}$)[a]	728 nm (1.68)	731 nm (1.55)	728 nm (1.77)
THF	λ_{max} Q$_y$[a]	696 nm (1.47)	701 nm (1.34)	696 nm (1.54)
KBr disc	ν_{N-H}	3297 cm^{-1}	3302 cm^{-1}	3297 cm^{-1}
$CHCl_3$	ν_{N-H}	3308 cm^{-1}	3310 cm^{-1}	3308 cm^{-1}
10^{-3}M, C_6D_6	δ_{N-H} (50 °C)	−0.148 ppm	−0.052 ppm	−0.165 ppm
THF	rel. k $_{(photodecomp.)}$[b]	1.13	1.43	1.00

[a] ε values were obtained from the Beer–Lambert plots over the concentration range 5×10^{-7} to 5×10^{-5}M. The plots remained linear up to 1×10^{-4} M. [b] Relative pseudo first order rates of photodecomposition in aerated solutions of compounds upon irradiation using UV lamps, starting molarity 10^{-5} M.

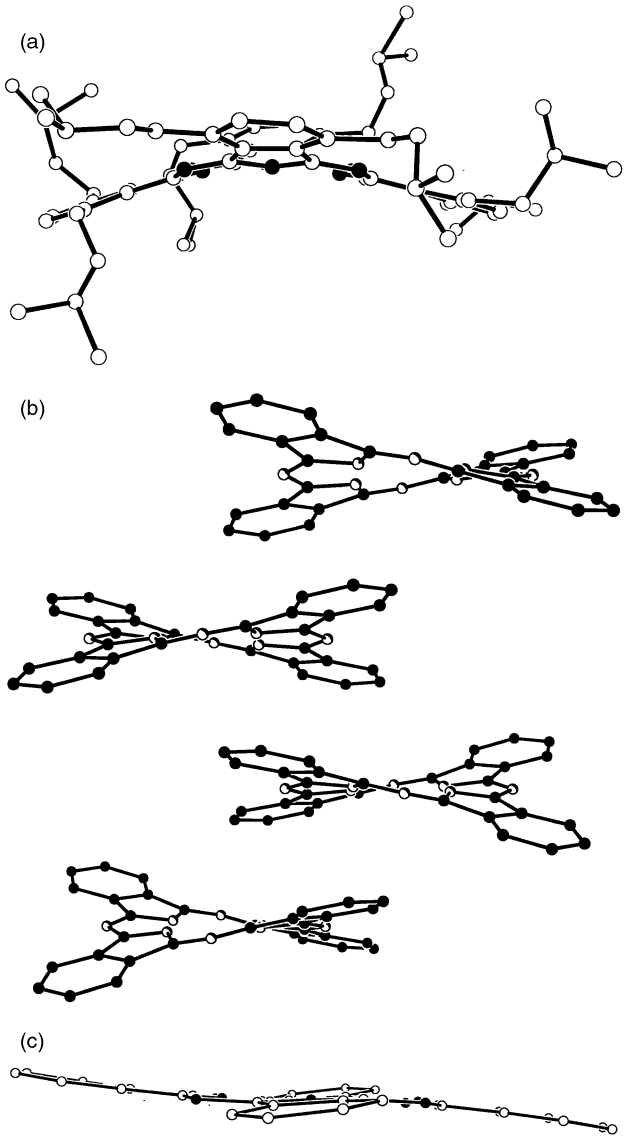


Fig. 1 (a) Representation of the molecular structure of 1,4,8,11,15,18,22,25-octaisopentylphthalocyanine, **4**. (b) The structure with the alkyl chains removed for clarity and illustrating the stacking of the molecules within a column. (c) A view of the ring conformation of compound **2**[13] with the hexyl groups removed.

in THF was monitored by the disappearance of the Q-band on UV irradiation (S.Y.L.V.A.N.I.A. Blacklight-blue, 8 W), (Table 1). The consumption of compound followed first order kinetics with the rate of photobleaching slowest for **5** and fastest for **4**. This is likely to be a further manifestation of the significant ring distortion of **4**.

In conclusion, the work demonstrates that the conformation of the Pc ring can be adjusted by judicious choice and location of substituents leading to a concomitant fine tuning of spectroscopic properties and photochemical stability.

This work was undertaken as a contribution to projects run under the auspices of CEC COST programme 514 and CEC RTN contract HPRN-CT-2000-00020.

First published as an Advance Article on the web

The tribenzyl complex (Pr^i_2tacn)Zr(CH_2Ph)$_3$ eliminates toluene upon heating with concomitant ring-opening of the anionic ancillary macrocycle to yield [CH_2=CHNCH_2-CH_2N(Pr^i)CH_2CH_2NPr^i]Zr(CH_2Ph)$_2$; the latter features a new class of dianionic pincer ligand.

Non-metallocene complexes of Group IV metals have recently been the subject of renewed interest due to the realization that new ligand environments might result in novel patterns of reactivity.[1–3] For example, Group IV metal complexes bearing bi-[4–8] or tridentate[9–15] diamide ligands have attracted attention as potential alternatives to the classical homogeneous Ziegler–Natta polymerization catalysts that are mostly based on bis- or monocyclopentadienyl ligands. In contrast, tridentate mono-amide ligands have received scant attention, an exception being the tridentate, acyclic monoanion, [($Me_2NCH_2SiMe_2$)$_2$N]$^-$, for which Ti, Zr and Hf derivatives have been described.[16]

We[17] and others[18] recently described the use of the lithium salt of diisopropyltriazacyclonone as a synthon in the development of new constrained-geometry ligand systems.[17,18] By utilizing a ligand system in which the nitrogen donors are part of a macrocycle, we reasoned that metal complexes would necessarily bind the azamacrocycle facially, in closer analogy to cyclopentadienyl complexes. Here we report the use of this fragment as an anionic, tridentate diamino-amido ancillary ligand for the stabilization of zirconium complexes and the conversion of this ligand into a dianionic acyclic variant.

As shown in Scheme 1, {(Pr^i_2tacn)Li}$_2$ reacts with $ZrCl_4(THF)_2$ in THF to yield the mono-ligand complex, (Pr^i_2tacn)$ZrCl_3$ **1** as an analytically-pure pale yellow solid in low yield. Alternately, **1** can be synthesized *via* a two-step process in nearly 90% overall yield: reaction of (Pr^i_2tacn)H with Zr(NEt_2)$_4$ quantitatively generates (Pr^i_2tacn)Zr(NEt_2)$_3$ **2** as a yellow oil which is sufficiently clean to be used without further purification. The latter reacts smoothly with excess Me_3SiCl in hot toluene to give **1**, which precipitates in pure form. Compound **1** is soluble in methylene chloride and only sparingly soluble in solvents such as THF, diethyl ether or toluene.

(Pr^i_2tacn)H reacts with Zr(CH_2Ph)$_4$ in diethyl ether to form the tribenzyl species (Pr^i_2tacn)Zr(CH_2Ph)$_3$ **3** in good yield. Compound **3** may also be synthesized from the trichloride **1** and 3 equiv. of benzyl Grignard, although the former reaction is substantially cleaner. The ^{1}H NMR spectrum of **3** shows a doublet for the diastereotopic isopropyl resonances and the methylene protons of the triazacyclononane ring appear as broad singlets. Also, the two isopropyl methyl groups give rise to a single peak in the {^{1}H}^{13}C NMR spectrum (18.9 ppm) in contrast to the two distinct singlets observed for **1** (19.5 and 18.1 ppm). The six benzylic protons are equivalent on the NMR time scale, resulting in a singlet in the ^{1}H NMR spectrum (2.71 ppm) and a broad resonance in the {^{1}H}^{13}C NMR spectrum (76.1 ppm).

Compound **3** is monomeric in the solid-state (see Fig. 1)† with the triazacyclononane ring attached facially to the metal through all three nitrogen atoms. The zirconium center is best described as distorted octahedral, with the N–Zr–C_{trans} angles ranging from 152.06(8) to 159.46(7)°; additionally, the three C–Zr–C angles vary from 91.10(8) to 96.33(9)°. Two of the benzyl

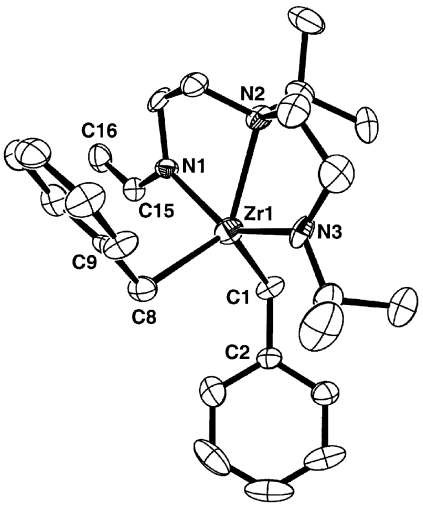

Fig. 2 ORTEP view of $[CH_2{=}CHNCH_2CH_2N(Pr^i)CH_2CH_2N\text{-}Pr^i]Zr(CH_2Ph)_2$ **4** drawn with 50% probability ellipsoids. Selected bond distances (Å) and angles (°): Zr1–N1 2.131(5), Zr1–N2 2.410(5), Zr1–N3 2.043(5), Zr1–C1 2.289(6), Zr1–C8 2.295(6), C15–C16 1.317(9); N1–Zr1–N2 71.3(2), N1–Zr1–N3 142.3(2), N1–Zr1–C1 100.5(2), N1–Zr1–C8 94.3(2), N2–Zr1–N3 71.5(4), N2–Zr1–C1 124.3(2), N2–Zr1–C8 125.1(2), N3–Zr1–C1 105.3(2), N3–Zr1–C8 101.9(2), C1–Zr1–C8 110.2(2), Zr1–C1–C8 114.7(2), Zr1–C8–C9 109.2(4).

ligands are positioned with their phenyl rings pointing downwards with respect to the tacn ring, while the third has its phenyl ring pointing upwards, being disposed almost parallel to the azamacrocycle. Two of the benzyl groups possess normal Zr–C–C bond angles (113.7(2) and 116.3(2)°) while the third displays an angle that is larger than expected (Zr1–C15–C16 = 133.5(2)°). The disposition of the benzyl groups is similar to that found for $Cp^*Ti(CH_2Ph)_3$, in which a single anomalous Ti–C–C angle is a consequence of a double agostic CH_2–Ti interaction.[19] Owing to the broadness of the peak arising from the benzylic methylene groups in the $\{^1H\}^{13}C$ NMR spectrum, we were unable to extract the C–H coupling constant to determine if any additional interaction was present in our case; it is likely that this unusually large angle is a result of packing forces in the crystal.

Heating $(Pr^i_2tacn)Zr(CH_2Ph)_3$ **3** for 24 h at 80 °C results in elimination of one equiv. of toluene and complete conversion to a new metal complex. The ^1H NMR spectrum reveals a total lack of symmetry in solution as evidenced by the presence of four isopropyl methyl doublets and separate multiplets for each of the methylene protons of the ligand backbone. Particularly diagnostic of this new species are resonances consistent with a vinyl group; a doublet of doublets corresponding to one olefinic proton is present at 7.92 ppm ($^3J_{H\text{-}H'}$ = 8.4, $^3J_{H\text{-}H''}$ = 14.8 Hz) with the other two protons of the vinyl unit giving rise to two doublets farther upfield (4.12 ppm, $^3J_{H\text{-}H'}$ = 8.4 Hz; 3.93 ppm, $^3J_{H\text{-}H''}$ = 14.8 Hz). These conclusions are supported by $\{^1H\}^{13}C$ NMR spectroscopy which shows four separate isopropyl methyl peaks, two isopropyl methine resonances and distinct peaks for four methylene groups of the ancillary ligand. ^{13}C DEPT experiments allowed the vinyl resonances to be assigned (143.1 and 79.0 ppm); the presence of a vinyl group is visible in the IR spectrum which shows a strong absorption in the olefinic region (*ca.* 1600 cm^{-1}).

To further investigate the structure of the thermolysis product, we turned to X-ray diffraction (Fig. 2).† The ORTEP of **4** shows that the zirconium center is coordinated by two benzyl groups and a new tacn-derived pincer ligand in which the original anionic, macrocyclic, diamino-amido ligand has been transformed into a dianionic, acyclic, diamido-amino moiety. Additionally, one of the ethylene units of the triazacyclononane ring has been converted into a vinyl group (C15–C16). The zirconium center is best described as distorted trigonal bipyramidal, with N1 and N3 occupying the axial sites (N1–Zr1–N3 = 142.3(2)°). Both amido nitrogens in **4** display trigonal planar geometries, with the sum of the three angles subtended by nitrogen approaching 360°. The metal center displays two short zirconium–nitrogen bonds (Zr1–N1 = 2.131(5), Zr1–N3 = 2.043(5) Å) and one longer bond (Zr1–N2 = 2.410(5) Å) consistent with a diamido-amino ligand. The benzyl groups are unremarkable (Zr–C–C_{benzyl} = 109.2(4), 114.7(4)°), although they are inequivalent by ^1H and ^{13}C NMR spectroscopy. This implies that the structure observed in the solid state is maintained in solution, and the benzyl groups are not averaged by some fluxional process as is observed for tribenzyl **3**.

In order to test the generality of this reaction, $(Pr^i_2tacn)ZrCl_3$ **1** was reacted with three equiv. of RLi (R = Me, CH_2SiMe_3, Ph). The NMR spectra of these products also indicate the formation of $[CH_2{=}CHNCH_2CH_2N(Pr^i)CH_2CH_2NPr^i]ZrR_2$ with the elimination of the corresponding alkane. A related ligand decomposition has been observed for the tantalum species $[N_3N]TaMe_2$ ($[N_3N] = [N(CH_2CH_2NSiR_3)_3]^{3-}$, R = Me[20], Et[21]). Thermolysis of the deuterated complex $(Pr^i_2\text{-}tacn)Zr(CD_2C_6D_5)_3$ affords C_7D_7H, ruling out α-hydrogen abstraction and a benzylidene intermediate. A more detailed study of the kinetics and mechanism of this ring-opening reaction will be reported shortly, along with other examples of the synthetic utility of $(Pr^i_2tacn^-)$.

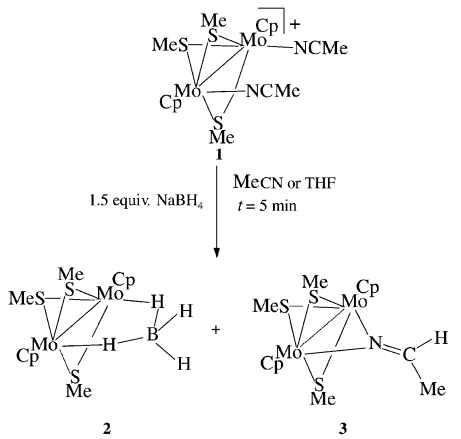
First published as an Advance Article on the web

The reaction of $NaBH_4$ with the bis-nitrile compound $[Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2](BF_4)$ 1 unexpectedly gives rise to the rare, stable μ-(η¹-H):(η¹-H) tetrahydroborato complex $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}BH_4)]$ 2, in addition to the expected azavinylidene product $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}NCHMe)]$ 3.

The versatility shown by the tetrahydroborate anion in binding to transition metal ions is well known: it can bind *end-on* to a single metal atom through one, two or three hydrogen atoms [η¹-H, η²-H,H or η³-H,H,H modes] or *side-on via* an η²-B,H interaction.[1,2] The same variable hapticity is observed in metal clusters: BH_4^- can link two metal atoms through μ-(η³-H,H,H):(η³-H,H,H), μ-(η²-H,H):(η²-H,H), μ-(η¹-H):(η¹-H) or μ-(η²-H,H):(η¹-H) bridges.[2] Of these four bridge types only the $\{M_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}BH_4)\}$ core, which is a straightforward modification of the *end-on* η²-H,H mode of coordination, is relatively common. The $\{M_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}BH_4)\}$ bridge is particularly rare: we know only of single structurally characterized examples for three metals: Ir, Ru and Mn.[3–5] The three complexes involved each contain H^- as well as BH_4^- ligands and were obtained during studies of the synthesis and reactivity of polyhydride complexes in whose formation they are thought to be intermediate.[3,4]

We now report that $NaBH_4$ in acetonitrile reacts readily at room temperature with the bis-nitrile compound $[Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2](BF_4)$**1**[6] to afford a true μ-η¹-η¹-tetrahydroborate bridge in the novel, diamagnetic complex $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}BH_4)]$ **2**, together with the azavinylidene product $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}NCH(Me)]$ **3**. Formation of **2** involves substitution of the two acetonitrile ligands by BH_4^-, while the azavinylidene species **3** arises from the transfer of hydride to a coordinated acetonitrile (Scheme 1). Complexes **2** and **3** were obtained in different ratios which depend upon the solvent: **2**:**3** = 80:20 in MeCN but 20:80 in THF. They were separated by chromatography on a silica gel column using hexane–dichloromethane as eluent. Recrystallisation of **2** and **3** from diethyl ether afforded orange crystals.† **2** and **3** have been fully characterized by NMR and IR spectroscopy, microanalysis, and single crystal X-ray analysis.‡§



Scheme 1

The IR and $^{11}B\{^1H\}$ NMR spectra both revealed the presence of coordinated borohydride in **2**. In the $^{11}B\{^1H\}$ NMR spectrum a single broad resonance at δ −27.0 confirmed these assignments. The ^1H NMR spectrum displayed a broad high-field resonance at δ −15.79 (in $CDCl_3$) assignable to two equivalent Mo–H–B bridges. The detection of the two terminal hydrogens bound to the boron atom, at δ 2.32 and 1.28, required the recording of a ^1H spectrum with selective ^{11}B decoupling. The results of 2D ^1H–^1H and ^1H–^{11}B correlation NMR experiments are in accord with these assignments. A ^{11}B-decoupled ^1H–^1H 2D-experiment showed the two resonances at δ 2.32 and 1.28, to be coupled to each other and also to the peak at δ −15.79 (in toluene-d_8), and a ^1H–^{11}B inverse-correlation experiment confirmed that these protons are bound to the boron atom. The well resolved $^2J_{HH}$ couplings (*ca.* 18, 3 and 3 Hz) suggested significant deviations from regular tetrahedral coordination at the boron atom. Moreover, the observation of these couplings at room temperature and further variable temperature NMR experiments between 293 and 363 K implies that the commonly observed interchange of bridging and terminal hydrogens in BH_4 does not occur in **2** in this temperature range. The structure of **2** (Fig. 1)§ involves covalent interaction of the $\{Mo_2Cp_2(\mu\text{-}SMe)_3\}^+$ moiety with a BH_4^- anion through two bent 3c–2e Mo–H–B bonds [Mo–H_b 1.87(5), 1.84(5); B–H_b 1.19(5), 1.20(5) Å; Mo–H–B 121(3), 125(3)°]. The molecule contains a distorted tetrahedral μ-η¹:η¹-BH_4 ligand in which the bridging B–H_b bonds are somewhat longer than the terminal B–H_t bonds

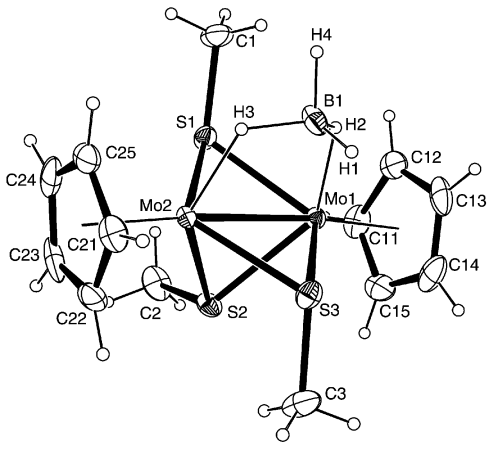


Fig. 1 An ORTEP drawing (20% thermal ellipsoids) of the complex $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}BH_4)]$ **2**. Selected bond lengths (Å) and angles (°): Mo1–Mo2 2.653(1), Mo1–S1 2.4544(12), Mo1–S2 2.4313(12), Mo1–S3 2.4499(12), Mo2–S1 2.4513(11), Mo2–S2 2.4280(12), Mo2–S3 2.4531(12); Mo2–S1–Mo1 65.48(3); Mo2–S2–Mo1 66.18(3), Mo2–S3–Mo1 65.52(3); Mo1–H2 1.87(5), Mo2–H3 1.84(5), B1–H2 1.19(5), B1–H3 1.20(5), B1–H1 1.08(5), B1–H4 1.11(5); H2–B1–H4 96(3), H3–B1–H4 98(3), H1–B1–H2 118(4), H1–B1–H3 115(4), H2–B1–H3 110(3), H1–B1–H4 116(4), Mo1–H2–B1 125(3), Mo2–H3–B1 121(3). Minor disorder sites of the bridging ligands [occupancy 5.6(2)%] are not shown.

DOI: 10.1039/b006457m

[B–H_t 1.08(5), 1.11(5) Å]. The Mo–B distances [2.681(6), 2.711(6) Å] are nearly equal and their length suggests that there is little or no direct Mo–B bonding. Indeed, they are longer than the single Mo–Mo bond [2.653(1) Å]. In all other {$M_2(\mu\text{-}\eta^1:\eta^1\text{-}BH_4)$} bridge systems the M–B distances are shorter than the M–M bond length. Thus, in the diiridium complex [$Ir_2(C_5Me_5)_2H_3(\mu\text{-}BH_4)$] the Ir–B distances are 2.214(4) Å, compared with an Ir–Ir bond length of 2.823(1) Å. In this case it has been suggested that the two bridging hydrogen atoms of the BH_4^- ligand are almost completely transfered to the iridium atoms and that the BH_4^- coordination should be described as $\mu\text{-}(\eta^2\text{-}B,H):(\eta^2\text{-}B,H)$ rather than $\mu\text{-}(\eta^1:\eta^1\text{-}BH_4)$.[3] In the dimanganese species [$Mn_2(\mu\text{-}H)(\mu\text{-}BH_4)(CO)_6(\mu\text{-}Ph_2PCH_2PPh_2)$][5,7] the Mn–B distances [2.557(3), 2.607(4) Å] are again shorter than the Mn–Mn bond length [2.989(1) Å] and may indicate some direct Mn–B bonding. The Mn–H bond lengths [1.65(4), 1.68(4) Å] are slightly shorter than the Mo–H distances in **2**. The B–H_b [1.24(4), 1.18(4) Å] and B–H_t [1.08(4), 1.09(4) Å] distances are comparable with those in **2** indicate that hydrogen transfer from boron to the metal atoms is small compared with the Ir_2 complex. The third example of a $\mu\text{-}(\eta^1:\eta^1\text{-}BH_4)$ ligand is found in [$Ru_2(C_5Me_5)_2H_3(\mu\text{-}BH_4)$].[4] The Ru–B distances [2.406(4) Å] are consistent with closed 3c–2e Ru–H–B interactions though they are again shorter than the Ru–Ru bond [2.895(1) Å].[8] Two features of complex **2** appear therefore to be unprecedented: (i) the presence of a $\mu\text{-}\eta^1:\eta^1$-tetrahydroborate bridge which involves very weak or no direct interaction between boron and the metal atoms and (ii) the stability of this bridge which does not depend on the presence of H^-, as is the case with the Ir, Mn and Ru species.

The hydride transfer from BH_4^- to the dimolybdenum site is stopped at a very early stage in **2**. The reaction can also continue to completion, with hydride adding to one acetonitrile ligand, as is shown by the isolation and characterization of **3**.‡ In the IR spectrum of **3** a C≡N bond was revealed by a typical band at 1624 cm^{-1}. In the ^1H NMR spectrum a quadruplet at δ 7.69 and a doublet at δ 1.82 (J_{HH} 4.6 Hz) indicate that a hydride has been transferred to one of the acetonitrile ligands. The structure of **3** was confirmed by X-ray analysis (Fig. 2).§ It was found to consist of a typical [$Mo^{III}_2Cp_2(\mu\text{-}SMe)_3$] unit[6] bridged by the nitrogen atom of the azavinylidene N=C(H)Me ligand.

The reaction of BH_4^- with transition metal halides is a standard route to the borohydride complexes which are thought to be intermediates in the conversion of metal halides to metal hydrides.[2a] The simultaneous formation of **2** and **3** reveals a competition between the incomplete transfer of hydride to the bimetallic site and the reduction of one acetonitrile ligand (MeC≡N) into an azavinylidene group (MeCH=N), this latter transformation being favored in THF rather than in acetonitrile. Finally, the four known structural examples of $M_2(\mu\text{-}BH_4)$ system may represent different stages in the double σ-activation of an XH_4 entity at a bimetallic site: in **2** and in the Mn complex the H atoms bridge M and B atoms which do not interact directly; in the Ir complex H transfer is nearly complete and the Ir–B distance is close to the value expected for a single bond; an intermediate stage between these extremes is illustrated by the Ru complex. Further experiments to convert **2** into dimolybdenum hydride and dimolybdenum borane complexes of higher nuclearity are now under investigation.

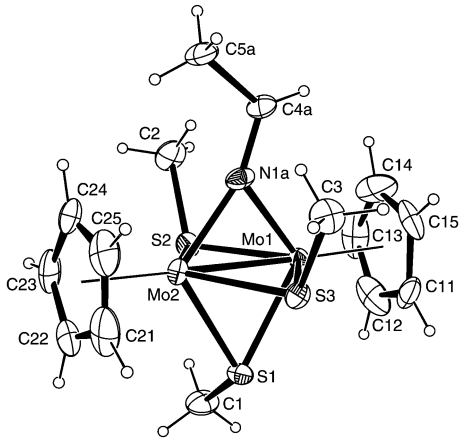

Fig. 2 An ORTEP drawing (20% thermal ellipsoids) of the complex [$Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}CHCH_3$] **3**. Selected bond lengths (Å) and angles (°): Mo1–Mo2 2.564(1), Mo1–S1 2.446(2), Mo1–S2 2.450(2), Mo1–S3 2.467(2), Mo2–S1 2.448(2), Mo2–S2 2.456(2), Mo2–S3 2.472(2), Mo1–N1A 2.089(8), Mo2–N1A 2.067(8), N1A–C4A 1.38(2), C4A–C5A 1.58(3); Mo1–S1–Mo2 63.18(5), Mo1–S2–Mo2 63.01(5), Mo1–S3–Mo2 62.54(5), Mo1–N1A–Mo2 76.2(2). Random disorder of the azavinylidene C atoms over two sites is not shown.

† *Experimental procedure:* A solution of **1** (0.2 g, 0.32 mmol) in acetonitrile (10 mL) [or a suspension of **1** in thf (10mL)] was treated with $NaBH_4$ (20 mg, 0.53 mmol) at room temperature. The red solution turned readily to orange. After stirring for 5 min the solvent was removed under vacuum and the residue was extracted with diethyl ether. This extract was chromatographed on a silica gel column and elution with hexane–dichloromethane gave two orange bands of **2** and **3**. Recrystallisation from diethyl ether of the two fractions afforded orange crystals of **2** (92 mg, 60%, in MeCN) and **3** (8 mg, 5%, in MeCN). Anal. for $C_{13}H_{23}BMo_2S_3$ **2**. Calc.: C, 32.6; H, 4.8; B, 2.3. Found: C, 32.4; H, 4.8; B, 2.0%. Anal. for $C_{15}H_{23}NMo_2S_3$ **3**. Calc.: C, 35.6; H, 4.6; N, 2.8. Found: C, 35.9; H, 4.7; N, 2.8%.

The synthesis of the largest perfluoro macrocycles; perfluoro [60]-crown-20 and perfluoro [30]-crown-10†

Han-Chao Wei and Richard J. Lagow*

Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712-1167, USA. E-mail: rjlagow@mail.utexas.edu

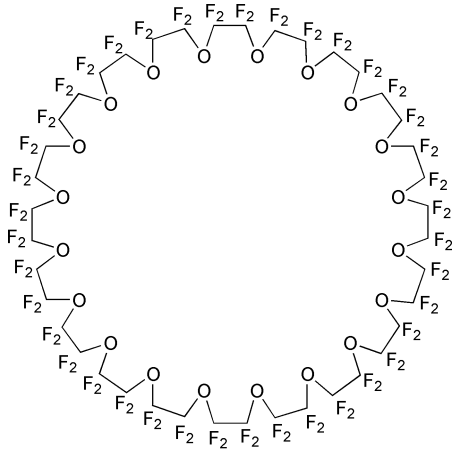
Received (in Columbia, MO, USA) 23rd May 2000, Accepted 22nd August 2000
First published as an Advance Article on the web 16th October 2000

The largest perfluoro macrocycles, perfluoro [60]-crown-20 and perfluoro [30]-crown-10, have been synthesized using the new continuous addition solution phase direct fluorination technique and characterized using ^{19}F NMR and mass spectrometry.

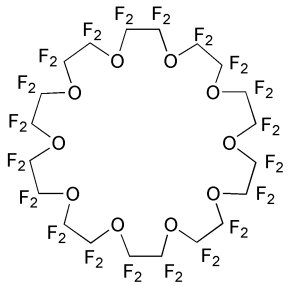
The syntheses of perfluoro crown ethers were first reported in 1985.[1] Perfluoro macrocycles have important medical applications such as ^{19}F NMR imaging and oxygen carrier applications.[2,3] Perfluoro crown ethers generally do not form stable complexes with cations because the basicities of perfluoro crown ethers dramatically decrease as the amount of fluorine substitution increases.[4,5] However, perfluoro crown ethers form complexes with anions, such as O_2^- and F^-, in gas phase reactions.[6] Prior to 1997, only thirteen perfluoro macrocycles were reported and all were synthesized by members of our fluorine research group using low temperature, below room temperature, direct fluorination synthetic techniques.[1,3,7–9] In this paper, we have explored the possible synthesis of perfluorinated organic compounds at higher temperature, above room temperature, during the initial stage of fluorination. The largest perfluoro macrocycles, perfluoro [60]-crown-20 **1** and perfluoro [30]-crown-10 **2**, have been successfully synthesized by using a new continuous addition solution phase direct fluorination technique. In the future, the synthesis of higher molecular weight perfluoro macrocycles will enable us to further explore the chemistry of the perfluoro macrocycles, such as ion complex chemistry and oxygen carrier applications.

In general, the rate of fluorination must be slow enough to allow vibrational energy relaxation processes to occur by collisions in an inert solvent. Many direct fluorination reactions are performed below room temperature during the initial stage of fluorination because reaction rates are so fast that excessive fragmentation occurs and a much lower temperature is required. We initially lowered the fluorination temperature to minimize possible ring opening reactions during fluorination of [60]-crown-20. Several first attempts to perfluorinate [60]-crown-20 at lower temperatures, 0, −10, −20 and −30 °C, during the initial stage of fluorination were unsuccessful. Interestingly, as the temperature of the initial stage of fluorination decreased, the degree of fluorination decreased and only partial fluorination occurred. These observations were confirmed by ^{1}H, ^{19}F NMR spectroscopy and mass spectrometry. Therefore, we increased the initial stage reaction temperature to 26 °C and succeeded in the synthesis of perfluoro [60]-crown-20 **1**.

At room temperature, [60]-crown-20 molecules are conformationally flexible[8] and hydrogen atoms can be replaced by fluorine even at sites which are sterically protected by the configuration of the carbon skeleton of [60]-crown-20 during fluorination. In contrast, the [60]-crown-20 molecules are less flexible at lower temperatures. Once the 'surface' hydrogen atoms of [60]-crown-20 are replaced by fluorine, the non-bonding electron cloud of the fluorine atoms tends to repel the oncoming fluorine molecules as they approach the [60]-crown-20 molecules and only partially fluorinated products are obtained. Under such vigorous fluorination conditions, higher temperature solution phase fluorination, fragmentation products were also obtained and the yield of perfluoro [60]-crown-20 was 14%. However, perfluoro [30]-crown-10 **2** was synthesized in 50% yield using the direct fluorination method with reaction temperatures escalating from −20 to 26 °C, as described in the literature.[9,10] The spectral data were in agreement with the structural assignments of perfluoro [60]-crown-20 **1** and perfluoro [30]-crown-10 **2**.[11]



1



2

In conclusion, the largest perfluoro macrocycle, perfluoro [60]-crown-20 **1** and perfluoro [30]-crown-10 **2**, were synthesized by direct fluorination and characterized using ^{19}F NMR spectroscopy and mass spectrometry. Perfluoro [60]-crown-20 **1** and perfluoro [30]-crown-10 **2** are expected to be biologically inert, in contrast to their hydrocarbon analogues, and may be useful in biological or medical applications where physiologically inert or oxygen carrying fluids are required. Perfluoro [60]-crown-20 **1** has also shown potential as a very clean, high mass compound for use as a mass spectral marker material in the chemical ionization negative mode.

11 The starting materials, [60]-crown-20 and [30]-crown-10, were synthesized by the following procedures from the literature (ref. 8). *Synthesis of perfluoro [60]-crown-20*. In a typical reaction, the direct fluorination reaction was performed in a similar manner to the reactions that have been described in the literature (ref. 9 and 10). [60]-Crown-20 (1 g) was dissolved in 1,1,2-trichloro-1,1,2-trifluoroethane (300 mL) and chloroform (3 mL), then the solution was slowly introduced into a stainless steel reactor which contained 1,1,2-trichloro-1,1,2-trifluoroethane (600 mL), sodium fluoride (100 g) and a fluorine–helium mixture. During the next 72 h the relative fluorine concentration was slowly increased. Filtration of the solution and removal of 1,1,2-trichloro-1,1,2-trifluoroethane by simple distillation produced a white waxy solid and a viscous oil. The product was purified by preparative gas chromatography on an OV-210 column at 200 °C. Pure perfluoro [60] crown-20 was collected by preparative GC as white waxy solid in 14% yield. Negative chemical ionization mass spectrometry: *m/z* (formula, identification, intensity) 2320 ($C_{40}F_{80}O_{20}$, M^-, 100). The elemental compositions were studied by high resolution mass spectrometry in chemical ionization negative mode. The results were consistent with $C_{40}F_{80}O_{20}$ (Calc.: 2319.7706; Found: 2319.7688). ^{19}F NMR ($CFCl_3$) δ −89.45 (s, 80F). *Synthesis of perfluoro[30]-crown-10*. Perfluoro [30]-crown-10 was synthesized in a similar manner to perfluoro [60]-crown-20. The product was purified by preparative gas chromatography on a OV-210 column at 150 °C. Pure perfluoro [30]-crown-10 was collected by preparative GC as a colorless liquid in 50% yield. Fast atom bombardment (FAB) mass spectral analysis (negative mode): *m/z* (formula, identification, intensity) 1159 ($C_{20}F_{40}O_{10}$, M^-, 100). The elemental compositions were studied by high resolution mass spectrometry in FAB negative mode. The results were consistent with $C_{20}F_{40}O_{10}$ (Calc.: 1159.8853; Found: 1159.8844). ^{19}F NMR ($CFCl_3$) δ −89.48 (s, 40F). More experimental details are described in ESI.†

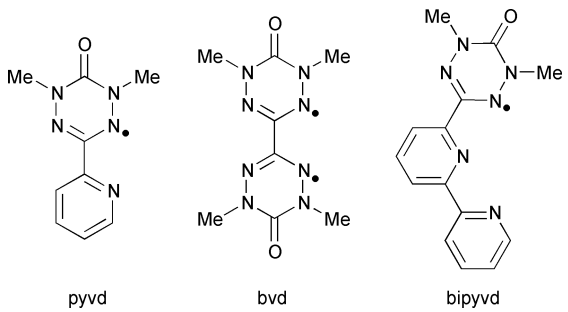
Received (in Irvine, CA, USA) 1st August 2000, Accepted 25th September 2000
First published as an Advance Article on the web

Magnetic susceptibility measurements on a structurally characterized nickel(II) complex of a tridentate verdazyl radical indicate very strong ferromagnetic Ni–verdazyl intramolecular exchange interactions (J > +200 cm^{-1}).

Metal complexes of coordinated radicals have been actively pursued as components of new molecular magnetic materials. A principal advantage of paramagnetic ligands is that direct magnetic exchange coupling between metal and ligand spins is possible. Although a large number of metal–radical systems have been studied, the *variety* of radical-based ligands is somewhat limited. Most work has been carried out with ligands based on the nitroxide family[1–3] and TCNE[4] and TCNQ[5] radical anions, although there has been a growing interest in exploring alternative radicals as ligands.[6] Derivatives of the verdazyl radical family[7] offer an attractive alternative to the conventional radical ligands because of their abundance of donor atoms. Verdazyls such as pyvd and bvd possess chelating environments that are excellent structural mimics of 2,2′-bipyridine and 2,2′-bipyrimidine, respectively, and transition metal complexes of both radicals have been reported.[8–11] Given the huge interest and success in employing oligopyridines as ligands in metallo-supramolecular chemistry,[12–14] it is appealing to consider creating oligopyridine analogues in which one or more of the heterocyclic rings is replaced by a verdazyl radical. The preservation of the chelating environment makes such systems attractive both for self-assembly processes and for the desirable metal–radical exchange coupling. As an initial foray in this direction, we present the synthesis, coordination chemistry, and magnetic properties of a nickel complex of the tridentate verdazyl 1,5-dimethyl-3-(2,2′-bipyridin-6-yl)-6-oxoverdazyl, bipyvd, a radical that possesses a coordination pocket analogous to that of 2,2′:6′,2″-terpyridine.



The bipyvd ligand was prepared[15] from 2,2′-bipyridine-6-carbaldehyde[16] using established procedures.[17,18] Reactions of bipyvd with $NiCl_2$ in the presence of $NaPF_6$ produced Ni(bipyvd)$_2^{2+}$·2PF_6^- (**1**) which crystallized as an acetone solvate.‡ Fig. 1 shows the molecular structure of the cation of **1**, which consists of two tridentate bipyvd ligands surrounding the nickel ion in a pseudo-octahedral coordination sphere.§ The local geometry at the nickel is D_{2d} distorted from ideal octahedral geometry, as is also the case for structurally characterized Ni(terpy)$_2^{2+}$ complexes.[19,20] The six Ni–N bonds occur in three pairs with a distinct progression of bond lengths: two short bonds to each of the central pyridine nitrogens (N5 and N11, mean bond length 1.996 Å), two slightly longer bonds to the terminal pyridine nitrogens (N6 and N12, 2.098 Å) and two yet longer bonds to the verdazyl ring nitrogens (N1 and N7, 2.211 Å). The structural features of the verdazyl rings of the ligands are quite similar to other 1,5-dimethyl-6-oxoverdazyls, although there is a slight asymmetry in the bond lengths and angles induced by coordination to nickel (see supporting information). Each of the two bipyvd ligands are essentially planar and are oriented perpendicular to one another, with an interligand dihedral angle of 92.4°. Overall, the general structural features of this complex, particularly with respect to the local coordination environment at Ni, are strongly reminiscent of Ni(terpy)$_2^{2+}$-based systems,[19,20] further validating the *structural* analogy between oligopyridine-substituted verdazyls and the 'parent' oligopyridines.

The UV–visible spectrum of **1** exhibits an absorption maximum at 438 nm (ε = 5700 L mol^{-1} cm^{-1}), which is slightly red shifted with respect to the spectrum of free bipyvd (λ_{max} = 400 nm, ε = 1900). The complex is therefore appropriately described as consisting of a nickel(II) center and two radicals. The temperature dependence of the effective

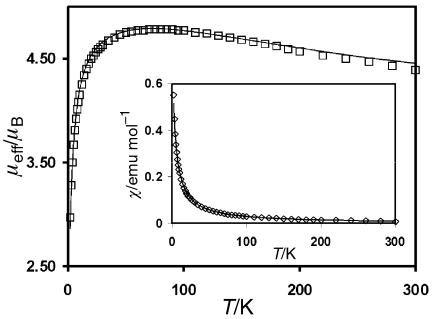

Fig. 2 Plot of μ_{eff} *vs.* T for **1**. The solid line corresponds the model fit according to parameters described in the text. The inset displays the corresponding χ *vs.* T profile.

magnetic moment of **1** is presented in Fig. 2.¶ The room temperature value (4.4 μ_B) is significantly higher than that expected for a non-interacting $S = 1$ Ni^{II} ion and two $S = \frac{1}{2}$ radicals (3.9 μ_B for $g = 2.1$). As the temperature decreases, μ_{eff} increases to a maximum value of 4.8 μ_B at 85 K and then rapidly decreases on further cooling. The high temperature behaviour provides evidence for strong ferromagnetic interactions between the Ni^{II} spins and each of the two radical centers. The magnetic data were fitted to a three-spin model in which the two radicals ($S_{A1} = S_{A2} = \frac{1}{2}$) are both ferromagnetically coupled to a nickel ion ($S_B = 1$) by exchange constant J_1 and coupled to each other with value J_2. Attempts to model the magnetic behaviour of **1** yielded several different solutions with essentially the same quality fits to the experimental data. In these various solutions, the radical–radical coupling J_2 varied from +40 to −70 cm^{-1}, precluding any firm conclusions regarding the nature of the magnetic interactions between coordinated radicals. The metal–radical exchange J_1 was also variable, although the *smallest* acceptable fitted value was +200 cm^{-1} (and values of up to +330 cm^{-1} were obtained in some solutions). This implies that the observed magnetic properties are largely determined by the very strong ferromagnetic metal–radical coupling. The uncertainty in the coupling parameters may be a reflection of the difficulties associated with quantifying exchange integrals in strongly ferromagnetically coupled systems.[21] We are currently preparing analogous bipyvd complexes of diamagnetic metal ions in order to explicitly determine the radical–radical coupling. In the absence of any knowledge regarding the true value of J_2 we arbitrarily set it equal to zero, producing the following parameters: $J_1 = +320$ cm^{-1}, $J_2 = 0$ cm^{-1}, $g = 2.11$, $\theta = -5$ K, TIP (temperature-independent paramagnetism) = 0.00022 cm^3 mol^{-1}, ρ (fraction of paramagnetic impurity) = 0.014 ($R = 0.0321$; $R = [\Sigma(\chi_{obs} - \chi_{calc})^2/\Sigma(\chi_{obs})^2]^{1/2}$). The Weiss-like constant θ was employed as a pseudo-intermolecular exchange parameter necessary to model the low temperature magnetic behaviour; analysis of the molecular packing in **1** reveals neighbouring verdazyl rings in somewhat close proximity (ESI†). The overlap of adjacent verdazyl moieties offers a probable intermolecular exchange pathway, although zerofield splitting of the high-spin Ni^{II} ground state may also contribute to the low temperature behaviour.

We recently reported similarly strong coupling in a nickel complex of pyvd which contains two hfac ligands.[11] In this system the ferromagnetic verdazyl–nickel coupling was explained by invoking well-established orbital orthogonality arguments.[21] The intramolecular exchange coupling in compound **1** is similar in nature and establishes that verdazyl–nickel ferromagnetic coupling is a general phenomenon and is not dependent on the nature of the ancillary ligands. This stands out in sharp contrast to the behaviour of virtually all other metal-radical complexes described to date, in which strong *anti*-ferromagnetic or weak ferromagnetic coupling is the rule. The only other complexes which we are aware of with comparable ferromagnetic exchange properties are semiquinone complexes of Ni^{II} and Cu^{II}.[22] Moreover, the structural similarities of verdazyl–metal binding to that seen in complexes of oligopyridines brings a significant component of structural design into the construction of metal–radical assemblies because of the well-established binding modes of oligopyridines. We are enthusiastic about the prospects of making new high-spin clusters and solids based on nickel(II) and oligopyridine-based verdazyls.

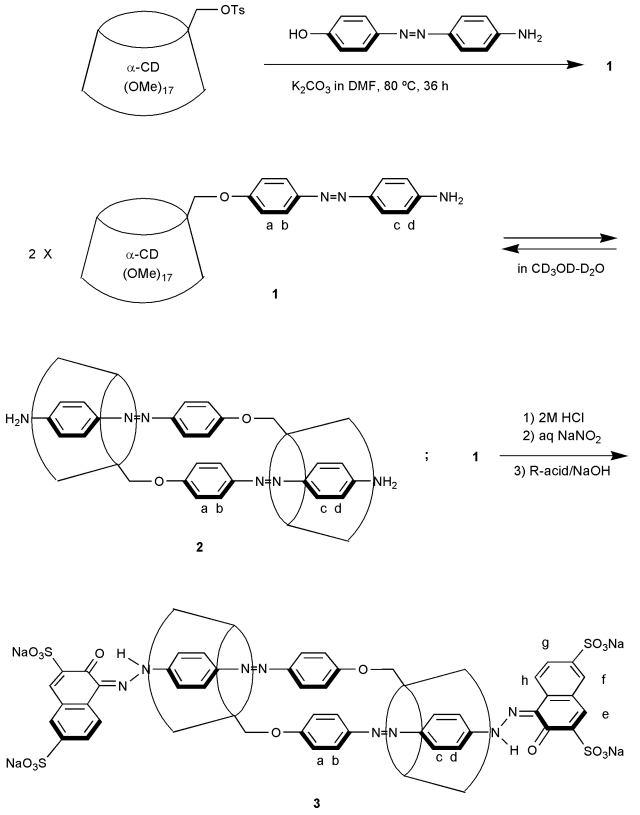
First published as an Advance Article on the web 16th October 2000

The first Janus [2]rotaxane 3 has been synthesized by bis-azo coupling of 2-naphthol-3,6-disulfonic acid with a Janus [2]pseudorotaxane 2 prepared by dimerization of 6-*O*-[(4-aminophenylazo)phenyl]-permethylated α-cyclodextrin 1 and characterized by MALDI-TOF-MS and ^{1}H NMR methods.

Mechanically interlocked compounds such as rotaxanes and catenanes have become of interest since the first creative development of molecular machines associated with a so-called mechanical bond characteristic of such compounds.[1] Recently, we have reported the rare lipophilic [2]supercyclodextrins with a 'doubly pseudorotaxaned' superstructure, corresponding to the cyclic homo-dimers of azophenol-branched permethylated α-cyclodextrins (CDs).[2] Although such double-[2]pseudorotaxanes[3] have a tendency to exist only under limited conditions of the temperature, concentration, and medium, they must be regarded as fascinating precursors for so far unknown double-rotaxanes. To fix the dissociable structures of the precursors by capping with bulky stoppers on the terminal groups, azo coupling reactions provide a promising approach because of their practical feasibility in aqueous solutions at low temperatures, with low activation energies. In fact, Anderson *et al*. have succeeded in preparing azo dye [2]- and [3]-rotaxanes in this manner.[4] Here, we describe the synthesis of the first 'Janus [2]rotaxane'[5] **3**[6] from a lipophilic α-CD monomer **1** bearing a diazotizable 4-aminoazobenzene *via* dimerization to a [2]pseudodoublerotaxane **2**.

Competitive substitution reaction of 6-*O*-monotosyl permethylated α-CD[2] with an excess of 4-amino-4′-hydroxyazobenzene as a bifunctional nucleophile gave a mixture of 6-*O*-[(4-aminophenylazo)phenyl]- and 6-deoxy-6-[(4-hydroxyphyenylazo)phenylamino]-permethylated α-CDs (Scheme 1). The former desired compound **1** could be separated from the latter by extraction with toluene from the alkaline aqueous phase, and obtained in 38% yield after purification by preparative GPC column chromatography.[7]

The self-association of monomer **1** has been examined by solvent-, temperature- and concentration-dependent ^{1}H NMR methods. A spectrum observed at ambient temperature from a solution of **1** in CD_3OD–D_2O (6 : 1) is understood in terms of an equilibrium mixture of two species, **1** and its complex **2** [Fig. 1(b)]. The complexed species disappeared completely at 55 °C to result in the uncomplexed species alone, the spectrum of which [Fig. 1(a)] is similar to that of **1** obtained in $CDCl_3$. By contrast, the association complex **2** was found to exist exclusively in CD_3OD–D_2O (1 : 1) at 23 °C [Fig. 1(c)]. The superstructure of the Janus [2]pseudorotaxane **2** is confirmed by both the determination of the value $n = 2.0$[8] of the degree of association according to the method[2b] reported previously and the appearance of the four sets of doublets due to the aromatic protons. The spectral features mentioned above indicate that the dimerization equilibrium in Scheme 1, for which the association constant K_a was evaluated to be 430 M^{-1},[8] occurred in hydrophilic media at room temp. and that its exchange rate was slow but the free rotations of the guest azobenzene-rods were fast on the NMR timescale. Similar phenomena have been described in other lipophilic α-CD–azobenzene dyads.[2]



Scheme 1

The aromatic protons of **2**[9] were assigned by difference NOE and decoupling experiments in CD_3OD–D_2O (6 : 1) and (1 : 1), respectively. The observations of two correlations due to H_a–H_b and H_c–H_d and of the chemical exchange involving H_c and H_d are compatible with the assignment shown in Fig. 1(c). The up-

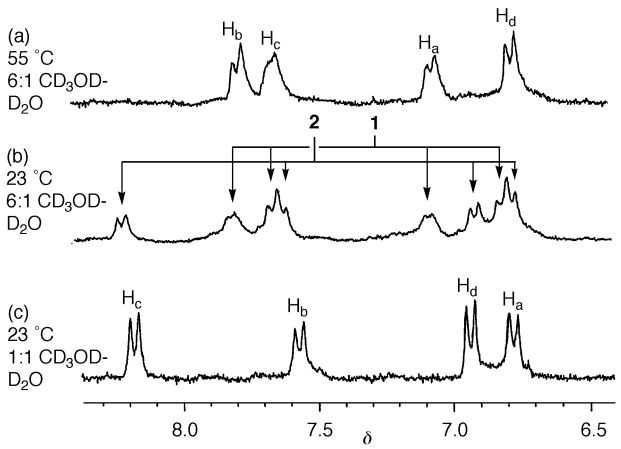


Fig. 1 270 MHz ^{1}H NMR spectra of solutions of **1**.

and down-field shifts of H_a (−0.27), H_b (−0.19), H_c (+0.56) and H_d (+0.12 ppm) after the dimerization resemble those observed previously with the other [2]supercyclodextrins[2] and therefore, these shifts also support the Janus [2]pseudorotaxane **2** for which a cyclophane-like π–π stacking between the two phenol residues and the binding of the terminal aniline residues with the CD cavities are characteristic.

Bis-azo coupling experiments to introduce two bulky naphthols as stoppers were carried out as follows. To prepare the bis-diazonium salt of **2**, a cold aqueous solution of sodium nitrite was added in portions to a cold solution of the aniline derivative **1** in 2 M HCl. The reaction mixture was treated with an alkaline solution of 2-naphthol-3,6-disulfonic acid (R-acid) at room temperature for 3 h. After neutralization followed by purification by reverse phase column chromatography, the desired Janus [2]rotaxane **3**[10] was isolated in 84% yield as red–purple solid. The symmetrical and dimeric structure of **3** has been confirmed by the observations of a 1 : 1 ratio of the naphthol to the azobenzene moiety in its ^{1}H NMR spectrum and of a peak at *m/z* 3549 corresponding to $[M+Na]^+$ in its MALDI-TOF-MS spectrum. It is interesting that the possible coupling product of **1** with the R-acid could not be detected. Thus, it is unlikely that the bis-aniline **2**, its dihydrochloride and the corresponding bis-diazonium salt dissociate into the monomeric species during the coupling processes.

The ^{1}H NMR spectral features of **3** reflect its Janus [2]rotaxane skeleton. It was anticipated that the stoppers introduced at the terminal ends have substantial substituent effects on the aromatic protons H_d situated at the *ortho* positions while this is not so for H_a and H_b which lie further away. Indeed, the following reasonable differences in their chemical shifts were found: $\Delta\delta = \delta(\mathbf{3}) - \delta(\mathbf{2})$, −0.04 for H_a, −0.04 (H_b), +0.17 (H_c), and +1.21 ppm (H_d). Further, no difference between the spectra of **3** recorded at 24 and 90 °C in D_2O was observed, supporting the fixed superstructure. At present, there is no evidence for a potential oscillation, like the stretching vibration of the covalent bond for a diatomic molecule, with respect to the mechanical bond between the two components of **3**.

In conclusion, we have demonstrated that a [2]supercyclodextrin prepared by self-assembly of an α-cyclodextrin–azobenzene dyad serves as a precursor for a very rare Janus [2]rotaxane. Synthesis of other Janus [2]rotaxanes are currently in progress in our laboratory.

We are grateful to Dr. Ken-ichi Sugiura in our laboratory for his helpful discussions.

Received (in Oxford, UK) 30th August 2000, Accepted 20th September 2000
First published as an Advance Article on the web

A new type of zeolite is found for the title microporous germanate whose peculiar connectivity between the 3- and 9-ring layers creates cages in which an extra-framework hydroxy group is confined.

Zeolites have found a number of applications in fields of commercial importance, notably as catalyst, adsorbents and ion exchangers.[1–4] Relating to the germanium zeotypes, the possibility of designing new open frameworks increases greatly due to the possible co-existence of different coordination polyhedra around Ge (tetrahedra, octahedra and trigonal bipyramid), which implies different charged frameworks without doping with trivalent cations. Nevertheless, novel microporous germanium frameworks had not been synthesized until recently.[5–11]

In terms of our interest in the structure–properties relationship for this kind of compound, we were concerned in the design and study of precise atomic architectures of zeotypes. In previous work the existence of $Ge_7O_{15}^{2-}$ (ICMM1)[12,13] and $Ge_9O_{19}^{2-}$ (ICMM2)[14] were reported. Here, we report the structure ICMM3, the first zeotype in which it is clear that one confined hydroxy group acts as a template.

ICMM3 was synthesized hydrothermally from a reaction mixture containing GeO_2, $MeNH_2$, H_2O and ethylene glycol in molar ratios 1 : 8 : 25 : 15. The mixture was introduced and sealed in a Teflon-lined stainless steel autoclave and heated at 170 °C for 4 days. After optimizing the reaction conditions, the yield was 100%. The purity of the resulting solid product was checked by X-ray powder diffraction.†

A suitable crystal of the compound with hexagonal platelike features was selected and mounted in a diffractometer equipped with a CCD detector. Crystals were pseudo-hexagonally twinned so that the space group appeared to have a pseudo-6_3 axis along *b*, however, the structure was solved and refined in the monoclinic space group $P2_1$ with *a* and *c* equal and β = 120°. Upon determining the crystal structure, the composition was found to be $Ge_8O_{16}(OH)^-(MeNH_3)^+MeNH_2$ in which the eight Ge atoms are at the center of more or less distorted tetrahedra [range of Ge–O bond lengths 1.72(2)–1.79(2) Å; O–Ge–O bond angles 95.5(7)–120.1(8)°, Ge–O–Ge 110.2(7)–143.5(7)°]. The tetrahedra are linked together in the *ac* plane giving rise to infinite GeO_2 layers which are constructed from a secondary structural building unit (SBU) denoted 4 = 1, joined by 3-tetrahedra rings into an infinite 9-tetrahedra ring containing sheet. This arrangement was also present in ICMM1 and in ICMM2. In the former zeotype, GeO_6 octahedra were involved in both 3- and 9-rings.

Every two GeO_2 adjacent sheets are joined through the three free oxygen atoms of the 3-ring tetrahedra creating thick blocks. These connections give rise to cages which are formed by six germanium atoms (three of each layer) and the three bringing oxygen atoms (Figs. 1 and 2). Inside these cages one atom of oxygen is found which corresponds to a confined OH^- anion the hydrogen atom of which was located and isotropically refined [O–H 0.8(1) Å]. This oxygen interacts with the six germanium atoms of the cage at distances in the range 2.12(2)–2.44(2) Å. Depending on these distances the surrounding germanium polyhedra are distorted to a greater or lesser degree, distortion ranging from the nearly regular tetrahedron of Ge(1) to what can be considered as trigonal bypiramids of Ge(4) and Ge(6) when including the fifth Ge–O interaction.

Cohesion between blocks is established, as also found in ICMM2, through the only oxygen atom [O(8)] not involved in connectivities within double layers. Also, as in ICMM2, the blocks are mutually shifted.

This 3D structure contains intersecting tunnels along the three directions: one set of tunnels runs in a zigzag fashion along the *b* direction as a consequence of the shifted pillaring of the $9R_b$ 9-rings. Perpendicular to the *b* direction 8-ring 8R intersecting tunnels can be seen along the (101), (100) and (001) directions accordingly with the pseudo-hexagonal symmetry present in the crystals.

There are two crystallographically independent molecules of methylamine in the asymmetric unit, situated in the 8R channels

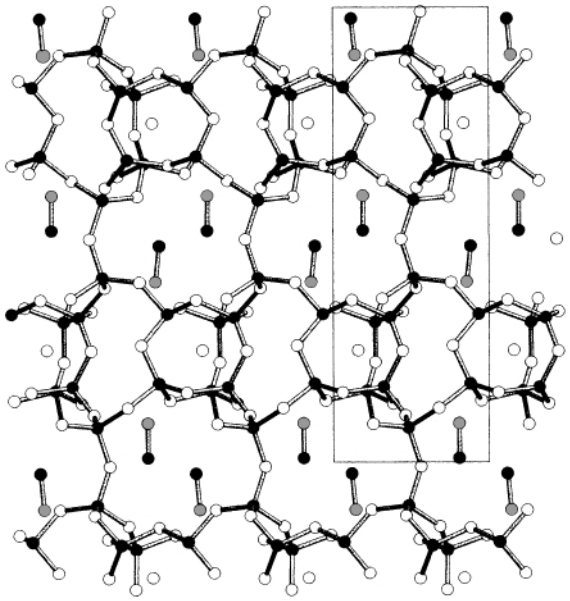

Fig. 1 View of the structure of ICMM3, showing the blocks and connectivity between them. Black, white and gray spheres are Ge, O and atoms of the amines, respectively.

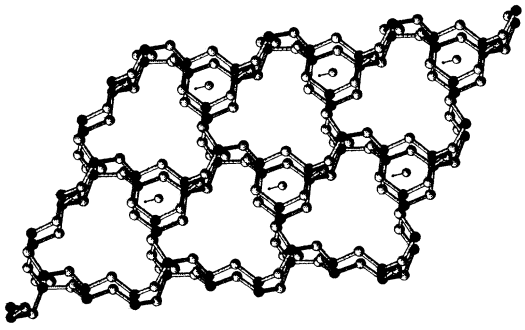

Fig. 2 View along the *b* direction of the double layer showing the confined OH group.

DOI: 10.1039/b007054h

formed between blocks. They are bonded to different oxygen atoms of the framework through hydrogen bonds. Although hydrogen atoms involving amines could not be reliably located, the range of the N···O distances [2.86(1)–3.08(1) Å], as well as their number, seem to indicate that many of these hydrogen bonds are bifurcated. Owing to the existence of one OH^- anion, it is clear that to maintain electrical neutrality, a protonated amine is required. Protonation is established through the different C–N bond lengths [1.56(4) and 1.41(4) Å] as well as by spectroscopy. The IR spectrum shows a band at 3400 cm^{-1} due to the stretching vibrations of the OH groups while bands at 2792 and 2876 cm^{-1} arise from N–H vibrations, which are characteristic of a primary amine in its protonated form. Stretching vibrations of non-protonated amine sites occur at 3100 and 3164 cm^{-1}.

TGA–DTA in N_2 atmosphere (50 ml min^{-1}) shows one progressive weight loss between 375 and 550 °C accompanied by an endothermic effect corresponding to the loss of both methylamine molecules and the OH^- group. Powder X-ray diffraction and IR spectra show that the structure is maintained upon heating to 375 °C during 4 h in air but collapses to give amorphous GeO_2 after prolonged heating.

In conclusion, a zeolite type microporous germanate has been synthesized. Its framework exhibits a peculiar connectivity between the 3- and 9-ring layers. Every two of these layers are joined through the three free oxygen atoms of the 3-ring tetrahedra. This joining creates cages in which an extra-framework hydroxy group is trapped. The negative charge of this OH^- group is compensated by one intratunnel protonated methylamine molecule.

Efficient photodecarboxylation of aroyl-substituted phenylacetic acids in aqueous solution: a general photochemical reaction

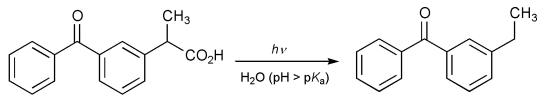
Photolysis (254–350 nm) of a variety of aroyl-substituted phenylacetic acids and *p*-acetylphenylacetic acid in aqueous solution at pH > pK_a resulted in efficient photodecarboxylation (Φ = 0.2–0.7), to give in most cases a single product arising *via* the corresponding arylmethyl carbanion, indicating that photodecarboxylation is an efficient and general reaction for these types of compounds.

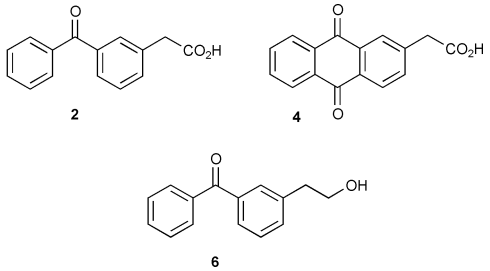
The photodecarboxylation of organic carboxylates and carboxylic acids continues to be an area of active research interest.[1–3] This is an example of a simple photochemical extrusion reaction that is comparable to the well-known photodecarbonylation of ketones. However, mechanistically, photodecarboxylation of carboxylic acids is more complex. The mechanism in which carbon dioxide is eliminated from photoexcited (organic) carboxylic acids has been classified into several types with the simple heterolytic and homolytic mechanisms being the most readily visualized.[1] Some recent papers dealing with photodecarboxylation of some non-steroidal anti-inflammatory drugs (NSAIDs) suggest that new insights and potentially new reactive systems await discovery.[2,3*a–e*] A particular example that attracted our attention is the highly efficiently (Φ = 0.75) photodecarboxylation of ketoprofen [**1**, eqn. (1)] in aqueous solution orginally reported by



1 (1)

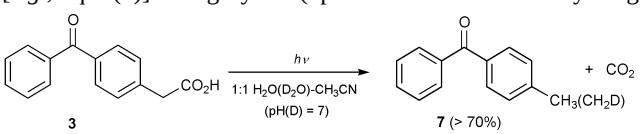
Costanzo *et al.*[2] At least two groups[3*a–e*] have studied the mechanism of the photodecarboxylation. The latest report we are aware of is from Scaiano and co-workers[3*a*] who showed that the reaction proceeds from the singlet excited state of the carboxylate form and that water is not essential (but probably helpful). Singlet state reactivity is unusual for benzophenone photochemistry. The nature of the primary photochemical step remains an issue. It could be either (a) a simple heterolytic cleavage mechanism to generate the carbanion directly or (b) a mesolytic mechanism in which there is an electron transfer from the carboxylate oxygen to the ketone to generate a biradical anion, followed by bond cleavage to give the carbanion.

Ketoprofen (**1**) is an aroyl-substituted phenylacetic acid. Compounds of this general structural type are readily available by routine synthesis. The high (and clean) reactivity of **1** suggested to us that other aroyl-substituted phenylacetic acids might react in a similar manner and that a general type of efficient photodecarboxylation awaits discovery. The availability of compounds of similar structural type that also react will certainly help in the elucidation of the reaction mechanism. We have now made five analogs of **1**, *viz.*, **2**–**6**. Acids **2** and **3** are simple analogs of ketoprofen (**1**). If the photodecarboxylation of **1** is respresentative of a general process, compounds **2** and **3** should react, neglecting of course any dramatic substituent effects on excited state reactivity that we have not taken into account. Compounds **4** and **5** have a different carbonyl chromophore (anthraquinone and acetophenone, respectively). If the reaction is general for other types of carbonyl chromophores, these compounds might be expected to show reactivity as well. Finally, we have changed the nature of the 'leaving group' in **6**. Here, the leaving group is formally formaldehyde, which is much less labile than CO_2. If **6** reacts in an analogous manner (*i.e.* deformylation to give the corresponding carbanion), then the reaction is indeed much more general than ever suspected. In this report, we show that all of **2**–**6** react in the manner anticipated (with varying degrees of efficiency, all generally high) demonstrating that the photodecarboxylation of aroyl and acetoyl-substituted phenylacetic acids is a general reaction. Moreover, less labile leaving groups such as formaldehyde may also be used.



Carboxylic acids **2**–**5** were readily made by conversion of the corresponding commercially available methyl-substituted derivative to the α-bromo compound (NBS–CCl_4), followed by reaction with NaCN–EtOH and then hydrolysis using either conc. HCl or aqueous H_2SO_4. All of the acids were purified by repeated crystallization from aqueous EtOH to achieve > 98% purity.† Keto-alcohol **6** was readily prepared by BH_3–THF reduction of **2**.

Photolysis of **2**–**4** in 1 : 1 H_2O–CH_3CN (50 mL total volume; water portion set to pH 7 with dilute NaOH after adding compound to ensure complete dissociation of the acid; ≈ 10^{-3} M substrate; Rayonet photochemical reactor; 254, 300 or 350 nm lamps; quartz vessel; solution cooled with a cold-finger to ≈ 15 °C; purged continuously with argon; 5–20 min) gave cleanly the corresponding photodecarboxylation product [*e.g.*, eqn. (2)] in high yield (up to 100% on sufficiently long



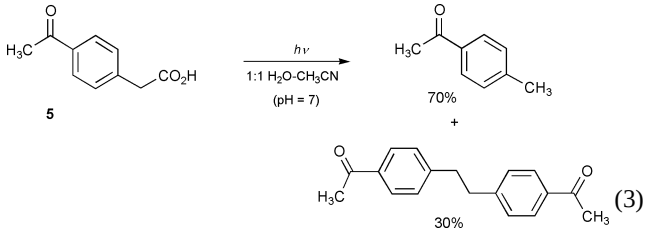
3 **7** (> 70%) (2)

photolysis time). No reaction was observed when the solution was kept in the dark. Quantum yields for photodecarboxylation were estimated using the reaction of ketoprofen (**1**) as a secondary standard (Φ = 0.75, in neat water, pH 7)[2] and ^{1}H NMR to monitor conversions. These experiments gave high quantum yields for the photodecarboxylations for **2**–**4** (in 1 : 1 H_2O-CH_3CN, pH 7): **2** (Φ = 0.66); **3** (Φ = 0.62); **4** (Φ = 0.22). Photolysis of **2**–**5** in neat CH_3CN under photolysis times used above gave no more than 5% reaction and the compounds could be essentially recovered unchanged.

It's clear from these results that (efficient) photodecarboxylation is a general photoreaction for aroyl-substituted phenyl-

DOI: 10.1039/b006724p

acetic acids. Quantum yields decreased on lowering the pH‡ which is consistent with the carboxylate form being reactive, consistent with the latest findings for ketoprofen (**1**) reported by Scaiano and co-workers.[3a] Furthermore, photolysis of **2** and **3** in D_2O–CH_3CN (as above) gave exclusively the corresponding α-deutero-methyl product, consistent with a carbanion intermediate [eqn. (2)]. Interestingly, photolysis of acetophenone derivative **5** gave two products in a 7 : 3 mole ratio (Φ for loss of substrate ≈ 0.2), respectively [eqn. (3)]: the expected simple decarboxylation product (*p*-methylacetophenone) *via* a simple phenylmethyl carbanion and a 'dimeric' product formally derivable from the phenylmethyl radical *via* coupling. Independent photolysis of *p*-methylacetophenone under identical conditions gave no reaction. Although radical coupling products have not been observed for ketoprofen (**1**) or from any of **2**–**4**, the fact that it is observed for **5** indicates that a radical-type mechanism (*e.g.* initial electron transfer from the carboxylate to the ketone)[3a–c] cannot be excluded for the photodecarboxylation. The reactivity of acetophenone derivative **5** allows for detailed investigations on this reaction pathway.



(3)

The generally high reactivity towards photodecarboxylation of the above aroyl (and acetoyl) substituted phenylacetic acids prompted us to think about the possible driving force for these reactions. A simple rationalization (assuming S_1 reactivity) is that the excited singlet states of these compounds have highly polarized π electron densities, shifted towards the keto oxygen. This would favour loss of CO_2 *via* benzylic C–C bond heterolysis, and subsequent generation of the carbanion. This mechanism bypasses the need for an initial electron transfer from the carboxylate oxygen to the carbonyl group, which appears to be warranted only for **5**. In any event, we wanted to test the former proposal and have made derivative **6** to test whether a similar reaction could operate using a much poorer 'leaving group', *viz.*, formaldehyde, and a moiety incapable of efficient electron transfer to the carbonyl group. To our surprise, photolysis of **6** in 1 : 1 H_2O–CH_3CN gave the anticipated deformylated product [*p*-methylbenzophenone (**7**)] although with yields that are several fold (5–10%) less than observed for the corresponding acid **2**, along with what appears to be major product(s) derived from photoreduction of the ketone. However, photolysis at pH 12 resulted in clean deformylation (> 70% yield) consistent with a hydroxide ion catalyzed process which would be required for deformylation *via* a carbanion intermediate. These initial results suggest that the aroylphenylmethyl group may be thought of as 'photolabile' carbanion leaving group which is able to induce a variety of benzylic C–C bond heterolysis in appropriately designed molecular systems. This is akin to the nitrobenzyl group[4] and selected diarylmethyl systems[5] that are known to have this ability.

In summary, we have shown that the photodecarboxylation of aroyl and acetoyl-substituted phenylacetic acids is a general reaction, all proceeding with high quantum yields. Less labile 'leaving groups' such as formaldehyde may also be used. In this way, one may visualize the aroyl-substituted phenylmethyl group to be a photolabile carbanion leaving group. This type of general reactivity may have application in the design of photolabile protecting groups and other photochemical applications in addition to providing new structural types for the elucidation of detailed reaction mechanism.

First published as an Advance Article on the web

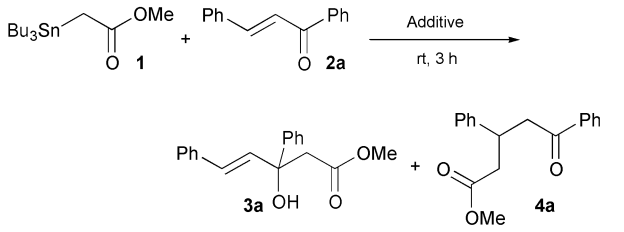
The reaction of α-stannyl ester with α,β-unsaturated ketones in the presence of stannous chloride ($SnCl_2$) and chlorosilanes (Me_3SiCl or Me_2SiCl_2) gave 1,2- and 1,4-addition products, respectively.

The regioselective addition of a nucleophile to α,β-unsaturated carbonyl compounds (1,2- or 1,4-addition) has been focused on in modern organic syntheses. An enolate or its equivalent is often used for the functionalised nucleophile to unsaturated carbonyls. Heathcock reported excellent results using lithium enolate in which either kinetic or thermodynamic conditions effectively control the regioselectivity.[1] The correlation between the character of the metal in the enolate and the regioselectivity was also investigated.[2] We have recently reported the 1,4-addition of organotin ketone enolate using a high coordination method.[3] An organotin ester enolate, however, has significantly different reactivity and character as compared with an organotin ketone enolate and is not suitable for the reaction conditions developed for ketone enolates. For the organotin ester enolates, the equilibrium between *O*-stannylated and *C*-stannylated forms largely lies towards the *C*-stannylated species above 0 °C.[4] The stannylation of lithium ester enolate is reported to give only a *C*-stannylated ester compound (the α-stannyl ester) after distillation,[5] although stannyl ketone enolate generally exists as an equilibrium mixture of both forms.[6] Since enol forms generally show higher reactivity than keto forms, the α-stannyl ester has a lower reactivity than ketone enolates.[7,8] During our study of the activation methodology of α-stannyl ester, we found a novel approach to regiocontrol in the reaction of α,β-unsaturated ketones with α-stannyl ester as an ester enolate equivalent.

First, we examined additives for the reaction of α-stannyl ester **1** with chalcone **2a** and the results are summarized in Table 1. An attempt without additives resulted in no reaction (entry 1). The use of $BF_3{\cdot}OEt_2$ as an additive was not effective at all (entry 2). $TiCl_4$ afforded a low yield of 1,4-addition product **4a** (entry 3). Recently, we have reported a carbonyl allylation system using tributylallyltin(IV) and $SnCl_2$ in which transmetallation occurs to generate an active species.[9,10] This activation methodology was applied to the reaction of **1** in the presence of $SnCl_2$ to give β-hydroxy ester **3a** in 63% yield with excellent selectivity in 1,2-addition manner (entry 4). On the other hand, the addition of chlorotrimethylsilane gave selectively **4a** in practical yields, which were influenced by the solvents used. Nitromethane was the solvent of choice and gave the sole product **4a** in 95% yield (entry 6). These results encouraged us to develop these reaction systems using α-stannyl ester for regioselective addition to α,β-unsaturated ketones.

Next, we explored the generality of this regiocontrolled system using either $SnCl_2$–MeCN or Me_3SiCl–$MeNO_2$ with various types of enones **2a**–**e**, and showed the results in Table 2.† Excellent regiocontrol was observed in the reaction with phenyl ketone **2b**, which has an alkyl substituent on the terminal olefinic carbon (entries 3 and 4). In the reaction with alkyl ketone **2c** using $SnCl_2$, the low yield of **3c** in entry 5 was ascribed to the polymerization of the starting enone, although regioselectivity was high (entry 5). Chlorotrimethylsilane gave 83% yield of products with high selectivity (entry 6). The cyclic substrate **2d** was also applied to these systems. When

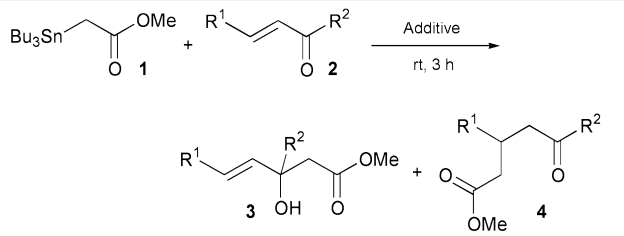
Table 1 Effect of additives on regioselective addition of **1** to enone **2a**[a]



Entry	Additive	Solvent	Yield (%)	Ratio of **3a**/**4a**
1	None	MeCN	0	—
2[b]	$BF_3{\cdot}OEt_2$	CH_2Cl_2	0	—
3[b]	$TiCl_4$	CH_2Cl_2	19	< 1/99
4	$SnCl_2$	MeCN	63	> 99/1
5[c]	Me_3SiCl	MeCN	47	< 1/99
6[c]	Me_3SiCl	$MeNO_2$	95	< 1/99

[a] All reactions were carried out in solvent (1 mL) using **1** (1.2 mmol), unsaturated ketone **2a** (1.0 mmol), and additive (1.2 mmol). [b] Reaction temperature −78 °C to rt. [c] Additive (2.0 mmol) was used.

Table 2 Control of regioselectivity in addition of **1** to various enones **2**[a]



Entry	Enone	Additive	Solvent	Yield (%)	Ratio of **3**/**4**
1		$SnCl_2$	MeCN	63	> 99/1 (**3a**/**4a**)
2		Me_3SiCl	$MeNO_2$	95	< 1/99
3		$SnCl_2$	MeCN	91	> 99/1 (**3b**/**4b**)
4		Me_3SiCl	$MeNO_2$	92	< 1/99
5		$SnCl_2$	MeCN	23	> 99/1 (**3c**/**4c**)
6		Me_3SiCl	$MeNO_2$	83	5/95
7		$SnCl_2$	MeCN	50	> 99/1 (**3d**/**4d**)
8		Me_3SiCl	$MeNO_2$	90	< 1/99
9		$SnCl_2$	MeCN	80	> 99/1 (**3e**/**4e**)
10		Me_3SiCl	$MeNO_2$	59	46/54
11		Me_2SiCl_2	$MeNO_2$	63	5/95

[a] All reactions were carried out in solvent (1 mL) using **1** (1.2 mmol), unsaturated ketone **2** (1.0 mmol). Either $SnCl_2$ (1.2 mmol) or chlorosilanes (2.0 mmol) were used as additives.

DOI: 10.1039/b004817h

acetonitrile was used as a solvent in the reactions with **2a**–**d** in the presence of chlorotrimethylsilane, the same or lower yields were observed but selectivity was not significantly affected. In the reaction with 4-phenylbut-3-en-2-one **2e**, the 1,2-adduct **3e** was obtained in good yield with perfect selectivity (entry 9). However, the reaction using chlorotrimethylsilane did not give selective 1,4-addition (**3e**/**4e** = 46/54, entry 10). The low selectivity is ascribed to the conjugation of the phenyl group with the olefinic moiety which could be kept by 1,2-addition and broken by 1,4-addition.[11] Unexpectedly, Michael adduct **4e** was favored (**3e**/**4e** = 5/95) when dichlorodimethylsilane was used as an additive instead of chlorotrimethylsilane (entry 11).

Although the exact reaction mechanism for either course using stannous chloride or chlorosilanes is not clear, the regiocontrol can be explained by the following assumption at the present stage. In the $SnCl_2$ system, the active tin(II) species generated by transmetallation has high Lewis acidity.[9,10] The strong interaction between carbonyl oxygen and the tin center in the nucleophile effectively accelerates the carbostannylation. The resulting Sn–O bond is strong enough for irreversible reaction. In order to examine the chlorosilane system, an NMR study was performed. The mixture of **1** and chlorotrimethylsilane in acetonitrile underwent transmetallation to give tributylchlorostannane and silylketene acetal, as determined by NMR.[12,13] After standing for 48 h at rt, the silylketene acetal completely disappeared and α-silyl ester was observed by NMR.[14,15] This resulting solution including silyl ester and tributylchlorostannane was inert to chalcone **2a**. These results suggest that tributylchlorostannane would act as a Lewis acid for Mukaiyama-type Michael addition of silylketene acetal.[16] Another possibility, namely, that further transmetallation to give stannylketene acetal from chlorostannane and silylketene acetal, which would have high reactivity and a short life time under the conditions employed in this procedure, is not completely ruled out at this stage.[4] The difference in active species generated in each system causes the highly regiocontrolled reactions.

The solvent effect of acetonitrile or nitromethane on yields probably relates to their coordination ability to the concerned active species. The additive effect of chlorosilanes on selectivity of **3e**/**4e** is still not clear.

In conclusion, regioselective addition of α-stannyl ester to α,β-unsaturated ketones was achieved in 1,2- and 1,4-addition manner by using stannous chloride and chlorosilanes as additives, respectively. The transmetallation of stannyl ester with these additives generates the key reactive intermediates with proper selectivities. α-Stannyl esters will be attractive functionalized nucleophiles with these activation methodologies because they are easy to prepare and handle and can be stored for months owing to their moderate stability. The detailed reaction mechanism is now under investigation and will be reported in a full account.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture, of the Japanese Government. Thanks are due to Mr H. Moriguchi, Faculty of Engineering, Osaka University, for assistance in obtaining MS spectra.

Enantiopure arene dioxides: chemoenzymatic synthesis and application in the production of *trans*-3,4-dihydrodiols

Derek R. Boyd,* Narain D. Sharma, Colin R. O'Dowd and Francis Hempenstall

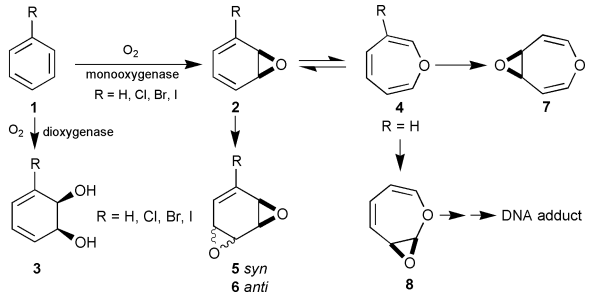
Received (in Cambridge, UK) 21st August 2000, Accepted 27th September 2000
First published as an Advance Article on the web

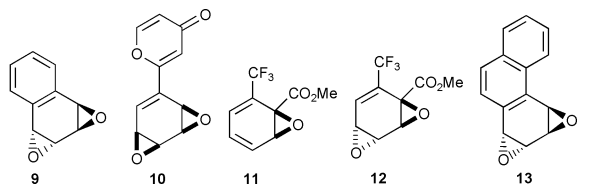
Enantiopure *syn*- and *anti*-arene dioxides are synthesised from *cis*-dihydrodiol metabolites; *anti*-benzene dioxides are reduced to enantiopure *trans*-3,4-dihydrodiols while *syn*-benzene dioxides racemise thermally *via* 1,4-dioxocins.

The metabolism of monocyclic arenes by bacteria (procaryotes) occurs *via* dioxygenase-catalysed dihydroxylation to yield *cis*-dihydrodiols (*e.g.* metabolite **3** from benzene **1**, R = H).[1] In fungi or animals (eucaryotes) however, benzene ring metabolism proceeds *via* monooxygenase-catalysed epoxidation to yield a rapidly equilibrating arene oxide–oxepine tautomeric mixture (*e.g.* metabolites **2** ⇌ **4** from benzene **1,** R = H, Scheme 1).[2]



Scheme 1

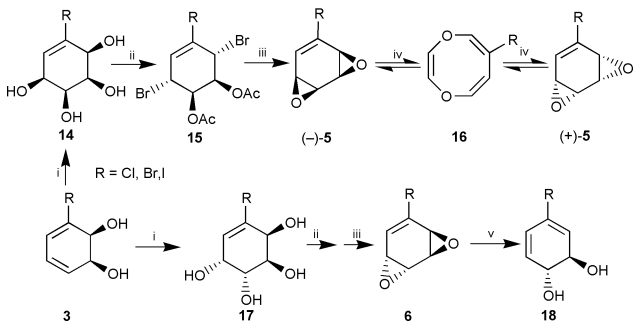
When further oxidation of benzene oxide–oxepine, **2** ⇌ **4** (R = H), was carried out using dimethyl dioxirane (DMD) as oxidant epoxidation occurred exclusively on the oxepine valence tautomer **4**. The minor symmetrical oxepine epoxide **7** was isolated but the major oxepine epoxide **8** rearranged spontaneously to *Z*,*Z*-muconaldehyde.[3] Oxepine epoxide **8** and *Z*,*Z*-muconaldehyde have been implicated in DNA adduct formation and possibly the carcinogenicity of benzene (Scheme 1).[4] Evidence that arene dioxides can be formed in eucaryotic systems is provided by the isolation of the *anti*-naphthalene dioxide **9** as a liver metabolite of naphthalene,[5] and the *syn*-benzene dioxide **10** as a fungal metabolite.[6]



Following earlier studies of remote site epoxidation of arene oxide derivatives of polycyclic arenes using DMD,[7] we have extended this method to the synthesis of *anti*-arene dioxides in mono- and polycyclic arenes. Thus the stable benzene oxide metabolite **11**[8] was found to yield only *anti*-benzene dioxide **12** upon treatment with DMD. The formation of **12** from a benzene oxide tautomer, and of oxirane **7** from an oxepine tautomer,[3] indicates that epoxidation can occur on either form. The DMD epoxidation of configurationally stable (+)-1*R*,2*S*-naphthalene oxide ([α]$_D$ +145, $CHCl_3$) gave only (+)-1*R*,2*R*,3*R*,4*R*-*anti*-naphthalene dioxide **9** ([α]$_D$ +1, $CHCl_3$).† Conversely phenanthrene 3,4-oxide was found to spontaneously racemise *via* an undetected oxepine intermediate and only the racemic form of *anti*-dioxides **13** could be obtained by DMD oxidation. The spontaneous racemization of benzene oxides[9] similarly precludes the synthesis of enantiopure *anti*-benzene dioxides by the chemical oxidation route.

Racemic samples of *syn*-**5**[10] (R = Br, CO_2H, CHO) and *anti*-benzene dioxides **6**[11–13] (R = H) were synthesised earlier by multistep routes; only compound **6** (R = H) was obtained in enantiopure form.[12,13] The availability of *cis*-dihydrodiol enantiomers **3** (R = Cl, Br, I) from bacterial metabolism,[1,2] prompted the following new approach to the synthesis of enantiopure *syn*-**5** and *anti*-benzene dioxides **6**, (Scheme 2). A mixture of *syn*- (**14**, 85%) and *anti*-tetraol (**17,** 15%) derivatives of *cis*-dihydrodiols **3** (R = Cl, Br, I), obtained (80% yield) using the osmylation procedure reported by Donohoe *et al.*,[14] was separated (charcoal–Celite chromatography, EtOH–H_2O as eluent). Reaction of *syn*-tetraols **14** (R = Cl, Br, I) with 2-acetoxyisobutyryl bromide afforded *bis*-bromoacetates **15** (R = Cl, Br, I) in *ca*. 86% yield. Cyclization using NaOMe yielded the 3*S*,4*S*,5*S*,6*S*-*syn*-benzene dioxides **5** (R = Cl, Br, I, in *ca*. 75% yield) with [α]$_D$ values of −59, −56, and −56 in $CHCl_3$ respectively. Reaction of the *bis*-acetonide derivative of *syn*-tetraol **14** (R = I) with PhMgBr, and deprotection of the acetonide groups, yielded *syn*-tetraol **14** (R = Ph), which was similarly converted to 3*S*,4*S*,5*R*,6*R*-*syn*-benzene dioxide **5** (R = Ph, [α]$_D$ −42, $CHCl_3$). Application of this method to *anti*-tetraols **17** (R = Cl, Br, I) gave 3*R*,4*R*,5*S*,6*S*-*anti*-benzene dioxides **6** (R = Cl, Br, I, 78 % yield) with [α]$_D$ values of −115, −54, and −6 in $CHCl_3$ respectively (Scheme 2). Hydrogenolysis (H_2, Pd/C, NaOAc, MeOH) of the 3,4-acetonide derivative of *anti*-tetraol **17** (R = I), and deprotection, yielded the parent compound conduritol E, **17** (R = H), [α]$_D$ − 320, H_2O; it was converted to 1*R*,2*R*,3*R*,4*R*-*anti*-benzene dioxide **6** (R = H, [α]$_D$ −319, $CHCl_3$) using the method shown in Scheme 2.

The method of conversion of *cis*-dihydrodiols to *anti*-arene dioxides (Scheme 2) was also applied to polycyclic arenes. Thus, 1*R*,2*R*,3*R*,4*R*-*anti*-naphthalene dioxide **9** ([α]$_D$ + 1, $CHCl_3$; +14, MeOH)† was synthesised from the available *cis*-1*R*,2*S*-dihydrodiol metabolite of naphthalene ([α]$_D$ + 247, $CHCl_3$). Similarly the *cis*-3*S*, 4*R*-dihydrodiol metabolite of



Scheme 2 *Reagents*: i, OsO_4, CH_2Cl_2, TMNO; ii, $AcOCMe_2COBr$, MeCN; iii, NaOMe, Et_2O; iv, toluene, 85 °C; v, CO, $Pd(OAc)_2$, K_2CO_3, THF–H_2O.

DOI: 10.1039/b006837n

phenanthrene ($[\alpha]_D$ + 35, MeOH) was converted to an enantiopure sample of 1*R*,2*R*,3*R*,4*R*-*anti*-phenanthrene dioxide **13** ($[\alpha]_D$ + 47, MeOH).

Attempts to form the carbomethoxy-substituted *anti*-benzene dioxide **6** (R = CO_2Me) from the corresponding vinyl iodide **6** (R = I), using a reported[15] palladium-catalysed carbonylation procedure for aryl iodides (CO, $Pd(OAc)_2$, K_2CO_3, THF–H_2O, rt) formed *trans*-3,4-dihydrodiol **18** (R = I, $[\alpha]_D$ −145, MeOH) in excellent yield (>85%) after 0.75 h. The *anti*-benzene dioxides **6** (R = Cl, Br) also yielded 1*R*,2*R*-*trans*-3,4-dihydrodiols **18** (R = Cl, $[\alpha]_D$ −176, MeOH) and **18** (R = Br, $[\alpha]_D$ −253, MeOH) in high yields; a complex mixture of products was obtained from the corresponding *syn*-benzene dioxides **5** (R = Cl, Br, I). The mechanism of conversion of *anti*-benzene dioxides **6** to the corresponding *trans*-3,4-dihydrodiols **18** may involve opening of one epoxide ring followed by formation of a π-allyl palladium complex and rearrangement, *via* an oxetane intermediate, with CO acting as a reducing agent.

The *trans*-dihydrodiols **18** (R = H, Cl, Br) have been detected as minor metabolites of the parent benzene substrates in animal liver systems and have been converted to diol epoxides which are implicated in DNA adduct formation and mutagenicity.[16,17] Palladium-catalysed reaction of *trans*-dihydrodiol **18** (R = I) under similar conditions (CO, $Pd(OAc)_2$, NaOAc, MeOH, rt), but for an extended period (18 h) resulted in the substitution of the iodine atom with a carbomethoxy group to give the 3*R*,4*R*-*trans*-dihydrodiol **18** (R = CO_2Me, $[\alpha]_D$ −94, MeOH) in 80% yield. The *trans*-3,4-dihydroxy-3,4-dihydrobenzoic acid **18** (R = CO_2H), a hydrolysis product of chorismic acid, appears to be a growth promoter.[17] The four step approach to the synthesis of single enantiomer *trans*-3,4-dihydrodiols **18** (R = Cl, Br, I) from *cis*-2,3-dihydrodiols (Scheme 2) represents a significant improvement over earlier routes requiring eight[9] or more[16] steps. The *syn*-benzene dioxides **5** (R = Cl, Br, I, Ph), in common with other *syn*-benzene dioxides **5** (R = H, CO_2H, CHO),[8] were found to undergo a retro-Diels–Alder cycloaddition reaction to yield the corresponding 1,4-dioxocins **16** at relatively low (~85 °C) temperature. Since an enantiopure sample of a *syn*-benzene dioxide was available, a thermal racemization study on the (−)-*syn*-dioxide of iodobenzene **5** (R = I) was carried out (toluene, 85 °C). Total racemization occurred over 2 h (HPLC by Chiralcel OB, α 1.32, iPrOH:hexane, 1:5). NMR analysis showed that the equilibrium mixture contained both the residual *syn*-benzene dioxide **5** (R = I), as a minor component (12%), and the corresponding 1,4-dioxocin isomer **16** (R = I) as a major component (88%). Chromatographic separation of compounds **16** and **5** (R = I) followed by heating either component as before yielded the same equilibrium mixture. This unusual example of a concerted racemisation of four chiral centres in one enantiomer was not observed for the *anti*-benzene dioxide **6** (R = I).

In conclusion we have shown that: (i) arene oxides yield isolable *anti*-arene dioxides by DMD oxidation, (ii) enantiopure samples of *syn*-**5** and *anti*-arene dioxides **6**, **9**, **13** are obtained in high yields from the corresponding *cis*-dihydrodiol metabolites, (iii) *anti*-benzene dioxides **6** are precursors for a new route to *trans*-3,4-dihydrodiols **18**, (iv) racemisation of a *syn*-benzene dioxide enantiomer containing four chiral centres occurs thermally.

We thank Dr R. Agarwal for assistance with preliminary work on the synthesis of polycyclic arene dioxides, Professor D. B. Harper and Dr J. Hamilton for a sample of arene oxide metabolite **11**, Dr R. Schobert for helpful discussion and the Queen's University of Belfast for financial support (CRO'D, FH).

Notes and references

† The $[\alpha]_D$ values observed for the enantiopure *anti*-arene dioxides **6** (R = H) and **9** are significantly different from those reported,[12] furthermore, the stereochemistry of (+) *anti*-dioxide **9** was incorrectly assigned.[12]

Received (in Basel, Switzerland) 26th April 2000, Revised manuscript received 22nd September 2000, Accepted 28th September 2000
First published as an Advance Article on the web

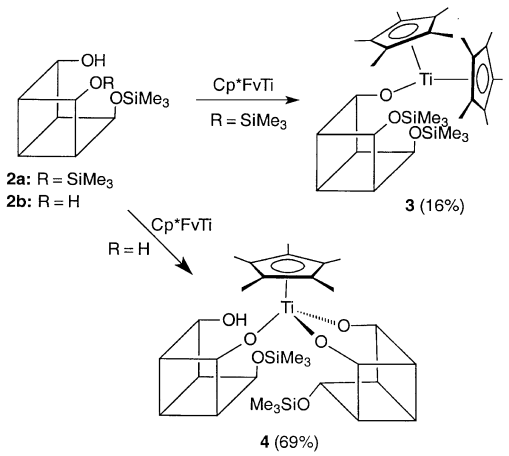
Constituting a novel synthetic route to model compounds for titanium catalysts immobilized on silica, the disilylated silsesquioxane derivative $Cy_7Si_7O_9(OH)(OSiMe_3)_2$ 2a, has been reacted with the 'tucked-in' fulvene complex Cp*Ti-($C_5Me_4CH_2$) to give the titanium(III) silsesquioxane Cp^*_2Ti-$[Cy_7Si_7O_{10}(OSiMe_3)_2]$ 3, while treatment of Cp*Ti-($C_5Me_4CH_2$) with $Cy_7Si_7O_9(OH)_2(OSiMe_3)$ 2b affords the mono(pentamethylcyclopentadienyl) complex Cp*Ti[Cy_7-$Si_7O_{11}(OSiMe_3)$][$Cy_7Si_7O_{10}(OH)(OSiMe_3)$] 4 which is an advanced model compound for a catalytically active titanium center on a silica surface.

Silsesquioxanes of the general formula $(RSiO_{1.5})_n$ are an unusual class of organosilicon compounds offering numerous exciting applications in catalysis[1] and materials science[2,3] alike. According to Feher *et al*., incompletely condensed silsesquioxanes such as $Cy_7Si_7O_9(OH)_3$ **1** (Cy = cyclohexyl) share structural similarities with β-cristobalite and β-tridymite and are thus quite realistic models for the silanol sites on silica surfaces.[4–10] These include the first trivalent titanasilsesquioxane, blue dimeric $[Cy_7Si_7O_{12}Ti]_2$, which was prepared by treatment of **1** with $Ti[N(SiMe_3)_2]_3$.[7] It is now generally accepted that metallasilsesquioxanes derived from **1** are suitable model systems for heterogeneous silica-supported transition metal catalysts. Moreover, it has turned out that certain metallasilsesquioxanes, especially those of Ti and V, are veritable catalysts themselves *e.g.* in the metathesis, polymerization and epoxidation of olefins.[1] We report here a novel preparative route leading to model compounds for titanium olefin polymerization catalysts immobilized on silica surfaces which involves addition of functionalized silsesquioxane precursors across the Ti–C bond of the 'tucked in' fulvene titanium complex (η^5-C_5Me_5)(η^5,η^1-$C_5Me_4CH_2$)Ti (= Cp*FvTi).[11–13]

Treatment of Cp*FvTi with 1 equivalent of the disilylated silsesquioxane precursor **2a** resulted in clean formation of the titanium(III) silsesquioxane complex **3** which was isolated in the form of air-sensitive, dark green crystals (Scheme 1). The low isolated yield (16%) can be traced back to the very high solubility of **3** even in non-polar organic solvents.

The X-ray structure of **3**‡ (Fig. 1) shows that upon protonation of the coordinated tetramethylfulvene ligand a Cp^*_2Ti unit has been generated which is now coordinated to a 'model silanized silica surface'. The Ti–O bond length in **3** is 1.927(2) Å. In accordance with the presence of a decamethyltitanocene(III) derivative a very broad ^{1}H NMR signal ($\nu_{1/2} \cong$ 1000 Hz) at δ 14.6 could be unambiguously assigned to the C_5Me_5 protons which is in good agreement with values reported by Pattiasina *et al.* for a series of Cp^*_2TiX complexes (X = Cl, Br, I, BH_4, NMe_2, OBu^t, O_2CH; δ 14.1–18.4, $\nu_{1/2}$ = 620–5000 Hz).[12,13]

The new synthetic route using the fulvene precursor Cp*FvTi was also successfully employed in the preparation of a compound which can be regarded as one of the most advanced molecular models for a catalytically active titanium center on a silica surface. Reaction of Cp*FvTi with the monosilylated silsesquioxane precursor **2b** in refluxing toluene afforded a



Scheme 1 Synthesis of complexes **3** and **4**.† *Reaction conditions*: toluene, 2 h reflux, crystallization from hexane.

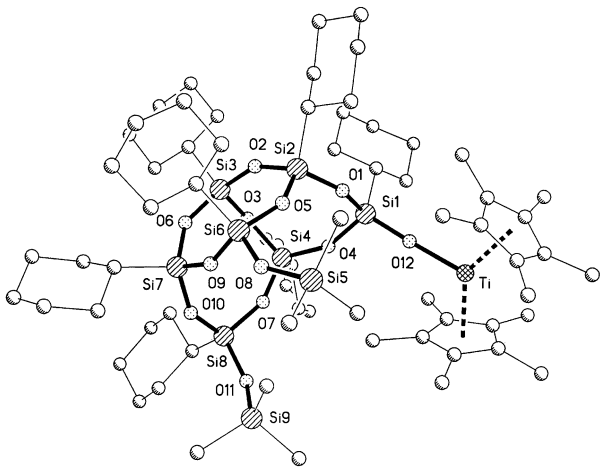


Fig. 1 Structure of **3** in the crystal. Selected interatomic distances (Å) and bond angles (°): Ti–O(12) 1.927(2), Si(1)–O(12) 1.595(2), Ti–C 2.411(3) (av.), Ti–O(12)–Si(1) 177.8(1), Si(6)–O(8)–Si(5) 146.1(1), Si(8)–O(11)–Si(9) 147.7(1).

yellow crystalline material which was shown to be the novel mono-Cp* titanium(IV) silsesquioxane complex Cp*Ti[Cy_7-$Si_7O_{11}(OSiMe_3)$][$Cy_7Si_7O_{10}(OH)(OSiMe_3)$] **4** (69% yield). The surprising outcome of this reaction is the exclusive formation of a Cp^*Ti^{IV} complex in which two silsesquioxanes are bonded in different ways to a single titanium center. In the course of the reaction 1 equivalent of pentamethylcyclopentadiene is eliminated (GC control).

An X-ray diffraction analysis‡ (Fig. 2) clearly shows that **4** is an advanced and highly 'realistic' molecular model for a Ti olefin polymerization catalyst immobilized on a silica surface. A mono(pentamethylcyclopentadienyl) titanium unit resides on

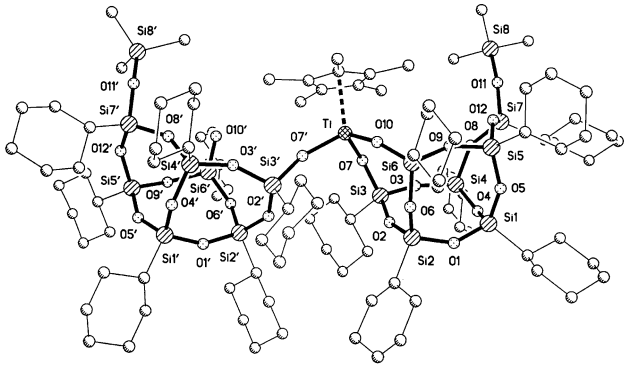

Fig. 2 Structure of **4** in the crystal. Selected interatomic distances (Å) and bond angles (°): Ti–O7 1.789(3), Ti–O7′ 1.794(3), Ti–O10 1.805(3), Ti–C 2.317(5), Si3–O7 1.575(3), Si3′–O7′ 1.571(3), Si6–O10 1.580(3); O7–Ti–O7′ 104.3(2), O7–Ti–O10 103.9(2), O7′–Ti–O10 105.3(2), Ti–O7–Si3 148.9(2), Ti–O7′–Si3′ 162.9(2), Ti–O10–Si6 154.8(2).

a 'model silica surface' formed by one chelating and one monodentate silsesquioxane ligand. With an average of 1.796(3) Å the three Ti–O bond lengths are virtually identical. A highly unusual feature of **4** making this compound a particular 'realistic' model system is a silanol function in close proximity to the Ti center. Very weak hydrogen bonding interaction of this silanol group with a cage oxygen atom (C8′) apparently prevents the molecule from intermolecular protonation of the remaining Cp* ligand, thereby 'taming' the reactivity of the Si–OH function.

We conclude that reactions of the fulvene precursor Cp*FvTi with functionalized silsesquioxanes represent a novel salt-free route to advanced molecular model systems for Ti olefin polymerization catalysts immobilized on a silica surface. The new method should have the potential of being more generally applicable to other silsesquioxane reagents as well as the zirconium analogues.

We thank the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm Siliciumchemie) and the Fonds der Chemischen Industrie for financial support.

First published as an Advance Article on the web

The tetrafunctional N-donor ligand 1 is able to form homoleptic complex cations with dodecahedral ($[Fe\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]^{2+}$ 2) or tetrahedral ($[Cu_2\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]^{2+}$ 3) binding domains.

Polyfunctional ligands which are able to either act as fully chelating systems towards one metal ion or to divide their donor functions into separate domains to bind different metal ions offer fascinating perspectives in the synthesis of complexes with complementary topological properites.[1–3]

Though principally ambivalent in this sense, 1,10-phenanthroline systems normally act in a chelating fashion due to steric hindrances caused by the polycyclic aromatic system.[4,5] We report herein the first instance where a Schiff-base derivative of 1,10-phenanthroline containing four nitrogen donor functions—namely $C_{12}H_6N_2(CHNC_6H_4SMe)_2$ **1**—behaves in an ambivalent fashion towards different metal ions in homoleptic bis-ligand complex cations and describe the structural properties of $[Fe\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]^{2+}$ **2** and of $[Cu_2\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]^{2+}$ **3**.

Ligand **1** (ESI†) was synthesised from 2,9-diformylphenanthroline[6] and 2-methylmercaptoaniline. The mononuclear iron(II) complex cation **2** was obtained by reaction of **1** with $FeCl_2{\cdot}4H_2O$ and isolated as $[Fe\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]_2[Cl_3FeOFeCl_3][ClO_4]_2{\cdot}4DMF$.‡ The dinuclear copper(I) cation **3** was obtained by reaction of **1** with $Cu(MeCN)_4BF_4$[7] or with $Cu(ClO_4)_2{\cdot}6H_2O$ and isolated as $[Cu_2\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2][BF_4]_2$ or as $[Cu_2\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2][ClO_4]_2{\cdot}3DMF$ respectively.

The crystal structure of **2**§ (Fig. 1) shows that the eight nitrogen donor atoms of the two ligands define a distorted triangulated dodecahedron around Fe(II) which is composed of two sets of trapezoidal arrangements in perpendicular orientations. These sets belong to different ligands and form two interpenetrating tetrahedra, a flattened one consisting of N(1), N(2), N(5) and N(6) and an elongated one defined by N(3), N(4), N(7) and N(8). The shortest Fe–N bonds [N(2), N(6): 2.180 Å; N(1), N(5): 2.242 Å] are formed by the aromatic donor functions which define the flattened tetrahedron. The elongated tetrahedron is composed of the imine donor functions and makes two slightly longer Fe–N_{imino} bonds [N(3), N(7): 2.389 Å] and two substantially longer ones [N(4), N(8): 2.769 Å]. According to this distance distribution, the overall coordination around iron(II) should be described as a distorted 4 + 2 + 2 dodecahedral geometry. The two phen moieties are planar within experimental error (mean deviation 0.026 and 0.037 Å, respectively) and nearly perpendicular (interplanar angle 100.7°) to each other. The complex anion $[Cl_3FeOFeCl_3]^{2-}$ has crystallographically imposed inversion symmetry resulting in an apparently linear Fe–O–Fe bridge [Fe–O 1.759(1) Å]. From an inspection of the atomic displacement parameters, however, it cannot be ruled out that the linear bridge represents only the mean geometry of slightly bent molecules which are distributed throughout the crystal in a disordered fashion. This dinuclear iron(III) species has been described frequently in the literature in compounds with a variety of different counter cations.[8]

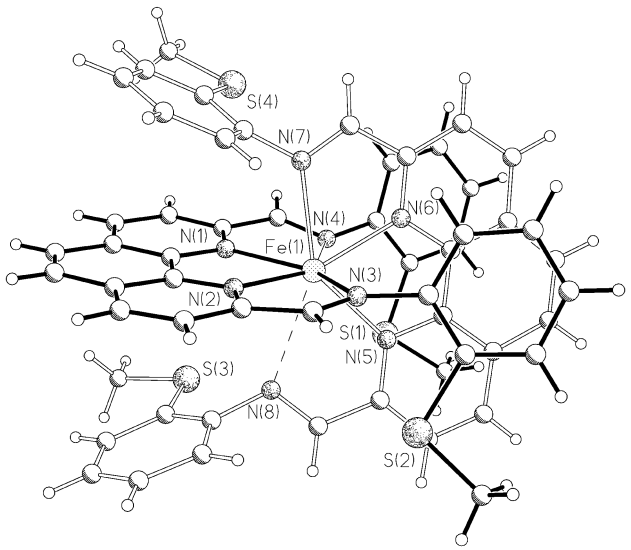

Fig. 1 Structure of $[Fe\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]^{2+}$ **2** in crystals of $[Fe\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2][Cl_3FeOFeCl_3][ClO_4]_2{\cdot}4DMF$. Selected bond distances (Å): Fe(1)–N(1) 2.246(3), Fe(1)–N(2) 2.178(3), Fe(1)–N(3) 2.397(3), Fe(1)–N(4) 2.809(3), Fe(1)–N(5) 2.238(3), Fe(1)–N(6) 2.183(3), Fe(1)–N(7) 2.399(3), Fe(1)–N(8) 2.729(3).

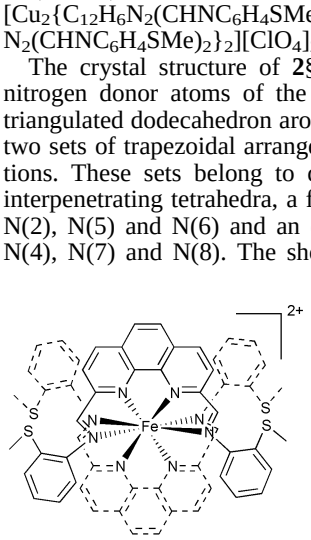
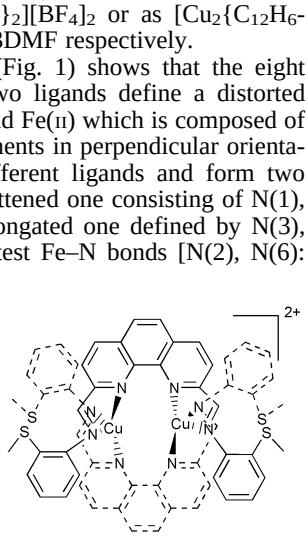


2



3

The structure of **3** is shown in Fig. 2. Though the spatial distribution of the nitrogen donor functions within the complex cation is closely related to that observed in **2**, the overall symmetry is remarkably higher in this case. Cation **3** belongs to the point group D_2 with the principal twofold axis passing through the Cu atoms. The second rotation axis passes through

† Electronic supplementary information (ESI) available: synthesis, characterisation, Mössbauer and NMR data, structure of **1**. See http://www.rsc.org/suppdata/cc/b0/b005671p/

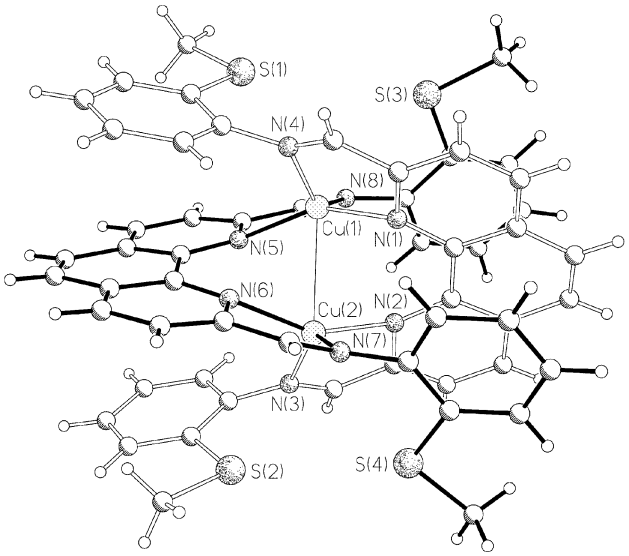


Fig. 2 Structure of $[Cu_2\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]^{2+}$ **3** in crystals of $[Cu_2\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2][ClO_4]_2\cdot 3DMF$. Selected bond distances (Å): Cu(1)–N(1) 2.052(2), Cu(1)–N(4) 2.044(2), Cu(1)–N(5) 2.057(2), Cu(1)–N(8) 2.048(2), Cu(2)–N(2) 2.060(2), Cu(2)–N(3) 2.041(2), Cu(2)–N(6) 2.061(2), Cu(2)–N(7) 2.046(2).

the midpoints of the homonuclear six-membered carbon rings of the phenanthroline systems, and the third axis is normal to the others. None of these axes is crystallographically imposed. The dodecahedral (bitetrahedral) nitrogen framework around iron in **2** is now split into two distinct sub-sites hosting the copper ions in a fashion completely different from the mononuclear iron complex. Each copper ion is in a highly distorted tetrahedral environment formed by two phenanthroline-type and two imine-type nitrogen atoms from different ligands each. The angles defined by those CuN_2 triangles which are bisected by the principal twofold axis are 74.8° for Cu(1) and 74.3° for Cu(2), and the corresponding N–Cu–N angles within these triangles are 152.1(1) and 138.0(1)° for Cu(1) and 154.1(1) and 137.0(1)° for Cu(2). The N-donor functions of both phen systems are bonded to two different metal atoms each which are located at opposite sides of the aromatic plane. This type of bonding introduces steric strain to the ligand and leads to a significant twisting of the individual rings of the polycyclic aromatic system. Consequently, the N–C–C–N fragments are no longer planar, and the corresponding torsion angles are 9.4° [N(1), N(2)] and 10.4° [N(5), N(6)] respectively. The copper atoms are 2.695(1) Å apart from each other. Cation **3** is an extremely rare example of a complex containing 1,2-bifunctional nitrogen donor ligands with phenanthroline-like rigid geometries which do not act as chelating groups towards metal ions. To our knowledge, the only other example is the binuclear complex cation $[Cu_2\{C_{12}H_6N_2(CHNC_6H_4F)_2\}_2]^{2+}$.[4]

The structures of the complex cations **2** and **3** show some striking similarities. The close relationship between them can best be explained by removing the binuclear copper system and placing a divalent iron atom into the centroid of the molecule. This system has a highly symmetrical nitrogen environment around the central metal which can be described in terms of a triangulated dodecahedron with center-to-vertex distances of 2.182 Å (mean of 4) for the compressed tetrahedron and of 2.828 Å (mean of 4) for the elongated one. The hypothetical complex cation thus derived can easily be transformed to the complex cation **2** by a formal relaxation process which shortens two of the four long nitrogen–iron contacts within the elongated nitrogen tetrahedron to *ca.* 2.398 Å. This process is accompanied by a rotation of the methylthio-substituted phenyl rings which are attached to the conserved nitrogen donor functions of the elongated nitrogen tetrahedron around the N–C bond by 180°.

The Mössbauer spectra of a crystalline sample of $[Fe\{C_{12}H_6N_2(CHNC_6H_4SMe)_2\}_2]_2[Cl_3FeOFeCl_3]$-$[ClO_4]_2\cdot 4DMF$ in the range 80–300 K show a superposition of two quadrupole doublets (I) and (II) with an intensity ratio of close to unity (48 : 52) at 80 K. We assign subspectrum (I) to cation **2** and subspectrum (II) to $[Cl_3FeOFeCl_3]^{2-}$. The parameters of the subspectrum (I) (δ 1.18 mm s^{-1}; ΔE_Q = 2.45 mm s^{-1}) are surprisingly close to those typical for ferrous iron in octahedral environments.[9] They do not reflect any particularity in the electronic structure that could be related to the eight-coordination of iron in **2**.

The results presented here indicate that the highly conjugated ligand **1** acts either as a normal chelating tetradentate ligand or as a binucleating bis-didentate ligand depending on the nature of the central metal ion.

First published as an Advance Article on the web

Novel mesoporous TS-1 catalyst is shown to be active in epoxidation of oct-1-ene and significantly more active in epoxidation of cyclohexene than conventional TS-1.

Since the first report by Taramasso *et al.*[1] there have been numerous demonstrations of the outstanding catalytic properties of titanium silicalite 1 (TS-1) for selective oxidation and epoxidation of various organic compounds with aqueous hydrogen peroxide. However, TS-1 suffers from intracrystalline diffusion limitations owing to the small size of the zeolite micropores; this limitation is most pronounced for low-temperature liquid phase reactions with bulky reactants and products. This has stimulated research into zeolites with larger pores (*e.g.* BEA, UTD-1) and amorphous mesoporous titanium-containing materials. Mesoporous materials only exhibit high selectivities towards epoxides if organic peroxides are used as oxidants.[2] This reduces the environmental and economic advantages, since management of by-products due to reduced selectivities and decomposition of the organic oxidant becomes an important issue. Comparative studies of TS-1 and Ti-BEA have shown that different catalytic behaviour and lifetime are to be expected,[3] *i.e.* the excellent catalytic properties of TS-1 might not be observed for Ti-BEA. The diffusional properties of TS-1 catalysts can be altered by preparation of nanosized TS-1 (*e.g.* by the recently developed Confined Space Synthesis method[4,5]), but separation of the finely crystalline catalyst from the product mixture might involve costly high-speed centrifugation or flash distillation.

Recently we reported the preparation of mesoporous zeolite single crystals that compared with conventional zeolite crystals, exhibiting significantly improved diffusional properties.[6] Typical mesoporous zeolite single crystals of $1.0 \times 0.5 \times 0.5$ mm^3 incorporate an interconnected network built from more than 1500 primary carbon particles during growth. Contrary to nanosized TS-1, separation of mesoporous TS-1 from the product mixture can be performed by simple filtration. Here, the catalytic performance of mesoporous TS-1 in the epoxidation of linear and cyclic alkenes is compared with that of conventional TS-1.

Carbon Black Pearls 700® (supplied by Carbot Corp.) with an average particle diameter of 18 nm (ASTM D-3249) were impregnated to incipient wetness with a clear solution of tetrapropylammonium hydroxide, water and ethanol. After evaporation of the ethanol, the carbon particles were impregnated with 20% excess (relative to incipient wetness) of a mixture of tetraethylorthotitanate and tetraethylorthosilicate. The composition of the resulting synthesis gel was 20 TPA_2O:TiO_2:100 SiO_2:200 H_2O, and the resulting zeolite concentration *ca.* 20 wt%. After ageing for a minimum of 3 h at room temperature, the impregnated carbon black was introduced into a stainless steel autoclave containing sufficient water to produce saturated steam. The autoclave was heated slowly (0.5 °C min^{-1}) to 170 °C and maintained at this temperature for 72 h. After cooling the autoclave to room temperature, the product was suspended in water and isolated by suction filtration. The product was washed four times as a suspension with water and then dried at 110 °C for 10 h. The carbon black was removed in a muffle furnace by controlled combustion in air at 550 °C for 8 h. In this manner a white material was obtained which according to chemical analysis was shown to contain < 0.5 wt% C.

Micron-sized TS-1 with a similar titanium content, prepared according to ref. 7, was used as a reference.

XRPD showed that both samples consisted of highly crystalline MFI-structured material. Characterisation by diffuse UV–VIS reflectance spectroscopy and Raman spectroscopy verified the presence of titanium in the zeolite framework while no extra-framework anatase was detected. Chemical analysis of the two TS-1 samples gave Si/Ti ratios of 110 in both cases. Electron microscopy of the conventional TS-1 revealed a highly crystalline material consisting of twinned coffin-shaped crystals with a narrow size distribution of *ca.* 1.5 μm as shown in Fig. 1.

Transmission electron micrographs were recorded with a Philips CM200 FEG, operating at 200 kV. The sample was suspended in ethanol and dispersed on a copper grid coated with lacey carbon film.

Relatively large (*ca.* 0.3–1.2 μm) and well shaped crystals are obtained by hydrothermal crystallisation in carbon black, and a representative crystal is shown in Fig. 2. Inspection of high-resolution transmission electron micrographs revealed lattice fringes extending through the entire crystal. The significant mesoporosity was observed as bright spots, *ca.* 20 nm in diameter, dispersed throughout the entire crystal. This diameter matches that of the carbon primary particles (18 nm) which occupy these positions prior to combustion. It was shown by N_2 adsorption/desorption that the mesoporous TS-1 exhibited a

DOI: 10.1039/b006460m

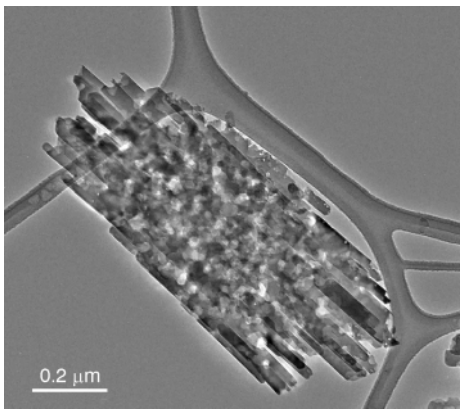

Fig. 2 Transmission electron microscopy image of mesoporous TS-1 single crystal.

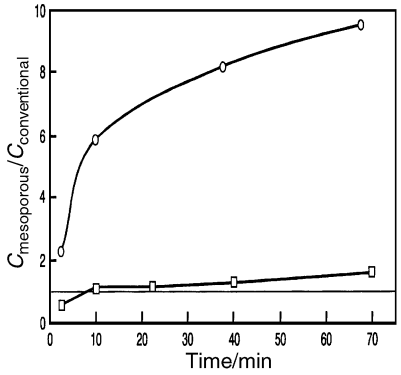

Fig. 3 Ratio of product concentrations [sum of epoxide and secondary products; (■) from oct-1-ene and (●) from cyclohexene] obtained with mesoporous and conventional TS-1 as a function of the contact time. It is seen that mesoporous TS-1 has a similar activity for oct-1-ene epoxidation as conventional TS-1. However, the mesoporous TS-1 is significantly more active for cyclohexene epoxidation.

porosity similar to that reported previously for ZSM-5 prepared by a similar route.[6]

The two TS-1 samples were tested as catalysts for epoxidation of oct-1-ene and cyclohexene with aqueous hydrogen peroxide using methanol as solvent and *n*-heptane as internal standard. The reaction was performed at ambient pressure in a magnetically stirred round-bottomed flask fitted with a condenser and placed in a thermostated oil bath. Alkene (4.2 ml of oct-1-ene or 2.7 ml of cyclohexene), 20.0 ml methanol, 0.75 ml *n*-heptane (internal standard) and 0.18 g of TS-1 catalyst were added to the flask and preheated to the reaction temperature (40 °C). The kinetic experiment was started when 0.50 ml 35 wt% H_2O_2 was added; samples of the reaction mixture were taken at regular intervals. The samples were cooled, the zeolite catalyst removed by filtration and analysed by GC. The initial hydrogen peroxide/olefin molar ratio was 0.25, and the H_2O_2/titanium molar ratio was *ca.* 230. The selectivities towards the corresponding epoxides were > 90% in all cases. The catalytic performance of the two types of TS-1 is compared by plotting the ratio of product concentrations as a function of time. This is illustrated in Fig. 3 for the epoxidation of oct-1-ene and cyclohexene.

Similar product concentrations ($C_{mesoporous}/C_{conventional} = 1$) are obtained when the epoxidation of oct-1-ene is catalysed by mesoporous and by conventional TS-1. This suggests that the epoxidation of oct-1-ene is not limited by intra-crystalline diffusion and therefore not dependent on whether or not the crystals are mesoporous. The results also suggest that the intrinsic activity of mesoporous TS-1 is similar to conventional TS-1. In contrast, the epoxidation of cyclohexene exhibits a product concentration ratio, which exceeds a value of 10 within the contact times studied. Since the experiments with oct-1-ene suggest similar intrinsic activity of the two types of TS-1, the enhanced catalytic performance of the mesoporous sample must be due to a better accessibility of the active sites. Experiments using cyclooctene have also been performed, showing a similar pattern as observed for cyclohexene. Thus, the improved catalytic activity of the mesoporous TS-1 is attributed to its improved diffusional properties compared with conventional micron-sized TS-1.

Compared with conventional TS-1, mesoporous TS-1 improves the catalytic performance without changing the product distribution, which might be an advantage compared with the alternative of using titanium-containing zeolites with larger pores. Generally, it seems possible to prepare mesoporous crystals of most zeolites with the present technique. This may lead to improved new catalysts for many different zeolite catalysed reactions. Particularly, in bifunctional catalysis it appears attractive to disperse another catalytic functionality 'inside' every individual zeolite crystal.

Aqueous solutions of hypovalent gallium; reductions using gallium(I)†

Shawn Swavey* and Edwin S. Gould*

Department of Chemistry, Kent State University, Kent, Ohio 44242, USA

Received (in Cambridge, UK) 19th June 2000, Accepted 25th September 2000
First published as an Advance Article on the web

Solutions 0.2 mol dm^{-3} in Ga^{I}, prepared by dissolving Ga_2Cl_4 in dry acetonitrile, are stable for more than seven days and may be diluted 300- to 1000-fold with O_2-free water to give Ga^{I} preparations that may be handled by conventional techniques; these Ga^{I}(aq) solutions readily reduce I_3^-, Br_2(aq), $IrCl_6^{2-}$, $Fe(bipy)_3^{3+}$ and aquacob(III)alamin (B_{12a}) but are inert to $Co(NH_3)_5Cl^{2+}$ and $Co(NH_3)_5Br^{2+}$; reduction of $HCrO_4^-$ in 2-ethyl-2-hydroxybutanoate buffers yields the Cr^{IV} chelate of the buffering anion.

Accounts of the generation of gallium(I) species in aqueous solution are exceedingly scarce,[2,3] and no redox studies of this unusual state appear to have been described. A standard potential for Ga(III,I), −0.755 V (25 °C) has been documented.[2]

The crystalline compound 'gallium dichloride' (Ga_2Cl_4) is known to feature equal numbers of Ga(I) and Ga(III) centers ($Ga^{I}Ga^{III}Cl_4^-$).[4] Employing this as a source of hypovalent gallium, we have prepared aqueous Ga(I) solutions which have allowed us, utilizing conventional methods, to compare rates at which this s^2-center reacts with a variety of oxidants.

Manipulations of Ga_2Cl_4 (Aldrich) were carried out under high purity N_2 or Ar. Solutions were prepared by dissolving 1.25 g of this halide in 8.0 ml of anhydrous MeCN under a constant flow of protective gas. After 5 min of stirring, a silver-colored precipitate separates. The clear yellow supernatant solution, which was obtained by centrifuging, was found to be 0.20 mol dm^{-3} in Ga^{I} (spectrophotometric redox titration *vs.* KI_3 at 353 nm) and remained unchanged on standing for seven days. Aqueous solutions for kinetic experiments, prepared by 300- to 1000-fold dilutions of the MeCN solutions with O_2-free water, were stable for 10–15 min in the absence of electrolyte. For slow reactions (*e.g.* reduction of vitamin B_{12a}) fresh aqueous solutions were prepared for each individual run. The rate of the Ga(I)–I_3^- reaction was not appreciably changed by increasing [MeCN] from 0.02 to 0.50 mol dm^{-3}, or by adding $GaCl_3$ in concentration three times that of Ga^{I}.

Solutions of Ga(I) rapidly reduce I_3^-, Br_2(aq), $IrCl_6^{2-}$, $HCrO_4^-$, $Fe(CN)_6^{3-}$ and $Fe(bipy)_3^{3+}$. Reduction of B_{12a} [aquacob(III)alamin] is slow, and there is no perceptible reaction with $Co(NH_3)_5Cl^{2+}$ or $Co(NH_3)_5Br^{2+}$. Each mol of Ga(I) consumes very nearly 1.0 mol of I_3^- or Br_2 but 2.0 mol of the le$^-$ oxidants $IrCl_6^{2-}$ and $Fe(bipy)_3^{3+}$, reflecting the expected conversion to Ga^{III} with oxidants of either type [eqn. (1) and (2)]:

$$Ga^{I} + Br_2 \rightarrow Ga^{III} + 2Br^- \quad (1)$$

$$Ga^{I} + 2\ Fe(bipy)_3^{3+} \rightarrow Ga^{III} + 2\ Fe(bipy)_3^{2+} \quad (2)$$

Oxidation by $HCrO_4^-$ utilizes 0.64 ± 0.01 mol of Cr^{VI} in 0.01 M $HClO_4$ but 1.1 mol of oxidant when carried out in 2-ethyl-2-hydroxybutanoic acid buffer (EHBA/EHB$^-$, pH 3.3), indicating predominant conversion to Cr^{III} in the absence of this chelating ligand [eqn. (3)] but formation of Cr^{IV} in its presence [eqn. (4)]:

$$3Ga^{I} + 2\ Cr^{VI} \rightarrow 3\ Ga^{III} + 2\ Cr^{III}\ (\text{pH 1–2}) \quad (3)$$

$$Ga^{I} + Cr^{VI} \xrightarrow[\text{buffer}]{\text{EHBA}} Ga^{III} + Cr^{VI}\ (\text{EHB}^-\ \text{complex}) \quad (4)$$

The pink product of eqn. (4) showed a strong peak at 510 nm, typical of EHB-chelated Cr^{IV}.[5]

The reactions listed in Table 1 are first order in each of the redox partners. Although oxidations by $IrCl_6^{2-}$ and $Fe(bipy)_3^{3+}$ almost certainly pass through the intermediate state Ga^{II}, kinetic profiles for these oxidants exhibit no discontinuity attributable to the accumulation or decay of this odd-electron species, implying a two-step sequence (5), in which

$$Ga^{I} \xrightarrow[\text{slow}]{Ir^{IV}} Ga^{II} \xrightarrow[\text{rapid}]{Ir^{IV}} Ga^{III} \quad (5)$$

the initial step is rate-determining and the more rapid follow-up step is kinetically silent. The relative rates of the two steps suggest that Ga^{II}, the s^1 intermediate, is much more strongly reducing than the parent s^2 cation, a difference applying also to the related p-block triads, Tl(III,II,I),[7] In(III,II,I)[8] and Ge(IV,III,II).[9]

As has been recently noted[1] for Ge^{II} (an isoelectronic state), Ga^{I} resists oxidation by both $Co(NH_3)_5Cl^{2+}$ and by its Co(III)Br counterpart. These Co(III) oxidants offer remarkably facile inner-sphere le$^-$ paths to aqua complexes of d- and f-block reductants,[10] but such routes are denied to this pair of $4s^2$ species which react primarily as 2e$^-$ donors. This marked mechanistic shift probably results in part from less effective halo-ligation to this main group center and, in part, from its modestly reducing $E°$(I,II) value (in contrast to the more negative potential for its II–III conversion).

In contrast, we find the cobalt(III) corrin derivative, aquacob(III)alamin (B_{12a}) to be reduced smoothly to its Co(II) analog. We suspect that this reaction is initiated by the two-unit reduction (very likely by oxo-transfer) to the known Co^{I} complex, B_{12s} [cob(I)alamin], a hypovalent species which has been shown[11] to undergo very rapid comproportionation with B_{12a} [eqn. (6)]:

$$Co^{III} \xrightarrow{Ga^{I}} Co^{I} \xrightarrow{Co^{III}} 2\ Co^{II} \quad (6)$$

Table 1 Reductions with aqueous gallium(I)[a]

Oxidant	Product	k/dm^3 mol^{-1} s^{-1}
I_3^-	I^-	(1.47 ± 0.09) × 10^4
Br_2 (aq)	Br^-	(2.05 ± 0.05) × 10^4
$IrCl_6^{2-}$	$IrCl_6^{3-}$	(7.3 ± 0.05) × 10^2
$Fe(bipy)_3^{3+}$	$Fe(bipy)_3^{2+}$	(8.9 ± 0.2) × 10^4
$HCrO_4^-$ (pH 2.0)	Cr^{III}	(2.7 ± 0.1) × 10^3
B_{12a} (Co^{III})	B_{12r} (Co^{II})[b]	7.1 ± 0.3
$[Co(NH_3)_5Br]^{2+}$		< 0.02
$[Co(NH_3)_5Cl]^{2+}$		< 0.01

[a] Reactions at 25 °C; μ = 0.5 M ($NaClO_4$, LiCl or KI); [H$^+$] = 0.01–0.05 M; [Ga^{I}] = (1.0–12.0) × 10^{-4} M; [oxidant] = (4.0–12.0) × 10^{-5} M. [b] Spectrum of product corresponded to that reported by Pratt.[6]

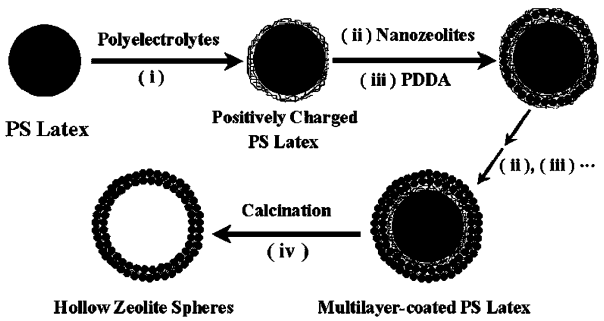
Received (in Cambridge, UK) 9th August 2000, Accepted 21st September 2000
First published as an Advance Article on the web

Hollow spheres of zeolite have been fabricated through a layer-by-layer technique using polystyrene spheres as templates and nanozeolites as 'building blocks', followed by calcination.

Hollow spheres have found many applications in chemistry, biotechnology and materials science owing to their characteristic macroscopic structure.[1,2] Fabrication of hollow spheres with well defined nanoscaled pores on the shell may open up possibilities for various new application fields, such as controlled release capsules, artificial cells, chemical sensors, shape-selective adsorbents and catalysts. Up to now, only hollow spheres of mesoporous silica have been obtained by spray drying and emulsion/phase separation techniques.[3–5] Zeolites are ideal construction materials for the shell of hollow spheres owing to their high thermal stability, large microporosity, high shape-selectivity and intrinsic chemical activity. However, the present methods of preparing hollow mesoporous silica spheres cannot be used to fabricate hollow zeolite spheres, because the synthetic conditions and formation mechanisms of mesoporous silica and zeolites are totally different. Recently, a layer-by-layer (LbL) technique based on electrostatic interaction or hydrogen bonding has been widely adopted to fabricate films on the surfaces of flat and spherical substrates.[6,7] It has been noticed that colloidal zeolites are negatively charged in basic solution and can aggregate readily to form hierarchical structures such as membranes, fibers and micro/macroporous zeolite monoliths.[8,9] The electrostatic attraction between a negatively charged nanozeolite and an oppositely charged polymer is an effective driving force for the self-assembly of zeolite–polymer multilayers on colloidal templates. A new procedure for fabricating hollow zeolite spheres involving polystyrene (PS) latex templated electrostatic LbL self-assembly of nanozeolite/polymer multilayers followed by removal of the template and the polymer is reported in this work.

Nanocrystals of zeolite β (40 ± 5 nm), silicalite-1 (50±10 and 80 ± 10 nm) were prepared according to the literature methods,[10,11] and characterized by XRD, IR and SEM. The nanozeolites were centrifuged, washed and dispersed in 0.1 mol L^{-1} NaCl solution at pH 9.5. The fabrication procedure for hollow zeolite spheres is depicted in Scheme 1. First, the positively charged PS latex templates were prepared by depositing five layers of polyelectrolytes of cationic poly(diallyldimethylammonium chloride) (PDDA) and anionic poly(styrenesulfonate, sodium salt) (PSS) in the order of PDDA/PSS/PDDA/PSS/PDDA.[2,7] Then, the nanozeolite and PDDA were alternately deposited on the positively charged PS substrates to form homogeneous nanozeolite/PDDA multilayers. All the above adsorption steps were performed in 0.1 mol L^{-1} NaCl solution with a liquid/solid volume ratio of 50 at pH 9.5 and ambient temperature for 20 min, and after each adsorption step the sample was centrifuged, washed and redispersed. To remove the PS latex template and the polymers, the samples were heated to 873 K at a heating rate of 5 K min^{-1} in nitrogen, and kept at 873 K in nitrogen for 4 h and subsequently in air for 8 h.

Homogeneous deposition of nanozeolite particles on PS latex templates is a crucial step in the preparation of hollow zeolite spheres using the LbL technique. The success of this process largely depends on the electrostatic interaction between the nanozeolite and PDDA. Hence, pH and ionic strength of the colloidal solution are important. In neutral solution, most of the coated spheres are coalesced and have very rough surfaces [Fig. 1(a)]. In addition, the nanozeolite particles form aggregates in solution. This is probably because the charge density on the nanosilicalite-1 surface is rather low near its isoelectric point (pH = 7).[12] At pH 11, discontinuous defects [see arrows in Fig. 1(c)] on the sphere surface are observed even after four nanozeolite/PDDA layer pairs are deposited. Under such conditions, most of the silanol groups on the surface of the nanozeolite particles exist in the form of Si–O^-, which increases the repulsive force between the particles and inhibits the formation of a compact coat. The best result is obtained at pH 9.5 [Fig. 1(b)], when the amount of negative charge on the zeolite particles is just adequate for them to deposit onto the positively charged PS spheres densely and compactly. NaCl was added into the solution to adjust the ionic strength. Without adding salt, defects were observed on the sphere surface even after four layers of zeolites were deposited. As the salt concentration was increased to 0.1 mol L^{-1}, the coat on the sphere surface became uniform and dense. This shows that a proper ionic strength of the solution is necessary to screen the nanozeolite particles from mutual repulsion and to facilitate the formation of a uniform and compact zeolite coat on the templates.[13]



Scheme 1 The procedure for preparing hollow zeolite spheres.

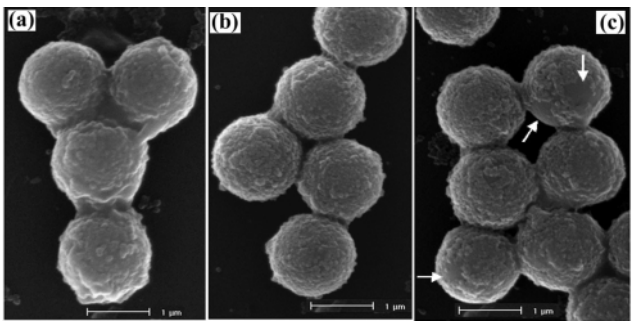


Fig. 1 SEM micrographs of polyelectrolyte-modified PS latices deposited with two nanosilicalite-1/PDDA layer pairs, (a) in neutral solution, (b) at pH = 9.5 and (c) four nanosilicalite-1/PDDA layer pairs at pH = 11.0.

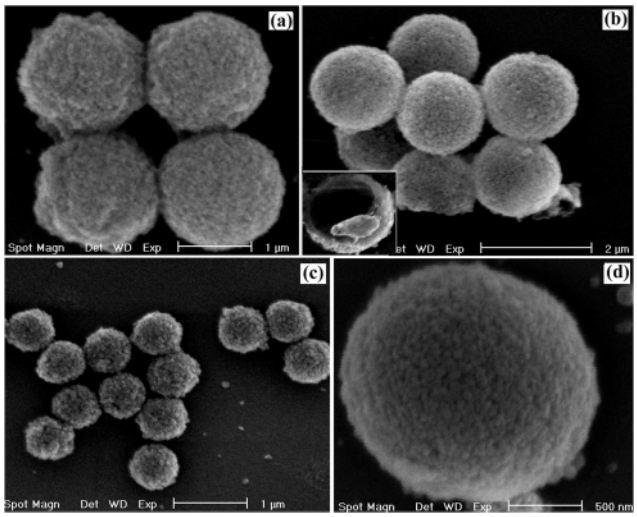

Fig. 2 SEM micrographs of samples deposited with four nanozeolite/PDDA layer pairs, (a) PS latices (ϕ = 1.47 μm) coated with zeolite β, (b) hollow zeolite β sphere templated by PS latices (ϕ = 1.47 μm), (c) hollow zeolite β sphere templated by PS latices (ϕ = 0.53 μm), (d) hollow silicalite-1 sphere templated by PS latices (ϕ = 1.47 μm).

SEM micrographs of hollow spheres of zeolite β and silicalite-1 templated by PS latices with diameters ϕ of 1.47 and 0.53 μm are shown in Fig. 2. The PS latices are homogeneously covered with zeolite nanoparticles. The inset in Fig. 2(b) shows that the spheres are hollow after calcination and the thickness of the shell is rather uniform. The surface of the hollow spheres is smoother than the coated PS latices, implying that the zeolite nanoparticles are more closely packed after calcination. Also, it was observed that the smaller the PS latices and the nanozeolite particles employed, the easier it was to keep the hollow spheres intact. Almost all the hollow spheres were intact, when the samples were prepared by depositing four layers of 40 nm zeolite β onto PS latices of 0.53 μm [Fig. 2(c)]. The percentage of intact spheres in the final product was also influenced by the number of deposited nanozeolite layers. Hollow spheres were not formed if only one layer of zeolite was deposited, but the formation of such spheres did occur, under the appropriate conditions, when two layers were deposited. The shell thickness of the hollow spheres could be tailored through varying the number of deposited nanozeolite layers. The thickness of shells composed of two, four and six layers of zeolite β nanocrystals was *ca.* 70, 140 and 200 nm, respectively.

XRD patterns of calcined hollow spheres of zeolite β and silicalite-1 are shown in Fig. 3. The patterns are almost the same as those of the original nanozeolites of zeolite β and silicalite-1, indicating that the crystalline structure and crystal size of the zeolites are unaltered after fabrication. Energy dispersive X-ray analysis established that the elemental composition of the shell is in accord with the nanozeolites used. Only characteristic bands of the zeolites appear in the IR spectra of the calcined samples,[10,11] indicating the PS latex core and other organic species are totally removed. Such novel materials are expected to have potential applications as controlled release capsules, artificial cells and catalysts owing to their unique 'cage structure' with microporous shells.

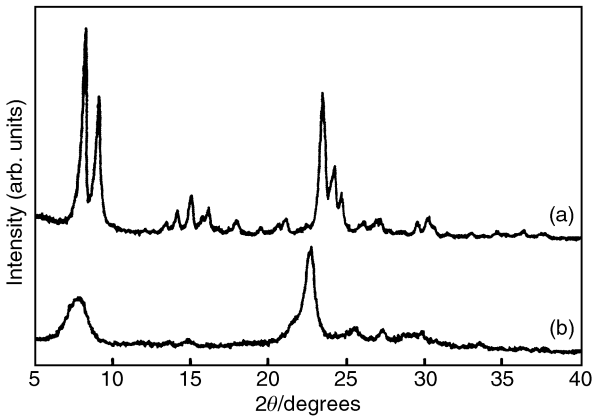

Fig. 3 XRD patterns of hollow spheres of silicalite-1 (a) and zeolite β (b).

In conclusion, hollow spheres of zeolite β and silicalite-1 with different sizes were fabricated efficiently and conveniently through LbL self-assembly of nanozeolite–polymer multilayers on a PS latex, coupled with removal of the core by calcination. The pH and ionic strength of the colloidal solution, crystal size of nanozeolites and size of PS latex templates are factors affecting the fabrication of hollow zeolite spheres. Hollow spheres of other zeolites such as ZSM-5 and TS-1 have also been successfully fabricated in the same manner (to be published). Currently, the application of these novel materials in catalysis, separation and delivery systems is in progress in our laboratory.

Multilayer ultrathin films of molecular titania nanosheets showing highly efficient UV-light absorption

First published as an Advance Article on the web

Titania nanosheet crystallites have been self-assembled layer-by-layer with poly(dimethyldiallyl ammonium chloride) onto substrates to produce ultrathin nanostructured films which exhibit highly efficient optical absorption with a sharp peak at 266 nm.

In the past decade, titania thin films have attracted tremendous attention for their optical and photochemical applications, *e.g.* UV-light shielding, solar energy conversion and detoxification of pollutants.[1] For these applications, it is of great importance to fabricate titania thin films with a well controlled nanostructure. Among a range of film growth strategies, the Langmuir–Blodgett technique and self-assembly procedure *via* sequential adsorption[2] are the most feasible and widely applicable to tailor stable and high-quality films on a nanometer-scale range. Recently these approaches have been applied for the synthesis of multilayer titania films by several groups.[3–6] These preparations incorporated titania particles of several nm in size as a film component. Hence, the resulting multilayer films were composed of alternating layers of two-dimensionally packed nanoparticles and organic substances as a binder. The titania nanoparticles were synthesized by hydrolyzing an appropriate Ti salt. It is sometimes difficult to prepare extremely small sized particles in high quality, particularly in terms of crystallinity, uniform shape and size, which is essential for fabrication of well organized films.

Recently we have demonstrated that colloidal titania nanosheets of composition $Ti_{1-\delta}O_2$ ($\delta \approx 0.09$) can be derived by completely delaminating a layered titanate.[7] The obtained semiconductor crystallite, as the elementary fragment of the layered crystals prepared at a high temperature, is characterized by its very high two-dimensionality, with a thickness of molecular dimension as well as high crystallinity, which leads to novel physicochemical properties which are distinct from those of titania nanoparticles.[8] These features of the nanosheet crystallites may have some advantages to better control nanostructures in the layering process and some enhanced physical properties may be expected for resulting multilayer assemblies in comparison with films composed of nanoparticles. Here, we report the layer-by-layer construction of a well organized multilayer system of titania semiconductor nanosheets and organic polymers, which efficiently absorb UV light with a wavelength below 300 nm.

The titania nanosheet crystallites, $Ti_{1-\delta}O_2$ ($\delta \approx 0.09$), were obtained by chemically delaminating a protonic titanate of γ-FeOOH type layered structure, $H_{0.7}Ti_{1.825}\square_{0.175}O_4{\cdot}H_2O$ (□ = vacancy),[9] into its colloidal single layers upon action of an aqueous solution of tetrabutylammonium hydroxide (TBAOH).[7] The multilayer films were prepared by repeating the following adsorption procedures for the desired number of cycles.

Each cycle involves the immersion of a substrate such as Si wafer or quartz glass into the colloidal suspension of the titania nanosheets for 20 min, rinsing with Milli-Q filtered water (> 17 MΩ cm^{-1}), and then dipping in an aqueous solution of poly(dimethyldiallyl ammonium chloride) (PDDA) for 20 min, and finally washing with water. A polycation such as PDDA was employed as a counterpart for the self-assembly process because the titania nanosheets are negatively charged. The substrates were cleaned prior to the film deposition by a method described in the literature[10] and then primed with poly(ethylenimine), PEI, to introduce positive charge onto their surface. The concentration of the titania suspension and the PDDA solution were 0.08 and 20 g dm^{-3}, respectively. The pH values of both were adjusted to *ca*. 9 by adding an appropriate amount of HCl or TBAOH. The PDDA was added as a 0.5 mol dm^{-3} NaCl solution.

Consecutive adsorption procedures as described above yielded visibly transparent thin films, the growth process of which was followed by several characterization techniques. UV–VIS absorption spectra show progressive enhancement as a function of the layer pair number (Fig. 1). The spectral profile with a pronounced peak at 266 nm is characteristic of titania nanosheets in aqueous suspension.[8] The polycations, PDDA and PEI, do not show substantial absorption in the energy region shown. Consequently, the nearly linear growth of the absorption peak indicates that an approximately equal amount of $Ti_{1-\delta}O_2$ was deposited for each adsorption procedure. The modest increase in background at a wavelength of > 300 nm may arise from light scattering by the nanosheet crystallites oriented parallel to the substrate surface with lateral sizes in the submicro- to micro-meter range.

X-Ray diffraction patterns (Fig. 2) illustrate the evolution of a Bragg peak suggesting a periodicity of 1.4 nm. This diffraction peak is attributable to a so-called superlattice reflection of the inorganic/organic repeating nanostructure. The nanosheet crystallite $Ti_{1-\delta}O_2$ has an atomic architecture of γ-FeOOH type in which TiO_6 octahedra at two different levels along the sheet normal are connected with each other *via* edge-sharing to produce the two-dimensional sheet.[8] Its thickness is

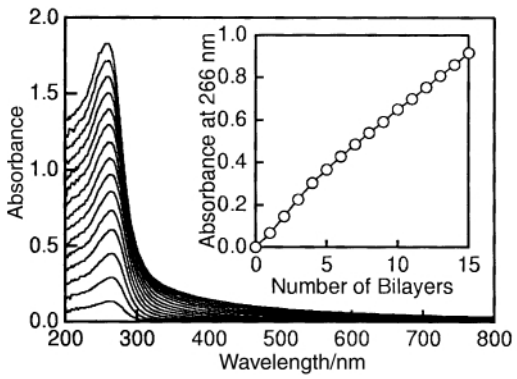

Fig. 1. UV–VIS absorption spectra of $Ti_{1-\delta}O_2$/PDDA multilayer films grown on SiO_2 glass; 0.5 × the observed absorbance at 266 nm is plotted in the inset taking into account the presence of the film on both sides of the substrate.

DOI: 10.1039/b006720m

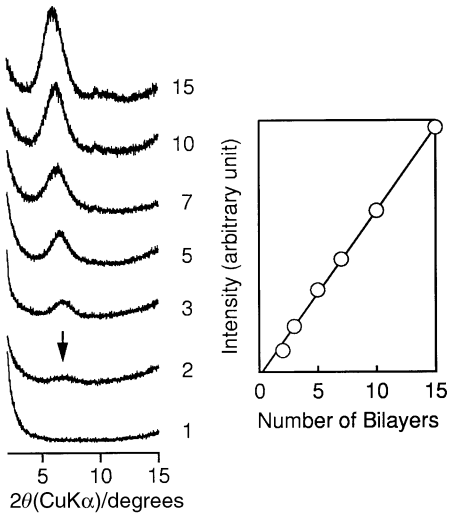

Fig. 2. X-Ray diffraction patterns of $Ti_{1-\delta}O_2$/PDDA films on SiO_2 glass with the number of layer pairs indicated.

estimated to be 0.75 nm taking into account the outermost edges of surface oxygen atoms. Accordingly, the thickness for the PDDA layer should be 0.65 nm. This dimension is reasonable for the PDDA molecular structure at the salt concentration under which the film was grown.

The intensity of the basal diffraction series for a system of N parallel nanosheets can be calculated using eqn. (1):[11]

$$I(0k0) = \frac{1}{N}\frac{1+\cos^2 2\theta}{\sin^2\theta\cos\theta}F^2(0k0)\frac{\sin^2(\pi Nk)}{\sin^2(\pi k)} \qquad (1)$$

where the second, third and fourth terms are the Lorentz-polarization factor, structure factor and interference function, respectively. Since the latter term is proportional to N^2 at $k = \pm 1, 2, 3$, the $0k0$ peak intensity is linearly dependent on N. This was experimentally observed as shown in inset, suggesting successful construction of the multilayer film.

The diffraction peak was detectable even for the two-unit system, *i.e.* PEI/$Ti_{1-\delta}O_2$/PDDA/$Ti_{1-\delta}O_2$. The well ordered nature of this multilayer system is principally explained by the fact that the interpenetration of inorganic and organic components is strongly reduced owing to the two-dimensional architecture of the rigid inorganic nanosheets. This is in sharp contrast to other multilayer films composed of organic polymers where neighboring layers intermingle considerably.[2]

The ultrathin titania films obtained in this study have a molecularly ordered array of the components. The film architecture is based on platelets rather than particles as found for titania films reported previously.[3–6] The multilayer repeat dimension of 1.4 nm is finer than for such previously reported films (> 3 nm).

The optical properties are also noteworthy, particularly in terms of sharp and highly efficient absorption in the UV region (< 300 nm). The sharp absorption edge, which is significantly blue-shifted relative to bulk TiO_2, may be associated with exciton confinement in the two-dimensional semiconductor crystallites which are of sub-nm thickness.[8] Theoretical calculations predict very small values, 0.3–1.9 nm, for the Bohr radius of the first exciton in TiO_2, or the threshold at which quantum size effects manifest themselves.[12,13] On the basis of the experimental data, Serpone *et al.*[14] have claimed that the exciton radius is < 1 nm. Titania nanoparticles reported so far are mostly larger in size than this size-quantization threshold. On the other hand, the nanosheet thickness is small enough to expect carrier confinement. To our knowledge, a dimension as small as 0.75 nm (the nanosheet thickness) has not previously been reported for titania systems.

The absorption efficiency was several times higher than for films incorporated with titania nanoparticles.[3–6] The optical density at a wavelength of 266 nm was 0.065 for one titania-nanosheet layer (inset in Fig. 1). Comparable data for multilayer films with titania nanoparticles and amino acid capped particles are reported to be 0.016 ± 0.008 (at 190 nm) and 0.017 (232 nm), respectively.[4,6] Note that the optical density for the nanosheet system was higher despite its smaller thickness of the titania layer (0.75 nm) in comparison with those of nanoparticles (2.3–3 nm). Although there are several factors to be considered for the origin of this intense absorption, we speculate that the size effect on oscillator strength is a likely explanation. Its significant enhancement with decreasing the size of semiconductor nanocrystallites has been theoretically predicted and has been experimentally observed for CdS nanoclusters.[15] The findings here strongly suggest promising potential of the present system for its use as photovoltaic, photochromic and catalytic devices and sensors.

The UV spectral changes along with the kinetic results for the title reaction suggest that the reaction proceeds through a rapidly formed stable intermediate which decomposes slowly to the product.

Acyl-transfer and related reactions such as phosphoryl- and sulfonyl-transfer reactions are central to our understanding of biochemical pathways. Consequently, there has been considerable interest in examining this large class of reactions.[1–11] Acyl-transfer reactions may proceed either through a stepwise mechanism with an addition intermediate or through a concerted mechanism, depending upon the nature of the nucleophile and structure of the substrate.[1–11] For example, it has generally been understood that reactions of esters with amines proceed through a stepwise mechanism, in which the rate-determining step (RDS) changes from breakdown to formation of the intermediate as the attacking amine becomes more basic than the leaving group by 4–5 pK_a units.[2–4] However, the corresponding reactions with anionic nucleophiles are still controversial.[5–11]

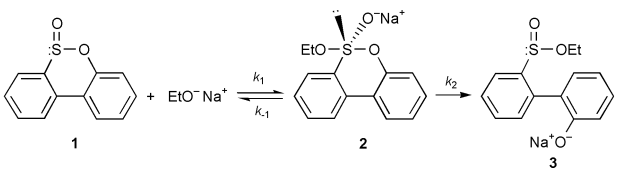
Buncel *et al.* have suggested that acyl-transfer reactions proceed through a stepwise mechanism, based on Hammett plots obtained from reactions of a series of substituted phenyl acetates, phosphinates and sulfonates with anionic nucleophiles.[5,6] Recently, Okuyama *et al.* arrived at a similar conclusion for buffer catalyzed hydrolysis of sulfinate esters.[7] By contrast, Williams *et al.* have concluded that acyl-transfer reactions with anionic nucleophiles proceed through a concerted mechanism, based on linear Brønsted-type plots obtained from reactions of *p*-nitrophenyl acetate and related phosphinate and sulfonate esters with a series of substituted phenoxides.[8] The cross interaction correlations of Jencks,[9] isotope effect studies by Hengge[10] and Marcus analysis by Guthrie[11] have all supported the concerted process.

However, there has been no definitive evidence such as spectroscopic data for any intermediate. We now report, along with kinetic evidence for a stepwise mechanism, the first spectroscopic observation of an intermediate in the reaction of a sulfinate ester (**1**, dibenzo[1,2]oxathiin-6-oxide) with EtONa in anhydrous EtOH, as shown in Scheme 1.

Fig. 1 shows UV spectral changes for the reaction of **1** with EtONa in EtOH. The first spectrum from the top has been taken from the substrate alone in EtOH, and the next ones have been recorded immediately after addition of EtONa at intervals of 180 s. The time between the first and the next spectrum is less than 3 s, but even with this short period the spectral change between the two is significant. Furthermore, there is no isosbestic point discernable in the UV spectra. In subsequent experiments with different concentrations of EtONa, a similar result is found, *i.e.* rapid spectral change upon addition of nucleophile followed by slow modification of the spectrum, but the initial spectral change becomes more significant with increasing concentration of EtONa. Such spectral changes, as well as the absence of isosbestic points, definitely suggest that the present reaction proceeds through rapid formation of a stable intermediate which decomposes slowly to the product.

The initial spectral change has been followed using a stopped-flow spectrophotometer and is illustrated in Fig. 2. These spectral changes were monitored for 16 ms at an interval of 2 ms. Two isosbestic points are observed in Fig. 2, indicating that there is no stable intermediate during this fast process. Therefore, based on the spectroscopic data, it is proposed that the present reaction proceeds in two steps with rapid formation of an intermediate shown as **2**, that decomposes slowly to the product **3**,[12] as shown in Scheme 1.

Further support for the stepwise mechanism can be provided by determination of the microscopic rate constants, k_1, k_{-1}, and k_2 in Scheme 1. Therefore, a kinetic study was performed to determine the k_1 value in Scheme 1 using a stopped-flow technique under pseudo-first-order conditions. The plot of pseudo-first-order rate constants (k_{obs}) *vs.* the concentration of EtONa exhibits good linearity with a large positive intercept (Table 1, ESI†). In a separate control experiment, **1** was shown to be inert in EtOH in the absence of EtONa, indicating that the positive intercept in the plot of k_{obs} *vs.* [EtONa] cannot be ascribed to ethanolysis of **1**, but represents the reverse reaction, k_{-1}. Therefore, the microscopic rate constants (k_1 and k_{-1}) of



Scheme 1

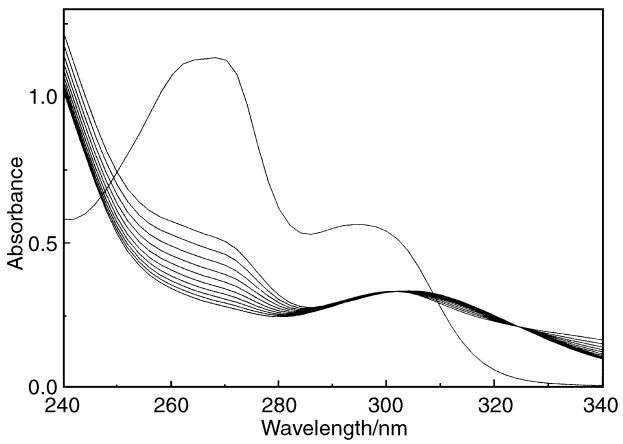


Fig. 1 Repetitive scanning of the UV spectra for the reaction of **1** with EtONa (**1** ⇌ **2** → **3**) in anhydrous EtOH at 25.0 ± 0.1 °C. [**1**] = 7.50×10^{-5} M, [EtONa] = 12.1×10^{-3} M. Time interval less than 3 s for the first and second spectrum from the top, and 180 s for the remainder. See text.

DOI: 10.1039/b006439o

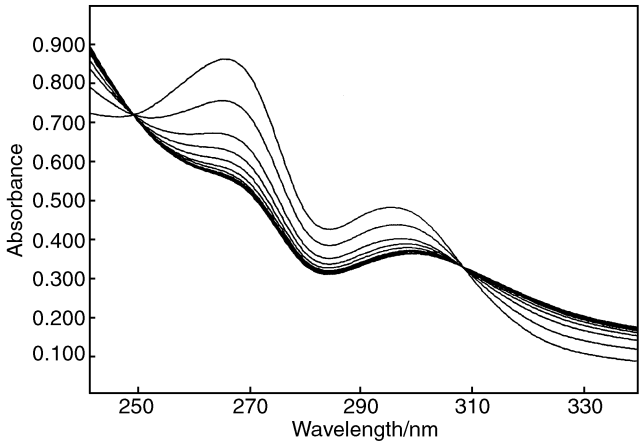

Fig. 2 Repetitive scanning of the stopped-flow spectra for the reaction of **1** with EtONa (**1** ⇌ **2**) in anhydrous EtOH at 25.0 ± 0.1 °C. [**1**] = 8.12×10^{-5} M, [EtONa] = 13.0×10^{-3} M. Time interval = 2 ms.

the fast equilibrium process (**1** ⇌ **2**) can be calculated according to eqn. (1), *i.e*. from the slope and intercept of the plot of k_{obs} *vs*. [EtONa]. The k_1 and k_{-1} values determined in this way are 14,500 $M^{-1}s^{-1}$ and 30.5 s^{-1}, respectively.

$$k_{obs} = k_1[\text{EtONa}] + k_{-1} \quad (1)$$

In order to determine the k_2 value in Scheme 1, the slow reaction process (**1** ⇌ **2** → **3**) has been monitored. The plot of k_{obs} *vs*. [EtONa] yields a curvilinear trace that levels off as the concentration of EtONa increases (Table 2, ESI†). Eqn. (2) may be derived for a reaction which proceeds through a rapid pre-equilibrium as in the present system.[13]

$$k_{obs} = k_1k_2\,[\text{EtONa}]/\{k_1[\text{EtONa}] + k_{-1} + k_2\} \quad (2)$$

Eqn. (2) resembles the Michaelis–Menten equation[14] which accounts for enzyme catalyzed reactions. In this case, the plot of k_{obs} *vs*. [EtONa] should reach a maximum and then flatten out as the concentration of EtONa increases, as found in the present system. Rearrangement of eqn. (2) gives eqn. (3).

$$1/k_{obs} = 1/k_2 + \{k_{-1} + k_2\}/\{k_1k_2\,[\text{EtONa}]\} \quad (3)$$

Consequently, if the present reaction proceeds as in Scheme 1, the plot of $1/k_{obs}$ *vs*. 1/[EtONa] should be linear. In fact, a linear plot has been obtained (Fig. S1, ESI†). From the intercept of the linear plot, the $1/k_2$ value has been calculated. The k_2 value determined in this way is 1.36×10^{-3} s^{-1}, which is much smaller than the k_{-1} value. The relative magnitude of these microscopic rate constants is clearly consistent with the preceeding proposal based on the spectral data shown in Figs. 1 and 2. The small k_2 (1.36×10^{-3} s^{-1}) as compared to k_{-1} (30.5 s^{-1}) would permit observation of the putative intermediate **2**.

Since ethoxide is more basic than aryloxide by 4–5 pK_a units in EtOH,[6b] one might expect EtO^- would be a poorer leaving group than aryloxide. However, in fact, the k_{-1} value has been determined to be over 10^4 times larger than the k_2 value in the present system. Therefore, the present result is quite surprising, and suggests that basicity alone does not determine nucleofugality in this system. Since cyclic sulfinate esters have been suggested to be thermodynamically stable,[15–17] one might suggest that thermodynamic stability of **1** would accelerate the k_{-1} step and retard the k_2 step in Scheme 1. This argument gains support from the fact that the product (**3**) reverts quantitatively to the reactant (**1**) upon acidification of the reaction mixture. However, solvent effect may also be important in the present system. Note that reaction of **1** with OH^- in H_2O is much faster than the corresponding reaction with EtONa in EtOH,[7a] and there is no accumulation of intermediate in H_2O (Fig. S2, ESI†, *e.g*. good isosbestic points at 242 and 306 nm). Furthermore, we have noticed that the reaction of **1** with EtONa is accelerated significantly by addition of H_2O into the reaction medium, even in very small amounts.

However, more systematic studies are required in order to elucidate how the solvent stabilizes or destabilizes reactants, TS and intermediate. Reactions of **1** with various nucleophiles and in different solvents are currently under way to investigate further the reaction mechanism.

The authors are grateful for the financial support from KOSEF (1999-2-123-003-5 and 2000-123-02-2).

By impregnating γ-Al_2O_3 with cerium/zirconium citrate solutions and subsequent calcination, nanostructured $Ce_mZr_{1-m}O_2$ mixed oxides supported on Al_2O_3 are obtained, which feature remarkably high oxygen storage even after calcination at 1100 °C for 24 h.

The oxygen storage/release capacity (OSC) of a three-way catalyst (TWC) is a measure of the ability to attenuate the negative effects of rich/lean oscillations of exhaust gas composition through the Ce^{3+}/Ce^{4+} redox process.[1] By maintaining a stoichiometric composition at the catalyst, the highest conversion efficiency of the exhaust is attained. Accordingly, the efficiency of the OSC is monitored by the vehicle emission on-board diagnostics; decline of OSC being an indication of TWC failure, which makes its substitution mandatory by environmental regulations. In modern TWCs, the OSC is achieved by adding a CeO_2–ZrO_2 mixed oxide component.[2,3] Advent of the 'light-off catalyst', *i.e.* a secondary converter close coupled to the engine, exposes the TWCs to very high temperatures, which requires their thermal stability up to 1100 °C.[4]

$Ce_mZr_{1-m}O_2$ (13 wt%)/γ-Al_2O_3 (m = 1, 0.6, 0.2, denoted as CZXX/Al_2O_3, XX = 100, 60, 20) were prepared by using a modified citrate complexation method;[5] by a single-step wet impregnation of the resulting citrate-containing solution on γ-Al_2O_3 (BET surface area 186 $m^2\ g^{-1}$, pore volume 1.03 ml g^{-1}). $Ce(NO_3)_3{\cdot}6H_2O$ (99.99%, Aldrich) was dissolved in water and mixed with an aqueous solution of $ZrO(NO_3)_2$ (20% ZrO_2, MEL Chemicals), then a water solution of citric acid (99.7%, Prolabo) was added. The metal cation to ligand ratio was 1 to 2.1. The resulting solution was stirred at 75 °C for 5 h, then at room temperature (r.t.) for 12 h, and finally concentrated to perform the 'incipient wetness' impregnation of the support. The resulting material was dried at 120 °C for 12 h, heated to 500 °C at a rate of 3 °C min^{-1} and then calcined at this temperature for 5 h to obtain a yellow powder. These samples are indicated as being 'fresh'. Catalysts were aged by calcination in air. Temperature programmed reduction (TPR) was carried out in a conventional instrument.[3] Dynamic-OSC was measured by alternately pulsing CO (100 μl) and O_2 (100 μl) over the sample (30–100 mg, maintained in a flow of Ar of 25 ml min^{-1}).[3] Powder XRD spectra were collected on a

[a] t″, t′ and t are tetragonal phases (space group $P4_2/nmc$) with pseudo-cubic cell parameter ratio (c/a), respectively, of 1.000, 1.002–1.010 and 1.02; c phase: cubic fluorite type of lattice (space group $Fm3m$).[2] When a mixture of phases was detected the approximate composition was evaluated: c phase: $Ce_{0.8}Zr_{0.2}O_2$; t phase $Ce_{0.2}Zr_{0.8}O_2$. [b] For consistency OSC (O_2 uptake) is given per g of CZ mixed oxide. Dynamic-OSC measured at the indicated temperatures. Total-OSC was measured as O_2 uptake at 427 °C after a TPR up to 1000 °C and assuming a full re-oxidation.[2] 5–7, 15–18 and 18–20 ml O_2 $g_{solid\ solution}^{-1}$ were obtained, respectively, for CZ20/Al_2O_3, CZ60/Al_2O_3 and CZ100/Al_2O_3. [c] Some δ-Al_2O_3 was also detected in a few samples and the sum of θ- and δ-Al_2O_3 is given.

DOI: 10.1039/b006674p

Siemens Kristalloflex Mod.F Instrument (Ni-filtered Cu-Kα radiation). The profile fitting of the XRD patterns was performed by a Rietveld analysis program (RIETAN94). High resolution electron microscopy (HREM) measurements were performed using a JEOL 4000-EX microscope equipped with a top-entry specimen holder with 0.18 nm point resolution with an accelerating voltage of 400 kV. Digital processing was carried out by using a CCD camera and the SEMPER 6+ software package.

Table 1 reports the effects of calcination of the fresh samples on textural, structural and OSC properties. Calcination at 700–1100 °C progressively transforms γ-Al_2O_3 into θ-Al_2O_3 and α-Al_2O_3, the latter being the only phase detected after 24 h at 1100 °C. Consistent with the literature, these transformations are hindered by the presence of either CeO_2[6] or ZrO_2.[7] This effect is noticeable after calcination at 1100 °C for 24 h; the highest surface area (63 m^2 g^{-1}) being observed for CZ20/Al_2O_3. XRD analysis by Rietveld refinement of CZ20/Al_2O_3 calcined at 1100 °C for 5 h revealed the presence of a single phase CZ solid solution. Lattice parameters a = 3.6296(5) and c = 5.2317(5) Å were calculated for the tetragonal cell, which compare well with a = 3.6396(1) and c = 5.2382(1) Å obtained for CZ20 after calcination at 1000 °C. This indirectly confirmed that no appreciable phase segregation occurred. Some CeO_2 non-incorporated into the mixed oxide was detected for CZ60/Al_2O_3, in accord with a previous observation that compositional inhomogeneities are favoured at intermediate compositions.[7] There is a synergic stabilisation between the CZ and Al_2O_3 component, since the sintering of CZ is retarded by the presence of Al_2O_3, particularly at high ZrO_2 content. For CZ20/Al_2O_3 calcined at 1100 °C a crystallite size of 11 nm was evaluated from the XRD analysis. These findings were confirmed by HREM analysis which revealed the presence of tetragonal $Ce_{0.2}Zr_{0.8}O_2$ particles in the range 9–20 nm [Fig. 1(a)]. The nanosized nature of the CZ component seems attributable to the presence of zirconia rather then ceria, since significantly higher particle sizes were detected by XRD for CZ100/Al_2O_3.

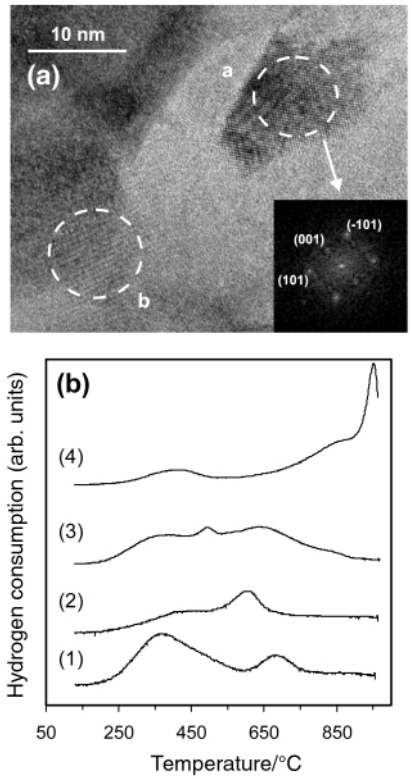

Fig. 1 (a) HREM image of $Ce_{0.2}Zr_{0.8}O_2/Al_2O_3$ calcined at 1100 °C for 5 h. The digital diffraction pattern of area 'a' was indexed as tetragonal $Ce_{0.2}Zr_{0.8}O_2$ viewed along the [0,1,0] axis. In the zone marked 'b', interplanar distances typical of θ-Al_2O_3 were found; (b) Comparison of TPR profiles of $Ce_{0.2}Zr_{0.8}O_2/Al_2O_3$ (1) fresh, (2) calcined at 1100 °C for 5 h, and CeO_2/Al_2O_3 (3) fresh and (4) calcined at 1100 °C for 5 h.

Fig. 1(b) compares the TPR profiles of fresh and calcined (1100 °C) samples of CZ20/Al_2O_3 and CZ100/Al_2O_3. High temperature ageing leads to most reduction occurring at high temperatures in CZ100/Al_2O_3, consistent with the relatively high CeO_2 particle size.[6] In contrast, reduction at relatively low temperature persists in CZ20/Al_2O_3 even after high temperature calcination. Either $CeAlO_3$ or crystalline CeO_2 were detected by XRD after the TPR/oxidation at 427 °C experiment carried out on CZ100/Al_2O_3. Dispersing CeO_2 over Al_2O_3 led to deactivation of OSC in CeO_2/Al_2O_3 owing to formation of $CeAlO_3$.[8] Within the sensitivity of the XRD method (estimating an upper limit of *ca*. 5% $CeAlO_3$ with respect to the CZ phase in the CZ/Al_2O_3 material for non-detection) no formation of $CeAlO_3$ was detected in any of the CZ20/Al_2O_3 samples. This indicates that incorporation of ZrO_2 into CeO_2 prevents this undesirable deactivation pathway. The more ZrO_2 is added to CeO_2, the more effective stabilisation is achieved, highlighting the crucial role of ZrO_2 in improving the stability of these systems. Phase separation into CeO_2-rich and ZrO_2-rich phases was indeed detected at 1100 °C in CZ60/Al_2O_3, leading to partial formation of $CeAlO_3$ after TPR/oxidation at 427 °C.

The effects of addition of Al_2O_3 to CZ on the dynamic-OSC are remarkable (Table 1): (i) there is a strong improvement of the dynamic-OSC in the fresh CZ/Al_2O_3 samples compared to the unsupported ones; (ii) thermal ageing at 1000–1100 °C leads to an almost complete deactivation of the dynamic-OSC in unsupported CZ; (iii) such ageing decreases dynamic-OSC of CZ/Al_2O_3 compared to fresh samples, however, appreciably high OSC persists, which is comparable or higher than that of fresh CZ; (iv) thermally stable dynamic-OSC was detected in CZ20/Al_2O_3, which remarkably did not decline by increasing the calcination time at 1100 °C up to 24 h. We tentatively attribute these improved properties to an intimate contact between the CZ20 and Al_2O_3 phases generated by the synthesis method, which stabilises high dispersion of the CZ component (by contrast physical mixtures of CZ and Al_2O_3 calcined at 1100 °C for 5 h showed negligible dynamic-OSC). In summary, materials, which are highly suitable for thermally demanding redox reactions, such as those mediated by TWCs, can be obtained by supporting zirconia rich CeO_2–ZrO_2 mixed oxides over Al_2O_3.

Three new tungsten(VI) oxide hybrid materials, $[WO_3(pyz)_{0.5}]$ (pyz = pyrazine) 1, $[WO_3(bpy)_{0.5}]$ (bpy = 4,4′-bipyridyl) 2 and $[W_3O_{10}(enH_2)]$ 3, have been hydrothermally synthesized: 1 and 2 exhibit covalent/coordination hybrid framework connectivities while the structure of 3 consists of novel layers comprised of distorted $\{WO_6\}$ octahedra linked through edge- and corner-sharing interactions.

Crystal engineering of low-dimensional and porous materials is the main concern of many current research projects, owing to their potential applications in catalysis, sorption, separation and photochemistry.[1–6] Hydrothermal crystallization, in the presence of organic templating species, has been demonstrated to be a versatile technique for the synthesis of these kinds of materials.[4–6] Of significant importance is the ability of the organic molecules to influence profoundly the structure of synthesized products, and to direct their formation with particular structural and physical properties. The exquisite control over the detailed topology of the anionic framework that can be achieved by altering the steric and electronic properties of the template has been exploited to synthesize materials with an astonishingly diverse range of structural characteristics. In addition to silicon, aluminium and phosphorus,[6,7] a wide variety of other main group and transition metals such as Ga,[8] Mo,[9] V[10] and Fe[11] have been incorporated into the three-dimensional framework and two-dimensional network structures through hydrothermal synthesis in the presence of organic templating agents.

The chemistry of tungsten oxide clusters and their derivatives has been extensively studied owing to their unusual magnetic properties, potential medical uses derived from their antiviral and antibacterial activities, relevance in the design and development of new materials, proven roles in catalysis, and promise as catalysts for chemical transformations.[12] Although organic amines have been extensively used as templating or structure-directing agents in hydrothermal reactions, little work has been reported on their use in the hydrothermal synthesis of new tungsten oxides with the exception of $[H_3N(CH_2)_6NH_3]_4[W_{18}P_2O_{62}]\cdot H_2O$[13] and a few Keggin species.[14] Here, we report the hydrothermal synthesis and structural characterization of three novel tungsten(VI) oxide hybrid materials: $[WO_3(pyz)_{0.5}]$ **1**, $[WO_3(bpy)_{0.5}]$ **2** and $[W_3O_{10}(enH_2)]$ **3**.

Compounds **1**–**3** were prepared from hydrothermal mixtures of $Na_2WO_4\cdot 2H_2O$, $MCl_2\cdot nH_2O$ (M = Cu, Zn), organoamines and H_2O, heated to 140–160 °C for 120–264 h.‡ Crystal structures were solved from the data collected using a Siemens P4 X-ray diffractometer.§ The IR spectra of **1**–**3** exhibited strong bands in the range 910–960 cm^{-1} attributed to ν(W=O). Thermogravimetric analysis indicated weight losses corresponding to the loss of ligands.¶

The structure of $[WO_3(pyz)_{0.5}]$ **1** consists of layers of corner-sharing $\{WO_5N\}$ octahedra parallel to the *ab*-plane linked through pyz molecules into a 3-D tungsten oxide/pyz framework [Fig. 1(a)]. The 3-D architecture of **1** can be described as an interwoven net of inorganic metal oxide layers and organic tethers. The tungsten oxide layers are stacked along the *c* axis in an ABAB… sequence. The connectivity between the tungsten oxide layers and pyz molecules results in one-dimensional rectangular channels along the *b* axis circumscribed by six $\{WO_5N\}$ octahedra and two pyz molecules. The dimensions of the channels are *ca.* 7.7 × 5.2 Å. The coordination geometry at the W site is defined by one terminal oxo group, four bridging oxo groups and one pyz nitrogen donor with W–O bond lengths of 1.680(2), 4 × 1.8741(3) Å and W–N bond length of 2.440(3) Å. The significant lengthening in the W–N distance reflects the strong *trans* effects of the terminal oxo group.

Compound $[WO_3(bpy)_{0.5}]$ **2** has a similar topology to compound **1**. As shown in Fig. 1(b), the structure of **2** consists of W/O/N layers, parallel to the *ab*-plane, of corner sharing $\{WO_5N\}$ octahedra bridged through bpy ligands into a 3-D covalent/coordination hybrid framework. The connectivity between the tungsten oxide layers and bpy molecules results in one-dimensional rectangular channels along the [1 1 0] direction circumscribed by six $\{WO_5N\}$ octahedra and two pyz molecules. The dimensions of the one-dimensional rectangular channels are *ca.* 11.9 × 5.2 Å. Each W site receives

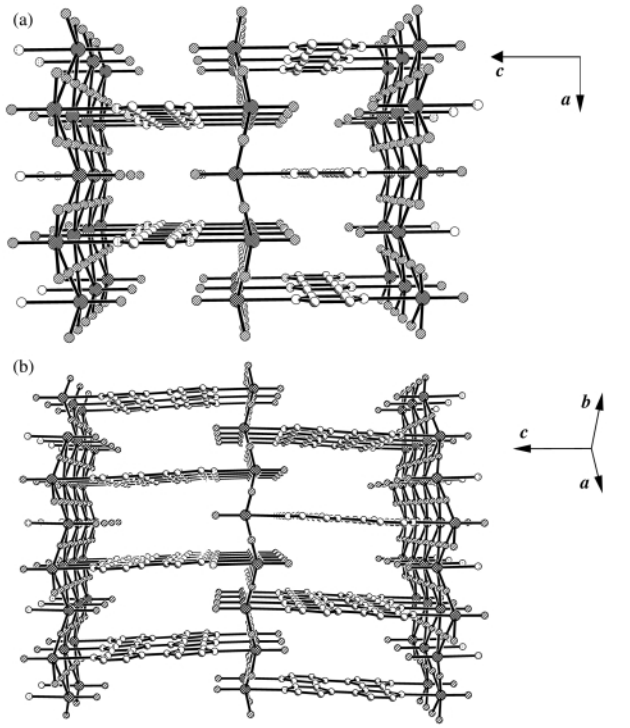

Fig. 1 (a) Crystal structure of $[WO_3(pyz)_{0.5}]$ **1** viewed along the *b* axis. (b) Crystal structure of $[WO_3(bpy)_{0.5}]$ **2** viewed along the [1 1 0] direction. Coordination of ligands (pyrazine or 4,4′-bipyridyl) to tungsten oxide layers results in a 3-D inorganic–organic framework with 1-D rectangular channels.

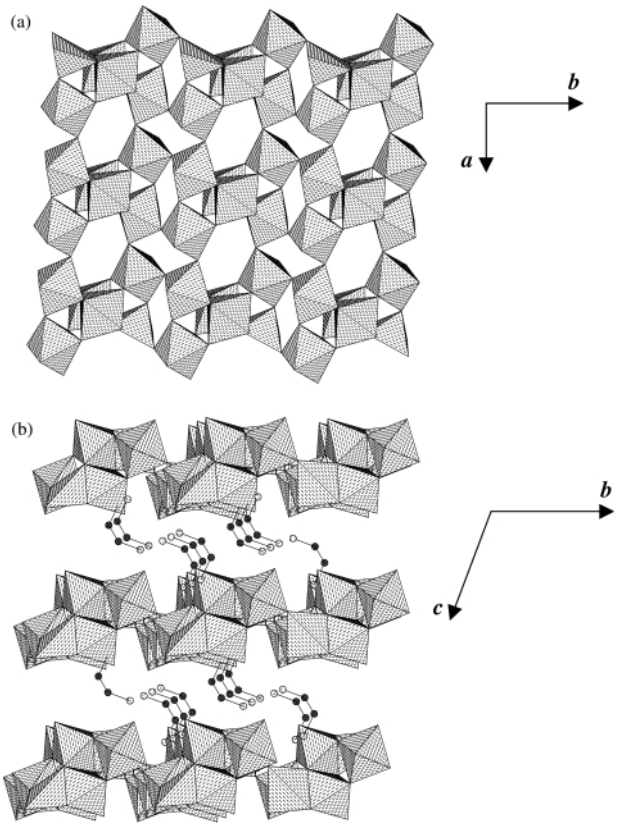

Fig. 2 (a) A polyhedral packing view of the $[W_3O_{10}]^{2-}$ layers of $[W_3O_{10}(enH_2)]$ **3** showing the puckered six-membered rings. (b) A polyhedral and ball-and-stick view of $[W_3O_{10}(enH_2)]$ **3.**

contributions from four bridging oxo groups, one terminal oxo group and one nitrogen donor with W–O bond lengths of 1.678(11), 2 × 1.8936(4), 1.851(13) and 1.897(12) Å, and W–N bond length of 2.409(14) Å.

The inorganic layers of compounds **1** and **2** are analogous to that of three-dimensional ReO_3-type WO_3 (r-WO_3).[15] However, the inorganic layers in r-WO_3 are connected through shared corners forming a three-dimensional structure whereas the tungsten oxide layers in compounds **1** and **2** are cross-linked by organodiamines through coordination bonds giving rise to their three-dimensional organic/inorganic hybrid structures. It is noteworthy that the synthesis conditions of compounds **1** and **2** differ from their molybdenum isostructures, $MoO_3(pyz)_{0.5}$ and $MoO_3(bpy)_{0.5}$.[16,17] It should also be noted that some carbon atoms in compounds **1** and **2** are disordered over two sites.

In contrast to the three-dimensional covalent/coordination hybrid frameworks of **1** and **2**, the structure of $[W_3O_{10}(enH_2)]$ **3** consists of $[W_3O_{10}]^{2-}$ layers [Fig. 2(a)], separated by interlamellar enH_2^{2+} cations [Fig. 2(b)]. The tungsten oxide layers contain infinite ribbons, two polyhedra thick, of edge- and corner-sharing {WO_6} octehedra running parallel to the *b* axis. These infinite ribbons are connected by shared corners resulting in the layer structure of **3**. The {WO_6} octohedra are distorted with W–O distances in the range 1.722(9)–2.307(7) Å. The layer structure of compound **3** exhibits a puckered six-membered ring circumscribed by six tungsten octahedra as shown in Fig. 2(a). Ethylenediamine cations are located between adjacent layers and are linked to the oxygen atoms of the tungstate units *via* hydrogen bonds.

It should be noted that the structure of anionic layer of compound **3** is quite different from that of $K_2W_3O_{10}$[18] although the tungstate anions in these two compounds have the same stoichiometry. The three-dimensional framework of $K_2W_3O_{10}$ consists of corner- and edge-sharing {WO_6} octahedra. Moreover, the structures of known trimolybdates $[Mo_3O_{10}]^{2-}$ are composed of infinite chains of polymolybdate anions,[19,20] and the existence of a layered trimolybdate $[Mo_3O_{10}]^{2-}$ has not yet been reported. More interestingly, a one-dimensional example of compound **3** has also been isolated from hydrothermal media.[21]

The success in synthesizing compounds **1**–**3** provides innovative examples of the utility of the template-mediated hydrothermal method for the construction of versatile tungsten oxide hybrid solids. It further demonstrates the multifunctional roles of organoamines functioning as ligands bound to the tungsten oxide skeleton, as in compounds **1** and **2**, and as a simple counter ion in compound **3** in the cooperative assembly of organic/tungsten oxide hybrid materials. The current success opens up an exciting area of research in which the structural versatility of tungsten oxide materials can be evolved from the introduction of appropriate templates and optimization of reaction conditions.

First published as an Advance Article on the web

Sterically hindered chiral (salen)manganese complexes bearing long perfluoroalkyl substituents are synthesized and successfully employed as catalysts in the enantioselective (ee = 50–87%) epoxidation of alkenes under fluorous biphasic conditions.

Following the pioneering work of Horváth and Rábai,[1] a number of reagents and catalysts bearing appropriate perfluoroalkyl substituents ('fluorous compounds') have been prepared and used in 'fluorous biphase chemistry'.[2] Catalytic reactions in fluorous biphasic systems present several advantages over their classical homogeneous counterparts.[3] Fluorous chemistry has also a great potential for enantioselective transformations, offering both an easy way to recover precious chiral reagents or catalysts and unusual solvation effects. Nevertheless, only a few chiral fluorous compounds have been prepared to date and the actual influence of perfluoroalkyl substituents (R_F) and perfluorocarbon solvents on the outcome of asymmetric reactions is virtually unknown.[4] We have reported the first example of a fluorous biphasic enantioselective reaction, namely the epoxidation of alkenes in the presence of the optically active fluorous (salen)Mn^{III} complexes Mn-**1** and Mn-**2** (Jacobsen–Katsuki catalysts, Fig. 1).[4a] Good chemoselectivity and efficiency were observed in the epoxidation of several substrates, and recycling of the catalysts was also demonstrated. However, high levels of enantioselectivity were not attained, except in the epoxidation of indene (ee = 90%). This behaviour was tentatively ascribed to the low steric hindrance of the R_F groups in the 3,3'- and 5,5'-positions of the ligands and to the inadequate electronic shielding of the metal site from the strong electron-withdrawing effect of these substituents.[4c]

Second-generation (salen)Mn^{III} complexes Mn-**3** and Mn-**4** (Fig. 1) were designed with these assumptions in mind. In order to better shield the metal site, the R_F substituents in 5,5'-positions were replaced by perfluoroalkyl-substituted aryl moieties. Moreover, sterically demanding *tert*-butyl substituents were introduced in the key-positions 3,3' of ligands **3** and **4**.

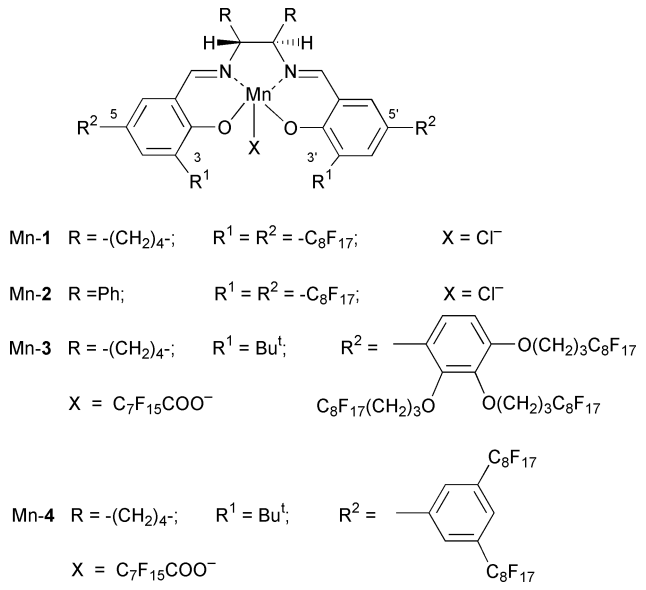

Fig. 1 First- (Mn-**1**, Mn-**2**) and second-generation (Mn-**3**, Mn-**4**) fluorous chiral (salen)Mn complexes.

Both salicylaldehydes **7** and **10**, the key intermediates for the synthesis of ligands **3** and **4**, were prepared starting from aldehyde **5**,[5] as shown in Scheme 1. Pd^0-catalyzed cross-coupling reaction of **5** with boronic acid **6** (yield = 86%),[6] followed by *O*-deprotection (89%) and *O*-alkylation with $C_8F_{17}(CH_2)_3I$ (37%), afforded the fluorous salicylaldehyde **7**. Mono- and bis-*O*-alkylated biaryl compounds were isolated from the reaction mixture by column chromatography and reused in following runs.

In the case of salicylaldehyde **10,** aldehyde **5** was used as a precursor of aryl boronic acid **8**, whereas perfluoroalkyl-substituted aryl bromide **9** was prepared by copper-mediated cross-coupling reaction of 1,3,5-tribromobenzene with 2 equiv. of $C_8F_{17}I$. The bis(perfluoroalkyl) derivative was obtained as the main product and isolated in reasonable yields (60%) after crystallization from CH_2Cl_2 and then from Et_2O. Pd^0-catalyzed cross-coupling reaction of crude aryl boronic acid **8** with **9**, followed by deprotection with BBr_3 gave the desired salicylaldehyde **10** in 62% yield.

Condensation of two equivalents of salicylaldehyde **7** or **10** with (1*R*,2*R*)-(−)-1,2-diaminocyclohexane in boiling ethanol afforded the fluorous salen ligands **3** (72%) and **4** (95%), respectively.[7] Mn^{III} complexes Mn-**3** and Mn-**4** were prepared by reaction of the corresponding ligand with an excess of $Mn(OAc)_2{\cdot}4H_2O$ in refluxing ethanol under aerobic conditions, followed by anion exchange with LiCl and then $C_7F_{15}COONH_4$. The exchange of Cl^- for the fluorophilic

$C_7F_{15}COO^-$ anion resulted in the sought preferential solubility of Mn-**3** and Mn-**4** in perfluorocarbons, as verified by partition experiments in biphasic mixtures *n*-perfluorooctane/organic solvents. Partition coefficients, determined by UV–Vis spectroscopy at 25 °C,[8] were found to be quite similar for the two complexes, ranging from 1.21 for Mn-**3** in *n*-perfluorooctane/hexane, to >1000 for Mn-**3** and Mn-**4** in *n*-perfluorooctane/CH_3CN and *n*-perfluorooctane/toluene.

First- and second-generation (salen)Mn^{III} complexes were initially compared in the homogeneous epoxidation of 1,2-dihydronaphthalene in CH_2Cl_2/benzotrifluoride, using *meta*-chloroperbenzoic acid/ *N*-methylmorpholine *N*-oxide (*m*-CPBA/NMO) as the oxidant at −50 °C.[9] Second-generation catalysts afforded ee values much higher than those obtained with Mn-**1** and Mn-**2** (63% *vs*. 16 and 12%, respectively) and slightly improved epoxide yields (70% with Mn-**3** and Mn-**4** *vs*. 60% with Mn-**1** and Mn-**2**). Other oxidising agents commonly used in association with (salen)Mn^{III} complexes were also tested and the superiority of the new complexes was confirmed.

PhIO together with small amounts of pyridine *N*-oxide (PNO) was used as the oxidising system in the next fluorous biphasic reactions that were run in *n*-perfluorooctane/CH_3CN (Table 1).† This set of conditions was chosen taking into account the favourable partition coefficients of the catalysts and considering that homogeneous epoxidation reactions with PhIO/PNO are conveniently carried out in CH_3CN at 0–25 °C.[10] Both reaction yield and enantioselectivity rose with temperature under fluorous biphasic conditions: the best results were obtained at 100 °C, corresponding to the boiling point of *n*-perfluorooctane (Table 1, entries 1–5). Blank experiments evidenced that only traces of epoxide are formed at this temperature in the absence of the fluorous catalysts. The results obtained in the fluorous biphasic epoxidation of 1,2-dihydronaphthalene with PhIO/PNO at 100 °C (entry 5) compare favourably to those reported for the same reaction in CH_3CN in the presence of Jacobsen's catalyst, a commercially available, standard (salen)Mn^{III} complex (yield = 70%, ee = 46%).[11]

The fluorous layer, easily separated upon cooling, could be reused up to three times after the first run as exemplified in the case of triphenylethylene (entries 8–10). Catalytic activity generally dropped in the fourth run due to the oxidative decomposition of the catalyst, as evidenced by the progressive disappearence of the characteristic UV–Vis absorption bands of the (salen)Mn^{III} in the fluorous phase and by the absence of such bands in the organic phase. Such behaviour is in agreement with previous literature reports dealing with (salen)Mn^{III} complexes immobilised by other techniques.[11]

The use of the second-generation (salen)Mn^{III} complexes considerably widen the scope of the fluorous biphasic epoxidation reaction, since these catalysts not only afford good epoxide yields, but also ee ranging from 50 to 87% with several substrates. This finding strongly supports our aforementioned hypotheses about the role of R_F substituents on the catalytic activity of (salen)Mn^{III} complexes. The relative importance of electronic and steric effects in determining the enantioselectivity of fluorous (salen)Mn^{III} complexes and the design of new chiral fluorous catalysts are currently investigated in this laboratory.

We thank the COST Action D12 'Fluorous medium: a tool for environmentally compatible oxidation processes'.

Notes and references

† General procedure for the asymmetric epoxidation of alkenes under fluorous biphasic conditions: in a 10 ml Schlenk vessel placed in a thermoregulated bath at 100 °C, 1 ml of a 0.2 M solution of alkene in CH_3CN containing *o*-dichlorobenzene (0.1 M, internal standard for GC) and 0.2 ml of a 0.25 M solution of pyridine *N*-oxide (PNO) in CH_3CN were added under nitrogen to 1 ml of a solution of the catalyst in *n*-perfluorooctane. PhIO (67 mg, 0.3 mmol) was quickly added under a nitrogen stream. The two-phase mixture was magnetically stirred at 1300 ± 50 rpm and cooled to room temperature at the end of the reaction. The brown fluorous layer was separated, washed with CH_3CN (2 × 0.5 ml) and reused in further runs (see Table 1). The combined organic layers were washed with saturated aqueous Na_2SO_3 (1 ml), brine (1 ml) and dried ($MgSO_4$). Epoxide yield and enantiomeric excess were determined by gas-chromatographic analysis of the organic solution.

FEATURE ARTICLE

On the organometallic chemistry of gallium and the dynamics of Ga–Ga bond formation

Gregory H. Robinson

First published as an Advance Article on the web 31st October 2000

Recent advances in the organometallic chemistry of gallium are presented with an historical perspective and a particular emphasis toward the dynamics of the Ga–Ga bond.

Introduction

Due to the fortuitously combined efforts of Dmitri Mendeleev and Paul-Émile Lecoq de Boisbaudran, the main group metal gallium holds a paradoxically unique distinction of having many of its physical and chemical properties foretold *prior* to its actual discovery. While developing the theory of chemical periodicity in 1870, Mendeleev not only predicted the existence of a yet to be discovered element thought to reside between aluminium and indium, *eka-aluminium*, in his periodic arrangement of the elements, but he also boldly and accurately predicted a number of properties of this mystery element. Indeed, Mendeleev proposed a value of 5.9 g cm^{-3} for the density of eka-aluminium and predicted that this element would be discovered using spectroscopic analysis.[1] The fact that the actual events regarding the discovery of gallium and the subsequent development of organogallium chemistry would rival a compelling work of fiction only adds to the lore.

In the summer of 1875, following more than a decade of fundamental research upon which the science of spectroscopy would ultimately rest, Lecoq de Boisbaudran observed the first spectroscopic evidence of what he believed to be a new chemical element. While working in Paris in September 1875 Lecoq de Boisbaudran proudly obtained more than a gram of this mysterious element after having begun with several hundred kilograms of the appropriate zinc blende ore. Lecoq de Boisbaudran aptly named this new element *Gallia*, in honor of his beloved France (Latin, *Gallia*: France). Upon the determination of several chemical and physical properties of gallium, it became increasingly apparent that this low-melting metal was indeed the element which had been so confidently predicted by Mendeleev in 1870. The genius, if not the persistence, of Mendeleev emerged once more when Lecoq de Boisbaudran initially reported the density of gallium as 4.7 g cm^{-3}. Mendeleev wrote to Lecoq de Boisbaudran suggesting that he re-examine the value of 4.7 g cm^{-3} as it was at odds with his predicted value of 5.9 g cm^{-3}.[2] The correct value for the density of gallium is 5.904 g cm^{-3}.

The historical development of the organometallic chemistry of gallium is no less dramatic than that just offered concerning its discovery. Triethylgallium, Et_3Ga, as described by Dennis and Patnode in 1932, was the first reported organometallic compound of gallium.[3] The saga of the synthesis of triethylgallium is of an unusually intriguing, if not tragic, nature. Clearly noted in the 1932 article, another graduate student, Mr. H. A. Lovenberg, had been pursuing the synthesis of the first organogallium compounds and had actually begun the preparation of triethylgallium several years prior to the Dennis and Patnode 1932 article. Shortly after the flask had been charged with the ethylmagnesium bromide/gallium bromide reaction mixture and the flask had been sealed and secured, Mr. Lovenberg met an untimely death. This same flask containing the $EtMgBr/GaBr_3$ reaction mixture remained untouched, perhaps even lost, until Mr. Pathode happened upon it in January 1931 and continued the synthesis.[3] Triethylgallium monoetherate was isolated by Dennis and Pathnode as a colorless, moderately viscous, pyrophoric liquid [eqn. (1)]:

$$3EtMgBr + GaBr_3 \xrightarrow[Et_2O]{} 3MgBr_2 + Et_3Ga(Et_2O) \quad (1)$$

Dennis and Patnode also reported that ether-free triethylgallium could be isolated by reaction of gallium metal with diethylmercury. In an ironic postscript, the contribution of Mr. Lovenberg did not result in his being granted posthumous co-authorship on the 1932 article.

Although the simple gallium alkyls share some similarities to aluminium alkyls (*i.e.*, colorless, air-sensitive liquids), there are notable differences. For example, simple aluminium alkyls, such as trimethylaluminium,[4] are dimeric, bridging through electron deficient three center–two electron, 3c–2e, bonds, while the corresponding organogallium compounds are exclusively monomeric. In addition, the pyrophoric nature of aluminium alkyls is generally more substantial than that observed for gallium alkyls.

For decades following their discovery, organogallium compounds garnered limited attention and were largely considered little more than laboratory curiosities. Indeed, Pauling once opined that the chemistry of gallium [along with indium and thallium] was limited and of 'little practical importance'.[5] Insofar as this may have been a perfectly accurate description of the chemistry of gallium of the day, the organometallic chemistry of gallium (and indium and thallium) has since been shown to be as rich as it is varied. This Feature Article will examine some of the more significant recent discoveries in organogallium chemistry with a particular emphasis on ster-

Gregory H. Robinson (b. 1958) gained a B.S. degree in chemistry from Jacksonville State University (1980) and a Ph.D. degree at The University of Alabama (1984), working under the direction of Professor Jerry L. Atwood. Beginning his academic career at Clemson University (1985), he was promoted to full professor in 1995. Robinson was awarded an Alexander von Humboldt Research Fellowship in 1994 conducting research at the Technische Universität Berlin in the laboratory of Prof. Dr Herbert Schumann. In 1995 he joined the faculty at The University of Georgia where he now holds the title of Distinguished Research Professor of Chemistry. His research interests are in the organometallic chemistry of the main group elements.

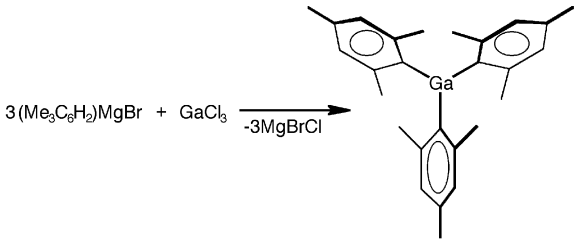
ically demanding organogallium compounds and the nature of the gallium–gallium bond.

Sterically demanding organogallium compounds

Generally, the phenyl substituent is not considered to be very bulky or sterically demanding. Nonetheless, the phenyl ligand is quite significant as it serves as the base unit from which very important sterically demanding ligands are derived. Much like trimethylaluminium, triphenylaluminium was shown to be dimeric,[6] bridging through a carbon atom of the phenyl ring. In contrast, triphenylgallium was demonstrated to be monomeric.[7] Interestingly, the phenyl rings of Ph_3Ga were observed to only be slightly out of the plane of the GaC_3 core. The nearly coplanar nature of the phenyl rings with the gallium core in Ph_3Ga allowed for secondary interactions of each gallium center with the *meta*-carbon atoms of other Ph_3Ga moieties in the unit cell.

The fact that sixteen years passed between the structural characterization of triphenylgallium and its next logical aryl derivative of trimesitylgallium, $(Me_3C_6H_2)_3Ga$, belies the latent development of this chemistry. Ironically, the preparation of $(Me_3C_6H_2)_3Ga$ in 1986 was analogous to that employed more than five decades earlier in the 1932 synthesis of triethylgallium, namely the reaction of the appropriate Grignard reagent with a gallium halide [eqn. (2)].[8]



(2)

Trimesitylgallium was isolated as colorless, air-sensitive crystals. It is an interesting coincidence that the synthesis and molecular structure of trimesitylaluminium[9] and trimesitylgallium[8] were published as consecutive articles in the same issue of the journal *Organometallics*. Although the molecular structure of $(Me_3C_6H_2)_3Ga$ revealed the gallium center to be in a virtually idealized trigonal planar environment, the aromatic rings of the mesityl ligands assumed a propellor-like arrangement about the gallium center at an angle of 55.9° between each ring and the metal coordination plane. This is most unlike the case for triphenylgallium wherein the aromatic rings were only slightly out of the metal center plane. As a consequence of the steric crowding about the metal center, trimesitylgallium was shown to be a very weak Lewis acid incapable of forming stable adducts with either Et_2O or THF.

Significant developments in the organometallic chemistry of sterically demanding organogallium compounds were few for the next ten years at which point an even more sterically demanding ligand system was examined relative to gallium. The ligand system which was chosen by this laboratory was the substituted *m*-terphenyl ligands initially reported by Hart and coworkers.[10] In notable contrast to the syntheses of triethylgallium and trimesitylgallium, wherein Grignard reagents were utilized in the syntheses, we employed lithium derivatives of *m*-terphenyl ligands. Reaction of 2,6-dimesitylphenyllithium with gallium chloride affords bis(2,6-dimesitylphenyl)gallium chloride, $[(Me_3C_6H_2)_2C_6H_3]_2GaCl$ (Fig. 1).[11] This organometallic compound was the first example of an *m*-terphenyl ligand being attached to a main group metal. Secondly, it is noteworthy that two such bulky ligands were accommodated by the gallium atom. This point is particularly manifested in the geometry about the metal center. Unlike triethylgallium and trimesitylgallium, in which the metal center is trigonal planar, the steric interaction between the two *m*-terphenyl ligands in

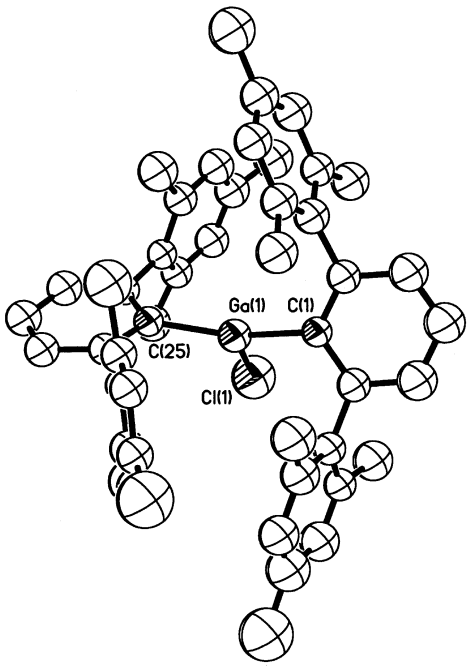


Fig. 1 Crystal structure of $[(Me_3C_6H_2)_2C_6H_3]_2GaCl$.

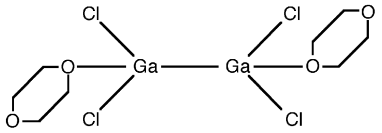
$[(Me_3C_6H_2)_2C_6H_3]_2GaCl$ was such that the C–Ga–C bond angle was widened substantially beyond the 120° expected for trigonal planar to 154°. This is sufficient to warrant the description of this compound as T-shaped. Normally, the T-shaped orientation is reserved for the well known interhalogen compounds such as ClF_3 and BrF_3 wherein the central atom has two lone pairs of electrons to assist in stabilizing this rather obscure geometry. Thus, $[(Me_3C_6H_2)_2C_6H_3]_2GaCl$ is the first unambiguous example of a Group 13 metal organometallic complex assuming a T-shaped geometry. The synthesis and molecular structure of the corresponding T-shaped bis(2,6-dimesitylphenyl)gallium bromide has also been recently reported.[12]

Perhaps the only tri(aryl)-based molecule possibly more sterically crowded than the T-shaped bis(2,6-dimesitylphenyl)gallium halides is (2,6-dimesitylphenyl)(dimesityl)gallium, $(Me_3C_6H_2)_2C_6H_3Ga(C_6H_2Me_3)_2$.[12] This compound, isolated from reaction of $(Me_3C_6H_2)_2C_6H_3GaCl_2$ with two equivalents of mesityllithium, arguably, represents the most sterically crowded gallium center ever observed. The aromatic rings about the GaC_3 core approach orthogonality at angles of 82.4, 82.4 and 86.3°.

Gallium(II) halides: useful synthetic reagents

As recently as 1979 the notion of discrete 'gallium(II) dihalides' was a novel concept. A study by Beamish, Small, and Worrall offered an unambiguous perspective on the existence of gallium(II) halides with the synthesis and molecular structure of $Ga_2Cl_4(dioxane)_2$,[13] isolated from recrystallization of Ga_2Cl_4 from 1,4-dioxane at 0 °C. The gallium atoms are clearly four-coordinate, each bonding to two chlorine atoms, one dioxane adduct, and the other gallium atom with a Ga–Ga distance of 2.406(1) Å.



The bromide derivative, $Ga_2Br_4(dioxane)_2$, has a similar structure along with a Ga–Ga bond distance of 2.395(6) Å.[14] Gallium(II) chloride bis(dioxane) will prove pivotal in the

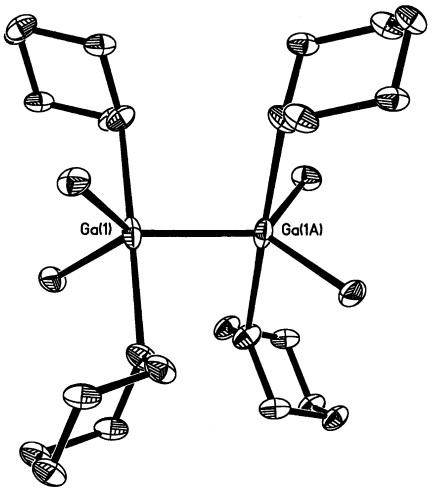


Fig. 2 Crystal structure of $Ga_2Cl_4(dioxane)_4$.

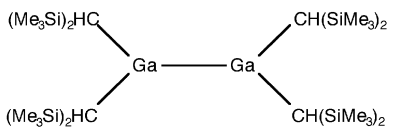
development of the stabilization of the Ga–Ga bond in some organometallic gallanes (*vide infra*).

Recently we made a surprising discovery concerning 1,4-dioxane adducts of gallium(II) chloride. Upon slow room temperature (as opposed to 0 °C) recrystallization of Ga_2Cl_4 from 1,4-dioxane we isolated a tetrameric dioxane adduct, $Ga_2Cl_4(dioxane)_4$.[15] Both gallium atoms in $Ga_2Cl_4(dioxane)_4$ reside in almost idealized trigonal bipyramidal environments [O–Ga–O 179.10(10)°] about the two gallium atoms (Fig. 2).

The five-coordinate trigonal bipyramidal gallium atoms of $Ga_2Cl_4(dioxane)_4$ are easily compared with the four-coordinate tetrahedral gallium atoms of $Ga_2Cl_4(dioxane)_2$ which was prepared more than twenty years earlier. Surprisingly, the Ga–Ga bond distance of 2.3825(9) Å in $Ga_2Cl_4(dioxane)_4$ is shorter than the values reported for $Ga_2Cl_4(dioxane)_2$ [2.406(1) Å] and $Ga_2Br_4(dioxane)_2$ [2.395(6) Å]. The Ga–O bond distance in $Ga_2Cl_4(dioxane)_4$ (2.4087 Å), however, is notably longer than that reported for $Ga_2Cl_4(dioxane)_2$ [2.027(2) Å]. The Ga–Cl bonds are generally unremarkable. While very weak secondary $Cl_{(Ga)}\cdots H_{(dioxane)}$ interactions were suggested in the original paper, this compound is perhaps best described as a monomeric unit. It is important to note that the tetra-dioxane adduct bears a striking resemblance to an indium compound containing an In–In bond and stabilized by four THF units, $In_2Cl_4(THF)_4$, recently reported by Schmidbaur and coworkers.[16] Ga_2Cl_4-$(dioxane)_4$ is a rare example of five-coordinate gallium atoms engaging in Ga–Ga bond formation.

Gallium(II) dichloride bis(dioxane), $Ga_2Cl_4(dioxane)_2$,[13] proved critical in the preparation of the first organometallic compound unambiguously shown to contain a Ga–Ga bond. Uhl *et al*. prepared $[(Me_3Si)_2HC]_2Ga–Ga[CH(SiMe_3)_2]_2$ (below) by reaction of $Ga_2Cl_4(dioxane)_2$ with $LiCH(SiMe_3)_2$.[17]



The Ga–Ga bond distance in $[(Me_3Si)_2HC]_2Ga–Ga[CH(SiMe_3)_2]_2$ was shown to be 2.541(1) Å.

In an effort to approach a measure of multiple bond character in the Ga–Ga bond, the same workers reduced $[(Me_3Si)_2HC]_2Ga–Ga[CH(SiMe_3)_2]_2$ with ethyllithium to afford red–black crystals of the corresponding radical anion, $[(Me_3Si)_2HC]_2Ga–Ga[CH(SiMe_3)_2]_2^{\bullet-}$,[18] to yield a 'one electron π-bond'. Both EPR and single crystal X-ray diffraction were in support of this description. The Ga–Ga bond distance of 2.301(1) Å in $[(Me_3Si)_2HC]_2Ga–Ga[CH(SiMe_3)_2]_2^{\bullet-}$ represents a decrease of 0.240 Å from the neutral gallane.

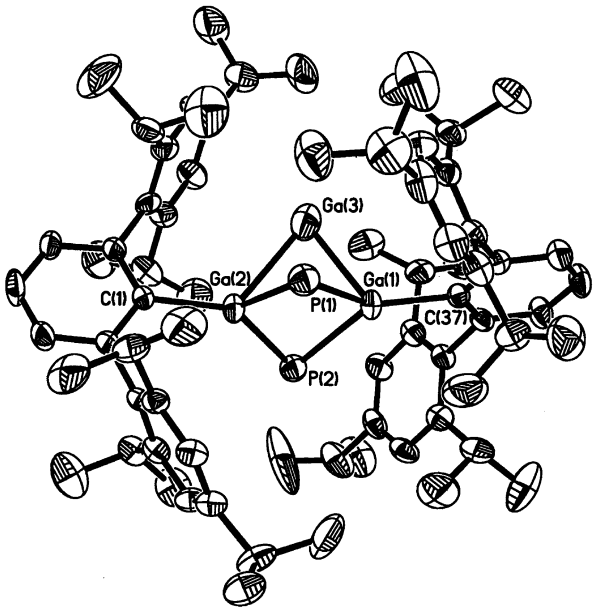


Fig. 3 Crystal structure of $[(Pr^i_3C_6H_2)_2C_6H_3]Ga\{H_2PGa(H)PH_2\}$-$Ga[C_6H_3(C_6H_2Pr^i_3)_2]$.

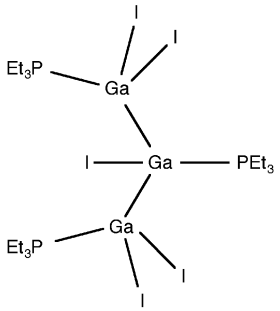
Although *m*-terphenyl ligands have been shown by this laboratory to be effective in the stabilization of compounds containing Ga–Ga bonds, their general reactivity had not been examined relative to Lewis bases. Recently we explored the reaction of $[(Pr^i_3C_6H_2)_2C_6H_3]GaCl_2$ with the sterically demanding Lewis base tris(trimethylsilyl)phosphine, $P(SiMe_3)_3$. This reaction affords the unusual organometallic compound $[(Pr^i_3C_6H_2)_2C_6H_3]Ga\{H_2PGa(H)PH_2\}Ga[C_6H_3(C_6H_2Pr^i_3)_2]$ (Fig. 3).[19]

The isolation of this compound was as unexpected as it was interesting. Noteworthy is the fact that the compound contains a –Ga–Ga–Ga– linkage. Just as striking is the *m*-terphenyl ligand stripping from the central gallium atom (being replaced by a hydrogen atom) and the stripping of the tris(trimethylsilyl) groups from the two phosphorus atoms (being replaced by two hydrogen atoms each). While it may be reasonable to dismiss the five hydrogen atoms, two on each of the two phosphorus atoms and one on the central gallium atom, as having originated from the stripped *m*-terphenyl ligand, there are other possibilities. For example, it is also reasonable that the ligand stripping may have initiated hydride abstraction from the solvent (or *vice versa*). The phosphine hydrogen atoms and the gallium hydride were prominently manifested in IR and NMR spectroscopy. Moreover, theoretical calculations of IR bands on the model molecule $MeGa\{H_2PGa(H)PH_2\}GaMe$ are in good agreement with the experimental IR spectrum.[19] The asymmetric nature of the Ga(1)–Ga(3)–Ga(2) linkage, at distances of 2.5145(13) and 2.7778(14) Å for Ga(1)–Ga(3) and Ga(2)–Ga(3), respectively, is interesting. It should be noted, however, that this compound is not strictly governed by a symmetry element (*i.e.*, mirror plane or two-fold axis) which would impose a symmetrical –Ga–Ga–Ga– linkage. Even as the Ga–Ga bond distances in $[(Pr^i_3C_6H_2)_2C_6H_3]Ga\{H_2PGa(H)PH_2\}Ga[C_6H_3(C_6H_2Pr^i_3)_2]$ are somewhat elongated, they compare well with other Ga–Ga bond distances observed in tetrahedra or heteronuclear trigonal bipyramids (*vide infra*).

The literature reveals another compound containing a Ga–Ga–Ga linkage in $Ga_3I_5{\cdot}3PEt_3$ (below), isolated from ultrasonic irradiation of gallium and diiodine in the presence of triethylphosphine.[20]

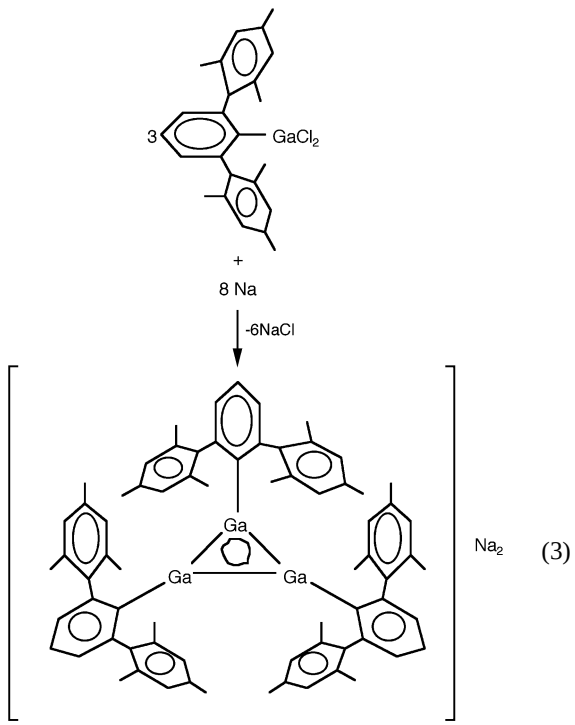
In this mixed-valent compound, a Ga(I) centre is the bridging moiety for two Ga(II) units with Ga–Ga distances of 2.451(1) and 2.4560(1) Å. The Ga–I bond distances in the two terminal GaI_2 units [2.610(1) Å] are slightly shorter than the central Ga–I [2.627(1) Å]. The Ga–Ga–Ga bond angle is 121.9(1)°. This



value is compared with 69.68° for the corresponding Ga–Ga–Ga bond angle observed in $[(Pr^i_3C_6H_2)_2C_6H_3]Ga\{H_2P\text{-}Ga(H)PH_2\}Ga[C_6H_3(C_6H_2Pr^i_3)_2]$, a striking difference of almost 50°.

Cyclogallenes: metalloaromatic compounds

Even though gallium has demonstrated limited catenation abilities, as evidenced by the synthesis of (previously discussed) compounds containing –Ga–Ga–Ga– linkages, reports of an entirely new class of organogallium compounds are perhaps more substantial. Sodium metal reduction of the *m*-terphenylgallium dichloride $[(Me_3C_6H_2)_2C_6H_3]GaCl_2$ in diethyl ether has been shown by this laboratory (below) to afford dark red crystals of $Na_2[(Me_3C_6H_2)_2C_6H_3Ga]_3$ [eqn. (3)].[21]



(3)

The X-ray crystal structure of $Na_2[(Me_3C_6H_2)_2C_6H_3Ga]_3$ (Fig. 4) reveals a perfectly planar gallium three-membered ring, Ga–Ga bond distances of 2.441(1) Å, and Ga–Ga–Ga bond angles within the ring of 60.01°.

Upon closer examination a more intriguing aspect of the $Na_2[(Me_3C_6H_2)_2C_6H_3Ga]_3$ compound began to emerge. The gallium atoms are taken to be sp^2 hybridized along with one unhybridized p orbital on each gallium atom. Moreover, the three p orbitals are populated by two electrons, one from each of the two sodium atoms. Thus, this first example of a gallium ring compound, a cyclogallene, is also a 2π aromatic system. The synthesis and molecular structure of a potassium based cyclogallene, $K_2[(Me_3C_6H_2)_2C_6H_3Ga]_3$, was subsequently reported (similar bond distances and angles were observed).[22] The Ga–Ga bonds within these rings are shorter than most of the

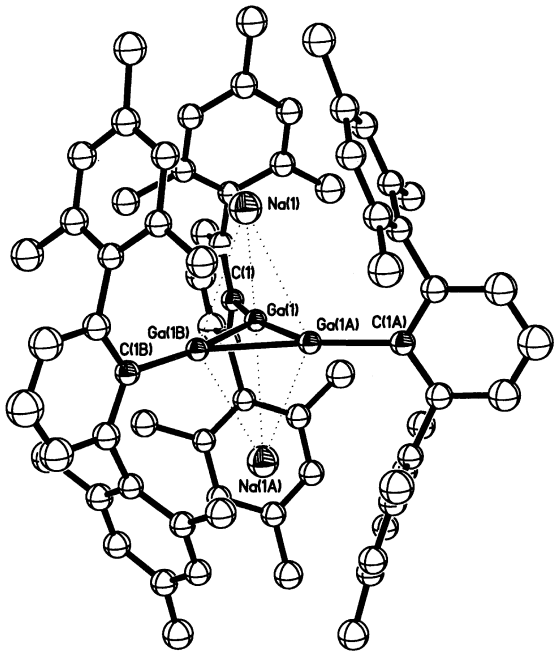


Fig. 4 Crystal structure of $Na_2[(Me_3C_6H_2)_2C_6H_3Ga]_3$.

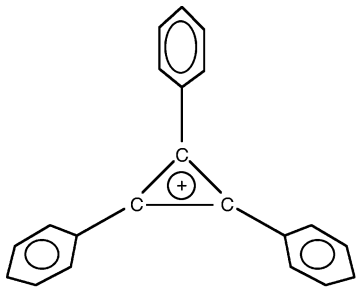
reported gallanes. In addition, these ring compounds bear a striking resemblance to the smallest aromatic moiety—the triphenylcyclopropenium cation reported by Breslow more than four decades ago.[23]



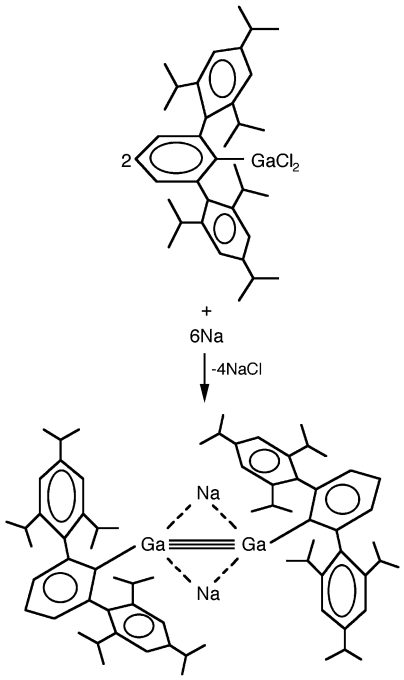
The nucleus independent chemical shifts (NICS) values[24] calculated for cyclogallenes[25] were supportive of aromatic behavior. Thus, the term *metalloaromaticity*,[22] intended to denote traditional aromatic behavior derived from a metallic ring system, was deemed warranted for these novel compounds. Metallic ring systems demonstrating traditional aromatic behavior present a serious challenge to borazine's long held position as the most important inorganic aromatic system.[26]

The gallium–gallium triple bond: a provocative compound, a vigorous debate

Even as it is the simplest of all alkynes, it is generally accepted that acetylene is also the most important compound possessing the iconic carbon–carbon triple bond. Moreover, the chemical bonding in acetylene is elegantly simplistic as interpreted by valence bond theory: a perfectly linear H–C–C–H molecular structure, as a consequence of sp hybridized carbon atoms, coupled with a tubular-shaped electron density. To be sure, the concept of a main group metal compound being analogous to acetylene would prove formidable.

In an effort to ascertain the extent to which slight modifications in the *m*-terphenyl ligand would affect the nature of the resulting organometallic compound we sought to modify the ligand. We slightly modified the peripheral substituents on the *m*-terphenyl ligand from methyl groups (in the case of cyclogallenes) to isopropyl groups. Thus, we prepared the $[(Pr^i_3C_6H_2)_2C_6H_3]Li$ lithium salt and allowed it to react with gallium chloride. Sodium metal reduction of the resulting

sterically demanding gallium based *m*-terphenyl, $[(Pr^i_3C_6H_2)_2C_6H_3]GaCl_2$, which is dimeric in the solid state, bridging through two chlorine atoms,[27] affords Na_2-$[\{(Pr^i_3C_6H_2)_2C_6H_3\}Ga{\equiv}Ga\{C_6H_3(C_6H_2Pr^i_3)_2\}]$ [eqn. (4)].



(4)

The article which reported the synthesis and molecular structure of this reaction product, entitled *How Short is a –Ga≡Ga– Triple Bond?*[28] made a most provocative claim: that the $[\{(Pr^i_3C_6H_2)_2C_6H_3\}Ga{\equiv}Ga\{C_6H_3(C_6H_2Pr^i_3)_2\}]^{2-}$ dianion represented a digallium analog of acetylene, or a *gallyne*, the first moiety claiming to contain a Ga≡Ga triple bond. The molecular structure of $Na_2[\{(Pr^i_3C_6H_2)_2C_6H_3\}Ga{\equiv}Ga\{C_6H_3$-$(C_6H_2Pr^i_3)_2\}]$ is shown in Fig. 5.

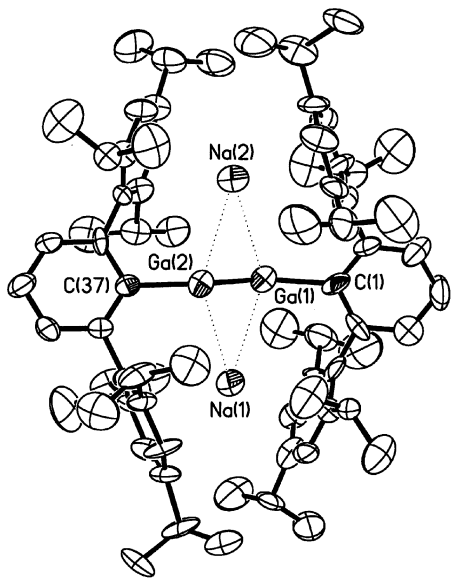


Fig. 5 Crystal structure of $Na_2[\{(Pr^i_3C_6H_2)_2C_6H_3\}Ga{\equiv}Ga\{C_6H_3$-$(C_6H_2Pr^i_3)_2\}]$.

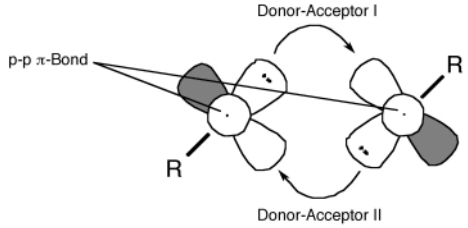
The inherent significance of such a claim is evidenced by the fact that it resulted in two highly publicized reports in *Chemical & Engineering News*.[29,30] The Ga–Ga bond distance in the dianion of 2.341 Å is among the shortest distances reported for a compound containing a gallium–gallium bond. However, the decidedly nonlinear C–Ga–Ga–C core linkage of 127 and 134° was most *unacetylenic*. Our justification in describing the metal–metal bonding as a gallium–gallium triple bond goes far beyond the short Ga–Ga bond distance. Indeed, *where heavier main group element compounds (beyond carbon) are concerned, short bond distances are neither necessary nor sufficient to constitute multiple bonding*. Essentially, the nature of a chemical bond is first and foremost determined by the electronic structure, not by the molecular geometry. Theoreticians and computational quantum chemists have been predicting for years (prior to the gallyne report) that if such a main group metal compound could be synthesized possessing a homonuclear diatomic triple bond, its structure would *not* be linear (as in the case of acetylene), but rather it would possess a non-linear *trans*-bent structure,[31] as in the gallyne. Perhaps most informative, workers such as Kobayashi and Nagase[32] (and references cited therein) have long predicted that, at the expense of the linear disilyne model H–Si≡Si–H ($D_{\infty h}$), the *trans*-bent disilyne model H–Si≡Si–H (C_{2h}) would be favored.

Opposition to the gallium–gallium triple bond was swift and vigorous.[30] Utilizing density functional theory (DFT) Cotton, Cowley, and Feng (CCF)[33] examined a number of main group element moieties containing multiple bonds including P_2, P≡C–R, R–P=P–R, R_2–Ge=Ge–R_2. These results were compared with calculations on the closely related (2,6-diphenyl)-phenyl gallyne model, $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$. The principal conclusion put forth by CCF (beyond a discussion on the presence and/or absence of a gallium hydride in the gallyne): 'With or without hydrogen atoms, there can only be a Ga=Ga double bond [one σ bond and one π bond which may be described by two canonical molecular orbitals], namely, Na_2[R–Ga=Ga–R], rather than Na_2[R–Ga≡Ga–R] for the case of no hydrogen atoms.' Importantly, the CCF effort, in posing an argument against a Ga≡Ga triple bond, failed to address the concept of bond orders, an obvious and puzzling omission. Allen, Fink and Power[34] also argued against the gallium–gallium triple bond in the gallyne. These workers simply, if pejoratively, stated (among other things) that 'there is no GaGa σ bond [in the gallyne].' Furthermore, these workers proceeded to address bond orders *without providing or calculating a bond order for the Ga–Ga interaction in question*. Allen, Fink and Power summarily stated, 'The results of these studies provide strong evidence that the Ga–Ga or Ge–Ge bond orders in such molecules are significantly less than three and, in the case of the gallium species, *very probably between one and two*.' Our calculated bond orders of 2.36 and 3.02 {for $[HGa{\equiv}GaH]^{2-}$ (C_{2h})} and 2.79 for $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$ would appear to refute this work (*vide infra*).

Offering a rebuttal to the more credible CCF position, we also published a detailed DFT study firmly in support of the gallyne model and the Ga≡Ga triple bond, entitled '*The Nature of the Gallium–Gallium Triple Bond*'.[35] Our position is unambiguous: the $Na_2[\{(Pr^i_3C_6H_2)_2C_6H_3\}Ga{\equiv}Ga\{C_6H_3(C_6H_2Pr^i_3)_2\}]$ gallyne consists of two donor–acceptor bonds and one π bond, thus resulting in a gallium–gallium triple bond, albeit a *weak triple bond*. Klinkhammer,[36] utilizing the Natural Bond Orbitals technique (NBO), states that the bonding (of the gallyne) bears a striking similarity to that put forth by Lappert[37] in 1976 for the distannene $[(Me_3Si)_2CH]_2Sn{=}Sn[CH(SiMe_3)_2]_2$: namely, the Sn=Sn double bond is constituted by two donor–acceptor bonds resulting in 'a "bent" and weak Sn–Sn double bond.' Specifically, one may interpret the bonding in the gallyne, writes Klinkhammer, as two donor–acceptor bonds (as in the distannene) which are 'augmented by an additional π bond to yield a Ga≡Ga triple bond (below).'

Indeed, Power and Brothers,[38] describing $[(Me_3$-$Si)_2CH]_2Sn{=}Sn[CH(SiMe_3)_2]_2$ as 'a tin analogue of a substituted ethene,' prophetically opined: 'The discovery of such compounds [as $[(Me_3Si)_2CH]_2Sn{=}Sn[CH(SiMe_3)_2]_2$] has shown that the classical σ/π-model of the double bond in carbon, nitrogen, or oxygen compounds does not necessarily apply to the heavier elements.'



Thus, an interesting dichotomy emerges most unlike the case for multiple bonds involving carbon: even as the bonding in the gallyne is described as a triple bond, this interaction is admittedly *weak*. Indeed, a recent study examining force constants given by DFT frequency calculations shows that the gallium–gallium bond in $Ga_2H_2^{2-}$ is only slightly strengthened with respect to the Ga–Ga single bond in $Ga_2H_6^{2-}$.[39] Another recently published work entitled '*How Strong is the Gallium ≡Gallium Triple Bond?*', found that the gallium–gallium bond strength in the Na_2[H–GaGa–H] gallyne model is weaker than the gallium=gallium double bond in the $Na_2[H_2Ga{=}GaH_2]$ model gallene.[40] The fact that these workers conclude that the gallium–gallium bond is weak is perfectly consistent with our original position. Other workers have also referred to the gallyne as having a weak Ga≡Ga triple bond.[41]

Relative to bond orders, there are a number of ways in which they may defined and calculated. Nonetheless, if the same method is applied to a series of moieties, logical trends should emerge. Thus, in this work we calculated the bond orders by the Wiberg Bond Index (WBI)[42] and the Natural Localized Molecular Orbital Natural Population Analysis (NLMO/NPA)[43] obtaining values of 2.36 and 3.02, respectively, for the *trans*-bent $[H–Ga{\equiv}Ga–H]^{2-}$ (C_{2h}) gallyne model. These bond orders are, at minimum, supportive of a multiple bond considerably beyond that of a double bond. The bond order of 3.02 is clearly deserving of the triple bond label.

Earlier this year we published a second detailed theoretical examination of the gallyne in a more realistic model: we used the same gallyne model that Cotton had used, namely $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$.[44] A cursory examination of the optimized $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$ gallyne model (Fig. 6) reveals that this molecule is very similar to the experimentally prepared gallyne, differing only in the absence of the six isopropyl substituents.

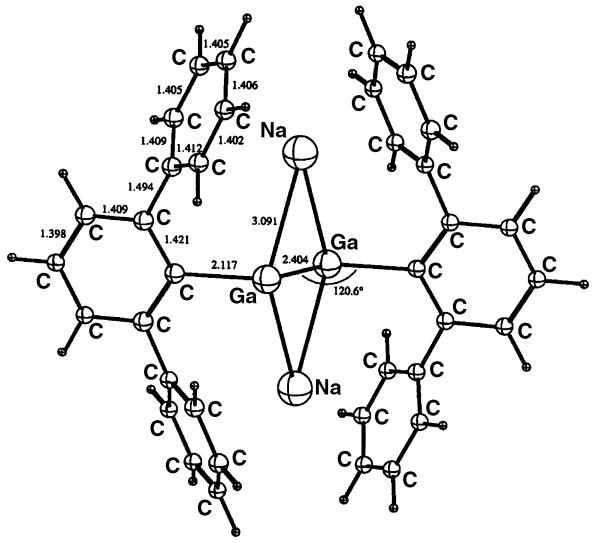


Fig. 6 Geometry (C_{2h}) of the $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$ molecule optimized at the B3LYP level of theory with a basis set of 836 contracted Gaussian functions.

The $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$ structure was fully optimized with the B3LYP method utilizing a substantial basis set of 836 contracted Gaussian functions. In this work we obtained a NLMO/NPA bond order of 2.79 for $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$, thus offering support for a weak Ga≡Ga triple bond in the model compound and in the experimental gallyne.

The associated bond distances and angles are similar to the experimental values. The calculated Ga–Ga bond distance of 2.404 Å, although similar to, is somewhat shorter than that reported for the simplest gallyne model, Na_2[H–Ga≡Ga–H] (2.441 Å), and considerably shorter than the methyl gallyne derivative, Na_2[Me–Ga≡Ga–Me] (2.508 Å). There should be little cause for concern with this trend, however. A similar trend is observed in the disilyne model series H–Si≡Si–H (2.111 Å), Me–Si≡Si–Me (2.123 Å) and R–Si≡Si–R (2.095 Å) (R = large substituent).[32] As suggested by CCF, we also observed that the optimized structure allows for twisting of the four substituent phenyl rings toward the sodium atoms at a distance of 2.8 Å. This has the effect of shortening the Ga–Ga distance (as compared to those simpler gallyne models which do not have aryl substituents). It is important to point out, however, that our optimized Ga–Ga distance is longer than that reported in the CCF study. We believe that this is due to the relatively small basis sets used by these workers (6-31G and 6-311G, without polarization and diffuse functions).

Relative to the Ga–Ga bond distances, our calculated bond distance of 2.404 Å is 0.085 Å longer than the experimental value of 2.319(3) Å. We view this as an indication that the gallium–gallium bond in the experimental compound may be a bit more substantial than for the gallyne model. The experimental Ga–C bond distance of 2.044 Å compares to a calculated value of 2.117 Å. In contrast, the experimental Ga–Na (3.081 Å) distances compare well to the calculated value (3.091 Å). Finally, a NLMO/NPA bond order of 2.79 was obtained for $Na_2[(Ph_2C_6H_3)Ga{\equiv}Ga(C_6H_3Ph_2)]$.

An elegantly detailed examination of homonuclear multiple bonding between main group elements was recently put forth by Grützmacher and Fässler.[45] While presenting an informative historical perspective on chemical bonding and the development of the symbols used to denote bonding, these workers utilized electron localization function (ELF) to examine and interpret the bonding in the gallyne and other heavier main group moieties involving multiple bonds. Grützmacher and Fässler reached an unambiguous conclusion regarding the heavier main group elements:

> "The classical multiple bond indicators—bond lengths and bond strengths—have no meaning for multiple bonds in which elements from the higher periods are involved. However, they are valid for an exceptional element: carbon."

This striking position, also put forth by Klinkhammer,[36] underscores the awkward reality that most of our theories of structure and bonding are based upon the element carbon. The resulting implication: What holds for carbon need not necessarily hold for the heavier main group elements. The conclusion of Grützmacher and Fässler relative to the gallyne: these workers refer to the Ga–Ga interaction as a 'slipped triple bond' as compared to an 'unslipped triple bond' in the case of acetylene. Grützmacher and Fässler[45] further add, 'Clearly this compound [the gallyne] has a [Ga≡Ga] triple bond.'

Concluding remarks

The synthesis and molecular structure of organogallium compounds are an interesting area of study. A number of novel compounds have been prepared in recent years. Few topics in organogallium chemistry have generated more interest than the report of a compound containing a Ga≡Ga triple bond.[46] The fact that this compound has served as a substrate upon which fundamental questions of structure and bonding may be pondered and debated is most significant. It would appear that

some of our long-standing theories of structure and bonding may be inadequate to describe sufficiently novel organometallic compounds.

Received (in Cambridge, UK) 24th August 2000, Accepted 2nd October 2000
First published as an Advance Article on the web 23rd October 2000

The combination of the neodymium *tert*-butoxide [$Nd_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(THF)_2$] 1 with 1 equivalent of a dialkylmagnesium reagent affords an efficient catalyst for the pseudo-living polymerization of ethylene.

Trivalent rare earth metal hydrides and alkyl complexes stabilized by two cyclopentadienyl-type ligands, Cp_2LnR have attracted much attention because of their high efficiency in polymerizing ethylene.[1] Currently, there is considerable interest in developing related organolanthanide complexes involving ancillary ligands other than the commonly used Cp-type ligands. In this respect, hard, electronegative ligands such as alkoxides are particularly attractive because they offer strong metal–oxygen bonds that are expected to stabilize complexes.[2] Although the mixed Cp*–aryloxide system $[Y(C_5Me_5)(OC_6H_3\text{-}Bu^t_2\text{-}2,6)(\eta\text{-}H)]_2$ has been shown to be active for the polymerization of α-olefins,[3] no equivalent Cp-free alkoxy catalyst system had been developed to date.[4] We report here that some lanthanide *tert*-alkoxides are efficient inorganic precatalysts, when combined with dialkylmagnesium compounds, for the pseudo-living polymerization of ethylene and ethylene–MMA block copolymerization.

The reaction of $NdCl_3$ with 3 equiv. of $NaOBu^t$ in THF at 25 °C for 3 days gives a single primary product **1**, that can be isolated in 80–90% yield as a very air-sensitive compound. An X-ray crystallographic study revealed that **1** is a trimetallic compound with the formula $[Nd_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(THF)_2]$ (Fig. 1).[5] Some lanthanum analogues isostructural to **1** have been reported: $La_3(OBu^t)_9(THF)_2$ **2**, prepared by ionic metathesis,[6] and $[La_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(HOBu^t)_2]$ **3**, obtained by alcoholysis of $La\{N(SiMe_3)_2\}_3$.[7] Complexes **2** and **3** are, however, respectively, much less efficient than **1** and totally inefficient for the polymerization catalysis described hereafter.

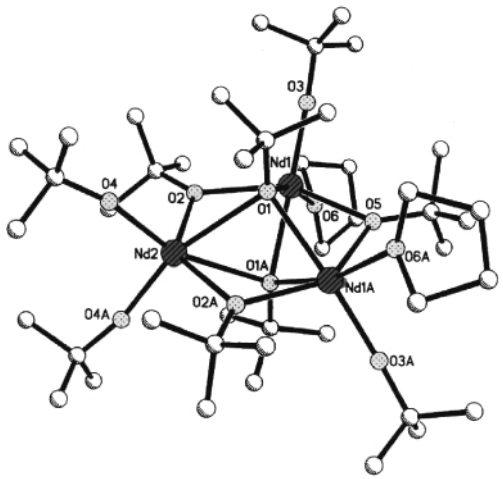

Fig. 1 Molecular structure of **1** in the crystal. Selected bond lengths (Å): Nd1–O3 2.147(4), Nd1–O2 2.333(3), Nd1–O5 2.399(3), Nd1–O1 2.409(3), Nd1–O1A 2.520(3), Nd1–O6 2.661(4), Nd1–Nd1A 3.6318(6), Nd1–Nd2 3.7161(4), Nd2–O4 2.163(3), Nd2–O2 2.458(3), Nd2–O1 2.624(3).

The addition of 1 equivalent of di(*n*-hexyl)magnesium to **1** in toluene solution at 0 °C offers an active catalyst for ethylene polymerization. The typical ethylene flow rate for a batch experiment conducted under 1.1 atm is shown in Fig. 2. The maximum consumption of ethylene, reached after a few minutes, corresponds to the appearance of insoluble polymer. The typical average catalytic activity calculated over 1 h on the basis of the amount of Nd initially introduced is *ca.* 10 g $mmol^{-1}$ h^{-1} atm^{-1} at 0 °C. This places this new catalyst system on a moderate rate of effectiveness on Gibson's scale,[1d] and compares well to traditional alkyl–lanthanocenes under similar conditions. The Mg(*n*-hex)$_2$–**1** system gives linear high density and highly crystalline (>80%) polyethylene (T_m = 139–141 °C) with M_n = (3–4) × 10^5 and M_w/M_n = 2.3–2.5. GPC analysis of aliquots revealed that the molecular weight and the polydispersity do not increase significantly during the reaction course. These results are tentatively ascribed to slow *in situ* catalyst generation, rapid propagation relative to the rate of initiation and/or concomitant heterogenezation due to precipitation of long-chain metal–alkyl species from solution. The monomodality of the GPC curves is, however, consistent with the generation of one type of active species. Progressive deactivation of the catalyst system was observed above 20 °C, resulting in lower productivities and formation of low molecular weight PE (*e.g.* at 80 °C: $[a]_{1h}$ = 0.6 g $mmol^{-1}$ h^{-1} atm^{-1}, M_n = 1720, M_w/M_n = 1.55, 29% vinyl terminations).

When the polymerization was carried out at 0 °C in the presence of $PhSiH_3$ as a transfer agent[8] (10 equiv. *vs.* Nd), the activity profile and the productivity over 1 h were the same as those observed in the absence of this reagent. The polymer recovered after MeOH quenching and work-up was shown by ^1H and ^{13}C NMR to be end-capped $PhSiH_2$–polyethylene, with M_n = 14 300 and broad polydispersity (M_w/M_n = 25). Using 2% of H_2 in ethylene as an alternative transfer agent[9] resulted in

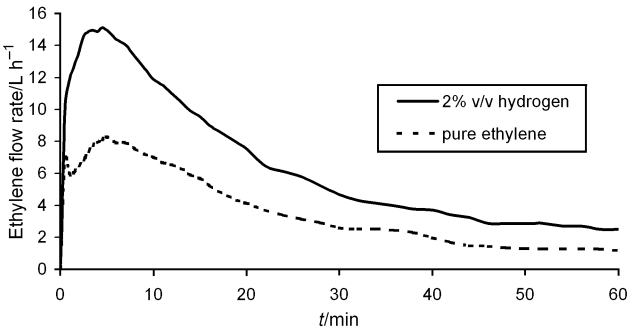

Fig. 2 Typical ethylene consumption plots observed with the **1**–Mg(*n*-hex)$_2$ system with pure C_2H_4 and a 98 : 2 v/v C_2H_4–H_2 mixture (0.33 mmol **1**, 1.0 mmol Mg, 100 mL toluene, 0 °C, 1.1 atm ethylene kept constant).

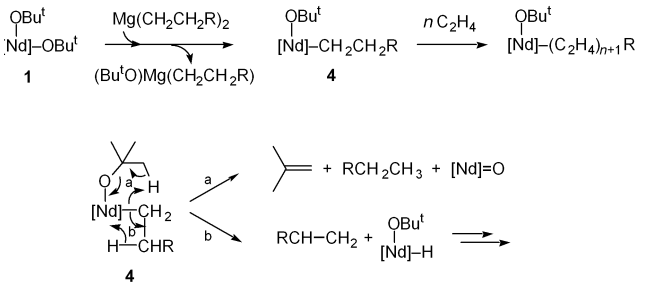
DOI: 10.1039/b006941h



Scheme 1 Schematic presentation of proposed activation (up) and deactivation (down) pathways.

a *ca*. 25% increase in the catalyst productivity (Fig. 2) and formation of polyethylene with M_n = 17 000 (constant value ± 500 for five samples collected every 10 min) and broad polydispersity (M_w/M_n = 5.8). In both cases, no end-group associable with conventional (*e.g.* β-H elimination) chain transfer processes was detected by NMR in the polymers. Further evidence for the pseudo-living character of the Mg(*n*-hex)$_2$–**1** catalyst system at 0 °C is provided by the possibility of achieving ethylene–MMA block copolymerization through initial homopolymerization of ethylene and sequential addition of MMA.[10]

All of these results support a polymerization mechanism for the present system similar to that established for traditional lanthanocenes. We assume that alkylation of **1** by the dialkylmagnesium[11] *in situ* generates an active alkyl–Nd species **4** (Scheme 1). Preliminary NMR investigations of Mg(CH$_2$CH$_2$R)$_2$–**1** systems (R = H, Et, Bu) show the formation, at as low as −60 °C, of the corresponding alk-1-ene, RCH=CH$_2$, in 15–40% yield *vs*. Nd. This is consistent with the formation of an alkyl–Nd species **4** which further evolves, *e.g. via* β-H elimination (a). Also, the slow formation of isobutene in 2–40% yield *vs*. Nd with concomitant release of the alkane [clearly evidenced with SiMe$_4$ upon using Mg(CH$_2$SiMe$_3$)$_2$] supports the generation of **4** and indicates that *tert*-butoxy ligands are likely involved in the degradation of the active species (b).[12]

Among the large variety of alkylating reagents so far investigated in combination with **1**, only dialkylmagnesium derivatives, in particular those bearing long alkyl chains, led to appreciable ethylene polymerization activity. Best activities are obtained with 1.0 equiv. of MgR$_2$ *vs*. Nd, as deviation from this stoichiometry resulted in a rapid drop in catalytic activity. Other tris(alkoxy)lanthanide complexes have been investigated as precatalysts, among which some show similar properties but contrasting performances; *e.g.* the Sm^{III} *tert*-butoxide–Mg(*n*-hex)$_2$ system gives low molecular weight PE ([*a*]$_{1h}$ = *ca*. 2 g mmol^{-1} h^{-1} atm^{-1}, M_n = 2500, M_w/M_n = 6.1). On the other hand, alkoxylanthanide precursors such as **3** or its Nd equivalent, both prepared by alcoholysis of amide precursors, are totally inactive. In fact, alkoxy ligands having no hydrogen in the β-position, the absence of coordinated protic solvent and of chloro ligands, as well as structural constraints in the nuclearity of the complex appear to be prerequisites for the successful development of these new-generation lanthanide catalysts.

This work was supported by Rhodia, the Ministère de l'Industrie and the CNRS. We thank Dr J. Vaissermann, Paris, for initial efforts in elucidating the crystal structure and Professor R. F. Jordan, Chicago, for GPC facilities.

An approach to open-chain 1,5-stereocontrol using a silyl group

Ian Fleming* and Chandrashekar Ramarao

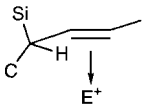
First published as an Advance Article on the web 23rd October 2000

Nucleophilic attack by an ethylcuprate on the α,β-unsaturated ketone 3 takes place *anti* to the silyl group to give largely (96:4) a single product 4, fragmentation of which removes the silyl group, and reveals a pair of stereogenic centres having an open-chain 1,5 relationship 9.

We have developed a substantial body of chemistry in which a stereogenic centre carrying a silyl group controls the stereochemistry of electrophilic attack on a C=C double bond in the sense **1**,[1] and we have also adapted these reactions to control

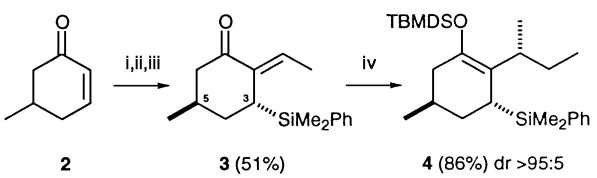


1

more distant open-chain relationships, including 1,4 in the course of syntheses of tetrahydrolipstatin[2] and of nonactin,[3] and 1,6 in an S_E2'' reaction.[4] The use of a silyl group to control 1,4-relationships has also been exploited by Procter[5] and by Panek.[6] We have now developed a method for the control of a 1,5-relationship, which we describe here. The essence of our approach is successively to set up two 1,3-relationships, moving the stereochemistry three atoms along the chain each time. By using a silyl group in the middle, we can remove the intervening functionality and stereochemistry to reveal the open-chain 1,5-relationship.

We began with the well established 1,3-control seen in conjugate additions to 5-substituted cyclohexenones,[7] which we already knew was well behaved when the nucleophile was a silyl group.[8] On this occasion we used the phenyldimethylsilylzincate reagent[9] with 5-methylcyclohex-2-enone **2** (Scheme 1), and the intermediate zinc enolate readily underwent an aldol reaction with acetaldehyde to give a β-hydroxy ketone as a mixture of diastereoisomers. Dehydration gave, as far as we could tell, a single α,β-unsaturated ketone **3** with the C-5 methyl and C-3 silyl groups *trans* to each other and the exocyclic double bond with a *Z* configuration (COSY and NOESY). This set up the first 1,3-relationship, and we set up the second by conjugate addition of an ethylcuprate reagent in the presence of *tert*-butyldimethylsilyl chloride. This gave a silyl enol ether **4** as a single diastereoisomer (^{1}H-NMR, >95:5), which proved (see below) to have the relative configuration illustrated.

We carried out the complementary sequence, trapping the zinc enolate with propionaldehyde instead of acetaldehyde, and adding a methylcuprate to the α,β-unsaturated ketone **5**, which gave largely (86:14) the alternative stereoisomer **6** (Scheme 2).



2 **3** (51%) **4** (86%) dr >95:5

Scheme 1 *Reagents and conditions*: i, $PhMe_2SiZnMe_2$ Li, THF, −78 °C, 1 h; ii, MeCHO, −78 °C, 2 h; iii, MsCl, Py, $CHCl_3$, reflux, 16 h; iv, TBDMSCl, Et_2CuLi LiCN, THF, −78 °C, 1 h.

This time we could clearly see the signals (^{1}H-NMR) of the minor isomer, which were identical to those we had already seen for the isomer **4**. Clearly, the reaction had been stereochemically highly controlled, and either stereoisomer, **4** or **6**, could be obtained with nearly equal ease.

We hydrolysed the silyl enol ether **4**, and obtained a single diastereoisomer of the ketone **7**, which was unaffected by treatment with sodium methoxide, suggesting that it was the thermodynamically favourable isomer (Scheme 3). We then applied a fragmentation reaction developed by Nishiyama and Itoh,[10] using the oxime acetate **8**, and obtained the alkene **9** with the 1,5-relationship between C-3 and C-7 revealed in an open chain. That the alkene had a *trans* double bond showed that the relative stereochemistry assigned (COSY and NOESY) to C-2 in the ketone **7** was correct, since Itoh has shown that this type of fragmentation is stereospecifically *anti*.

We proved the relative stereochemistry between the 1,5-related centres, by carrying out the same sequence using enantiomerically pure (5*R*)-methylcyclohex-2-enone **1**,[11] and obtained the nitrile **9** enantiomerically pure at C-3. Ozonolysis and borohydride reduction gave 2-methylbutanol, derivatisation of which with Mosher's acid gave us the known esters (Scheme 4).[12] The major component **10** was the *R*,*R*-diastereoisomer (^{1}H-NMR), and a minor component (4%) was now detectable and identifiable as the *R*,*S*-diastereoisomer, allowing us to measure, more accurately than it had been possible to from the earlier NMR spectra, the degree to which we had been successful in the conjugate addition step **3** → **4**.

We suggest that, if the silyl group in the α,β-unsaturated ketone **3** were equatorial **11**, it would suffer from steric compression with the methyl group on the exocyclic double

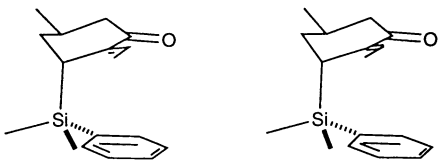
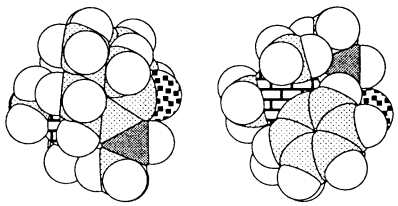
bond. In consequence, even though a trimethylsilyl group has a larger A-value than a methyl group (2.5[13] and 1.74, respectively), the lower-energy conformation of the enone **3** probably has the methyl group equatorial and the silyl group axial **12**, where, in any case, it only has one 1,3-diaxial interaction. With the silyl group held on the lower surface, nucleophilic attack can be expected to take place on the top surface *anti* to the bulky group **12** (arrow), and hence give the silyl enol ether with the relative configuration **4**.

To support this argument, we carried out molecular modelling calculations (Macromodel), which confirmed that the conformation with the silyl group axial **12** had the lowest energy,[14] with the stereo drawings **13** giving a more accurate



13

picture of the minimised structure. Looking at the space-filling versions **14** (from above) and **15** (from below) illustrates the difference between the two surfaces of the enone **3**—the β-carbon (darker grey) in the top view is exposed, but in the bottom view it is hindered by the substituents on the silyl group.[15]



14 top view **15** bottom view

Furthermore, the calculation for the second α,β-unsaturated ketone **5** revealed why it suffered a lower degree of stereocontrol in the conjugate addition step—the methyl group of the ethyl group was oriented upwards, hindering the top surface more than the top surface of the α,β-unsaturated ketone **3** = **12** = **13**.

The stereocontrol in this system is interesting from two points of view. In the first place, it shows that the silyl group is not so hindering that it cannot adopt the axial position, and yet simultaneously it does hinder the approach of the incoming nucleophile. The long Si–C bond takes the silyl group far enough away from the cyclohexane ring to make 1,3-diaxial interactions less severe than they would be for a carbon-based group, and yet the length of the Si–C bonds to the three other substituents on the silicon atom causes them to occupy much of the space below the double bond. In the second place, this is the first reaction that we have studied in which the double bond

Scheme 5 *Reagents and conditions*: i, Me_2CuLi, THF, −78 °C, 1 h; ii, TBDMSCl, HMPA, Et_3N, −78 °C → rt, 1 h; iii, EtCHO, $TiCl_4$, CH_2Cl_2 −78 °C, 2 h; iv, TsOH, toluene, reflux, 1 h; v, Me_2CuLi, THF, −78 °C, 1 h; vi, TMSCl, HMPA, Et_3N, −78 °C → rt, 1 h.

adjacent to the stereogenic centre carrying a silyl group has undergone *nucleophilic* attack. All our work in the past has involved electrophilic attack. Since the sense of attack, *anti* to the silyl group **1**, is the same, it may be that we have here some indication that the stereocontrol is largely steric in origin. This conclusion stems from the prejudice that nucleophilic attack and electrophilic attack would take place in opposite senses if purely electronic effects were operative.

Although this may be a little too simplistic, we can be sure that the silyl group is an important component in ensuring the high levels of diastereocontrol that we have seen, for we have carried out a similar set of reactions with the C-5 methyl group and the C-3 silyl group in **5** interchanged (Scheme 5). Starting with the silicon-containing cyclohexenone **16**,[16] and using a methylcuprate to set up the 1,3-related centres in the enone **17**. This time, the conjugate addition of the methylcuprate gave both possible diastereoisomers **18** in equal amounts. Presumably a methyl group on C-3, although surely held axial, shields the bottom surface from attack to the same extent as the upturned methyl group on the side chain shields the top surface.

We thank Avra Laboratories, Hyderabad, for a maintenance grant (C. R.), and Setu P. Roday for help with the molecular modelling.

Synthesis and crystal structure of [IBa(OBu^t)$_4${Li(thf)}$_4$(OH)]: a mixed ligand heterometallic cluster with an unusual low coordination number for barium

Katharina M. Fromm,*[a] Estelle D. Gueneau[a] and H. Goesmann[b]

[a] *University of Geneva, Sciences II, 30, Quai Ernest-Ansermet, CH-1211 Geneva 4, Switzerland. E-mail: Katharina.Fromm@chiam.unige.ch*

Received (in Cambridge, UK) 12th July 2000, Accepted 5th October 2000
First published as an Advance Article on the web 25th October 2000

The reaction of [BaI$_2$(thf)$_5$] with LiOBu^t in THF in the presence of hydroxide yields a volatile mixed alkali and alkaine earth metal cluster with an unusually low coordination number for the alkaline earth cation; due to the presence of the alkoxide groups, the cluster is volatile at temperatures below 200 °C.

Recently, many organolithium compounds have been structurally investigated, their structure being of interest for the elucidation of possible reaction mecanisms in organic metallation reactions. Thus, it has been shown that metallated organic compounds tend to form aggregated species in the solid state as well as in solution. For example, LiMe, NaMe and MOBu^t, M = Rb, K, form tetrahedral tetramers,[1,2] LiEt forms hexameric units[3] and NaOBu^t has been shown to have one hexameric and one nonameric molecule in its structure.[4] LiOBu^t forms a hexameric aggregate in the gas phase as well as in solution and the solid state.[5] We here describe the reaction of this compound with [BaI$_2$(thf)$_5$] in THF which yields the mixed metal cluster [IBa(OBu^t)$_4${Li(thf)}$_4$(OH)] **1**.†

In our attempts to make alkaline earth metal cluster compounds in analogy to transition metal clusters, we use an alkaline earth metal halide and an alkali metallated organic compound in order to eliminate alkali halide and to enforce aggregation of the alkaline earth compound.[6] Herein, we report on the reaction of BaI$_2$ with LiOBu^t in THF preceded by the synthesis and isolation of LiOBu^t.[5]

The reaction of 4 equiv. of LiOBu^t dissolved in THF under partial hydrolysis or directly in the presence of LiOH with a THF-solution of 1 equiv. of BaI$_2$ containing [BaI$_2$(thf)$_5$][7] at −20 °C yields colorless blocks of **1** [eqn. (1)], suitable for single crystal X-ray analysis.[8]

$$[BaI_2(thf)_5] + 4\,[Li(OBu^t)] + OH^- \rightarrow [IBa(OBu^t)_4\{Li(thf)\}_4(OH)]\ \mathbf{1} + I^- \quad (1)$$

The compound crystallises in the tetragonal space group *P*4/*nmm* (No. 129) with two molecules per unit cell. The structure can be described as a square antiprism formed by four Li atoms in one plane and four O atoms of the OBu^t ligands in the other square plane, the Li-face being capped by an OH-group and the O-face by a Ba–I unit leading to an overall almost spherical entity. Its formation can be explained by the successful substitution of one iodide and five thf molecules of [BaI$_2$(thf)$_5$] by a [LiOBu^t]$_4$-unit and a μ_4-capping OH-group (Fig. 1), the latter being introduced by partial hydrolysis of the THF solution of LiOBu^t or LiOH. In fact, compound **1** can be obtained in a yield of up to 65% when the reaction is carried out in the presence of 1 equiv. of LiOH relative to BaI$_2$. The coordination sphere of barium is built up by the one remaining iodide and four OBu^t-groups to give a tetragonal pyramidal geometry. Barium has thus a coordination number of five which is unusually low for such a big cation (ionic radius of 1.36 Å for a coordination number of 6)[9] and only possible by the steric protection by the OBu^t-ligands. The four thf molecules, each one coordinating a lithium ion to yield a tetrahedral coordination sphere for the alkali metal, form a calix[4]arene-like cavity of an average diameter of 7.5 Å, this diameter taking into account the disorder positions of the thf molecules. The μ_4-capping OH-group presents an oxygen with five bonding partners.

The alkaline earth cation Ba lies on a crystallographic 4*mm* site (0, $\frac{1}{2}$, *z* (*c*)) as do the halide I and the O3-hydroxy group. The Li-atom is found on a crystallographic mirror plane *m* (*y*, 0, −*z* (*i*)), the oxygen atom O1 of the OBu^t-groups are on a crystallographic mirror plane *m* (-*x*+$\frac{1}{2}$, *x*, −*z* (*j*)) together with the attached C1 atom and one of the three methyl groups C2. The main symmetric features of the molecule are thus the four-fold axes through I, Ba and O3 as well as the two mirror planes through Li and O1. In the crystal, the neutral clusters are arranged along the C_4-axis with rather long I–O3(H3) hydrogen bonds of 3.935 Å.[6]

The terminal Ba–I distance at 3.344(2) Å is extremely short due to the low coordination number of barium and even shorter than the smallest Ba–I distance in solid BaI$_2$ of 3.38 Å.[10] In [BaI$_2$(thf)$_5$],[7] the terminal Ba–I distances are 3.374(2) and 3.3822(2) Å for a coordination number of seven for the barium. The Ba–O distances in **1** are 2.597(6) Å and thus shorter than in the six-coordinate [Ba(OBu^t)$_2$(HOBu^t)$_2$]$_4$ (2.673(8) Å).[11] The four OBu^t-groups form, together with the four Li(thf) units a square antiprism, the two square faces being twisted by 41.85° to each other. The Li–Li contacts at 2.716(18) Å are shorter than in elemental lithium (3.0390 Å), but longer than in similar

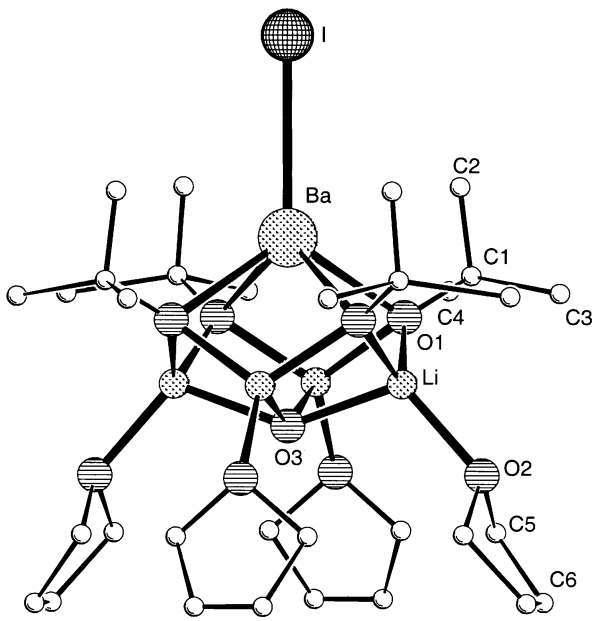

Fig. 1 Crystal structure of **1**. Selected bond lengths [Å] and angles [°]: Ba–I 3.344(2), Ba–O1 2.597(6), Ba–O3 3.115(10), Li–O1 1.962(8), Li–O2 1.997(14), Li–O3 2.035(14), Ba–Li 3.108(13), Li–Li 2.716(18), O1–Ba–I 120.77(12), O1–Ba–O1(*trans*) 118.5(2), O1–Li–O2 122.3(4), O1–Li–O3 91.3(5), O2–Li–O3 113.7(8), Li–O3–Li(*trans*) 141.4(9), cavity diameter (thf) 7.5 Å in average.

compounds like $[Ph_2P(NSiMe_3)]_2CLi_2$[12] with 2.393–2.410 Å. The enlargement relative to the literature data is probably due to the short Ba–O3 contact of 3.115(10) Å in which the alkaline earth cation strongly attracts the OH^- anion which caps the Li_4-square. This also leads to the formation of the very flat square antiprism in which the plane containing the four Li atoms is only 1.115 Å apart from the plane containing the oxygen atoms of the OBu^t groups. Thus, the O3 atom is 0.672 Å above the Li_4 plane, and the Ba atom is 1.328 Å below the O_4 plane. For the Li–O3 and the Li–O2 bonds, bond lengths of 2.035(14) Å and 1.997(14) Å, respectively are observed.

Similar structures containing a square arrangement of four alkali metals are the above mentioned $[Ph_2P(NSiMe_3)]_2CLi_2$,[12] $[Na_4][P\{Si(F)R_2\}(SiPr^i_3)]_2$, (R = 2,4,6-$Pr^i_3C_6H_2$),[13] $[(LiOBu^t)_{10}(LiOH)_6]$,[14] $[Me_2C(CH_2)_3CMe_2NLi]_4$,[15] $[\{Li(NBu^t)_3S\}_2]$[16] or $[Li_4L{\cdot}LiOH{\cdot}4hmpa]$, ($H_4L$ = *tert*-butylcalix[4]arene)[17] as well as $[(Bu^tO)_8Li_4K_4]$.[18] In the $[(LiOBu^t)_{10}(LiOH)_6]$ structure, one can also find the square Li_4O_4-antiprism which is capped on one side by an HO ligand. This fragment shows similar Li–OBu^t and Li–OH bond lengths to **1** at 1.877(10)–2.063(9) and 1.905(11)–2.066(10) Å, respectively.

Similar low coordination spheres for barium are known for instance in the sterically hindered molecule $[(thf)Ba_3(\mu_4\text{-}PSiBu^t_3)_2\{\mu_2\text{-}P(H)SiBu^t_3\}_2]_2$[19] where coordination numbers 5 and 4 for Ba are stabilised by THF or agostic interactions with Bu^t-groups respectively. In the case of **1**, one can also discuss agostic interactions with neighbouring Bu^t-groups since the Ba–(C2)CH_3 distances are in the range of 3.41(3) Å. Other examples for the stabilized low coordination number of 5 for barium are the compounds $[\{BaNP(NMe_3)_2NP(NMe_2)_2NSiMe_3\}_4]$,[20] $[Ba_2\{(C_6H_{11})NC(Me)CHC(Me)N(C_6H_{11})\}_3\{(SiMe_3)_2N\}]$,[21] $[(Et_3PO)_2Ba_2Cu_4(OBu^t)_8]$[22] and $[H_3Ba_6(O)(OBu^t)_{11}(OCEt_2CH_2O)(thf)_3]$[23] for which the Ba–O($\mu_3$-$OBu^t$) distances at 2.76(1) Å are much longer than in **1**. An even lower coordination sphere of 4 in $[BaY_2\{\mu\text{-}OCH(CF_3)_2\}_4(thd)_4]$ (thd = 2,2,6,6-tetramethylheptane-3,5-dionato),[24] $[Ba\{N(SiMe_3)_2\}_2(thf)_2]$ and $[Ba\{N(SiMe_3)_2\}_2(thf)]_2$[25] or 3 in $[Ba\{N(SiMe_3)_2\}_2]$[25] for the alkaline earth metal cation is observed. Another molecular cluster compound combining lithium and barium is the $\{[Ba_6Li_3O_2][OC(CH_3)_3]_{11}(OC_4H_8)_3\}$ in which an oxygen-centered Ba_6-octahedron is fused *via* one triangular face to an oxygen-centered Li_3Ba_3-prism.[26]

As compound **1** is volatile in vacuum at temperatures lower than 200 °C due to the presence of alkoxide groups, its potential application as a barium source in *chemical vapour deposition* processes in order to synthesise high temperature superconductors will be tested. The syntheses of further mixed metal clusters are also under current investigation.

Received (in Corvallis, OR, USA) 11th August 2000, Accepted 7th September 2000
First published as an Advance Article on the web 23rd October 2000

Highly functionalized alternating polyketones which possess epoxide groups in the side chains are synthesized by cationic palladium(II) complex catalyzed copolymerization of vinyl epoxides (non-conjugated diene monoepoxides) with carbon monoxide. Catalytic amounts of formic acid and 1,4-naphthoquinone promote the copolymerization significantly without effecting the epoxide group, with $[Pd(L)(MeCN)_2](BF_4)_2$ (L = (*R*,*R*)-Me-DUPHOS) as the catalyst.

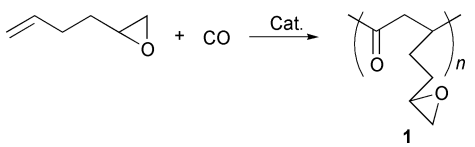
Alternating aliphatic polyketones, a new class of engineering thermoplastics made from alk-1-enes and CO, have attracted great interest in polymer science in recent years.[1] The monomers are readily available in high purity and at a relatively low cost, and the polyketones have interesting and unique properties, and may replace conventional engineering thermoplastics in several areas of application (*e.g.* polyketone derived from ethylene and CO).[2]

Another important aspect of polyketones is the presence of carbonyl groups in the polymer backbone that makes them suitable for functional group modifications,[3] and hence polyketones which possess other functional groups in the side chains can serve as excellent starting materials or pre-polymers for other classes of valuable polymers. One of the major goals in this area is the synthesis of highly functionalized polyketones from functionalized alkenes and CO. There are very few examples of the copolymerization of functionalized alkenes with CO.[4–9]

A number of cationic palladium(II) complexes with weakly or non-coordinating counteranions, and phosphine or nitrogen ligands, have been used for the copolymerization of olefins with CO. In the case of higher α-olefins, using a chiral bidentate ligand can afford optically active copolymers with nearly complete head-to-tail regioselectivity and isotacticity, higher molecular weights and higher polymer yields compared to other achiral bidentate ligands.[5,7–9]

The epoxide group is one of the most versatile and important functional groups in organic synthesis. We now wish to report the synthesis of alternating highly functionalized polyketones, which possess epoxide groups in the side chains, *via* cationic palladium(II) catalyzed copolymerization of vinyl epoxides with CO. Given the facility with which epoxides undergo palladium catalyzed rearrangment[10] and other reactions of epoxides, the selectivity for the olefinic unit in the reactions described herein, is indeed impressive.

We first examined the copolymerization of 1,2-epoxyhex-5-ene with CO as a model reaction using, as catalyst, various kinds of cationic palladium(II) complexes with bidentate or monodentate chiral and achiral phosphine ligands [reaction (1)].



(1)

† Electronic supplementary information (ESI) available: general procedure for the copolymerization of vinyl epoxides with CO and spectral data of copolymers. See http://www.rsc.org/suppdata/cc/b0/b006641i/

Among the reported catalyst systems, only $[Pd(L)(MeCN)_2](BF_4)_2$ (L = (*R*,*R*)-Me-DUPHOS, Me-DUPHOS = 1,2-bis(2,5-dimethylphospholano)benzene) previously used for the copolymerization of functionalized (–CO_2H or −OH) alkenes with CO by Sen and co-workers,[5] gave traces of co-oligomer when 1,2-epoxyhex-5-ene was reacted with CO (1000 psi) at 40 °C, in nitromethane and $CHCl_3$ (run 1, Table 1). Quinones are known to promote the copolymerization,[11] so we examined the effect of quinones as a promoter. 1,4-Naphthoquinone gave better results than other quinones such as 1,4-benzoquinone or 2-*tert*-butyl-1,4-benzoquinone. Repetition of the same reaction in the presence of a catalytic amount (3.1 mol%) of 1,4-naphthoquinone afforded the corresponding copolymer (**1**) in moderate molecular weight but in only 10% yield (run 2, Table 1). We then searched for another promoter or coinitiator which could enable this copolymerization to occur without effecting the epoxide group. It was found that a catalytic amount of HCO_2H can significantly improve the yield of the epoxypolyketone. When the copolymerization was performed in the presence of a catalytic amount of 1,4-naphthoquinone and HCO_2H as promoters, as well as the palladium complex, up to 63% yield of copolymer **1** was obtained in moderate molecular weight (run 4, Table 1). Even HCO_2H alone can be used as a promoter with copolymer **1** formed in 26% yield but the molecular weight was lower than using only 1,4-naphthoquinone (compare runs 2 and 7, Table 1). The exact role of HCO_2H is not clear but it can possibly generate palladium hydride, which is known as an active catalyst [reaction (2)].[1c,12] The effect of monomer concentration

$$(\text{Me-DUPHOS})(\text{MeCN})_2\text{Pd}^{2+} + \text{HCO}_2\text{H} \xrightarrow[-\text{MeCN}]{} (\text{Me-DUPHOS})(\text{MeCN})\text{Pd}^{+}\text{H} + \text{CO}_2 + \text{H}^{+} \quad (2)$$

Table 2 The copolymerization of vinyl epoxides with CO[a]

Run	Epoxide	Time/h	Result	
			Copolymer, yield (%)	M_w (M_w/M_n)[b]
1		40	**3**, 58	30 500 (1.97)
2		40	**4**, 52	33 600 (1.41)
3		18	**5**, 41	28 500 (3.40)
4		48	**6**, 77	3 350 (1.28)
5		24	—	—

[a] Reaction conditions were the same as for run 4 in Table 1. [b] Molecular weights were measured by GPC relative to polystyrene standards.

was not critical but higher concentrations afforded higher molecular weights for the epoxypolyketones (run 4–6, Table 1). A 1:1 (v/v) mixture of nitromethane and $CHCl_3$ was the best solvent system. Use of only chloroform as the solvent gave trace amounts of copolymer **1** (run 9, Table 1) while use of only nitromethane gave lower yields than the mixed solvent system (run 8, Table 1).

The above results indicate that the optimum conditions for the copolymerization of 1,2-epoxyhex-5-ene with CO are 0.25 mol% of $[Pd(MeCN)_4](BF_4)_2$, 0.25 mol% of (*R*,*R*)-Me-DUPHOS, 3.1 mol% of 1,4-naphthoquinone and 7.5 mol% of HCO_2H in nitromethane and solvent at 40 °C under 1000 psi of CO (run 4, Table 1).

Under the optimum reaction conditions, principally the poly(1,4-ketone) structure (**1**) of the corresponding copolymer was obtained and soluble in organic solvents like CH_2Cl_2, THF or DMSO. However if the copolymerization was performed for an extended reaction time (more than 24 h) or isolated as a pure solid, the structure of the copolymer was that of a poly(spiroketal-1,4-ketone) which is insoluble in common organic solvents and even in fluorinated alcohols. The solid state ^{13}C NMR spectrum of the poly(spiroketal-1,4-ketone) indicated a 1:1 ratio of the poly(1,4-ketone) and poly(spiroketal), with resonances of 1,4-keto groups and spiroketal groups appearing at 211.5 and 110.5 ppm respectively. The values of 1,4-keto and spiroketal groups of other polyketones (higher α-olefins or other functionalized alkenes and CO) occur at 211–214 and 112–114 ppm respectively.[5,8] The structure of the copolymer **1** (*i.e*. poly(1,4-ketone)) was determined by ^{13}C NMR and IR, and was supported by elemental analysis.† The IR spectrum displays a carbonyl stretching band at 1706 cm^{-1}, and the epoxy group bands appeared at 1260, 914 and 835 cm^{-1}. The ^{13}C NMR spectrum (DMSO-d_6) showed a resonance at 211.8 ppm due to the carbonyl group, and resonances at 44.5 and 43.5 ppm which are due to the CH_2CH units in the polymer backbone. Resonances at 51.5 and 46.5 ppm are due to the epoxide carbons in the side chains and the $(CH_2)_2$ units in the side chains appeared at 29.4 and 27.3 ppm. The chemical shift values for the carbonyl and main chain carbons of the ^{13}C NMR spectrum, and the simplicity of the spectrum, support the copolymerization as a highly regio (head-to-tail) and diastereoselective (isotactic) process.[5,7,8]

Several other vinyl epoxides were copolymerized with CO under the optimum reaction conditions found for the copolymerization of CO and 1,2-epoxyhex-5-ene (run 4, Table 1), and the results are summarized in Table 2.†

In the case of 1,2-epoxyoct-7-ene, where the epoxy group is far from the olefinic unit compared with 1,2-epoxyhex-5-ene, the copolymerization was slower but the molecular weight of the copolymer **3** was higher than that of **1** (run 1, Table 2). 1,2-Epoxydec-9-ene gave similar results to that of 1,2-epoxyoct-7-ene, affording **4** but with narrower polydispersity when compared with 1,2-epoxyhex-5-ene and 1,2-epoxyoct-7-ene (compare run 6, Table 1, run 1 and 2, Table 2). The copolymerization of 4-vinyl-1,2-epoxycyclohexane (*cis* and *trans* mixture) with CO afforded the corresponding copolymer **5** in reasonable yield and molecular weight, but with broad polydispersity (M_w/M_n = 3.40, run 3, Table 2). Allyl glycidyl ether, which has not been successfully copolymerized with CO in the past,[4] can also undergo smooth copolymerization under the reaction conditions described above, affording the copolymer **6** in 77% yield. Interestingly, the molecular weight was very low (M_w = 3350, run 4, Table 2) compared to vinyl epoxides not having an ether group. The copolymer **6** was slightly soluble in DMSO, and the molar optical rotation was + 3.4° (*c* = 6.1 mg ml^{-1}, DMSO). Finally in the case of conjugated diene monoxide, 1,2-epoxybut-3-ene, the copolymerization with CO did not proceed under the usual conditions, and the starting epoxide was recovered unchanged (run 5, Table 2).

In conclusion, the copolymerization of vinyl epoxides and CO proceeds in good yields and moderate molecular weights, in the presence of $[Pd((R,R)\text{-Me-DUPHOS})(MeCN)_2](BF_4)_2$ as the catalyst, with HCO_2H and 1,4-naphthoquinone as promoters. Complete chemoselectivity was observed, even in the presence of a reactive epoxide group. These polyketones, with epoxides in the pendant chain, will be of considerable value as precursors to novel polymeric materials by ring opening reactions of the epoxide groups.

We are grateful to Dow Chemical Co. for support of this research. We are indebted to Drs Marv Dettloff and Jerry White of Dow Chemicals for their excellent suggestions regarding this project.

Reduction of aldehydes using trialkylboranes in ionic liquids

George W. Kabalka* and Rama R. Malladi

Departments of Chemistry and Radiology, The University of Tennessee, Knoxville, TN 37996-1600 USA. E-mail: kabalka@utk.edu

Received (in Corvallis OR, USA) 1st September 2000, Accepted 25th September 2000
First published as an Advance Article on the web 31st October 2000

Non-aqueous ionic liquids, molten salts, have been found to enhance organoboron mediated reductions of aldehydes.

In recent years, chemists have developed new synthetic methodologies which are environmentally benign.[1] For example, ionic liquids have been found to be useful in many environmentally sensitive industrial applications.[2] More recently, ionic liquids have attracted interest as reaction media in organic and organometallic synthetic manipulations such as hydrogenation,[3] allylation,[4] Heck-vinylation,[5] epoxidation,[6] Diels–Alder reactions,[7] and Suzuki cross-coupling reactions.[8] These solvents possess a number of interesting properties, which include a lack of vapor pressure, ease of reuse, absence of flammability and a tolerance for large temperature variations.

The reduction of aldehydes by organoborane reagents is an important organic transformation. Generally, boron hydrides are utilized as reducing agents due to their facile reactivity.[9] Trialkylboranes, most notably the pinanyl derivatives, have also been found to be especially useful reducing reagents.[10,11] However, reductions involving simple trialkylboranes generally require reaction temperatures in excess of approximately 150 °C.[12] We have discovered that ionic liquids, such as 1-butyl-3-methylimidazolium tetrafluoroborate ([Bmim][BF_4]),[13] 1-ethyl-3-methylimidazolium tetrafluoroborate ([Emim][BF_4]), and 1-ethyl-3-methylimidazolium hexafluorophosphate ([Emim][PF_6]) enhance the rate of trialkylborane reductions. For example, tributylborane reduces benzaldehyde at rt in [Emim][PF_6] although the reaction can be carried out more rapidly at 100 °C (Table 1).

Both aromatic and aliphatic aldehydes are reduced by tributylborane in ionic liquids (Table 2). The presence of a *para*-substituted electron-donating group appears to hinder the reaction. Only one alkyl group is utilized, and thus an equimolar ratio of aldehyde and tributylborane is required. Presumably this is a consequence of the weaker Lewis acidity of the dialkylborinic ester generated after the first reduction, reaction 1.

(1)

The fact that the organic products are readily removed from the ionic liquids *via* extraction is especially appealing. We routinely recycled the ionic solvents and found no decrease in reduction yields.

The reduction of benzaldehyde is representative: benzaldehyde (106 mg, 1.00 mmol) and [Emim][PF_6] (250 mg) were placed in a 10 mL round-bottomed flask. Tributylborane (182 mg, 1.00 mmol) was added and the mixture stirred at rt for 48 h. The product was extracted into ether (2 × 5 mL) the extracts were combined and dried over anhydrous $MgSO_4$. The solvent was removed under reduced pressure and then purified by silica gel chromatography to yield 102 mg (94%) of benzyl alcohol.[14]

Table 1 Reduction of benzaldehyde with tributylborane in different ionic liquids

Ionic liquid	Time/h	Yield (%)[c]
[Bmim BF_4]	16[a]	93
[Emim BF_4]	16[a]	90
[Emim PF_6]	16[a]	96
[Emim PF_6]	48[b]	94

[a] Reactions were carried out at 100 °C. [b] Reaction was carried out at rt. [c] Isolated yield.

Table 2 Reduction of aldehydes with tributylborane in [Emim][PF_6]

Aldehydes	Time/h	Yield (%)[c]
C_6H_5CHO	16[a]	100
p-BrC_6H_4CHO	16[a]	100
m-BrC_6H_4CHO	16[a]	100
o-FC_6H_4CHO	16[a]	100
p-FC_6H_4CHO	16[a]	100
p-CH_3OC_4CHO	24[a]	40
o-$CH_3C_6H_4CHO$	16[a]	98
p-$CH_3C_6H_4CHO$	16[a]	96
$C_{10}H_{20}O$	48[b]	100
$C_{10}H_{20}O$	24[a]	100
$(CH_3)_3CCHO$	48[b]	100

[a] Reactions were carried out at 100 °C. [b] Reactions were carried out at rt. [c] NMR yield.

Ionic liquids are excellent solvents in which to carry out reductions using trialkylboranes. The reaction proceeds readily with aromatic and aliphatic aldehydes. Separation of the products from the ionic liquid is straightforward as is recycling of the solvent.

We wish to thank the U.S. Department of Energy and the Robert H. Cole Foundation for support of this research.

A possible antimalarial action mode of qinghaosu (artemisinin) series compounds. Alkylation of reduced glutathione by *C*-centered primary radicals produced from antimalarial compound qinghaosu and 12-(2,4-dimethoxyphenyl)-12-deoxoqinghaosu

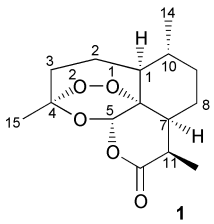
Dong-Ye Wang and Yu-Lin Wu

State Key Laboratory of Bio-organic & Natural Products Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Fenglin Road, Shanghai 200032, China. E-mail: ylwu@pub.sioc.ac.cn

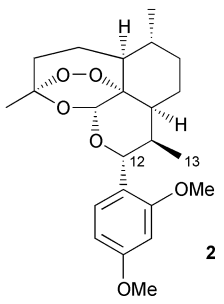
Received (in Cambridge, UK) 23rd August 2000, Accepted 3rd October 2000
First published as an Advance Article on the web 31st October 2000

Antimalarial compound qinghaosu (1) and its phenyl derivative 2 were reacted with reduced glutathione (GSH) and Fe(II/III) to give, besides other known degradation products, an interesting adduct from a primary *C*-centered free radical and GSH. Because GSH plays a very important role in the cell cycle, this finding may eventually lead to a new understanding of its mode of action.

Qinghaosu (artemisinin, **1**) originally isolated from a traditional Chinese herb,[1] and its derivatives are the most promising antimalarial medicines. Their unique 1,2,4-trioxane peroxy



1



2

structure has been proved to be essential for antimalarial activity[2] and is entirely different from that of previous generations of antimalarial drugs such as quinine and chloroquine. Cell-biological studies showed that qinghaosu's toxicity appeared to be the consequence of the membrane damage that might result from protein alkylation.[3] On the other hand, alkylation of a simplified heme *in vitro* has also been reported,[4] but this does not provide a full description of the antimalarial mechanism of qinghaosu and its derivatives. We have reported the reaction mechanism of the Fe(II)-induced cleavage of the peroxide bond in qinghaosu and its derivatives and certified the presence of *C*-centered radicals derived from this cleavage and the following radical rearrangement.[5,6] At the same time the DNA damage associated with this process has also been observed in our laboratory.[5] A parallel correlation[7] between the chemical reactivity of Fe(II)-induced cleavage of the peroxide in qinghaosu's derivatives and their antimalarial activity *in vivo* and also the intermolecular interaction[8]—abstraction of a hydrogen atom from cysteine and attachment to the cysteine sulfur atom—of the primary *C*-centered radicals involved in the degradation of qinghaosu have been found in our previous work. Continuing these explorations we have synthesized a pair of C-11 epimers of 12-(2,4-dimethoxyphenyl)-12-deoxoqinghaosu (**2**) and found once again the parallel relationship of reactivity of their Fe(II)-induced cleavage and antimalarial activity. In the presence of cysteine and catalytical ferrous or ferric ion a stable product from cysteine and the primary free radical from phenyl qinghaosu **2** could be isolated and identified. These experimental results[9] provided further evidence for the participation of a primary carbon centered free radical in the antimalarial action of qinghaosu compounds.

With the adduct of cysteine and the primary free radical derived from qinghaosu and its derivatives in hand, it would be interesting to observe if an adduct could form from glutathione and this free radical. Malaria parasite infected red cells have a high concentration of the reduced glutathione (GSH, the main reducing agent in physiological systems).[10] It was also reported that an excess GSH in the parasite may be responsible for protecting the parasite from the toxicity of heme.[11] In general, GSH takes part in many biological functions, including the detoxification of cytosolic hydrogen peroxide and organic peroxides and then protects cells from oxidative stress. Therefore, depletion of GSH or inhibiting glutathione reductase in tumor or parasite cell will induce oxidative stress and then kill these cells,[12] which may explain the mechanism of some antitumor or antiparasite agents. In addition, an alternative promising approach to finding new antitumor or antiparasite agents is provided.

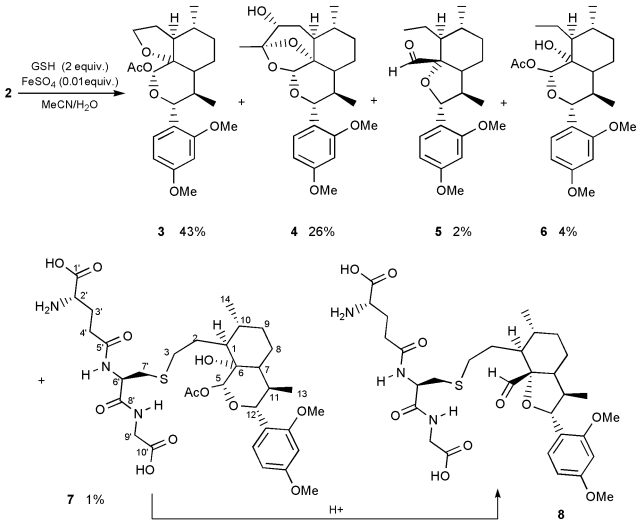
Here we report that the *C*-centered radicals of compound **2** and qinghaosu (**1**) can abstract a hydrogen atom from GSH, and, the novel adducts between **2**, **1** and GSH are characterized.

The 12-(2,4-dimethoxyphenyl)-12-deoxoqinghaosu (**2**) prepared from dihydroqinghaosu is a UV detectable, stable, lipophilic and hence easily handled qinghaosu derivative. It is also a more active antimalarial agent than qinghaosu and artermether. Therefore compound **2** was firstly used as the substrate to react with GSH in the presence of catalytic amounts of ferrous sulfate. Thus, a mixture of GSH, AcONa, a catalytic amount of $FeSO_4 \cdot 7H_2O$ and 0.5 equivalents of compound **2** in aq. MeCN was stirred at rt for 3 days. From the organic extract, starting material **2** (20%) and known compounds[9] **3**, **4**, **5**, and **6** (43%, 26%, 2%, and 4%, respectively) were obtained. On the other hand adduct **7**[13] (1%) was isolated from the aqueous layer by column chromatography (RP-C-18) (Scheme 1).

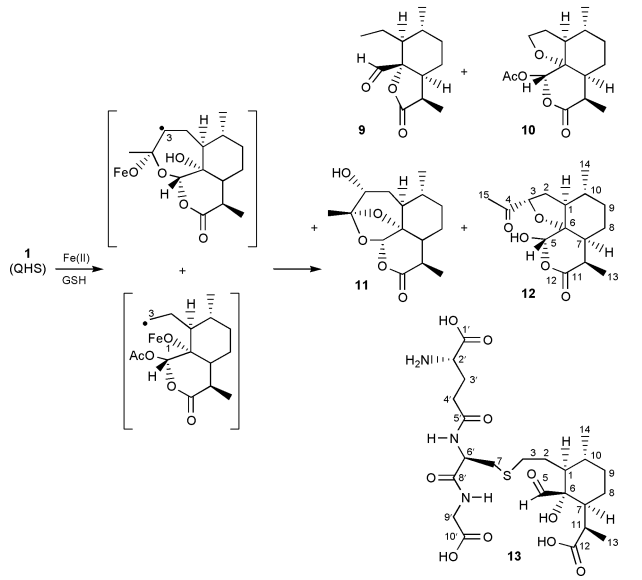
It is reasonable to propose that adduct **7** is formed by coupling the primary *C*-centered free radical and GSH. Adduct **7** gives a typical ESI mass spectrum peak at $m/z = 735$ ($M + Na - 1$) and all the corresponding proton resonances in the NMR spectra. Adduct **7** tends to rearrange to give compound **8** in acidic medium, partial rearrangement could be observed even in deuteriated water in the NMR tube.

The successful isolation of adduct **7** encouraged us to explore the reaction of GSH with qinghaosu–Fe(II/III) and search for the products from both the organic and water phases. The reaction of qinghaosu (**1**) with 2 equivalents of GHS and 0.04 equivalent Fe(II) was performed at 37 °C under argon. After 12 hours all qinghaosu was consumed to yield known compounds **9**[8] (5%), **10**[6] (41%), **11**[6] (26.4%), and **12** (1%, a C-3 epimer of known compound), all collected from the organic phase, and **13**[14] (4%) collected from the aqueous phase of the reaction mixture after work-up (Scheme 2). The reaction also proceeds wider acid conditions in the range pH 1–7, giving slight variations in the yields of **9** and **13**.

The most interesting adduct **13** is a highly polar, water soluble compound, which was recovered from the reaction



Scheme 1



Scheme 2

mixture by chromatography on reverse phase silica gel (RP-C18, H_2O). On thin-layer chromatography (TLC, with 3 : 1 : 1 n-BuOH–AcOH–H_2O) **13** could be visualized by 0.5% ninhydrin in EtOH as a pink spot. The mass spectrum (ESI) exhibited typical peaks at *m/z* 548 $(M + H)^+$, 570 $(M + Na)^+$, and 586 $(M + K)^+$. Its high resolution mass spectrum (SI) exhibited the peaks at *m/z* 570.2090 $(M + Na)^+$, and 592.1916 $(M - H + 2Na)^+$. NMR analyses were performed in D_2O, including ^1H and ^{13}C NMR, DEPT, DQ-COSY, NOESY, HMQC (^1J) and long-range (^3J) proton-carbon correlation (HMBC). Compound **13** showed several cross-peaks (H-7′/H-3, H-6′/H-3) in NOESY and (H-7′/C-3, H-3/C-7′) in HMBC spectrum. The data undoubtedly showed that a σ-bond was present between the sulfur of the glutathione residue and C-3 in the qinghaosu part. Compound **13** was therefore the result of an adduct between primary carbon-radical derived from qinghaosu and GS$^{\cdot}$.

In conclusion, qinghaosu (**1**) and its phenyl derivative **2** could be degraded in the presence of reduced glutathione (GSH) and a catalytical amount of Fe(II/III). Besides known products previously isolated from the reaction of qinghaosu and its derivative with ferrous ion, an interesting adduct from the primary *C*-centered free radical derived from qinghaosu and *S*-centered free radical from GSH was isolated and structurally elucidated by NMR and other spectroscopy. In *Plasmodium* parasite the GSH concentration is maintained by means of the glutathione reductase catalyzed reduction of glutathione disulfide (GSSG) at the expense of NADPH. GSH plays an important role in protecting the parasite from oxidative stress. The formation of a GSH–qinghaosu adduct reduces the amount of GSH and the adduct itself might also cause inhibition of the glutathione reductase in the parasite. Therefore the present finding may lead to a new understanding of the mode of action of these antimalarial drugs.

First published as an Advance Article on the web 31st October 2000

The ionic salt [bmim][BF_4] is an attractive solvent for Wittig reactions, allowing both easier separation of alkenes from Ph_3PO together with efficient reuse of the solvent.

Ionic liquids are a new class of solvents which have attracted growing interest over the past few years due to their unique physical and chemical properties.[1] They usually consist of poorly coordinating ion pairs, and a classical example is the readily accessible 1-butyl-3-methylimidazolium tetrafluoroborate [bmim][BF_4], which is a colourless mobile but non-volatile liquid with no smell (Fig. 1).[2] Since such solvents easily dissolve metal salts and transition metal catalysts interesting developments have recently appeared in synthesis using organometallic reagents.[3] Some applications of these solvents in organic chemistry have also been reported, for instance in alkylations,[4] benzoin condensation,[5] and Diels–Alder[6] and Friedel–Crafts[7] type reactions. Furthermore, their possible use for selective extraction of organic compounds has been noted recently.[8]

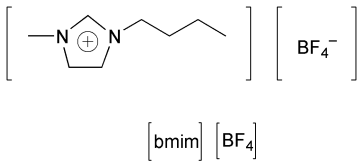

Fig. 1

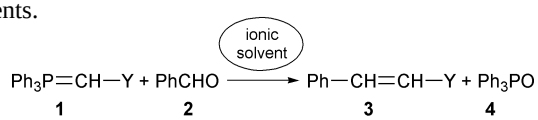
The Wittig reaction is amongst the most popular methods for C=C bond formation, giving in most cases good to excellent stereocontrol.[9] The separation of the alkene from the by-product (Ph_3PO) is a classical problem: it is usually done by crystallisation and/or chromatography. In this communication we demonstrate the usefulness of the ionic solvent [bmim] [BF_4] as a medium to perform Wittig reactions using stabilized ylides allowing both easier separation of alkenes from Ph_3PO and also the recycling of the solvent. Phosphorane **1a** and benzaldehyde were selected as first models (Scheme 1) to develop this method and study the selectivity in the extraction by appropriate solvents.



a: Y = COMe; **b**: Y = CO_2Me; **c**: Y = CN

Scheme 1

The reaction was complete in 2.5 h at 60 °C and the results obtained with different solvents are reported in Table 1.†

Table 1 Recovery of **3a** in three different combinations of solvents

	Exp. 1		Exp. 2		Exp. 3	
	Ether[a]	Tol[b]	tBuOME[a]	Tol[b]	Hexane[a]	Tol[b]
3a yield (%)	79	—	87	—	49	41
Ph_3PO yield (%)	21	72	11	78	1	54

[a] First solvent of extraction. [b] Second solvent of extraction.

Extraction of the reaction mixture with Et_2O gave **3a**‡ (79% isolated yield after filtration on a short SiO_2 pad) and Ph_3PO (21%). Further extraction with toluene removed almost completely the residual Ph_3PO and phosphorane.

Careful ^1H and ^{13}C NMR analysis of the ionic solvent after these successive extractions gave no evidence for residual PhCHO and **3a** (less than 2% for both compounds). Only residual **1a** and a small amount ($\approx$5%) of Ph_3PO could be detected. Slightly better results were obtained with tBuOMe as the first solvent (87% of **3a** with only 11% of Ph_3PO). Extraction with hexane was not convenient, even though very little Ph_3PO was obtained in that case.

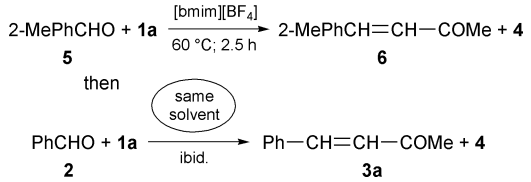
One of the advantages of ionic solvents is ease of recycling. As indicated in Table 2, such is indeed the case for this Wittig reaction since excellent yields of **3a** were obtained, even after 6 consecutive runs.

Table 2 Reuse of [bmim]BF_4] in the reaction of **1a** + **2**

Run	1	2	3	4	5	6
3a Yield (%)[a]	82	83	86	82	90	91
3a Yield (%)[b]	86	88	93	92	88	92

[a] Extraction with Et_2O. [b] Extraction with tBuOMe.

A more difficult challenge was to reuse the solvent, *but for two different Wittig reactions*. This was established in the following way (Scheme 2): the reaction of **1a** with *o*-tolualdehyde gave **6** in excellent yield (95%). Then, the *same* ionic solvent was used for the reaction of **1a** with benzaldehyde: careful ^1H and ^{13}C NMR analysis of the product isolated in the latter reaction indicated that **3a** was obtained, with no trace ($\leqslant$2%) of **6**.



Scheme 2

Other stabilized ylides can also be used the obtain alkenes **3** in good yields (Table 3).

Finally, this method could also be extended to other aldehydes (Table 4). Various aromatic and aliphatic aldehydes,

Table 3 Reaction of phosphorus ylides **1** with **2** in [bmim][BF_4]

Y	**3** Yield (%)	*E*/*Z*[a]

RCHO + **1a**		RCH=CHCOMe + Ph_3PO	
R	Time/h	Yield olefin (%)	*E*/*Z*[a]
4-Cl-Ph-	2.5	86	97/3
4-NO_2-Ph	2.5	44[b]	98/2
4-MeO-Ph-	72	82	96/4
2-Me-Ph-	4	95	96/4
Cyclohexyl-	4	80	85/15
C_5H_{11}	12	82	98/2
i-Butyl-	4	84	98/2
(*E*) Ph-CH=CH-	12	86	90/10
(*E*) Me-CH=CH-	12	88	95/5

[a] Established using ^{1}H NMR. [b] Low solubility of this olefin in either.

as well as enals react with **1a** to give corresponding alkenes in good yield and selectivity. In the case of the *para*-nitro derivative however athough the Wittig reaction was complete, the corresponding alkene was isolated in lower yield due to the low solubility of the product in ether. For these stabilized ylides, the *E*-stereoselectivity in the ionic solvent appears at least equivalent, if not better, than the reactions performed in the usual organic solvents.[9] The only exception was **1c** which is a little less selective (see Table 3).

In conclusion, Wittig reactions of stabilized ylides with aldehydes are easily performed in the ionic solvent [bmim][BF_4]. This method offers attractive possibilities for selective extraction of alkenes and Ph_3PO. Furthermore it is possible to efficiently reuse the ionic solvent.

Notes and references

† Representative procedure, preparation of **3a**: a solution of benzaldehyde **2** (0.2 mL, 2 mmol) and phosphorane **1a** (0.689 g, 2.16 mmol) in the [bmim][BF_4] salt (2 mL) was heated at 60 °C, under magnetic stirring, for 2.5 h. The reaction mixture was extracted first with tBuOMe (3 × 3mL) and then with toluene (3 × 3 mL). The extracts were evaporated *in vacuo*. Filtration of the tBuOMe extract on a short SiO_2 pad gave **3a** (0.254 g, 87% yield) and then Ph_3PO (0.061 g, 11% yield). Similarly, the toluene extract yielded Ph_3PO (0.434 g, 78% yield).

‡ All isolated compounds gave spectra (^{1}H and ^{13}C NMR) consistent with indicated structures and in agreement with literature data. For the alkenes, isolated yields refer to the (*E* + *Z*) mixtures.

First published as an Advance Article on the web 31st October 2000

A hydroxybenzaldehyde derivative which has isobutenyl linkage reacts with a variety of diamines to efficiently result in a 2:2 macrocyclic compound.

Macrocyclic compounds are extensively studied from the viewpoints of molecular recognition, artificial catalyst, supramolecular structures, and so on.[1] In general, their preparation is not very efficient because competitive reactions may occur, resulting in several kinds of oligomeric compounds. In order to selectively obtain a desired macrocycle, researchers have developed several techniques such as template-assisted or preorganization-assisted syntheses combined with the high dilution method. Since the high dilution method is effective only when an individual reaction is fast enough, each reactant needs to have high activity, which must be maintained during a long period of dropwise addition in a carefully assembled apparatus. In spite of such efforts, the yield usually reaches only 30–60% at most.[2] Even if intramolecular hydrogen bonding works well for the preorganization,[3] stepwise syntheses are necessary to achieve a sufficient yield.

In contrast to kinetic control by, for example, the high dilution method, the concept of self-organization or self-assembly could be useful as another way for an efficient preparation of macrocycles if a desired compound is thermodynamically favoured. In this communication, we report on a hydroxybenzaldehyde derivative that reacts with a variety of diamines to give a 2:2 macrocyclic compound in a good yield under relatively mild and simple conditions. Herein we discuss the role of intramolecular hydrogen bonding that controls the direction of functional groups during the cyclisation step.

A procedure to prepare **1** and **2** is shown in Scheme 1. The second step is a tandem Claisen rearrangement,[4] in which an isobutenyl aryl ether is transformed into the corresponding bisphenol compound. By heating **1** at 220 °C for 10 h under reduced pressure, **2** was obtained in 79% isolated yield. Compounds **1** and **2** were recrystallized from ethyl acetate and MeOH, respectively.‡

Fig. 1(a) and (b) show the X-ray crystal structures of **1** and **2**, respectively,§ which provide information about hydrogen bonding in each compound. In **1**, the aldehyde hydrogen is positioned towards the phenolic ether oxygen, indicating a hydrogen bonded pseudo five-membered ring. In **2**, each carbonyl oxygen is positioned towards the neighbouring hydroxy group to form a hydrogen bonded pseudo six-membered ring. These hydrogen bonding structures are reflected in the ^{1}H NMR spectra: the signal of the aldehyde proton of **1** appears at 10.49 ppm, whereas that of **2** appears at 9.88 ppm. The downfield shift of 0.61 ppm in **1** was caused by the hydrogen bond between ether oxygen and aldehyde hydrogen atoms. For **2**, the relatively lowfield signal of phenolic OH proton (11.27 ppm) implies the hydrogen bonding between the hydroxy group and carbonyl oxygen.

THF solutions of **2** (0.1 M) and *p*-phenylenediamine (0.1 M) were mixed and stirred over 30 h at rt. Then, MeOH was slowly

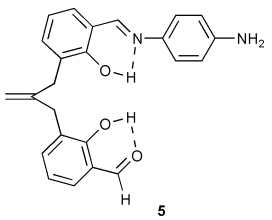
Table 1 The yields (%) of tetraimine (**3a**–**f**) and tetramine (**4a**–**f**) from a variety of diamines (**a**–**f**)

	3a–**f**[a]	**4a**–**f**[b]
a *p*-phenylenediamine	76–89	47–69
b *m*-phenylenediamine	58–64	61–81
c *o*-phenylenediamine	90–97	53–59
d *trans*-1,4-cyclohexanediamine	57–79	87
e naphthalene-1,5-diamine	80–90	70–79
f *p*-xylylenediamine	33	75

[a] Yields of crude solid. [b] Yields of **4a**–**f** from **3a**–**f**.

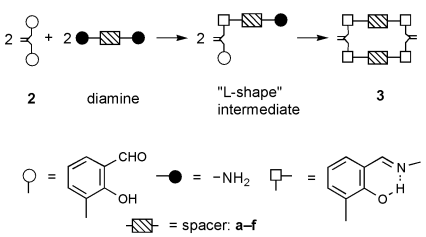
added to the solution until a yellowish orange solid precipitated (crude yield >80 %). FAB MS and ^{1}H NMR measurements revealed that the solid was 2:2 adduct **3a**, and that the amount of higher oligomeric compounds was too small to accurately determine their structures and yields. Since it was difficult to purify **3a** by recrystallisation or column chromatography due to its low solubility, it was used for the next step after washing with $CHCl_3$. To a THF–MeOH suspension (v/v = 7/3) of **3a** (0.736 g/50 ml), four equiv. of sodium borohydride were added at rt, resulting in cyclic polyamine **4a** as a colorless solid (69 %).‡ Similarly, by using *o*-phenylenediamine, *m*-phenylenediamine, *trans*-1,4-cyclohexanediamine, naphthalene-1,5-diamine, and *p*-xylylenediamine instead of *p*-phenylenediamine, **4b**–**f** were prepared respectively (Scheme 1).‡ In the case of naphthalene-1,5-diamine, DMF was used as solvent in the cyclisation step. In some cases, a catalytic amount of hydrochloric acid was used for the Schiff base formation. The yields are summarized in Table 1.

It is noteworthy that the reaction selectively affords the 2:2 compounds in a relatively concentrated solution. For *p*-phenylenediamine, it is confirmed that a major product in an early stage of this reaction is the linear imine **5** (see Fig. 2) resulting from 1:1 condensation of **2** and the diamine, suggesting that the reaction proceeds as illustrated in Scheme 2. This scheme can be applied to the cases of the other diamines. For aromatic amines (X = **a**, **b**, **c**, and **e**), the Schiff base formation is slow enough so that the reaction can proceed stepwise, resulting in high yields of the 2:2 macrocycles. Similarly, *trans*-1,4-cyclohexanediamine (X = **d**), which has aliphatic amine groups, afforded the 2:2 compound in a good yield. On the other hand, the yield for *p*-xylylenediamine (X = **f**), which also has aliphatic amine groups, was relatively low.



5

Fig. 2 Presumptive hydrogen bonding for *p*-phenylenediamine Schiff base of **2**.



Scheme 2

These results imply that the yield is much affected by the flexibility of the amine rather than its reactivity.

In contrast to **2**, attempts to prepare macrocycles from **1** were not successful. Although the products have not been characterised in detail, the reaction might give a mixture of several oligomeric compounds. Although there is a difference in substitution position between **1** and **2**, these results suggest that the hydroxy groups of **2** play an important role in selectively forming the 2:2 macrocycles.

A typical ^{1}H chemical shift of such an hydroxy group for **3a**–**f** was 13–14 ppm, indicating a strong interaction between the hydroxy and imine groups by making a pseudo six-membered ring even in solution. For **5**, the corresponding ^{1}H NMR peak was observed at 13.88 ppm, indicating similar hydrogen bonding. Such a hydrogen bond can fix this molecule into an 'L-shape' (Fig. 2), and thereby prevents it from making an intramolecular Schiff base linkage to give a 1:1 macrocycle. As shown in Scheme 2, if two L-shaped molecules are present in high concentration, the probability of the formation of 2:2 macrocycles will increase. For the Schiff base of **1**, however, one can not expect so strong a hydrogen bond that the conformational freedom of the molecule is reduced. This would be a reason why a selective macrocyclisation of **1** and diamine is not successful.

In summary, a novel bishydroxybenzaldehyde that we synthesized *via* tandem Claisen rearrangement is a useful building block for preparation of a new series of macrocyclic polyamine compounds. These compounds can be regarded as derivatives of salophane,[5] and therefore are expected to act as good metal ligands. Furthermore, taking advantage of hydrogen bonding interactions, these cyclic salophanes might act as molecular hosts, artificial catalysts, and so on. In fact, recently **4a** has been found to react selectively with *p*-quinones to reduce them into hydroquinones. We will describe an electrochemical study on this system elsewhere.[6]

Toward benign syntheses of pyridines involving sequential solvent free aldol and Michael addition reactions

Gareth W. V. Cave and Colin L. Raston*

Centre for Green Chemistry, School of Chemistry, Monash University, Clayton, Melbourne, Victoria, 3800, Australia. E-mail: c.raston@sci.monash.edu.au

Received (in Cambridge, UK) 13th September 2000, Accepted 27th September 2000
First published as an Advance Article on the web 31st October 2000

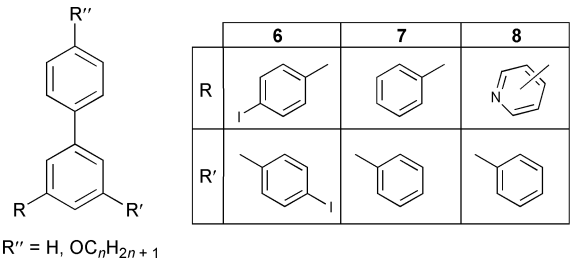
Kröhnke type pyridines are readily accessible *via* a sequential solventless aldol condensation and Michael addition involving solid NaOH, followed by treatment with ammonium acetate in acetic acid, as a one pot reaction, which enables both symmetrical and unsymmetrical 2,6-bisaryl substituted pyridines to be isolated in high yield, typically > 75%.

Kröhnke type pyridines[1] and other substituted pyridines including the related terpyridines[2-4] are prominent building blocks in supramolecular chemistry with their π-stacking ability, and directional H-bonding and coordination. In general, conventional methods used in the synthesis of substituted pyridines use volatile organic solvents and display only moderate to low yields.[2,5,6] In developing a more versatile route to such compounds, where possible adopting the principles of 'Green Chemistry',[7] we have established that using solventless conditions involving sequential aldol and Michael addition reactions results in a dramatic improvement in yield, and indeed allows access to a range of compounds not accessible using conventional methods involving organic solvents. Overall, this versatile new approach can be applied to the synthesis of a range of symmetrical and unsymmetrical terpyridines, and pyridines in general bearing aryl groups in the 2, 4 and 6 positions.

The significance of our findings also relates to reducing the use of organic solvents as potentially toxic and hazardous materials,[7] as well as its simplicity and mild conditions, and inherent lower costs, with more likely industrial applications. Moreover, the findings are further credence to challenge the conventional view of using organic solvents in synthesis even in the absence of reasons to do so.[8] The use of solventless reactions is gaining prominence with recent advances in solventless reactions under mild conditions including the aldol condensation,[8–12] and others recently reviewed by Tanaka and Toda.[8]

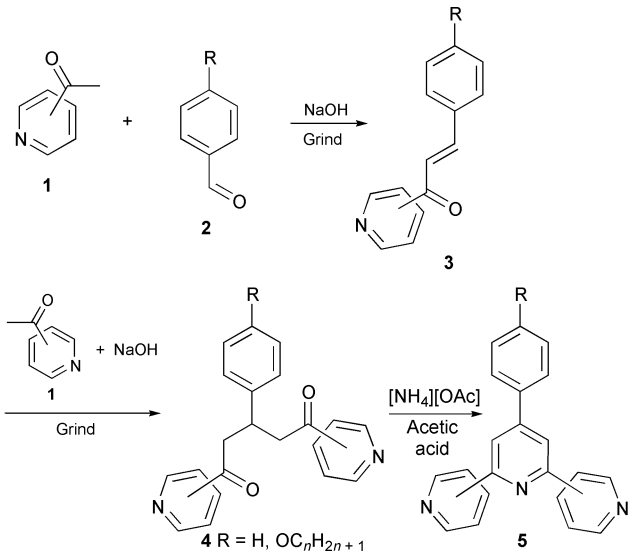
Synthetic details are summarised in Scheme 1.† In a typical experiment, the benzaldehyde **1** and acetylpyridine **2** analogues were mixed together as liquids with a pestle and mortar in the presence of NaOH. Over a period of *ca*. 10 min constant aggregating, the reaction solidified as the aldol condensation product **3**. For the same reaction using two equiv. of the acetylpyridine **2**, the initial product **3** underwent a Michael addition to form the diketone **4**. The addition of a second acetylpyridine **1** to the condensation product **3** provided a direct route to unsymmetrical diketones. The facile formation of **3** and **4** is essentially quantitative and subsequently does not require isolation from the reaction mixture before the tertiary step whereby the diketone **4** was consequently treated with ammonium acetate in acetic acid to generate the terpyridyl product **5** in high yield, > 75%. The structure of the 4,4″ isomer of **5**, R = OC_8H_{17}, *viz*. 4′-(4-octyloxyphenyl)-4,2′:6′,4″-terpyridine, Fig. 1, has been determined from X-ray diffraction data‡ as a representative of compounds prepared thus far using this new synthetic strategy.

The new method herein has also been applied to a number of analogues including the formation of a series of 2,6-bis(4-iodophenyl)-4-phenylpyridines (**6**), 2,4,6-triphenylpyridines (**7**) and bipyridines (**8**).



A synthetic route to a diketone similar (pyridine nitrogens in the 2′ position, R = ^{t}Bu) to the intermediate **4** was reported to yield the Michael addition product, *ca*. 40% yield, by reacting two equiv. of 2-acetylpyridine with the *para*-substituted benzaldehye in the presence of NaOH, in EtOH.[13] All of our corresponding reactions, conducted using the solventless conditions described above, were determined to be essentially quantitative by ^{1}H and ^{13}C NMR techniques. This therefore allows the intermediate **4** to be reacted on to form the product **5** and thus dispense with extensive recrystallisation and/or chromatographic purification steps. It is noteworthy that when these solvent based methods are adopted in an attempt to prepare 4′-(4-alkoxyphenyl)-4,2′:6′,4″-terpyridines, only the cyclohexyl product **9** is isolated from the complex reaction mixture which is devoid of target molecules. Compound **9**, which was characterised using NMR data, R = OC_4H_9, and X-ray diffraction data, R = H, does however incorporate the expected intermediate **4**.[14]

Typically unsymmetrical Kröhnke type pyridines have been synthesised by reacting the aldol product **3** with a *N*-[1-oxo-



Scheme 1

DOI: 10.1039/b007431o

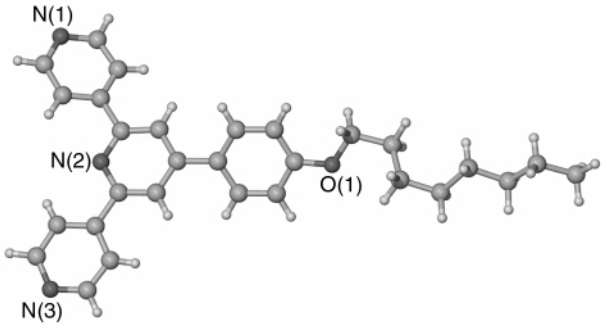


Fig. 1 Molecular structure of 4′-(4-octyloxyphenyl)-4,2′: 6′,4″-terpyridine.

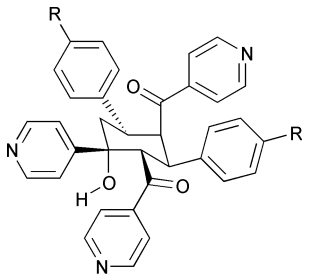

9 R = H, OC_nH_{2n+1}

(2-aryl)ethyl]pyridinium iodide or bromide and ammonium acetate.[2,3] These reactions seldom afford the products in more than a 45% yield, and this coupled with the fact that the pyridinium halide often has to be synthesised can lead to an expensive, time consuming protocol. The versatility of the solventless reactions is demonstrated by the facile inexpensive formation of such unsymmetrical Kröhnke type pyridines as **5** and **8** in high yield.

The above solventless reactions involve the reaction of liquids formed by mixing two organic compounds, at most only one of them being a solid, with the solid intermediate (**3**) reacted with a liquid. At no time was there a reaction of a solid with a solid, athough this is possible given our previous endeavours with solventless aldol condensation involving two organic solids which show that the primary process is the formation of a eutectic mixture with a melting point below rt. This mixture then reacts with the solid NaOH *en route* to the product, rather than two solids reacting through crystal deformation mechanisms.[8,15]

We thank the Australian Research Council for the support of this work, and Michaele Hardie for assistance in the crystallography.

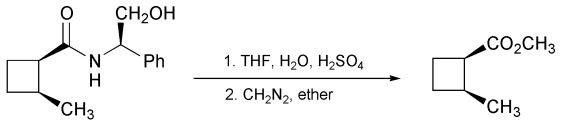
First published as an Advance Article on the web 31st October 2000

An X-ray crystallographic structure determination for the related (*R*)-(−)-2-phenylglycinol derived amide demonstrates that (+)-*cis*-1-methoxycarbonyl-2-methylcyclobutane is the (1*R*,2*S*) isomer.

In the course of work requiring synthetically useful amounts of chiral 2-methylcyclobutanecarboxylic acid derivatives of securely known absolute stereochemistry we prepared a sample of (+)-*cis*-1-methoxycarbonyl-2-methylcyclobutane, 99% ee by GC on an Astec 10-m octakis(2,6-di-*O*-pentyl-3-trifluoroacetyl) γ-cyclodextrin capillary column. The observed rotation of our sample, $[\alpha]_D$ +58 ($CHCl_3$), seemed hardly consistent with a report[1] that the (+)-enantiomer of this ester of better than 97% ee had a rotation of $[\alpha]_D$ +22.4 ($CHCl_3$). An X-ray crystallographic structure determination[2] for the corresponding amide (**2**) derived from (*R*)-(−)-2-phenylglycinol quickly settled the stereochemical point (Scheme 1, Fig. 1).



2 (1*R*,2*S*)-(+)-**1**

Scheme 1

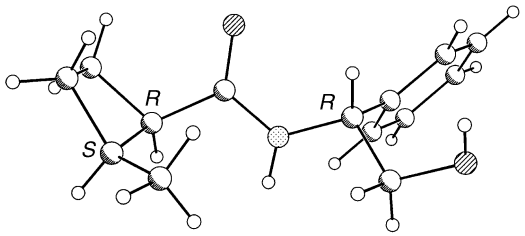


Fig. 1 X-ray crystallographic structure based drawing of *N*-[(*R*)-α-(hydroxymethyl)benzyl]-(1*R*,2*S*)-*cis*-2-methylcyclobutanecarboxamide (**2**).

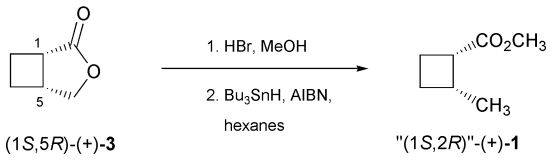
The relative stereochemistry provided by the X-ray structure and the known absolute stereochemistry of the (*R*)-phenylglycinol unit[3] provide unambiguous evidence for a sure assignment of absolute stereochemistry: (+)-*cis*-1-methoxycarbonyl-2-methylcyclobutane, $[\alpha]_D$ +58 ($CHCl_3$), is (1*R*,2*S*)-(+)-**1**.

The earlier assignment of (1*S*,2*R*) absolute stereochemistry for (+)-**1**[1] must be reversed, and some assignments of absolute stereochemistry for related structures need to be reconsidered. The concerns are of more than academic interest, for structural correlations leading to configurational assignments based on links to (1*R*,2*S*)-(+)-**1** extend to numerous natural products as well as patented analogs of leukotriene, oxetanocin A, prostaglandins, and spermine.[4]

The original stereochemical assignment depended on a structural correlation from the bicyclic lactone (1*S*,5*R*)-(+)-**3** to (+)-**1** (Scheme 2). A sample of (+)-**3**, $[\alpha]_D$ +116.7 ($CHCl_3$), was combined with HBr in CH_3OH to give *cis*-1-methoxycarbonyl-2-(bromomethyl)cyclobutane; reduction of the CH_2Br group to CH_3 with Bu_3SnH gave (+)-**1**, $[\alpha]_D$ +22.4 ($CHCl_3$), in 97% yield.[1] Since the stereochemical correlation of Scheme 2 leads



(1*S*,5*R*)-(+)-**3** "(1*S*,2*R*)"-(+)-**1**

Scheme 2 Reported[1] structural correlation.

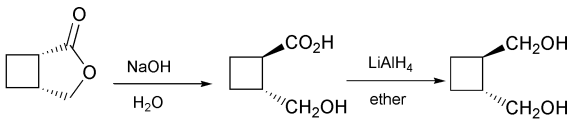
to the wrong assignment of absolute sterechemistry for (+)-**1**, either the stereochemical assignment for (+)-**3** must be reversed, or the synthetic chemistry involved must, somehow, be misformulated.

The reference compound (+)-**3** had been assigned (1*S*,5*R*) stereochemistry based on a correlation with a chiral sample of *trans*-1,2-di(hydroxymethyl)cyclobutane (Scheme 3).[5] Lactone (+)-**3** ($[\alpha]_D$ +118.7 ($CHCl_3$), 100% ee) was hydrolyzed and epimerized to afford a *trans*-2-(hydroxymethyl)cyclobutanecarboxylic acid as a viscous oil, $[\alpha]_D$ −32.4 ($CHCl_3$), in 52% yield.[5] Reduction gave "(1*R*,2*R*)"-(−)-**5**, $[\alpha]_D$ −4.8 (EtOH), in 97% yield. The literature cited for the "(1*R*,2*R*)" *trans*-diol reported $[\alpha]_D$ −4.3 (EtOH),[6] a seemingly fair match. The reference diol (−)-**5** was thought to be essentially 100% ee, based on criteria related to circular polarization of luminescence;[7] it was derived from (−)-*trans*-cyclobutane-1,2-dicarboxylic acid,[7] a compound of securely known (1*R*,2*R*) absolute stereochemistry.[8]

In the published account of the conversion of (−)-*trans*-cyclobutane-1,2-dicarboxylic acid to the "(1*R*,2*R*)" *trans*-diol,[7] no sign of rotation for the diol was cited[9,10] Reduction of (1*S*,2*S*)-(+)-*trans*-cyclobutane-1,2-dicarboxylic acid ($[\alpha]_D$ +156.4 (H_2O)) with $LiAlH_4$ gives (1*S*,2*S*)-(−)-**5**, $[\alpha]_D$ −67.1 (benzene).[11] In an independent study, the (1*R*,2*R*)-(−)-diacid was reduced to (1*R*,2*R*)-(+)-**5**, $[\alpha]_D$ +64 (benzene).[12]

The chemical correlation steps in Scheme 3 apparently involve a great loss of optical purity. For *trans*-diol "(1*R*,2*R*)"-(−)-**5** $[\alpha]_D$ −4.8 (EtOH) was reported,[5] far from the value more recently determined for the (1*S*,2*S*) isomer, $[\alpha]_D$ −67.1 (benzene).[11] The base-catalyzed reaction in Scheme 3, conducted with conc. aq. NaOH in a stainless steel tube at 130 °C over 8 days,[5] may well have involved more than a simple epimerization at C1 adjacent to the carboxylic acid (carboxylate anion) function.[13]

Given the poor preservation of stereochemical integrity and the faulty reference sample employed, the synthetic steps in Scheme 3 cannot provide a sure designation of configuration for lactone (+)-**3**. Nevertheless we believe that lactone (+)-**3** is indeed the (1*S*,5*R*) isomer, even though the original grounds for the assignment now appear to be indecisive, since it has been converted through a rational synthetic sequence to a sample of enantiomerically pure (+)-grandisol.[14]



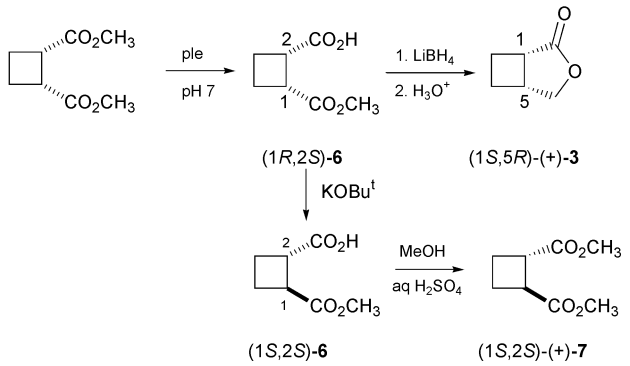
(+)-**3** "(1*R*,2*R*)"-(−)-**4** "(1*R*,2*R*)"-(−)-**5**

Scheme 3 Reported[5] correlation of (+)-**3** with *trans*-diol (−)-**5**.

DOI: 10.1039/b006639g

A related stereochemical puzzle is posed by various reports of pig liver esterase (ple) catalyzed hydrolyses of *cis*-1,2-di(methoxycarbonyl)cyclobutane (Scheme 4): the reported $[\alpha]_D$ values of the ester-acid products are −3.6 ($CHCl_3$),[15] −3.0 ($CHCl_3$),[16] +1.6 ($CHCl_3$),[17] +2.7 (EtOH)[18] and +4.4 (EtOH).[19]

Correlations establishing the absolute stereochemistry of ester-acid **6** are outlined in Scheme 4. A levorotatory sample of **6** ($[\alpha]_D$ −3.0 ($CHCl_3$)) was converted as shown to (+)-**3**, $[\alpha]_D$ +106.7 ($CHCl_3$), estimated to be of 97% ee.[16] Thus the assignment is (1*R*,2*S*)-**6**. A dextrorotatory sample of **6** ($[\alpha]_D$ +4.4 (EtOH)) was correlated with (1*S*,2*S*)-(+)-1,2-di(methoxycarbonyl)cyclobutane,[8] (1*S*,2*S*)-(+)-**7** (86% ee by chiral GC; $[\alpha]_D$ +120 (acetone), +119 ($CHCl_3$)), confirming the assignment (1*R*,2*S*)-**6**.[19]



Scheme 4 Correlations[16,19] of (1*R*,2*S*)-**6** with lactone (+)-**3** and diester (+)-**7**

We believe that all enantioselective ple-catalysed hydrolyses of *cis*-1,2-di(methoxycarbonyl)cyclobutane favor formation of (1*R*,2*S*)-(−)-**6**, and that its specific rotation is small. During hydrolyses and isolation procedures a base-catalysed epimerization might occur to a small extent, converting *cis* product (1*R*,2*S*)-(−)-**6** to *trans* ester-acid (1*S*,2*S*)-(+)-**6** having a much larger specific rotation.[8] A minor amount of (1*S*,2*S*)-(+)-**6** in a product mixture might well escape detection and yet have a major impact on the observed specific rotation.

Accordingly, samples of **6** having $[\alpha]_D$ −3.0 ($CHCl_3$)[16] and $[\alpha]_D$ +4.4 (EtOH)[19] are not enantiomeric:[19] both samples are more likely to be largely (1*R*,2*S*)-(−)-**6**, containing different, small, easily overlooked amounts of (1*S*,2*S*)-(+)-**6**. Similarly, samples of **6** with reported $[\alpha]_D$ values of +1.6 ($CHCl_3$)[17] and −1.8 ($CHCl_3$)[20] are not enantiomeric, and the stereochemical assignment "(1*S*,2*R*)"-(−)-**6** suggested by Lukas[20] must be reversed. The "(1*S*,2*R*)"-(−)-**6** sample was obtained from (1*R*,2*S*)-(+)-1-(methoxycarbonyl)cyclobut-3-ene-2-carboxylic acid[21] through a catalytic hydrogenation and correlated with an enantiomer of **3** that could only be formed from (1*R*,2*S*)-**6**.[20]

The present work establishes that (+)-**1** is the (1*R*,2*S*) isomer. We believe that (+)-**3** is (1*S*,5*R*), and that all ple hydrolyses of *cis*-1,2-di(methoxycarbonyl)cyclobutane give predominantly (1*R*,2*S*)-(−)-**6**, in spite of reports of variable and sometimes positive $[\alpha]_D$ values, for under the reaction conditions small amounts of (1*S*,2*S*)-(+)-**6** may be formed.

13 'Based on the new configurational assignment of (+)-**1**, Professors Jones and Toone speculate that in the vigorous conditions required in their correlation, the C-1 center epimerized to some degree, either during the acid-catalyzed ring opening of cyclobutane lactone (+)-**3**, or from hydrogen atom migration to give a tertiary radical in the subsequent tin hydride mediated reduction step (reactions ii and iii of Scheme 1 of ref. 1), giving compound **1** with an invalid sign of rotation. They also note that the active site model interpretation of the ple-catalyzed hydrolysis of (±)-**1** must be revised, with the cyclobutyl ring occupying the H_L site. They suggest that this interesting, and unexpected, situation is dictated by the fact that the previously anticipated preferred binding of **1** depicted in Fig. 2 of ref. 1 is less favorable than having BOTH the hydrophobic groups binding in hydrophobic sites. This extra benefit is achievable with the cyclobutyl group of the (1*R*,2*S*)-**1** substrate located in the H_L site and the methyl group in the H_S site, which is then in accord with a (1*S*,2*R*) configuration for the recovered ester **1**, as required by the present study. They feel that this preferred binding mode is a special case elicited by the particular substitution pattern of **1**, and do not expect this intriguing facet of ple specificity to apply to substrates with larger hydrophobic group differences.' Received (in Corvallis, OR) 16th August 2000, Accepted 8th September 2000
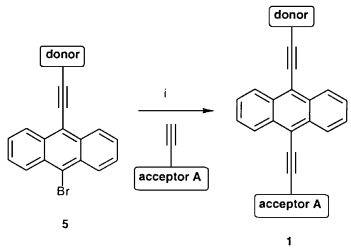
First published as an Advance Article on the web 31st October 2000

The donor–acceptor dye cassettes 1–4 were designed to capture energy at a single wavelength and to convert it to well-resolved, intense fluorescence emissions; in practice, Stokes' shifts of 40–148 nm, quantum yields of 0.12–0.60, and efficient energy transfer was demonstrated.

Many biological experiments involve irradiating sets of different fluorescent labels with a single excitation source.[1,2] To be effective in such multiplexing experiments, dyes must give fluorescence emission peaks that are both well resolved and intense. These requirements place conflicting demands on the labels. Having sets of dyes that emit close to the excitation wavelength causes resolution problems, while including dyes that emit far from the excitation wavelength gives loss of intensity. In response to this problem, radiationless electronic energy transfer has been used to improve resolution and/or intensities in multiplexing.[3] Systems which exploit this characteristic relay energy from a donor-dye (that absorbs at relatively short wavelengths) to an acceptor-dye that fluoresces at longer wavelengths. Experimentally, it is most convenient if the donor and acceptor components of such systems are introduced simultaneously as a single unit, *i.e.* in an "energy transfer cassette". A challenge in this emerging field[3] is to form cassettes that circumvent the limitations of the classical fluorescein–rhodamine systems (*e.g.* resolution, pH dependence, gel mobility shifts). To address this issue, our group is preparing cassettes wherein the donors and acceptors are linked *via* rigid conjugated linkers that allow radiationless electronic energy transfer through bonds (Dexter and superexchange mechanisms) and/or through-space (Förster mechanism).[4] This communication describes synthesis and spectroscopic studies of new cassettes based on the 4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene (BODIPY®) dyes shown below.

To access the cassettes, iodoaryl-substituted BODIPY®s were prepared[5,6] then transformed into the corresponding alkynes by Sonogashira couplings (trimethylsilylethyne, cat. $Pd(PPh_3)_4$, CuI, NEt_3, THF; then removal of the silane, Bu_4NF, THF, −78 °C, 10 min). Invariably, the yields for these two reactions were very high (up to 99%). Sonogashira reactions were also used to assemble the cassettes from the BODIPY® starting materials. Scheme 1 outlines a synthesis of a linear cassette **1**. The branched derivatives **2**–**4** were obtained *via* similar sequences featuring Sonogashira couplings.



Scheme 1 *Reagents and conditions*: i, cat. $Pd(PPh_3)_4$, CuI, DABCO, toluene, 80 °C, 26 h (51%).

Cassette **1** was prepared mainly to assess its spectroscopic properties; it does not have a functional group that could be conveniently used to link to a biomolecule. A succinimide ester was incorporated into cassette **2** so that, in subsequent work, this dye could be used as a label. Activated esters of aromatic acids, however, are less active than their aliphatic analogs, hence cassettes **3** and **4** were functionalized with glycine attachment points. These variations have no effect on the spectroscopic properties of the dyes reported in this communication; this discussion is only included here to explain how these differences between the structures are consistent with the overall direction of this project.

Table 1 summarizes some light spectroscopic properties of the cassettes dissolved in $CHCl_3$. Using EtOH as the solvent had little effect (a few nm blue-shift relative to $CHCl_3$) on the position and band shape of the fluorescence and absorption spectra (data not shown). The UV absorption spectra of the cassettes resemble those that would be obtained by superimposing the donor and acceptor spectra, indicative of two independent dye fragments. However, when irradiated at the absorption maxima of the donor, the donor fluorescence is almost completely quenched. Thus energy is absorbed at wavelengths corresponding to the donor fragment and emitted at wavelengths governed by the acceptor part, hence large *pseudo*-Stokes' shifts result. Förster radii of the cassettes were determined and found to be significantly greater than the calculated donor–acceptor distances, hence the calculated energy transfer efficiencies were high.[7,8] Experimentally, it was shown that the energy transfer efficiencies (E_{expt}) were very high, meaning the cassettes are very effective. These are slightly

[a] Additional data (not shown here) was obtained on the donor and acceptor fragments A–C as the corresponding aryl iodides to calculate some of the parameters listed. [b] Calculated from molar absorptivity of the acceptor and corrected fluorescence spectrum of the donor *via* a literature procedure;[8] the κ^2-values (average angular dependence of dipole–dipole coupling in the dynamic limit) used were 0.5 for **1** and 0.665 for **2**–**4**.[10] [c] Estimated using standard bond lengths. [d] From Förster theory as described; uncertainties of the values are within 0.010.[11] [e] From steady-state fluorescence and absorption measurements; uncertainties of the values are within 0.010.[11] [f] From $\phi^{DA} = \phi^{A}E_{expt}(\tau^{A,DA})(\tau^{A})^{-1}$ where $\tau^{A,DA}$ and τ^{A} denote the fluorescence lifetime of the acceptor in the presence and absence of the donor, respectively. [g] Determined using fluorescence and absorption spectra.[9] As references of fluorescence quantum yields were used; *N*,*N*′-bis(1-hexylheptyl)-3,4:9,10-perylene-bis(dicarboximide) in CH_2Cl_2 (Φ = 0.99[12]), 3,3′,4,4′-difluoro-1,3,5,7-tetramethyl-4-borata-3a-azonia-4a-aza-*s*-indacene in MeOH (Φ = 0.94[13]) and Cresyl violet in MeOH (Φ = 0.54[14]).

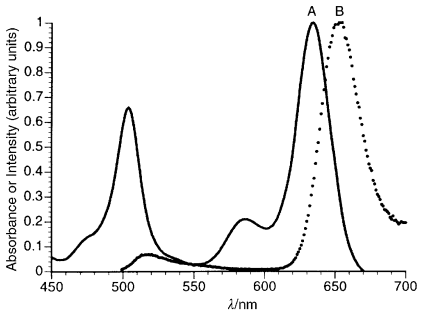

Fig. 1 Absorption ——— (A) and emission •••••• (B) spectra for cassette **4**.

lower than the calculated values, perhaps because the calculations assume energy transfer *via* the dipole–dipole coupling mechanism, which is not a good approximation when distances of interaction are compatible with the molecular size.[7] For all systems studied, the fluorescence decays were not perfectly well described by a single exponential function. Instead bi-exponential fits were found to be acceptable (data not shown). Weighted residuals, reduced χ^2 parameter and the Durbin-Wattson parameter judged upon the goodness of fit. Values considered acceptable were, of the reduced χ^2 parameter < 1.2 and of the Durbin-Wattson parameter > 1.7. The origin to the non-exponential relaxation is not known, but a possible explanation could be connected to a non-homogeneous distribution of the mutual donor and acceptor orientations. Average fluorescence lifetimes varied from 0.9 to 4.2 ns. The fluorescence quantum yields upon exciting the donor (Φ^{DA}) were calculated in two ways for the cassettes, namely; from fluorescence lifetime data (see table text) and by using fluorescence and absorption spectra.[9] The corresponding fluorescence quantum yields (Table 1) are lower than those of the acceptor fragments (data not shown). The fact that there is also a discrepancy in fluorescence lifetimes may partly be assigned to non-radiative processes, other than the Förster mechanism. Despite this, the energy transfer efficiencies are high.

Data from cyclic voltammetry studies demonstrated that the donor and acceptor parts of the cassettes do not communicate electronically in the ground state. For example, cassette **4** displays four distinct redox waves (in CH_3CN at 100 mVs^{-1}, glassy carbon electrode). These are two oxidative ($E_{1/2}$ = +0.62 and +0.78 V *vs.* ferrocene), and two reductive ($E_{1/2}$ = −1.19 and −1.52 V) waves; all four of which can be assigned to redox processes of the single dye portions. This confirms the conclusion from the spectroscopic studies that the donor and acceptors behave as distinct entities, rather than a unified, conjugated system.

In conclusion, this work shows that the BODIPY® fluorophores conjugated in cassettes **1**–**4** exhibit extremely high energy transfer from the donor to the acceptor giving enhanced resolution and intensities for the system when irradiated at the donor absorption maxima. The *pseudo*-Stokes' shifts for the dyes vary between 40 and 148 nm, and their quantum yields are from 0.12 to 0.60. It appears that in these systems *para* or *meta*-orientations (*cf.* **1** and **3**) make no significant difference. Even though these dyes have donor and acceptor fragments that are connected *via* a conjugated linker, steady-state and time-resolved fluorescence measurements are consistent with highly efficient energy transfer according to the Förster mechanism alone.

We thank Ben Lane for running the ^{11}B NMR spectra for this study. Financial support for this work was provided by the NIH (HG01745), The Swedish Natural Science Research Council (NFR K6501981724/2000), The Kempe Foundation, and The Robert A. Welch Foundation.

Azidohydroperoxidation of pinenes: stereoselectivity pattern and the first X-ray structure of a 2-azidohydroperoxide

Axel G. Griesbeck,* Johann Lex, Kurt M. Saygin and Jörg Steinwascher

Institute of Organic Chemistry, University of Cologne, Greinstr. 4, D-50939 Köln, Germany. E-mail: griesbeck@uni-koeln.de

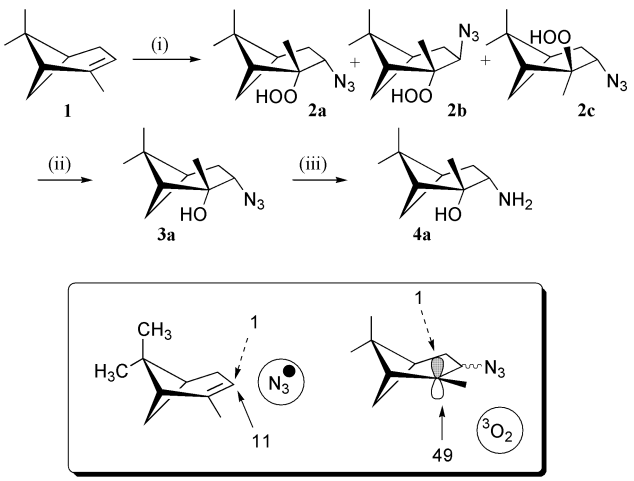
The photoinduced electron transfer of azide anions in the presence of an excited organic dyestuff, oxygen, and α- or β-pinene, respectively, gave 2-azidohydroperoxides in excellent regio- and good diastereoselectivity.

Photooxygenation in the presence of azide anions leads to difunctionalized products which can derive either from an azide trapping reaction of cyclic peroxidic intermediates or from an oxygen trapping reaction of intermediary α-azido carbon radicals.[1–3] The resulting 2-azidohydroperoxides have seldom been isolated and are usually reduced to the corresponding azido- or aminoalcohols.[4] Recent investigation by Workentin *et al.* showed that azidyl radicals are produced under photoinduced electron transfer (PET) conditions and these highly reactive azidyl radicals readily add to nucleophilic alkenes.[5]

In order to evaluate the facial selectivity of the azidyl radical addition in combination with simple diastereoselectivity originating from the secondary attack of molecular oxygen, we investigated the enantiomerically pure α- and β-pinene as substrates. The trisubstituted α-pinene (**1**) was among the most reactive alkenes when irradiated with visible light in the presence of azide anions, oxygen and an organic dye (Scheme 1). The crude reaction mixture consisted of a mixture of diastereoisomeric azidohydroperoxides **2a**–**c** (d.r. 90:8:2) and the corresponding azidoalcohols **3** which could be separated chromatographically (total yield 58%). The hydroperoxide–alcohol ratio could be altered by use of different PET-sensitizers and variation of the water content and was optimal (79:21) for rhodamine B in a 95:5 MeOH–H_2O mixture. Stern–Volmer analysis of the fluorescence quenching gave a rate constant for PET from N_3^- to rhodamine B of $k_{ET} = 1.6 \times 10^9$ M^{-1} s^{-1} (Fig. 1) comparable with the rate constants determined for 9,10-dicyanoanthracene[6] and thioxanthone.[7]

The configuration of the major diastereoisomer **2a** was determined by NOE-spectroscopy and by comparison of the aminoalcohol **4a** which resulted from the LAH-reduction of **2a**



Scheme 1 *Reagents and conditions*: (i) NaN_3, O_2, Rh-B, *hν*, MeOH–H_2O, (ii) $NaBH_4$, MeOH, (iii) $LiAlH_4$, Et_2O.

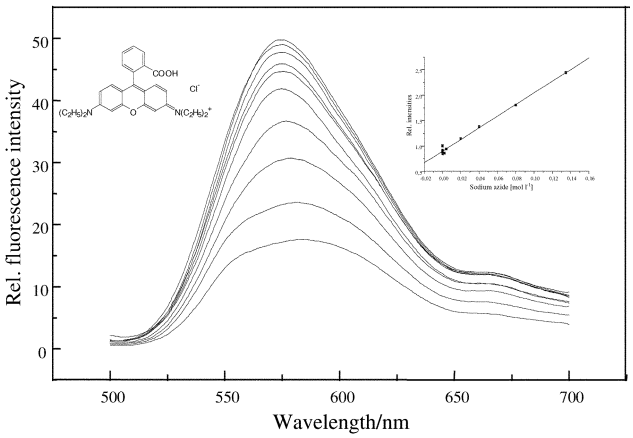


Fig. 1 Fluorescence quenching of rhodamine B by azide anions.

with the literature-known compound.[8] The relative configuration of the two minor components were determined from the $^3J_{HH}$ coupling constants of the hydrogen proximal to the azido group. Thus, the primary attack of the azidyl radical proceeds with a 11:1 *endo*-selectivity and the subsequent oxygen attack with a 49:1 *endo*-selectivity.

Unexpectedly, β-pinene (**5**) also showed noticeable reactivity under standard reaction conditions (Scheme 2): the azidohydroperoxides **6a**,**b**† (Fig. 2) were formed with a dr of 76:24 (72% based on converted **5b**). The addition of molecular oxygen was again directed by the shielding effect of the dimethylmethylene bridge in **5**. From both the azidohydroperoxides **6a,b** as well as the azidoalcohol **7a** the aminoalcohol **8a**, was generated by LAH-reduction. Crystallization from hexane–ethyl acetate gave single crystals of the azidohydroperoxide **6a**. X-Ray structure analysis of **6a** revealed that the molecules are connected by intermolecular hydrogen bonds between the OOH group and the internal nitrogen of the azido function.

Thus, this procedure serves as a simple synthetic approach to aminoalcohols from unsaturated substrates from the 'chiral pool'. Additionally, the pinene skeleton offered the opportunity to study the rate of oxygen addition due to the highly reactive cyclobutylcarbenium radicals (radical clocks) formed after azidyl radical addition. The corresponding ring-opening processes have been studied in free radical additions to α- and β-

pinene and rate constants of 8×10^5 s^{-1} were determined.[9] In our hands, less than 5% of ring-opening products (from **2** and **5**) were detected in the crude NMR-spectra. From this data, a bimolecular rate constant for the oxygen addition step of $> 5 \times 10^9$ l M^{-1} s^{-1} resulted. This value is in good agreement with the rate constants determined for the reaction of triplet oxygen with benzylic radicals ($1.6–4.9 \times 10^9$ l M^{-1} s^{-1}).[10] Decreasing the oxygen concentration, *e.g.* by use of air instead of a pure oxygen gas flow gave a number of products. These could not be identified.

The azidohydroperoxidation reaction was also applied for the allylic hydroperoxide **9** (available *via* photooxyenation of α-pinene **1**) and proceeded smoothly to give the corresponding azido *bis*-hydroperoxide which was reduced *in situ* to the azidodiol **10** (Scheme 3).

Stereo- and regiospecific polymerization of cyclic conjugated dienes using highly active nickel catalysts†

Mitsuru Nakano,* Qing Yao, Arimitsu Usuki, Shinobu Tanimura and Takaaki Matsuoka

Functional Polymer Synthesis Laboratory and Computational Materials Engineering Laboratory, Toyota Central R&D Labs., Inc., Yokomichi 41-1, Nagakute, Aichi 480-1192, Japan. E-mail: mnakano@mosk.tytlabs.co.jp; Fax: +81-561-63-6137; Phone: +81-561-63-5251

Received (in Cambridge, UK) 15th August 2000, Accepted 2nd October 2000
First published as an Advance Article on the web 31st October 2000

A markedly active and selective nickel catalyst, bis(allylnickel bromide)–methylaluminoxane, has been developed for cyclohexa-1,3-diene polymerization; the obtained crystalline polymer is a 1,4-linked *cis*-syndiotactic structure as determined by NMR and molecular dynamics using the COMPASS force field.

Interest in cyclic olefin polymers has been growing dramatically over the past decade due to their thermal and chemical stabilities and high mechanical strength and modulus that originates from the restricted molecular motion of a cyclic group. In addition, cyclic olefin polymers are recognized as promising optical materials because of their low birefringence. Among the various cyclic unsaturated compounds, we have focused on cyclohexa-1,3-diene (CHD) because it can be converted from cyclohexene, a known inexpensive by-product from ε-caprolactam synthesis. However, the monomer is so bulky that most catalysts are not effective for CHD polymerization.[1] Grubbs and coworkers reported that bis[(η^3-allyl)(trifluoroacetato)nickel(II)] catalyzed the polymerization of CHD derivatives, though the catalytic activity was not high enough for rapid CHD homopolymer production.[2] Recently, *n*-BuLi–TMEDA was developed for living anionic polymerization of CHD by Natori *et al*.[3] In this anionic polymerization system, however, the regio- and stereostructure of poly(CHD) were poorly controlled. To our knowledge, there are very few reports of initiators having high regio- and stereoselectivity *and* high catalytic activity. We herein report a markedly active bis(allylnickel bromide) (ANiBr)–methylaluminoxane (MAO) catalyst for CHD polymerization. Furthermore, the polymer obtained from the catalyst system exhibited a very high regio- and stereoregular structure, which was fully characterized by NMR and molecular dynamics using the COMPASS force field.

CHD polymerization catalyzed by ANiBr–MAO was rapidly completed at rt.[4] As shown in Table 1, the polymer yields are quite high, especially in halogenated aromatics or in cyclohexane. On the other hand, both the zirconium- and titanium-based catalysts had low activities for CHD polymerization, resulting in low yields of polymer. Late transition metal catalysts such as neutral allylnickel and cationic allylpalladium complexes were also ineffective for CHD polymerization. The ANiBr–MAO catalyst exhibited extremely high activity for the following reasons: (1) allylnickel should have an identical structure with the propagating species, allowing immediate initiation. (2) MAO activates ANiBr to form a highly electron-deficient species. (3) ANiBr has very high solubility in various organic solvents. (4) Allylnickel species should have enough space for the sterically demanding monomer.

In order to explore the polymerization mechanism, we synthesized the well-structured single component Ni complex[5] [(η^3-allyl)Ni(cycloocta-1,5-diene)]$^+$B(C_6F_5)$_4^-$ for CHD polymerization. Although the complex exhibited slightly lower catalytic activity than ANiBr–MAO, the obtained polymer showed the same regio- and stereostructure as the one produced using ANiBr–MAO (*vide infra*), which means that the cationic allylnickel is presumably the true propagating species in the CHD polymerization.

Since the CHD homopolymer[6] is insoluble in any organic solvents, buta-1,3-diene (BD) was copolymerized with CHD to determine the regiostructure of the polymer obtained.[7] Since no signals of the 1,2-poly(BD) units were observed around 114 and 143 ppm in the ^{13}C NMR spectrum of the copolymer, only the 1,4-poly(BD) units were taken into account to assign the ^{1}H NMR signals of poly(BD). Based on ^{1}H COSY spectra,† all signals were assigned as follows (Fig. 1). For the poly(CHD) unit, protons of H_o, H_a and H_b are identified with peak A at 5.73 ppm, peak D at 2.01 ppm and peak E at 1.56 ppm, respectively. On the other hand, peaks B and C are due to protons of H_o' and H_a' in the 1,4-poly(BD) unit, respectively. Assuming that the integral value of peak B is 2.0, peak A can be estimated to be 5.27. Concerning the number of protons in poly(CHD), H_o is equal to H_a in the 1,4-unit while H_o is 3/2 of H_a in the 1,2-unit. Therefore, the calculated value of the integral area of peaks C

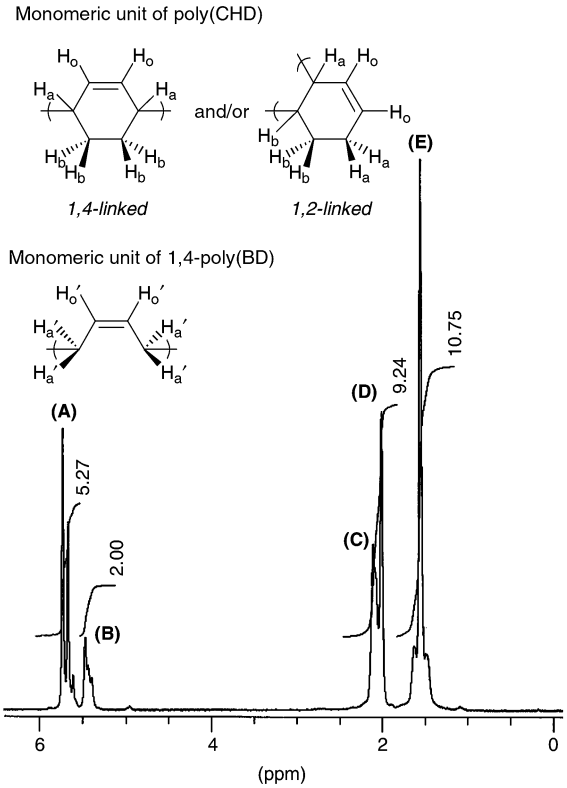

Fig. 1 ^{1}H NMR spectrum of CHD–BD copolymer catalyzed by ANiBr–MAO (polymer composition of [CHD]/[BD] = 72/28).

and D should be in the region from 9.27 (= 2.00 × 2 + 5.27) to 11.91 (= 2.00 × 2 + 5.27 × 3/2). The observed value of 9.24 is practically the same as 9.27, which means the CHD segment is perfectly 1,4-linked as well as the poly(BD) segment. In addition, the observed integral value of peak E is also very close to the calculated one, leading us to postulate that 1,4-linkage is dominant in the poly(CHD) main chain. Another experiment confirming the regiostructure was the synthesis of CHD oligomer anchored by a soluble poly(norbornene) with high molecular weight. The propagating species of norbornene polymerization initiated with ANiBr–MAO was long-lived enough to produce a soluble norbornene–CHD diblock copolymer. The ^{1}H NMR spectrum showed a sharp single peak of olefinic protons at 5.75 ppm, which is totally different from the doublet signal of anionically polymerized CHD.[3]

As shown in Fig. 2(a), the poly(CHD) catalyzed by *n*-BuLi-based initiator revealed the typical amorphous XRD pattern even when the polymer main chain consisted of >90% 1,4-units.[3] On the other hand, the poly(CHD) obtained with the ANiBr–MAO catalyst was found to be highly crystalline with

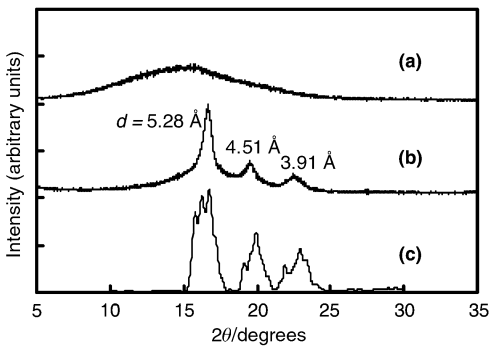

Fig. 2 X-ray diffraction patterns of (a) poly(CHD) obtained from *n*-BuLi–TMEDA, (b) poly(CHD) obtained from ANiBr–MAO, (c) *cis*-syndiotactic 1,4-poly(CHD) simulated using the COMPASS force field.

three major peaks based on a X-ray powder diffraction (XRD) spectrum (Fig. 2(b)). Additionally, the crystalline XRD pattern did not change when the poly(BD) unit was introduced into the main chain though the peak intensity decreased. The crystallinity of poly(CHD) initiated with ANiBr–MAO catalyst should originate from the stereoregular structure. In general, there are four stereoisomers, *i.e. cis*-isotactic, *cis*-syndiotactic, *trans*-isotactic and *trans*-syndiotactic in 1,4-linked poly(CHD).[8] We performed constant-temperature and constant-pressure molecular dynamics simulations of the crystalline poly(CHD) at 300 K and under zero pressure using the COMPASS force field. By use of the simulated atomic coordinates of the crystalline poly(CHD), time-averaged X-ray powder diffraction spectra were calculated. Interestingly, it was confirmed that only the simulated crystalline structure of the *cis*-syndiotactic 1,4-linked poly(CHD) could reproduce the experimental XRD pattern shown in Fig. 2(c). Although Ni-catalyzed poly(CHD) is believed to be a *cis*-rich structure from a *syn*-coordinative mechanism,[9] this simulation is the first evidence of the stereoregular structure of poly(CHD).

In summary, it was found that the ANiBr–MAO catalyst showed remarkably high activity for the CHD polymerization. The obtained polymer was a *cis*-syndiotactic 1,4-linked structure, which induced crystallization. In order to precisely control the poly(CHD) structure, further intensive studies using other nickel catalysts with dimine or phenanthroline ligands are in progress.

The authors are grateful to Ms K. Fukumoto for the NMR analyses.

4 A typical polymerization was performed with stirring at rt in a 20 ml glass bottle which was successively charged with 4.5 ml of toluene, 1 g (12.5 mmol) of CHD, 4.4 mg (24 μmol) of ANiBr, and 0.95 g of MAO (toluene solution, 2.6 mmol of Al). The polymerization solution immediately became heterogeneous at rt as a white precipitate formed. The reaction was quenched in a solution containing 500 ml MeOH and 10 ml 1 M HCl with a small amount of 2,6-di-*tert*-butyl-4-methylphenol as the antioxidant reagent. After drying under vacuum, an off-white powdery polymer was obtained.

6 CP–MAS ^{13}C NMR (300 MHz): δ 130 (–*C*H$_2$=), 40 (–H*C*<), 25(–*C*H$_2$–). Elemental analysis. Calcd for $(C_6H_8)_n$: C, 90.0; H,10.0. Found : C, 87.4; H, 9.8. The obtained polymer was stable up to 320–330 °C under N_2 and the melting point was not observed below 320 °C by DSC or a polarized microscopy.

7 The copolymerization of CHD with BD was accomplished by ANiBr–MAO catalyst to produce a copolymer almost quantitatively (yield 95%). While the monomer feed ratio was [CHD]/[BD] = 70/30, the polymer composition was determined to be [CHD]/[BD] = 72/28 by ^{1}H NMR. Based on GPC in *o*-dichlorobenzene at 135 °C, M_n, M_w and PDI were estimated to be 29.3 × 10^3, 63.0 × 10^3 and 2.15 (*vs.* polystyrene standards), respectively. Although the relative reactivity of CHD was somewhat higher than that of BD in the copolymerization, the regiostructure of the CHD segment did not change throughout the polymerization.

8 In this context, *cis–trans* means that bridging C–C bonds between monomer units are in a *cis–trans* relationships on the face of the cyclohexenyl ring.

First published as an Advance Article on the web 31st October 2000

$Ir(acac)_3$ supported on a carbon fiber-anode catalyzed the oxidations of alkanes (cyclohexane, *n*-hexane, adamantane) by generating strong electrophilic oxygen species from H_2O at 1.3 V (Ag|AgCl) with high current efficiency, for example, 45% for cyclohexanone formation.

Direct oxidation of alkanes is one of the key oxidation processes expected in the 21st century. On the other hand, the electroorganic synthesis of chemicals is also expected to be a key technology in green chemistry because the electrolysis can be operated under mild conditions. However, it is not so easy to realize direct oxidation of alkanes by electrolysis because their redox potentials [1.85 V (*vs.* NHE) for cyclohexane to 2.25 V for methane in aqueous solutions at pH = 0[1]] are higher than those of solvents and electrolytes. Some work on the anodic oxidation of alkanes in aqueous media >358 K has been reported but current densities were <0.1 mA cm^{-2} and the product was CO_2.[2] In non-aqueous media, oxidation of adamantane to adamantane derivatives was performed at >2.0 V and 303 K but the current density was <4 mA cm^{-2}.[3] Most of all successful electrochemical systems for the oxidation of alkanes applied an electrochemical reductive activation of O_2 at the cathode, indirect electrochemical oxidation, though the current efficiency of the produced oxygenates were low at <10%.[4]

We have recently reported an indirect anodic epoxidation of propene to propene oxide on PtO_2/Pt-anode and oxidation of benzene to benzoquinone on a carbon fiber-anode at 293 K.[5,6] A membrane electrolysis cell was assembled as [reactant|porous anode|silica wool membrane impregnated with H_3PO_4 aq.|porous Pt-graphite-cathode|H_2O(g), He]. An advantage of this system compared with conventional ones is that the separation procedure of the products from electrolyte is quite easy. We proposed that a nascent oxygen species generated on the anode from H_2O would oxidize propene and benzene, *i.e.* indirect electrochemical oxidation at the anode.[5,6] However, the two anodes mentioned above were not active at all for the oxidation of alkanes. Therefore, the purpose of this work was to design a new active anode for the oxidation of alkanes with H_2O by using the membrane electrolysis cell.

Fig. 1 shows the catalytic activities of various anodes for the oxidation of cyclohexane during electrolysis of H_2O in H_3PO_4 (aq) (0.7 mol l^{-1}) at 298 K. The anodes were prepared by the hot-press method from various electrocatalyst powders [metal blacks and metal compounds (0.5 mol%) supported on carbon fibers (CF)] and poly(tetrafluoroethylene) (PTFE) powder[4] with a geometric surface of *ca.* 2 cm^2. The membrane electrolysis cell attached to various anodes was assembled and the anode compartment was filled with pure cyclohexane (40 ml). The electrocatalytic oxidation of cyclohexane with H_2O was carried out by applying the anode potential; 1.5 V (Ag|AgCl) at Pd-black, Pt-black, Ir-powder, Ir-black anodes and 1.8 V at FeCl(TPP)/CF, Co_2O_3/CF, MnO_2/CF, Ir/CF, IrO_2, $IrCl_3$/CF, $IrCl_4$/CF anodes. Products were cyclohexanone (CyO), cyclohexanol (CyOH), adipic acid (AA), CO_2 and O_2. The results in Fig. 1 indicate that Ir compounds, especially $Ir(acac)_3$ supported on carbon fiber (CF), are active for the CyO formation, though current efficiencies (CE) estimated from eqn. (1) were not good.

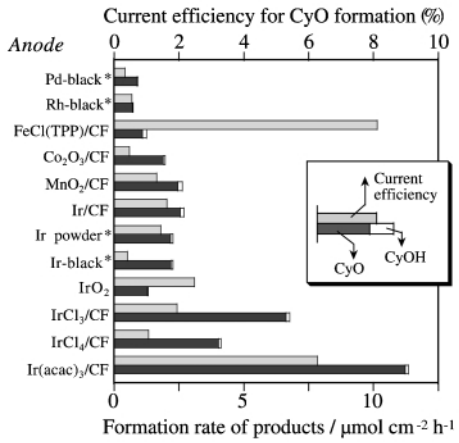

Fig. 1 Electrocatalytic oxidation of cyclohexane with H_2O over various anodes at 1.8 V (Ag|AgCl) or 1.5 V(*) at 298 K.

Therefore, attention was paid to the electrocatalytic function of the most active $Ir(acac)_3$/CF anode.

$$\text{cy-}C_6H_{12} + H_2O \rightarrow \text{cy-}C_6H_{10}O + 4\ H^+ + 4\ e^- \qquad (1)$$

To increase electrocatalytic activity for the oxidation of cyclohexane, (i) preparation conditions of the Ir-anode [types of carbon material, amounts of $Ir(acac)_3$ loading (0–2 mol%), amounts of PTFE (1–50 mg) and impregnation methods] were tested. The best components of the Ir-anode were [$Ir(acac)_3$ (0.025 mol%)/CF] (50 mg) and PTFE (5 mg). (ii) The study on the effects of various electrolytes (H_3PO_4, HCl, $HClO_4$, H_2SO_4, HNO_3, Na_2SO_4, NaOH and KOH) in the membrane and their concentrations on the oxidation of cyclohexane indicated that the best electrolyte was H_2SO_4 (aq) (1 mol l^{-1}).

Fig. 2(a) shows the formation rates of the products as a function of the anode potential by using the best anode and electrolyte described above. In the upper part (b), the current density and the current efficiency (CE) were plotted. When the anode potential was increased above 1.3 V (Ag|AgCl), the current density and the formation rates of CyO and CO_2 rapidly increased. The potential of 1.3 V for the onset of oxidation is far lower than the theoretical oxidation potential of 1.65 V (1.85 V *vs.* NHE) at pH = 0.[1] This result suggest that an indirect electrochemical oxidation of cyclohexane proceeds on the Ir-anode. The maximum formation rate of CyO was obtained at *ca.* 1.5 V. Here, the turnover number of Ir for CyO formation exceeded 110 in 1 h. In contrast, the formation rates of CO_2 and O_2 continuously increased when increasing the anode potential further. The decrease in the formation rate of CyO above 1.5 V may be due to the desorption of active oxygen species on the Ir-anode to the gas phase or to the consumption of the active oxygen in the successive oxidation of CyO to adipic acid or CO_2. Thus, the CE for the CyO formation decreased from 20 to 8% upon increasing the anode potential.

Effects of solvents (CH_2Cl_2, CCl_4, Et_2O, DMF and THF) on the oxidation were studied to optimize the oxidation. When a mixture of CH_2Cl_2 and cyclohexane (50:50 vol%) was used for the oxidation at 1.5 V, the CE for CyO formation dramatically

DOI: 10.1039/b006107g

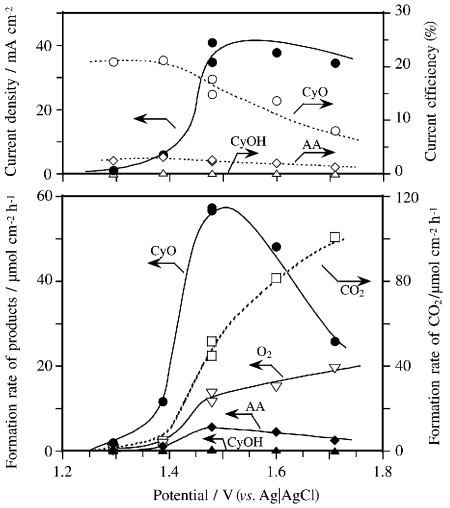

Fig. 2 Effects of anode potentials on (a) the formation rates of products and (b) current and current efficiency for the oxidation of cyclohexane on the $Ir(acac)_3$/CF anode with H_2O at 289 K.

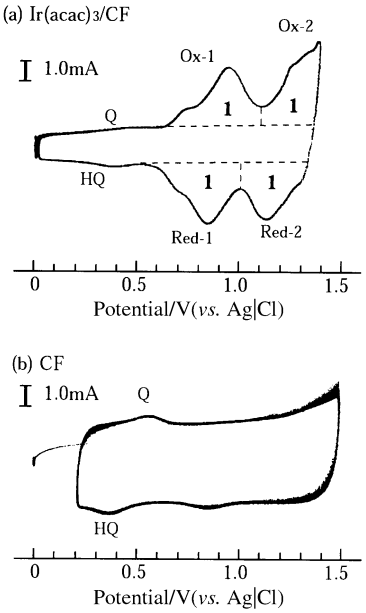

Fig. 3 Cyclic voltammograms of $Ir(acac)_3$/CF and CF electrodes in H_2SO_4 (aq) (1 mol l^{-1}) at atmospheric pressure of Ar. Scan speed 0.5 V s^{-1}.

increased from 15 to 45% while retaining a high formation rate of CyO. The increase in the CE was due to the decrease in both current and formation rates of CO_2 and O_2. If these by-products are formed through eqns. (2)–(4), their CE are estimated to be 18, 0.1, 10 and 15% for adipic acid, CyOH, CO_2 and O_2 respectively, giving a sum of CE of 88% at 1.5 V.

$$\text{cy-}C_6H_{12} + 4\ H_2O \rightarrow C_4H_8(CO_2H)_2 + 10\ H^+ + 10\ e^- \quad (2)$$

$$\text{cy-}C_6H_{12} + 12\ H_2O \rightarrow 6\ CO_2 + 36\ H^+ + 36\ e^- \quad (3)$$

$$\text{cy-}C_6H_{12} + H_2O \rightarrow \text{cy-}C_6H_{11}OH + 2\ H^+ + 2\ e^- \quad (4)$$

On the other hand, the CE for the formation of H_2 at the cathode was almost 100% within experimental error of ±2%. These results suggest the formation of undetectable products or oxidation of the anode itself.

A conventional H-type cell with the same [$Ir(acac)_2$ (0.025 mol%)/CF] anode was applied for the oxidation of cyclohexane dissolved in MeCN or dispersed as micelles in aqueous H_2SO_4. However, the oxidation of cyclohexane did not proceed at all. Our membrane electrolysis method is unique for the oxidation. After the oxidation, no Ir compounds were present in the reaction mixture or H_2SO_4 (aq) in the membrane according to ICP analysis. This result strongly suggests that Ir species are fixed on the CF.

Fig. 3 shows cyclic voltammograms (CV) of (a) the [0.025 mol% $Ir(acac)_2$/CF] electrode and (b) the CF electrode in aqueous H_2SO_4 under atmospheric pressure of Ar (geometric areas of both electrodes was 0.02 cm^2). Several redox couples were observed in the CV (a) of $Ir(acac)_3$/CF not observed in the CV (b) of CF, except for the redox couple due to quinone/hydroquinone groups present on carbon surfaces. A redox couple at 0.8–0.9 V (Ag|AgCl) (Ox-1/Red-1) can be assigned to Ir^{3+}/Ir^0.[7] The ratio of peak areas of Ox-1, Red-1, Ox-2 and Red-2 in Fig. 3(a) were roughly estimated to be 1 : 1 : 1 : 1. These facts suggested that the couple at higher potential (Ox-2/Red-2) can be ascribed to the transfer of three electrons, probably the redox couple Ir^{6+}/Ir^{3+} according to eqn. (5) or (6).

$$Ir^{3+} \rightarrow Ir^{6+} + 3\ e^- \quad (5)$$

$$Ir^{3+} + H_2O \rightarrow [IrO]^{4+} + 2\ H^+ + 3\ e^- \quad (6)$$

We believe that the formation of such high oxidation state Ir species[8] on CF would catalyse the oxidation of cyclohexane at > 1.3 V(Ag|AgCl).

To gain information about the reactivity of active species, oxidations of CyOH (4.8 mol l^{-1}), CyO (4.8), hexane (3.8) and adamantane (0.25) dissolved in CH_2Cl_2 were studied at an anode potential of 1.5 V (Ag|AgCl). CyOH was efficiently oxidized to CyO with a high CE of 73% (assuming $2e^-$ oxidation). On the other hand, CyO was oxidized to adipic acid with a low CE of 17% ($6e^-$ oxidation). These results suggest that active species generated on the Ir-anode oxidizes cyclohexane to CyO through CyOH. Deep oxidations of CyO to adipic acid and CO_2 were not fast. In oxidation of hexane, hexan-2-one (CE 14.0%, assuming $4e^-$ oxidation), hexan-3-one (13.9%, $4e^-$ oxidation) and hexanoic acid (0.4%, $6e^-$ oxidation) were produced. The relative reactivities of secondary and primary C–H bonds (2° : 1°) in hexane were estimated from the quantities of the oxygenated products and found to 250 : 1 when normalized per C–H bond. Thus the secondary C–H bond was selectively oxygenated on the Ir-anode. In oxidation of adamantane, 1-adamantanol (CE 4.9%, assuming $2e^-$ oxidation) and 2-adamantanone (0.7%, $4e^-$ oxidation) were produced. The low CE observed here was due to the low solubility of adamantane in CH_2Cl_2 solvent. The relative reactivities of tertiary and secondary C–H bonds (3° : 2°) was 42 : 1. These results suggest that the active species has very strong electrophilicity for the oxidation of alkanes. This strong electrophilicity must be caused by the high oxidation state of Ir species suggested by CV experiments (Fig. 3).

Catalytic asymmetric homo-aldol reaction of pyruvate—a chiral Lewis acid catalyst that mimics aldolase enzymes

Karsten Juhl, Nicholas Gathergood and Karl Anker Jørgensen*

Center for Metal Catalysed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark

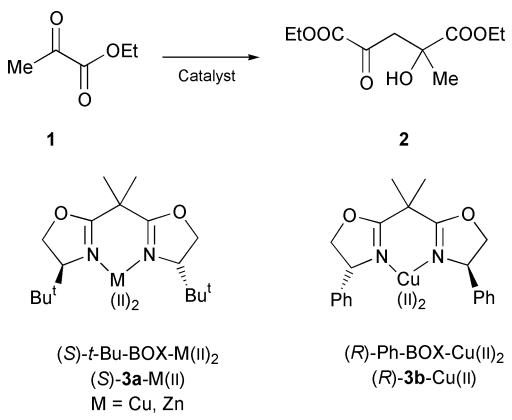
Received (in Cambridge, UK) 4th September 2000, Accepted 27th September 2000
First published as an Advance Article on the web 31st October 2000

The first catalytic asymmetric homo-aldol reaction of ethyl pyruvate leading to diethyl-2-hydroxy-2-methyl-4-oxoglutarate in up to 96% enantiomeric excess is reported; this reaction has been investigated for various catalysts, amines and solvents, and it is demonstrated that this new reaction leads to a simple synthetic procedure for the formation of optically active isotetronic acid derivatives.

The aldol reaction is one of the most powerful methods for the formation of C–C bonds. The ability to control the absolute configuration of the newly formed stereogenic centre is of fundamental importance. Nature has solved this problem using enzymes and a variety of different aldolase enzymes can catalyse the aldol reaction.[1] For the chemist, the search for methods that predictably transfer chirality catalytically and efficiently by reagent control is a challenging goal. In recent years a number of methods have been developed for the catalytic asymmetric aldol reaction with both high efficiency and enantioselectivity.[2]

In nature aldolase enzymes typically catalyse the stereoselective addition of a ketone donor to a carbonyl acceptor, while the chemical methods normally require more reactive species such as silyl enol ethers,[3] enol-methyl ethers,[4] or ketene silyl acetals,[3a–c,5] except for the multifunctional catalyst systems, containing a Lewis acid and a Brønsted base.[6] This communication presents the first chiral Lewis acid complex acting as a 'pyruvate-dependent aldolase', *i.e.* a type II aldolase, that catalyses a highly enantioselective homo-aldol reaction of ethyl pyruvate.[7] Furthermore, it will be shown that the reaction can be used for the synthesis of an optically active isotetronic acid derivative in two steps, a significant improvement compared with recent multi-step and complex synthetic approaches.[8]

Chiral bisoxazoline–metal(II) complexes are known to act as effective catalysts for enantioselective addition reactions to carbonyl groups.[9] Ethyl pyruvate **1** reacts in the presence of chiral bisoxazoline–metal(II) complexes[3c,d,10] in a homo-aldol reaction to give diethyl-2-hydroxy-2-methyl-4-oxoglutarate **2** [eqn. (1)] and some representative results are shown in Table 1.



(1)

The homo-aldol reaction of ethyl pyruvate **1** proceeds with > 80% conversion. The reaction of **1** catalysed by (*S*)-**3a**-Cu(OTf)$_2$ (10 mol%) gives diethyl-2-hydroxy-2-methyl-4-oxoglutarate **2** with 65% ee (entry 1). The (*S*)-**3a**-Zn(OTf)$_2$ complex can also catalyse the homo-aldol reaction of **1**, but the other enantiomer of **2** is formed with low ee (entry 2). The addition of *N*,*N*-dimethylaniline (DMA) to the reaction increases the ee of **2** and for the reaction catalysed by (*S*)-**3a**-Cu(OTf)$_2$ (10 mol%) and DMA (5 mol%) 96% ee is achieved (entries 3, 4). The enantioselectivity of the homo-aldol reaction is dependent on the amine added. For the other amines tested the highest ee is 93% using PhNBn$_2$ (entry 7), while *e.g.* 60% ee is obtained for Et$_3$N (entry 9).

The enantioselectivity of the homo-aldol reaction of ethyl pyruvate **1** catalysed by (*S*)-**3a**-Cu(II) is dependent on the copper(II) counterion, the solvent and amine as shown in Table 2. For the reaction catalysed by (*S*)-**3a**-Cu(OTf)$_2$ in the presence of 10 mol% DMA in Et$_2$O and THF, 79% ee and 69% ee of the same enantiomer of **2** are obtained, respectively (entries 1, 2). Changing the solvent to CH$_2$Cl$_2$ leads to a change of enantioselection to 12% of the other enantiomer of **2** in the presence of 10 mol% DMA (entry 3). The homo-aldol reaction is also dependent on the counterion. Changing the counterion from OTf to SbF$_6$ in CH$_2$Cl$_2$, in the absence of an amine, leads to a drop in enantioselectivity of **2** from 11% ee to 0% ee (entries 4, 5). This counterion effect in CH$_2$Cl$_2$ is more dramatic in the presence of 10 mol% DMA, as a change in ee from 12% to 63% was observed (entries 3, 7). When using the (*S*)-**3a**-Cu(SbF$_6$)$_2$ catalyst an increase in ee of homo-aldol product **2** by adding 10 mol% DMA occurs in CH$_2$Cl$_2$ (entries 5, 7). To study the effect of different amines on the enantioselectivity of the (*S*)-**3a**-Cu(SbF$_6$)$_2$ catalysed reaction in CH$_2$Cl$_2$, Et(i Pr)$_2$N, PhNBn$_2$ and CyNMe$_2$ were screened. A drop in ee from 63% in the presence of DMA (entry 8) to 30% was found for Et(i Pr)$_2$N (entry 11), but we were pleased to observe an increase in ee to 75% and 77% for PhNBn$_2$ and CyNMe$_2$, respectively (entries 9, 10).

It is important to note that the enantioinduction of the (*S*)-**3a**-Cu(II) catalytic system can be switched by changing only one

Table 1 Homo-aldol reaction of ethyl pyruvate **1** in the presence of (*S*)-**3a**-M(OTf)$_2$ (M = Cu, Zn) and (*R*)-**3b**-Cu(OTf)$_2$ and various amines in Et$_2$O at room temperature[a]

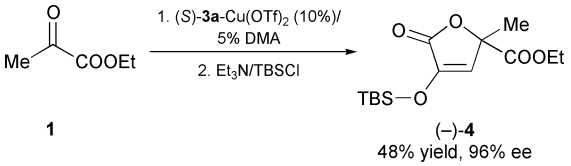
11	(*S*)-**3a**-Cu(SbF_6)$_2$ (10)	Et(^{i}Pr)$_2$N (10)	CH_2Cl_2	(+)-30

[a] All reactions give 70–80% conversion, except entry 11 (25% conversion). [b] Relative to ethyl pyruvate. [c] Ee measured by GC using Chrompack CP-Chirasil Dex CB (β-PM) column. [d] (+)/(−), sign of the optical rotation of isotetronic acid derivative (**4**). [e] DMA = *N*,*N*-dimethylaniline. [f] Cy = cyclohexyl.

parameter: the solvent (entry 1 *vs*. 3; Et_2O *vs*. CH_2Cl_2), the counterion (entry 1 *vs*. 8; OTf *vs*. SbF_6) or the presence of an amine (entry 6 *vs*. 8; no amine *vs*. 10 mol% DMA). At the present stage of investigations we are not able to fully account for the change in reaction course, but work is ongoing to elucidate the reaction mechanism.

The chiral bisoxazoline–metal(II) complex, (*S*)-**3a**-Cu(II) (M = OTf, SbF_6), is thus a simple chiral Lewis acid complex which mimics the pyruvate-dependent type II aldolase. This new catalytic enantioselective reaction can be used for the synthesis of the optically active isotetronic acid derivative **4** [eqn. (2)].



1 (−)-**4** 48% yield, 96% ee (2)

Isotetronic acids have been found to exhibit important biological effects such as aldose reductase inhibitory activity[11] and antitumor activity.[12] Reaction of the homo-aldol product **2** with Et_3N and TBSCl gives **4** in 48% isolated yield (from **1**)† under non-optimised reaction conditions.[13] The formation of **4** where the catalytic enantioselective approach is the first step, is a significant improvement compared to the multi-step and complex synthetic approaches previously reported.[8]

In summary, a catalytic highly enantioselective homo-aldol reaction of ethyl pyruvate giving diethyl-2-hydroxy-2-methyl-4-oxoglutarate in up to 96% ee has been developed. This reaction which mimics the pyruvate-dependent aldolase can be used for the preparation of optically active isotetronic acid derivatives in two steps.

† Representative procedure for the catalytic asymmetric homo-aldol reaction: To an oven or flame dried Schlenk flask Cu(OTf)$_2$ (36.2 mg, 0.10 mmol) and 2,2′-isopropylidenebis[(4*S*)-4-*tert*-butyl-2-oxazoline] (32.4 mg, 0.11 mmol) were added. The mixture was stirred under vacuum for 2 h and filled with Ar. Dry solvent (2 mL) was added and the solution was stirred for 2 h. The amine was added followed by the addition of ethyl pyruvate (110 μL, 1.0 mmol). The reaction mixture was stirred for 40 h and was then flushed through a plug of silica with Et_2O as the eluent. Solvent was removed *in vacuo* and the residue was redissolved in CH_2Cl_2 followed by the addition of dry Et_3N (200 μL, 1.5 mmol) and TBSCl (196 mg, 1.3 mmol). The solution was stirred overnight and was purified by FC (SiO_2, 12% Et_2O–pentane) to yield 3-*tert*-butyldimethylsilyloxy-5-methyl-2-oxo-2,5-dihydrofuran-5-carboxylic acid ethyl ester (**4**) as a clear colourless oil (72 mg, 0.24 mmol, 48%).^{1}H-NMR (400 MHz, $CDCl_3$) δ 6.23 (s, 1H), 4.21 (q, J = 7.2, 2H), 1.69 (s, 3H), 1.27 (t, J = 7.2, 3H), 0.96 (s, 9H), 0.24 (s, 6H); ^{13}C-NMR (100 MHz, $CDCl_3$) δ 169.0, 168.1, 143.2, 124.4, 81.7, 62.4, 25.4, 22.9, 18.3, 14.0, 1.0; IR : ν/cm^{-1}: 2958 (m), 2934 (m), 2861 (m), 1890 (s), 1745 (s), 1656 (s), 1473 (w), 1330 (w), 1257 (s), 1208 (s), 1097 (s); HRMS: calcd. for $C_{14}H_{24}O_5Si$ [M + Na]$^+$ 323.1291, found 323.1290; $[\alpha]_D^{23}$ = −84 (c = 0.01, CH_2Cl_2) 96% ee by chiral GC using a Chrompack CP-Chirasil Dex CB (β-PM) column, τ(major) = 20.3 min, τ(minor) = 20.6 min.

B3LYP/6-31G(d) theory predicts the experimental *endo–exo* selectivity of intramolecular Diels-Alder reactions of C9-substituted 1,3,8-nonatrienes: the reactions are concerted but the transition structures are remarkably asynchronous.

The intramolecular Diels-Alder (IMDA) cycloaddition is a strategy-level reaction in synthesis[1] that is being viewed increasingly as a biosynthetic event.[2] If this process is to reach its optimum synthetic potential and be fully understood in its biological setting, the stereochemical outcome of IMDA reactions must be more readily predicted and understood. *Exo* and *endo* transition structures (TSs) have been located for the prototype 1,3,8-nonatriene and 1,3,9-decatriene IMDA reactions at the HF/3-21G level of theory.[3,4] These structures were used to construct empirical force field models for a wide range of IMDA reactions.[5] While this hybrid quantum mechanics–molecular mechanics model reproduces many experimentally determined diastereoselectivities with remarkable accuracy, terminally activated 1,3,8-nonatrienes in which the dienophile activating group is disposed in a *Z*-orientation are predicted to form *cis*-fused bicyclic cycloadducts when, in fact, the *trans*-fused stereoisomer is the major observed product.[5]

In studies directed towards unearthing the reasons for the *exo* preference‡ of IMDA reactions of terminally activated 1,3,8-nonatrienes, we have examined the intramolecular cycloadditions of **1**, **2** and several related compounds using B3LYP/6-31G(d) theory. Thus, *exo* and *endo* TSs for nine related systems have been located at a higher level of theory than in any previous investigation into IMDA reactions. Our results confirm the asymmetric stretch–twist asynchronous transition state model proposed for 1,3,8-nonatriene IMDA reactions,[6] reveal hidden TS features and shed new light on their *endo–exo* preferences.

To confirm the experimental *exo* preference of terminally activated trienes, two IMDA precursors differing only in dienophile geometry were prepared and cyclised.[7] Triene precursors **1** and **2** (Fig. 1)§ were prepared by esterification of 2,4-hexadien-1-ol with maleic anhydride–diazomethane[8] and methyl fumaroyl chloride[9] respectively. Thermolysis of the *Z*-dienophile precursor **1** in dilute toluene solution at 110 °C was complete within 2 h to afford a 79 : 21 mixture of *exo* and *endo* stereoisomers. Intramolecular cycloaddition of *E*-dienophile precursor **2** proceeded more slowly to afford a 65 : 35 mixture of *exo* and *endo* stereoisomers, again in good yield. The *exo* preference of the IMDA reaction of both **1** and **2**, and the increased *exo* selectivity of the *Z*-dienophile precursor are mirrored in the trimethylene tether series.[10] That these thermal intramolecular cycloadditions are under kinetic control was demonstrated by subjecting pure samples of each of the

stereoisomers **3**–**6** to the cycloaddition reaction conditions. In each case, no isomerisation was observed.

Table 1 presents data for fully optimised B3LYP/6-31G(d) *endo* and *exo* IMDA TSs¶ of related ester-linked 1,3,8-nonatrienes.‖ An *endo* selective IMDA reaction is predicted for the parent acrylate derivative (Table 1, entry 1).** The calculations correctly predict the qualitative trends in *exo*–*endo* selectivity for **1** and **2**, *i.e.* strong *exo* selectivity for **1** (entry 8) and less so for **2** (entry 9). Three important conclusions may be drawn from the data of Table 1: (1) For C9-substituted trienes, the *exo*–*endo* selectivity is strongly dependent on the *E*–*Z* stereochemistry of the dienophile. Thus, *Z*-dienophiles (entries 2, 4, 6 and 8) are predicted to be significantly *exo* selective, while the *E*-dienophiles exhibit either a less pronounced shift towards the *exo* product (entries 7 and 9) or no change (entries 3 and 5). The presence of a terminal diene substituent (Y) has a negligible effect upon this preference (compare entries 6 *vs.* 8; 7 *vs.* 9). (2) In stark contrast to IMDA reactions of C1-substituted trienes,[11] the *exo*–*endo* selectivity is scarcely affected by the electronic demands of the C9-substituent (compare data for NH_2 *vs.* CN or CO_2Me). (3) All TSs display substantial bond forming asynchronicity which is particularly pronounced for the C9-substituted systems. In all cases the developing *internal* bond is more advanced than the developing *peripheral* bond, as indicated by the difference between their lengths, Δr ($= r_2 - r_1$): upon introduction of a C9 substituent (either *E* or *Z*), Δr increases from 0.19 Å (entry 1) to 0.51–0.77 Å, for the *exo* TSs, and from 0.08 Å to 0.37–0.63 Å, for the *endo* TSs. The large Δr values for the substituted systems is mainly due to much longer developing peripheral bonds in these TSs, with r_2 becoming as long as 2.74 Å (entry 8, *exo* TS).††

Our calculations support the Houk twist-asynchronous model[1,4,5,6] for explaining the influence of C9-substituents on the stereochemistry of IMDA reactions. In this model, applied to a trimethylene tether,[6] attention is focussed on strain in the developing cyclopentane ring in the IMDA TS. This strain is alleviated by reducing the magnitude of the C5–C4–C8–C7 dihedral angle θ_2 which may be achieved by twisting the TS about the C4–C8 bond such that C9 rotates in the *exo* (*outside*)[6] direction for the *exo* TS, and in the *endo* (*inside*)[6] direction for the *endo* TS. For a C9-substituted triene, this twisting is more facile for the *exo* TS than for the *endo* TS, since *endo* twisting in the *endo* TS probably leads to increased Pauli overlap repulsion‡‡ between the C9-substituent and the diene. The θ_1 (C3–C4–C8–C9 dihedral angle) values for the *Z*-substituted systems are consistent with this conjecture, with θ_1 displaying a large *exo* twist of 9–12° for the *exo* TSs, but a smaller *endo* twist of 1–8° for the *endo* TSs, relative to the unsubstituted system.

In contrast, the enhanced twist-asynchronicity seen in the *Z*-substituent TSs is absent in the corresponding *E*-substituent TSs since the θ_1 values for these TSs are similar to that for the unsubstituted TS (entry 1). This lack of enhanced twist asynchronicity is consistent with the reduced *exo* selectivity calculated for the *E*-substituted systems, compared to the corresponding *Z*-substituent series. What is the origin of this reduced *exo* preference for *E*-substituted nonatrienes?

Fig. 2 shows the *exo* and *endo* TSs for the parent acrylate compound (Table 1, entry 1), as viewed from the developing *peripheral* (C1–C9) bond. The preferred direction of asynchronous twist of the dienophile about the shorter *internal* (C4–C8) bond is depicted by a curved arrow. The approximate direction of the π electron density surface vector of the diene is depicted by solid arrows. The position of C9 substituents are indicated by *E* and *Z*.

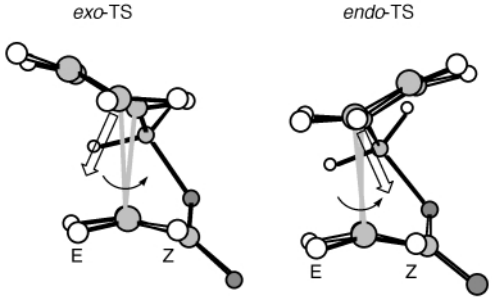

Fig. 2 Fully optimised B3LYP/6-31G(d) *exo* and *endo* TSs for the parent acrylate (Table 1, entry 1). See main text for key to arrows.

In the *exo* TS, preferred *exo* twisting of the dienophile about the C4–C8 axis moves the *Z*-substituent further from the diene, thereby reducing diene–substituent overlap repulsion. In contrast, preferred *endo* twisting in the *endo* TS moves the *Z*-group further into the diene region and overlap repulsion should increase, but slightly (because of the canting of the diene plane with respect to the dienophile). These effects combine to give strong *exo* selectivity for *Z*-substituted systems. For the *E*-substituted systems, *exo* twisting in the *exo* TS brings the substituent closer to the π electron density (once again, due to the canting of the diene), resulting in increased overlap repulsion. This outcome occurs also for preferred *endo* twisting in the *endo* TS. Consequently, on the basis of our refined Houk twist-asynchronicity model, reduced *exo*–*endo* selectivity is *expected* for *E*-substituted nonatrienes.

The authors thank The Australian Research Council for the award of a Senior Research Fellowship (to MNP-R) and a project grant (to MSS) and the New South Wales Centre for Parallel Computing for allocation of CPU time (to MNP-R).

Notes and references

‡ In intramolecular Diels-Alder reactions, we use the terms *endo* and *exo* to describe the orientation of the dienophile tether connection with respect to the diene. An *endo* orientation of the dienophile tether 'substituent' affords the *cis*-fused bicycle; an *exo* orientation of the dienophile tether furnishes the *trans*-fused cycloadduct.

§ For ease of comparison between the all-carbon prototype and other derivatives (such as the substituted esters described here), 1,3,8-nonatriene numbering is retained throughout.

¶ For entries 6–9, two discrete orientations of the terminal ester group with respect to the dienophile C=C bond are possible, namely s-*cis*- and s-*trans*. Both s-*cis* and s-*trans* TSs gave similar *exo*:*endo* product ratios and only data for the slightly lower energy s-*cis* TSs are given in Table 1.

‖ All TSs were fully optimised and characterised by B3LYP/6-31G(d) harmonic frequency calculations.

** Our B3LYP6-31G(d) calculations correctly predict predominant *endo* selectivity for the IMDA reaction of the trimethylene tether analogue of entry 1 (Table 1): the calculated *endo*:*exo* ratio is 83:17, compared to the experimentally observed value of 69:31.[3]

†† IRC calculations carried out on several substituted systems depicted in Table 1 show that these IMDA reactions are concerted, notwithstanding their marked asynchronicity.

‡‡ Electrostatic repulsion and secondary orbital overlap effects may also play a role.

First published as an Advance Article on the web 31st October 2000

B3LYP/6-31G(d) theory has been used to construct a transition structure model which correctly accounts for the observed π-diastereofacial selectivity in intramolecular Diels-Alder reactions induced by allylic substituents attached to the diene.

In addition to the extraordinary number of synthetic studies reported on the intramolecular Diels-Alder (IMDA) reaction,[1] there is growing interest in its stereochemical interpretation by computational methods.[2] The stereochemical outcome of IMDA reactions is complicated by *endo–exo*- and π-facial attributes, factors which allow up to four stereoisomeric products for each concerted process. We recently reported some of the first examples of IMDA reactions in which the stereocontrolling group is at the terminus of the diene (Fig. 1).[3] Whilst *exo* cycloadducts were formed exclusively in all cases, the level of π-diastereofacial selectivity was tuned by altering the substituents at the allylic stereocentre (C*) of **1**. The source of the *exo* preference of this general class of IMDA reactions was discussed in the previous communication.[4] Herein we explain our observed *π-facial* selectivities using transition structure (TS) models based on B3LYP/6-31G(d) theory, which has been shown to give good descriptions of TSs for the intermolecular Diels-Alder reaction.[5]

The origin of the observed π-facial selectivity in the IMDA reaction of **1** (Fig. 1), in terms of identifying the preferred disposition of the allylic substituents R, X and H among the *inside* (*in*), *anti* (*an*), or *outside* (*ou*) positions in TS **7** (Fig. 2), was investigated by carrying out B3LYP/6-31G(d) density functional theory calculations on the TSs for the IMDA reaction of **4**, which serves as a good simulacrum of **1**. In addition to the three conformations about the C1–C* bond, three conformations about the allylic C*–O bond and s-*cis*–s-*trans* orientations of the C9–CO_2CH_3 bond are possible (see **8**, Fig. 2). Thus, in principle, there are 18 diastereomeric TSs for *each* diastereomeric *exo* cycloadduct, **5** and **6**.‡ Two sets of six fully optimised lowest energy TSs associated with the different C1–C* conformations **7** were located, one set with the *Z*-ester adopting the s-*cis* conformation and the other with the *Z*-ester group in the s-*trans* conformation.

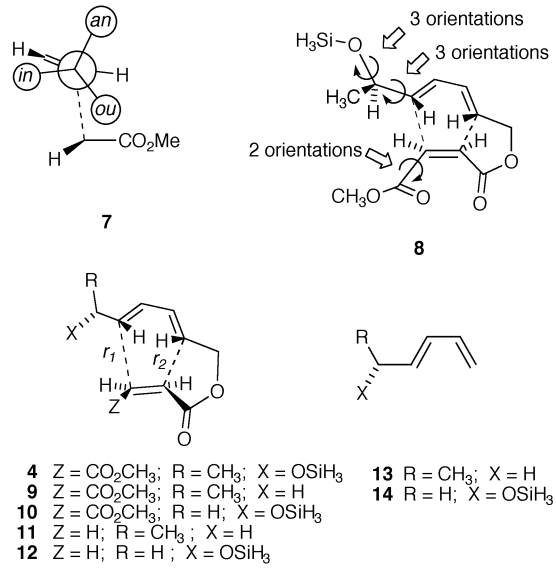

Fig. 2 Positioning of substituents in the IMDA TSs of **4** (**7** and **8**) and structures under investigation (**4**, **9**–**14**).

The relative energies, together with B3LYP/6-31G(d) zpe corrections, of the six diastereomeric TSs **4a**–**4f** for the IMDA reaction of **4**, in which the *Z*-ester adopts the s-*cis* conformation, are given in Table 1 and the profiles of the structures are shown

Table 1 B3LYP/6-31G(d) relative energies (kJ mol^{-1})[a]

Structure	*in*	*an*	*ou*	E_{rel}
4a[b]	$OSiH_3$	CH_3	H	0.0 (0.0)
4b[b]	H	$OSiH_3$	CH_3	4.0 (4.2)
4c[b]	CH_3	H	$OSiH_3$	14.5 (14.6)
4d[b]	$OSiH_3$	H	CH_3	4.8 (4.6)
4e[b]	CH_3	$OSiH_3$	H	10.5 (11.3)
4f[b]	H	CH_3	$OSiH_3$	5.55 (5.4)
9a[c]	H	CH_3	H	0.0 (0.0)
9b[c]	H	H	CH_3	5.4 (5.5)
9c[c]	CH_3	H	H	2.3 (2.0)
10a[c]	$OSiH_3$	H	H	0.0 (0.0)
10b[c]	H	$OSiH_3$	H	5.9 (6.8)
10c[c]	H	H	$OSiH_3$	12.6 (12.7)
11a	H	CH_3	H	0.0 (0.0)
11b	H	H	CH_3	4.5 (3.9)
11c	CH_3	H	H	4.3 (4.1)
12a	$OSiH_3$	H	H	0.0 (0.0)
12b	H	$OSiH_3$	H	2.2 (3.15)
12c	H	H	$OSiH_3$	2.1 (1.75)

[a] Relative energies corrected for zero point energy in parentheses. [b] s-*cis* ester conformation. [c] s-*trans* ester conformation.

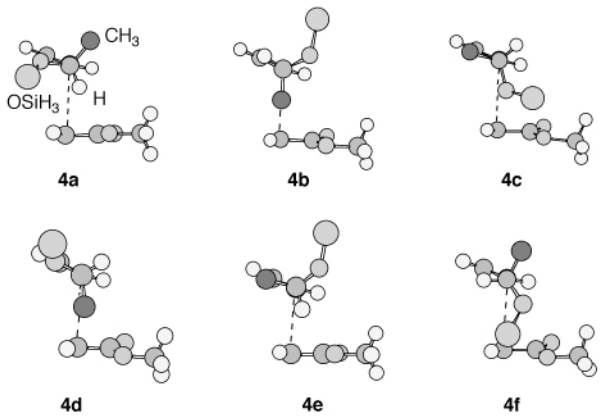

Fig. 3 The six TSs located for the IMDA reaction of **4**, as viewed down the C1–C4 axis (*cf.* **7**, Fig. 2). The developing *peripheral* C1–C9 bond is shown as a dashed line. Tether atoms are omitted for clarity.

in Fig. 3. The other set of six TSs associated with the s-*trans* conformation of the *Z*-ester are slightly higher in energy, by 2.5–6.0 kJ mol^{-1}, with respect to their corresponding s-*cis* congeners. In all other respects, the two sets of TSs show similar trends and so, unless stated otherwise, the following discussion refers to the *s-cis* set of TSs. The following five important points emerge from this study: (1) The lowest energy TS is **4a**, in which the silyloxy group adopts the *inside* position and the methyl group the *anti* position. This TS leads to formation of **5**, possessing the same configuration as **2**, the observed major product. The same major product is predicted from analysis of the TSs associated with the *Z*-ester adopting the s-*trans* conformation. (2) The three TSs **4a**–**4c** give **5**, whereas the three TSs **4d**–**4f** give the minor product **6** having the same configuration as the observed minor adduct **3**. A Boltzmann analysis of the two sets of conformations at 110 °C, including zpe corrections, gives a predicted product distribution of **5**:**6** = 74:26. A similar analysis carried out on the two sets of three TSs associated with the s-*trans Z*-ester conformations predicts a product distribution of **5**:**6** = 81:19. These analyses are in very good qualitative agreement with the experimental product distribution of **2**:**3** = 82:18 for the IMDA reaction of **1** (refluxing toluene) and provide compelling evidence in support of the reliability of our theoretical model. (3) The preferences of the methyl and silyloxy groups for the *anti* and the *inside* positions, respectively, in the lowest energy TS **4a** are a consequence of their respective innate tendencies to adopt these positions, irrespective of the presence of the other substituent. This conclusion is borne out by the calculations on **9** and **10**, each of which contains only one of these substituents. Thus, the most favourable TS for **9** is **9a**, with methyl in the *anti* position, and that for **10** is **10a**, with silyloxy in the *inside* position. The same trend is found for **11** and **12** in which the C9-ester substituent is absent, thereby demonstrating that the presence of this group is not required for inducing the conformational preferences of the methyl and silyloxy groups in these systems.§ (4) Inspection of the profiles of the TSs **4a**–**4f** (Fig. 3) reveals that the allylic substituents show little staggering about the forming *peripheral* bond (r_2) that is normally characteristic of additions to allylic systems.[6] Indeed, the C1–C* conformations in these TSs are essentially the same as those for isolated allylic ethers, with one substituent eclipsing the double bond.[7] This is hardly a surprising finding, given the extended length of the developing *peripheral* bond[4] (the *peripheral* bond length reaches a peak at 2.93 Å for **4d**). Model B3LYP/6-31G(d) calculations on the planar 1-ethyl-s-*cis*-butadiene **13**¶ show that the staggered conformer is favoured over the eclipsed conformer by 2.7 kJ mol^{-1}, which is similar to the energetic preference of the *anti* conformation over the *inside* conformation in the TSs for both **9** and **11**. In contrast, the calculations for **14** demonstrate that the eclipsed conformation is favoured over the staggered conformation by 2.7 kJ mol^{-1}, in reasonable agreement with the results for the TSs for **10** and **12**. (5) Our model for the favoured TS for IMDA reactions, in which the silyloxy group adopts the *inside* position and the alkyl group the *anti* position, is reminiscent of that proposed for *intermolecular* 1,3-dipolar cycloadditions of nitrile oxides to chiral allylic ethers.[6,8]

In conclusion, our model may be used to predict the degree of π-facial selectivity of IMDA reactions with substituents at the allylic position of the diene. The preferred TS, with the C* alkyl substituent *anti* and RO group *inside*, will be further favoured energetically by increasing the size of the alkyl group, for steric reasons, and by increasing the electron density at the oxygen atom of the RO group, for electrostatic reasons. The *inside* preference for the RO group may arise from an attractive electrostatic interaction between the oxygen atom and the hydrogen atom at C2. This would explain why greater π-facial selectivity is observed in IMDA reactions of silyl ethers (*e.g.* **1**) than the corresponding alcohol (Fig. 1; X = OH).[3] Our calculations predict even stronger selectivity for a metal alkoxide (Fig. 1; X = OM).

The authors thank the Australian Research Council for the award of a Senior Research Fellowship (to MNP-R) and a project grant (to MSS) and the New South Wales Centre for Parallel Computing for allocation of CPU time (to MNP-R).

Notes and references

‡ Cycloadducts **5** and **6** result from dienophile approach from below and above the plane of the diene respectively to enantiomerically pure **4**. For simplicity, the π-facial selectivity of this IMDA reaction was evaluated computationally by locating IMDA TSs for dienophile approach to the lower face of the diene for each enantiomer of **4**: *cf.* S. S. Wong and M. N. Paddon-Row, *J. Chem. Soc., Chem. Commun.*, 1991, 327.

§ With the exception of **4c**, the energetic ordering of the TSs calculated for **4a**–**4f** may be correctly deduced from the monosubstituted allylic systems **9** and **10** by simply adding the relative energies of the various pairs of TSs.

¶ The butadiene moiety in **4a**–**4f** is only *ca.* 5° off planarity.

The single-crystal X-ray structure of $\{[HPPh_3]^+\}_2[B_4F_{10}O_2]^{2-}$ 2 reveals trigonal planar oxygen atoms in a rare example of a B_2O_2 ring; extended Hückel and *ab initio* molecular orbital calculations provide insight into the bonding and the geometry about oxygen.

As part of a study of the solid-state structures and NMR spectra of $R_3P{\cdot}BX_3$ adducts, we found that addition of $BF_3{\cdot}OEt_2$ to a hexane solution of PPh_3 yielded $Ph_3P{\cdot}BF_3$ **1**† as a white precipitate. Adduct **1** was previously synthesised from BF_3 and PPh_3 in CH_2Cl_2.[1,2] Attempts to grow single crystals of **1** from CH_2Cl_2–toluene led to the formation of several cube-shaped crystals. X-Ray diffraction studies showed these to be $\{[Ph_3PH]^+\}_2[B_4O_2F_{10}]^{2-}$ **2**,‡ which contains an unusual B_2O_2 ring. This salt apparently resulted from hydrolysis of **1** due to traces of adventitious water.

The novel dianion in the crystal of **2** (Fig. 1) lies on a centre of inversion and thus the B_2O_2 ring is rigorously planar. The B–O bond distances in the ring are 1.498(2) and 1.505(2) Å. The ring is nearly square, with O–B–O and B–O–B internal angles of 88.8(1) and 91.2(1)°, respectively. A BF_3 group is co-ordinated to each oxygen atom, with the B–O bond distance of 1.512(2) Å, and two fluorine atoms are bonded to each ring boron atom. The B–F bond distances in the BF_2 and BF_3 groups are very similar, averaging 1.362(3) and 1.374(5) Å, respectively. Interestingly, the coordination about oxygen is trigonal planar with the sum of the angles being 359.9(2)°.

Although fluoroborates with rings containing five or more atoms are known,[3,4] the dianion in **2** represents the only structurally well characterised discrete ring consisting solely of boron, fluorine and oxygen atoms. Unlike the common six-membered rings containing alternating boron and oxygen,[5] and four-membered rings containing alternating aluminium and oxygen,[6] only four crystal structures containing four-membered B_2O_2 rings have been reported.[7–10] Three of the structurally characterised compounds contain trigonal planar oxygens at the B_2O_2 ring: the porphyrin complex,[7] $[B_2O_2(BCl_3)_2(TpClpp)]$ (TpClpp = dianion of 5,10,15,20-tetra-*p*-chlorophenyl-porphyrin), neutral $[Me_2B–O–BMe_2]_2$,[8] and the 4-oxa-3-borahomoadamantane dimer.[10] A further example of trigonal planar oxygen was recently described by Schröder's group[11] in a complex with alkoxide bridging between BF_3 and a copper atom. In $\{C_6F_4\text{-}1,2\text{-}[B(C_6F_5)_2]_2(\mu\text{-}OR)\}^-$ (R = Me, C_6F_5), it was suggested[12] that the planar geometry about the oxygen could be due either to the bulky groups about O, or to the bite angle of the bidentate moiety coordinated to it. Our dianion $B_4O_2F_{10}^{2-}$ in **2** is simple and elegant with only 16 atoms, making it ideal for theoretical studies.

We have carried out extended Hückel and *ab initio* MO calculations to gain insight into the bonding within the ring and the geometrical preference at oxygen in **2**. EHMO calculations[13,14] were performed on both the dianion $B_4O_2F_{10}^{2-}$ and the $B_2O_2F_4^{2-}$ fragment, and the resulting energy level diagram is shown in Fig. 2, along with plots of the frontier orbitals of the $B_2O_2F_4^{2-}$ fragment; lower lying orbitals include the B–F bonds, fluorine p electrons and the oxygen and boron s orbitals. The bonding in the $B_2O_2F_4^{2-}$ square can be seen to arise from the B–O σ bonds in HOMO-3 and HOMO-4. The in- and out-of-plane combinations of the other oxygen p orbitals produce the four remaining orbitals drawn at the left side of Fig. 2; from the HOMO downwards these are O–O σ*, π*, π, σ. The Lewis basicity of the $B_2O_2F_4^{2-}$ square arises from the in-plane HOMO and HOMO-5 which overlap with the out-of-phase and in-phase combinations of BF_3 acceptor orbitals in the $B_4O_2F_{10}^{2-}$ dianion. The O–O π* and π orbitals are not involved in bonding to the BF_3 groups. The fact that O–O σ* is the $B_2O_2F_4^{2-}$ HOMO is thus likely responsible for the observed trigonal planar coordination at oxygen.

Ab initio MO calculations (GAUSSIAN94)[15] on the $B_2O_2F_4^{2-}$ fragment at the MP2/6-31G* level of theory revealed the energies of the frontier orbitals to be in the same order as in Fig. 2 with the O–O σ* and σ orbitals (HOMO and HOMO-5) significantly lower in relative energies. On coordinating two BF_3 groups to $B_2O_2F_4^{2-}$ to generate **2**, the O–O σ and σ* orbitals provide the electrons used in O–BF_3 bonding and are significantly lowered in energy; as a result the unperturbed O–O π* and π orbitals become HOMO and HOMO-1 respectively.

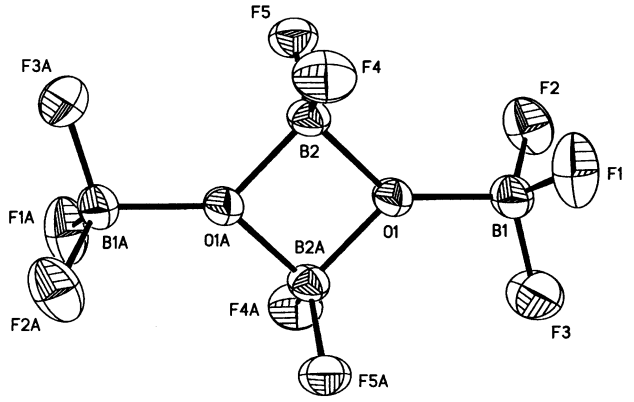

Fig. 1 Structure of the $B_4O_2F_{10}^{2-}$ dianion in **2** drawn with 50% probability ellipsoids showing the atom numbering. Selected bond distances (Å) and angles (°) for **3**: B(1)–O(1) 1.512(2), B(2)–O(1) 1.498(2), B(2)–O(1A) 1.505(2), B(1)–F(1) 1.380(3), B(1)–F(2) 1.372(2), B(1)–F(3) 1.369(3), B(2)–F(4) 1.362(2), B(2)–F(5) 1.362(2); O(1)–B(2)–O(1A) 88.83(12), B(2)–O(1)–B(2A) 91.17(12), B(1)–O(1)–B(2) 136.21(14), B(1)–O(1)–B(2A) 132.48(14).

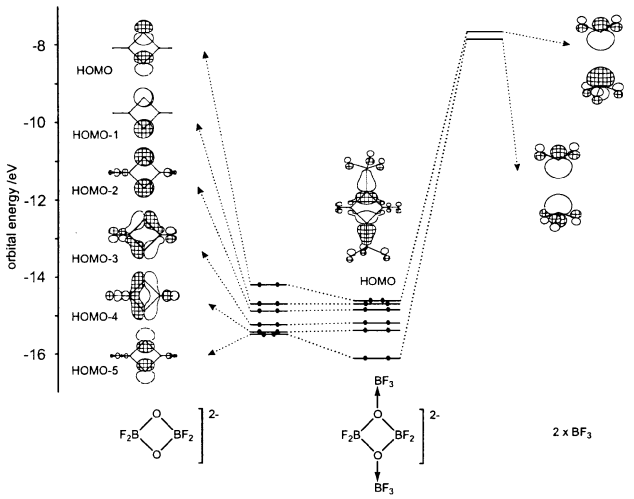

Fig. 2 Extended Hückel molecular orbital interaction diagram for the $B_4O_2F_{10}^{2-}$ anion in **2**.

DOI: 10.1039/b006685k

Geometry optimization of the dianion $B_4O_2F_{10}^{2-}$ in **2** at MP2/6-31G* revealed a minimum virtually identical to that found experimentally with O–B–O and B–O–B internal angles of 89.1 and 90.9° respectively. However, geometry optimization of the discrete fragment $B_2O_2F_4^{2-}$, resulted in a minimum with O–B–O and B–O–B internal angles of 97.5 and 82.5° respectively, and the O–O π* orbital as the HOMO. Thus, coordination of the two BF_3 Lewis acids to the in-plane oxygen orbitals stabilises the antibonding O–O σ* level without the need for significant lengthening of the O–O separation *via* distortion of the B_2O_2 square.

Alternative structures involving pyramidalisation at each oxygen atom can be accounted for by a mixing of the oxygen in- and out-of-plane orbitals (HOMO/HOMO-1 and HOMO-2/HOMO-5) to generate donor orbitals in either *cisoid* or *transoid* arrangements. These have been examined through qualitative Walsh diagrams (Fig. 3) with the observed structure at the energy minimum.

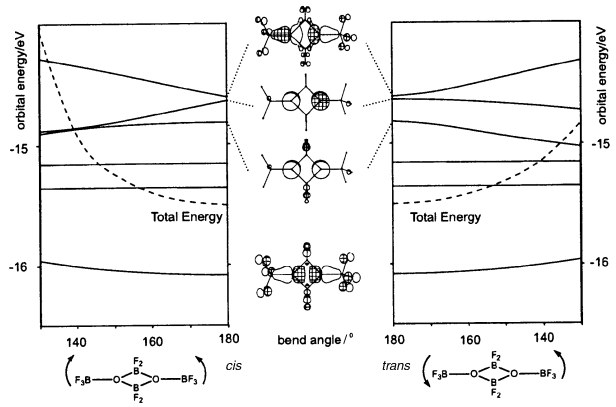

Fig. 3 Walsh diagrams for pyramidalisation at oxygen in the $B_4O_2F_{10}^{2-}$ dianion, calculated at the extended Hückel level. Total energies (in eV): planar, −2229.245; 130° *trans*, −2228.578; 130° *cis*, −2227.807.

Clearly, B_2O_2 rings are inherently destabilised by four-electron interactions of both σ- and π-symmetry between the oxygen atoms. Stable systems can be formed by complexation of Lewis acids such as BX_3, or, in the case of Al_2O_2 systems, by increasing the separation between the oxygen centres.

First published as an Advance Article on the web

The fully deprotonated tetrathiacalix[4]arene 1^{4-} in 1,3-alternate conformation and bearing four carboxylate units was shown to act as a tecton leading, in the presence of Ag^+ cation, to a 2-D coordination network in the crystalline phase which can be described as discrete binuclear [1^{4-}, $(Ag^+)_2]^{2-}$ complexes interconnected by Ag^+ cations.

Molecular networks are defined as infinite architectures possessing translational symmetry of assembling nodes (interaction patterns) and are obtained under self-assembly conditions from molecular components capable of reversible and mutual interactions. Coordination networks, based on exo-ligands and metal cations, form a subclass of molecular networks and are currently under active investigation.[1] The majority of coordination networks reported to date are based on two component systems composed of an organic exo-ligand bearing coordination sites oriented in a divergent manner and a metal cation. Furthermore, the ligands employed so far are mainly of the bis-monodentate,[2] bis-bidentate,[3] tetrakis monodentate[4] or bis-tridentate[5] types bearing almost exclusively nitrogen atoms as coordination sites.

For the design of coordination networks, instead of considering a two component system for which both the metal centre and the free exo-ligand act as tectons, a further conceptually new design principle may be based on the use of a metal complex acting as a metallatecton and a metal cation. The design of such a system may be based on a ligand bearing multiple coordination sites allowing, on one hand, the formation of a endomolecular complex with a metal cation M, and on the other, the interconnection of the latter complex into a coordination network using either the same metal cation M or another metallic centre M′. A similar strategy, based on the simultaneous use of coordination and hydrogen bonds has already been investigated with success.[6]

In the present contribution we report, to the best of our knowledge, the first example of a 2-D coordination network based on the use of the above mentioned strategy.

Compound **1**,[7] a tetrathiacalix[4]arene derivative in 1,3-alternate conformation and bearing four carboxylic acid groups, presents several interesting features (Scheme 1). In its fully deprotonated form, $\mathbf{1}^{4-}$ possesses a total of 16 heteroatoms (12 O and 4 S atoms) which may participate in the coordination of metal cations. Its 1,3-alternate conformation[7] allows the positioning of two coordination poles (one may define a coordination pole as a set of coordination sites located in close proximity and capable of coordinating to metal centres) below and above the main plane of the backbone with a 90° angle between them. Each coordination pole is composed of two carboxyl units and two ether junctions. Importantly, owing to the connection of the carboxyl groups to O atoms of the calix by a CH_2 unit, the ether O atom and one of the two oxygen atoms of the carboxyl group may adopt a *syn* conformation leading to a chelate of the glycol type capable of binding metal cations. Thus, within each coordination pole, two such units may bind a metal cation leading to a discrete binuclear metal complex (Fig. 1). This type of coordination mode has been previously observed and structurally proven for the dipotassium salt of a calix[4]arene derivative in 1,3-alternate conformation and bearing amide groups[8] and for the sodium salt of a calix[4]diquinone derivative which was also found to form a 1-D network.[9] It is worth noting that upon formation of the binuclear complex, the remaining O atoms on carboxylate groups would be blocked and oriented in a divergent fashion. Thus, for the formation of coordination networks, the discrete binuclear complex mentioned above which may act as a tetrakis monodentate metallatecton, may be interconnected using metal cations through the remaining O atoms (Fig. 2). The dimensionality of the coordination networks which may be formed using ligand **1** depends on the coordination requirements (coordination number and geometry) of the metal cation used. In principle, either 2- or 3-D networks may be expected.

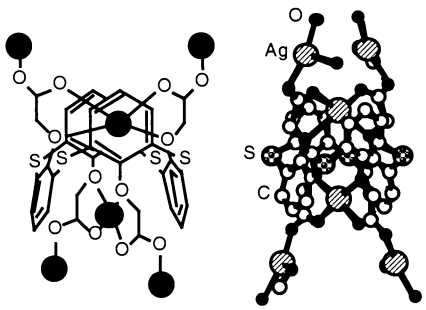

Fig. 1 Schematic representation of the binding mode of Ag^+ cations by ligand $\mathbf{1}^{4-}$ (left) and a portion of the X-ray structure showing the two modes of coordination for the cations with H atoms omited for clarity. For distances and angles see text.

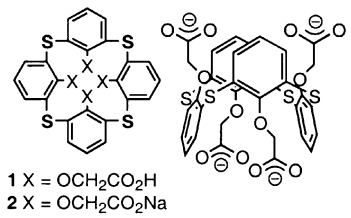

Scheme 1

Dealing with the metal cation, as mentioned above, owing to the fact that the formation of coordination networks using the ligand $\mathbf{1}^{4-}$ requires two different binding modes, silver appeared to be the most suitable cation. Indeed, Ag^+ forms kinetically labile complexes and shows rather loose coordination requirements since it may tolerate bi-, tri- or tetra-dentate ligands with linear, trigonal or tetrahedral coordination geometries. The Ag^+ cation has been extensively used for the formation of coordination networks.[10] In our own studies, Ag^+

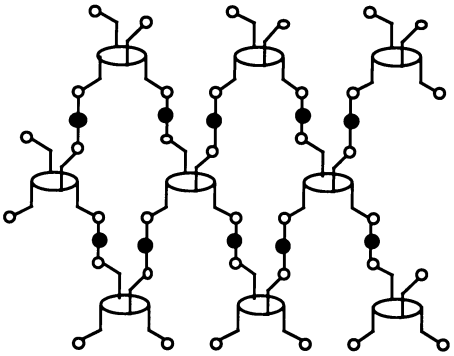

Fig. 2 Schematic representation of the 2-D network formed through interconnection of [$\mathbf{1}^{4-}$, $(Ag^+)_2]^{2-}$ units by Ag^+ cations. For clarity, the Ag^+ cations forming the binuclear complex are not shown.

has been used to form metallamacrocycle,[11] linear,[4] helical[12] and tubular[4b,11b] coordination polymers.

Compound **1** was prepared[7] in four steps stating with *p-tert*-butyltetrathiacalix[4]arene[13] and its 1,3-alternate conformation was established by X-ray diffraction on a single crystal.[7] [$\mathbf{1}^{4-}$, $(Na^+)_4$] was generated upon treatment of **1** in MeOH by addition of 4 eq. of NaOH in H_2O. The removal of volatiles afforded a white solid which was dried in vacuum overnight. Upon slow diffusion at r.t. of a MeOH solution (1 ml) containing [$\mathbf{1}^{4-}$, $(Na^+)_4$] (10 mg) into an aqueous solution (1 ml) of $AgNO_3$ (2 mg), colourless crystals were obtained after three days. An X-ray study† on a single crystal showed the following relevant features (Figs. 1–3): the crystal is composed of $\mathbf{1}^{4-}$, $4Ag^+$, MeOH and H_2O solvent molecules. $\mathbf{1}^{4-}$ adopts the 1,3-alternate conformation thus presenting two carboxylate moieties on each face. The $OCH_2CO_2^-$ fragments adopt a *syn* conformation (OCCO dihedral angles of 14.0 and 11.9° on one side and −9.2 and −11.6° on the other). For the carboxylate units the C–O distance varies between *ca*. 1.23 and 1.27 Å. Dealing with silver, among the four present, two types of Ag^+ cation are observed. For the first variety composed of two Ag^+ cations, both are coordinated, one on each face, to the ligand thus affording the binuclear [$\mathbf{1}^{4-}$, $(Ag^+)_2]^{2-}$ complex. Both Ag^+ cations are tetracoordinated to four O atoms with two short (2.2–2.3 Å) and two long (2.6–2.9 Å) O–Ag distances and adopt a strongly distorted square planar coordination geometry (OAgO angles varying from *ca*. 63 to 171°). However, owing to the fact that on each side of the complex the Ag^+ cations are located in close proximity to two carbon atoms belonging to two opposite aromatic rings (d_{C-Ag} = 3.2–3.3 Å, with CAgC angle of 8.8°), one may describe the coordination geometry around the silver cation as distorted octahedral.

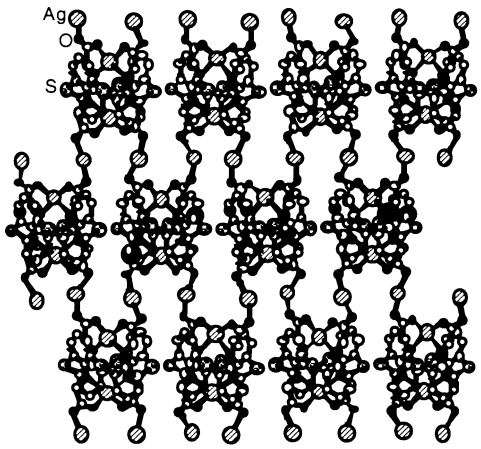

Fig. 3 A portion of the X-ray structure of the 2-D network formed between $\mathbf{1}^{4-}$ and Ag^+. H atoms and solvent molecules are not shown for clarity. For distances and angles see text.

The other type of Ag^+ cations serve to interconnect the dianionic binuclear [$\mathbf{1}^{4-}$, $(Ag^+)_2]^{2-}$ complexes which act as tectons, thus leading to the formation of a 2-D coordination network (Fig. 2). The interconnection is achieved through Ag–O bonds (d_{Ag-O} varying between *ca*. 2.2 and 2.4 Å) engaging the remaining O atoms on the carboxylate units (d_{C-O} = 2.24–2.26 Å) (Fig. 3). The coordination sphere around the metal centres is composed of three O atoms among which one MeOH (d_{Ag-O} of *ca*. 2.40 Å) or one H_2O (d_{Ag-O} of *ca*. 2.39–2.69 Å) solvent molecules with distorted trigonal coordination geometry (OAgO angles of 89.4, 117.4 and 151.2° for Ag^+ coordinated to MeOH and 95.8, 124.0 and 140.0° for Ag^+ coordinated to H_2O).

In conclusion, using the tetraanionic form of the thiacalix-[4]arene bearing four carboxylate units and Ag^+ cation, a 2-D coordination network has been obtained and structurally characterised in the crystalline phase. The network was composed of discrete binuclear [$\mathbf{1}^{4-}$, $(Ag^+)_2]^{2-}$ complexes acting as metallatectons interconnected by Ag^+ cations. The effect of the number of negative charge on the calix unit on the formation of coordination network, as well as the nature of the connecting cation are currently under investigations.

***In situ* time-resolved synchrotron X-ray and neutron powder diffraction studies indicate that the negative thermal expansion and 'trap door' cation relocations observed in zeolite rho result from water-mediated chemical changes that occur during dehydration.**

Zeolite rho exhibits exceptional flexibility, and its structure is particularly sensitive to cation identity, temperature, and hydration.[1] For example, Sr^{2+}-exchanged zeolite rho (Sr-rho) shows a large negative thermal expansion.[2] A more dramatic effect has been observed in Cd-rho, where Cd^{2+} cations relocate upon heating in a 'trap door' mechanism opening the access to the pores of RHO.[3,4] Both transformations have been previously attributed to temperature-driven phase transitions. To better understand the origin of these structural changes, time-resolved *in situ* synchrotron X-ray powder diffraction and neutron powder diffraction were performed using Pb-rho and Cd-rho. We found that both phenomena result from chemical changes that occur during dehydration rather than being a result of composition-independent, purely temperature-driven effects.

The RHO topology is composed of a body-centered cubic arrangement of truncated cuboctahedra or α-cages linked *via* double 8-rings of corner-connected tetrahedra. Three sites with unique coordination environments can accommodate charge-balancing, extra-framework cations: the single 8-ring (S8R), double 8-ring (D8R) and single 6-ring (S6R) sites. Each site has a distinct coordination environment, and cations preferentially occupy one of these sites depending upon their ionic radii. The framework can adopt a centric (C-form, $Im\bar{3}m$) or acentric (A-form, $I\bar{4}3m$) structure depending upon the unit cell composition and the temperature.[5,6]

Na,Cs-rho, the parent material used for cation-exchange, was prepared using a modification of the method described by Robson.[7] Pb-rho and Cd-rho were then prepared using standard ion-exchange techniques.‡ Time-resolved X-ray powder diffraction data were collected on the X7B beamline at the National Synchrotron Light Source (NSLS) using an *in situ* dehydration cell with an imaging plate detector.§[8] Neutron powder diffraction data were collected on the BT-1 powder diffractometer at the National Institute of Standards and Technology (NIST) Center for Neutron Research. Rietveld structure refinements[9] were performed with the GSAS package.[10]

Upon heating Pb-rho in the *in situ* synchrotron X-ray diffraction experiment, two distinct regions of cell contraction are observed (Fig. 1): a rapid decrease in cell length between 25 and 75 °C, and a second, more gradual decrease up to a temperature of approximately 500 °C. Rietveld refinements using these data indicate that the abrupt cell contraction is related to a conversion from the centric to the acentric form and that the gradual decrease in the unit cell length is coupled with a migration of Pb^{2+} from the S8R to the D8R site. Neutron powder diffraction studies were performed on partially deuterated Pb-rho.¶ Data were collected at room temperature on the sample dehydrated under vacuum at 250 °C. This sample was then heated to 550 °C under active vacuum ($< 10^{-4}$ Pa), and additional data were collected at this temperature and, after cooling *in vacuo*, at room temperature. Difference Fourier analysis of the neutron powder diffraction data collected on the sample dehydrated at 250 °C reveals the presence of D_2O at the D8R site and Pb^{2+} at the S8R site. In contrast, no D_2O is found when the sample is heated to 550 °C, nor when this sample is cooled to room temperature; in these models, Pb^{2+} ions are located at the D8R site, consistent with the changes in the Pb^{2+} occupancy observed from the *in situ* synchrotron X-ray powder diffraction data. The small difference between cell constants in these two samples is consistent with normal thermal expansion ($\approx 0.2\%$).

These results indicate that Pb-rho is not completely dehydrated under the gentle heating conditions that are typically used for dehydration, 200 °C $\leqslant T \leqslant$ 300 °C. Both regions of unit cell contraction are attributable to the loss of water. The first region corresponds to the loss of unbound water, while contraction in the second region can be attributed to the loss of water coordinated to Pb^{2+}. Up to a temperature of approx-

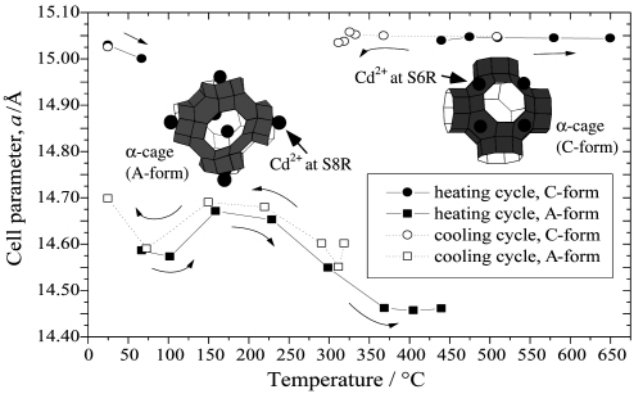

Fig. 2 The cell parameter of Cd-rho heated under air. Schematic diagrams illustrate the siting of Cd^{2+} in the α-cages.

imately 450 °C, both the cell parameter and the composition of the sample are still changing. It is likely that the presence of water strongly correlates with the siting of Pb^{2+} since they change in a concerted manner as a function of temperature. As water leaves the framework, Pb^{2+} must shift towards the D8R site, which provides a better coordination environment for Pb^{2+} in the absence of water. These observations may clarify the observation of the large negative thermal expansion observed for Sr-rho.[2] Since the large-volume, low-temperature phase was collected *in vacuo* at 100 °C and the small-volume, high-temperature phase was collected after heating at 200 °C, it is likely that dehydration was incomplete in the low-temperature phase and the observed negative thermal expansion can be attributed to dehydration.

In situ synchrotron X-ray powder diffraction data indicate that water plays an important role in the greater than 5 Å 'trap door' motion of Cd^{2+} in Cd-rho.[3] Upon heating in either air (Fig. 2) or vacuum (Fig. 3), there is an initial decrease in cell parameter from 25 to 75 °C due to the loss of unbound water, a more gradual change in cell parameter between 75 and 450 °C, then a large increase in the cell parameter which is accompanied by a change from the acentric to centric structure and a relocation of Cd^{2+} from the S8R site to the S6R site. There is a marked difference in the behavior of Cd-rho when cooling under ambient atmosphere (Fig. 2) and vacuum (Fig. 3). With the exception of a small temperature hysteresis, the reaction pathway is directly reversed upon cooling under ambient atmosphere. In contrast, these changes *do not occur* upon cooling under vacuum. These observations indicate that water plays a role in the relocation from the S6R back to the S8R. It is also likely that water acts as a transport agent in the original cation relocation from the S8R to the S6R site; the cell parameter of Cd-rho at 450 °C (14.45 Å) is larger than that of Pb-rho (14.35 Å) although the cationic radius of Cd^{2+} (1.09 Å) is smaller than that of Pb^{2+} (1.33 Å). *In situ* neutron diffraction

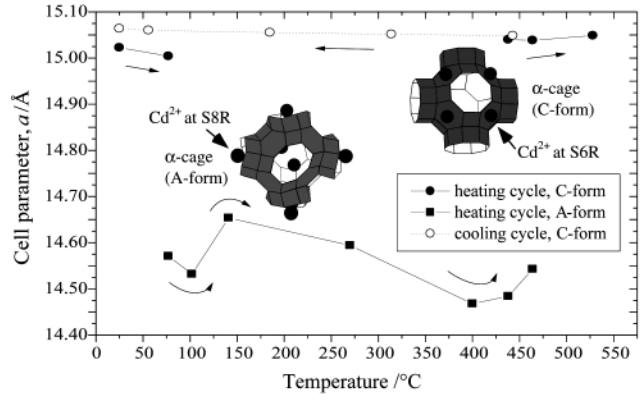

Fig. 3 The cell parameter of Cd-rho heated under vacuum. In the absence of water, there is no phase transformation upon cooling. Schematic diagrams illustrate siting of Cd^{2+} in the α-cages.

studies are planned to determine the siting of D_2O at intermediate temperatures.

There are two modes of cation relocation in zeolite rho: the transition from the S8R site to the D8R site and the 'trap door' relocation from the S8R site to the S6R site. The present work indicates that these relocations are mediated by water. As coordinating water is removed from the structure, extra-framework cations must change their coordination environments by migrating to new sites in order to satisfy their coordination requirements. While dehydration is the driving force for cation relocations, cationic size appears to determine which relocation mechanism occurs. In hydrated samples, all divalent cations studied reside at the S8R site. Even though this site is large, all cations can have their coordination requirements met by binding with water in the sample. Dehydration, and the resulting loss of coordinated water, has a large effect on the cation coordination sphere. Larger cations such as Ca^{2+}, Sr^{2+}, Pb^{2+}, Ba^{2+}, can have their bonding requirements met by relocating to the D8R site. To satisfy the bonding requirements of a smaller cation such as Cd^{2+}, a larger framework distortion must occur. Because of its smaller size, the S6R site presents an attractive binding site in the absence of water. Through water mediation, Cd^{2+} can relocate to this site. Rather than being purely temperature-driven transformations, all cation relocations and the dramatic negative thermal expansion effects observed in zeolite rho appear to be a result of chemical changes that arise from dehydration.

This work was supported by a grant from the National Science Foundation (DMR 97-13375). This work made use of the X7B beamline at the NSLS, supported by the U.S. Department of Energy, Division of Materials Sciences and Division of Chemical Sciences (DEAC02-98CH10886).

Notes and references

‡ Chemical analysis by ICP and microprobe gave unit cell compositions of $Pb_{6.7}Cs_{0.7}Al_{11.7}Si_{36.3}O_{96}{\cdot}wH_2O$ and $Cd_{5.5}Cs_{0.3}Al_{11.7}Si_{36.3}O_{96}{\cdot}wH_2O$ for Pb-rho and Cd-rho, respectively.

§ The sample to detector distance, zero point, and imaging plate tilt were determined from LaB_6 (NIST SRM 660a) prior to the experiment[11] (Cd-rho: λ = 0.9372 Å; Pb-rho: λ = 0.9042 Å). Approximately 3 mg of powdered sample loaded in a 0.5 mm quartz capillary was exposed either to vacuum (< 1 Pa) or ambient atmosphere. A continuous heating or cooling rate between 3 °C min^{-1} and 6 °C min^{-1} was used. Temperatures were calibrated against the thermal expansion of an Ag standard. Data were integrated using FIT2D.[11] Anomalous scattering terms for Cd (f' = −0.53 electrons and f'' = 1.97 electrons) and Pb (f' = −8.76 electrons and f'' = 9.30 electrons) were taken from FPRIME.[10,12]

¶ Samples were deuterated by several cycles of vacuum dehydration at 200 °C (< 10^{-2} Pa) followed by contact with D_2O vapor at room temperature.

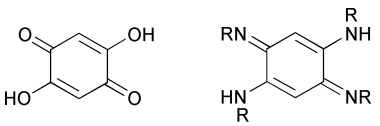
Received (in Cambridge, UK) 24th September 2000, Accepted 10th October 2000
First published as an Advance Article on the web

A new method for the synthesis of *N*,*N*′,*N*″,*N*‴-tetraalkyl 2,5-diamino-1,4-benzoquinonediimines is described together with the structure of a binuclear Pt(II) complex with such a bridging ligand which provides an extended π-system.

The coordination complexes derived from 2,5-dihydroxy-1,4-benzoquinone **1** display many interesting features and possess a rich redox chemistry. Indeed, the deprotonated, enolate form of **1** can react with metal ions to form dinuclear complexes of particular interest owing to the specific electronic properties induced by the quinone system.[1–3] The related 2,5-diamino-1,4-benzoquinonediimines **2a**,**b** could give access to a wider range of metal complexes because of the suitable overlap between the nitrogen and metal orbitals.



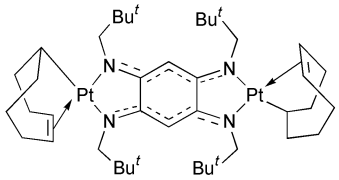
1 **2a**: R = alkyl **2b**: R = H

Such compounds are expected to increase the scope of bonding patterns and electronic delocalization compared to other bridging nitrogen ligands such as terpyridine systems,[4] Creutz–Taube species[5] and *p*-benzoquinonediimine-bridged ligands.[6,7] The direct use of **2b** has been shown to be unsuitable since coordination of metal fragments renders the benzoquinonediimine bridge more susceptible to nucleophilic attack.[8] In contrast, *N*-substitution by electron-donating groups should lead to more stable complexes toward dioxygen and/or water. Since ligands of type **2a** are only accessible by self-condensation of aniline and/or 1,4-diaminobenzene,[9–12] one faces considerable limitations in the nature of the substituents on both types of nitrogen atoms. Here we describe a new strategy to access such ligands and demonstrate their ability to function as bridging chelates in dinuclear chemistry.

Compound **3**·4 HCl was first reacted smoothly in MeCN and excess NEt_3 at room temperature with trimethylacetyl chloride (4 equiv.) to afford **4** which is almost insoluble in most solvents so that only characterization in the solid state is reported (Scheme 1).‡ Reduction of **4** with $LiAlH_4$ in CCl_4 did not lead to the corresponding tetraamino derivative **5** but to yellow **6** which is formed in 18% yield during aerobic work-up. A single crystal X-ray analysis (Fig. 1) established its *p*-benzoquinonediimine form.§ The C(2)–C(3′) bond length of 1.508(3) Å is indicative of the lack of conjugation between the two halves of this 12π electron system[13] and is even slightly longer than the corresponding distance in Bandrowski's base [1.485(6) Å].[14] The π-electron conjugation is thus confined to the upper and lower halves of the ligand. A fast intramolecular double proton transfer involving two tautomers generates in solution a structure of higher symmetry, which accounts for the NMR data.[15]‡

† Dedicated to Professor B. T. Heaton on the occasion of his 60th birthday, with our warmest congratulations and best wishes.

The metallation reaction of **6** with $[PtCl_2(cod)]$ (2 equiv.) at room temperature in CH_2Cl_2 required basic conditions and afforded **7** (*ca*. 15% yield) the ^1H NMR spectrum of which revealed no NH resonances. The molecular structure of **7** was elucidated by X-ray crystallography (Fig. 2).§



7

The molecule is centrosymmetric and the dianion-derived from **6** chelates each of the two Pt centres, thus acting as a tetradentate bridging ligand. The coordination geometry around the platinum centre is square planar, with the metal being only slightly out the molecular plane. The Pt atom completes its coordination with a Pt–C(19) σ-bond [2.12(1) Å] and a Pt–olefinic π-bond [with Pt–C distances of 2.17(2) and 2.140(9) Å]. Accordingly, the Pt···C(18) separation of 2.677(1) is non-bonding. The most striking feature of **7** is that electronic delocalization of the π-system occurs, in contrast to **6**, and is confined to the upper and lower halves of the ligand, as shown by the C(1)–C(2) bond length of 1.53(1) Å. The delocalization pathway also differs from that in complexes where the metal centres are linked by substituted *p*-benzoquinonediimines.[6,7] This important feature may be of wider occurrence in such systems than previously believed.[16,17] The molecular structure of **7** indicates that π-backbonding from the Pt orbitals into a π* orbital of the quinonediimine is occurring: the N(1)=C(1), C(1)–

Selected bond lengths (Å) and bond angles (°): C(1)–C(2) 1.358(4), C(1)–C(3) 1.437(3), C(2)–C(3′) 1.508(3), C(2)–N(1) 1.346(3), C(3)–N(2) 1.286(3); C(2)–N(1)–C(4) 124.7(2), C(3)–N(2)–C(9) 120.1(2), C(2)–C(1)–C(3) 121.9(2), C(1)–C(2)–C(3′) 120.8(2), C(1)–C(2)–N(1) 125.7(2), C(1)–C(3)–N(2) 127.7(2), C(3′)–C(2)–N(1) 113.5(2).

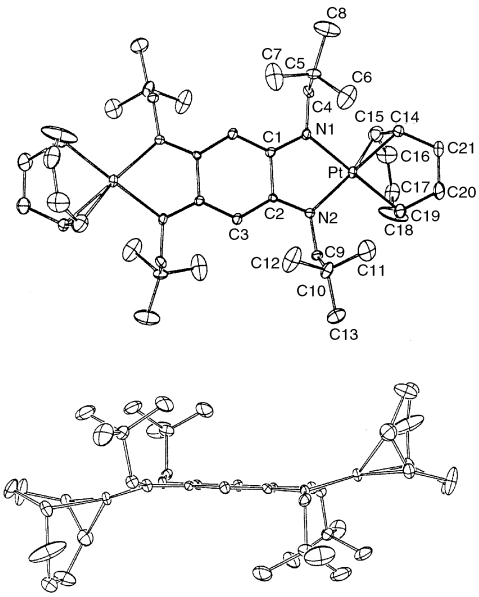

Fig. 2 Top- and side-views of the structure of **7** in the crystal. Selected bond lengths (Å) and bond angles (°): Pt–N(1) 2.082(7), Pt–C(14) 2.140(9), Pt–C(15) 2.17(2), Pt–C(19) 2.12(1), N(1)–C(1) 1.33(1), C(1)–C(2) 1.53(1), C(1)–C(3′) 1.40(1), C(2)–C(3) 1.37(1), C(2)–N(2) 1.33(1); N(1)–Pt–N(2) 78.2(3), N(1)–Pt–C(19) 174.2(4), N(2)–Pt–C(19) 99.6(3), C(14)–Pt–C(15) 36.4(4), Pt–N(1)–C(1) 114.5(6), N(1)–C(1)–C(2) 113.5(7), N(1)–C(1)–C(3′) 127.6(7), N(2)–C(2)–C(3) 127.1(7), C(1)–C(2)–C(3) 117.5(7).

C(3′), C(3′)=C(2′) and C(2′)–N(2′) bonds of the bridge show alternating lengthening and shortening relative to those of the free ligand (Table 1). Such differences are also observed in *p*-benzoquinonediimine systems.[7] Complex **7** is the first example of a binuclear complex bridged with ligands of type **2a** and extends previous results on related mononuclear complexes.[18,19] The electronic spectrum of **7** reveals a metal-to-ligand charge transfer (MLCT) absorption at λ_{max} = 504 nm.

Table 1 Comparison of interatomic distances (Å)

	C=N	C–C	C=C	C–N
6	1.286(3)	1.437(3)	1.358(4)	1.346(3)
7	1.33(1)	1.37(1)	1.40(1)	1.33(1)

Further studies on the electronic properties of **7** and analogous molecules are in progress as well as the synthesis of potential new mixed-valence dimers based on **6**.

We thank the Ministère de l'Education Nationale, de la Recherche et de la Technologie and the CNRS for financial support and Dr A. DeCian and N. Kyritsakis for the X-ray structure determinations.

Irradiation (^{60}Co γ-rays) of crystalline bis(but-3-enoato)-zinc, a two-dimensional coordination polymer with a bilayer packing motif, affords isotactic zinc poly(but-3-enoate).

Nearly four decades ago, Morawetz and Rubin demonstrated that ^{60}Co γ-irradiation of alkali metal acrylates and methacrylates produced high molecular weight, atactic polymer.[1] Irradiation of crystalline potassium acrylate **1** (2–8 kGy) led to high molecular weight polyacrylate (M_w = 100 000–400 000) with yields in the range 3–34%. Fankuchen reported that crystals of **1** were orthorhombic, space group $P2_12_12_1$, with a = 20.5, b = 4.15 and c = 5.73 Å.[2] Although structure–reactivity relationships have never been established for this interesting system, the short repeat distance of 4.15 Å requires that the crystal structure of **1** contains short contacts of *ca.* 4.15 Å, and the observed reactivity implies that the intermolecular orientation is appropriate for polymerization. In a recent study, we observed that upon ^{60}Co γ-irradiation, aquabis(but-3-enoato)-calcium **2** undergoes solid-state polymerization to high molecular weight polymer (M_w = 400 000) in high yield (97%).[3] The polybutenoates thus formed are again atactic, as also observed in a recent reinvestigation of polystyrenes formed by heating or irradiation of solid styryl monomers.[4] The crystal structure of **2** contains short –C=C–···–C=C– contacts (3.73–3.90 Å), usually considered as an important criterion for the onset of solid-state reactivity.[5] By contrast to the behavior of salts of vinylic monomers, irradiation or heating of *trans*-but-2-enoates affords a single dimer or trimer in cases where two, four or eight diastereomers are possible.[6–8] The relatively few examples of solid-state polymerization of metal salts of vinylic acids suggested to us that the 'structure–reactivity database' was too small to conclude that stereocontrol during polymerization was either unlikely or impossible for such materials. As part of our program in the discovery of new solid-state reactions, we undertook a study of the structure and reactivity of bis(but-3-enoato)zinc. Preliminary screening of several M^+ and M^{2+} systems with small radii, low coordination number and a high potential for bilayer formation[9] indicated that the zinc salt was both highly crystalline and sensitive to ^{60}Co γ-irradiation.

Anhydrous bis(but-3-enoato)zinc **3** was prepared readily by the slow addition of but-3-enoic acid to a stirred aqueous suspension of $ZnCO_3$. After stirring overnight, excess $ZnCO_3$ was removed by filtration; evaporation of the filtrate gave crystalline **3** in high yield (70–80%). Single crystals of **3** decomposed quickly at room temperature in an X-ray beam, suggesting that this was a highly reactive material. Exposure of **3** to large γ-ray doses resulted in a maximum conversion to polymer **4** of *ca.* 50%. NMR spectra of the crude material indicated the presence of monomer, polymer and a small amount of side product(s). Examples of dose/conversion data to polymer, based on extraction of monomer and side products: 61 kGy/2.9%; 102 kGy/9.8%; 316 kGy/21.9%; 592 kGy/47.8%. Further irradiation did not lead to significantly higher degrees of conversion (1570 kGy/48.9%). The NMR spectrum of the purified product, as the free acid in D_2O–DC1, showed the probable formation of a poly(but-3-enoate): δ_H 1.9–2.2 (2H, br d, CH_2CO_2H), 1.6–1.7 (1H, br), 1.3–1.5 (1H, br), 0.9–1.2 (1H, br); δ_C 180 (C), 29.0–40.5 (CH_2, CH). The stereochemistry of **4** was assigned as isotactic by analogy to the ^{1}H NMR spectrum of polypropylene and the expected shift due to a carboxy group. The backbone methylene protons are non-equivalent in isotactic polypropylene; thus three absorptions are seen for the backbone methylene and methine protons with an integration of 1 : 1 : 1 as in **4**.[10] The backbone methylene protons are equivalent in syndiotactic polypropylene, so that there are only two absorptions for the backbone protons with an integration of 1 : 2. A more complex pattern is observed in atactic polypropylene. The molecular weight of **4**, $\bar{M}_w$ = 2128, $\bar{M}_n$ = 1801, D = 1.2, determined by GPC, is consistent with the formation of a low molecular weight oligomer, containing 8–10 monomer units.

Solid-state polymerization of alkali and alkaline earth acrylates and methacrylates (^{60}Co γ-rays),[1] as well as crystalline styryl monomers (^{60}Co γ-rays or heating)[4] leads to *atactic* polymer. Despite the observed lack of stereocontrol, it now seems apparent that topochemical effects are responsible for at least the *onset* of reactivity in a number of cases;[4,8] later, other factors (*e.g.* crystal degradation) intervene such that the product obtained is atactic. However, elegant studies of methacrylate solid-state polymerization have demonstrated that stereocontrol is indeed operative in the *early* stages of solid-state polymerization.[11,12] The dearth of structural information available for reactive, solid materials containing terminal vinyl groups limits our understanding of the structural factors responsible for solid-state reactivity. With this in mind, but also perhaps in order to provide insight into the isotactic nature of the product as well as the maximum *ca.* 50% conversion, we carried out an X-ray structure determination of **3**. The structure determination was carried out at 173 K on a Nonius Kappa-CCD diffractometer in order to prevent the X-ray induced decomposition observed at room temperature on a conventional diffractometer; no decomposition was observed at 173 K on the CCD instrument.

The crystal structure of **3** consists of tetrahedral zinc ions, bridged infinitely by two symmetry-independent but-3-enoate moieties.† The result, shown in Fig. 1, is a two-dimensional coordination polymer, roughly parallel to crystal *bc* planes. As

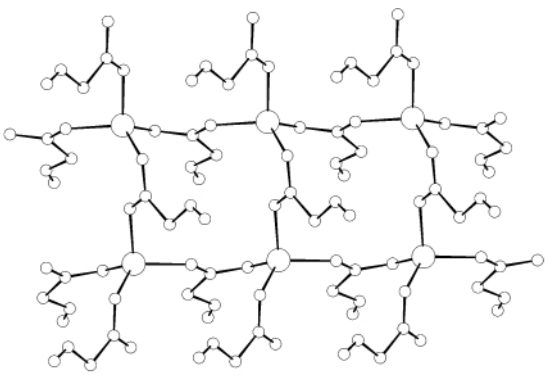

Fig. 1 View of the two-dimensional coordination polymer in **3** showing zinc ions bridged in a *syn, anti*-fashion by the but-3-enoate ligands.

DOI: 10.1039/b007334m

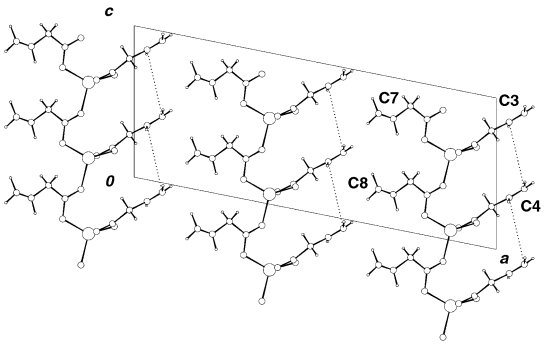

Fig. 2 View of the unit cell of **3**, showing C(3)···C(4) contacts of 4.21 Å (dotted lines), and identification of the 'unreactive' vinyl group [C(7), C(8)], separated by 4.42 Å (no connection shown).

shown in Fig. 2, the two-dimensional coordination polymers pack in a bilayer motif. Bilayer packing arrangements occur with >90% frequency for metal carboxylate coordination polymers where the acids have ⩾4 carbon atoms.[9] As we have described previously, the two-dimensional coordination polymer, generated by metal carboxylate interactions, including carboxylate bridging, serves as a bifunctional template.[13] The first function of such a template is to generate a bilayer structure: the organic tails of the carboxylate groups will be oriented in a roughly perpendicular direction to the bilayer. Secondly, depending on the nature of the bridging, the tails may be forced into very short contact. In the crystal structure of compound **3** (Fig. 2), one set of but-3-enoates is nearly parallel (interplanar angle 9.1°), with a C(3)–C(4) ($x, -2-y, z-\frac{1}{2}$) distance of 4.21 Å. The other set of but-3-enoates are separated, within the bilayer, by a minimum distance C(7)–C(8) ($x, -2-y, z-\frac{1}{2}$) of 4.42 Å and an interplanar angle of 119.0°. There are pairs of 'dimeric' contacts *across* the bilayer [C(3)–C(8) ($\frac{1}{2}+x, \frac{1}{2}+y, z$), 4.01 Å, not shown in Fig. 2]. While such contacts might lead to a dimeric product and may account for observed traces of side product, the resultant reaction pathway cannot account for polymer formation. Thus the 'head-to-head', nearly parallel arrangement shown in Fig. 2 leads to isotactic polymer, in a genuine topochemical fashion.[5] Further, since the C(7)=C(8) double bonds are separated by an amount significantly greater than 4.2 Å,[5] no reactivity is observed (or expected) for this set of but-3-enoates, and the maximum yield possible will be 50%. Topochemical factors thus control both the product stereochemistry and the extent of reaction.

In summary, we have discovered a new solid-state reaction that leads to isotactic oligomer. Such an event is unprecedented for reactive solid materials containing terminal vinyl groups. The present case, as well as the trimerization of sodium *trans*-but-2-enoate[7] to yield sodium (2*R**,3*R**,4*S**,5*R**)-2,4-dimethylhept-6-ene-1,3,5-tricarboxylate **5** represent the only two examples of high-yield, solid-state oligomerization reactions of compounds containing RCH=CH– groups that lead to stereoregular products. The formation of both **4** and **5** lend strong support to the ideas advanced some time ago by the groups of Morawetz and Lando, that the early stages of solid-state polymerization often show strong evidence of stereoregularity, and thus likely occur under topochemical control.[11,12] Further, the stereoregularity observed for **4** and **5** may represent a 'snapshot' of the early stages of a broader class of solid-state polymerization reactions. The synthesis, structure determination and solid-state polymerization of related new materials will help to uncover additional examples that clarify this issue. Such experiments, as well as conventional and 'tail' UV-irradiation[14] of **3**, are underway in our laboratories.

We thank the National Science Foundation (DMR-9629994) for the partial support of this research.

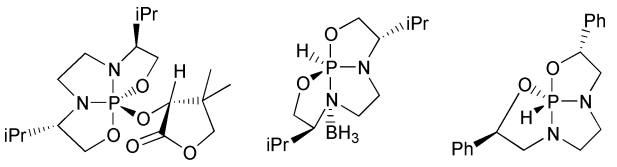
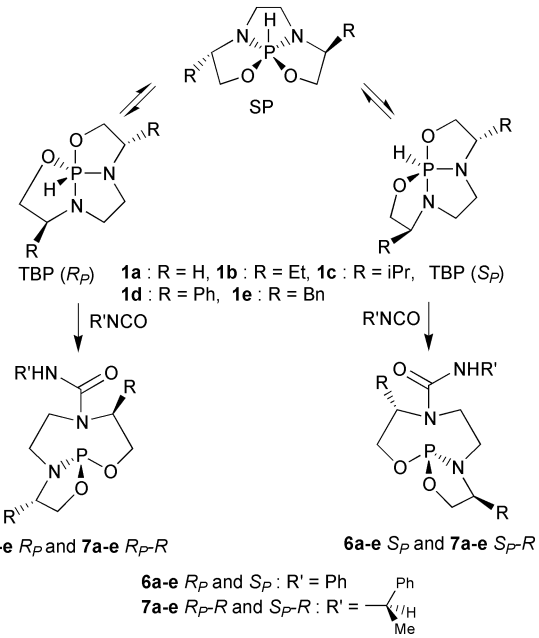
Received (in Liverpool, UK) 18th July 2000, Accepted 3rd October 2000
First published as an Advance Article on the web

Asymmetric addition of isocyanate compounds on chiral triquinphosphoranes, tricyclic hydridophosphoranes, led by a total diastereoselective opening of the diazaphospholidine ring. This provides chiral bicyclic oxazaphospholidines in which an eight-membered ring is fused to the oxazaphospholidine ring by the P–N bond.

Chiral tricoordinated organophosphorus compounds containing an oxazaphospholidine ring have been applied with success in enantioselective catalysis[1] and in asymmetric synthesis.[2] We wish to report herein an original synthesis of new enantiopure bicyclic oxazaphospholidines based on the reaction between isocyanate compounds and chiral triquinphosphoranes.‡ This new class of chiral tricyclic phosphoranes was synthesized from enantiopure diaminodiols having a C_2 symmetry axis.[3] Those phosphoranes exist as two trigonal bipyramid structures (TBP) with opposite absolute configuration at the phosphorus atom, R_P and S_P, in fast equilibrium by a Berry pseudorotation process *via* a SP transition state (Scheme 1).[3,4] We have described the first asymmetric addition of chiral triquinphosphorane **1c** to ketopantolactone and to $BH_3{\cdot}SMe_2$ complex leading to chiral alkoxyphosphorane[3c] **2** and chiral triquinphosphorane–borane[3b] adduct **3**, respectively. The X-ray diffraction structure of **3** revealed that the borane group coordinated to the axial nitrogen atom of the TBP structure is in the *syn* position with respect to the P–H bond and in the *anti* position with respect to the adjacent pseudoaxial isopropyl substituent.[3b,5] Phenyl isocyanate **4** and (*R*)-phenylethyl isocyanate **5** reacted readily with the triquinphosphoranes **1a**–**e**[6] to afford chiral bicyclic oxazaphospholidines **6a**–**e** and **7a**–**e**, respectively, in which an eight-membered ring is fused to the oxazaphospholidine ring by the P–N bond (Scheme 1).



2 **3** **9**



Scheme 1 Pseudorotation process and addition of isocyanates **4** and **5** on triquinphosphoranes.

Oxazaphospholidines **6a** and **7a** were formed in quantitative yield by direct reaction of the parent triquinphosphorane **1a** with isocyanates **4** and **5**, respectively, in toluene solution at −30 °C. The exclusive formation of these new compounds could be monitored by ^{31}P NMR spectroscopy showing only one downfield singlet at 130.1 ppm for racemic **6a** and two signals at 130.70 and 130.77 ppm for **7a** in a 1:1 ratio corresponding to the diastereomers **7a**-R_P and **7a**-S_P. Due to the high energy barrier for the epimerization of the tricoordinated phosphorus atom (30–35 kcal mol^{-1}),[7] this result shows that no dynamic chiral discrimination occurred during the attack of chiral isocyanate **5** on the two enantiomeric structures **1a**-R_P and **1a**-S_P in fast equilibrium.

In the case of chiral triquinphosphoranes **1b**–**e**, ^{31}P NMR monitoring showed that condensation of isocyanates **4** and **5** occurred with a total diastereoselective opening of the diazaphospholidine ring, to afford a single diastereomer as shown by the ^{13}C and ^{31}P NMR spectra. Compound **7e** reacted with $BH_3{\cdot}SMe_2$ complex in toluene solution to give the borane adduct **8** in which the borane is coordinated to the phosphorus atom (δ ^{31}P: 120.3 ppm). The structure of adduct **8** and the absolute configuration of the phosphorus atom were determined by single X-ray diffraction (Fig. 1).[8] The nitrogen, oxygen, and boron atoms around the phosphorus center adopt a slightly distorted tetrahedral arrangement with bond angles between 95.0 and 119.8°. Because the complexation of borane occurs with retention of configuration at the phosphorus atom, the borane adduct shows that the diastereoselective opening of the diazaphospholidine ring led to a tricoordinated compound with the S_P absolute configuration. The shortness of the P1–N6 bond [1.637(5) Å instead of 1.67–1.70 Å usually][9] can in part be assigned to negative hyperconjugation, due to electron donation from π_N to σ^*_{P-B} orbitals.[10] In fact the N6 nitrogen exhibits a planar configuration [sum of bond angles 359.8(4)°].

The newly formed eight-membered ring adopts a twist–boat–chair conformation and the five-membered ring a slightly flattened envelope conformation with the C19 atom as the tip. The benzyl group bound to the C11 carbon of the oxazaphospholidine ring is in the *syn* position with respect to the boron atom whereas the benzyl group bound to the C9 carbon of the eight-membered ring is in the *anti* position.

Taken together, these results suggest that just like borane,[3b] isocyanates attack preferentially the least hindered axial nitrogen atom of the S_P phosphorane diastereomer (Scheme 2).

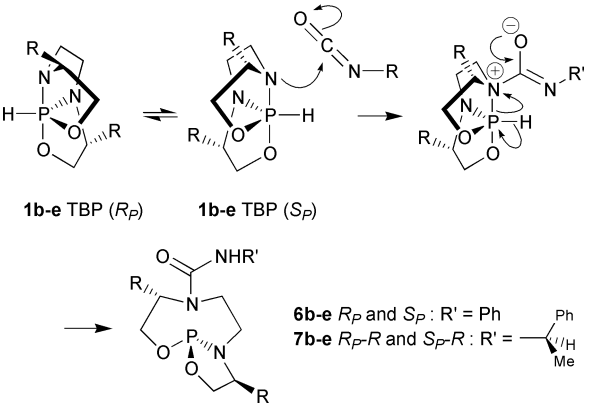

Scheme 2 Addition mechanism of isocyanates **4** and **5** on triquinphosphoranes **1b**–**e**.

In fact, the TBP-S_P, the pseudoaxial substituent is in an *anti* position with respect to the lone pair of the axial nitrogen atom whereas it is in a *syn* position in TBP-R_P. The diastereoselectivity observed can thus be rationalized in terms of a kinetically controlled process in which the minor triquinphosphorane diastereomer (29%) reacts faster than the major one (71%) to afford only one diastereomeric oxazaphospholidine.[4]

The importance of steric factors was further confirmed by the fact that the diastereoselectivity of the isocyanate addition depends on the position of the substituents. Indeed, in the case of triquinphosphorane **9**,[11] in which the phenyl substituents are β to the nitrogen atom, the diastereoselectivity of the addition of isocyanates **4** and **5** decrease to 77 and 93%, respectively.

In summary, we disclose for the first time the formation of enantiomerically pure P^{III} oxazaphospholidines from chiral pentacoordinated phosphoranes. These new compounds feature an eight-membered ring, difficult to synthesize with classical methods.[12] Research to evaluate the efficiency of these new compounds in asymmetric catalysis either as ligands or as catalysts is in progress.

We gratefully acknowledge financial support from the CNRS and fellowships from the MNRT (C. M. and G. D.). We thank Dr M. Giorgi and Professor M. Pierrot from the 'Université d'Aix-Marseille' for the X-ray structure determinations.

A new SO_4^{2-}/ZrO_2/MCM-41 superacid catalyst has been successfully synthesized and is *ca*. 2.5–3 times more active than the conventional SO_4^{2-}/ZrO_2 superacid catalyst for MTBE synthesis and *n*-pentane isomerization.

It is well known that zirconia, when modified with anions such as sulfate, forms a highly acidic or superacidic catalyst. In recent years, sulfated zirconia superacids have attracted increasing attention because these catalysts are found to be well suited for catalyzing reactions of industrial importance, such as hydrocarbon isomerization, etherification reactions, *etc*.[1–8] However the non-uniform pore size and relatively small surface area of SO_4^{2-}/ZrO_2 may limit its potential application for catalyzing bulky molecules. The use of M41s and other mesoporous materials,[9–12] which have very uniform mesopores and very high surface area, as catalyst supports for SO_4^{2-}/ZrO_2 should greatly expand the catalytic properties and capabilities of SO_4^{2-}/ZrO_2 for some applications. This is because such mesoporous materials, which have relatively small diffusion hindrance, can aid the diffusion of bulky organic molecules in and out of their mesopores quite easily.[9] Although many superacid catalysts have been developed using silica, alumina and microporous zeolites as supports,[2–8] there are still many limitations in their applications because of diffusion problems. Although a direct preparation of mesoporous sulfated zirconia has been recently reported,[13] the resulting materials had relatively small surface areas compared to that of conventional SO_4^{2-}/ZrO_2 and they were not tested for a particular reaction. Up to now, no silica-based M41s superacid materials nor gas-phase synthesis of MTBE from methanol and *tert*-butyl alcohol on acidic mesoporous catalysts have been reported. In this work, the active superacid SO_4^{2-}/ZrO_2 component has been successfully supported on the surface of MCM-41 to form a new SO_4^{2-}/ZrO_2/MCM-41 superacid catalyst, which is found to be 2.5–3 times more active than the conventional SO_4^{2-}/ZrO_2 superacid catalyst for MTBE synthesis and *n*-pentane isomerization.

$Zr(OH)_4$ was supported onto the surface of MCM-41 through chemical liquid deposition and hydrolysis of $Zr(OPr^n)_4$. Pre-dried siliceous MCM-41 powder having a BET surface area of 1311 $m^2\ g^{-1}$ and a pore diameter of 31.1 Å was dispersed into a mixed solution of $Zr(OPr^n)_4$ and *n*-hexane under vigorous stirring. After evaporating off the solvent, the solid was transferred into a glass container containing an NaCl-saturated aqueous solution at the bottom of the container in order to achieve complete hydrolysis at room temp. overnight. Pure $Zr(OH)_4$ was also prepared through hydrolysis of anhydrous $ZrCl_4$ in ammonia solution with a pH of 9–10.[3] After drying both samples at 100 °C overnight, the two resulting solids were immersed into 0.5 M H_2SO_4 solution at room temp. for 30 min. The sulfated $Zr(OH)_4$/MCM-41 and $Zr(OH)_4$ were then filtered off, dried at 100 °C overnight and calcined at 600 °C in air for 3 h to form SO_4^{2-}/ZrO_2/MCM-41 and SO_4^{2-}/ZrO_2. The content of ZrO_2 in the SO_4^{2-}/ZrO_2/MCM-41 catalyst was analyzed by ICP to be *ca*. 41 wt%. It should be noted that, when $ZrCl_4$ was used as a precursor in the preparation of $Zr(OH)_4$/MCM-41, the mesoporous structure of MCM-41 collapsed in the basic medium required for the hydrolysis of $ZrCl_4$.

XRD was used to characterize the regular mesoporous structure of MCM-41 and the resulting crystalline phase of bulk and supported ZrO_2. Fig. 1 shows that, for SO_4^{2-}/ZrO_2 calcined at 600 °C, three intense diffraction peaks at *ca*. 30, 50 and 60° and several small peaks at *ca*. 35 and 62° can be observed. These diffraction peaks show the presence of the tetragonal ZrO_2 crystalline phase, rather than the monoclinic ZrO_2 phase, and the absence of other impurities. This result shows that the introduction of SO_4^{2-} anions can remarkably stabilize the metastable tetragonal ZrO_2 phase, which is known to be an ideal crystalline phase for high catalytic activity.[2,4,6] The XRD pattern of SO_4^{2-}/ZrO_2/MCM-41 shows three clear and intense peaks below 10°, showing that the regular hexagonal mesostructure of the MCM-41 support is still maintained even after it has gone through the processes of chemical liquid deposition of ZrO_2, impregnation of sulfuric acid and high-temperature calcination. Furthermore, only a very small XRD peak at *ca*. 30° is observed on SO_4^{2-}/ZrO_2/MCM-41, showing that most of the ZrO_2 has been highly dispersed on the MCM-41. However, when this XRD picture is enlarged 5 ×, three diffraction peaks at *ca*. 30, 50 and 60° can be observed. This shows that, under very high loading of zirconia, a very small amount of ZrO_2 clusters (present as tetragonal ZrO_2 phase) might be formed within or outside the MCM-41 structure. BET analyses show that SO_4^{2-}/ZrO_2/MCM-41 (686 $m^2\ g^{-1}$) has a much larger surface area than SO_4^{2-}/ZrO_2 (101 $m^2\ g^{-1}$). The pore size of SO_4^{2-}/ZrO_2/MCM-41 (29.1 Å) is less than that of MCM-41 (31.1 Å), showing that the supported ZrO_2 has been dispersed onto the surface of mesopores of MCM-41.

The *in situ* FTIR spectrum of SO_4^{2-}/ZrO_2 measured after evacuation at 400 °C for 2 h shows an absorption band at 1378 cm^{-1}, corresponding to the asymmetric stretching frequency of covalent S=O; this band is often regarded as the characteristic

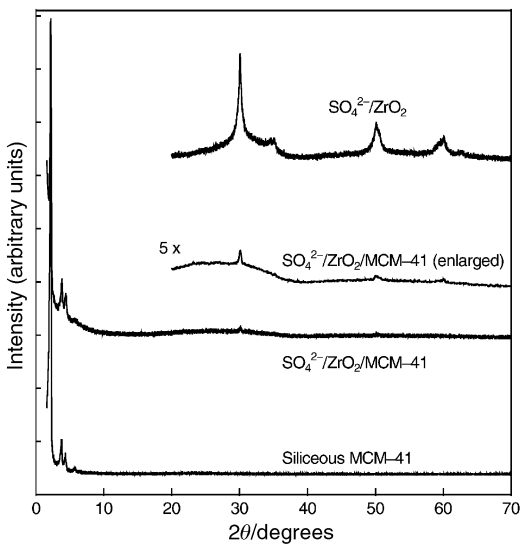

Fig. 1 XRD patterns of SO_4^{2-}/ZrO_2 and SO_4^{2-}/ZrO_2/MCM-41 superacid catalysts calcined in air at 873 K for 3 h and of siliceous MCM-41.

† Electronic supplementary information (ESI) available: characterization data for catalysts. See http://www.rsc.org/suppdata/cc/b0/b006051h/

DOI: 10.1039/b006051h

band of SO_4^{2-} on promoted superacids.[2–4,6] This band shifts to 1363 cm^{-1} for SO_4^{2-}/ZrO_2/MCM-41; the shifting is attributed to the influence of the interaction between ZrO_2 and framework SiO_2. TGA spectra show that both samples display common double-stage weight-loss features: the first below 200 °C (due to the evaporation of physically adsorbed water and other molecules), and the second between 580 and 900 °C (attributed to the removal of SO_4^{2-} species interacting with ZrO_2). The similarities of the decomposition temperature between these two samples indicate that the distribution of SO_4^{2-} species on both SO_4^{2-}/ZrO_2 and SO_4^{2-}/ZrO_2/MCM-41 is quite similar. Based on the amount of weight loss, SO_4^{2-}/ZrO_2 and SO_4^{2-}/ZrO_2/MCM-41 calcined at 600 °C contain 5.8 and 7.6 wt% of sulfate ions, respectively. Since the ZrO_2 content in SO_4^{2-}/ZrO_2/MCM-41 is nearly half of that in SO_4^{2-}/ZrO_2, this result shows that the highly dispersed ZrO_2 on MCM-41 can expose more ZrO_2 and adsorb more SO_4^{2-} anions than bulk crystalline ZrO_2.

The acid strengths of SO_4^{2-}/ZrO_2 and SO_4^{2-}/ZrO_2/MCM-41 samples calcined at 600 °C for 3 h were measured by the change of the color of a Hammet indicator added to the dried powder sample dissolved in the solvent. Both samples are found to have an H_0 value around −13.8 (measured in 2,4-dinitrotoluene), a typical value for superacids,[2–6] showing that they are *ca.* $10^4\times$ more acidic than 100% H_2SO_4. After calcination at 650 °C for 3 h, the acid strengths for both samples were increased to H_0 *ca.* −16.0 (measured in 1,3,5-trinitrobenzene).

Pyridine adsorption *in-situ* IR spectra were measured for both samples to measure the presence of Bronsted and Lewis acid sites. This was done by first pretreating a self-supporting wafer (15 mg) of the sample at 400 °C for 3 h under a vacuum of 10^{-6} mbar before adsorbing an excess of pure pyridine at room temperature, followed by evacuation at 200 °C for 30 min.[8] FTIR spectra on these two superacid catalysts show that they contain strong Bronsted acidity (at 1540 cm^{-1}) and Lewis acidity (at 1450 cm^{-1}). The intensities of Bronsted acid (having an integrated area of 1.20) and Lewis acid (having an integrated area of 1.43) sites of SO_4^{2-}/ZrO_2/MCM-41 are much stronger than the Bronsted acid (0.70) and Lewis acid (1.00) sites of SO_4^{2-}/ZrO_2. Both TGA and FTIR results show that SO_4^{2-}/ZrO_2/MCM-41 has more exposed Bronsted and Lewis acid sites than SO_4^{2-}/ZrO_2.

For the isomerization of *n*-pentane, which is a model reaction for characterizing the catalytic properties of these superacid catalysts, 0.5 g of powder catalyst was placed in a glass batch reactor and activated in vacuum at 250 °C for 3 h before 1 ml of pure *n*-pentane was introduced into the reactor and the reaction carried out at 60 °C under vigorous stirring. For the gas-phase synthesis of MTBE from MeOH and Bu^tOH in a fixed-bed reactor, the catalyst (0.20 g) was dehydrated in a flow of helium before a mixture of MeOH and Bu^tOH (with a molar ratio of 10:1 and a WHSV of 10 h^{-1}) was pumped into the reactor heated at 140 °C. Table 1 shows that both superacid catalysts have rather high activities for both reactions, with SO_4^{2-}/ZrO_2/MCM-41 always showing higher catalytic activity than SO_4^{2-}/ZrO_2. For the isomerization of *n*-pentane, the TON of SO_4^{2-}/ZrO_2/MCM-41 is almost 3 × that of SO_4^{2-}/ZrO_2, while the selectivity of product to isopentane is 98–99% for both catalysts. Increasing the batch reaction time gradually increases the TON of both catalysts to approach the equilibrium value. For the synthesis of MTBE, the TON of SO_4^{2-}/ZrO_2/MCM-41 is nearly 2.5 × that of SO_4^{2-}/ZrO_2, while a complete selectivity to MTBE is obtained on both catalysts. With an increase of reaction time, the TON of both catalysts remain almost unchanged. The reaction results show that the higher catalytic activity of SO_4^{2-}/ZrO_2/MCM-41, as compared to SO_4^{2-}/ZrO_2, is attributed to the increase of the number of active acid sites due to the highly exposed and easily accessible active sites of SO_4^{2-}/ZrO_2 on the surface of MCM-41. All of these results further elucidate the advantages of using a high BET surface area and uniform mesoporous material as a support for superacid catalysts for MTBE synthesis and other acid-catalyzed organic reactions in the future.

Table 1 Catalytic activities of SO_4^{2-}/ZrO_2 and SO_4^{2-}/ZrO_2/MCM-41 superacid catalysts

		SO_4^{2-}/ZrO_2		SO_4^{2-}/ZrO_2/MCM-41	
Reactant	*t*/min	TON[a]	Selec.(%)	TON[a]	Selec.(%)
n-Pentane	60	0.27	98[b]	0.81	100[b]

First published as an Advance Article on the web 31st October 2000

The fabrication of a new bilayer TiO_2/Nb_2O_5 nanoporous electrode that improves the performance of dye sensitized solar cells by more than 35% is reported.

The high light-to-energy conversion efficiencies achieved with dye sensitized solar cells (DSSCs) may be attributed to the nanoporous TiO_2 electrodes.[1] These electrodes consist of nanosize semiconductor colloids that are sintered on a transparent conducting substrate resulting in a porous geometry and a very large surface area. Both the low absorbance of dye monolayers and the low efficiency of dye multilayers necessitate the large surface area. However, the resulting electrode geometry introduces special characteristics, some of which reduce the performance of the DSSCs.[2–4] One of these characteristics relates to the small size of the individual colloidal particles that cannot support a high space charge.[2,4,5] In other words an energy barrier is not formed at the electrode–electrolyte interface.

Upon illumination of a DSSC, an electron is injected from the dye into the TiO_2 film followed by a hole transfer to the electrolyte[1,6] The injected electrons must cross the TiO_2 film and reach the conducting substrate, while the oxidized ions diffuse towards the back electrode where they are re-reduced.[1,6] The porous geometry that permits the presence of the electrolyte through the entire electrode provides a high surface area for recombination between the injected electrons and the holes in solution[2,7] In the absence of an energy barrier at the electrode–electrolyte interface, the rate of this recombination process may be very high depending on the properties of the hole carrier.[2,5,8,9] For this reason, DSSCs utilizing the I^-/I_3^- redox couple perform better than similar cells consisting of faster couples.[10] Furthermore, part of the low efficiencies observed with solid electrolytes is attributed to this recombination process.[3] The formation of an energy barrier at the surface of the TiO_2 electrode that will enable the use of various mediators has the prospect of improving the performance of DSSCs significantly.

We report here on the fabrication of a nanoporous wide band gap semiconductor electrode that has an inherent energy barrier at its surface. To the best of our knowledge, this is the first time such an electrode has been reported. The new electrode consists of an inner nanoporous TiO_2 matrix covered with a thin layer of Nb_2O_5. The conduction band potential of Nb_2O_5 (0 V *vs.* NHE at pH 0) is *ca.* 100 mV more negative than that of the TiO_2.[11] As illustrated in Fig. 1, this potential difference forms an energy barrier at the electrode–electrolyte interface, which can reduce the rate of recombination processes of the photoinjected electrons. A comparison of two similar DSSCs that differ only in their nanoporous electrodes, shows that the new bilayer electrode is superior to the standard one with respect to all cell parameters. This superiority measured with many cells results in a 35% increase of the overall conversion efficiency.

The TiO_2 nanoporous matrix of 6 μm thickness was prepared from colloids with particles of 23 nm diameter. The colloid and the matrix preparation methods are reported elsewhere.[12] The Nb_2O_5 coating was prepared by dipping the sintered TiO_2 matrix in a dry solution of 0.005 M niobium isopropoxide in isopropyl alcohol for 30 s, followed by washing with dry isopropyl alcohol and sintering at 500 °C in air for 30 min. The dipping was performed under dry nitrogen atmosphere. The thickness of the electrode measured with a Mitutoyo, Surftest SV 500 profilometer did not change upon coating. XPS measurements of the coated electrodes show that the average metal mol fraction of Nb was 36% with the remainder Ti. Given this molar ratio, a 2.7 nm thick Nb_2O_5 layer is calculated when assuming that the TiO_2 colloids are spherical and single sized, and that the Nb_2O_5 coating is uniform.

A sandwich-type configuration was employed to measure the DSSCs. A Pt coated F-doped SnO_2 film was used as a counter electrode, and 0.5 M Li/0.05 M I_2 in 1 : 1 acetonitrile–NMO was used as electrolyte. The dye [*cis*-di(isothiocyanato)-*N*-bis(4,4′-dicarboxy-2,2′-bipyridine)ruthenium(II), (N3)] was adsorbed by immersing the electrodes overnight in a 0.5 mM ethanol solution of the dye. The oxidation potential of the dye (*ca.* 1.09 V *vs*. NHE in acetonitrile) is sufficient to allow injection into both TiO_2 and Nb_2O_5.[11] The amount of dye adsorbed on the electrode was measured by visible absorption of the electrode using a HP 8453 spectrophotometer. Illumination of the cell was conducted using a calibrated Xe lamp. IPCE measurements were performed using a ScinceTech 9010 monochromator scaled to 6 nm bandwidth.

We describe here a comparison of two typical DSSCs that differ in their type of electrode. One cell contained the new bilayer electrode and the other served as a reference, consisting of a standard nanoporous TiO_2 electrode. Both cells were studied under similar conditions. The reference electrode and the TiO_2 matrix were made from the same batch and separated only after the first sintering process. After the Nb_2O_5 coating of the TiO_2 matrix was performed, both electrodes were sintered again to ensure similarity. The thickness of both electrodes was 6 μm, and the same amount of dye was adsorbed on both films as confirmed by absorption spectra. Finally, the undyed electrodes had the same transparent appearance showing transmission spectra that differed slightly only in the band gap region. Under illumination equivalent to sunlight, Nb_2O_5 coating of the TiO_2 resulted in an increase of all cell parameters. The photocurrent increased from 10.2 to 11.4 mA cm^{-2}, the photovoltage from 659 to 732 mV, and the fill factor from 51.1 to 56.4%. As a result, the maximum power of the cell was increased from 3.45 to 4.70 mW cm^{-2}.

The improved cell performance achieved by the new bilayer electrode may be attributed to the energy barrier formed by the

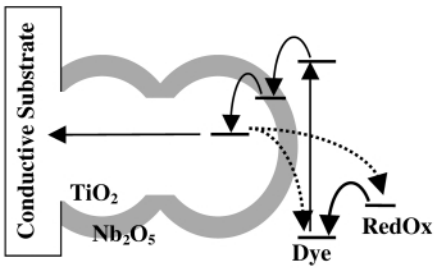

Fig. 1 A schematic view of the new bilayer nanoporous electrode which consists of a nanoporous TiO_2 matrix covered with a thin layer of Nb_2O_5. The Nb_2O_5 coating forms an inherent energy barrier at the electrode–electrolyte interface, which reduces the recombination rate of the photoinjected electrons.

DOI: 10.1039/b005921h

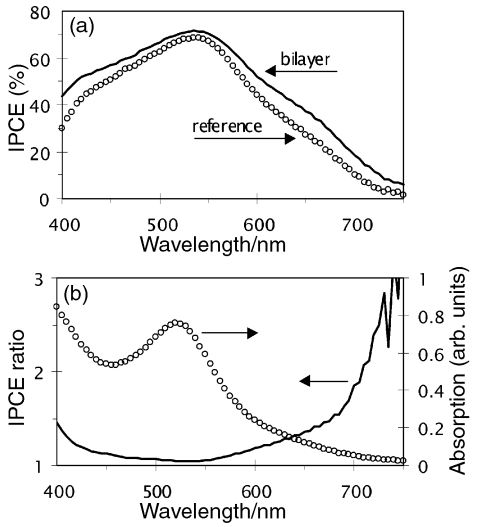

Fig. 2 (a) IPCE curves of the reference dye sensitized solar cell and the cell containing the bilayer electrode. The IPCE curves resemble the absorption spectrum of the electrodes shown in (b) which shows the ratio between the IPCE values of the two solar cells as a function of the illumination wavelength revealing its wavelength dependence.

deposition of the thin Nb_2O_5 layer. The Nb_2O_5 layer apparently decreases the rate of recombination of the photoinjected electrons with the dye and the electrolyte. This phenomenon is revealed best from incident photon to current efficiency (IPCE) measurements for the two cells. As shown in Fig. 2(a) the curves of both cells resemble the absorption spectrum of the N3 dye. The measured IPCE values of the cell containing the bilayer electrode are higher than those of the reference cell throughout the visible spectrum. However, the improvement in the conversion efficiency is wavelength dependent as indicated by the ratio between the IPCE values of the two cells (the improvement factor). Fig. 2(b) shows that this factor increases at illumination wavelengths in which the absorption coefficient of the dye becomes low.

The improved performance evident from Fig. 2(a) is not necessarily the result of a change in the collection efficiency. This improvement can be related to other factors, such as the injection yield.[1] However, the wavelength dependence of the improvement factor can be directly related to the electron collection.[13] The mean distance a photoinjected electron must diffuse in order to reach the current collector increases as the absorption coefficient of the dye decreases thus changing the light absorption profile. This phenomenon means that recombination events are expected to increase as the absorption coefficient of the dye decreases.[13] In other words, a change in the rate of recombination is expected to have a more significant effect at the low dye absorption coefficient regions. Fig. 2(b) indicates that this is the case of the new bilayer electrode.

The results presented above clearly demonstrate that the bilayer electrodes are superior to the standard single material nanoporous electrodes in terms of the performance of DSSCs. These results suggest that the improvement is achieved by the formation of an energy barrier at the electrode–electrolyte interface, which slows the recombination process. However at this stage of research we lack information on the quality of the coating with respect to its homogeneity throughout the film which affects the ability to determine the exact thickness of the coating. In addition, it is still unclear to what extent the new electrode can improve the performance of DSSCs in which mediators other than the I^-/I_3^--based electrolyte are used. Research towards better understanding of this system and further performance improvement are currently being undertaken.

We thank the National Center for Photovoltaics at NREL and The Israel Science Foundation founded by The Israel Academy of Science and Humanities for supporting this research.

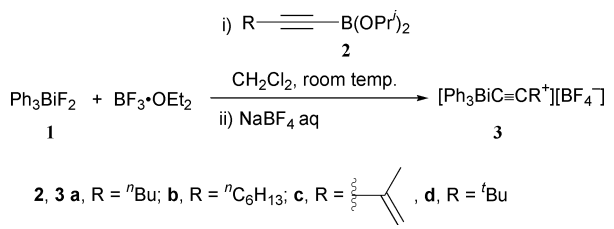
Received (in Cambridge, UK) 23rd August 2000, Accepted 2nd October 2000
First published as an Advance Article on the web

Treatment of triphenylbismuth difluoride with alkynyldiisopropoxyboranes in the presence of BF_3·OEt_2 in CH_2Cl_2 gives alkynyltriphenylbismuthonium tetrafluoroborates, which react with sodium *p*-toluenesulfinate in dual reaction modes depending on the solvents employed.

The chemistry of onium salts with an acetylenic group on the cationic heteroatom constitutes an attractive area of study in terms of both heteroatom and acetylene chemistry.[1] In general, three reaction sites are conceivable for this class of compounds: the heteroatom center, the acetylenic α-carbon and the acetylenic β-carbon. Owing to this diversity, such compounds have recently been utilized as versatile reagents in organic synthesis.[1] However, no information is yet available for alkynylbismuthonium salts owing to the lack of a general method for constructing a Bi–C_{sp} bond. Recently, the Lewis acid-promoted reactions of triarylbismuth difluorides with organometallic reagents have proven to be efficient methods for the preparation of various types of bismuthonium salts bearing a Bi–C_{sp^3} or Bi–C_{sp^2} bond ($[Ar_3BiR^+][X^-]$; R = alkyl, alkenyl, aryl).[2] Owing to the high leaving ability of the triarylbismuthonio group, this class of compounds has been shown to have unique reactivities that differ significantly from those of lighter element counterparts. These results have led me to disclose the nature of the Bi–C_{sp} bond in bismuthonium salts. Reported here are the first synthesis, crystal structure and reactions of alkynyltriphenylbismuthonium salts.

As shown in Scheme 1, alkynyltriphenylbismuthonium tetrafluoroborates **3a–d** were prepared by the reaction of triphenylbismuth difluoride **1** with the corresponding alkynyldiisopropoxyboranes **2a–d**[3,4] in the presence of BF_3·OEt_2 (Table 1).† No Bi–C_{sp} coupling took place in the absence of the Lewis acid, as was observed in the reaction of **1** with other types of organoboronic acids.[2f,g] Compounds **3** were isolated as colorless solids in 88–93% yields by recrystallization from CH_2Cl_2–Et_2O and characterized by NMR, IR and mass spectrometry.



Scheme 1

Table 1 Alkynyltriphenylbismuthonium tetrafluoroborates **3**

Entry	**3**	Yield (%)	Mp/°C
1	**3a** ($[Ph_3Bi^+C{\equiv}C^nBu][BF_4^-]$)	88	137–138
2	**3b** ($[Ph_3Bi^+C{\equiv}C^nC_6H_{13}][BF_4^-]$)	93	83–85
3	**3c** ($[Ph_3Bi^+C{\equiv}CC(Me){=}CH_2][BF_4^-]$)	89	139–141
4	**3d** ($[Ph_3Bi^+C{\equiv}C^tBu][BF_4^-]$)	90	160–161

The structure of **3d** was further determined by X-ray crystallography (Fig. 1).‡ The bismuth center of **3d** adopts a pseudotrigonal bipyramidal (TBPY) geometry with three phenyl *ipso* carbons at the equatorial sites and an acetylenic α carbon and a fluorine atom at the apical sites. The Bi···F(1) distance of 2.749(4) Å is longer than the sum of their covalent radii (2.10 Å) but much shorter than the sum of their van der Waals radii (3.75 Å),[5] indicating that the tetrafluoroborate anion interacts strongly with the cationic bismuth center. Owing to this interaction, the B–F(1) bond is slightly longer than other B–F bonds. The TBPY geometry observed for **3d** may be attributable to the steric as well as electronic character of the acetylenic group: known alkyl-, alkenyl- and aryl-triphenylbismuthonium tetrafluoroborates all adopt a distorted tetrahedral geometry with the spatially separated BF_4^- anion.[2a,b,d,f,g] The Bi–C(1) bond length [2.151(8) Å] is slightly shorter than the Bi–C_{Ph} bond lengths [2.179(9)–2.235(9) Å], reflecting the difference in electronic properties between the C_{sp} and C_{sp^2} atoms. The C(1)–C(2) bond length [1.19(1) Å] is almost identical to that of a typical C≡C triple bond (1.20 Å), and the acetylenic moiety is bent slightly at the C(1) atom. Although the reason for this bent conformation is not clear at present, it might be due to the steric effect caused by the neighboring molecules. In $CDCl_3$, the *ortho* protons of the phenyl groups of **3** were observed at relatively lower field (δ 8.25) than those of tetrahedral bismuthonium salts (δ 7.7–7.8), suggesting that the TBPY geometry of **3** is also maintained in solution.

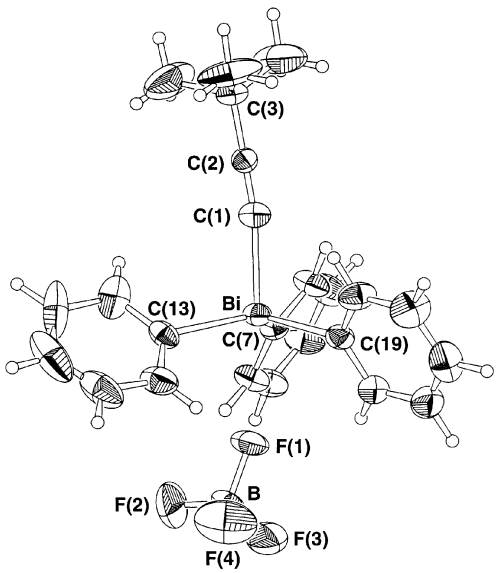


Fig. 1 ORTEP diagram (30% probability ellipsoids) of **3d**. Selected bond lengths (Å) and angles (°): Bi–C(1) 2.151(8), Bi–C(7) 2.210(8), Bi–C(13) 2.235(9), Bi–C(19) 2.179(9), B–F(1) 1.38(1), B–F(2–4) 1.29(1)–1.33(1), C(1)–C(2) 1.19(1), C(2)–C(3) 1.47(1), Bi···F(1) 2.749(4); C(1)–Bi–C(7) 100.1(3), C(1)–Bi–C(13) 98.6(3), C(1)–Bi–C(19) 102.6(3), C(7)–Bi–C(13) 122.1(3), C(7)–Bi–C(19) 111.9(3), C(13)–Bi–C(19) 116.4(3), Bi–C(1)–C(2) 170.9(8), C(1)–C(2)–C(3) 178.6(10).

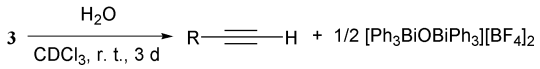
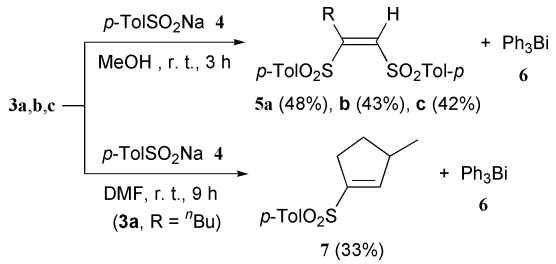
DOI: 10.1039/b006881k

Alkynylbismuthonium salts **3** were slowly hydrolyzed in open air or in wet solution to give μ-oxobis(triphenylbismuth) bis(tetrafluoroborate)[2a] and parent acetylenes (Scheme 2). Thus, it is reasonable to assume that the hydroxy group of water is bound to the bismuth atom. This mode of hydrolysis is in marked contrast to that observed for methyltriphenylbismuthonium tetrafluoroborate, which produces methanol, triphenylbismuthine and fluoroboric acid.[2g] In this case, the hydroxy group is bound to the methyl group. These two results reflect the difference in reactivity between the Bi–C_{sp} and Bi–C_{sp^3} bonds in bismuthonium salts.



Scheme 2

The reaction of alkynyltriphenylbismuthonium salts **3** with a sulfinate anion was examined (Scheme 3). The treatment of **3a** with 2 equiv. of sodium *p*-toluenesulfinate **4** in MeOH afforded (*Z*)-1,2-bis(*p*-toluenesulfonyl)hex-1-ene **5a** (R = ^{n}Bu) in 48% yield together with triphenylbismuthine **6**.§ The (*Z*)-configuration of **5a** was determined by comparison with the spectral properties of analogous compounds[6] as well as by NOE experiment. Compounds **3b** and **3c** also reacted with **4** in MeOH to give the corresponding disulfones **5b** (R = ^{n}C_6H_{13}, 43%) and **5c** [R = C(Me)=CH_2, 42%], respectively, with good recovery of **6**. By contrast, when a similar reaction of **3a** was carried out in DMF, 1-sulfonyl-3-methylcyclopentene **7** was obtained as a major product (33%) and **5a** was not formed at all.§



Scheme 3

Plausible mechanisms for the sulfonylations of **3a** are depicted in Scheme 4. The initial stage in both reactions would be a Michael addition of the sulfinate anion to the β-alkynyl carbon. In MeOH, the resulting ylide **8** would be protonated to produce an alkenylbismuthonium intermediate **9**, which subsequently reacts with the sulfinate anion to give **5** with retention of the configuration.[2d] In DMF, ylide **8** would eliminate bismuthine **6** to generate an alkylidene carbene intermediate **10**, which undergoes 1,5-C–H insertion to give cyclopentene **7**. Similar types of tandem bis-sulfonylation and sulfonylation/C–H insertion reactions were reported for alkynylselenonium[7] and alkynyliodonium salts,[8] respectively. Interestingly, alkynylbismuthonium salts **3** react with the same nucleophile *via* two different pathways depending on the solvents employed.

This work was partially supported by a Grant-in-Aid (No. 12640516) from the Ministry of Education, Science, Sports and Culture of Japan. The author thanks Professor Hiroyuki Furuta and Mr Hazumi Nomura for their assistance with the X-ray crystallography.

Phase-boundary catalysis: a new approach in alkene epoxidation with hydrogen peroxide by zeolite loaded with alkylsilane-covered titanium oxide

Hadi Nur, Shigeru Ikeda and Bunsho Ohtani*

Catalysis Research Center, Hokkaido University, Sapporo 060-0811, Japan. E-mail: ohtani@cat.hokudai.ac.jp

Received (in Cambridge, UK) 1st August 2000, Accepted 4th September 2000
First published as an Advance Article on the web 31st October 2000

An NaY zeolite, modified with partly alkylsilane-covered titanium oxide and located at the boundary between aqueous and organic phases (a phase-boundary catalyst), acts as a catalyst for alkene epoxidation without stirring or the addition of a co-solvent to drive liquid–liquid phase transfer.

Utilization of hydrogen peroxide (H_2O_2) as an oxidant for organic substrates has received much attention in recent years because of its environmental implications; it gives only water as a product in a wide range of oxidation reactions. Moreover, it is less expensive and more accessible than other oxidizing agents, such as organic peracids or hydroperoxides. However, H_2O_2 is generally supplied as an aqueous solution, and when the substrate to be oxidized is insoluble in water, it is necessary to add a co-solvent to obtain a homogeneous reaction mixture.[1,2] Here, we propose a novel integrated chemical system, which we have termed 'phase-boundary catalysis', using aqueous H_2O_2 for the oxidation of organic compounds without any co-solvent. For this system, a particulate zeolite catalyst has been designed and prepared in order to be placed at the phase boundary between aqueous H_2O_2 and an organic substrate. Several authors have reported a 'triphase system' in which the homogeneous modification of a particulate catalyst loaded with metal ions or their complexes as active sites induced or accelerated the oxidation of organic substrates with H_2O_2 in aqueous solution.[3–7] In such triphase systems, however, vigorous stirring, leading to sufficient mass transfer, is required to drive the reaction. However, our strategy is different from those previously reported because we aim at placing the bifunctional particles, containing both hydrophilic and hydrophobic regions, at the phase boundary in order to catalyze the epoxidation reaction without requiring an emulsion containing the catalyst by stirring.

Modified zeolite on which the external surface was partly covered with alkylsilane was prepared in two steps. First, titanium(IV) tetraisopropoxide [$Ti(OPr^i)_4$, Wako Pure Chemical] was impregnated from benzene solution into NaY zeolite powder (JRC-Z-Y5.5, supplied by the Catalysis Society of Japan) and heated at 383 K overnight to give sample W-Ti-NaY. 500 μmol of Ti was used per gram of NaY unless otherwise stated. In the second step, *n*-octadecyltrichlorosilane (OTS, Tokyo Kasei) in toluene was impregnated into the W-Ti-NaY powder containing water (0.5 cm^3 g per g of NaY) and heated at 383 K overnight. Due to the hydrophilicity of the W-Ti-NaY surface, addition of a small amount of water (0.5 g per g of W-Ti-NaY) led to aggregation owing to the capillary force of water between particles. Under these conditions, it is expected that only the outer surface of aggregates, in contact with the organic phase can be modified with OTS, and indeed almost all of the particles were located at the phase boundary when added to an immiscible water–organic solvent (W/O) mixture. The partly modified sample is denoted W/O-Ti-NaY. Fully modified Ti-NaY (O-Ti-NaY), prepared without the addition of water in the above second step, is readily suspended in an organic solvent as expected. At present, it is not clear whether the position of alkylsilane attachment is on the zeolite, on the Ti oxide (hydroxide), or on both.

In the water adsorption experiment at room temperature, it was observed that the adsorption capacity of modified zeolites (8 mmol g^{-1} for both W/O-Ti-NaY and O-Ti-NaY) was not greatly different from that of the parent NaY zeolite (11 mmol g^{-1}), suggesting that alkylsilane modification did not block the pores of zeolites. This observation is in agreement with the finding reported by Singh and Dutta.[8]

Oct-1-ene (Kanto Chemical, 97%) was purified by passing it through a column of basic alumina and was used as a substrate for epoxidation reaction. Typically, oct-1-ene (4 ml), 30% aqueous H_2O_2 (1 ml) and catalyst powder (50 mg) were placed in a glass tube, and the reaction was performed with or without stirring for 20 h at ambient temperature. As can be seen in Table 1, all of the modified zeolites showed activity for epoxidation of oct-1-ene to give 1,2-epoxyoctane. GC analyses (Shimadzu GC-14B) indicated that 1,2-epoxyoctane was the sole product, and other probable by-products, such as octanone, octan-1-ol, octan-2-ol or octane-1,2-diol, were not produced. NaY modified by Ti-species only (W-Ti-NaY) was hydrophilic in nature, and was suspended in water when added to a W/O mixture. W-Ti-NaY showed appreciable epoxidation ability only under vigorous stirring, *i.e.* in the W/O emulsion, but was negligibly active without stirring, as shown in Fig. 1. Modification of Ti-NaY by alkylsilane led to a significant rate enhancement. In particular, partial modification by alkylsilane (W/O-Ti-NaY, entry 3) led to better activity than full modification (O-Ti-NaY, entry 4). A reference experiment using non-porous silica (Wako Pure Chemical, < 200 mesh) was also carried out. Silica was modified in a similar manner to that of W/O-Ti-NaY. The epoxidation result showed that the yield of 1,2-epoxyoctane was lowered ten-fold compared to W/O-Ti-NaY (entry 8), suggesting that the pores might be playing a role in the catalytic reaction.

Table 1 Catalytic room-temperature epoxidation of oct-1-ene[a]

Entry	Catalyst	Epoxide yield/μmol	TON for Ti
1	None	0.1	—
2	W-Ti-NaY	2.5	0.1
3	W/O-Ti-NaY	27.4	1.1
4	O-Ti-NaY	5.9	0.2
5	(Solution)[b]	0.1	—
6	W/O-Ti-NaY (reused)[c]	16.4	0.7
7	W/O-Ti-NaY[d]	22.7	45.4
8	W/O-Ti-silica[e]	2.9	0.1

[a] All reactions were carried out at room temperature for 20 h with oct-1-ene (4 ml), 30% H_2O_2 (1 ml) and catalyst (50 mg) with vigorous stirring; the concentration of Ti and alkylsilane = 500 μmol g^{-1}. [b] The aqueous phase of entry 3 after the reaction. The reaction was conducted for 9 h. [c] The reaction was performed after washing and drying of the catalyst. [d] Concentration of Ti = 10 μmol g^{-1}. [e] Nonporous silica (Wako Pure Chemical, < 200 mesh) was modified in a similar way to that of W/O-Ti-NaY.

The recovered and dried W/O-Ti-NaY catalyst was reused in a fresh W/O mixture and showed *ca.* 60% activity. To the remaining reaction mixture, without the catalyst, was added 30% H_2O_2 aqueous solution, and the mixture was vigorously

DOI: 10.1039/b006207n

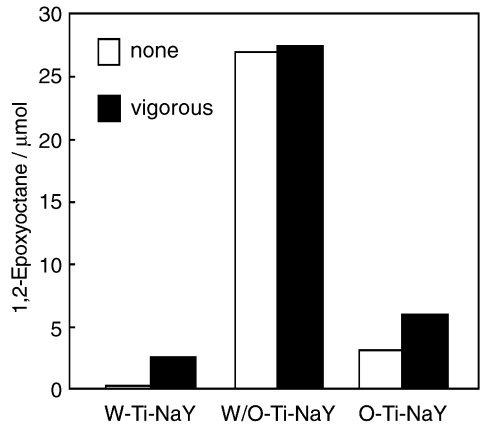

Fig. 1 Effect of stirring on the yield of 1,2-epoxyoctane.

stirred at ambient temperature. A negligible increase in the amount of epoxide could be seen. These facts suggest that epoxide formation occurs at the phase boundary, and not from any leached Ti species. Although the turnover number (TON), the molar ratio of the epoxide to the loaded Ti, was almost unity for the reaction with W/O-Ti-NaY (entry 3) for relatively larger Ti loading, W/O-Ti-NaY with a lower Ti concentration (10 μmol g^{-1}) (entry 7) gave a TON of *ca.* 45, indicating catalytic action of the Ti species. Higher loading might induce aggregation leading to inner inactive sites. One of the most striking features of W/O-Ti-NaY is shown in Fig. 1; the partial alkylsilane modification not only enhanced the epoxidation but also changed the mode of reaction. As described above, W-Ti-NaY showed activity only under vigorous stirring, and a similar behavior was seen for the O-Ti-NaY system in which the epoxide yield under static conditions was almost half of that of the stirred reaction mixture. On the other hand, the activity of W/O-Ti-NaY was not dependent on the stirring rate, *i.e.* this catalyst does not require the formation of W/O emulsion, completely at variance with previously reported results for the 'triphase system'.[7] The amphiphilic nature of W/O-Ti-NaY, enabling it to sit just at the W/O phase boundary, may account for the constant activity. Therefore, the rate of this phase-boundary catalysis depends only on the apparent area of the W/O interphase. In fact, when a narrow-bore reaction tube was used to decrease the apparent interphase area, the activity was reduced, as expected (data not shown).

All of the results mentioned above seem consistent with the mechanism of phase-boundary catalysis; amphiphilic particles having active sites (Ti-species) lie at the W/O interphase to catalyze the chemical reaction. However, the apparent rate of epoxidation was much lower than those previously reported.[4] One of the reasons for the low activity in our catalysts is the presence of few four-coordinate Ti species which are considered to be the most active species in olefin epoxidation.[9] It should be noted that we used the Ti-loaded NaY zeolite as an easily available material and the catalyst and the reaction conditions have not been optimized. Further study for improvement of catalytic activity by generating four-coordinated Ti species in the catalytic system is now underway. Thus, we have shown a new concept of phase-boundary catalysis, that is applicable when amphiphilic particles, molecular assemblies, or films with adequate active sites are used, to a wide range of catalytic reactions.

H. N. thanks the Japan Society for the Promotion of Science (JSPS) for granting a Postdoctoral Fellowship. We are grateful to the Catalysis Society of Japan for the supply of zeolite samples. This research was partly supported by a Grant-in-Aid for Encouragement of Young Scientists (No. 99302) from Ministry of Education, Science, Sports and Culture, Japan. Dr Hisashi Semba (Nippon Shokubai) is acknowledged for his stimulating suggestions and discussion.

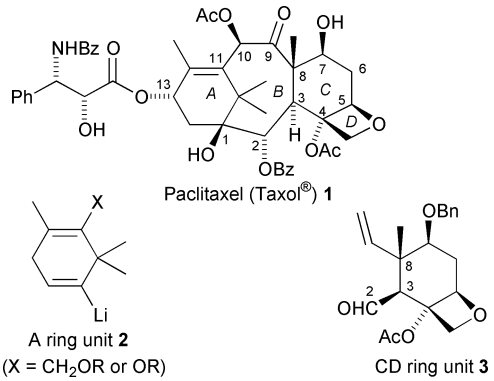
Received (in Cambridge, UK) 31st July 2000, Accepted 5th October 2000
First published as an Advance Article on the web 31st October 2000

The chiral synthesis of the fully functionalized CD ring unit of paclitaxel 3 is described; the three component coupling reaction of a cyclohexenone derived from D-glucal by way of Ferrier's carbocyclization with vinyl cuprate and formaldehyde effectively constructed the carbon framework of 3.

Paclitaxel (Taxol®) **1** is a well-documented natural diterpenoid and is known to show highly promising antitumor activity.[1] The challenging structure as well as important biological activities of **1** has attracted much attention of the synthetic community, and six successful total syntheses of **1** have been reported to date.[2] Our own synthetic endeavor to paclitaxel required the fully functionalized CD ring unit **3** as the key intermediate; the formyl function at C-3 (paclitaxel numbering) would be utilized for the coupling reaction with a paclitaxel A-ring **2**, and the vinyl group at C-8 would serve as the key functionality for the construction of a taxane skeleton. Successful precedents for preparation of taxane tricarbocyclic structures by way of final B-ring closure of connected AC ring systems revealed the possibility of this approach.[3] The highly oxygenated structure of **3**, which contains five contiguous chiral centers including a quaternary carbon and a strained oxetane ring is synthetically fascinating, and it is a significant aim to establish an effective synthetic route to **3** from readily available material for the development of a novel approach to the clinically important compounds.[4] In this communication, we report a synthesis of **3**, which utilized commercially available tri-*O*-acetyl-D-glucal **4** as a chiral starting material.



The known methyl glycoside **5**,[5]† derived from **4** in a two step reaction (90% overall yield) (Scheme 1) was converted into primary iodide **6**† in 87% yield, which was then treated with NaH and benzyl bromide to afford enopyranoside **7**† in 80% yield. Ferrier's carbocyclization[6] of **7** using a catalytic amount of $Hg(OCOCF_3)_2$,[7] followed by β-elimination cleanly generated cyclohexenone **8** (80% yield). Reaction of **8** with MeLi gave 1,2-adduct **9**, whose oxidation with PCC afforded **10** in 83% yield from **8**.

With a chiral cyclohexenone **10** in hand, generation of the quaternary carbon at C-8 and the C–C bond at C-3 by a three component coupling reaction[8]‡ of **10**, a vinyl metal species, and formaldehyde in a one-pot reaction was investigated. Treatment of **10** with higher order vinylcuprate [$(vinyl)_2$-$CuCNLi_2$] in Et_2O at −78 °C caused the stereoselective conjugated addition of the vinyl group to give an enolate intermediate,§ which was then reacted with a THF solution of formaldehyde at −60 °C to provide **11** {mp 50–52 °C; $[\alpha]_D^{23}$ + 12 (*c* 1.0, $CHCl_3$)} and its C-3 isomer **12** {$[\alpha]_D^{23}$ + 93 (*c* 1.0, $CHCl_3$)} in 62 and 33% isolated yields, respectively. The observed coupling constants and NOE unambiguously supported the structure of **11** (Scheme 2). Base-induced epimerization of **12** gave an additional amount of **11** (44% yield, **12** was recovered in 51% yield); thus **11** was obtained in 76% overall yield from **10** after one-cycle epimerization of **12**. Protection of the hydroxy group in **11** as a THP ether afforded **14** in 90% yield. To introduce an hydroxy function at C-5, ketone **14** was treated with LiHMDS at −78 °C, and the resulting kinetic enolate was trapped with TMSCl to provide silylenol ether, which was then reacted with MCPBA at −20 °C followed by treatment with TMSCl and triethylamine to give **15** and **16** in 53 and 26% isolated yields, respectively. Reaction of **15** with Tebbe's reagent[9] and subsequent removal of the silyl protecting group under basic conditions afforded *exo*-alkene **17** in 64% yield.¶ Vanadium catalyzed epoxidation[10] of **17** gave **18** as a single isomer in 81% yield. Reaction of **18** with potassium acetate in DMF, followed by treatment with acetic anhydride and pyridine at rt gave **19** in 95% yield. The secondary hydroxy group in **19** was mesylated to afford **20** (96% yield). Removal of the *O*-acetyl group, followed by reaction with DBU[4c] in toluene at 100 °C cleanly generated oxetane **21** in 65% yield. Acetylation of tertiary alcohol in **21** afforded **22** (100%). Deprotection of the *O*-THP group in **22** with CAN[11]‖ gave **23**, which was oxidized with TPAP[12] to furnish the desired aldehyde **3** {$[\alpha]_D^{23}$ −137 (*c* 0.07, $CHCl_3$)} in 80% yield from **22**. The observed NOE between the methyl at C-8 and the formyl hydrogen, H-20, and H-6_β, and between H-7 and H-3 clearly supported the assigned structure.

We thank Professor Takashi Takahashi and Dr Takayuki Doi (Tokyo Institute of Technology, Japan) for valuable discussions and information. Financial support of the Grant-in Aid for Scientific Research on Priority Area from the Ministry of

Notes and references

† This compound was an anomeric mixture (α : β = *ca.* 4 : 1), and used in the next reaction without separation.

‡ A similar approach (starting from D-glucose) has been reported by Ermolenko, see ref 4*d*.

§ Conjugated addition of the vinyl group to enone **10** was found to proceed highly stereoselectively. When the intermediate enolate was treated with aqueous NH_4Cl, a 1,4-adduct was obtained as a single isomer in 95% yield. Reduction of the 1,4-adduct with $NaBH_4$ afforded a cyclohexanol derivative **13**, which was acylated with (*R*)- and (*S*)-acetylmandelic acid (DCC, DMAP) to give (*R*)- and (*S*)-acetylmandelate derivatives, respectively. ^1H NMR analyses of the acetylmandelates revealed that they showed quite different spectra, and no signal due to the (*R*)-isomer was observed in the spectrum of the (*S*)-isomer, indicating the cyclohexanol **13** possessed high optical purity (~100% ee), and no racemization had occurred during the preparation of **8** and **10** and the 1,4-addition process.

¶ When compound **16** was subjected to the same reaction conditions, no reaction took place resulting in the recovery of **16**.

‖ Under the conditions of deprotection of the *O*-THP group with PPTS in EtOH, the primary hydroxy group in the resulting **23** further attacked the oxetane ring to generate a significant amount of a THF derivative.

Received (in Cambridge, UK) 17th August 2000, Accepted 5th October 2000
First published as an Advance Article on the web 31st October 2000

The synthesis of 3,3-disubstituted and 3-methyleneoxindoles by palladium(0) catalysed cyclisation of carbamoyl chlorides onto proximate alkene or alkyne groups has been achieved in good yields.

3,3-Disubstituted oxindoles are common structural motifs in a wide range of natural products. Gelsemine,[1] paraherquamides[2] and spirotryprostatins[3] represent classes that possess oxindole cores and have interesting biological profiles. 3-Methyleneoxindoles, on the other hand, are versatile intermediates in synthesis. Recently, Williams *et al.*[4] used a diasterospecific cycloaddition onto a methyleneoxindole in their total synthesis of spirotryprostatin B. Classically, spirooxindoles can be synthesised *via* an oxidative rearrangement of indoles[5] and methyleneoxindoles can be accessed by Wittig–Horner[6] type reactions of isatin. Oxindoles can conceptually be constructed by palladium catalysed processes in a number of ways. There are examples of intramolecular Heck and intramolecular cyclisation–anion capture reactions on acrylamide derivatives of 2-iodoanilines.[7] We have applied our palladium catalysed cyclisation–anion capture methodology to 3,3-disubstituted oxindoles (including spirooxindoles)[8] *via* formation of bond **a** (Fig. 1). We have also developed a 3-component process[9] which constructs bonds **a**, **b**, and **c**. We now describe palladium catalysed cyclisation–anion capture processes involving formation of bond **b** (Fig. 1).

The use of carbamoyl chlorides in palladium catalysed cross-coupling reactions with stannanes was reported by Jousseaume and Dubac.[10] Its use in Heck-type cyclisations[11] is rare, perhaps because the initial reports employed forcing conditions and toxic cosolvents for the synthesis of lactams. Our plan was to use 2-ethynyl- or 2-isopropenyl-phenylcarbamoyl chlorides as oxindole precursors (Fig. 1) in cyclisations which do not terminate *via* β-hydride elimination (as in Heck processes) but involve a group or atom transfer. This process (known as cyclisation–anion capture)[12] allows a large variety of groups to be introduced onto the oxindole. By this route, (*Z*)-3-methyleneoxindoles are stereospecifically formed and 3,3-disubstituted oxindoles can be potentially synthesised by a catalytic, enantioselective process.

The synthesis of the required carbamoyl chlorides was achieved from the appropriate 2-haloaniline in high overall yield (Scheme 1). 2-Iodoaniline **1** is converted to its *N*-benzyl derivative **2** using a reductive amination protocol. Treatment of

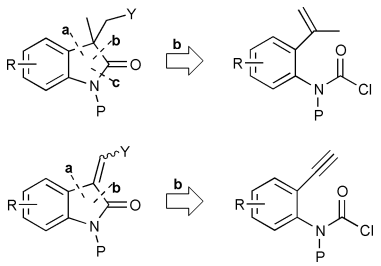

Fig. 1

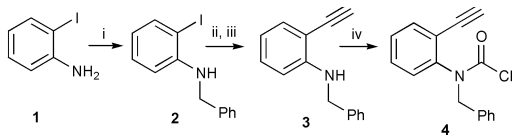
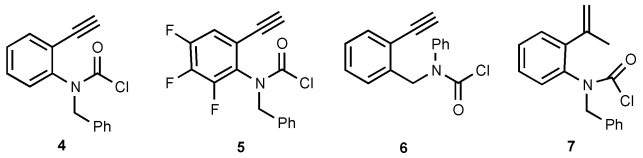


Scheme 1 *Reagents and conditions*: i, PhCHO, MeOH, reflux then $NaBH_4$, reflux (45%, 86% based on 52% conv.); ii, TMSA, $Pd(PPh_3)_4$, CuI, NEt_3, DMF, rt (90%); iii, TBAF, THF–H_2O, rt (91%); iv, $COCl_2$, $NaHCO_3$, DCM–H_2O, 0 °C (93%).

2 with a two step Sonagashira[13]-deprotection procedure then affords the 2-ethynyl derivative **3**. Finally, addition of phosgene[14] to aniline **3** at 0 °C for 10 min affords carbamoyl chloride **4**.

A range of carbamoyl chlorides **4**–**7** were synthesised in a similar way to provide a selection of 5- and 6-membered heterocycle precursors. These carbamoyl chlorides are air and moisture insensitive and can be purified on flash silica. Substrates **4** and **5** are 3-methyleneoxindole precursors, whilst **6**



is an example of a 6-ring isoquinolinone precursor. Carbamoyl chloride **7** was synthesised from commercially available 2-isopropenylaniline.

Initially, we focused on the use of tributylstannanes as anion capture agents for these substrates.[15] It was found that treatment of **4** with tributyl(2-thienyl)tin and $Pd(OAc)_2$–tris(2-furyl)phosphine in toluene at 50 °C for 5 min affords the desired 3-methyleneoxindole **8** in 88% yield (Scheme 2). Repetition of this latter reaction using 1 mol% $Pd(OAc)_2$–2 mol% tris(2-furyl)phosphine and a reaction time of 30 min afforded **8** in 91% yield emphasising the scope for considerable reduction in catalyst loading. The use of tributyl(phenylethynyl)tin also resulted in a high yield of product (81%), whilst vinyl transfer affords a 4 : 3 mixture of geometrical isomers **10** and **11** in 76% overall yield. Cyclisation–anion capture employing tributyl(2-furyl)tin was also complete within 5 min at 50 °C, and afforded (*Z*) **12** in 78% yield.

This methodology can also be extended to 6-ring cyclisation–anion capture and to the synthesis of 3,3-disubstituted oxindoles (Scheme 3).

Cyclisation of **6** affords **13** (87%), a 4-methyleneisoquinolin-3-one in 5 min at 50 °C. However, cyclisation onto the isopropenyl group of **7** to form **14** is much slower (4 h), but proceeds in excellent yield (84%). The use of boronic acids as anion capture reagents[8] is currently being studied. A preliminary study involving **7** and phenylboronic acid afforded **15** (50%) (Scheme 3). This reaction was considerably slower (50 h, 90 °C) than those involving organostannane anion capture reagents and since a small amount of water was present

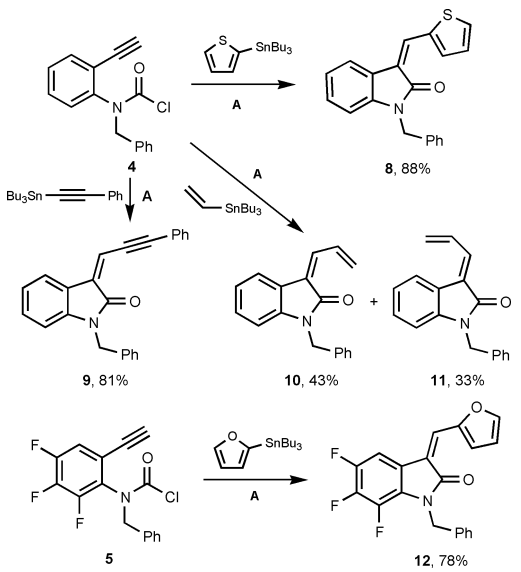
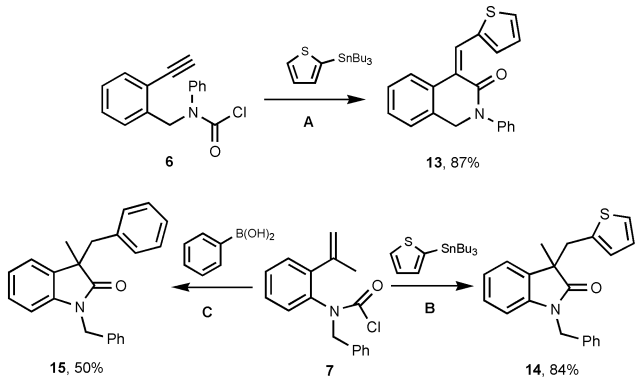


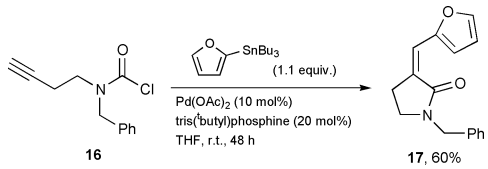
Scheme 2 *Reagents and conditions*: **A** = $Pd(OAc)_2$ (10 mol%), tris(2-furyl)phosphine (20 mol%), 1.1 equiv. Bu_3SnY, toluene, 50 °C. All reactions were complete within 5 min at 50 °C.



Scheme 3 *Reagents and conditions*: **A** = $Pd(OAc)_2$ (10 mol%), tris(2-furyl)phosphine (20 mol%), 1.1 equiv. Bu_3SnY, toluene, 50 °C, 5 min; **B** = $Pd(OAc)_2$ (10 mol%), tris(2-furyl)phosphine (20 mol%), 1.1 equiv. Bu_3SnY, toluene, 85 °C, 4 h; **C** = $Pd(OAc)_2$ (10 mol%), triphenylphosphine (20 mol%), 2 equiv. $PhB(OH)_2$, toluene, water (2 drops), 90 °C, 50 h.

(Scheme 3, **C**) there was some destruction of the carbamoyl chloride **7**.

The presence of the benzene ring in the above examples is one factor promoting the rapid cyclisation of these carbamoyl chlorides. To extend the scope of this cyclisation–anion capture methodology, we synthesised an example of a non-aryl based carbamoyl chloride. Substrate **16** was derived from but-3-yn-1-ol *via* its tosylate and reacted with benzylamine and then phosgene[14] in the normal fashion. At the typical reaction temperature of 50 °C, only 35% of product **17** was isolated. However, replacing tris(2-furyl)phosphine by the electron rich



tris(*tert*-butyl)phosphine gave, over 48 h at rt, a 60% yield of lactam **17**.

The two strategic bond formation modes (Fig. 1, **a** and **b**) allow both (*E*)- and (*Z*)-3-methyleneoxindoles to be accessed stereoselectively. Thus formation of bond **a** by palladium catalysed cyclisation onto a proximate alkyne with anion capture affords *E*-isomers[16] whilst formation of bond **b** by palladium catalysed cyclisation affords *Z*-isomers.

In summary, these preliminary results on the palladium catalysed cyclisation–anion capture of carbamoyl chlorides demonstrate that (*Z*)-3-methylene- and 3,3-disubstituted oxindoles can be accessed under mild conditions in high yields. Further studies of these and related processes are in hand.

We thank the EPSRC, University of Leeds and Zeneca Agrochemicals for support.

Palladium catalysed tetramolecular queuing cascades of aryl iodides, carbon monoxide, amines and a polymer supported allene

Ronald Grigg,*[a] William MacLachlan[b] and Marcello Rasparini[a]

[a] *MIDAS Centre, School of Chemistry, University of Leeds, Leeds, UK LS2 9JT. E-mail: R.Grigg@chem.leeds.ac.uk*

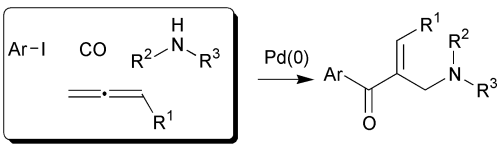
Received (in Cambridge, UK) 6th September 2000, Accepted 5th October 2000
First published as an Advance Article on the web 31st October 2000

Chemo- and regio-specific palladium catalysed four component processes, involving formation of 3 new bonds, initiated by oxidative addition of Pd(0) with aryl iodides followed by sequential incorporation of CO (1 atm), a polymer supported allene and an amine provides complex heterocycles with 3 points of diversity in good yield and excellent purity after cleavage.

A well designed cascade can deliver highly complex molecules whilst avoiding lengthy multistep procedures and the need for protection–deprotection of many functional groups.[1] This approach can be further enhanced by locating one of the reagents on a polymer support thus allowing the pure final product to be isolated by washing the resin and cleavage.

The objective of the present study was to explore the reactivity of a polymer bound allenic alcohol in a palladium catalysed four-component queuing cascade[2] (Scheme 1).

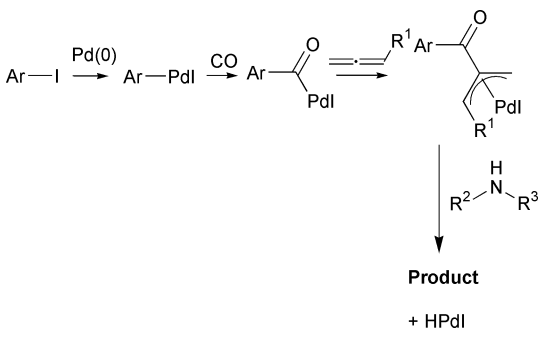


Scheme 1

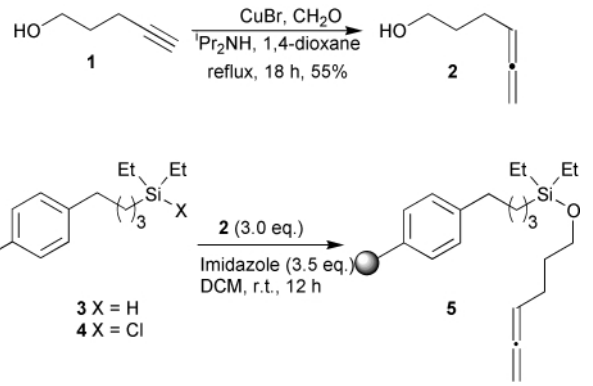
This cascade is initiated by addition of Pd(0) into the Ar–I bond, followed by CO insertion, allene insertion and capture of the resultant π-allylpalladium(II) complex by a secondary amine (Scheme 2).

In this preliminary study we attached hexa-4,5-dien-1-ol **2** (prepared from the alkyne 1 by a Crabbé[3] reaction) to a gel-type polystyrene resin by means of a traceless silicon linker. The reason for this choice is three-fold: alkyl substituted allenes are particularly stable, the alcohol group is convenient for the introduction of further diversity and the cleavage conditions were anticipated to be particularly mild (Scheme 3).

The silane resin **3** (Argonaut Technologies, loading 1.59 mmol g^{-1} SiH) was chlorinated and immediately loaded[4] with the allenic alcohol **2** to give the resin **5** (loading 1.45 mmol g^{-1}).[5] The colourless resin **5** was characterised by gel-phase ^{1}H NMR (250 MHz, CDCl3) δ = 3.7 (C*H*$_2$CH=C=CH$_2$), 4.7



Scheme 2



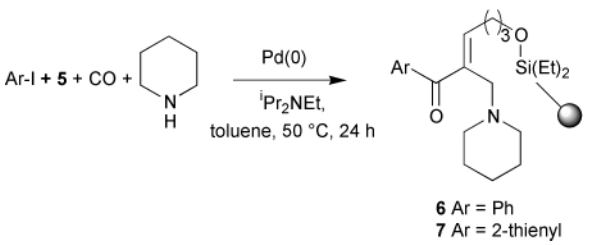
Scheme 3

(C*H*=C=C*H*$_2$), 5.1 (C*H*=C=CH$_2$) and FT-IR (KBr disc) 1953 cm^{-1} (CH=C=CH$_2$ stretch).

The experimental conditions for the palladium-catalysed cascade (Scheme 4) were as follows: resin **5** (1.0 mol eq.), iodobenzene or 2-iodothiophene (4.0 mol eq.), ^{i}Pr$_2$NEt (5.0 mol eq.), piperidine (4.0 mol eq.), Pd(OAc)$_2$ (0.1 mol eq.), tris(2-furyl)phosphine (0.2 mol eq.), toluene (10 ml $mmol^{-1}$) and a balloon containing carbon monoxide attached to the reaction vessel. After all the components were added to the flask containing the resin swollen in toluene, a sequence of evacuation (water pump–CO addition) was performed three times. Subsequently the flask was immersed in an oil bath at 50 °C and magnetically stirred for 24 h.

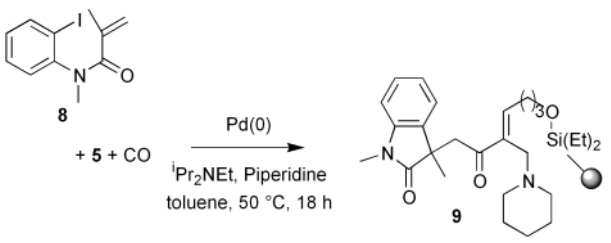
The reaction was monitored by FT-IR following the disappearance of the allene stretching band at 1953 cm^{-1}. After 24 h a small allenic peak was still present. The resin was washed with DMF, 1:1 DMF–H$_2$O, DCM, MeOH, dried and recycled in a second run to complete the conversion. The reaction was not optimised at this stage. The rate determining step appears to be the oxidative addition of Pd(0) into the Ar–I bond. Thus the iodoacrylamide **8** undergoes complete conversion to product in 18 h. In the case of **8** initial coordination of Pd(0) to the olefinic bond would facilitate the oxidative addition step, which is followed by a facile 5-*exo-trig* cyclisation, carbonylation, allene insertion and amine capture (Scheme 5).

Cleavage of indolinone **9** was achieved using HF/Py (0.4 M HF/Py, THF). Reaction times longer than 25 min led to the formation of a diastereomeric mixture of tetrahydrofurans (1:1

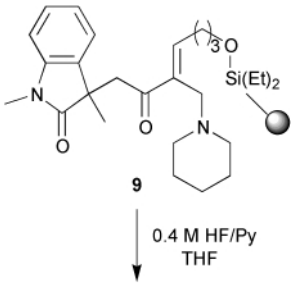


Scheme 4

DOI: 10.1039/b007170f



Scheme 5



Scheme 6

ratio by HPLC, 70% yield); **10** deriving from acid-catalysed intramolecular Michael addition (Scheme 6).

After exposing the resin for 20 min to the cleavage mixture the filtrate was quenched with a saturated solution of $NaHCO_3$, extracted with AcOEt, the solvent removed *in vacuo* to afford the alcohol (60%) whose purity was 98% by HPLC-MS. The residue was acetylated (Ac_2O, pyridine, DMAP, DCM, 2 h, rt) and the acetate **11** was purified by silica gel chromatography (AcOEt–PE–triethylamine 50 : 50 : 2) and obtained in 90% yield from the alcohol (Scheme 7).

The loading of resin **9** was found to be 1.1 mmol g^{-1} (calculated on the yield of the crude product after cleavage).

Similarly the resins **12**–**14** were prepared. After cleavage and work-up the alcohols **15**–**17** were found to be 98% pure by HPLC-MS and no further purification was carried out.[6]

It is worth noting that all the products **11**–**17** were obtained as single stereoisomers.[7]

In conclusion, the resin supported allene **5** is an excellent scaffold for the construction of complex heterocycles. Further investigations using a broader range of anion capture agents and starter molecules are in progress.

5 The loading was the average of two determinations: 1) weight increase after washing and overnight drying *in vacuo*, 2) yield of **2** after cleavage (TBAF, 1.0 M in THF) and chromatographic purification (Et_2O–PE 1 : 1).
6 Overall from **5** to **15**–**17**.
7 In similar experiments we found that the C=C geometry is *Z* (NOE data): this stereochemical outcome is rationalised by attack of the amine on the more stable *anti* π-allylpalladium(II) complex (R. Grigg and M. Rasparini, unpublished data).

A simple, rational synthesis of *meso*-substituted A_2B-corroles†

Daniel T. Gryko*

Institute of Organic Chemistry of Polish Academy of Sciences, Kasprzaka 44/52, 01-224 Warsaw, Poland. E-mail: sfinks@icho.edu.pl

Received (in Liverpool, UK) 14th August 2000, Accepted 3rd October 2000
First published as an Advance Article on the web 31st October 2000

Five unsymmetrically *meso*-substituted corroles have been synthesized from dipyrromethanes and aldehydes in yields of up to 19% *via* a new two-step one-flask procedure.

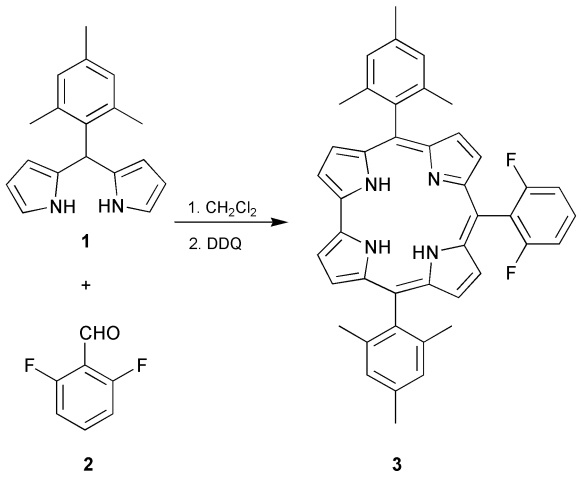
Although the existence of corroles was reported a long time ago,[1] their chemistry has been overshadowed by the easy accessibility of porphyrin chemistry.[2] Corroles are aromatic tetrapyrrole macrocycles bearing a direct pyrrole–pyrrole link, thereby constituting a bridge between porphyrins (*e.g.* heme) and corrins (*e.g.* vitamin B_{12}). Recently, corrole chemistry has received new impetus due to the discovery of novel ligand properties of this contracted macrocycle[3–5] as well as the advent of efficient synthetic methodologies affording corroles in gram quantities.[6–8] Most of the corrole syntheses known till 1999 (biladiene cyclization,[9] *meso*-carbon or sulfur extrusion of *meso*-thiaporphyrin,[10] or direct synthesis from monopyrrole precursors[11,12]) are lengthy. The very recently reported syntheses of core-modified corroles also require preparation of several precursors.[13,14]

Pioneering studies by Paolesse *et al*.[6] and Gross *et al*.[7,8] have demonstrated that the non-catalyzed reaction of pyrrole with aldehydes results in the formation of *meso*-substituted A_3-corroles. These simple and efficient synthetic methods have already opened a new avenue for in-depth studies of the coordination chemistry of corroles.[5] Nevertheless a potential use of corroles as surrogates for vitamin B_{12} and related compounds in biomimetic models of enzymic catalysis would benefit significantly from the ability to incorporate different groups at distinct sites at the perimeter of the macrocycle. On the other hand it is known that the acid catalyzed reaction of pyrrole with an aldehyde gives an A_4-porphyrin whereas the acid-catalyzed condensation of a dipyrromethane (DPM) with an aldehyde gives the corresponding *trans*-A_2B_2-porphyrin.[15] Hence I assumed that the non-catalyzed reaction of a DPM with a reactive aldehyde would lead to the formation of the corresponding A_2B-type *meso*-substituted corrole. The preliminary results of this study are presented in this paper.

The conditions for the non-catalyzed reaction of pyrrole with aldehydes[6–8] and the stoichiometry of the envisioned reaction prompted me to initiate studies using the following conditions: aldehyde–dipyrromethane ratio, 1:2; reaction time, 2 h; rt; a small amount of solvent; and 1 eq. of DDQ as an oxidant. The reaction of mesityldipyrromethane **1**[16] (a potential precursor of facially-encumbered and hence more soluble corroles) and 2,6-difluorobenzaldehyde **2** (bearing electron-withdrawing substituents) was chosen as a model system for the optimization study (Scheme 1). Indeed, condensation of both substrates in methylene chloride for 2 h followed by subsequent reaction with DDQ smoothly afforded the desired corrole **3** in 11% yield (Table 1, entry 1). This initial success quickly led to the systematic study of reaction conditions. In an effort to improve the yield of corrole **3**, the concentration and ratio of reagents, solvent, time, and amount of DDQ were altered. In addition, the influence of some simple additives (TBABr and TBAF) was examined. The results of this study are presented in Table 1.

† Electronic supplementary information (ESI) available: experimental procedures and spectral data for compounds **3** and **10**–**13**. See http://www.rsc.org/suppdata/cc/b0/b006734m/

When the ratio of aldehyde to DPM was changed to 1:1 (corresponding to the stoichiometry of porphyrin forming reaction) (entry 2), an appreciable increase in the yield of corrole **3** to 17% was obtained. An increased amount of DDQ gave no further increase in the yield of corrole (entry 3). It is well known that the porphyrin-forming reaction as well as many other macrocyclisation reactions require a low concentration of reactants to achieve reasonable yields. Thus, the corrole-forming reaction was carried out under more dilute conditions (entries 4 and 5). The decrease in concentration of both substrates to 0.27 mol dm^{-3} resulted in a slight increase while further dilution caused a sudden drop in the yield of corrole **3**. Use of a large excess of aldehyde **2** did not give any improvement (entry 6). Hence, for further reactions the ratio of reactants was kept constant at 1:1. Because both substrates were still present in the reaction mixture after 2 h, the condensation time was extended (entries 7 and 8). However,



Scheme 1

Table 1 Effects of various conditions on the reaction of mesityldipyrromethane **1** and aldehyde **2**

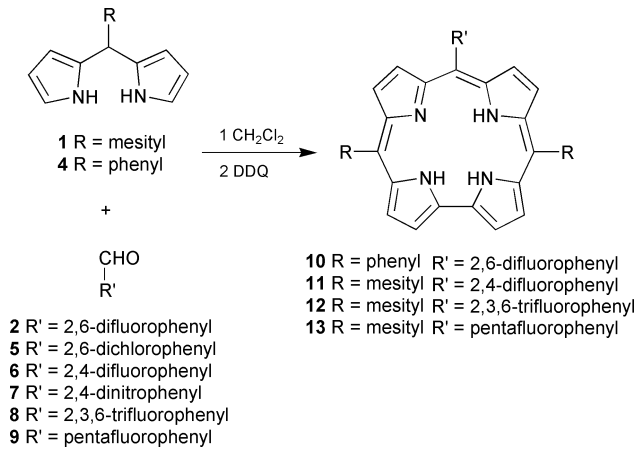
[a] Time of condensation prior to addition of DDQ. [b] Isolated yield. [c] 0.2 eq. of TBABr was added. [d] 0.2 eq. of TBAF was added. [e] $CHCl_3$ was used instead of CH_2Cl_2.

DOI: 10.1039/b006734m

prolonging the reaction time from 2 to 5.5 h did not improve the yield of the product **3** (entry 7). The complete consumption of the substrates was observed after 16 h, then DDQ was added. Surprisingly even traces of corrole **3** were not found in the reaction mixture (entry 8). The idea of adding of soluble inorganic salts was inspired by the beneficial effects of salts observed in the porphyrin-forming reaction.[17] The addition of TBABr resulted in a modest decline in yield whereas no corrole was formed upon reaction in the presence of TBAF (entries 9 and 10). A control experiment with 0.5 eq. of DDQ resulted in a decreased yield of corrole (entry 11). Furthermore, upon changing the solvent from CH_2Cl_2 to $CHCl_3$ the yield of corrole decreased to 9% (entry 12). It is noteworthy to add that no porphyrin was observed under any of these conditions.

The optimized procedure (entry 4) (CH_2Cl_2, conc. of both substrates = 0.27 mol dm^{-3}, 2 h, rt, 1 eq. of DDQ) was applied to a variety of substrates (Scheme 2, Table 2). Reactive aldehydes with various electron-withdrawing groups (F, Cl, NO_2) (**2**, **5**, **6**, **7**, **8**, **9**) were used in conjunction with mesityldipyrromethane **1** and phenyldipyrromethane **4**.[16] In each case with aldehydes possessing at least two fluorine substituents, the corresponding corroles[18] (**10**, **11**, **12** and **13**) were readily isolated in modest yield after straightforward column chromatography. No porphyrin product was observed in these reactions.[19] It was surprising to find that the yields of corroles in the reactions employing 2,4-difluorobenzaldehyde **6** (entry 4) and 2,3,6-trifluorobenzaldehyde **8** (entry 6) were significantly lower than the yield achieved starting from 2,6-difluorobenzaldehyde. On the other hand, 2,6-dichlorobenzaldehyde **5** (entry 3) and 2,4-dinitrobenzaldehyde **7** (entry 5) did not afford any corrole. At present there is no satisfactory explanation for such a significant difference in behavior of these aldehydes. Generally, it is reasonable to assume that a mechanism analogous to that suggested by Gross *et al.*[8] accounts for the formation of corroles from dipyrromethanes. If so, the course of this reaction is not only dependent on the reactivity of the aldehyde (Ar-CHO) but is also influenced by the steric effects of substituents and by the nature of the arylmethylene unit (Ar-CH_2-) as an anionic leaving group.



Scheme 2

Table 2 Yield of corroles formed from various dipyrromethanes (DPM's) and aldehydes

Entry	Aldehyde	DPM	Yield (%)[a]
1	**2**	**1**	19
2	**2**	**4**	9
3	**5**	**1**	0
4	**6**	**1**	4[b]
5	**7**	**1**	0
6	**8**	**1**	10
7	**9**	**1**	8

[a] Isolated yield. [b] Condensation of aldehyde and DPM was performed for 5 h prior to addition of DDQ.

In summary, conditions have been identified for a rational two-step synthesis of A_2B-type *meso*-substituted corroles bearing one fluorinated substituent. The main advantages of this method are as follows: (1) a two-step procedure from commercially available materials, (2) short reaction time, (3) straightforward purification, and (4) reaction at high concentration (thereby easy to scale-up). This approach should prove useful for the preparation of a variety of corroles and may open the door to new practical applications of these macrocycles. Further studies aimed at extending the scope of this method and gaining insight into the influence of various factors on the corrole-forming reaction are in progress.

18 The purity of each corrole is >99% based on TLC, ^{1}H NMR spectroscopy, and electrospray mass spectrometry. It is noteworthy to add that the ^{1}H NMR spectra of corroles derived from mesityldipyrromethane (**3**, **11**, **12** and **13**) exhibit very sharp signals, in contrast to corrole **10** or 5,10,15-triphenylcorrole[6] which exhibit broad AB patterns.
19 One exception occurred with pentafluorobenzaldehyde **9**, which gave traces (*e.g.* 1%) of 5,15-dimesityl-10,20-bis(pentafluorophenyl)porphyrin.

Enhanced product selectivity in the Mizoroki–Heck reaction using a supercritical carbon dioxide–liquid biphasic system

Yoshihito Kayaki, Yushi Noguchi and Takao Ikariya*

Graduate School of Science and Engineering, Tokyo Institute of Technology and CREST, Japan Science and Technology Corporation, O-okayama, Meguro-ku, Tokyo 152-8552, Japan. E-mail: tikariya@o.cc.titech.ac.jp

Received (in Cambridge, UK) 23rd August 2000, Accepted 2nd October 2000
First published as an Advance Article on the web 31st October 2000

Arylation of ethylene catalysed by Pd complexes bearing triphenyl phosphite ligands proceeds efficiently in a $scCO_2$–liquid biphasic system to give a mixture of arylated products; the selectivity of monoarylated products, styrene derivatives, can be improved by increasing the CO_2 pressure, where the monoarylated products are effectively extracted from the liquid reaction phase into the $scCO_2$ phase to prevent over-reactions to diarylated products.

There has been extensive interest in supercritical fluids (SCFs) as reaction media for molecular catalysis.[1] Their unique physical properties tuned by a small change in the pressure and temperature allows improved performance of molecular catalysts in terms of the reaction rates and selectivities.[2] Besides these benefits for catalysis, the use of SCFs can also offer great opportunities to solve the frequently encountered problem of efficient separation of the molecular catalysts by controlling the pressure of the media.[3] Recently, a biphasic reaction system consisting of a supercritical fluid phase and a solvent phase including H_2O was examined for the purpose of separating and recycling metal catalysts.[4] In the case where CO_2-insoluble substrates form the liquid phase under supercritical or subcritical CO_2 conditions, the high volatility of CO_2 allows it to help selectively remove the CO_2-soluble product from the reaction phase, resulting in a solvent-free reaction. However, the catalyst performance in such a multiphase system has not been systematically investigated except for a recent report on solvent-free synthesis under subcritical CO_2 conditions.[5,6] We now report Mizoroki–Heck arylation of ethylene in a CO_2–liquid biphasic system in which monoarylated products can be preferentially obtained in condensed CO_2 where the selectivity is controllable by a change in the pressure of CO_2.

The arylation of ethylene with aryl halides has been well investigated in liquid solvents.[7] In a single reaction phase, the initial products, styrene derivatives are subject to further reaction with aryl halides to afford stilbenes and 1,1-diphenylethylenes, resulting in a significant decrease in the selectivity for the monoarylation. If one of the desired products, styrene in this case, has high solubility in $scCO_2$ compared to that of the byproducts, the use of $scCO_2$ will enable the separation of the initial product from the liquid phase[8] to suppress the subsequent reactions of styrene (Fig. 1).

We first examined the phase behaviour of iodobenzene, ethylene, $N(C_2H_5)_3$ and styrene under subcritical and supercritical CO_2 conditions.† A visual inspection of these compounds in a window-equipped 50 mL reactor vessel confirmed that 1.0 mmol of styrene was completely dissolved in $scCO_2$ under 100 atm at 130 °C whereas some droplets of iodobenzene were observed under the same conditions. In the presence of subcritical CO_2 gas, these materials, except ethylene, precipitate to form the liquid phase where a neat reaction can be performed. Thus, the significant difference in the solubility of these compounds in $scCO_2$ should allow one to extract styrene preferentially from the liquid phase, leading to the efficient control of the styrene formation.[9]

The screening experiments with Pd catalyst bearing tertiary phosphine or phosphite ligands revealed that

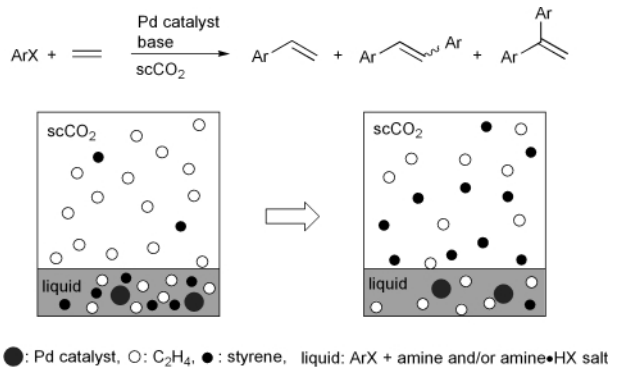

Fig. 1 Schematic illustration of phases during a $scCO_2$–liquid biphasic Mizoroki–Heck reaction. At the initial stage of the reaction, aryl halide, amine and some amine·HX salt are precipitated as a liquid containing the Pd catalyst. At the final stage of the reaction, an excess amount of amine and amine·HX salt form a liquid phase and monoarylated product is extracted into the $scCO_2$ phase. Ar = aryl group, X = I, Br in this case.

$PdCl_2\{P(OC_6H_5)_3\}_2$ (**1**) is the best choice of catalyst for the arylation because of its excellent activity[10] and suitable solubility (discussed later) under the reaction conditions at 130 °C and 100 atm.‡ Although complex **1** has been found to partially dissolve in $scCO_2$ under the same conditions,[11] it should stay in the liquid phase rather than the $scCO_2$ phase because of its higher solubility in the liquid substrates phase.

The reaction of iodobenzene with ethylene (10 atm) catalysed by the $P(OC_6H_5)_3$–Pd complex **1** (substrate/catalyst = 1000 : 1) at 130 °C in the presence of $N(C_2H_5)_3$ as a base proceeded rapidly to an almost quantitative conversion under solvent-free conditions (without CO_2). As listed in Table 1, styrene was obtained in 57% selectivity along with (*E*)-stilbene and 1,1-diphenylethylene in 31 and 11% yields, respectively. Notably, as illustrated in Fig. 2, the selectivity for the styrene formation was remarkably improved with an increase in the pressure of CO_2 above the critical pressure of 73 atm to attain over 80% at 100 atm and the same temperature. Further increase in the pressure above 100 atm resulted in the selectivity approaching 100% albeit with a significant drop in the yield. The decrease in the total efficiency at higher CO_2 pressures was

Table 1 Mizoroki–Heck reaction of iodobenzene with C_2H_4 in $scCO_2$[a]

Run	Medium	Conv. (%)	Styrene Yield (Sel.) (%)	1,1-Diphenylethylene : (*E*)-stilbene
1	—	95	54 (57)	2.8 : 1

7	CO_2, 150	19	18 (99)	N.d.

[a] Reaction was conducted at 130 °C for 18 h, in a 50 mL reaction vessel containing 10 μmol of Pd catalyst **1**, iodobenzene and triethylamine. Iodobenzene : **1** : $N(C_2H_5)_3$ = 1,000 : 1 : 1,400.

DOI: 10.1039/b006846m

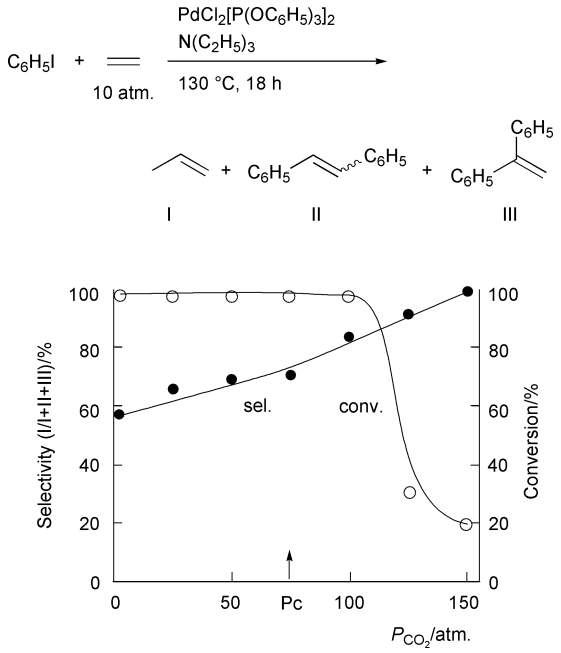

Fig. 2 Selectivity and conversion profile as a function of the CO_2 pressure for the reaction of iodobenzene **2a** and ethylene catalysed by Pd complex **1** in condensed CO_2. Condition: $C_6H_5I:N(C_2H_5)_3$:Pd catalyst = 1000:1400:1, C_2H_4 10 atm.

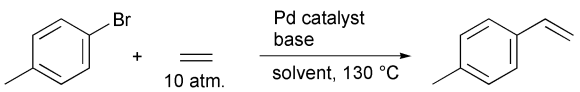
mainly due to the disappearance of the liquid phase since everything dissolved in the $scCO_2$, where the homogeneous reaction in $scCO_2$ possibly occurred. In fact, separate experiments showed that the arylation using CO_2-soluble trialkyl phosphite–Pd catalysts[12] in the homogeneous $scCO_2$ phase did not provide turnover numbers higher than those obtained in the liquid phase. These results, in addition to the phase behaviour discussed above, clearly indicate that below 100 atm of CO_2 pressure the reaction occurs rapidly mainly in the liquid phase to give the initial product styrene, which is effectively extracted in the $scCO_2$ phase because of its reasonably high vapor pressure (430 mmHg at 125 °C) and high solubility in $scCO_2$ under the reaction conditions. The use of supercritical or even subcritical gaseous CO_2 might help to separate the desired product from the liquid reaction phase into the $scCO_2$ or vapor phase to avoid further reactions which may produce undesired multiarylated products.

A remarkable advantage of this biphasic system can be demonstrated by the reaction of *p*-bromotoluene substrate/catalyst = 100) and ethylene (10 atm) catalysed by complex **1** in the presence of (DBU) and 1-ethylpiperidine (Table 2). A mixture of these bases serves as an efficient promoter for the less reactive bromoarenes possibly because of their strong basicity. Although the reaction of the bromoarene proceeded much more slowly than that of iodoarene, it reacted with ethylene under neat conditions without CO_2 to give products in moderate selectivity as shown in Table 2 (Run 1). Using CH_3CN as a liquid solvent, the reaction proceeded to 74% conversion after 96 h to give the monoarylated product in 82% selectivity (Runs 2 and 3). In contrast to these liquid phase reactions, the outcome of the reaction in the $scCO_2$–liquid biphasic system was significantly improved, the styrene selectivity increasing from 68 to 88% at near complete conversion after 18 h (Run 4).[13]

Table 2 Pd-catalysed reaction of *p*-bromotoluene and ethylene in $scCO_2$ and other media[a]



Run	Medium	Time/h	Conversion (%)	Selectivity (%)
1		18	100	68
2	CH_3CN, 10 mL	18	14	100
3	CH_3CN, 10 mL	96	74	82
4	CO_2, 100 atm	18	97	88

[a] Reaction was conducted at 130 °C for 18 h, in a 50 mL reaction vessel containing 100 μmol of Pd catalyst **1**. Base = DBU + 1-ethylpiperidine, *p*-bromotoluene:**1**:DBU:1-ethylpiperidine = 100:1:140:150.

In conclusion, the arylation of ethylene catalysed by Pd complex with phosphite ligands selectively afforded monoarylated products in the $scCO_2$–liquid biphasic system. A combination of the rapid reaction in the liquid phase and the extraction of the product with $scCO_2$ provided a significant improvement in the product selectivity.

Notes and references

† Safety warning: Operators of high-pressure equipment should take proper precautions to minimize the risk of personal injury.

‡ Standard procedure for the arylation: The reactor was charged with argon gas and was placed in the oven at 130 °C before introduction of reagents. A mixture of the substrate (1.0 mmol), base (1.4 mmol) and DMF (0.01 mL) solution of Pd catalyst (0.01 mmol) was added into the reactor with a syringe through an opening against the flow of CO_2. Subsequently, C_2H_4 (10 atm) was introduced, and then CO_2 (0–150 atm) was added with an HPLC pump. After stirring for 18 h, the reactor was cooled in a bath of methanol with dry ice. The mixture of C_2H_4 and CO_2 was vented, and the reactor was slowly warmed to rt. The yields of products were determined by GC analyses.

Oxidation of water-insoluble alcohols in supercritical CO_2 over a Pd–Pt–Bi/C catalyst in a continuous fixed bed reactor affords high reaction rates and yields up to 98% of the corresponding ketones, aromatic and α,β-unsaturated aliphatic aldehydes, without the risk of using a flammable organic solvent.

Partial oxidation of alcohols over supported platinum metal catalysts is an attractive, environmentally friendly process: air or oxygen can be used as oxidant in aqueous medium under mild conditions. Primary and secondary alcohols are readily oxidized to carboxylic acids and ketones, respectively, but partial oxidation of primary alcohols to aldehydes is limited to aromatic and α,β-unsaturated aliphatic alcohols where hydration and further dehydrogenation of the intermediate aldehyde is minor.[1–4] Drawbacks of the method are the frequently observed catalyst deactivation necessitating high catalyst–substrate ratio (20–50 mass%),[3,5] and the explosion risk in the case of readily dehydrogenating substrates.[6] Oxidation of water-insoluble alcohols is rather slow in organic solvents[7] and because of safety reasons the process is unattractive even on a laboratory scale.[5]

To overcome these restrictions, the organic solvent can be replaced by supercritical carbon dioxide ($scCO_2$),[8,9] *i.e.* CO_2 under conditions above its critical temperature (T_c = 31.1 °C) and pressure (p_c = 73.8 bar). Supercritical CO_2 has a number of distinct advantages over conventional organic liquid solvents, among which adjustable solvent strength and favorable transport properties are probably the most important. This medium is especially attractive for the oxidation of weakly polar, water-insoluble alcohols, due to the low polarity of $scCO_2$. Besides, CO_2 is relatively inert and non-flammable under oxidizing conditions. Products and solvent can easily be separated by releasing the pressure of the reaction mixture.

There are only two examples of the partial oxidation of alcohols with a solid catalyst in $scCO_2$ reported in the literature. Oxidation of methanol on iron oxide containing aerogels,[10] and ethanol on Pt/TiO_2,[11] affords the corresponding aldehydes in moderate yields (15–30%) compared to the conventional gas phase oxidation of small chain aliphatic alcohols.[12] Here we show that oxidation in $scCO_2$ is an excellent alternative to liquid phase reactions in organic solvents, affording the conversion of water-insoluble alcohols to (deactivated) carbonyl compounds at high rate and selectivity.

The experiments have been performed in a high-pressure continuous fixed bed reactor over a promoted noble metal catalyst (4% Pd–1% Pt–5% Bi/C).† It has been shown before that Bi or Pb promotion can remarkably enhance the performance of Pt and Pd.[4,5] For the study of the influence of reaction parameters, the conditions were chosen to achieve conversions in the range 2–10% in order to minimize the temperature gradients in the catalyst bed. In some cases the contact time and temperature were increased to achieve high conversions, though optimization of the reaction conditions was not attempted. These results, illustrating the potential of the method in the synthesis of activated and non-activated aldehydes and ketones, are collected in Table 1.

Octan-2-ol has been converted to octan-2-one with higher than 99.5% selectivity even at around 70% conversion. Only traces of oct-2-ene (by dehydration) and oct-4-ene (by dehydration and subsequent double bond migration) have been formed. The yield (68%) could be further increased by applying a higher amount of catalyst or lower mass flow rate. The octan-2-one yield increased exponentially with increasing temperature and approximately linearly with contact time. A bell-shaped curve was found for the effect of oxygen concentration in the feed (Fig. 1). The drop after the maximum in yield is attributed to the so-called over-oxidation of the catalyst, a phenomenon commonly observed with platinum metal catalysts.[3,5,6] The rate of oxidative dehydrogenation of alcohols is considerably higher on the reduced metal surface than on the oxygen-covered metal. Though oxygen is necessary to shift the alcohol–carbonyl compound equilibrium by oxidizing the hydrogen abstracted from the substrate, too high surface oxygen coverage reduces the overall reaction rate. An additional effect is the decreasing density of $scCO_2$ with increasing oxygen concentration, which may reduce the solubility of reactant and product. Changes in density of $scCO_2$ can also explain the influence of total pressure in the reactor. At constant temperature the yield reached a maximum at 110–120 bar.

Oxidation of octan-2-ol was relatively slow compared to the conversion of other secondary alcohols, such as 1-phenylethanol (Table 1). The transformation of 1-phenylethanol to acetophenone was nearly quantitative. Only traces of bis(1-

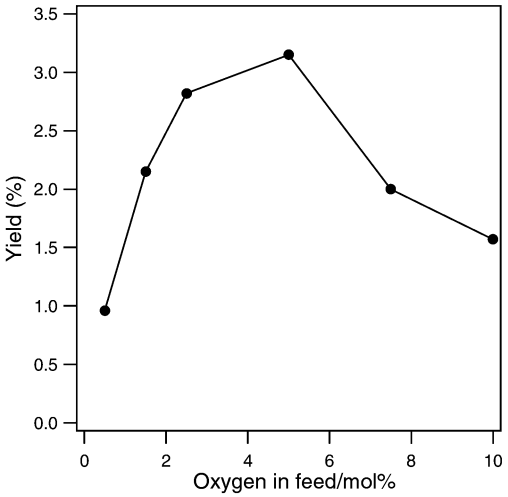

Fig. 1 Effect of oxygen concentration in the feed on the yield of octan-2-one. Conditions: 100 °C, 95 bar, 2 g catalyst, 2.46 mol h^{-1}, 5 mol% octan-2-ol, rest O_2 and CO_2.

phenylethyl) ether were detected. In these reactions the solid substrate was dissolved in butanone for feeding, because the reactor tubes and valves were not heatable. Comparative experiments with octan-2-one indicated that the yield decreased with increasing amount of this co-solvent suggesting that its amount should be kept at a low level (Fig. 2). The change in reaction rate may be connected to H-bonding between the substrate and co-solvent. Formation of H-bonded species (clusters) can change the phase behavior in $scCO_2$.

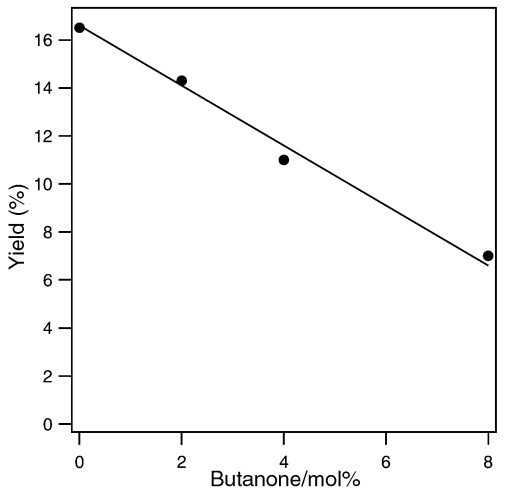

Fig. 2 Dependence of octan-2-one yield on butanone concentration in the feed. Conditions: 120 °C, 120 bar, 2 g catalyst, 3.28 mol h^{-1}, 2 mol% octan-2-ol, 4 mol% O_2, rest CO_2.

Transformation of primary alcohols to aldehydes under similar conditions was fast but non-selective (Table 1). For example, octan-1-ol was oxidized to a mixture of octanal, octanoic acid and octyl octanoate. Oct-2-enal and dioctyl ether were produced in traces. Transient experiments indicated that the acid-catalyzed side reactions (ester and ether formation) were accelerated by the product octanoic acid. In general, the selectivity to octanal decreased rapidly with increasing conversion, especially at high temperature. Relatively good selectivity could be achieved by working at 60–80 °C and high contact time (Table 1). Still, the aldehyde yield was always less than 20%. For comparison, partial oxidation of primary aliphatic alcohols is non-selective also in aqueous medium,[4] due to the high reactivity of aliphatic aldehydes for hydration and subsequent rapid dehydrogenation.

Remarkably better selectivities can be achieved when the product aldehyde is stabilized by an aromatic ring or a C=C double bond. Benzyl alcohol was oxidized to benzaldehyde, benzoic acid and benzyl benzoate. Higher than 99% selectivity for benzaldehyde was obtained at 60–80 °C (Table 1). At 100 °C or higher the selectivity dropped below 80%. Clearly, good yields can be achieved only at moderate temperature and longer contact time (higher amount of catalyst and/or lower mass flow rate). Oxidation of *p*-anisyl alcohol to *p*-anisaldehyde afforded even better yields, presumably due to the electron-releasing methoxy group in the para position (Table 1).

The highest aldehyde yield with high selectivity was obtained in the oxidation of the α,β-unsaturated alkylaromatic alcohol, cinnamyl alcohol. The negative impact of the co-solvent, used for dosing the solid substrate, is confirmed by the last two entries in Table 1. The aldehyde yield dropped from 78 to 61% when the alcohol was diluted with double the amount of butanone. Again, dosing of melted substrate can eliminate this complication.

From the results presented we can conclude that the aerobic oxidation of alcohols to carbonyl compounds in $scCO_2$ is a good alternative to the well-known aqueous phase oxidation on supported platinum metal catalysts. The present method has obvious advantages for the transformation of water-insoluble alcohols, avoiding the application of flammable organic solvents. Aqueous phase oxidations are typically performed at 40–90 °C for 3–10 h reaction time.[2–6] In the present study only 10–25 s residence time was necessary to achieve 65–98% yields of ketones, aromatic and α,β-unsaturated aldehydes. The yields and selectivities may be further improved by applying longer residence times at relatively low temperature, and by direct dosing of melted substrates (without co-solvent). No catalyst deactivation or metal leaching was observed with time-on-stream. Generally, steady-state conditions were reached within 2–3 h. The limitation of the method is similar to that of the aqueous phase oxidation on platinum metal catalysts, namely that primary aliphatic aldehydes cannot be synthesized with good selectivity.

Notes and references

† *Experimental procedure*: The reactions have been performed in a tubular flow reactor with an inner diameter of 13 mm and 38 ml volume. The alcohols were dosed by a Gilson 305 piston pump. Oxygen was supplied to the reactor using a six-port valve dosing 0.05 ml pulses at constant frequency. The constant pressure in the system was maintained by a backpressure regulator with CO_2. The total gas flow was controlled at the vent. The 4% Pd–1% Pt–5% Bi/C catalyst (CEF 196 RA/W, Degussa, BET surface area 930 m^2 g^{-1}) was reduced *in-situ* in hydrogen at 100 °C for 2 h prior to the kinetic measurements. For the parameter study the feed flow consisted of 5 mol% alcohol, 2.5 mol% oxygen and 92.5 mol% CO_2. 2 g catalyst was used, and a feed flow rate of 2.46 mol h^{-1}. The liquid products were separated from CO_2 and identified by GC and GC-MS. Yield and selectivities were determined by GC analysis using the internal standard method.

CoAPO-CHA molecular sieves with Co(II) occupying 75% of the framework Al sites can be synthesized in the presence of ethanol and caesium.

Microporous crystalline aluminophosphate ($AlPO_4$-*n*) molecular sieves have a strict alternation of aluminium– and phosphorus–oxygen tetrahedra and their frameworks are neutral and, as a consequence, do not possess ion-exchange or acidic properties.[1] Acidic and redox sites can be generated in these materials by incorporating transition metal ions in the framework positions of these molecular sieves. This incorporation process gives rise to materials with interesting catalytic properties.[1–3] In this respect, the isomorphous substitution of Co(II) in $AlPO_4$-*n* materials has been studied in great detail, although the amounts of framework Co(II) remain still relatively low.[4–8] To the best of our knowledge, the framework Co : Al ratio reported is always < 1 with the exception of some $AlPO_4$-*n* molecular sieves with extremely small pores.[5,6,8] In fact, up to now not more than 38% of the Al(III) sites have been replaced by Co(II) in $AlPO_4$-*n* molecular sieves with pore openings > 3.5 Å. An example is CoAPO-50 with a framework substitution of 37.5%,[9] while for CoAPO-46 *ca*. 26% of the Al(III) sites can be replaced by Co(II).[10] It has also been reported that CoAPO materials with a chabazite structure can be prepared containing *ca.* 30% framework Co(II) by using $[NEt_4]_2CoCl_4$ and tetraethylamine hydroxide as the Co(II) source and template, respectively.[4] In this work, we report on the synthesis of crystalline CoAPO molecular sieves with the CHA structure having a Co : Al ratio substantially > 1. This high substitution degree has been made possible by using ethanol as solvent and by adding appropriate amounts of caesium to the synthesis gel.

CoAPO-CHA materials were prepared with H_3PO_4 (85 wt.%, Acros), $Co(MeCO_2)_2{\cdot}4H_2O$ (97 wt.%, Acros), pseudoboehmite (70 wt.% Al_2O_3, Catapal), caesium chloride (p.a., Acros), triethylamine (TEA, 99%, Acros) and ethanol (99.7–100%, BDH Laboratory) starting from the following gel composition: $(1.0–2.3)TEA{\cdot}(0\text{-}0.8)Cs_2O{\cdot}(0.6–1.6)CoO{\cdot}(0.2–0.7)Al_2O_3{\cdot}P_2O_5{\cdot}(30–60)EtOH$. A typical synthesis procedure is as follows: 2.93 g H_3PO_4 was dissolved into a mixture of 30 ml ethanol and 3.00 g CsCl. Then, 5.22 g $Co(MeCO_2)_2{\cdot}4H_2O$ was added to the solution, followed by the addition of 0.37 g pseudoboehmite and 2.73 g TEA under constant stirring. This mixture was then further stirred for *ca*. 1 h in an ice bath. Finally, the resultant mixture was transferred into a Teflon-lined autoclave and crystallization was carried out at 190 °C for 14 days. The obtained solid was filtered off, washed and dried at 60 °C. ICP was used to analyze the chemical composition of the initial gels and the as-synthesized samples, while XRD was used to identify the crystalline phase of the materials synthesized.

Table 1 gives an overview of the prepared CoAPO-CHA materials, the sample notations and the chemical compositions of the gel materials and final solids. Fig. 1 shows, as examples, the powder X-ray diffraction patterns of CsCoAPO-1.50 and CoAPO-1.50 and indicates that the as-synthesized solids are well crystalline and possess a CHA structure.[4,11] It is also clear that the addition of Cs(I) to the synthesis gel results in a decrease of the intensity of the peaks at lower 2θ values, particularly those at *ca*. 9.4 and 20.5°. It was observed that these peaks further decrease in intensity with increasing Cs(I) content in the synthesis gel, while at the same time the peaks at 2θ *ca.* 24.6,

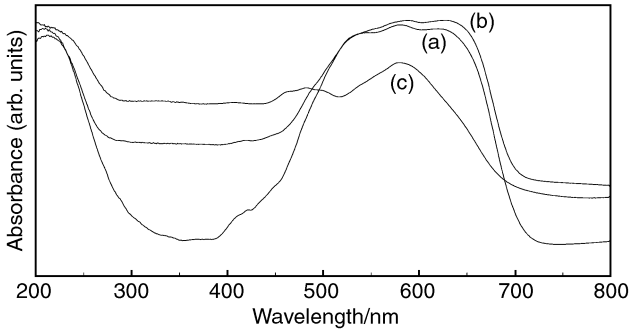

Fig. 2 DRS spectra of as-synthesized (a) and calcined (b) CsCoAPO-4.0, and calcined CoAPO-1.5 (c).

25.8, 30.5 and 37.0° increase in intensity. Such intensity changes are typical for isomorphous substitution processes.

Besides the key factors of the charge and geometry of the structure-directing amine molecules,[5] the solvent also plays a very important role in increasing the concentration of transition metals in the framework. It was reported that the Co : Al ratio of the reaction mixture can be maximized to 0.5 if TEA was used as a template in the hydrothermal synthesis of CoAPO-CHA.[5] We found that attempts to synthesize the samples with reaction mixtures containing higher cobalt contents led to the formation of a pale blue crystalline mixture of CoAPO-5 and an unknown phase. In contrast, when ethanol is used as solvent, pure CoAPO-CHA molecular sieves with an intense blue colour can be synthesized with the synthesis gel having a Co : Al ratio up to 0.67. The framework Co : Al ratio of the as-synthesized material is *ca.* 0.57, as estimated from the (P − Al) : Al ratio (Table 1). The blue colour and the absence of pink materials is indicative of tetrahedral Co(II) in the framework. The amount of framework Co(II) is much higher than that reported previously in the literature. However, further increase of the Co(II) content in the reaction mixture not only results in the formation of pink materials, but also decreases the relative amount of framework Co(II) of the as-synthesized samples. Thus, the more Co(II) in the synthesis gel, the less Co(II) in the framework. In particular, when the Co : Al ratio of the reaction mixture is > 1.5, the pink colour of the material cannot be removed by washing.

It is known that alkali metal cations have a strong influence on the crystallization of molecular sieves. We found that by introduction of Cs(I) cations in the synthesis gel, the Co : Al ratio of the reaction mixture can be dramatically increased to 4.0 for the synthesis of CHA-type Co-containing aluminophosphate molecular sieves. These materials are not contaminated with pink crystalline impurities. These as-synthesized CsCoAPO-*x* (*x* represents the Co : Al ratio of the reaction mixture) samples all have a deep blue colour. This is evident from the diffuse reflectance (DRS) spectrum of CsCoAPO-4.0 shown in Fig. 2(a). The strong triplet bands between 500 and 650 nm confirm that most of the Co(II) ions have been incorporated into the framework lattice, while a broad and weak band around 480 nm indicates the presence of only a small amount of extraframework Co(II).

Table 1 clearly shows that the Co : Al ratio of the CsCoAPO-*x* samples is basically the same as that of the reaction mixture, which is expected if Co(II) isomorphously substitutes for Al(III) in the framework. This behavior is different from that observed for the synthesis conducted in the absence of Cs(I). When the Co : Al ratio of the reaction mixture < 1, the (Co+Al) : P ratio of the as-synthesized solid, *e.g.* CsCoAPO-1.0, is very close to 1. This fact strongly supports the incorporation of most Co(II) in the framework lattice sites. With the addition of more cobalt into the reaction mixture, the (Co+Al) : P ratio is gradually > 1, indicating that a small amount of extraframework Co(II) ions is present in the products. This is in accord with the chemical analysis results. Nevertheless, it can be seen that the (P − Al) : Al ratio of the CsCoAPO-*x* samples maximally reaches about 3.12 (CsCoAPO-4.0), which means that *ca.* 75% framework Al sites have been replaced with Co(II). Table 1 also indicates that the amount of caesium needed in the synthesis increases with increasing cobalt content. The amazing ability of Cs(I) to increase the Co(II) concentration in the framework can be related to its role as a counter cation, possibly resulting in a decrease of framework distortion owing to a stronger Cs–O bond than the TEA–O bond, and consequently an increase of the stability of the as-synthesized CsCoAPO-CHA. Thus, Cs(I) promotes the incorporation of Co(II) into the framework of the CoAPO-CHA material.

As expected, the hydrothermal stability of the as-synthesized products decreases upon increasing the Co : Al ratio. It was found that CsCoAPO-*x* synthesized with reaction mixtures having a Co : Al ratio > 2.33 gradually becomes pale blue upon washing with water. This is further evidenced by the corresponding DRS spectra in which the triplet bands characteristic of tetrahedral Co(II) obviously decrease in intensity at the expense of the appearance of an absorption at 480 nm typical for extraframework octahedral Co(II). This may be due to the hydrolysis of framework Co(II) since this ion shows a strong interaction with water, and competes with Cs(I) for H_2O coordination.[5] Therefore, the products synthesized with high amounts of cobalt should be better washed with ethanol.

On the other hand, Cs(I) as a counter cation can effectively prevent oxidation of Co(II) to Co(III) during calcination. Upon calcination at 550 °C for 6 h, the sample CoAPO-*x* becomes yellow-greenish, and even pink materials are evident when the Co : Al ratio of the synthesis gel is > 0.43. This is evidenced by DRS for the CoAPO-1.5 sample [Fig. 2(c)]. This spectrum is characterized by a band at *ca.* 450–500 nm and a band at *ca.* 320 nm, indicating the presence of octahedral Co(II) and Co(III), respectively. This shows that many framework Co(II) ions have been expelled from the framework, indicating the instability of CoAPO-*x* molecular sieves. In contrast, the calcined CsCoAPO-*x* is still deep-blue, as confirmed by the strong triplet bands at *ca.* 530, 580 and 630 nm in the DRS spectrum of the calcined CsCoAPO-4.0 sample [Fig. 2(b). This proves that the presence of Cs(I) can stabilize tetrahedral Co(II) in the framework of CoAPO-CHA materials.

In conclusion, Co-rich CoAPO molecular sieves with CHA structure have been prepared using ethanol and Cs(I) as solvent and counter cation, respectively. Co(II) can be maximized to occupy about 75% of the framework metal sites. The presence of Cs(I) significantly inhibits the oxidation of Co(II) to Co(III).

A pentameric thymidyl pyrrolidine–amide oligonucleotide mimic (POM) was synthesised and shown to bind with very high affinity to complementary single stranded RNA and DNA, whilst exhibiting kinetic binding selectivity for RNA over DNA.

The sugar–phosphodiester backbone of nucleic acids has been replaced by many alternative neutral and anionic backbones.[1] There have also been reports of zwitterionic and cationic oligonucleotides with pendant aminoalkyl side chains attached to the sugar ring, pyrimidine base, or to various phosphorus internucleoside linkages.[2] Despite this, only a few *de novo* modified oligonucleotides have been reported with positively charged backbones.[3] Here we introduce a novel pyrrolidine–amide oligonucleotide mimic (POM) **1** (Scheme 1), which is derived by replacing the furanose sugar of native nucleic acids with a pyrrolidine ring which will be protonated and positively charged at physiological pH.[3d] An X-ray crystal structure[4] of a protonated pyrrolidine ring, which is stereochemically identical and both electronically and sterically similar to the pyrrolidine ring in **1**, closely resembles the northern (N) conformation of uridine in the crystalline state.[5] Semi-empirical quantum mechanical calculations (MOPAC 6.0) also revealed that the lowest energy conformation of a model pyrrolidine **2** closely resembles the preferred N-conformation of the ribose ring in native RNA. In addition, the rigid amide linkage is a viable replacement for the phosphodiester group in DNA resulting in modified oligonucleotides that form stable duplexes with RNA and DNA.[6]

To begin investigating the nucleic acid binding properties of POM a pentamer, T_5-POM **3**, was synthesised, in solution, from *trans*-4-hydroxy-L-proline *via* the ester **4**[7] (Scheme 2). Lithium borohydride reduction of the ester and benzoyl groups of **4** gave the alcohol **5**, which was subjected to a Mitsunobu reaction to afford the phthalimide derivative **6**. Removal of the phthalimide and Boc groups gave the amines **7** and **8** respectively, which were used as the building blocks for the construction of oligomers by an *N*-alkylation or *N*-acylation strategy. In the former approach primary amine **7** was treated with bromoacetic anhydride to give the bromoacetamide **9** which was coupled

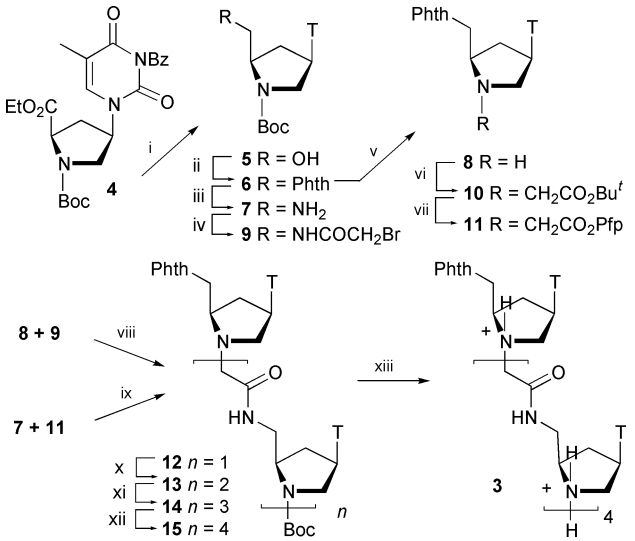

Scheme 2. *Reagents and conditions*: i, $LiBH_4$ (2 eq.), THF, 0 °C → rt, 15 h, 69%; ii, phthalimide, PPh_3, DEAD (all 1.3 eq.) in THF, −15 °C → rt, 15 h, 63%; iii, 25–30% aq. $MeNH_2$, 1 h, 40 °C, 89%; iv, bromoacetic anhydride (1 eq.), AcCN–CH_2Cl_2, −8 °C → rt, 5 min, 97%; v, CH_2Cl_2–CF_3CO_2H (2:1), 4 h, 86%; vi, *tert*-butyl bromoacetate (1.5 eq.), DIPEA (3 eq.), DMF, 0 °C → rt, 18 h, 92%; vii, CH_2Cl_2–CF_3CO_2H (4:1), 3 h, then pyridine (2 eq.), CF_3CO_2Pfp (1.2 eq.), DMF, 2 h, 78%; viii, **8** + **9** (1:1), DIPEA (3 eq.), DMF, rt, 18 h, 98%; ix, **7** + **11** (1:1) CH_2Cl_2, rt, 3 h, 100%; x, CH_2Cl_2–CF_3CO_2H (4:1), rt, 4 h, then DIPEA (5 eq.), DMF, **9**, rt, 97%; xi and xii, repeat conditions for **12** → **13**, 96 and 91%; xiii, MeOH–H_2O (1:1) saturated with $HCl_{(g)}$, rt, 2 h, 95%. DIPEA = diisopropylethylamine, Pfp = pentafluorophenyl, Phth = phthalimide, T = thymidyl. New compounds were characterised by ^1H and ^{13}C NMR, IR, UV, MS, mp, $[\alpha]_D$.

with the secondary amine **8** resulting in the dimer **12**. Boc deprotection of **12** and a second coupling with **9** results in the trimer **13.** These steps were repeated to give the tetramer **14** and pentamer **15**, which on treatment with HCl resulted in T_5-POM **3** as an highly water soluble HCl salt. Alternatively, treatment of the secondary amine **8** with *tert*-butyl bromoacetate followed by acidolysis and esterification with pentafluorophenyl trifluoroacetate gave the Pfp-ester **11** which was used to acylate primary amine **7** to give dimer **12**.

UV thermal denaturation experiments were then carried out with an equimolar mixture of T_5-POM **3** and poly(rA) (Table 1). At pH 7, 0.12 M K^+ a single hyperchromic shift was observed with a melting temperature (T_m) of 49 °C (*ca.* 10 °C per base). In comparison, native $d(T)_5$ showed no hyperchromic shift with poly(rA), above 8 °C under identical conditions, whilst $d(T)_{20}$ formed a duplex with poly(rA) with a T_m of 42 °C (2.1 °C per base). Peptide nucleic acid (PNA) lys-T_5-lysNH_2 exhibited only slightly higher affinity for poly(rA) (T_m = 56 °C). Furthermore, no hyperchromic shifts were observed for T_5-POM **3** with non-complementary poly(rC), (rG) and (rU), whilst Job plots of **3** with poly(rA) revealed a 1:1 binding stoichiometry consistent with the formation of a Watson–Crick base paired duplex.

Table 1 Transition melting temperatures (T_m) of T_5-POM **3** with poly(rA) and poly(dA).

		T_m/°C	
$[K^+]$/M	pH	Poly(rA)[a]	Poly(dA)[b]
0.12	7.0	49 (56)[c]	57 (48)[c]
0.22	7.0	52	n.d.[d]
0.62	7.0	54	42, 66[e]
1.20	7.0	55	61
0.12	8.0	45	n.d.[d]
0.12	7.5	46	n.d.
0.12	6.5	54	n.d.
0.12	6.0	57	35, 64[e]

[a] T_5-POM **3** and poly(rA) (42 μM each in bases) in 10 mM K_2HPO_4(total volume 1 cm³) adjusted to the appropriate ionic strength and pH. UV absorbance (A_{260}) was recorded with heating at 5 °C min^{-1} from 25 to 93 °C, cooling at 0.2 °C min^{-1} to 15 °C and heating at 0.2 °C min^{-1} to 93 °C. The T_m was determined from the first derivative of the final slow heating curve. [b] **3** and poly(dA) (210 μM each in bases) in 10 mM K_2HPO_4 (total volume 0.2 cm³) were incubated for 48–96 h at 25 °C, diluted to 1 cm³ adjusting to the appropriate ionic strength and pH, cooled to 15 °C at 1 °C min^{-1}, heated at 0.2 °C min^{-1} to 93 °C from which the T_m was measured as above. [c] T_m values for lys-T_5-lysNH_2 PNA (PE Biosystems). [d] T_m not determined. [e] Two transitions observed.

Surprisingly however, increasing the salt concentration resulted in slightly higher T_m values. This is in contrast to other cationic modified oligonucleotides that show a marked decrease in duplex and triplex stability with RNA and DNA at higher salt concentration, which is attributed to a reduction in the electrostatic attraction between the oppositely charged backbones.[3] The T_m of **3** with poly(rA) was also highly dependent on pH with more stable duplexes formed at lower pH. This suggests that the extent of protonation of the nitrogen atom of the pyrrolidine ring, is important for binding to RNA. However, factors other than electrostatic attraction, perhaps conformational changes brought about by protonation, are more likely to be the cause of increased duplex stability.

Remarkably no melting was observed between T_5-POM **3** and equimolar poly(dA) under identical conditions. Only after a five-fold increase in concentration of both **3** and poly(dA) followed by an extended period of incubation (48–96 h) was it possible to observe melting, suggesting T_5-POM binds much more slowly to poly(dA) than poly(rA). On the other hand the affinity of **3** for poly(dA) was considerably higher than for poly(rA) (T_m = 57 °C, pH 7, 0.12 M K^+), whilst lys-T_5-lysNH_2 PNA exhibited a lower affinity for poly(dA). Noticeably upon increasing the salt concentration (0.62 M K^+) or lowering the pH to 6, two melting temperatures were observed consistent with triple helix to duplex and duplex to single strand transitions. Job plots of **3** with poly(dA) indicated a 2:1 (T:A) binding stoichiometry consistent of triplex formation.

To investigate the difference in the association kinetics of T_5-POM **3** with DNA and RNA, the change in A_{260} with time was recorded immediately following mixing of equimolar amounts of the polyadenylates with **3** (Fig. 1). With poly(rA) at pH 7, 0.12 M K^+ and a base concentration of 42 μM for each oligomer, a 29% hypochromic shift was observed with a $t_{1/2}$ for association of *ca*. 7 min. Under identical conditions no hypochromic shift was observed with poly(dA) even after 15 h. However, increasing the concentration of both T_5-POM **3** and poly(dA) fivefold resulted in a moderate 6% hypochromic shift with a $t_{1/2}$ of at least 30 min. This clearly shows that T_5-POM **3** binds much more slowly to poly(dA) than (rA). It was also apparent from these experiments that T_5-POM binds faster to poly(rA) at lower pH and salt concentration, suggesting that electrostatic attraction increases the rate of association.

The high affinity, sequence specific binding and relative rates of association of T_5-POM **3** with DNA and RNA were confirmed using surface plasmon resonance (SPR). In these experiments 5′-biotinylated $d(A)_{20}$, $r(A)_{20}$ and a mixed sequence DNA 30–mer were immobilised *via* streptavidin into a dextran matrix upon a gold surface. A solution of T_5-POM **3** was then injected across each surface and the SPR response was measured against time (see ESI†). This revealed that **3** does bind strongly to both $d(A)_{20}$ and $r(A)_{20}$ but associates faster with $r(A)_{20}$ than $d(A)_{20}$. Significantly, the response sensogram of the mixed sequence DNA was identical to the control non–derivatised surface.

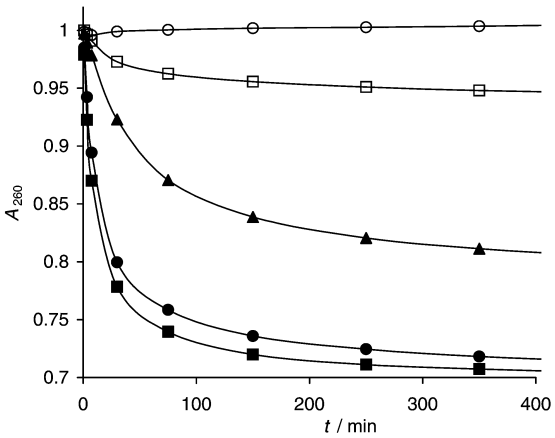

Fig. 1 Normalised UV absorbance (A_{260}) of T_5-POM **3** with poly(rA) and (dA) *vs.* time at 25 °C. **3** and poly(dA) (42 μM each in bases), 0.12 M K^+, pH 7 (○); **3** and poly(dA) (210 μM), 0.12 M K^+, pH 7 (□); **3** and poly(rA) (42 μM), 0.22 M K^+, pH 7 (▲) ; **3** and poly(rA) (42 μM), 0.12 M K^+, pH 7 (●); **3** and poly(rA) (42 μM), 0.12 M K^+, pH 6 (■).

In conclusion we have introduced a novel class of modified nucleic acids with a pyrrolidine–amide backbone and shown that the pentamer T_5-POM **3** binds sequence specifically to both ssDNA and ssRNA with an affinity that is much higher than native nucleic acids. Furthermore, T_5-POM binds much faster to ssRNA than ssDNA. Other oligonucleotides such as 2′,5′-linked RNA and DNA exhibit a thermodynamic binding selectivity for native ssRNA over ssDNA,[8] but as far as we are aware T_5-POM is the first modified oligonucleotide that can kinetically discriminate between the two. This kinetic preference may be due to folding of the polyadenylates induced by base pairing with T_5-POM, given that RNA would be expected to fold more readily than DNA. In addition the formation of tertiary interactions could also explain the high stability of T_5-POM complexes with complementary nucleic acids. The synthesis of longer mixed sequence POMs, using solid phase methods, is underway in order to explore the generality of these findings.

We thank the EPSRC for a studentship to D. T. H.

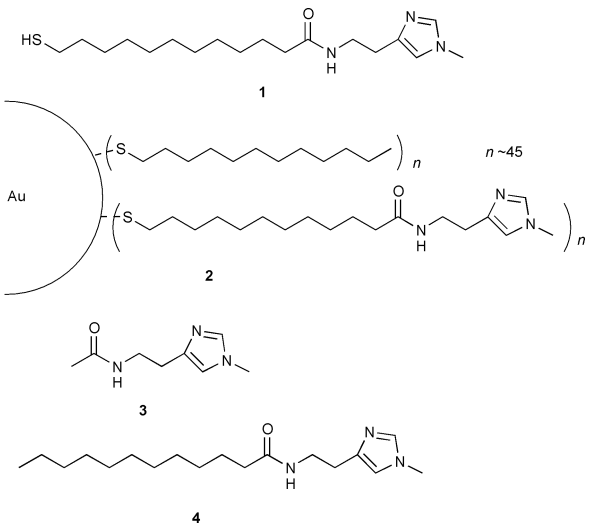
First published as an Advance Article on the web

New *N*-methylimidazole-functionalized gold clusters 2 catalyze, in 6:4 methanol–water solution, the cleavage of 2,4-dinitrophenyl acetate with more than an order of magnitude rate acceleration with respect to acetyl-*N*-methylhistamine 3; comparison with dodecanoyl-*N*-methylhistamine 4 comicellized with Brij 35 reveals that 2 is still a better catalyst than the comicellar system and highlights analogies and differences between the two systems.

The last few years have witnessed a growing interest in nanomaterials for their potential applications ranging from catalysis to technology. Among them monolayer-protected gold clusters (Au-MPCs) appear particularly promising. Since the seminal work by Brust, Schiffrin *et al.*[1] these materials can be easily obtained as systems which are stable,[2] soluble in organic solvents (according to the properties of the protecting monolayer) and rather monodisperse in size. However, in spite of these interesting properties, reports concerning applications of Au-MPCs in catalysis are rather limited. In particular, the potential for cooperativity between several functional groups assembled on gold nanoclusters has not been specifically exploited so far. This communication addresses these aspects of Au-MPCs.

The conventional preparation procedure of the nanoparticles calls for the synthesis *in situ* by reduction of an Au(III) salt in the presence of the functional thiol derivative, followed, when required, by further derivatization[3] or by solution exchange of hydrocarbon-protected Au-MPC with a suitable functional thiol.[4] Following this latter approach we have first prepared gold nanoparticles protected with a monolayer of dodecanthiolates (C12) according to the detailed protocol reported by Murray and coworkers.[5] The resulting Au-MPC-C12 proved to be rather monodisperse by transmission electron microscopy (TEM) with an average core diameter of 2.2 ± 1.0 nm. This result, combined with the elemental analysis, indicates that the clusters are composed mainly of $Au_{225}(C12)_{90}$. Subsequently, we accomplished the place-exchange reaction[4,6] by codissolving MPC-C12 and thiol **1**† in dichloromethane–methanol (1:1) under an entering:exiting ligand ratio of 1:1.5. The resulting material was purified by exclusion chromatography [Sephadex LH-60, CH_2Cl_2–MeOH (1:1)]. Proton NMR spectra‡ reveal that the obtained Au-MPC comprises a 1:1 mixture of dodecane- and *N*-methylimidazole-functionalized thiolates. TEM measurements show that during the place-exchange process the average dimension of the gold core remains unchanged while the size distribution becomes slightly larger. The presence of a 1:1 mixture does not necessarily mean a random distribution. As recently reported,[7] in solution there may be rearrangement of thiols on the Au surface.

In the design of **2** our specific goal was the realization of a catalytically active Au-MPC for the cleavage of a carboxylate ester. Furthermore we wanted to verify the possibility of cooperativity of the active functional groups because of their confinement on the surface of Au-MPC **2**. For this purpose imidazole (or *N*-methylimidazole) appeared to be a suitable



candidate because of its key role as a catalyst in many hydrolytic systems where cooperativity between two such units has been reported.[8,9]

Cleavage of 2,4-dinitrophenyl acetate (DNPA), as a model ester, was studied in a methanol–water (6:4) solution, in which the new MPCs **2** are fully soluble, in the pH range 4.5–7.2. The reactions were monitored by UV–VIS following the formation of the 2,4-dinitrophenolate at 400 nm and 25 °C. For comparison purposes acetyl-*N*-methylhistamine **3** was also used as a reference monomeric catalyst.

The dependence of the second order rate constant, k_2,§ with pH for Au-MPC **2** and monomeric catalyst **3** is shown in Fig. 1 where the remarkable rate acceleration exerted by the nano-

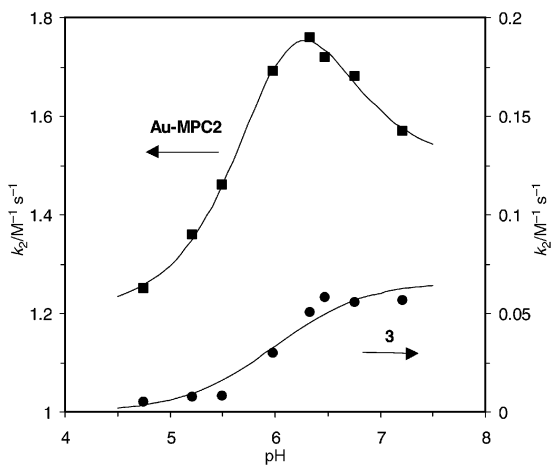


Fig. 1 pH dependence of the second order rate constants for the hydrolysis of 2,4-dinitrophenyl acetate in MeOH–H_2O (6:4) in the presence of Au-MPC **2** (■) or of the model system **3** (●). The solid curves are the best fitting of the experimental points.

DOI: 10.1039/b005244m

particles relative to **3** can be readily appreciated. Although the pK_a of *N*-methylimidazole of **2** could not be determined because of its insolubility at the high concentration required for the potentiometric titration, it is likely to be similar to the value (6.2) determined for **3** in the solvent mixture employed for the kinetic experiments. The low dependence of k_2 from pH in the pH range 5–7, with a small maximum in the proximity of the pK_a, supports cooperativity between two methylimidazoles in the DNPA cleavage by the nanocluster (general acid/general base or nucleophilic catalysis). The solid curves of Fig. 1 represent the computer-generated best fitting of the experimental points assuming a cooperative process (Au-MPC) and nucleophilic catalysis (**3**). A fair comparison between the two systems can be made at the pH values of the maxima of the two curves (pH 7.2 for **3** and 6.1 for **2**). Under these conditions the nanoclusters-catalyzed process is *ca.* 30 times faster than that using monomeric **3**. The kinetic behavior is very similar to that reported by the group of Baltzer[8] who studied four helix bundle-forming hydrolytic peptides bearing multiple imidazole side arms where cooperativity had been clearly demonstrated.

We note here that the system is really catalytic as all kinetic reactions were performed using an excess substrate (up to 7 : 1) over catalyst and the kinetic profile followed, in all cases, a well behaved pseudo-first-order process accounting for all added substrate.

Because gold nanoclusters **2** present structural analogies with a micellar aggregate we also tested the lipophilic *N*-methylhistamine derivative **4** in Brij 35 comicelles. As expected, micellar aggregates exist only in aqueous solution and not in the methanol–water mixture used for the study of **2**, as the hydrophobic effect that is at the basis of monomer aggregation vanishes in this solvent. Consequently, the catalytic efficiency in the mixed solvent is rather poor and similar to that of **3**. Comicellar **4**/Brij 35, however, binds DNPA in water (pH 6.3) with $K_b = 40\ M^{-1}$ and, in this solvent, accelerates the rate of its cleavage with k_{lim}, the pseudo-first-order rate constant for the fully bound substrate, of $2.5 \times 10^{-2}\ s^{-1}$. The comparison between the two systems is complicated by the fact that, because of the mixed solvent and the very low concentration of **2** used, the Au-MPCs are not expected to significantly bind the substrate. For this reason we have determined the second-order rate constant for the micellar system at very low surfactant concentration in the linear part of the rate *vs.* concentration profile above the critical aggregate concentration. At pH 6.2 the rate acceleration over that of the monomeric catalyst **3** is 35 for **2** and 22 for the comicelles indicating a slightly better efficiency of the Au-MPCs.

In conclusion we have reported the very first example of functional gold nanoclusters which are catalytically active in the hydrolysis of an activated ester. These systems present analogies with micellar aggregates although they exist under solvent conditions where micelles do not survive. Furthermore, the cooperative effects of the functional moieties may be exploited at very low concentration of the catalyst because the nanocluster does not require the critical aggregate concentration necessary for the formation of micelles. As for these properties, Au-MPCs resemble dendrimers, although the synthetic effort required for their formation is much less demanding. We believe that these systems present great potentialities as catalysts, and work aimed at the realization of new Au-MPCs bearing different functional groups, as well as small peptides, is in progress in our laboratory.

We are indebted to Professor P. Tecilla for helpful discussion.

Supramolecular similarities between a diastereomer pair and their truncated derivative: common tetrameric synthon and isostructurality

Alajos Kálmán,* László Fábián and Gyula Argay

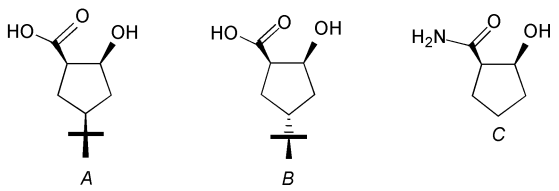
A common tetrameric supramolecular synthon and an unexpected isostructurality reveal similarities between the crystal structures of three related cyclopentane derivatives fused together by OH···O and NH···O hydrogen bonds.

Since the fundamental statements of Lehn[1] the concept that crystals are solid state supermolecules built by connecting molecules with intermolecular interactions has been widely accepted by both organic and structural chemists. In particular, Desiraju[2,3] has made relevant contributions to this concept by classifying the governing principles of supramolecular chemistry. He distinguishes anisotropic long range forces (hydrogen bonds) from the similarly important isotropic van der Waals forces. The magnitude of the latter is proportional to the size of the molecule.[4] From this it follows that packing similarities between crystals of small molecules can primarily be attributed to directional interactions. A basic description of these similarities can be given by means of supramolecular synthons.[2,3] When similarities, expressed by synthons and/or the corresponding graph set notations,[5] extend to the three dimensional arrangement of the molecules, crystals may be homo- or even isostructural.[6,7] Present work demonstrates an inherent relationship between graph set notations, synthons and isostructurality.



Crystal structures of three chemically-related small molecules *A*, *B* and *C* exemplify:

(1) a common tetrameric supramolecular synthon which establishes a genetical connection between the structures of diastereomers *A* and *B*. They crystallize with the two most frequently occurring space groups in CSD,[8] *i.e.* $P2_1/c$ (20%) and $P\bar{1}$ (35.5%).
(2) an unprecedented form of isostructurality discovered between the monoclinic ($P2_1/c$) structures of *B* and its *tert*-butyl-free derivative *C*. The isostructurality[6] of two small molecules differing substantially both in volume (by 33.5%) and shape forced us to reconsider the early view of Kitaigorodskii[9] on the conditions and limits of isomorphism.

The three crystal structures† **A**, **B** and **C** have a common OH···O=C (No. 1), and an alternative (O=C)–XH···OH (X = O for *A* and *B*, or NH for *C*) hydrogen bond (No. 2), respectively. In structure **C** there is an additional –NH···O=C(–$\underline{\text{N}}\text{H}_2$) hydrogen bond (No. 3). Structure **A**, with space group $P\bar{1}$, is composed from pairs of parallel and infinite rows of the 'all-*cis*' diastereomers *A* bound by the hydrogen bonds No. 1 [Fig. 1(A)]. Each row is homochiral and an enantiomer of the other. Each enantiomer pair is fused together by the No. 2 hydrogen bonds around an inversion center located at 0, ½, ½, closing a 12-membered ring described by graph set notation $R_2^2(12)$. This very closed pattern of the No. 1 and 2 hydrogen bonds topologically hinders the formation of the most common synthon **1**[2] between the well separated carboxyl groups. Instead of synthon **1** (Fig. 2), there is a second ring described by the $R_4^4(12)$ graph set notation which is enlarged by two additional –OH moieties from a third and fourth molecule,[10] respectively. This tetrameric synthon (Fig. 2) is located around the inversion center at ½, ½, ½ and repeated by unit translation.

The triclinic $P\bar{1}$ structure of diastereomer *A* is a *par excellence* case of the simplest molecular self-complementarity. Similarly, diastereomer *B* builds up a canonical structure with the most common space group $P2_1/c$. In structure **B** [Fig. 1(B)] hydrogen bonds No. 1 link the glide plane-related molecules parallel with the *c* axis. Pairs of parallel but folded and heterochiral rows are held together by the same tetrameric synthons recognized in the triclinic structure **A**. The $R_4^4(12)$ rings are closed around inversion centers at 0,0,0, 0,0, ½, *etc.* The 'homochiral parts' of this network are constructed by the No. 2 hydrogen bonds around the screw axes at 0,0,¼, 0,0,¾, *etc.*, forming infinite helices around the *b* axis. Thus, the infinite ribbons in structure **A** maintained by centres of inversion and

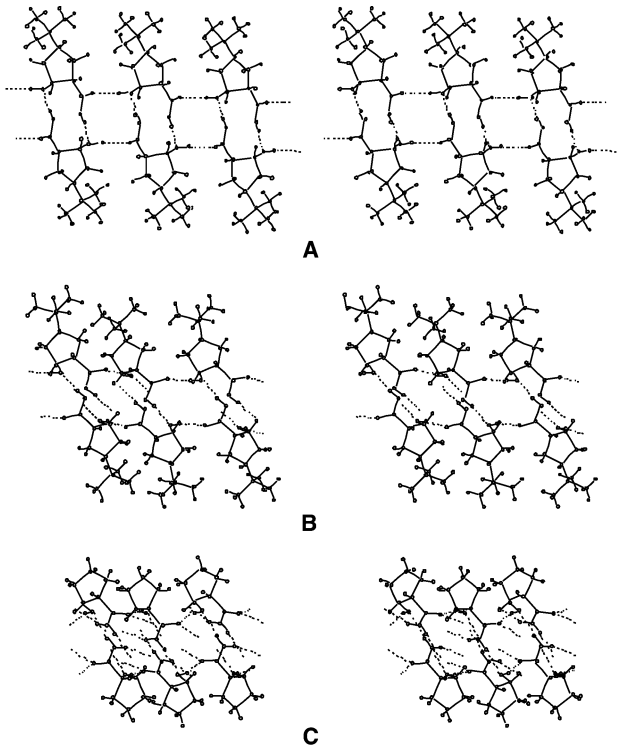


Fig. 1 Stereoview of the structures **A**, **B** and **C**. In **A**, projected in the (−1, −1,0) plane for clarity, hydrogen bonds form C(6) chains and $R_2^2(12)$ dimers. The generated $R_4^4(12)$ rings – identified as a tetrameric synthon – can also be recognized in structures **B** and **C** related by visible degree of isostructurality.

DOI: 10.1039/b005422o

translation are self-organized into 2D-stacks in structure **B** by the homochiral screw axes and heterochiral glide planes. They jointly generate centres of inversion surrounded by the supramolecular synthons **1***. From structure **A** it follows that the formation of this synthon is sterically preferred. *Mutatis mutandis* [*i.e.* $R_2^2(12)$ dimers of **A** are replaced by C(6) helices] this conclusion is also valid for structure **B**. This underscores the genetic relationship between these structures which can be regarded as *configurational* polymorphs.[11] The close relationship between their space groups $P\bar{1}$ and $P2_1/c$ is also shown[12] by migration and multiplication of pseudo-symmetries 2_1* and *c** in oblique unit cells with space group $P\bar{1}$ and $Z = 8$.

Interestingly, the higher ($P2_1/c$) and the lower ($P\bar{1}$) degree of self-complementarity exhibited by the *B* and *A* molecules equally result in the same packing coefficient[13] (0.68) for structures **B** and **A**. Nevertheless, the predominance of the monoclinic molecular array over a triclinic close packing is shown by the structure of molecule *C* [Fig. 1(C)]. It is a truncated (*i.e. tert*-butyl moiety-free) form of both diastereomers *A* and *B* and instead of a CO_2H group it possesses a $CONH_2$ moiety. However, **B** and **C** are homostructural[6,7] (Fig. 1) which implies that the tetrameric synthon is also retained. Naturally, owing to the OH $\rightarrow$ NH_2 replacement, now it is the enlarged form of the dimeric supramolecular synthon **3** (Fig. 2). From these it follows that the directional[4] hydrogen bond network in structure **B** is so stable that it survives the elimination of the bulky *tert*-butyl moiety. In other words, in special circumstances a small molecule such as *B* can maintain nearly isostructural close packing with an even smaller molecule *C*. Even the presence of an additional supramolecular synthon **4** (Fig. 2) built by hydrogen bond No. 3 cannot alter this pattern either.

The supramolecular synthon **1*** or **3*** is a common hallmark of the structural similarity shown by these related structures. It can be attributed to their special feature, *i.e.* two pairs of donor/acceptor functions maintaining the most common supramolecular cements, the OH···O and NH···O hydrogen bonds, which are located in the vicinal position on a small but flexible (pseudo-rotation) spacer. The *synclinal* position of the 1,2-*cis*-substituents on the flexible cyclopentane ring provides genuine steric conditions to the observed supramolecular arrangement.

This raises the question, how does the *cis*$\rightarrow$*trans* isomerization of the vicinal functions modify the close packing found in these structures? Moreover, how does the migration of the bulky *tert*-butyl moiety influence the pattern so stable in structure **B**? Modeling of structure **B** with molecules *A* revealed that such a packing is hindered by very short H···H contacts (*ca.* 1.15 Å). These and further questions will be answered in a full paper[14] to be published elsewhere.

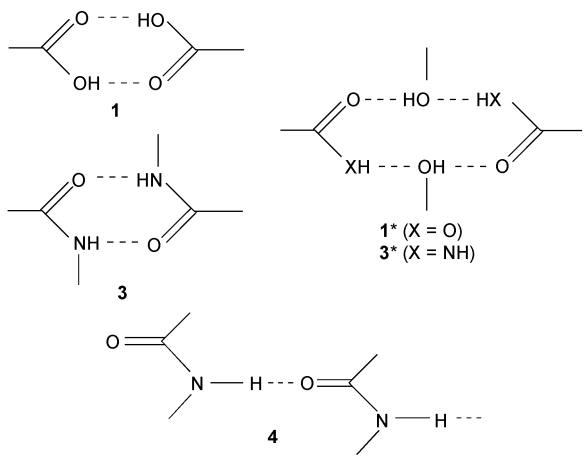

Fig. 2 The tetrameric synthon found in structures **A** and **B**. In **C**, $-CO_2H$ groups are replaced by –CONH moieties. **1**, **3** and **4** are the most common supramolecular synthons as labelled by Desiraju.[2]

Can 4,4′-bipyridine *N*,*N*'-dioxide play the same important role as 4,4′-bipyridine in the construction of metal coordination networks and crystal engineering?†

De-Liang Long, Alexander J. Blake, Neil R. Champness* and Martin Schröder*

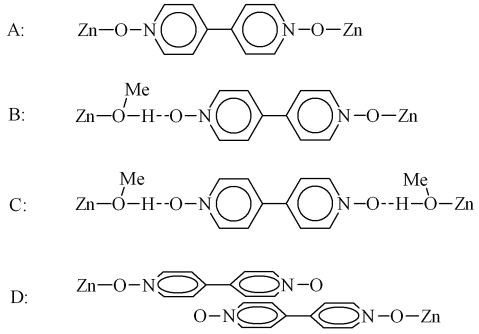
School of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: neil.champness@nottingham.ac.uk; M.Schroder@nottingham.ac.uk

Received (in Cambridge, UK) 15th August 2000, Accepted 2nd October 2000
First published as an Advance Article on the web

Various binding modes of 4,4′-bipyridine *N*,*N*′-dioxide (L) for crystal engineering are demonstrated in the complexes $[Zn(MeOH)_2L_3](SiF_6)\cdot 3MeOH$ and $[ZnL_6](NO_3)_2$, which include examples of M–L coordination bonds, hydrogen-bonding and π–π stacking interactions.

4,4′-Bipyridine and its analogues containing two 4-pyridyl donor units have been found to be useful bridging ligands in the construction of inorganic networks and crystal engineering, and this has resulted in a plethora of extended assemblies including helical networks and diamondoid, honeycomb, square-grid, ribbon, grid, T-shaped, ladder, brick wall and octahedral frameworks.[1,2] We demonstrated recently the use of 4,4′-bipyridine *N*,*N*′-dioxide (L) in the construction of lanthanide coordination polymers with unusual 2- or 3-D networks.[3] We now extend this work to d-block elements and confirm that L and related *N*-oxide ligands have enormous potential for the construction of unusual networks incorporating these metal ions. We report herein two Zn(II) complexes, $[Zn(MeOH)_2L_3](SiF_6)\cdot 3MeOH$ **1** and $[ZnL_6](NO_3)_2$ **2**, which contain *four* different connection modes of L *via* M–L coordination, hydrogen-bonding and π–π interactions. While **1** has a 3-D open-framework structure whose large pores accommodate methanol solvent molecules, **2** is a mononuclear complex which forms 2-D layers *via* extensive π–π stacking interactions.

Compounds **1** and **2** were prepared by mixing methanolic solutions of $Zn(SiF_6)$ or $Zn(NO_3)_2$, respectively, and 4,4′-bipyridine *N*,*N*′-dioxide.‡ Crystals of **1** were found to be unstable in air and decayed quickly *via* solvent loss. X-Ray analysis of **1** confirms a polymeric structure based on networks of six-coordinate Zn(II) centres linked by 4,4′-pyridine *N*,*N*'-dioxide ligands.§ The Zn(II) ions have an octahedral environment provided by four oxygen atoms from four different *N*-oxide ligands and two others from coordinated molecules of MeOH. The 4,4′-bipyridine *N*,*N*′-dioxide ligands bridge metal centres directly or through combinations of M–L coordination and hydrogen bonds in three distinct fashions A (A′), B and C as shown in Scheme 1 and Fig. 1. The 4,4′-bipyridine *N*,*N*′-dioxide ligands therefore sustain a 3D framework structure through *four* different linkages. If coordination bonds (A or A′) are taken into account alone the structure can be considered as having a two-dimensional brick-wall (6,3) topology. Linkages of type A and A′ propagate along the *a* and *b* axes, respectively, and are chemically equivalent but crystallographically different, the latter having an inversion centre at its midpoint. Ligand A is slightly bent, with the two pyridyl rings twisted by 17.9° and bridging two Zn(II) centres separated by 12.7 Å. Ligand A′ is planar by symmetry and bridges two Zn(II) centres lying 12.3 Å apart. Ligands adopting connection mode C modify the two-dimensional framework by joining the nodes at the centres of the long sides of the rectangle (*i.e.* across the centre of the "brick" in the brick-wall structure) to form a square grid network of (4,4) topology. Strong hydrogen-bonding is confirmed by the short O···O separation [2.571(7) Å] within the O–H···O unit in mode C. Ligands involved in connection mode B [O···O separation 2.652(6) Å] join sheets to build up a 3-D open network with channels of dimensions 10.2 × 14.2 Å extending along the *c* axis (Fig. 2).



Scheme 1 Modes of connection observed in compounds **1** and **2**.

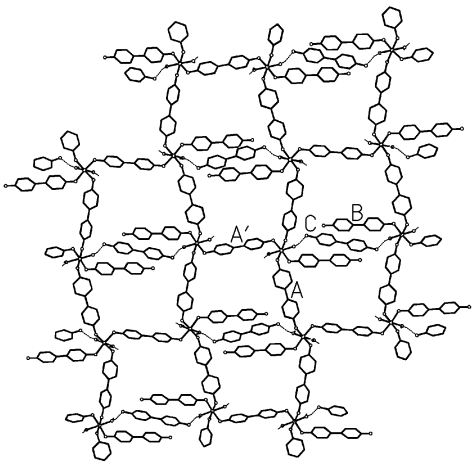


Fig. 1 View of the sheet observed in compound **1**. The $[SiF_6]^{2-}$ anion, methanol solvent molecules and hydrogen atoms are omitted for clarity.

4,4′-Bipyridine and its analogues containing two 4-pyridyl donor units can also adopt these coordination modes when forming complexes with either lanthanide[4,5] or d-block metals[6] but no examples of all three modes occurring in the same compound have been reported previously. The coexistence of three coordination modes for such a bidentate ligand is unique and indicates a real versatility in coordinative behaviour for *N*-oxide ligands.

Compound **2** is composed of discrete $[ZnL_6]^{2+}$ cations and uncoordinated nitrate anions. The Zn(II) centres are octahedral with a ZnO_6 environment, the six oxygen donors being derived from six different terminal 4,4′-bipyridine *N*,*N*′-dioxide ligands. The Zn(II) centre occupies a crystallographic inversion centre which results in three crystallographically independent ligands

† Electronic supplementary information (ESI) available: molecualr structures and labelling schemes for complexes **1** and **2**. See http://www.rsc.org/suppdata/cc/b0/b006679f/

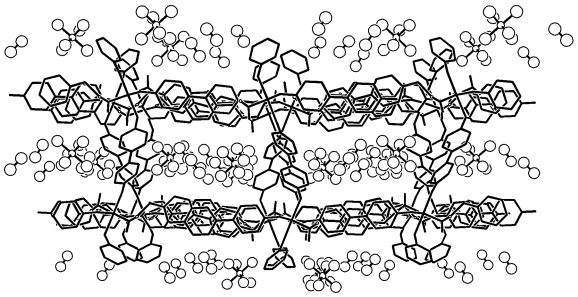

Fig. 2 View of the channels in compound **1**. Methanol solvent molecules and anions are highlighted by large open cycles. Hydrogen atoms are omitted for clarity.

with Zn–O bond lengths falling in the range 2.063(3)–2.109(3) Å, typical for Zn(II) complexes of pyridine *N*-oxide.[7] The pyridyl rings within each of these ligands are twisted with respect to each other, the twist angles ranging from 13.0 to 28.5°. To our knowledge this is the first example of a mononuclear complex of the 4,4′-bipyridine *N*,*N*′-dioxide ligand, which normally acts as a bridge between metal ions, either though M–L coordination or hydrogen bonds.[3]

Although all six 4,4′-bipyridine *N*,*N*′-dioxide ligands act as terminal ligands and the complex is mononuclear, an overall layered polymeric structure is observed for **2** *via* intermolecular π–π interactions. π–π Interactions have been used previously for the construction of coordination networks from discrete molecules,[8] but the mode found here is unique (Fig. 3). The six ligands are distributed alternatively in two planes around the Zn(II) centre so that the molecule has approximate D_{3h} symmetry. Each complex cation is involved in six ligand-to-ligand π–π interactions (mode D, Scheme 1) with six adjacent coplanar molecules to give an unprecedented (3,6) two-dimensional sheet. The plane/centroid distances for these π–π interactions are in the range 3.27–3.39 Å. It is important to note that the use of 4,4′-bipyridine *N*,*N*′-dioxide is crucial here; not only do the reduced steric requirements of the *N*,*N*′-dioxide ligand, compared with 4,4′-bipyridine, allow coordination of six ligands around the metal centre, but the angle subtended at the O-donor (the Zn–O–N bond angles for **2** range from 124.4 to 129.2°) is necessary to allow the construction of the two-dimensional sheet. These differences between donors based on bipyridine and those derived from bipyridine *N*,*N*′-dioxide are crucial to the differing roles they can play in coordination polymer chemistry.

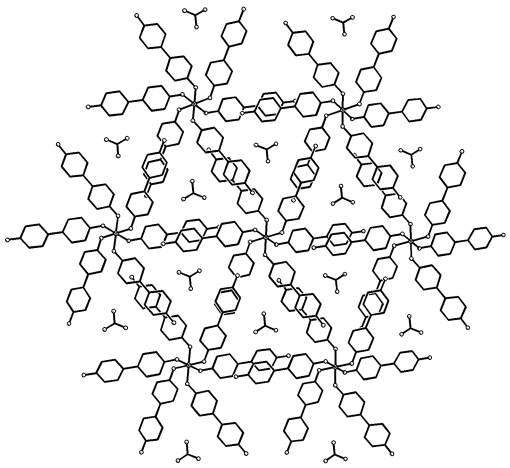

Fig. 3 View of the layer structure of (3,6) topology formed *via* π–π interactions in compound **2**. Hydrogen atoms are omitted for clarity.

Furthermore, comparison of the structures of **1** and **2** gives insight into the templating role of the anion in the construction of coordination polymer networks.[9] Thus for example in **2**, the nitrate anion appears to template the formation of a network of trigonal symmetry (Fig. 3) of specific stoichiometry. Efficient space-filling enables dense-packing to leave small trigonal holes that accommodate nitrate anions. Significantly, the formation of compound **2** is independent of M:L ratio, and is obtained even when a ratio of M:L ratio of 1:2 is used. The influence of the anion, therefore, appears significant enough to influence the oberved coordination of the bridging ligand and stoichiometry of the product isolated. Current works seeks to investigate further the binding of *N*-oxide ligands to d-, f-block and other elements.

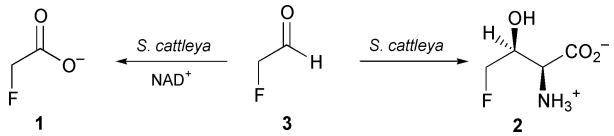
First published as an Advance Article on the web

Fluoroacetaldehyde is converted to fluoroacetate and 4-fluorothreonine in *Streptomyces cattleya* indicating that it is the biosynthetic precursor of both of these secondary metabolites.

Organic compounds containing a C–F bond are extremely rare in living organisms; only about a dozen have been identified, the majority in plants.[1] Fluoroacetate (FAc) **1** is the most widespread fluorinated natural product and its biosynthesis in plants has been the subject of investigation and some speculation for the past 50 years. Despite this interest little progress has been achieved in elucidating the mechanism of fluorination or the metabolic route involved.[2] However the discovery that FAc **1** and L-4-fluorothreonine (4-FT) **2** are secondary metabolites of *Streptomyces cattleya* has provided a convenient microbial system in which to study the biosynthesis of the C–F bond.[3]

Our investigations into the origin of these metabolites in *S. cattleya*[4–7] have consistently shown that, in terms of magnitude and regiochemistry, isotope incorporations into C-1 and C-2 of FAc **1** always mirror those into C-3 and C-4 of 4-FT **2** from a given isotopically labelled precursor. This finding suggests a single fluorination enzyme in *S. cattleya*. As the possibility of direct conversion of one fluorometabolite to the other has been eliminated,[4,5] each fluorometabolite must therefore arise by further metabolism of a common fluorinated intermediate. We now report results which indicate that this metabolic precursor is fluoroacetaldehyde **3**.

An aqueous sample of fluoroacetaldehyde **3** was prepared by PDC oxidation of fluoroethanol in dichloromethane, followed by distillation of the volatiles into water. The preparation contained both fluoroacetaldehyde **3** and fluoroethanol (ratio ~1:3). The fluoroacetaldehyde was characterized as the DNP derivative.[8] Incubation of resting cells suspensions[7] of *S. cattleya* with the fluoroacetaldehyde preparation (2 mM with respect to fluoroacetaldehyde in 50 mM MES buffer, pH 6.5, containing 176 mg wet wt cells ml^{-1}) resulted in the efficient and almost stoichiometric conversion of fluoroacetaldehyde **3** to FAc **1** over a 3 h period (Scheme 1). Analysis of the culture supernatant by ^{19}F-NMR indicated that only the fluoroacetaldehyde **3** was converted to FAc **1**, the fluoroethanol remaining unmetabolised. Previous studies have demonstrated[5] that fluoroethanol is metabolically inert in *S. cattleya* and this was confirmed by control experiments with resting cells which did not reveal any oxidation of fluoroethanol to fluoroacetate. To further investigate the conversion of fluoroacetaldehyde **3** to FAc **1** cell-free extracts of *S. cattleya* were prepared with a French press. The extract oxidised fluoroacetaldehyde to fluoroacetate only in the presence of NAD^+ ($NADP^+$ was ineffective), demonstrating that an aldehyde dehydrogenase mediated the conversion. The purified enzyme[9] also oxidised acetaldehyde, chloroacetaldehyde, glycolaldehyde and propionaldehyde (34, 79, 116 and 30% of the enzyme activity with fluoroacetaldehyde respectively) indicating that *S. cattleya* possesses a relatively non-specific NAD^+-dependent aldehyde dehydrogenase which efficiently converts fluoroacetaldehyde **3** to FAc **1**.



1 **3** **2**

Scheme 1

Sanada *et al.*[3] proposed that 4-FT **2** might arise by an aldol condensation between fluoroacetaldehyde and glycine, such that the latter contributes C-3 and C-4 of the amino acid. However, in experiments using [1-^{13}C]-, [2-^{13}C]- and [1,2-$^{13}C_2$]-glycine we have demonstrated[7] that glycine is not the condensing nucleophile as it is not incorporated directly into C-1 and C-2 of 4-FT **2**, so at present the origin of C-1 and C-2 of 4-FT **2** is unknown. Nevertheless fluoroacetaldehyde is an attractive precursor for C-3 and C-4 of 4-FT **2**. To establish a role for this compound in 4-FT **2** biosynthesis, its effect on 4-FT **2** production by resting cell suspensions of *S. cattleya* was measured by monitoring concentrations in culture supernatants using an HPLC assay.[10] The data from this experiment are presented in Fig. 1. When resting cell suspensions were incubated over a period of 6 h with the fluoroacetaldehyde–fluoroethanol preparation (176 mg wet wt cells ml^{-1} in 50 mM MES buffer pH 6.5, 2 mM fluoroacetaldehyde, 6 mM fluoroethanol), 4-FT **2** concentrations increased linearly with time ultimately attaining 49 μM. In suspensions with no supplementation or those incubated with 6 mM fluoroethanol alone, concentrations of 4-FT **2** did not exceed 7 μM after 6 h. Suspensions supplemented with 2 mM NaF (the optimal F^- concentration for fluorometabolite biosynthesis[4]) yielded 26 μM 4-FT **2** over the same time period. When 2 mM FAc **1** was

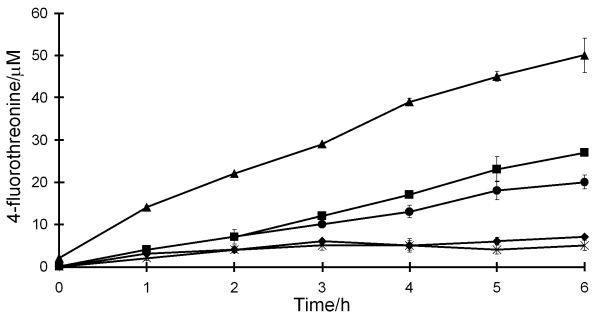


Fig. 1 L-4-Fluorothreonine **2** concentration in supernatant of resting cell suspensions of *S. cattleya* after addition of (a) fluoroacetaldehyde (2 mM)–fluoroethanol (6 mM) (▲); (b) NaF (2 mM) (■); (c) fluoroacetate (2 mM) (●); (d) fluoroethanol (6 mM) (**x**); (e) no supplementation (⧫). Data determined by HPLC analysis.[10] Error bars indicate the SD of triplicate samples.

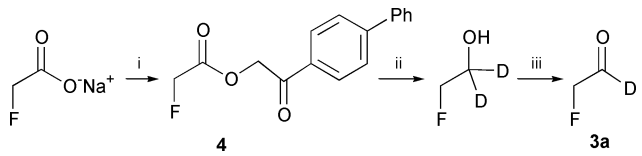
DOI: 10.1039/b007261n

incubated with cell suspensions a slight enhancement of 4-FT **2** biosynthesis was observed (19 μM after 6 h). As previous investigations involving incubation of [$^2H_2$]-fluoroacetate with cell suspensions of *S. cattleya* had demonstrated no direct conversion of FAc **1** to 4-FT **2**, this increase can probably be attributed to defluorination of FAc **1** and subsequent *de novo* synthesis of 4-FT **2** from F^-. Such cell suspensions are known to have a limited defluorinating activity with FAc **1**.[5] Thus fluoroacetaldehyde clearly stimulates 4-FT **2** biosynthesis in *S. cattleya* almost doubling the rate recorded in suspensions incubated under optimal F^- concentrations, an enhancement which is not explicable in terms of metabolism *via* fluoroethanol or fluoroacetate.

The biosynthetic relationship between fluoroacetaldehyde **3** and 4-FT **2** was further investigated using [1-$^2H_1$]-fluoroacetaldehyde **3a**, a synthesis of which was developed, by an adaptation of a previously reported synthetic route for isotopically labelled ethanol[11] (Scheme 2). The [1-$^2H_1$]-fluoroacetaldehyde preparation contained 5% [1,2-$^2H_2$]-fluoroacetaldehyde as an impurity. [1-$^2H_1$]-Fluoroacetaldehyde **3a** was administered as above to cell suspensions of *S. cattleya* and the incorporation of deuterium into C-3 of 4-FT **2** was monitored by GC-MS[12] over time.



Scheme 2 i. *p*-Phenylphenacyl bromide, 18-crown-6, acetonitrile–toluene (1:1); ii. LiAl^2H_4, diethyl ether, 2-phenoxyethanol quench, distillation; iii. PDC, diethyl ether–dichloromethane (1:9).

The GC-MS data presented in Table 1 show substantial incorporation of a single ^2H atom into (C-2+C-3+C-4) of 4-FT **2** after 7 h. This label can only reside on the C-3–C-4 fragment of 4-FT **1** as there is no significant labelling at C-2. During the same time period there was also a small but significant incorporation (1.7%) of two ^2H atoms into these positions of the amino acid. It is revealing that the ratio of *M*+1:*M*+2 for (C-3+C-4) directly reflects the ratio (~20:1) of $^2H_1$:$^2H_2$ label in the fluoroacetaldehyde administered to the cells. Similar results were obtained for the samples incubated for 20 h. These findings provide compelling evidence that fluoroacetaldehyde **3** is incorporated as an intact unit into C-3 and C-4 of 4-FT **2**. Interestingly the incubation of resting cell suspensions with 0.25 mM chloroacetaldehyde resulted in the detection in the supernatant of small quantities of an amino acid with a mass spectrum similar to that predicted for 4-chlorothreonine.[13] This observation provides further support for the participation of fluoroacetaldehyde in an aldol condensation leading to 4-FT **2** biosynthesis.

Table 1 ^2H Incorporation into 4-FT **2** after labelled fluoroacetaldehyde ([1-^2H]-, 95%; [1,2-$^2H_2$]-, 5%) was incubated with resting cell suspensions of *S. cattleya*. The data are corrected for natural abundances. Means and standard deviations were obtained from 10 replicate analyses

	^2H-Incorporation (%)			
	(C-1+C-2)		(C-2+C-3+C-4)	
Incubation time (h)	M+1	M+2	M+1	M+2
7	< 0.5	< 0.5	33.5 ± 0.09	1.7 ± 0.05
20	< 0.5	< 0.5	22.4 ± 0.10	1.2 ± 0.04

In conclusion we have demonstrated that cell free extracts of *S. cattleya* contain a fluoroacetaldehyde dehydrogenase which efficiently converts fluoroacetaldehyde to FAc **1**. Fluoroacetaldehyde also markedly enhances the biosynthesis of 4-FT **2** by resting cells of *S. cattleya*. Furthermore incubation of resting cells with ^2H-labelled fluoroacetaldehyde indicates incorporation of the compound as an intact unit into C-3 and C-4 of 4-FT **2**. These observations are consistent with a role for fluoroacetaldehyde as the common intermediate in the biosynthesis of both fluorometabolites and it may emerge that fluoroacetaldehyde is the immediate post fluorination product.

We thank the BBSRC and BNFL for financial support and Dr Harold Eccles of BNFL and Dr Roy Bowden of F2-Chemicals for useful discussions.

FEATURE ARTICLE

Watching solids crystallise using *in situ* powder diffraction

Richard I. Walton† and Dermot O'Hare*

Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR. E-mail: dermot.ohare@chem.ox.ac.uk

Received (in Cambridge, UK) 26th September 2000, Accepted 17th October 2000
First published as an Advance Article on the web 9th November 2000

The study of the chemical processes that occur during the synthesis of inorganic solids has attracted much recent attention. The ultimate aim of these experiments is the atomic level understanding of reaction mechanisms which lead to the formation of extended inorganic solids, so that rational design of new materials can be achieved. Solid-state syntheses are typically performed under non-ambient temperature and pressures in sealed containers so specialised apparatus must be constructed to allow us to directly probe these reaction mixtures. We review the use of *in situ* powder diffraction to investigate the formation of crystalline solids in real time, and discuss the latest developments in the technology required for these challenging experiments.

1 Introduction

The study of inorganic solid-state chemistry has seen a renaissance in the last 20 years, which has in the most part been brought about by the introduction of new techniques for structural elucidation (CCD cameras for crystallography data collection, and new solid-state NMR techniques, for example), and the investigation of new preparative methods (in particular *chimie douce* methods, such as hydrothermal chemistry and sol–gel techniques).[1,2] An astonishing diversity of novel materials is presently being prepared and characterised, as evidenced by the large numbers of published reports of new inorganic solids. These materials can have technologically valuable properties such microporosity, photophysical properties, electrochemical activity, superconductivity and magnetic behaviour, and thus research in solid-state inorganic chemistry can have significant application focus. A pressing aim of the fundamental research in this area is a quantitative knowledge of the mechanism of nucleation and growth of inorganic solids; this understanding would allow the rational design of new materials for application in the same way that the organic chemist is able to synthesise a complex molecule by use of specific starting materials and reaction conditions. The difficulty in the rational design of new solids is largely due to the lack of mechanistic data currently available, *i.e.* a quantitative understanding at an atomic level of the chemical processes leading to the formation of solids. This is perhaps not too surprising since many materials crystallise from complex heterogeneous mixtures held at elevated pressures or temperatures in sealed, thick-walled reaction vessels.

This article is concerned with recent developments in the use of powder diffraction techniques to follow the course of the synthesis of inorganic solids *in situ* under real reaction conditions. Diffraction clearly is an appropriate technique when following the formation of a crystalline solid and as we will demonstrate, in addition to obtaining qualitative information about the course of a reaction and phase identification at each step, time-resolved diffraction techniques allow quantitative kinetic information to be extracted, since the intensity of a Bragg reflection is directly proportional to the amount of diffracting solid. This information is the first step in being able to postulate reaction mechanisms.

In order to measure powder diffraction data from a reacting mixture of chemicals at non-ambient temperatures (and often pressures) the design and construction of specialised apparatus is required. Powder diffraction patterns of solids under non-ambient temperatures have been recorded since the earliest days of X-ray diffraction,[3] and the construction of furnaces for use in diffraction experiments has been well reviewed.[4] Such high temperature diffraction techniques are now routinely used to investigate the phase transitions and thermal stability of solids, but when the requirement to reproduce real reaction conditions is introduced, for example the use of a solvent or a reactive gas atmosphere, greater constraints are placed upon the experiment. The three most important points to consider when constructing a reaction cell for *in situ* powder diffraction studies are that: (i) the intensity of the radiation used must be high enough to achieve good signal:noise in the diffraction data above diffuse scatter of the amorphous components (solvent for example), (ii) the radiation must be able to penetrate the cell walls and not be obstructed by bulky heating devices or pressure containment, and (iii) the experiment must be optimised to enable rapid data acquisition for kinetic studies. We will limit our discussion to such apparatus, and select examples of experiments that best

† Present address: School of Chemistry, Stocker Road, University of Exeter, Exeter, UK EX4 4QD.

Richard Walton completed his BA degree in Chemistry at the University of Oxford in 1994 after research with Dr A. M. Chippindale into open-framework gallium phosphates which was awarded a university undergraduate thesis prize. In 1997 he received his PhD from the University of Reading following research with Dr S. J. Hibble into the structure of amorphous transition-metal chalcogenides. The same year he returned to Oxford to undertake postdoctoral research with Professor O'Hare on the use and development of in situ *powder diffraction techniques. He has recently been appointed to a university lecturership in Inorganic Chemistry at the University of Exeter.*

Dermot O'Hare obtained his first degree in Chemistry from the University of Oxford in 1982 and then remained at Oxford for his D.Phil under the supervision of Malcolm Green, where he worked on carbon–hydrogen bond activation using metal atom chemistry. In 1990 he was appointed to a University Lectureship in Inorganic Chemistry and Septcentenary Tutorial Fellowship at Balliol College in 1990. His current interests span a wide range of inorganic chemistry from synthetic molecular organometallic chemistry through to solid state chemistry. He received the RSC's Sir Edward Frankland Fellowship in 1996–97. In 1998, he received the RSC Corday–Morgan Medal and Prize and the Exxon Chemicals European Science and Engineering award.

illustrate the various *in situ* diffraction techniques currently in use. We begin our article by briefly discussing recent experiments performed using laboratory X-ray diffractometers, before considering experiments performed at synchrotron X-ray sources and at neutron sources.

2 *In situ* diffraction using laboratory X-ray sources

Many modern laboratory diffractometers can be readily modified to enable data to be collected at elevated temperatures, and some of the commercially available environmental chambers can be adapted for the study of the formation of crystalline inorganic solids. Environmental cells for studying the reactions between mixtures of gases and solids or simply solid-solid reactions have been most commonly described. For example Gavra and McMurray constructed a furnace to study gas/solid reactions at temperatures of up to 300 °C and pressures of 50 atm,[5] and used the cell to study the reaction between $EuNi_5$ and H_2 *in situ* at pressure of up to 50 atm, directly observing the formation of crystalline $EuNi_5H_{5.5}$, a material of potential use for hydrogen storage.[6] Samples were contained in 0.3 mm quartz capillaries. A more robust cell has been described by Puxley *et al.*; their apparatus could operate at temperatures of up 1000 °C using a larger amount of solid placed on a flat plate.[7] Data were collected from catalysts under reactive active gas atmospheres, and during the solid-state reaction between SnO_2 and Bi_2O_3. Another good example of the monitoring of a solid-state reaction in the laboratory with powder diffraction is the work of Bondioli *et al.* who studied the formation of the ferroelectric material $BaTiO_3$ from TiO_2 and $BaCO_3$ as a function of temperature up to 1200 °C. They were able to show that $BaTi_2O_4$ is present as a metastable phase at lower temperatures, and proposed a stepwise course of reaction.[8] A recent example of the use of a laboratory diffractometer to follow the formation of an inorganic material form a liquid medium was described by Rathousky *et al.* who followed the precipitation of the mesoporous silica MCM-41.[9] This study was performed at room temperature from a liquid/solid mixture in a *ca.* 0.5 mm^3 container. A small *d*-spacing region of diffraction data was monitored at 130 s intervals, allowing the appearance of the characteristic low-angle diffraction peak of MCM-41 to be monitored in real time.

Lindén *et al.* also studied the formation of mesoporous MCM-41 in the laboratory, using an ingenious tubular reactor in which reagents were mixed and allowed to flow along the apparatus through an X-ray diffraction cell.[10] By varying the length of the tube, or flow rate, samples of material could be studied *in situ* after different periods of reaction. Although meaningful kinetic data would be difficult to determine using this method, the measurement of diffractograms of material under real conditions allows the time-scale of reaction to be judged efficiently, even for reactions taking place on in sort times (less than 3 minutes for MCM-41). Mechanistic insight was possible for the case of the MCM-41 preparation, since under reaction conditions the material was observed to be less condensed than on isolation since on removal of hydration water de-swelling takes place.

These selected examples of the use of laboratory X-ray diffraction to follow chemical reactions illustrate that simple reaction cells can be constructed and mechanistic inferred during the formation of inorganic solids using readily available apparatus. In general, however, even with the best available rotating anode X-ray sources the time resolution is low (data must be collected on time-scales of minutes) and so it is difficult to extract accurate quantitative kinetic information. In addition, the limited range of X-ray energies available from laboratory diffractometers places severe limits of the amount of sample that can be studied and the size of reaction chamber used, because high levels of X-ray absorption greatly affects the quality of data that may be obtained from the sample within the cell. A point to bear in mind is that when scaling reactions down to very small quantities, genuine laboratory reactions conditions may no longer be reproduced. Problems in sampling a representative small portion of a mixture of reagents could arise, especially when mixtures of solids and liquids are studied, giving rise to results that are difficult to reproduce and/or interpret. Nevertheless laboratory diffractometer-based studies play a valuable rôle; they are readily available and provide a straightforward means to begin mechanistic of reactions producing solid materials.

3 *In situ* diffraction using synchrotron X-ray sources

3.1 Monochromatic radiation (angular dispersive diffraction)

Synchrotron-generated X-rays typically have intensity up to 10 orders of magnitude greater than the most brilliant laboratory-generated X-rays, Fig. 1. The high flux of X-rays from a synchrotron allows diffraction experiments to be performed using bulky sample containers since significant attenuation of the incident beam can be tolerated. Another advantage of synchrotron-generated radiation is that X-rays with short wavelengths (and hence high energies) can be utilised; these are less absorbed than higher wavelength X-rays, and so are useful when sample containers are must be penetrated. The experimental geometry of the experiments which use monochromatic synchrotron-generated X-rays are virtually identical to any laboratory diffractometer, but the time taken to record a diffraction pattern, especially when a static position-sensitive detector is used so that all data are accumulated simultaneously, is dramatically shortened; reactions can be followed in milliseconds rather than minutes.

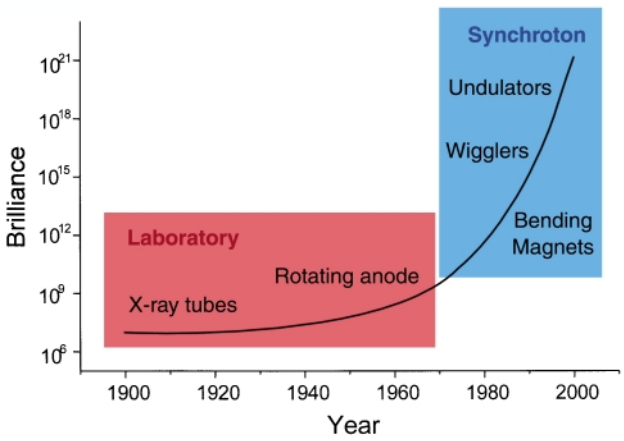

Fig. 1 A schematic of the historical development of available brilliance of X-rays from different sources. Brilliance is defined as number of photons per second per square millimetre per square milliradain per 0.1% bandwidth).

As with the experiments already discussed, much work using synchrotron X-rays has concentrated on the reactions between solids and gases, or solid-solid reactions. Good examples of such experiments are those by Larsen and co-workers who designed a cell to enable self-propagating high-temperature syntheses to be followed in time intervals as short as 10 ms.[11,12] Blocks of solid reagents (*ca.* 0.01 cm^3) are electrically ignited by a tungsten coil and the solid combustion reactions generate temperatures of up to 4000 K; diffraction data are measured by two fixed-angle detectors, each positioned to monitor an area of interest in the diffractogram. The technique has been used to

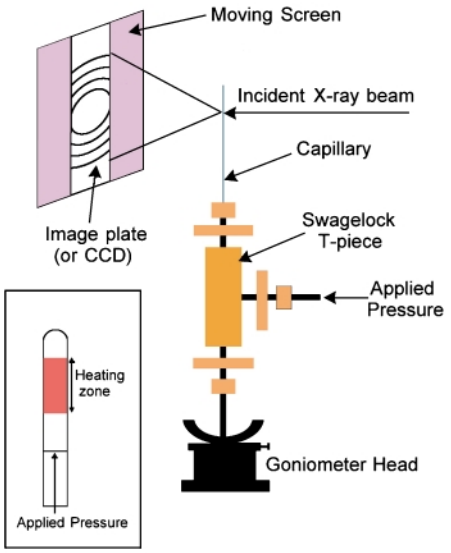

Fig. 2 A schematic of the apparatus developed by Norby and coworkers for time-resolved diffraction studies of hydrothermal crystallisations. The inset shows an enlargement of the capillary.

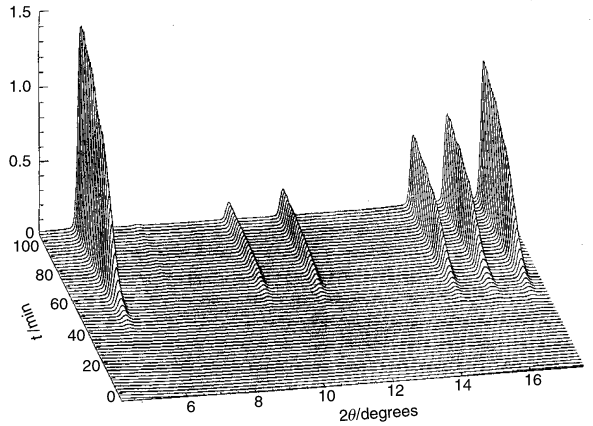

Fig. 3 Time-resolved diffraction patterns measured during the crystallisation of CoAPO-5, a microporous cobalt aluminophosphate from an amorphous gel by Norby and Hanson. Data were recorded at 200 °C in 1 min intervals. Figure reproduced with permission from ref. 19.

study syntheses of the carbide TaC.[13] and the ferroelectric $BaTiO_3$.[14] In the former case, the course of reaction was followed at 50 ms intervals and the material was observed to form *via* Ta_2C from Ta and C, with a total reaction time of only 50 s. This is a dramatic illustration of the power of synchrotron techniques for *in situ* studies of chemical reactions.

Norby *et al.* have developed in the last five years a synchrotron X-ray diffraction cell for study the hydrothermal crystallisation of inorganic materials.[15] This apparatus, Fig. 2, uses a quartz capillary as a sample container, pressure is applied externally to balance the pressure generated during a reaction and a 5 mm part of the tube heated by a hot air flow (up to 250 °C when pressures of 45 atm may be produced). Rapid data collection is made possible by use of a novel translating image plate detector. High resolution angular dispersive data are extracted by scanning the image plate after each experiment. Integration of the image plate data typically gives time resolution of 1–2 minutes.[16] Norby and his collaborators have used the apparatus to great effect in the study of the crystallisation of metal-substituted aluminium phosphates,[17–20] materials with useful catalytic properties. Fig. 3 shows typical diffraction data measured using the technique; in this case the crystallisation of CoAPO-5, a microporous cobalt aluminium phosphate from an amorphous gel.[19] As well as direct observation of the time-scale of reaction, these measurements allowed the determination of quantitative kinetic data by monitoring the area of a Bragg reflections with time and such data analysis has enabled rate constants to be determined, and kinetic models for these crystallisations to be proposed.[18,20] The same hydrothermal apparatus has also been used to follow the crystallisation of aluminosilicate zeolites[21,22] and a microporous manganese germanium sulfide.[23] Gross *et al.* used a similar cell to investigate the stability of silica/surfactant nanocomposites, precursors to mesoporous silicas when heated under hydrothermal conditions at 180 °C.[24]

The hydrothermal capillary apparatus has very recently been developed further to allow reactions under more extreme conditions to be studied. By using high energy X-rays ($\approx$35 keV, $\lambda \approx 0.32$ Å) generated at the European Synchrotron Radiation Facility, France and at Brookhaven National Laboratory, USA, Norby *et al.* showed that it is possible to penetrate a steel capillary.[25] Time-resolved diffraction data were measured at 350 °C, 200 atm during the transformation of a zeolite into a dense aluminosilicate. The *in situ* diffraction patterns obtained were of sufficient quality to allow structural information to be extracted by using the Reitveld method; such detailed structural characterisation of materials under reaction conditions is vital for understanding their properties.

3.2 Polychromatic radiation (energy-dispersive diffraction)

Synchrotron-generated X-rays are produced with high intensity over a wide energy range (typically 10 to 120 keV). This unique feature obviously offers the possibility of selection of a specific X-ray wavelength for any given diffraction experiment, but also the opportunity to perform powder diffraction experiments in the energy dispersive mode, utilising all the incident X-ray flux in a single experiment. In the energy-dispersive X-ray diffraction (EDXRD) experiment the intensity spectrum of scattered X-rays from the sample is measured by a fixed-angle solid-state photon counting and energy discriminating detector, and each Bragg reflection is characterised by an energy which is dependent on the angle of the detector.[26] Since no monochromation is employed and only minimal collimation of the incident X-ray beam is used, the flux incident on the sample is high (*ca.* 10^{10} photons s^{-1}) and of sufficient intensity and energy to probe large volume samples in thick-walled reaction vessels. The geometry is particularly suitable for the use of environmental cells, since the fixed-angle detector means that only small windows are necessary for the passage of X-rays through the apparatus so devices with heaters or bulky pressure containment can easily be constructed.[27] The EDXRD method is widely used for the study of the pressure induced phase-transitions of inorganic solids where very confined cells are used,[28] but because data acquisition can be performed in times of the order of seconds the technique is also very useful for kinetic studies. One particular merit of the EDXRD technique is that reactions cells can be 'laboratory-sized', identical in design to apparatus used in preparative chemistry, so that more realistic, bulk reaction conditions are mimicked; this is in contrast to the techniques discussed in section 2.1, which use scaled-down reaction cells to minimise absorption.

Barnes and coworkers have pioneered the use of EDXRD for the study of chemical reactions, and have followed the reactions involved in the hydration of calcium silicate cements on time-scales down to 0.3 s per diffraction pattern.[29–31] These workers also first described the use of EDXRD methods to follow hydrothermal crystallisations. They designed a reaction cell made from the high performance polymer PEEK, that allowed use at temperatures up to 100 °C. They were able to monitor the crystallisation of sodalite, a dense aluminosilicate zeolite, from the layered material kaolinite and determined crystallisation curves describing extent of reaction as a function of time.[32] The hydrothermal formation of the large pore aluminophosphate VPI-5 was also studied by these workers using the EDXRD

method.[33] The operating temperature of this early cell was limited by its design and the performance characteristics of the PEEK cell material. We have subsequently described the construction of a large-volume hydrothermal reaction cell from which EDXRD data may be collected at up to 250 °C, more typical of the temperatures used in hydrothermal synthesis.[34] This reaction cell is virtually identical in design and construction to the 23 mL Parr hydrothermal autoclaves widely used in many research laboratories, but the steel walls of the cell are thinned to 0.3 mm to minimise absorption of X-rays, Fig. 4 The

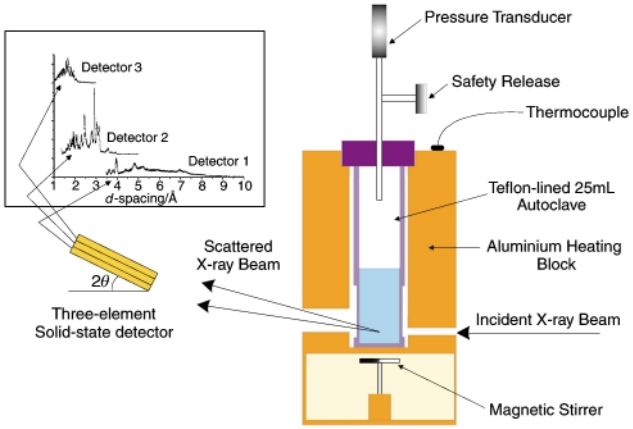

Fig. 4 A schematic of the Oxford/Daresbury hydrothermal autoclave used for energy-dispersive X-ray diffraction studies, developed by us for use on Station 16.4 of the UK synchrotron source at Daresbury Laboratory.

Oxford/Daresbury hydrothermal cell has been used on Station 16.4 of the Daresbury SRS, the UK synchrotron radiation source, to study the crystallisation of a wide range of inorganic materials by several groups. The cell has been much used for studying the formation of microporous solids; our group has studied the formation of porous layered tin sulfides,[35] open-framework gallium fluorophosphates,[36–38] and zeolites,[39,40] and Thomas and coworkers have used the cell to study the formation of transition-metal substituted aluminophosphates.[41–43] One important observation we have made during the study of the crystallisation of gallium fluorophosphates is that under certain reaction conditions previously unknown intermediate crystalline phases are observed to form before the onset of the crystallisation of the expected microporous phase, Fig. 5. For

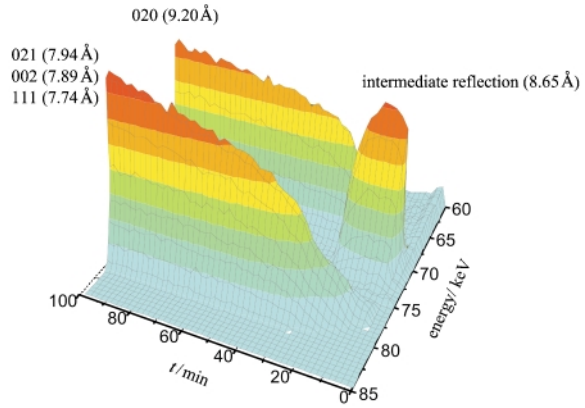

Fig. 5 A small part of energy-dispersive X-ray diffraction data (30 s intervals) measured *in situ* during the crystallisation of the open-framework gallium fluorophosphate ULM-3 from an amorphous phosphate gel at 180 °C. The use of P_2O_5 as a reagent results in the formation of a previously unknown crystalline intermediate phase before the onset of crystallisation of the product.

the case of the microporous phase ULM-3, a transient crystalline intermediate is only stable under hydrothermal conditions; if the reaction cell is allowed to cool when the intermediate is present, transformation into another, as yet unidentified, phase takes place.[38] This is a dramatic illustration of the need to study reactions under real conditions, and of how quenching experiments are not always a reliable method of determining the species present at reaction conditions. In this particular case it has subsequently lead us to discover some new related metastable gallium fluorophosphates.[44,45]

In addition to the direct observation of crystallisation on a short time-scale, the *in situ* EDXRD method has allowed much new information about the kinetics of the crystallisation of microporous solids to be determined. By determination of changing Bragg peak areas, it is possible to extract quantitative kinetic information, since the intensity of a Bragg reflection is directly proportional to the amount of diffracting solid.[46] Fig. 6,

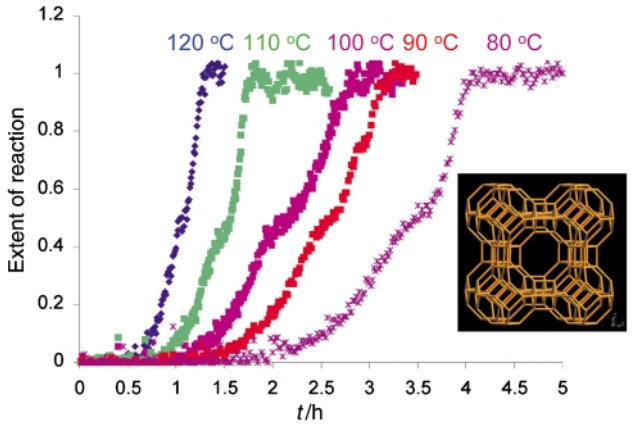

Fig. 6 Crystallisation curves for sodium aluminosilicate zeolite A (inset) determined using the *in situ* EDXRD technique. Diffraction patterns were collected every 30 s while an amorphous aluminosilcate gel was heated in the autoclave.

for example, shows crystallisation curves we have recently obtained from a study of the hydrothermal formation of sodium zeolite A, one of the most widely used microporous materials in many industries.[40] The unusual two-step crystallisation curve has never been reported previously, and was only revealed by continuous monitoring of the reaction with high time resolution (30 s per diffraction pattern). The effect is highly dependent on reaction conditions and is believed to arise from dissolution of an amorphous precursor gel controlling the rate of reaction. Such an observation sheds new light on zeolite crystallisation, and these measurements using EDXRD on short time scales will provide new data for computer modelling studies, and ultimately mechanistic information. A recent development in the use of *in situ* EDXRD is the installation of a three element solid-state photon counting, energy discriminating detector on Station 16.4 of the SRS;[47,48] this allows three *d*-spacing regions of the powder diffraction pattern to be measured simultaneously and permits unambiguous phase identification, which has been particularly useful in the study of microporous materials.[49]

As well as the studying the formation of microporous materials, the Oxford/Daresbury hydrothermal autoclave has been used by other groups to monitor the formation of inorganic solids. Cahill *et al.* studied the formation of iron sulfides using the cell, and were able to establish a pathway of progressive sulfidation of FeS to FeS_2.[50] Shaw *et al.* recently studied the hydrothermal formation of calcium silicate minerals; this study was performed at the Advanced Photon Source, USA, which offers *ca.* 10 times greater X-ray flux than the SRS, enabling reactions to be performed in cells with thicker walls, and consequently at temperatures of up to 330 °C.[51]

EDXRD has been used by our group in Oxford to study the formation and behaviour of a wide range of other inorganic solids. Time-resolved EDXRD studies of intercalation reactions of layered solids have been very important in understanding their mechanism, and this area has recently been reviewed.[52,53] We have also investigated the kinetics and mechanism of formation mesoporous silicas and the different growth mechanism for MCM-41 *versus* the mesoporous silicate FSM-16,

which is derived from kanemite,[54] and of the crystallisation of gibbsite,[55] an important material in aluminium manufacture. The *in situ* EDXRD method is clearly easily extended to following reactions under conditions more extreme conditions than the hydrothermal reactions discussed above, with simple modification of furnace design. We have very recently described the construction of a furnace that operates at 1000 °C and from which EDXRD data can be measured.[56] We have studied the formation of some dense metal oxides at *ca.* 800 °C, both by a traditional ceramic methods using the carbonates of the constituent metals, and by a molten-salt method in liquid alkali-metal halide fluxes. We were able to follow the decay of starting materials, and subsequent growth of the layered perovskite $RbCa_2Nb_3O_{10}$ and show the enhancement of crystallisation rate in the alkali-metal flux.[56] Parkin *et al*. have recently begun a study of self-propagating high-temperature reactions (SHS) using EDXRD on Station 16.4 at the SRS. To study these reactions they have pushed the data collection intervals down to just 100 ms.[57] They also studied the effects of a magnetic field on these reactions using EDXRD.

In summary we anticipate that further advances in apparatus design are likely to follow shortly, and allow reactions over a wide spectrum of temperatures and pressures to be followed by EDXRD.

4 *In situ* diffraction using neutron sources

The complementarity of neutron diffraction and X-ray diffraction for the structural characterisation of materials is well known, in particular the use of neutron diffraction to locate light atoms in the presence of heavy atoms, especially hydrogen atoms, and in the determination of the spin arrangement of magnetically ordered materials.[58] In the context of performing *in situ* diffraction studies, neutron diffraction offers distinct advantages over many of the X-ray diffraction experiments. For example, many materials have very low neutron absorption cross-sections which means that reaction vessels can be constructed which give rise to low backgrounds in diffraction data. Processes involving light atoms, such as reactions involving water can be followed. In additon, use of time-of-flight neutron diffraction with fixed-angle detectors would simplify apparatus construction. One disadvantage of neutron diffraction is the much lower flux available from currently available neutron sources at present compared to synchrotron X-ray sources; this means that at present the time resolution of time-resolved neutron diffraction experiments is relatively poor (of the order of minutes rather than sub-second), but recent development in the area shows the great promise of the method.

Pannetier is well known for his many time-resolved neutron diffraction studies of chemical reactions;[59] he and his coworkers have concentrated on fairly simple systems, such as hydration reactions,[60] and the reactions of solids with gases.[61] Christensen and coworkers performed an extensive study of the reactions between silicates and water under moderate temperatures (up to *ca.* 120 °C) using *in situ* neutron diffraction and were able to measure diffraction data in periods as short as 5 minutes.[62–66] The same workers also performed the first *in situ* neutron diffraction study of a hydrothermal crystallisation, in this case the formation of iron(III) oxides from amorphous iron hydroxides at 120 °C.[67] They were able to measure crystallisation curves and efficiently monitor the effect of experimental parameters on reaction rate. When performing neutron diffraction studies, it is usual to use deuterated reagents to minimise the large incoherent scattering of protons, however the use of protonated reagents can reveal additional information. For example Tuttillas *et al.* studied the calcination of zirconium hydroxide, used to prepare zirconia, with *in situ* powder neutron diffraction at the Institut Laue Langevin (ILL). They were able to detect a massive decrease in background when dehydration was complete (and all protons were lost from the reagents) allowing one step of the reaction to be pinpointed.[68]

Polak *et al.* described the design of an autoclave to allow the acquisition of neutron diffraction data during the hydrothermal crystallisation of tobermorite, a calcium silicate used in cements, and of some zeolites.[69] The cell could operate at temperatures of up to 250 °C, and external pressure was applied. One draw-back of this cell design was the dominance of the Bragg reflections due to the sample containment (aluminium with a Teflon liner) in the measured diffraction data; this could severely limit the amount of structural information available. Our recent work, in collaboration with colleagues at ISIS, the UK neutron spallation source, on the use of neutron diffraction to follow hydrothermal crystallisations has resulted in the design and construction of a novel null-scattering environmental cell from which time-resolved diffraction data can be measured at temperatures of up to 250 °C and pressures of 20 atm.[70] The cell (Fig. 7) is constructed from a Ti-Zr alloy whose

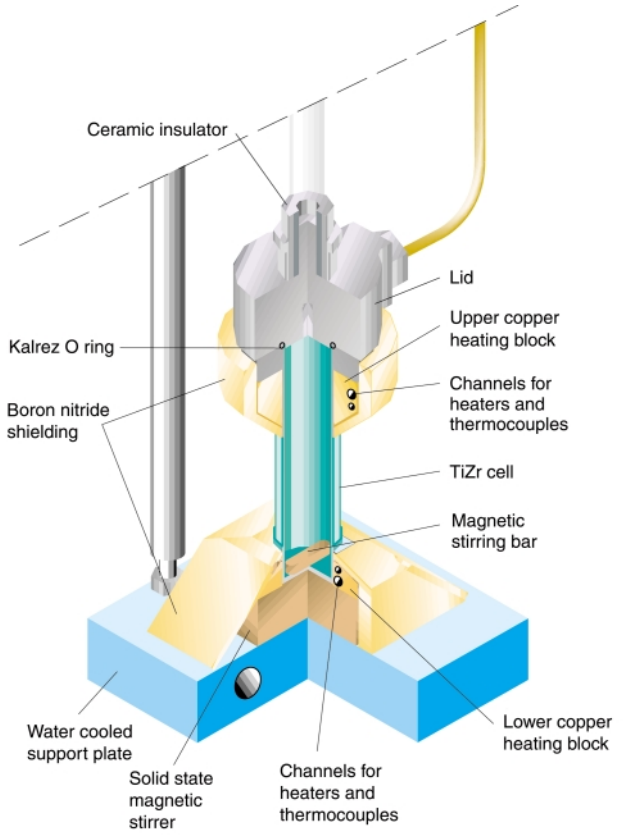

Fig. 7 Schematic of the Oxford/ISIS hydrothermal reaction cell for *in situ* neutron powder diffraction measurements.

component metals are mixed in such a ratio as to cancel their negative (Ti 67.7 atom %, $b = -3.44$ fm) and positive (Zr 32.3 atom%, $b = 7.16$ fm) neutron scattering lengths. The cell is protected from corrosive reagents by a thin internal layer of gold metal, thus the cell is invisible to neutrons and can contain reactive mixtures of solids and liquids. We have commissioned the Oxford/Isis hydrothermal cell on the medium-resolution high-flux diffractometer POLARIS initially and most recently have tested it on GEM, a new neutron diffractometer with a large array of detectors which allows rapid data collection.[71] Our first experiments have addressed the hydrothermal formation of barium titanate, an important ferroelectric material used in the electroceramics industry.[72] The industry requires the crystallisation of the phase pure tetragonal polymorph. The presence of the highly X-ray absorbing barium ions in the sample mixture meant that it was impossible to study this system even using synchrotron X-ray diffraction. However, using *in situ* neutron diffraction we were able to observe directly the dissolution of both the crystalline starting materials, TiO_2

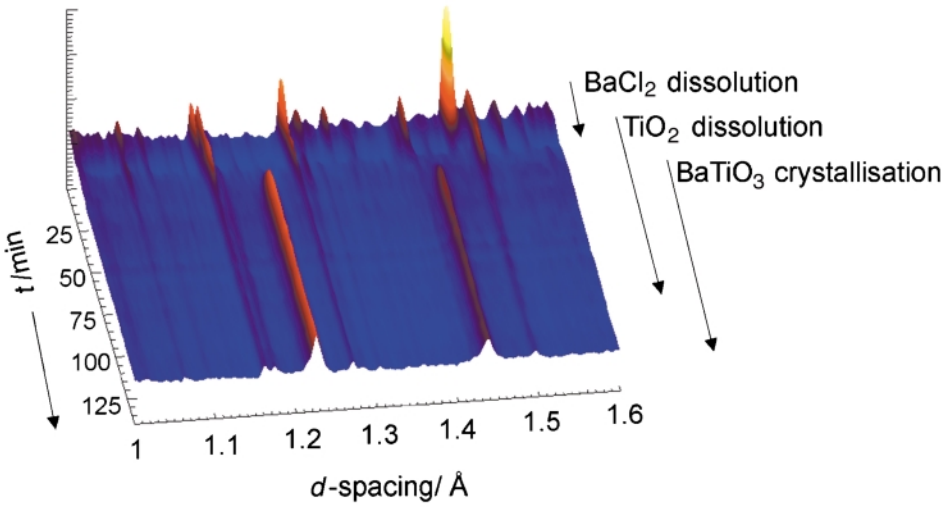

Fig. 8 *In situ* neutron diffraction data measured during the formation of the ferroelectric barium titanate from $BaCl_2$ and TiO_2 in NaOD solution at 200 °C. Data were collected at 5 min intervals using the GEM diffractometer at ISIS.

and $Ba(OD)_2{\cdot}8D_2O$, before the onset of crystallisation of $BaTiO_3$. This allowed us to conclude that a dissolution–precipitation mechanism predominates, rather than a heterogeneous transformation mechanism. Fig. 8 shows *in situ* neutron diffraction data measured using GEM where data were collected in 5 min intervals. As well as the new mechanistic insights, we were able to measure high resolution diffraction data that are suitable for Reitveld profile analysis, Fig. 9. This is a step

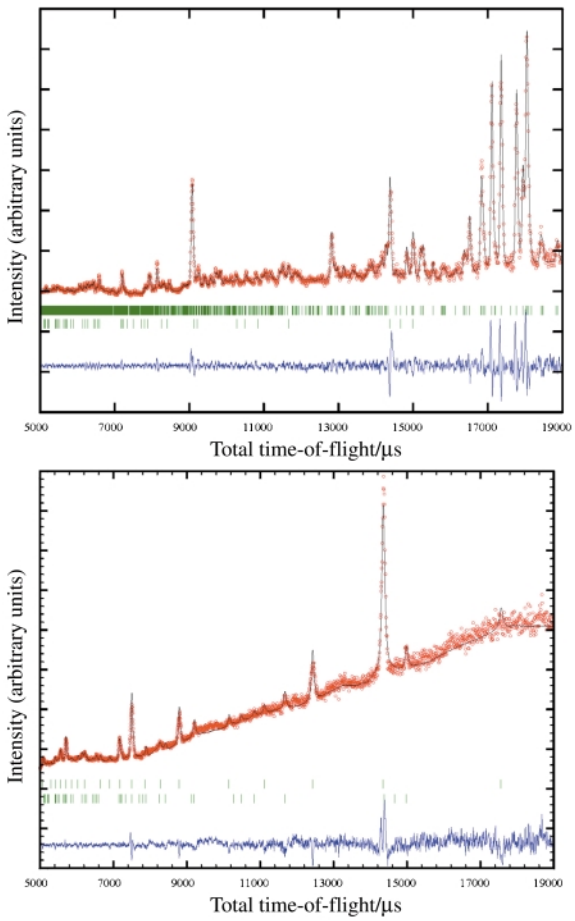

Fig. 9 Neutron diffraction data measured *in situ* during the hydrothermal formation of $BaTiO_3$ from $Ba(OD)_2.8D_2O$ and TiO_2 (a) after 15 min, and (B) after 12 h.

forward in *the in situ* study of hydrothermal reactions, and shows the potential use of neutron diffraction in real time structural determination of crystalline solids under laboratory reaction conditions. We have most recently used the Oxford/ISIS hydrothermal cell to study the formation of some aluminosilicate zeolites, the archetypal materials synthesised hydrothermally. We have followed the crystallisation of sodium zeolite A and monitored its collapse into the dense phase hydroxosodalite.[73]

Other recent highlights in the use of powder neutron diffraction to monitor the formation of inorganic solids include following the crystallisation of superconductors from melt-cast precursors,[74] and a study of the reaction between Nd/Fe/V alloys and nitrogen at 800 °C.[75] In the latter study data were collected in around 5 min intervals, and were of sufficient quality to perform Reitveld refinement, and allowed structural determination *in situ*. This study was performed using the recently constructed D20 diffractometer at the ILL, which offers a combination of high neutron flux and high count rate by a novel large surface area position-sensitive detector.[76] Undoubtedly this instrument will lead to many more kinetic studies of solid-state reactions in the coming years.

5 *In situ* powder diffraction combined with spectroscopic probes

The *in situ* diffraction techniques described above yield information about the growth and decay of crystalline ordered materials during the course of a chemical reaction. As the above discussion demonstrates, these methods allow the course of reactions to be observed in real time, including the detection of crystalline intermediate phases, and kinetic information can be determined. Bragg diffraction, however, does not probe any amorphous phases present. For instance no information about the changing local atomic structure of the gel-precursor to zeolites in a hydrothermal crystallisation is obtained. In order to achieve the monitoring of both long-range crystallographic order and short-range atomic order, several ingenious experiments have been designed, combining *in situ* diffraction with spectroscopic methods. The most powerful of these methods is the use of combined X-ray absorption fine structure spectroscopy and X-ray diffraction (XAFS/XRD). This was first described by Couves *et al.* in 1991,[77] and has since been used to monitor various reactions involving solids such as solid-state transformations,[78–80] polymerisations,[81] thermal decompositions,[82,83] and widely used for monitoring catalytic processes under operating conditions.[84,85] High-intensity synchrotron generated X-rays are required for such studies.

Fig. 10 shows the arrangement of a typical XAFS/XRD experiment. This set-up was used by Sankar *et al.* to follow the formation of a microporous cobalt aluminophosphate from an amorphous gel.[86] XRD data were measured for 220 s, followed

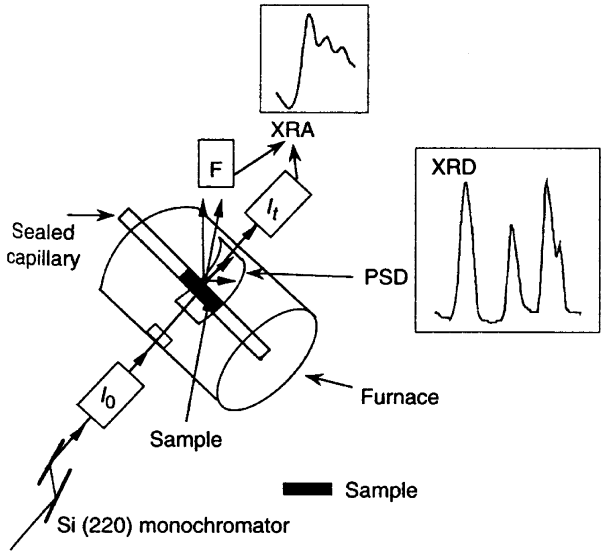

Fig. 10 A schematic of the XAFS/XRD experiment used to follow the crystallisation of a cobalt aluminophosphate. Figure reproduced with permission from ref. 86.

by XAFS data at the cobalt K-edge for the same time (alternation between the two measurements is necessary as the XRD data are acquired with a constant wavelength whilst the XAFS data require a scan over a wavelength range). Changes in the local environment of cobalt were monitored, and related to the changes in long range order apparent in the diffraction pattern, Fig. 11. It was thus shown that the coordination of

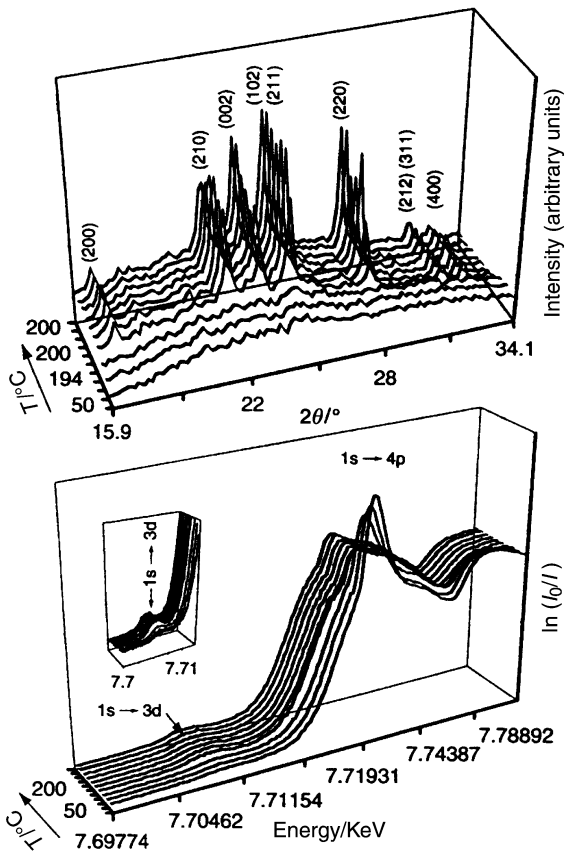

Fig. 11 XRD (top) and Co K-edge EXAFS (bottom) recorded during the crystallisation of CoALPO-5 at 180 °C from an amorphous gel. Figure reproduced with permission from ref. 86.

cobalt changes from octahedral to tetrahedral in the gel immediately prior to crystallisation. The same apparatus was also used to follow the formation of a bismuth molybdate catalyst from a precursor gel,[87] and of small particles of cadmium oxide from a hydroxy gel.[88] In both cases monitoring changes in local atomic environment and relating them to crystallographic order allowed new insights into the reaction mechanism.

6 Conclusions and outlook

The measurement of powder diffraction data during the synthesis of many inorganic materials requires the design and construction of specialised apparatus, but in the last five years much progress has been made. The experiments we have surveyed here represent in most cases the first attempts to determine kinetic and mechanistic information about reactions involving the formation of solids from heterogeneous media. The reactivity and structures of solids under non-ambient conditions have been probed directly for the first time. As is apparent from our review, the most impressive advances have been made in the area of hydrothermal chemistry, with several groups developing apparatus that are now widely used on a routine basis to follow directly the crystallisation of a range of porous materials with useful properties. This undoubtedly reflects the fact that hydrothermal chemistry has found to be an incredibly fertile method for the synthesis of new inorganic solids, and is currently used to prepare a diversity of materials from new zeolitic solids[89] to metastable metal oxides.[90] Given the success in using powder diffraction to follow hydrothermal crystallisations, extension of the methodology to other preparative methods is likely to follow shortly; systems such as alkali-metal–chalcogenide fluxes[91] and solvothermal synthesis in alcohols or amines[92] which are currently the focus of attention in synthetic solid-state chemistry.

With the now almost routine measurements of the course of solid-state reactions, a large amount of kinetic data has been accumulated, as well as much qualitative information about the course of reaction and identification of intermediates. Analysis of these data is one of the first steps in proposing reaction mechanisms, but clearly much more work is required in this new field before the rational design of new materials is possible. Computer modelling will undoubtedly have an important rôle in understanding the data obtained by the techniques we have reviewed, and is an area which is developing rapidly; for example the early stages of the formation of zeolite has been modelled in some detail recently and the energetics of these solution-mediated reactions calculated,[93] and the prediction of the structures of new solids using computer-modelling techniques is currently the focus of much attention.[94,95]

In this article we have emphasised how recent progress in the use of *in situ* powder diffraction methods has been intimately linked to developments at synchrotron and neutron sources. The availability of high intensity synchrotron-generated X-rays over a wide energy range and the design of new neutron diffractometers to enable rapid data collection has instigated many of the experiments we have described. As well as the continued use of the experiments already in use, new developments are likely to enable other new experiments to be designed and realised. In many parts of the world new synchrotron and neutron sources are being constructed, including a third-generation synchrotron source in the UK to replace the SRS, and a new spallation neutron source at Oak Ridge USA. These will offer increasingly higher fluxes of radiation and the possibility of rapid data collection; features vital for the future development of *in situ* powder diffraction methods.

7 Acknowledgements

We thank our many colleagues and collaborators who have been involved in the work we have performed in the field of time-resolved diffraction; in particular the instrument scientists at the Daresbury and Rutherford Laboratories who have made much of our work possible. We thank the Leverhulme Trust and

EPSRC for the award of research grants for this work and which has allowed us access to the CLRC laboratories.

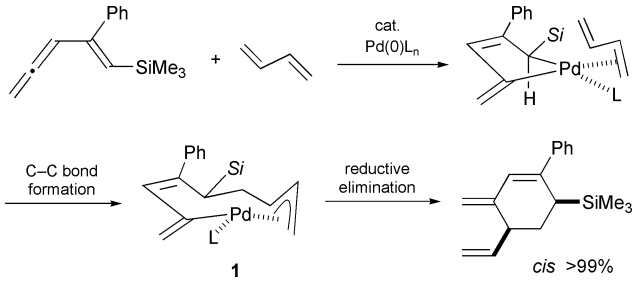
First published as an Advance Article on the web 7th November 2000

A catalytic asymmetric [4 + 2] cycloaddition reaction of a vinylallene with buta-1,3-diene was developed in which a palladium complex modified by a ferrocene-derived chiral monophosphine ligand acted as a template transferring chirality to the product.

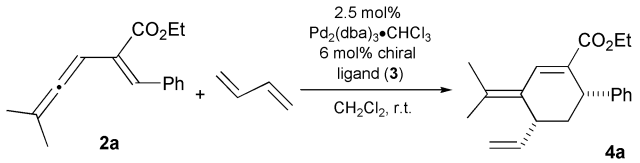
Cycloaddition reactions are among the most powerful methods for the rapid construction of carbocycles and heterocycles alike.[1] The [4 + 2] cycloaddition is most widely used to build six-membered ring carbon skeletons. However, strenuous reaction conditions are required for the combination of 1,3-dienes and dienophiles lacking electron-withdrawing or -donating substituents, which limits the range of the synthetic utility. The use of transition metal complexes as the promoter[2] provides considerably wider substrate scope. The transition metal acts as the template bringing the unsaturated substrates together in an array to promote the cycloaddition reaction. We have developed the palladium-catalysed directed intermolecular [4 + 2] cycloaddition between a vinylallene and an ordinary 1,3-diene.[3–5] The initially formed palladacyclopentene intermediate couples with a 1,3-diene before undergoing a ring-flipping isomerization, resulting in a highly stereospecific reaction [eqn. (1)]. We anticipated that a palladium complex modified by a chiral ligand would possibly differentiate the enantiofaces of vinylallene in its s-*cis* form and that this differentiation would be directly transferred to the product. This paper describes the catalytic asymmetric [4 + 2] cycloaddition of a vinylallene[6] with buta-1,3-diene which employs a palladium complex modified by a ferrocene-derived chiral monophosphine ligand as a template.



(1)

Initially, a variety of chiral phosphines were screened in the standard test cycloaddition reaction using vinylallene **2a** and buta-1,3-diene (excess). The catalyst complex was prepared by treatment of $[Pd_2(dba)_3{\cdot}CHCl_3]$ with a chiral phosphine ligand *in situ*. Highly reputed bidentate chiral diphosphine ligands like DuPHOS (1,2-bis[2,5-dimethylphospholanyl]benzene) and CHIRAPHOS (2,3-bis(diphenylphosphino)butane gave only low enantioselectivities. No reaction occurred with BINAP. Since our proposed mechanism involves a square planar palladium(II) intermediate **1** in which three of the four coordination sites are occupied by the cycloaddition partners, we supposed that monodentate ligands would be more effective transmitters of chirality. Whereas MOP (2-diphenylphosphino-1,1′-binaphthalene) afforded only 15% ee, a better result was

Table 1 Asymmetric induction in palladium-catalysed directed [4 + 2] cycloaddition of **2a** with buta-1,3-diene



Entry	Chiral ligand	Isolated yield (%) Enantioselectivity	Entry	Chiral ligand	Isolated yield (%) Enantioselectivity
1	 **3a**	90 47 % ee	7	 **3g**	85 47 % ee

6	 **3f**	90 63 % ee			

[a] Conversion of **2a**. The product was not isolated.

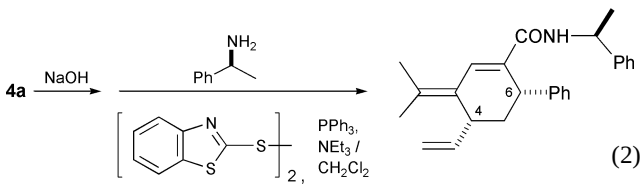
DOI: 10.1039/b007781j

Table 2 Palladium-catalysed asymmetric [4 + 2] cycloaddition of vinylallenes (**2**) with 1,3-dienes[a]

Entry	Vinylallene (**2**)	1,3-Diene	Product (**4**)[b]	Isolated yield (%) Enantioselectivity
1	 **2b**		 **4b**	63 82 % ee
2	 **2c**		 **4c**	89 77 % ee
3	 **2d**		 **4d**	76 52 % ee
4	 **2c**		 **4e**  **4f**	89 (**4e**:**4f** = 81:19)[c] **4e** 63 % ee **4f** 65 % ee

[a] The reaction was carried out using 5 mol% of palladium(0) and 6 mol% of **3k** in CH_2Cl_2 at rt. [b] The absolute configuration was not determined. [c] The ratio was determined by HPLC.

obtained with PPFA (2-(1-dimethylaminoethyl)-1-diphenylphosphinoferrocene 27% ee). Among ferrocene-derived ligands, the monodentate phosphine ligand **3a** gave a moderate selectivity (Table 1, entry 1). This result directed our detailed investigation to ligands of analogous structures. The ligands **3b**–**k** listed in Table 1 were prepared‡ and applied to the test reaction. Ligand **3b** lacking a silyl group at the *ortho* position gave a low selectivity (entry 2). The triphenylsilyl-substituted ligand **3c** gave slightly better selectivity than the trimethylsilyl-substituted ligand **3a** (entry 3). Diphenylphosphine-substituted ligands were significantly more effective than dicyclohexylphosphine derivatives (entry 4). The effect of the electronic nature of the diarylphosphinyl group was examined in detail (entries 5–11). Ligands having an electron-withdrawing group gave comparable or better selectivities than **3c**. In particular, the phosphine possessing two 3,5-bis(trifluoromethyl)phenyl groups (**3k**) afforded the highest enantioselectivity of 83% ee.§¶ Although solvents other than DCM were also screened, little effect was observed in terms of the enantioselectivity. The absolute stereochemistry of the major enantiomer was determined to be (4*R*,6*S*) by an X-ray crystallographic study of the amide derived from **4a** and (*S*)-1-phenylethylamine [eqn. (2)].



(2)

Thus, **3k** proved to be the ligand of choice, and was applied to the reactions of other vinylallenes with buta-1,3-dienes.‖ The [4 + 2] cycloadducts were produced with moderate to good enantioselectivities in good yields (Table 2). Note that a useful level of asymmetric induction was obtained in the case of **2c** lacking any coordinating heteroatom functionalities (entry 2). For the unsymmetrical 1,3-diene (2-methylbuta-1,3-diene), incorporation of the more substituted C–C double bond was favoured to afford **4e** as the predominant product (entry 4).

A number of highly successful asymmetric [4 + 2] cycloadditions have been reported in which the carbonyl group of an electron-deficient dienophile coordinates to a chiral Lewis acid to induce an excellent enantioselection.[1] On the other hand, it is difficult to gain stereocontrol over a substrate lacking coordinating heteroatom functionalities. The asymmetric [4 + 2] cycloaddition documented herein presents a promising new example which may be applied to such unactivated substrates. The full potential of this new process remains to be elucidated.

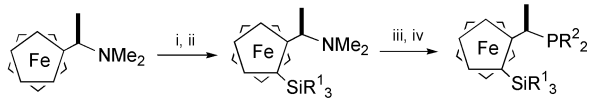
† Present address: Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-0033, Japan.

‡ The chiral ferrocenyl phosphines **3** were prepared as follows [eqn. (3)]:



(3)

i, BuLi; ii, Cl-SiR^1_3; iii, Ac_2O; iv, R^2_2P-H /AcOH

ortho-lithiation of (*R*)-*N*,*N*-dimethyl-1-ferrocenylethylamine (**5**) with butyllithium followed by treatment with chlorosilane afforded (*S*)-1-silyl-2-[(*R*)-1-(dimethylamino)ethyl]ferrocene **6**. A diarylphosphinyl group was then introduced by successive treatment of **6** with excess acetic anhydride, and then with diarylphosphine in acetic acid to furnish (*S*)-1-silyl-2-[(*R*)-1-(diarylphosphino)ethyl]ferrocene **3**.

§ The experimental procedure for the formation of **4a** is as follows: to a mixture of $[Pd_2(dba)_3{\cdot}CHCl_3]$ (3.4 mg, 3.3 μmol) and the ligand **3k** (7.4 mg, 7.9 μmol) in CH_2Cl_2 (3 mL) under N_2 at rt were successively added buta-1,3-diene (4.4 M in CH_2Cl_2, 0.3 mL, 1.32 mmol) and the vinylallene **2a** (32.0 mg, 0.132 mmol). The reaction was complete within 10 min. The mixture was evaporated under vacuum, and the residue was subjected to preparative TLC (silica gel, ether–hexane = 1:10) to afford **4a** (33.2 mg, 85%) as a colorless oil. $[\alpha]_D^{20}$ + 12.3 (*c* 1.0, $CHCl_3$). The enantioselectivity was determined to be 83% ee by chiral HPLC analysis [SUMICHIRAL OA-2500-I (4.0 × 250 mm), 1.0 mL min^{-1}, hexane–$ClCH_2CH_2Cl$–EtOH = 2000:20:1, (4*S*,6*R*) t_1 = 17 min, (4*R*,6*S*) t_2 = 19 min].

¶ Platinum was also tested as a metal using $Pt(cod)_2$ and provided 77% ee. However, platinum suffered from low conversion.

‖ Cyclohexa-1,3-diene failed to undergo the cycloaddition, suggesting that 1,3-diene reacts in its s-*cis* form as shown in eqn. (1).

Received (in Cambridge, UK) 18th August 2000, Accepted 9th October 2000
First published as an Advance Article on the web 7th November 2000

Small peptides selected from a library of 62 000 chemically synthesized peptides were able to recognize a monosaccharide specifically and efficiently using both sandwiching and hydrogen bonding interactions, much like sugar-binding proteins (lectins) with the appropriate orientation of amino acid side chains.

Protein–oligosaccharide interactions play a key role in the control of various normal and pathological processes.[1,2] Because of their importance, there has been considerable drive toward the better understanding of the saccharide (carbohydrate) binding specificity of proteins (lectins). Progress has been made using X-ray crystallography, isothermal titration microcalorimetry and site-directed mutagenesis experiments.[3–6] These numerous studies have found diverse mechanisms for saccharide recognition by proteins that have evolved independently but that share some key features. High selectivity for a saccharide is achieved through a combination of hydrogen bonding to the saccharide hydroxy groups and van der Waals packing of the hydrophobic sugar face against aromatic amino acid side chains forming what is called sandwiching interaction.[7,8] Since the binding of saccharides by proteins involves a variety of recognition processes and the proteins themselves exhibit considerable structural diversity, it is difficult to obtain detailed information using thermodynamic and kinetic parameters resulting from the analysis of a large lectin–oligosaccharide complex. Establishing a model system is one of the essential methods to reveal function and mechanism of the specific interactions quantitatively, but there is no good model system that includes the two binding interactions found between proteins and saccharides.

Here, a small oligopeptide–monosaccharide complex was developed as a model system for wild type protein–saccharide complexes which includes the hydrogen bonding and sandwiching recognition mechanisms. Firstly, in order to investigate the relationship between peptide conformation and sandwiching interaction ability, we synthesized alanine-based oligopeptides with one or two tryptophan residues to test the sandwiching interaction between the monosaccharide and the two tryptophan indole side chains, KW (S *i*+0), KWW (S *i*+1), KWAW (S *i*+2), KWAAW (S *i*+3), KWAAAW (S *i*+4), KWAAAAW (S *i*+5) and KWAAAAAW (S *i*+6).† Fig. 1 shows relative fluorescence intensities (ΔF) of these peptides in the presence (F) and absence (F^0) of D-galactose, $\Delta F = (F - F^0) \times 100/F^0$.‡ Because ΔF shows saccharide sandwiching ability of the oligopeptide,[8] these results indicate that the oligopeptide is able to recognize the monosaccharide effectively with W residues at *i* and *i*+4. Aoyama and co-workers showed only two residual peptides, W–W, can recognize maltodextrin *via* sugar–bisindole interaction,[12] as the result of the (S *i*+1) peptide. Our results show that the (S *i*+4) peptide is capable of recognizing a monosaccharide more efficiently than the (S *i*+1) peptide and that the aromatic residues at *i* and *i*+4 have a critical role in this recognition. Previously, tryptophan and porphyrin binding peptides were obtained using combinatorial chemistry and phage display, respectively.[9–11] These peptides also had two aromatic residues and recognized each target molecule using only the sandwiching interaction with these two aromatic residues. Therefore, if both the hydrogen bonding and sandwiching interaction can be introduced suitably in one peptide, more efficient and specific recognition of a monosaccharide could be acquired, even in a small oligopeptide.

We have attempted to put both of the binding modes in the appropriate orientation into a small peptide using combinatorial chemistry. It was shown that the two aromatic residues at *i* and *i*+4 had a critical role for the sandwiching interaction by the fluorescence measurements of (S *i*+0 ~ 6) peptides. Therefore, using a basic split and mix method on a solid phase,[12] a biased combinatorial peptide library with Aro-X-X-X-Aro, where Aro is an L-aromatic amino acid and X is a natural L-amino acid (except C), was synthesized to have sandwiching interaction with *i* and *i*+4 aromatic residues. D-Erythrose ($HOCH_2$-$[CH(OH)]_2CHO$, Sigma–Aldrich Co.) was chosen as a target monosaccharide because D–erythrose is a light yellow syrup and can be followed with visible light.[13] The peptide library and D-erythrose were mixed, gently shaken overnight in a buffer containing 10 mM NaCl, 10 mM Na_2HPO_4, and 1 mM EDTA (pH 7.0) at rt then washed with buffer solution to eliminate any non-specific interactions. It was confirmed that the background signal arising from the non-specific interaction between D-erythrose and the beads in the selection procedure is low enough to select specific colored beads. Using a microscope, 15 beads were then selected from a library theoretically containing

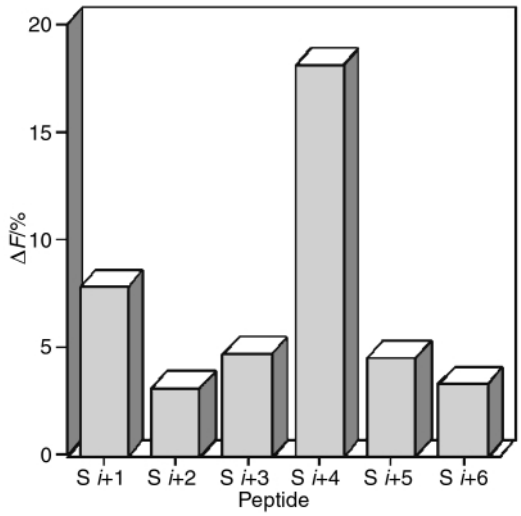

Fig. 1 Ratio of fluorescence intensities (ΔF) of 5 μM peptides at 348 nm and 1.0 °C. All experiments were carried out in a buffer of 10 mM NaCl, 1 mM Na_2HPO_4 and 1 mM EDTA (pH 7.0). The excitation wavelength for Trp is 278 nm and detected at 348 nm.

Table 1 Binding constants and free energies of peptide–saccharide complexes at 1 °C

Peptide sequence	$K_a/10^4$ M[a]		$-\Delta G^0$/kcal mol^{-1} [b]	
	D-Erythrose	D-Galactose	D-Erythrose	D-Galactose
WGDEY	35.0 ± 2.9	5.22 ± 0.42	6.95 ± 0.05	5.91 ± 0.04
WADEF	26.5 ± 2.3	3.81 ± 0.27	6.80 ± 0.05	5.75 ± 0.04
KWAAAW	0.41 ± 0.06	3.89 ± 0.13	4.53 ± 0.06	5.76 ± 0.02

[a] K_a values were estimated by the curve fitting procedure described in the text. [b] $-\Delta G^0$ values were determined with the equation $\Delta G^0 = -RT\ln K_a$

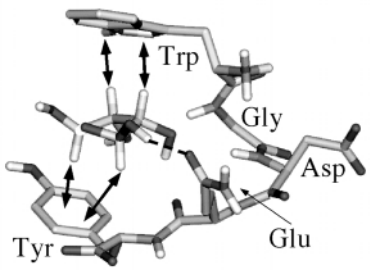

Fig. 2 Minimized energy structure of WGDEY–D-erythrose. Lines and dotted lines indicate CH-π and hydrogen-bonding interaction, respectively.

62 000 kinds of peptides. Ten of the 15 selected peptides had a common motif: WNNNF/T where two of the three N residues were negatively charged amino acids (D or E).

To confirm the highly selective monosaccharide binding by motif peptides and to investigate the motif peptide–D-erythrose interaction, association constants (K_a) of motif peptides for monosaccharides were estimated from fluorescence intensity change by a curve fitting procedure described previously,[14] using the same buffer as the selection experiments. Table 1 shows the K_a of WGDEY and WADEF with D-erythrose and a reference sugar (D-galactose), respectively, and the values of the (S *i*+4) peptide with sugars as references. The difference observed between motif peptides-D-erythrose and motif peptide-D-galactose suggests that motif peptides can recognize a target molecule selectively. Affinity of the lectin for a monosaccharide is usually weak with association constants in the millimolar range, yet it is often highly selective.[2] On the other hand, affinity constants for binding of a simple oligosaccharide to most lectins are estimated to be 10^3–10^6 M^{-1}).[15] Therefore, the K_a value of the motif peptide-D-erythrose is large enough for a monosaccharide recognition protein. The difference between $\Delta G°$ of motif peptides-D-erythrose (−7.0 and −6.8 kcal mol^{-1}) and reference peptide-D-galactose (−4.5 kcal mol^{-1}) is about −2.5 kcal mol^{-1}. The net contributions of an intramolecular hydrogen bond between protein side chains and an intermolecular hydrogen bond between protein and water were estimated to be −2.3 and −1.2 kcal mol^{-1}, respectively.[16] Furthermore, hydrogen bonds in proteins and α-helical peptides were estimated to be −1.3 and −1.0 kcal mol^{-1}, respectively.[17,18] Therefore, one or two appropriate hydrogen bonding interactions were successfully introduced into the selected peptides-D-erythrose interaction using combinatorial chemistry. Fig. 2 shows the minimized energy structure of WGDEY–D-erythrose complex§ which suggests that the peptide sandwiches D-erythrose with W and Y and that a hydrogen bond is formed between the hydroxy group of D-erythrose and a polar side chain of the peptide. Both thermodynamic and molecular modelling results indicate that the motif peptides can bind D-erythrose with the two binding manners as observed in the wild-type saccharide binding proteins. These results also show that all (*i* ~ *i*+4) residues have critical roles for specific monosaccharide recognition. The *i* and *i*+4 aromatic residues are necessary to form a sandwiching interaction, and the acidic residues at *i*+1, *i*+2 and *i*+3 are well suited for hydrogen-bonding interactions. Other selected small residues such as A and G are also important to fit peptide structure for the multi-point saccharide recognition. These delicate residue arrangements were achieved with a combination of rational design studies and a biased combinatorial library.

In summary, the smallest model system of saccharide-binding protein with both hydrogen bonding and the sandwiching interaction was developed using a combination of rational design and combinatorial chemistry. This system is very useful to obtain quantitative parameters of general saccharide–protein interactions.

We thank Dr Angel Maki, Department of Chemistry, Stanford University, for critical reading of the manuscript and helpful comments. This work was supported in part by Grants-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan, and Grants from 'Research for the Future' Program of the Japan Society for the Promotion of Science.

Notes and references

† All peptides used in this study were synthesized by the Fmoc procedure on a solid support of Fmoc-NH-SAL resin then purified by HPLC. These peptides were named as S *i*+*x* (*x* = 0–6) by means of short oligopeptides which have one or two Trp residues at *i* and *i*+*x*. The peptide sequences were confirmed by peptide sequencing.

‡ All fluorescence spectra were measured from 250 to 350 nm and excited at 278 nm in a 1 cm path length cuvette in the presence and absence of D-Gal at 1.0 °C. All experiments were done in a buffer of 10 mM NaCl, 1 mM Na_2HPO_4 and 1 mM $EDTA_4$ (pH 7.0). Peptide and saccharide concentrations were 5 μM and 50 mM, respectively.

§ The minimized energy structure was obtained after molecular calculation using QUANTA 96/CHARMM 23.2 on a Silicon Graphics Indigo^2 workstation running IRIX 5.3. The energy of the complex was minimized by the parameter of Newton-Raphson and VERLET with an adopted basis set. Dynamics simulation of the minimized energy structure was performed to obtain various conformations as initial coordinates for the calculation. The VERLET algorithm with a time step of 1 fs was used in the dynamics simulation. The system was heated from 0 to 1000 K for the conformational search in the MD simulation.

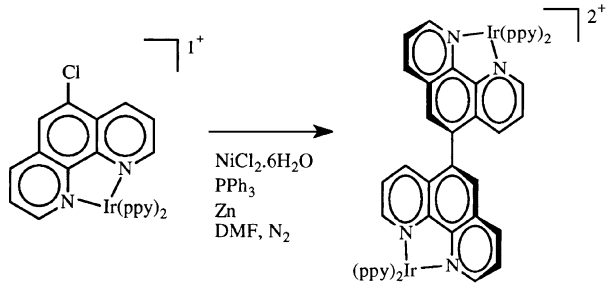
First published as an Advance Article on the web 7th November 2000

Four new homometallic dinuclear Ir^{III}, Ru^{II} and Os^{II} complexes are prepared and their luminescence properties and redox behavior are reported; the bis-phenathroline bridging ligand is found to isolate the two components of each dinuclear system because of its unusual nonplanar structure.

Luminescent and redox-active multinuclear metal complexes are extensively investigated because of their interest in the design of novel systems for photochemical energy conversion and for the elaboration of optical information at the molecular level.[1] Beside standardized synthetic methods like the so-called 'complexes as ligands and complexes as metals' approach,[2] metal-catalyzed coupling reactions involving suitable metal precursors are attracting an increasing attention due to the relatively high yields of these reactions and the unambiguity of the products obtained.[3]

In this paper we demonstrate the feasibility of the application of the coupling reaction to suitable Os^{II} polypyridine and Ir^{III} cyclometallated precursors, by the preparation of new luminescent and redox-active homometallic dinuclear Os^{II} and Ir^{III} compounds, and report the absorption spectra, luminescence properties and redox behavior of these new compounds. To the best of our knowledge, it is the first time that this synthetic approach has been applied to luminescent Os^{II} and Ir^{III} complexes. For the sake of completeness, an analogous Ru^{II} polypyridine complex was also prepared and its absorption spectrum, luminescence properties and redox behavior studied. The new compounds synthesized were $[(ppy)_2Ir(phen–phen)Ir(ppy)_2]^{2+}$ (**1**; ppy is the monoanion of 2-phenylpyridine; phen–phen = 5,5′-bis(1,10-phenanthroline)), $[(bpy)_2Ru(phen–phen)Ru(bpy)_2]^{4+}$ (**2**; bpy = 2,2′-bipyridine); $[(bpy)_2Os(phen–phen)Os(bpy)_2]^{4+}$ (**3**) and $[(Me_2bpy)_2Os(phen–phen)Os(Me_2bpy)_2]^{4+}$ (**4**; Me_2bpy = 4,4′-dimethyl-2,2′-bipyridine).‡

The only published procedure for the synthesis of the free bridging ligand phen–phen (5,5-bis(1,10-phenanthroline)) is based on Skraup reactions applied to a benzidine derivative,[4] however this procedure is both toxic and low yielding. The incorporation of coupling methodologies into the synthesis would avoid both, although previous attempts involving copper coupling reactions on 5-bromo-1,10-phenanthroline have failed.[4] We attempted to apply nickel coupling reactions to 5-chloro-1,10-phenanthroline (Cl–phen) to form the free ligand, but this method failed, possibly due to the destabilisation of the nickel tetrakis(triphenylphosphine) catalyst involved in the reaction. However, upon complexation with $Ru(bpy)_2Cl_2$ to yield the new $[Ru(bpy)_2(Cl–phen)]^{2+}$ complex, the phenanthroline moieties couple together in a good yield, 65%, to form the homometallic dimer **2**. Preparation of the new compounds $[Os(bpy)_2(Cl–phen)]^{2+}$, $[Os(Me_2bpy)_2(Cl–phen)]^{2+}$ and $[Ir(ppy)_2(Cl–phen)]^{+}$ by standard literature procedures[5] afforded us suitable precursors to synthesise osmium and iridium homometallic dinuclear compounds by the same coupling reaction. This method yielded the desired compounds **1**, **3**, and **4** (Scheme 1) without particular problems and with comparable yields with respect to the Ru^{II} dimer.



Scheme 1

Each of the four dinuclear compounds exhibits a reversible two-electron oxidation process in acetonitrile solution (Table 1), which can be assigned to simultaneous one-electron oxidation involving the identical metal centres. As expected and in agreement with the above assignment, the osmium species are oxidized at less positive potentials than the ruthenium species. The Ir-centred oxidation process occurs at a typical potential for Ir^{III} cyclometallated species;[5b,6] its reversibility also suggests that an Ir–C^- σ-bond orbital, sometimes playing the role of the donor orbital in the oxidation process,[6] is not involved in such a process in **1**. The coincidence of the two metal-centred oxidation processes in all the complexes indicates that the metal–metal electronic interaction across the phen–phen briding ligand is weak.

The reduction patterns of all the complexes (Table 1) show series of reversible two-electron reductions. The process at less negative potential occurs at similar potentials for all the complexes, and is therefore assigned to the reduction of the two phenanthroline halves of the phen–phen bridging ligand, which is the only polypyridine ligand common to all the species. The two-electron nature of this process suggests that the two phenanthroline halves of the bridge are reduced simultaneously, and indicates that these moieties are isolated from an electrochemical viewpoint. This result is quite surprising on considering the redox behavior of similar systems, such as the $[(bpy)_2Ru(bpy–bpy)Ru(bpy)_2]^{4+}$ complex (bpy–bpy = 4,4′-bis(2,2′-bipyridine)), in which only monoreduction of the

2	+1.31	−1.26; −1.47; −1.78
3	+0.86	−1.26; −1.46; −1.77
4	+0.78	−1.23; −1.53

† Electronic supplementary information (ESI) available: spectral data for **1**–**4**, cyclic voltammogram for **3** and absorption and emission spectra for **1**–**3**. See http://www.rsc.org/suppdata/cc/b0/b006456o/

DOI: 10.1039/b006456o

bridge occurs (at −1.10 V *vs*. SCE) before bpy-centred reductions take place;[7] that result suggested that in the bpy–bpy ligand the LUMO orbital in which reduction takes place extends over the two bipyridine halves of the bridging ligand (because the reduction is much easier than in isolated bpy), indicating that the reduced form of the bridging ligand is planar. However, planarity is forbidden in the case of the phen–phen bridging ligand used here, because of strong steric constraints. The absence of planarity is therefore suggested to be responsible for the electrochemical isolation of the two halves of phen–phen.[8] The successive two-electron reduction process of **1** occurs at a potential typical for ppy reduction in cyclometallated complexes[5b] and is attributed to simultaneous one-electron reduction of two ppy ligands coordinated to different metal centres. The second, bielectronic processes of **2** and **3** is attributed to simultaneous one-electron reduction of two bpy ligands coordinated to different metals and the third bielectronic process is assigned to one-electron reduction of the two remaining bpy ligands. The second bielectronic reduction of **4** is analogously assigned to simultaneous one-electron reduction of two Me_2bpy ligands coordinated to different metals, slightly shifted to more negative potentials compared to that of **2** and **3** because the two methyl substituents make the ligand more difficult to reduce. The same reason probably moves the expected reduction of the other Me_2bpy ligands out of the potential window investigated (+2.00 to −2.00 V *vs*. SCE).

The visible region of the absorption spectra of the Ru^{II} and Os^{II} complexes is dominated by moderately intense metal-to-ligand charge-transfer (MLCT) bands, whereas intense ligand-centred (LC) bands dominate the UV region (Table 2).[1a,9] In particular, by comparison among the various compounds and literature data,[9] the bands at about 285 nm can be assigned to spin-allowed bpy-centred transitions, the bands at about 270 nm are assigned to spin-allowed LC transitions involving the phen–phen bridge, the broad absorption features in the 400–500 nm region are attributed to spin-allowed MLCT transitions (with those involving the bridging ligand lower in energy than those involving the peripheral ligands), and the absorption bands at wavelengths longer than 500 nm to spin-forbidden MLCT transitions (such bands are particularly evident in the osmium-containing compounds due to enhanced spin–orbit coupling). For the Ir^{III} dinuclear complex **1** (Table 2), the UV region is also mainly dominated by LC spin-allowed transitions, with spin-allowed MLCT transitions contributing to the absorption spectrum at about 380 nm. The broad, weaker absorption feature in the 400–500 nm region is attributed to spin-forbidden MLCT transitions.[5b,6]

Table 2 Relevant spectroscopic and photophysical data in CH_3CN deaerated solutions at room temperature

Compound	Absorption λ_{max}/nm (ε, M^{-1} cm^{-1})	Luminescence		
		λ_{max}/nm	τ	ϕ
1	265 (108900) 374 (16500)	613	386 ns	0.123
2	284 (126800) 452 (34800)	617	1.3 μs	0.069
3	289 (130200) 432 (29900) 478 (30500)	743	222 ns	0.023
4	288 (118600) 485 (27700)	787	214 ns	0.0044

All the four new dinuclear complexes exhibit relatively intense room temperature luminescence (Table 2). In all the cases, on the basis of the luminescence energies, spectra, lifetimes and quantum yields, emission can be attributed to ^{3}MLCT levels. The redox data also suggest that for all the compounds the emitting ^{3}MLCT state involves the phen–phen bridging ligand. Differences among excited state energies in the various compounds are in line with redox and absorption data. The values calculated for the radiative and radiationless rate constants of the emitting excited state decay in **1**–**4** can be rationalized by considering the energy gap law[10] and the larger singlet character of the emitting level in the osmium and iridium complexes compared to the ruthenium one, which accelerate both the formally forbidden radiative and radiationless decay processes.

We thank MURST (Project: fotosintesi artificiale) and the European Community (TMR Network on nanometer size metal complexes) for financial support.

8 It should be considered that this does not mean that the phen–phen bridging ligand is not suitable to build up multinuclear systems featuring intercomponent energy or electron transfer. It has been demonstrated that even electronic interactions as small as 10 cm^{-1} (well beyond the limit of the coupling which is possible to evidence by redox experiments) are enough to allow fast energy and electron transfer processes (see: F. Scandola, M. T. Indelli, C. Chiorboli and C. A. Bignozzi, *Top. Curr. Chem.*, 1990, **158**, 73).

Does *C*-methylcalix[4]resorcinarene always adopt the crown shape conformation? A resorcinarene/bipyridine/decamethylruthenocene supramolecular clathrate with a novel framework structure†

Yuegang Zhang, Christopher D. Kim and Philip Coppens*

Department of Chemistry, State University of New York at Buffalo, Buffalo, New York, 14260-3000, USA. E-mail: coppens@acsu.buffalo.edu

Received (in Columbia, MO, USA) 5th June 2000, Accepted 11th October 2000
First published as an Advance Article on the web 8th November 2000

Decamethylruthenocene acts as the template for the self-assembly of a 2:4:1 *C*-methylcalix[4]resorcinarene/bipyridine/decamethylruthenocene supramolecular structure with large hydrophobic cavities.

As part of a survey of candidates for time-resolved diffraction studies of excited state structures we have previously reported binary phases of 4,4′-dihydroxybenzophenone and *p*-amino-*p*′-nitrobiphenyl and photoinactive 'spacer' molecules.[1,2] Molecular dilution achieved in host–guest crystals has several advantages in time-resolved work, as discussed elsewhere.[3] We report here, on a complex crystalline phase containing decamethylruthenocene (DMR), which has a long-lived triplet state.

MacGillivray *et al*. reported the entrapment of acetylated ferrocene derivatives within the supramolecular deep cavity *C*-methylcalix[4]resorcinarenes (CMCR)/4,4′-bipyridine.[4,5] Though decamethylruthenocene is larger than diacetylferrocene, the cavity formed by *C*-methylcalix[4]resorcinarene, which is extended through hydrogen bonding with the bipyridine molecules, appeared sufficiently flexible to accommodate larger guests.

Needle shape orange crystals of CMCR/4,4′-bipyridine/DMR crystal were grown by slow cooling (one day) of a boiling 96% ethanol (3 mL) solution of *C*-methylcalix[4]resorcinarene (27.2 mg, 0.05 mmol), 4,4′-bipyridine (15.6 mg, 0.10 mmol) and decamethylruthenocene (18.5 mg, 0.05 mmol). Low temperature X-ray structure determination[6] shows an arrangement in which one DMR, two water and two ethanol solvent molecules are located in cavities within a hydrogen-bonded framework formed by the host molecules, with a 2:4:1 CMCR/bipyridine/DMR ratio, as illustrated in Fig. 1. The clathrated DMR molecules occupy one of two center-of-symmetry related positions in a disordered arrangement.

The *C*-methylcalix[4]resorcinarene (CMCR) molecules have a 'flattened cone' conformation (Fig. 2), using the terminology introduced by Gutsche[7] (Fig. 2), different from the crown shape of all the other reported X-ray structures of CMCR. Intramolecular hydrogen bonding is absent in this conformation. While *C*-methylcalix[4]resorcinarene derivatives adopting the 'flattened cone' conformation occur when their hydroxy groups are substituted by ethoxy[8] or trimethylsiloxy groups,[9] or the hydroxy groups are coordinated with metal,[10] which eliminates the possibility of intramolecular hydrogen bonding, this is the first observation of a non-substituted non-metal-atom-containing *C*-methylcalix[4]resorcinarene in this conformation.[11]

Four O–H···O hydrogen bonds link pairs of neighboring resorcinarenes into columns parallel to the crystallographic [011] direction,[12] while O–H···N hydrogen bonds to the nitrogen atoms at each end of the interspersed bipyridine molecules link the columns into 'skewed-brick' sheets parallel to the (1 $\bar{1}$ 1) plane.[13] The DMR molecules serve as templates for the self-assembly of the framework, which is isomeric to MacGillivray's one dimensional polymer.[14] The template-induced architecture of the host framework is of much current interest.[15] Large hydrophobic cavities, in which the guest molecules are located, occur in the space between the bipyridyl molecules (Fig. 3). Successive sheets perpendicular to (1 $\bar{1}$ 1) are linked by weaker interactions, including C-H···O hydrogen bonds. The two independent bipyridine molecules are twisted by 32.04(14) and 17.15(20)°, respectively.

Though crystals of neat DMR are disordered at ambient temperature,[16] low temperature X-ray analysis shows the structure to be fully ordered at 90 K, with a doubling of the unit cell.[6] Comparison of the DMR molecules in the two structures shows only negligible differences, the Ru–Cp distances averag-

ing 1.805(16) and 1.792(7) Å respectively in the complex, compared with 1.800(3) and 1.800(3) Å in the neat DMR structure.

The impetus for the current study was the long lifetime of the $^3E_1$ triplet state of DMR, reported as 627 μs (4.2 K), compared with 127 μs for ruthenocene (1.5 K).[17] Spectroscopic experiments[18,19] and calculations[20,21] indicate a significant change in inter-ring distance on excitation of ruthenocene, which is to be investigated by time-resolved synchrotron diffraction methods. Using equipment described elsewhere,[22] we have measured the 16 K lifetimes of the DMR triplet state in both the resorcinarene/DMR complex and neat DMR as 492 and 460 μs, respectively. While the DMR concentration is much lower in the complex crystal (0.602 *vs.* 3.71 M in the neat crystal), the difference could reflect a slightly different temperature.[23] Other measurements on lifetimes in host–guest complexes show no clear relation between excited-state lifetime and molecular concentration.[24]

In summary, decamethylruthenocene acts as the template for the self-assembly of the 2:4:1 *C*-methylcalix[4]resorcinarene/bipyridine/decamethylruthenocene supramolecular crystal. The crystal has a layered structure with two-dimensional planes of hydrogen-bonded molecules, and contains 'flattened cone' shaped calix[4]resorcinarene molecules. The decamethylruthenocene molecules are located in hydrophobic cavities lined by the *C*-methyl groups and the bipyridyl hydrogen atoms. It is likely that other hydrophobic molecules of comparable size can be similarly accommodated in this type of structure, thus suggesting additional applications in crystal engineering and supramolecular chemistry. We have already obtained *C*-methylcalix[4]resorcinarene/bipyridine/benzophenone crystals with similar framework and 'flattened cone' shaped calix[4]resorcinarene molecules.[25]

The picket fence porphyrin complex [Fe(tpivpp)(NO)] undergoes complete conversion to the isolable *N*-bound nitrite derivative [Fe(tpivpp)(NO_2)(py)] in air in the presence of pyridine: reconversion to the starting nitrosyl complex is achieved using triphenylphosphine as reductant.

The study of the reactions of nitric oxide ligands in iron nitrosyl porphyrins is receiving increased attention in bioinorganic chemistry.[1] This is due, in part, to a need to understand the fate of the NO group after it binds to the metal center in heme biomolecules and related model complexes, and to elucidate the chemical processes involved in the conversion of the coordinated NO group to nitrite. There are very interesting results in the literature regarding the formation of coordinated NO_2 groups in iron porphyrins.† For example, Scheidt and coworkers have prepared and structurally characterized a series of [Fe(por)(NO)(NO_2)] complexes by the reaction of $[Fe(por)]_2O$ or [Fe(tpivpp)(NO)] with an excess of NO,[2] and they have proposed the intermediacy of reactive nitrite compounds during the formation of nitrate [Fe(por)(NO_3)] products (por = tpivpp, oep, tpp, ttp) from their nitrosyl precursors.[3,4] Ford and Lorkovic have demonstrated that NO_2 (N_2O_3; derived from reaction of NO gas with trace oxygen) reacts with [Fe(tpp)(NO)] to give [Fe(tpp)(NO)(NO_2)].[5]

Surprisingly, and although it is of fundamental interest in heme–NO chemistry, no direct chemical evidence has been reported on the straightforward conversion of the coordinated NO group in an iron nitrosyl porphyrin to an isolable nitrite complex.‡ We now produce the first unambiguous experimental evidence that the [Fe(tpivpp)(NO)] compound converts to the [Fe(tpivpp)(NO_2)(py)] derivative in air and in the absence of added NO.

The X-ray structure of [Fe(tpivpp)(NO)] is shown in Fig. 1.§¶ Reaction of this compound in $CHCl_3$ with air in the presence of pyridine results in its complete conversion to [Fe(tpivpp)(NO_2)(py)]‖** within 1 h as judged by IR spectroscopy of KBr pellets of dried aliquots.†† When the reaction of [Fe(tpivpp)(NO)] (20–50 mg, 0.018–0.040 mmol) with air and pyridine is performed in a $CHCl_3$–heptane mixture, and the solvent allowed to evaporate over a 3 d period, needle-shaped crystals of the [Fe(tpivpp)(NO_2)(py)]·py product were obtained in 70–80% isolated yields. The observed Fe–NO_2 distances of 1.92–1.97 Å in the [Fe(tpivpp)(NO_2)(py)] products are longer than the axial Fe–NO distance in the precursor [Fe(tpivpp)(NO)] complex (1.65–1.74 Å), and the nitrite O-atoms point towards the HN groups of the picket fence (O···N distances of 3.7–3.8 Å) suggesting possible stabilization of the bound nitrite through weak H-bonding interactions.

The added base is essential for the generation of the stable ferric nitrite derivative, since the reaction of [Fe(tpivpp)(NO)] with air in $CHCl_3$ solution (without added pyridine) results in its quantitative conversion to the known ferric chloro [Fe(tpivpp)(Cl)] complex (λ_{max} = 417 nm).[12,13] We have found that this latter reaction is also enhanced by UV–VIS light (*e.g.* when monitoring the reaction by UV–VIS spectroscopy). We have also confirmed an earlier observation that air oxidation of the non-picket fence [Fe(por)(NO)] compounds (por = tpp, ttp, oep) results in the isolation of the $[Fe(por)]_2O$ oxo dimers,[4] suggesting that the picket fence pocket is indeed crucial for the stabilization of the singly-oxidized nitrite product.

Deoxygenation of the coordinated nitrite to nitrosyl in this picket fence [Fe(tpivpp)(NO_2)(py)] complex in $CHCl_3$ (under a nitrogen atmosphere) is achieved by the addition of triphenylphosphine. The reaction is complete within 15 min, and the five-coordinate nitrosyl [Fe(tpivpp)(NO)] complex is obtained in 80% isolated yield, with triphenylphosphine oxide as the oxidized product. The overall reaction is shown in eqn. (1):

$$[Fe(tpivpp)(NO)] \underset{PPh_3\ (-\ OPPh_3)}{\overset{air,\ py}{\rightleftharpoons}} [Fe(tpivpp)(NO_2)(py)] \quad (1)$$

The conversion of coordinated nitrite to nitrosyl has precedent in iron porphyrin chemistry. For example, (i) the anionic bis-nitro $[Fe(tpivpp)(NO_2)_2]^-$ complex undergoes rearrangement in the presence of boron trifluoride to [Fe(tpivpp)(ONO_2)] and [Fe(tpivpp)(NO)] in some organic solvents,[3] and (ii) oxygen-atom transfer to organic compounds by the [Fe(oep)Cl]/nitrite mixture is believed to occur *via* the intermediacy of '[Fe(oep)(NO_2)]', although this intermediate was not unambiguously identified.[14]

The observation of this base-assisted stabilization of an iron-bound nitrite product derived from its nitrosyl precursor has implications for the reactivity of the bound NO group in nitrosyl heme proteins containing *trans* axial N-bases, and suggests that

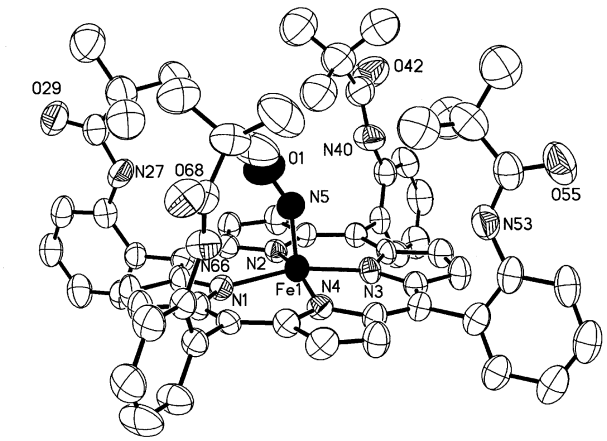

Fig. 1 Molecular structure of [Fe(tpivpp)(NO)]. The nitrosyl group is disordered over two positions, and only one of these positions is shown. Hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Fe(1)–N(por) 1.991(5)–2.007(5), Fe(1)–N(5) 1.65(5), Fe(1)–N(5′) 1.74(6), N(5)–O(1) 1.17(5), N(5′)–O(1′) 1.20(7); Fe(1)–N(5)–O(1) 149(4), Fe(1)–N(5′)–O(1′) 137(4).

DOI: 10.1039/b006775j

iron-bound nitrite could be one of several products or intermediates in some heme–NO ligand oxidations.

¶ The X-ray structure of the related [Fe(tpivpp)(NO)][K(NO$_2$)(18-crown-6)] has been reported.[8] The [Fe(por)(NO)] compounds are commonly referred to as ferrous nitrosyls.[1]

‖ This compound was initially prepared from the reaction of the anionic bis-nitro [Fe(tpivpp)(NO$_2$)$_2$]$^-$ complex with pyridine.[9]

** We have obtained three solid-state X-ray structures of this [Fe(tpivpp)(NO$_2$)(py)]·solvate product from these reactions that differ in the nature of the solvate (pyridine, chloroform or dichloromethane). These structures are available in the above .cif file, and are similar to the previously reported structure of [Fe(tpivpp)(NO$_2$)(py)]·PhCl.[9] The structure of the anionic five-coordinate [Fe(tpivpp)(NO$_2$)]$^-$ compound is known.[10] Anionic iron porphyrin nitrites also have rich electrochemistry.[11]

†† KBr pellets were used to observe the ν_{NO} (1675 cm^{-1}) and ν_{NO_2} (1307 cm^{-1}) bands. These bands were confirmed by the use of the ^{15}N-labeled [Fe(tpivpp)(^{15}NO)] (λ_{max} = 409 nm) precursor: $\nu_{^{15}NO}$ of 1641 cm^{-1} for the nitrosyl complex, and $\nu_{^{15}NO_2}$ 1289 cm^{-1} for the nitrite derivative. We have not been able to determine the position of the second ν_{NO_2} band owing to extensive overlap with the porphyrin bands. Also, the UV–VIS spectrum of [Fe(tpivpp)(NO$_2$)(py)] (λ_{max} = 419 nm) is very similar to that of the six-coordinate nitrosyl [Fe(tpivpp)(NO)(py)] complex (λ_{max} = 419 nm), making the monitoring of the reaction by UV-VIS spectroscopy very difficult.

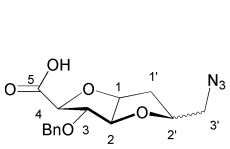
Received (in Cambridge, UK) 31st July 2000, Accepted 13th October 2000
First published as an Advance Article on the web

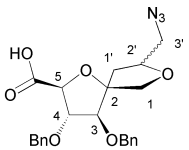
Bicyclic amino acids derived from the natural sugars D-arabinofuranose and D-fructofuranose have been synthesised; their ability to induce a turn conformation in peptides has been exploited in the preparation of a cyclic RGD loop mimetic.

The conformational rigidity of the pyran and furan rings makes sugar amino acids (SAAs) interesting building blocks in the induction of precise secondary structures in peptides and in the construction of peptidomimetics. In this context, β-D-glucopyranose was used as scaffold in the preparation of the first nonpeptide somatostatin mimetic;[1] in a different biological context the same sugar moiety was employed to present the guanidine group crucial for the biological activity of thrombin inhibitors.[2] By varying the mutual positions of the amino and carboxylic groups in the glucopyranose scaffold, a set of SAAs was designed and found to be capable of inducing linear or β-turn conformations when incorporated into Leu-enkephalin peptide analogues.[3] Oligomers of pyranose sugar amino acids[4] ('carbopeptoids') have been synthesised, and the furanose ring has also been exploited as a building block for carbopeptoid assembling.[5] Homo-oligomers of tetrahydrofuran amino acids derived from the arabinofuranose were shown to adopt a novel repeating β-turn type secondary structure in tetrameric units stabilized by intramolecular hydrogen bond.[6]

We present here the design and the synthesis of novel azido



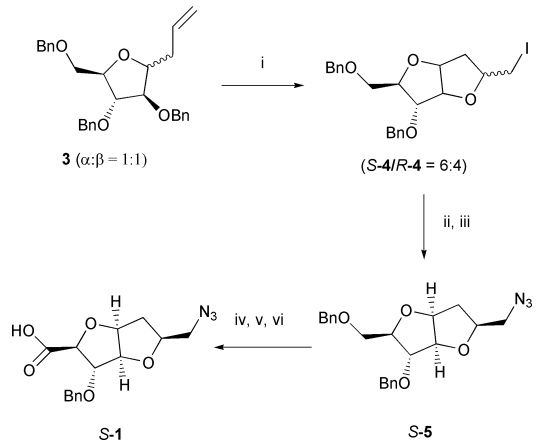
1



2

acids (**1** and **2**) with bicyclic structures, derived from D-arabinofuranose and D-fructofuranose respectively. Given that the azido group is chemically equivalent to a protected amine, these compounds can be used as building blocks for solid phase assembly of peptoids. Our main goal in the design of this type of SAAs was to lock the furanose ring in a rigid conformation through the formation of fused rings or spiro-bicycles, thus mimicking protein reverse turns (**1**) or constraining a linear peptide conformation (**2**). The transformation of the commercially available starting materials into the corresponding bicyclic azido acids are based on the same synthetic strategy, once the respective allyl-*C*-furanosides have been formed (Schemes 1 and 2).

The 2,3,5-tri-*O*-benzyl-D-arabinofuranose was converted into the anomeric acetate **3**, which was allylated by treatment with allyltrimethylsilane in the presence of catalytic amounts of BF_3–Et_2O. The reaction, effected at rt in dry acetonitrile, afforded **4** as a 1:1 mixture of α and β diastereomers (72% yield). Iodocyclization (Scheme 1) was then carried out with iodine in CH_2Cl_2 at 0 °C. This step is crucial to the formation of the bicyclic structures of the arabino- and fructo-derived compounds and consists of the opening of the intermediate iodonium ion by attack of the γ-benzyloxy groups in the 5-*exo*-



Scheme 1 *Reagents and conditions*: i, I_2, CH_2Cl_2, 0 °C, 12 h; ii, separation of diastereomers by flash chromatography; iii, Bu_4NN_3, toluene, 60 °C; iv, Ac_2O, CF_3COOH, 0 °C; v, MeONa, MeOH; vi, CrO_3–H_2SO_4, acetone–water.

mode with formation of a cyclic iodoether with debenzylation.[7] Obviously, only the β anomer of **4** reacted and this allowed the easy separation from the α-anomer. The bicyclic iodoether **5** was obtained as a mixture of diastereomers (95% yield based on the β anomer), the major isomer having the 2′-(*S*) configuration (20% d.e.). Compounds *R*-**5** and *S*-**5** were separated by flash chromatography and their relative configurations at the C-2′ assigned by NOESY analysis.[8] The reaction of the iododerivative **5** with tetrabutylammonium azide in toluene to give azidoderivative **5** (60 °C, 24 h, 87% yield), as well as the subsequent synthetic steps, were carried out separately on the two diastereoisomers with similar yields. In order to introduce the carboxylic function, **5** was regioselectively debenzylated at the primary hydroxy group by controlled acetolysis (Ac_2O, CF_3COOH, 0 °C), followed by saponification of the acetate and

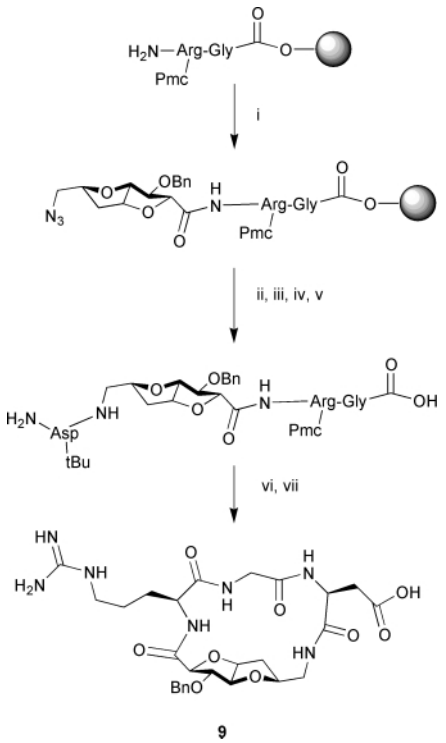
DOI: 10.1039/b006192l

Jones oxidation. Compound **1** was obtained in 48% yield over three steps. The spiro-azido acid **2** was prepared in a similar way, as shown in Scheme 2, the iodocyclization of **6** affording stereoselectively *R*-**7** as the major product[9] (d.e. 33%). The iododerivative was reacted with tetrabutylammonium azide in toluene (60 °C, 24 h) then submitted to acetolysis affording *R*-**10**,[10] and finally converted into azido acid *R*-**2**. The overall yields for the transformation of **3** into **1** and of **6** into **2** were respectively 40% and 35%, *S*-**1**[11] and *R*-**2** being obtained as the major isomers.

NMR and molecular dynamics indicate that both arabino- and fructo-derived bicycles adopt rigid, spatially well-defined conformations. In particular the sugar-amino acids derived from precursors *S*-**1** and *R*-**1** are rigid turn mimetics, both molecules can be incorporated in peptide sequences and used to replace *i* + 1 and *i* + 2 residues of a protein β-turn.

Moreover, these conformationally constrained sugar-amino acids may be incorporated as rigid templates into cyclic peptides in order to lock a bioactive conformation. Several templates have been included in cyclic peptides containing the RGD loop with the aim of obtaining new inhibitors of the adhesive interaction between the $\alpha_v\beta_3$ and the $\alpha_{IIb}\beta_3$-type integrins and their ligands.[12] As example, cyclic peptide **9** was synthesised on solid phase (Scheme 3) by the well-established Fmoc protocol. The dipeptide Arg(Pmc)-Gly was assembled onto Sasrin resin with a loading of 0.47 mmol g^{-1}, then compound *S*-**1** was coupled in the presence of HBTU,[13] HO-Bt and DIPEA. The *N*-terminal azide reduction to the amine and the coupling with Fmoc-Asp(tBu) was effected one-pot in the presence of DIC, Bu_3P, HO-Bt in dry DMF–toluene (2 : 1) at rt for 24 h.[14] This reaction was found to be very efficient and high yielding (as assessed from the loading value calculated after the Fmoc deprotection of the aspartate), in sharp contrast with the inefficiency of other well-established methods we employed to reduce this azide. The tetrapeptide was then cleaved from the resin (1% TFA in CH_2Cl_2 with immediate neutralisation of the effluents with pyridine) maintaining all protecting groups, purified by flash chromatography on silica gel, cyclised in a dilute solution of DMF (peptide conc. 0.5 mM) in the presence of HBTU, HO-Bt and DIPEA and finally totally deprotected with TFA–TIS–water (95 : 2.5 : 2.5), affording **9**[15] in 63% yield over the last two steps.



9

Scheme 3 *Reagents and conditions:* i, *S*-**1**, HBTU, HOBt, DIPEA, DMF, rt, 4 h; ii, Bu_3P, DIC, Fmoc-Asp(OtBu), rt, 24 h; iii, piperidine 20% in DMF; iv, 1% TFA in DCM, neutralisation of the effluent with pyridine; v, 0.5 mM peptide in DMF, HBTU, HOBt, DIPEA, 12 h, rt; vi, 95% TFA, 2.5% TIS, 2.5% H_2O, 10 h, rt.

The high efficiency of the synthesis of compounds **1** and **2** is likely to offer opportunities for the preparation of a wide range of carbohydrate-derived bicyclic amino acids with improved conformational rigidity to be used as templates, inducing precise secondary structure conformations in peptides. Detailed conformational analysis of these compounds was carried out by NMR and molecular dynamics and will be reported elsewhere.

We gratefully acknowledge the contribution of Carola Cassani to the experimental work.

8 A consistent NOESY crosspeak (400 MHz, $CDCl_3$) was observed between H-2′ and H-3 protons for the diastereoisomer *R*-**5**, that was absent for *S*-**5**.

9 A sequential NOESY correlation allowed the unambiguous attribution of the configuration at C-2′: for diastereoisomer *R*-**5** H-3/H-1′b and H-2′/H-1′a NOESY crosspeaks were observed thus indicating that H-3 and H-2′ point towards different spatial regions. For diastereoisomer *S*-**8**, H-3/H-1′b and H-2′/H-1′b NOESY crosspeaks were observed.

Chirality amplification in dynamic helical columns in water

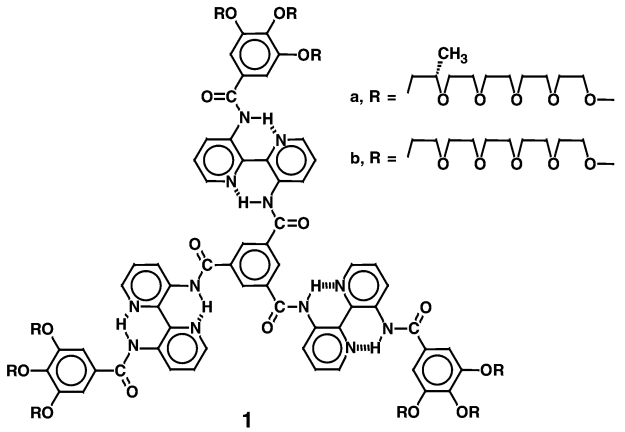
First published as an Advance Article on the web

Extended core discotic molecules self-assemble in water by different secondary interactions to give well-defined, helical columns in which the chirality of one chiral molecule is transferred to on average 12 achiral molecules.

Amplification of chirality, generating homochiral molecules or architectures, is one of the fascinating aspects of life that chemists have repeatedly tackled.[1] Approaches have ranged from crystallization-induced resolution to asymmetric synthesis, while Green pioneered the amplification of chirality at helical macromolecular backbones.[2] We have shown that the addition of small amounts of homochiral seed molecules to dynamic, racemic supramolecular architectures of achiral building blocks in solution generates homochiral supramolecular assemblies.[3,4] For well-defined columns formed by *N*-acylated 3,3′-diamino-2,2′-bipyridine based C_3-extended core discotics, we determined that a single chiral molecule imposes its chirality on 80 achiral molecules at rt.[3] In columnar assemblies of alkyl substituted benzene-1,3,5-tricarboxamides, one chiral seed can even direct the chirality of 200 molecules.[4] For aggregates not formed by directional secondary interactions, such as alkoxy substituted polythiophenes, the amplification of chirality was found to be orders of magnitude lower.[5] The solvents used for the study of these architectures, as well as for other chirality transferring supramolecular systems reported so far,[6] are apolar and organic, favouring specific polar secondary interactions. The creation of well-defined chiral supramolecular architectures in water is a subject of increasing importance and one of the goals in bio-inspired supramolecular chemistry.[7]

In the C_3-extended discotic **1**, oligo(ethylene oxide) side chains have been incorporated. The synthesis and the lyotropic behaviour of chiral **1a** in *n*-butanol, have been described elsewhere.[8] Compound **1a** is molecularly dissolved in $CHCl_3$, but is aggregated in *n*-butanol[9] as evidenced by a red-shift in the UV-Vis spectra with respect to those in $CHCl_3$, broad signals in ^{1}H-NMR spectra and a fluorescent species with a long life time.[8] Furthermore, at low temperatures, the columnar aggregates of **1a** in alcohols are chiral, as evidenced from the appearance of a strong Cotton effect ($g_{abs} = 3 \times 10^{-3}$) in the chromophore corresponding to the aromatic core.[10] We have now synthesized achiral **1b** and studied the self-assembly of **1a**–**1b** mixtures in water. Different interactions are shown to be operative in the self-assembly in water and one chiral molecule is able to induce chirality into 12 achiral molecules at 5 °C.

Compounds **1a**,**b** dissolve in water due to their hydrophilic side chains, but intriguingly, aggregation takes place as evidenced by broad signals in the ^{1}H-NMR spectra and a red shift of the UV-Vis spectra, and a strong intensity of the luminescence compared to solutions in $CHCl_3$. This aggregation in water resembles that of chromonics that are known to aggregate *via* hydrophobic interactions of their aromatic cores.[11] Remarkably and in contrast to chromonics, the architectures are chiral and well-defined as evidenced by the appearance of a Cotton effect for **1a** at the wavelength corresponding to the aromatic core ($g_{abs} = 1.4 \times 10^{-3}$). Apparently, the arene–arene interactions of the aromatic cores create a hydrophobic micro-environment that allows for structuring *via* the specific, solvent-sensitive interactions.[8]



Furthermore, this shows that the peripheral chirality of the individual molecules can be transmitted to the centre of the self-assemblies by cooperative side-chain interactions.

In order to investigate the self-assembly, we studied the solution of **1a** in water as a function of temperature. Raising the temperature from 0 to 90 °C resulted in gradual changes in the UV (Fig. 1, top) and CD spectra (Fig. 1, bottom) as well as the fluorescence characteristics (not shown). In contrast to the *n*-butanol solutions that showed a highly cooperative loss of chirality around 20 °C,[8] the Cotton effect of the aqueous solutions only decreased slowly from 0 to 70 °C. At temperatures as low as 0 °C the Cotton effect is still temperature-sensitive, suggesting that the individual molecules are not yet fully locked in one defined position. The bandshape characteristics of the UV-spectra and the high luminescence suggest that the molecules remain aggregated at all temperatures. The stacking at high temperatures is in contrast with the behaviour of **1** in *n*-butanol[8] and to that of chromonics in general.[11] We attribute this behaviour to the combination of a large aromatic core, allowing for strong arene–arene interactions, and the

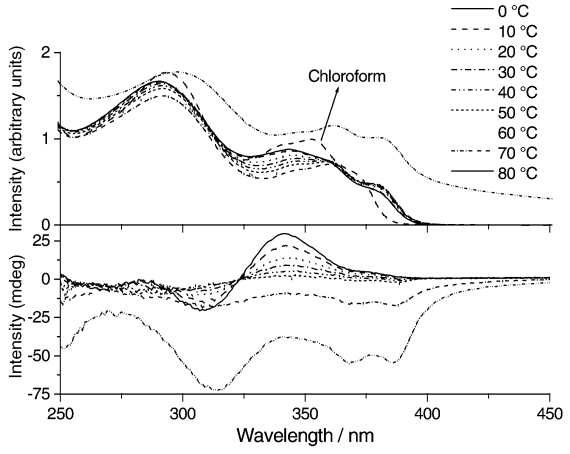


Fig. 1 Temperature dependent UV-Vis (top) and CD (bottom) spectra of **1a** in water (2.6×10^{-5} M). Furthermore, the UV-Vis spectrum of **1a** in chloroform (2.6×10^{-5} M) is shown.

DOI: 10.1039/b007502g

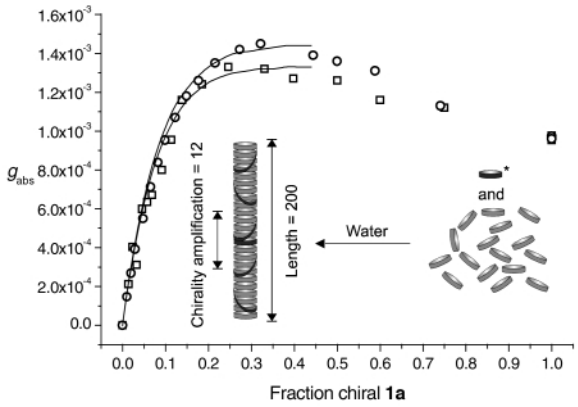

Fig. 2 Dependence of the overall chirality on the mole fraction of chiral **1a** in water at 5 °C, expressed in terms of the *g*-value measured at the maximum of the Cotton effect at 336–341 nm. Measurements were recorded at 10^{-5} M in a 1 cm cell (circles) and at 10^{-4} M in a 1 mm cell (squares). The solid lines represent the best fit to the data using a cooperativity length of 12 molecules and a K_{ass} of 1×10^8 L mol^{-1}.

LCST behaviour of oligo(ethylene oxide)s in water. Dilute solutions of **1a**/**b** in water become turbid around 70 °C (Fig. 1). The turbidity is ascribed to the formation of clusters of columns. At 60 °C a Cotton effect with opposite sign appears (Fig. 1 bottom). Whether this 'inversion' results from the formation of clusters with super-helical structure, or is simply due to scattering of the large particles is not clear yet.

'Sergeant and Soldiers' experiments[12] on **1a**/**1b** mixtures in water were conducted at two different concentrations at 5 °C (Fig. 2) to investigate the possibility of amplification of chirality. Indeed, chirality is amplified in the assembly; the maximal expression of chirality is reached after the addition of 25–30% chiral compound. Adopting the model of Havinga,[3] the association constant (K_{ass}) was calculated to be 1×10^8 L mol^{-1}, with a cooperativity length of 12 molecules. This means that at 10^{-4} M columns with a degree of polymerisation as high as 200 are being formed[13] and that 15–20 chiral molecules are needed to achieve a homochiral column. We are aware of the fact that the model is not exactly suited for the system in water, since it is made for single molecules forming a columnar stack whereas in water non-chiral columns, already present, become chiral. However, to a first approximation the calculated data seem to fit well with the results observed.

The high stability and order of the columns, essential for obtaining chirality amplification, is reflected in a strong time-dependence for the columns to become homochiral; after addition of a small aliquot of chiral **1a** to a solution of achiral **1b** it takes approximately 1.5 h before full amplification of chirality is reached. This phenomenon either results from a diffusion-limited transport of molecules from one stack to the other, or, more likely, is due to an extremely ordered and stable packing of the molecules, both **1a** and **1b**, in the columns.

Fig. 2 clearly shows that in water the intensity of the Cotton effect for particular mixtures is significantly higher than for pure chiral **1a**. In addition, it was established that in water the UV-Vis spectra of **1a** and **1b** differ and as a consequence the CD spectra, for which the maximum has been shifted from 342 nm for pure chiral **1a** to 336 nm for the mixtures with low 'seed' content (Fig. 3). These results demonstrate that the efficiency of packing in columns is different for **1a** and **1b**. The stronger Cotton effect of the mixtures suggests the packing of the achiral molecules to be superior. We attribute the differences in packing to the differing hydrophobicities of **1a** and **1b** and the increased steric hindrance in stacks of **1a** caused by the extra nine branching methyl groups.

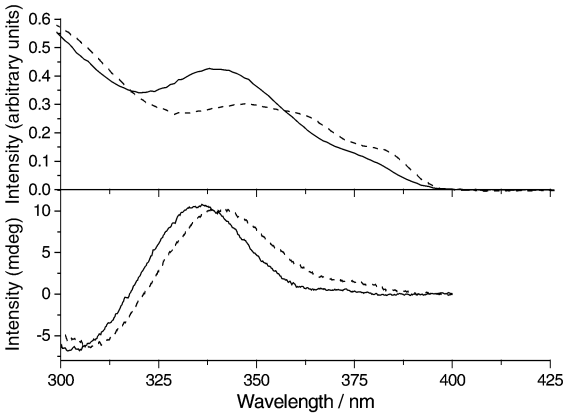

Fig. 3 UV-Vis (top) and CD (bottom) spectra of **1a** (----) and a mixture containing 8% **1a** and 92% **1b** (——) in water at 5 °C at a total constant concentration of 10^{-5} M.

In conclusion, we have demonstrated the creation of well-defined chiral self-assembled structures in aqueous solutions. Although the aggregation process of **1a** in water has similarities with that in organic solvents,[8] the special behaviour in water and the interaction of water with ethylene oxide side-chains results in striking differences. Currently, we are trying to elucidate the specific role of the water in the formation of the (chiral) supramolecular architectures based on **1a** and **1b**.

The National Research School Combination–Catalysis is thanked for funding.

Reduction of benzoyl tributylphosphonium chlorides by samarium diiodide as a novel access to 4-benzoylbenzaldehydes

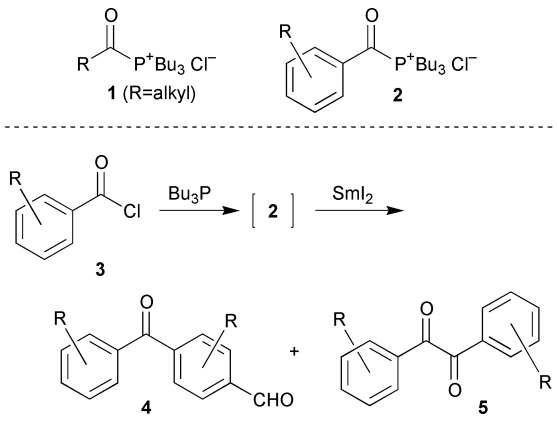
Hatsuo Maeda,* You Huang, Nagomi Hino, Yuji Yamauchi and Hidenobu Ohmori

Graduate School of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-oka, Suita, Osaka 565-0871, Japan

Received (in Cambridge, UK) 6th September 2000, Accepted 17th October 2000
First published as an Advance Article on the web 9th November 2000

Addition of samarium diiodide to a well-stirred THF solution of benzoyl tributylphosphonium chlorides generated *in situ* from benzoyl chlorides and tributylphosphine at −40 °C gave 4-benzoylbenzaldehydes as predominant products from benzoyl chlorides without *para*-substituents, while benzoyl chloride bearing *p*-methyl or chloro groups was exclusively converted into the corresponding α-diketone.

Recently it was found that the reduction potentials of alkanoyl- and benzoyltributylphosphonium ions (**1** and **2**, respectively) (Scheme 1), anodically generated from carboxylic acids and tributylphosphine (Bu_3P) or formed from acid chlorides and Bu_3P, are much more positive than those of the corresponding acid chlorides;[1,2] hence **1** and **2** are converted into aldehydes without over-reduction to alcohols by reduction using a cathode,[1] Zn or Zn–Cu couple[3] more feasibly than the corresponding carboxylic acids or acid chlorides. In addition, electrochemical reduction of **1** was shown to provide a novel tool for the generation of acyl radical or acyl anion equivalents, which are utilized in intramolecular C–C bond formation.[4] However, the synthetically intriguing species generated from **1** or **2** have not been applied to intermolecular reactions. This is probably because **1** and **2** are highly reactive acylating reagents.[4–6] During electrochemical generation of an acyl radical or acyl anion equivalent from **1** or **2**, excess of the acylating reagent remains. Such circumstances may have induced formation of a complex mixture in the cathodic reaction of **1** or **2** with an electrophile or radical acceptor through acylation of all anionic species generated during the electrolysis. Thus, it is speculated that an immediate and total transformation of **1** or **2** into the corresponding acyl radical or acyl anion equivalent prevents such an undesired process. It was reported that benzoyl chlorides **3** were reduced by samarium diiodide (SmI_2)[7] as a one-electron reducing reagent, leading to formation of the corresponding α-diketones (**5**).[8,9] Based on the reduction potentials, it was postulated that **2** will be more feasibly reduced by SmI_2 than the corresponding **3**, namely, that SmI_2-reduction will satisfy the above requirement for the reduced species of **2** to enter intermolecular reaction. Thus, we examined the reduction of **2** itself by SmI_2 as a preliminary study to develop the intermolecular reaction of an acyl radical or acyl anion equivalent generated from **1** or **2**, and obtained interesting results different from those for the case of **3** itself. We report herein that SmI_2–reduction affords benzoylbenzaldehydes **4** as predominant products from **2** without *para*-substituents and **5** exclusively from **2** bearing *para*-substituents (Scheme 1).



Scheme 1

It was reported that **4** can be prepared by the following methods: (1) SmI_2-induced coupling of benzaldehydes followed by PDC oxidation;[10] (2) benzylic bromination of 4-methylbenzophenone followed by periodate oxidation;[11] (3) oxidative transformation of 4-methylbenzophenone into the corresponding benzaldiacetate followed by acid hydrolysis,[12,13] (4) photolysis of benzaldehyde–cyclodextrin complexes in the solid state.[12] However, the following factors seem to attenuate their synthetic utilities: in the first method, the yields of coupling products from substituted benzaldehydes were rather low; it is unlikely that starting materials with a variety of substituents for the second and the third methods are easily available; the fourth method was applied only to unsubstituted benzaldehyde and its generality is unknown. Thus, it is worthwhile developing a simple and general method for preparing **4**, taking into consideration not only the drawbacks of these methods but also the facts that **4** was used as an important intermediate for synthesis of an HIV-1 integrase inhibitor[11] and antifungal agents.[14]

The typical procedure is as follows: to a THF solution of **3** (1.0 mmol) cooled to −40 °C, Bu_3P (1.1 mmol) was added under an argon atmosphere and the resulting mixture was stirred for 20 min. To the vigorously† stirred mixture, a THF solution (0.1 M, 20 ml) of SmI_2 was added using a syringe. After stirring for 5 min at the same temperature, the reaction was quenched by addition of 1 M HCl (5 ml). The entire mixture was poured into H_2O (20 ml) and extracted with ether (50 ml × 3). The combined organic layer was washed with 5% K_2CO_3 and brine (40 ml each), and dried over $MgSO_4$. After removal of the solvent, the residue was subjected to column chromatography (SiO_2, hexane–AcOEt). Thus obtained products were characterized by ^{1}H-NMR, ^{13}C-NMR, IR, and mass spectra or by comparison with spectroscopic data in the literature.[10,11,15] The regiochemistry in **4b**, **4c**, **6**, and **4f** (*cf.* Table 1) was tentatively assigned to be *para* with respect to the aldehyde groups, based on the results for **2** with *para*-substituents as described below.

The results obtained for benzoyltributylphosphonium chlorides **2** derived from several benzoyl chlorides **3** are shown in Table 1. Reduction of phosphonium chloride **2a** with SmI_2 afforded keto aldehyde **4a** as a sole product in an excellent yield (run 1). Without *in situ* transformation into **2a**, benzoyl chloride was converted only to the corresponding α-diketone in 38% yield under essentially the same conditions, suggesting that reduction of **2** by SmI_2 proceeds in a different manner from that of **3** itself. Similarly, **2b** and **2c** bearing *o*- or *m*-methyl groups were transformed into **4b** and **4c**, respectively, in excellent yields, although formation of the corresponding α-diketone in small amounts was noted (runs 2 and 3). In contrast to the case of **2b** and **2c**, reduction of **2d** with a *p*-methyl group resulted in exclusive formation of α-diketone **5d** (run 4), suggesting that

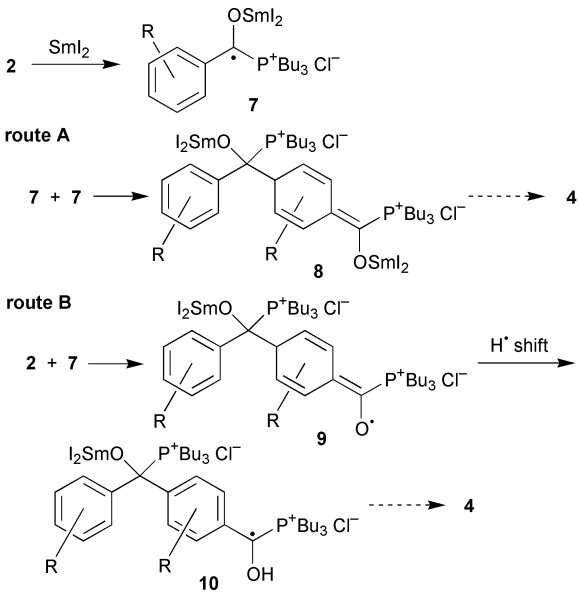
Table 1 Reduction of benzoyl tributylphosphonium ions (**2**) *in situ* generated from benzoyl chlorides and Bu_3P by SmI_2

Run	2	Product
1	**2a** (R=H)	**4a** (80%)[a,b]
2	**2b** (R=2-CH_3)	**4b** (80%), **5b** (10%)[c]
3	**2c** (R=3-CH_3)	**4c** (71%), **5c** (13%)
4	**2d** (R=4-CH_3)	**5d** (59%)[c]
5	**2e** (R=2-Cl)	**6** (50%)
6	**2f** (R=3-Cl)	**4f** (45%), **5f** (42%)
7	**2g** (R=4-Cl)	**5g** (56%)[c]

[a–c] Physical data are available in ref. 10, 12 and 11 respectively.

SmI_2-reduction of **2** favors formation of **4** *via* coupling at the *para*-position. In reaction with SmI_2, **2f** and **2g** with *m*- or *p*-chloro groups exhibited a tendency similar to **2c** and **2d**; in the former case, **4f** was obtained as a major product and the latter case predominantly afforded α-diketone **5g** (runs 6 and 7). Interestingly, reduction of **2e** bearing an *o*-chloro group led to the formation of a triply coupled product **6** in 50% yield (run 5). These results demonstrated that SmI_2-reduction of **2** provided a novel access to **4** from **3** without *para*-substituents, and the transformation seems to prefer electron-donating substituents to electron-withdrawing substituents on the aromatic ring of **3**. It should be mentioned here that the decanoyl tributylphosphonium ion (**1** with R = n-$C_{10}H_{21}$ in Scheme 1) generated from decanoyl chloride and Bu_3P was reduced under essentially the same conditions, affording only decanal in 39% yield.

For formation of **4** by SmI_2-reduction of **2**, two plausible routes can be considered as depicted in Scheme 2, although the detailed mechanism is not clear at present. By one-electron reduction, characteristic of SmI_2,[7] a neutral radical **7** would be formed from **2**. One of the routes to **4** includes a head-to-tail coupling of the radical (route A). The other comprises radical addition of **7** to **2** (route B). When the procedure with a reverse addition was utilized, namely, when **2** was added to a THF solution of SmI_2 cooled at −40 °C, the yields of **4** were markedly decreased: **4a** (57%) and benzil (9%) from **2a**; **4b** (33%) and **5b** (61%) from **2b**; **4c** (32%) and **5c** (61%) from **2c**. These results suggest that effective formation of **4** needs generation of **7** in the presence of excess **2**, namely, that route B is more likely than route A. In addition, route B seems to provide a reasonable explanation that formation of the triply



Scheme 2

coupled product **6** is initiated by addition of a radical such as **10** to **2**.

Since benzoyl chlorides **3** with a wide variety of substituents are commercially available and the present transformation is carried out in one-pot, the SmI_2 reduction of benzoylphosphonium ions **2** is thought to be more straightforward and applicable for the preparation of various types of **4**. Further work is under way to examine the generality of the present methodology as a method of preparing **4** and to shed light on the mechanism of its formation.

This work was supported in part by a Grant-in-Aid for Scientific Research on Priority Areas (B) (10208205) from the Ministry of Education, Science, Sports, and Culture, Japan.

Notes and references

† Vigorous stirring was essential for the formation of **4** in high yields, when SmI_2 was added to a THF solution of **2**.

Latent chemical behavior revealed in the crystalline state: novel photochemistry of a *cis*-9-decalyl aryl ketone

Eugene Cheung, Ting Kang, John R. Scheffer* and James Trotter

First published as an Advance Article on the web 9th November 2000

The case of a ketone whose photochemistry in solution is markedly different from that observed in the crystalline state is reported.

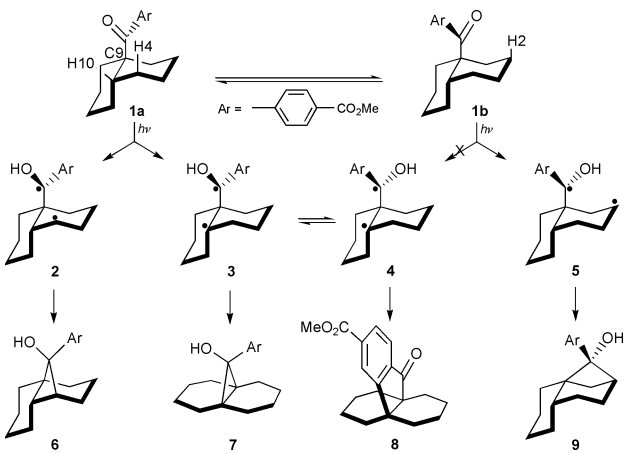
Molecules in crystals may be thought of as residing in reaction cavities whose walls are composed of the neighboring molecules in the lattice.[1,2] When the central molecule in this ensemble is caused to react in some way, for example by UV irradiation, the cavities often restrict certain reaction pathways and allow others, thus generally leading to a reduced number of products compared to reactions carried out in more forgiving fluid media. In some cases, the pathway favored in solution is topochemically forbidden in the solid state (*i.e.* prevented by lattice restraints), and when this is the case, less topochemically demanding reactions leading to new products take over.[3] To put it another way, organic (and inorganic) molecules can be thought of as having *latent reactivity* that is expressed only when they are caused to react in the crystalline state; by restricting chemistry to fluid media, these new reactions would be missed. In the present communication we report an example of this type of behavior in the photochemistry of a *cis*-9-decalyl aryl ketone.

The molecule in question is *cis*-9-decalyl *p*-carbomethoxyphenyl ketone (**1**), mp 85–86 °C (Scheme 1).[4] Irradiation of acetonitrile solutions of this compound (145 mg, 100% conversion) through Pyrex afforded cyclobutanols **6** (47%) and **9** (47%) along with 6% of cyclopentanone **8**. In contrast, when crystals of ketone **1** were irradiated (Pyrex, −20 °C to minimize melting, 76 mg, 100% conversion), the product mixture consisted of cyclobutanol **6** (81%) and the novel cyclopropanol derivative **7** (19%). The structure and stereochemistry of each photoproduct were deduced from FTIR, HRMS, 1D, 2D and NOE difference NMR, and microanalysis. The structures of compounds **6** and **8** were also verified by single crystal X-ray diffraction studies.†

What is responsible for the remarkable difference in product structure and distribution in going from solution to the solid state? To help answer this question, the X-ray crystal structure of ketone **1** was determined (Fig. 1).† This conformation, which is depicted by structure **1a** in Scheme 1, clearly indicates that the ketone oxygen atom is directed toward hydrogen atoms H4 (2.55 Å) and H10 (2.38 Å). This is significant, because these are the very hydrogen atoms abstracted in the first step of the formation of solid state photoproducts **6** and **7**, respectively. Abstraction of H4 takes place through a 6-membered transition state and leads to 1,4-hydroxybiradical **2**, whose closure occurs with retention of configuration at the carbonyl carbon affording cyclobutanol **6**.[5] Abstraction of H10, on the other hand, is a relatively rare 5-membered transition state process that produces 1,3-biradical **3** leading to cyclopropanol **7**.[6] Both biradical closure processes are similar in that they occur without the need for any large molecular motions, *i.e.* they are not topochemically restricted by the confines of the solid state reaction cavity.[7]

Biradicals **2** and **3** are presumably formed in acetonitrile as well, and indeed, photoproduct **6** is a major product in this medium. Cyclopropanol **7** is not formed in solution, however, its place being taken by cyclopentanone **8**. The reason for this difference, we suggest, is that ring closure of biradical **3** to cyclopropanol **7** is slow (ring strain), and in solution, rotation of biradical **3** about the C9 to carbonyl carbon bond to form biradical **4** is faster. This places the aromatic ring in proximity to the radical at C10, and radical coupling of **4** at the *ortho* position followed by tautomerization and oxidation leads to cyclopentanone **8**.[8] Why, then, is no photoproduct **8** formed in the solid state? The simple reason is that the required rotation about the C9 to *carbonyl* carbon bond in biradical **3** is topochemically restricted in the crystal. The aromatic ring would have to sweep through a large volume of space—a motion prohibited by the solid state reaction cavity.

A final point concerns the formation of cyclobutanol **9** in solution but not in the solid state. Formation of this photoproduct necessarily involves abstraction of H2, and this is not possible in the crystal because the C=O···H2 abstraction



Scheme 1

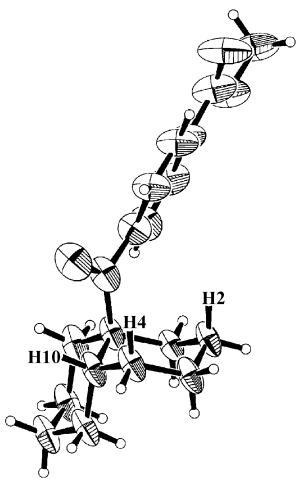


Fig. 1 ORTEP drawing of conformer **1a**

DOI: 10.1039/b007398i

distance in conformer **1a** is too great (3.47 Å).[9] In solution, on the other hand, ketone **1** can adopt alternative low energy conformations that permit abstraction of H2. Molecular mechanics calculations (Hyperchem MM+ and MacroModel MM3*) show that ketone **1** has two lowest energy conformations that differ in energy by only 0.1 kcal mol^{-1}. One of these is **1a**, the conformation adopted in the crystal, and the other is **1b**, in which abstraction of H2 (2.40 Å) is favored geometrically over abstraction of H4 (3.22 Å) or H10 (3.83 Å). We therefore postulate that cyclobutanol **9** is formed in solution from conformer **1b** *via* abstraction of H2 (6-membered transition state) followed by closure of the resulting 1,4-hydroxybiradical **5**.[10]

In summary, the latent solid state photochemical behavior of ketone **1** is manifested by the formation of cyclopropanol **7**, a product not observed in solution. Similarly, irradiation of ketone **1** in solution leads to two new photoproducts (**8** and **9**) not observed in the solid state. These reactivity differences can be explained on the basis of the conformational freedom (or lack thereof) that the reactants and intermediates experience in the two media.

Synthesis of *N*-1-oxypyrimidine 1,3-dioxolane and 1,3-oxathiolane nucleosides

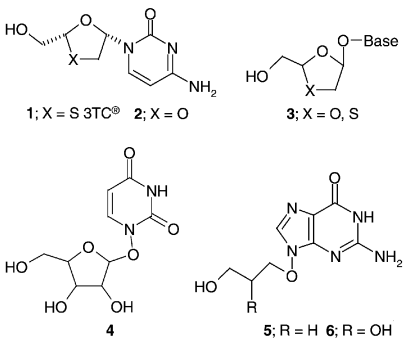
Nghe Nguyen-Ba, Nola Lee, Laval Chan and Boulos Zacharie*

BioChem Pharma Inc. 275 Armand-Frappier Blvd., Laval, Québec, Canada H7V 4A7

Received (in Corvallis, OR, USA) 10th August 2000, Accepted 15th September 2000
First published as an Advance Article on the web 9th November 2000

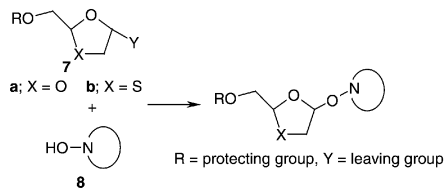
Two series of 1,3-dioxolanes and 1,3-oxathiolane nucleosides containing *N*-1-oxypyrimidine were synthesized as potential antiviral agents.

The potent activity displayed by 3′-azido-3′-deoxythymidine (AZT)[1] against human immuno-deficiency virus (HIV) prompted further design and evaluation of nucleoside analogues.[2] However, the toxicities associated with these compounds as well as the development of resistant viral strains upon prolonged treatment indicates that there is still a need for novel therapeutic agents.[3] One approach is to replace the carbohydrate moiety of 2′,3′-dideoxynucleoside analogues with other five membered rings.[3b,4] It has been demonstrated that heterosubstitution of these rings has a profound effect on the biological activity of the resulting nucleoside analogue[5] as displayed by (−)-2′-deoxy-3′-thiacytidine (3TC®, Epivir) **1**[5c,6] and (+)-2′-deoxy-3′-oxacytidine (Troxacitabine) **2**.[7]



As part of an ongoing search for new antiviral leads, we further explored this class of 3′-heterosubstituted nucleosides. We synthesized a novel class of these compounds where the 1,3-oxathiolane or 1,3-dioxolane ring is linked to the heterocyclic base through a nitrogen–oxygen bond. This is exemplified by the general structure **3**. The structure of these nucleosides are analogous to those of biologically active compounds[8] such as 1-(α-D-ribofuranosyloxy)uracil **4**,[8b] 9-(3-hydroxypropoxy)guanine **5**[8c] and 9-(2,3-dihydroxypropoxy)guanine **6**.[8d] As an example, **6** showed more potent and selective activity than acyclovir against HSV-1, HSV-2 but was less active than acyclovir against VZV.[8c,d]

The synthetic route to (±)-1,3-dioxolane and 1,3-oxathiolane nucleoside analogues **3** is based upon reaction of *N*-1-hydroxyheterocycles **8** with a dioxolane or oxathiolane moiety **7** bearing a suitable leaving group Y (Scheme 1).



Scheme 1

Our strategy was to build stepwise the *N*-1-hydroxypyrimidine base **8** since its direct synthesis by oxidation of the base has not yet been achieved. *N*-1-Hydroxyuracil **12** was selected as the key base in this series.[9] The preparation of this compound is described in Scheme 2. Treatment of *O*-benzylhydroxylamine with aqueous acidic potassium cyanate afforded urea **9** in 80% yield. This was reacted with sodium hydride followed by ethyl 3,3-dimethoxypropionate to give the protected uracil **10**. This compound was hydrogenated to give *N*-1-hydroxyuracil **12**. Similarly, *N*-1-hydroxythymine **13** was prepared by reacting the urea **9** with ethyl 3,3-diethoxy-2-methylpropionate followed by deprotection of the benzyl group of compound **11**. These pyrimidine bases **12** and **13** were also synthesized by Klötzer using a similar approach.[10] *N*-1-Hydroxycytosine was prepared from its precursor uracil. For example, reaction of *N*-1-benzyloxyuracil **10** with phosphorus oxychloride, triethylamine and triazole gave the triazolo derivative which was treated with ammonia then debenzylated to give *N*-1-hydroxycytosine **15** in 75% yield (Scheme 2).

Unlike 1-(benzyloxy)imidazole which is unstable under alkaline conditions,[8a] the *N*-1-benzyloxypyrimidines **10**, **11**, **14** are stable under a variety of conditions. These include acidic and basic conditions, as well as temperatures (< 90 °C) and catalytic hydrogenation. In addition, the final free *N*-1-hydroxy compounds **12**, **13**, **15** can be stored for months at 0 °C without decomposition.

Two approaches were considered for the preparation of pyrimidine and purine nucleosides. The first route was based upon coupling of a suitably functionalised *N*-1-hydroxy base with 1,3-dioxolane or 1,3-oxathiolane sugars under Mitsunobu conditions. Unfortunately, this reaction appeared to be ineffective and resulted in low yield. In fact, the Mitsunobu reaction between acylated furanose and 1-hydroxybenzotriazole gave similar results.[11] The second approach offers a more general route for the synthesis of these nucleosides. Scheme 3 illustrates a representative example where the sugar moieties of 1,3-dioxolane or 1,3-oxathiolane were reacted with iodo- or bromotrimethylsilane then the solution was treated with a mixture of sodium hydride and *N*-1-hydroxyuracil **12** or

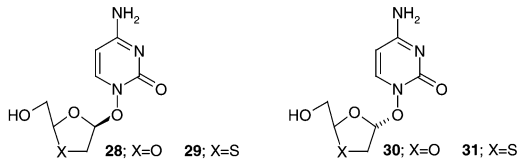
thymidine **13** in DMF. This gave the desired nucleoside **16** and **17** or **18** and **19**, respectively, as a 1 : 1 mixture of *cis* and *trans* isomers in 72 and 66% yields, respectively.[12] Replacement of halotrimethylsilane with trimethylsilyl triflate or the base sodium hydride with triethylamine did not alter the ratio of isomers but reduced the yield. Separation of the isomers **16**–**19** by chromatography followed by deprotection with methanolic ammonia gave the expected nucleosides **20**–**27** in high yields.[13]

Similarly, cytosine derivatives **28**–**31** were produced in a 1 : 1



mixture of *cis* and *trans* isomers under the same conditions starting from *N*-1-hydroxycytosine **15**. Direct conversion of uracil nucleoside **16** or **17** to the corresponding cytosine using the triazolo–phosphorus oxychloride–ammonia procedure was not successful and gave low yield of the expected product **28**–**31**.

The anti HIV, HBV, HSV-1 and HSV-2 activities of (±)-1,3-dioxolane and 1,3-oxathiolane nucleoside analogues **20**–**27**, **28**–**31**, were evaluated and compared with 3TC® (Epivir) and AZT. All of them were found to be inactive and non-toxic, except the cytosine derivative **29** which displayed weak inhibition of extracellular HBV.

In summary, described herein is a novel class of (±)-1,3-dioxolane and 1,3-oxathiolane nucleoside analogues. The biological results demonstrate that linking the sugar to the heterocyclic base through an oxygen causes dramatic reduction in antiviral activity in this series of compounds.

We thank Drs R. Storer and T. Bowlin for reading the manuscript, Mrs L. Bernier and J. Dugas for technical assistance with HPLC purification, and Mrs L. Marcil for secretarial and technical assistance.

Tetracationic Zn(II) porphyrinates and tetraanionic calix[4]arenes can be assembled in polar solvents to obtain cage-like complexes in an entropy driven process. These structures are remarkably stable even in the presence of water or competing salts.

Metalloporphyrins are well known for their ability to bind a variety of small molecules[1–6] and for their catalytic properties.[7,8] Moreover, they have been intensively studied with respect to their occurrence in metalloporphyrin-dependent proteins,[9,10] in which they display largely differentiated chemical properties. The chemical behavior of a metalloporphyrin is strongly affected by the surrounding environment.[11] For example, the peptidic backbone in metalloporphyrin-dependent proteins is able to fine-tune the chemical properties of the metal center by means of non-covalent interactions. Most studies with synthetic porphyrins heavily rely on the covalent modification of the macrocyclic structure,[1,12] while studies on porphyrins with a non-covalently organized periphery have hardly been reported so far. In this communication we describe the formation and characterization of cage-like complexes **1·2**, consisting of cationic porphyrins **1** and anionic calix[4]arenes **2** (see Fig. 1), *that are very stable in polar solvents* such as MeOH DMSO and DMPU.‡§

Zinc(II) *meso*-tetrakis(*N*-alkylpyridinium-3-yl)-porphyrins **1a–c** were prepared in three steps starting from pyridine-3-carboxyaldehyde and pyrrole in an overall yield of 14–18% following literature procedures.[5] Tetrasulfonatocalix[4]arene **2** was obtained in 84% yield by sulfonation of the parent 25,26,27,28-tetrakis(2-ethoxyethoxy)calix[4]arene with concentrated sulfuric acid using a slightly modified literature procedure.[13]

The assembly process was first studied by UV spectroscopy. Addition of calix[4]arene **2** to a solution of porphyrins **1** in MeOH ($2–3 \times 10^{-6}$ M) causes a bathochromic shift (3–5 nm) of the porphyrin's Soret band with a concomitant 20–25% decrease in ε (molar absorptivity) at λ_{max}. This behavior is characteristic for cationic pyridiniumyl porphyrins that form ion-pair complexes in water.[14] Non-linear least-squares fitting analysis of the spectral changes using a 1 : 1 binding model gave association constants in the order of 10^7 M^{-1} for the complexes **1·2** (see Table 1). The presence of a well-defined isosbestic point during the titration strongly supports the proposed formation of a 1 : 1 complex. These high values most likely reflect the perfect complementarity in charge distribution of the two interacting molecular ions leading to the formation of strong, cooperative salt bridges. Nevertheless these ion-pair complexes remain highly dynamic structures as we were unable to observe any time dependent phenomenon either by NMR or by UV-vis experiments.

In order to determine the thermodynamic parameters associated with the assembly formation, the stability constant of complex **1a·2** was determined at different temperatures. Van't Hoff analysis of the binding data revealed that the process is strongly entropically driven (129 ± 24 J K^{-1} mol^{-1}) with a very small exothermic contribution (-8.0 ± 6.7 kJ mol^{-1}). Therefore, we conclude that the release of solvent molecules is the

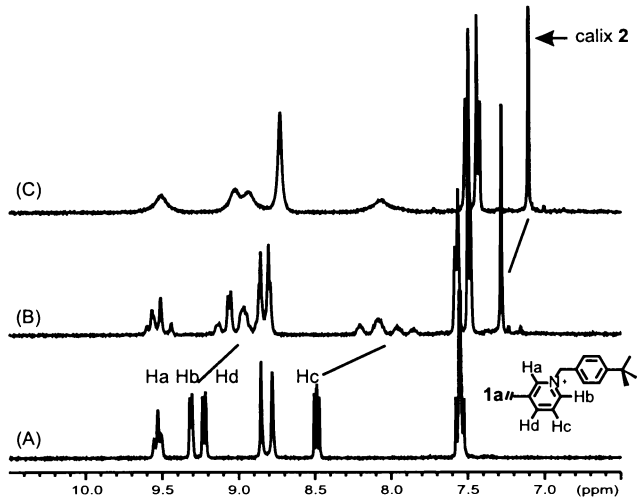

Fig. 2 ^{1}H NMR of (A) porphyrin **1a**, (B) 1:1 mixture of **1a** and **2** at 298 K, (C) 1:1 mixture of **1a** and **2** at 343 K.

main driving force for the formation of the highly stable ion-pair complexes **1·2** in MeOH.[15]

Structural investigation of complex **1a·2** by ^{1}H NMR spectroscopy was performed in CD_3CN–D_2O (6.5:1.5). At ambient temperatures the porphyrin proton signals show a complicated set of signals that indicate the presence of a mixture of isomeric structures with reduced symmetry. The calix[4]arene strongly influences the atropoisomerization equilibrium of the porphyrin,[5] without inducing a particular conformational preference. Coalescence of the various signals occurs at higher temperatures, whereby the position of the averaged signals is significantly shifted upfield in comparison to the corresponding signals in the free porphyrin. The largest shifts are observed for protons H_b, H_c and H_d (0.3–0.7 ppm) (see Fig. 2), which suggests that these protons are located in closest proximity to the calix[4]arene unit. Molecular simulation studies (CHARMm 24.0) support this view and further show that the structure in which the alkyl chains are pointing away from the calix[4]arene minimizes the distance between opposite charges in the two building blocks.¶

The cage-like structure of these ion-pair complexes prompted us to study their formation in other polar solvents such as DMSO and DMPU, from which the individual molecules are more bulky than MeOH. Titration experiments with **1a** and **2** in these solvents also gave well-defined isosbestic spectral variations. However, no shift in the maximum (DMSO) or a 5 nm blue shift (DMPU) was observed. This indicates a different solvation shell around the porphyrin upon formation of the complex in these solvents. Moreover, the $K_{1:1}$ values are one order of magnitude smaller than in MeOH (Table 1), which might indicate that MeOH is probably a very good guest for the cage-like complex‖ and enhances the stability of the system. Further experiments on solvent or guest encapsulation in these cage-like structures are currently ongoing in our laboratories.

Furthermore, we examined the effect of adding salts on the stability of the ion-pair complexes: association constants were determined for assembly **1a·2** in DMSO at different concentrations of $NaClO_4$. A logarithmic plot of $K_{1:1}$ and $[NaClO_4]$ shows a bimodal linear relationship with a slope of 1.91 ± 0.11 for $[NaClO_4] > 2 \times 10^{-3}$ M. This behavior suggests that, at high concentrations of Na^+, calix[4]arene **2** complexes two Na^+ ions in a cooperative fashion, as indicated by the sharp curvature at the breaking point, with $\beta = 2.2\ 10^5\ M^{-2}$. Determination of the $K_{1:1}$ value at 10^{-2} M of Bu_4NClO_4 clearly showed a smaller effect in comparison to $NaClO_4$ at the same concentration ($pK_{1:1}$ = 5.22 ± 0.08 and 4.56 ± 0.03 for Bu_4NClO_4 and $NaClO_4$ respectively). Therefore, it can be concluded that addition of inert salts, as much as 4500 times the concentration of the building blocks, only reduces the stability of the complex by a factor of 10.

Finally, we have found that the influence of the presence of water on the stability of the assemblies is very small. The log $K_{1:1}$ value is 6.04 ± 0.02 in a H_2O–DMPU mixture (x_{water} = 0.26), which is comparable to the value of 6.16 ± 0.01 obtained in pure DMPU (see Table 1).

In conclusion we have shown that stable cage-like complexes are obtained by self-assembly of cationic porphyrins and anionic calix[4]arenes in polar solvents. These assemblies are formed as a result of multiple electrostatic interactions between oppositely charged building blocks and are highly stable in polar solvents, like MeOH DMSO and DMPU. Furthermore, they remain stable even in the presence of water and, to a large extent, upon the addition of electrolytes.

These investigations are supported by the Netherlands Research Council for Chemical Sciences (CW) with financial aid from the Technology Foundation STW.

Notes and references

‡ DMPU = 1,3-dimethyl-3,4,5,6-tetrahydropyrimidin-2(1*H*)-one).

§ Self-assembled molecular capsules formed by means of ionic interactions have been reported using cyclotriveratrylene building blocks[16] or cyclodextrin derivatives.[17] In the first case the authors did not report the formation constant for the 1:1 complex and they observed the presence of oligomers at 7 mM in DMSO-d_6. In the paper dealing with cyclodextrins indirect proof for the existence of the capsules was obtained from the calculation of self-diffusion coefficients *via* ^{1}H NMR techniques.

¶ The symmetrical situation as observed from a gas-phase simulation (see ESI) is likely reflecting the structure of the complex at temperatures higher than rt.

‖ Coordination of MeOH to zinc(II) porphyrin hosts have been observed in several cases.[18]

Original manuscript received 2nd August 2000, Revised manuscript received 2nd October 2000, Accepted 16th October 2000
First published as an Advance Article on the web 9th November 2000

A novel thymidine analogue containing both 5-aminopropargyl† and 2′-aminoethoxy modifications has been synthesised and incorporated into a triplex-forming oligonucleotide; the combination of the two amino groups on the same nucleoside greatly enhances triplex stability.

DNA triple-helix formation by sequence-specific triplex-forming oligonucleotides is of considerable interest because of its great potential in a variety of analytical and therapeutic applications, including selective control of gene expression,[1] site-directed mutagenesis,[2] gene repair,[3] *in situ* chromosome labelling and other molecular diagnostics.[4] Although triplex-forming oligonucleotides bind with high specificity, their binding is usually much weaker than that of the underlying DNA duplex. In part this is thought to be due to the charge repulsion resulting from bringing together the three polyanionic DNA strands. Studies by ourselves and others[5] have shown that the introduction of positively charged groups at multiple sites in the backbone, sugar or base can produce stable triplexes, but to date only one such group has been added per nucleoside. Combining two of these modifications in a single nucleoside should produce stable triplexes across a wide range of salt concentrations, particularly under physiological conditions.

To test this hypothesis, we have synthesised a thymidine analogue containing two modifications that individually are known to stabilise triplexes: 5-aminopropargyl[6] and 2′-aminoethoxy.[7] These groups were specifically chosen so that the amines would act at different sites in a cooperative manner. An obvious synthesis for such a compound appears to be alkylation of the 2′-position of the nucleoside as reported for the 2′-aminoethoxy thymidine analogue.[7] However this strategy was not successful for our compound due to side reactions at the 5-position of the pyrimidine. We therefore had to adopt a longer route including a glycosylation step after introduction of the aminoethoxy moiety onto the sugar. The successful synthesis of the doubly modified monomeric thymidine building block **6** is shown in Scheme 1.

Alkylation of the protected β-Me ribofuranoside **1**[8] with methyl bromoacetate in the presence of sodium hydride (74% yield), followed by reduction of the ester by $LiBH_4$ and replacement of the hydroxy group by a phthalimide substituent using Mitsunobu[9] conditions yielded **2** (89% for two steps). Phthalimide is a suitable protecting group for oligonucleotide synthesis because of its stability to the acidic conditions encountered in dimethoxytrityl removal and ease of removal in standard basic conditions at the end of the synthesis. Attempted glycosylations[10] with **2** resulted in ring opening of the sugar. The anomeric position was therefore activated by means of an acetyl group *via* acetolysis with acetic anhydride and a catalytic amount of sulfuric acid in glacial acetic acid. Under these conditions[8] the TIPDS was replaced by acetyls to afford **3** in 95% yield. Triacetate **3** was transformed into the desired nucleoside **4** in 82% yield with silylated 5-iodouracil in the presence of TMSOTf (Vorbrüggen reaction conditions,[11] 82% yield, 2:1 β–α separable mixture). The β-anomer was then deacetylated using NaOMe powder in MeOH and the reaction was quenched by Dowex 50 (pyridinium form) then directly tritylated with freshly recrystallised dry DMTrCl in pyridine to yield **5** (63% for two steps). The aminopropargyl moiety was added protected as the trifluoroacetamide (equally suitable to oligonucleotide synthesis as phthalimide) by a palladium coupling reaction[12] in 89% yield. Conventional phosphitylation of the 3′-hydroxy group in an inert atmosphere using 2-cyanoethoxy(*N*,*N*-diisopropylamino)chlorophosphine afforded the phosphoramidite monomer **6** suitable for oligonucleotide synthesis in 70% yield.

Oligonucleotide syntheses were performed on an ABI 394 automated DNA/RNA synthesiser following standard cycles. The monomer **6** was incorporated in good yield (5 min coupling, > 98.5%) and oligonucleotides were deprotected with concentrated aqueous NH_3 at 55 °C for 5 h. After reversed-phase HPLC purification, the oligonucleotides were desalted (Sephadex G25) and characterised by ESMS.

We synthesised the intramolecular triplex forming oligonucleotide P3 containing a double substitution of the modified monomer **6** and the UV-melting curve was monitored at pH 7 (Table 1). P3 showed an increase in T_m of 22.9 K relative to P2 which contains two aminopropargyl modifications and an increase of 48.7 K relative to unmodified oligonucleotide P1. The general sequence of oligonucleotides P1, P2 and P3 was

Table 1 Melting temperatures (T_m) measured at pH 7.0; 50 mM phosphate buffer with 100 mM NaCl : L, octanediol linker; ^{p}U, 5-aminopropargyl modified T; X, bis-amino modified T

	Oligonucleotide	T_m/K
P1	T_6-L_2-T_6-AGTCT-L_2-AGACT-A_6	295
P2	T^{p}UT^{p}UTT-L_2-T_6-AGTCT-L_2-AGACT-A_6	320.8
P3	TXTXTT-L_2-T_6-AGTCT-L_2-AGACT-A_6	343.4

chosen as this motif is known to give clear triplex melting transitions.[6]

Footprinting data from a 9-mer oligonucleotide containing three bis-amino-modified thymidines (XTTXTTCXT) showed a reduction in the intensity of bands within the footprint by 50% at a concentration of 1.0 ± 0.5 μM. This is in contrast to the same sequence with three aminopropargyl T nucleosides which failed to show a footprint at concentrations as high as 50 μM. The footprints were located at a single target site within a 110 base pair fragment indicating that the oligonucleotide retained considerable sequence selectivity.

The above UV-melting data (intramolecular triplexes) and DNase I footprinting experiments (intermolecular triplexes) show that the 5-aminopropargyl/2′-aminoethoxy combination contributes significantly to triplex stabilisation, and is greatly superior to the aminopropargyl substitution alone. Hence the doubly modified nucleotide **6** appears to be a very promising building block for triplex-forming oligonucleotides.

We thank the Cancer Research Campaign for supporting this work.

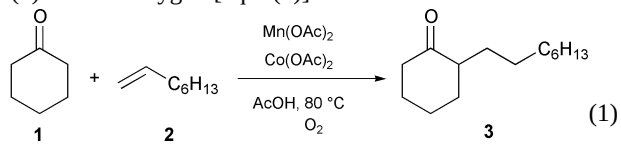
Radical addition of ketones to alkenes catalyzed by $Mn(OAc)_2$ combined with $Co(OAc)_2$ using dioxygen as oxidant was developed; for instance, the reaction of cyclohexanone with oct-1-ene in the presence of very small amounts of $Mn(OAc)_2$ and $Co(OAc)_2$ under air (1 atm) gave 2-octylcyclohexanone in good selectivity; from styrene, a six-membered cyclic peroxide was isolated in good yield.

Free radical reactions in organic synthesis have been recognized as a powerful tool for the construction of C–C and C–X (X = H or heteroatoms) bonds.[1] However, a limited number of methods have appeared for the generation of α-keto carbon radicals in spite of their synthetic importance.[1,2] Among the methods developed for this purpose, peroxide- and metal-initiated reactions of ketones are often used.[2a–d] Thus, the addition of α-keto radicals to alkenes which leads to α-alkylated ketones is practiced by the use of high oxidation state metal ions such as Mn(III), Ce(IV), Ag(II) and Pb(IV).[2c,d] Unfortunately, most reported procedures call for a large quantity of the metal reagent. To the best of our knowledge, there is only one report on the catalytic addition of α-keto radicals to alkenes *via* a catalytic process using $AgNO_3$ and $Na_2S_2O_3$ as the reoxidant.[3] If the addition of ketones to alkenes can be achieved by using a catalytic amount of metal ions in combination with an appropriate oxidizing agent, the reaction would become an effective tool for the synthesis of α-alkylated ketones. From environmental and economic aspects, molecular oxygen is the best candidate as the oxidant to regenerate the reduced metal ions to a high oxidation state, but such a catalytic system has not yet been developed. Here we wish to report a novel catalytic radical addition of ketones to alkenes by Mn(II) combined with Co(II) under dioxygen [eqn. (1)].



1 2 3 (1)

To highlight the possibility of using dioxygen as reoxidant, the addition of cyclohexanone (**1**) to oct-1-ene (**2**) was carried out in the presence of a catalytic amount of $Mn(OAc)_3$ (0.5 mol%) having one-electron oxidizing ability under either an inert gas (N_2) or air (1 atm) in AcOH at 80 °C for 5 h (Table 1, runs 1 and 2).† The reaction under N_2 led to an adduct, 2-octylcyclohexanone (**3**), in low yield (4%), while the reaction under air afforded **3** in better yield (26%). This fact indicates that the reduced Mn(II) species can be continually reoxidized to Mn(III) by O_2 making use of $Mn(OAc)_2$, which is cheaper than $Mn(OAc)_3$, more viable for reactions under O_2 instead of $Mn(OAc)_3$. In fact, $Mn(OAc)_2$ in the presence of O_2 promoted the reaction to a similar extent as $Mn(OAc)_3$ did (run 3). Needless to say, the reaction did not take place at all by $Mn(OAc)_2$ under N_2 (run 4).

The present reaction was found to be facilitated by adding a small amount of $Co(OAc)_2$ (0.1 mol%) to $Mn(OAc)_2$ (0.5 mol%) to give **3** in 88% selectivity at 41% conversion (run 6), while the reaction was not induced by Co(II) alone (run 7).‡ The addition proceeded smoothly even with a very small amount of $Mn(OAc)_2$ and $Co(OAc)_2$ (run 10). Since Co(II) ions are well-known to react easily with O_2 to form a Co(III)–dioxygen complex such as a superoxocobalt(III) or peroxocobalt(III) complex,[4] it is thought that such a Co(III) species catalyzes the reoxidation of the reduced Mn(II) to Mn(III) under O_2.

Table 1 Reaction of cyclohexanone (**1**) to oct-1-ene (**2**) by $Mn(OAc)_2$ combined with $Co(OAc)_2$ under various conditions[a]

Run	mol% Mn	mol% Co	Oxygen source (N_2–O_2 atm)	Time/h	Conv. (%)[b]	Select. (%)[c]

16	0.1	0.05	0.5 : 0.5	10	70	85

[a] **2** (2 mmol) was allowed to react with **1** (20 mmol) under dioxygen in the presence of $Mn(OAc)_2$ and $Co(OAc)_2$ in AcOH (2 mL) at 80 °C. [b] Conversion of **2**. [c] Based on **2** reacted. [d] $Mn(OAc)_3$ was used instead of $Mn(OAc)_2$. [e] Yield based on **2** used. [f] AcOH (0.5 mL) was used. [g] **1** (5 eq.) was used.

The remarkable effect of oxygen concentration on the reaction of **1** with **2** was observed (runs 11–16). When a mixed gas of 0.5 : 0.5 atm of N_2–O_2 was employed, **3** was obtained in 83% selectivity at 72% conversion (run 12).

On the basis of these results, the addition of various ketones to alkenes was examined under the optimized reaction conditions (Table 2).

Both cyclic and aliphatic ketones were added to **2** to give the corresponding adducts in fair to good yields (runs 1–4). The reaction of an unsymmetrical ketone such as pentan-2-one (**4**) with **2** led to two structural isomers, 3-ethylundecan-2-one (**5**) and tridecan-4-one (**6**), in a ratio of *ca.* 6 : 1. The preferential formation of **5** is believed to be due to the fact that the secondary carbon radical is more easily generated than the primary one.

From isopropenyl acetate, γ-acetoxy ketone was obtained in relatively good selectivity (run 5). The reaction of **1** with styrene (**7**) did not form the expected adduct but gave a cyclic peroxide (**8**) in 41% yield (run 6). Such six-membered cyclic peroxides are known to exhibit significant biological activities.[5] The peroxide **8** may be formed through the reaction path shown in Scheme 1. A benzyl radical (**B**) derived from the addition of an α-keto radical (**A**) to **7** reacts with O_2 rather than **1**, giving an alkylperoxy radical (**C**) which then undergoes intramolecular cyclization leading to **8**.[6] It is believed that the benzyl radical **B** which is stabilized by conjugation with the phenyl group is

Table 2 Reaction of various ketones with alkenes[a]

Run	Ketone	Alkene	Conv. (%)[b]	Products	Select. (%)[c]
1		**2**	78		85
2[d]		**2**	68		82
3		**2**	73		62
4	 **4**	**2**	78	 **5** +  **6**	71 (6 : 1)[e]
5	**1** 		86		61

7[d,h]	**1**	**7**	96	**8**	70[i]

[a] Alkenes (2 mmol) were allowed to react with ketones (20 mmol) under 0.5:0.5 atm of N_2–O_2 in the presence of $Mn(OAc)_2$ (0.5 mol%) and $Co(OAc)_2$ (0.1 mol%) in AcOH (2 mL) at 80 °C for 10 h. [b] Conversion of alkenes. [c] Based on alkenes reacted. [d] Ketone (10 mmol) was used. [e] Ratio of **5**:**6**. [f] Reaction was carried out at 70 °C for 3 h. [g] ^{1}H-NMR yield based on **7** used. [h] Reaction was carried out in the absence of $Co(OAc)_2$ under O_2 (1 atm). [i] Isolated yield based on **7** used.

unable to abstract a hydrogen atom from **1**. Since Co ions are known to promote the redox decomposition of the peroxides,[7] the reaction was conducted without Co(II) to give **8** in 70% yield (run 7).

In conclusion, we have developed a novel catalytic method for the addition of ketones to alkenes by the combined use of Mn(II) and Co(II) salts using dioxygen as the reoxidant. This method provides an alternative route to α-alkylated cycloalkanones which are attractive compounds as fine chemicals such as fragrances. Further investigation to extend the present method and to elucidate the role of the Co(II) species is currently in progress.

The branched *C*-trisaccharide analogue of α-D-Man-(1→3)-[α-D-Man-(1→6)]-D-Man has been synthesised by the SmI_2-mediated coupling of two mannosyl pyridyl sulfone units to a monosaccharide dialdehyde. This approach represents a highly convergent synthesis of a *C*-oligosaccharide.

C-Disaccharides, in which the interglycosidic linkage has been replaced by a methylene group, have proved to be valuable tools for studying conformational preferences of their parent *O*-glycosides both in solution and protein bound, as well as providing important insight into the mechanism of glycoside cleaving enzymes (glycosidases) owing to the inability of *C*-disaccharides to undergo hydrolysis.[1] Many synthetic approaches to these analogues have therefore been devised, but have mainly been restricted to disaccharides and not higher oligomers thereof owing to the synthetic challenge in preparing such compounds.[2,3] In previous reports, we have shown that reductive samariation of glycosyl pyridyl sulfones in the presence of a *C*-formyl branched sugar is a viable approach for the stereoselective construction of *C*-disaccharides.[4,5] The synthetic approach to these sugar mimics employs intact carbohydrate units as both *C*-glycosyl donors and acceptors, which are complementary to approaches exploited in standard *O*-glycoside synthesis. This suggested the possibility of applying this procedure for the construction of branched *C*-oligosaccharides as well, by a multiple *C*-glycosylation step of a carbohydrate unit containing more than one *C*-formyl chain. In this communication, we report on the success of this goal in the highly convergent construction of the *C*-glycoside analogue of the core region, α-D-Man-(1→3)-[α-D-Man-(1→6)]-D-Man, of the asparagine-linked oligosaccharides.

The synthetic approach to the branched *C*-trisaccharide **1** is illustrated in Fig. 1, comprising of the direct double coupling of dialdehyde **3** with two equivalents of the configurationally stable anomeric samarium species **2**, which in turn may easily be prepared *via* the *in situ* reduction of the anomeric pyridyl sulfone.[4,5] Subsequent radical-based deoxygenation of the two hydroxy groups formed would then complete this short synthesis of the protected *C*-trisaccharide.

We began the synthesis of the branched *C*-trisaccharide with the construction of the dideoxymannosyl unit **9** containing the C3 and C6 formyl groups *via* the stepwise introduction of two alkene groups at the denoted positions, as illustrated in Scheme 1.† Regioselective opening of the easily available epoxide **4** (5 steps from 1,6-anhydroglucose[6]) with excess vinylmagnesium bromide[7] and subsequent dibenzylation afforded the alkene **5** in 42% yield. In order to introduce the second alkene group at C-6, we took advantage of a recent report by Clark *et al.* in their synthetic approach to the marine polycyclic ethers of the brevetoxin and ciguatoxin family.[8] Hence, methanolysis of **5** led to the opening of the anhydro-ring affording only the methyl α-mannoside **6**, which could easily be transformed to the corresponding triflate by treatment with Tf_2O–2,6-lutidine. Alkynylation with the lithium anion of TMSacetylene in THF–HMPA then afforded the C6-alkyne branched sugar **7** (53%, 2

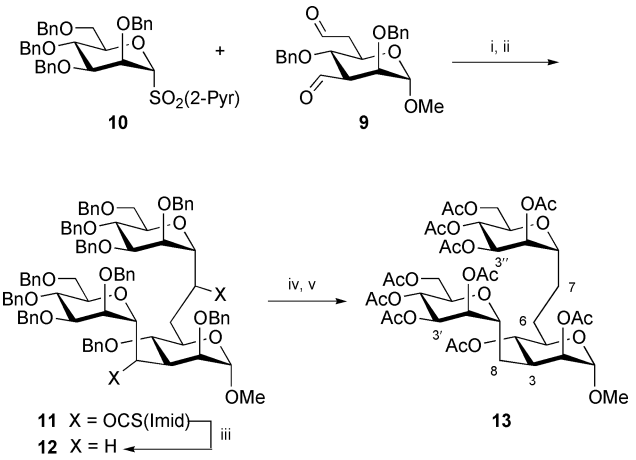
DOI: 10.1039/b007117j



Scheme 2 *Reagents and conditions:* i, 4.7 equiv. of **10**, 10 equiv. of SmI_2, THF, 20 °C; ii, 25 equiv. of $(Imid)_2CS$, CH_3CN, reflux, 67% (2 steps); iii, 4 equiv. of F_5C_6OH, 5.2 equiv. of Ph_3SnH, AIBN (cat.), toluene, 90 °C, 53%; iv, Pd/C, H_2, MeOH–AcOH; v, Ac_2O, DMAP (cat.), pyridine.

steps), which was first desilylated and then hydrogenated with Lindlar's catalyst providing the dialkene **8** in 77% yield (2 steps). Finally, ozonolysis led to the required dialdehyde **9**.

The key coupling step of the dialdehyde with the mannosyl pyridyl sulfone **10** was achieved by quickly adding a 0.1 M solution of SmI_2 (10 equiv.) to a mixture of **9** with excess **10** (4.7 equiv.) at 20 °C leading to the immediate consumption of both reagents (Scheme 2).[4,5] Subsequent work-up led to a complex mixture of diastereomers, which was immediately subjected to a surplus of thiocarbonyldiimidazole (25 equiv.) in refluxing acetonitrile. A quick reaction was observed as monitored by TLC analysis leading to the introduction of a single thiocarbonylimidazole unit, which was most likely to occur at the sterically less encumbered carbon adjacent to C6. However, the slow evaporation of the solvent under heating finally led to the formation of a second more polar product at the expense of the first, which was identified as compound **11** as a mixture of diastereomers containing two functionalised alcohol groups (67% yield, 2 steps). The slow removal of the solvent is necessary for the successful introduction of the second thicarbonylimidazole moiety as previously observed in similar cases for the functionalisation of sterically hindered secondary alcohols.[4]

Finally, radical-based deoxygenation employing our established procedure with the F_5C_6OH–Ph_3SnH–AIBN combination in hot toluene[4] completed this short synthesis of the desired branched *C*-trisaccharide **12**, obtained as a single stereoisomer in 53% yield. Further characterisation of **12** was made by its conversion to the decaacetate **13** easily prepared by a two-step protocol involving catalytic hydrogenation and peracetylation.‡,§

In conclusion, we have successfully applied the SmI_2 promoted *C*-glycosylation procedure to the expedient and convergent synthesis of a branched *C*-trisaccharide related to the core structure of the asparagine-linked oligosaccharides. Work can now commence in studying its conformational behaviour in comparison to its parent *O*-glycoside, the investigation of which will be reported in due course.

We thank the Danish National Science Foundation (THOR programme), The University of Aarhus, and the Carlsberg Foundation for generous financial support.

Notes and references

† We initially attempted several routes to introduce simultaneously the two alkene units into the easily available methyl 2,4-di-*O*-benzyl-α-D-mannopyranoside, although this synthetic pathway was unrewarding.

ChemComm

Dynamic kinetic asymmetric synthesis of β-aminoalcohols from racemic epoxides in cyclodextrin complexes under solid state conditions†

L. Rajender Reddy, N. Bhanumathi and K. Rama Rao*

Organic Chemistry Division-I, Indian Institute of Chemical Technology, Hyderabad-500 007, India. E-mail: ramaraok@iict.ap.nic.in

Received (in Cambridge, UK) 12th June 2000, Accepted 16th October 2000
First published as an Advance Article on the web 9th November 2000

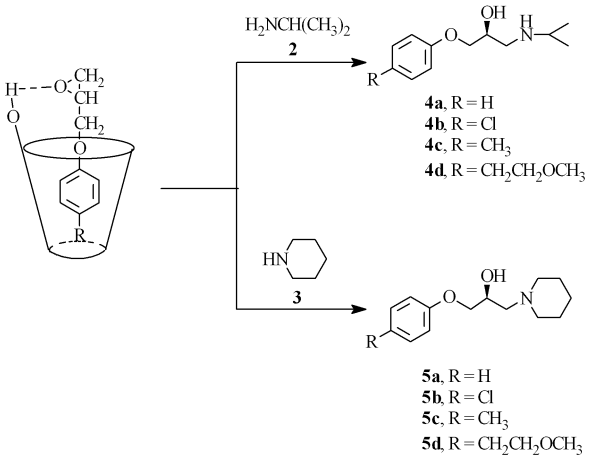
It has been shown for the first time that enantiopure β-aminoalcohols can be prepared from racemic epoxides by dynamic kinetic resolution involving enantio-differentiating racemisation in cyclodextrin complexes under solid state conditions.

The novel phenomenon of converting racemic substrates into a single enantiomer of the product by dynamic kinetic resolution *via* racemisation of the substrates has been a formidable challenge in asymmetric synthesis.[1] Recently, it has been receiving increasing attention and attempts are being made to achieve every useful asymmetric synthesis by dynamic kinetic resolution since it overcomes the severe limitation of the conventional kinetic resolution where the maximum yield of one stereoisomer of the starting material or product is only 50%. But, so far there is no report on the dynamic kinetic asymmetric synthesis of β-aminoalcohols of great significance from the easily accessible and inexpensive racemic epoxides. The β-aminoalcohol moiety is present in many natural products and drugs and acts as an intermediate in various asymmetric transformations.[2] The approaches hitherto reported from the racemic epoxides involve only kinetic resolution.[3] Further to our studies on cyclodextrins as chiral templates for the enantioselective synthesis of a variety of chiral building blocks,[4] we report herein the first biomimetic approach for the synthesis of a single enantiomer of β-aminoalcohols from the corresponding racemic epoxides by dynamic kinetic resolution involving enantio-differentiating racemisation in cyclodextrin complexes.[5]

The cyclodextrins are cyclic oligosaccharides possessing hydrophobic cavities and they mimic enzymes in their capability to bind substrates selectively and catalyse chemical reactions by supramolecular catalysis involving reversible formation of host–guest complexes with substrates through non-covalent bonding. Apart from this, with the cyclodextrin cavity being chiral it can induce asymmetric reactions.[6] It requires the following criteria to be fulfilled to ensure rigidity for chiral recognition by cyclodextrins: (i) a phenyl ring which can fit into the cyclodextrin cavity to form an inclusion complex, (ii) a functional group at the stereogenic center to form a strong interaction at the cyclodextrin cavity entrance. Since aryloxyepoxides **1** fulfil these criteria, they have been chosen as substrates.

The inclusion complexes of aryloxyepoxides **1** with β-cyclodextrin (β-CD) were prepared as described earlier.[4] The reaction of these cyclodextrin complexes of epoxides **1** with amines **2** or **3** (Scheme 1) when carried out in water as the reaction medium, yielded aminoalcohols that were nearly racemic (ee 2%). This may be due to free movement of the guest molecule in solution. Hence, it was planned to carry out these reactions in the solid state where the movement of the guest molecule would be restricted, resulting in better chiral recognition.

An intimate mixture of the epoxide **1**–β-cyclodextrin complex (1:1) and the amine **2** or **3** was mixed in equimolar amounts in an agate mortar using a pestle and the mixing continued until the starting epoxide disappeared on TLC (3–12 h). The time taken was always dependent on the frequency of mixing. However, in the case of amine **2**, it was added in excess due to its volatility and was added intermittently during the course of mixing. The resulting aminoalcohols **4** and **5** were extracted with ethyl acetate and purified through the formation followed by release of their hydrochlorides. The isolated yield of the product was always in the range 70–79% and the enantioselectivity was excellent in some of the compounds (Table 1). Compounds **4b** and **5b** have shown 100% ee followed by compound **4c** (ee 89%) and **4d** (ee 85%). The enantiomeric excesses (ee) of the products (**4** and **5**) were determined by chiral HPLC analysis. These aminoalcohols **4** and **5** have been shown to have *R* configuration by comparison of the sign of rotation with those of the known compounds.[7] However, these reactions when carried out using α-cyclodextrin inclusion complexes, gave enantioselectivities that were far lower than those obtained with β-cyclodextrin. This may be due to ineffective complexation.



Scheme 1

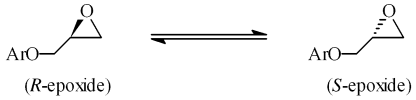
The formation of enantiopure β-aminoalcohols (**4** and **5**) from the racemic epoxides **1** may be postulated as follows:

Table 1 Solid state asymmetric synthesis of β-aminoalcohols

Entry	Product	ee (%)[a]	Yield (%)[b]
1	4a	73.8	79
2	4b	100	75
3	4c	89	72
4	4d	85	70
5	5a	1.4	74
6	5b	100	70
7	5c	0.8	76
8	5d	3.5	73

[a] Determined by HPLC analysis with the chiral column 'Diacel Chiralcel OD' (0.46 cm ϕ × 25 cm) using hexane: propan-2-ol: diethylamine (80:20:0.1) as eluent at a flow rate of 0.5 ml min^{-1} using UV detection (254 nm). [b] Isolated yields.

DOI: 10.1039/b004643o



Scheme 2

The fact that the epoxide **1** isolated from the cyclodextrin complex is racemic and the yields of the aminoalcohols **4** and **5** were always more than 50%, suggests that kinetic resolution is not operating under these conditions as then only a maximum of 50% conversion can be expected. Hence, in the present investigation, to get a single enantiomer of the product (**4** or **5**) from the racemic starting epoxide **1**, it requires interconversion of one of the enantiomers of the epoxide **1** (Scheme 2). This is possible through racemisation which is controlled by entropy effects.[8] Racemisation can take place in the present case by the interconversion of the epoxide enantiomer facilitated under solid state conditions. Though racemisation is quite a slow process in the absence of suitable driving mechanism *i.e.* the external amine in the present case, the racemisation of the β-CD complexes of the individual *R* and *S* epoxides of **1a** (R = H) has been attempted by grinding them intimately for 5 h and analysing by chiral HPLC.[9] It is observed that racemisation does indeed take place only with *S*-enantiomer to an extent of ≅2% as seen by the change in %ee. This reaction also further substantiates the process of dynamic kinetic resolution *i.e.* as the *R*-enantiomer of the epoxide (**1**) in the CD complex reacts with the amine, the *S*-epoxide gets converted to the *R*-epoxide to take the reaction forward, leading to only the *R*-enantiomer of the product (**4**).

Thus, when one of the enantiomeric forms of the epoxide **1** in the β-cyclodextrin cavity, due to its favourable geometry, is captured selectively by the external amine (**2** or **3**), the phenomenon of dynamic kinetic resolution sets in under the reaction conditions. Hence, by dynamic kinetic resolution through racemisation of the starting epoxide, it is possible to get enantiomerically pure aminoalcohols (**4** and **5**). This has also been confirmed from the individual experiments utilizing either *R* or *S* epoxides (Scheme 3). Both *R* and *S* epoxides gave the aminoalcohol (**4a**) mainly as the *R* enantiomer (90% ee by HPLC). This gives further evidence to show that racemisation of the starting epoxide and dynamic kinetic resolution are operating under the reaction conditions to give a single enantiomer of the product.

Thus, in conclusion, it has been shown for the first time that enantiopure β-aminoalcohols of high potential can be made from the easily accessible and inexpensive racemic epoxides. This can be achieved by dynamic kinetic resolution involving

Received (in Cambridge, UK) 1st September 2000, Accepted 10th October 2000
First published as an Advance Article on the web 9th November 2000

A pentamethine cyanine dye has been synthesised that is fluorescent when protonated, becoming non-fluorescent upon proton abstraction. The probe has a pK_a of 7.5, with observable changes in the fluorescent emission properties across a pH range of 6.0–8.0, therefore providing a useful probe for studying pH in biological media.

Cyanine dye[1] fluorescent probes are useful markers for flow cytometry,[2] sequencing assays[3] and high throughput screening.[4] These probes have high extinction coefficients (> 200000 l mol^{-1} cm^{-1}), can be designed with long excitation and maximum fluorescent emission wavelengths (> 600 nm) and with lower molecular weights than the majority of commercially available natural fluorophores.[5] These fluorescent cyanine dyes also have the added value of containing reactive functional groups, such as an *N*-hydroxysuccinimidyl ester or an isothiocyanate facilitating a covalent link to a biomolecule. More recently, attention has also focussed on the synthesis of more specialised probes,[6] or "functional dyes", that can act as molecular and optical switches.[7] Indeed, many of these dyes are designed to be environmentally sensitive, acting as ionophores for protons, Ca^{2+}, Na^+ or K^+ or as small molecule sensors for cyclic adenosine monophosphate[8] or inositol phosphate.[9]

One subject of ongoing interest is acidity regulation in mammalian cells.[10] Monitoring small changes in proton concentration is important for the study of numerous signal transduction pathways and ligand interactions with G-protein coupled receptors. The majority of commercially available pH sensitive fluorescent dyes employed in intracellular studies[5] provide a reduced fluorescent signal in acidic media or alternatively the pK_a of the dye is outside the critical intracellular pH window of between 5–8 pH units.

We now report an example of a fluorescent pentamethine cyanine dye (Cy5™) that is sensitive to proton concentration over a pH range of 6–9 (Fig. 1). The intensity of the fluorescent emission (665 nm) for this probe increases with increasing proton concentration. This probe is analogous to a number of previously reported benzothiazolium[11] trimethine cyanine dyes with pH sensitive UV/visible absorption properties, although in addition, the design of our fluorescent probe includes several other important elements. The presence of a sulfonic acid functional group aids solubility in aqueous media and the position of such functional groups is also known to reduce probe aggregation in solution.[12] There is also a pendant carboxylic acid group that can be easily converted to the reactive *N*-hydroxysuccinimidyl ester for biolabelling. Furthermore, unlike previously reported cyanine dyes,[1] the pH sensitivity is introduced *via* a non-*N*-alkylated indolium moiety whereupon protonation and deprotonation occurs depending upon the localised hydrogen ion concentration.

The probe exists in two forms, as either the fluorescent cyanine dye or the complementary non-fluorescent base (Fig. 1). The intense cyanine dye absorption and emission properties are largely due to a resonance effect between the two nitrogen atoms of the two indole rings *via* the conjugated pentamethine bridge. Abstraction of a proton from this system destroys this resonance, and subsequently leads to the non-fluorescent base form. Moreover, this property provides excellent resolution at long wavelengths (> 600 nm) where little else in a biological sample is likely to absorb.

The probe was synthesised by standard cyanine dye methods.[1] 1-Ethyl-2,3,3-trimethyl-3*H*-indol-1-ium-5-sulfonate[1] and 5-carboxymethyl-2,3,3-trimethyl-2,3-dihydroindole[13] were condensed with malonaldehyde bis(phenylimine) in the presence of acetic acid, acetic anhydride and pyridine at 70 °C . The product was purified by reverse phase HPLC[14] and conversion to the NHS (*N*-hydroxysuccinimidyl) ester is facile by standard methods. A typical conversion to the NHS ester involves reacting the dye in DMSO with 1 eq. of PyBOP (benzotriazol-1-yloxytripyrrolidinophosphonium hexafluorophosphate, *N*-hydroxysuccinimide and 1.1 eq. of diisopropylethylamine. Stirring for 1 h gives quantitative conversion. TLC analysis (10% methanol–DCM on SiO_2) observes a fast running blue spot R_f = 0.60. R_f of the free acid = 0.41. Hydrolysis of this material gives the free acid by TLC.

The fluorescent properties of this dye can be seen in Fig. 2. Equimolar solutions of the dye were made up in phosphate buffers[15] over a pH range of between 4.5–9. It can be observed that the fluorescent characteristics of the probe are greatly reduced as the buffers become less acidic in nature. This is due to increased deprotonation of the cyanine dye and leads to a larger population of the non-fluorescent base species. Similar experiments with a commercial bis(*N*-alkylated) sample of

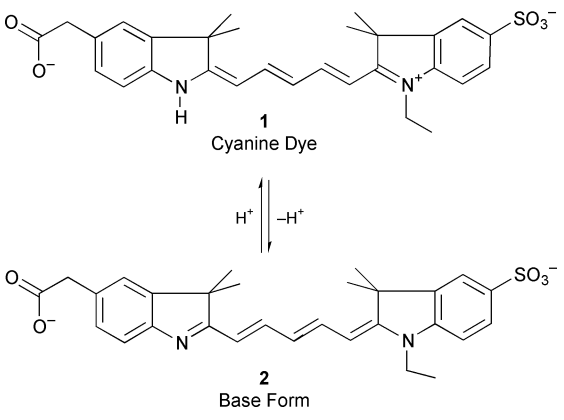

Fig. 1 The cyanine dye-base form of the pH sensitive fluorescent probe.

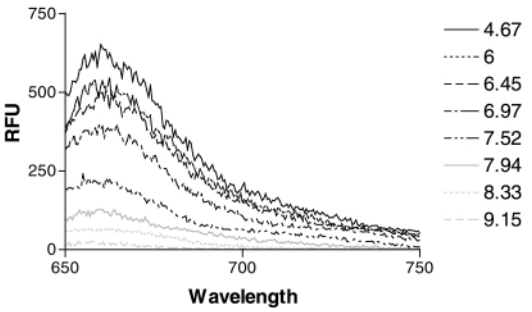

Fig. 2 Fluorescence characteristics of the pH sensitive probe as a function of pH (~ 0.1 μmol of complex, λ_{ex} = 630 nm, 295 K. Readings were made using a Perkin-Elmer LS50B fluorimeter in fluorescence mode, with excitation and emission slits set at 2.5 nm and with 3 ml quartz cuvettes).

Cy5™ showed no change in the emission properties of the probe over the same pH range. Furthermore, the photostability of the fluorescent form of this probe was comparable to the non-pH sensitive cyanine pentamethine dyes (Cy5™) routinely used in biological studies.

Further proof of this acid–base equilibrium can be achieved by observation of the UV/visible spectra of **1** in phosphate buffers of different pH (Fig. 3). It can be seen that as the buffer solutions become less acidic, the characteristic absorption maximum for the pentamethine cyanine dye at 645 nm is greatly reduced as a new peak evolves at 480 nm. This absorption peak is due to the increased presence of the base form (**2**) of the probe by proton abstraction from the pentamethine cyanine dye. A further observation is the presence of an isosbestic point at 545 nm. This gives a good indication that the solutions are all of similar ionic strength.[16] It is therefore likely that the proton concentration alone is responsible for the different observed spectra, and that this phenomenon cannot be attributed to the differing concentrations of any other ions present in the buffer solution.

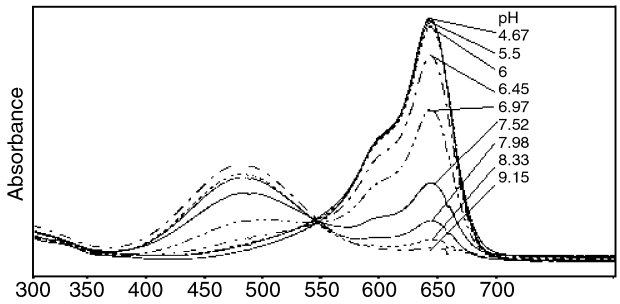

Fig. 3 UV/visible absorption spectra of **1** (and **2**) as a function of pH (from a Hewlett Packard 8453 UV/vislble spectrophotometer with diode array detector, 1 cm pathlength quartz cuvettes).

Fig. 4 illustrates the pH response of probe **1** as a function of I/I_{max} *vs.* pH, where I is the measured fluorescent emission at that pH, and I_{max} is the maximum output of the probe. It can be seen that a regular sigmoidal response is observed for this probe in response to pH. The pK_a of **1** can be estimated where I/I_{max} is 0.5. This provides a pK_a value of 7.5 (296 K) for this probe.

A current limitation in the application of many current pH sensitive fluorescent probes is due to lack of any specific labelling functionality present on the dye such as an NHS ester. The presence of these groups allows specific biomolecules or particular functional groups, *e.g*. primary amines to be targeted, and a subsequent range of bioassays to be performed using the dye-labelled biomolecule. The presence of a pendant carboxylic acid allows rapid conversion to the *N*-hydroxysuccinimidyl ester and therefore facilitates the labelling of biological molecules such as proteins or antibodies.[17] The reactive form of this probe has been employed to label aliphatic amine groups present on the outer membrane of a CHO cell. Upon constitutive endocytosis the probe becomes internalised into acid vesicles with a subsequent increase in fluorescent emission.[18] Furthermore, the pK_a of the probe when bioconjugated did not change implying that the carboxylic acid present in the free form of the probe does not affect the pH sensitive fluorescent properties. Details of these cellular studies will be reported elsewhere.

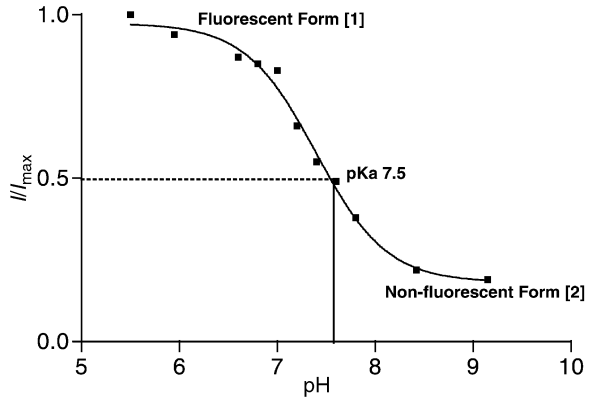

Fig. 4 pH Dependence of **1** (I/I_{max}) at 295 K in phosphate buffers of differing pH (λ_{exc} = 630 nm λ_{em} = 665 nm. Readings were made using a Perkin-Elmer LS50B fluorimeter in fluorescence mode, with excitation and emission slits set at 2.5 nm and with 3 ml quartz cuvettes. Each point is the average of 10 measurements).

Furthermore many other probes offer a reduced fluorescent emission in acidic conditions and the spectral data acquired often requires deconvolution due to both protic and non-protic forms being fluorescent and thus, these probes are of interest for ratiometric pH studies. In contrast, this pH sensitive cyanine probe has only one fluorescent form and is therefore useful for high throughput studies whereby a change in fluorescent emission can be easily and rapidly observed. The long emission wavelength of this pentamethine pH sensitive cyanine dye is also of value for biological studies, due to the increased light penetration into cell tissue of the excitation lasers. A range of homologous pH sensitive fluorescent pentamethine cyanine dyes is now being synthesised and evaluated and will be reported in subsequent communications.

MEC thanks Adam Colebrook and Tony Rees for the accurate mass spectroscopic analysis and J. Tony Smith and Martyn Birch for stimulating discussion.

First published as an Advance Article on the web 9th November 2000

A series of dimeric compounds 1a–c designed around the epoxide domain of the azinomycins have been synthesised and demonstrated to be highly efficient DNA interstrand cross-linking agents.

Chemical agents capable of inducing DNA interstrand cross-links (ISC's) comprise an extremely important class of clinical cancer chemotherapeutic agent.[1] Indeed, several important drugs used for the treatment of this disease (*e.g.* cisplatin, chlorambucil and melphalan) are known to induce ISC formation. In 1986, two new cytotoxic agents named azinomycin A and B were isolated from the culture broths of *Streptomyces griseofuscus* S42227 which were shown to possess significant *in vivo* anti-tumour activity (Fig. 1).[2] Using synthetic oligonucleotide duplexes, Armstrong *et al.* demonstrated that azinomycin B causes interstrand cross-links in the major groove of DNA by alkylation at N-7 of guanine (G) and reaction with another purine residue (A or G) two bases along on the complementary DNA strand.[3] More recently, Fujiwara *et al.* provided the first direct evidence for the involvement of the electrophilic epoxide and aziridine moieties in the DNA cross-linking event using self-complementary oligodeoxynucleotide $[d(TAGCTA)_2]$.[4] Whilst reactions with the nucleophilic purine residues of DNA is clearly essential for ISC formation, the poor chemical stability of these agents especially the 1-azabicyclo-[3.1.0]hexane ring system is undesirable from the point of view of possible drug development. Indeed, the high reactivity of this heterocyclic system has severely hampered efforts to complete the total synthesis of these natural products.[5] Since several studies have determined that simplified derivatives based upon the epoxide domain of the azinomycins are highly cytotoxic,[6] we reasoned that dimeric structures based upon this motif joined by a suitable linker might serve as effective DNA cross-linking agents (Fig. 1). Such compounds might be expected to display enhanced chemical stability with respect to the natural products. Furthermore, by fine tuning the nature of the aromatic residues and the linker, agents capable of targeting specific base sequences can be imagined.

To test our hypothesis, we chose to prepare three bisepoxides **1a–c** containing flexible hydrocarbon linker units of varying lengths between the two epoxide subunits. The synthesis of these bisepoxides was accomplished in a straightforward fashion from enantiomerically pure epoxy ester (2*S*,3*S*)-**2**.[7] Selective cleavage of the benzyl ester by hydrogenation and coupling of the resultant acid with 0.5 molar eq. of ethylenediamine furnished bisepoxide **1a** in 69% yield (Scheme 1).† Similarly, (2*S*,3*S*)-**2** was transformed into bisepoxides **1b** and **1c** using 0.5 molar eq. of 1,4-diaminobutane and 1,6-diaminohexane, respectively. All three bisepoxides were produced as crystalline solids which displayed good thermal and hydrolytic stability.‡

With these bisepoxides in hand, we turned our attention to studying their interstrand cross-linking activities using an agarose gel assay.[8] Monoepoxide **3**[7] was used as a control in these experiments. In contrast to epoxide **3** which displays no ISC activity at concentrations up to 50 μM, bisepoxide **1a** induces cross-links at concentrations as low as 0.1 μM and effects 100% cross-linking at 10 μM (Fig. 2). Bisepoxides **1b** and **1c** bearing progressively longer linkers between the two epoxide centres also induce ISC in double stranded DNA. Bisepoxide **1b** induces some ISC's at 0.1 μM with 100% ISC's being observed at just 1 μM; **1c** induces appreciable levels of cross-linking at the somewhat higher concentration of 10 μM. It is interesting to observe that bisepoxides **1a** and **1b** are more effective ISC agents in this assay than the clinically important anti-cancer drugs cisplatin, melphalan and chlorambucil (data not shown). To gain preliminary information concerning the

K562	0.067	0.027	0.062

[a] Dose of drug inhibiting growth by 50% following a 96 h exposure (1 h in the case of K562) as determined by the SRB assay[10] (MTT assay[11] in the case of K562). [b] Cell line with acquired resistance to cisplatin.

sequence selectivity of bisepoxides **1a–c**, we have evaluated them in a Taq DNA polymerase stop assay.[9] All three bisepoxides and epoxide **3** induce Taq stops preferentially at G residues indicating alkylation at these bases. Interestingly, the bisepoxides block polymerase at fewer bases than the corresponding monoepoxide **3**, indicating enhanced sequence specificity.

The cytotoxicity of bisepoxides **1a–c** was determined against a small panel of human tumour cell lines [A2780, CH1, SKOV-3 (all ovarian), HT-29 (colon), K-562 (leukemia)] (Table 1). All the compounds display potent cytotoxicity in a range of cell lines including one with acquired resistance to the drug cisplatin (CH1cisR) where no cross resistance was observed. In some cell lines, epoxide **3** shows comparable potency to these bisepoxides (*e.g.* CH1, IC_{50} 0.056 μM), however in other lines it is markedly less potent (*e.g.* K562, IC_{50} 0.493 μM).

In conclusion, we have demonstrated that the chemically stable bisepoxides **1a–c** are easy to prepare and are highly effective ISC agents. Our findings suggest that a spacer consisting of a chain of approximately four carbon atoms is optimal for cross-linking ability. Furthermore, we have determined that these bisepoxides are highly cytotoxic. In future studies, we plan to determine how the nature of the aromatic residue and the conformational flexibility of the linker influence ISC activity and how the sequence specificity of these agents can be enhanced.

Generation of aminoacyl radicals from 1-carbamoyl-1-methylcyclohexa-2,5-dienes: a new tin-free homolytic route to β- and γ-lactams

Leon V. Jackson and John C. Walton*

University of St. Andrews, School of Chemistry, St. Andrews, Fife, UK KY16 9ST. E-mail: jcw@st-and.ac.uk

Received (in Cambridge, UK) 13th September 2000, Accepted 3rd October 2000
First published as an Advance Article on the web 9th November 2000

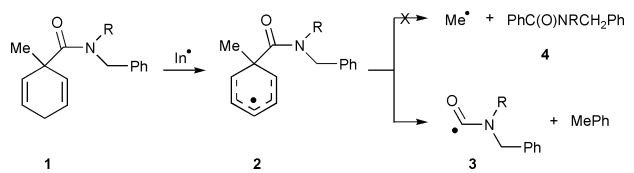
Radical induced homolyses of 1-carbamoyl-1-methylcyclohexa-2,5-dienes took place cleanly to yield aminoacyl radicals, with no competition from the alternative dissociation to methyl radicals: β- and γ-lactams were obtained from ring closures of suitably unsaturated model compounds.

The quest for 'cleaner' free-radical precursors, independent of tin and other toxic metal involvement, and hence suitable for pharmaceutical syntheses,[1] was aided by the discovery that esters of 1-methylcyclohexa-2,5-diene-1-carboxylic acid and of 2,5-dihydrofuran-2-carboxylic acid selectively furnished alkyl radicals on induced homolysis.[2] These reagents were employed with moderate success in benign chain alkylations of olefins, and in cyclisations, affording product yields in the range 35–65%.[3] The main limitation to the scope of their deployment was unwanted competition from an alternative dissociation of intermediate 1-methyl-1-carboxylatocyclohexadienyl radicals, that generated methyl radicals and benzoate esters as by-products. These findings triggered the idea that analogous amides **1** might function as sources of aminoacyl radicals **3**. It was anticipated that the greater stability of aminoacyl radicals, in comparison to alkoxyacyls, would favour the desired dissociation of the delocalised radical **2** to aminoacyl **3**, over the alternative dissociation to Me˙ and amide **4** (Scheme 1). Moreover, it was expected that aminoacyls would not decarbonylate at moderate temperatures and hence could be incorporated in free-radical chain cyclisations.

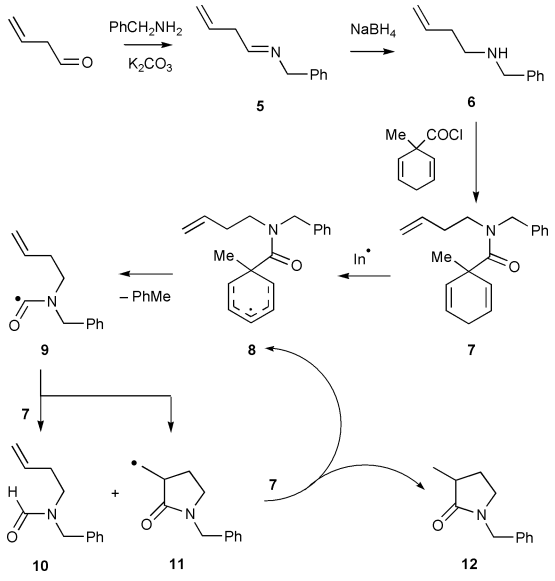
To test this possibility, amide **7** was prepared as illustrated in Scheme 2. Benzylimine **5** was reduced to *N*-but-3-enylbenzylamine **6** with sodium borohydride and hence, by reaction with 1-methylcyclohexa-2,5-diene-1-carbonyl chloride,[3] to amide **7**. Preliminary observations were carried out using EPR spectroscopy to monitor radical intermediates generated on photolysis of a solution of **7** in di-*tert*-butyl peroxide (DTBP) as initiator (In). Below about 30 °C the EPR spectrum showed a single radical with hyperfine splittings (hfs) and *g*-factor entirely as expected for cyclohexadienyl radical **8**; and similar to parameters previously reported for related radicals.[3,4] Above this temperature the spectrum of radical **8** weakened and by about 60 °C was entirely replaced by a new spectrum consisting of a simple nitrogen triplet (g = 2.0018, a(N) = 2.21 mT, DH_{pp} = 0.24 mT). These EPR parameters are very similar to those of archetype aminoacyls *e.g.* EtNHC˙(O) (*trans*-radical: g = 2.0018, a(N) = 2.24 mT)[5] and we attribute the spectrum to radical **9**. Clear-cut spectroscopic evidence for the ring closed radical **11** was not forthcoming; partly because of sample boiling and weak spectra at higher temperatures.

Photolysis of a solution of amide **7** in DTBP with unfiltered light from a 400 W medium pressure Hg lamp at 50 °C for 8 h afforded γ-lactam **12** as the main product (53%) together with smaller amounts of formamide **10** (37%) from direct reduction. Similar results were obtained simply by heating **7** with dibenzoyl peroxide (1.5 equiv.) in benzene for 24 h. Acyl radicals often cyclise in the *endo* mode[6] and, in the case of **9**, this would have produced 1-benzylpiperidin-2-one containing a 6-membered ring. However, spectral evidence was unequivocal in support of structure **12** and none of the piperidine derivative was perceptible under our conditions.[7] Most significantly, none of the aromatic amide of type **4** was detectable, even by GC-MS, and hence the adverse dissociation of delocalised radical **8** to Me˙ was negligible. This implied that amides of type **1** had high potential as clean aminoacyl radical sources, with promise of considerable generality for syntheses of a variety of lactams.

Carbapenems and nocardicins are important monocyclic antibiotic classes containing smaller, β-lactam rings that might, therefore, be accessible starting from appropriate amidocyclohexadienes. Radical cyclisations to afford 4-membered rings *via* 4-*exo*-*trig* ring closures are not generally favoured, but instances leading to β-lactams have been reported.[8–11] Suitably unsaturated aminoacyl radicals were generated from amides **13** and **17a**,**b**. EPR spectroscopic observations with amide **13** followed the same pattern as with amide **7** *i.e.* on photolysis with DTBP the spectrum showed the cyclohexadienyl radical at lower temperatures and aminoacyl radical **14** at higher temperatures (> *ca.* 40 °C). In preparative scale experiments at 60 °C, carbapenem derivative **15** was isolated as the major product (34%) along with formamide **16** (31%). Analogous aminoacyl radicals containing propargyl and cyanomethyl chains were generated from amides **17a** and **17b**. However, the formamides **18a**,**b** were the major products isolated. Neither of these radicals underwent efficient 4-*exo*-ring closure, pre-

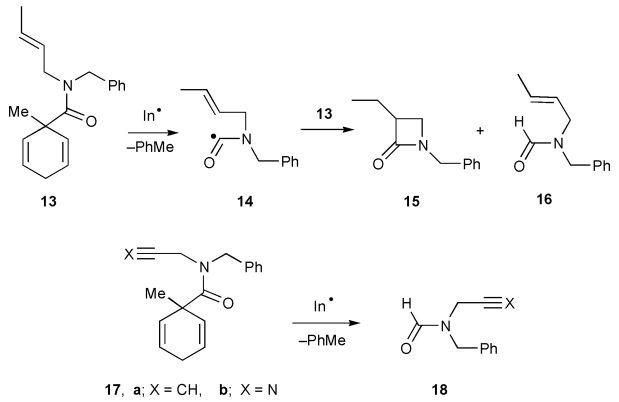


Scheme 1



Scheme 2

DOI: 10.1039/b007454n



Scheme 3

sumably because of the extra strain involved in forming 4-membered rings containing exocyclic double bonds.

In summary, therefore, radical induced homolyses of cyclohexadienyl amides of type **2** took place cleanly to yield aminoacyl radicals, with no competition from the alternative dissociation to methyl radicals. Model β- and γ-lactams were obtained from ring closures of alkenylaminoacyl radicals. Consequently, these amides, which are easily prepared from unsaturated amines and 1-methylcyclohexa-2,5-diene-1-carboxylic acid, furnish mild, tin-free routes to small, and probably medium ring lactams, eminently suitable for conversion to useful biologically active compounds.

We thank the EPSRC (grant GR/L49185) for financial support.

Selectivity of cyano-Gilman cuprates: synthesis of 10-membered ring cyclophanes

S. M. Humayun Kabir*† and Masahiko Iyoda

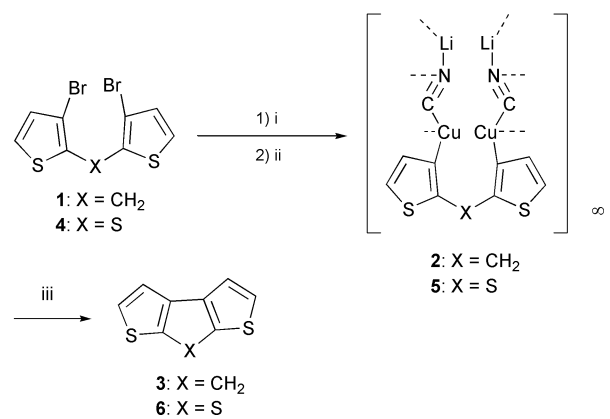
Department of Chemistry, Graduate School of Science, Tokyo Metropolitan University, Hachioji, Tokyo 192-0397, Japan

Received (in Cambridge, UK) 6th October 2000, Accepted 17th October 2000
First published as an Advance Article on the web 10th November 2000

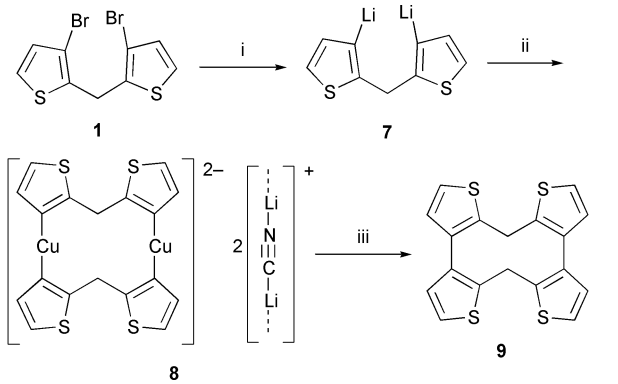
The oxidation of cyano-Gilman cuprates, derived from dibromodithienyl sulfide, dibromodithienyldimethylsilane and dibromodithienylmethane, with molecular oxygen furnishes 10-membered ring cyclophanes selectively and an X-ray analysis of cyclophane 9 reveals that it possesses an *anti* conformation.

Oxidative coupling of Gilman cuprates, prepared from 2 equivalents of an organolithium reagent with 1 equivalent of CuI, was reported to produce bialkyls.[1] Lipshutz *et al*. reported for the first time, the chemistry of lower- and higher-order cyanocuprates and discussed their reactivities in Michael additions and substitution reactions.[2–6] Later, the same group reported the oxidative dimerizations of higher-order cyanocuprates to produce unsymmetrical biaryls.[7] Rajca *et al*. utilized lower-order cyanocuprates for the synthesis of polycyclic aromatics.[8] We recently described the selectivity of lower-order cyanocuprates to produce five-membered rings through intramolecular cyclizations.[9] Here, we report the selectivity of higher-order cyanocuprates or cyano-Gilman cuprates[6] for the formation of 10-membered rings *via* intermolecular cyclization reactions.

The reaction of 3,3′-dibromo-2,2′-dithienylmethane **1**[10,11] with Bu^{n}Li (2 equiv.), followed by treatment with CuCN (2.5 equiv.) produced lower-order cyanocuprates **2**. The oxidation of lower-order cyanocuprates with molecular oxygen produced five-membered ring compound **3**,[9–11] as shown in Scheme 1. Similar reactions were also accessible for compound **6** and its isomer.[9,12] Interestingly, the successive addition of butyllithium and copper(I) cyanide to compounds **1**, **10** and **11**,[9–13] followed by oxidation with molecular oxygen gave 10-membered ring cyclophanes, selectively. Thus the reaction of 3,3′-dibromo-2,2′-dithienylmethane **1** with Bu^{n}Li (2 equiv.) at −78 °C in THF gave a lithio derivative through halogen–lithium exchange, which was treated with CuCN (1 equiv.) to produce cyano-Gilman cuprates **8**. The oxidation of cyano-Gilman cuprates with molecular oxygen afforded 10-membered ring cyclophane **9** in 45% yield. The course of the reaction can be concisely represented as shown in Scheme 2.

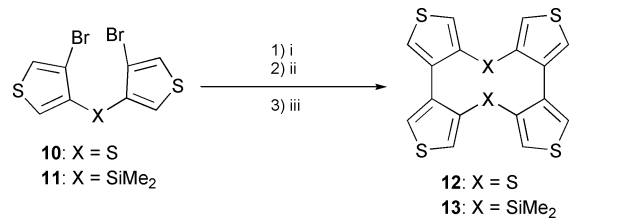


Scheme 1 *Reagents and conditions*: i, Bu^{n}Li (2 equiv.), THF, −78 °C; ii, CuCN (2.5 equiv.), −78 °C to room temp.; iii, O_2, −78 °C to room temp.



Scheme 2 *Reagents and conditions*: i, Bu^{n}Li (2 equiv.), THF, −78 °C; ii, CuCN (1.0 equiv.), −78 °C to room temp.; iii, O_2, −78 °C to room temp.

Similarly, reactions with 4,4′-dibromo-3,3′-dithienyl sulfide **10** and 4,4′-dibromo-3,3′-dithienyldimethylsilane **11** offered the opportunity to obtain cyclophanes **12** and **13**, as shown in Scheme 3. Analogous reactions afforded cyclophanes **12** and **13** in 40 and 42% yields, respectively.



Scheme 3 *Reagents and conditions*: i, Bu^{n}Li (2 equiv.), THF, −78 °C; ii, CuCN (1.0 equiv.), −78 °C to room temp.; iii, O_2, −78 °C to room temp.

The ^{1}H NMR spectrum of **9** shows two doublets for the methylene protons at δ 4.47 and 4.02, which is clearly understood from its X-ray structure (Fig. 1).‡ Owing to the rigidity of the central 10-membered ring, the methylene protons show a coupled AB pattern and thereby appear as doublets.§ The steric repulsion between methylene protons in **9** leads to an *anti* conformation and the dihedral angle between two planes, one defined by the C2–C3 and C2–C6 bonds, and the other defined by the C2–C6 and C6–C7 bonds, is *ca.* 45°. A molecular model of **9** also suggests an *anti* conformation, which forces the bithiophene moieties into a twisted form. This is also the case for **13** with rather bulky $SiMe_2$ bridging moieties. Unlike **9** and **13**, **12** shows a *syn* conformation, owing to the absence of additional atoms on the sulfide bridges. Interestingly, AM 1

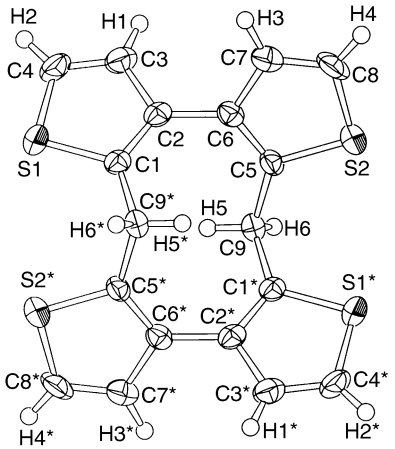

Fig. 1 X-Ray structure of **9**.

calculations on **12** and **13** are consistent with the molecular models.

The absence of π-conjugations in **9** is clearly observed from its UV spectrum. The absorption maximum exhibits a hypsochromic shift in comparison with 3,3′-dithienyl sulfide [**9**: λ_{max} = 245.5 nm (log ε = 4.24); 3,3′-dithienyl sulfide: λ_{max} = 272 nm].[14] A similar hypsochromic shift of the absorption maximum is also observed for **13** [λ_{max} = 243.5 nm (log ε = 4.05)]. Interestingly, the cyclophane **12** exhibits a bathochromic shift [λ_{max} = 289.5 nm (log ε = 4.51)], which indicates extended conjugation and also suggests a *syn* conformation.

Finally, cyclic voltammetry of **12** shows one reversible wave corresponding to radical cation or diradical dication and the half-wave potential ($E_{1/2}$) is 0.1 V (*vs.* Fc/Fc$^+$ in 0.1 M $NBu^n_4ClO_4$– PhCN).

In conclusion, the oxidation of cyano-Gilman cuprates with molecular oxygen produced 10-membered ring cyclophanes selectively and interesting properties of these cyclophanes have been established.

This work was supported by the Japanese Ministry of Education, Science, Sports and Culture (Monbusho) under a fellowship to S. M. H. K. We thank Dr M. Yoshida for helpful discussions.

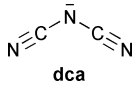
First published as an Advance Article on the web 10th November 2000

The $M(bipy)_3^{2+}$ cations in the isomorphous structures of $[M(bipy)_3][M'(dca)_3]_2$, [dca = dicyanamide, $N(CN)_2^-$; M = Fe, M′ = Mn 1, Fe 2 or M = Ni, M′ = Mn 3] are contained within hexagonal windows of anionic 2D (6,3) $M(dca)_3^-$ sheets; weak antiferromagnetic coupling is observed between metal centres within the anionic networks of all three compounds.

Our recent work, and that of others, on the topology and magnetism of binary transition metal(II) dicyanamides $M(dca)_2$ [dca = $N(CN)_2^-$] and on neutral adducts of type $M(dca)_2L_x$, where x = 3 for L = H_2O, x = 2 for L = pyridine, MeOH, EtOH, DMF and x = 1 for L = pyrazine, 4,4′-bipyridine, H_2O and 2-aminopyridine, has revealed a fascinating array of structures and magnetic phenomena.[1,2] To date all compounds reported have been homometallic. However, we have recently extended our dicyanamide work to include the anionic coordination polymers $M(dca)_3^-$ and $M(dca)_4^{2-}$ first reported by Köhler *et al.* but without any crystallographic or magnetic characterisation.[3] We have found that the network topology of the anion is dependent on the counter-cation used—the networks are in fact cation templated.[4] We realised that these systems also offered the possibility of making heterometallic systems through the use of paramagnetic metal-containing counter-cations. Thus we report here the structural and magnetic properties of new anionic metal dicyanamide systems containing $M(bipy)_3^{2+}$ (bipy = 2,2′-bipyridine) counter-cations. Future work will involve use of spin-crossover Fe(II) and Co(II) cationic chelates to search for cooperative effects when such centres are dispersed in a 2D host lattice (*vide infra*).

Reaction of sodium dicyanamide, $M(bipy)_3^{2+}$ and the appropriate metal nitrate or perchlorate gave dark red crystals of $[Fe(bipy)_3][M(dca)_3]_2$, M = Mn **1**, Fe **2** and orange/pink crystals of $[Ni(bipy)_3][Mn(dca)_3]_2$ **3**.† The structures were determined by single crystal X-ray crystallography and found to be isomorphous.[5] Bulk sample purities were confirmed by powder X-ray diffraction. The structures consist of infinite hexagonal (6,3) anionic sheets of $M(dca)_3^-$ and $M(bipy)_3^{2+}$



dca

counter-cations (Fig. 1). Each octahedral metal atom in a sheet is bridged by three pairs of dca ligands, coordinating through only the terminal nitrile nitrogen atoms, to three other metal atoms. There are two crystallographically unique metal atoms in the sheets, and within each sheet they are arranged in an alternating fashion [M–N 2.203(3)–2.238(2) Å (**1**), 2.130(2)–2.185(2) Å (**2**) and 2.200(2)–2.242(2) Å (**3**)]. These sheets lie in the *yz* plane, and stack in the *x* direction. The $M(bipy)_3^{2+}$ counter-cations lie inside the hexagonal windows of the sheets (Fig. 2).

There are a number of close contacts between the cations and the anionic networks. The most significant of these are H···C contacts of 2.695 Å (C–H···C = 116.7°), 2.745 Å (148.0°), 2.775 Å (123.6°) for **1**; 2.690 Å (116.6°), 2.674 Å (148.2°), 2.798 Å (121.6°) for **2**; and 2.700 Å (114.0°), 2.714 Å (148.9°), 2.770 Å (126.4°) for **3** and H···N contacts of 2.675 Å (C–H···N = 140.5°), 2.682 Å (121.1°) for **1**; 2.602 Å (140.1°), 2.683 Å (117.0°) for **2**; and 2.663 Å (139.3°), 2.673 Å (119.9°) for **3**.

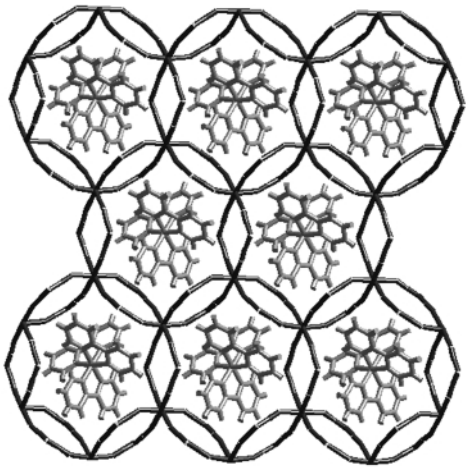


Fig. 1 The sheet structure of **1**–**3**.

There are also edge-to-face [centroid–centroid = 5.07 Å (**1**), 5.02 Å (**2**) and 5.04 Å (**3**)] and vertex-to-face [centroid–centroid = 4.96 Å (**1**), 4.92 Å (**2**) and 4.91 Å (**3**)] inter-cation interactions between the pyridyl rings of cations in adjoining sheets.

It is of interest to compare these structures to a number of closely related oxalate networks reported. Numerous hexagonal 2D (6,3) sheet structures have been reported for metal oxalate $[M_2(ox)_3]^{n-}$ networks with a variety of counter-cations,[6] including paramagnetic ones such as $[(Cp^*)_2M]^+$.[7] In contrast to the structures reported here, however, the counter-cations lie *between* the sheets rather than *within* the planes of the sheets. This is due to the smaller size of the hexagonal windows in the oxalate sheets compared to the dca sheets. Interestingly, when oxalate networks are crystallised with $M(bipy)_3^{n+}$ counter-cations, chiral 3D (10,3)-a networks are formed.[6b,c] Each crystal contains cations of only one handedness, and all $M(ox)_3^{n-}$ centres are also of a single hand. In contrast, the structures described here contain cations of both handedness, with each anionic sheet containing counter-cations of only one hand but successive anionic sheets containing counter-cations of alternating hands. As for the oxalate analogues, each (6,3) $M(dca)_3^-$ sheet contains $M(dca)_6^{4-}$ centres of alternating hands. The structure is nonetheless non-centrosymmetric (space group *Fdd*2) as layers of opposite cation chirality are related by glide planes rather than inversion centres. The alternating layers stack

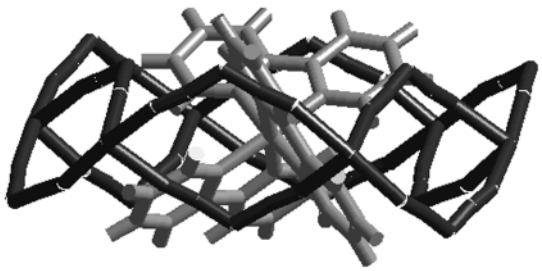

Fig. 2 Location of a $M(bipy)_3^{2+}$ cation inside a hexagonal window of a $M(dca)_3^-$ sheet.

DOI: 10.1039/b007080g

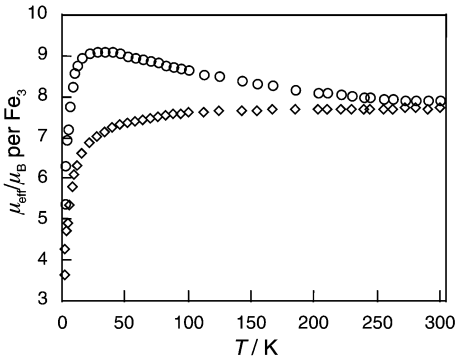

Fig. 3 Plots of μ_{eff} (per Fe_3) *vs.* temperature for $[Fe(bipy)_3][Fe(dca)_3]_2$ **2** measured in a field of 1 T as a neat powder (○) and dispersed in vaseline (◇).

such that successive layers are offset from each other, and hexagonal channels are not formed.

Since it contains a diamagnetic cation, $Fe(bipy)_3^{2+}$, the μ_{eff} value at room temperature of 8.04 μ_B for **1** is that due to $Mn(dca)_3^-$ alone. The variation in temperature mirrors that found for salts such as $PPh_4[Mn(dca)_3]$, which contain a 2D sheet structure, different to that of **1**. μ_{eff} values in **1** remain constant down to 50 K then decrease rapidly below this due to weak antiferromagnetic coupling. In an applied field of 1 T, **2** shows a μ_{eff} value at 300 K of 7.7 μ_B, per Fe_3, which, when the sample is dispersed in a vaseline mull to prevent crystallite torquing, remains constant down to 50 K and then decreases rapidly to 3.6 μ_B at 2 K because of weak antiferromagnetic coupling combined with zero field splitting effects (Fig. 3). Since the $Fe(bipy)_3^{2+}$ group is d^6 low spin the expected μ_{eff} value for uncoupled ($S = 0, S = 2, S = 2$) centres, with $g = 2.0$, is 48 = 6.93 μ_B, excluding orbital contribution/spin–orbit coupling effects on the high spin $Fe^{II}(dca)_3^-$ centre and second order Zeeman effects (TIP) on the $Fe(bipy)_3^{2+}$. An interesting feature, and one possibly overlooked in high-spin Fe(II) systems, including crossover studies, is the field induced torquing which occurs when a neat solid sample was used (Fig. 3). It can be seen that, as the temperature is raised from 2 K, in $H = 1$ T, a ferromagnetic like plot is obtained with a broad maximum in μ_{eff}, the room temperature value being similar to that in the mull sample. This effect arises from anisotropy in the susceptibility of high spin Fe(II), as was also found in Mn(III).[8] It is possible, therefore, to draw wrong conclusions, particularly in extended systems of the present type and caution is warranted.

Compound **3** also displays Curie-like susceptibilities with a value of μ_{eff} (per mol) of 8.7 μ_B at 300 K, which decreases gradually to reach 8.2 μ_B at 50 K then rapidly to 4.9 μ_B at 2 K. The data are again compatible with essentially isolated cationic and extended anionic sublattices, the latter showing weak antiferromagnetism [μ(uncoupled) = 8.83 μ_B for $S = 1 + S = 5/2 + S = 5/2$]. Despite this lack of cation (paramagnet)–anion interaction, the prospect of obtaining unusual magnetic effects when spin-crossover cations are incorporated remains positive since it is well known that weak intermolecular perturbations (*e.g.* solvate, H-bonding, π–π stacking) can sensitively influence the crossover and cooperative behavior in crystals.[9]

Colloidal suspensions of template-removed zeolite nanocrystals†

Huanting Wang, Zhengbao Wang and Yushan Yan*

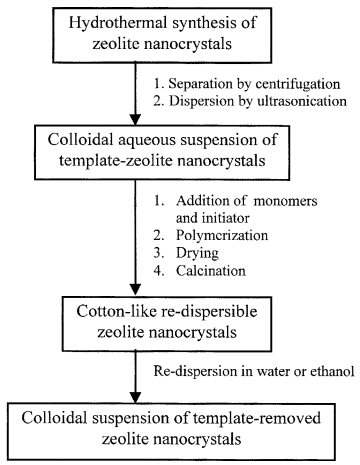
Department of Chemical and Environmental Engineering, University of California, Riverside, CA 92521, USA. E-mail: yushan.yan@ucr.edu

Received (in Irvine, CA, USA) 1st August 2000, Accepted 13th October 2000
First published as an Advance Article on the web 10th November 2000

Colloidal suspensions of template-removed zeolite nanocrystals were prepared by using an organic polymer network as a temporary barrier during calcination to prevent zeolite nanocrystal aggregation.

There is considerable interest in the synthesis of colloidal zeolite nanocrystals because they can serve as model systems for the fundamental study of zeolite crystal growth.[1–5] Colloidal suspensions of zeolite nanocrystals have also been used to deposit seed layers for preparation of zeolite membranes.[6,7] Very recently, construction of hierarchically porous crystalline structures through templated self-assembly of colloidal zeolite nanocrystals has also been reported.[8,9] Colloidal suspensions of zeolite nanocrystals are usually synthesized *via* hydrothermal procedures using clear aqueous solutions.[1–9] In most of these syntheses, organic templates (or structure-directing agents) are used, and the colloidal crystals so obtained contain organic template in their void spaces. We are interested in using colloidal suspensions of organic-functionalized zeolite nanocrystals as building blocks to construct hierarchical porous inorganic–organic hybrid materials that have potential applications in separation, catalysis, and microelectronics.[10–13] For this purpose, suspensions of template-free nanocrystals are required. Thus far, the most commonly used method for template removal is through high temperature calcination in air or oxygen. This method, however, has proved unsuitable for colloidal nanocrystals because it leads to significant irreversible aggregation.[8,9]

Here we report a novel approach to prepare colloidal suspensions of template-free zeolite nanocrystals by using an organic polymer network as a temporary barrier to isolate as-synthesized nanocrystals during template removal. Scheme 1 shows a flowchart of the preparation process. This approach appears general for all zeolites, however, only the preparation of a colloidal suspensions of template-free silicalite nanocrystals is reported here as an example. To the best of our knowledge, this is the first report on colloidal suspensions of calcined zeolite nanocrystals.



Scheme 1 Preparation protocol for colloidal suspensions of template removed zeolite nanocrystals.

† Electronic supplementary information (ESI) available: Suppl. Figs. 1–3: TGA curves, XRD patterns and IR spectra. See http://www.rsc.org/suppdata/cc/b0/b006518h/

An aqueous colloidal suspension of template-containing silicalite nanocrystals was synthesized as follows.[8] A clear synthesis solution was prepared by dropwise addition of tetrapropylammonium hydroxide solution (TPAOH, Aldrich) into tetraethyl orthosilicate (TEOS, Aldrich) with strong agitation followed by 1–3 days of aging at 30 °C under stirring. The final solution molar composition was 1 TPAOH : 2.8 SiO_2 : 11.2 EtOH : 40 H_2O. Crystallization was carried out at 80 °C for 3 days with constant stirring at 250 rpm. A stable aqueous suspension of silicalite nanocrystals was obtained by repeated cycles of centrifugation at 15 000 rpm, decanting, and ultrasonic redispersion in pure water until pH < 8. Other dispersants such as ethanol could also be used if desired.

The water soluble organic monomers acrylamide CH_2=CHCONH$_2$ (AM, Aldrich), and *N*,*N*′-methylenebisacrylamide, $(CH_2$=CHCONH$_2)_2CH_2$ (MBAM, Aldrich), and the initiator $(NH_4)_2S_2O_8$ (Aldrich) were used to prepare the polymer network. Typically, 1.0 g AM, 0.1 mg MBAM and 25 mg $(NH_4)_2S_2O_8$ were added under stirring into 10 g of a silicalite colloidal suspension with 5 wt% solid loading. After the monomers were dissolved, the mixture was ultrasonicated for 15 min to ensure complete dispersion of the silicalite nanocrystals. The aqueous solution containing the monomers has a fairly low viscosity and could readily be polymerized and crosslinked *via* a free-radical mechanism into an elastic hydrogel once the temperature was increased to 50 °C or a catalyst [*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED)] was added at room temperature.[14] Polyacrylamide hydrogels have been commonly used as binders in ceramic forming processes[14] and are expected to be compatible with silicalite nanocrystals whose surface silanol groups interact favorably with –NH_2 groups. The solid polymer–silicalite composite was dried at 80–100 °C overnight before it was carbonized under nitrogen at 550 °C for 2 h (heating rate 2 °C min^{-1}) and then calcined at 550 °C for 3 h under air (Scheme 1).

TGA was used to monitor the thermal decomposition of dried polymer–silicalite composite under N_2 and air (ESI†). Under N_2 a weight loss of *ca.* 18% was recorded between room temperature and 280 °C, due to desorption of water and TPAOH. A weight loss of *ca.* 42% occurred between 280 and 600 °C as a result of decomposition of occluded TPA and carbonization of the polymer network. Based on a theoretical value of 11.7% weight loss for TPA decomposition (four TPA^+ cations per silicalite unit cell),[9] the weight loss during carbonization was estimated to be 28 wt%. The residual silicalite was 16 wt% after heating under air at 550 °C which removes carbon completely, and thus the carbon is calculated to be 24 wt%. TG analysis of a sample without incorporation of the polymer network shows that template TPAOH can be removed completely through this procedure.

Fig. 1 shows SEM images of silicalite nanocrystals after direct drying and calcination in the absence of a polymer network barrier. Clearly, direct drying of an as-synthesized silicalite suspension by evaporation leads to densely packed crystals [Fig. 1(a)], which upon calcination aggregate irreversi-

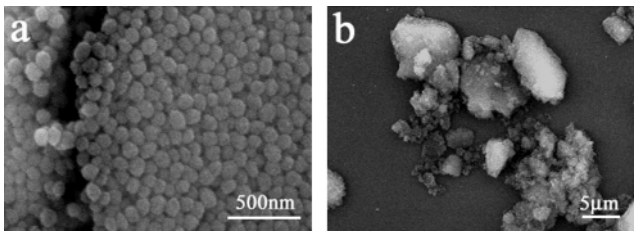


Fig. 1 SEM images of silicalite nanocrystals prepared without polymer network barrier: (a) after drying, (b) after calcination.

bly into large solid particles and grinding using a mortar and pestle for 2 h did not appear to improve its re-dispersibility. These particles cannot be re-dispersed into a suspension, and precipitated quickly after mild shaking [Fig. 1(b)].

The aggregation of zeolite nanocrystals is a result of condensation reactions between surface silanol groups of zeolite nanocrystals.[8,9] For condensation reactions to occur, close packing of the nanocrystals is required [Fig. 1(a)].[8,9] The function of the polymer network used here is to keep the nanocrystals separated during carbonization and calcination. Fig. 2 shows SEM images of the composite after drying, carbonization and calcination. After drying, the silicalite nanocrystals are uniformly distributed and well separated in the polymer network [Fig. 2(a)]. Carbonization at 550 °C generated large voids in the composite owing to production of gaseous products [Fig. 2(b)].[15] SEM examination of the carbon skeleton shows that zeolite nanocrystals are uniformly distributed and well separated within the carbon matrix [Fig. 2(c)]. Final calcination removes the carbon barrier and leads to a loose cotton-like white powder [Fig. 2(d)]. We have carried out extensive SEM studies on suspensions with various solid loading and aging times (*e.g.*, 3–4 months) by dip-coating the nanocrystals onto silicon wafers. The substrate withdrawal rate was 1 cm s^{-1} and clean-room-grade wafers were cut into 2 × 2 cm square pieces and used without further cleaning. Our SEM results suggest that the calcined nanocrystal powders can be easily dispersed in water and many other dispersants such as ethanol to form stable suspensions. Uniform films can be formed using suspensions of template-removed silicalite nanocrystals with an appropriate solid loading, and this indicates that the processed nanocrystals have good film-forming properties. Fig. 2(e) shows an example of such a film (*ca.* 0.3 μm thick).

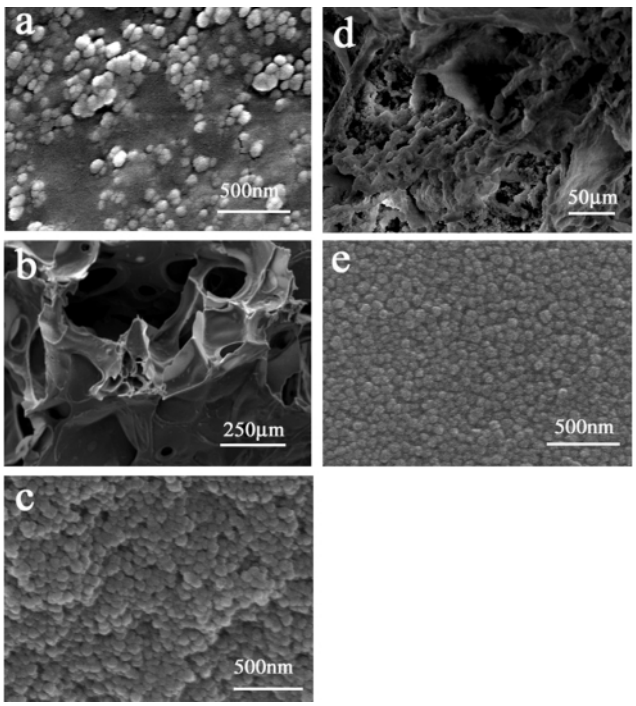

Fig. 2 SEM images of silicalite nanocrystals prepared with a polymer network barrier: (a) after drying, (b) after carbonization (low magnification), (c) after carbonization (high magnification) showing the carbon skeleton, (d) after calcination, (e) silicalite film dip-coated from a colloidal suspension of template-removed nanocrystals.

The powder X-ray diffraction (PXRD) pattern of a re-dispersible white powder sample matches that of a typical 100% crystalline nanoslicalite sample (ESI†).[8,9] FTIR spectra show the nanopowder has an MFI type structure (band at 550 cm^{-1}, with *ca.* 97% crystallinity) and a high concentration of terminal Si–OH groups (band at 972 cm^{-1}) (ESI†).[8,9] N_2 adsorption measurements show that the BET surface area and pore volume for the cotton-like sample are 355 m^2 g^{-1} and 0.18 cm^3 g^{-1}, respectively. These data show that the polymerization, carbonization and calcination processing has no influence on crystallinity and porosity of the nanocrystals.

The weight ratio of polymer to nanocrystals appears important in determining the re-dispersibiltiy of the nanocrystals. We have examined several polymer/zeolite weight ratios and a ratio around 2.0 sufficiently separates nanocrystals. It is recognized that the nanocrystals do move closer and may even contact one another during the final burn-off of carbon. SEM images clearly show that the contact areas among nanocrystals are rather small within the cotton-like nanopowder. It is also possible that during the early stage of calcination some reactive silanol groups on isolated (by carbon) nanocrystals condensed among themselves, and this in turn should reduce the amount of surface silanol groups and the probability of aggregation.

In conclusion, we have demonstrated that colloidal suspensions of template-free zeolite nanocrystals can be prepared by using an organic polymer network as a temporary barrier to avoid nanocrystal aggregation during calcination. Work is under way on organic functionalization of zeolite nanocrystals and construction of hierarchical inorganic–organic hybrid materials using zeolite nanocrystals as building blocks. It is noted here that this approach is not zeolite specific, and thus could become a general strategy for retrieving various nanoparticles from synthetic solutions without aggregation.

This work is partly supported by CE-CERT of UC-Riverside, UC-SMART, UC-TSR&TP, UC-EI, and a UC Regents Faculty Fellowship to Y. Y. We thank Dr. Re Lai and Mr. Piboon Pantu of Caltech for N_2 adsorption measurements.

First published as an Advance Article on the web

Gaseous N_2 has been efficiently introduced in the hollow cavities of aligned CN_x nanotubes (15–80 nm od) by pyrolysing a jet (spray) solution of $Fe(C_5H_5)_2$ and $PhCH_2NH_2$ in an Ar atmosphere at 850 °C; the aligned material consist of large arrays (2.5 cm²) of CN_x ($x < 0.05$) 'bamboo-like' nanotubes (< 100 μm in length); high resolution electron energy loss spectroscopy (HREELS) line-scans and elemental mapping studies reveal that N gas was encapsulated within the hollow compartments of the CN_x nanotubes; these results demonstrate for the first time, that CN_x nanotubes can be used to fabricate gas storage components.

Carbon nanotubes[1] can behave as efficient gas and metal containers. In particular, it has been demonstrated that metals, metal carbides, oxides, chlorides, *etc*.[2–4] can be introduced into the carbon nanotube cores by methods involving: (a) chemical treatments[5] (by boiling suspensions of nanotubes in aqueous nitric acid for several hours), (b) arc discharge[6] (by arcing graphite electrodes packed with a metal); (c) solid state reactions[7] (by heating nanotubes with halides under vacuum) and (d) electrochemical techniques[8] (by passing a current through graphite electrodes in molten ionic salts at *ca.* 600–700 °C). Unfortunately, these are not able to encapsulate gaseous substances.

Recent studies have revealed that H_2 and Ar can be stored in single[9,10] and multiwalled carbon nanotubes,[11] respectively. However, these processes involve at least two steps including the material production and the gas introduction. In the case of multiwalled nanotubes (MWNTs), Ar has been introduced using high Ar pressures for 48 h at 650 °C. Here we report an alternative route to introduce N_2 inside multiwalled CN_x ($x <$ 0.05) 'bamboo-like' nanotubes using a single step reaction process [spray pyrolysis of $Fe(C_5H_5)_2$ (ferrocene) and $PhCH_2NH_2$ (benzylamine) solutions]. The products were studied using scanning electron microscopy (SEM), high resolution transmission electron microscopy (HRTEM) and HREELS.

The pyrolysis apparatus[12] consists of a 300 mm long furnace fitted with a quartz tube (id 10 mm, 800 mm long). One end of the tube is attached to a Pyrex cone (id 0.35 mm), which is connected to a container used for storing and releasing ferrocene/benzylamine solutions. A nozzle (consisting of a capillary) is contained in the Pyrex cone with an exit diameter of 0.5 mm. The reaction tube was preheated to 850 °C; subsequently the solution (0.2 g. ferrocene in 2 ml benzylamine) was released and sprayed by flowing Ar (Messer Griessheim 99.999%) around the cone/nozzle area into the hot zone. The spraying time lasted between 5 and 10 min, usually using 1 ml of the solution. The furnace was maintained at this temperature for an additional 15 min in order to anneal the products.

SEM studies were carried out using a JEOL-JSM 6300F operated at 2–5 kV and a Zeiss DSM 982 Gemini operated at 1–2 kV. HRTEM observations were made using a JEOL-JEM4000 EX operating at 400 kV. Energy-dispersive X-ray (EDX) spectroscopy data were obtained using a Noran Ins. detector fitted within the JSM 6300F microscope. HREELS studies were performed in a dedicated STEM VG-HB 501UX equipped with a Gatan Digi-PEELS 766 detector.

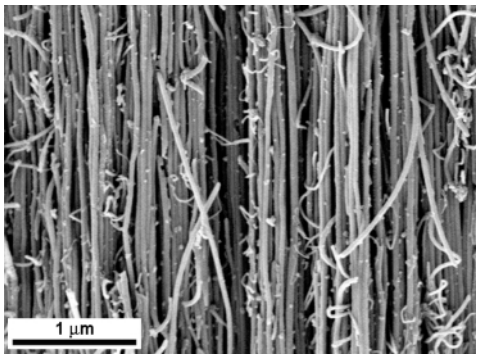

Fig. 1 SEM image of a typical film of aligned CN_x nanotubes of uniform diameter (*ca*. 40 nm od).

The pyrolysed material, scratched from the internal tube surface (hot zone), consists of large black and shiny films of area 2.5 cm² and 100–200 μm thick. SEM studies reveal that the films are composed of aligned tubular structures (100 μm long, 15–80 nm od). Fig. 1 shows a typical region of aligned nanotubes observed within the films.

TEM and HRTEM studies indicate that the material mainly consists of nanotubes exhibiting compartmentalized morpholo-

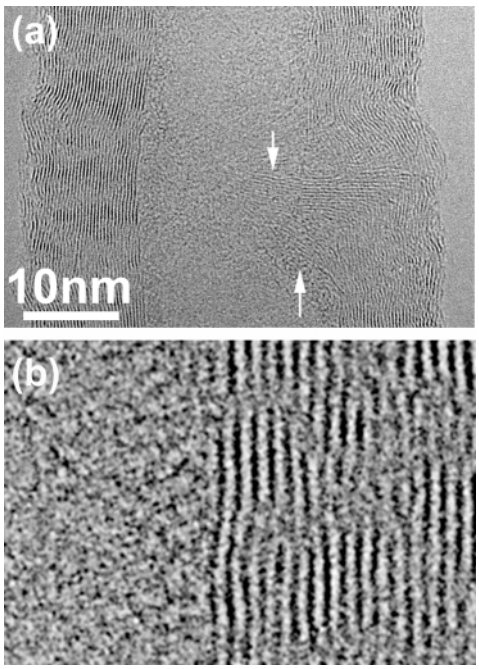

Fig. 2 HRTEM images of a CN_x nanotube: (a) tube segment showing 'graphitic' walls parallel to the tube axis as well as an inner core. It is important to note that the inner core contrast (amorphous-like) suggests the presence of a foreign non-crystalline material. In addition, some inter-linked planes appear to cross the core of the tube, creating compartments (arrows); (b) higher magnification of a CN_x nanotube exhibiting the degree of crystallinity of walls as well as the amorphous-like core (interlayer spacing 0.34 nm).

DOI: 10.1039/b008253h

gies resembling 'bamboo-like' structures, similar to those observed in CN_x nanofibres.[13,14] Fe particles (identified by EDX and electron diffraction) were also observed at the tips of the nanotubes. This confirms that catalytic nanotube growth took place. It is noteworthy that the presence of other carbonaceous material within the samples was notably absent. HRTEM images showed that the tubes were hollow with wide inner cores (>10–20 nm), but compartmentalized forming pockets caused by inter-linkage of graphitic planes across the inner core of the tubes [Fig. 2(a)]. Close inspection of the tubular structures confirmed that the walls consisted of parallel graphite-like sheets [<30 walls; Fig. 2(b)]. We also note that the hollow core of the tubes exhibited an amorphous-like appearance [Fig. 2(a)], suggesting that a foreign material was encapsulated.

EEL spectra of the nanofibres revealed the presence of ionisation edges at *ca.* 284.5 and 400 eV corresponding to the C and N K-excitations. The near edge fine structure of the carbon K-edge confirms that the material is 'graphitic'. Interestingly, a first EELS measurement on a typical CN_x tube revealed a high intensity peak at (401 ± 0.5) eV, clearly indicating the presence of molecular N_2[15] [Fig. 3(a)]. Following this measurement a 'hole' was formed due to the heavy electron irradiation. A subsequent spectrum recorded in the same area revealed a completely different N-K edge exhibiting a π*-peak at (399 ± 0.5) eV and a broad σ*-peak [Fig. 3(a)], which is commensurate with the incorporation of N within the sp^2-carbon network (usually observed in CN_x nanofibres[13,14]). The latter observations suggest that N gas was trapped within the hollow nanotube core, and after our first measurement the effect of focusing the electron beam on the tube caused the tube to open, thus releasing the encapsulated N_2 gas. Once a 'hole' was created, N_2 gas was not detected in neighboring areas.

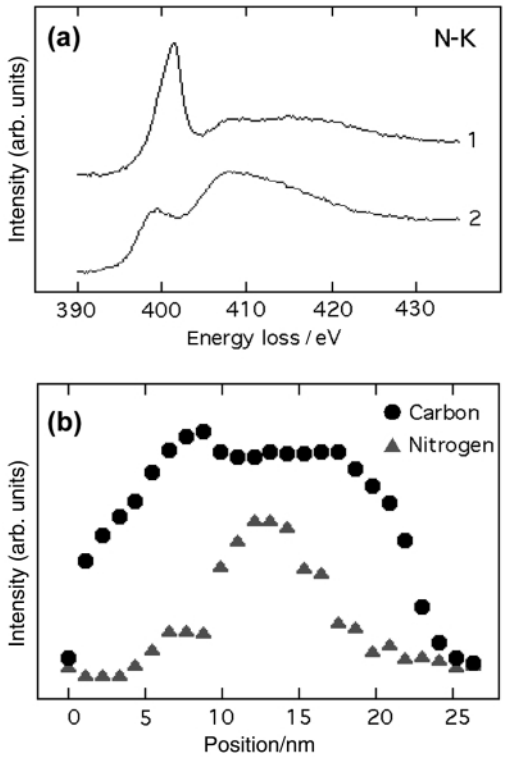

Fig. 3 (a) EEL spectra of the N-K edge representative of a CN_x nanotube. The first measurement (spectrum 1) reveals the presence of molecular nitrogen (peak at 401 ± 0.5 eV). In a second measurement (spectrum 2) recorded at the same position, the sharp peak disappears and a maximum appeared at 399 ± 0.5 eV, corresponding to N incorporated within a C-network. During measurements, we noted that a 'hole' (caused by electron irradiation) was only created when molecular N was trapped inside the tube; (b) concentration profiles of C and N across the diameter of a 25 nm CN_x nanotube derived from EELS line-scans. These indicate the presence of C on the periphery and N mainly within the inner core of the structures. The central 'dip' in the carbon profile is commensurate with an internal core, filled with N.

In order to confirm the presence of N in the nanotube core, HREELS line scans were performed across several tubes. A typical line-scan across the tube axis [Fig. 3(b)] reveals that the C and N concentration profiles 'anticorrelate' across the tubes. A similar behaviour has been observed in Ar filled nanotubes.[11] The line-scans confirm that nitrogen was indeed encapsulated within the hollow cores and not only concentrated within the walls as observed in previous studies.[13,14] Approximately 10–35% of the tubes investigated appeared to be filled with nitrogen gas. In addition, elemental mapping using EELS (not shown here) revealed that N was localised in pockets (consistent with the compartmentalized carbon morphologies) within the nanotube cores. From representative EEL spectra, it was estimated that the N content within the empty CN_x nanotubes (without N_2 gas trapped) was *ca.* $\leqslant$5%. It is noteworthy that the N encapsulation was stable over several weeks and that the gas-filled tubes were not affected after long dispersion periods in acetone.

Our results demonstrate a single-step pyrolytic route to fill CN_x nanotubes with N gas. We have also shown that CN_x nanotubes and nanofibres can be considered as efficient gas containers owing to the presence of pockets (bamboo-like structures), which ensure the encapsulation of gases. The CN_x structures could also serve as containers in order to study liquefaction of N_2 at low temperatures. To the best of our knowledge, this is the first time that N has been incorporated in nanotubes. These observations pave the way to the fabrication of novel gas storage components using spray pyrolysis.

We thank the Alexander von Humboldt Stiftung (M. T.), CONACYT-México grant J31192U (M. T.), the Max-Planck-Gesellschaft (R. K.) and the DFG grant Ru342/11-2 (M. R., T. S.) for financial support. We are also grateful to P. Kopold, H. Labitzke, G. Preininger and S. Kühnemann for electron microscopy support and technical assistance. We also thank N. Grobert, M. Mayne, Ph. Kohler-Redlich and H. Terrones for useful discussions.

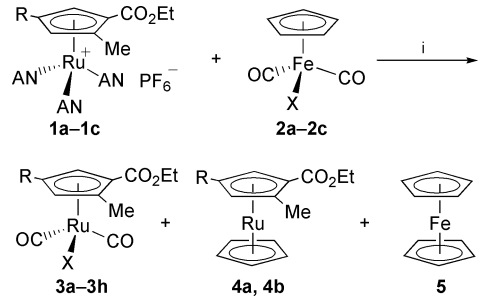
Multiple ligand transfer reaction between planar-chiral cyclopentadienylruthenium complexes [Cp′Ru(AN)$_3$][PF$_6$] [(Cp′ = 1-(CO$_2$Et)-2-Me-4-RC$_5$H$_2$, R = Me, Ph, Bu^t, AN = acetonitrile] and iron complexes CpFe(CO)(L)X (L = PMe$_3$, PPh$_3$; X = I, Br) results in formation of metal-centered chiral ruthenium complexes Cp′Ru(CO)(L)X with a diastereoselectivity (de) up to 68%.

Half-sandwich transition metal complexes CpML$_3$ with a three-legged piano stool structure are fascinating molecules owing to their potential as catalytic or stoichiometric mediators in precise organic syntheses and some of their chiral versions have recently been applied in asymmetric organic synthesis.[1] Although most chiral organometallic complexes have chiral organic groups on the ligands, chiral half-sandwich complexes can be formed in the absence of chiral ligands. While coordination of three different ligands to a metal generates a stereogenic center at the metal atom,[2] unsymmetrically substituted cyclopentadienyl ligands provide planar chirality.[3] Studies on such chiral complexes give us fundamental and important information that serves for the development of novel asymmetric reactions.

We have been studying planar-chiral Ru complexes with trisubstituted cyclopentadienyl ligands.[4,5] Recently we also reported a novel multiple ligand transfer reaction between [CpRu(L)(AN)$_2$][PF$_6$] [L = AN, CO, P(OMe)$_3$; AN = acetonitrile] and CpFe(CO)(L′)X [L′ = CO, PMe$_3$, PMe$_2$Ph, PMePh$_2$, PPh$_3$, P(OPh)$_3$; X = I, Br, Cl].[6] Now, we have examined multiple ligand transfer reactions using planar-chiral cyclopentadienylruthenium complexes and found the induction of Ru-centered chirality by planar chirality on ligand transfer from Fe complexes.

Table 1 lists the results obtained from the reactions of the trisubstituted cyclopentadienyl ruthenium tris(acetonitrile) complex [Cp′Ru(AN)$_3$][PF$_6$] **1**[4] with Fe complex **2** of the type CpFe(CO)$_2$X. Thus, treatment of Ru complex **1a** [Cp′ = η^5-1-(CO$_2$Et)-2,4-Me$_2$C$_5$H$_2$] with an equimolar amount of CpFe(CO)$_2$I **2a** in refluxing CH$_2$Cl$_2$ for 3 h produced a triple ligand transfer product, Cp′Ru(CO)$_2$I **3a**, in 76% yield (Scheme 1). Similar reactions of **1a** with CpFe(CO)$_2$Br **2b** and CpFe(CO)$_2$Cl **2c** gave Cp′Ru(CO)$_2$Br **3b** and Cp′Ru(CO)$_2$Cl **3c**, respectively. Ru complexes **1b** [Cp′ = η^5-1-(CO$_2$Et)-2-Me-4-PhC$_5$H$_2$) and **1c** [Cp′ = η^5-1-(CO$_2$Et)-2-Me-4-Bu^{t}C$_5$H$_2$] also produced the corresponding dicarbonylruthenium complexes **3d**–**h**. The resulting Ru complex **3** was fully characterized by spectral analyses and X-ray crystallography.† The geometry around the metal atom is similar to those of analogous iron complexes (*R*)- and (*S*)-Cp′Fe(CO)$_2$I [Cp′ = η^5-1-(CO$_2$Men)-2-Me-4-PhC$_5$H$_2$; Men = (*l*)- or (*d*)-menthyl].[7]



Scheme 1 *Reagents and conditions*: i, CH$_2$Cl$_2$, reflux, 3 h.

When enantiomerically pure planar-chiral complexes (*R*)- and (*S*)-[Cp′Ru(AN)$_3$][PF$_6$] **1d** [Cp′ = η^5-1-(CO$_2$Adm)-2,4-Me$_2$C$_5$H$_2$; Adm = 2-adamantyl] were used as starting materials in the reaction with **2a**, the corresponding Ru complexes (*R*)- and (*S*)-Cp′Ru(CO)$_2$I **3i** were isolated, respectively, in an enantiomerically pure form [(*R*)-**3i**: [α]$_D$ = +143° (*c* 0.100, CH$_2$Cl$_2$); (*R*)-**3i**: [α]$_D$ = −142° (*c* 0.105, CH$_2$Cl$_2$)]. ^{1}H NMR experiments using a chiral shift reagent Eu(hfc)$_3$ unequivocally indicate that no racemization of the planar-chiral cyclopentadienyl ligand occurred in the multiple ligand transfer reactions.

Then, we investigated the influence of planar chirality of the cyclopentadienyl group on the stereochemistry at the Ru center of the triple ligand transfer product Cp′Ru(CO)(L)X **7** from the reaction with CpFe(CO)(L)X **6** (L = PMe$_3$, PPh$_3$; X = I, Br) (Scheme 2). As illustrated in Scheme 3, complex **7** contains two diastereomerically related pairs, each of which consists of enantiomers. Thus, the diastereoselectivity of metal-centered chirality affected by the planar chirality of cyclopentadienyl group was appraised by the diastereomer ratio of **7** (Table 2). Although other Ru complexes **3** and/or **4** were also produced as

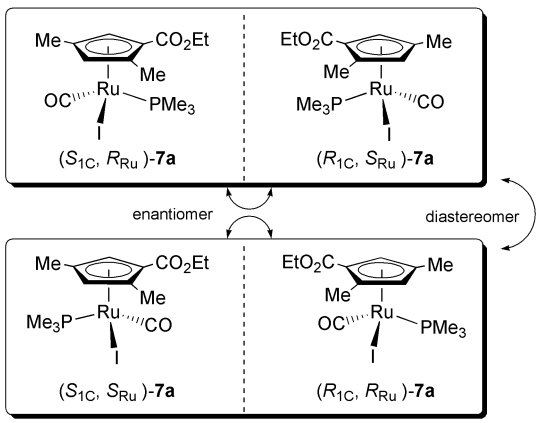

Scheme 3 Stereoisomers of **7a**.

well as **7** in the reaction of **1** and **6**, they were easily separated by column chromatography on silica gel. Yields of products depended both on the substituents on the cyclopentadienyl group as well as the phosphine initially coordinated to Fe. Reactions with **6a** with PMe$_3$ gave desired complex **7** in moderate yields (runs 1, 4 and 5), while yields of **7** were low in the reactions with **6b** and **6c** having PPh$_3$ (runs 2 and 3). To our surprise, the best result (68% de) in the diastereoselectivity of **7** was oberved in the reaction of **1a** having a small substituent (Me) on the cyclopentadienyl group with **6a** having a small phosphine ligand (PMe$_3$) (run 1). Reactions of **1b** and **1c** having a larger substituent (Ph or Bu^t) on the cyclopentadienyl group gave complexes **7c** and **7d** in 22 and 40% de, respectively (runs 4 and 5). Although asymmetric induction at a Ru center by a chiral organic group on the cyclopentadienyl ring has been attempted in the ligand exchange reaction of (η^5-C$_5$H$_4$R*)Ru(CO)$_2$X (R* = neomenthyl) with phosphine and phosphite, the diastereoselectivities of products (η^5-C$_5$H$_4$R*)Ru(CO)(PR$_3$)X were fairly low (up to 19% de).[8]

Fortunately single crystals of the major diastereomer selectively grew on recrystallization of a diastereomeric mixture of **7a** from Et$_2$O–hexane. As seen in Fig. 1 the molecular structure of the major diastereomer of **7a** was established by X-ray analysis to possess the configuration (R_{C1},S_{Ru})/(S_{C1},R_{Ru}).† Previously we also found the induction of metal-centered chirality by CO insertion into the Fe–C bond of planar-chiral Fe complexes giving Cp′Fe(CO)(PPh$_3$)(COMe) **8**.[9] Facile isomerization of complex **8** around the metal center under the employed reaction conditions suggested that the selectivity of the resulting complex is controlled by thermodynamic factors. In contrast, no isomerization at a Ru center was observed for a CH_2Cl_2 solution of the major diastereomer of **7a**, isolated by recrystallization (*vide supra*), under reflux for 3 h. The reactions presented here provide the first induction of metal-centered

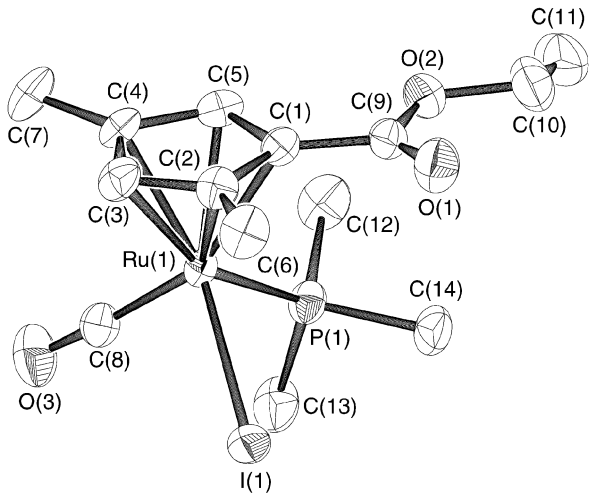

Fig. 1 ORTEP diagram of (R_{C1},S_{Ru})/(S_{C1},R_{Ru})-**7a** (major diastereomer). Hydrogen atoms are omitted for clarity.

chirality in ligand transfer reactions. Further investigation focusing on the mechanism of asymmetric induction is now in progress.

An unusually rapid Claisen rearrangement involving ring expansion

Gianluca Dimartino and Jonathan M. Percy*

First published as an Advance Article on the web 10th November 2000

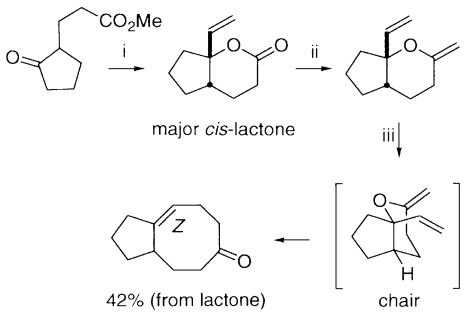
A Claisen rearrangement of a partially-fluorinated system involving ring expansion occurred at an unusually low temperature, 100 °C lower than a comparable system from the literature.

Paquette and co-workers showed how the Claisen rearrangement could be used to transform readily available vinylic lactones into medium-ring carbocycles during a series of landmark natural product syntheses.[1] The Tebbe reaction[2] fulfils a critical role in providing the vinyl ether component of the allyl vinyl rearrangement precursor; Scheme 1 summarises the sequence.

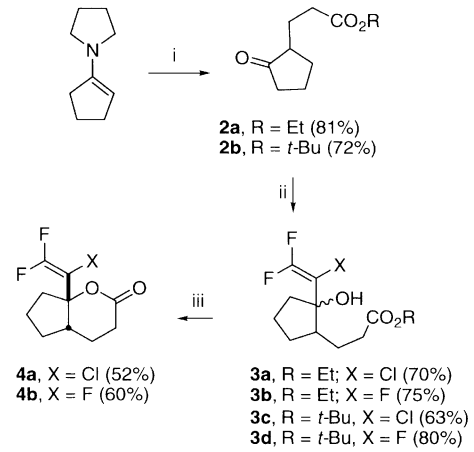
The rearrangement step requires the use of high temperatures and some special experimental precautions;[3] after the Tebbe reaction, the allyl vinyl ether is sealed in base washed tubes to minimise decomposition through enol ether protiolysis and Paquette notes that following minimal enol ether purification, traces of the Tebbe reagent by-products may be present in the rearrangement medium. Given that aluminium reagents are indeed known to cause dramatic accelerations of [3,3]-Claisen rearrangements,[4] some assistance to the rearrangement would not be surprising, though the nature of the active Lewis acid is not clear nor is the effect large given the reaction conditions (23 h at 175 °C in Scheme 1). Double bond migration can also compete with rearrangement forming non-productive allyl vinyl ethers.

We were interested to see if halogenation of the allylic fragment would accelerate the ring expansion and lower the reaction temperature. The literature suggests that γ,γ-difluorination accelerates [3,3]-Claisen rearrangements in some cases;[5] though the idea has not been tested fully and definitive theoretical work does not exist, a general concensus exists that the rehybridisation of an sp^2 CF_2 centre to sp^3 is favoured as geminal CF_2-substitution destabilises the alkene. Unambiguous accelerative effects exerted in γ,γ-difluorinated systems have also been reported in other rearrangement systems including [2,3]-Wittigs,[6] heteroatomic [2,3]-rearrangements[7] and oxy-Cope[8] reactions.

Stork enamine chemistry allowed the syntheses of ketoesters **2a** and **2b** and the addition of 1-chloro-2,2-difluoroethenyllithium[9] generated from 1-chloro-2,2,2-trifluoroethane afforded good yields of alcohol products **3a** as a mixture of diastereoisomers (Scheme 2); we assume that the major product has a *trans*-relationship between the sidechains.[3]



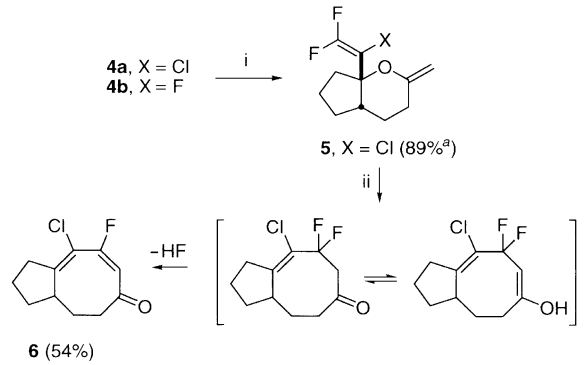
Scheme 1 *Reagents and conditions*: i, vinylmagnesium bromide; ii, $Cp_2TiCl(CH_2)AlMe_3$ (Tebbe reagent); iii, 175 °C, 23 h.



Scheme 2 *Reagents and conditions*: i, ethyl acrylate or *tert*-butyl acrylate, dioxane, rt, 18 h; ii, 1-chloro-2,2-difluoroethenyllithium or 1,2,2-trifluoroethenyllithium, THF, −78 °C to rt; iii, CF_3CO_2H, THF, rt.

No lactone products were detected; what we expected was the collapse of the initial alkoxide onto the ester in at least one of the diastereoisomers. After isolating the hydroxyester, we tried to lactonise it under acidic and basic conditions but failed. Instead of hydrolysing the acid, we synthesised *tert*-butyl ester **3c** as a mixture of diastereoisomers; a single lactone, to which we assigned structure **4a**, was isolated in moderate yield after treatment of these hydroxyesters with trifluoroacetic acid in dichloromethane. Presumably, alkyl–O cleavage and carboxy protonation allows closure to the lactone; it seems less likely that the acid intercepts an allylic cation generated by protonation of, and departure of water from, the hydroxyacid. A similar successful sequence started from 1,2,2,2-tetrafluoroethane (HFC-134a) and afforded lactone **4b**.[10]

With the lactone in hand, we attempted the Tebbe reaction† (Scheme 3) and succeeded in transforming lactone **4a** completely to a new product as evinced by ^{19}F NMR, to which we assign structure **5**.

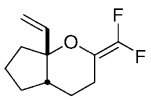


Scheme 3 *Reagents and conditions*: i, $Cp_2TiCl(CH_2)AlMe_3$, PhMe–THF, 0 to 60 °C; ii, xylene, sealed base-washed tube, 85 °C, 4 h. [a] Estimated yield based on clean ^{19}F NMR and full conversion of **4a**.

DOI: 10.1039/b007549n

In contrast, the fluorinated congener **4b** decomposed completely under Tebbe conditions. All attempts to purify and rigorously characterise **5** resulted in decomposition so we simply heated **5** at 85 °C; complete consumption took place within 4 h and a new UV active product **6** was formed.‡ The rearrangement conditions contrast sharply with those in Scheme 1. We contend that this represents an unusually facile [3,3]-Claisen ring expansion; as the Claisen rearrangement is not usually reversible, it is hard to see how dehydrofluorination *after* the rearrangement could accelerate the rearrangement itself. Enol formation from the initial ketonic product followed by elimination of HF does result in the formation of a conjugated system so dienone formation is not surprising.

We are currently in pursuit of **7** in which the fluorine atoms



7

are in the vinyl component of the Claisen precursor, so that we can compare the positional effects of fluorine atom substitution and retain both fluorine atoms in a structurally novel product.

In summary, we have shown that the rearrangement precursor can be assembled rapidly, that the fluoroallyl fragment survives Tebbe reaction conditions and that fluorine atoms at C-γ in the allyl fragment appear to lower considerably the barrier to ring expansion Claisen rearrangement.

The authors wish to thank the Engineering and Physical Sciences Research Council of Great Britain for a Project Studentship (to G. D.) under the ROPA Scheme and ICI Klea for a generous donation of HFC-134a.

Notes and references

† Tebbe procedure and ^{19}F NMR data for **5**: Tebbe reagent (2.2 ml of a 0.5 M solution in toluene, 1.1 mmol) was added to a stirred solution of lactone **4a** (0.236 g, 1.0 mmol) in dry THF (10 ml) at 0 °C. Fifteen min after the addition the mixture was allowed to warm to rt and stirred for a further 20 min. The mixture was then heated to 60 °C for 30 min, then cooled to 0 °C before being quenched with 15% NaOH solution (5 ml). After gas evolution had ceased, ether (10 ml) was added and the mixture was dried, filtered and evaporated. The residue was eluted through a short column of alumina with petroleum ether to provide **5** (0.20 g, 89% estimated) as the only fluorine-containing product: δ_F(282 MHz, $CDCl_3$) −81.8 (d, $^2J_{F\text{-}F}$ 38.7, 1F), −84.9 (d, $^2J_{F\text{-}F}$ 38.7, 1F). As **5** was expected to be unstable, it was taken on directly without further purification.

‡ Thermal rearrangement and selected data for **6**: **5** (0.234 g, 1.0 mmol) was dissolved in xylene (5 ml) in an Ace tube that had been washed with NaOH (5 M aqueous solution). The tube was then sealed and heated to 85 °C in an oil bath. The reaction was followed by ^{19}F NMR of aliquots until the starting material was consumed completely (4 h). Concentration and purification *via* silica gel column chromatography (10% ether in light petroleum) gave **6** (0.116 g, 54%) as a yellow oil; R_f (10% ether in light petroleum) 0.2 (95% by GC); δ_H(300 MHz, $CDCl_3$) 5.87 (d, $^3J_{H\text{-}F}$ 20.2, 1H), 3.03–2.88 (m, 1H), 2.87–2.53 (m, 2H), 2.42–2.30 (m, 1H), 2.20–2.02 (m, 1H), 1.98–1.05 (m, 6H); δ_F(282 MHz, $CDCl_3$) −83.9 (d, $^2J_{F\text{-}H}$ 20.0); ν_{max} (film)/cm^{-1} 1662, 1627; [HRMS (CI, M[NH_4^+]) Found: 232.0912. Calc. For $C_{11}H_{16}ClFNO$: 232.0905]; *m/z* (CI) 232 (M+NH_4^+), 215 (M+H^+); λ_{max} (CH_2Cl_2) 284 nm (ε 3600 dm^3 mol^{-1} cm^{-1}).[11]

Di-π-methane photorearrangement of *trans*-1,3-diphenylpropene upon excitation to higher singlet states in polar solvents

M. Consuelo Jiménez, Miguel A. Miranda* and Rosa Tormos

Departamento de Química, Instituto de Tecnología Química UPV-CSIC, Camino de Vera s/n, Apdo. 22012, 46071 Valencia, Spain. E-mail: mmiranda@qim.upv.es

Received (in Liverpool, UK) 27th July 2000, Accepted 16th October 2000
First published as an Advance Article on the web 10th November 2000

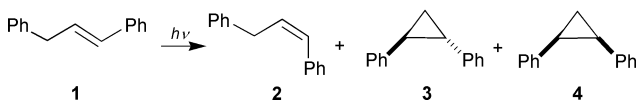
A dramatic enhancement of the di-π-methane rearrangement is observed upon excitation of *trans*-1,3-diphenylpropene (1) to its higher singlet states in acetonitrile, which leads to *trans*-1,2-diphenylcyclopropane (3) as a major photoproduct.

The photochemistry of *trans*-1,3-diphenylpropene (**1**) has attracted considerable attention in the past.[1–10] In addition to the *cis* isomer **2**, small amounts (*ca*. 5%) of *trans*- and *cis*-1,2-diphenylcyclopropane (**3** and **4**) were also detected after 17 h irradiation in benzene or cyclohexane with 254 nm UV-light (Scheme 1).[1] Under these conditions, the quantum yield of cyclopropane formation was found to be *ca.* 5×10^{-3}, and the reaction rate constant was *ca*. 8×10^{-5} s^{-1}.[10] This cyclization, which in the original paper[1] appeared 'to be without analogy', is considered 'one of the earliest examples of the di-π-methane rearrangement',[7] a reaction named according to Zimmerman and extensively investigated during the last decades.[11–13]

In spite of the considerable efforts devoted to the study of both the synthetic and mechanistic aspects of the di-π-methane rearrangement, there are two issues that have not been studied in a sufficiently systematic way and therefore require further investigation: the wavelength effects and the influence of polar solvents. We have undertaken a study of these two aspects in the case of *trans*-1,3-diphenylpropene (**1**) and found dramatic variations of the reaction efficiency. According to the obtained results, the di-π-methane rearrangement of **1** is markedly enhanced upon excitation to higher singlet states in polar solvents. This provides new mechanistic insights into the reaction and can be used as a tool to increase its preparative value.

Compound **1** was prepared following a known procedure.[14] Solutions of **1** (5 mM) in the indicated solvents were irradiated inside a Luzchem multilamp photoreactor, using the light from four 8W-lamps with emission maxima at 254 or 300 nm (Gaussian distribution), through quartz or Pyrex, respectively. The course of the reaction was followed by GC and ^{1}H-NMR; the degrees of conversion, the product distributions and the mass balances were determined using adequate standards. The results are shown in Fig. 1.

As expected,[1] very minor amounts of *trans*-1,2-diphenylcyclopropane (**3**) were formed in cyclohexane as solvent, whichever the irradiation wavelength employed. Prolonged irradiation at 254 nm resulted in partial isomerization of **3** to the *cis*-cyclopropane **4** (data not shown); in any case the combined yield of cyclopropanes never exceeded 10%. By contrast, upon irradiation of **1** in acetonitrile solution at 254 nm the di-π-methane rearrangement was dramatically enhanced, and **3** became the major product (after 100 min, the chemical yield was almost 50%). This effect was not observed when irradiation of **1** was performed at longer wavelengths. The same trend was found in solvents of intermediate polarity, where **3** was also obtained in significant yields (*e.g.* 30% in THF after 100 min irradiation at 254 nm).



Scheme 1

In order to obtain more reliable quantitative data, the di-π-methane rearrangement quantum yields were determined using the *trans–cis* isomerization of β-methylstyrene (ϕ = 0.2)[15] as actinometer. Table 1 shows that, while in a hydrocarbon solvent $\phi_{di\text{-}\pi}$ was lower than 10^{-2} (in agreement with the literature data of 5.10^{-3}), in acetonitrile it was at least one order of magnitude higher.

As the di-π-methane rearrangement of **1** and related systems is thought to occur from excited singlet states, it appeared of interest to characterise such excited states by carrying out a steady-state and time-resolved fluorescence study in the two solvents. The obtained results are shown in Table 1.

The emission spectrum consisted of a band with maximum at 308 nm. It was found to be independent of the excitation wavelength. The main maximum of the excitation spectra was located at 254 nm; smaller bands appeared at 285 and 294 nm (see Fig. 2). Thus, **1** emits from its lowest lying singlet state, even upon excitation to the higher singlet states.

The fluorescence quantum yields and the singlet lifetimes were smaller in acetonitrile than in hexane (Table 1). No significant effect of the excitation wavelength on these parameters was observed.

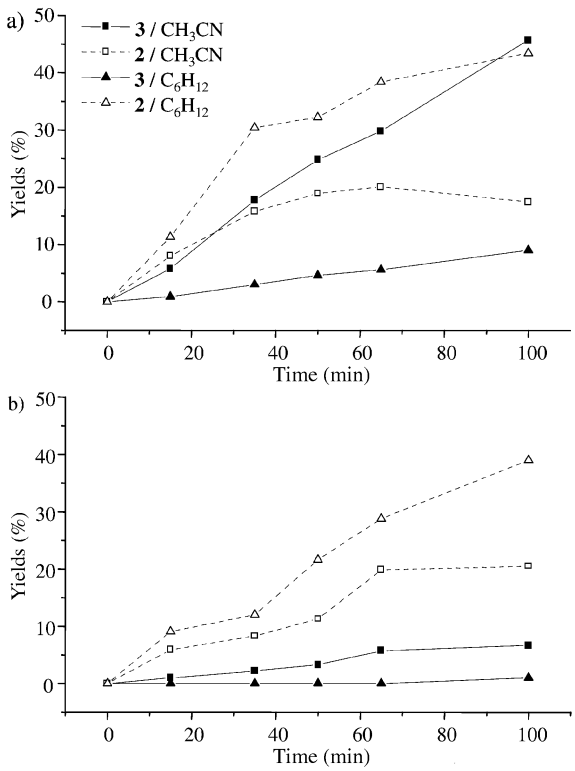


Fig. 1 Preparative yields of formation of **2** and **3**, upon irradiation of **1** in acetonitrile and cyclohexane for different times, a) at 254 nm and b) at 300 nm.

DOI: 10.1039/b006267g

Table 1 Photophysical and photochemical data of **1** at room temperature[a]

Solvent	ϕ_F	$10^{-7}k_F/s^{-1}$	τ_F/ns	$\phi_{di\text{-}\pi}$	$10^{-6}\ k_{di\text{-}\pi}/s^{-1}$	ϕ_{cis}
Hexane	0.27 (0.36)	5.5	6.1 (6.1)	< 0.01	< 1	0.12 (0.12)
Acetonitrile	0.13 (0.15)	10	2.5 (2.6)	0.11 (0.04)	44	0.10 (0.11)

[a] In general, the data have been obtained upon excitation at 254 nm. The fluorescence quantum yield and lifetimes using 285 nm as the excitation wavelength are given in brackets.

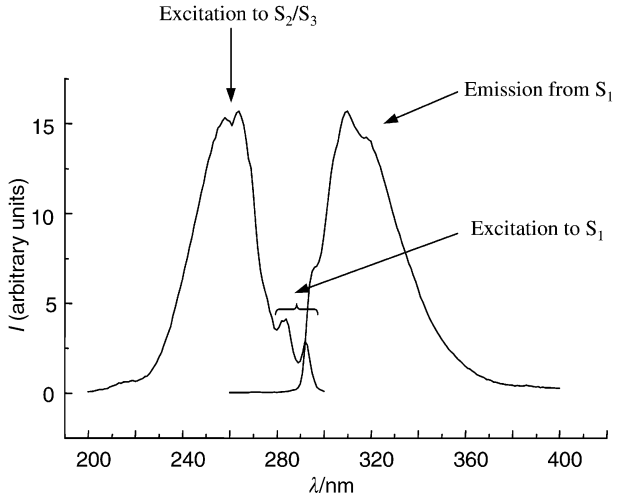

Fig. 2 Excitation and fluorescence emission spectra of **1** in hexane at room temperature.

All the accumulated experimental data on the photochemistry of **1** indicate that, although the nature of the emitting singlet state depends neither on the polarity of the solvent nor on the excitation wavelength, the di-π-methane rearrangement to **3** is strongly influenced by these factors. The sharp enhancement of this reaction upon excitation to higher singlet states in polar solvents is an unexpected behaviour, which is difficult to explain based on the currently accepted models.[11–13] In principle, **1** might photoionize from a higher singlet state in polar solvents, giving rise to the radical cation; this could be the actual rearranging species. An alternative possibility would be to start from the treatment of styrene photoreactivity based on conical intersections.[16] The order of vertically excited singlet states of styrene is believed to be $S_1 < S_2 + S_3$, where S_2 and S_3 (which possesses ionic character) overlap strongly. A conical intersection between S_3/S_2 and S_1 could provide a route to the di-π-methane product **3**. This would explain the need for excitation at shorter wavelength (to populate S_3) and the marked effect of solvents able to modify the energy surfaces of polar excited states.

We are indebted to Professor F. D. Lewis for his helpful comments. Financial support by the DGICYT (PB 97-0339) is gratefully acknowledged. M. C. J. thanks the European Commission for a Grant (MCFI-1999-00101).

Sol–gel transcription of novel sugar-based superstructures composed of sugar-integrated gelators into silica: creation of a lotus-shaped silica structure†

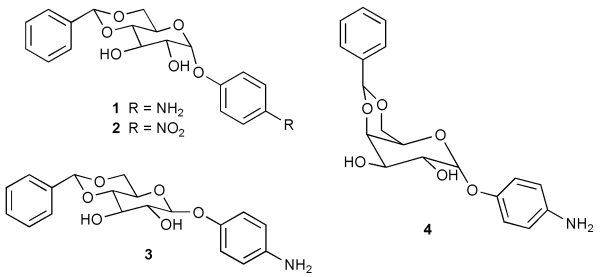
Jong Hwa Jung, Masato Amaike and Seiji Shinkai*

Chemotransfiguration Project, Japan Science and Technology Corporation (JST), 2432 Aikawa, Kurume, Fukuoka 839-0861, Japan. E-mail: seijitcm@mbox.nc.kyushu-u.ac.jp

Received (in Cambridge, UK) 6th September 2000, Accepted 23rd October 2000
First published as an Advance Article on the web 10th November 2000

Novel silica materials bearing single or multiple (lotus-shaped) hollow fiber structures with 5–10 nm inner diameters and a spherical structure were created using sugar-integrated organogelators (1–4) as templates by sol–gel polymerization of TEOS.

The sol–gel synthesis of well-ordered inorganic materials offers a new and wide-ranging approach to useful materials with controlled architecture and porosity across a range of length scales.[1,2] The direct synthesis of discrete inorganic architectures necessitates the use of dispersed organic supramolecular structures with commensurate dimensionality; for example, hollow fibers of silica have been prepared by self-assembled phospholipid fibers,[3] viroid cylinders,[4] organic crystals[2] or cholesterol-based organogel fibers as templates.[5–9] In particular, cholesterol-based organogel templates have created various hollow silica fibers with linear,[5] helical[6] and multi-layered structures[7] by sol–gel polymerization. Such results indicate that the cholesterol-based organogel fibers act as efficient tubular templates in the polymerization process.[5–9] It is already known that either cationic charge or efficient hydrogen-bonding interaction is necessary for the sol–gel transcription in order to adsorb 'anionic' silica particles onto the organic molecular assemblies.[5–9] Meanwhile, the sugar-based gelators provide various, morphologically novel superstructures such as linear,[10] helical,[10–12] bundled,[12] multi-layered cigar-like[12] and vesicular[13] structures according to their self-assembling manner in the gel phase. Despite their structural variety, however, the transcription of sugar-based organogel structures into the silica gel is unprecedented, because i) introduction of a moderate amount of cationic charge into the organogelator is very difficult and ii) the gelation ability is markedly reduced in the protic sol–gel medium necessary for sol–gel polymerization. To overcome this dilemma, we designed sugar-based organogelators **1**, **3** and **4** in which the amino group not only stabilizes the organogels due to the intensified inter-gelator hydrogen bonds[10] but also binds TEOS through hydrogen-bonding interactions.[7,8] If this idea were to work as expected, one could transcribe the novel sugar-based organogel superstructures into the silica through sol–gel polymerization. We have found that the novel morphologies of the sugar-based gelators are successfully transcribed into the silica prepared under the specific sol–gel polymerization conditions.



Compounds **1**–**4** were synthesized according to the method reported previously.[10] These compounds could gelate organic solvents such as carbon disulfide, carbon tetrachloride, toluene, ethanol, butan-1-ol, hexan-1-ol or ethylacetate,[14] indicating that they act as versatile gelators of organic solvents. In order to obtain visual insights into the aggregation mode, we observed the xerogel structures of their ethanol (or water) organogels by TEM and SEM. Fig. 1 shows typical pictures obtained from the xerogels **1**, **3** and **4**. The organogel **1** forms a 3-D network with small 5–20 nm frizzled fibrils. On the other hand, the organogel **3** shows a straighter and larger fiber structure with 50–150 nm diameter. One can observe many stripes in a gigantic organogel fiber that was stained prior to organogel fiber growth (Fig. 1c). The size of these stripes is comparable with that of the α-glucose-type organogel fiber. When stained with OsO_4 solution after organogel fiber growth, these stripes could not be observed (Fig. 1b). More interestingly, the α-galactose-type organogel **4** showed the fiber structure in ethanol (the picture is not shown here) and the spherical structure with 200–350 nm outer diameter in water (Fig. 1d).

To transcribe the superstructures formed in the organogels into the silica structure, we carried out sol–gel polymerization of TEOS using **1**–**4** in the ethanol gel phase according to the method described previously.[7,8]† We observed the SEM pictures of the silica obtained from **1** and **2** (Fig. 2a). The silica obtained from **1** shows the tubular structure with outer diameter of 20–30 nm and length of 350–700 nm whereas the silica obtained from **2** showed the conventional granular structure (not shown). It is hardly conceivable that the amino group is protonated in the presence of benzylamine. These results indicate, therefore, that the tubular structure of the silica was successfully transcribed by the hydrogen-bonding interaction

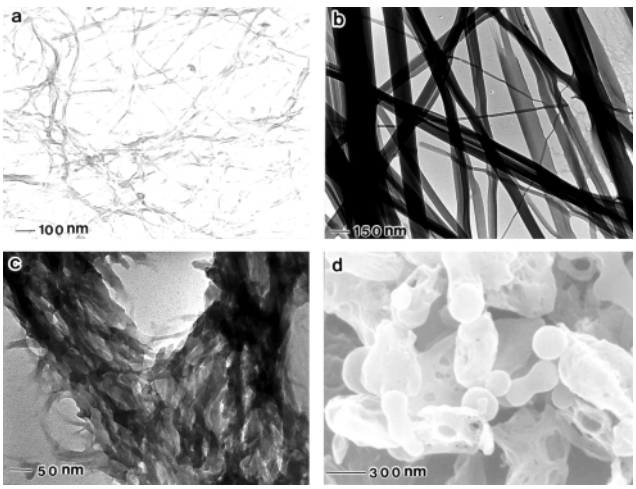


Fig. 1 TEM pictures of xerogels (a) **1** + EtOH, (b and c) **3** + EtOH and (d) SEM picture of xerogel **4** + water. In (c), the organogel was stained with OsO_4 prior to fiber grown up.†

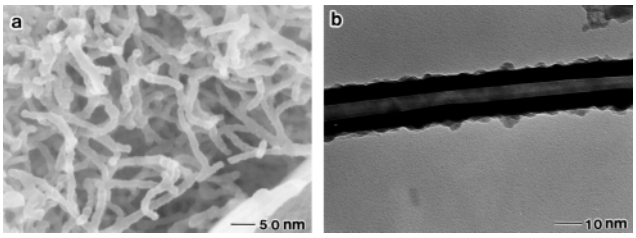

Fig. 2 SEM (a) and TEM (b) pictures of the silica obtained from ethanol organogel **1** after calcination.

between the amino group of **1** and TEOS (or oligomeric silica particles).

To further corroborate that the organogel fibers really acted as template for the growth of the tubular silica, we took the TEM pictures after removal of **1** by calcination. Very interestingly, we found the silica obtained from **1** to have an inner tube structure with 5–10 nm diameter (Fig. 2b). The inner diameter is comparable with that of the outer diameter of the fibrous organogel structure. The results again support the view that oligomeric silica particles are adsorbed onto the neutral organogel fiber through hydrogen-bonding.

In contrast, β-glucose-type organogel **3** resulted in tubular silica with a larger outer diameter of 150–200 nm (Fig. 3a). Why is the diameter of the silica obtained from organogel **3** larger than that obtained from organogel **1**? To solve this problem, we carefully took a number of TEM pictures to confirm the template effect. Very surprisingly, the TEM pictures of the silica obtained from **3** consistently reveal that the silica has an inner diameter of 50–100 nm and an outer diameter of 150–200 nm (Fig. 3b). Furthermore, the silica in the inner tube is composed of micro-tubes of 5–10 nm diameter, in total giving rise to a lotus-like structure. The inner diameter of 5–10 nm is comparable with that of the organogel fiber obtained from **1**. We now consider, therefore, that the silica was transcribed from the hierarchical bundle structure of **3**, because β-glucose-type organogel **3** features stronger intermolecular hydrogen-bonding interaction than that of α-glucose-type organogel **1**, keeping the aggregate structure more stably.[10] This novel structure in silica has been created by transcription of bundled organogel fibers.

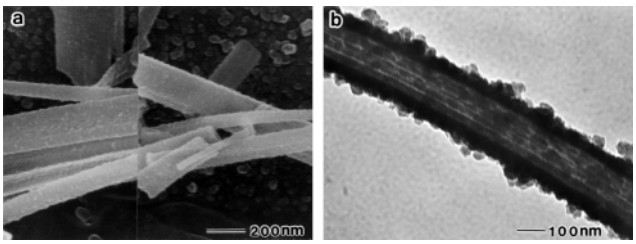

Fig. 3 SEM (a) and TEM (b) pictures of the silica obtained from ethanol organogel **3** after calcination.

Fig. 4 shows SEM pictures of the silica structure obtained from aqueous gel **4** by sol–gel polymerization. The silica obtained from ethanol organogel shows a fiber structure with *ca.* 1400 nm diameter, whereas the silica obtained from aqueous gel shows a hollow spherical structure with 500–1000 nm inner diameter and a 200–300 nm thick wall, which probably consists of multi-layers. These results indicate that the sugar-integrated gel systems can create various silica structures in the gel phase.

As a summary of the foregoing observations, we now propose the mechanism for the formation of the novel lotus-type silica structure from organogel **3** and that of the single hollow fiber silica structure from organogel **1** (Fig. 5). Oligomeric silica species are adsorbed onto the surface of the bundled fibrous structure of **3** and the polymerization further proceeds along these bundled fibrils. This propagation mode eventually yields the lotus-type silica after combustion of gelators by calcination (Fig. 5c; lower). In contrast, **1** provides the minute fibrous structure. Then, the tubular silica grows up by sol–gel

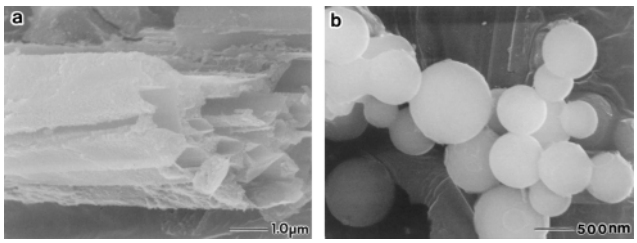

Fig. 4 SEM pictures of the silica obtained from (a) ethanol organogel **4** and (b) aqueous gel **4** after calcination.

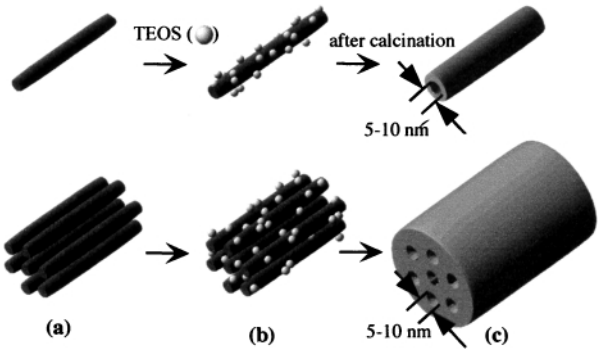

Fig. 5 Schematic representation for the creation of the lotus-like silica structure from the organogel state of **3** (lower) and single hollow fiber silica from **1** (upper) by sol–gel polymerization: (a) gelators; (b) sol–gel polymerization of TEOS and adsorption onto the gelators and (c) lotus-like silica structure (lower) and single hollow fiber structure (upper) of the silica formed after calcination (SEM and TEM pictures in Figs. 2 and 3 were taken at this stage).

polymerization along this surface (Fig. 5b). As supported by the correlation between the xerogel structures (Fig. 1) and the resultant silica gel structures (Figs. 2 and 3), the sugar-based organogel structures are directly and scrupulously transcribed into the silica structures utilizing hydrogen-bonding interactions.

In conclusion, the present paper has demonstrated a new methodology to prepare lotus-like and spherical structures of silica using sugar-integrated organic gelators. These novel silica structures are created by hydrogen-bonding interactions with the fine structure of the gelators. We believe that this concept will be more generally applicable to further new silica preparations using various organogel superstructures as templates.

Vitamin D_1

Edwin S. Tan,† Fook S. Tham,‡ and William H. Okamura*

Department of Chemistry, University of California, Riverside, CA 92521 USA. E-mail: william.okamura@ucr.edu

Received (in Corvallis, OR, USA) 1st September 2000, Accepted 13th October 2000

The X-ray crystallographic structure of vitamin D_1 reveals a sandwich-like 1 : 1 heterodimeric complex of lumisterol$_2$ and vitamin D_2 with the latter in its α-chair conformer.

Vitamin D_1, the very first anti-rachitic factor, which played a historical role in the development of the vitamin D field, was discovered by Windaus[1] with contributions from Askew and co-workers[2] and Reerink and Van Wijk[3] in 1931. This sharp melting, biologically active substance, produced photochemically from ergosterol (provitamin D_2, **3a**), was soon thereafter discovered to be a 1 : 1 crystalline heterodimer of lumisterol$_2$ (**4a**) and vitamin D_2 (**1a**).[1] This was all at a time when the involvement of previtamin D_2 (**2**), pyrocalciferol (**5**) and isopyrocalciferol (**6**) in the now well accepted scheme (Fig. 1) was not yet recognized.[4] Early unsuccessful attempts to obtain the X-ray structure of crystalline, monoclinic D_2 were reported by Bernal in 1932[5] and by Bernal and Crowfoot in 1935,[6] but interestingly, the successful completion of the structure was not completed until 1994![7] The X-ray structure of the monoclinic isomorph revealed that the D_2 was essentially the same as that in the very interesting finding in 1976[8] by Hull *et al.* that the crystalline orthorhombic form of pure **1a** (a feature also characteristic of **1b**, vitamin D_3[9]) exists as a pseudo-homodimer. What is novel about **1a** (and also **1b**) is that it crystallizes as a 1 : 1 complex of α- and β-A-ring chairs (Fig. 2), the former with an equatorial disposition of the C-3 hydroxy and the latter with an axial orientation of the same hydroxy. Not surprising is that in solution vitamin D_2 exists as a dynamically equilibrating mixture of the same α- and β-chairs and that this ratio is solvent dependent.[10]

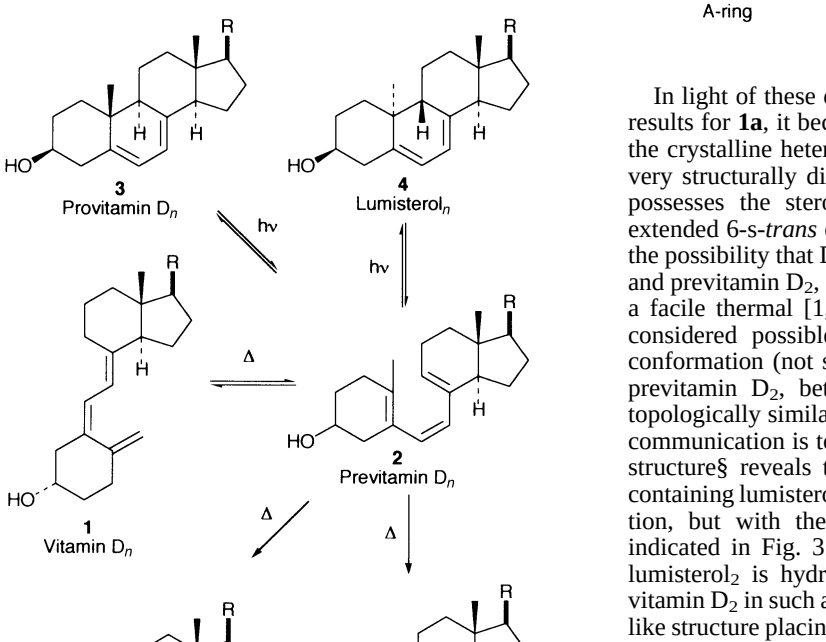

Fig. 1

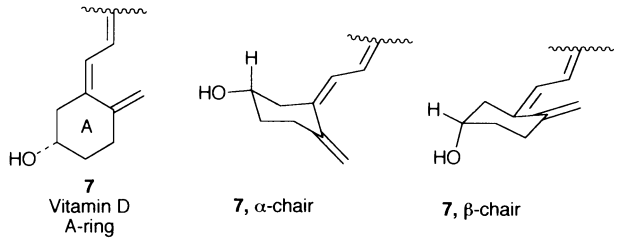

Fig. 2

In light of these divergent solid state and solution structural results for **1a**, it became of interest to consider the structure of the crystalline heterodimeric D_1, a complex of two seemingly very structurally dissimilar molecules **4a** and **1a**. The former possesses the steroid skeleton, but the latter exists in an extended 6-s-*trans* conformation. It was intriguing to entertain the possibility that D_1 might in fact be a complex of lumisterol$_2$ and previtamin D_2, a substance related to vitamin D_2 by way of a facile thermal [1,7]-sigmatropic shift. Alternatively, it was considered possible that the D_2 might exist in its 6-s-*cis* conformation (not shown), thus rendering it, like the putative previtamin D_2, better able to co-crystallize with the more topologically similar lumisterol$_2$ molecule. The purpose of this communication is to report that in fact the single crystal X-ray structure§ reveals that vitamin D_1 is simply a 1 : 1 complex containing lumisterol$_2$ and vitamin D_2 in its 6-s-*trans* conformation, but with the A-ring in the α-chair conformation as indicated in Fig. 3. It is interesting that the axial 3β-OH of lumisterol$_2$ is hydrogen bonded to the equatorial 3β-OH of vitamin D_2 in such a manner as to form a face to face sandwich-like structure placing the two C_{18} angular methyl group carbons in close proximity with one another.

Samples of vitamin D_1 were prepared by collecting crystals (mp, 119–121 °C; literature[2] mp 124–125 °C) from a slowly evaporating solution containing a 1 : 1 mixture of lumisterol$_2$ and vitamin D_2 (acetone). Similar attempts to obtain crystalline

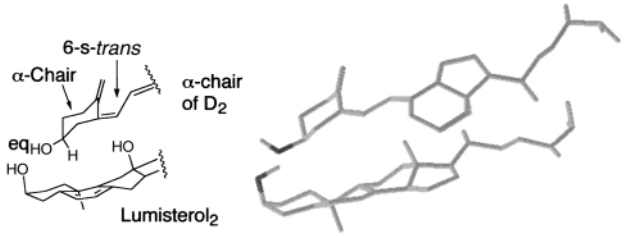

Fig. 3

DOI: 10.1039/b007191i

material from a 1 : 1 mixture of previtamin D_2 (**2a**) and vitamin D_2, lumisterol$_3$ (**4b**) and vitamin D_3 (**1b**), or previtamin D_3 (**2b**) and vitamin D_3 failed. Lumisterol$_2$ and previtamin D_2 were prepared by photochemical irradiation of **3a** (Hanovia 450 W medium pressure mercury lamp, pyrex vessel, EtOH) followed by HPLC purification (20% EtOAc–hexanes, silica column). Previtamin D_2 could also prepared by thermal equilibration with vitamin D_2 followed by HPLC separation.[11] Lumisterol$_3$ and previtamin D_3 were prepared in a similar way from 7-dehydrocholesterol or from vitamin D_3 as appropriate. The X-ray structures of pure lumisterol$_2$ and lumisterol$_3$ have been previously reported[12] as have vitamin D_2 and D_3.[7–9] Thus, the vitamin D_1 result reported herein represents a unique combination of these earlier crystallographic results.

Synthesis of 1,2-*trans C*-glycosyl compounds by reductive samariation of glycosyl iodides

Nicolas Miquel, Gilles Doisneau and Jean-Marie Beau*

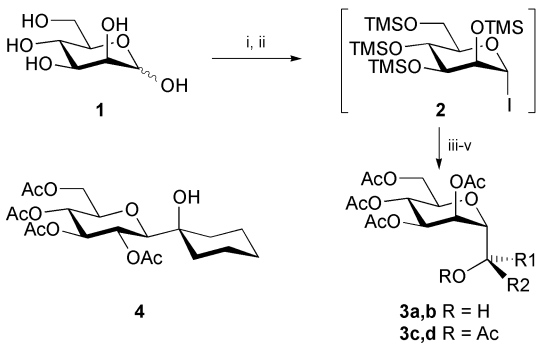
Laboratoire de Synthèse de Biomolécules, UMR CNRS 8614, Institut de Chimie Moléculaire, Université Paris-Sud, F-91405 Orsay Cedex, France. E-mail: jmbeau@icmo.u-psud.fr

Received (in Liverpool, UK) 3rd August 2000, Accepted 16th October 2000
First published as an Advance Article on the web

Reductive samariation of per-*O*-trimethylsilyl or benzyl glycopyranosyl iodides in the presence of carbonyl compounds provides the corresponding 1,2-*trans*-*C*-glycosyl compounds in good yields.

Numerous synthetic methods have been developed for the preparation of *C*-glycosyl compounds, analogues of glycosides in which the interglycosidic oxygen atom has been replaced by a carbon atom.[1] Recent work in our laboratory has focused on a direct method for the synthesis of *C*-glycosyl compounds derived from neutral hexoses by the reductive samariation of anomeric 2-pyridyl sulfones in the presence of carbonyl compounds (Barbier procedure).[2] While the procedure is efficient with the manno series,[3] it is unsatisfactory with the gluco- or the galactopyranosyl series[2] because of too high a level of the competing β-elimination (an elimination–C–C bond formation ratio of approximately 1:1). We now report an unexpected solution to this problem starting from glycosyl iodides as efficient *C*-glycosyl donors in reductive samariation experiments. These glycosyl halides, first prepared by the reaction of glycosyl bromides with sodium iodide[4] and rarely used as electrophilic *O*-glycosyl donors,[5] can be prepared from methyl glycosides, glycosyl acetals and glycosyl acetates,[6] hemiacetals[7] or trimethylsilyl glycosides.[8] Either a rapid synthesis of structurally simple *C*-glycosyl compounds from commercial free sugars *via* the per-*O*-trimethylsilyl glycosyl iodides,[8] or a multi-step construction of more complex *C*-glycosyl compounds with the more practical per-*O*-benzyl iodides is possible.

Silylation of D-mannopyranose **1** and treatment of a DCM solution of the per-*O*-silylated derivative with iodotrimethylsilane (TMSI) according to the procedure of Uchiyama and Hindsgaul[8] provided anomeric iodide **2** which, after solvent removal, was successively treated with the carbonyl compound (2 equiv.) and a THF solution of SmI_2 (2.2 equiv.) at rt (Scheme 1 and Table 1). On completion of the reaction, indicated by the disappearance of the blue color of SmI_2 in approximately 1.5 h, the products were desilylated by addition of acidic MeOH and analyzed as their acetylated compounds. For the acetylation



Scheme 1 *Reagents and conditions*: i, TMSCl, Et_3N, DMF, 0 °C; ii, 1.1 equiv. of TMSI, CH_2Cl_2, 25 °C, 0.5 h; iii, 2 equiv. of carbonyl compound, 2.2 equiv. of SmI_2, THF, 25 °C, 1.5 h; iv, MeOH, 1 M HCl, (3:1, v/v), 25°C; v, Ac_2O, 2,6-lutidine, 25 °C.

Table 1 SmI_2-induced coupling of silylated glycopyranosyl iodides with carbonyl compounds[a]
