where the size of the involved water-cluster varies from $n = 1$ to 3. For reaction (2) both laboratory studies[7,8] and direct dynamics studies by us[9] on the atmospheric reaction rate constants showed that owing to hydration to sulfuric acid, the lifetime of SO_3 is comparable to that of SO_2 which undergoes oxidation by hydroxyl radicals. The good agreement in the obtained rates demonstrates the reliability of the theoretical methods, namely variational transition state theory corrected for microcanonical optimized multidimensional tunneling on the basis of a hybrid density functional theory potential energy surface [B3LYP/6-31+G(d)].[10,11] Because of the thermodynamic instability of 'sulfurous acid' (H_2SO_3) this species has never been isolated, and accordingly no experimental studies have been performed on reaction (1). This instability has been noted in the literature[12] and is here confirmed to amount to 6.8 kcal mol^{-1} in electronic energy at the CCSD(T)/aug-cc-pVDZ//MP2/aug-cc-pVDZ level of theory. Application of the theoretical approach to the unimolecular isomerization in reaction (1) leads to the reaction rates shown in Fig. 1. It becomes clear that the hydration of SO_3 is much faster than the hydration of SO_2 if more than one water molecule is allowed to participate for all temperatures prevailing in our atmosphere. Only in the case of very low water vapor pressures, under which conditions no complexes of $>1:1$ stoichiometry form, and at temperatures below 150 K the hydration of SO_2 is faster than the one of SO_3. However, 'faster' here in fact means 'less slow' as both conversions are unmeasurably slow under such conditions. In contrast to the facile and fast reactions in aqueous solution ($k = 3.4 \times 10^6$ s^{-1})[13] and the gas–liquid interface[14] the pure gas-phase process involving SO_2–water clusters[15] is very slow. As a consequence, the reaction path not involving hydration of SO_2, namely oxidation of SO_2 with subsequent hydration of SO_3, will be favored under atmospheric conditions. This arises mainly from the fact that the barrier for the SO_2 hydration decreases from 33 kcal mol^{-1} ($n = 1$) to 20 kcal mol^{-1} ($n = 2$) and 13 kcal mol^{-1} ($n = 3$), whereas the barrier for hydration of SO_3 decreases from 28 kcal mol^{-1} ($n = 1$) to 4 kcal mol^{-1} ($n = 3$, rotary)[9] according to the B3LYP/6-31+G(d) level of theory. At the CCSD(T)/aug-cc-pVDZ//MP2/aug-cc-pVDZ level of theory taking electron correlation more accurately into account, the barriers are different by at most 10%. In the literature at the G2[16] and QCISD(t) levels[12] the barriers are also found to be similar.

Additionally, the preassociation reaction forming the hydrogen bonded complex is more favorable for SO_3 than for SO_2, as indicated by a gain in electronic energy of 19.8 kcal mol^{-1} compared to 14.7 kcal mol^{-1} [CCSD(T)/aug-cc-pVDZ//MP2/aug-cc-pVDZ values for $n = 2$]. Therefore, the difference in the overall rate constant is increased by four orders of magnitude at 250 K in addition to the difference seen in Fig. 1. For a first order rate law for SO_2 or SO_3 this implies that the SO_2 pressure has to be 10 orders of magnitude higher than the SO_3 pressure at 250 K and as much as 20 orders of magnitude higher at 150 K for SO_2 hydration to become competitive. However, at an altitude of 30 km the steady state concentration of SO_3 of *ca.* 10^5 molecules cm^{-3} compared with that of SO_2 of *ca.* 10^{10} molecules cm^{-3} is only lower by 5 order of magnitude.[8] It is, therefore, safe to assume that the dominant mechanism converting S(IV) to S(VI) species if *first* the oxidation of SO_2 by OH$^{\cdot}$ and *second* the isomerization of a SO_3–H_2O cluster of a

Reaction of $(NH_4)_2MoS_4$ and $(NH_2OH)_2{\cdot}H_2SO_4$ under hydrothermal conditions led to the new compound $(NH_3OH)_{3.9}MoS_{4.8}$ I, which crystallises from acetone solution producing hollow tubules of nanoscopic size (50–500 nm diameter, 0.1–20 μm length); thermal decomposition of I led to the formation of highly dispersed tubular MoS_2.

The recent discovery of hollow graphite tubules of nanometer dimensions[1] has greatly stimulated the study of nanoscopic structures. Nanotubes are envisaged for potential applications in several areas such as catalysis, composite materials and nanowires, up to artificial muscles and intramolecular junctions.[2] Several types of nanotubes (and generally, hollow microtubules) have been synthesised. Arc discharge or high temperature treatment of molecular precursors have been applied to elaborate the nanotubes of simple materials such as C,[1] MoS_2[3] or BN.[4] Fullerene-like nanoparticles and nanotubules of the MS_2 sulfides (M = Mo, W) could be obtained using high temperature reactions of the corresponding oxides with H_2S, or by means of sonoelectrochemical syntheses.[5] Different types of nanoscopic tubules were obtained at low temperatures, using templating reactions with organic surfactants. This approach has led to hollow tubules of oxides such as SiO_2[6] or V_2O_5.[7] Tubular MoS_2 has been prepared by decomposition of $(NH_4)_2MoS_4$ within the pores of an alumina membrane, followed by dissolution of the templating oxide in aqueous NaOH.[8]

Here, we report on a new type of inorganic hollow tube, formed at low temperature without addition of template. A newly synthesised compound $(NH_3OH)_xMoS_y$, ($3 < x < 4$, $4 < y < 5$) prepared hydrothermally, led to tubules upon crystallization at room temperature.

The preparation technique was as follows. To a stainless steel vessel were added solutions of 2.8 g $(NH_4)_2MoS_4$ (ATM) in 100 ml of water and 8 g $(NH_2OH)_2{\cdot}H_2SO_4$ dissolved in 100 ml of water. An H_2S pressure of 20 bar was then applied to the reaction mixture and after 30 min at 493 K a brown powder was filtered off, washed with distilled water and dried in air. The product was then treated with acetone in a Soxhlet apparatus for 2 h. A dark red washing solution of **I** was obtained and a brown insoluble residual **II** (*ca.* 1 g) was collected from the filter. The acetone solution was cooled to room temperature and evaporated in a glass vessel in air. After evaporation of the acetone, 0.7 g of light brown powder **I** was obtained.

The solids were characterised by several physico-chemical techniques, including X-ray diffraction (XRD), FTIR spectroscopy and surface area measurements. High resolution transmission electron microscopy (HREM) combined with EDX analysis was performed on a JEOL 2010 microscope. EXAFS measurements were performed at the Laboratoire d'Utilisation du Rayonnement Electromagnétique (LURE), on the XAS2 spectrometer. Measurements were carried out in transmission mode at the Mo K edge in the range 19900–21000 eV at 8 K. The EXAFS data were treated with SEDEM[9] and FEFF[10] programs. X-Ray photoelectron spectra (XPS) were measured on a VG ESCALAB 200R spectrometer using Al-Kα radiation. Thermal decomposition of solids was studied using a mass-spectrometer Gas trace A instrument (FISONS Instruments).

Dispersed MoS_2 for catalytic applications is often obtained from the decomposition of ATM. To prepare dispersed MoS_2 in an aqueous medium, we studied the reactions of ATM in the presence of inorganic reducing agents, such as hydroxylamine and hydrazine.[11] If a solution of $(NH_2OH)_2{\cdot}H_2SO_4$ was added at room temperature to aqueous ATM, an MoS_3 suspension was formed according to reaction (1), due to the acidic pH of the reaction medium.

$$(NH_4)_2MoS_4 + 2\ H^+ \rightarrow MoS_3 + 2NH_4^+ + H_2S \qquad (1)$$

However, under the mild hydrothermal conditions used (20 bar H_2S, 493 K, 30 min), MoS_3 reacted further to give a dark brown solid **I** which was insoluble in water but partially soluble in acetone. According to chemical analysis, solid **I** had composition $(NH_3OH)_{3.9}MoS_{4.8}$, close to the idealised formula $(NH_3OH)_4MoS_5$.

The insoluble brown residual **II** had chemical composition $MoS_{7.88}$, close to the MoS_8 stoichiometry. The amounts of nitrogen and oxygen in solid **II** were $< 0.5\%$.

Scanning electron microscopy revealed that **I** consists mostly of hollow tubes of different diameters and lengths. The external diameter of tubules varied from 50 to 500 nm whereas the length was between 0.1 and 20 μm. Some irregular spherical agglomerates were also observed. Transmission electron microscopy (Fig. 1) showed that the tubes are hollow, with straight walls. Electron diffraction did not reveal any crystal ordering in the tubules or spherical agglomerates.

Solid **II** consisted of shapeless agglomerates and was XRD amorphous but was fairly homogeneous according to HREM

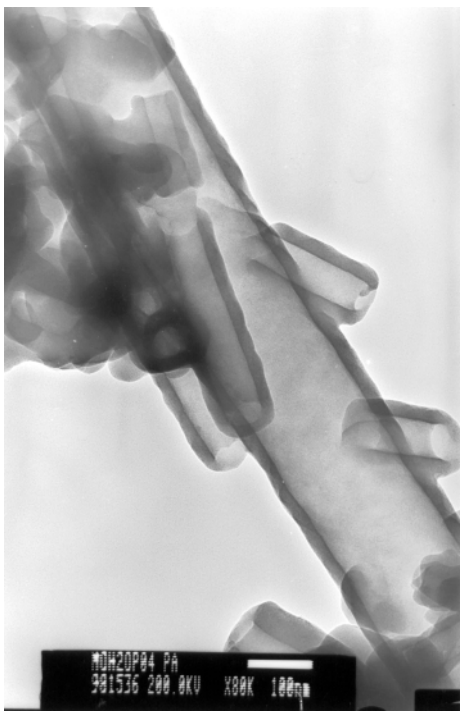

Fig. 1 Transmission electron micrograph of tubules of solid **I**.

DOI: 10.1039/b001406k

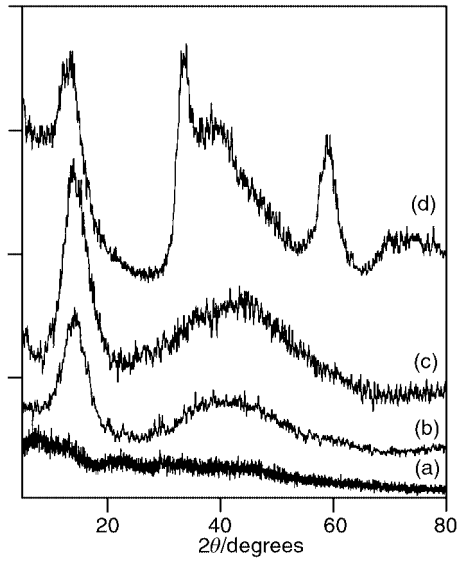

Fig. 2 Powder XRD patterns of (a) solid **I**, (b) solid **II**, (c) reference MoS_3 and (d) MoS_2 obtained from decomposition of **I** at 823 K.

and EDX studies. Formation of **II** has been observed under different reaction conditions. A solid of composition $MoS_{7.6}$ was obtained at 1 bar of H_2S and 373 K (in this case an acetone-soluble product was not formed). We suggest therefore that solid **II** is a distinct compound close to the MoS_8 composition.

The preparation of microtubules **I** was reproduced under various reaction conditions. For example, at 473 K and for a reaction time of 1 h, a solid of composition $(NH_3OH)_{3.4}MoS_{4.7}$ was obtained, in somewhat lower yield and with a decreased but still high number of tubules. Tubules **I** could be repeatedly redissolved in acetone and reprecipitated by slow evaporation, either at ambient conditions or at 313 K.

The role of hydroxylamine in the synthesis is, as yet, not clear but is certainly important, since without addition of hydroxylamine only poorly crystallised MoS_2 was obtained under the same reaction conditions. Our attempts to prepare single crystals of **I** suitable for structure determination, *via* crystallisation from alcohols or methylformamide were not successful.

The powder XRD pattern of **I** [Fig. 2(a)] showed only a broad peak, corresponding to an interplanar distance of *ca.* 1.08 nm. Solid **II** [Fig. 2(b)] was also XRD amorphous, with broad maxima close to those of the MoS_3 reference sample [Fig. 2(c)].

In the IR spectrum of **I**, intense absorptions at 499 and 350 cm^{-1} were observed, characteristic for Mo–S bonds.[12] The IR spectrum of **II** showed the same Mo–S features, and a broad peak at *ca.* 520 cm^{-1} attributed to S–S stretching vibrations. Comparison of the IR spectra suggests that **II** contains many S–S bonds whereas they are absent in **I**.

XPS binding energies were studied at the Mo 3d and S 2p levels (C 1s reference binding energy = 284.5 eV). The binding energies are estimated at an accuracy of *ca.* 0.2 eV. Single molybdenum species were observed in both **I** and **II**. The Mo $3d_{5/2}$ binding energies in **I** and **II** were 229.8 and 229.1, respectively, suggesting that in **I** the electron density on Mo is lower, than in **II**. The sulfur S 2p binding energies are 163.2 and 162.8 eV for **I** and **II**, at the positions of ionic (sulfoxide) sulfur[13] and terminal bidentate S_2^{2-} species, respectively.[14] Both changes of molybdenum and sulfur signals from **I** to **II** correspond to the removal of S–S bridges with simultaneous formation of terminal Mo–S species, in which sulfur is probably coordinated to nitrogen or oxygen.

Results of EXAFS studies of **I** and **II** are listed in Table 1 and compared to the literature data on Mo coordination in some reference compounds. For the EXAFS fit for **I** and **II**, the energy shift ΔE_0 was 4 eV for the Mo–S and 9 eV for the Mo–Mo shell. Debye–Waller factors for both shells were in the range *ca.* 2.10–5 nm^2. According to the EXAFS fitting results, molybdenum has approximately the same number (*N*) of S and Mo neighbours in **I** as in MoS_3, but a considerably longer Mo–Mo distance. By contrast, a short Mo–Mo distance was observed in **II**, but the number of S neighbours is significantly higher than in MoS_3, and even higher than that in $MoS_{4.7}$.[15]

Table 1 EXAFS fitting results of molybdenum coordination in **I** and **II** as well as for some reference sulfide compounds

Sample (state[a])	Mo–S	*N*(S)	Mo–Mo	*N*(Mo)	Ref.
I (am)	2.33	1.3	3.05	1.08	—
	2.49	3.8			
II (am)	2.40	4.1	2.75	0.92	—
	2.48	4.5			
MoS_3 (am)	2.43	6	2.75	1	15
$MoS_{4.7}$ (am)	2.44	7.33	2.78	1.33	15
MoS_3 (am)	2.44	5.5	2.75	1–2	16
$(NH_4)_2Mo_2S_{12}\cdot 2H_2O$ (cr)	2.38–2.5	8	2.82	1	17

[a] am = Amorphous, cr = crystalline.

Both **I** and **II** are chemically derived from MoS_3 (which itself possesses a poorly organized, probably chainlike structure). It can be suggested that **I** and **II** are formed by addition of sulfide ions or of zerovalent sulfur to the MoS_3 chains, giving, respectively, MoS_5^{2-} (solid **I**) or MoS_8 (solid **II**). Since **I** is soluble in acetone it is probably oligomeric with short chains, whereas **II** is insoluble in any solvent, which suggests a three-dimensional or chainlike structure. The reason why a tubular morphology is adopted by **I** is not yet understood and the reaction mechanism requires further clarification.

Heating compound **I** under an inert gas flow at 823 K leads to its decomposition with formation of pure MoS_2 [Fig. 2(d)]. Decomposition of **I** was monitored by mass spectrometry which established a multistep process with formation of water and ammonia at *ca.* 435 K, and water and nitrogen at 683 K. According to thermogravimetric analysis, the mass loss at 823 K was 64%, whereas the calculated value for $(NH_3OH)_4MoS_5$ decomposition to MoS_2 is 59%. The MoS_2 obtained from **I** showed a specific surface area of 65 $m^2\ g^{-1}$ with retention of the same tubular morphology as the precursor. The synthesis reported here provides therefore a route to large scale production of hollow microtubules of the technologically very important MoS_2.

2D correlation IR spectroscopy of xylene isomerisation on H-MFI zeolite

F. Thibault-Starzyk,* Alexandre Vimont, Christian Fernandez and Jean-Pierre Gilson

Laboratoire Catalyse & Spectrochimie, CNRS - Institut des Sciences de la Matière et du Rayonnement, 6 Boulevard du Maréchal Juin, F-14050 Caen cedex, France. E-mail: fts@ismra.fr

Received (in Oxford, UK) 10th March 2000, Accepted 26th April 2000
Published on the Web 22nd May 2000

2D correlation IR spectroscopy (2D-COS) allows quantitative monitoring of xylene isomers in the pores of H-MFI zeolite under working conditions; coke bands invisible in the direct spectra are detected, indicating traces of coke localised on specific OH groups.

IR spectroscopy is nowadays used routinely for the study of the surface of working heterogeneous catalysts in catalytic reactors equipped with IR transparent windows. It has, for example, been applied to xylene isomerisation in zeolites.[1] The main difficulty resides in the complexity of the spectra, and in the choice of adequate bands for the characterisation and quantification of species of interest. Detection of trace compounds is often a problem because of the low signal to noise ratio obtained at high temperatures in the IR cell. New data treatment methods such as 2D correlation IR spectroscopy (2D-COS) have led to significant improvements in this area.[2,3] We report here, the application of 2D-COS to the *in situ* IR study of *o*-xylene isomerisation in H-MFI zeolite under working conditions. This led to an improvement in the quantitative monitoring of xylene isomers in the micropores of the solid and to the detection of traces of coke in the catalyst. A correlation was found between the degree of coke incorporation and the perturbation of specific hydroxy groups in the solid.

Experiments were performed in a microreactor-IR cell already described elsewhere,[4] in which the spectra of both the self supported wafer of the catalyst and the adsorbed species can be recorded during the reaction up to 725 K. A nitrogen gas stream was diverted to a saturator filled with *o*-xylene and maintained at a constant temperature (300 K) and the resulting mixture fed to the reactor/IR cell. The reaction conditions were: 473–573 K, 8 Torr *o*-xylene partial pressure, WHSV: 2.7 h^{-1}. The reaction products exiting the reactor were analysed by gas chromatography. The spectrometer was a Nicolet Magna 750, used at 2 cm^{-1} resolution (Happ-Genzel apodisation function).

The spectrum of the activated zeolite at 473 K shows in the ν(OH) stretching vibration region two intense bands at 3738 and 3602 cm^{-1}, assigned to the stretching vibrations of silanols and acidic bridged hydroxy groups, respectively. Upon *o*-xylene adsorption at this temperature, the intensities of both bands immediately decreased. Attenuation is moderate for the silanol band (10%), indicating only a weak interaction. By contrast, the intensity decrease of the acidic hydroxy band is much more substantial (70% reduction) and can be assigned to the formation of hydrogen bonds with the aromatic molecule. The perturbed OH leads to a broad band centred at 3200 cm^{-1}. At the same time, a complex group of bands appears between 1380 and 1600 cm^{-1}, assigned to vibrations of the adsorbed *o*-xylene. During the first few minutes of reaction, a new band appears at 1605 cm^{-1}, assigned to the ν_{8a} or ν_{8b} vibration of *m*-xylene (1610 cm^{-1} in the liquid phase). Although *p*-xylene should exhibit an intense and characteristic band (1515 cm^{-1} in the liquid phase), this is not observed on the surface, although *p*-xylene is present in the reaction products (GC analysis). This is probably related to its fast diffusion in the pore system preventing its building up and detection inside the catalyst pores under our reaction conditions (2 ± 0.2% conversion).

2D-IR spectroscopy was introduced by Noda *et al.*,[2] and was initially based on time resolved IR spectroscopy of a sinusoidal perturbation such as that produced by the mechanical strain of a vibrating polymer. Noda later proposed to generalise his method to non-sinusoidal perturbations such as irradiation or electrochemical perturbations,[3] leading to significant increases in sensitivity and resolution of complex band groups. Here, we consider the chemical reaction as the perturbation. We used 2D-COS analysis of a series of spectra recorded between 4 and 14 min reaction time in the *o*-xylene isomerisation reaction to resolve the aromatic vibration bands (Fig. 1).

2D-COS allows analysis of spectral changes with time. Spectra can be obtained either by a Fourier transform of the interferograms recorded at regular time intervals, or by a simple covariance analysis in the spectral series, by use of eqn. (1)

$$\mathrm{COV}\,(\nu_1,\nu_2) = \frac{1}{N}\sum_{i=1}^{i=N}[A_i(\nu_1) - \bar{A}(\nu_1)][A_i(\nu_2) - \bar{A}(\nu_2)]$$

$$r(\nu_1,\nu_2) = \frac{\mathrm{COV}\,(\nu_1,\nu_2)}{\sigma_{\nu 1},\sigma_{\nu 2}} \qquad (1)$$

where N is the total number of spectra recorded, $A_i(\nu_1)$ the absorbance at ν_1 for the ith spectrum, $\bar{A}(\nu_1)$ the absorbance at ν_1 for the reference spectrum and $r(\nu_1, \nu_2)$ the correlation coefficient between intensities at wavenumbers ν_1 and ν_2. The reference spectrum is generally the arithmetic mean spectrum but the first spectrum or the spectrum at steady-state can also be used. $\sigma_{\nu 1}$, $\sigma_{\nu 2}$ are the standard deviations at ν_1 and ν_2, respectively. A 2D display of the covariance or correlation between all frequencies in the spectrum gives information on the relationship existing between various bands, depending on their simultaneous or independent intensity variations. In the following, we elect to split the graphical display into two separate sets for positive and negative covariance, to identify bands varying in the same way (positive covariance, Fig. 2) or in opposite ways (negative covariance, not shown). During isomerisation, *o*-xylene is progressively replaced by *m*-xylene which accumulates in the pore system. A negative correlation

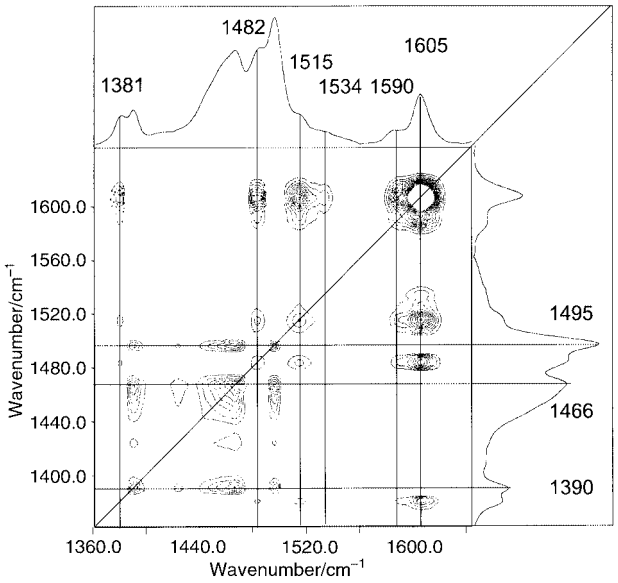

Fig. 2 2D positive covariance map obtained with 34 spectra recorded between 4 and 14 min reaction time at 473 K. The spectra shown on the axes are the mean spectra in the series.

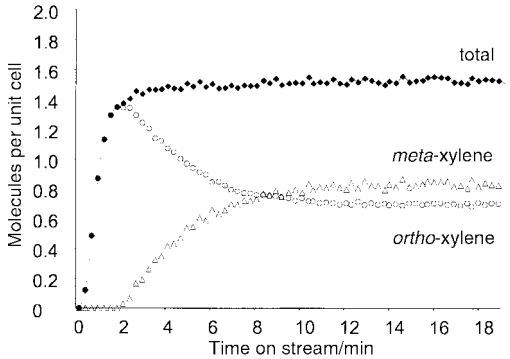

Fig. 3 Concentration of isomers in the pores at 473 K determined by IR using bands studied by 2D-COS.

should therefore appear between the *o*-xylene bands (whose intensities decrease) and the *m*-xylene bands (whose intensities increase). On the other hand, bands having contributions from *o*-xylene are autocorrelated, as are bands having contributions from *m*-xylene. Assignment of bands is thus considerably eased. Additionally, it was possible to detect very weak bands which are invisible in the normal 1D spectra. At 473 K, *m*-xylene bands occur at 1605, 1590, 1535, 1515, 1482 and 1381 cm^{-1}, and *o*-xylene bands are at 1495, 1466, 1458, 1423, 1412 and 1390 cm^{-1}. The regions exhibiting the most intense negative correlation were chosen for the *in situ* quantitative monitoring: 1605 cm^{-1} for *m*-xylene and 1466 cm^{-1} for *o*-xylene. Approximate extinction coefficients for these two bands were determined by adsorbing the two pure isomers on the catalyst at 400 K (highest temperature achievable without isomerisation) under the same conditions in the IR cell and in a thermogravimetric MacBain balance. The obtained values were ε_{1605} = 0.026 ± 0.004 cm μmol^{-1} and ε_{1466} = 0.029 ± 0.004 cm μmol^{-1}. The IR intensities of these two bands can be used to measure the concentrations of the isomers in the pore system and their change with time on stream (Fig. 3).

2D-COS is particularly powerful when applied to spectra recorded at higher temperature, with low signal to noise ratio, during the reaction at 573 K. When the steady state is reached after the initial adsorption step, no change is observable in the 1D spectra, but 2D-COS clearly shows a cross-peak in the region of aromatic vibrations at 1596 cm^{-1} (Fig. 4, left). A very weak band is found at this wavenumber in the 1D spectra, which is masked by overlapping xylene bands. The negative covariance map between the region of aromatic vibrations and ν(OH) bands (Fig. 4, right) indicates a link between the 1596 cm^{-1} band and a decrease of the intensity of two bands located at 3727 and 3656 cm^{-1} assigned to low frequency silanols and to extraframework AlOH groups, respectively.[5] By flushing the catalyst surface with pure helium at the reaction temperature, adsorbed xylenes are eliminated, and the corresponding bands disappear. A species, however, remains adsorbed on the surface, and is characterised by a band at 1596 cm^{-1}. Additionally ν(OH) bands are not completely recovered, and (very) weak negative bands appear in the difference spectrum at 3727 and 3656 cm^{-1}. These correspond to the perturbation of the low wavenumber silanols and of the extraframework AlOH groups detected in the course of the reaction by 2D-COS. We interpret this result in terms of traces of coke (bands around 1600 cm^{-1} are generally observed after coke formation on zeolites in hydrocarbon conversion reactions),[6,7] localised on these specific silanol and AlOH groups, but not on the acidic (bridged OH) sites. Coke is only present in trace amounts and the activity remains constant throughout the reaction. A slight increase in *para*-selectivity is however observed by GC analysis of the products. Unambiguous determination of the localisation of these OH groups in the microporous structure is currently in progress.

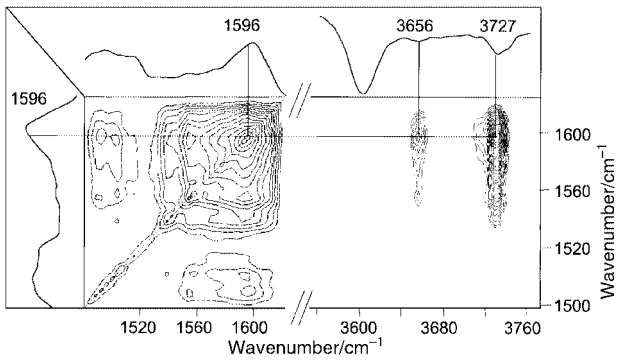

Fig. 4 Left: positive covariance analysis of the 1360–1650 cm^{-1} region during isomerisation at 573 K (188 spectra, 60 min). A large covariance peak centred at 1596 cm^{-1} was detected which could not be assigned to a xylene isomer. The weak signal to noise ratio in the direct spectra did not allow its observation without 2D-COS. Right: negative covariance analysis of the same series of spectra between the band at 1596 cm^{-1} and the ν(OH) region. Although adsorbed *m*-xylene led to the band at 1600 cm^{-1}, the maximum negative correlation was observed at 1596 cm^{-1}. It should be noted that the perturbation of the acidic sites [ν(OH) at 3600 cm^{-1}] was not linked to the perturbations described here. The spectra on the axes are not normal 1D spectra, but are mean spectra of the series which are displayed for clarity.

2D-COS treatment of the spectra is therefore a powerful new technique; it enables a much more detailed analysis of IR spectra, in particular for the monitoring of the working catalyst. Non-interfering bands can be chosen for the quantitative measurement of surface species under reaction conditions at 473K. At higher temperature (lower signal to noise ratio), traces of coke can be detected on H-MFI zeolite, linked to the perturbation of specific OH groups (not those of the acidic sites).

The development of an electropolymerisable unit for TTF-thiophene fused monomers

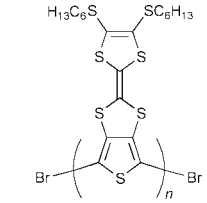
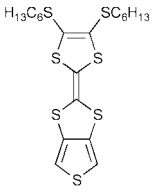
A novel poly(terthiophene) species provides the first example of an annelated TTF-thiophene derivative which can be polymerised electrochemically.

In general, the electropolymerisation of a conducting polymer is of particular interest for the following reasons: (i) the process is relatively cheap and can be performed on a small scale; (ii) the 'clean' reaction proceeds in the absence of a catalyst or other chemical reagents; (iii) the electrochemistry of the polymer can be investigated almost immediately and (iv) the electronic bandgap of the polymer can be measured by cyclic voltammetry and is usually comparable to the optical bandgap measured by UV–VIS spectroscopy.

Although we have recently prepared polymer **1** using chemical coupling methods,[1] the electropolymerisation of thiophene units bearing fused **2**[2] or covalently attached[2,3] TTFs



1



2

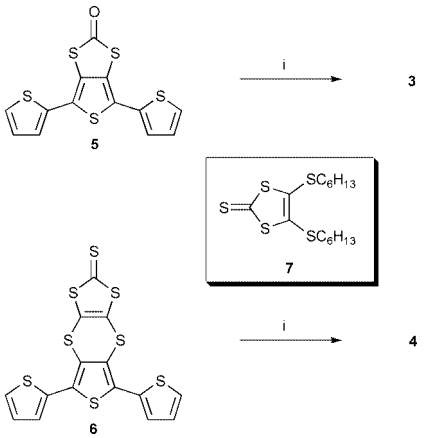
has so far eluded the field. The consensus of opinion points towards the fulvalene acting as a radical scavenger which, together with some degree of intramolecular coulombic repulsion between charged oxidised intermediates, renders the thiophene moiety inert to oxidative coupling reactions. The electrosynthesis of polythiophenes, linked to TTF units *via* saturated spacer groups, has been well established by the group of Roncali,[4] yet the successful electropolymerisation of conjugated TTF-thiophene monomers remains a challenge. In response to this, we have prepared compounds **3** and **4**, which are terthiophene analogues of **2**. The propensity towards electropolymerisation for these derivatives should be improved by the increased donor ability of the thiophene functionality (the oxidation potential of oligothiophenes decreases with an extension of the chain length).

The target compounds were prepared using standard phosphite-mediated cross-coupling reactions of 1,3-dithiole-2-chalcogenones (Scheme 1).[5] Thus, terthiophenes **5**[6] and **6**[7] were



Scheme 1 *Reagents and conditions*: i, $P(OEt)_3$, **7**, 120 °C, 6 h.

reacted with dithiole **7**[8] in the presence of triethyl phosphite at 120 °C, to afford compounds **3** and **4** (30–40% yield in both cases).‡

The electrochemical behaviour of compounds **2**–**4** is summarised in Table 1.§ All three compounds show two sequential reversible oxidation waves corresponding to the formation of the TTF radical cation and dication, respectively. It is noteworthy that the oxidation values for the two terthiophene derivatives are almost identical, thereby indicating that any inductive effect due to the 1,4-dithiin ring is negligible. However, each oxidation of the TTF moiety in **2** is shifted to a more positive value by *ca.* 100 mV, compared to derivatives **3** and **4**. The electronic effect of the fused thiophene ring upon the TTF unit can be explained by a σ electron-withdrawing effect in **2**, which is reduced by a counter-active π-resonance effect of the two peripheral thiophene rings in **3** and **4**.

The high value for the irreversible oxidation of the thiophene ring in **2** (E_3 = +2.18 V)[9] is unfavourable for electropolymerisation, however, the corresponding oxidation processes for compounds **3** and **4** are reduced to +1.55 and +1.52 V, respectively. These values are relatively high for terthiophene derivatives in general and are probably due to an electron withdrawing effect of the TTF dication. For electropolymerisation experiments, repetitive scanning over the range 0.0 to +1.6 V was performed, using a Ag/AgCl reference electrode and a gold disk working electrode in a dichloromethane–hexane (2 : 1) solution containing tetrabutylammonium hexafluorophosphate (0.1 M) as the supporting electrolyte. As we have observed previously,[9] monomer **2** failed to polymerise; however, we were quite surprised to discover different electrochemical reactivities

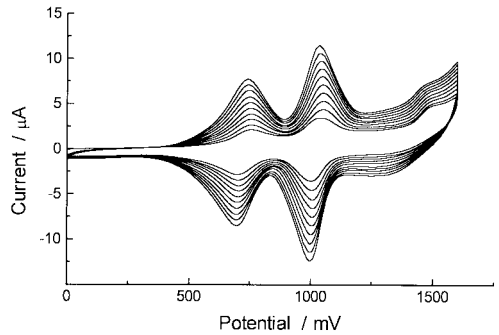

Fig. 1 Electropolymerisation of **4** in dichloromethane–hexane (2 : 1).

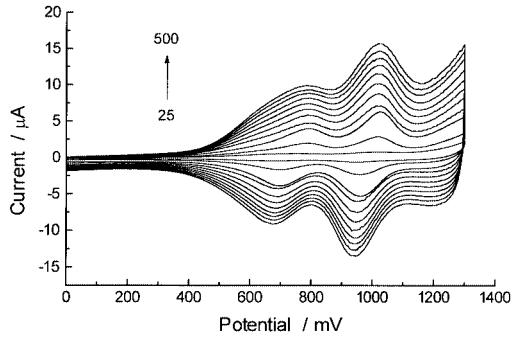

Fig. 2 Cyclic voltammograms of poly(**4**) in monomer-free acetonitrile solution at scan rates of 25, 50, 100, 150, 200, 250, 300, 350, 400, 450 and 500 mV s^{-1}.

for compounds **3** and **4**, despite the close similarity in redox potentials. Although, in the case of **3**, we observed the formation of a red film on the surface of the electrode, cyclic voltammetry clearly showed that this was not of polymeric nature. Conversely, reproducible films of poly(**4**) were obtained under identical conditions; a typical trace showing polymer growth over 10 cycles can be seen in Fig. 1. The proportionally higher increase in current between scans for $E_2^{\frac{1}{2}}$, compared to the first oxidation wave, has been seen previously in poly(bithiophenes) linked to TTF units *via* saturated spacer groups.[4c] This type of behaviour shows that the second oxidation of the TTF species develops independently of charge-transport through the film, which is not the case for $E_1^{\frac{1}{2}}$.

Fig. 2 features cyclic voltammograms of poly(**4**) at various scan rates (25–500 mV s^{-1}) in monomer-free acetonitrile solution. The relationship between the maximum peak current and the scan rate (100–500 mV s^{-1}) is linear with a high correlation coefficient ($r > 0.996$). This behaviour is typical of an electroactive polymer attached to an electrode surface and exemplifies the stability of poly(**4**) towards p-doping up to +1.3 V. At higher potentials the CV behaviour becomes ambiguous. Although the polymer does not appear to decompose or break down in the range −1.5 to +2.0 V, the CVs obtained within these limits are poorly defined and irreproducible.

Poly(**4**) was prepared on ITO glass and the electronic spectrum of the film was recorded. Two broad peaks are observed at λ_{max} = 459 and 833 nm (λ_{max} for compound **4** in dichloromethane is at 344 nm, Fig. 3). The latter peak indicates that the as-grown polymer remains in the oxidised state, however, since doped polythiophene and $TTF^{\bullet+}$ species absorb in this region, the identity of the oxidised species is uncertain. Rinsing the polymer film thoroughly with hydrazine had no effect on the electronic spectrum of poly(**4**), showing that the polymer is quite stable in the doped state. However, after repetitive cycling of the polymer film over the range −0.3 to 0.0 V for 2 h, we were able to obtain the electronic spectrum of the neutral polymer (Fig. 3). A broad band is observed (λ_{max} = 449 nm), extending to *ca.* 736 nm, which is typical behaviour for a

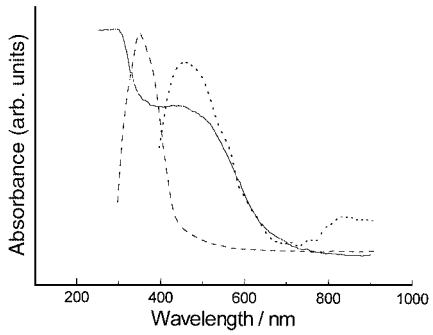

Fig. 3 Electronic absorption spectra of compound **4** in dichloromethane (- - - - -), oxidised poly(**4**) on ITO glass (·····) and neutral poly(**4**) on ITO glass (——).

polythiophene system. The absence of a second peak above 800 nm confirms the neutral state of poly(**4**) and the optical bandgap of the neutral polymer (1.69 eV) was found to be somewhat higher than the bandgap determined electrochemically (1.39 V).

In summary, we have presented a logical strategy towards the design of a polymerisable fused TTF-thiophene derivative. Beginning with a monomer unit **2** which has been acknowledged as being *a priori* for the formation of a regiospecific TTF-thiophene polymer,[10] we have highlighted the problems which arise from unfavourable interactions between the two redox units towards electropolymerisation. On one hand, the use of a terthiophene building-block is essential for a low oxidation value of the polymerisable moiety. Secondly, since **3** cannot be polymerised electrochemically, the incorporation of a fused 1,4-dithiin bridging unit in **4** presumably ensures a favourable spin density distribution in the radical trication for polymerisation to take place. We conclude that, in order to understand the nature of poly(**4**) at higher and lower potentials, a detailed spectroelectrochemical investigation would be extremely worthwhile.

Colloids as redox sensors: recognition of $H_2PO_4^-$ and HSO_4^- by amidoferrocenylalkylthiol–gold nanoparticles

Agnès Labande and Didier Astruc*

Received (in Oxford, UK) 27th March 2000, Accepted 4th May 2000
Published on the Web 23rd May 2000

Gold colloids containing a mixture of alkylthiol and amidoferrocenylalkylthiol (AFAT) ligands are new redox sensors for $H_2PO_4^-$ and HSO_4^-.

A promising approach towards nanoscopic materials is the investigation of their supramolecular properties which may lead to new sensors, catalysts and nanoscale electronic devices.[1] Only a few molecular recognition studies have been reported with colloids, however.[3] We wished to combine the effect of the topology in alkylthiol–gold nanoparticles and the supramolecular properties of their redox-active termini for their use as exo-receptors.[4] In order to attain this goal, we have synthesized functional alkylthiol–gold nanoparticles containing a mixture of alkylthiol ligands and amidoferrocenylalkylthiol (AFAT) ligands (Fig. 1). We then monitored the titration of $NBu^n_4^+$ salts of $H_2PO_4^-$ and HSO_4^- by these nanoparticles using cyclic voltammetry (CV). These ligands have been introduced and studied by Creager on gold surfaces,[5] and ferrocenylalkylthiol colloids are known,[6] but the introduction of an amido group close to the ferrocene center now adds the supramolecular aspect to these colloids.

Recognition of anions is an important topic because a number of anions are found in biological systems.[7] In particular, Beer showed that amidoferrocenyl groups linked to endo-receptors are able to sense anions.[4a–c] We now find that the redox potential of the amidoferrocenyl group is sufficiently perturbed by the synergy between the hydrogen-bonding, electrostatic interaction and topology in alkylthiol–gold nanoparticles containing AFAT ligands (unlike in alkylamidoferrocene monomers) to recognize $H_2PO_4^-$ and HSO_4^-.

The AFAT-containg colloids were synthesized by ligand substitution using Brust's colloids, leaving the gold core unchanged.[2] We have applied this technique with a variable proportion of amidoferrocenylalkylthiol ligands of variable lengths (11 and 6 C atoms)[11] and verified using TEM that the core size is not modified upon ligand substitution. Indeed, the combination of elemental analysis, ^{1}H NMR spectroscopy and TEM leads, for instance, to an average number of 269 gold atoms per core of 2 nm diameter and 80–106 dodecanethiolate chains.[8] Table 1 shows the proportion of AFAT ligands (determined by ^{1}H NMR) which is introduced onto the nanoparticles as a function of the amount engaged in the ligand-substitution reactions. Saturation is reached for 38 AFAT ligands per particle. These thermally stable nanoparticles are unaffected by air and are soluble in CH_2Cl_2.

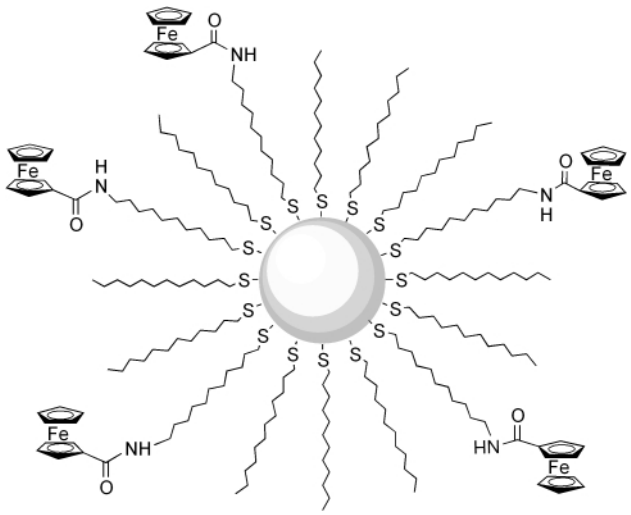

Fig. 1 Gold nanoparticles containing, on average, 29% of AFAT ligands (29-Fc).

The CVs of these colloids containing a variable amount of AFAT ligands always show a reversible ferrocene/ferrocenium wave (Pt, CH_2Cl_2, 0.1 M $[NBu^n_4][PF_6]$) at $E_{1/2}$ = 0.220 V *vs.* $FeCp_2^{0/+}$ in CH_2Cl_2[12] with some adsorption indicated by the E_{pa}–E_{pc} values (typically 20 mV) lower than the 58 mV value expected at 20 °C for classic monoelectronic waves. The observation of a single wave is due to the fact that all the redox centers of a particle appear identical and independent of the electrochemical time scale, indicating that the rotation of the particles and H-bonding formation and cleavage are faster than this time scale. Mediation of electron transfer among the ferrocenyl sites may also occur.[9] Addition of $[NBu^n_4][H_2PO_4]$ to a CH_2Cl_2 solution of these nanoparticles leads to the appearance of a new, cathodically shifted, wave the intensity of which increases at the expense of the initial wave. The replacement of the initial wave by the new one is complete after addition of 1 equivalent $[NBu^n_4][H_2PO_4]$ per AFAT branch (Fig. 2), indicating a 1:1 interaction between the anion and the amidoferrocenium group. It is remarkable that the potential shift upon addition of the anion is large ($\Delta E°$ = 220 mV) and constant whatever the proportion of AFAT ligand in the nanoparticles (from 7 to 38%) and its length (6 or 11 CH_2 units). This shift is much larger not only than that obtained for the alkylamidoferrocene monomer $FcCONHCH_2CH_2OPh$ (45 mV) but also for the tripod $PhC(CH_2CH_2CH_2NHCOFc)_3$ (110 mV), and is analogous to the value observed with a nona-branched amidoferrocene dendrimer.[9] Thus, it is probable that the channels defined between the parallel ligands create sufficient steric strain to provide a favorable particle effect comparable to

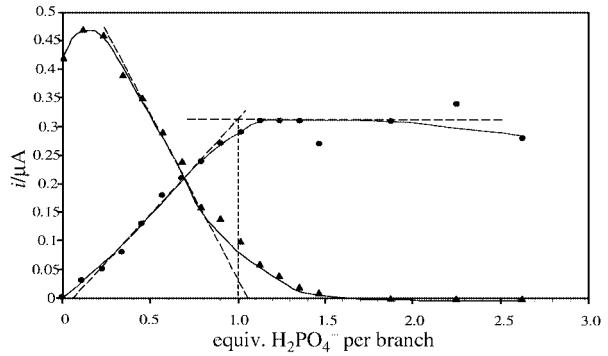

Fig. 2 Titration of the 20-Fc (AFAT) nanoparticles with $[NBu^n_4][H_2PO_4]$ monitored by CV. Decrease of the intensity of the initial ferrocene CV wave and increase of the intensity of the new wave *vs.* the number of equivalents of $[NBu^n_4][H_2PO_4]$ added per Fc (AFAT) branch; nanoparticles: 5×10^{-6} M in CH_2Cl_2; $[NBu^n_4][H_2PO_4]$: 10^{-2} M in CH_2Cl_2, $[NBu^n_4][PF_6]$: 0.1 M, 20 °C, reference electrodes: SCE and $FeCp_2$; auxiliary and working electrodes: Pt, scan rate: 200 mV s^{-1}. Plots of these intensities with particles containing various numbers of Fc (AFAT) branches (see text) gave analogous results: (▲) initial wave, (●) new wave.

the dendritic effect observed with metallodendrimers. This $\Delta E°$ value means that the apparent association constant $K_{(+)}$ between $H_2PO_4^-$ and the polyferrocenium form of the particle is 5350 ± 550 times larger than that, $K_{(0)}$, related to the neutral polyferrocene form (electrostatic effect).[10]

Gratifyingly, this technique also allows confirmation of the number of AFAT ligands in the particles determined by ^{1}H NMR, *viz*. 10–30% AFAT ligands on the particles (Table 2). It is also possible to titrate $[NBu^n_4][H_2PO_4]$ in the presence of both $[NBu^n_4][HSO_4]$ and NBu^n_4Cl (in addition to the electrolyte $[NBu^n_4][PF_6]$ in large excess), but the initial wave is now progressively shifted cathodically instead of being progressively replaced by another wave. This dramatic change of behavior may be understood in terms of a dynamic equilibrium among various anion complexes and by the fact that the kinetics of complexation can be different in the presence of a single anion or a mixture of anions.[11]

Finally, it is possible to titrate $[NBu^n_4][HSO_4]$ alone since the initial wave of those particles which have a low content of AFAT ligands (10–20%) is progressively shifted cathodically by addition of this anion up to 40 mV after addition of 1 equivalent of $[NBu^n_4][HSO_4]$, which again corresponds to a 1:1 interaction, with an apparent association constant $K_{(+)} = 480 \pm 120$ mol^{-1} L at a concentration of 10^{-2} M.[10] It is noteworthy that the $\Delta E°$ value is much smaller for HSO_4^- than for $H_2PO_4^-$, which shows the selectivity of the recognition by these nanoparticles. When the AFAT ligand content of the particles is larger (29–38% AFAT) or the chain shorter (C_6), this 1:1 interaction is no longer found, and equivalence points are reached with a lower quantity of added $[NBu^n_4][HSO_4]$. This distortion might best be accounted for by intramolecular amide–amide double hydrogen-bonding of two neighboring AFAT ligands at high AFAT ligand content. This effect is also more pronounced for HSO_4^- than for $H_2PO_4^-$. The moderate adsorption as monitored by the $E_a - E_p$ values along these titration studies changes slightly during the titration, but does not disturb the titrations. These particles do not recognize chloride, bromide and nitrate anions and thus there is a selectivity for the above oxo-anions. We are now continuing our research with other particles of similar and different types to extend the scope of the present reasults and investigate solvation and pH effects.

Table 2 Determination of the average number of AFAT ligands in the nanoparticles

	Total number of AFAT ligands			
		Titration by CV		
	H NMR	H_2PO_4	$H_2PO_4^{-a}$	HSO_4^-
7-Fc (C_{11})	8	8.3	—	—
13-Fc (C_{11})	10	9.5	9	10.25
20-Fc (C_{11})	21	22	19	18
29-Fc (C_{11})	31	29	25	17[b]
38-Fc (C_{11})	39	32	29.5	13[b]
18-Fc (C_6)	16	14	—	9[b]

[a] Titration carried out in the presence of excess $[NBu^n_4][HSO_4]$ (5×10^{-6} mol) and NBu^n_4Cl (2.5×10^{-6} mol). [b] Low value due to intramolecular H-bonding at high content of the AFAT ligand (see text).

In conclusion, these particles are used as exo-receptors which can sense $H_2PO_4^-$ and HSO_4^- owing to their hydrogen-bonding capacity with these oxo-anions, and excellent selectivity between the two oxo-anions has been found. They can be compared to dendrimers, but they show effects which are different, although the particles are as efficient as nona-amidoferrocene dendrimers to sense HPO_4^- (some of our polyamidoferrocene dendrimers[9b] do not recognize HPO_4^-). The particles also present a great advantage in that they are synthesized in one step whereas dendritic syntheses require a large number of steps.

We thank Michel Chambon for accurate TEM studies and the Institut Universitaire de France, the CNRS, the Université Bordeaux I and the Région Aquitaine (thesis grant to A. L.) for financial support. This paper is dedicated to the memory of John Osborn.

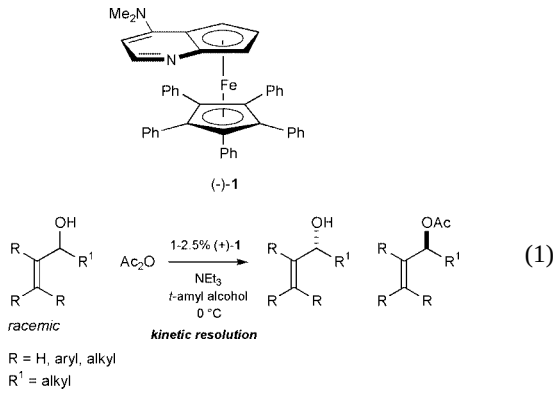
A planar-chiral DMAP derivative is shown to serve as an effective catalyst for the kinetic resolution of allylic alcohols; to illustrate its practical utility, the catalyst is applied to the resolution of two alcohols that have been employed as intermediates in recent natural product total syntheses.

During the mid-1990s, Evans *et al.*[1] and Vedejs and Chen[2] reported the first stoichiometric chiral acylating agents that are effective for the kinetic resolution of alcohols [selectivity factor (*s*) > 10],[3] work that marked an important first step in the development of non-enzyme-based methods for enantioselective acylation.[4] Soon thereafter, the groups of Vedejs,[5] Oriyama,[6] Fuji,[7] Miller[8] and ourselves[9] described the first chiral non-enzymatic acylation *catalysts* that are effective for the kinetic resolution of alcohols. With regard to substrate scope, the generality that has been reported to date follows the order: arylalkylcarbinols[10] > cycloalkanols[11] > propargylic alcohols[12] > allylic alcohols.[13]

Our work on catalytic enantioselective acylation has focused on the application of planar-chiral DMAP derivative **1** to the kinetic resolution of arylalkylcarbinols and of propargylic alcohols.[9] In addition, we observed in a 1997 study that we could resolve two *allylic* alcohols with good selectivity.[9a,14] Herein, we report a systematic investigation of the kinetic resolution of allylic alcohols by catalyst **1** [eqn. (1)], establishing fairly broad substrate scope and applying the method to two alcohols that have served as key building blocks in recent natural product syntheses.



(1)

We have found that catalyst **1** can effect the kinetic resolution of most families of allylic alcohols with good selectivity [Table 1; 1.0–2.5% (+)-**1**, Ac_2O, NEt_3, *t*-amyl alcohol, 0 °C]. Allylic alcohols that do not possess a substituent either geminal or *cis* to the hydroxy-bearing group are usually resolved with modest selectivity (entry 1). A notable exception to this generalization occurs when there is a phenyl group in the *trans* position, in which case the selectivity factor increases dramatically (entry 2).

Allylic alcohols that possess a substituent geminal to the hydroxy-bearing group are usually resolved effectively by catalyst **1** (entries 3–8); again, the presence of a phenyl substituent in the *trans* position leads to substantially improved enantioselection (entry 9 *vs.* entries 3–8). Similarly, kinetic resolutions of allylic alcohols that possess a substituent *cis* to the hydroxy-bearing group generally proceed with good selectivity (entries 10–12). Furthermore, tetrasubstituted allylic alcohols are acylated with high stereoselection (entry 13).

Table 1 Kinetic resolutions of allylic alcohols catalyzed by (+)-**1** (Ac_2O, NEt_3, *t*-amyl alcohol, 0 °C)

Entry	Unreacted alcohol, major enantiomer	Selectivity factor[a] (ee of unreacted alcohol)
1		**5.4** 92% ee @ 75% conv.

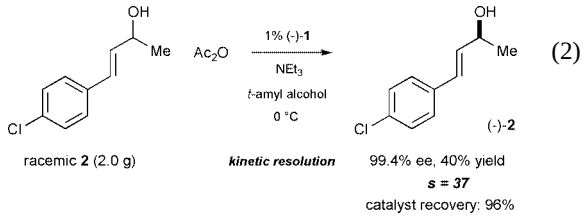
[a]The selectivity factors are the average of two runs.

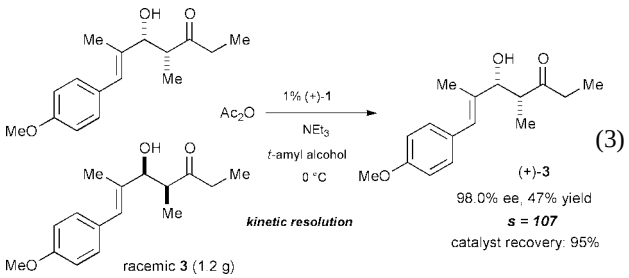
† Electronic supplementary information (ESI) available: full experimental details. See http://www.rsc.org/suppdata/cc/b0/b002041i/

In order to demonstrate the utility of this method, we have applied catalyst **1** to the kinetic resolution of two allylic alcohols that have served as key intermediates in recent natural product total syntheses. For example, Brenna *et al.* employed (−)-**2** in a 1997 synthesis of (−)-baclofen,[15] which is used as a muscle relaxant. We have determined that catalyst **1** effects the kinetic resolution of racemic **2** with a selectivity factor of 37 [eqn. (2)]. This reaction was run on a 2 g scale, exposed to air, thereby illustrating the practicality of the process. At the conclusion of the kinetic resolution, 96% of the catalyst was recovered.



(2)

Aldol adduct (+)-**3** is a key intermediate in the recent Sinha–Lerner synthesis of epothilone A,[16] an exciting new potential anti-cancer drug.[17] Adduct (+)-**3** has itself been the focus of much attention, owing to the fact that it can be generated by an aldolase antibody through kinetic resolution of racemic **3** (96% ee at 60% conversion ⇒ $s \sim 17$).[16,18] We have determined that catalyst **1** can also effect the kinetic resolution of this compound, with a selectivity factor of 107 [eqn. (3); reaction run exposed to air on a 1.2 g scale; acetylated **3**: 52% yield, 91.8% ee].[19]



(3)

In conclusion, we have established that planar-chiral DMAP derivative **1** is the most versatile non-enzymatic acylation catalyst for the kinetic resolution of allylic alcohols that has been reported to date, furnishing good selectivity for most substrates. Furthermore, we have illustrated the usefulness of this method by applying it to the kinetic resolution of two alcohols that have served as intermediates in recent natural product total syntheses.

Support has been provided by Bristol-Myers Squibb, Merck, the Natural Sciences and Engineering Research Council of Canada (predoctoral fellowship to J. T.), the National Institutes of Health (National Institute of General Medical Sciences, R01-GM57034), Novartis, Pfizer, and Pharmacia & Upjohn.

This paper is dedicated to the memory of John A. Osborn.

19 In the air, *t*-amyl alcohol (8.75 mL; distilled from CaH_2) and NEt_3 (0.36 mL, 2.6 mmol; EM Science, 98%) were added to a vial containing the alcohol (1.16 g, 4.42 mmol) and (+)-**1** (29.0 mg, 0.0439 mmol). The vial was closed with a Teflon-lined cap and sonicated to help dissolve the catalyst. The reaction mixture was cooled in an ice bath, and Ac_2O (0.25 mL, 2.6 mmol; Mallinckrodt, 99.8%) was added. After 42.5 h, the reaction was quenched with MeOH (0.25 mL). The mixture was passed through a silica gel column (20 → 100% EtOAc–hexanes, then 50% NEt_3–EtOAc) to separate the alcohol and the acetate from the catalyst [27.6 mg (95%) of pure catalyst was recovered]. The alcohol and the acetate were then separated by flash chromatography (10 → 25% EtOAc–hexanes), which afforded 0.70 g (52%) of acetate (HPLC analysis ⇒ 91.8% ee) and 0.55 g (47%) of alcohol (HPLC analysis ⇒ 98.0% ee). These ee values correspond to a selectivity factor (*s*) of 107 at 51.6% conversion.

ChemComm

Regioselectivity of the insertion of propene with achiral Pd(II) catalysts to highly isotactic poly[1-oxo-2-methylpropane-1,3-diyl]. Is the syndiotactic structure accessible?

Achiral cationic palladium catalysts, modified with 1,2-bis-(diarylphosphinomethyl)benzene ligands with different electronic properties, can efficiently produce poly(propene-*alt*-CO) with essentially complete regioregularity and high isotacticity, depending on the aryl substituent; the stereochemistry of the copolymers obtained is barely, if at all, influenced by the regiochemistry of the olefin insertion.

The alternating copolymerization of aliphatic olefins with carbon monoxide has attracted much attention in the last few years.[1–5] Useful catalytic systems in terms of productivity for this process are cationic palladium complexes of the type [(P–P)Pd$(S)_2$]$(X)_2$ [P–P is a chelate diphosphine ligand, typically

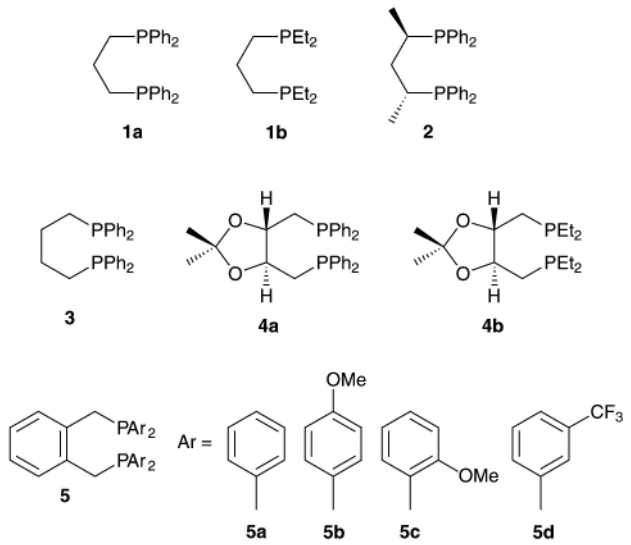

Fig. 1

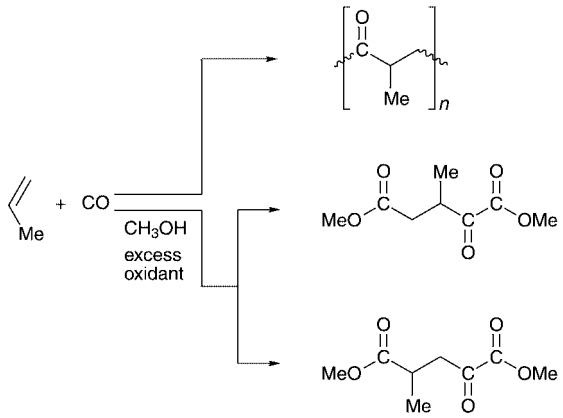
1,3-bis(diphenylphosphino)propane **1a** (Fig. 1), S is a solvent molecule and X a weakly coordinating anion].[6]

When 1-olefins are used as the substrate, the microstructure of the produced copolymers depends on the characteristics of the regio- and stereo-chemistry of the step that corresponds to the migratory insertion of the olefin.[7] For the series of 1,3-propanediyl ligands tested so far in the copolymerization of aliphatic olefins, two factors have been identified as playing a role in the production of stereo- and regio-regular copolymers: chirality of the catalytic system, which brings about efficient enantioface discrimination and basicity of the ligand necessary to achieve regiospecificity during the insertion process.[8] The two selectivities seem to influence each other. Whereas the prototypical catalyst precursor **1a** leads to the production of stereoirregular poly(propene-*alt*-CO) (Scheme 1), which has a maximum head-to-tail (ht) diad content of *ca.* 60%,[9] the ht diad content for **2** can be as high as 90%[8] and is *ca.* 100% for **1b**[10] or for similar alkyl substituted ligands. At the same time a shift towards the preferential formation of *l*-sequences is observed.



Scheme 1

The activity of ligand **3** was similar to that of ligand **1a**, but it showed somewhat better regioselectivity.[6,9]

Based on the above results, it was expected that **4a** would produce a substantially stereoregular material, which however is not the case.[9,11] Even **4b** did not seem to be very efficient from a stereochemical point of view, considering that the reported optical rotation of the produced copolymer is quite low.[12,13] The characteristics of these catalytic systems are clearly influenced to a considerable extent by the size of the coordination ring on the metal. We have continued our study, the aim of which is the identification of the factors involved in the regio- and stereo-chemical control of the insertion of the olefin substrate for this important carbonylation reaction, with the ultimate goal of achieving syndiotactic copolymerisation of aliphatic 1-olefins. We made the unexpected observation that electronic factors can substantially influence the regioselectivity and the enantioface discrimination of the efficient and largely regioregular copolymerization of propene with carbon monoxide caused by ligand **5a**.

Starting with ligands **5** (**5a** and **5c** have already been used for related copolymerization reactions[14,15]), the corresponding [(P–P)Pd$(H_2O)_2$]$(CF_3SO_3)_2$ derivatives **6** were synthesized[16] and used as catalyst precursors for the copolymerization of propene with carbon monoxide as well as for the triple carbonylation to dimethyl 3- and 4-methyl-2-oxopentanedioates (Table 1 and Scheme 1).[17] The catalytic activity of **5a** is about four times larger than that of **1a** under the same reaction conditions. Electron withdrawing and electron donating aryl substituents result in lower catalytic activity. The activity loss is larger for the latter substituents, particularly in conjunction with steric effects (**5b** and **5c**). Moreover, the results presented in Table 1 and in Fig. 2 reveal the good performance of the tested catalysts, especially of **5d**, with respect to regio- and stereo-chemistry. The concentration of the band associated to the isotactic pentad (82%) implies that the content of *l*-diads is $> 96\%$.[18]

The regioselectivity of the olefin insertion is inferred from the isomeric ratio of 3- to 4-methyl-2-oxopentanedioate

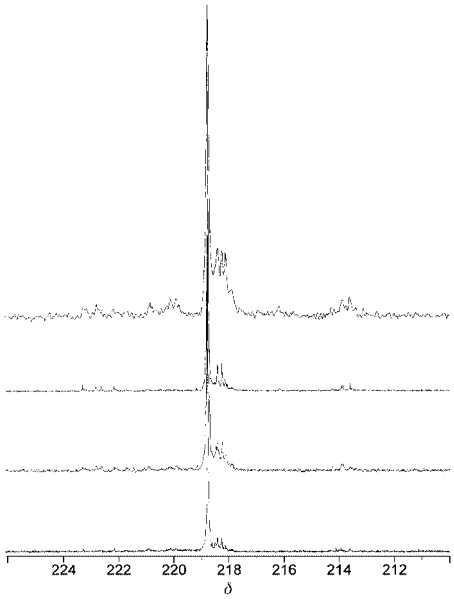

Fig. 2 ^{13}C NMR [125 MHz, $(CF_3)_2CDOD$] spectrum of the carbonyl region of poly(propene-*alt*-CO) prepared with catalysts **5** (from the bottom to the top: **5d**, **5b**, **5a** and **5c**).

(Scheme 1), which is affected by the tendency of propene to insert with primary or with secondary regiochemistry into a L_nPd–CO–OMe intermediate.[17] Catalysts **5c** and **5d** display an essentially reversed regioselectivity but, nevertheless both systems give poly(propene-*alt*-CO) with quite high regioregularity and a largely prevailing isotactic structure. Even though **5c** and **5d** are regioisomerically different, the position of the trifluoromethyl substituent in **5d** should have no influence on the electronic characteristics of the catalytic system.[19] Considering the achiral nature of the ligands,[20] it seems obvious that the enantioface discrimination during the copolymerization process is chain-end controlled. Chain-end control and secondary insertion result in the formation of syndiotactic copolymers during the related styrene copolymerization.[21] Therefore the reported results raise doubts about the accessibility of syndiotactic copolymerization of aliphatic 1-olefins with catalyst precursors containing diphosphines.

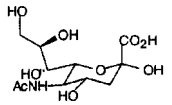
The *trans*-sialidase from *Trypanosoma cruzi* efficiently catalyses transfer of α-sialyl residues from *p*-nitrophenyl sialic acid (*p*-nitrophenyl *N*-acetylneuraminic acid) to acceptors containing β-galactose units.

The sialic acids are a class of C_9 monosaccharides comprising over thirty five variants.[1] The archetypal member is *N*-acetylneuraminic acid **1**. Colloquially this is referred to as



1

'sialic acid' unless another member of the family is indicated. Sialic acids are ubiquitous components of mammalian glycoproteins.[2] They are present in numerous other glycoconjugates[1] and are crucial determinants of their biological properties.[3]

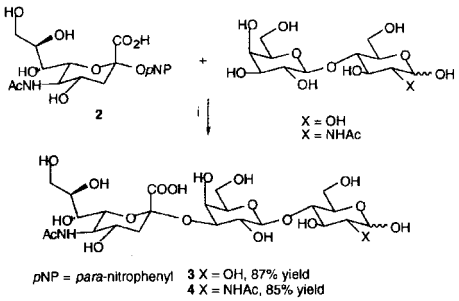
Non-enzymatic syntheses of sialic acid-containing oligosaccharides[4] suffer from the drawbacks of a requirement for multiple protection–deprotection sequences and problems of control of configuration at the anomeric centre. In addition yields may be affected by side reactions involving 2,3-elimination. Accordingly, enzymatic methods have received much attention. Sialyl transferases catalyse sialylation regiospecifically and in high yield.[5] A major drawback to their use is that they require cytidine monophosphate *N*-acetylneuraminic acid (CMP-NeuAc) as sialyl donor. Although non-enzymatic syntheses of CMP-NeuAc have been reported[6] enzymatic methods have been preferred[7] and have been developed to permit multigram production[8] and *in situ* regeneration of the sialyl donor.[9]

Owing to the complexity of the donor and the limited availability of appropriate enzymes, sialylations with sialyl transferases have usually been limited to the preparation of sialylated oligosaccharides on the μmol scale. Sialyl transfers catalysed by sialidases has been demonstrated but proceed in extremely low yields ($< 15\%$).[10]

Against this background, the report of a novel retaining α-*trans*-sialidase in the parasite *Trypanosoma cruzi* was of particular interest.[11] Noteworthy was the finding that sialyl transfer was catalysed with much greater efficiency than hydrolysis.[12] The *trans*-sialidase required sialyl glycosides or oligosaccharides as sialyl donors. It was stated to be selective for transfer to β-galactosyl units; α-galactosides were reported not to be acceptors.[13]

The *trans*-sialidase has been shown to transfer sialyl residues α(2 → 3) on to galactose residues using sialyllactose,[14–17] 4-methylumbelliferyl α-sialoside[18–20] or *p*-nitrophenyl α-sialoside[13,21,22] as donors. However, the full synthetic potential of the enzyme has not been realised. The studies described above were carried out either on an analytical scale or, if preparatively, on a scale of < 10 μmol. We have now developed an approach that permits the synthesis of sialyl galactosides on a mmol or greater scale. The key to the improvement reported here is the use of the irreversible sialyl donor *p*-nitrophenyl α-sialoside **2** made readily available by improvement of a published synthesis[23] and the use of the recombinant form of the *T. cruzi trans*-sialidase referred to above, and which consists of the *N*-terminal catalytic domain. This fragment expresses the full catalytic activity of the wild-type enzyme.[24]

The effectiveness of the *trans*-sialidase is evident in the synthesis, on a mmol scale, of sialyllactose **3** and sialyl-*N*-acetyllactosamine **4** (Scheme 1). Yields of sialylated products are essentially quantitative; the data in Scheme 1 relate to pure, isolated products. It was noteworthy that hydrolysis of the sialyl donor **2** occurred to a significant extent only in the absence of acceptor.



Scheme 1 *Reagent*: i, *trans*-Sialidase from *Trypanosoma cruzi*.

Because it had been reported that the *trans*-sialidase does not catalyse transfer to α-galactosides,[13] the acceptor behaviour of methyl α- and β-galactopyranosides **5** and **6**, respectively, was studied (Scheme 2). The β-anomer was an efficient acceptor giving the sialylgalactoside **7** in 81% yield. Surprisingly, the α-anomer was also sialylated to give glycoside **8** with moderate efficiency (54% yield). Clearly, a small aglycone in the α-anomeric position does not constitute a total barrier to *trans*-sialylation. However, it was considered that the presence of a bulky carbohydrate moiety in place of the much smaller methyl group in glycoside **5** would indeed create problems. Accordingly we studied the acceptor properties of disaccharide glycoside **9**. To our surprise, this was efficiently sialylated but the product was found to be the branched trisaccharide **10** (Scheme 3), formed in 89% yield. Thus the barrier to sialylation of α-galactosides is clearly expressed but the predeliction for sialylation of β-galactosides was not negated by substitution at C-6 in the acceptor.

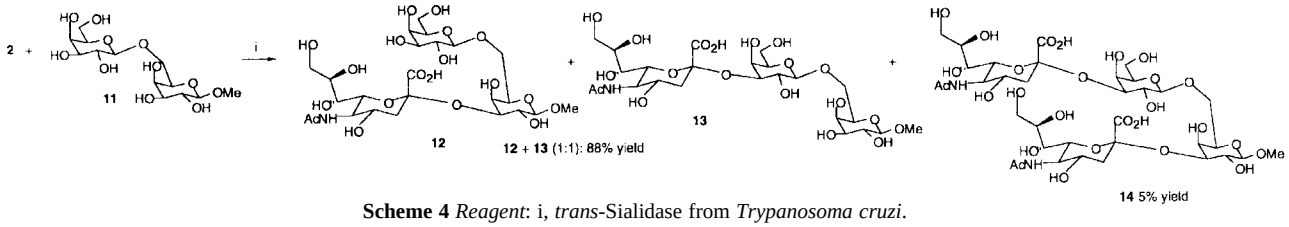

Scheme 4 *Reagent*: i, *trans*-Sialidase from *Trypanosoma cruzi*.

With β-D-Gal*p*-(1 → 6)-β-D-Gal*p*–OMe **11** as acceptor a mixture of three products was obtained (Scheme 4). The major component (88% isolated yield) proved to be a 1 : 1 mixture of the 3- and 3′-monosialylated products **12** and **13** which required HPLC separation. The third, minor product, formed in 5% isolated yield, proved to be the bis-sialylated product **14**. It was established that both of the monosialylated compounds **12** and **13** were converted quantitatively into the tetrasaccharide **14**. The selectivity for β-configured oligosaccharide acceptors and the specificity for α-(2 → 3) transfer were emphasised by the failure of sialyl transfer to α-D-Gal*p*-(1 → 3)-β-D-Gal*p*-(1 → 4)-D-GlcNAc*p*, α-D-Gal*p*-(1 → 3)-β-D-Gal*p*–OMe and α-D-Gal*p*-(1 → 3)-α-D-Gal*p*–OMe.

The studies reported here establish the *T. cruzi trans*-sialidase as a highly efficient catalyst for the sialylation of β-galactosides on a mmol scale. Moreover, they reveal the previously unsuspected ability of the enzyme to catalyse the formation of branched structures. We find that the enzyme is readily immobilised (Eupergit C) and retains its activity undiminished over at least nine catalytic cycles. Clearly, it should now be considered as a viable alternative to CMP-sialic acid-dependent sialyl transferases for α-2,3-sialylation of β-galactose-terminated oligosaccharides and with the added potential for sialylation of C-6-subsituted internal β-galactose units.

Besides its importance for the synthesis of sialyl oligosaccharides, the *T. cruzi trans*-sialidase provides a paradigm for the development, through mutagenesis, of glycosidases that would have high glycosyl transfer but low hydrolytic activity. The *T. cruzi* enzyme is homologous (*ca.* 70% identity for 640 amino acids) with the sialidase from *T. rangeli*, which lacks *trans*-sialidase activity. The latter enzyme has been crystallised. X-Ray structures have been determined at 2.2 Å resolution for the enzyme and at 2.9 Å resolution for the complex between the enzyme and 2,3-didehydro-2-deoxy-*N*-acetylneuraminic acid.[25] Homology modelling combined with mutagenesis studies have revealed several structural features that are crucial for the expression of *trans*-sialidase activity in the *T. cruzi* enzyme.[25,26] The acceptor studies reported here will also contribute to the elucidation of the *trans*-sialidase/sialidase mechanistic dichotomy.

Field and coworkers have also obtained evidence for the formation of branched sialyl galactosides (*cf.* Schemes 3 and 4).[27] We thank Professor Field for a useful exchange of information.

In a typical procedure, the *p*-nitrophenyl glycoside of sialic acid (0.1 g, 0.223 mmol) and *N*-acetyllactosamine (0.5 g, 1.31 mmol) in sodium acetate buffer (50 mM, pH 6.0, 7 cm^3) were incubated at 30 °C with recombinant *trans*-sialidase (1.38 U cm^{-3}, 0.225 cm^3) for 9 h. The reaction was stopped by filtration through a PTFE filter (0.45 μm pore size). The filtrate was applied to a Bio-Gel P-2 column which was eluted with water to give sialyl-*N*-acetyllactosaminelactose [α-Neu5Ac-(2 → 3)-β-D-Gal*p*-(1 → 4)-D-GlcNAc*p*] **4** (Scheme 2), 0.133 g (85%).

We thank Glaxo Wellcome for a gift of sialic acid and the BBSRC for financial support.

The self-assembly of long chain alkoxy-substituted benzoic acids around tribasic core 1 provides a simple and flexible way to supramolecular liquid crystals with columnar mesophases.

During the last years several groups have developed a number of supramolecular approaches to the preparation of liquid crystals with columnar mesophases.[1] Disc-shaped mesogens can result, for example, from the association of a varying number of amphiphilic molecules whose incompatible polar and non-polar parts segregate on a microscopic scale. Microsegregation is seen as an important driving force in the formation of smectic, columnar and cubic phases; the type of liquid-crystalline phase depends on the curvature of the interface.[2] Typical examples for columnar systems are Lattermann's monoaryl esters of *cis*,*cis*-1,3,5-cyclohexanetriol,[3] Praefcke's inositol derivatives,[4] Tschierske's laterally substituted terphenyls,[2] and Percec's taper-shaped benzo-crown ethers.[5] The dimerisation of mesogenic benzamides,[6] of phenanthridinones,[7] the trimerisation of phthalhydrazides,[8] complexes of a 2,4,6-triarylamino-1,3,5-triazine with benzoic acids,[9] and complexes of certain pyridine derivatives with carboxylic acids[10,11] illustrate how the discotic unit can be made up of a defined number of components that are held together by hydrogen bonding. Non-covalent complexation between non-identical components has so far led to columnar phases in only a few exceptional cases.[9–11]

We have recently described that non-convalent complexes are readily obtained from carboxylic acids and trisimidazoline base **1**; these are held together by hydrogen bonds and salt bridges in non-polar solvents.[12] Two X-ray crystal structures indicated that such carboxylic acid complexes have an almost disc-like flat shape and therefore fulfill one of the structural requirements for discotic liquid crystals.[12a,13] Here, we report a new type of supramolecular liquid crystal based on the assembly of benzoic acids, which are substituted with a sufficient number of long alkoxy side chains, around a tribasic core **1**.

Long chain alkoxy-substituted benzoic acids **2a**–**d**[14] and tris(imidazoline) base **1**[12] were prepared as described in the literature. All compounds were used after extensive purification, which included gradient sublimation of **1** at 310 °C/ 10^{-4} mbar. Complexes **3a**–**d** were prepared by dissolution of the respective benzoic acid **2a**–**d** (3 equiv.) and base **1** (1 equiv.) in hot ethanol (*ca*. 80 mL per mmol of **1**). The hot solution was filtered and, if necessary, concentrated until the still warm solution became cloudy. The salts crystallised in analytically pure form upon standing at room temperature (Scheme 1). All complexes gave satisfactory ^{1}H NMR, ^{13}C NMR, IR and elemental analysis data.

As might be expected from multiple substitution with long-chain alkoxy groups, complexes **3a**–**c** showed high solubility in non-polar organic solvents, such as chloroform (solubility typically > 200 mg mL^{-1}), toluene, or even hexane, whereas polar solvents (DMSO, alcohols) were generally found to be non-solvents. The diagnostic downfield ^{1}H NMR chemical shifts for the NH signal ($\delta_H \approx 13$) as well as for the singlet assigned to the core's aromatic protons ($\delta_H \approx 10.1$ in $CDCl_3$ or C_6D_6) emphasised that the equilibrium between the salt and its ionic components lies on the side of the hydrogen-bonded 3:1 complex in non-polar solvents.[12] No evidence for dissociation was observed for any of the carboxylic acid complexes in chloroform solutions at concentrations > 10^{-5} M. It is therefore expected that dissociation is even more unfavourable in the condensed phase.

Although neither **1** nor benzoic acids **2** are mesogenic, differential scanning calorimetry (DSC) and polarising optical microscope (POM) experiments confirmed that complexes **3a**–**c** transform to birefringent, shearable liquid-crystalline mesophases at *ca*. 80 °C (Table 1). The clearing temperatures of the mesophases of all three complexes were above 200 °C. Crystal–mesophase melting transitions exhibited large enthalpic changes (138 J g^{-1} for **3c**), whereas enthalpies for the clearing transition from the mesophase to the isotropic liquid were much smaller (17 J g^{-1} for **3c**) albeit still considerably higher than for a typical smectic phase.

A very fine texture was observed during the first heating of complexes **3a**–**c**. Subsequent slow cooling (cooling rate ≤2 °C min^{-1}) from the isotropic melt led—after significant supercooling (*ca*. 15 °C for **3a**)—to the dendritic growth of homeotropic finger-like contours (Fig. 1) that are characteristic for columnar mesophase formation.[15] Further cooling to room temperature again produced a fine-structured texture, and even the previously homeotropic regions finally showed birefringence. The thermal stability of the mesophases was, however,

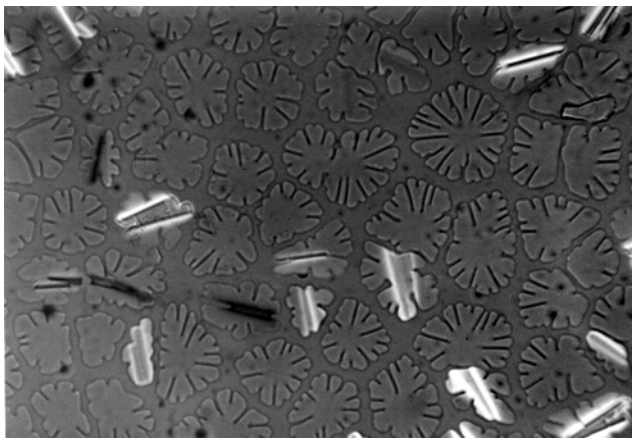

Fig. 1 Representative optical polarised micrograph showing the dendritic growth of homeotropic contours at 200 °C after slow cooling of complex **3b** from the isotropic melt (polarisers not completely crossed).

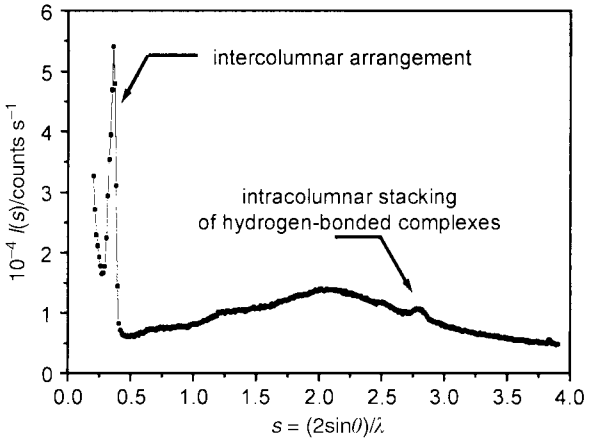

Fig. 2 Typical X-ray scattering diagram of hydrogen-bonded complex **3b** taken at 150 °C in the mesophase region.

somewhat limited. After prolonged annealing at 170 °C or heating at temperatures > 200 °C for more than a few minutes, extended domains evolved which lacked birefringence and were surrounded by brown shades indicating decomposition of the textures. Interestingly, the liquid-crystalline domains of the 3,4-disubstituted **3b–c** were found to be larger than those of the symmetrical complex **3a**, both during the first heating process and subsequent cooling. Although complex **3d** became malleable upon heating above 70 °C, a single dodecyloxy group per benzoic acid unit was evidently insufficient to stabilise a liquid-crystalline phase.

X-Ray scattering experiments confirmed the presence of liquid-crystalline mesophases in the high temperature regime of complexes **3a–c**. Fig. 2 shows a typical scattering pattern with a maximum at low angles, corresponding to Bragg spacings in the range of 3–4 nm, a broad maximum due to liquid-like arrangement of the terminal alkyl chains and a well defined maximum at wide angles, corresponding to a Bragg spacing of 0.36 nm. The value of the Bragg spacing associated with the scattering maximum at small angles clearly indicates that the scattering units are significantly larger compared to the dimensions of either the tribasic core or the benzoic acid derivatives. The Bragg spacing of 0.36 nm points towards a regular stacking of the aromatic components, a feature which is well known from structural studies on mesophases formed by covalently bonded discotic mesogens.[16] The presence of only a single maximum at low angles in the scattering pattern from non-oriented systems does not allow an assignment of the specific type of columnar arrangement; however, we obtained reasonable estimates for the macroscopic density by assuming hexagonally ordered columns of regularly stacked hydrogen-bonded complexes. Further studies on the morphology using X-ray scattering and AFM are in progress.

We thank Professor G. Wulff, to whom this paper is dedicated on the occasion of his 65th birthday, and the Deutsche Forschungsgemeinschaft for continuing support, Ms S. Johann for experimental help, and Professor W. Mormann (University of Siegen) for stimulating discussions.

Radical carbon–carbon coupling reactions *via* organoboranes

Christine Cadot, Janine Cossy and Peter I. Dalko*

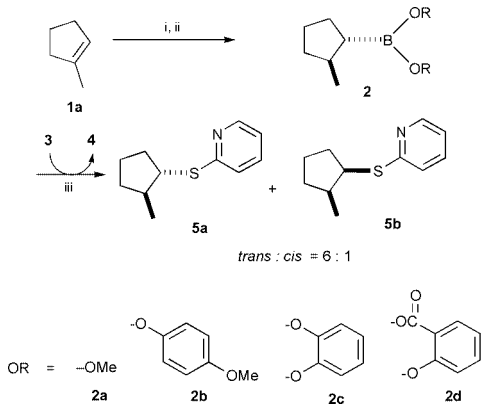
Laboratoire de Chimie Organique associé au CNRS, ESPCI, 10 rue Vauquelin, 75231 - Paris Cedex 05, France. E-mail: peter.dalko@espci.fr

Received (in Liverpool. UK) 7th March 2000, Accepted 26th April 2000
Published on the Web 22nd May 2000

Alkylboronic esters give rise to free-radical alkylation products in the presence of phenylcarbonyloxy(pyridine-2-thione) (Barton's ester) and a variety of Michael acceptors under irradiation.

The use of organoboranes in free-radical reactions[1–5] suffers from a notable limitation. The radicals generated from these compounds using, for example, molecular oxygen fail to add to certain good radical traps such as unsaturated esters, nitriles or sulfones.[1–3] The reason for this lack of reactivity is the unfavourable equilibrium in the postulated enol radical[2] required in the propagation step of the chain process. The design of a simple chain sequence, which eliminates the problem of the propagation step, is therefore of interest.

The boronate intermediates **2a**–**d** were prepared by hydroboration of olefin **1a** using borane–dimethylsulfide complex, followed by addition of NEt_3 and quenching of the aminoborane intermediate with alcohol or phenol derivatives (Scheme 1). The homolytic fragmentation of the boronates has been studied in the presence of phenylcarbonyloxy(pyridine-2-thione) (PTOC ester) **3**† (2 equiv.),[6] and irradiation at 0–5 °C, using a commercial halogen lamp (300 W).[7]‡ In all experiments, the reaction afforded the desired thiopyridyl derivatives **5a** and **5b** in a 6 : 1 *trans–cis* selectivity, independent of the ligand used. In addition, a variable amount of thiopyridyl dimer, characteristic of the Barton reaction, and benzoic acid arise from the decomposition of the postulated intermediate **4** (*vide infra*, Scheme 4) under the hydrolytic work-up.



Scheme 1 *Reagents and conditions*: i, $BH_3{\cdot}Me_2S$ (1.25 equiv.), THF, 0–5 °C, 2 h; ii, NEt_3 (1.25 equiv.), 0–5 °C, then alcohol or phenol (1.25 equiv. per OH), room temp.; iii. **3** (2 equiv.), *hν*, CH_2Cl_2/PhH, 0–5 °C, 2 h. Yields (for three steps combined): **a**, 13%; **b**, 43%; **c**, 68%; **d**, 23%.

Among the tested derivatives, dimethyl boronate **2a** afforded poor yield of **5** (13% combined). Better yields were obtained using aryl boronates such as **2b** (43%). Similarly to oxygen initiated reactions, the best results were observed using the catechol derivative **2c** (68%).[5] Ligands substituted by electron withdrawing groups such as the salicylate **2d** afforded lower yields of **5** under the same conditions (23%).

The radical alkylation reaction was examined in the presence of the conventional Michael acceptors, **6a**–**e**, shown in Scheme 2. The catechol boronates were prepared, as before, by hydroboration of olefins **1a**–**d** followed by quenching with an equimolar amount of catechol and were not isolated. These intermediates were irradiated, respectively, in the presence of PTOC ester **3** (2 equiv.) and an excess of Michael acceptors **6a**–**c** (3–5 equiv.) (Scheme 2). The reaction afforded the adducts **7a**–**h** as inseparable mixtures of the diastereomers.§ In each reaction, a good selectivity, in favour of the *trans* isomer was observed and was determined after the cleavage of the thiopyridyl group (*vide infra*).¶ Likewise, β-pinene **1d** was hydroborated using either borane–dimethyl sulfide complex or thexylborane under standard conditions[10] followed by fragmentation and quenching of the corresponding aminoboranes with equimolar amounts of catechol. As before, the boronate was not isolated. Fragmentation in the presence of an excess (2 equiv.) of PTOC ester **3** and alkylation using methyl acrylate afforded the desired adduct **7i**.‖ The isolated yield of this transformation was considerably lower (30%) than that of the alkylation of secondary radicals. This difficulty in alkylation of primary radicals follows the earlier observed trends.[1–5]

The relative stereochemistry of the carbon–carbon formation step was established after removing the thiopyridyl group. Although the α-keto thiopyridyl derivative **7g** (Scheme 3, entry 7) was reduced easily using samarium(II) iodide, other derivatives such as nitriles **7a** and **7f**, phosphonate **7b**, esters **7d**,**e** and **7h** and phenyl sulfone **7c** remained inert under these conditions. In these cases, the thiopyridyl esters were converted into the corresponding sulfones and were reduced using samarium iodide[11,12] in the presence or in the absence of HMPA as cosolvent (Scheme 3). Under these conditions the corresponding alkanes **8** were obtained upon quenching the organosamarium intermediates with water. The reaction conditions were not

DOI: 10.1039/b001903h

optimised for this reductive step and the low isolated yields observed for **8a**, **8d** and **8e** can be attributed to the volatility of the reduced products. In the examples discussed, this mild cleavage of the thiopyridyl group allowed unambiguous establishment of the stereoselectivity of the crucial carbon–carbon formation step (Scheme 3).

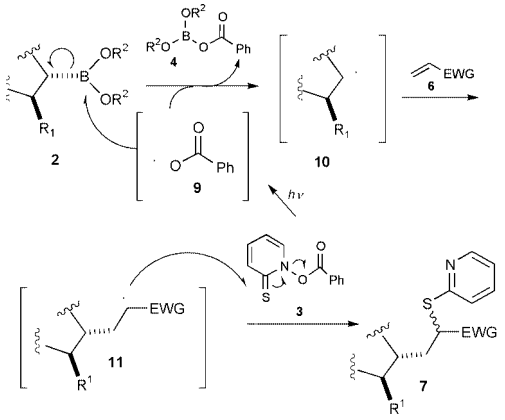
In the postulated mechanism of the reaction (Scheme 4) the formed arylcarbonyloxyl radical **9** reacts with the boronic ester **2** resulting in selective fragmentation of the weak B–alkyl bond.** The use of the PTOC esters also offers a logical solution to the chain propagation problem, this being assured by the presence of the thiopyridyl group, and eliminating the necessity of formation of the enol radical form of the addition product.



Scheme 4 Free-radical alkylation of alkylboronates **2** in the presence of phenylcarbonyloxy(pyridine-2-thione) **3** (Barton's ester) and olefin **6**.

In summary, a method, which combines the predictable and high degree of stereoselectivity of boron chemistry with a flexible method for radical carbon–carbon bond formation, is described.[4] In contrast to the previously developed methods,[1–3,5] the alkylation reaction can be extended to a seemingly unrestricted array of Michael acceptors. The reaction proceeds with addition of a thiopyridyl group in the α position of the radical trap. This function eventually can be selectively removed using SmI_2 after converting the thiopyridyl ether to the corresponding sulfone. Whilst organoboronates can be obtained in highly enantioenriched form using asymmetric hydroboration reactions,[13] this free-radical fragmentation/alkylation process may be of interest to develop new arrays of free-radical alkylation reactions in asymmetric synthesis. Beyond this, the synthetic value of the combination of boron and PTOC derivatives should also be contrasted with the generation of radicals by more conventional methods using organotin reagents.[14]

Notes and references

† The commonly used PTOC esters (Barton esters) are anhydrides of carboxylic acids and the thiohydroxamic acid *N*-hydroxypyridine-2-thione.

‡ The primarily generated acyloxyl radicals may undergo radical decarboxylation reactions.[8] Decarboxylation of such aryl and vinylcarboxyl radicals is generally too slow to be useful for synthetic purposes. Such species may have lifetimes in the microsecond range.[9] This sluggish decarboxylation renders it possible to use them as valuable free-radical chain carriers in the discussed reaction.

§ The diastereoselectivity was measured by GC–MS on the reduced products **8**.

¶ Although NMR analyses showed the formation of the *trans* isomer as the major product, the presence of the two possible thiopyridyl diastereomers rendered it difficult at this stage to establish the precise stereoselectivity.

‖ A roughly 1 : 1 mixture of the two inseparable diastereomers was obtained, according to ^{13}C NMR spectroscopy (162.5 MHz).

** The aryl radical, formed by classical decarboxylation of **9** would lead to a similar chain reaction. No evidence, however, of formation of aryl boronates in the reaction was found.

The reaction of cyclohexyl isocyanide and dimethyl acetylenedicarboxylate with aldehydes: a novel synthesis of 2-aminofuran derivatives

Vijay Nair* and A. U. Vinod

Received (in Cambridge, UK) 1st March 2000, Accepted 20th April 2000
Published on the Web 22nd May 2000

The 1:1 intermediate generated by the additon of cyclohexyl isocyanide to dimethyl acetylenedicarboxylate is trapped by aldehydes to yield 2-aminofuran derivatives in good yields.

The addition of nucleophilic carbenes such as isocyanides to dimethyl acetylenedicarboxylate has been investigated in detail.[1–3] The initially formed 1:1 zwitterionic species undergo further reaction with DMAD and isocyanide in different molar proportions, ultimately leading to a variety of complex heterocyclic systems.[4–9] This highly reactive intermediate **1** can manifest carbanion or carbene character or even resemble a cyclopropenone imine (Fig. 1).

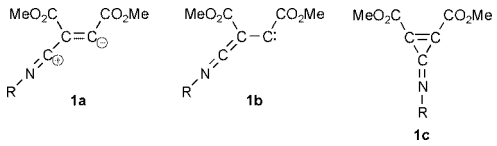

Fig. 1

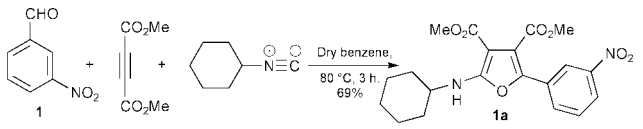
In the context of our general interest in the synthesis of heterocyclic compounds by the reaction of dipolar species with carbonyl compounds,[10,11] we were intrigued by the possibility of trapping the zwitterionic intermediate† derived from isocyanides and DMAD with aldehydes. It is noteworthy that previous attempts to trap **1** with various olefinic dipolarophiles have failed.[6] The preliminary results of our investigations validating the usefulness of this process, leading to a novel aminofuran synthesis are presented here.

A mixture of 3-nitrobenzaldehyde and dimethyl acetylenedicarboxylate in dry benzene at 80 °C, when treated with cyclohexyl isocyanide afforded aminofuran **1a** in 69% yield (Scheme 1).‡



Scheme 1

In the ^{1}H NMR spectrum, the two carbomethoxy groups were observed at δ 3.79 and 3.94 as two singlets and the NH proton resonated at δ 6.70 supporting the IR absorption at 3367 cm^{-1}. The ^{13}C signals for the two ester carbonyls were seen at δ 165.20 and 164.62.

Similar results were obtained with a number of other aldehydes and results are summarised in Table 1.§

A mechanistic rationale for the formation of the aminofurans is presented in Scheme 2.

In conclusion, we have found that the one pot reaction of isocyanides and DMAD with aldehydes leads to a facile synthesis of aminofuran derivatives. It should be mentioned that recently aminofurans have been found to undergo facile Diels–Alder reactions leading to hexahydroindolinones;[12] they also serve as useful intermediates in the synthesis of aromatic as well as aliphatic molecules.[13] It is conceivable that the novel three component reaction described herein will be applicable to the synthesis of a variety of heterocycles; further studies are in progress.

A. U. V. thanks CSIR, New Delhi, for a research fellowship. Thanks are also due to Dr Mangalam S. Nair and Ms Soumini Mathew for recording high-resolution NMR spectra.

Singlet–triplet energy gap in a cyclophane-based organic diradical with parallel exchange coupling pathways†

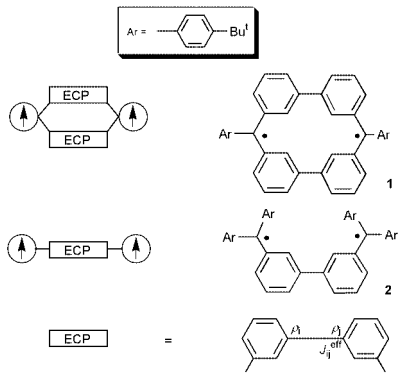
Andrzej Rajca,* Suchada Rajca and Jirawat Wongsriratanakul

Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304, USA. E-mail: arajca1@unl.edu

Received (in Columbia, MO, USA) 9th February 2000, Accepted 20th April 2000
Published on the Web 23rd May 2000

The novel cyclophane diradical 1 possesses a singlet ground state with a singlet–triplet energy gap (ΔE_{ST}) of −0.20 and −0.24 kcal mol^{-1}, as measured with SQUID magnetometry and EPR spectroscopy, respectively. This large ΔE_{ST} may in part be associated with the two parallel 3,3′-biphenyl exchange coupling pathways (ECPs).

Elucidation of the structural factors affecting the singlet–triplet energy gap (ΔE_{ST}) in organic diradicals is of primary importance in the design of building blocks for molecular magnets and extended polyradicals.[1–5] The value of ΔE_{ST} may also be viewed as a measure of covalent bond strength in typical, singlet ground state, molecules.[6] Both the sign and magnitude of the ΔE_{ST} are predominantly determined by the through-bond exchange coupling.[1,2] As we wish to probe the dependence of $|\Delta E_{ST}|$ on the number of connecting exchange coupling pathways (ECPs) between the radicals,[7,8] we have designed a cyclophane-based diradical **1**, in which two 3,3′-biphenyl units correspond to two parallel ECPs.[2,8] A molecule with one ECP, an analogue of **1**, is diradical **2**.[9] (Diradical **1** may be related to the extended polycarbene proposed by Mataga in 1968 and **2** is a derivative of the well known Schlenk hydrocarbon.[10,11])



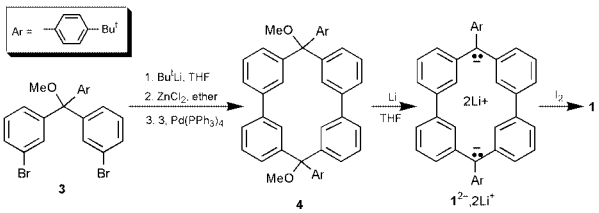
In the Heisenberg Hamiltonian model for a diradical ($H = -2J\boldsymbol{S}_1\cdot\boldsymbol{S}_2$, $S_1 = S_2 = ½$), $\Delta E_{ST} = 2J$. Here, J is the effective exchange interaction, which may be expressed in terms of the spin densities, ρ_i and ρ_j, and the effective exchange integral, J_{ij}^{eff}, between the connecting sites i and j,[12,13] giving

$$J = J_{ij}^{eff}\rho_i\rho_j, \quad \text{for the one-ECP system} \qquad (1)$$

$$J = 2J_{ij}^{eff}\rho_i\rho_j, \quad \text{for the two-ECP system} \qquad (2)$$

Therefore, $|\Delta E_{ST}|$ should be exactly doubled when the introduction of the second identical ECP does not affect the $J_{ij}^{eff}\rho_i\rho_j$ terms. The disjoint character of **1** and **2** is an important factor in minimizing the perturbation of ρ_i and ρ_j.[14] However, conformations of **1** and **2** will affect both $\rho_i\rho_j$ and J_{ij}^{eff}. Consequently, **1** should be viewed as an initial attempt to address the problem of multiple ECPs in diradicals. This novel approach to control exchange coupling should have implications for organic magnetism and weak covalent bonding.

Negishi coupling of compound **3** gave the macrocyclic diether **4**. Two stereoisomers of **4** were isolated in an overall yield of *ca*. 30% (Scheme 1).[15,16]† Both isomers possess qualitatively similar spectral data. FAB MS of **4** are dominated by the isotopic cluster ions corresponding to $(M - OCH_3)^+$, as expected for triarylmethyl ethers. ^{1}H and ^{13}C NMR spectra for **4** show the expected symmetry: all four benzene rings of the macrocycle are equivalent and the two 4-*tert*-butylbenzyl ether moieties are also equivalent.



Scheme 1

Diradical **1** is generated from **4** using the previously developed carbanion methodology for polyarylmethyl radicals such as **2** (Scheme 1).[9,17] NMR spectra for carbodianion **1**$^{2-}$ as its lithium salt in tetrahydrofuran-d_8 (THF-d_8) at an ambient temperature show analogous molecular symmetry to that of **4**.[17] The EPR spectrum of **1** in frozen 2-methyltetrahydrofuran–tetrahydrofuran (2-MeTHF–THF) at 70 K shows a six-peak pattern in the $\Delta m_s = 1$ region, characteristic of a triplet ($S = 1$) state with the center peak assigned to $S = ½$ impurities (Fig. 1).[18] The presence of the $S = 1$ state is confirmed by a weak transition in the $\Delta m_s = 2$ region. For **1**, the zero field splitting parameters (zfs), $|D/hc| = 0.0081$ cm^{-1} and $|E/hc| \approx 8 \times 10^{-4}$ cm^{-1}, are somewhat larger than those for **2** ($|D/hc| \approx 0.005$ cm^{-1} and $|E/hc| \approx 0$ cm^{-1}). Because **1** is constrained to the '*syn*' conformation and **2** was previously established to possess the '*syn*' conformation,[9] this difference in $|D/hc|$ values

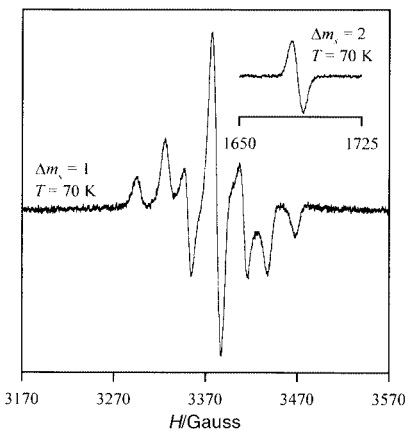


Fig. 1 EPR spectroscopy for diradical **1**, *ca*. 0.003 M in 2-MeTHF–THF (*ca*. 5/1).

DOI: 10.1039/b001273o

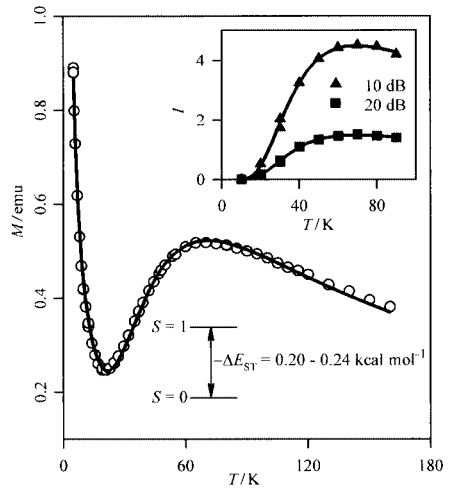

Fig. 2 Experimental determination of the singlet–triplet energy gap (ΔE_{ST}). Main plot: magnetization (M) by SQUID magnetometry. The solid line corresponds to a numerical fit with the following parameters (parameter dependence): $J/k = -61.4$ K (0.70), mol of diradical = 1.88×10^{-6} (0.69), mol of monoradical = 1.16×10^{-7} (0.05). Insert plot: EPR intensity (I) for the $\Delta m_s = 2$ signal *vs* temperature (T). The solid lines are two-parameter, $J/k = -55.5$ K and normalization constant, numerical fits with parameter dependence of 0.76. The EPR and SQUID data are obtained for **1** in 2-MeTHF/THF (*ca.* 5/1) and THF, respectively.

may arise from a significant delocalization of spin density into the proximate biphenyl moieties in **1**.[18,19] Furthermore, macrocyclic **1** is relatively persistent; more than half of the EPR signal intensity of **1** in 2-MeTHF–THF is left intact after 2 days at room temperature. However, attempts to isolate **1** as a solid were not successful.

At 4 K, the EPR spectrum for the $S = 1$ state becomes almost undetectable, suggesting that the observed $S = 1$ state is thermally populated. Measurement of the intensity (I) of the $\Delta m_s = 2$ signal *vs*. temperature (T) gives a curve with a maximum near $T = 70$ K. A numerical fit, based upon a simple two-center Heisenberg Hamiltonian ($H = -2J\boldsymbol{S}_1\cdot\boldsymbol{S}_2$), gives $J/k = -53 \pm 3$ K (Fig. 2).[2]

For 0.04 M **1** in THF, a plot of magnetization (M) *vs*. T in the range 5–100 K shows a broad maximum at $T_{max} \approx 60$ K and an upward turn at low temperatures, consistent with a singlet ground state of **1** and the presence of $S = \frac{1}{2}$ impurities.[20] A three-parameter fit to M *vs*. T gives $J/k = -60 \pm 2$ K (Fig. 2). At very low temperature, such as 3 K, M of a diradical with $J/k \approx -60$ K should be negligible. Numerical fits of M *vs*. magnetic field (H) data at 3 K to the Brillouin function with variable S and M at saturation (M_s) give $S = 0.5$, as expected for an $S = \frac{1}{2}$ impurity. M_s is within a few percent of the calculated value from the M *vs*. T fit.

Diradical **2** was reported to have J/k in the range -21 to -23 K.[9] Therefore, both **1** and **2** have singlet ($S = 0$) ground states and thermally populated $S = 1$ states; $\Delta E_{ST} = 2J$ for **1** (-0.20 to -0.24 kcal mol^{-1}) is about 2–3 times the value of $\Delta E_{ST} = 2J$ for **2** (-0.08 to -0.09 kcal mol^{-1}).

Previous work on derivatives of **2** indicated that the steric hindrance, causing out-of-plane twisting of the π-conjugated system, diminishes $|\Delta E_{ST}|$.[2,21] Possible conformations of **1** and **2** were obtained from MacroModel calculations.[22] The preference for the '*syn*' over the '*anti*' conformation in **2** (3 kcal mol^{-1}) is in agreement with the EPR data. The torsional angles indicate that the 3,3′-biphenyl moieties are significantly more twisted and bent in **1** (59–68°) *vs*. **2** (30°) (see ESI†); this implies that the J_{ij}^{eff} in **1** is smaller than in **2**. However, the torsional angles between the 3,3′-biphenyl and arylmethyl moieties in **1** and **2** are ~30 and 44°, respectively. This suggests that both ρ_i and ρ_j in **1** may be larger than in **2**. Therefore, it is reasonable to assume that the $J_{ij}^{eff}\rho_i\rho_j$ terms in eqns. (1) and (2) are comparable.[23]

In conclusion, the singlet–triplet energy gap in diradical **1**, with two parallel exchange coupling pathways, is more than doubled when compared to diradical **2**, with one exchange coupling pathway.

This research was supported by the National Science Foundation (CHE-9806954). The mass spectra were obtained at the Nebraska Center for Mass Spectrometry. The initial synthetic studies toward **4** were carried out by Chris Focke. We thank Professor Clark Stille of Columbia University for his help with parametrization of MacroModel for arylmethyl radicals.

Freebase- and metallated-tetrapyridylporphyrins self-organize through multiple hydrogen bonding to carboxylic acid terminated self-assembled monolayers on gold surfaces, thereby producing surfaces with two additional functional sites, the porphyrin cavity and the terminal pyridyl groups.

Self-assembled monolayers (SAMs) with terminal functional groups can be used to construct organic surfaces with a variety of functional properties. SAMs derive their chemical selectivity from the outermost few angstroms of the film,[1] and in recent years, there have been many examples of self-assembly and self-organization to rationally synthesize novel functional materials.[2] We have recently demonstrated design strategies for solid-state supramolecular arrays containing both mixed-metallated and freebase porphyrins leading to multichromophoric arrays of defined rigidity, dimensionality, porosity, and selectivity.[3] Organization of porphyrinic chromophores on thin film organic surfaces through hydrogen bonds provides another powerful means for the design of novel systems with useful functional properties (*e.g.* magnetic materials, sensors, and artificial photosynthetic systems).[4] Recent strategies to prepare SAMs with porphyrinic chromophores have relied on either the modification of the porphyrin periphery with thiol side-chains,[5,6] or on the coordination of thiols terminating in N-donor heterocycles to metal ions[4,7] or P-ligands[8] already bonded in the porphyrin cavity. These approaches permit only a single attachment site, and in the case of the metallated-porphyrins, do not allow for the presence or use of the freebase porphyrin. In this communication, we report our strategies to link freebase and metallated porphyrinic chromophores to surface-confined monolayers of functionalized organomercaptans through multiple hydrogen bonds.

It is well known that carboxylic acid groups preferentially bind with pyridines, amines, and aminopyridines through O–H···N or N–H···O hydrogen bonding, either in solution[9] or in the solid state.[10] Recently, acid-terminated SAMs have been used to bind vapor phase bases, such as pyridine, pyrazine, and decylamine through hydrogen bonding, but these hydrogen-bonded bases partially desorb upon exposure to nitrogen gas.[11] It occurred to us that stable hydrogen-bonded supramolecular arrays on acid terminated surfaces can be generated with the aid of multifunctional organic ligands where multiple hydrogen bonds formed between the organic ligand and acidic surface substantially enhance the stabilization energy. For this purpose, we have considered freebase- and metallated-tetrapyridylporphyrins (TPyP) as potential building blocks.

We constructed carboxylic acid-terminated monolayers of 11-mercaptoundecanoic acid, $HS(CH_2)_{10}COOH$ (MUA), and 4-mercaptobenzoic acid, $HS(C_6H_4)COOH$, on gold surfaces for studying the hydrogen bonding properties of TPyP. SAMs were prepared by immersing thin gold films (*ca.* 100 nm thick deposited onto chromium primed Si(100) wafers) in *ca.* 1 mM methanolic solutions of the organomercaptans for 12–24 h. The acid-terminated monolayers obtained were thoroughly rinsed with ethanol and dried with argon before being immersed in *ca.* 0.1 mM chloroformic solutions of TPyP or ZnTPyP. After 1–12 h, the samples were removed and copiously rinsed with chloroform. The latter step is critical to yield reproducible results, since the chloroform rapidly evaporates when the sample is removed from solution. Also, it should be mentioned here that our attempts to generate acid-terminated SAMs hydrogen-bonded with porphyrins directly by dissolving both porphyrin and mercaptoacids together in methanol or chloroform did not yield reproducible thin films.

The presence of TPyP and ZnTPyP on carboxylic acid terminated SAMs was detected by X-ray photoelectron spectroscopy (XPS). The characteristic peaks for N and Zn identified the metallated-porphyrin along with O and S from the SAMs, as shown in Fig. 1. Analysis of the XPS data yielded a coverage of 0.04 monolayers of ZnTPyP, or approximately 6×10^{13} ZnTPyP molecules per cm^2. Several control experiments were conducted to verify the hydrogen bonding requirement to form the porphyrin monolayer. For example, XPS indicated that freebase or metallated TPyP does not adsorb to a methyl-terminated SAM $[HS(CH_2)_9CH_3]$ and tetraphenylporphyrin (*i.e.* no acceptor group available for hydrogen bonding) does not adsorb to a MUA/Au surface.

Low contact angle measurements of water on MUA/Au (28°) and MBA/Au (31°) are in accord with the hydrophilic nature imparted to the surfaces by the acid terminal groups. The contact angles were 6–10° higher when measured with the porphyrin-terminated groups (ZnTPyP/MUA/Au, 36°; ZnTPyP/MBA/Au, 37°; TPyP/MUA/Au, 38°; TPyP/MBA/Au, 37°), indicating the partial hydrophobic nature (caused by the large aromatic moieties) of these monolayers.

Ellipsometry was used to measure the thickness of TPyP on MUA/Au. In order to limit experimental errors in calculating the thickness of the organic layers on the gold surface, we have considered the average of three measurements at different points on each sample surface.[12] The thickness of the porphyrinic layer on MUA surfaces is calculated by subtracting the height of the acids MUA/Au (16.3 Å)[13] and the hydrogen bonding distance of carboxylic acid–pyridine (2.7 Å) from the total height above the gold surface Au/MUA/TPyP (27.9 Å). The thickness of the porphyrin layers is thus calculated to be *ca.* 10.2 Å.

The consistent thickness of about 10 ± 2 Å obtained for porphyrin layers on MUA/Au surfaces indicates the nature of the hydrogen bonding to TPyP. In principle, TPyP can hydrogen bond with the acidic moieties in three different ways, which involve hydrogen bonding of one, two, or possibly even four pyridyl groups, as shown in Fig. 2. The thickness of the porphyrins in these three different modes can be approximated

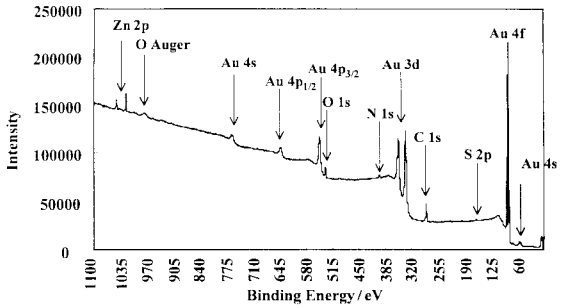

Fig. 1 XPS of ZnTPyP on MUA.

DOI: 10.1039/b002084m

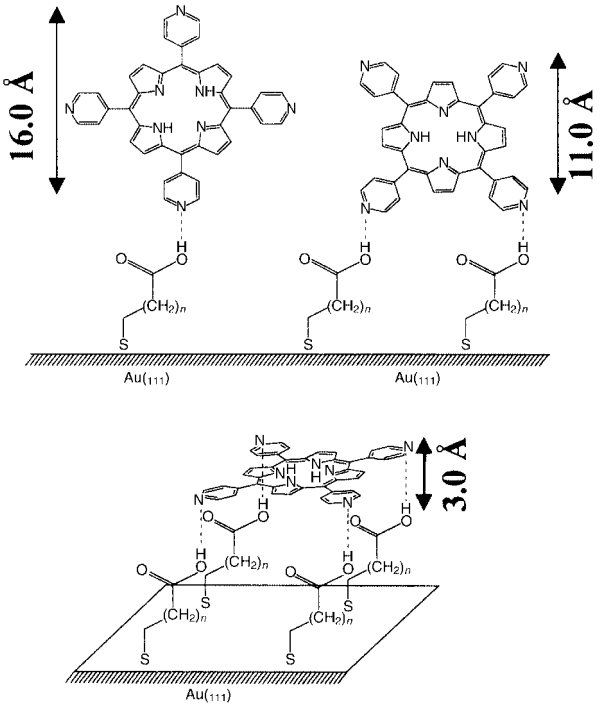

Fig. 2 Three possible orientations of TPyP on MUA.

as 16.0 Å (type-I), 10.8 Å (type-II), and 3.0 Å (type-III), if the O–H···N distance is taken into account. Within experimental uncertainty, the ellipsometry measurements correlate closely to the type-II hydrogen bonding, which is similar to that found in the solid state.

Further support for the model above comes from structural characterization of a cocrystal prepared by layering TPyP [0.5 mmol in TCE (1,1,2,2-tetrachloroethylene), 20.0 mL] with mercaptoacetic acid [2.0 mmol in MeOH, 10 mL]. Dimerization of the mercaptoacetic acid and inclusion of solvent led to the crystallization[14] of $[(S_2C_4H_{12}O_4)_2(TPyP)]\cdot 3TCE$. The crystal structure (Fig. 3) reveals the formation of linear 1D tapes with adjacent TPyP molecules bridged by hydrogen bonds to both ends of two mercaptoacetic acid dimers. These hydrogen bonded tapes are exactly analogous to the 1D tapes formed by coordination of HgX_2 to the external pyridyl moieties.[3]

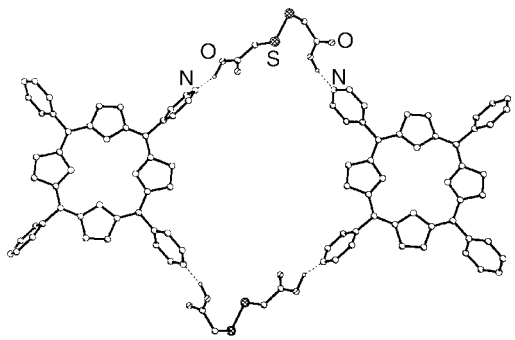

Fig. 3 A portion of the one dimensional molecular tape formed by hydrogen bonding in $[(S_2C_4H_{12}O_4)_2(TPyP)]\cdot 3TCE$. (The solvent has been omitted for clarity.)

The work presented here demonstrates a strategy to form stable hydrogen bonded arrays of both freebase- and metallated-porphyrins on acid-terminated gold surfaces for the design of functional materials. Some of the important implications of this include: (i) using multiple hydrogen bonds, the extended functional arrays are even stable enough to be seen in XPS studies. (ii) The optical properties of the surfaces can be fine-tuned by the organization of multiple porphyrinic chromophores in controlled metallation states and orientations at the interface. (iii) Use of the freebase porphyrin allows additional metal ion coordination *in situ* (as, for example, in applications involving metal ion sensors where the chromophoric response changes with metallation state). (iv) The pyridyl ligands of TPyP exposed on the surface (*i.e.* those not involved in the hydrogen bonding) serve as binding sites for systematically generating mixed multiple layers through additional hydrogen bonds.

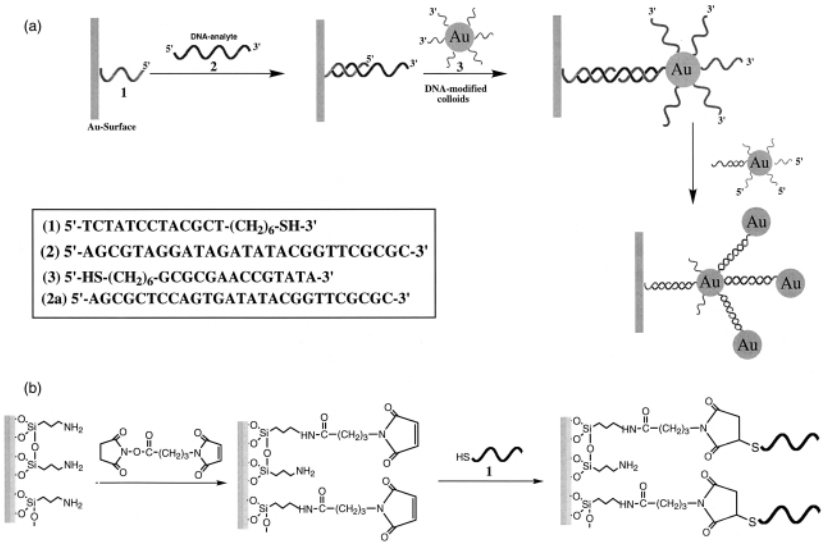
Dendritic amplification of DNA analysis is accomplished by the application of 5′- and 3′-terminated oligonucleotide-functionalized Au-colloids complementary to the analyte DNA.

The development of DNA sensors attracts recent research efforts directed to gene analysis, identification of genetic disorders, tissue matching, and forensic applications.[1,2] Photonic detection of DNA was accomplished by the use of fluorescence-labeled oligonucleotides,[3] the use of surface plasmon resonance, SPR,[4] and through the application of oligonucleotide-modified Au-nanoparticles which exhibit plasmon absorbance.[5,6] Electronic transduction of oligonucleotide–DNA recognition events, and the amplified transduction of DNA sensing, are major challenges in DNA-based bioelectronics.[7] Electrostatic attraction of transition metal complexes[8] or dyes[9] was used for the voltammetric probing of the formation of double-stranded assemblies. Amplified electronic transduction of DNA sensing events was accomplished by the application of enzyme labels that bind to the double-stranded (ds) assembly,[10] the use of protein labels,[11] or the use of branched oligonucleotides.[12] Other amplification routes of DNA sensing events included the application of enzymes that biocatalyze the precipitation of an insoluble product on the transducer,[13] or the use of liposomes that bind to the ds-DNA assembly.[14,15] Electrochemical[12–15] or microgravimetric, quartz-crystal-microbalance,[11,16] methods have been applied as electronic transduction signals for the sensing events. Here, we report on a novel method to amplify DNA sensing events by the application of oligonucleotide-functionalized Au-nanoparticles for the amplified sensing of DNA by a dendritic-type amplification route. Microgravimetric, quartz-crystal-microbalance (QCM) experiments are used to follow the amplified DNA-sensing processes.

Scheme 1(a) shows the method of the amplified sensing of a target DNA. A primer thiol-functionalized oligonucleotide **1** is assembled on the Au-electrode, and the target analyte DNA **2**, hybridizes with the sensing interface. The primary amplification of the sensing process is performed by the interaction of the surface with the **3**-functionalized Au-particles. The secondary, dendritic-type amplification is performed by the interaction of the resulting interface with the analyte sample **2** that is pretreated with the **1**-functionalized Au-nanoparticle. The mass associated with the Au-nanoparticles linked to the crystal in the primary hybridization step, and the dendritic structure formed in the secondary hybridization process, amplify the sensing of **2**. Note that the amplifying Au-nanoparticles that are used in the two modification steps have different modification layers, and are functionalized with the 3′-terminated and the 5′-terminated thiolated oligonucleotides, **3** and **1**, respectively. Both oligonucleotides, **3** and **1**, are complementary to the two ends of the analyte **2**. The **1**- and **3**-functionalized Au-nanoparticles were prepared according to the literature[6] by the reaction of citrate-stabilized Au-nanoparticles (12 ± 1 nm, 5 mL) with the thiolated oligonucleotides **1** or **3** for 20 h.

Fig. 1(A), curve (a), shows the frequency changes of the Au-quartz crystal (AT-cut, 9 MHz) functionalized with **1** (surface coverage 1.4×10^{-11} mol cm^{-2}) as a result of interaction with the analyte **2** (2×10^{-8} M). A frequency decrease of *ca*. 9 Hz is observed. Treatment of the resulting interface with the **3**-functionalized Au-nanoparticles results in an additional frequency change of *ca*. 60 Hz [Fig. 1(A), curve (b)], indicating that the binding of the Au-nanoparticles indeed amplified the primary sensing of **2**. The amplified sensing of **2** is specific and the interaction of the sensing interface with the non-complementary DNA **2a**, at a high concentration (5×10^{-6} M), does not yield any change in the crystal frequency (*ca*. −1 Hz) even after its interaction with the **3**-functionalized Au-nano-



Scheme 1 (a) Dendritic amplified DNA-sensing using oligonucleotide-functionalized Au-nanoparticles. (b) Immobilization of the thiolated oligonucleotide **1** on a glass support.

DOI: 10.1039/b002221g

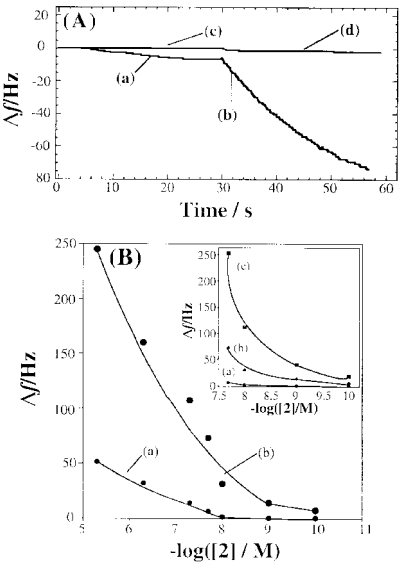


Fig. 1 (A) Time dependent frequency changes of a **1**-functionalized Au-quartz crystal upon interaction with: (a) the analyte DNA **2** (2×10^{-8} M). (b) After treatment of the double-stranded assembly of **1** and **2** with the **3**-functionalized Au-nanoparticles. (c) After treatment of the sensing interface with **2a** (5×10^{-6} M). (d) After treatment of the resulting surface with the **3**-functionalized Au-nanoparticles. All measurements were performed in $2 \times$ SSC buffer, pH = 7. (B) Frequency changes of the **1**-functionalized Au-quartz crystal upon the dendritic amplified sensing of different concentrations of the analyte DNA **2**: (a) upon the association of the analyte **2** with the sensing interface. (b) Upon the amplification of the primary double-stranded assembly of **1** and **2** with **3**-functionalized Au-nanoparticles. (c) Upon the dendritic amplification of the primary **1**–**2**–**3**–Au-nanoparticle array with the **2**–**1**–Au-nanoparticle probe. The Δf values reported in curves (a) and (b) were measured in solution ($2 \times$ SSC, pH = 7.0). The Δf values reported in curve (c) were measured in air. The double-stranded oligonucleotide–DNA assemblies in the first or second amplification steps were interacted for 25 min with the **3**-functionalized Au-nanoparticles or the **1**-functionalized Au-colloid. (SSC = 10 mM sodium citrate and 150 mM NaCl.)

particles [Fig. 1(A), curves (c) and (d), respectively]. The specificity of the sensing process is observed for at least three-base mismatches between the analyte and the probe monolayer interface. The crystal frequency changes resulting upon the primary amplified sensing of different concentrations of **2**, and those originated upon the secondary dendritic-type amplification, are shown in Fig. 1(B) and its inset, respectively. Note that the frequencies of the crystals resulting in the secondary amplification process are measured in air. The primary amplification path enables the sensing of the analyte **2** in the concentration range 2×10^{-8}–1×10^{-10} M, where no noticeable frequency changes can be observed as a result of the hybridization of **2** with the sensing interface itself. The secondary amplification step results in a dendritic type, non-linear amplified transduction of the initial sensing process [Fig. 1(B), inset]. For example, while the primary binding of the **3**-functionalized Au-nanoparticle to the sensing interface treated with 2×10^{-8}, 1×10^{-8}, 1×10^{-9} or 1×10^{-10} M of **2** results in frequency changes of −70, −40, −12 and −8 Hz, respectively, the secondary amplification process introduces a net decrease in the crystal frequencies corresponding to −250, −115, −45 and −20 Hz at these concentrations of **2**. The non-complementary DNA **2a** (1×10^{-6} M) does not show any frequency change of the crystal upon an attempt to follow the two-step amplification route. At a concentration of 2×10^{-8} M of the analyte **2**, the degree of amplification of the primary hybridization process by the two-step Au-nanoparticle array is *ca.* 30-fold within a probing time-frame of 50 min (Δf changes from 8 to 245 Hz). The dendritic-type amplification of the sensing of **2** by the two Au-nanoparticles probes is further supported by optical measurements (Fig. 2). The primer

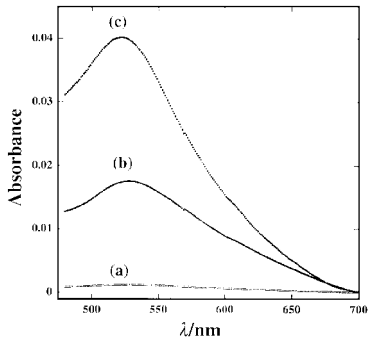

Fig. 2 Absorption spectra of a glass support: (a) after modification with **1** according to Scheme 1(B). (b) After interaction of the **1**-functionalized glass with **2** and then with the **3**-functionalized Au-nanoparticles. (c) After amplifying the primary **1**–**2**–**3**–Au-nanoparticle array with the **2**–**1**–Au-nanoparticle probe solution.

oligonucleotide **1** was immobilized on a glass support as shown in Scheme 1(B). Treatment of the **1**-functionalized glass with the analyte **2** and then with the **3**-functionalized Au-nanoparticles, results in the spectrum shown in Fig. 2, curve (b), consisting of the characteristic plasmon absorbance of Au-nanoparticles. Upon treatment of the sensing interface with the second amplification step, the Au-nanoparticle absorbance band is enhanced *ca*. 2.5-fold.

In conclusion, we have demonstrated the use of oligonucleotide-functionalized Au-nanoparticles as amplifying probes for microgravimetric QCM DNA-sensing. By the use of two different Au-nanoparticle probes consisting of oligonucleotide-functionalized Au-nanoparticles, complementary to the two ends of the analyte DNA, non-linear amplification of the sensing event was observed.

This research project is supported by the Israel–Japan Binational Program.

The Ti-mediated allylsilane addition to bicyclic lactams occurs with high stereoselectivity and combined with a ring closure metathesis provides the title compounds in high ee.

Indolizidines represent an important class of biologically active compounds, including such alkaloids as slaframine, castanospermine (a potent glycosidase inhibitor) and a number of poisonous-frog alkaloids typified by pumiliotoxin B[1] (Fig. 1). Development of a general method to access these 1-azabicyclo-[4.3.0]nonanes would provide a useful tool in studying a host of derivatives.

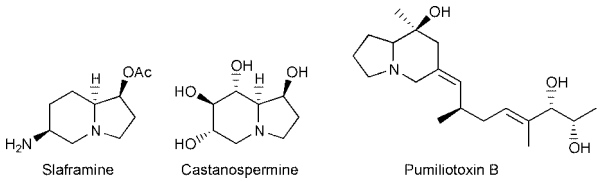

Fig. 1

The construction of optically pure heterocycles using the bicyclic lactam template has been of great interest in our group,[2] and over the years we have published[3] applications of the [4.3.0] bicyclic lactam to access a variety of alkaloids (*e.g.* 1-deoxy-6-epicastanospermine and coniceine), Fig. 2.

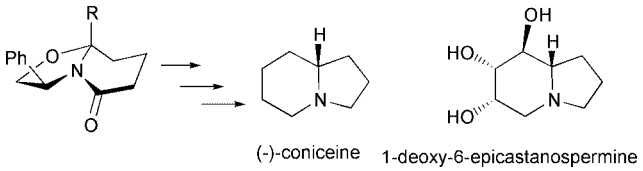

Fig. 2

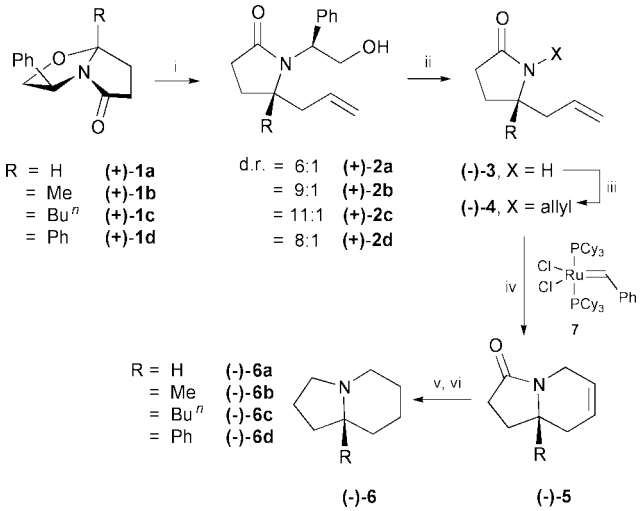
We now report a general protocol utilizing bicyclic lactams **1a**–**d** for the construction of a variety of enantiomerically pure indolizidines (Scheme 1) including the naturally occurring parent ring system, (−)-coniceine **6a**.

The synthetic route to the 1-azabicyclic systems **6** began by the addition of allyltrimethylsilane to a dichloromethane solution of the enantiomerically pure bicyclic lactam and titanium tetrachloride to furnish the 5-substituted pyrrolidinone **2** with diastereomeric ratios ranging from 6:1 to 11:1. After the diastereomers in **2** were separated (silica gel column chromatography) the chiral auxiliary was removed by dissolving metal reduction using calcium metal (NH_3, −78 to −30 °C over 4 h) affording **3**. It is noteworthy that for compound **2d** containing two possible benzylic cleavage sites only the exocyclic *N*-benzyl bond was cleaved. Introduction of the *N*-allyl group to give **4** proceeded smoothly by addition of allyl bromide to the sodium salt of the pyrrolidinone. The bis-olefin **4** was subjected to a ring-closing metathesis (10 mol% **7** as catalyst, 25 °C, 1,2-dichloroethane) to afford the indolizidinones **5** in excellent yields.[4] Hydrogenation of the olefinic bond and reduction of the lactam carbonyl provided the target compounds **6a**–**d** in 32–51% overall yield. In the case where R = H, the reaction sequence provided a 49% overall yield of (−)-coniceine, which

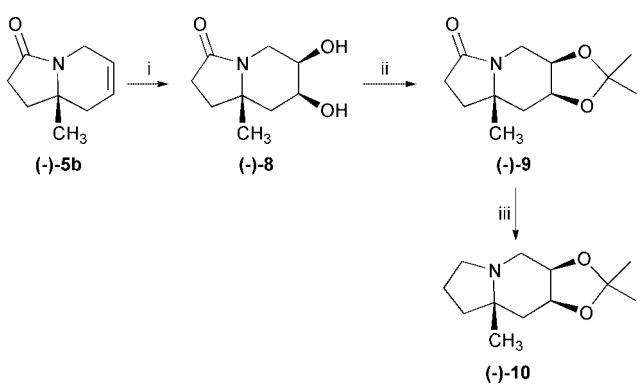


Scheme 1 *Reagents and conditions*: i, allyltrimethylsilane, $TiCl_4$, 68–79% 6:1–11:1 dr; ii, Ca/NH_3, 73–89%; iii, NaH/allylbromide, 81–92%; iv, cat. **7** (10 mol%), 89–93%; v, H_2, $Pd(OH)_2$, 92–96%; vi, $LiAlH_4$, 83–89%.

was identical with a sample previously reported from these laboratories.[3a]

To further illustrate the versatility of this methodology, the oxygenated derivatives of **6** were obtained by dihydroxylation of metathesis product **5b** providing the 3,4-dihydroxy indolizidinone **8** as a 4:1 mixture of diastereomers which were separable by column chromatography (Scheme 2). In order to simplify the purification and reduce water solubility of the diol **8**, it was protected as the acetonide **9** and reduced to the indolizidine **10** using lithium aluminium hydride. This route provides enantiomerically pure hydroxylated derivatives of 1-azabicyclo[4.3.0]nonanes.

In summary, a general method for the construction of a variety of optically pure indolizidines using the chiral non-racemic [3.3.0] bicyclic lactams **1a**–**d** in combination with ring-closing metathesis has been illustrated. The utility of this method is exemplified by the synthesis of (−)-coniceine with excellent stereocontrol and overall yield.[5]



Scheme 2 *Reagents and conditions*: i, OsO_4/NMO, 73% 4:1 dr; ii, 2,2-dimethoxypropane, TsOH, 94%; iii, $LiAlH_4$, 89%.

5 *Typical procedure*; the synthesis of **5c** from **1c**: A dichloromethane solution of the bicyclic lactam **1c** (1.4 g, 5.48 mmol) was cooled to −78 °C and $TiCl_4$ (9 ml of 1.0 M solution in dichloromethane, 1.6 equiv.) was slowly added *via* syringe followed by allyltrimethylsilane (1.3 mL, 1.5 equiv.). The solution was stirred under an argon atmosphere and allowed to warm to r.t. over a 4 h period. A solution of saturated NH_4Cl (50 mL) was added in one portion and the layers were separated. The aqueous layer was washed with dichloromethane (3 × 50 mL), the combined organic layers were dried over Na_2SO_4 and concentrated to an oil. ^1H NMR analysis of the crude material was used to analyze the diastereomeric ratio. Column chromatography (SiO_2, EtOAc) provided 1.25 g of **2c** (76%) as a colorless solid: mp 98 °C; $[\alpha]_D$ −177 (*c* 1.9, $CHCl_3$); δ_H (300 MHz, $CDCl_3$) 0.97 (t, *J* 7 Hz, 3H), 1.26–1.45 (m, 4H), 1.58–1.71 (m, 2H), 1.89–2.06 (m, 4H), 2.49 (t, *J* 9 Hz, 2H), 4.08–4.27 (m, 3H), 4.70–4.97 (m, 3H), 5.36 (dddd, *J* 17, 13, 10, 7 Hz, 1H), 7.24–7.43 (m, 5H); δ_C (75 MHz, $CDCl_3$) 14.0, 22.9, 25.5, 27.6, 30.4, 37.7, 44.7, 60. 3, 65.5, 68.2, 199.0, 127.2, 127.7, 128.2, 132.3, 139.1, 177.4; IR(film) ν/cm^{-1} 1658, 3351. Anal. Calc. for $C_{18}H_{27}NO_2$: C, 75.71; H, 9.03. Found: C, 75.44; H, 9.03%. A dichloroethane solution of the bis-olefin **4c** (200 mg, 0.9 mmol) was added to a solution of catalyst **7** (74 mg, 10 mol%). The purple solution slowly changed to brown. After 6 h the reaction was concentrated *in vacuo* to an oil and chromatographed (SiO_2, EtOAc) to provide **5c** (179 mg, 92%) as a colorless solid: mp 63 °C; $[\alpha]_D$ −58 (*c* 1.0, $CHCl_3$); δ_H (300 MHz, $CDCl_3$) 0.91 (t, *J* 7 Hz, 3H), 1.12–1.39 (m, 4H), 1.48–1.82 (m, 3H), 2.01–2.21 (m, 3H), 2.38–2.53 (m, 2H), 3.40 (d, *J* 9 Hz, 1H), 4.38 (d, *J* 9 Hz, 1H), 5.71 (m, 2H); δ_C (75 MHz, $CDCl_3$) 14.1, 23.1, 25.9, 27.8, 29.9, 30.3, 36.0, 38.4, 60.0, 122.8, 123.8, 173.5; IR(film) ν/cm^{-1} 1692.

Preparation of optically active *n*-butyl(methyl)phenyl-, *tert*-butyl(methyl)phenyl- and isopropyl(methyl)phenylsilanes from the corresponding silyl chlorides using 2,2′-dihydroxy-1,1′-binaphthyls as resolving agents

Enantiomeric silanes 4a, 4b and 4c were obtained from the corresponding racemic silyl chlorides *via* diastereomeric derivatives with (*R*)-[1,1′]binaphthalenyl-2,2′-diol; the optical purity of silanes 4a and 4c was determined (> 98% ee) by HPLC using a chiral cyclodextrin-based column.

Increasing attention has been recently paid to the preparation and synthetic applications of organosilicon compounds with a stereogenic silicon atom.[1,2] Chiral tri(alkyl/aryl)silanes appear to be the most important reagents and synthetic intermediates in this field, owing to their facile reactions with carbon–carbon multiple bonds[3] and easy transformations into other organosilicon compounds, among others, to silyl halides. The pioneering work on tri(alkyl/aryl)silane stereochemistry has been conducted long ago using methyl(naphthyl)phenylsilane[4,5] which is crystalline and relatively easy to obtain in an optically pure form. Some other optically active silanes (non-crystalline in the majority of cases when the naphthyl group is not present) have been prepared only recently. Masuda and coworkers[6] have reported the preparation of several optically active tri(alkyl/aryl)silanes by asymmetric synthesis involving chiral auxiliaries. It has been shown that enzymatic methods have a considerable potential in synthesis of optically active organosilicon compounds.[7–9] Since racemic silane derivatives are readily available, a racemate resolution may provide a convenient and amenable to large-scale approach to a variety of optically active silanes. Along such lines, a method for the preparation of enantiomers of *tert*-butyl(methyl)phenylsilane **4a** (Scheme 1) from racemic *tert*-butyl(methyl)phenylsilyl chloride **2a**, based upon resolution of a particular racemic intermediate with enantiomeric 2-aminobutanols has been developed in our laboratories.[10] However, all our attempts to extend this method to other alkyl/arylsilanes failed. In the search for a more general procedure for racemic silane resolution we have chosen enantiomeric [1,1′]binaphthalenyl-2,2′-diols (BINOLs) as the resolving agents. These easily accessible crystalline compounds have found broad application as ligands and chiral recognition agents;[11,12] however, to the best of our knowledge, their use as resolving agents has not been reported. We present here a method for the preparation of enantiomeric silanes **4a–c** with use of BINOLs. We also report the first direct determination of optical purity of silanes by GC with a chiral column, which provides an important tool for further work with optically active silanes.

Treatment of the lithium derivative of (*R*)-BINOL **1** with racemic *tert*-butyl(methyl)phenylsilyl chloride[7] **2a** yielded diastereomeric derivatives **3a** quantitatively. This diastereomer mixture was separated on a silica gel column to give pure crystalline diastereomers **3a**(Si*R)* and **3a**(Si*S*) and some mixed fraction.† Complete separation of **3a**(Si*R*) and **3a**(Si*S*) was achieved using preparative HPLC‡ and their yields and some physical data are given in Table 1. The absolute configuration of the diastereomer **3a**(Si*R*) (more mobile on chromatography) follows from its single crystal X-ray analysis,§ and a plot of the X-ray structure of **3a**(Si*R*) is shown in Fig. 1. In a similar manner BINOL derivatives of *n*-butyl(phenyl)methylsilane **3b** and phenyl(isopropyl)methylsilane **3c** were prepared and their respective diastereomers were separated by chromatography. The yields and some physical properties of these compounds are given in Table 1. Neither of the diastereomers of **3b** or **3c** could be obtained in crystalline form.

[a] Determined by GC analysis using a chiral column (B-DM; ASTEC; 50 m × 0.32 mm; 100 kPa).

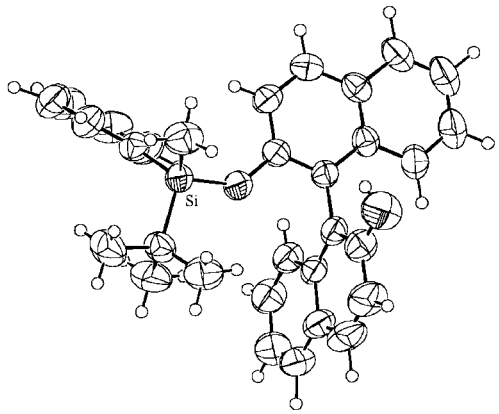

Fig. 1 X-Ray crystal structure of **3a**(Si*R*).

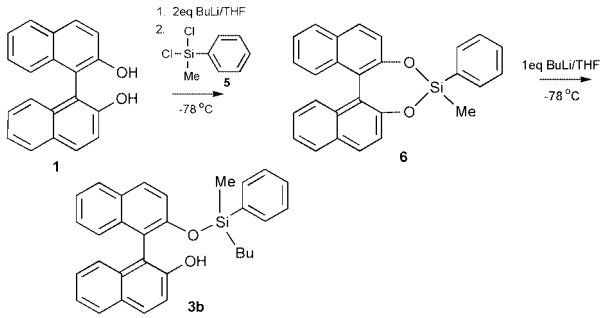
In order to generate optically active silane and to recover the BINOL, diastereomer **3a**(Si*R*) was reduced with $LiAlH_4$ in diethyl ether. Silane **4a**(*S*) was obtained in 83% yield, 95% ee. Specific rotation¶ and optical purity of this product (determined by GC analysis on a chiral column, *vide infra*) are presented in Table 2. Transformation of **3a**(Si*R*) into **4a**(*S*) indicates that $LiAlH_4$ reduction of the BINOL derivative occurred with retention of configuration around the Si atom, as expected by analogy to other O–Si derivatives.[13] Reduction of the more mobile diastereomer **3b**(Si*R*) afforded dextrorotatory silane **4b**(*S*).

Similarly, reduction of all other diastereomeric silyloxy derivatives afforded optically active silanes with yields and some properties compiled in Table 2. The optical purity of enantiomeric silanes **4c** was very high while the enantiomeric purity of **4b** could not be determined (*vide infra*). The absolute configuration of silanes **4b** and **4c** could not be determined by X-ray measurements. However, comparison with **4a** and some other silanes described[14] indicates an Si*S* configuration for the dextrorotatory enantiomers.

An attempt was made to use BINOL as a template for asymmetric synthesis of silanes. Treatment of *rac*-BINOL **1** (Scheme 2) with 2 mol equivalents of *n*-butyllithium followed by dichloro(methyl)phenylsilane (THF, −78 °C) gave an unstable intermediate which could not be isolated, presumably the [1,3,2]dioxasilepane derivative **6**. However, treatment of **6** *in situ* with 1 mol equivalent of *n*-butyllithium (THF, −78 °C) afforded **3b** as a mixture of diastereomers in a 1:1 ratio. Interestingly, stable [1,3,2]dioxasilepane derivatives with biphenyl frameworks have been prepared.[15]



Scheme 2

Determining the optical purity of silanes **4a**–**c** was crucial for their intended use in asymmetric synthesis. An attempt was made to apply several analytical methods, including HPLC on chiral columns and NMR measurements in the presence of shift reagents. Eventually, it was found that GC analysis using a commercial cyclodextrin-based chiral column (B-DM; ASTEC; 50 m × 0.32 mm) provided base-line separation of enantiomers **4a** at 70 °C [R_t = 75.51 min, (*R*); R_t = 77.00 min (*S*)] and **4c** at 120 °C [R_t = 25.37 min (*S*); R_t = 26.95 min (*R*)]. Conversely, silane **4b** bearing an *n*-butyl group showed no enantiomer separation even for a much longer retention time. To the best of our knowledge, GC chiral column separation of **4a** and **4c** represents the first direct determination of enantiomeric purity of tri(alkyl/aryl)silanes.

In conclusion, a method for preparation silanes **4a**–**c** of high enantiomeric purity has been developed. It has been shown that the enantiomeric purity of virtually unpolar silanes may be determined by GC using a cyclodextrin-based chiral column.

Financial support from the State Committee of Scientific Researches, Poland and the Volkswagen Foundation, Germany, is gratefully acknowledged.

Molecular insight into the non-innocence of a silica-support: the structure of a platinum–silsesquioxane derivative

Elsje Alessandra Quadrelli, John E. Davies, Brian F. G. Johnson* and Neil Feeder

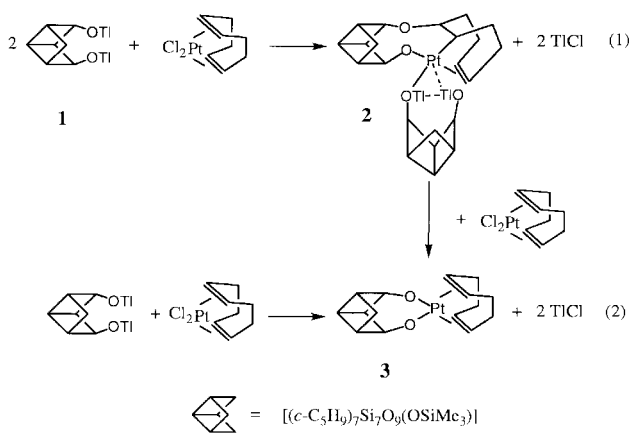
University Chemical Laboratories, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: bfgj1@cam.ac.uk

Received (in Cambridge, UK) 4th February 2000, Accepted 27th April 2000
Published on the Web 25th May 2000

The cyclooctadiene ligand within the square planar Pt(II) complex [$PtCl_2(C_8H_{12})$] undergoes nucleophilic attack from a siloxo group of the thallated polyhedral silsesquioxane [(c-$C_5H_9)_7Si_7O_9(OSiMe_3)(OTl)_2$], to yield [($c$-$C_5H_9)_{14}Si_{14}O_{18}(OSiMe_3)_2O_4(\eta^4$-$C_8H_{12})PtTl_2$]; given the analogy between the silsesquioxane moiety and a silica surface, the presence of an SiO–C bond between the siloxo-cage and the Pt-bound olefinic ring is significant in the context of surface non-innocence in heterogeneous catalysis.

Metalla-derivatives of partially condensed silsesquioxanes (POSS) provide an appropriate manifold for gaining molecular insight into the nature of silica-supported heterogeneous catalysts.[1] Complexes of metallic POSS with centres are known to display close structural and chemical resemblance to their heterogeneous counterparts.[1] Here, we wish to report the structure of a highly novel mixed-metal silsesquioxane complex [[(c-$C_5H_9)_7Si_7O_9(OSiMe_3)O_2]_2(\eta^4$-$C_8H_{12})PtTl_2$] **2** that displays an unprecedented siloxo-metallacycle derived from the formal oxidative-addition of a Pt–OSi bond across a carbon–carbon double bond of a coordinated diolefin. Such interaction models a direct involvement of a 'non-innocent' silica surface into the activation of an unsaturated substrate. To date, no other molecular model for such 'support–catalytic center' interaction had been reported.

Upon addition of [$PtCl_2$(cod)] (cod = cycloocta-1,5-diene) to a benzene solution containing 2 equivalents of [(c-$C_5H_9)_7Si_7O_9(OSiMe_3)(OTl)_2$] **1**,[2] the mixed-metal compound **2** is formed in low yield (*ca.* 6%) (Scheme 1).† Compound **2** may also be isolated by fast addition of [$PtCl_2$(cod)] to an equimolar solution of **1**, followed by rapid work-up of the reaction mixture. Conversely, if [$PtCl_2$(cod)] is added slowly to an equimolar benzene solution of **1** and the mixture allowed to stand for 56 h, elimination of 2 equivalents of TlCl is observed and the metalla-silsesquioxane [(c-$C_5H_9)_7Si_7O_9(OSiMe_3)O_2Pt(\eta^4$-$C_8H_{12})$] **3** can be isolated in moderate yield (53%) (Scheme 1). Compound **2** has also been found to react with 1 equivalent of [$PtCl_2$(cod)] to give **3**.



Scheme 1

Compound **2** was initially characterised by its ^{1}H NMR spectrum in C_6D_6 which clearly indicates that the Pt(cod) moiety is coordinated to the silsesquioxane cage. However, a complete elucidation of the structure based on the NMR data is hindered by the overlap of cyclopentyl and cyclooctadienyl resonances. The molecular structure of compound **2** was elucidated by single-crystal X-ray diffraction analysis (Fig. 1).‡

Compound **2** consists of two silsesquioxane moieties bridged by a trinuclear (C_8H_{12})$PtTl_2$ core. The metallic unit shows a Tl–Tl distance of 3.7382(13) Å and a Tl–Pt distance of 3.2393(15) Å. The central thallium atom [Tl(I)] forms an angle with its neighbours of 63°43′. The geometry at the platinum metal, excluding the thallium contact, is square planar with mean deviation from the plane of 0.1712 Å. The thallium atom sits above the plane, forming an angle with the perpendicular to the plane of 27°. The Pt(II) centre completes its coordination sphere with two Pt–O bonds [2.142(9) and 2.064(10) Å], one Pt–C σ-bond [2.05(3) and 2.16(4) Å, in the two disordered rings present in the solid state structure] and a Pt–C=C π bond [with Pt–C distances of 2.10(2) Å]. Such coordination results form the cyclooctadiene ring having undergone nucleophilic attack from a siloxo moiety. The structural disorder results from the SiO^- nucleophilic attack occurring at both possible sites of the C=C 1,2-double bond. The oxidative addition yields reaction both on Pt–C and a SiO–C bond [O–C 1.55(3) Å]. The C–C distances of 1.53(3) and 1.49(3) Å in the disordered structure show substantial lengthening with respect to the coordinated olefinic C=C bond [1.36(2) Å]. Both oxygen atoms involved in the Pt–O bonds are also involved in a Tl–O bond [2.514(11) and 2.681(11) Å]. This μ_2-siloxo-binding mode contributes one electron to the overall electron count for the platinum centre. The apparent electron deficiency at the Pt(II) centre may be taken to explain the presence of the thallium–platinum contact. Thallium(I)–platinum(II) bonds are known,[3] although in scarce

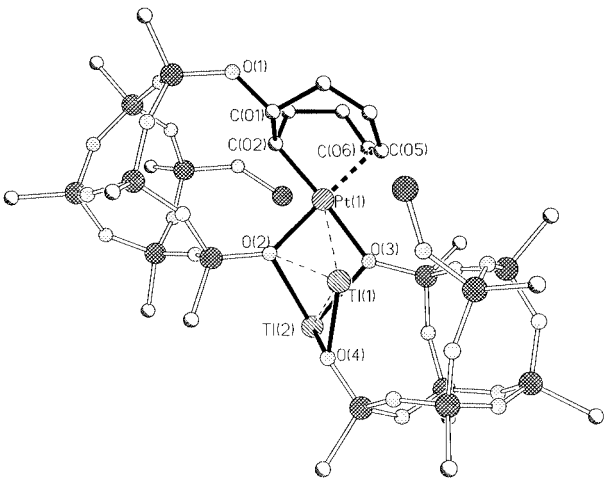


Fig. 1 Molecular structure of **2**. No H and only *ipso* carbons of cyclopentyl rings are shown for clarity. Only one of the two disordered cod rings is shown for clarity. See text for selected bond lengths and angles.

DOI: 10.1039/b000992j

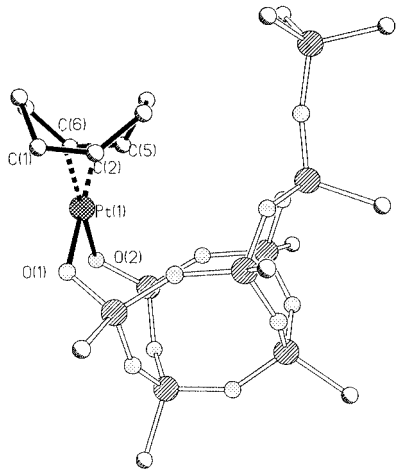

Fig. 2 Molecular structure of **3**. No H atoms and only *ipso* carbons of cyclopentyl rings are shown for clarity. Selected interatomic distances (Å) and angles (°) (CNT is the centroid of the coordinated double bond): Pt1–O1 1.987(5), Pt1–O2 1.990(5), Pt1–C1 2.16, Pt1–C2 2.139, Pt1–C5 2.143(7), Pt1–C6 2.131(7), Pt1–CNT1 2.015, Pt1–CNT2 2.021, C1–C2 1.376(10), C5–C6 1.387(11); O2–Pt1–O1 90.4(2), O1–Pt1–CNT1 90.3(3), CNT1–Pt1–CNT2 89.4(3).

number. They vary in length between 2.860 Å[3c] and 3.135 Å,[3b] making the presently reported one the longest to date. The bonding geometry encountered here is reminiscent of those previously reported, with the Tl–Pt vector approaching the prependicular of the square planar Pt(II) complex.[3b]

The most striking feature of compound **2** is the presence of a σ bond between the siloxane frame and the metal coordinated cyclooctenyl ligand. To our knowledge, this would appear to be the first derivative that displays activation of a metal ligand by the silsesquioxane frame. The only two previously reported platinasilsesquioxanes are [(*c*-C_5H_9)$_7$$Si_7O_9$(OSi$Me_3$)$O_2$Pt(dppe)][4] (dppe = diphenyldiphosphinoethane) and [(*c*-C_6H_{11})$_7$$Si_7O_9$($OSiMe_3$)$O_2$Pt(η^4-$C_8H_{12}$)].[1b] While no experimental details are available for the latter, the former has been fully characterised, and consists of a square planar Pt(dppe) complex of the dipodal silsesquioxane cage. The chemistry at the platinum centre can be described as resulting from the exchange of two chloride ions from the appropriate Pt(II) salt with a dipodal silsesquioxane frame, with no other variation in the remaining coordination sphere of the metal centre. This reaction, which is the most used synthetic strategy for obtaining metalla silsesquioxanes,[1c] has been applied successfully in this work and compound **3** obtained [see reaction (2) in Scheme 1].§ This has been characterised by analytical and spectroscopic techniques, and its molecular structure determined by a single crystal X-ray diffraction study (Fig. 2),‡ making it the first organometallic platina-silsesquioxane structurally characterised.

The structure of **3** is similar to the dppe derivative described above. The Pt(cod) moiety retains most of its structural characteristics upon grafting onto the silanol. The presence of two distinct ^{1}H NMR resonances for the olefinic protons confirms the asymmetry in the ring-coordination arising from the presence of the POSS cage. This complex is also related to the complex [(η^4-cod)Pt($OSiPh_3$)$_2$],[5] obtained from the reaction of [$PtCl_2$(cod)] with triphenylsilanol.

The structures of compounds **2** and **3** shed considerable light into the nature of silica-supported platinum-based catalysts. With compound (η^4-cod)Pt($OSiPh_3$)$_2$,[5] they are the only reported organometallic siloxo complexes of platinum(II), and therefore constitute the only available models for silica supported organoplatinum catalysts. Such heterogeneous systems are of interest, given their use as catalysts in the heterogeneous hydrogenolysis of hydrocarbons.[5] As with supported heterogeneous catalysts in general, the molecular structure of their active site is seldom known with precision. In such materials the activity is normally believed to reside at the metal centre, although the existence of a 'support-effect' in the solid state has been invoked.[6] Compound **3** shows no interaction of the 'silica-like' silsesquioxane frame with the coordinated unsaturated substrate. Such structural motif models a catalyst supported on an *inactive* silica surface, and modeled in POSS chemistry. In contrast, compound **2** exemplifies the opposite situation; the coordinated unsaturated bond establishes a direct bond with the 'silica-like' part of the metalla-POSS emphasising the possible non-innocence of a silica surface.

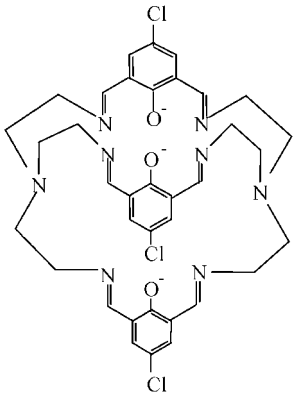
Received (in Cambridge, UK) 21st December 1999, Accepted 3rd May 2000

The heterodinuclear cryptate [DyCuL(DMF)](ClO$_4$)$_2$·MeCN [where L denotes the deprotonated anionic cryptand obtained by condensation of tris(2-aminoethyl)amine with 2,6-diformyl-4-chlorophenol] has been obtained by a stepwise method; the presence of copper(II) and dysprosium(III) in the cavity of the cryptand was evidenced by X-ray structure analysis and ESMS spectroscopy.

Heterodinuclear complexes have received much attention owing to their electronic, electrochemical, and magnetic properties arising from the metal–metal interaction,[1] and mimicking of the active centers of some metalloenzymes, for example, copper–zinc superoxide dismutase,[2] cytochromic oxidase,[3] hydrogenase,[4] *etc*. Heterodinuclear complexes of dinucleating 'Robson-type' macrocycles[5] have been recognized for many years.[6] Most of these are two-dimensional macrocyclic complexes encapsulating transition metal ions. A few d–f heteronuclear macrocyclic complexes have been reported.[7] Since it was found that the Gd(III)–Cu(II) intramolecular interaction in the complexes is ferromagnetic,[8] interest has been aroused in the synthesis of d–f heteronuclear macrocyclic complexes in order to develop new functions. The cryptates have good thermodynamical stability and kinetic inertness toward metal dissociation. The first homodinuclear lanthanide cryptate was synthesized in 1999,[9] but up to date no examples of heteronuclear d–f cryptates have been described in the literature. Here, we report the first example of a d–f heteronuclear Dy(III)–Cu(II) complex of a Robson-type cryptand together with its crystal structure. The mononuclear dysprosium cryptate was synthesized by metal-templated reaction between 2,6-diformyl-4-chloro-phenol (dcp) and tris(2-aminoethyl)-amine (tren) in the presence of hydrated dysprosium nitrate in 3:2:1 mol ratio in absolute methanol. After refluxing for 3–4 h, the yellow mononuclear dysprosium cryptate was produced, which was used as a precursor to synthesize the heteronuclear complex. The yellow complex (117 mg, 0.1 mmol) was dissolved in methanol (20 cm^3) containing a small amount of DMF. The pH of the solution was *ca*. 6. After adding an excess of CaH_2 powder, the pH of the solution changed to 7–8. After filtering the solution, copper perchlorate (0.1 mmol) in methanol (5 cm^3) was added resulting in a green solution. After refluxing for *ca*. 2 h a red solid was produced. Slow diffusion of diethyl ether into an acetonitrile solution of the complex gave red prismatic crystals of [DyCuL(DMF)](ClO$_4$)$_2$·MeCN suitable for an X-ray study,†‡ where L is the deprotonated anionic cryptand obtained by condensation of tren with dcp (Scheme 1).

The ESMS spectra display intense peaks corresponding to the fragments [DyCu(L − 3Cl)(DMF)(MeCN)]$^{2+}$ (100), [DyCu(L − 3Cl)(DMF) + (Cl$^-$) + 2(MeOH)]$^+$ (42) and [DyCu(L − 3Cl)(DMF) + (Cl$^-$) + 2(MeOH) + (MeCN)]$^+$ (24%), confirming the presence of the Dy(III)–Cu(II) core in the cryptate. It is found that the chlorine atom of the phenyl rings can be lost under ESMS conditions, whereas the Dy(III)–Cu(II) macrobicycle remained intact and [DyCu(L − 3Cl)(DMF)(MeCN)]$^{2+}$ appears with 100% base peak intensity.



Scheme 1 Anionic cryptand L.

Structural analysis of this complex comfirmed the presence of the Dy(III)–Cu(II) unit in the cavity of the macrocycle. The crystals contain the cation [DyCuL(DMF)]$^{2+}$, two independent perchlorate anions and an acetonitrile molecule. Fig. 1 illustrates the structure of the cation.

The Dy(III) ion is located at one end of the cavity and is eight coodinated with the bridgehead nitrogen atom [N(1)], three imino-nitrogen atoms [N(2), N(3), N(4)], the three μ-phenolate oxygen atoms [O(1), O(2), O(3)] and the oxygen atom O(4) of DMF. The coordination polyhedron is best described as distorted dodecahedral. The Dy–N(imino) distances are in the range 2.443–2.509 Å, with Dy(III)–N(1) 2.617 Å, shorter than found in a Dy(III) mononuclear cryptate reported by Fenton and coworkers,[10] however the Dy(III)–O(phenolate) distances are longer than those reported in the literature.[10] The other end of the cavity is occupied by the Cu(II) ion. Three μ-phenolate oxygen and three imino-nitrogen atoms coodinate to Cu(II), forming a distorted octahedron. The Dy···Cu distance is

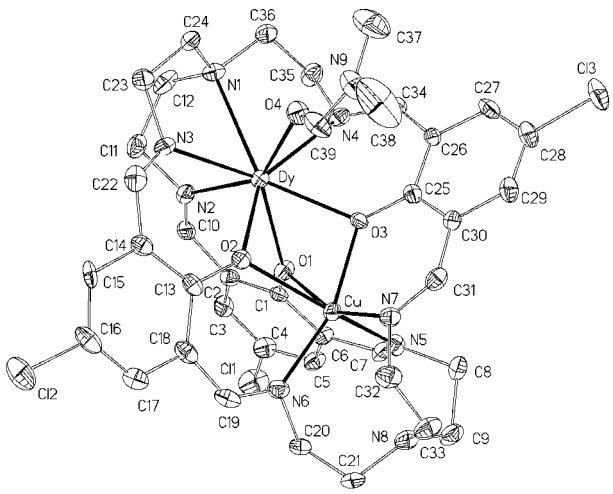


Fig. 1 Crystal structure of [DyCuL(DMF)]$^{2+}$.

DOI: 10.1039/a909926n

3.255 Å. The Dy(III)–O(1)–Cu(II), Dy(III)–O(2)–Cu(II) and Dy(III)–O(3)–Cu(II) angles are 92.1, 90.0 and 97.1°, respectively. The distance between the two bridgehead nitrogens, N(1)···N(8) 9.003 Å, is larger than that found for a mononuclear dysprosium(III) cryptate (8.361 Å)[10] or in a homobinuclear Lu(III) cryptate (8.65 Å),[9] and slightly shorter than that in $[Cd_2L]^{2+}$ (9.01 Å),[11] revealing that the cryptand (L) can expand or contract as appropriate to encapsulate one or two metal ions.

Previously we have described a mononuclear neodymium(III) cryptate of ligand L in which one water molecule was encapulated as a guest.[12] In the present work we have extended the work *via* a stepwise synthesis to introduce a 3d metal ion which occupies the position of the water molecule in the cavity. Further d–f heteronuclear cryptates consisting of transition metals [copper(II), nickel(II), *etc*.] and other lanthanide ions have also been synthesized and will be reported elsewhere.

A novel and highly efficient approach to angularly fused tricycles has been developed through the employment of selective tandem ring closing metathesis reactions.

Angularly fused tricycles represent a structurally intriguing unit present in many natural products and have attracted the attention of synthetic chemists for a number of years.[1] Amongst prominent targets of this class of compounds are triquinanes and marine alkaloids, of which there are a plethora of examples with a variety of biological activities. In the process of our investigations into the scope of tandem ring closing metathesis (RCM) reactions[2] for the synthesis of functionalised carbon skeleta,[3,4] we have turned our attention to the application of this technique to the formation of angularly fused tricycles by employing the general strategy outlined in Fig. 1. Specifically, we were interested in observing the relative ease of tricycle formation (mode a cyclisation) *versus* that of spirocyclisation (mode b cyclisation), and additionally, whether spirocycles would themselves participate in tricycle formation. In this regard, the groups of Grubbs[4a] and Mioskowski[4e] have shown that tandem metathesis (mode a type) cyclisation products are highly favoured, and can indeed be generated by ring opening/closing metathesis of mode b type substrates.

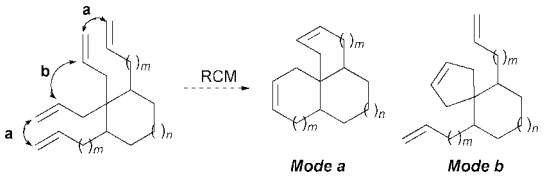

Fig. 1

We prepared a suitable model system through a routine two step procedure, which provided both *syn*- and *anti*-diols **2** and **3** which were readily separated by column chromatography (Scheme 1).

With the desired tetraenes in hand, we turned our attention to the tandem RCM reaction paying particular regard to the selectivity of tricycle *versus* spirocycle formation. Subjection of *syn*-tetraene **2** to 20 mol% Grubbs' catalyst PhCH=Ru(P-$Cy_3)_2Cl_2$ **I** for 48 h gave a complex reaction mixture[5] from

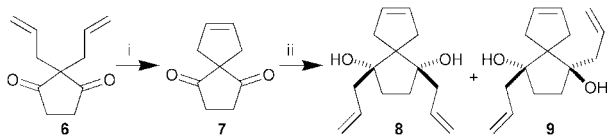
which the desired tricycle **4** could be isolated in 38% yield as a stable crystalline solid (Table 1, entry 1). In contrast to **2**, the *anti*-diol **3** underwent smooth and selective cyclisation to tricycle **5** in high yield (Table 1, entry 2).[6]‡

We were intrigued that the potentially competing spirocyclisation process was not evident under any of the reaction conditions employed, however, we could not rule out the possibility that the spirocycles were formed transiently and reacted *in situ* to furnish the observed tricyclic products. In an attempt to further clarify this issue, we prepared the appropriate spirocycles by the route shown in Scheme 2.

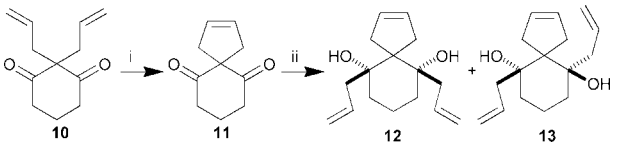
Surprisingly, RCM of diene **6** was rather sluggish and required extensive heating and relatively high catalyst loadings to achieve useful product yield.[7] Nonetheless, the subsequent Grignard alkylation reaction proceeded smoothly to provide a mixture of *syn*- and *anti*-diols in good yield.

Both spirocyclic substrates **8** and **9** were stable to the Ru-catalyst at 25 °C but provided the corresponding tricycles in



Scheme 2 *Reagents and conditions*: i, 10 mol% **I**, 60 °C, DCE, 48 h, 67%; ii, CH_2=$CHCH_2MgCl$, 66%, 5:1 *syn*:*anti*.

DOI: 10.1039/b002136i



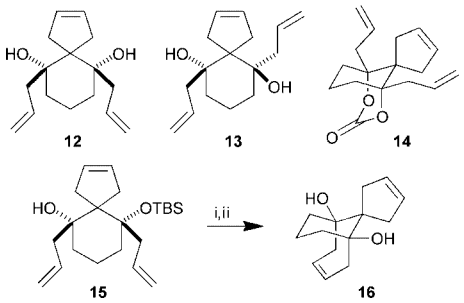
Scheme 3 *Reagents and conditions*: i, 2 mol% **I**, 25 °C, CH_2Cl_2, 16 h, 92%; ii, CH_2=$CHCH_2MgCl$, 85%, 2 : 1 *syn* : *anti*.

comparable yields to those from the appropriate tetraenes in the presence of 10 mol% **I** at elevated temperatures (entries 3 and 4 of Table 1). These results demonstrate that whilst spirocycles **8** and **9** have not been observed in the RCM reactions of **2** and **3**, they cannot be ruled out as intermediates in the reaction process.

In extending this chemistry to six-membered ring analogues we encountered some surprising differences in reactivity. Firstly, all attempts to add allyl magnesium halides to 2,2-diallylcyclohexa-1,3-dione (**10** in Scheme 3) failed to furnish the desired tetraene substrate. We therefore turned our attention to the preparation of the corresponding spirocyclic substrates as outlined in Scheme 3.

In sharp contrast to the RCM reaction of diene **6**, cyclohexane analogue **10** underwent smooth ring closure at room temperature in the presence of 2 mol% **I** to provide the spirocycle **11** in excellent yield. Additionally, this substrate was readily alkylated to give the expected diols **12** and **13** in good yield.

Once again, in contrast to the cyclopentanedione spirocycles, we have found the corresponding cyclohexane analogues to be extremely unreactive towards Ru-catalysed tricycle formation. As outlined in Scheme 4, the *syn*- and *anti*-spirocycles **12** and **13** were inert to metathesis even on prolonged heating with 20 mol% Ru-catalyst. Protection of the diol unit as mono-silyl ether **15** provided bridged bicycle **16** in 64% overall yield, after removal of the TBS-group, as the only metathesis reaction product. In this particular case, it is likely that the increased steric demands of the OTBS unit provides a greater concentration of the diaxial diene conformation and facilitates seven-membered ring closure. We therefore tethered the diol units in the axial position by the preparation of cyclic carbonate **14**,[8] however, once again this substrate was found to be unreactive.



Scheme 4 *Reagents and conditions*: i, 15 mol% **I**, 80 °C, C_6H_6, 48 h; ii, TBAF, 64% overall yield.

The notable difference in reactivity of the cyclopentane-derived spirocycles in comparison to the cyclohexane analogues is unclear at present, however, the relative ease of RCM of diene **10** in comparison to **6** and the ready conversion of spirocycles **8** and **9** *versus* that of **12** and **13** suggests that these differences may originate from the relative strain in the respective cyclopentene moieties.[9] Nonetheless, we have shown that tandem RCM is a viable method for the rapid assembly of *cis,trans*- and *cis,cis*-fused tricyclic skeleta.[10] The application of this methodology in target orientated synthesis and the further study of the selectivity issues raised in this communication are currently under investigation.

We are grateful to the EPSRC for studentships (M. J. B. and A. S. E.) and to AstraZeneca for financial support.

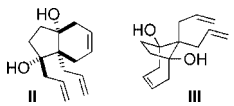
5 We have isolated and tentatively assigned (NMR and mass spectrometry) compounds **II** and **III** from the reaction mixture. Their rigorous characterisation is currently underway and will form part of a full account.



6 The stereochemical assignment of **5** is based on the significant stability of the *cis,cis*-isomer over the alternative *trans,trans*-isomer, calculated to be *ca*. 30 kcal mol^{-1} using AM1 semiempirical methods implemented using Spartan™ software. The assignment of **4** was based on X-ray crystallographic analysis.

7 In the course of this study the RCM reaction of diene **6** was reported to proceed in good yield (77%) at room temperature: S. Kotha, E. Manivannan, T. Ganesh, N. Sreenivasachary and A. Deb, *Synlett*, 1999, 1618. This result could not be reproduced in our hands.

8 Prepared by addition of diol **12** to oxalyl chloride in the presence of pyridine and DMAP catalyst.

9 Additionally, the poor reactivity of the cyclohexane system may originate from the inability of the appropriate alkene units to attain sufficient alignment for metathesis. We thank a referee for this suggestion.

10 All compounds exhibited satisfactory analytical and spectral data.

Formation of a diphosphine: synthesis and molecular structure of bis(tetraphenylbutadienyl)diphosphine, $(Ph_4C_4)P–P(C_4Ph_4)$

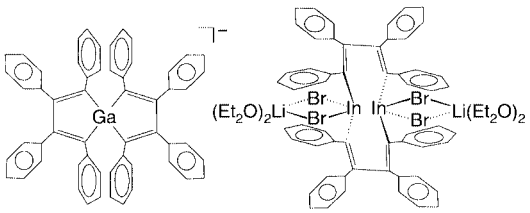
Received (in Columbia, MO, USA) 14th February 2000, Accepted 5th April 2000
Published on the Web 25th May 2000

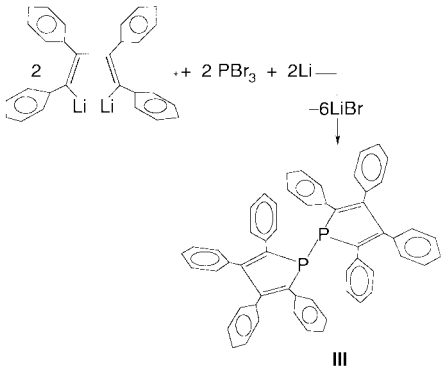
Reaction of 1,4-dilithiotetraphenylbutadiene with phosphorus(III) bromide affords bis(tetraphenylbutadienyl)diphosphine, $(Ph_4C_4)P–P(C_4Ph_4)$, with a phosphorus–phosphorus bond length of 2.2051(11) Å.

Bis(2,4,6-tri-*tert*-butylphenyl)diphosphene, $(Bu^t_3C_6H_2)P{=}P(C_6H_2Bu^t_2)$,[1] the first compound shown to contain a formal phosphorus–phosphorus double bond [P–P 2.034(2) Å], was prepared by the magnesium metal reduction of $(Bu^t_3C_6H_2)PCl_2$. Indeed, alkali (or alkaline earth) metal reduction is one of three general routes to diphosphines (the other two being heating a phosphinous halide, R_2PCl, with a secondary phosphine or with an alkali metal phosphine),[2] a significant development in main group chemistry. Furthermore, as evidenced by subsequent studies concerning $(Bu^t_3C_6H_2)P{=}P(C_6H_2Bu^t_3)$,[3] the chemistry of diphosphenes and diphosphines continues to be of interest to both synthetic and computational chemists. Crucial in the stabilization of $(Bu^t_3C_6H_2)P{=}P(C_6H_2Bu^t_3)$ was the utilization of the sterically demanding 2,4,6-tri-*tert*-butylphenyl ligand. In a related vein, this laboratory has recently examined the organogroup 13 (III) chemistry of 1,4-dilithiotetraphenylbutadiene resulting in two interesting complexes: (a) a spirogallane anion,[4] $[(Ph_4C_4)Ga(C_4Ph_4)]^-$ **I**; and (b) an In_2C_8 ten-membered ring, $(Et_2O)_2Li(Br)_2In\{(C_4Ph_4)\}_2In(Br)_2Li(OEt_2)_2$ **II**.[5]



I **II**

Herein, we report the synthesis[6] and molecular structure[7] of bis(tetraphenylbutadienyl)diphosphine, $(Ph_4C_4)P–P(C_4Ph_4)$ **III**, readily isolated from reaction of 1,4-dilithiotetraphenylbutadiene,[8] prepared by the action of an excess of metallic lithium on diphenylacetylene, with phosphorus(III) bromide (Scheme 1). This compound, characterized by ^1H, ^{13}C and ^{31}P NMR spectroscopy elemental analyses and single-crystal X-ray diffraction (Fig. 1), is significant as it represents an interestingly facile, if unexpected, one-pot route to a diphosphine.



III

Scheme 1

The past two decades have witnessed a number of studies concerning compounds containing phosphorus–phosphorus bonds.[9] Indeed, this laboratory has had an interest in the preparation of diphosphines having previously reported the synthesis and molecular structure of $[(Me_3Si)_2P\{Me_2Ga\}_2PMe]_2$,[10] isolated from reaction of $Me_3P–GaMe_3$ with $P(SiMe_3)_3$, having a P–P single bond length of 2.25(3) Å. Relative to diphosphenes it is important to note the previously reported σ-bonded pentamethylcyclopentadienyl-based diphosphene, bis(pentamethylcyclopentadienyl)diphosphene, $(\sigma\text{-}C_5Me_5)P{=}P(\sigma\text{-}C_5Me_5)$.[11] The phosphorus atoms in $(\sigma\text{-}C_5Me_5)P{=}P(\sigma\text{-}C_5Me_5)$ are two-coordinate (σ-bonding to one of the carbon atoms of the ring and to the other phosphorus atom) with a P–P double bond length of 2.031(3) Å.

A number of points regarding the structure and bonding in $(Ph_4C_4)P–P(C_4Ph_4)$ are relevant. As expected, the five-membered butadienyl rings are planar about the phosphorus atoms with the phenyl rings arranged in a propeller-like fashion. Indeed, the molecule resides in a *trans* configuration. The environment about the phosphorus atoms must be considered distorted pyramidal thereby precluding significant interaction of the phosphorus lone electron pairs with the conjugated system of the tetraphenylbutadienyl moieties. The P–C bond lengths are generally unremarkable. Clearly. the phosphorus–phosphorus bond of 2.2051(11) Å in $(Ph_4C_4)P–P(C_4Ph_4)$ must be considered a single bond. Moreover, the ^{31}P NMR resonance of δ −15.98 in $(Ph_4C_4)P–P(C_4Ph_4)$ is also consistent with a P–P single bond. For comparison, the ^{31}P resonance of $(\sigma\text{-}C_5Me_5)P{=}P(\sigma\text{-}C_5Me_5)$ was reported at δ 504 (121 MHz, C_6D_6)

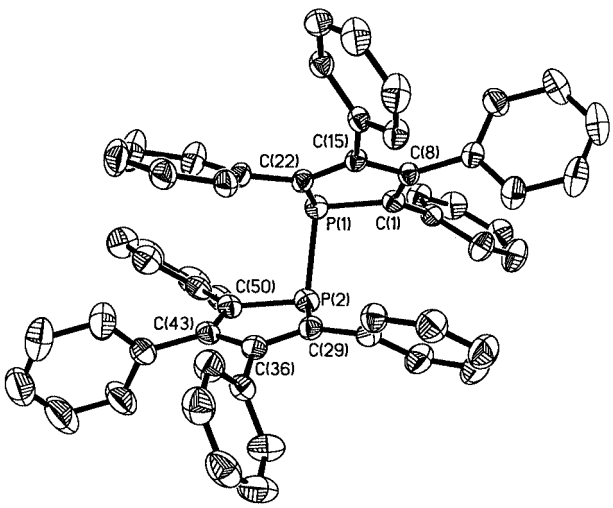


Fig. 1 Molecular structure of $(Ph_4C_4)P–P(C_4Ph_4)$. Bond distances (Å) and angles (°): P(1)–C(22) 1.797(3), P(1)–C(1) 1.799(3), P(1)–P(2) 2.2051(11), P(2)–C(29) 1.796(3), P(2)–C(50) 1.799(3); C(22)–P(1)–C(1) 91.16(12), C(22)–P(1)–P(2) 108.13(9), C(1)–P(1)–P(2) 100.16(9), C(29)–P(2)–C(50) 91.26(14), C(29)–P(2)–P(1) 106.14(10), C(50)–P(2)–P(1) 99.92(10).

DOI: 10.1039/b001257m

while that for the [*trans*-{[Fe(CO_4)]$_2$[PCH($SiMe_3$)$_2$]$_2$}] diphosphene was reported at δ 384.55 (external 85% H_3PO_4) [P–P 2.039(1) Å].[9b]

It is significant that the tetraphenylbutadienyl moiety continues to find utility in main group chemistry. It is noteworthy that the title compound bears some resemblance to the previously reported bis[1-(trimethylsilyl)-2,3,4,5-tetraphenyl-1-silacyclopentadienyl] compound isolated in 54% yield from the sonication of 1,1-dichloro-2,3,4,5-tetraphenyl-1-silacyclopentadiene in the presence of three equivalents of metallic lithium.[12]

We are grateful to the National Science Foundation (G. H. R.: CHE-95-9520162) and to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this work.

Pentamethylmolybdenum

Beatrice Roessler, Sven Kleinhenz and Konrad Seppelt*

Institut für Chemie der Freien Universität Berlin, Fabeckstraße 34-36, D-14195 Berlin, Germany. E-mail: seppelt@chemie.fu-berlin.de

Received (in Cambridge, UK) 4th February 2000, Accepted 30th March 2000

Pentamethylmolybdenum has been prepared and characterized by single crystal structure determination, EPR, and Raman spectroscopy.

The total number of homoleptic[1] neutral metal methyl compounds is small. $Ti(CH_3)_4$ has never been obtained free of donor molecules.[2] $Nb(CH_3)_5$ and $Ta(CH_3)_5$ have been obtained in the pure state,[3] and the structure of the latter has been determined by electron diffraction.[4] $W(CH_3)_6$ and $Mo(CH_3)_6$ are known including their peculiar crystal structures,[5–7] as is $Re(CH_3)_6$.[6,8] Here we describe the formation of $Mo(CH_3)_5$.

In attempts to obtain $Mo(CH_3)_6$ by reacting $MoOCl_4$ with $Zn(CH_3)_2$[7] we have occasionally observed that in high vacuum a blue compound sublimed off into a −196 °C cold trap. We have been able to obtain a single crystal from this material which has been identified as $Mo(CH_3)_5$ by a single crystal structure determination. Subsequently we developed a preparative route from $MoCl_5$ (1.63 mmol) and a slight excess of $Zn(CH_3)_2$ (5.87 mmol) in 20 ml diethyl ether between −78 and −20 °C.[9] After pumping off all volatile materials at −78 °C, 15 ml *n*-pentane was added, and the suspension stirred for 30 min at −78 °C. At −20 °C the solvent was pumped off, and the tail of this vacuum distillation contained a light blue compound. Most of the solvent was pumped off at −78 °C and recrystallisation from $CF_3CH_2CF_3$ between −40 and −60 °C afforded turquoise needles, which turned black upon contact with traces of oxygen or upon warming above −10 °C. $Mo(CH_3)_5$ is thus thermally less stable than $Mo(CH_3)_6$.

The result of the single crystal structure determination is shown in Fig. 1† which shows that the molecule is a square pyramid. For comparison we also prepared $Ta(CH_3)_5$ and succeeded in obtaining single crystals of it by crystallizing a sample from $CF_3CH_2CF_3$ between −40 and −78 °C.† Both molecular structures are virtually identical, in spite of the fact that one is a d^0 and the other a d^1 system. The structural similarity is strikingly different from the $W(CH_3)_6$ ($Mo(CH_3)_6$)/$Re(CH_3)_6$ pair, where the d^1 system is different from the d^0 systems.[5,6]

The only, but still marginal, differences between the $Mo(CH_3)_5$ and $Ta(CH_3)_5$ structures are (i) the larger C_{apical}–M–C_{basal} angles in $Mo(CH_3)_5$, and (ii) the larger bond length difference between apical and basal metal–C bonds for $Ta(CH_3)_5$.

We also calculated the structures of $Mo(CH_3)_5$ and $Ta(CH_3)_5$ using a density functional (DFT) approach, using electron core potentials[10] for Mo and Ta atoms and the 6-311 G(d,p) basis set for C and H.[11] The square pyramidal (*SPY*) structure is energetically strongly favored over the trigonal bipyramidal structure (*TBPY*). For the square pyramidal structures all geometric parameters have been refined independently. In order to obtain energetic and structural data for the trigonal bipyramidal structures one C–M–C angle has been fixed at 180°, while all other variables have been set free. The energy difference between the *SPY* and *TBPY* structures is calculated as 53.4 kJ mol^{-1} for $Ta(CH_3)_5$, (*cf.* 32.2 kJ mol^{-1} in an earlier calculation[12]). For $Mo(CH_3)_5$ the energy difference is even larger at 97.5 kJ mol^{-1}. At present it cannot be said with certainty if this large energy difference is a consequence of imperfect calculations, due to the open shell system. If it is real, this would indicate a strong steric activity of the d^1 electron which would be very unusual. Table 1 gives a summary of experimental and calculated structures of both compounds.

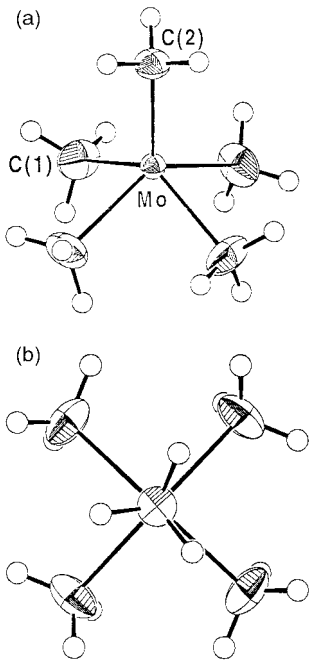

Fig. 1 (a) Crystal structure of $Mo(CH_3)_5$. ORTEP with 50% probability ellipsoids. (b) View along the fourfold axis. The hydrogen positions of the apical methyl group are fourfold disordered and only one orientation is shown. The ORTEP for $Ta(CH_3)_5$ is essentially the same.

Table 1 Bond lengths (pm) and angles (°) for the tetragonal pyramidal structures of $Mo(CH_3)_5$ and $Ta(CH_3)_5$

	$Mo(CH_3)_5$		$Ta(CH_3)_5$			
	X-Ray	DFT calculation[a]	X-Ray	Electron diffraction[b]	DFT calculation	MP2 calculation[c]

DOI: 10.1039/b000987n

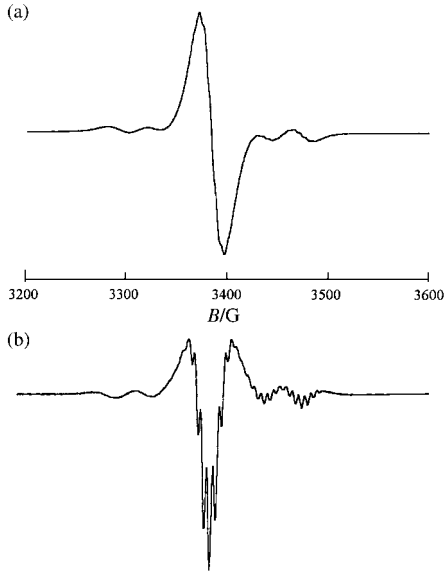

Fig. 2 Isotropic EPR spectrum of $Mo(CH_3)_5$ in *n*-pentane solution at 130 K, 9.44 GHz. g = 1,993, $a(^{95}Mo/^{97}Mo)$ = 4.8(1) mT, a_H' = 0.54(1) mT: (a) first derivative and (b) second derivative spectrum.

The Raman spectrum of $Mo(CH_3)_5$ shows bands (relative intensities in parentheses) at 1181(10), 960(10), 90(50), 882(10), 783(10), 672(60), 620(30), 565(15), 523(100), 507(70), 451(15), 366(25), 308(100), 267(10) and 167(10) cm^{-1} while the region above 2700 cm^{-1} is obscured by the solvent pentane.

$Mo(CH_3)_5$ is paramagnetic and shows an EPR spectrum which is in full agreement with its structure (Fig. 2). Hyperfine splitting due to the two isotopes ^{95}Mo and ^{97}Mo (15.92 and 9.5% natural abundance), both with nuclear spin 5/2 and virtually identical gyromagnetic moments gives rise to six satellite resonances, two of which are obscured by the central line. The further fine structure is well resolved in the second derivative representation, and fits to a ^1H hyperfine structure due to an even number of equivalent hydrogen atoms and particularly well to a binomial distribution of 12th degree. Hyperfine structure due to the three apical hydrogen atoms is not resolved (Fig. 2). In agreement with this the calculation reveals that the unpaired electron has approximately two thirds Mo $4d_{z^2}$ and one third Mo $4d_{x^2-y^2}$ character.

The oxidative-addition reaction of $Pt(PEt_3)_3$ with the phosphine–borane adducts $PhPH_2·BH_3$ and $Ph_2PH·BH_3$ leads to regioselective insertion of the $Pt(PEt_3)_2$ fragment into the P–H bond to afford the hydride complexes *trans*-[PtH(PPhR·BH_3)(PEt_3)$_2$] (R = H 1, R = Ph 2); reaction of 2 with $PhPH_2·BH_3$ leads to an unusual ligand exchange reaction which generates 1 and $Ph_2PH·BH_3$.

The discovery of new synthetic methods for the formation of homonuclear or heteronuclear bonds between main group elements is of importance for the construction of inorganic polymer chains and also for the general development of p-block chemistry.[1,2] Transition metal-catalyzed routes represent a particularly attractive approach to this problem.[2,3] Recently we reported a novel metal-catalyzed route to linear and cyclic oligomeric and also high molecular weight poly(phosphinoboranes) which involved dehydrocoupling of phosphine–borane adducts in the presence of late transition metal complexes (Scheme 1).[4,5] A plausible first step in these reactions involves insertion of the transition metal into either the P–H or B–H bond of the adduct. Subsequent steps may involve σ-bond metathesis and/or oxidative addition/reductive elimination processes. Significantly, no homodehydrocoupling products with P–P or B–B bonds have been detected from these reactions to date. It should be noted that the insertion of transition metals into the P–H bonds of secondary phosphines has ample precedent. For example, oxidative addition of P(III)–H bonds at Pt(0) or Pd(0) centers has been demonstrated and such processes are believed to be a key step in the catalytic hydrophosphination of alkenes and alkynes.[6] On the other hand, a range of mono- and dinuclear boryl complexes have recently been reported as a result of the ambient temperature reactions of the B–H bonds in $Me_3P·BH_3$ or $Me_3P·BH_2BH_2·PMe_3$ at metal centers.[7,8] In order to investigate potential pathways during the transition metal mediated P–B bond formation reactions we are studying the hitherto unexplored coordination chemistry of phosphine–borane adducts with both P–H and B–H bonds. Here, we report the oxidative-addition reactions of $Ph_2PH·BH_3$ and $PhPH_2·BH_3$ with the electron rich Pt(0) complex $Pt(PEt_3)_3$ and a preliminary reactivity study of the resulting phosphine–borane complexes.

Reaction of the primary phosphine–borane adduct $PhPH_2·BH_3$ with a stoichiometric amount of $Pt(PEt_3)_3$ in toluene at 60 °C and subsequent crystallization from hexanes resulted in the formation of a yellow solid **1** (23% isolated yield, quantitative by ^{11}B and ^{31}P NMR before workup) which was characterized by multinuclear NMR spectroscopy in $CDCl_3$.† The spectroscopic data for the product was consistent with a structure **1** in which insertion of Pt into a P–H bond rather than the B–H bond had taken place. For example, the product displayed two distinct sets of signals in the ^{31}P NMR spectrum: a doublet at δ 17.9 was assigned to the PEt_3 ligands attached to platinum, showing coupling to another phosphorus nucleus (J_{PP} 19.4 Hz) as well as ^{195}Pt satellite signals (J_{PPt} 2572 Hz). Furthermore, a broad doublet at δ *ca.* −48.7 indicated coupling to a quadrupolar boron nucleus and one hydrogen substituent (J_{PH} 299 Hz) and showed ^{195}Pt satellites with the magnitude J_{PPt} *ca.* 1440 Hz. This signal was assigned to the phosphorus of the fragment Pt–PPhH·BH_3. The ^{11}B NMR spectrum showed a single broad resonance at δ −33.2 which is in the region typical for BH_3 adducts of phosphines. The key ^1H NMR spectroscopic feature is the low-frequency hydride resonance at δ −5.74, which appears as a doublet of triplets with a larger coupling to one phosphorus atom (J_{HP} 124.6 Hz) and a smaller coupling to two phosphorus atoms (J_{HP} 15.4 Hz) as well as ^{195}Pt satellites (J_{HPt} 872 Hz). This suggested the presence of one *trans* substituent (PPhH·BH_3) and two *cis* substituents (PEt_3), with respect to the hydride ligand.

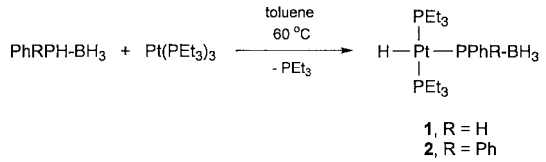

Scheme 2

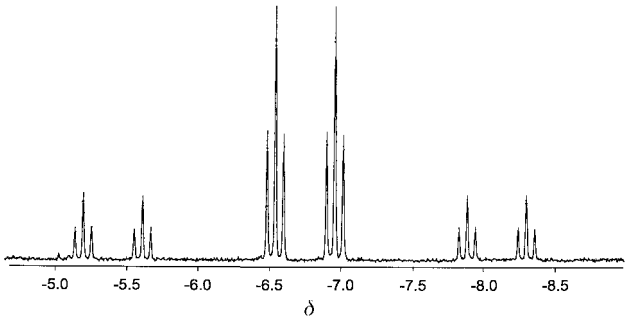

Fig. 2 ^{1}H NMR spectrum (300 MHz, C_6D_6) of the hydride region of **2** [J_{HP}(*trans*) 124.4 Hz, J_{HP}(*cis*) 16.9 Hz, J_{HPt} 805 Hz, PtH].

The molecular structure of compound **1** was confirmed by single crystal X-ray analysis‡ and is consistent with the solution NMR data. A SHELXTL drawing is shown in Fig. 1. The geometry around the Pt(II) center is close to square-planar with *trans* PEt_3 ligands. Although the platinum hydride ligand was not observed in the X-ray study its presence is clearly indicated by the large P(3)–Pt(1)–P(2) angle of 168.26(5)° and, as discussed, from the ^{1}H NMR spectroscopic data. The lengths of the bonds Pt(1)–P(2) [2.2863(13) Å] and Pt(1)–P(3) [2.2771(14) Å] are shorter than the Pt(1)–P(1) bond [2.3477(14) Å], presumably as a consequence of the *trans* influence of the hydride ligand. A similar observation was made in the hydride complex *cis*-[PtH(P(O)Ph_2)(PPh_2(OH))(PEt_3)].[9]

A similar reaction was observed between the secondary phosphine–borane adduct $Ph_2PH{\cdot}BH_3$ and 1 equivalent of $Pt(PEt_3)_3$ (Scheme 2). The orange–yellow platinum complex **2** was isolated in 67% yield. For **2**, signals in the ^{31}P NMR spectrum are observed at δ 16.7 (PEt_3) and δ −3.7 ($PPh_2{\cdot}BH_3$) and in the ^{11}B NMR spectrum at δ −31.4. Fig. 2 shows the hydride region of the ^{1}H NMR spectrum of **2** with the characteristic dt coupling pattern which is flanked by ^{195}Pt satellite signals (J_{HPt} 805 Hz).

Compound **1** represents the first example of a metal complex of a primary phosphine–borane adduct and only two other examples of transition metal complexes of secondary phosphine–borane adducts analogous to **2** are known; a tetrahedral iron complex, [Fe(η^5-C_5Me_5)(CO)$_2$($PPh_2{\cdot}BH_3$)],[10] and a square-planar palladium complex, [Pd(dppp)-(C_6F_5)($PPh_2{\cdot}BH_3$)] [dppp = 1,3-bis(diphenylphosphino)propane], a proposed intermediate in the Pd-catalyzed coupling of secondary phosphine–boranes with aryl halides.[11] However, the synthesis of the latter compounds involved nucleophilic substitution steps rather than insertion of the transition metal fragment.

The isolation of novel complexes **1** and **2** *via* oxidative addition suggests that P–H bond activation may be the key initial step in the late transition metal-catalyzed formation of P–B bonds. In order to explore the reactivity of the complexes, a solution of **2** in C_6D_6 was treated with another equivalent of $PhPH_2{\cdot}BH_3$. After 8 h at room temperature the solution had changed from orange to yellow, however, no P–B coupling reaction was observed by ^{31}P NMR spectroscopy. Surprisingly, a complete exchange of the phosphine–borane ligand had occurred to form exclusively complex **1** together with $Ph_2PH{\cdot}BH_3$ (Scheme 3).

Scheme 3

The demonstration of a novel phosphine–borane ligand exchange reaction at the Pt center indicates that relatively complex reaction chemistry may need to be unravelled if a full mechanistic understanding of late transition metal-catalyzed P–B bond formation reactions is to take place. Detailed studies of the reactivity of novel complexes such as **1** and **2** and analogs directed towards this goal are in progress.

Double fluorescence resonance energy transfer to explore multicomponent binding interactions: a case study of DNA mismatches

Imogen Horsey, W. Scott Furey, Joseph G. Harrison, Mark A. Osborne and Shankar Balasubramanian*

Published on the Web 25th May 2000

A first demonstration, using a four-component system of complementary and single base-mismatched oligonucleotides, that double fluorescence resonance energy transfer (FRET) can be used to interrogate multicomponent interactions in molecular complexes.

The study of intermolecular interactions is key to the understanding of fundamental biological processes. It is well established that many important biological complexes rely upon binding interactions between multiple components. A number of experimental approaches exist for the study of such non-covalent interactions, but few are capable of conveniently providing information about interactions between several components. Fluorescence resonance energy transfer (FRET)[1] between donor and acceptor fluorophores has been usefully employed in the study of molecular interactions in homogeneous solution.[2,3] Furthermore, the theory is sufficiently well understood to carry out inter- or intra-molecular distance mapping experiments,[4] typically in the 10–100 Å range. FRET experiments to study intermolecular interactions are usually carried out for two components (*i.e.* with a single donor and single acceptor). However, if a donor fluorophore is brought in proximity to more than one type of acceptor fluorophore, there exists the possibility of multiple FRET interactions resulting from irradiation at a single wavelength (Fig. 1). In principle it should be possible to simultaneously obtain information about multicomponent binding interactions. FRET has been used to study nucleic acid interactions in examples that include; duplex hybridisation,[5] triple helix[6] and DNA tetraplex formation,[7] and also for DNA diagnostic assays using molecular beacons to analyse point mutations.[8] We report a homogeneous system of oligonucleotides in which double FRET interactions have been used to study specific binding interactions between four components. The studies comprise of sequence-specific nucleic acid interactions and the localisation of single base mismatches, but the general principle will apply more broadly to other mutually binding systems.

The design of this four component system (Fig. 1) comprises a 27mer oligonucleotide (**M**) and three labelled 9mer oligonucleotide sequences (**R**, **F** and **T**), each of which is complementary to discrete, adjacent sections of the 27mer.[9] Each 9mer included a 5-propargylamino-modified thymidine base,[10] which was postsynthetically modified by reaction with the activated *N*-hydroxysuccinimide ester of either rhodamine-X (**R**OX), fluorescein (**F**AM) or carboxy-X-rhodamine (**T**MR) as indicated in Fig. 1. The excitation and emission maxima of these fluorophores are resolvable and the emission spectrum of FAM overlaps significantly with the excitation spectra of both TMR and ROX. On binding of all three 9mers to the target 27mer to give a fully assembled complex, the donor fluorophore (FAM) is *ca.* 20–25 Å from *both* acceptor fluorophores (TMR and ROX) such that excitation of FAM would lead to significant energy transfer to both TMR and ROX.[11] This was monitored by observing both the donor quenching effects and the sensitised emission of the two acceptor fluorophores.

The fluorescence spectrum for the matched four component system (**R**:**F**:**T**:**M**) is shown in Fig. 2(a) along with spectra of

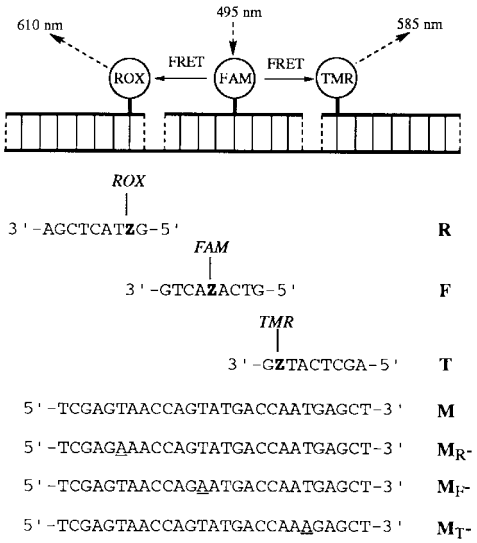

Fig. 1 Schematic of the four-component system, with the sequences used shown below. **Z** = 5-propargylamino dT, ROX = carboxy-X-rhodamine, FAM = carboxyfluorescein, TMR = carboxytetramethylrhodamine. The underlined bases represent T–A single base substitutions. The ROX (**R**), FAM (**F**) and TMR (**T**) labelled oligonucleotide probes bind contiguously on the target (**M**). Oligonucleotide targets $\mathbf{M_R}^-$, $\mathbf{M_F}^-$ and $\mathbf{M_T}^-$ incorporate a single internal A:A mismatch opposite probes **R**, **F** or **T**, respectively.

the individual two component systems (**R**:**M**, **F**:**M**, **T**:**M**) that contribute to the former. Three additional target 27mers ($\mathbf{M_R}^-$, $\mathbf{M_F}^-$ and $\mathbf{M_T}^-$) were designed each with a single central A:A base mismatch to perturb binding of oligonucleotide component **R**, **F** or **T** respectively and examine the effect on energy transfer between the donor and both acceptors (Fig. 1).[12] The fluorescence spectra of these mismatched systems (**R**:**F**:**T**:$\mathbf{M_R}^-$, **R**:**F**:**T**:$\mathbf{M_F}^-$, **R**:**F**:**T**:$\mathbf{M_T}^-$) are presented in Fig. 2(b) where it is clear that mismatches are distinguished by distinct differences

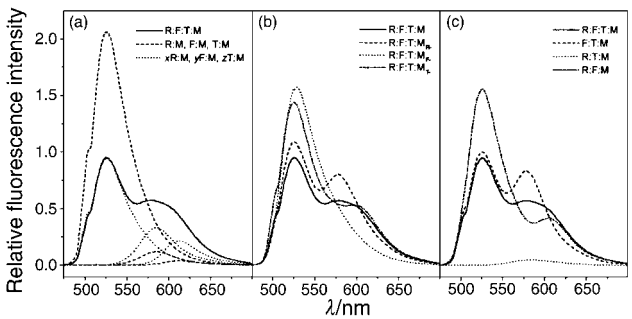

Fig. 2 Relative fluorescence profiles (arbitrary units) for; (a) the basis two-component systems **R**:**M**, **F**:**M**, **T**:**M** (- - - -) and the matched four-component system **R**:**F**:**T**:**M** (——). Also shown is the scaled contributions of **R**:**M**, **F**:**M** and **T**:**M** (· · · · ·) to **R**:**F**:**T**:**M** where $x = 5.33$, $y = 0.46$, $z = 2.75$; (b) mismatched systems **R**:**F**:**T**:$\mathbf{M_R}^-$ (- - -) **R**:**F**:**T**:$\mathbf{M_F}^-$ (· · · · ·) and **R**:**F**:**T**:$\mathbf{M_T}^-$ (··——··——); (c) control systems **F**:**T**:**M** (- - -), **R**:**T**:**M** (· · · · ·) and **R**:**F**:**M** (··—··—).

in the fluorescence profiles. Melting temperature studies confirmed that the unlabelled (non-fluorescent) 9mers exhibited good discrimination between matched (80–87% bound at 25 °C) and mismatched (< 20% bound at 25 °C) targets.

Control experiments [Fig. 2(c)] were performed on three-component matched systems containing two of the three fluorescent 9mer oligonucleotides bound to the 27mer target. These were the ROX–FAM FRET couple (**R**:**F**:**M**), the TMR–FAM FRET couple (**F**:**T**:**M**) and the ROX–TMR non-FRET pair (**R**:**T**:**M**).

In order to determine the variations in the relative fluorescence contribution of individual fluorophores to each system, the fluorescence spectra were deconvoluted using a set of simultaneous equations.[13] Using this method, each of the three hybridised matched systems **R**:**M**, **F**:**M** and **T**:**M** was assigned a standard value of 1 for the individual contribution to the fluorescence signal of ROX, FAM and TMR, respectively at their respective maximum emission intensities (610, 525, 585, nm). The contributions to the fluorescence resulting from FRET were then determined relative to these values. The relative fluorescence intensities and the calculated contributions from ROX, FAM and TMR to the single four-component matched system, the four-component mismatched systems and controls are summarised in Table 1. The matched system (**R**:**F**:**T**:**M**) exhibited FRET between the donor and *both* acceptors, as indicated by a decrease in the relative fluroescence of FAM (1.0 to 0.46) and an increase in the relative fluroescence of ROX (1.0 to 5.33) and TMR (1.0 to 2.75).

In **R**:**F**:**T**:$\mathbf{M_R}^-$, the mismatch will significantly reduce the proportion of **R** binding. In this case, the system should be very similar to the **F**:**T**:**M** control system. The relative emissions of FAM (0.53) and TMR (4.65) compare well with the **F**:**T**:**M** system (relative emissions of 0.48 and 5.26 respectively). The second mismatch system (**R**:**F**:**T**:$\mathbf{M_F}^-$) will reduce the binding of **F**, which results in no observed FRET between the donor and either acceptor. This resembles the control system **R**:**T**:**M**, in which **F** does not bind, and ROX or TMR produces no significant FRET emission signal. The final system (**R**:**F**:**T**:$\mathbf{M_T}^-$) positions a mismatch that prevents binding of **T**. The result is FRET between FAM and ROX only, as in the control system **R**:**F**:**M**. The two systems compare well, with the relative emissions of FAM (0.69) and ROX (7.37) being very similar to the **R**:**F**:**M** system (relative emissions of 0.75 and 7.40, respectively).

An alternative format for analysis involved fluorescence imaging of samples in a multiwell plate. Samples containing each of the three 9mers (**R**, **F**, **T**) and one of the four matched (**M**) or mismatched ($\mathbf{M_R}^-$, $\mathbf{M_F}^-$, $\mathbf{M_T}^-$) targets were irradiated at 488 nm and emission measured through a 530(±15) nm (FAM), 570(±15) nm (TMR) or 610 nm (ROX) longpass filter. Data were obtained for multiple repeats of each four-component system and analysed using the simultaneous equation method.[13] A plot of relative ROX *vs.* relative TMR emission for each sample from both the earlier fluorimeter studies and fluorimager microtitre plate assays is shown in Fig. 3. Data points were

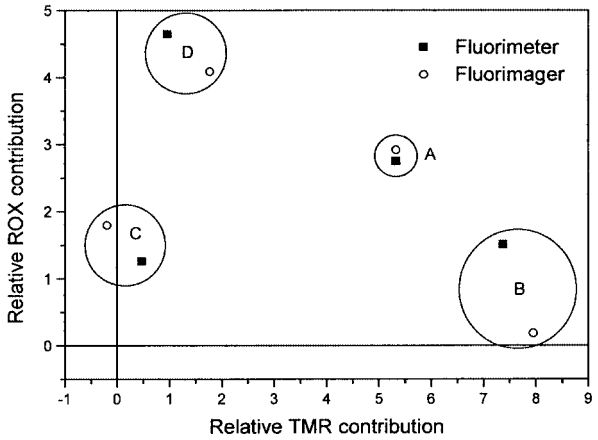

Fig. 3 Relative contributions of both TMR and ROX to fluorescence on binding 9mers to each of the four 27mer targets. Region A corresponds to the matched four component system **R**:**F**:**T**:**M** and regions B, C, D to the mismatched systems **R**:**F**:**T**:$\mathbf{M_R}^-$, **R**:**F**:**T**:$\mathbf{M_F}^-$ and **R**:**F**:**T**:$\mathbf{M_T}^-$ respectively. Fluorimager data (○) have been normalised to the TMR contribution in the matched four-component system of the fluorimeter data (■).

observed to fall into four distinct regions corresponding to the four target types. Region A represents the situation in which both TMR and ROX emission are observed (*i.e.* the matched system, **R**:**F**:**T**:**M**). Region B defines the **R**:**F**:**T**:$\mathbf{M_R}^-$ mismatched system, in which there is TMR emission but no ROX emission. Region C represents the **R**:**F**:**T**:$\mathbf{M_F}^-$ mismatch, which does not exhibit FRET because the donor (FAM) oligonucleotide does not bind. Finally, region D defines the **R**:**F**:**T**:$\mathbf{M_T}^-$ mismatch, in which there is only ROX, but no TMR emission.

These studies provide an insight into the fluorescence behaviour of a double FRET system. The results have shown that a single base mismatch can be detected and mapped in a four component system. Careful design and judicious selection and placement of fluorophores, will enable the general principle to be applied to the study of other multimolecular complexes, and address whether specific combinations of molecules complex under a given set of conditions. The microplate studies also suggest that double FRET can be utilised in a multiplexed format for a more routine analysis of multicomponent interactions.

A 14-electron ruthenium hydride: the key intermediate in the synthesis of ruthenium carbene complexes; X-ray structure of [RuHCl(PPr$^i_3$)$_2$]

Paul A. van der Schaaf,* Roman Kolly and Andreas Hafner

Ciba Specialty Chemicals, CH-4002 Basel, Switzerland. E-mail: paul.van_der_schaaf@cibasc.com

Received (in Basel, Switzerland) 20th March 2000, Accepted 3rd May 2000

A simple one-pot procedure for the synthesis of ruthenium benzylidenes (Grubbs' catalyst) has been developed in which a novel, highly reactive 14-electron ruthenium monohydride, prepared from [RuCl$_2$(cod)] and two bulky phosphines in boiling propan-2-ol without the use of hydrogen gas, is reacted with hydrogen chloride, an alkyne and styrene.

The discovery and isolation of the first well-defined ruthenium carbenes of the type [RuCl$_2$(=CH–CH=CPh$_2$)(PR$_3$)$_2$][1] by Grubbs and coworkers in 1992 followed by the second generation of the type [RuCl$_2$(=CHPh)(PR$_3$)$_2$][2] have changed the impact of the olefin metathesis reaction in many chemical applications dramatically.[3] Because of our long standing interest in metathesis chemistry,[4] we, as did many others, investigated the use of these well-defined ruthenium carbene catalysts intensively. We found that with these ruthenium carbenes the total catalyst loading in, for example, the polymerization of dicyclopentadiene (DCPD) dropped significantly compared with our recently published method using an arene ruthenium catalyst, such as [(*p*-cymene)RuCl$_2$(PCy$_3$)] (Cy = cyclohexyl).[5] However, the existing syntheses for these ruthenium carbenes rely on barely accessible or unstable and toxic organic compounds which act as the carbene source, *e.g.* phenyl diazomethane for the synthesis of ruthenium benzylidenes. Therefore, for successful commercial applications, new synthetic routes have to be developed which can be scaled-up more easily. Parallel to our efforts, Werner and coworkers developed a new route to benzyl substituted ruthenium carbenes,[6] whereas Grubbs and coworkers developed novel routes to vinyl and phenyl substituted ruthenium carbenes.[7] In both synthetic routes the key intermediate is the ruthenium monohydride dihydrogen species [RuHCl(H$_2$)(PCy$_3$)$_2$], prepared from [RuCl$_2$(cod)] (cod = cycloocta-1,5-diene) and PCy$_3$ in an atmosphere of dihydrogen, which is subsequently reacted with phenyl acetylene or a propargylic chloride, respectively. We now report a simple one-pot procedure for the synthesis of ruthenium carbenes in which the key intermediate, a novel 14-electron species, is prepared starting from [RuCl$_2$(cod)], 2 equivalents of a bulky phosphine, and an appropriate base, but *without* the use of dihydrogen.[8]

Recently, Werner and coworkers published their results on treating a 'red solution' formed upon heating [RuCl$_2$(cod)] with an excess of PPr$^i_3$ in butan-2-ol under an atmosphere of dihydrogen with phenyl acetylene.[6] This reaction led to the formation of [RuCl$_2$(=CHCH$_2$Ph)(PPr$^i_3$)$_2$] in *ca.* 65% yield. The active ruthenium species in the 'magic' red solution, however, was unknown. Addition of diethyl ether to this red solution led to the isolation of the ruthenium(IV) complex [RuH$_2$Cl$_2$(PPr$^i_3$)$_2$]. It was reported that this ruthenium(IV) dihydride species reacts with phenyl acetylene predominantly yielding the five-coordinate vinylidene complex [RuCl$_2$(=C=CHPh)(PPr$^i_3$)$_2$] with the above mentioned benzyl substituted ruthenium carbene [RuCl$_2$(=CCH$_2$Ph)(PPr$^i_3$)$_2$] only as the side product. It was speculated that the active species in the red solution which led to the ruthenium carbene complex was the monohydride–dihydrogen complex [RuHCl(H$_2$)(PPr$^i_3$)$_2$]. Surprisingly, when we carried out the reaction *without* the use of dihydrogen, the reaction worked as well. We prepared a 'red solution' by boiling [RuCl$_2$(cod)] for 3 h with 2 equiv. of PPr$^i_3$ and 1 equiv. of NEt$_3$ in propan-2-ol under an argon atmosphere. ^{1}H NMR investigations on this solution showed a broad triplet at δ −17, indeed indicating the possible presence of the above mentioned ruthenium monohydride dihydrogen species [RuHCl(H$_2$)(PPr$^i_3$)$_2$].[9] By slowly cooling this red solution from 80 °C to room temperature we could isolate the hydride as blocky, orange crystals. Surprisingly, an X-ray structure determination on these crystals revealed the hydride species to be a tetracoordinate, 14-electron d^6 species with formula [RuHCl(PPr$^i_3$)$_2$] **1**.† Fig. 1 shows the molecular geometry of **1** which can be best described as a square-planar structure with the bulky triisopropylphosphines in *trans* positions.‡

Very recently, Caulton and coworkers also described a 14-electron ruthenium monohydride as the intermediate in the synthesis of heteroatom substituted ruthenium carbene complexes using vinyl ethers as the carbene source.[10] However, this hydride, prepared by dehydrohalogenation of [Ru(H)$_2$Cl$_2$(PR$_3$)$_2$] with lithium 2,2,6,6-tetramethylpiperidide, appears to be a halide bridged dimer.[11]

Subsequent addition of phenyl acetylene and styrene to the red solution containing **1** resulted in the isolation of the 'Grubbs' catalyst' [RuCl$_2$(=CHPh)(PPr$^i_3$)$_2$] in moderate yields. However, when we first added an extra equivalent of hydrogen chloride to the hydride solution at −20 °C, subsequently added the acetylene and styrene, warmed the reaction mixture to room temperature and stirred it for an additional hour, the yield could be increased to 75%.§

In the first step of the reaction, the preparation of monohydride **1**, the formation of 3 equivalents of acetone were detected by gas chromatography; 1 equivalent is the result of the hydride formation whereas the other 2 equivalents originate from the reduction of cod to cyclooctane, which was detected by gas chromatography. Upon addition of the HCl solution in diethyl ether the typical sharp ^{1}H NMR hydride signal at δ −17 disappeared and a very broad signal at δ −5 could be observed. Unfortunately, we were unable to isolate a distinct compound. However, in analogy to the previously described HCl addition

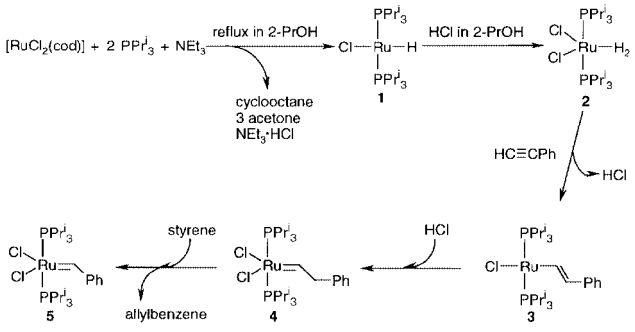

Scheme 1

to a similar osmium carbonyl complex,[12] we propose that the intermediate is the ruthenium(II) dichloride dihydrogen complex **2**. This dihydrogen complex reacts upon addition of phenyl acetylene to generate a short-lived 14-eletron alkenyl complex **3** along with the formation of a molecule HCl. **3** immediately reacts with HCl to form the more stable benzyl substituted ruthenium carbene **4**. A simple metathesis reaction with styrene then gives the Grubbs ruthenium benzylidene catalyst **5** which can be easily isolated by filtration and purified by washing with cold methanol. The complete postulated reaction mechanism is depicted in Scheme 1.

These results demonstrate a very simple one-pot synthesis procedure for the preparation of multigram quantities of the Grubbs catalyst without the use of dihydrogen gas, and utilizing only commercially available starting materials. The novel intermediate monohydride complex was isolated and fully characterized and appeared to be a mononuclear, square-planar, 14-electron species. The reactivity of this monohydride species in other reactions, *e.g.* hydrogen transfer reactions, is currently under investigation.

Notes and references

† An X-ray structure determination of the deuterium analog of **1**, *i.e.* [RuDCl(PPr^i_3)$_2$] **1D** prepared in propan-2-ol-d_8, revealed exactly the same structure. To have absolute proof of this unexpected result we also determined the structure of the tricyclohexylphosphine analogue [RuHCl(PCy_3)$_2$] **1Cy**, prepared using DBU as base instead of NEt_3. This complex also has a square-planar geometry with the two bulky phosphines in *trans* positions.

‡ *Crystal data* for **1**: $C_{18}H_{43}ClP_2Ru$, M = 457.98, monoclinic, space group $P2_1/c$ (no. 14), a = 8.0682(5), b = 8.9506(8), c = 16.6435(12) Å, β = 92.76(1)°, V = 1200.5(2) Å^3, Z = 2, μ(Mo-Kα) = 0.895 mm^{-1}, 9038 reflections measured, 2295 unique (R_{int} = 0.042), observed 1938 [$I > 2\sigma(I)$], Final R_1 = 0.038 (obsd. data), wR_2 = 0.122 (all data).

For **1D**: $C_{18}H_{42}DClP_2Ru$, M = 457.98, monoclinic, space group $P2_1/c$ (no. 14), a = 8.0641(8), b = 8.9361(6), c = 16.6840(15) Å, β = 92.74(1)°, V = 1200.9(2) Å^3, Z = 2, μ(Mo-Kα) = 0.895 mm^{-1}, reflections measured 8559, independent 2272 (R_{int} = 0.022), observed 1977 [$I > 2\sigma(I)$]. Final R_1 = 0.042 (obsd. data), wR_2 = 0.1421 (all data).

For **1Cy**: $C_{36}H_{67}ClP_2Ru$, M = 698.36, triclinic, space group $P\bar{1}$ (no. 2), a = 9.8438(8), b = 10.2011(8), c = 10.8356(9) Å, α = 114.29(1), β = 108.48(1), γ = 90.82(1)°, V = 927.4(13) Å^3, Z = 1, μ(Mo-Kα) = 0.603 mm^{-1}, 6747 reflections measured, 3181 independent (R_{int} = 0.025), observed 2953 [$I > 2\sigma(I)$]. Final R_1 = 0.041 (obsd. data), wR_2 = 0.128 (all data). Twinned crystal with 6% overlapped reflections, which were omitted. Full spheres of intensity data were collected at 223 K on a Stoe Image Plate Diffraction system using Mo-Kα graphite monochromated radiation. Image plate distance 70 mm, ϕ oscillation scans 0–200°, step $\Delta\phi$ = 1°, 2θ range 3.27–52.1°, d_{max}–d_{min} = 12.45–0.81 Å.

The structures were solved by direct methods using the program SHELXS-97.[13] The refinements and all further calculations were carried out using SHELXL-97.[14] The alkyl group H-atoms were included in calculated positions and treated as riding atoms using SHELXL-97 default parameters. In all three compounds the hydride (H1Ru) could be located from a final difference map (*ca.* 1.7 e Å^{-3}), at a distance of 1.6–1.8 Å from the Ru atom. In the final refinement cycles it was held fixed with a U_{iso} = 1.5U_{eq}(Ru) Å^2. The non-H atoms were refined anisotropically, using weighted full-matrix least squares on F^2. An empirical absorption correction was applied for all three compounds but a small amount of residual density was still located near the Cl atoms. All three structures are centrosymmetric implying disordered structures with the Cl and hydride sites being 50% occupied.

§ *Synthetic procedure*: a suspension of [$RuCl_2$(cod)] (5.00 g, 17.8 mmol) in 125 ml propan-2-ol was treated with PPr^i_3 (7.0 ml, 36.6 mmol) and NEt_3 (5.0 ml, 36.0 mmol) and refluxed under argon for 3 h. The resulting red coloured, clear solution was cooled to −20 °C and changed to an orange suspension. To this suspension was added dropwise 35 ml of a 1 M HCl solution in diethyl ether over a period of *ca* 15 min keeping the temperature around −20 °C. The reaction mixture was stirred for an additional 10 min, and phenylacetylene (4.0 ml, 36.4 mmol) was added dropwise keeping the reaction mixture below −15 °C. Subsequently, the reaction mixture was stirred for 2 h at between −20 and −15 °C. The resulting purple suspension was treated with styrene (8.0 ml, 70 mmol), the temperature was slowly raised to room temperature and the reaction mixture was allowed to stir for an additional hour. The reaction mixture was partially concentrated and the product filtered off. The purple product was washed with methanol (2 × 10 ml), and dried *in vacuo*. This procedure yielded 7.7 g of [$RuCl_2$(=CHPh)(PPr^i_3)$_2$] (75%). A similar procedure can be used for the synthesis of [$RuCl_2$(=CHPh)(PCy_3)$_2$], except that DBU has to be used as base instead of NEt_3.

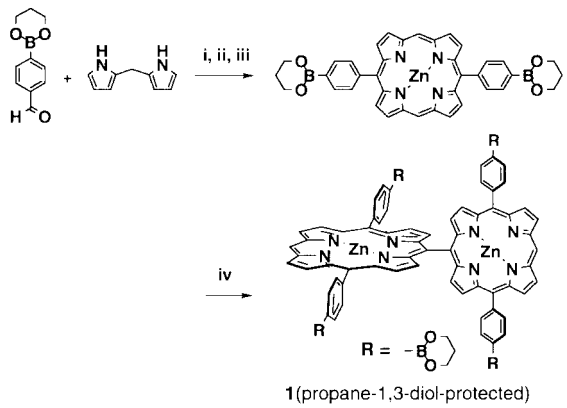
Published on the Web 25th May 2000

A meso–meso-linked porphyrin dimer 1 bearing four boronic acid groups shows high selectivity for maltotetraose (*n* = 4) among maltooligosaccharides (*n* = 1–7), indicating that this class of porphyrins acts as a novel scaffold to design oligosaccharide receptors.

The specific interaction between phenylboronic acids and saccharides or related compounds has been attracting increasing attention as a novel force for sugar recognition in aqueous systems.[1–8] Since one phenylboronic acid reacts with two OH groups to form a cyclic boronate ester, monosaccharides usually bearing five OH groups tend to form 1 : 2 monosaccharide–phenylboronic acid complexes.[1,9–13] However, the stability order of these complexes is always the same, which is governed by the inherent structure of monosaccharides.[2–4,14,15] Of such monosaccharides, fructose has a high association constant whereas glucose has a low association constant.[14,15] In contrast, diboronic acids which can react with four of the five OH groups to form intramolecular 1 : 1 complexes show a different stability order, which is related to the specific spatial position of two boronic acid groups. This implies that one can recognise a specific saccharide by appropriate manipulation of two boronic acids in the same molecule and the concept may be extended to the selective binding of oligosaccharides. This idea has been tested with a few diboronic acid systems bearing a 'long' spacer: *e.g.* diphenyl-3,3′-diboronic acid, stilbene-3,3′-diboronic acid and *cis*-5,15-bis[2-(dihydroxyboronyl)phenyl]-10,20-diphenylporphine show some selectivity for certain disaccharides but the selectivity observed so far is not very high.[16–18] We thus considered that one should look for a 'long' and 'rigid' scaffold by which one might finely tune the distance between two boronic acid groups. Recently, it was found that the meso–meso coupling reaction of Zn(II) porphyrinates is efficiently mediated by $AgPF_6$[19] to yield oligomeric porphyrins. These new compounds seem to satisfy the prerequisites mentioned above. As a preliminary step to use these compounds as scaffolds for saccharide recognition, we designed compound **1**. Very interestingly, we have found that **1** shows a high affinity with maltotetraose among maltooligosaccharides. To the best of our knowledge, this is the first artificial saccharide receptor which shows selectivity for oligosaccharides.

Compound **1** was synthesised from 4-(1,3-dioxaborinan-2-yl)benzaldehyde and dipyrrylmethane according to Scheme 1 and identified as its propane-1,3-diol-protected species by ^{1}H NMR and MALDI-TOF mass (*m/z* 1386.9) spectra and elemental analysis.‡ Since ^{1}H NMR spectroscopy showed that the protecting groups are readily eliminated in aqueous media to yield **1**, it was used for the spectroscopic measurements without deprotection treatment. From examination of Lambert–Beer plots, we found that **1** tends to aggregate in water-rich solvents. We thus chose a water (pH 10.5 with 50 mmol dm^{-3} carbonate buffer)–MeOH (2 : 3 v/v) mixture into which **1** was solubilised discretely.

† Electronic supplementary information (ESI) available (i) Fig. A and B (Job plot for **1**+M_4 and possible binding mode for **1**/M_4, respectively). See http://www.rsc.org/suppdata/cc/b0/b003365k/



Scheme 1 *Reagents and conditions* [yields]: i, TFA, CH_2Cl_2, r.t. then chloranil, reflux [30%]; ii, $Zn(OAc)_2$, $CHCl_3$–MeOH, r.t. [88%]; iii, propane-1,3-diol, benzene, reflux [98%]; iv, $AgPF_6$/MeCN, $CHCl_3$, r.t. [4%].

The absorption spectrum of **1** showed a split Soret band (412.0 and 448.0 nm) and a few Q bands (516.0, 560.0 and 594.5 nm). When maltooligosaccharides (M_n: α-1,4-linked oligomers of D-glucose) were added, the absorption spectra were scarcely changed, indicating that the skeleton of compound **1** is fairly rigid. In the circular dichrosim (CD) spectra, on the other hand, exciton-coupling-type CD bands appeared in the Soret band region (Fig. 1). It is seen from Fig. 1 that the CD spectra consist of two exciton-coupling bands: for the **1**·M_4 complex (Fig. 1), a negative band at higher wavelength and the positive band at shorter wavelength. The strongest peak appears at 417 nm where two CD bands overlap. The CD intensity at 417 nm is summarised in Table 1. It is seen from Table 1 that: (i) the complex with D-glucose (M_1) is almost CD-silent, (ii) maltose (M_2) and maltotriose (M_3) give a weak negative 417 nm peak whereas maltotetrose and higher-order maltooligosaccharides (M_5–M_7) all give a positive 417 nm peak and (iii) a particularly strong CD band is observed for M_4. The results indicate that (i)

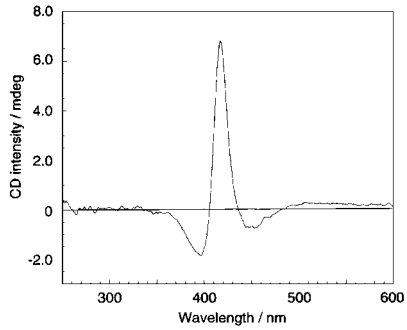


Fig. 1 CD spectrum of **1** (5.00×10^{-6} mol dm^{-3}) with a 1 cm cell in the presence of maltotetraose (50 mmol dm^{-3}) in a water (pH 10.5 with 50 mmol dm^{-3} carbonate)–MeOH (2 : 3) mixture at 25 °C. A similar CD spectral shape was also observed (although the intensity was different) in the presence of other maltooligosaccharides.

Table 1 CD intensity at 417 nm and binding parameters obtained from Hill's plots and substitution methods

Saccharide	CD intensity[a]/ mdeg	K^b/dm^6 mol^{-2}	m^b	K^c/dm^6 mol^{-2}
Glucose (M_1)	0.2	—	—	2.5×10^3
Maltose (M_2)	−0.5	—	—	1.5×10^3
Maltotriose (M_3)	−0.2	—	—	2.0×10^3
Maltotetraose (M_4)	6.8	6.3×10^5	1.7	—
Maltopentaose (M_5)	1.9	1.3×10^4	1.8	—
Maltohexaose (M_6)	1.4	1.6×10^4	1.8	—
Maltoheptaose (M_7)	1.7	2.0×10^3	1.5	—

[a] See caption of Fig. 1. [b] Determined from Hill's plots. [c] The 1:2 to 1:2 substitution (*e.g.* from **1**·$(M_4)_2$ to **1**·$(M_1)_2$) is assumed for the calculation.

D-glucose is too small to bridge two boronic acid groups, (ii) the two porphyrin planes are oriented in opposite directions for the M_2, M_3 complexes and M_4–M_7 complexes, respectively, and (iii) M_4 forms a particularly stable complex with **1**.

To obtain further insights into the binding mode, the complex stoichiometries were estimated by a Job plot method for M_4–M_7 which show measurable CD intensity. A typical example for M_4 is shown in Fig. A(ESI):† a maximum is observed at ([**1**]/([**1**] + [M_4]) = 0.33. This supports the view that **1** binds two M_4 guests to form the stable complex. Similar 1:2 stoichiometries were also observed for M_5, M_6 and M_7. The computational studies (Discover 3/Insight II 98.0) predict that in the most stable conformation the two porphyrin planes cross at 90°, in which the distance between two boron atoms is 1.58 nm. This distance is comparable with that between the 1,2-diol and 4,6-diol in the two terminal D-glucose units of M_4 (*ca.* 1.5–1.8 nm). One may thus illustrate a binding mode for the 1:2 **1**/M_4 complex as shown in Fig. B(ESI).†§

The CD spectra measured as a function of M_4–M_7 concentrations provided several isosbestic points. As typical examples, plots of CD intensity at 417 nm *vs.* [M_4] and [M_5] are shown in Fig. 2. The sigmoidal curvatures indicate that the 1:2 complexes are formed in a cooperative manner. Similar sigmoidal dependences were also observed for M_6 and M_7. The binding of the guest to **1** is cooperative. This cooperative guest binding profile can be analysed with the Hill equation: $\log [y/(1 - y)] = m\log[\text{guest}] + \log K$, where K and m are the association constant and Hill coefficient, respectively, and $y = K/([\text{guest}]^{-m} + K)$.[20] From the slope and the intercept obtained using the linear portion at $\log [y/(1 - y)] = 0$–0.8 we obtained K and m values for M_4–M_7. The determination of K values for M_1–M_3 was difficult because of their weak CD intensity, but measurements were obtained by a substitution method using the **1**·M_4 complex, that is, by the CD intensity decrease induced by addition of M_1–M_3, and the results are summarised in Table 1. Examination of Table 1 reveals that: (i) the magnitude of K is correlated with the CD intensity, (ii) the largest K is observed for M_4, which is 48- and 39-fold larger, respectively, than those of M_5 and M_6 and (iii) the m values are smaller than 2.0, indicating the weak positive allosterism and the presence of the 1:1 species in the low saccharide concentration region. This novel binding mode implies that the binding of the first guest which intramolecularly bridges two boronic acid groups suppresses the rotational freedom of the porphyrin rings and preorganises the two residual boronic acids so that they can easily complex the second guest.

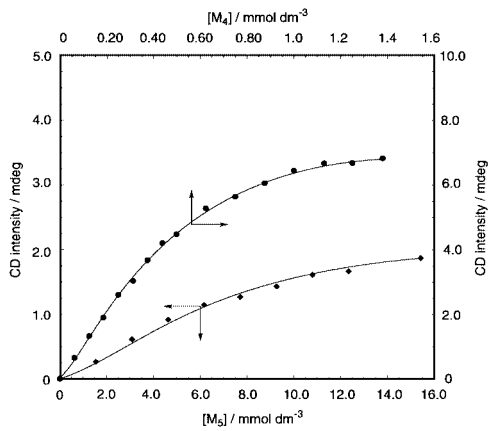

Fig. 2 Plots of CD intensity (417 nm) for **1** (5.00×10^{-6} mol dm^{-3}) *vs.* [M_4] and [M_5].

In conclusion, it was shown that the meso–meso-linked porphyrin dimer is a useful scaffold to separate two boronic acid groups so that they can show selectivity for oligosaccharides. We believe that this study is very important in revealing boronic acid–saccharide interactions toward selective recognition of oligosaccharides.

Notes and references

‡ In step iv (Scheme 1), by-products were detected in which the boronic acid groups were substituted by OH groups. The raw yield of **1** estimated by HPLC was *ca.* 20%.

§ Conformations with low potential energy encountered during a 100 ps MD simulation at 300 K were selected. The system was minimised using conjugate gradient and Newton–Raphson methods until convergence was attained for a gradient of 0.01 kcal mol^{-1} Å^{-1}. The force field used in this study was the ESFF.

In the course of investigations on new Ziegler–Natta-analogous catalyst systems, the first 'constrained geometry' complexes of titanium with a bridging boron atom have been conveniently obtained by a high yield synthesis and were structurally characterized.

Since 1990[1] 'constrained geometry' complexes as catalysts for olefin polymerization have attracted considerable interest, since they show some distinct advantages in comparison to metallocene-based Ziegler–Natta type catalysts,[2] such as formation of copolymers and an increased stability towards MAO even under thermally harsh reaction conditions.[1d]‡ Very recently it was shown by us[3] and others [4] that [1]borametallocenophanes of group 4 elements are easily accessible, highly active catalysts for the polymerization of ethene and propene.

In order to combine the properties of the small and Lewis acidic bridging boron atom with the advantages of constrained geometry catalysts we prepared the compounds [{η^5:η^1-$C_5H_4B(NPr^i_2)NPh$}TiX_2] (X = NMe_2, **1**; X = Cl, **2**).

Similarly to the synthesis of the corresponding [1]boratitanocenophanes [{$(\eta^5$-$C_5H_4)_2BNR_2$}$Ti(NMe_2)_2$],[3a] complex **1** is obtained in a convenient three-step synthesis according to Scheme 1 as an orange, crystalline material in 80% yield. Subsequent treatment of **1** with an excess of Me_3SiCl gave the corresponding dichloro complex **2** in almost quantitative yield as a yellow solid. The structures of **1** and **2** in solution were derived from the multinuclear NMR data.§ In the ^{1}H NMR spectra both compounds show the expected two pseudo-triplets for the cyclopentadienyl protons forming an AA′BB′ spin system. Double sets of signals for the isopropyl groups in the ^{1}H and ^{13}C NMR spectra indicate a hindered rotation with respect to the boron–nitrogen double bond in **1** and **2**. The ^{11}B NMR spectra show signals at δ 27.8 (**1**) and 28.4 (**2**), in the expected range for aryl(diamino)boranes.

Suitable single crystals of **1** (Fig. 1) for an X-ray structural analysis¶ were obtained from hexane at −30 °C. The compound crystallises in the triclinic space group *P*1 and the molecule adopts C_1 symmetry in the crystal. Both atoms B and N2 are trigonal planar, and the planes C20–N2–C23 and N1–B–C1 are almost coplanar with a dihedral angle of 2.2(3)°. The B–N distances of 1.428(3) Å (B–N1) and 1.409(3) Å (B–N2) are in the expected range for B–N double bonds, and the Ti–N distances were found to be *ca*. 1.91 Å for N3 and N4, respectively, while the Ti–N1 distance is markedly longer at 2.020(2) Å.

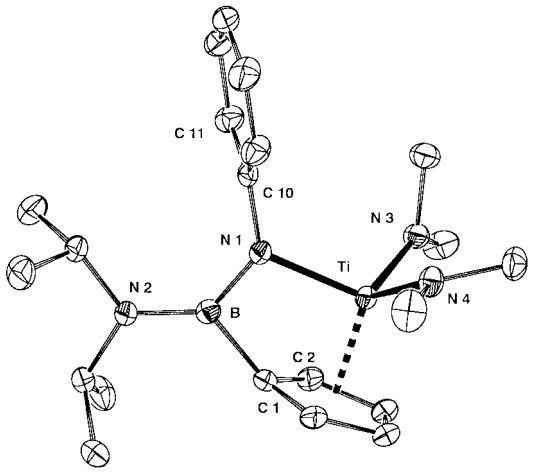

Fig. 1 Molecular structure of **1**. Selected distances (Å) and angles (°): B–N(1) 1.428(3), B–N(2) 1.409(3), Ti–N(1) 2.020(2), Ti–N(3) 1.9045(19), Ti–N(4) 1.913(2), N(3)–Ti–N(4) 103.44(9), N(1)–B–N(2) 131.0(2), C(1)–B–N(1) 103.57(18). Thermal ellipsoids are drawn at the 30% probability level.

Preliminary polymerisation experiments showed compound **2** to be an effective catalyst for the polymerisation of ethene in the presence of MAO. In a typical experiment polyethylene with a molecular weight of *ca*. 470 000 was obtained with an activity of 500 kg polymer (mol cat h)$^{-1}$. As to be expected,[5] complex **1** showed a considerably lower activity towards the polymerisation of olefins. Further investigations of the catalytic properties of compound **2** and related complexes for ethene/styrene-copolymerisation are in progress.

Characterization of imidazolate-bridged Cu(II)–Zn(II) heterodinuclear and Cu(II)–Cu(II) homodinuclear hydroperoxo complexes as reaction intermediate models of Cu,Zn–SOD

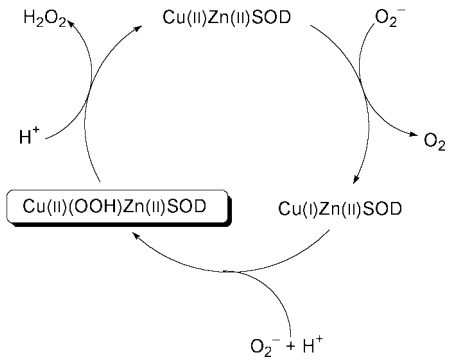
Received (in Cambridge, UK) 20th March 2000, Accepted 19th April 2000
Published on the Web 25th May 2000

Imidazolate-bridged Cu(II)–Zn(II) heterodinuclear and Cu(II)–Cu(II) homodinuclear hydroperoxo complexes are generated in the reactions between imidazolate-bridged heterodinuclear and homodinuclear complexes and H_2O_2 in the presence of triethylamine base and characterized spectroscopically as reaction intermediate models of Cu,Zn–SOD.

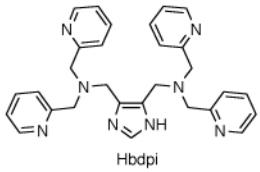
Copper–zinc superoxide dismutase (Cu,Zn–SOD) contains an imidazolate-bridged Cu(II)–Zn(II) heterodinuclear metal center in its active site.[1–6] This enzyme catalyses a very rapid two-step dismutation of superoxide to dioxygen and hydrogen peroxide through an alternate reduction and oxidation of the active-site copper ion as shown in Scheme 1.[5–7] An outer-sphere electron transfer from superoxide to the Cu(II) center occurs to produce O_2 and a Cu(I) center which may be oxidized by another molecule of superoxide in the presence of protons to produce H_2O_2 *via* a hydroperoxo–Cu(II) species (Scheme 1).[6,7] The hydroperoxo–copper(II) species is a key intermediate in biological oxidations catalyzed by copper enzymes including SOD. However, hydroperoxo–copper(II) complexes have been rarely characterized,[8] and there has been no report on the characterization of SOD model hydroperoxo–copper(II) complexes.

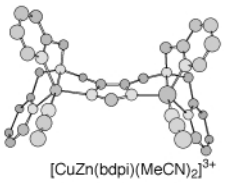
Several imidazolate-bridged heterodinuclear complexes have so far been reported as models of Cu,Zn–SOD using two independent mononuclear complexes and a bridging imidazolate ring.[9] However, the lack of binding site of O_2^- in these dinuclear complexes has precluded the characterization of the hydroperoxo–copper(II) intermediate. We have recently prepared imidazolate-bridged Cu(II)–Zn(II) heterodinuclear and Cu(II)–Cu(II) homodinuclear complexes with a newly designed dinucleating ligand, Hbdpi {Hbdpi = 4,5-bis[di(2-pyridylmethyl)aminomethyl]imidazole}.[10]

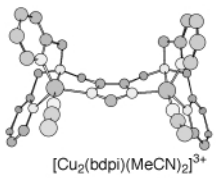
These SOD model complexes have a pentacoordinate structure at each metal ion including a solvent molecule which



Scheme 1







can be readily replaced by a substrate. We report herein the first characterization of SOD model hydroperoxo–Cu(II) intermediates generated by the reactions of hydrogen peroxide with imidazolate-bridged Cu(II)–Zn(II) heterodinuclear and Cu(II)–Cu(II) homodinuclear complexes.

The addition of a large excess of hydrogen peroxide to a MeOH solution of $[CuZn(bdpi)(MeCN)_2](ClO_4)_3 \cdot 2MeCN$ **1** or $[Cu_2(bdpi)(MeCN)_2](ClO_4)_3 \cdot MeCN \cdot 3H_2O$ **2** in the presence of a base such as triethylamine at −80 °C resulted in slight color change from greenish blue to green. The absorption spectra of the resulting solutions are shown in Fig. 1, where an intense band at 360 nm is observed in each case.

No decay of these bands was observed at −80 °C but they disappeared at room temperature. The absorbance of the

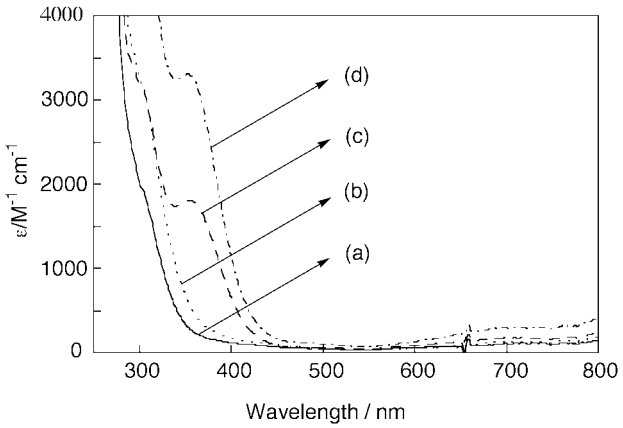


Fig. 1 Absorption spectra of (a) complex **1** (0.2 mM) and (b) **2** (0.2 mM) and those observed upon addition of a large excess of H_2O_2 to a MeOH solution of (c) **1** and (d) **2** in the presence of triethylamine at –80 °C.

DOI: 10.1039/b002208j

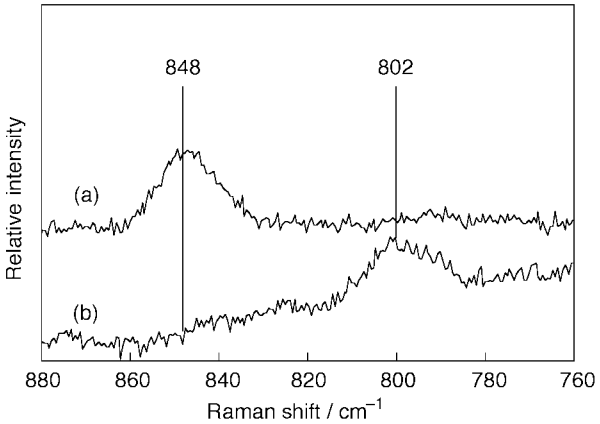

Fig. 2 Resonance Raman spectra obtained with 351 nm excitation of (a) a large excess $H_2{}^{16}O_2$ and (b) $H_2{}^{18}O_2$ in an MeOH solution of complex **1** in the presence of triethylamine at –80 °C.

intermediate **3** derived from complex **1** is about half that of intermediate **4** derived from the same concentration of **2**.

The resonance Raman spectrum of **3** in MeOH measured at −80 °C (laser excitation wavelength 351 nm) shows (Fig. 2) a strong resonance-enhanced Raman band at 848 cm^{-1}, which shifted to 802 cm^{-1} ($\Delta\nu$ = 46 cm^{-1}) when ^{18}O-labeled H_2O_2 was used. The resonance Raman spectrum of **4** was essentially the same as that of **3** ($H_2{}^{16}O_2$: 848 cm^{-1}, $H_2{}^{18}O_2$: 802 cm^{-1}, $\Delta\nu$ = 46 cm^{-1}). The ν value (848 cm^{-1}) of **3** is slightly lower than the value (856 cm^{-1}) reported for the mononuclear hydroperoxo–Cu(II) complex [Cu(II)(bppa)(OOH)](ClO$_4$) [bppa = bis(6-pivalamide-2-pyridylmethyl)(2-pyridylmethyl)amine], which is the only example of a structurally characterized hydroperoxo–Cu(II) complex.[8c] The $\Delta\nu$ value of **3** corresponds exactly to that of [Cu(II)(bppa)(OOH)](ClO$_4$) (46 cm^{-1}) in $H_2{}^{18}O_2$.[8c] The hydroperoxo–Cu(II) complex also has an intense absorption band at 380 nm which is slightly red-shifted as compared to **3** (Fig. 1).[8c] The intense absorption band has been assigned to the charge-transfer transition of the hydroperoxo group to copper(II) ion (LMCT).[8c]

The resonance Raman and absorption spectra in comparison with those of [Cu(II)(bppa)(OOH)](ClO$_4$) strongly indicate formation of hydroperoxo–Cu(II) intermediates, [CuZn(bdpi)(OOH)]$^+$ **3** and [Cu$_2$(bdpi)(OOH)$_2$]$^+$ **4** in the reactions of **1** and **2** with H_2O_2. This assignment is consistent with the half intensity in the absorption band at 360 nm of **3** as compared to **4** (Fig. 1), since **4** contains two Cu–OOH moieties.

Formation of hydroperoxo–Cu(II) intermediates was further confirmed by the ESI mass spectra of **3** and **4** in MeOH at −80 °C, which exhibited signals at *m/z* 651 and 681, respectively.[11] The observed mass and isotope patterns corresponded to the ions [CuZn(bdpi)(OOH)]$^+$ and [Cu$_2$(bdpi)(OOH)$_2$]$^+$, respectively. The use of $H_2{}^{18}O_2$ instead of $H_2{}^{16}O_2$ resulted in the expected change of mass numbers of **3** and **4** to *m/z* 655 and 685, respectively.

The EPR spectrum of **3** was typical of a trigonal-bipyramidal copper complex ($g_{\|}$ = 2.09, $g_{\perp}$ = 2.22, $A_{\|}$ = 8.9 mT and $A_{\perp}$ = 11.3 mT at 77 K in MeOH). These EPR parameters are quite close to those of **1** ($g_{\|}$ = 2.10, $g_{\perp}$ = 2.25, $A_{\|}$ = 10.4 mT and $A_{\perp}$ = 11.5 mT at 77 K in MeOH) and the X-ray structure of **1** shows a trigonal bipyramidal coordination environment of the copper ion.[10] Thus, the copper coordination site of **1** occupied by a solvent molecule may be substituted with hydroperoxide in the reaction with H_2O_2 in the presence of triethylamine base without changing the copper coordination geometry. The EPR spectrum of **4** gave a fairly broad signal centered at $g \cong 2.13$ without hyperfine structure, and this spectral feature is the same as that of **2**. This also indicates that the structure of the intermediate **4** maintains the imidazolate-bridged structure.

These results clearly demonstrate that hydroperoxo–Cu(II) complexes **3** and **4** are generated from imidazolate-bridged Cu(II)–Zn(II) and Cu(II)–Cu(II) SOD model complexes **1** and **2** which utilize their binding sites by reaction with H_2O_2 in the presence of triethylamine base. The hydroperoxo–Cu(II) complexes characterized in this study could serve as SOD intermediate models, providing valuable insight into the SOD catalytic mechanism.

We are grateful to Professor Osamu Yamauchi, Nagoya University, for valuable discussions. This work was partially supported by Grants-in-Aid for Scientific Research Priority Area (Nos. 11228205, 11136229, 11116219 and 11118244) from the Ministry of Education, Science, Culture and Sports of Japan.

11 The flow pass (fused silica capillary, *ca*. 400 mm long, 0.075 mm inner diameter) in the system was precooled by flushing with MeOH cooled at –80 °C in an acetone/dry ice bath prior to measurements. A solution of **3** or **4** cooled at −80 °C was delivered to the sprayer through the fused silica capillary under a constant Ar pressure (0.1 MPa). The sprayer was held at a potential of −4.5 kV, and compressed N_2 was employed to assist liquid nebulization. The orifice potential was maintained at −25 V. The positive ion ESI mass spectra were measured in the range *m/z* 100–1000.

Nitrous oxide decomposition active site on Ni–MgO catalysts characterized by X-ray absorption fine structure spectroscopy

Received (in Cambridge, UK) 6th April 2000, Accepted 8th May 2000

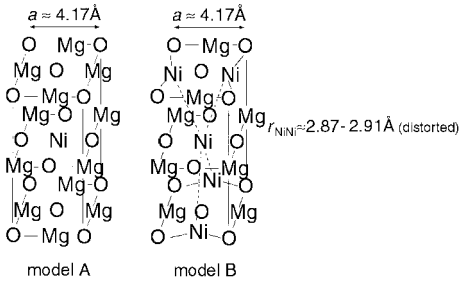
A contracted Ni^{2+} coordination site distorted in the direction of Ni···Mg and Ni···Ni was found to be responsible for catalytic N_2O decomposition when Ni^{2+} is diluted in a MgO matrix (Ni^{2+}/Mg^{2+} atomic ratio ≈ 1.0) based on a local structure study by nickel K-edge X-ray absorption fine structure spectroscopy.

Nitrous oxide is one of the gases which affects the environment. Catalysts for nitrous oxide decomposition have not been well developed compared with various catalysts for nitric oxide decomposition.[1] Nickel–MgO[2] and cobalt–MgO[3,4] are reported to form solid solutions. Metal ion-exchanged zeolites have been reported to be unstable to the effects of formed water during NO or N_2O decomposition reactions. A thermally and water-stable Co–MgO solid solution has been applied to N_2O decomposition.[4] The formation of an fcc structure-based solid solution was demonstrated by EXAFS (extended X-ray absorption fine structure) within the range of Co atom% [*i.e.* Co/(Co + Mg) × 100] of 0–5. However, a severe decrease of catalyst surface area and activity was found when the cobalt content exceeded *ca.* 10 atom% owing to the formation of the Co_3O_4 spinel phase.[4] Herein, the structure of Ni–MgO catalysts was investigated by EXAFS, XANES (X-ray absorption near-edge structure) and XRD (X-ray diffraction). Solid solution formation and the correlation between the local coordination structure of Ni ions and N_2O decomposition reactivity are discussed.

Powders were prepared by the impregnation of nickel nitrate into MgO and were heated in air at 1173 K for 24 h and in H_2 at 573 K for 1 h. With increase of nickel concentration, the BET surface area monotonously decreased from 50 $m^2\ g^{-1}$ (MgO) to 14 $m^2\ g^{-1}$ (Ni–MgO, Ni 33.6 atom%) and then remained constant upon further increase of nickel content. The decomposition of N_2O (0.1%) in helium (balance to 101.3 kPa) was monitored at 873 K in a flow system (flow rate 100 ml min^{-1}, 0.2 g catalyst used). The steady-state formation rate of N_2 (and O_2) per unit BET surface area increased linearly from 2 μmol N_2 $h^{-1}\ m^{-2}$ (MgO) to 51 μmol $h^{-1}\ m^{-2}$ (Ni–MgO, Ni 50.0 atom%), and then gradually decreased to 22 μmol $h^{-1}\ m^{-2}$ (NiO). The presence of nickel at the catalyst surface is essential for increased N_2O decomposition, but an excess of nickel (> 50 atom%) was detrimental to the performance of the catalyst.

Normalized Ni K-edge XANES spectra for Ni–MgO catalysts and NiO are shown in Fig. 1A.[5] The rising edge was always within 8339.4–8339.8 eV, demonstrating the valence state of nickel was +2 in the range of Ni 1.5–100 atom%. As the nickel content increases, the two peaks at 8342 and 8355 eV gradually decreased. The peaks at 8362 and 8389 eV for Ni 1.5 atom% [Fig. 1A(a)] gradually shifted, and finally reached 8365 and 8398 eV, respectively, for NiO [Fig. 1A(f)]. The peak intensity at 8389–8398 eV gradually decreased.

These experimental spectra were compared to XANES data generated by *ab initio* calculations. A code FEFF8 was applied to fcc-based model clusters within 6.0 Å from the absorbing Ni atom in self-consistent field (SCF) and multiple scattering calculation modes.[6,7] The imaginary optical potential used in the calculations of the exchange-correlation potential was fixed to 1.5 eV. The XANES spectrum was generated for an isolated Ni^{2+} model which contains only one Ni^{2+} ion at the center of a MgO cluster matrix (Fig. 1B, solid line). The peaks at 8342, 8349 (main peak) and 8389 eV in the XANES of Fig. 1A(a) (Ni 1.5 atom%) were reproduced in the spectra by FEFF8, but the calculated peak at 8359 eV did not correspond to any peaks in Fig. 1A. The gradual decrease in the peaks at 8342 and 8389 eV with increase of Ni^{2+} content was reproduced by FEFF8 (Fig.



Scheme 1 Ni–MgO models. Model A: Ni 25 atom% unit cell model. Model B: Ni 50 atom% unit cell model. Half of the unit cell is drawn for B. All XANES calculations using FEFF8 were performed for complete (undistorted) fcc coordinates.

[a] $R_f = \int|k^3\chi(\text{obs.}) - k^3\chi(\text{fit})|^2dk/\int|k^3\chi(\text{obs.})|^2dk$. [b] According to X-ray crystallography.

1B and C). The peak at 8359 eV in Fig. 1B shifted to 8362 eV for models A and B (Scheme 1) and then to 8365 eV for the NiO model (Fig. 1C).

Based on these trends (peak position and intensity), the local structure of Ni^{2+} in Ni–MgO (Ni 1.5 atom%) corresponds to model A. The experimental spectra for Ni–MgO (Ni 4.4 and 9.5 atom%) were similar to theoretical XANES for model B. The spectra for Ni 33.6 and 50.0 atom% [Fig. 1A(d), (e)] were more similar to theoretical XANES for model B than that for NiO (Fig. 1C). Each peak in the theoretical XANES spectra for the surface isolated Ni^{2+} model was smeared out (Fig. 1B, dotted line), and did not resemble any spectra in Fig. 1A. Hence, impregnated nickel appears to be distributed statistically inside the MgO matrix and less appears at the MgO surface. Although imaginary optical potential values and Debye–Waller factors were varied, the shoulder peak at 8355 eV in Fig. 1A was not reproduced in theoretical XANES spectra.[8]

Ni K-edge EXAFS spectra for Ni–MgO catalysts were analyzed.[9] The model parameters of Ni-O, Ni···Mg, and Ni···Ni bonds were generated by FEFF8 in SCF mode. The application of SCF FEFF8 parameters to this system was validated by the curve fit for NiO (Table 1 entry f) which was in accord with crystallographic data (entry g).[10] The coordination number had an error of 12–26% for Ni–O and Ni···Mg and an error of 30–80% for Ni···Ni due to the fit procedure and FEFF theoretical parameters. For Ni–MgO catalysts, the best fit results and fit errors based on 10–20 relatively good fits (R_f < 2.0%) for each spectrum are listed in Table 1. Obtained Ni–O and Ni···Mg distances for Ni 1.5 atom% indicate the same or slightly smaller (< 0.007 Å) coordination distance compared to the pure MgO framework (a = 4.2112 Å). Ni–MgO, (Ni 1.5 atom%) corresponds to either model A (Scheme 1) or an isolated single Ni^{2+} atom model in bulk MgO, in both cases there is no second shell Ni···Ni bond.

With an increase of Ni content above 4.4 atom%, N_{Ni-O} and r_{Ni-O} remained almost constant while the $N_{Ni\cdots Ni}/N_{Ni\cdots Mg}$ ratio gradually increased (Table 1, entries b–e). Model B (Scheme 1) has eight Ni···Mg and four Ni···Ni bonds, corresponding to Table 1, entries d and e. XANES generated for a model with one to two Ni^{2+} at next-nearest sites (intermediate between models A and B) was similar to XANES generated for model B (four next-nearest Ni^{2+}), consistent with obtained local coordination by EXAFS (Table 1, entries b and c). The value of a according to XRD monotonously decreased from 4.211 ± 0.002 Å (Ni 4.4 atom%) to 4.190 ± 0.001 Å (Ni 50.0 atom%).[11] When the Ni^{2+} ion concentration is nearly one per unit cell (Ni–MgO, Ni 4.4 atom%), the Ni^{2+} site is locally contracted in an undistorted cell with $a \approx 4.17$ Å. With two Ni^{2+} ions per unit cell (Ni–MgO, Ni 33.6 and 50.0 atom%), the Ni^{2+} sites are locally contracted and distorted in the direction of Ni···Mg and Ni···Ni (2.87–2.92 ± 0.02 Å), smaller than $\sqrt{2}r_{Ni-O}$ [2.950–2.953 (±0.007 Å)] by 0.03–0.08 Å.

Models with locally contracted Ni^{2+} sites (Table 1, entries c–e) shows significantly different Ni···Mg and Ni···Ni distances (2.97–2.94 Å) in the whole range of Ni (0.02–100 atom%) of ref 12. The lower calcination temperature of Ni–MgO samples (773 K)[12] may be the reason for this discrepancy, compared to the temperature of 1173 K used in this work and 1473 K in ref 3. Solid solution formation from supported NiO particles over MgO was suggested to proceed at > 1073 K.[2]

The reason for the dependence of N_2O decomposition rates on Ni^{2+} content in catalysts can be addressed based on the determined Ni^{2+} local structure. Contracted Ni^{2+} sites at the surface are responsible for the dissociation of the N_2–O bond. As the nickel content increases, the number of contracted Ni^{2+} site increases and therefore the N_2 formation rate per unit BET surface area increases to Ni 50 atom%. The next elementary step, $O(ads) + O \rightarrow O_2$, relates to the activity decrease above Ni 50 atom%. An isotope study utilizing ^{18}O labeling of the catalyst surface and $^{16}O(ads)$ resulted in exclusive $^{16}O^{18}O$ formation, *i.e.* the step $O(ads) + O(surf) \rightarrow O_2$. The Ni^{2+} local coordination for a Ni content of 50.0 atom% (Table 1, entry e) corresponds to model B (Scheme 1). The rate of $^{16}O^{18}O$ formation was in the order, Ni–MgO (Ni 50.0 atom%) > MgO > NiO, suggesting that surface oxygen bonded to Mg^{2+} is more reactive and diagonal distortion of Ni···Mg and Ni···Ni destabilizes lattice oxygen. The nitrous oxide adsorption was weak and not detected by FTIR. Raman and IR spectroscopy may give further insight of distorted lattice vibration around doped Ni^{2+}.[13]

Transition metal complexes of the weakly coordinating carborane anion $[CB_{11}H_{12}]^-$: the first isolation and structural characterisation of an intermediate in a silver salt metathesis reaction

Nathan J. Patmore,[a] Jonathan W. Steed[b] and Andrew S. Weller*[a]

[a] *Department of Chemistry, University of Bath, Bath, UK BA2 7AY. E-mail: a.s.weller@bath.ac.uk*

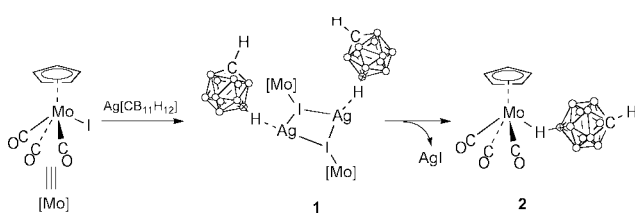
Received (in Cambridge, UK) 31st March 2000, Accepted 8th May 2000

Reaction between $CpMo(CO)_3I$ and $Ag[CB_{11}H_{12}]$ eventually affords $CpMo(CO)_3(\eta^1\text{-}CB_{11}H_{12})$, *via* the dimeric compound $[CpMo(CO)_3I{\cdot}Ag\{CB_{11}H_{12}\}]_2$ which represents the first structurally characterised intermediate in a silver salt metathesis reaction.

The ubiquitous silver halide metathesis reaction, used to generate vacant sites on a metal fragment, finds application in many transition metal-mediated reactions, especially *in situ* catalyst generation.[1] Typically, the counter ion paired in such transformations is triflate, $[OTf]^-$, $[BF_4]^-$ or $[PF_6]^-$, and halide metathesis is considered to be rapid. Over ten years ago, Reed and coworkers reported[2] that very weakly coordinating anions, such as the monocarborane $[closo\text{-}CB_{11}H_{12}]^-$,[3] could dramatically slow the rate of metathesis when paired with Ag^+, suggesting that the exceptionally low nucleophilicity of the anion was a limiting factor in these reactions. Reaction between $CpFe(CO)_2I$ ($Cp = \eta^5\text{-}C_5H_5$) and $Ag[CB_{11}H_{12}]$ was proposed (by ^1H NMR and IR data) to proceed through an intermediate adduct, $CpFe(CO)_2I{\cdot}Ag[CB_{11}H_{12}]$, similar to Mattson and Graham's[4] proposed intermediate adduct, formed between $CpFe(CO)_2I$ and $Ag[BF_4]$. However, neither of these transient species (or other related[5] compounds) have been placed on a firm structural footing. Given the widespread use of the silver salt metathesis reaction, the identity of the intermediates in these reactions is of significant interest.

We have a current interest in the transition metal chemistry associated with carboranes such as $[CB_{11}H_{12}]^-$, and as part of this investigation have been studying the reactions of $CpMo(CO)_3X$ (X = Cl, I) with $Ag[CB_{11}H_{12}]$ and derivatives, with the anticipation of forming complexes *via* extrusion of AgX. We report here, the isolation and full characterisation, including the X-ray crystal structure, of the intermediate formed in this silver salt metathesis reaction.

Reaction between $CpMo(CO)_3Cl$ and $Ag[CB_{11}H_{12}]$ in CH_2Cl_2 over 2 days resulted in the precipitation of AgCl and the isolation, in essentially quantitative yield, of $CpMo(CO)_3(\eta^1\text{-}CB_{11}H_{12})$ **2** (Scheme 1). Compound **2** has been fully characterised by multinuclear NMR spectroscopy† and by an X-ray diffraction study[6] and shows the expected[2] 3c–2e Mo–H–B agostic bonding. Compound **2** displays two CO stretching modes in its IR spectrum, at 2071 and 2001 cm^{-1}. Monitoring the reaction by IR spectroscopy showed that the reaction proceeded through an intermediate species [as found for $CpFe(CO)_2I$[2]], but at no time was there a single component observed in the reaction mixture. Moving to $CpMo(CO)_3I$ resulted in a slowing down of the reaction, so that formation of **2** now took 7 days, while after *ca.* 3 h of stirring there was only one component in the reaction mixture, which displayed IR stretches at 2054 and 1973 cm^{-1}, intermediate between the starting material and product. Monitoring this reaction by IR and ^1H NMR spectroscopies showed that this was indeed an intermediate species, continued stirring for 7 days resulting in the clean formation of **2**. Careful recrystallisation of this intermediate overnight at −30 °C afforded small red crystals in reasonable isolated yield (50%), which were pure by IR, microanalysis and NMR spectroscopy,‡ and shown by X-ray diffraction§ to be $[CpMo(CO)_3I{\cdot}Ag\{CB_{11}H_{12}\}]_2$ **1**: the first structurally characterised intermediate in a silver salt metathesis reaction.



Scheme 1

The solid state structure of **1** is shown in Fig. 1. It is apparent that it adopts a centrosymmetric dimeric structure, with an I–Ag–I–Ag central core hinged around the Mo(1)–I(1)–I(1A)–Mo(1A) vector by 123.2°. The two Ag–I lengths are significantly different, Ag(1)–I(1) 2.9748(10) Å and Ag(1)–I(1A) 2.7599(9) Å. While similar central cores to **1** are known,[7,8] the presence of two additional [M]–I–Ag bridges appended to such a motif is unprecedented. However, there are silver adduct species of transition metal halides that show similar features,[9] such as the recently reported complex $[\{TpRe(NC_6H_4Me\text{-}p)(Ph)I\}_2Ag][PF_6]$[10] [Tp = tris(pyrazolyl)borate] in which silver bridges two {[Re]–I} fragments. The carborane anion is intimately connected with silver, showing a short (1.96 Å) Ag–H–B interaction [Ag(1)–B(12) 2.659(10) Å]. The cages are orientated *syn* to one another with respect to the Mo–I–I–Mo vector, leaving the silver atoms with an apparent vacant coordination site. Inspection of the packing diagram for **1** reveals that this site is occupied by another short (1.96 Å) Ag–H–B interaction arising from an adjacent carborane cage in the lattice, meaning that each cage bridges two silver centres [through H(12) and H(7)]. This results in a chain-like structure

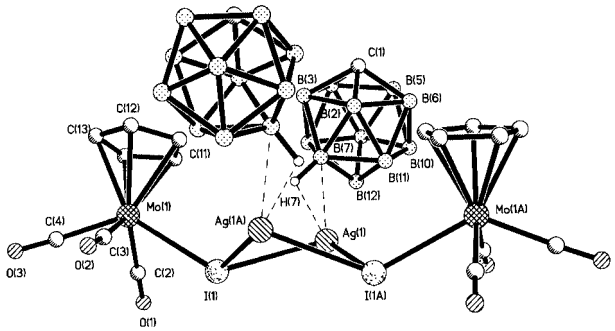


Fig. 1 Structure of the dimeric unit in complex **1**. Atom labels suffixed 'A' are generated crystallographically. Hydrogen atoms [except H(7)] are omitted for clarity. Selected bond lengths (Å) and angles (°): Mo(1)–I(1) 2.8599(8), Ag(1)–I(1) 2.9748(10), Ag(1A)–I(1) 2.7599(9), Ag(1)–B(7) 2.659(10), Ag(1)–H(7) 1.96; Ag(1)–I(1)–Ag(1A) 71.19(3), I(1)–Ag(1)–I(1A) 97.10(3).

DOI: 10.1039/b002585m

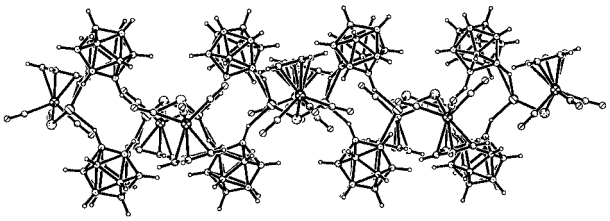

Fig. 2 Extended solid state structure of **1** viewed along the crystallographic '*a*' axis.

along the '*a*' axis in the crystal (Fig. 2). A similar bridging motif has been observed in the simple salt $Ag[CB_{11}H_{12}]\cdot 2C_6H_6$,[2] while dimeric structures formed from single Ag–H–B interactions have also been reported.[11,12]

Although it is unlikely that this polymeric structure persists on dissolution in CH_2Cl_2, evidence for coordination of the carborane cage to Ag in solution comes from inspection of the ^{11}B NMR spectra. The room temperature $^{11}B\{^1H\}$ NMR spectrum (128 MHz) shows two peaks at δ −11.1 and −14.6 in the ratio 1 : 10 (latter peak a 5 + 5 coincidence), significantly different from the free anion (*vide infra*), the unique boron resonance being shifted upfield by *ca.* 5.5 ppm with respect to $Ag[CB_{11}H_{12}]$ [$\delta_{^{11}B}$ −5.4 (1B), −10.6 (5B) and −12.3 (5B) in d_6-acetone]. This chemical shift difference suggests sustained Ag–H–B interaction(s) in solution and is consistent with the observed Ag–H–B contacts in the solid state. In the room-temperature $^1H\{^{11}B\}$ NMR spectrum the unique BH is observed at δ 2.12 and shifts slightly to δ 1.92 on cooling to −90 °C, showing no Ag–H coupling, although such interactions are rarely observed. The ^{109}Ag NMR spectrum displayed a single sharp line at δ 1335, shifted significantly downfield from the normal range ($\delta_{^{109}Ag}$ *ca.* 500) expected for Ag(I) centres.[13]

Overall metathesis can be dramatically suppressed in this system by moving to the less nucleophilic and sterically bulkier carborane anion $Ag[CB_{11}H_6Br_6]$. Stirring for 1 h results in the clean formation of the analogous intermediate complex to **1**,[14] but, surprisingly, no subsequent metathesis was observed, even after extended stirring for 7 days. This result is in accord with the previous observation that the relative nucleophilicity of the conjugate anion in these reactions is rate determining.[2] Nevertheless, the cessation of this reaction at the intermediate stage is, to our knowledge, without precedent. It should be noted, however, that metathesis does not proceed to completion when Vaska's complex and $Ag[CB_{11}H_{12}]$ are combined, but in this system a strong Ag–Ir bond is formed instead,[15] very different from the structure of **1**.

In summary, we have presented here the first fully characterised (NMR, X-ray diffraction) intermediate in a silver salt metathesis reaction, and found it to have a dimeric {[Mo]–I}–Ag–{[Mo]–I}–Ag core in the solid state. This result leads us to speculate upon the motifs accessible using combinations of other $CpML_nX_y$ fragments and monocarborane anions, and we are currently actively pursuing this. Moreover, the lack of metathesis consummation with $Ag[CB_{11}H_6Br_6]$ demonstrates that there is a significant degree of kinetic control in a reaction that is normally considered very facile. This has potential implications for the synthesis of transition metal complexes bearing very weakly coordinating anions *via* silver salt metathesis.

We thank the EPSRC and King's College London for the provision of the X-ray diffractometer and the Nuffield Foundation for the provision of computing equipment (J. W. S.). The Royal Society (A. S. W.) and the University of Bath (N. J. P.) are thanked for financial support. Dr Mary Mahon is thanked for useful discussions and Dr J. P. Rourke is thanked for his assistance in obtaining the ^{109}Ag spectrum of **1**.

Novel class of ammonia synthesis catalysts

Claus J. H. Jacobsen

Haldor Topsøe Research Laboratories, Nymøllevej 55, DK-2800 Lyngby, Denmark. E-mail: chj@topsoe.dk

Received (in Oxford, UK) 10th April 2000, Accepted 9th May 2000

Ternary nitrides Fe_3Mo_3N, Co_3Mo_3N and Ni_2Mo_3N, exhibit high catalytic activities in ammonia synthesis; promotion of Co_3Mo_3N with caesium results in higher activity than that of the commercial multi-promoted iron based catalyst.

During the 20th century the catalytic ammonia synthesis has grown to be among the most important industrial processes. More than 1% of the total global energy consumption is currently used for ammonia production. Therefore, improvements in this process could have a significant impact on the consumption of fossil fuels. Consequently, a continuous effort has been made to improve both the Haber–Bosch process and the promoted iron based catalyst discovered by Mittasch and coworkers. Despite these efforts, the preferred industrial ammonia synthesis catalyst is still a multi-promoted iron catalyst very similar to that developed almost a century ago. It was realized by the group of Haber that both osmium and ruthenium catalysts exhibit high ammonia synthesis activities.[1]

Detailed accounts of the previous work on non-iron catalysts have been published.[2,3] Recently, a promoted ruthenium catalyst supported on a special graphite carrier was introduced in commercial operation.[4,5] However, it is not clear whether the improved activity of such catalysts is justified by the significantly higher cost and shorter life-time relative to the traditional iron catalyst. Clearly, it would be very desirable to develop new, active and stable catalysts that do not contain noble metals. We have found that the ternary nitrides Fe_3Mo_3N, Co_3Mo_3N and Ni_2Mo_3N are active and stable ammonia synthesis catalysts at industrially relevant conditions. Addition of a small amount of Cs to Co_3Mo_3N results in a catalyst with a higher activity than that of the commercial multi-promoted iron catalyst.[6]

Ternary nitrides were obtained by two different routes. The first is based on ammonolysis of solid oxide precursors as reported in the literature.[7] The oxide precursors were obtained by mixing a solution of the desired metal nitrate salt (M = Fe, Co, Ni) with a solution of ammonium heptamolybdate. The mixture was evaporated to dryness and calcined at 400 °C for 2 h. The resulting $MMoO_4{\cdot}xH_2O$ was heated at 0.1 °C min^{-1} to 600 °C in a stream of 4.5% NH_3 in 3 : 1 H_2–N_2. After cooling to room-temperature it was confirmed by X-ray powder diffraction that pure Fe_3Mo_3N, Co_3Mo_3N and Ni_2Mo_3N were formed when Fe : Mo = 1, Co : Mo = 1 and Ni : Mo = 2/3, respectively. It was also found that if a Ni : Mo ratio of 1 was used, the X-ray powder patterns could be assigned to a mixture of Ni_2Mo_3N and NiMo alloy and *not* to Ni_3Mo_3N as previously suggested.[8] Alternatively, the ternary nitrides were prepared from high surface area molybdenum nitride obtained by temperature programmed reaction of MoO_3 with NH_3 as described by Volpe and Boudart.[9] The resulting Mo_2N with a surface area of > 200 $m^2\ g^{-1}$ was successively impregnated with saturated solutions (followed by drying) of the desired metal nitrate solution to obtain the correct stoichiometry. Subsequently, the sample was dried and heated at 0.1 °C min^{-1} to 600 °C in a stream of 4.5% NH_3 in 3 : 1 H_2–N_2. It was confirmed by X-ray powder diffraction that Fe_3Mo_3N, Co_3Mo_3N and Ni_2Mo_3N were also formed by this procedure.

Addition of controlled amounts of caesium nitrate to the catalysts could be achieved either by impregnation of the oxide precursors prior to ammonolysis or directly onto the nitride catalyst before testing.

X-Ray powder patterns were recorded by slow scanning on a Philips vertical goniometer equipped with a θ-compensating divergence slit and a diffracted beam graphite monochromator utilizing Cu-Kα radiation. Crystal sizes were estimated from the broadening of the diffraction peaks using the Scherrer equation. *In situ* X-ray powder patterns were obtained as previously described.[10]

Surface areas were obtained from isotherms measured with a Quantachrome Autosorb using N_2 as adsorbant at 77 K.

Catalytic ammonia synthesis activities were recorded at pressures from 1 to 100 bar, temperatures between 320 and 500 °C, and in 3 : 1 and 1 : 1 H_2–N_2 gas mixtures using the set-up previously described.[11] The reported activities are based on the mass of catalyst loaded into the reactor and given as ml ammonia (at STP) produced per hour per gram of catalyst.

In order to conclusively establish that the ternary nitrides are stable under ammonia synthesis, an *in situ* XRPD experiment was conducted. A small amount of $NH_5(CoOHMoO_4)_2$ was loaded into a capillary reactor and transferred to the *in situ* XRPD set-up. A stream of pure ammonia was passed through the sample while it was heated at 0.5 °C min^{-1} to 600 °C at ambient pressure. It was seen that the starting material, $NH_5(CoOHMoO_4)_2$ (prepared by precipitation from a cobalt nitrate and ammonium heptamolybdate solution kept at pH = 8 for 3 days) initially transformed into Co and MoO_2 at 470 °C and a little later MoO_2 transforms into γ-Mo_2N. Finally, Co_3Mo_3N is formed at 600 °C from Co and γ-Mo_2N. From this reaction sequence it was natural to attempt the preparation of Co_3Mo_3N by impregnation of γ-Mo_2N with a metal salt followed by ammonolysis. In principle, this method might be applicable for the preparation of a wide range of ternary or quarternary nitride materials. When formation of Co_3Mo_3N was confirmed in the *in situ* XRPD set-up the sample was cooled to 400 °C and the gas changed to a 3 : 1 mixture of H_2–N_2 at 25 bar. No further changes in the X-ray powder pattern were observed and it was possible to detect formation of ammonia using a Baltzers quadrupole mass spectrometer connected to the exit stream from the capillary reactor.

Fig. 1 shows the X-ray powder pattern obtained at 400 °C, 25 bar in a 3 : 1 mixture of dihydrogen and dinitrogen. All

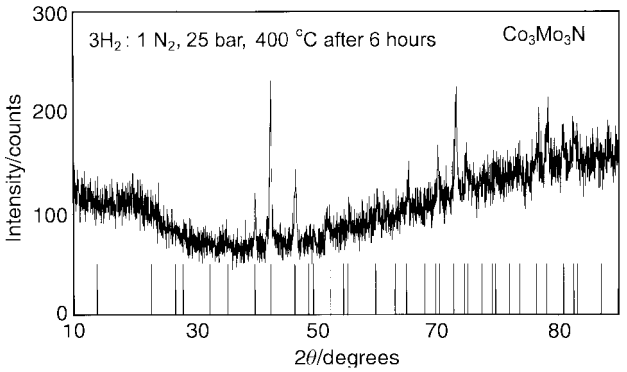

Fig. 1 *In situ* X-ray powder pattern obtained from Co_3Mo_3N at 400 °C, 25 bar in a 3 : 1 mixture of dihydrogen and dinitrogen. Calculated positions of the diffraction lines for Co_3Mo_3N are also shown.

DOI: 10.1039/b002930k

Table 1 Selected properties of molybdenum nitride and ternary nitride catalysts

Catalyst	Space group	BET surface area/m² g^{-1}	Average crystal size/nm
γ-Mo_2N	*Pm*3*m*	203	3.6
Fe_3Mo_3N	*Fdm*	8	45.0
Co_3Mo_3N	*Fd*3*m*	11	39.0
Ni_2Mo_3N	$P4_132$	7	44.0

diffraction lines are assigned to Co_3Mo_3N and it is concluded that Co_3Mo_3N is stable under ammonia synthesis conditions. *In situ* XRPD experiments were not conducted with Fe_3Mo_3N and Ni_2Mo_3N. However, no other compounds or phases were found using XRPD on spent catalyst samples.

Table 1 summarizes selected properties of the ternary nitrides prepared by ammonolysis of mixed oxide precursors. For comparison γ-Mo_2N is also included. It is seen that significantly lower surface areas are obtained for the ternary nitrides compared to that of γ-Mo_2N. The surface areas are in reasonable agreement with those estimated from the average crystal sizes. Promotion of the catalysts with *ca.* 5 wt% caesium did not result in a significant change in crystal size or surface area.

Catalytic activities were measured at 400 °C and 100 bar pressure. The inlet gas contained 4.5% ammonia in 3:1 dihydrogen–dinitrogen. The flow rate was adjusted to obtain 12% ammonia in the exit gas. Table 2 summarizes the activities of the unpromoted and caesium-promoted catalysts. It is observed that the activities are significantly enhanced by caesium promotion. For comparison the activity of a commercial multi-promoted iron catalyst, KM1,[12] is *ca.* 750 ml ammonia h^{-1} g^{-1} under similar conditions but at 410 °C.[13] Fig. 2 directly compares the activity of the caesium-promoted Co_3Mo_3N with that of the commercial catalyst at 400 °C and 50 bar in a 3:1 mixture of dihydrogen and dinitrogen. The feed flow was varied to study the influence of the exit concentration of ammonia on the activity. It is seen that both catalysts are inhibited by ammonia. Under these conditions the Cs/Co_3Mo_3N catalyst is significantly more active than the commercial iron catalyst. An activation energy of 54 kJ mol^{-1} was found for Cs/Co_3Mo_3N at constant conversion using the activity data at 50 bar and 320, 360, 400 and 440 °C. It should be noted that all activities reported here are based on the mass of catalyst. Industrially, the volume-based activities are usually more relevant and in this context it is important to note that the bulk densities of the nitride catalysts are as high as those of iron based catalysts.

Table 2 Catalytic ammonia synthesis activities of molybdenum nitride and ternary nitride catalysts at 400 °C, 100 bar and *ca.* 8% ammonia

Catalyst	Ammonia production/ml h^{-1} g^{-1}
γ-Mo_2N	30
Fe_3Mo_3N	90
Co_3Mo_3N	120
Ni_2Mo_3N	80
Cs/Fe_3Mo_3N	440
Cs/Co_3Mo_3N	1040
Cs/Ni_2Mo_3N	530

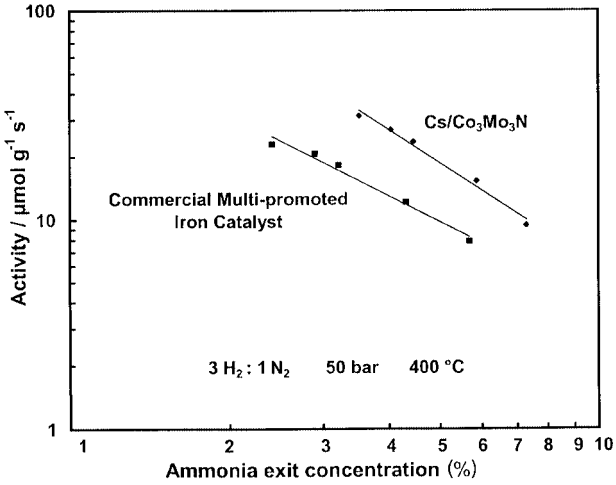

Fig. 2 Catalytic activities of caesium-promoted Co_3Mo_3N and a commercial multi-promoted iron catalyst.

Previously, molybdenum nitride has been reported to exhibit high activity in catalytic ammonia synthesis.[14] However, it is seen that the activities of the ternary nitride catalysts are significantly higher. Particularly, the caesium promoted Co_3Mo_3N catalyst appears interesting. Since the ternary nitride catalysts are formed by ammonolysis at 600 °C they are expected to be very stable during the conditions of ammonia synthesis. The activity shown for Cs/Co_3Mo_3N was unchanged after two weeks at 400 °C and 50 bar. Possibly, other ternary nitrides will also be active ammonia synthesis catalysts.

I would like to thank A. M. Molenbroek for obtaining the *in situ* XRPD patterns and J. Hartvig and L. Jensen for measuring the catalytic activities.

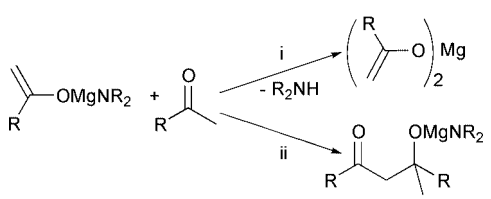
Received (in Cambridge, UK) 11th April 2000, Accepted 9th May 2000

A reactive magnesium enolate intermediate has been identified containing the remarkable composition of four metals, eight enolates (six bridging and two terminally bound) and two unenolised ketones, and its implications in the aldol addition reaction are discussed.

Enolate anions are key intermediates in numerous transformations including alkylations, Michael reactions, protonations, acylations and aldol additions.[1] We have recently begun an investigation into the use of magnesium bisamides, $(R_2N)_2Mg$, as reagents and have found significant differences in their reactivity, and more importantly in their selectivity, compared with their Li analogues. Recently reported uses of Mg-bisamides include the regio- and stereo-selective synthesis of kinetic silyl enol ethers,[2] the formation of secondary and tertiary β-hydroxy ketones *via* aldol addition reactions,[3] and as asymmetric induction reagents in enantioselective deprotonation reactions.[4] Herein, we discuss the formation and structure of a novel magnesium bisenolate and consider its role as a model complex in the aldol addition reaction.

The organometallic complexes produced by the reaction of magnesium bishexamethyldisilazide **1** with 2,4,6-trimethylacetophenone **2** (between 2 and 6 mol equiv.) in hexane solution were initially determined by ^{1}H NMR spectroscopic analysis of the solids precipitated from solution.† Only enolate and unenolised ketone were present in the solids, and the absence of any amide suggested formation of a magnesium bisenolate. This is in marked contrast with our previous studies[3] of the reaction between **1** and 2 mol equiv. of a series of methyl ketones [O=C(Me)R, where R = Bu^t, Ph, Bu^n, Pr^i or cyclohexyl], which undergo aldol addition reactions. Furthermore, the aldol reaction sequence is supported by the structural characterisation of the amido(aldolate) $[\{(Me_3Si)_2NMg(\mu\text{-}OC(Me)^tBuCH_2C(^tBu)=O)\}_2]$ **3**,[3] *i.e.* enolisation followed by aldol addition with retention of one amido unit attached to the metal. Following initial formation of an amido(enolate), two distinct routes are in competition either enolisation or aldol addition (Scheme 1). Formation of a bisenolate in preference to an amido(aldolate) for the reactions involving **2** is most likely due to a combination of the steric crowding and the electronics of the ketone which retard the addition reaction.[5] The presence of an amido(enolate) intermediate in these reactions was confirmed by *in situ* ^{1}H NMR spectroscopic monitoring of the equimolar reaction between **1** and **2**. In addition, bisenolate was also detected in these mixtures demonstrating a competitive reaction even at this stage. Further support for an amido(enolate) reaction intermediate comes from the recent structural elucidation of $[\{(Me_3Si)_2NMg\{\mu\text{-}OC(Ph)=CHMe\}\cdot THF\}_2]$ **4**, formed by reaction of **1** with 1 equiv. of propiophenone.[2b]



Scheme 1 Formation of (i) bisenolate or (ii) amido(aldolate) *via* an amido(enolate); aggregation state is ignored.

Repeated attempts at crystal growth from the reactions between **1** and **2** resulted in the formation of crystallites too small for conventional single crystal diffraction but were suitable for analysis using synchrotron radiation.‡ This study revealed the complex $[Mg_4\{OC(Mes)=CH_2\}_8\cdot\{O=C(Mes)\text{-}Me\}_2\cdot(C_6H_5(Me)_2)]$ **5** (Mes = 2,4,6-$Me_3C_6H_2$), which is centrosymmetric and contains the novel composition (ignoring the inclusion solvent toluene) of four magnesiums, six bridging enolates, two terminal enolates (O2 and O2*) and two ketones (O1 and O1*) coordinated to the terminal metal centres (Fig. 1). The linear arrangement of the metals in a limited tetrameric complex represents a completely new structural motif in magnesium coordination chemistry.[6] Although rare, tetrameric conformations, where the metals form either rhombohedral or tetrahedral geometries respectively, are known.[6] The structure of **5** can be described as a section of polymeric bisenolate consisting of linked orthogonal Mg_2O_2 rings which has been intersected by donor solvent, interestingly in this case unenolised ketone.

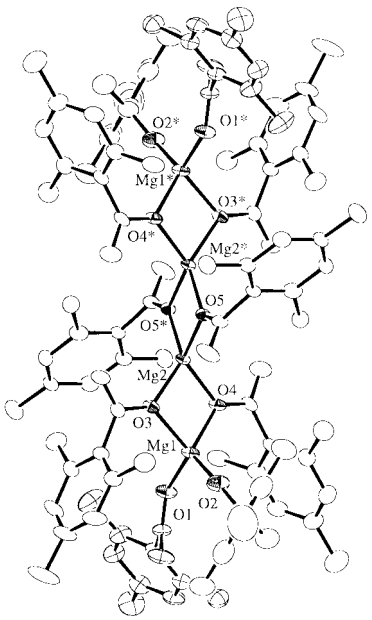


Fig. 1 Molecular structure of **5** with hydrogen atoms and solvents of crystallisation omitted for clarity. The ketone ligands are highlighted with hatched ellipses. Selected bond lengths (Å) and angles (°): Mg(1)–O(1) 2.012(3), Mg(1)–O(2) 1.845(3), Mg(1)–O(3) 1.991(3), Mg(1)–O(4) 1.970(3), Mg(2)–O(3) 1.969(3), Mg(2)–O(4) 1.965(3), Mg(2)–O(5) 1.978(3), Mg(2)–O(5*) 1.963(3); O(1)–Mg(1)–O(2) 110.08(13), O(1)–Mg(1)–O(3) 114.54(12), O(1)–Mg(1)–O(4) 108.28(12), O(2)–Mg(1)–O(3) 117.88(13), O(2)–Mg(1)–O(4) 122.24(14), O(3)–Mg(1)–O(4) 81.16(10), O(3)–Mg(2)–O(4) 81.83(11), O(4)–Mg(2)–O(5) 125.96(12), O(3)–Mg(2)–O(5) 117.87(11), O(3)–Mg(2)–O(5*) 135.08(12), O(4)–Mg(2)–O(5*) 121.39(11). * Indicates the transformation $1-x, 1-y, 1-z$.

DOI: 10.1039/b002892o

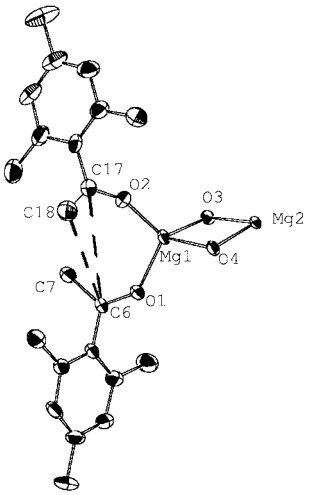

Fig. 2 View of the terminally bound groups in **5**. Important interatomic distances (Å): C(18)–C(6) 4.156(7), C(17)–C(6) 4.164(6), C(18)–O(1) 4.237(6), C(17)–O(1) 4.021(5).

Diphenylmagnesium adopts a polymeric structure[7] similar to the core of **5** but deaggregates only to monomers on addition of either THF or TMEDA.[8] The highly unusual tetrameric framework adopted by **5** may be explained by analysis of the structure. The two central aromatic rings, connected to O(5) and O(5*), are oriented *anti* to one another, whereas the aromatic groups of the terminal rings, connected to O(3) and O(4), are *syn* with respect to each other and are directed towards the terminal metal, Mg(1). If the polymeric form of the bisenolate has a similar structure the steric crowding induced by the *syn* aromatic groups may result in weak links in the polymer chain, leading to preferential scission at these sites. Alternatively, **5** may be the end product of chain growth with the *syn* aromatic groups on O(3) and O(4) blocking any further propagation.

The geometric parameters within **5** are in accord with those expected for Mg-alkoxides.[6] Each metal is four coordinate with no significant interactions to either the arene rings or the olefinic groups (all Mg–C are > 3 Å). The central Mg_2O_2 ring is strictly planar, whereas the two terminal rings are buckled, with each of the atoms deviating from the mean plane by 0.56(1) Å, and with an interplanar angle between the central and outer rings of 80.13(9)°.

A remarkable feature of **5** is the presence of solvating ketone in addition to enolate groups, hence **5** can be considered as a model, aggregated, pre-aldol intermediate. Although there has been much speculation about the importance of pre-solvation in similar transformations, in particular for Li-mediated reactions,[9] surprisingly little direct evidence for its existence has been reported.[10] In part, this is due to the high reactivity of these complexes. In this instance the aldol addition reaction is disfavoured facilitating the isolation of **5**. Nevertheless, the self-coupled tertiary β-hydroxy ketone derived from **2** was detected in low yield (< 5%) on extended reaction times. In contrast, secondary β-hydroxy ketones could be readily prepared (> 80% yield) by reaction of the enolate solutions with aldehydes.

Finally, it is intriguing to speculate on the orientations adopted by the terminally bound enolate and ketone groups within **5**. The olefinic carbons C(17) and C(18) are essentially equidistant to the carbonyl carbon C(6) of the ketone and hence the centre of the π-bond is oriented appropriately for nucleophilic attack of the carbonyl through a six-membered transition state similar to that postulated in the Zimmerman–Traxler model (Fig. 2).[11] Such a mechanism would involve aldol addition *via* the terminal and not the bridging enolate groups of the aggregate.

Notes and references

† **5**: a solution of **1** (3 mmol) in hexane (10 mL) was cooled to −78 °C and **2** (6–18 mmol) was added dropwise by syringe over a period of 2 min. The mixture was allowed to warm to ambient temperature after 15 min and stirred for a further two days. The resulting white solids were filtered off, washed with hexane and analysed by ^{1}H NMR spectroscopy. Subsequent recrystallisation of the solids from hexane–toluene yielded small crystals, which were used for the X-ray diffraction analysis. The varying amount of unenolised ketone present (between 0.1 and 0.8 equiv.) is consistent with more than one type of solvated enolate present, most likely dimers or monomers. However, these could not be separated for unambiguous analysis and limited the analysis of the products to NMR spectroscopy. *In situ* ^{1}H NMR spectroscopic studies indicated complete reaction of **1** with available ketone after several hours at ambient temperature. ^{1}H NMR (400 MHz, [$^2H_5$]pyridine, 25 °C); bisenolate: δ 7.00 (s, 2H, *m*-H, Mes), 3.91, 3.81 [d, ^2J(HH) 1.7 Hz, 1H, C=CH_2] 2.63 (s, 6H, *o*-CH_3), 2.33 (s, 3H, *p*-CH_3); unenolised ketone: δ 6.78 (s, 2H, *m*-H, Mes), 2.42 (s, 3H, *p*-CH_3), 2.19 (s, 9H, *m*-CH_3 and CH_3); amido(enolate): δ 6.89 (s, 2H, *m*-H, Mes), 4.48, 3.91 [d, ^2J(HH) 1.3 Hz, 1H, C=CH_2), 2.59 (s, 6H, *o*-CH_3), 2.27 (s, 3H, *p*-CH_3), 0.29 (s, 18H, $SiMe_3$).

‡ *Crystal data* for **5**: $C_{124}H_{148}Mg_4O_{10}$, M = 1895.66, T = 150(2) K, measurements were performed at Station 9.8, Daresbury SRS with Si111 monochromated radiation (λ = 0.6884 Å). A single crystal of dimensions 0.18 × 0.08 × 0.02 mm was mounted in inert oil and transferred to the cold N_2 gas stream of the diffractometer. Triclinic, space group $P\bar{1}$, a = 11.8142(7), b = 11.8617(7), c = 20.5469(13) Å, α = 74.844(2), β = 84.437(2), γ = 83.078(2)°, U = 2752.5(3) Å^3, Z = 1, μ = 0.185 mm^{-1}, D_c = 1.144 Mg m^{-3}, $2\theta_{max}$ = 45 °, 10156 reflections collected, 7669 unique, (R_{int} = 0.0425) all were used in the calculations. All non-hydrogen atoms were treated anisotropically and all hydrogens included in a riding model. The final $wR(F^2)$ was 0.1823, conventional R was 0.0680 and S = 1.002 for 637 parameters. Highest residual electron density 0.260 e Å^{-3}. Programs were standard (G. M. Sheldrick, University of Göttingen, Germany) diffractometer control software and members of the SHELX family. The structure was solved using direct methods and refined by full-matrix least-squares refinement on F^2. The unit cells of several crystals from different reaction batches were checked to confirm that the synthesis of **5** was reproducible.

Received (in Cambridge, UK) 17th March 2000, Accepted 8th May 2000

The title compound is unique in such a way that among the vast number of synthetic phosphates and naturally occurring phosphate minerals it is the first example in which four different types of monophosphate, PO_4, $H_{0.5}PO_4$, HPO_4 and H_2PO_4, are present in the same structure.

Metal phosphates have been the subject of intense research owing to their rich structural chemistry and potential applications as ion exchangers, ionic conductors, catalysts and nonlinear optical materials.[1–6] In addition to the metal phosphates prepared in laboratories, phosphate minerals are also found in natural rocks; one example is the well known naturally occurring iron phosphate, cacoxenite, with a remarkable open-framework structure.[7] Some of the synthesized aluminophosphates or derived materials adopt structures that are similar to the naturally occurring aluminosilicates.[8] Anhydrous phosphates such as $LiTi_2P_3O_{12}$ and $LiZr_2P_3O_{12}$ have been prepared using high-temperature solid-state reactions. Many other metal phosphates containing PO_4, HPO_4, H_2PO_4 or combinations of the three have also been synthesized by hydrothermal methods. Hydrogen bonds are often formed in these crystalline hydrogen phosphates and unsymmetrical O–H···O bonds are usually observed. Symmetrical hydrogen bonds, which occur in many dicarboxylates with O···O distances of < 2.5 Å, are rarely found in phosphates. Here, we present the synthesis and characterization of a novel gallophosphate $[Ga_4(C_{10}H_9N_2)_2(PO_4)(H_{0.5}PO_4)_2(HPO_4)_2(H_2PO_4)_2(H_2O)_2]\cdot H_2O$ **1**. Among the vast numbers of metal phosphates that have been synthesized, none has the unique composition of **1** which contains four different types of monophosphates, *viz.* PO_4, $H_{0.5}PO_4$, HPO_4 and H_2PO_4, in the same structure. For $H_{0.5}PO_4$ there is an inversion center at the center of the short, symmetrical O–H–O bonds. We have prepared the monophasic phase and single-crystal X-ray diffraction and ^{31}P magic angle spinning (MAS) NMR have been applied to study the four different coordination environments for phosphorus.

Solvothermal reaction of $Ga(NO_3)_3\cdot 4H_2O$, 4,4′-bipyridine, H_3PO_4, H_2O and butan-1-ol in the molar ratio of 1:3:8:55.5:76.5 in a Teflon-lined acid digestion bomb at 165 °C for 3 d produced compound **1** in 66% yield based on Ga. A suitable colorless crystal was selected for structure determination by single-crystal X-ray diffraction.† The bulk product is monophasic as judged by powder X-ray diffraction (Anal. Calc.: C, 18.25; H, 2.27; N, 4.01. Found: C, 18.21; H, 2.37; N, 4.25%). ^{31}P MAS NMR spectra were acquired at a ^{31}P frequency of 161.73 MHz on a Bruker DSX-400 spectrometer under conditions of high-power proton decoupling. A pulse length of 4 μs ($\pi/4$) and a repetition time of 30 s were used. The ^{31}P chemical shifts were reported relative to 85% H_3PO_4 as external reference. The Hartmann–Hahn condition for ^1H to ^{31}P CP experiments was determined using $(NH_4)_2HPO_4$. The $^1H \rightarrow {}^{31}P$ CP spectra were recorded using a single-contact pulse sequence with reversal of spin temperature in the rotating frame and with proton decoupling during the ^{31}P signal acquisition. This pulse sequence was used for ordinary CP experiments as well as for $T_{1\rho}^{H}$ and $T_{1\rho}^{P}$ relaxation measurements.

Compound **1** has a one-dimensional chain structure. The fundamental building unit consists of two $Ga(1)O_5N$ octahedra, two monoprotonated 4,4′-bipyridine molecules which coordinate to Ga(1), two $Ga(2)O_4$ tetrahedra and seven phosphates of four different types. The connectivity between units is made by $P(1)O_4$ groups that join the GaO_5N and GaO_4 polyhedra to those in the neighboring units and thus form infinite chains parallel to the [001] direction (Fig. 1). $H_{0.5}P(4)O_4$ coordinates to one GaO_4 tetrahedron and two GaO_5N octahedra. The hydrogen atom in $H_{0.5}PO_4$ lies on an inversion center and is shared by two $H_{0.5}P(4)O_4$ groups on the adjacent chains. The O–H bond length in the symmetrical O–H–O bonds is 1.231 Å.[9] $HP(3)O_4$ has one oxygen bridging to GaO_4 and extends away from the chain as a pendant group, which accounts for the relatively larger thermal parameters of the atoms in the group. Of the three remaining P(3)–O bonds, the longest one constitutes the P–OH group, while the other two receive hydrogen bonds from adjacent chains. $H_2P(2)O_4$ is connected to GaO_5N and GaO_4 with the two hydroxo groups being H-bonded to two adjacent chains. All H atoms except those for O_w were found in difference Fourier maps and refined isotropically. The infinite chains are held in position by a network of hydrogen bonds, generating tunnels parallel to [001], within which the monoprotonated 4,4′-bipyridine and lattice water molecules reside (Fig. 2). The lattice water molecule has a site occupancy of 0.5 and is held in the crystal lattice by hydrogen bonds.

Fig. 3 shows the room temperature ^{31}P MAS NMR spectrum of **1**. Four resonances at −0.4, −9.2, −11.3 and −17.9 ppm with relative intensities very close to 1:1:1:0.5 respectively are observed. These signals correspond to the four distinct crystallographic phosphorus sites. In studies of a series of layered Ti, Zr and Al phosphates by MAS NMR spectroscopy, Nakayama *et al*. reported that the isotropic ^{31}P chemical shifts of H_2PO_4, HPO_4 and PO_4 groups appear around −10, −20 and −30 ppm, respectively.[10] Turner *et al.* noted that with increasing radius of the metal ion within one group of elements, the ^{31}P signal shifts downfield (*e.g.* BPO_4: −29.5 ppm, $AlPO_4$:

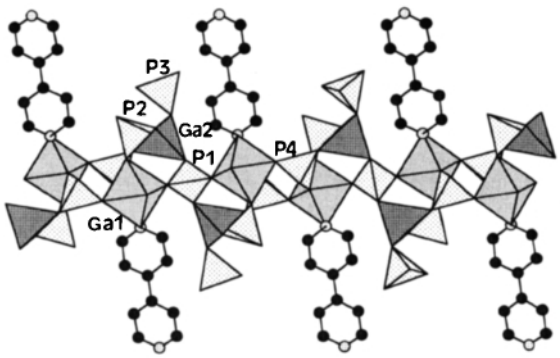

Fig. 1 Section of an infinite chain in **1** viewed along the [010] direction. GaO_5N octahedra are medium gray, GaO_4 tetrahedra are dark gray and PO_4 tetrahedra are light gray. Solid circles and stippled circles are the C and N atoms of 4,4′-bipyridine ligand, respectively.

DOI: 10.1039/b002182m

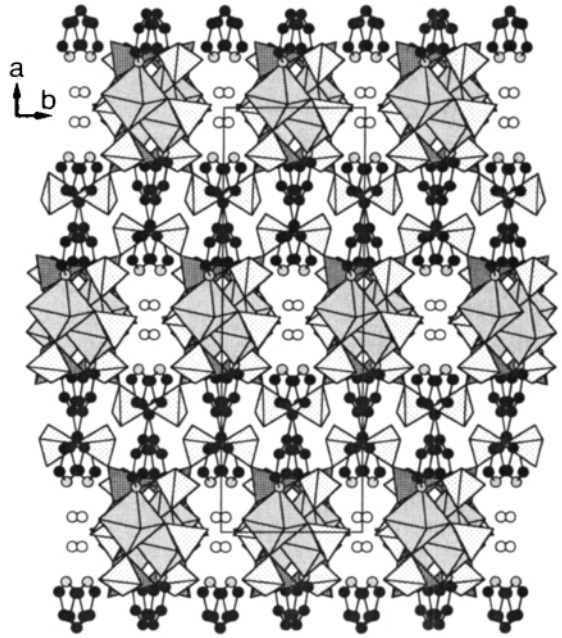

Fig. 2 Structure of **1** viewed along the [001] direction. Open circles are water oxygen atoms.

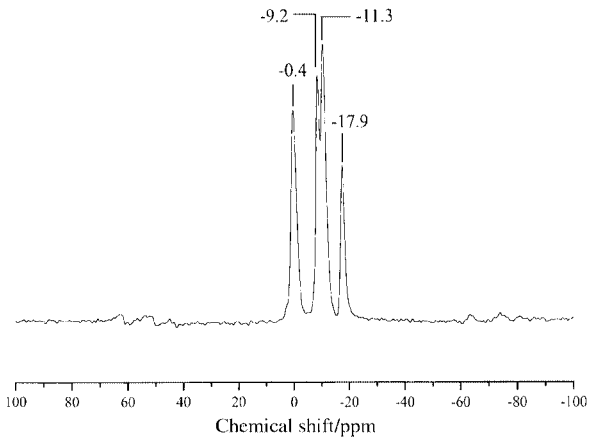

Fig. 3 Proton-decoupled ^{31}P MAS NMR spectrum of **1** acquired at a spinning frequency of 10 kHz. The isotropic chemical shifts are labeled; all other peaks in this spectrum are spinning sidebands. The peaks from left to right are assigned to H_2PO_4, HPO_4, $H_{0.5}PO_4$ and PO_4 groups, respectively.

−24.5 ppm, $GaPO_4$: −9.8 ppm).[11] Wessels *et al.* indicated that for microporous gallophosphates chemical shifts in the range from −10 to −20 ppm generally correspond to Q^4 groups, whereas values close to −5 ppm correspond to Q^3 groups.[12] Based on the above results we conclude that for gallophosphates the isotropic ^{31}P chemical shifts move to high-field values with decreasing protonation and the signals of Q^4 groups shift upfield relative to Q^3 groups. Consequently, the component at −17.9 ppm is assigned to P(1) (PO_4 group), which is also in agreement with the peak intensity. The other three peaks at −0.4, −9.2 and −11.3 ppm can be assigned to the three distinct P sites P(2) (H_2PO_4 group), P(3) (HPO_4 group) and P(4) ($H_{0.5}PO_4$ group), respectively. The HPO_4 peak is located at nearly equal distance from the H_2PO_4 and PO_4 peaks.

$^1H \rightarrow {}^{31}P$ CP experiments at various contact times have been performed to estimate the proximity of the protons and the phosphorus atoms. In theory, the growth of the ^{31}P CP intensity depends on the contact time, the rate constant of magnetization transfer (T_{cp}), the $^{31}P/^1H$ population ratios (ε) and the $T_{1\rho}$ values for both nuclei. The poor CP efficiency for the resonance at −17.9 ppm indicates that the phosphorus atom is not in close proximity to the protons, consistent with the assignment of this resonance to the PO_4 group. On the other hand, the enhancement of signal intensities for the resonances at −0.4, −9.2 and −11.3 ppm at short-contact times is observed. $T_{1\rho}$ values measured for the ^{1}H spins (*ca.* 22 ms) are much shorter than those of the ^{31}P spins in the different phosphate groups (320–580 ms). Fits to these CP intensity data with the measured $T_{1\rho}$ values, using modified versions of the expressions by Mehring[13] and Walter *et al.*[14] and ignoring the contributions from distant water and bipyridyl molecules, demonstrate that the $^{31}P/^1H$ population ratios involved in the CP transfer for the resonances at −0.4, −9.2 and −11.3 ppm are close to 0.5, 1.1 and 2.1, respectively. In addition, T_{cp} values, which are related to the dipolar coupling between ^{1}H and ^{31}P nuclei, are 0.6, 0.85 and 2.15 for the resonances at −0.4, −9.2 and −11.3 ppm, respectively. Both $^{31}P/^1H$ population ratios and T_{cp} values are reasonably in agreement with the above assignment.

In summary, this work illustrates that a novel 1-D gallium phosphate with an unique composition is synthesized under solvothermal conditions and structurally characterized by single-crystal X-ray diffraction and ^{31}P MAS NMR spectroscopy. The compound is unique in that, among the vast number of synthetic phosphates and naturally occurring phosphate minerals it is the first example in which four different types of phosphate, PO_4, $H_{0.5}PO_4$, HPO_4 and H_2PO_4 are present.

Notes and references

† *Crystal data* for $[Ga_4(C_{10}H_9N_2)_2(PO_4)(H_{0.5}PO_4)_2(HPO_4)_2(H_2PO_4)_2(H_2O)_2]\cdot H_2O$: monoclinic, space group *C*2/*c* (no. 15); a = 26.4161(6), b = 8.0416(1), c = 20.3515(4) Å, β = 111.194(1)°; V = 4030.8(1) Å^3, Z = 4, 3120 absorption corrected reflections with $F_o > 4\sigma(F_o)$ out of 4388 unique reflections ($2\theta_{max}$ = 56.1°) measured at 23 °C for a colorless crystal of dimensions 0.135 × 0.063 × 0.027 mm on a Siemens Smart-CCD diffractometer on convergence gave final values of R_1 = 0.0429, $wR_2(F^2)$ = 0.0906, GOF = 1.068, residual electron density between −0.59 and 0.69 e Å^{-3}. Bond-valence calculations indicated that O(3), O(5), O(8), O(9), O(10), O(11) and O(15) had valence sums of 1.33, 1.20, 1.33, 1.17, 1.37, 1.17 and 0.31, respectively, and all other oxygen atoms had values close to 2. The site occupancy factor of O_w is 0.5. All non-hydrogen atoms were anisotropically refined, and all hydrogen atoms except those for O_w were located in difference Fourier maps and refined isotropically. Atoms O(3), O(5) and O(9) are hydroxo oxygens. O(15), which is coordinated to Ga(1), is a water oxygen. The valence sums of O(8) and O(10) are satisfied by forming hydrogen bonds with phosphate groups on different chains.

9 Short O–H–O bonds that are crystallographically symmetrical range in length from *ca.* 2.4 to 2.6 Å, and it appears that those with O··O distances < *ca.* 2.5 Å have a single potential minimum (A. F. Wells, *Structural Inorganic Chemistry*, Clarendon Press, Oxford, 5th edn., 1984, p. 359.) The O··O distance in **1** is only 2.46 Å, indicating that the H atom is probably at mid-point. However, we cannot exclude the possibility that the H is dynamically disordered between two positions related by the center of symmetry. In that case the formula of the title compound becomes $[Ga_4(C_{10}H_9N_2)_2(PO_4)_2(HPO_4)_3(H_2PO_4)_2(H_2O)_2]\cdot H_2O$.

Ag nanowire formation within mesoporous silica

Michael H. Huang, Amer Choudrey and Peidong Yang*

Department of Chemistry, University of California, Berkeley, CA 94720, USA. E-mail: pyang@cchem.berkeley.edu

Received (in Oxford, UK) 27th March 2000, Accepted 9th May 2000

Uniform Ag nanowires have been synthesized within nanoscale channels of mesoporous silica SBA-15 by a simple chemical approach, which involves $AgNO_3$ impregnation, followed by thermal decomposition.

Owing to their high surface areas and uniform pore sizes, mesoporous silica materials have been widely used as host materials for loading catalysts,[1,2] polymers,[3–7] metals[8] and semiconductor nanoparticles[9–13] that have potential catalytic, environmental[14] and optoelectrical applications.[15,16] While there was certain success with the formation of continuous polymer nanofibers within mesoporous silica, inorganic metal or semiconductor nanowire formation within mesoporous MCM-41 materials has been largely elusive and in many cases incomplete filling or nanoparticles were observed. Here we report a simple chemical methodology for the formation of uniform Ag nanowires within mesoporous silica SBA-15.[17] This process involves $AgNO_3$ solution impregnation followed by thermal decomposition. Transmission electron microscopy studies on these samples show unambiguously that these continuous Ag nanowires are made of long polycrystalline domains. They have uniform diameters of 5–6 nm, and large aspect ratios between 100 and 1000. Thus, the current process represents a viable approach for synthesizing uniform metallic nanowires and may be applicable for making other inorganic nanowires with complex compositions.

Mesoporous silica SBA-15 was synthesized in accordance with the published procedure[17] using tri-block copolymer poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) $EO_{20}PO_{70}EO_{20}$ as template in acidic conditions. Briefly, a solution of $EO_{20}PO_{70}EO_{20}$:2 M HCl:TEOS:H_2O = 2:60:4.25:15 (mass ratio) was prepared, stirred for several hours at 40 °C, and then heated at 100 °C overnight. The solid products were filtered off and calcined at 500 °C for 5 h. Low-angle X-ray diffraction [Fig. 1, inset (a)] and transmission electron microscopy [TEM, Fig. 2(a)] studies on these samples indicate they are mesoporous silica consisting of well-ordered hexagonal packed channels with diameters of 5–6 nm.

To prepare nanowires within these nanoscale channels, 20 mg of SBA-15 powder was soaked in 10 ml of 0.2 M $AgNO_3$ EtOH–H_2O (1:1 v/v) solution and the suspension was stirred overnight at room temperature. The product was filtered off, rinsed with deionized water, and subjected to thermal treatment

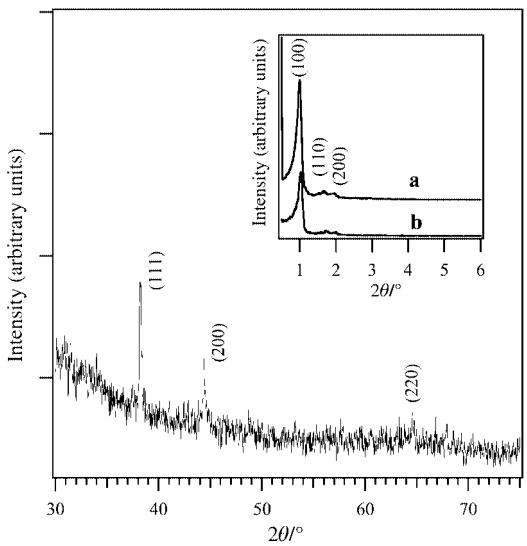

Fig. 1 High-angle X-ray diffraction pattern (Siemens, D5000) of the silver nanowire/SBA-15 composite. The low-angle X-ray diffraction patterns for SBA-15 before (a) and after (b) Ag nanowire loading are shown in the inset.

(b) Low magnification TEM image of SBA-15 mesoporous silica after the Ag nanowire loading; Ag nanowires appear as dark lines in the image. (c) High-magnification TEM image of the Ag nanowires within the SBA-15. A selected area electron diffraction pattern recorded on several Ag nanowires is shown in the inset of (c).

DOI: 10.1039/b002549f

at 300 °C in air for 2 h to decompose the impregnated $AgNO_3$ and form Ag nanowires.

The $AgNO_3$ impregnated sample was colorless while a brown/grey color appeared once the sample was treated at 300 °C. X-Ray diffraction indicates the mesoscopic ordering of SBA-15 was maintained after the $AgNO_3$ loading and the thermal treatment with the observation of low angle peaks that can be indexed as (100), (110) and (200) reflections of the hexagonal mesostructure of SBA-15 [Fig. 1, inset (b)]. Meanwhile, high angle diffraction peaks were observed after the thermal treatment. These diffraction peaks can be readily indexed according to the crystalline Ag structure with cubic lattice constant of $a = 4.07$ Å.

The thermally treated sample was also characterized by TEM [Fig. 2(b), (c)]. While there is a small amount of spherical Ag particles (5–30 nm in diameter) on the external surface of the SBA-15, extensive Ag nanowire formation can be seen in the large area view of the sample [Fig. 2(b)]. A high-magnification image of the sample [Fig. 2(c)] clearly indicates that these nanowires are continuous and essentially follow the curvature of nanoscale channels. They have uniform diameters of 5–6 nm, which are consistent with the sizes of the nanoscale channel templates. These nanowires also possess large aspect ratios from 100 to 1000, which have not been seen previously in many studies using MCM-41,[8] carbon nanotubes[18] or porous alumina[19] as host matrices. By performing an over-focus and under-focus imaging series in the microscope, it is confirmed that these nanowires are actually embedded within the channels instead of being located on the external surface. Furthermore, the highly crystalline nature of the Ag nanowires was confirmed by selected area electron diffraction measurement made on these nanowire arrays [Fig. 2(c) inset]. The diffraction spots/rings can be again indexed as (111), (200), (220) and (311) reflections according to the cubic structure of Ag. The appearance of diffraction rings/spots indicates that the Ag nanowires are comprised of polycrystalline domains with large aspect ratios.

It was found that in order to achieve complete filling of the mesopores within SBA-15, a proper selection of the initial impregnation solution is critical. For example, we attempted using $AgNO_3$ solution in pure water or EtOH–H_2O (3 : 7 or 8 : 2 v/v), in all cases, only spherical Ag particles were obtained after the thermal treatment with a low percentage of channel filling. This incomplete filling is directly related to the very different surface tensions of H_2O and ethanol (71.99 and 21.97 mN m^{-1}, respectively, at room temperature).

N_2 sorption measurements were also carried out on the samples before and after the Ag loading. It was found that the pore volumes decrease from 0.93 cm^3 g^{-1} for as-made SBA-15 to 0.61 cm^3 g^{-1} for Ag-loaded samples. This further confirms that Ag nanowires are indeed located inside the host channels and the loading efficiency is comparable with previous experiments using MCM-41/48.[3,9,11] The capability of nanowire array formation within SBA-15 clearly indicates that the mesopores used to template Ag nanowires are highly ordered with few local defects [Fig. 2(a)] and they are also robust enough to sustain the thermal treatment. Thus we believe SBA-15 should be an ideal host material for making nanowire arrays of metals and many other systems. Initial results indicate that it is possible to form Co, Ni, NiO, Fe_2O_3 and polymer nanowire arrays within the SBA-15 matrix using a similar procedure.

We have also characterized the optical properties of these Ag nanowire arrays. Two plasmon absorption bands (410 and 580 nm) were observed in our preliminary studies. Further studies of the physical properties of these nanowires are currently in progress.

This research was funded by Camille and Henry Dreyfus Foundation, 3M Corporation and University of California, Berkeley. We thank Dr C. Nelson for the help during transmission electron microscopy studies, Professor G. D. Stucky at University of California, Santa Barbara for helpful discussions, Professor J. R. Long for use of the UV–VIS spectrometer and Professor Don T. Tilley for use of the surface area measurement unit. We also thank the National Center for Electron Microscopy for the use of their facilities.

Instability of [60]fullerene anions in dichloromethane: a synthetic avenue to $C_{60}>(CH_2)_n$ methanofullerenes

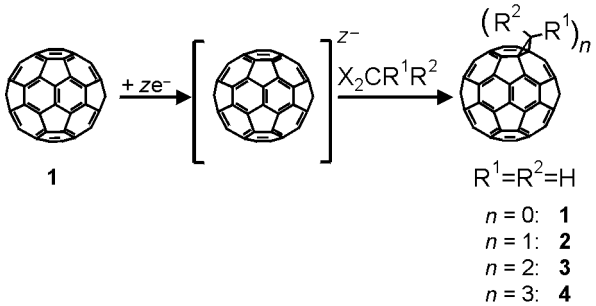
Marcel W. J. Beulen and Luis Echegoyen*

Department of Chemistry, University of Miami, Coral Gables, Florida 33124, USA. E-mail: echegoyen@miami.edu

Received (in Columbia, MO, USA) 29th December 1999, Accepted 26th April 2000

The trianion of C_{60} reacts readily with the commonly used electrochemical solvent dichloromethane to form methanofullerenes of the type $C_{60}>(CH_2)_n$, signaling a cautionary warning against the use of this solvent for electrochemical studies of fullerenes and opening up a new synthetic avenue for these adducts.

Since the discovery of C_{60} in 1985[1] and its subsequent preparation in large scale in 1990[2] the rich electronic properties of this fullerene have been probed by electroanalytical techniques such as cyclic voltammetry (CV) and Osteryoung square wave voltammetry (OSWV).[3] Many different experimental conditions have been used for these studies including a wide variety of supporting electrolytes and solvents (*e.g.* chlorobenzene, tetrahydrofuran, pyridine, nitrobenzene, *N*,*N*,-dimethylformamide and dichloromethane).[4] However, a very common choice has been dichloromethane, and a very large number of fullerene derivatives have been and continue to be investigated in this solvent.[5] Preliminary reports identifying the instability of C_{60}^{3-} in CH_2Cl_2 were published in 1991 and 1992, but no details nor product analyses were presented.[6,7] Since we have also performed electrochemical studies of fullerenes in CH_2Cl_2 and observed quite unusual behavior[8] and since we published the electrosynthesis of [6,6]methanofullerenes by reacting the C_{60} monoanion and dianion with dihalomethano compounds (X_2CRR'; X = Br, I; R = H, R′ = CN or CMe_3),[9] see Scheme 1, we decided to investigate the behavior of the C_{60} anions in this solvent under bulk electrolytic conditions.



Scheme 1 Formation of methanofullerenes from the anions of C_{60}.

In a typical experiment, *ca.* 2 mg of C_{60} were suspended in dichloromethane and the anions of this fullerene were generated by controlled-potential bulk electrolysis. We followed the stability of these anions *in situ* by CV and OSWV.† The generation of the monoanion (at −0.85 V *vs*. a Ag-wire pseudo-reference electrode) and dianion (at −1.25 V) was straightforward and resulted in well defined electrochemistry [see Fig. 1(a) for the dianion]. No apparent reaction of the mono- or di-anion with the solvent was noted during or after electrolysis.[10] The trianion was generated by controlled potential electrolysis (CPE) applying a potential *ca.* 150 mV more cathodic than the third reduction potential of C_{60} (−1.60 V). This resulted in a steady current after a few minutes, instead of the typical and expected current exponential decay observed during CPE generation of the monoanion and dianion of C_{60}, indicating that a chemical reaction occurs during electrolysis. Arbitrarily, the

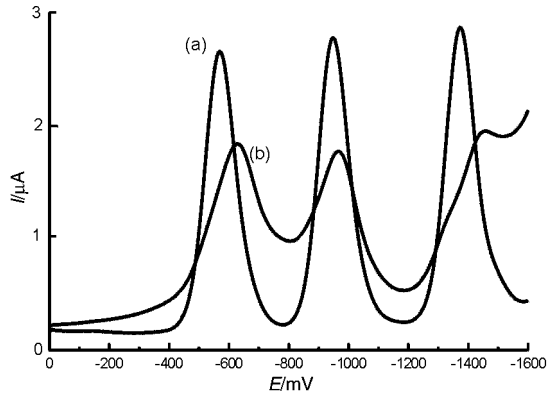


Fig. 1 OSWV of C_{60} in dichloromethane at the dianionic (a) and trianionic (b) states.

electrolysis was interrupted when *ca.* 8 electrons per C_{60} molecule were discharged (reaction time: 30 min). The OSWV was completely changed at this point [Fig. 1(b)] with the waves being much broader. Reoxidation of the reaction mixture and subsequent purification by column chromatography resulted in fullerene products in *ca.* 75% yield. Analysis of the reaction mixture by HPLC, UV–VIS spectroscopy, MALDI-TOF mass spectrometry and NMR spectroscopy showed that scarcely any C_{60} remained. UV–VIS spectroscopy showed a broad peak at *ca.* 425–435 nm while the characteristic C_{60} peak at 406 nm had disappeared. HPLC measurements [eluent hexane–toluene (10 : 1)] indicated the presence of several products, all slightly more polar than C_{60} itself. These products were assigned by MALDI-TOF mass spectrometric analysis (see Fig. 2), which showed the formation of several adducts of C_{60}, with $C_{60}>(CH_2)_2$ as the main product (**1**: 2%; **2**: 20%; **3**: 50%; **4**: 15%, based on HPLC, see Scheme 1 for structure assign-

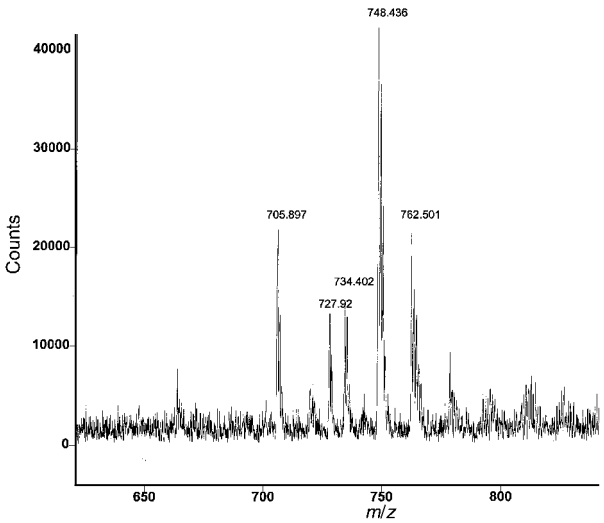

Fig. 2 Maldi-TOF spectrum of the reaction mixture after electrolysis at the trianionic state.

DOI: 10.1039/b001021i

ments).[11] In practice, two different isomers can form in this reaction ([6,6] closed methanofullerenes or [5,6] open methanoannulenes).[12] Based on ^{1}H NMR spectroscopy, which showed several resonances (due to regioisomers of the bis- and tris-adducts) in the range δ 3.4–3.9 for the bridgehead CH_2-protons, but no AB quartets at δ 2.9 and 6.4 (expected for the 5,6 isomer),[12] the isolated isomers were assigned to be of the [6,6] closed methanofullerene type.[13] Therefore, reaction of the C_{60} trianion with the solvent dichloromethane leads to the same type of fullerene derivatives as those formed during the reaction of the C_{60} monoanion and dianion with the diiodo and dibromo reagents previously described.[9] Interrupting the electrolysis at an earlier stage led to the formation of fewer adducts. A reaction time of *ca.* 15 min (*ca.* 4 electrons per C_{60}) resulted in a product ratio of 1 : 1 of C_{60} (**1**) to $C_{60}{>}CH_2$ (**2**) (overall yield: 85%), as determined from HPLC and MALDI-TOF spectrometric measurements.

In conclusion, our experiments clearly showed that C_{60} in its trianionic state is not stable in dichloromethane, and reacts with the solvent to form methanofullerenes. The lower reactivity of this chlorinated compound compared to the corresponding iodo and bromo compounds is compensated by its high abundance. Therefore, this solvent should be used only with extreme caution in the electrochemistry of fullerenes. Additionally, the potential application of the reaction of dichloromethane with the trianion of C_{60} to electrosynthesize methanofullerenes with a variable number of CH_2 groups ranging from one to six is currently under investigation. Of special interest is the regioisomeric distribution observed, to see how it compares with that obtained from other synthetic strategies. Generally, the results described in this study and in previous work show that the anions of C_{60} react with dihaloalkyl compounds in three different ways: the monoanion reacts with activated dihalomethano compounds [$Br_2CH(CN)$],[9b] the dianion reacts with non-activated dihalomethano compounds ($I_2CH[CMe_3]$),[9a] and the trianion reacts with the non-activated and less reactive dihalomethano compounds (Cl_2CH_2).

Financial support for this work from the National Science Foundation through grant CHE-9816503, and the Netherlands Organization for Scientific Research (NWO, talent stipendium, M. W. J. B.) is greatly appreciated.

Notes and references

† *Electrochemistry*: details of the experimental electrochemical set-up for the CV, OSWV and bulk electrolysis measurements have been described elsewhere.[14] Briefly, electrochemical measurements were performed using a BAS 100W Electrochemical Analyzer (Bioanalytical systems). An electrochemical cell designed to carry out CV, OSWV and bulk electrolysis under high vacuum was used. For CV and OSWV, a glassy-carbon working electrode, a silver wire pseudo-reference electrode, and a Pt-mesh counter electrode were used. Bulk electrolysis was carried out using Pt mesh electrodes for both working and counter electrodes. As supporting electrolyte, tetrabutylammonium hexafluorophosphate was used.

ChemComm

Preparation of an MFI-type zeolite membrane on a porous glass disc by substrate self-transformation

Wei-Yang Dong and Ying-Cai Long

Department of Chemistry, Fudan University, Shanghai 200433, P.R. of China. E-mail: yclong@fudan.edu.cn

Received (in Cambridge, UK) 6th March 2000, Accepted 5th May 2000

An MFI-type zeolite membrane containing boron has been prepared on the surface of a boron–silicon porous glass disc by substrate self-transformation in the vapor of ethylamine (EA) and H_2O; both XRD and SEM show that the zeolite crystals on the surface of the porous glass disc were in random orientation; the thickness of the membrane layer was *ca*. 10–20 μm; permeation of O_2 and N_2, and the chemical composition of the membrane were measured.

In the last decade, the study of zeolite membranes has become an important research topic in the area of inorganic membrane materials because of their uniform microporous structure, and high thermal and chemical stability. Many methods for preparing zeolite membranes on various substrates have been developed, including: hydrothermal crystallization;[1] *in situ* hydrothermal synthesis,[2] vapor phase synthesis,[3] sol–gel methods,[4] zeolite-filled (embedded) methods,[5] chemical growth,[6] galvanic metal deposition,[7] leakage-blocked method,[8] synthesis by microwave heating,[9] *etc*. Supports used include porous ceramic discs[2] or tubes,[10] porous glass discs[11] or tubes,[12] porous sintered stainless steel discs,[13] various kinds of metal discs,[1] glass discs or pipes,[4] Teflon slabs and sleeves,[11] single-crystal silicon wafers,[1] filter paper,[14] quartz plate, mica discs, cordierite discs, mullite, stainless steel networks[1] and liquid mercury.[15]

Zeolite ZSM-5 and ZSM-35 membranes were synthesized using the vapor phase method according to Dong *et al.*[3] in which a glass disc or pipe was put on the surface of aluminosilicate gels, or embedded in the gels. These syntheses were carried out at 473 K in amine vapor for 3–7 days. ZSM-35 membranes and ZSM-5 membranes were obtained in the vapor of *n*-propylamine($PrNH_2$)–H_2O and diethylamine(Et_2NH)–H_2O or ethylenediamine(EDA)–triethylamine(Et_3N)–H_2O, respectively. Since this work, zeolite membranes have been synthesized *via* vapor phase methods by many researchers. Here, we report a novel finding related to the synthesis of an MFI-type zeolite membrane in the vapor phase. The zeolite membrane was prepared on the surface of a boron–silicon porous glass disc by substrate self-transformation in ethylamine (EA)–H_2O vapor.

A porous glass disc (18.5 × 17.5 × 2.5 mm, Shanghai Silicate Institute), was used as the starting substrate. The chemical composition of the glass, as measured by chemical titration, was B_2O_3 = 2.5 wt%, Al_2O_3 = 0.37 wt%, SiO_2 = 96.68 wt%, Na_2O = 0.44 wt%. The chemical composition of the membrane was determined with a Field Emission Auger Microprobe, MICROLAB 310F, (VG Scientific, Surface Analysis Company) using Mg-Kα radiation at an X-ray power of 300 W, under a vacuum of 3.0×10^{-8} Mbar. The most probable pore diameter of the substrate was 7.5 nm. The disc was placed in a Teflon holder in a 35 ml stainless steel autoclave, containing *ca*. 10 ml of 50 wt% ethylamine aqueous solution. The porous glass disc was placed in a position so that the disc did not directly contact with the liquid mixture at both room and reaction temperature. The synthesis reaction was carried out in an oven at 180 ± 2 °C for 144 h. After cooling to room temperature, the disc was removed, and dried at 80 °C for 12 h. Both surfaces (A and B) of the disc were transformed to MFI zeolite crystals after this treatment in vapor. Calcination of the membrane was conducted in a crucible oven. One of the two surfaces of the disc (B) was polished before calcination. Permeability of gases on both the calcined zeolite membrane and the substrate was studied at room temperature with the supported membrane and substrate mounted in a special separator. The flow rate of the gas was measured with a soap bubble flowmeter, and the difference of the pressure between two sides of the disc kept at 0.1 MPa.

Fig. 1 shows typical XRD patterns of MFI-type zeolite on both sides of the disc after reaction [Fig. 1(a) and (b)]. The XRD patterns show that the zeolite crystals are in random orientation on the surfaces of the disc. The surfaces of the initial porous glass disc are amorphous [Fig. 1(c)].

SEM shows that the surfaces of the initial porous glass disc are rough and uneven [Fig. 2(a)]. After synthesis, both sides of the disc are covered by MFI zeolite crystals with random orientation [Fig. 2(b)–(d)], consistent with the XRD results. The size of the crystals is *ca*. 15–25 μm [Fig. 2(b)], and the thickness of the membrane layer is *ca*. 10–20 μm [Fig. 2(c) and (d)]. There are no zeolite crystals on the inner surfaces of the disc [Fig. 2(c) and (d)], indicating that the zeolite crystals only formed on the outer surfaces of the disc.

The chemical composition of the membrane, measured by surface analysis, is B_2O_3 = 3.70 wt%, Al_2O_3 = 0.55 wt%, SiO_2 = 95.25 wt%, Na_2O = 0.50 wt%. The permeabilities of O_2 and N_2 through the substrate are 5.06×10^{-8} and 5.56×10^{-8} mol m^{-2} s^{-1} Pa^{-1}, respectively. The calculated ideal selectivity of O_2/N_2 (0.91) is very close to the Knudsen value (0.94), showing

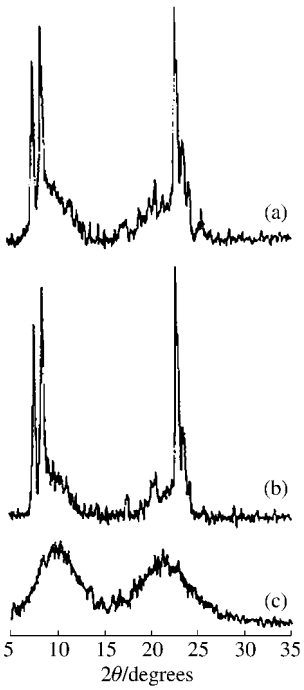

Fig. 1 XRD patterns: (a) surface A of the membrane, (b) surface B of the membrane and (c) surface of the initial porous glass disc.

DOI: 10.1039/b001814g

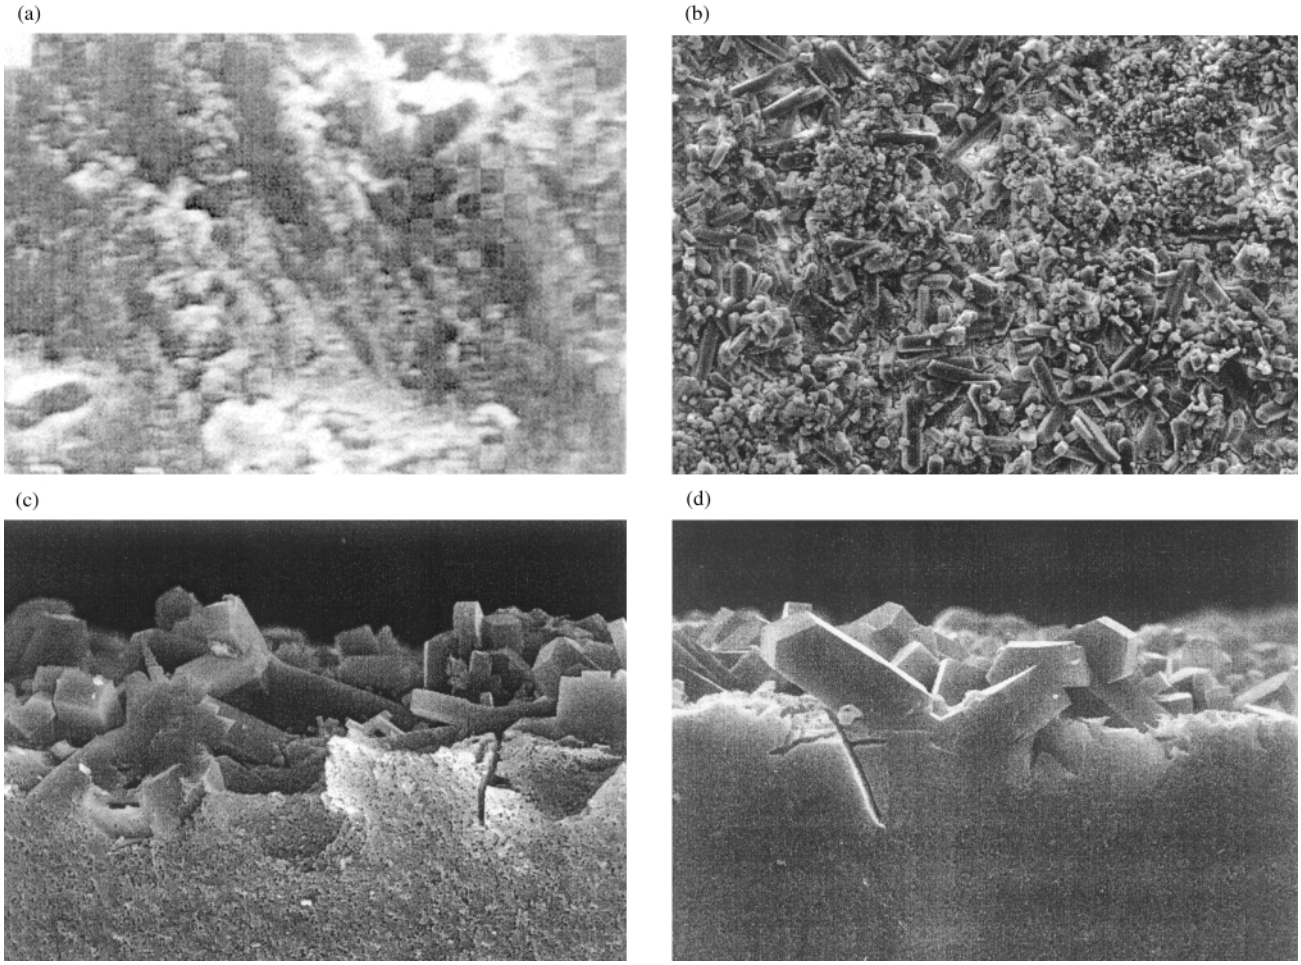

Fig. 2 SEM photographs: (a) the surface of the initial porous glass disc; magnification 1950×, (b) plane view of surface A of the membrane, (c) cross-section of surface A of the membrane, (d) cross-section of surface B of the membrane, before polishing.

that the substrate shows no preferential selectivity for the penetration of O_2 and N_2. On the calcined boron-containing MFI-type zeolite membrane, the permeabilities of O_2 and N_2 are 0.095×10^{-8} and 0.15×10^{-8} mol m^{-2} s^{-1} Pa^{-1}, respectively. The calculated ideal selectivity of O_2/N_2 (0.63) is obviously lower than that for Knudsen behaviour and for the substrate. The fact indicates that the membrane selectively permeates N_2

We are very grateful to Professor Zi Gao for her helpful suggestions and discussions.

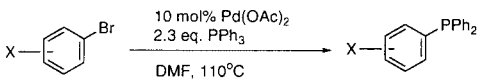
Palladium catalyzed phosphination of substituted aryl bromides using triarylphosphines as the phosphinating agents has been developed; this method tolerates ketone, aldehyde, ester, nitrile, ether and chloride functional groups.

Triarylphosphines constitute one of the most important class of ligands in transition metal catalyzed reactions.[1] Although there is a necessity to incorporate functional groups in aromatic phosphines in order to tailor the phosphines for modifying catalysis, synthetic methods available are limited in scope. Traditional methods for preparation of these phosphines can be classified into two major categories. The first method involves the reactions of aryl Grignard or organolithium reagents with chlorophosphine, but it is limited to compounds that are not base sensitive.[2] The second method is transition metal catalyzed phosphination. Though it is useful, limitations do exist. Both nickel catalyzed phosphination of aryl triflates using diphenylphosphine[3] or chlorodiphenylphosphine[4] require use of air- and moisture-sensitive phosphinating reagents and the latter method is not tolerant to easily reducible functional groups since Zn metal is used.[4] The Pd/$Ph_2P(O)H$ route requires subsequent reduction by trichlorosilane.[5] The Pd/(trimethylsilyl)diphenylphosphine system is limited to aryl iodides and cannot tolerate aldehyde functional groups.[6] The Pd/phosphine–borane method requires an extra deprotection step and cannot tolerate amine containing functional groups.[7] Generally, the above methods require the use of air-sensitive reagents and are limited in functional group tolerance. Herein, we report palladium catalyzed phosphination using readily available triarylphosphines as the phosphinating agent and functionalized aryl bromides as substrates to synthesize functionalized aromatic phosphines [eqn. (1)].



(1)

4-Bromoacetophenone was reacted with 2.3 equivalents of triphenylphosphine in the presence of 10 mol% palladium acetate catalyst in DMF at 110 °C to yield 4-(diphenylphosphino)acetophenone in 40% yield (Table 1, entry 1).† In addition, 4-bromobenzaldehyde can be phosphinated by triphenylphosphine to form 4-(diphenylphosphino)benzaldehyde in 32% yield (Table 1, entry 2). In contrast, the previous method for the preparation[8] of this phosphine, which finds many applications for water soluble polymers[9] and water soluble porphyrins,[10] involved a muti-step synthesis which required protection of the aldehyde.[8] Other functional groups, such as esters, nitriles, methyl ethers and halogens, are tolerant to this phosphination reaction (Table 1, entries 3–7). In contrast, previous syntheses of ester and nitrile containing phosphines required a long synthetic pathway.[11]

Similar rates of reaction were observed for electronically different non-coordinating aryl bromides (Table 1, entries 1,5,7). The rate of the reaction of coordinating substrates which contain ester, aldehyde or nitrile groups (Table 1, entries 2–4), required a longer reaction time. Presumably strongly coordinating substrates rendered the complex coordinatively saturated and hence reduced the catalytic efficiency. For 3- and 4-bromoanisole, the reaction times are similar but the yield of 3-(diphenylphosphino)anisole was higher (Table 1, entries 5 and 6).

10[20]		18	51[b]

[a]Isolated yield. [b]GC yield is reported as an average of two runs.

Either $Pd(PPh_3)_4$ or $Pd(OAc)_2$ can catalyze this reaction. $Pd(OAc)_2$ was employed as the catalyst since other triarylphosphines can be used as phosphinating reagents, such as trixylylphosphine, tri(*p*-methoxyphenyl)phosphine and tri(*p*-tolyl)phosphine (Table 2, entries 1–3). Therefore, a variety of different substituted phosphines can be readily prepared through this direct methodology.

A plausible mechanism (Scheme 1) for this phosphination starts with the *in situ* reduction of $Pd(OAc)_2$ by triphenylphosphine to Pd(0).[12] Subsequent oxidative addition with aryl bromide yields a aryl Pd(II) species. Reductive elimination with triphenylphosphine gives a phosphonium salt,[13] which then undergoes oxidative addition with the palladium species to

generate the coordinated phosphine product.[14] Finally ligand substitution by the other triphenylphosphine regenerates the Pd(0) species and substituted phosphine product.

In conclusion, our phosphination method tolerates a number of functional groups including ketones, aldehydes, esters, nitriles, methyl ethers and chloride. This palladium catalyzed phosphination avoids the problems of traditional raw materials and utilizes the most cost effective triphenylphosphine as the phosphinating reagent. This process has a great potential to tailor a variety of substituted phosphines by using different triarylphosphines as the reagent. Studies are continued to extend the scope of this reaction.

We thank the Research Grants Council of Hong Kong (EI00014) for financial support.

Notes and references

† *General experimental procedure*: 4-bromoacetophenone (100 mg, 0.5 mmol), $Pd(OAc)_2$ (11 mg, 0.05 mmol) and PPh_3 (301 mg, 1.15 mmol) were dissolved in dry DMF (2 mL) under nitrogen in a Telfon stopcock flask. The solution was heated to 110–115 °C and the reaction was monitored by GC–MS. The reaction mixture was then cooled down and DMF was removed by vacuum evaporation. After 20 h, the crude product was purified by column chromatography on silica gel using a solvent mixture of hexane–ethyl acetate (20 : 1) as the eluent to give 4-(diphenylphosphino)acetophenone in 40% yield as a white solid.

Isolation and characterisation of C_s-symmetry $C_{60}Me_5O_2OH$, the first methylated fullerenol; a bis-epoxide with two oxygens in a pentagonal ring

Hamad Al-Matar, Peter B. Hitchcock, Anthony G. Avent and Roger Taylor*

Received (in Cambridge, UK) 21st March 2000, Accepted 11th May 2000

From the reaction between [60]fullerene and MeLi, we have isolated $C_{60}Me_5O_2OH$, which has been characterised by both ^{1}H and ^{13}C NMR spectroscopy and by single-crystal X-ray analysis; uniquely, both epoxide groups bridge 5 : 6-bonds in the same pentagon.

The significance of epoxyfullerenes has yet to be fully recognised. They may be formed by: (i) partial hydrolysis of a halogenofullerene to a *cis* halohydroxy derivative, followed by adjacent elimination of hydrogen halide, giving for example, the abundance of epoxides amongst the products of fullerene fluorination;[1] (ii) ozonolysis;[2] (iii) epoxidation of the fullerene with a peracid;[3] (iv) direct reaction with oxygen, either in the arc-discharge reactors used for fullerene production,[4] or on standing[5] (this can be photochemically accelerated).[6] The extent to which cage addends moderate the latter process is not yet known, but it is probable that all fullerene derivatives undergo this oxidation to some extent.

The formation of the only bis-epoxy fullerenes characterised previously, $C_{60}O_2$, involves addition of oxygen across the 1,2- and 3,4-bonds in a given hexagon;[7] this motif is also believed to be present in $C_{60}O_3$.[8] In the heterocycle $C_{60}Ph_4(C_6H_4)O_2$, we conjectured that one oxygen is present as an epoxide bridging a 5:6-bond in the central pentagon.[9]

There are few reports of the methylation of fullerenes. Olah and coworkers detected the addition of up to 24 methyl groups (with $C_{60}Me_6$ and $C_{60}Me_8$ being prominent) from the reaction of [60]fullerene with Li–MeI.[10] Both 1,2- and 1,4-Me_2C_{60} have been obtained by electrochemical reduction,[11] and we have described preliminary results on the formation of $C_{60}Me_n$ (n = 4, 6, 8) and $C_{70}Me_n$ (n = 2, 4, 6, 8, 10).[12] Polyhydroxyfullerenes have been investigated extensively,[13] but, to date, only one monohydroxyfullerene ($C_{70}Ph_9OH$) has been characterised.[14]

We now report the isolation and full characterisation of the first methylated fullerene, (and methylated fullerenol) and the first bis-epoxide with both oxygens bridging a 5:6-bond. The structure was characterised by NMR spectroscopy, the interpretation of the latter being shown to be correct by single crystal X-ray crystallography.

An xs. of MeLi solution (4 ml of 1.0 M solution in THF–cumene, 110:90) was stirred under N_2 with $C_{60}Cl_6$ (100 mg),[15] at room temp. The orange solution turned brown–black immediately and stirring was continued overnight. Normal work-up followed by column chromatography (70–230 mesh silica gel), gave a major fraction (9:1 cyclohexane–toluene elution) and then a minor fraction (1:1 cyclohexane–toluene elution). This latter was purified further by HPLC using a 10 mm × 25 cm Cosmosil 'Buckyprep' column at a solvent flow rate of 4.7 ml min^{-1} to give $C_{60}Me_5O_2OH$, which eluted after 4.8 (toluene) or 8.8 min (1:1 toluene–heptane), and crystallised as ruby-red hexagonal plates.

The EI mass spectrum (Fig. 1) shows a peak due to the parent ion at 844 amu; notably, the C_{58} fragmentation ion peak at 696 amu is 40% of the intensity of the 720 amu peak. This is much higher than is found in the EI mass spectrum of C_{60} and arises because of the more facile loss of 2 CO molecules, which we have noted previously in the mass spectra of phenylated epoxides of [60]fullerene, where the intensity of the 696 amu peak was 30% of that of the 720 amu peak.[16] When the epoxide functions straddle 5:6-bonds, CO elimination creates a 7/5-membered ring combination, stabilised by the presence of sp^3 carbons bearing the addends.[16]

The IR spectrum (KBr) shows bands at 3520 (broad), 2971, 2924, 2857, 1438, 1384, 1099, 1074, 1047, 1037, 1016, 941, 665, 658, 572, 553, 535 and 513 cm^{-1}.

The ^{1}H NMR spectrum shows peaks at δ_H 3.88 (1 H, s, OH), 1.99 (3 H, s, Me_A), 1.86 (6 H, s, Me_C), 1.75 (6 H, s, Me_B). The peaks were identified by NOE couplings of 2.4, 2.5 and 0.6% between OH and Me_A, Me_B, and Me_C, respectively, and of 0.9 and 0.3% between Me_A and Me_B. Saturation transfer to water confirmed the presence of an OH group; the NOE couplings between OH and *all three* methyls confirmed that OH must be present in the central pentagon.

The ^{13}C NMR spectrum shows 24 2 C and 2 1 C peaks for the cage sp^2-carbons at δ_C (all 2 C except where indicated) 151.56, 148.79, 148.72, 148.69, 148.68, 148.59, 148.49 (1 C), 148.45, 148.44, 148.03, 147.99, 147.90, 147.87, 147.57 (1 C), 147.12, 145.13, 144.39, 144.03, 144.01, 143.97, 143.72, 143.38 (4 C), 143.30, 143.25, 143.08; the half-intensity on-symmetry plane peaks appear in the usual 147–149 ppm range. The sp^3-carbons appear at δ_C 86.60 (2 C, COC), 75.11 (1 C, COH), 72.35 (2 C, COC), 53.12 (1 C, C_1Me), 47.21 (2 C, $C_{15,30}$Me), 46.49 (2 C, $C_{4,11}$Me), 27.38 (1 C, Me_A), 24.88 (2 C, Me_C), 24.20 (2 C, Me_B).

The compound thus has C_s symmetry and was deduced to have the two epoxide functions in the central pentagon, since the only other reasonable locations would be across the 16,17- and 28,29-positions (Fig. 2). However, little difference in the

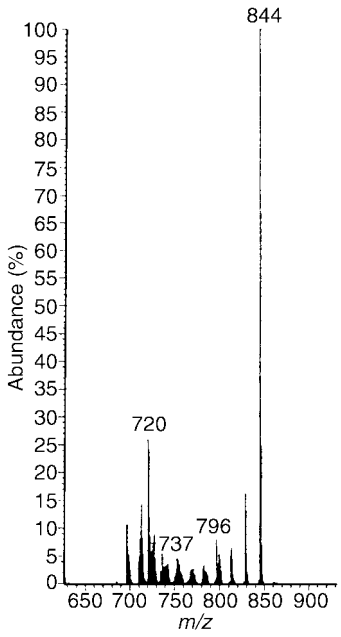

Fig. 1 EI mass spectrum (70 eV) for $C_{60}Me_5O_2OH$.

DOI: 10.1039/b002254n

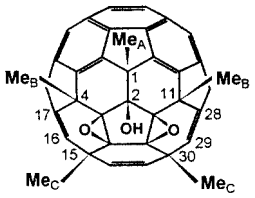

Fig. 2 Structure of symmetrical $C_{60}Me_5O_2OH$, showing numbering.

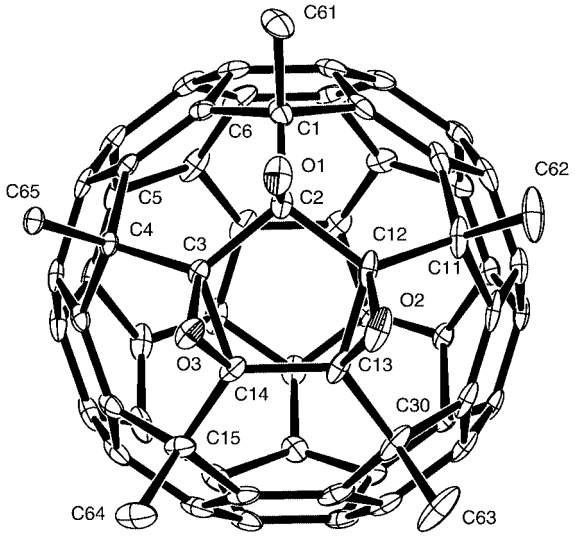

Fig. 3 X-Ray structure of $C_{60}Me_5O_2OH$.

chemical shifts for carbons C-17 and C-28, compared with C-16 and C-29 would then be expected, whereas an experimental difference of 14 ppm is found. This is consistent with two of the epoxide carbons being adjacent to that bearing the OH group (Fig. 2). The structure was confirmed by X-ray crystallography (Fig. 3).†

The structure is thus unique in having two epoxide functions straddling 5 : 6-bonds bonds in the central pentagon. The addend locations in $C_{60}X_6$ structures requires placing two double bonds in the central pentagon, thereby increasing the strain; this can be partially relieved by addition across these bonds. The C–C bonds bridged by the epoxide function are short, at 1.48 Å, whereas all other cage C–C bonds in the central pentagon area and the cage–Me bonds, have an average bond length of 1.55 ± 0.02 Å. The C–O–C bond angles are 61.5°, and some repulsion between the epoxides and the OH group is manifest in the C-3–O-3 bond (1.459 Å), which is longer than the O-3–C-14 bond (1.437 Å).

A notable feature (and one which we have found recently with phenylated [84]fullerene as well) is that on strongly heating the KBr disc (250 °C) of $C_{60}Me_5O_2OH$, a very sharp peak appears at 2170 cm^{-1} after 3 h and grows in intensity with heating during the next 24 h. This is consistent with the presence of matrix-isolated C_5,[17] and parallels earlier work in which similar treatment of KBr discs of insoluble [84]fullerene residues, produced a sharp band at 2035 cm^{-1} attributed to matrix-isolated C_3.[18] We hope to investigate this aspect more fully at a later date.

We thank Kuwait University for a research grant (to H. A.-M.).

Upper-rim monofunctionalization of calix[4]arene by organometallic diphenylphosphinorhodium complexes†

Martin Vézina, Jonathan Gagnon, Karine Villeneuve, Marc Drouin and Pierre D. Harvey*

Département de Chimie, Université de Sherbrooke, Sherbrooke, P.Q. Canada, J1K 2R1. E-mail: pharvey@courrier.usherb.ca

Received (in Irvine, CA, USA) 17th February 2000, Accepted 1st May 2000

Monofunctionalization of the calix[4]arene upper-rim is achieved by lithiation with Bu^{n}Li, followed by phosphination with Ph_2PCl of monobromotetra-*n*-propoxycalix[4]arene; subsequent reactions with $[Cp^*Rh^{III}Cl_2]_2$ and $Cp^*Rh^I(CO)_2$ provide the corresponding $Cp^*[Ph_2(calix)P]Rh^{III}Cl_2$, which can be converted to $Cp^*[Ph_2(calix)P]Rh^{III}(H)_2$ and $Cp^*[Ph_2(calix)P]Rh^I(CO)$, respectively.

Substituted derivatives of the bowl-like calix[4]arene are easy to synthesize and extremely rich chemistry has emerged from this simple molecule, primarily due to the pioneering work of Gutsche.[1] Many applications in the area of cation binding and transport are now known, and highly selective receptors and novel sensors for polyanionic species have been discovered with this host.[2] Recently, several researchers have prepared transition metal complexes of this platform molecule, mainly *via* the lower-rim section,[3] but some rare upper-rim functionalizations have also appeared in the literature.[4] Of particular interest, Matt and coworkers synthesized conic calix[4]arene complexes using two anchoring phosphine groups placed opposite to each other in the upper-rim.[5] Complexation induced a loop structure where the calix[4]arene cavity was blocked by the transition metal fragment, hence, losing its important hydrophobic hosting function. We now report the first monofunctionalization of the calix[4]arene upper-rim, using the Ph_2P complexing fragment, along with some of its Rh complexes. The complexation of an Rh residue near a hosting device offers the hope of convenient regioselective reactivity in situations where the reacting molecule reversibly binds the calix[4]arene cavity. Many Cp*Rh complexes are known to activate C–H bonds,[6] and anchoring this fragment onto the supramolecular calix[4]arene represents a unique opportunity of potential regioselective C–H bond activation. This work describes the syntheses and characterization of three (η^5-pentamethylcyclopentadienyl)rhodium complexes of diphenylphosphinocalix[4]arene.

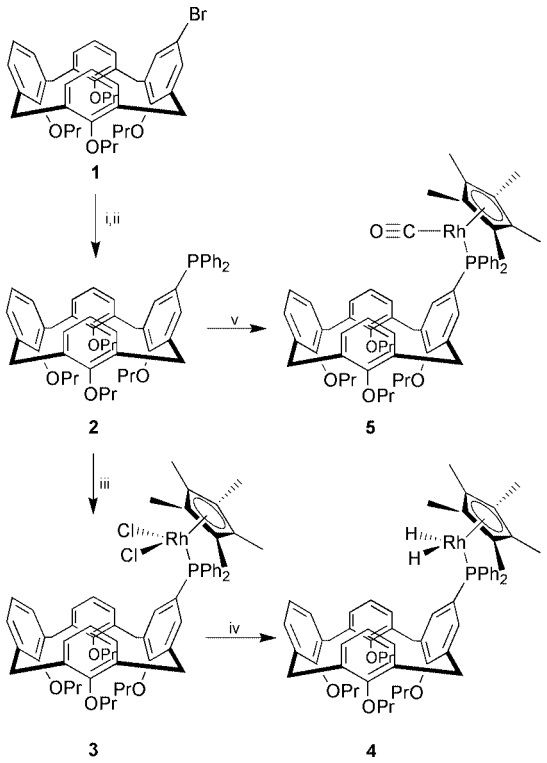
The entry into the monofunctionalization proceeds *via* the use of the known monobromotetra-*n*-propoxycalix[4]arene **1**.[7] In this case, simultaneous standard lithiation and phosphination procedures produce the monophosphine ligand: [eqn. (1) and (2)].

$$(PrO)_4calix–Br + Bu^nLi \rightarrow (PrO)_4calix–Li + Bu^nBr \quad (1)$$

$$(PrO)_4calix–Li + Ph_2PCl \rightarrow (PrO)_4calix–PPh_2 + LiCl \quad (2)$$

The latter is easily oxidized to its oxo form in the presence of air in solutions as evidenced from the X-ray structure determination to be described elsewhere, and therefore inert conditions must be used at all times.

The complexation routes of **2** with Cp*Rh complexes are shown in Scheme 1. Complex **3** is conveniently synthesized by directly reacting the known dimeric $[Cp^*RhCl_2]_2$[8] with **2**, and is obtained in 85% isolated yield. Complex **3** is relatively stable and has been structurally characterized by X-ray methods.‡ Fig. 1 shows the X-ray structure and confirms the expected monofunctionalization of the calix[4]arene. The coordination environment of the Rh^{III} metal center is relatively similar to that



Scheme 1 Synthesis of **2**–**5**. *Reagents and conditions*: i, BuLi/THF/−78 °C; ii, $ClPPh_2$/THF/−78 °C; *iii*, $[Cp^*RhCl_2]_2$/EtOH/reflux 5 h; *iv*, $NaBH_4$/EtOH/reflux 1 h; v, $Cp^*Rh(CO)_2$/benzene/reflux 24 h.

DOI: 10.1039/b001485k

of the reported less encumbered $[Cp^*Rh(Cl)_2P(Me)_2CH_2]_2$ complex.[9]

The key feature of this structure is that **3** exhibits calix C–P and P–Rh single bonds and at least 12 conformations are possible. Rotation around this C–P bond provides two rotamers where part of the cavity opening is covered by phenyl groups, and one where the metallic residue occupies this specific above position (C_s point group). The single crystal data shows one of the former described rotamers (Ph group on top of the cavity), and the Cp^*RhCl_2 fragment adopts a conformation exhibiting a minimum of steric hindrance between Cp* and Ph, as shown in Fig. 1. ^{1}H NMR spectroscopy clearly established the presence of fluxionality in **3**. Between 218 and 343 K, the spectra exhibit three main regions including the aromatic, methylene and propyl ^{1}H region, which all undergo coalescence processes. The most striking observation is that both the PPh_2 proton and aromatic signals coalesce at the same temperature of *ca.* 268 K, corresponding to $\cong$ 2.2 kJ mol^{-1}. This result strongly indicates that the fluxion must involve cooperative motions of the Ph groups and the calix[4]arene aromatic fragments. The most probable motion is rotation of the $Cp^*(PPh_2)RhCl_2$ group around the calix C–P single bond, where the Ph groups also rotate to pass over the bowlic structure of the calix[4]arene residue. Computer modellings clearly demonstrate that indeed rotations around the calix C–P bond must be accompanied by cooperative rotations of the Ph–P bond, somewhat similar to a 'merry-go-round' motion, allowing the Ph substituents to hop over the calix[4]arene 'walls'.

Complex **3** predictably reacts with $NaBH_4$ in refluxing ethanol to produce the corresponding dihydride **4**. The latter is very reactive, particularly in the presence of light and air, and must be freshly prepared prior to further studies. The presence of hydride groups in **4** is readily illustrated from its ^{1}H NMR and IR spectra which exhibit a characteristic resonance at δ –13.07 ($^1J_{HRh}$ = 28 Hz, $^1J_{HP}$ = 38 Hz), and an absorption at 2080 cm^{-1} (ν_{RhH}), respectively. Complexation of monophosphine ligand **2** can also be performed with the mononuclear $Cp^*Rh^I(CO)_2$ complex[10] *via* a simple thermally induced CO substitution, to form **5**. A single and characteristic ν_{CO} absorption is indeed observed at 1960 cm^{-1} in the solid state, and a complete characterization by standard methods (NMR, FAB mass, chemical analysis), confirms the identity and purity of this novel complex. Complex **5** is somewhat more stable than the dihydride **4**, but decomposition can also be observed upon UV–VIS light irradiation. Preliminary results show that indeed both **4** and **5** either thermally or photochemically eliminate H_2 and CO, respectively, to generate the very reactive species Cp^*Rh^IL (L = phosphine ligand, here **2**).[11] This important intermediate postulated as $Cp^*Rh[Ph_2P(calix)]$, is anticipated to activate C–H bonds,[12] and regioselectivity would be an unprecedented asset. Preparation of the more basic and less encumbered R_2P–calix ligand (R = Pr^i) and its Cp*Rh complex has been successful. Their structural properties and reactivities are under investigation, and will be published in due course.

Received (in Cambridge, UK) 12th April 2000, Accepted 8th May 2000

Oxidative addition of allylic substrates to coordinatively unsaturated ruthenium(II), (η^5-C_5Me_5)Ru(amidinate) complexes, afford cationic ruthenium(IV) compounds, [(η^5-C_5Me_5)Ru(amidinate)(η^3-allyl)]$^+$, which have been characterized by spectroscopic analysis and X-ray structure determination.

Studies on the structures and reactions of coordinatively unsaturated transition metal complexes have received much attention from organometallic chemists, because these compounds are believed to be involved in many transition metal-mediated organic reactions as important intermediates.[1] In particular, the structures and reactions of coordinatively unsaturated ruthenium(II) complexes have been actively investigated recently;[1] these studies contribute to the understanding of the factors leading to the stabilization of these complexes, *e.g.* steric effects, presence of π-donor ligands, metal-bond strength and their tendency towards oxidative addition of H_2 and $HSiR_3$.[1–3] Although the oxidative addition of allylic substrates to ruthenium(II) complexes[4] is an important elementary reaction in the catalytic transformation of an allyl moiety,[5] that to isolated coordinatively unsaturated ruthenium compounds has not, as yet, been studied.[1–3] We have recently reported a novel reactive complex, (η^5-C_5Me_5)Ru(amidinate) **1**, which shows signs of coordinative unsaturation, in which the amidinate ligand contributes to stabilizing the formally 16-electron configuration.[6] The fact that **1** is highly reactive towards the reaction with a variety of two-electron donor ligands stimulated us to explore the possibility that **1** may also be reactive towards oxidative addition reactions.[6] Here, we report that **1** readily reacts with an allylic substrate to give the corresponding cationic Ru(IV) allylic compound as shown in Scheme 1. This is the first example, to the best of our knowledge, of oxidative addition of allylic substrates to isolable coordinatively unsaturated ruthenium complexes. Additionally, the product is a rare example of an organoruthenium(IV) compound coordinated to nitrogen donor ligands.

Complex **1a** was treated with a stoichiometric amount of allyl chloride at −78 °C and the mixture was allowed to warm to room temperature. After 1 h, the solvent was removed *in vacuo*. Spectroscopic evidence suggests that the resulting yellow solid is [(η^5-C_5Me_5)Ru(amidinate)(η^3-allyl)]Cl **2a** (yield of the crude product > 95%) containing *ca.* 5% of (η^5-C_5Me_5)Ru(η^3-allyl)Cl_2.[4a] This new η^3-allyl complex **2a** is not very stable in solution and gradually decomposes to a mixture of intractable products. In contrast, **3a**, a stable analogue of **2a**, was successfully isolated as a yellow solid in 48% yield by exchange in $CHCl_3$ of the counter anion Cl^- to PF_6^- followed by recrystallization of the crude product. Complex **3a** could also be obtained directly from **1a** by treatment with allyl chloride in the presence of $NaPF_6$. The oxidative addition of allyl acetate or allyl methyl carbonate in the presence of $NaPF_6$ offers an alternative synthetic method for **3a** without formation of by-products; **3a** was isolated in quantitative yield. In a similar fashion, **3b**, a methallyl analogue of **3a**, and a compound **3c**, bearing a different amidinate ligand, were successfully prepared and characterized as shown in Table 1.

Table 1

Precursor	R^2	X	Method	Product	Isolated yield (%)
1a	H	Cl	A	**3a**	48
1a	Me	Cl	A	**3b**	55
1c	H	Cl	A	**3c**	62
1a	H	Cl	B	**3a**	64
1a	Me	Cl	B	**3b**	39
1c	H	Cl	B	**3c**	62
1a	H	OCOMe	B	**3a**	97
1a	H	OCO_2Me	B	**3a**	97

Complex **3a** was fully characterized by spectroscopic methods (^{1}H NMR, ^{13}C NMR, IR),‡ elemental analyisis and an X-ray crystal structure determination§ and an ORTEP drawing of **3a** is shown in Fig. 1. Complex **3a** has a square-pyramidal structure, with two nitrogen atoms of the amidinate ligand and terminal carbons of the η^3-allyl ligand at the basal positions. The orientation of the allyl group is *endo*, and variable temperature NMR studies showed that there is no equilibrium with the corresponding *exo* isomer. This *endo* orientation is also seen in (η^5-C_5Me_5)Ru(η^3-allyl)X_2 reported previously.[4a] The crystal structure of **3a**, in comparison with that of the starting

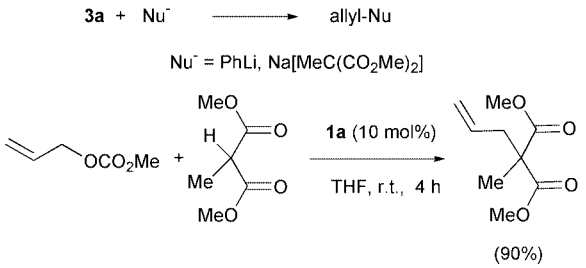
Selected bond lengths (Å) and angles (°): Ru(1)–C(1–5)$_{av}$ 2.263(4), Ru(1)–N(1), 2.128(3), Ru(1)–N(2) 2.125(3), Ru(1)–C(11) 2.193(5), Ru(1)–C(12) 2.132, Ru(1)–C(13) 2.206, C(11)–C(12) 1.385(8), C(12)–C(13) 1.379(8); N(1)–Ru(1)–N(2) 61.98(12), C(11)–Ru(1)–C(12) 64.1(2), C(11)–C(12)–C(13) 115.2(5).

material **1a** reveals that the Ru–N and Ru–C bonds (average) become longer [**1a**: Ru–N 2.073(3) Å, Ru–C_{av} 2.158(4) Å].

The chemical reactivity of the η^3-allyl moiety is an interesting problem for the exploration of stoichiometric and catalytic reactions mediated by **1** or **2**. Preliminary studies on the reactivity of **3a** revealed that it reacted with nucleophiles such as PhLi and sodium dimethyl methylmalonate but not with electrophiles such as aldehydes and unsaturated molecules such as ethylene and CO. The stoichiometric reaction of **3a** with PhLi in THF gave a mixture of 1-phenylprop-1-ene and 1-phenylprop-2-ene in a ratio of 1:2. Similarly, treatment of **3a** with sodium dimethyl methylmalonate resulted in formation of dimethyl allylmethylmalonate. In both of the reactions, regeneration of **1a** was also observed. The latter allylation reaction can be extended to a catalytic reactions when allyl methyl carbonate is used as the allylic substrate; **1a** (10 mol%) successfully catalyzed the reaction of allyl methyl carbonate with dimethyl methyl malonate in THF at room temperature to give the product in 90% yield (Scheme 2).

In conclusion, oxidative addition of allylic substrates to the isolable coordinatively unsaturated complex (η^5-C_5Me_5)Ru(η-amidinate), has been observed which leads to a new cationic organoruthenium(IV) complex [(η^5-C_5Me_5)Ru(η^3-allyl)(η-amidinate)]$^+$ stabilized by a nitrogen-donor ligand. This oxidative addition is envisioned to be extendable to stoichiometric and catalytic transformations of allylic substrates mediated by **1**–**3**, as already evidenced by our preliminary studies on the reactions of **3a** with nucleophiles.



Scheme 2

$\{Mn(OH_2)_2[Mn(bpym)(OH_2)]_2[Fe(CN)_6]_2\}_\infty$: a two-dimensional ferrimagnet with a partial cubane motif

Jennifer A. Smith, José-Ramón Galán-Mascarós, Rodolphe Clérac and Kim R. Dunbar*

Texas A&M University, Department of Chemistry, College Station, TX, 77842-3012, USA. E-mail: dunbar@mail.chem.tamu.edu

Received (in Irvine, CA) 23rd February 2000, Accepted 28th April 2000

$\{Mn(OH_2)_2[Mn(bpym)(OH_2)]_2[Fe(CN)_6]_2\}_\infty$, a two-dimensional cyanide-bridged polymer, exhibits canted ferrimagnetism with T_C = 11 K.

Molecule-based magnets are the focus of considerable current research effort, from both the fundamental and device-related perspectives. One of the more exciting developments in recent years is the design of magnets from a consideration of the sign and magnitude of superexchange between adjacent paramagnetic metal centers. The family of magnets based on the 3-D Prussian Blue structural motif nicely illustrates this strategy.[1] In these materials, deliberate choices of metal ions at the two ends of the CN^- bridge lead to well established ground states, and the symmetry of the magnetic orbitals allows for a reasonable prediction of the nature of the superexchange (antiferro- *versus* ferro-magnetic).[2] For example, $V[Cr(CN)_6]_{0.86}\cdot 2.8H_2O$ orders ferrimagnetically at 315 K[1*h*] (due to direct overlap of t_{2g} magnetic orbitals) whereas $CsNi[Cr(CN)_6]\cdot 2H_2O$ orders ferromagnetically at 90 K[1*g*] (due to orthogonality of the t_{2g} and e_g magnetic orbitals). In addition to the high-symmetry Prussian-Blue architectures, hexacyanometallate building blocks are found in other structural motifs, for example in the 3-D ferrimagnet $[Ni(tren)]_3[Fe(CN)_6]\cdot 6H_2O$ synthesized from $[Fe(CN)_6]^{3-}$ and $[Ni(tren)]^{2+}$ [tren is the tetradentate capping ligand tris(2-aminoethyl)amine].[6*e*] A number of 1-D chains,[4] 2-D layered materials[5] and 3-D networks[6] have also appeared in the literature, the common theme among all examples being the incorporation of cyanometallates into networks with metal ions that possess a capping ligand(s).

Our involvement in the chemistry of cyanide compounds is directed at the formation of clusters or low-dimensional materials from specifically tailored precursors.[7] For example, we reasoned that 1:1 reactions between *cis*-$[Mn(bpym)_2(H_2O)_2]^{2+}$ and $[Fe(CN)_6]^{3-}$ would yield a square with *cis*-$[Mn(bpym)_2]^{2+}$ corners linked by $[Fe(CN)_6]^{3-}$ edges or a zigzag bimetallic chain. Both of these hypotheses are based on the expectation that the only leaving groups would be the two water molecules on Mn^{II}. Herein, we report an entirely unexpected result, namely that the 2,2′-bipyrimidine chelates are also very good leaving groups in favor of the nitrogen end of a cyanide group in such reactions.

Brown crystalline needles are formed reproducibly by slow diffusion of a solution of $[Mn(bpym)_2(OH_2)_2][SO_4]$ (bpym = 2,2′-bipyrimidine) in MeCN into a solution of $K_3[Fe(CN)_6]$ in H_2O.[8] X-Ray crystallographic studies† revealed that the product is the neutral, 2-D polymer $\{Mn(OH_2)_2[Mn(bpym)(OH_2)]_2[Fe(CN)_6]_2\}_\infty$ **1**. The asymmetric unit of the structure consists of one $[Fe^{III}(CN)_6]^{3-}$ unit connected to two different types of Mn^{II} centers by cyanide bridges. One Mn atom (Mn2) has retained only one bpym ligand while the other one (Mn1) has lost both of its original bpym ligands. For simplicity in describing the repeat pattern, the building blocks of the layers are defined as $[Fe(CN)_6]^{3-}$ (Fe1), *trans*-$[Mn(OH_2)_2]^{2+}$ (Mn1), and *fac*-$[Mn(bpym)(OH_2)]^{2+}$ (Mn2) units. Each Fe^{III} ion forms bridges to three Mn2 and two Mn1 centers, which leaves one terminal CN^- ligand. The *trans*-$[Mn(OH_2)_2]^{2+}$ units are linked to four Fe^{III} ions, and each *fac*-$[Mn(bpym)(OH_2)]^{2+}$ building block is connected to three independent $[Fe(CN)_6]^{3-}$ anions. The resulting polymeric framework can be described as being composed of individual 1-D chains formed by edge-sharing $\{[Mn(bpym)(OH_2)]_2[Fe(CN)_6]_2\}$ squares. These chains, which exhibit a staircase motif, are stitched into layers by *trans*-$[Mn(OH_2)_2]^{2+}$ bridges that serve to link Fe atoms of adjacent chains and creates two new $\{[Mn(bpym)(OH_2)][Fe(CN)_6]_2[Mn(OH_2)_2]\}$ squares that share a corner (Mn1) [see Fig. 1(a)]. As the simplified diagram in Fig. 1(b) reveals the framework resembles a 2-D array of fused Mn_4Fe_3 cubes that are missing one vertex. It is of further interest to point out that the bpym ligands of adjacent layers are interdigitated to form a stacked column along the *c* axis with a mean spacing of 3.35 Å.

Magnetic studies were performed on a 3.3 mg batch of crystals using a MPMS-XL SQUID magnetometer. Between 50 and 300 K, the molar susceptibility χ_m can be fit to a Curie–Weiss law with C = 13.8 emu K mol^{-1} and θ = −12.8 K (inset in Fig. 2). The Curie constant is in good agreement with the expected spin-only value (13.875 emu K mol^{-1}) for three S = 5/2 Mn(II) and two low spin S = 1/2 Fe(III) centers. The sign of the Weiss constant indicates that local antiferromagnetic interactions dominate as expected for Fe^{III}–CN–Mn^{II} bridges where there is direct overlap of the t_{2g} magnetic orbitals. Below 50 K, χ_m deviates from the Curie–Weiss behavior and undergoes an abrupt increase at *ca*. 11 K which suggests the onset of magnetic ordering (Fig. 3). This state corresponds to a ferrimagnetic ordering, since the Fe^{III} and Mn^{II} spin centers interact antiferromagnetically with non-cancellation of spins. As Fig. 3 shows, the magnetization increases gradually, but saturation is incomplete at 7 T (M = 11.6 μ_B *cf*. the expected value of 13 μ_B). This behavior is a signature of a complicated magnetic structure (competing magnetic interactions with possibly some degree of spin canting), which is not unexpected in view of the crystal structure. No hysteresis was observed in the field dependence of the magnetization. Susceptibility

measurements of the ac type confirm the ferrimagnetic ordering at 11 K (Fig. 4) and reveal no significant frequency dependence.

The result presented here underscores the structural diversity of materials containing cyanometallate building blocks. The slow loss of 2,2′-bipyrimidine ligands from *cis*-$[Mn(bpym)_2(H_2O)_2]^{2+}$ in H_2O–MeCN contributes to the growth of crystals rather than the rapid deposition of powders which is the outcome of reactions that do not involve capping ligands. We are currently investigating reactions of other ligand-protected cations with hexacyanometallate anions, the results of which are forthcoming.

Construction of the 11-oxabicyclo[6.2.1]undecane core of the cladiellins by a novel rearrangement reaction

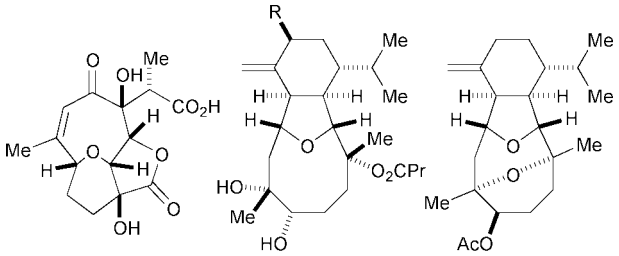
J. Stephen Clark* and Yung-Sing Wong

School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: j.s.clark@nottingham.ac.uk

Received (in Cambridge, UK) 29th March 2000, Accepted 8th May 2000

A novel approach to the stereoselective synthesis of the 11-oxabicyclo[6.2.1]undecane system found in the cladiellin (eunicellin) family of marine natural products is described.

Cladiellins (eunicellins) such as litophynin E,[1a] litophynin I[1b] and sclerophytin B[2] are highly oxygenated marine natural products that are part of a much larger family of cembranoids also comprising the briarellins, sacrodictyins and asbestinins.[3] Members of this family of natural products share an oxabicyclo[6.2.1]undecane sub-structure, and many of them possess potent anti-cancer, anti-inflammatory, insecticidal or anti-mollusc activity.[3]

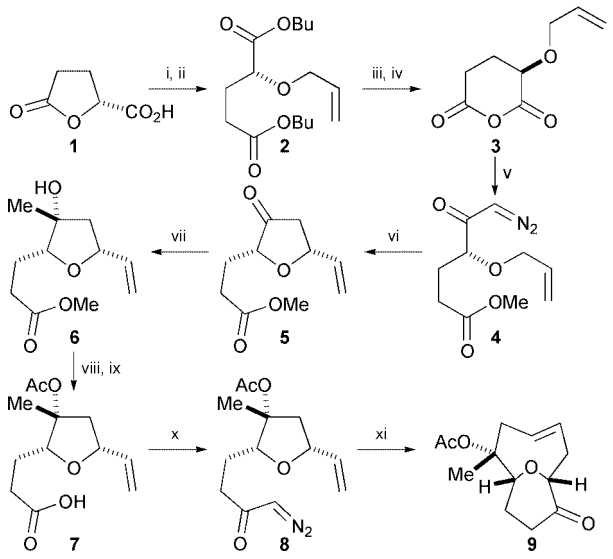


In the course of our research programme directed towards the synthesis of the highly oxygenated sesquiterpene neoliacinic acid,[4,5] we have discovered that it is possible to effect an unusual rearrangement reaction of the oxabicyclo[5.3.1]undecane system of this terrestrial natural product to give the oxabicyclo[6.2.1]undecane system found in the marine cembranoids. We now present the results of our studies and demonstrate that the reaction can be used to prepare the core structure of litophynins E and I.

The (*E*)-bicyclo[5.3.1]bicycloundecene **9**† required for our rearrangement studies was prepared from the commercially available compound (*R*)-γ-butyrolactone-γ-carboxylic acid **1**, which we obtained from (*R*)-glutamic acid (Scheme 1).[6] Ring opening of the lactone **1** was effected using a sub-stoichiometric amount of 10-camphorsulfonic acid (CSA) in a mixture of *n*-butanol and toluene at reflux,[7] and the resulting diester was then converted into the allyl ether **2** by silver(I) oxide promoted alkylation of the free hydroxy group with excess allyl bromide.[8] Saponification of the diester **2** and treatment of the resulting diacid with acetic anhydride provided the substituted glutaric anhydride **3**. Reaction of the cyclic anhydride **3** with a large excess of diazomethane resulted in contrasteric opening of the ring to afford the diazoketone **4** in reasonable yield, without formation of the other possible regioisomeric diazoketone product.‡ The diazoketone **4** was then treated with a sub-stoichiometric amount of $Rh_2(O_2CCPh_3)_4$, which delivered the 3(2*H*)-furanone **5** resulting from intramolecular C–H addition of the intermediate rhodium carbenoid.[4,9] Regioselective and stereoselective introduction of a methyl substituent was accomplished by treatment of the ketone **5** with trimethylaluminium at low temperature.[4,10] At this stage, some of the lactone produced by transesterification of the methyl ester with the tertiary alcohol was obtained, but the process was reversed by treatment of the mixture with triethylamine in methanol at reflux. The tertiary alcohol **6** was converted into the acid **7** by sequential acetylation and selective hydrolysis of the methyl ester, and the carboxylic acid **7** was then transformed into the diazoketone **8**. Treatment of the diazoketone **8** with copper(II) hexafluoroacetylacetonate generated an electrophilic copper carbenoid that underwent tandem oxonium ylide formation and [2,3]-sigmatropic rearrangement with ring expansion.[11] The reaction delivered the strained bridged-bicyclic ether **9** containing an (*E*)-alkene as the key intermediate.[4b] The corresponding (*Z*)-alkene isomer was prepared in 79% yield by treatment of **9** with AIBN and a sub-stoichiometric amount of ethanethiol in benzene at reflux.[4a]

It was immediately apparent that the rather unstable (*E*)-alkene **9** had unusual reactivity. Attempted epoxidation of the alkene **9** with *m*-CPBA in dichloromethane at reflux afforded a complex mixture of products and delivered a major compound that contained an *m*-chlorobenzoate group rather than the expected epoxide. In contrast, the (*Z*)-alkene isomer of **9** underwent conventional epoxidation under identical conditions to deliver the expected product as a *ca.* 3:1 mixture of diastereoisomers. Attempted epoxidation of the (*E*)-alkene **9** with milder oxidants such as DMDO also failed to yield the expected epoxide.

We suspected that the unusual reactivity of the (*E*)-alkene **9** was due to transannular reaction of the bridging ether oxygen,



Scheme 1 *Reagents and conditions*: i, Bu^{n}OH, CSA (cat.), PhMe, Dean–Stark, reflux (78%); ii, CH_2CHCH_2Br, Ag_2O, Et_2O, reflux (89%); iii, LiOH, THF, H_2O, reflux; iv, Ac_2O, reflux (83% over two steps); v, CH_2N_2, 0 °C → r.t., CH_2Cl_2–Et_2O (59%); vi, $Rh_2(O_2CCPh_3)_4$, CH_2Cl_2, r.t. (50%); vii, $AlMe_3$, CH_2Cl_2, −78 → −10 °C, then Et_3N, MeOH, reflux (71%); viii, Ac_2O, DMAP, CH_2Cl_2, r.t. DOI: 10.1039/b002511i

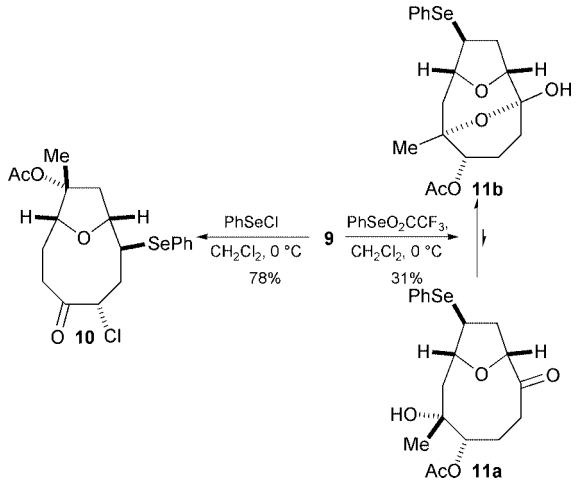
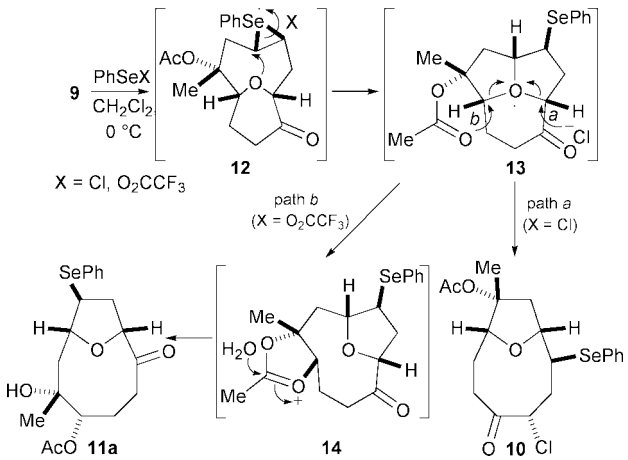


Scheme 2

which is forced to lie in close proximity to the alkene. In order to probe the reactivity of **9**, we investigated the reaction of this compound with electrophilic selenium reagents. Upon treatment with phenylselenenyl chloride, the *E* alkene **9** underwent rearrangement to provide the crystalline oxabicyclo[6.2.1]undecane **10** in good yield. In contrast, treatment of the (*E*)-alkene **9** with phenylselenenyl trifluoroacetate afforded the crystalline rearrangement product **11** in moderate yield. The structures of both the rearrangement products **10** and **11** were confirmed by X-ray crystallography;§ the rearrangement product **11** was found to exist as the hemiacetal **11b**¶ rather than the ring-opened tautomer **11a** in both the solid state and in solution. It is significant that the (*Z*)-isomer of the alkene **9** did not undergo rearrangement when treated with either selenium reagent, but instead reacted to give complex mixtures of products.

The formation of the rearranged bridged-bicyclic ethers **10** and **11** can be accounted for as shown in Scheme 3. Reaction of alkene **9** with either electrophilic selenium reagent results in stereoselective formation of the selenonium ion **12** and subsequent transannular attack of the bridging ether oxygen atom affords the tricyclic oxonium ion **13**. In the presence of chloride ion, nucleophilic attack occurs at the electrophilic site α to the carbonyl group (path *a*) and the bridged-bicyclic ether **10** is produced. In the presence of trifluoroacetate ion, the oxonium intermediate **13** does not suffer immediate attack by the weakly nucleophilic counterion. Instead, the acetate group participates in intramolecular S_N2 opening of the tricyclic oxonium ion (path *b*), and the oxonium intermediate **14** is produced. The ion **14** probably survives until work up, at which



Scheme 3

stage water attacks and the acetate group is transferred from the tertiary site to the less sterically congested secondary hydroxy group.

The rearrangement product **11a** contains most of the functionality that adorns the oxygen-bridged core of litophynins E and I.[1] The compound also possesses the correct absolute and relative configuration at the four oxygen-bearing stereogenic centres. Thus, we have prepared an advanced intermediate for the synthesis of litophynins E and I in 12 steps from the commercially available compound (*R*)-γ-butyrolactone-γ-carboxylic acid **1** (Scheme 1).

We are currently exploring the optimisation of the rearrangement reaction (**9** → **11**, Scheme 3), completion of the synthesis of litophynins E and I, and elaboration of tautomer **11b** to give sclerophytin B. The results of these studies will be reported in due course.

We thank the EPSRC for financial support. We are very grateful to Dr A. J. Blake and Dr C. Wilson for obtaining X-ray crystal data for compounds **10** and **11b**.

Notes and references

† Compound **9** has been prepared by us using an alternative route [see ref. 4*b*)].

‡ The only other product obtained was the dimethyl ester (9%) resulting from hydrolysis of the anhydride **3** and esterification of the resulting diacid.

Development of new methodology for the synthesis of functionalized α-fluorophosphonates and its practical application to the preparation of phosphopeptide mimetics

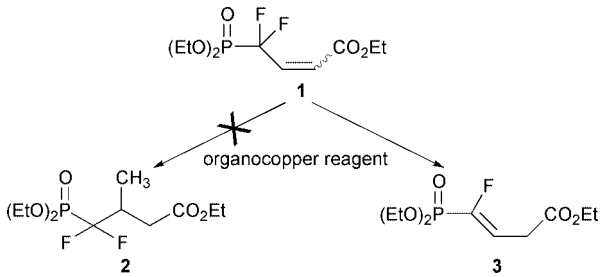
Akira Otaka,* Etsuko Mitsuyama, Hideaki Watanabe, Hirokazu Tamamura and Nobutaka Fujii

Graduate School of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan. E-mail: aotaka@pharm.kyoto-u.ac.jp

Received (in Cambridge, UK) 20th March 2000, Accepted 10th May 2000

New methodology for the synthesis of functionalized α-fluorophosphonates which utilizes organocopper-mediated reduction has been developed and applied to the preparation of a monofluoromethyl-substituted phosphoserine mimetic-containing peptide.

Naturally occurring phosphate-containing molecules play important roles in various cellular processes, including signal transduction.[1] Therefore, nonhydrolyzable phosphate mimetics have received considerable attention, with α,α-difluorophosphonates serving as potential phosphate mimics,[2] extensive synthetic and biological studies of which have been made.[3] In contrast, evaluation of α-monofluorophosphonates[4] as biological phosphate mimics has been somewhat limited due to lack of flexibility of practical synthetic methodology[5] for this kind of molecule. In our efforts to prepare difluoromethyl (CF_2)-substituted phosphothreonine mimetics,[6] we attempted conjugate addition of a methyl group to 3-(diethylphosphonodifluoromethyl)but-2-enoate **1**† using an organocopper reagent to construct the secondary phosphonate unit. Unexpectedly, the reaction predominantly afforded an organocopper-mediated reduction product, α-fluorovinylphosphonate **3**, and not the corresponding conjugate addition product **2** (Scheme 1). This is the first example of organocopper-mediated reduction of γ-difluoro-α,β-enoates yielding γ-fluoro-β,γ-enoates.



Scheme 1

The α-fluorovinylphosphonate[7] represents a potential synthetic intermediate for the preparation of α-fluorophosphonates. Accordingly, we describe herein the feasibility studies of our newly found reaction and its application to the synthesis of the monofluoromethyl (CHF)-substituted phosphoserine (pSer) mimetic 2-amino-4-fluoro-4-phosphonobutanoic acid (FPab) in a form suitably protected for the preparation of pSer mimetic-containing peptides.

Initially, we chose a difluoromethylphosphonate-bearing conjugate (2*S*)-bornane-[10,2]-sultam (Xs-sultam)-imide[8] **4** as a substrate for the copper-mediated reaction in order to allow subsequent stereoselective introduction of amino functionality under chiral auxiliary control. The sultam-imide **4** was treated under various conditions[9] and the results are shown in Table 1.‡

Reaction of **4** with either MeCu(CN)Li or $Me_2Cu(CN)Li_2$ in the presence of LiCl and/or $AlCl_3$ at −78 °C proceeded without accompanying alkylation, but rather provided the corresponding reduction product **5** with (*E*)-configuration§ in up to 80% isolated yields. Similarly, using methyl copper reagents, the formation of an alkylated product was also not observed. Use of methyl copper reagents was critical for conversion of **4** to **5**, since exposure of **4** to a butyl-copper reagent (run 14) afforded, besides **5**, a Bu-substituted Michael adduct (24%). The reaction presented here, different from other published protocols,[7,10] is conceptually a new methodology for the preparation of α-vinylphosphonates. Hydrogenation of the resulting α-vinylphosphonates affords the corresponding α-monofluorophosphonates, possessing a carboxy functionality which is amenable to further derivatization. Furthermore, starting from a common difluoromethylphosphonate intermediate, both the monofluoro- and corresponding difluoro-methylphosphoryl counterparts can be obtained.

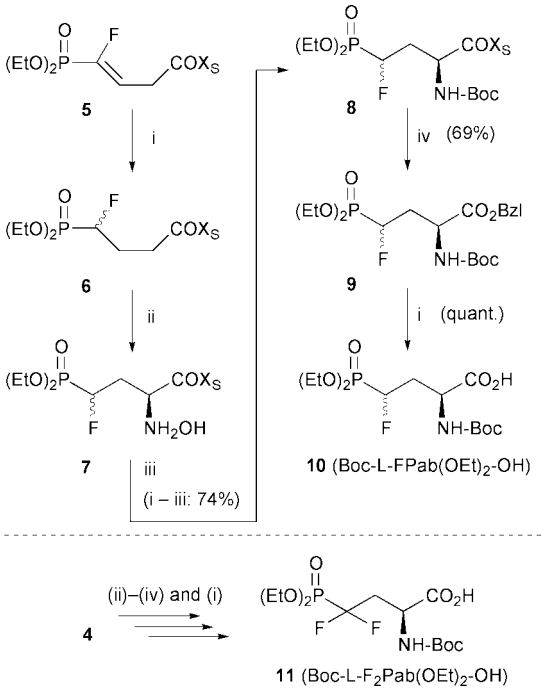
Next, we applied this methodology to the synthesis of CHF-substituted pSer mimetic (FPab) as shown in Scheme 2. Hydrogenation of α-vinylphosphonate **5** over Pd–C in AcOEt proceeded without diastereoselectivity to yield α-monofluorophosphonate **6** in quantitative yield. Reaction of 1-chloro-1-nitrosocyclohexane[11] in THF (blue) with the Na-enolate, resulting from treatment of **6** with NaHMDS in THF at −78 °C, proceeded with high diastereoselectivity to instantaneously afford a colorless solution of nitrone. Treatment of this solution with aqueous 1 N HCl, followed by extractive work-up, gave crude hydroxylamine **7**, which was taken to the next step without further purification. Reduction of **7** with Zn–AcOH in THF, followed by introduction of Boc protection onto the resulting NH_2 group using $(Boc)_2O$, gave Boc-protected **8**. The sultam moiety was then converted to the benzyl ester **9** utilizing

DOI: 10.1039/b002188l



Scheme 2 *Reagents*: (i) H_2/Pd–C, AcOEt; (ii) NaHMDS (1.1 eq.), 1-chloro-1-nitrosocyclohexane (1.1 eq.). THF then **1** N HCl aq.; (iii) Zn (40 eq.). AcOH (50 eq.) then $(Boc)_2O$ (2.0 eq.), CH_3CN; (iv) $Ti(CPr^i)_4$ (2.0 eq.), BzOH (44 eq.), toluene.

$Ti(OPr^i)_4$–benzyl alcohol in toluene at 120 °C. Hydrogenolytic debenzylation (H_2/10% Pd–C in AcOEt) of **9** gave the protected L-CHF-substituted pSer mimetic (Boc-FPab(OEt)$_2$-OH **10**). Application of a similar sequence of reactions to **4** gave enantiometically pure L-CF_2-substituted pSer mimetic[12] (F_2Pab) **11**. We speculate that FPab derivative **10** possesses the 2*S* configuration (L-amino acid), by analogy to F_2Pab derivative **11**, which is obtained from a difluoromethylphosphonate-containing Xs-sultam utilizing a similar reaction sequence and has the 2*S* configuration. To our knowledge, this is the first synthesis of a CHF-substituted pSer mimetic.

In order to examine the general applicability of protected FPab **10** to peptide synthesis, **10** was incorporated into the peptide sequence (H–Gly–FPab–Val–Pro–Met–Leu) using a standard Boc-based solid-phase protocol. The resulting protected peptide resin was treated with a one-pot, two-step deprotection methodology[13] consisting of high-acidity [1 mol dm^{-3} TMSOTf–thioanisole in TFA, *m*-cresol, ethanedithiol (EDT)] and low-acidity (1 mol dm^{-3} TMSOTf–thioanisole in TFA, *m*-cresol, EDT + DMS–TMSOTf), which was developed for practical deprotection of protected phosphoamino acid-containing peptide resins, to yield a crude deprotected peptide without accompanying partially Et-deprotected peptides.¶ After HPLC purification, an FPab-containing peptide was obtained in 63% yield. In order to confirm the 2*S* configuration of FPab, purified peptide was subjected to enzyme digestion using leucine amino peptidase (LAP).‖ Interestingly, it was found that the parent peptides were converted to 5-residue peptides, H–FPab–Val–Pro–Met–Leu–OH, with rates that varied between the diastereomers derived from the fluorine substitution in FPab and with only 10% of FPab being released from the resulting 5-residue peptide after 24 h of LAP treatment. On the other hand, D-FPab-containing peptides remained intact after 24 h digestion using LAP. The present methodology should allow the facile preparation of functionalized α-fluorovinylphosphonates and α-fluorophosphonates. Furthermore, it is tempting to speculate that FPab-containing peptides could serve as inhibitors against both proteases and phosphatases since peptides having FPab residues at the N-terminal position are resistant to the action of LAP.

We thank Dr Terrence R. Burke Jr., NCI, NIH, Bethesda, MD 20892, for proofing the manuscript. This work was supported in part by The Japan Health Sciences Foundation and Grants-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan.

Notes and references

† (*Z*)-3-(diethyldifluoromethyl)but-2-enoate **1** was prepared by coupling of ethyl (*Z*)-3-iodobut-2-enoate with $BrZnCF_2(O)(OEt)_2$ in the presence of CuBr in DMF.[14] The (*E*)-isomer was synthesized according to the literature method.[15] Sultam-imide **4** was synthesized *via* the following sequence of reactions: (i) transesterification of ethyl (*Z*)-3-iodobut-2-enoate to the corresponding *p*-methoxybenzyl (PMB) ester using $Ti(OPr^i)_4$ in PMB-OH; (ii) CuBr-mediated coupling, as mentioned above; (iii) removal of the PMB group with 95% aqueous TFA; (iv) coupling of the sultam.

‡ To a solution of CuCN·2LiCl in THF (1 mol dm^{-3}, 4.2 cm^3) was added MeLi·LiBr in Et_2O (1.5 mol dm^{-3}, 5.6 cm^3) at −78 °C. The mixture was allowed to warm to 0 °C and stirred at this temperature for 1–2 min. After re-cooling to −78 °C, **4** (763 mg, 1.68 mmol) in THF (5 cm^3) was added with a syringe. After being stirred at −78 °C for 1.5 h, the reaction was quenched by addition of sat. NH_4Cl–28% NH_4OH solution. Usual work-up followed by flash chromatography gave **5** (639 mg, 87% yield).

§ Coupling constants of **5** ($^3J_{HF}$ = 38.6, $^3J_{HP}$ = 7.3 Hz) are consistent with those of α-fluorovinylphosphonate possessing (*E*)-configuration ($^3J_{HPtrans}$ = 39–40, $^3J_{HPcis}$ = 7.6–10 Hz).[16]

¶ Protected peptide resin (Boc–Gly–FPab(OEt)$_2$–Val–Pro–Met–Leu–PAM resin, 0.05 mmol) was treated with 1 mol dm^{-3} TMSOTf–thioanisole (molar ratio 1:1) in TFA (2.5 cm^3) in the presence of *m*-cresol (125 mm^3) and EDT (125 mm^3) at 4 °C. After being stirred at 4 °C for 60 min, DMS (0.75 cm^3) and TMSOTf (0.5 cm^3) were successively added to the reaction with additional stirring at room temperature for 2 h. The reaction was quenched by addition of EtOH–H_2O. The aqueous layer was subjected to HPLC purification, yielding 22 mg of the desired peptide. Ion-spray MS *m/z* calcd for $C_{27}H_{49}N_6O_{10}SFP$ (MH^+) 699.76; found 699.50. Purified peptides, consisting of diastereomers derived from FPab, were eluted as two peaks incompletely resolved on HPLC.

‖ Peptides possessing L-phosphotyrosine mimetics as an FPab replacement were completely hydrolyzed by leucine amino peptidase, while D-phosphotyrosine mimetic-containing peptides remained intact.[17]

Received (in Cambridge, UK) 27th March 2000, Accepted 8th May 2000

A new arsenic-containing betaine, trimethyl(2-carboxyethyl)arsonium inner salt 2, has been identified in fish muscle tissue by liquid chromatography–mass spectrometry.

Arsenic is a common constituent of marine organisms where it occurs in a wide range of chemical forms.[1] The major form in marine animals is arsenobetaine **1**, while arsenic containing carbohydrates (dimethylarsinoylribosides) are the predominant forms in marine algae. The biogenesis of the various arsenic compounds is still not known, although plausible pathways have been proposed.[2,3] Unknown arsenic compounds have also been reported in marine samples, the most widespread of these being a cationic arsenical present in fish, molluscs and crustaceans.[4–9] This unknown compound was detected in aqueous (or aqueous methanol) extracts of tissues by HPLC with arsenic-specific detectors, such as an inductively coupled plasma mass spectrometer (ICPMS),[4–8] or an atomic fluorescence spectrometer.[9] Determination of the precise chemical structure of this compound may help elucidate biogenetic

$Me_3As^+CH_2COO^-$ **1** $Me_3As^+CH_2CH_2COO^-$ **2**

pathways for arsenic.

Recently, we analysed (HPLC–ICPMS) aqueous extracts of a range of tropical marine organisms, and found that a coral reef fish, *Abudefduf vaigiensis* (Pomacentridae), contained significant amounts of the unknown compound (8% of the total arsenic), in addition to arsenobetaine, which constituted *ca*. 90% of the arsenic. The extract from *A. vaigiensis* was subjected to TLC (cellulose on a glass plate; butan-1-ol–acetic acid–water 60 : 15 : 25); the cellulose support was then cut into narrow bands (5 mm), each of which was extracted with water (2.0 mL) and a portion (20 μL) of the extract analysed for arsenic by graphite furnace atomic absorption spectrometry. Arsenic was detected in three adjacent fractions in an apparently homogeneous band centred at R_f 0.54, matching the R_f for arsenobetaine. Subsequent HPLC–ICPMS analyses, however, showed that the two slower running TLC fractions contained all their arsenic as arsenobetaine, whereas the faster running fraction contained both arsenobetaine and the unknown arsenical (2 : 1 in terms of arsenic). The concentration of the unknown in this solution (175 ng As cm^{-3}) was now sufficient to enable detection of arsenic (*m/z* 75, As^+) by positive ion LC electrospray MS.[10]

Cation-exchange LC electrospray MS of the solution at 200 V fragmentor voltage and measuring *m/z* 75 yielded only two peaks with retention time 1.83 (arsenobetaine) and 4.31 min (unknown). The analysis was then repeated at 70 V fragmentor voltage and the eluent was analysed in scan mode measuring *m/z* 141–160 (we made the initial assumption that, under these conditions, we were seeing predominantly the $[M + H]^+$ molecular species). This process was repeated scanning from *m/z* 161–180, and so forth, up to *m/z* 400. Only one ion (*m/z* 193), eluting at 4.33 min matched the retention time for the unknown arsenic peak; the closest other ions had retention times of 4.02 (*m/z* 162) and 4.74 min (*m/z* 151). The procedure was then carried out at variable fragmentor voltages,[10] which enabled simultaneous detection of *m/z* 75 (arsenic) and 193 (presumed $[M + H]^+$ for the unknown); the retention times for the two peaks agreed exactly (Fig. 1).

The chromatographic properties and mass spectral data for the unknown were consistent with the structure of the arsenic betaine **2**. An authentic specimen of **2**, prepared[11] by reacting trimethylarsine with 1-bromopropionic acid, was then analysed by LC electrospray MS. It produced retention time and mass spectral data (Fig. 1) matching those obtained for the unknown. Our previous experience with the unknown had revealed a

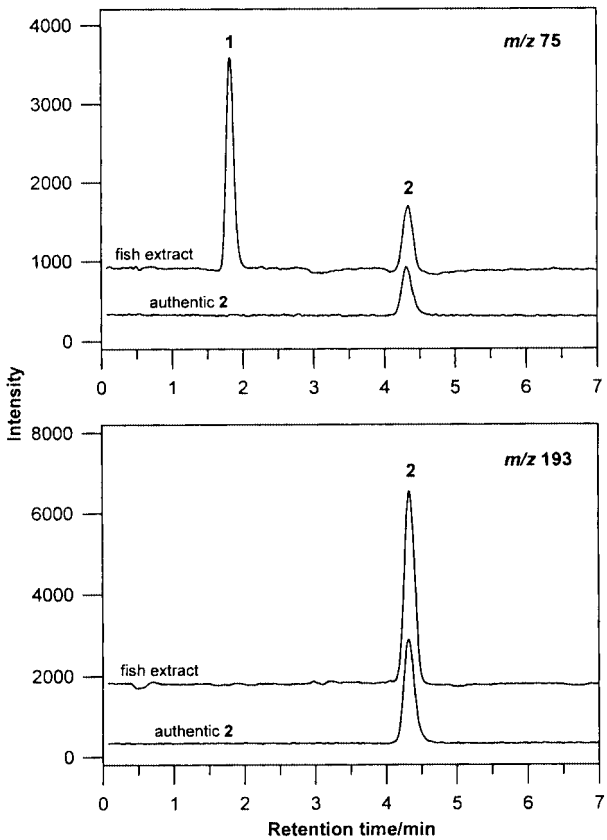

Fig. 1 LC electrospray mass chromatograms of partially purified extract from coral reef fish and authentic compound **2** at *m/z* 75 and 193. Intensity baselines for the fish extract have been offset (600 units for *m/z* 75 and 1500 units for *m/z* 193) to facilitate comparison with chromatograms for authentic compound **2**. LC conditions were: Ionospher C cation-exchange column (3 × 100 mm, 5 μm) from Chrompack; mobile phase was 20 mM aqueous pyridine pH 2.6 (adjusted with HCOOH) mixed with methanol (9 : 1) at 30 °C and flow rate 1.0 mL min^{-1}; 5 μL injection; ions were detected with a G1946A MSD single quadrupole mass spectrometer (Hewlett Packard, Waldbronn, Germany) equipped with an atmospheric pressure ionization (API) LC-MS interface operating at variable fragmentor voltages 70 (*m/z* 193) and 200 V (*m/z* 75).

DOI: 10.1039/b002392m

marked decrease in retention time (cation-exchange) as the pH of the mobile phase was increased, behaviour consistent with a bipolar compound. In the present study, when the chromatography was repeated at pH 4.0, the peaks (*m/z* 75 and 193) for the unknown and for authentic compound **2** both moved to retention time 1.65 min. Characteristic *m/z* fragments for compound **2** were then determined, and the optimal fragmentor voltage was found for the major fragments at *m/z* 120 (Me_3As^+) and 105 (Me_2As^+). LC electrospray MS with variable fragmentor voltages enabling simultaneous detection of the four ions characteristic of compound **2** (*m/z* 75, 105, 120 and 193), was performed on the fish extract, authentic compound **2**, and a co-injected mixture of the two; the mass chromatograms showed coincidence of peaks in all cases (Fig. 2). On the basis of these data, we assigned the new arsenic species from *A. vaigiensis* as trimethyl(2-carboxyethyl)arsonium inner salt **2**. Subsequent HPLC–ICPMS analyses of the sample and authentic material produced data entirely consistent with this assignment.

An unknown cationic arsenic compound (considered to be the same compound) has been reported as a constituent of several certified reference materials[4,5,9] including DORM-2[5] (dogfish muscle tissue from the National Research Council of Canada, Ottawa, Ontario, Canada). LC electrospray MS of an aqueous extract of DORM-2 indicated the presence of compound **2**. However, although the *m/z* 193 molecular species gave a clear signal, the low concentrations of **2** resulted in only a small *m/z* 75 peak. Verification of the new arsenic betaine **2** in DORM-2 was provided by HPLC–ICPMS (a more sensitive technique for determining arsenic ions) by co-chromatography with the authentic standard. The concentration found in this work (0.17 ± 0.05 mg As kg^{-1} dry mass, $n = 3$) is in good agreement with previously published data.[5] Possibly, in future studies on the new arsenic betaine, DORM-2 can serve as a reference sample for those laboratories that do not have access to synthetic material.

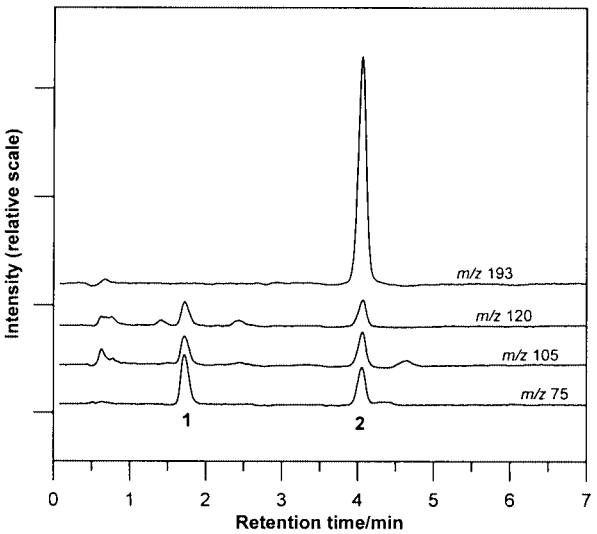

Fig. 2 LC electrospray mass chromatograms of partially purified extract from coral reef fish (5 μL) co-injected with a solution (10 μL) of authentic compound **2** (mixture was 1:1 in terms of concentration of **2**). LC-MS conditions were as described in Fig. 1, except that variable fragmentor voltages were 70 (*m/z* 193), 150 (*m/z* 120, 105), and 200 V (*m/z* 75).

The chromatographic properties of the arsenic betaine **2** match those for the unknown arsenic cation reported in certified reference materials and in a range of marine organisms.[4–9] Consequently, we consider it likely that **2** will prove to be a common constituent of marine animals, in many cases occurring together with arsenobetaine **1**, albeit at much lower concentrations. The presence of the two arsenic betaines **1** and **2** in marine animals offers some insight into the biogenesis of arsenic-containing natural products. A previously proposed pathway[2] suggested that arsenobetaine **1** might be derived from dimethylarsinoylribosides (common metabolites of algae), with the carboxymethyl group of **1** being formed from C4 and C5 of the ribose. Dimethylarsinoylribosides, however, seem less likely to be implicated in the biogenesis of **2** (*i.e.* as a source of the carboxyethyl group) and hence their involvement in the biogenesis of arsenobetaine **1** might also be questioned. A scheme recently proposed by Edmonds[3] may more readily account for the presence of both **1** and **2** in marine organisms. In that scheme, the possible 'arsenylation' of 2-oxo acids by a process analogous to their amination to amino acids was used to explain the origin of several naturally occurring arsenic compounds, including arsenobetaine. The proposed agent for 'arsenylation' was dimethylarsinous acid (Me_2AsOH), the reduced form of the common arsenic metabolite dimethylarsinic acid. Reaction of dimethylarsinous acid with the common 2-oxo compound oxaloacetic acid in the general scheme outlined by Edmonds[3] could give rise to compound **2**.

Identification of other unknown arsenic compounds detected in marine samples will improve our understanding of arsenic-containing natural products. Possibly, these compounds are also arsenic betaines, and structural information might quickly be obtained by mass spectrometric studies (LC–MS and MS/MS) focussing on such compounds.

We thank Jürgen Gailer for synthesising compound **2**, and John Edmonds for making available the contents of ref. 3 before it was published.

Received (in Cambridge, UK) 3rd April 2000, Accepted 17th May 2000

The photooxidation of α-pinene (α-PE) and *trans,trans*-1,4-diphenyl-1,3-butadiene (DPB) sensitized by 9,10-dicyanoanthracene (DCA) in mixed surfactant vesicles was selectively directed toward either the singlet oxygen mediated or the superoxide radical anion mediated products by controlling the status and location of the substrate and sensitizer molecules in the reaction media.

Dye-sensitized photooxidation of alkenes has been extensively investigated.[1] There are two well established types of dye-sensitized photooxidation: an energy-transfer pathway and electron-transfer pathway.[2] The energy-transfer pathway involves energy transfer from the triplet sensitizer to ground-state oxygen to generate singlet oxygen ($^1O_2$) which then reacts with the substrate. In the electron-transfer photosensitized oxidation, electron-deficient sensitizers are generally used. Electron transfer from the alkene to the sensitizer in its excited states results in formation of the alkene radical cation and the sensitizer radical anion, which subsequently reduces O_2 to give the superoxide radical anion ($O_2^{\bullet-}$). The generated superoxide radical anion then reacts with the alkene radical cation to yield the oxidation products. Unfortunately, in many cases the two types of photooxidation occur simultaneously, and the selectivity of the oxidation reactions is poor. Of the various approaches to increase selectivity, use of organized and constrained media has shown considerable promise.[3] Here, we report the photooxidation of α-pinene (α-PE) and *trans,trans*-1,4-diphenyl-1,3-butadiene (DPB) sensitized by 9,10-dicyanoanthracene (DCA) in mixed surfactant vesicles. We found that the oxidation could be directed selectively toward the products derived either from the energy transfer pathway or the electron transfer pathway by controlling the status and location of the substrate and sensitizer molecules in the reaction media.

The vesicles used in the present study were prepared by sonicating an equimolar mixture of a cationic surfactant (octyltrimethylammonium bromide, 8.2×10^{-2} M) and an anionic surfactant (sodium laurate, 8.2×10^{-2} M) in buffered solution (pH = 9.2) for 30 min at 50 °C.[4] These vesicles were found to be stable at room temperature and the dispersion solution was optically clear. The photosensitized oxidation was performed in two modes. In the first (mode 1), the sensitizer DCA was incorporated in the bilayer membrane of one set of vesicles and the substrate solubilized in another set of vesicles. Equal volumes of the two sets of vesicle dispersions were then mixed to prepare the samples for photolysis. Although sonication was performed during preparation of the component solutions, the final mixture was not sonicated. In this way intermixing of the solubilizates was prevented. In the second mode (mode 2) both the sensitizer and the substrate were incorporated in the bilayers of the same set of vesicles. Generally, the concentration of the olefins was *ca.* 1.0×10^{-3} M corresponding to thousands of substrate molecules in each vesicle, while the concentration of the sensitizer was generally *ca.* 1.0×10^{-4} M. The samples were irradiated under oxygen by using light with wavelength $\lambda > 400$ nm, ensuring the absence of direct excitation of the alkene substrate. After irradiation, the products were extracted with CH_2Cl_2 and analysed by gas chromatography. The material balance for all the reactions was generally > 95%.

Photooxidation of α-PE sensitized by DCA in homogeneous solution followed by reduction of the reaction mixture with sodium sulfite solution gave the ene product pinocarveol **1** and the non-ene products myrtenal **2**, epoxide **3** and aldehyde **4**, as shown in Scheme 1. The ene and the non-ene products have been proposed to be derived from the energy- and electron-transfer pathways, respectively.[5] The product distributions in acetonitrile and dichloromethane are given in Table 1. The product distribution of the photosensitized oxidation of α-PE in vesicles is dramatically altered compared with that in homogeneous solutions, and is remarkably dependent on the experimental mode. Photooxidation in mode 1 exclusively produced the ene product **1** (Table 1). In contrast, photooxidation in mode 2 only gave the non-ene products **2**–**4** (Table 1). These observations can be easily understood by consideration of the status and location of the substrate and sensitizer molecules in the reaction media. It has been established that DCA can act both as an energy-transfer sensitizer and an electron-transfer sensitizer.[6] In mode 1, the isolation of α-PE in one set of vesicles from DCA in another set of vesicles prevents them from undergoing electron transfer. Thus, no non-ene products were detected. On the other hand, $^1O_2$ can be generated in the DCA-incorporating vesicles by energy transfer from the triplet excited state of DCA to the ground state of oxygen. The species $^1O_2$ is small and uncharged and has a relatively long lifetime and properties which allow it to diffuse freely from one set of vesicles to another set of vesicles where reaction with the

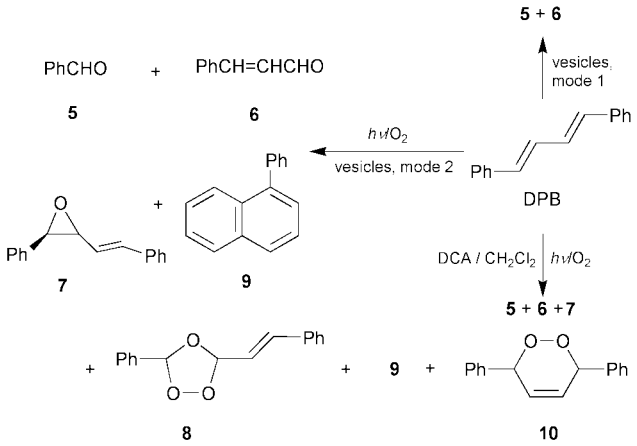

Scheme 2

olefins produces the ene product **1**. In mode 2, the DCA molecule is surrounded by a number of α-PE molecules. The high "local concentration" of α-PE and the close contact between DCA and α-PE molecules in the confined bilayer of vesicles leads to efficient quenching of the singlet excited state of DCA by α-PE *via* an electron-transfer process, generating DCA radical anions and α-PE radical cations. As a result, intersystem crossing from the singlet excited state to the triplet state of DCA can not compete with the quenching process by α-PE. Thus, subsequent triplet energy transfer to O_2 can not occur, and no singlet oxygen mediated product is produced. On the other hand, the generated DCA radical anions will efficiently undergo electron transfer to oxygen to produce superoxide radical anions, which subsequently react with α-PE radical cations located in the same vesicle to yield the non-ene products **2**–**4**.

Photosensitized oxidation of DPB in homogeneous solution has been extensively investigated.[5,7] Irradiation of an oxygen-saturated DPB solution in CH_2Cl_2 containing DCA with visible light gave benzaldehyde **5**, cinnamaldehyde **6**, epoxide **7**, ozonide **8**, 1-phenylnaphthalene **9** and endoperoxide **10** (Scheme 2) and the product distribution is shown in Table 1. **10** is a product of 1,4-cycloaddition of singlet oxygen ($^1O_2$) to DPB. Products **7**–**9** are derived from the electron-transfer pathway. Products **5** and **6** could be produced either *via* an energy- or electron-transfer pathway.[6] The photosensitized oxidation of DPB in vesicles in mode 1 gave **5** and **6** as the unique products (Table 1 and Scheme 2). We believe that these products are derived from the singlet oxygen pathway. In contrast, the photosensitized oxidation of DPB in vesicles in mode 2 only produced the electron-transfer mediated products **5**–**7** and **9** (Table 1) and no singlet oxygen products were detected. These observations demonstrate once again that the selectivity in photosensitized oxidation of alkenes can be directed by incorporation of the sensitizer and substrate in different or the same set of vesicles.

It is of note that the products in the reaction of DPB with singlet oxygen in vesicles are remarkably different from those in homogeneous solutions. The reaction in homogeneous solution yielded endoperoxide **10**, a 1,4-cycloaddition product of the diene to $^1O_2$, as the unique product (Scheme 2). In sharp contrast, the photosensitized oxidation in vesicles produced benzaldehyde **5** and cinnamaldehyde **6** in quantitative yield. Evidently, these products were derived from an intermediate dioxetane, a 1,2-cycloaddition product. It has been established that DPB in solution exists mainly in its transoid conformer,[7] and the cisoid form amounts to *ca.* 1%. The 1,4-cycloaddition of singlet oxygen to the 1,3-diene to form the endoperoxide is concerted and requires a six-membered ring transition state; only the cisoid conformer can satisfy such a requirement. Obviously, the organized semirigid environment in vesicles prevents DPB from undergoing transoid to cisoid conformational change and thus only the 1,2-cycloaddition products were obtained.

In conclusion, vesicles can be used to direct the photosensitized oxidation of olefins either toward the singlet oxygen mediated or the superoxide radical anion mediated products by controlling the status and location of the olefin and sensitizer molecules in the reaction media.

Received (in Liverpool, UK) 24th February 2000, Accepted 10th May 2000

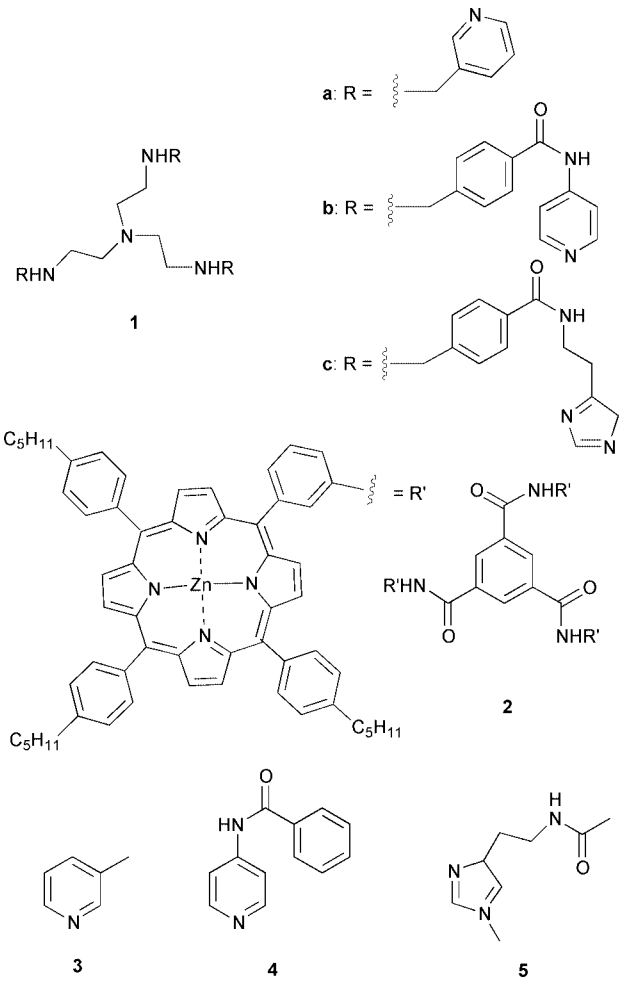
A series of tris(2-aminoethyl)amine (TREN) derivatives functionalized on the arms with pyridine or methylimidazole ligands bind very strongly to a trisporphyrin derivative *via* apical coordination, with formation of molecular cages; the strength of the binding (K_b up to $10^{8.8}$ mol^{-1} dm^3) depends on the structure of the TREN derivative as well as on its coordination to Zn(II).

The self assembly of proteins to elicit new and unique functions is a common feature in the biological world.[1] A case in point is HIV-1 protease, whose activity is dependent on a hydrogen bond-driven dimerization of two protein units.[2] The possibility of realizing molecules of controlled geometry and shape in the laboratory by assembling easily synthesized subunits is an appealing goal which is attracting enormous interest, demonstrated by the continuous flow of contributions appearing in the chemical literature.[3] Such 'supermolecules' may find useful application in molecular recognition and selective substrate transformation, sensing, signal transduction and, eventually, in the realization of miniaturized nanostructures. Metal–ligand coordination is one of the driving forces exploited for the assembly of these structures.[4] Examples are provided by the work of the Stang,[5] Fujita,[6] Hamilton,[7] Sauvage,[8] and Lehn[9] groups. Self-assembling porphyrin oligomers towards macrocycles or polymers have been reported by Hunter *et al.*,[10] while Tabushi and coworkers, as early as 1985,[11] elegantly demonstrated allosteric binding to a Zinc-gable porphyrin.

We report here on the formation of molecular cages driven by apical coordination of the terminal bases of tripodal ligands **1a**–**c** to the three zinc porphyrin units of **2**. The possibility of modifying the conformation of the tris(2-aminoethyl)amine (TREN) platform of derivatives **1a**–**c** *via* metal coordination gives the system a tunable geometry for controlling the binding to **2**.

Ligand **1a** was readily obtained by reaction of 3-pyridinaldehyde with TREN followed by reduction with $NaBH_4$. Ligands **1b**,**c** were prepared *via* condensation of TREN with the 4-formylbenzenamide derivatives, obtained by reaction of 4-formylbenzoyl chloride with 4-aminopyridine (**1b**) or methylhystamine (**1c**), followed by reduction with $NaBH_4$.† The trisporphyrin derivative **2** was prepared by coupling 1,3,5-benzene tricarbonyl trichloride with the corresponding aminoporphyrin,[12] followed by metallation with zinc acetate.† Porphyrin **2**, as well as the free bases **1a**–**c**, are soluble in chlorinated organic solvents. The solubility of the 1:1 Zn(II) complexes of the TREN derivatives in these solvents depends on the nature of the counterions: more hydrophilic nitrates are insoluble, while more lipophilic hexafluorophosphates are freely soluble in these media.

Trisporphyrin **2** shows a typical UV–vis spectrum, with maxima at 420 nm (ε = 430,000 mol^{-1} dm^3 cm^{-1}) and 550 nm (ε = 37,000 mol^{-1} dm^3 cm^{-1}), indicating that there is no intramolecular interaction between the porphyrins. Binding of an apical ligand causes a shift of these peaks to 430 and 565 nm, respectively. The very intense absorptions in the 420–430 nm region can be used for determination of the affinity constant with apical ligands and, in the present case, for the formation of cage complexes between **2** and **1**. Fig. 1 shows the changes in the absorption spectrum of **2** upon addition of increasing amounts of **1a** in CH_2Cl_2. The presence of a well-defined isosbestic point is suggestive of the formation of a single complex, and the fact that all the zinc porphyrin sites are fully complexed after the addition of one equivalent of ligand implies that a 1:1 cage complex has been formed. The complex so formed does not convert into species of different stoichiometry in the presence of up to a twofold excess of the TREN derivative, contrary to recent observations for a bisporphyrin receptor in the presence of multiarmed amines.[13] Clearly, a key role is played here by the complementary structure of the two subunits involved in the formation of the supramolecular cage complex. Analysis of the absorbance *vs.* concentration data‡ leads to a well-behaved complexation curve (Fig. 1, inset) which gives a very high binding constant (log K_b = 8.81) for the 1:1 complex. Similar curves were obtained for tripodal ligands **1b**,**c** and **1a**,**b**–Zn(II) complexes.



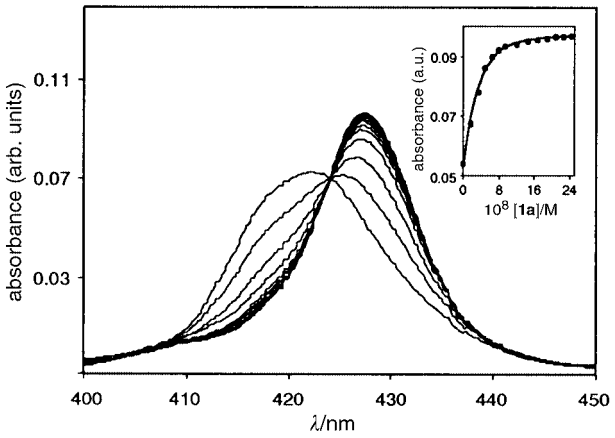


Fig. 1 Change in the absorbance of a 60 μM solution of **2** in CH_2Cl_2 upon addition of **1a**. Inset: binding isotherm of the data at 427 nm. The solid line represents the computer-generated best fit for a 1:1 complex.

The titration data are summarized in Table 1, along with the values determined for model ligands **3**–**5**. The values of the parameters EM and β are also listed in the table. EM§ corresponds to the ratio $\{(K_b)_{cage}/[(K_b)_{model}]^3\}^{0.5}$ and is the effective molarity for the intramolecular cyclizations required to form the cage. β[14] is simply the ratio $(K_b)_{cage}/(K_b)_{model}$ and gives an indication of the absolute strength of binding associated with the formation of the cage, with respect to the single apical coordination of the model compound to one porphyrin. Inspection of Table 1 reveals that tripodal ligand **1a** shows the highest binding constant to **2**, which reduces 30-fold upon Zn(II) binding to TREN. In the case of **1b**, the binding constant is lower and coordination of Zn(II) to TREN does not induce any significant change. Allowing for the stronger binding interaction of methylimidazole to the Zn-porphyrin (compared with pyridine), the least effective ligand is **1c**, with EM and β values significantly lower than those of **1a** and **1b**. The β values indicate that cooperative binding of the tripodal ligands to the three porphyrins leads to a higher affinity than single apical ligands (up to five orders of magnitude in the case of **1a**). Inspection of molecular models reveals that, in the case of **1b**, the length of the tripodal arms and their flexibility is such that coordination of Zn(II) does not significantly affect their binding geometry. However, this flexibility reduces the strength of binding with respect to **1a**, due to the freezing out of conformational mobility on complexation.[14] The disadvantage of flexibility is further evidenced by the relatively low values of EM and β for **1c**, which has even longer arms. For **1a**, the length of the arms¶ is such that apical binding to the porphyrins requires the latter to move out of the plane of the central benzene by rotation around the amide bonds pointing inwards (Fig. 2). Complexation of Zn(II) to the TREN platform further reduces the distance between the three pyridine nitrogens,

Table 1 Binding constants of trisporphyrin **2** to tripodal ligands **1a–c** and model ligands **3–5** in CH_2Cl_2[a] at 25 °C

Ligand	log K_b[b]	EM[c]	β[c]
3[d]	3.75 ± 0.02	—	—
1a	8.81 ± 0.07	6.0×10^{-2}	1.1×10^5
1a·Zn	7.36 ± 0.05	1.1×10^{-2}	4.1×10^3
4[d]	3.98 ± 0.03	—	—
1b	7.75 ± 0.09	8.0×10^{-3}	5.9×10^3
1b·Zn	7.64 ± 0.05	7.1×10^{-3}	4.6×10^3
5[d]	5.37 ± 0.07	—	—
1c[e]	7.50 ± 0.09	5.0×10^{-5}	1.3×10^2

[a] In the presence of 1% CH_3CN. [b] Binding constant are expressed in mol^{-1} dm^3. [c] See the text for the definition of EM and β. The units of EM are mol dm^{-3}, and β is dimensionless. [d] Binding constants of the model ligands are the microscopic values determined assuming independent binding to each porphyrin of **2**. [e] The binding of **1c**·Zn(II) to **2** does not follow a well behaved isotherm; for this reason it has been omitted.

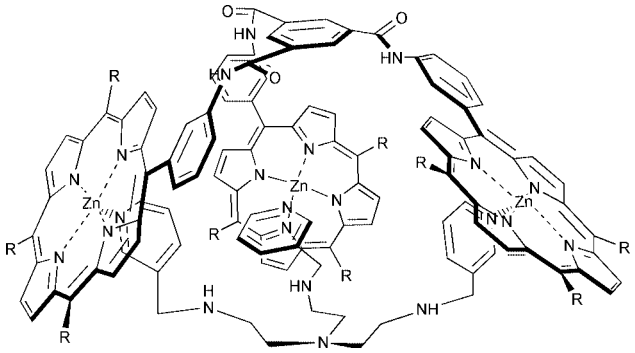

Fig. 2 Schematic diagram of the molecular cage formed by binding of **1a** to **2**.

imposing a more stringent geometric constraint for binding, resulting in a smaller binding constant.

In conclusion, we have shown that tripodal molecules, based on complementary porphyrins and pyridine or imidazole ligands, give highly symmetrical molecular cages with very strong binding constants which are potentially suitable for molecular recognition and selective transformation of substrates trapped in the cavity: work aimed at this goal is ongoing in our laboratories.

Notes and references

† All new compounds gave the expected ^{1}H- and ^{13}C-NMR spectra and the correct elemental analyses (C, H, N).

‡ The binding isotherm was fitted using the program HOSTEST II. See: C. S. Wilcox, in *Frontiers in Supramolecular Organic Chemistry and Photochemistry*, H.-J. Schneider and H. Dürr, VCH, Weinheim, 1991.

§ In the cage formation the first binding is intermolecular (K), the second binding is intramolecular ($EM_1 \times K$) and the third binding is also intramolecular ($EM_2 \times K$). Thus, the overall observed binding constant is $EM_1 \times EM_2 \times K^3$. Assuming that $EM_1 = EM_2$, the effective molarity is the square root of the product $EM_1 \times EM_2$.

¶ Energy minimization with the HyperChem program (Hyperchem 2 for Windows, © 1991, Hypercube Inc. and Autodesk Inc.) indicates that two Zn(II) ions in the porphyrin derivative **2** are *ca.* 20 Å apart when the molecule is flat. The distance between two pyridine nitrogens of **1a** is, in the fully stretched conformation, *ca.* 15 Å.

Möbius aromatics arising from a C=C=C ring component†

Sonsoles Martín-Santamaría, Balasundaram Lavan and Henry S. Rzepa*

Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY. E-mail: h.rzepa@ic.ac.uk

Received (in Cambridge, UK) 28th March 2000, Accepted 2nd May 2000

Replacement of one planar C=C unit in Hückel 4*n* + 2 aromatic rings by a twisted C=C=C results in chiral 4*n* π Möbius aromatic rings.

The history of aromatic chemistry is dominated by the concept of planar ring systems containing $4n + 2$ conjugated π electrons, the so-called Hückel rule of aromaticity. Heilbronner[1] in 1964 was the first to suggest that applying a Möbius twist to the ring would create an aromatic species if $4n$ π electrons were conjugated. The Möbius concept has been widely applied to considering the aromaticity of pericyclic transition[2] states, but only recently have candidates for stable Möbius aromatics been suggested. Schleyer and coworkers have reported that a Möbius twisted conformation of the $4n$ π system $C_9H_9^+$ is aromatic[3] on the basis of calculated nucleus independent chemical shifts (NICS),[2] a technique which appears reliable and useful at quantifying aromaticity. We recently reported calculations on two conformations of [16]annulene,[4] one being conventionally antiaromatic, but the other having a pronounced Möbius-like twist not associated with any particular region of the ring. This isomer exhibited a NICS value consistent with mild aromaticity rather than antiaromaticity. Here we suggest further candidates for consideration as Möbius aromatics.

Our initial focus was on the chiral species cycloheptatetraene **5**. The presence of a C=C=C substructure in the 7-membered ring reduces the dihedral angle between the 1,3 allene substituents from 90 to 47–50°, which has the effect of breaking the degeneracy of the two highest occupied allene orbitals (Fig. 1; see ESI†). Interaction of both resulting orbitals with the remaining ring π orbitals would create a similar Möbius topology to that envisaged by Heilbronner, the specific case of **5** resulting in what could be termed a [7]Möbius annulene. A NICS calculation (−6.5 ppm, Table 1) establishes that this orbital interaction results in a mildly aromatic system, being rather less so than benzene itself (NICS −10 ppm). NICS calculations on benzannulated derivatives of **5** were reported[5] but the aromaticity of the allene-derived ring was not discussed. The ~40° distortion at the allene unit in **5** is clearly destabilising, since the species is isolable only at low temperatures, dimerising at higher temperatures *via* a $\pi^2 + \pi^2$ cycloaddition (a process known to be inhibited by bulky groups at the 1,3 positions[6]). The calculated bond lengths for **5** also show some alternation, indicative of a reactive species (Fig. 2). The HOMO and HOMO − 1 AM1 orbits computed for **5** are both symmetric with respect to C_2 axis and derive from the twisted allene system, but are now delocalised over the entire ring, and show Möbius topology (Fig. 2). Heilbronner predicted the HOMO for a pure Möbius aromatic would exhibit degeneracy,[1] but purely in a Hückel MO context. No degenerate representations in C_2 symmetry are necessary in **5**, although we do note that the energy difference between HOMO and HOMO − 1 (1.6eV/AM1) is less than that for allene at this twist angle (2.2 eV, Fig. 1†).

As a ligand, **5** is unusual in binding metals to both 'faces' concurrently (*e.g.* **7**),[7] but this is perhaps not unexpected if one considers it having only a single π-face! We also estimate one consequence of **5** (and its metal complexes) being chiral. Thus a typical model chiral auxilliary (*e.g.* R = CHClI or R = camphorsultamil[8]) results in diastereoisomers differing in energy by about 0.4–0.6 kcal mol^{-1} (AM1), a relatively small discrimination, but possibly one capable of being increased by suitable design. **5** interconverts with its mirror image *via* the Hückel $4n + 2$ π aromatic **6** (cycloheptatrienylidene),[9] which at the correlated level (CASPT2) has recently been shown to be the transition state for this process (barrier ~20 kcal mol^{-1}).

Elaborating the theme of substituting C=C=C for C=C (Table 1) we noted that the small ring systems **1** and **2** would be classified as antiaromatic; **2** as a conventional 4π antiaromatic Hückel system with a triplet ground state and **1** as a $4n + 2$ 6π Möbius antiaromatic system. **1** appears not to exist as a minimum at the *ab initio* RHF level, whilst singlet **2** reveals an antiaromatic (positive) NICS value. No minimum for the anion **3** could be located for this putative 8π Möbius aromatic, all optimisations resulting in the aromatic Hückel valence bond isomer **4**, probably because twisting the allene component in **3** to accommodate a 6-membered ring requires too much energy. This is a lesser problem in the larger ring monocation **8**, which appears to be a C_2 symmetric 8π Möbius system exhibiting NICS aromaticity, as is the 8π dication **9**. The singlet neutral form of **9**/**11** as an antiaromatic $4n + 2$ 10π annulene distorts to remove all symmetry and localise the bonds, whereas the triplet neutral **9**/**10** retains C_2 symmetry as might be expected of a $4n + 2$ excited state Möbius aromatic, although the NICS value shows only slight aromaticity (−1.3 ppm).[10] Chiral 12π monoanion **10** and the dianion **11** also show aromatic NICS values and have non-planar twisted geometries (Table 1). Each ring of the chiral bicyclic analogue of naphthalene **12** shows only modestly aromatic NICS values. In this instance, the carbene valence bond isomer **13**, a bridged [10] $4n + 2$ Hückel aromatic annulene, is substantially lower in energy, making it unlikely that **12** is a viable synthetic target. System **14** is derived from the novel Hückel-aromatic S/N systems discovered by Rees and Surtees.[11] As an 8π Möbius, **14** has an aromatic NICS value (Table 1). The 12π system **15** has a much smaller NICS value, which might be related to the larger dihedral angle at the allene termini (75°, Table 1) reducing the Möbius like orbital mixing (*c.f.* Fig. 1†). Our results do imply that optimum Möbius aromaticity may be achieved at allene twists of ~30–60°.

The presence of two or more allene-like chiral Möbius components raises the possibility that these can oppose or cooperate. An even number of the former becomes equivalent to Hückel; but if the latter the topological implications become more complex. For **17** two conformations can indeed be located, one with C_S (Hückel) and the other with C_2 (Möbius) symmetry, the latter being lower in energy and higher in aromaticity (Table 1). In the 10π Hückel aromatic conformation of the alkyne **17**, the triple bond appears to act purely as a two electron contributor whereas in the C_2 form, a possible four-electron alkyne contribution results in 12π Möbius aromaticity. The alkene analogue **18** has smaller NICS aromaticity values and relative energies, due in part to the significant non-planarity of **18**. More intriguingly the higher aromaticity of **17** may be due

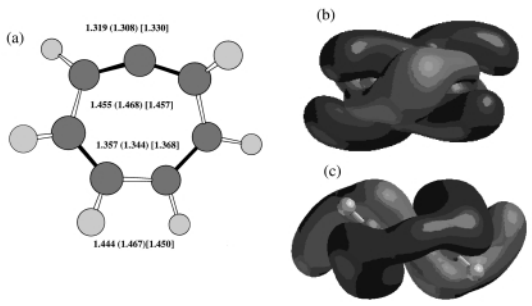

Fig. 2 Calculated geometry (a) (Å, AM1 (RHF-6-31G(d)) [B3LYP/6-31G(d)] and form of the AM1 HOMO (b) and HOMO − 1 (c) orbitals for **5**.

to in-plane trannulene like aromaticity.[12] The alkyne in **16** appears to act as a Möbius contributor, cooperating with the allene component to give a modestly aromatic 12π system. The isomers **19** and **20** also have two conformations. Hückel **19** as an 8 or 12π 4*n* antiaromatic has the expected positive NICS value, whilst C_2 symmetric **19** is slightly Möbius aromatic. Compared to **19**, isomers **20** show reversed NICS values (Table 1), and may be indicative of more complex topological contributions to the aromaticity. A single Möbius component inserted into *e.g.* [14]trannulene **21** appears much less aromatic than the trannulene itself (Table 1), but it does conform to a 4*n* rather than a 4*n* + 2 rule for aromaticity. Finally we note that C_2 symmetric **22** has three allene contributions and as a 12π system it would be expected to be Möbius aromatic. Two isomers were identified, one with C_2 and a lower energy and more aromatic form with C_3 symmetry in which all three allene units cooperate.

We conclude that a diverse range of Möbius 4*n* π aromatic systems can be constructed by using one or more twisted allene fragments as an initiator. The origins of the Möbius and Hückel contributions to the aromaticity and the nominal electron contributions (4*n* *vs.* 4*n* + 2) of these systems may be quite subtle. A dissection of these origins will be reported in a future article.

Molecular anatomy of RNA polymerase using protein-conjugated metal probes with nuclease and protease activities

Akira Ishihama

National Institute of Genetics, Department of Molecular Genetics, Mishima, Shizuoka 411-8540, Japan. E-mail: aishaham@lab.nig.ac.jp

Received (in Cambridge, UK) 20th October 1999, Accepted 2nd February 2000
Published on the Web 1st March 2000

Iron (*S*)-1-(*p*-bromoacetamidobenzyl)ethylenediaminetetraacetate (FeBABE) with the sequence-non-specific cleavage activity of nucleic acids and proteins was conjugated to protein Cys residues, and used for mapping the contact sites of both the α-subunit carboxy-terminal domain of *Escherichia coli* RNA polymerase on promoter UP elements and the σ^{70} and σ^{38} subunits on the respective promoters. The same chemical nuclease was also used as a chemical protease for mapping the subunit–subunit contact sites within the RNA polymerase. By using 2-iminothiolane as a linker, FeBABE could be conjugated to protein Lys residues and successfully used for mapping the contact surfaces of some *E. coli* transcription factors on the RNA polymerase holoenzyme.

Most of the biological reactions involved in transfer of genetic information such as replication, transcription and translation are carried out by macromolecular complexes consisting of a large number of proteins and nucleic acids. Regulation of these processes is mediated by rearrangements of protein–DNA, protein–RNA and protein–protein interactions. For instance, the transcription apparatus is composed of the DNA-dependent RNA polymerase, which consists of 4–5 (in the case of prokaryotes) to 12–18 subunits (in the case of eukaryotes), and hundreds of accessory transcription factors. Identification of the protein–DNA, protein–RNA and protein–protein contact networks within the transcription apparatus is crucial for understanding the molecular events carried out in transcription and its regulation. In order to meet the increasing demand for technical innovation for the molecular anatomy of these multi-component assemblies, a variety of new physical, chemical and genetic methods have been developed recently.

Akira Ishihama is Head of the Department of Molecular Genetics, National Institute of Genetics, Mishima, Japan. He obtained his PhD at Nagoya University in 1967, and subsequently worked with Jerard Hurwitz at the Albert Einstein College of Medicine, New York, on the structure–function relationship of bacterial RNA polymerase. He then returned to the Kyoto University Institute for Virus Research in 1970, and worked with the reconstitution of RNA polymerase. In Kyoto, he also began studying the molecular anatomy of viral RNA polymerases. In 1984, he moved to the National Institute of Genetics, and has contributed to the development of the novel research concerned with the molecular interaction between RNA polymerase and transcription factors. In Mishima, he also began studying the molecular anatomy of RNA polymerase II from the fission yeast. His current research interests include the functional modulation of RNA polymerases through protein–DNA, protein–RNA and protein–protein interactions.

Use of metals for cleavage of nucleic acids and proteins

Transition metals are known to catalyze a number of oxidative chemical reactions with deleterious effects in biological systems.[1–5] Iron promotes the formation of reactive radicals such as hydroxyl radicals, which indiscriminately damage all cellular components, even though iron is an indispensable element and the most abundant metal for living organisms. The high reactivities of iron have been put into practical use to explore the properties of macromolecular complexes.[6–11]

Initially free Fe^{2+} or FeEDTA was used to study the conformation of nucleic acids and their complexes.[12–18] The potential value of such reagents for protein mapping was first recognized by using untethered free FeEDTA, and a number of different approaches have been developed to use the metal complexes to map the overall surface of proteins.[19–21] Such methods are often called 'protein footprinting'. The broad specificity of hydroxyl radicals for attack at the backbones of nucleic acids and proteins permitted probing of nearly all the nucleotides and amino acids. FeEDTA complex offers the most general measure of surface accessibility, because its distribution around the target molecule is insensitive to charge, compared with free Fe^{2+}.[4]

The inception and development of methods for site-specific cleavage of nucleic acids and proteins with FeEDTA have led to development of artificial reagents with nucleolytic and proteolytic activities. Various attempts have been made to conjugate FeEDTA to proteins for monitoring of proximity mapping. For this purpose, bifunctional chelating agents were considered as linkers which possess both a strong metal-binding moiety and a group that binds to a biological molecule.[22] Applications of Cys-linked FeEDTA complexes have exploited oxidative chemistry to cut DNA[23] or RNA.[24,25] Most of these procedures are based on the high reactivity of H_2O_2 or O_2 and iron, which depends on the nature of the iron chelate involved.[4,26] For oxidative scission of nucleic acids, the generation of electrophilic species such as hydroxyl radicals is important.[14–16]

Likewise the artificial non-enzyme proteases have been developed in many laboratories.[27–29] It is essential that the protein cutting is only due to the tethered reagent and not to unchelated metal coordinated directly to sites on the protein. Protein-conjugated small metal chelates were shown to cleave polypeptide chains at sites determined by proximity to the chelates, apparently independent of the amino acid residues involved.[10,11,30] The net reaction involves hydrolysis, but not oxidation, of the peptide backbone. The peptide cleavage results from generation of a powerful nucleophile that selectively attacks peptide carbon rather than hydroxyl radicals.[31] The hydrolysis of protein backbones appears to be dominated by nucleophilic iron-peroxo complexes.[31] In the presence of H_2O_2

or O_2 and ascorbate, FeEDTA forms an intermediate oxygen-activated complex that leads to nucleophilic attack by oxygen on the carbonyl carbon of the peptide bond. The reactivities of nucleophiles, $HO–O^-$ and $CH_3O–O^-$, toward carboxylic esters are 100 times higher than hydroxide.

Development of chemical nucleases and proteases

A sulfhydryl-specific EDTA derivative, EDTA-2-aminoethyl 2-pyridyl disulfide (EPD) was developed to tether FeEDTA to protein Cys residues[32] and used for mapping the resolvase-binding site on DNA[23] and the binding sites of some RNA-binding proteins.[33] The newly developed method allowed the identification of regions or surfaces of proteins that are in close proximity to DNA or RNA, and of the portions of DNA or RNA that are closest to each EDTA-derivatized Cys, because the DNA cleavages are highly localized and their efficiency drops rapidly as a function of the distance between the Fe^{2+}EDTA complex and the DNA targets. EPD-Fe has also been applied for analysis of the protein–protein contact network within the non-native equilibrium protein folding intermediate.[32] Cys-linked FeEDTA chelates have since been used to study non-native conformation of Staphylococcal nuclease during folding of the protein.[14,32]

To avoid the need to add iron after conjugation of such metal-chelating reagents as EPD to target molecules, an iron-bound probe, iron (*S*)-1-(*p*-bromoacetamidobenzyl)ethylenediaminetetraacetate (FeBABE) was developed (Fig. 1),[29,34] which can

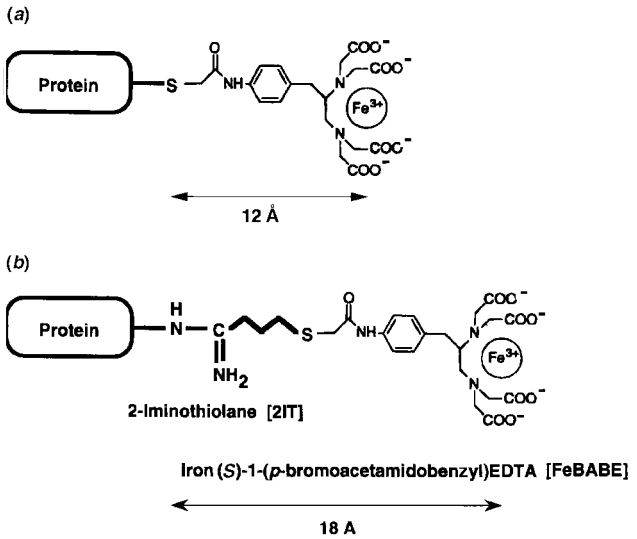

Fig. 1 Chemical probes with nuclease and protease activities. (*a*) Iron (*S*)-1-(*p*-bromoacetamidobenzyl)EDTA [FeBABE] can be conjugated to protein Cys residues.[29] (*b*) FeBABE in combination with 2-iminothiolane (2IT) can be conjugated to protein Lys residues.[53]

be handled in a manner analogous to many other protein-labeling reagents, such as fluorescent probes or cross-linkers. FeBABE can be tethered to proteins preferentially at Cys residues. Protein–FeBABE conjugates are formed under mild reaction conditions and are stable for long periods in the absence of activating reagents. Activation of the chelate iron is accomplished by a brief exposure, for instance for about 10 s, to H_2O_2 in the presence of ascorbate. This generates a highly reactive hydroxyl radical which induces cleavage of the backbones of DNA and RNA. In the presence of H_2O_2 and ascorbate, FeBABE forms an intermediate oxygen-activated complex which leads to nucleophilic attack by oxygen on the carbonyl carbon of the protein peptide bond and causes peptide hydrolysis.[31]

The chemistry of FeBABE was characterized by using proteins of known sequence or structure.[10,11,31] Since direct contact is required between FeBABE and the carbonyl carbon for protein cleavage to take place, the reaction is limited to peptide bonds that are within about 12 Å of the site of attachment of FeBABE (see Fig. 1). Because of this distance limitation and the required orientation for nucleophilic attack on the peptide carbon, it is expected that the number of cleaved sites will be relatively small. Using the human carbonic anhydrase as a model substrate, the efficiency of cleavage was estimated by measuring the cleaved fragments, as determined by the N-terminal sequences, to be 50–70%, indicating most of the cleavage was the hydrolysis of a peptide bond.[31] The high yield of products provides sufficient cleaved materials for sequence analysis. FeBABE is a powerful probe of protein structure, usable with relative ease in any system where Cys-linked reagents are applicable. The cleavage reaction is fast, highly selective, and proceeds in high yield under physiologial conditions. It forms hydrolytic products that are readily characterized by standard N-terminal sequencing of the resolved peptides. The results provide direct information on the proximity of the tethered probe to particular peptide bonds regardless of amino acid residue type, easily exceeding the scope and resolution of chemical cross-linking reagents.

Mapping of RNA polymerase contact sites on promoter DNA

FeBABE has been successfully used for the mapping of protein-bound sequences on DNA and RNA. In particular, a systematic search has been carried out in two cases: the RNA polymerase-contact sites on promoter DNA[35–39] and ribosomal protein-binding sites on rRNA.[40–44] The contact sites of proteins on DNA or RNA can be easily identified from the terminal sequences of fragments generated after cleavage with Fe-BABE.

The RNA polymerase core enzyme of *Escherichia coli* is composed of two α-subunits and one each of the β- and β′-subunits. The carboxy (C)-terminal domain (CTD; amino acid residues 234–329) of the RNA polymerase α-subunit plays a key role in molecular communications with class-I transcription factors and upstream (UP) elements of promoter DNA.[45,46] In order to identify possible differences in the functional roles of the two α-subunits, we established an *in vitro* reconstitution system of hybrid RNA polymerases containing two distinct α-subunit derivatives in a defined orientation.[35] In order to identify the binding sites of two αCTDs on the UP element DNA, a mutant α-subunit without a Cys residue was prepared, from which a number of α-derivatives with a single Cys residue at various positions along the CTD were constructed. After conjugation of FeBABE to the single-Cys mutant α-subunits, each was used, together with untethered wild-type α, for reconstitution of hybrid RNA polymerases containing one intact and one FeBABE-tethered mutant α-subunit. The reconstituted RNA polymerases were used for formation of promoter DNA complexes with or without a UP element, and the complexes were subjected to hydroxyl radical-based DNA cleavage mediated by FeBABE for identification of the contact DNA sequence of each αCTD. In the case of the P1 promoter of *E. coli* ribosomal RNA gene (*rrnB*) promoter, the two α-subunits were found to bind in tandem to two helix turns of the UP element, the β- and β′-associated α-subunits being bound to the promoter proximal and distal regions, respectively (Fig. 2).

The RNA polymerase σ-subunit is responsible for sequence recognition of DNA promoters, and in general bacteria contain multiple molecular species of the σ-subunit, each recognizing a specific set of promoter sequences. For instance, *E. coli* contains seven different σ-subunits.[47] The σ family proteins carry four regions of the conserved sequence. The contact-dependent DNA cleavage method was then applied for mapping spacial relations between the evolutionary conserved regions of various σ-subunits and each DNA strand along the respective promoter DNA. The library of single Cys mutants has been

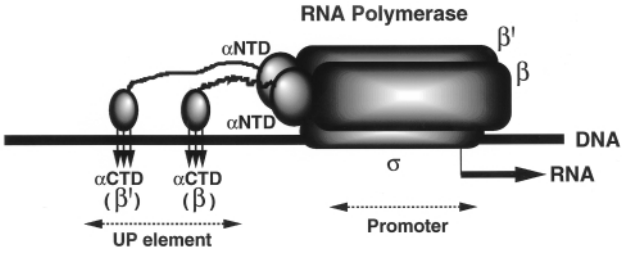

Fig. 2 Identification of the contact sites of RNA polymerase α-subunit on promoter UP element. FeBABE was conjugated at a single Cys residue (position 269) on the UP element contact surface of the α-subunit C-terminal domain (CTD). The reconstituted RNA polymerase holoenzyme containing the FeBABE-tethered α-subunits was used for mapping of the αCTD contact sites on the UP element of the *E. coli* ribosomal RNA (*rrnB*) gene, after sequencing the DNA cleavage sites by hydroxyl radical generated from the protein-tethered FeBABE upon addition of H_2O_2 and ascorbate.[35] The cleavage sites are shown by arrows.

constructed for σ^{70} (the σ major subunit for transcription of growth-related genes) and σ^{38} (the σ-subunit for stationary-phase genes). Results of the DNA cleavage mapping of open complexes using FeBABE-conjugated σ-subunits indicated that each conserved region of both σ^{70} and σ^{38} makes contact with different regions along the promoter DNA (Fig. 3).[37–39] The

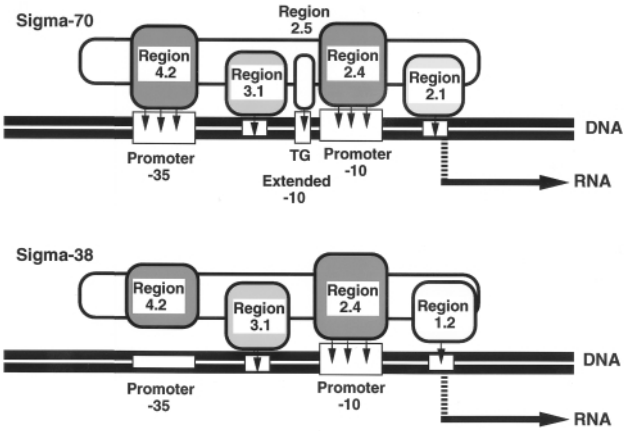

Fig. 3 Identification of the contact sites of RNA polymerase σ-subunits on promoters. FeBABE was conjugated at a single Cys residue located at various positions of single-Cys mutant σ^{70} and σ^{38} subunits of the *E. coli* RNA polymerase. The reconstituted RNA polymerase holoenzymes containing the FeBABE-tethered σ-subunits were used for mapping of the σ-subunit contact sites on the respective promoters, after sequencing the DNA cleavage sites by hydroxyl radical generated from the protein-tethered FeBABE upon addition of H_2O_2 and ascorbate.[37–39] The cleavage sites are shown by arrows. The σ family proteins contain four conserved regions. The regions 2, 3 and 4 are composed of 4, 2 and 2 subregions, respectively. In the case of the major σ^{70} subunit, the region 2.4 is involved in promoter -10 recognition while the region 4.2 recognizes the promoter -35 sequence.

results agreed well with the prediction from mutant studies of essential roles for two hexanucleotide sequences located at promoter -35 and -10. In addition, the determination of direct contact sites by the novel method revealed hitherto unidentified contacts involving sequences other than the -35 and -10 sequences. The comparison of promoter cleavage mapping by σ-conjugated FeBABE also revealed different modes of promoter DNA interaction between different σ-subunits.

Mapping of subunit-subunit contact sites within RNA polymerase

Proximity relationships between the two α-subunits of *E. coli* RNA polymerase were studied using a set of single Cys mutant α-subunits, each harboring a single Cys at various positions along the entire α polypeptide (Fig. 4). FeBABE conjugated to each of these Cys residues introduced both intramolecular and intermolecular cutting of the α-subunit in the presence of

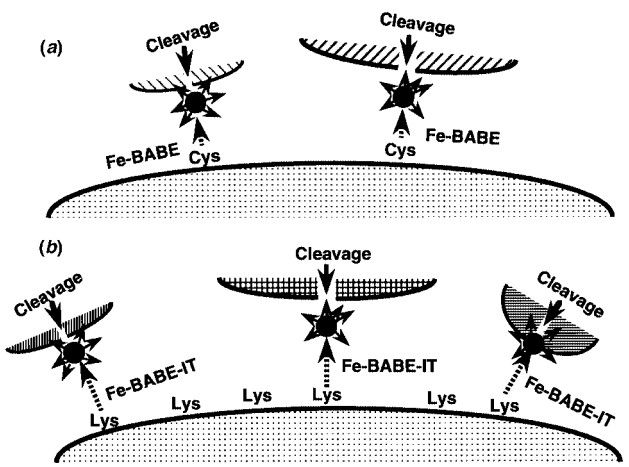

Fig. 4 Contact-dependent cleavage of proteins by the protein-conjugated FeBABE. (*a*) FeBABE can be conjugated to specific Cys residues of proteins (see Fig. 1). The polypeptide backbone of proteins, which are located near the protein-tethered FeBABE, is cleaved in the presence of ascorbate and H_2O_2. The protein–protein contact sites can be identified by tethering FeBABE at specific sites of the proteins using single Cys mutants. (*b*) FeBABE can also be conjugated to Lys residues using 2-iminothiolane (2-IT) as a linker (see Fig. 1). Lys is often involved in protein functions and exposed on protein surfaces. For mapping of protein–protein contact networks, mixtures of FeBABE-tethered proteins, each carrying a single FeBABE conjugation on average at one Lys residue, can be used for the peptide cleavage reaction after addition of H_2O_2 and ascorbate.

ascorbate and H_2O_2.[48] The intramolecular cutting was observed only within an individual N- or C-terminal domain, in agreement with the structural organization of α-subunits.[45,46] From the intermolecular cleavage mapping, the N-terminal assembly domains of two α-subunits were found to be assembled in an antiparallel fashion (Fig. 5).

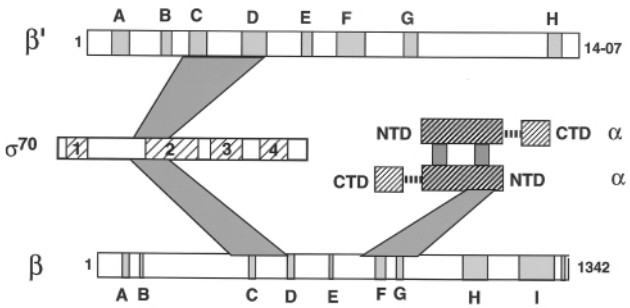

Fig. 5 Subunit–subunit contact sites within the RNA polymerase. FeBABE was conjugated at various positions of the α- or σ-subunits using collections of the respective single Cys mutant derivatives. The contact surfaces of these two small subunits on the two large subunits, β and β′, of the core enzyme were determined after identification of the contact-dependent cleavage sites by FeBABE in the presence of H_2O_2 and ascorbate.[48,49]

The RNA polymerase core enzyme acquires the promoter recognition activity by binding one of the σ-subunits. To characterize the proximity between the core enzyme and various σ-subunits, we analyzed the protein-cutting patterns produced by a set of covalently tethered FeEDTA probes positioned in or near all the four conserved regions. The protein cutting was identified at specific regions of both of the two large subunits, β and β′.[49,50] The σ-contact sites on the core enzyme are essentially the same between σ^{70} (or σ^{D}), the major σ-subunit for recognition of growth-related genes, and σ^{38} (σ^{S}) for recognition of the stationary phase-specific genes (Fig. 5). As proposed by Ghaim *et al.*,[51] Cys residues on the RNA polymerase fall into three categories: a small number of Cys residues are unreactive toward Fe-BABE, some are alkylated but produce no cleavage products upon treatment with ascorbate and peroxide, and some produce intra- and intersubunit cleavages.

The functional specificity of RNA polymerase holoenzymes (core σ-complexes) is further modulated by interaction with one or two of a total of 100–150 transcription factors.[47,52] The contact sites of these factors on RNA polymerase holoenzymes can also be monitored by using FeBABE tethered to each factor protein. For a large scale survey of the holoenzyme–transcription factor contact sites, a bifunctional linker probe, 2-iminothiolane (2-IT), was used for conjugation of FeBABE at Lys residues (see Fig. 1).[53] Transcription factors were conjugated with FeBABE at Lys residues, and the cutting sites of core enzyme subunits were successfully determined after mixing FeBABE-tethered transcription factors and holoenzyme followed by treatment with ascorbate and H_2O_2. The contact sites of σ^{70} and σ^{38} subunits on the β and β′ subunits determined using the newly developed method of a combination of 2IT and FeBABE were essentially the same as by direct conjugation of FeBABE to single Cys mutant σ-subnits. In addition to the σ family proteins, the contact sites have been determined for transcription elongation factors, NusA and GreA, and the RNA polymerase chaperon, owega.[51]

Protein-conjugated chemical probes with nucleolytic or proteolytic activities will be widely used for determining the molecular anatomy of multi-component complexes, in particular those involved in replication, transcription and translation.

The reagent FeBABE was developed in the laboratory of Claude F. Meares (University of California, Davis). The author thanks his many collaborators, whose names are listed in the references, for their contributions to this research. The work in the author's laboratory was financially supported by a Grant-in-Aid for Priority Project 'Biometals' (No. 08249103) from the Ministry of Education, Science, Culture and Sports of Japan, and the CREST (Core Research for Evolutional Science and Technology) fund of the Japan Science and Technology Corporation (JST.)

An alternative to interpenetration whereby nets with large windows may achieve satisfactory space filling

A coordination polymer in which copper acetate dimers are bridged by 3-connecting tpt ligands reveals an alternative means to interpenetration whereby frameworks with very large holes may achieve efficient space filling, namely, by forming π–π associations between tpt units of sheets *X* and *X* + 2 inside the holes of sheet *X* + 1.

The promise of ultimately being able to generate by deliberate design new solid materials with useful tailor-made properties provides much of the driving force for the present interest in coordination polymers. An outstanding feature of many coordination polymers is the presence of a number of independent networks which participate in mutual interpenetration, whereby favourable non-bonded interactions can be maximised and more efficient 3D packing achieved.[1] In a very loose and general sense it can be said that the larger the windows in a 2D or 3D net the more likely is interpenetration to occur and the larger is the number of independent nets passing through a particular window likely to be. The coordination polymer we describe below which consists of hexagonal grid (6,3) sheets is unusual in that interpenetration does not occur despite the fact that the hexagonal holes within the sheets are much larger than those present in numerous other (6,3) sheet systems which do participate in interpenetration.[1] The system we describe reveals an alternative means to interpenetration whereby a network with large holes can maximise favourable non-bonded interactions and achieve efficient space filling.

The vast majority of coordination polymers so far investigated have involved single metal centres linked together in a variety of ways by bridging ligands. Relatively little work has focussed on 2D and 3D networks in which bridging ligands link together metal clusters[2] with their interesting electronic, magnetic and catalytic properties. The copper acetate dimer, which we make use of here, is one of the simplest imaginable cluster species with the potential to provide an effectively linear link between donors; indeed, a number of 1D polymeric chains are known.[3] In order to generate 2D and 3D coordination polymers it is obvious that bridging ligands providing the nodes for the network will be required to have connectivity three or higher. We know of only two examples in which metal acetate dimers are connected into 2D or 3D networks.[4,5]

We report here the 2D (6,3) sheet polymer formed when copper acetate dimer units are linked together by the μ_3 bridging ligand 2,4,6-tri(4-pyridyl)-1,3,5-triazine, tpt, which has previously been shown to afford a number of high symmetry 3D coordination polymers.[6] Reaction of $Cu_2(O_2CCH_3)_4(H_2O)_2$ in methanol with tpt in benzyl alcohol yields green crystals of composition $[\{Cu_2(O_2CCH_3)_4\}_3(tpt)_2]\cdot 2MeOH$ (**1**),† whose structure was determined by single crystal X-ray diffraction.‡

Giant hexagonal grid sheets are present, a ring from which is shown in Fig. 1. As can be seen, the tpt units provide the 3-connecting nodes of the net and copper acetate dimers link node to node, the separation between which is *ca.* 18 Å. This generates very large holes.

The way in which efficient 3D packing is achieved without resort to interpenetration is most simply understood by considering the hypothetical stacking of idealised planar (6,3) nets in a manner which parallels that observed in the less regular real system. Any pair of neighbouring sheets are arranged in this idealised situation with half the nodes of one vertically above or below the mid-points of the hexagonal holes of the other, the remaining nodes of both sheets being located vertically above and below each other. By stacking the sheets in this manner to generate the ABCABC... sequence shown in Fig. 2(*a*) all nodes become equivalent (a real example of this arrangement is β rhombohedral graphite). As can be seen in Fig. 2(*a*) three types of columns of nodes perpendicular to the sheets are thereby generated. One type contains nodes from A sheets and B sheets but not from C sheets, which contribute only holes to these particular columns. If we refer to these columns as A/B columns, equal numbers of equivalent A/C and B/C columns are also present. One such column, the central one, is highlighted by the dashed line in Fig. 2(*a*). If the separation between sheets is *d*, the spacings between nodes in any one of the columns follows the sequence *d*, 2*d*, *d*, 2*d*, *d*, 2*d*... as can be seen in Fig. 2(*a*).

By making each of the initially planar trigonal nodes pyramidal in the appropriate direction and to the appropriate degree it is possible to contract each of the 2*d* separations within columns to *d*, as represented in Fig. 2(*b*). The individual sheets thereby acquire an undulating character and the overall structure becomes much more compact, the volume being reduced in the idealised case by close to one third. Pyramidalisation of the 3-connecting nodes allows new attractive node-to-node con-

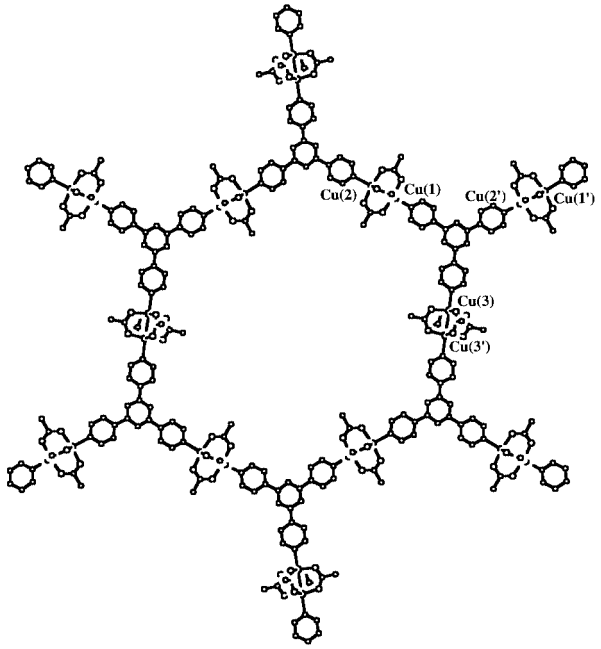

Fig. 1 A single hexagonal window in the (6,3) sheets of **1**. The ring 'diagonals' are *ca.* 34–37 Å.

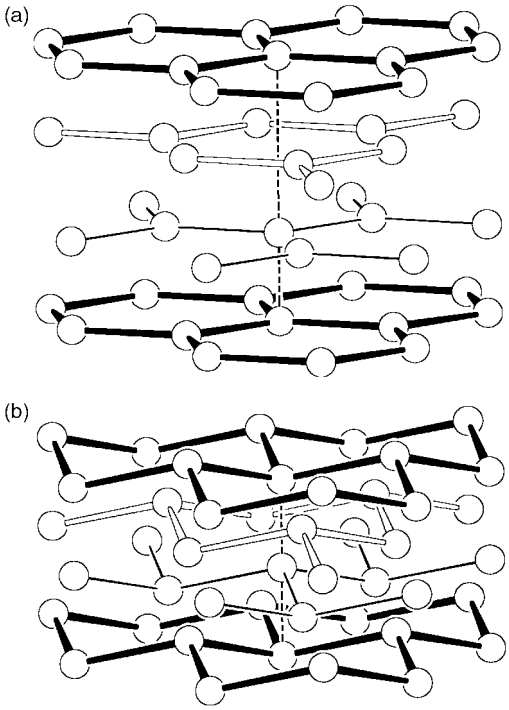

Fig. 2 (*a*) Four idealised planar (6,3) sheets stacked in the ABCA... pattern. (*b*) Hypothetical 'pyramidalisation' of the 3-connecting nodes that were planar in (*a*).

tacts to be made, which, it is interesting to note, involve nodes belonging to sheets that are not immediate neighbours. In effect the holes in any sheet are occupied by nodes belonging to the sheets on each side that come together to make favourable contact with each other around the centre of the hole. This can be easily seen by noting the effect of converting planar nodes in Fig. 2(*a*) to pyramidal nodes in Fig. 2(*b*) whereby the contact, highlighted by the dashed line, between the central node of the upmost sheet and the central node of the sheet depicted with thin bonds becomes shortened from 2*d* to *d*; this contact can be seen to be made through the ring of the intermediate sheet (shown with open bonds).

The 3D arrangement is a deformed version of the idealised structure shown in Fig. 2(*b*). The 3-connecting nodes in this real case are tpt units which remain internally approximately planar despite the fact they constitute pyramidal centres in the sense that lines drawn between triazine centroids make angles significantly less than 120°. The bending required to produce this pyramidalisation occurs mainly not within tpt units but between them; the most pronounced bending is seen at Cu(2) which is located 0.503 Å out of the plane of the coordinated pyridine ring. The node-to-node contacts indicated by a vertical dashed line in the idealised situation shown in Fig. 2(*b*), in the real system are π–π stacks of tpt units. Not only are the individual sheets distorted from hexagonal regularity but the columns are no longer perpendicular to the sheets; in addition the centres of the tpt triazine rings in the columns do not fall on a straight line nor are the average tpt planes perpendicular to the direction of the column. An outstanding feature of some highly symmetrical coordination polymers of tpt reported earlier[6] has been the appearance of tight pairs of tpt units with their triazine rings in close face-to-face π contact, one rotated 60° relative to the other around a 3-fold axis passing through the mid-points of both rings and perpendicular to them; these are examples of Piedfort pairs.[7] In the present structure there appears to be a dominant, structure-determining driving force for each tpt unit to become π-associated not with a single partner but with one on each side to generate an extended π stack. The closest non-hydrogen contacts between tpt units in the columns are not triazine-to-triazine but rather triazine-to-pyridine and the high symmetry of the Piedfort pairs is lost. The closest atom-to-atom contact on one side of a tpt unit to a tpt unit of an adjacent sheet is 3.327 Å, whilst on the other side the closest contact of 3.352 Å is to a tpt unit two sheets removed.

The methanol of solvation is hydrogen bonded to a particular one of the acetate units in the Cu(1)··Cu(2) dimer (O··O, 2.876 Å).

The variation of magnetic susceptibility of **1** with temperature is very much like that of the antiferromagnetically coupled parent complex $Cu_2(O_2CCH_3)_4(H_2O)_2$. Fitting of the data to the Bleaney–Bowers equation[8] for an isolated Cu^{II} dimer yielded parameter values $g = 2.0$, $J = -153$ cm^{-1}, $N\alpha = 60 \times 10^{-6}$ cm^3 mol^{-1}, fraction monomer = 0.02 (*cf.* $Cu_2(O_2CCH_3)_4(H_2O)_2$ $J = -148$ cm^{-1}). Thus there are negligible or very weak dimer–dimer interactions propagated by the tpt group. Related linear chains linked by pyrazines behave similarly.[9]

In conclusion, the structure reported here reveals an alternative means to interpenetration whereby large holes in the individual 2D sheets may be satisfactorily occupied by tpt nodes from the sheets on opposite sides which are attracted together to form π–π associations inside the hole.

Notes and references

† A buffer layer of benzyl alcohol (5 ml) was carefully layered over a solution of tpt (25 mg, 0.080 mmol) in benzyl alcohol (10 ml), and a layer of $Cu(O_2CCH_3)_2{\cdot}H_2O$ (38 mg, 0.19 mmol) in methanol (10 ml) was carefully placed on top of the buffer layer. Green crystalline **1** formed after 3 days (23 mg, 0.013 mmol, 41%). (Found: C, 41.44; H, 3.29; N, 9.79. Calc for $Cu_6C_{62}H_{68}N_{12}O_{26}$: C, 41.47; H, 3.89; N, 9.52%).

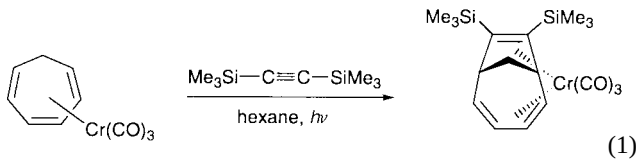
Received (in Cambridge, UK) 21st March 2000, Accepted 17th May 2000
Published on the Web 8th June 2000

Bridged triene η⁶-chromiumtricarbonyl complexes have been shown to undergo regioselective addition reactions with a range of nucleophiles including organolithium reagents and enolates.

Formation of the corresponding η⁶-chromiumtricarbonyl complex provides a versatile method for enabling nucleophilic addition to aromatic compounds, and can result in the formation of substituted aromatic complexes or non-aromatic products.[1] Less well known are the corresponding seven-membered complexes derived from tropone, cycloheptatriene, and related heterocyclic systems.[2] These compounds have been demonstrated to undergo formal cycloaddition reactions with either alkynes or 1,3-dienes, *e.g.* eqn. (1)[2c,3]



(1)

1 **2**

Cycloheptatriene complex **1** undergoes efficient cycloaddition with bistrimethylsilylacetylene to give the bridged product complex **2** in good yield.† It seemed to us that the type of activation towards nucleophilic substitution seen in the arene complexes might also be operative in triene complexes such as **2**, although, as far as we are aware, this mode of reactivity has not been demonstrated.[4] Here we describe the first examples of additions to such complexes, which occur in a highly regioselective fashion with a range of nucleophiles.

The readily available bis-silylated complex **2** was used for the majority of our initial studies, and also because the vinyl silane functionality in the products could be synthetically useful. Addition of a number of nucleophiles to a solution of **2** in THF at −78 °C, followed by protic work-up, resulted in the formation of the metal-free adducts **3** and/or **4** as shown in Table 1.‡

The complex reacted with several varied alkyllithiums, dimethylcyanocuprate, the lithium enolates derived from ethyl acetate or *N*,*N*-dimethylacetamide, two examples of lithiated nitriles and a lithiated sulfone.§ In every case the initial addition reaction appears to be highly regioselective for the terminus of the complexed diene, whereas the position of subsequent protonation appears to be highly dependent upon the nature of the group being introduced. In most cases the presumed intermediate anionic dienyl complex undergoes protonation distal to the entering substituent, to give exclusively or mainly isomer **3**, whereas in a few cases the alternative isomer **4** predominates.

Although the proposed structures accorded with our expectations, and were supported by high field NMR data, we were concerned by the variable ratios of the two products formed and could not entirely rule out the possibility that the isomers formed were alternative regio- or stereoisomers. Fortunately we were able to obtain X-ray crystal structure determinations of certain derivatives, including the nitrile **3** (R = CH_2CN) and the sulfone **4** (R = CH_2SO_2Ph), which are illustrated in Fig. 1 and 2, respectively.¶

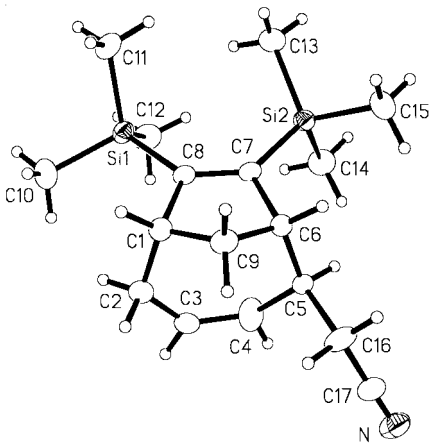


Fig. 1 Crystal structure of nitrile adduct **3** (R = CH_2CN).

3:**4**	7:1	1.3:1	**3**[a]	**3**[a]	**3**[a]	1:2	5:1	5:1	**3**[a]	1:5

[a] Only isomer **3** detected by ^{1}H NMR of crude product.

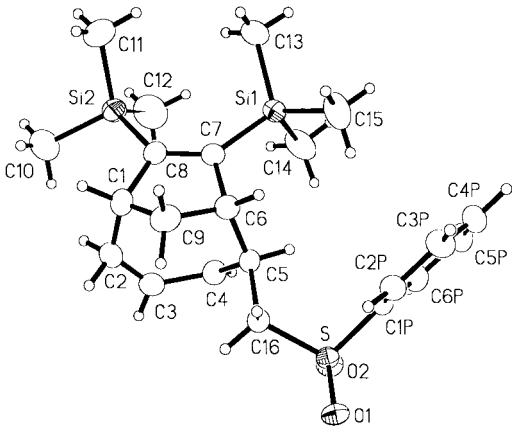

Fig. 2 Crystal structure of sulfone adduct **4** (R = CH_2SO_2Ph).

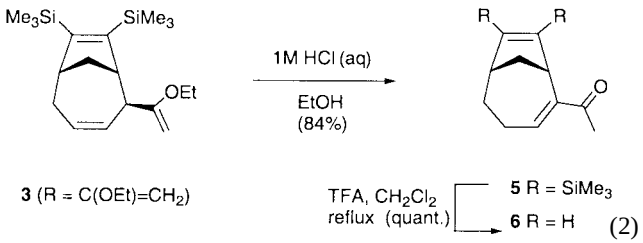
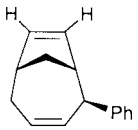
These two structures confirm that the initial nucleophilic addition to **2** is indeed highly regioselective for the diene terminus, and also that the new substituent is *exo*-orientated in the bridged product. The structures also confirm the contrasting alkene regiochemistry assigned by NMR, but at present we have no convincing explanation for the isomer ratios seen with the different nucleophiles.

It was of interest to briefly examine the transformations possible with these types of product, for example the alkenyl ether product **3** could be converted into the α,β-unsaturated ketone **5** on treatment with dilute acid, eqn. (2).



(2)

Treatment of this product under more vigorous acidic conditions (TFA, CH_2Cl_2, reflux) resulted in complete desilylation to give enone **6**. This type of desilylation was also shown to be possible on an alternative type of adduct, compound **3** (R = Ph), on reaction under the same conditions, to give product diene **7**.



7

In conclusion, we have demonstrated for the first time that efficient nucleophilic addition to bridged chromium complexes is possible. In the near future we hope to extend the chemistry to heterocyclic complexes, which could lead to a novel synthesis of the alkaloid anatoxin-a, and to provide further details of the scope and limitations of the chemistry.‖

We would like to thank the Engineering and Physical Sciences Research Council (EPSRC) and AstraZeneca for support of R. E. J. B. We also acknowledge EPSRC for funding for a diffractometer.

Notes and references

† We obtained a yield of 69%, with even higher yields being possible (80%) according to ref. 3(*b*).

‡ *Typical experimental procedure*: A solution of the appropriate nucleophile in THF was added dropwise to a stirred solution of the bridged triene chromium complex (usually **2**) in THF at −78 °C. The resultant solution was stirred at this temperature until reaction appeared complete by TLC (typically 1 h), and then saturated NH_4Cl(aq) solution was added and the mixture warmed to room temperature prior to extraction with Et_2O (3 × 5 ml). The combined organic extracts were back washed with water, brine, dried ($MgSO_4$) and concentrated *in vacuo*. Flash chromatography on silica gel afforded the addition adducts **3**/**4** as indicated in Table 1.

§ Nucleophiles which did not give clean reactions include the lithium enolate from acetophenone, PhMgCl, and the lithiated derivatives from benzylcyanide, 1,3-dithiane, methoxy methyl ether, *N*-boc-pyrrolidine and 2,3-dihydrofuran. It is unclear why some of these reactions failed, whereas closely related reactions indicated in Table 1 were successful. We have not so far been successful in quenching the intermediate anion with carbon electrophiles.

¶ For both **3** and **4** a crystal was encapsulated in a film of RS3000 perfluoropolyether oil and mounted on a glass fibre before transfer to the diffractometer.

Crystal data for **3**: $C_{17}H_{29}NSi_2$, M = 303.59, monoclinic, a = 11.370(2), b = 16.982(4), c = 19.115(4) Å, β = 103.657(4), U = 3587(2) Å^3, T = 150(2) K, space group $P2_1/c$ (no 14), Z = 8, D_c = 1.125 g cm^{-3}, μ(Mo-Kα) = 0.190 mm^{-1}, 8422 unique reflections measured and used in all calculations. Final R_1 [4937 $F \geqslant 4\sigma(F)$] = 0.0484 and wR (all F^2) was 0.125. Received (in Oxford, UK) 28th March 2000, Accepted 18th April 2000
Published on the Web 8th June 2000

The dibenzyl-substituted carbamic acid $(PhCH_2)_2NC(O)OH$ (1), its deprotonation product $[(PhCH_2)_2NH_2][(PhCH_2)_2NCO_2]$ (2) and $CoCl(NO)_2[PhP(OCH_2CH_2)_2N$-$C(O)OH]\cdot 2MeCOMe$(3·2MeCOMe) are reported, the diffractometric study showing the carbamic acids 1 and 3 to be paired through hydrogen bonds.

Carbamic acids $R_2NC(O)OH$ (R = alkyl, aryl) have been until now elusive compounds, even for primary amines,[1] owing to their tendency to undergo decarbonation[2] under reduced pressure of carbon dioxide [eqn. (1)] or deprotonation in the presence of amine [eqn. (2)]. Carbamic acid itself, $H_2NC(O)OH$, has not been isolated so far although it has been detected by IR at low temperature,[2] and some of its properties have been calculated theoretically.[3,4]

$$R_2NH + CO_2 \rightleftarrows R_2NC(O)OH \quad (1)$$

$$R_2NC(O)OH + R_2NH \rightleftarrows [R_2NH_2][R_2NCO_2] \quad (2)$$

Thus, although *N*-substituted carbamic species are believed to be key intermediates in biological carbonations,[5] and in the photosynthetic carbon cycle promoted by Rubisco (ribulose 1,5-biphosphate carboxylase),[6] no simple member of this class has been isolated and no crystal data are available. This paper covers this gap.

Secondary amines R_2NH (R = Bu^n, Pr^i, *c*-C_6H_{11}) as neat liquids were reacted with CO_2 at atmospheric pressure over reaction times of several hours up to constant volume, gas volumetric measurements showing the CO_2/R_2NH molar ratio to be close to 0.5, namely 0.56 (Bu^n, 9.6 °C), 0.44 (Pr^i, 19.3 °C) and 0.53 (*c*-C_6H_{11}, 24.9 °C). Accordingly, the corresponding dialkylammonium dialkylcarbamate is the predominant product of the reaction. By contrast, for R = $PhCH_2$, a $CO_2/(PhCH_2)_2NH$ molar ratio close to 1 was observed at 10.3 °C, showing the preferential formation of *N*,*N*-dibenzylcarbamic acid $(PhCH_2)_2NC(O)OH$ **1**. By operating in heptane at *ca.* 9 °C, the carbonation, monitored by gas volumetry, corresponded to the complete conversion to **1**. Well formed crystals of **1** were obtained from heptane (*vide infra*).

The carbonation of dibenzylamine was monitored by IR in a PCTFE medium. When dibenzylamine was submitted to a CO_2 atmosphere at room temperature, the spectrum corresponded to the formation of **2**. Cooling the PCTFE mull at *ca.* 5 °C under CO_2 led to the almost exclusive formation of **1** after several hours. The process can be reversed by increasing the temperature and/or reducing the partial pressure of CO_2. The ν(CO) band of the carbamic function at 1640 cm^{-1} suggests the presence of intermolecular hydrogen bonds, in substantial agreement with theoretical calculations and spectroscopic data at low temperature[2–4] for the NH_3/CO_2 system.

When the carbonation of dibenzylamine was conducted with a CO_2/amine molar ratio not exceeding 0.5, **2** was obtained.‡ The corresponding IR spectrum shows bands centred at 1530, 1432, 1410, 1330 and 1316 cm^{-1}. The 1530 cm^{-1} band is assigned to ν_{as}(CO) of the O_2CN moiety, which compares well with those at 1525 and at 1550 cm^{-1} for $[NH_4]O_2CNH_2]$[9] (thin film, −190 °C), and $[Me_2NH_2][O_2CNMe_2]$ (neat liquid), respectively.[10]

The structure of **1** consists of two crystallographically independent molecules‡ (Fig. 1), whose main bond distances and angles are listed in the figure legend. In agreement with earlier theoretical studies,[3] the molecule does not crystallize as its zwitterionic form. The adopted conformation meets the requirement of maintaining the bulky benzyl groups relatively far from the $–CO_2H$ function. The main difference between the two molecules is in the torsion angles N(1)–C(9)–C(10)–C(11) and N(2)–C(24)–C(25)–C(26) differing by 34°. Within the same molecule, the C–O bond distances differ by 0.08 or 0.06 Å, the longer distance being connected with the oxygen carrying the hydrogen. The carbamate moieties are substantially

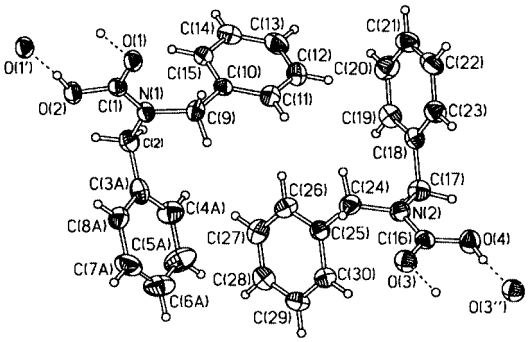

Fig. 1 The asymmetric unit of **1**. Thermal ellipsoids are at 50% probability. The hydrogen-bonded pairs are represented, together with the most populated positions of the disordered C(3)–C(8) ring. Relevant bond distances (Å) and angles (°). N(1)–C(2) 1.461(3), N(1)–C(9) 1.464(2), N(1)–C(1) 1.345(3), C(1)–O(1) 1.246(3), C(1)–O(2) 1.321(3), O(2)···O(1′) 2.556(2), N(2)–C(17) 1.465(3), N(2)–C(24) 1.468(3), N(2)–C(16) 1.340(3), C(16)–O(3) 1.254(3), C(16)–O(4) 1.315(3), O(3)···O(4″) 2.590(3); C(1)–N(1)–C(2) 123.5(2), C(1)–N(1)–C(9) 119.1(2), C(2)–N(1)–C(9) 117.5(2), O(1)–C(1)–N(1) 122.1(2), O(2)–C(1)–N(1) 115.1(2), O(1)–C(1)–O(2) 122.8(2), C(16)–N(2)–C(17) 123.1(2), C(16)–N(2)–C(24) 119.7(2), C(17)–N(2)–C(24) 116.8(2), O(3)–C(16)–N(2) 121.4(2), O(4)–C(16)–N(2) 115.8(2), O(3)–C(16)–O(4) 122.8(2). ′ = 3/2 − *x*, −1.2 − *y*, 1 − *z*; ″ = 2 − *x*, −*y*, 2 − *z*.

DOI: 10.1039/b002479l

planar (maximum deviation from planarity 0.07 Å). The N(1)–C(1) and N(2)–C(16) bond distances of 1.345 and 1.340 Å to the –C(O)OH function are substantially identical to the distance of 1.34 Å indicated by *ab initio* calculations.[3]

As in carboxylic acids, each molecule is connected through two end-on hydrogen bonds, which are shown in Fig. 1, in pairs related by an inversion centre.

Single crystals of **3** were obtained from an acetone solution of $CoCl(NO)_2[PhP(OCH_2CH_2)_2NH]$[11] upon carbonation at atmospheric pressure at −30 °C. The carbamic acid fragment‡ is paired through two end-on hydrogen bonds, similarly to **1**. The intermolecular O···O bond distance of 2.580 Å implies the existence of hydrogen atoms in between. The N–C(O)OH fragments in **1** and **3** do not differ significantly in bond distances and angles and, as expected, the C–O bonds are not equivalent.

Computational studies on the decomposition of ammonium carbamate[3,4] favour carbamic acid $H_2NC(O)OH$ as the intermediate, and its zwitterionic form as the transition state. The isolation of carbamic acids **1** and **3**, in the present study, shows for the first time that, under carbon dioxide at *atmospheric* pressure, carbonation of the secondary amine to the corresponding carbamic acid can be in fact a thermodynamically favourable process provided the appropriate substituents and reaction conditions are chosen, probably a determining factor in the stabilisation of the system being the hydrogen-bond network in the solid state, as previously observed in $Ag(O_3SOH)$.[12] The dialkylammonium carbamate may further slowly undergo carbonation to the acid or be kinetically or thermodynamically stabilized as such, depending on the nature of the group R. The zwitterionic form of the acid, $\{R_2NH^+CO_2^-\}$, may be a kinetically relevant intermediate undergoing fast deprotonation in the presence of amine.

The present findings are believed to be relevant, *inter alia*, to the problem of carbon dioxide fixation by amino groups in biopolymers in the solid state.[13]

Notes and references

‡ *Crystallography*: reflection intensities were collected on a Siemens P4 diffractometer for **1** and **2**, and on a Nonius CAD-4 diffractometer for **3**, both equipped with graphite-monochromatized Mo-Kα radiation (λ = 0.71073 Å). All data were collected in the ω–2θ scan mode.

Crystal data: for **2** at 173(2) K: $C_{29}H_{30}N_2O_2$; colourless monoclinic prisms. Cell parameters: a = 15.339(1), b = 8.850(1), c = 18.402(2) Å, β = 101.68(1)°, V = 5057.8(14) Å^3, Z = 4, D_c = 1.192 Mg m^{-3}, μ(Mo-Kα) = 0.084 mm^{-1}, space group $P2_1/n$ (no. 14), 3575 intensities collected between θ = 2.26 and 24.0° in the range $-17 \leqslant h \leqslant 0$, $0 \leqslant k \leqslant 8$, $-20 \leqslant l \leqslant 21$, and corrected for Lorentz and polarization effects; after merging (R_{int} = 0.0215), 3438 independent reflections; structure solved by direct methods (SIR92),[7] and refined (SHELXTL).[8] The nitrogen-bonded hydrogen atoms of the cation were located in the difference Fourier map, and were not refined; the other hydrogen positions were allowed to ride on the corresponding carbon atoms, obtaining R_1 [$I > 2\sigma(I)$] = 0.0447 and wR_2 = 0.1039 (298 parameters, without restraints).

For **1** at 173(2) K: $C_{15}H_{15}NO_2$; colourless needle-like prisms. Cell dimensions: a = 39.397(7), b = 5.545(1), c = 24.783(3) Å, β = 110.90(1)°, V = 2443.7(4) Å^3; monoclinic crystal, Z = 16, D_c = 1.267 Mg m^{-3}, μ(Mo-Kα) = 0.075 mm^{-1}, space group $C2/c$ (no. 15) or Cc, 4675 intensities collected between θ = 2.21 and 24.0° in the range $-44 \leqslant h \leqslant 1$, $-5 \leqslant k \leqslant 1$, $-26 \leqslant l \leqslant 28$, and corrected for Lorentz and polarization effects; after merging ($R_{int} = [\Sigma|F_o^2 - F_o^2(\text{mean})|/\Sigma(F_o^2)]$ = 0.0260), 3557 independent reflections; structure solved in the centrosymmetric space group (SIR92),[7] and refined (SHELXTL).[8] The abnormally large thermal ellipsoids of the aromatic ring suggested the presence of local rotational disorder. Two different phenyl rings of fixed geometry and rotated by slightly different angles around the C(2)–C(3) bond were then introduced in the same position, by fixing to unity the total occupancy of the site. The hydrogen within the C(O)OH group was located on the difference Fourier map and introduced in the calculations without refining; the other hydrogen atoms were introduced in calculated positions and allowed to ride on the corresponding carbon atoms. The final refinement cycles (353 parameters, no restraints) gave the reliability factors R_1 [$I > 2\sigma(I)$] = 0.0411 and wR_2 = 0.1012 (all data).

For **3** at 243(2) K: $C_{17}H_{26}ClCoN_3O_8P$; dark-brown prisms. Cell parameters: a = 9.612(2), b = 11.936(3), c = 12.371(4) Å, α = 73.34(2), β = 69.94(2), γ = 66.18(2)°, V = 1201.4(6) Å^3, Z = 2, D_c = 1.453 Mg m^{-3}, μ(Mo-Kα) = 0.937 mm^{-1}, triclinic, space group $P\bar{1}$ (no. 2), 3918 independent observed intensities collected between θ = 1.89 and 30.0° in the range $-12 \leqslant h \leqslant 13$, $-16 \leqslant k \leqslant 16$, $0 \leqslant l \leqslant 10$, and corrected for Lorentz, polarization effects and absorption (ψ-scan method); structure solution by direct methods and refined (SHELXTL).[8] The asymmetric unit turned out to contain two acetone molecules, one of them being affected by some orientational disorder. The hydrogen atoms were introduced in calculated positions and allowed to ride on the connected atoms. The final refinement cycles with anisotropic thermal factors for heavy atoms and isotropic ones for hydrogen atoms (280 parameters, no restraints) gave R_1 [$I > 2\sigma(I)$] = 0.0915 and wR_2 = 0.1321.

Solubilization of fullerenes in water by nucleophilic addition of cyclodextrin-R-monoamines to C_{60}, where R represents iminoalkyl and iminoaryl residues, is reported and studies involving the host–guest characteristics, free radical scavenging and DNA-cleaving properties indicate that this class of compounds has potential for a number of biological and medical applications.

Fullerenes are extraordinarily susceptible to attack by a variety of chemical reagents.[1] They exhibit high reactivity towards multiple addition of organic free radicals[2] and have been demonstrated to cleave DNA in the presence of light.[3] It has been reported recently that certain mutagenic and carcinogenic properties, and a number of neurodegenerative diseases, are associated with free radicals.[4] Hence, water-soluble fullerene compounds are suitable for potential biomedical applications. Previous approaches to the preparation of water-soluble fullerenes,[5] such as inclusion complexation with cyclodextrin or cyclodextrin prepolymers, multi-hydroxylation, 1,3-dipolar cycloaddition, nucleophilic cyclopropanation, polymer embedding *etc.*, are characterized by significant alteration of the fullerene molecule by modification. Our approach involves covalent binding of fullerenes with cyclodextrins (CD) leading to high water solubility and biocompatibility.

Nucleophilic additions of primary and secondary amines are known reactions and have been investigated for functionalization of the fullerene cage.[6] Preparation of fullerenylated aminopolymers has also been reported.[7] Synthesis of the fullerene–cyclodextrin conjugate (**4**) (Scheme 1)† was achieved by adding small volumes of a cyclodextrin monoamine (**3**) solution to a C_{60} solution at intervals of six hours, until about 30% of the fullerene remained unreacted.[7] The CD-amine–fullerene was purified by subsequent membrane filtration.[8] Separation from any higher derivatives was achieved by using membranes with a molar mass cut-off (MMCO) of 2000 g mol^{-1} and low-molecular weight components, if any, by membrane of MMCO of 1000 g mol^{-1}. FT-IR spectra of a model compound [60]fullerene-deoxy-6-(1,4-diiminophenyl)-β-cyclodextrin (**4a**) display the distinct features of the fullerene component. The UV–Vis spectrum (Fig. 1) shows considerable peak broadening beyond 350 nm for **4a**. Several authors have ascribed this behavior to aggregation of the molecules in water, confirmed further from dynamic light scattering studies.[5f,g] The ^{13}C NMR spectrum showed resonances due to the fullerene carbons at *ca.* 140 ppm.

To rule out the possibility of a competitive host–guest complexation reaction typical of cyclodextrins,[9] we synthesized the β-CD-1,4-diaminobenzene host–guest complex and characterized the material by various spectral techniques. Though the IR of both the inclusion complex and the covalently bonded CD-diamine (**3a**) did not show any significant differences, there were typical distinguishing patterns in the UV–Vis, ^1H NMR, TGA, and DSC data.

Cyclodextrin cage compounds have been demonstrated to be useful for several medical applications involving the host–guest complexation strategy and controlled release of the guest drug molecule.[10] In order to prove that the CD ring is still available for formation of inclusion complexes, we used *p*-nitrophenol (PNP) as a model molecule. The reaction between **4a** and PNP was monitored and compared with the reaction between β-CD and PNP by recording the change in the UV–Vis absorption pattern. It was seen that, with time, the peak at 405 nm gradually

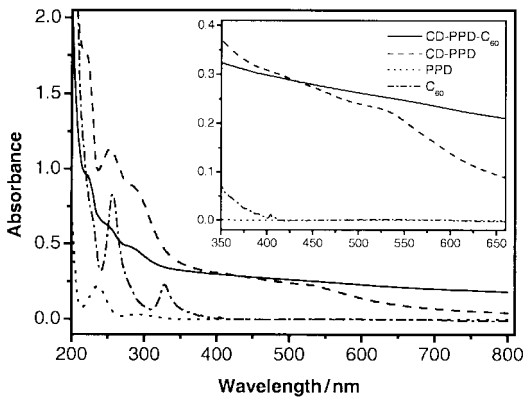

Fig. 1 UV–Vis spectra of C_{60} in hexane and *p*-phenylenediamine (PPD), mono-6-deoxy-6-(1,4-diiminodiphenyl)-β-cyclodextrin (CD-PPD), and [60]fullerene-deoxy-6-(1,4-diiminodiphenyl)-β-cyclodextrin (CD-PPD-C_{60}, **4a**) in water.

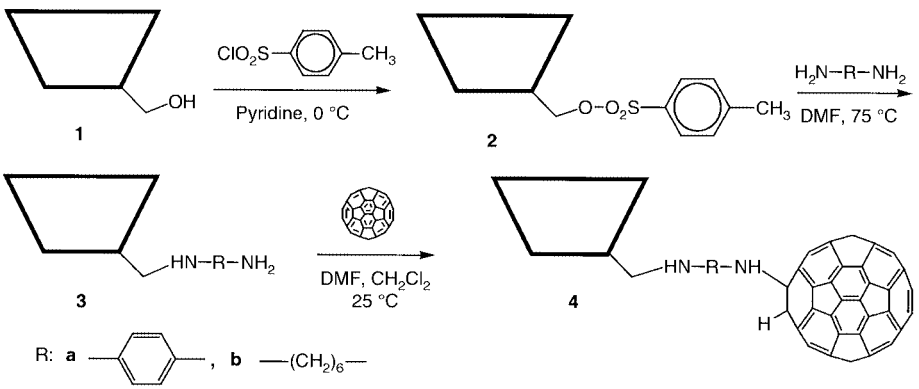

Scheme 1 Synthesis of fullerene–cyclodextrin conjugates.

increased in intensity for both the **4a**–PNP and β-CD–PNP experiments, whereas this absorption for PNP alone was not significant. The molar ratios **4a**:β-CD:PNP for **4a**–PNP and β-CD–PNP inclusion experiments were 1:2:8. It was observed that the rate of increase in the absorption intensity for β-CD–PNP complexation was nearly twice than that for the **4a**–PNP reaction, which means that the CD ring in **4a** is as active as that in free CD molecules.

It is known that C_{60} readily adds simple alkyl and aryl radicals[2] and undergoes radical polyreactions.[11] The stable free radical 1,1-diphenyl-2-picrylhydrazyl (DPPH) has been used to study the antioxidant activities of phenols and catechol.[12] We utilized this radical for the reaction with **4a** in ethanolic solution and monitored the absorbance at 517 nm. The reaction proceeded with a gradual decrease of absorbance at 517 nm, with a visual bleaching of the pink color of the radical solution, indicating that **4a** is an effective radical scavenger.

The interaction potential of fullerenes with biological molecules has been recently recognized, especially their ability to cleave DNA nucleotides[3b,c] *via* a singlet oxygen transfer at the guanosine base sequence.[3d] We conducted a screening experiment in which a sample of DNA oligonucleotide, which was purified by membrane filtration prior to use, was treated with **4a** in aqueous media. The UV–Vis spectrum of the solution mixture shows two peaks, one at 260 nm, characteristic of the DNA component, and another broad absorption with a maximum at 343 nm due to the fullerene compound. It was observed that the fullerene peak intensity gradually decreased, indicating that there had been a reaction with the DNA in which **4a** was gradually consumed. There was no noticeable decrease in the intensity of the DNA peak.

Upon diafiltration of the fullerene compound–DNA solution mixture (20 mL) through the membrane (MMCO 10 000 g l^{-1}, used for purification of crude DNA) with 800 mL water (filtration factor, $Z = 40$), the amount of DNA in the permeates sharply decreased and only a very small quantity of the DNA component was left in the retentate. This was ascertained from a rapid decrease in the characteristic DNA absorbance at 260 nm in the permeates. The molar mass of the DNA in these samples was measured by GPC. It was found that almost the entirity of the DNA had undergone cleavage, leaving behind no high molecular mass species.

We are grateful to KOFST and K-JIST, Korea, for partial financial support and to B. J. Choi and S. J. Choi for technical assistance.

Notes and references

† General procedure for synthesis of [60]fullerene-β-cyclodextrin conjugate (**4**): Amine **3** (0.02 mmol) dissolved in 10 mL DMF was added in small portions, keeping a gap of 6 h between each addition, to the fullerene (C_{60}) (14 mg, 0.02 mmol) dissolved in 100 mL methylene chloride, until 30% of the theoretical amount of fullerene remained unreacted. The mixture was stirred at 25 °C under N_2 (3–10 d), after which the organic solvent was removed. Then 200 mL water was added, the insoluble black residue filtered off and the filtrate freeze-dried. The crude sample was purified further by membrane filtration (details in the text). The yield and solubility of the fullerene–cyclodextrin conjugates varied, representing the characteristics of the amine component and the macrocycles, respectively.

Preparation of highly active NiW hydrotreating model catalysts with 1,2-cyclohexanediamine-*N*,*N*,*N*′*N*′-tetraacetic acid (CyDTA) as a chelating agent

G. Kishan, L. Coulier, V. H. J. de Beer, J. A. R. van Veen and J. W. Niemantsverdriet*

Received (in Oxford, UK) 25th April 2000, Accepted 16th May 2000
Published on the Web 8th June 2000

Changing the order in which oxidic W and Ni convert to sulfides by adding 1,2-cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (CyDTA) as a chelating agent for nickel in the preparation of NiWS–SiO_2 catalysts is the key ingredient in obtaining a high activity for thiophene hydrodesulfurization.

Stringent future legislation for low-sulfur diesel fuel places increasingly higher demands on the performance of hydrotreating catalysts.[1,2] Supported sulfides of molybdenum or tungsten promoted with nickel or cobalt are widely applied to this end.[2] In the preparation, sulfidation of the oxidic precursors in a mixture of H_2S–H_2 or in the sulfur-containing hydrocarbon feed is an essential step. The sulfidation of supported MoO_3 and oxidic CoMo and NiMo catalysts has received considerable attention.[3–10] The generally accepted view is that in order to obtain active CoMoS and NiMoS catalysts, sulfidation of molybdenum should precede that of cobalt and nickel, such that the reactive edges of the MoS_2 slabs can serve as anchoring sites for the promoter atoms.[8–10] Chelating agents such as nitrilotriacetic acid (NTA)[9,10] and ethylenediaminetetraacetic acid (EDTA)[4,5] assist in stabilizing nickel and cobalt, such that their conversion to sulfides is retarded with respect to molybdenum.

Much less is known about tungsten sulfidation. Tungsten oxide is more difficult to convert to sulfides than molybdenum.[3,11] Shimizu *et al.*[12] report that chelating agents improve the activity of NiW–Al_2O_3 catalysts in hydrodesulfurization of benzothiophene and hydrogenation of *o*-xylene. The origin of the promotional effect is not clear, however.

Our purpose is to demonstrate that addition of 1,2-cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (CyDTA) as a chelating agent for Ni in the preparation of NiWS–SiO_2 catalysts leads to a 2.3-fold increase in thiophene hydrodesulfurization activity, as compared to a standard NiWS–SiO_2 catalyst. We correlate the catalytic activity with the order in which nickel and tungsten convert to sulfides, as measured by X-ray photoelectron spectroscopy (XPS). To measure XPS spectra at improved resolution, we used model supports consisting of a thin hydrophilic SiO_2 layer on a silicon substrate.[13]

SiO_2 supports were prepared by oxidizing Si(100) at 750 °C for 24 h in air. Oxidized wafers were cleaned in H_2O_2–NH_3(aq) (3 : 2 v/v) at 65 °C and hydroxylated in boiling water for 30 min. The sample was covered with an aqueous solution of ammonium metatungstate (Merck), nickel nitrate [$Ni(NO_3)_2{\cdot}6H_2O$; Merck] and 1,2-cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid ($C_{14}H_{22}N_2O_8{\cdot}H_2O$; Merck) and spin coated under N_2 at 2800 rpm.[14] Concentrations were adjusted to result in loadings of 6 W atoms nm^{-2} and variable Ni loading between 1 and 6 atoms nm^{-2}. The amount of CyDTA added was equal to the amount of Ni present. Catalysts prepared without CyDTA were calcined (500 °C, 30 min), whereas NiW-CyDTA–SiO_2 catalysts were used without calcination. Sulfidation was carried out in a glass tube reactor with 10% H_2S in H_2 at a heating rate of 5 °C min^{-1} (2 °C min^{-1} for NiW-CyDTA–SiO_2) to the desired temperature, after which samples were kept at that temperature for 30 min. Next, the sample was cooled to room temperature under helium and transported to the XPS under N_2 atmosphere.

XPS spectra were obtained on a VG Escalab 200MK spectrometer, at a constant pass energy of 20 eV. Binding energies were corrected with reference to the Si 2p peak of SiO_2 at 103.3 eV.

Thiophene hydrodesulfurization was carried out with 5 cm^2 of model catalyst in a microflow reactor operating in batch mode (1.5 bar, 400 °C, with 4% thiophene in H_2), after sulfidation at 400 °C. Gas samples were taken with a syringe for gas chromatograph (GC) analysis of the products. All activity results presented are the average of at least six different measurements, which showed good reproducibility.

Fig. 1 shows W 4f and Ni 2p XPS spectra of the NiW-CyDTA–SiO_2 model catalyst after sulfidation at the indicated temperatures. The W 4f spectrum of the fresh catalyst shows a doublet at 35.6 eV characteristic of W(VI) oxide.[15] The small peak at 41.6 eV corresponds to the W $5p_{3/2}$ state. As Fig. 1 shows, sulfidation of W starts at 150 °C and is completed at 300 °C, where the W 4f spectrum shows a doublet at 32.6 eV, characteristic of WS_2.[15] Sulfidation of a Ni-free W–SiO_2 sample (not shown) proceeded similarly to the progression shown in Fig. 1A. Addition of CyDTA to W–SiO_2 in the preparation had no measurable effect on the sulfidation rate of tungsten.

Sulfidation of Ni, however, is greatly affected by CyDTA. The Ni 2p spectrum of fresh NiW-CyDTA–SiO_2 (Fig. 1B) exhibits the pattern characteristic of Ni^{2+}, with the Ni $2p_{3/2}$ peak at 855.4 eV accompanied by shake-up features.[15] The Ni $2p_{3/2}$ binding energy, however, is 1.5 eV lower than that of Ni in CyDTA-free Ni–SiO_2 and NiW–SiO_2 catalysts, evidencing complexation of nickel by CyDTA. As Fig. 1B shows, the complexed nickel is stable in H_2S–H_2 upto temperatures just below 250 °C. In contrast, NiO reacts in H_2S at room temperature, and conversion to nickel sulfide (Ni $2p_{3/2}$ binding energy of 854.0 eV[15]) is complete at 100 °C. The same is true for Ni sulfidation in NiW–SiO_2 catalysts, however, the Ni $2p_{3/2}$ peak shifts to a higher binding energy of 854.5 eV after complete sulfidation of W at sulfidation temperatures around 300 °C. We take the additional 0.5 eV shift of the Ni $2p_{3/2}$ peak as evidence that the initially formed Ni_3S_2 rearranges, and redisperses over the reactive edges of the WS_2 slabs, as proposed by Reinhoudt *et al.*[11]

Fig. 1B shows that CyDTA retards the sulfidation of Ni to *ca.* 250–300 °C. This temperature range coincides with the disappearance of the N 1s signal characteristic of the CyDTA ligand, indicating that the decomposition of the latter determines the rate of Ni sulfidation.

The activity of the catalysts for thiophene hydrodesulfurization is shown in Fig. 2. The blank silica support in the reactor has an order of magnitude lower activity than W–SiO_2, and shows mainly cracking products. The W–SiO_2 catalyst calcined at 500 °C is detectably active, with a product distribution showing predominantly 1-butene as the primary product. The Ni–SiO_2 catalyst calcined at 500 °C exhibits lower activity. Synergism is clearly observed in the standard NiW–SiO_2 model

DOI: 10.1039/b003272g

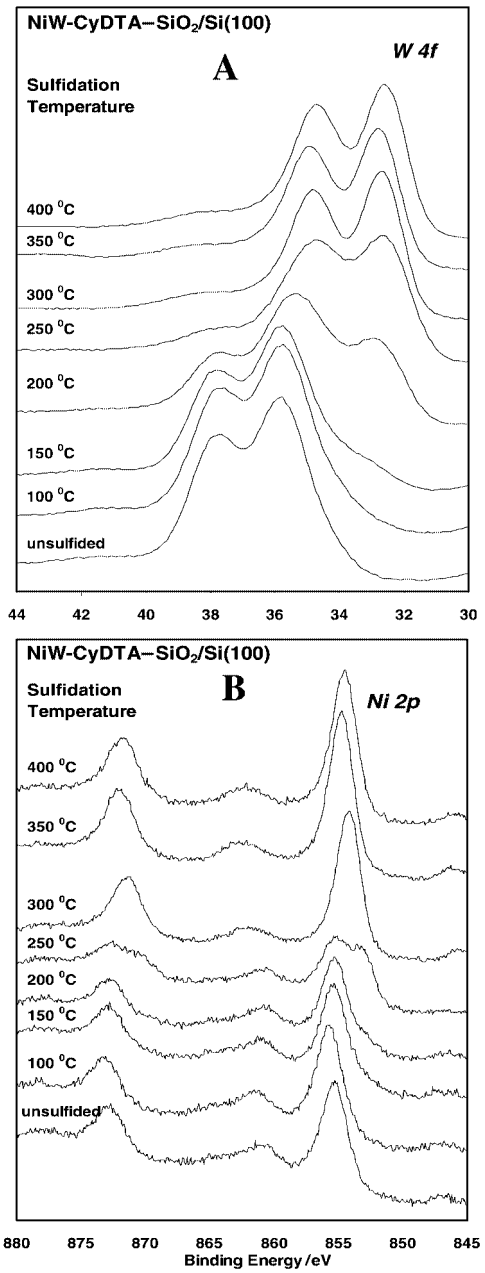

Fig. 1 (A) W 4f and (B) Ni 2p XP spectra of NiW-CyDTA–SiO_2/Si(100) model catalysts during sulfidation at various temperatures. The spectra show that CyDTA retards the sulfidation of Ni such that the sulfidation of W precedes that of Ni.

catalyst, for which the total activity is more than twice that of Ni–SiO_2 and W–SiO_2 combined. The highest activity is observed with NiW-CyDTA–SiO_2, which is about 2.3 times more active than a standard NiW–SiO_2 sample of the same nominal composition. The C_4-product distribution of this catalyst is: 40% 1-butene, 36% *trans*-2-butene and 24% *cis*-2-butene. Optimum activity was observed with NiW–SiO_2 catalysts containing 4 Ni atoms or more, in addition to 6 W atoms nm^{-2} on SiO_2. This level of conversion corresponds to a pseudo-turnover frequency of 4×10^{-2} mol (thiophene) mol(W + Ni)$^{-1}$ s^{-1}. Increasing the Ni loading further did not influence the activity significantly. Interestingly, the optimum Ni/W atomic ratio of 0.66 equals that in commercial NiW–Al_2O_3 catalysts.[2]

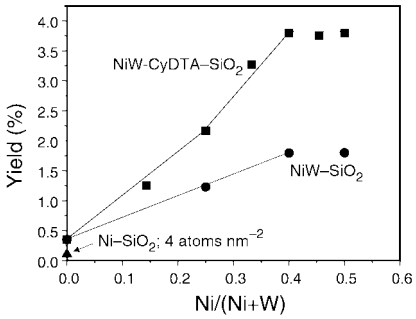

Fig. 2 Thiophene HDS activity as a function of Ni-content in NiWS–SiO_2/Si(100) model catalysts containing 6 W atoms nm^{-2} (batch reaction at 400 °C, runtime 1 h).

We attribute the high HDS activity of NiW-CyDTA–SiO_2 to the retardation of nickel sulfidation by the chelating agent to temperatures where WS_2 has already formed. As a result, Ni atoms released by CyDTA can move to the edges of WS_2 to form a finely dispersed NiW sulfide. A similar phase, commonly referred to as CoMoS, has been identified as the active phase in sulfided CoMo catalysts by Topsøe and coworkers.[2] A similar structure may be invoked to explain the high activity of sulfided NiW catalysts. The reason that standard NiW–SiO_2, in which Ni-sulfidation is not retarded by complexing agents, shows appreciable promotion of desulfurization activity is that the Ni_3S_2 phase which forms at low temperatures redisperses at higher temperatures and may still end up in the form of suboptimal clusters on the edges of WS_2, as recently proposed by Reinhoudt *et al.*[11] However, application of sufficiently stable chelating agents such as CyDTA, that retard Ni sulfide formation to temperatures where WS_2 has formed, results in the most active form of the NiWS catalyst, as demonstrated in this paper.

Received (in Cambridge, UK) 5th April 2000, Accepted 9th May 2000
Published on the Web 8th June 2000

A square-shaped π-conjugated porphyrin tetramer has prepared: the excitation energies of both the Soret and Q bands, 19 880 (503) and 15 180 cm^{-1} (659 nm), respectively, are quite low compared with those for the monomer and reported cyclic porphyrin oligomers.

Interdisciplinary research on porphyrin oligomers (POs) has been attracting much attention over the last two decades.[1] Studies are focused on the elucidation of the function of naturally occurring POs, such as the cyclophane-like dimeric *special pair* in the photosynthetic reaction center,[1] as well as the creation of component molecules for novel advanced materials.[2–8] Recently, many efforts have been made to prepare cyclic porphyrin oligomers (CPOs) motivated by the wheel-shaped oligomeric porphyrinoid architecture found in the light harvesting proteins.[9] After the pioneering work of Sanders and Anderson in 1989,[10] several CPOs have been reported, in which each porphyrin is connected by covalent[11–13] or coordination bonds.[14] However, the linkages are only limited to aryl-based *meso*-groups in which the porphyrin and linker π-systems are orthogonal. Therefore, the electronic interaction between the neighbouring chromophores in the ground state remains small.[7] With the aim of creating a highly conjugated CPO, we chose a diacetylene unit to connect porphyrins directly at the *meso*-position.[4–8, 15] Here we report the synthesis and some basic properties of a new cyclic π-conjugated porphyrin tetramer **1** (Fig. 1).

The synthetic route to **1** is shown in Scheme 1. An important key intermediate, 5,10-bis(3,5-di-*tert*-butylphenyl)porphyrin **3**, which acts as the corners of the square **1** was prepared in 3% yield by the coupling reaction of 3,5-di-*tert*-butylphenylbenzaldehyde and pyrrole with tripyrrane **2**, as reported by Taniguchi and coworkers,[16] in the presence of powdered NaCl.[17] After metallation of **3**, functionalization reactions were performed at the *meso*-positions, *i.e.* bromination (affording **5**), introduction of acetylene groups (to give **6**), and the removal of the TMS groups (providing **7**).† Glaser–Hay coupling[4] of **7** at a 2.6 mM concentration gave moderately soluble, brown coloured crude products. The resulting reaction mixture was analyzed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry to give a main peak for M^+ at *m/z* 3160, along with a weak one at *m/z* 2371. This clearly indicates the tetramer was formed exclusively (*m/z* calc. for M^+ of the cyclic tetramer, $C_{208}H_{200}N_{16}Ni_4$: 3159; *m/z* calc. for M^+ of the acyclic trimer, $C_{156}H_{152}N_{12}Ni_3$: 2371). Separation of the tetramer was successfully achieved using preparative gel permeation chromatography. The absence of C≡C–H and asymmetric C≡C stretching bands in the IR spectrum of **1**, characteristically observed for **7** at 3310s and 2106m cm^{-1}, respectively, suggest the tetramer to be cyclic. The simple pattern of ^{1}H-NMR peaks† also supports the cyclic structure having D_{4h} symmetry (*vide infra*). In a

typical reaction, 41.3 mg of **7**, 400.0 mg of Cu_2Cl_2, 0.55 mL of TMEDA, and 50 mL of dry CH_2Cl_2 gave 8.9 mg of the tetramer **1** as a lustrous dark-green solid (22% yield). It should be emphasised that this relatively high yielding formation of cyclic **1** occurred in the absence of template;[12] the isolated yield of the structurally similar square was 7% at most.[11]

The ^{1}H-NMR chemical shift of the internal protons (H^a: 10.09 ppm) is informative about the structure of **1** from the following two view points. First, compared to the corresponding protons of **7** ($H^{a'}$: 9.55 ppm), H^a is shifted to low field by +0.54 ppm. Although a similar downfield shift was observed for the linear porphyrin oligomers connected by the diacetylene linkages, *e.g.* +0.22 ppm for the dimer,[8] the shift for **1** is more than double this value. Second, the difference in the chemical shifts of the internal (H^a) and the external protons (H^b: 9.66 ppm) adjacent to the diacetylene units of **1** is +0.43 ppm. This value is also larger than that observed for **7** (+0.09 ppm: 9.55 ppm for $H^{a'}$ and 9.46 ppm for $H^{b'}$). These results suggest that the H^a-protons of **1** are affected by the ring current, not only of the two adjacent porphyrin rings, but also of the diagonal porphyrin in the square and also clearly suggests **1** to be cyclic.

The electronic spectra of **1** and **6** are shown in Fig. 2. The spectrum of **1** is composed of two main bands: Q-band-like band I and Soret-band-like band II.† Reflecting the highly conjugated structure, band I and band II appear at 15 180 (659) and 19 880 cm^{-1} (503 nm), respectively. Both band I and band II are shifted to lower energy compared with those of the monomer **6** by about 2900 cm^{-1}. Although these bands appear at much longer wavelengths than those of the porphyrin square connected by *meso*-aryl-based linkages reported by Lindsey and coworkers (λ_{max} = 23 260 cm^{-1}; 430 nm),[11] these wavelengths are similar to the corresponding linear tetramer.[6] The intensity of band I normalized per chromophore was increased compared with that of **6**. Conversely, the intensity of band II was decreased. This phenomenon suggests that the degeneracy of the a_{1u} and a_{2u} orbitals of the porphyrins is lifted[7] and that a new π-electronic system in the square is formed.

In conclusion, a novel and highly conjugated porphyrin square was prepared. In addition to the expanded π-system of the molecule, our square has a central cavity corresponding to the size of molecules such as hexamethylbenzene.[18] These characteristics will allow us to use the square as an advanced host molecule. We are currently investigating the photochemistry of the corresponding free base and zinc complex, as well as contraction and expansion of the square by replacing the diacetylene units with –C≡C– and –(C≡C–)$_n$ (n > 3) linkers, respectively, keeping the π-conjugation between the four porphyrins.

Encapsulation of Et_3N^+–H···OH_2 in a hydrogen-bonded resorcarene capsule

Alexander Shivanyuk,* Kari Rissanen* and Erkki Kolehmainen

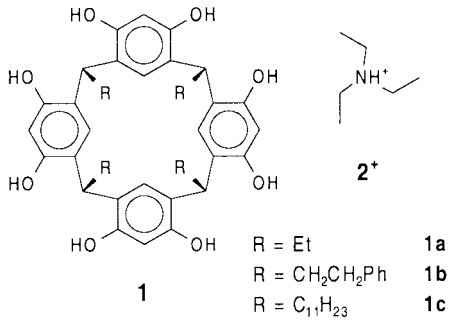
Department of Chemistry, University of Jyväskylä, PO Box 35, Jyväskylä, FIN-40351, Finland. E-mail: shivan@jyu.fi and kari.rissanen@jyu.fi

Received (in Cambridge, UK) 16th March 2000, Accepted 15th May 2000
Published on the Web 8th June 2000

In the crystalline state a resorcarene dimer linked by ten hydrogen-bonding water molecules encapsulates the hydrogen-bonded complex Et_3N^+–H···OH_2 while bromide anions are positioned outside the cavity.

Supramolecular encapsulation is a topic of considerable current interest.[1] Designed self-complementary molecules form dimeric[2] or tetrameric[3] hydrogen-bonded capsules including charged and neutral guest species. Resorcarenes **1** linked by smaller hydrogen-bonding molecules assemble into dimeric[4] and hexameric[5] hollow structures in the solid state**.** Molecular encapsulation of dimeric hydrogen-bonded complexes has been discovered recently in apolar solutions[6] however much less is known about such complexation in the crystalline state.[7]

Herein we describe the first single crystal X-ray structure of a hydrogen-bonded molecular capsule encapsulating the hydrogen-bonded heterocomplex Et_3N^+–H···OH_2.



Co-crystallization of **1a** with a ten-fold excess of Et_3NHBr from aqueous EtOH results in cubic crystals which, although unstable without solvent, were suitable for single crystal X-ray analysis.† The resorcarene molecules adopt a perfect cone conformation stabilized by four intramolecular hydrogen bonds between neighboring hydroxy groups. Two molecules of **1a**, sitting on a two fold crystallographic rotation axis, form a dimer held together by ten hydrogen-bonded water molecules disordered over 16 sites (Fig. 1). One $\mathbf{2}^+$ and one hydrogen-bonded water molecule [N1A···O12a 2.735(7) Å] are encapsulated in such a dimeric cavity.[8] Two opposite orientations occur for the encapsulated Et_3N^+–H···OH_2 with occupancy factors of 0.7 and 0.3. Furthermore, in each orientation the ethyl groups are strongly disordered owing to the fact that the three-fold axis of $\mathbf{2}^+$ coincides with the two-fold axis of the capsule. Encapsulated $\mathbf{2}^+$ is shifted by 0.28 Å from the center of the cavity[9] towards resorcarene molecule B. Several close non-bonded contacts (3.49–3.67 Å) were found between carbon atoms of Et_3N^+–H and resorcinol rings of **1a** which manifest C–H··π attractions. The encapsulated water molecule (O12a) is located deep in the resorcarene socket of molecule A forming four close non-bonded contacts to the aromatic C–H atoms of the resorcinol rings with O–C distances of 3.327(4) and 3.335(4) Å.[10] Such an arrangement allows O–H··π interactions between the encapsulated water molecule and the resorcinol rings. The hydrogen bonding in Et_3N^+–H···OH_2 should theoretically increase the positive charge on the hydrogen atoms of the water molecule and thus facilitate O–H··π attractions.

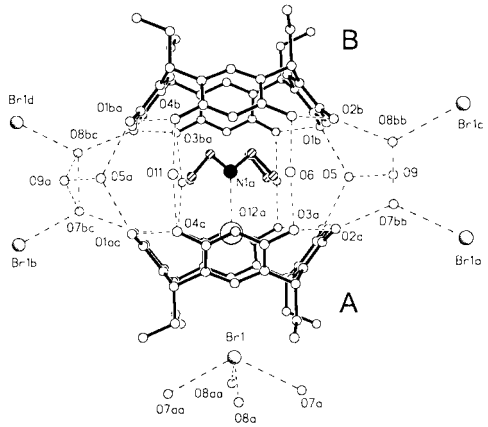


Fig. 1 Single-crystal X-ray structure of [(**1a**$_2$·10H_2O)-@($\mathbf{2}^+$·H_2O)]Br^-·4.8H_2O. All hydrogen atoms are omitted for clarity. Hydrogen bonds are indicated by dotted lines. The most populated orientation of the disordered cation and water molecule is indicated. The nitrogen atom of $\mathbf{2}^+$ and oxygen atom of encapsulated water molecule are shown with arbitrary radii. Distances between hydrogen-bonding oxygen atoms are between 2.606(3) and 2.791(5) Å. Distances between the hydrogen-bonded Br anion and water molecules are between 3.323(6) and 3.348(5) Å.

The bromide anion is positioned outside the cavity and lies within the shallow pocket formed by four pendant CH_2 groups of molecule A[11] and is solvated by four disordered hydrogen-bonded water molecules (Fig. 1). The shortest N···Br distance [8.212(6) Å] is *ca.* 2.5 times longer than in $\mathbf{2}^+$ Br^-.[12] The distance of the bromide anion to the carbon atom of the CH_2 group is 4.004(4) Å reflecting weak C–H···Br^- interactions. The hydrogen-bonded array of the resorcarene dimer is not saturated and therefore four symmetry related bromide anions are hydrogen bonded to the bridging water molecules (Fig. 1).

^{1}H NMR spectroscopy shows that no complex is formed between **1** and $\mathbf{2}^+$ in polar solvents such as methanol-d_4 or DMSO-d_6. However, in $CDCl_3$ saturated with H_2O, lipophilic resorcarenes **1b,c** strongly interact with $\mathbf{2}^+$ X^- (X^- = Cl^-, Br^-, ClO_4^-). At [$\mathbf{2}^+$ X^-]/[**1b,c**] ≥ 0.5, ^{1}H NMR spectra show sharp signals of methyl and methylene protons of the complexed cation which are both shifted upfield by *ca.* 1.3 ppm (Fig. 2). The exchange of complexed and free $\mathbf{2}^+$ is slow on the NMR timescale at 303 K (500 MHz) and the integration shows that two resorcarene molecules complex one cation $\mathbf{2}^+$. The signal of the water protons (5–6 H per **1c**) is shifted downfield ($\Delta\delta$ = 1.9 ppm) and the multiplet of resorcinol OH groups is centered at δ 9.5 owing to strong hydrogen-bonding. These results suggest that hydrogen-bonded water molecules participate in the formation of the 2:1 capsule also in $CDCl_3$.[13] These results are also in agreement with the fact that in dry $CDCl_3$ the systems **1b,c** + *n* $\mathbf{2}^+X^-$ exhibit broad ^{1}H NMR spectra, most probably owing to the formation of ill defined hydrogen-bonded aggregates. Detailed NMR investigations of these complex systems in apolar solvents are currently in progress and will be reported in due course.

In conclusion, the solid-state encapsulation of ammonium cations by a water linked dimer of **1a** is strongly dependent on

DOI: 10.1039/b002144j

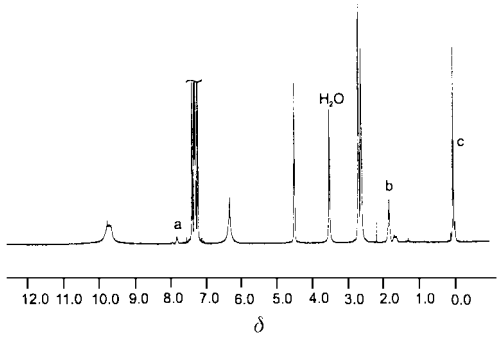

Fig. 2 ^{1}H NMR spectrum of 2 **1b** + **2**$^+$Cl$^-$ {[**1b**] = 3×10^{-2} M, 500 MHz, 303 K, $CDCl_3$}. The signals of the complexed cation are: a, NH; b, CH_2; c, CH_3.

the structure of the guest. For the previously studied complex with Et_4N^+[14] no anion is found while the negative charge was distributed over all oxygen atoms of the capsule. The smaller volume of Et_3NH^+ and the presence of the hydrogen bonding N–H group seem to be crucial for the encapsulation of Et_3N^+–H··OH_2 in the cavity of the resorcarene dimer. The incomplete saturation of the hydrogen-bonded array within the hydrogen bonded shell determines the strong hydrogen-bonding interaction of the capsule with external bromide anions. This feature is being currently explored for the rational design of externally tuned supramolecular containers.

† *X-Ray crystal structure analysis*: Data were recorded with a Kappa CCD difractometer using graphite monochromatised Mo-Kα radiation [λ(Mo-Kα) = 0.71073 Å]. The data was processed with Denzo-SMN v0.93.0 [Z. Otwinowski and W. Minor, *Processing of X-ray Diffraction Data Collected in Oscillation Mode*, *Methods in Enzymology*, vol. 276: *Macromolecular Crystallography*, Part A, ed. C. W. Carter, Jr. and R. M. Sweet, Academic Press, New York, 1997, pp. 307–326]. The structures were solved by direct methods (SHELXS-97: G. M. Sheldrick, *Acta Crystallogr., Sect. A*, 1990, **46**, 467) and refinements, based on F^2, were made by full-matrix least-squares techniques (SHELXL-97, G. M. Sheldrick, *A program for crystal structure refinement*, 1997, University of Göttingen, Germany). The hydrogen atoms were placed in calculated idealized positions with isotropic temperature factors (1.2 times the C temperature factor) and refined as riding atoms. The hydrogen atoms of water molecules and disordered cation were not located. The atoms of the cation in the less populated orientation as well as two strongly disordered water molecules were treated isotropically.

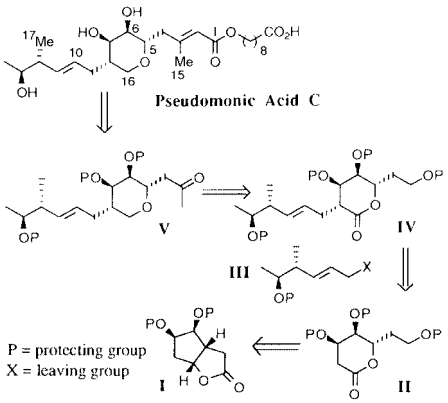
The total synthesis of pseudomonic acid C is described using an approach which gives access to analogues and putative biosynthetic precursors; the key step is installation of the C_7 side-chain *via* alkylation of a trisubstituted δ-lactone with complete stereocontrol and in 85% yield under conditions which avoid the possible competing elimination of a protected hydroxy group β to the carbonyl.

Pseudomonic acid C is one of a family of *C*-glycopyranosides produced by *Pseudomonas fluorescens*.[1] These compounds are potent inhibitors of Gram positive bacterial and mycoplasmal pathogens[2] and pseudomonic acid A (with a 10,11-epoxide) is used clinically for the treatment of bacterial skin infections. More recently new pseudomonic acid derivatives such as thiomarinol have been isolated from marine organisms.[3]

Despite their biological importance, the biosynthesis of these polyketide derived secondary metabolites[4] has not been established. Results of feeding studies with oxygen-18 precursors indicate that the oxygens attached to C-1, C-5, C-7 and C-13 are all derived from acetate whereas the oxygen at C-6 must originate from either the atmosphere or water.[5] These results are in accord with the proposal that the tetrahydropyran ring is formed either *via* an intramolecular conjugate addition of 5-OH to an enone or *via* an intramolecular S_N2 type attack of the 5-OH onto an activated 16-hydroxy group. However, the mechanism of cyclisation has not been established and its timing relative to other steps such as hydroxylation at C-6 or esterification at C-1 is not known. Therefore our goal was to develop a new and flexible approach to the synthesis of pseudomonic acid which would give access to acyclic compounds to examine these processes as well as to analogues for biological assessment. Previous routes have involved either elaboration of carbohydrates or the modification of dihydropyrans.[6] These approaches do not give access to the required putative biosynthetic intermediates and hence a new strategy was required.

The key features of this strategy (Scheme 1) are: (i) the enantioselective synthesis of a suitably protected functionalised δ-lactone **II** from the bicyclic lactone **I**; (ii) preparation of the C_7 side-chain **III** with a good leaving group to act as the electrophile for reaction with the enolate of **II**; (iii) installation of the C_7 side-chain with complete stereocontrol under conditions which avoid the possible competing elimination of a protected hydroxy group β to the carbonyl in **II** to give **IV**; (iv) reduction of the lactone **IV** to a tetrahydropyran followed by further manipulation of the side chain to methyl ketone **V** and chain extension with a known phosphonate[7] to the target compound. Lactone **IV** would be the precursor of the acyclic compounds required to examine the ring closure reactions.



Scheme 1

The first step was introduction of a *cis*-vicinal diol which was achieved *via* treatment of *cis*-bicyclo[3.2.0]hept-7-en-2-one **1** with catalytic osmium tetroxide giving a 9:1 mixture of *exo*:*endo* vicinal diols.[8] (−)-(1*S*,5*R*)-Bicyclic ketone **1** required as the starting material was prepared with 95% ee *via* resolution of the bisulfite adduct.[9] The *syn* diols could be protected as either the acetonide or benzyl ethers but, for ease of manipulation at later stages of the synthesis, the *tert*-butyldimethylsilyl (TBS) ether **2** was preferred (Scheme 2) Baeyer–Villiger oxidation proceeded as expected[10] with complete regiocontrol giving the required lactone **3** in 68% yield over the three steps from **1**.

Elaboration of bicyclic lactone **3** to the required δ-lactone **7** was accomplished by a straightforward sequence involving initial reduction of **3** with $LiAlH_4$ to diol **4**. Selective protection of the primary alcohol of **4** as either the benzoate, trityl ether or TBDPS ether proceeded in excellent yields (> 90%), but the best protecting group for later stages of the synthesis proved to be the TBS ether. Oxidation of alcohol **5** with TPAP[11] followed by treatment of the resultant cyclopentanone **6** with MCPBA gave δ-lactone **7** possessing the stereogenic centres which would become C-5, C-6 and C-7 of pseudomonic acid.

The key stage of the total synthesis was the alkylation to introduce selectively the C_7 side chain of pseudomonic acid. Examples of alkylation of δ-lactones have been reported,[12] and Seebach *et al.*[13] showed that stereocontrol of the methylation of a δ-lactone possessing a free hydroxy group β to the carbonyl could be achieved using chelation control with the alkoxide. However, we found no literature precedents for alkylation of a δ-lactone possessing a β-silyl ether and it was anticipated that β-elimination to give the α,β-unsaturated lactone may be a competing process.

Allylic bromides have been used as electrophiles in the alkylation of simple δ-lactones in natural product synthesis[14]

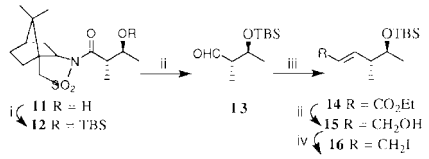
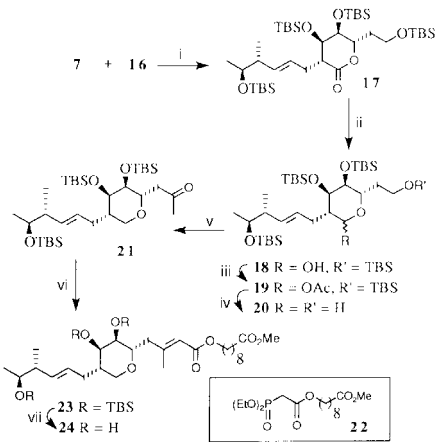


Scheme 4 *Reagents and conditions*: i, TBSOTf, pyridine, CH_2Cl_2; ii, DIBAL-H, CH_2Cl_2, −78 °C; iii, $(EtO)_2POCHCO_2Et$, BuLi, THF; iv, DIPHOS (1,2-bis(diphenylphosphino)ethane), I_2, 0 °C.

and so we carried out model studies using allyl bromide. Treatment of trisubstituted δ-lactone **8** with LDA followed by addition of allyl bromide gave, at best, 20% yield of the alkylated product **9** (Scheme 3). HMPA has been used to improve yields in the alkylation of δ-valerolactone,[15] but on addition of HMPA to our reaction, β-elimination occurred giving the α,β-unsaturated lactone **10** as the major product. However, when the reaction was repeated with the more reactive allyl iodide as the electrophile, **9** was obtained in 84% yield. From NMR studies it was evident that a single product had been isolated and the X-ray crystal structure confirmed that the allyl group in **9** was indeed on the opposite face to the protected vicinal diol as required for the synthesis of pseudomonic acid.

The next stage was the preparation of the C_7 side chain **III** with iodide as the leaving group. The enantioselective synthesis of the analogous alcohol **15** (92% de) has been described by Keck and Tafesh.[16] We adopted a similar approach to **15** (Scheme 4) but used the known alcohol **11**[17] to establish the two asymmetric centres. Protection as the TBS ether **12** and reductive cleavage of the auxiliary using DIBAL-H at −78 °C gave aldehyde **13** in 93% yield over the two steps. Chain extension of **13** to **14** followed by reduction with DIBAL-H gave the required allylic alcohol **15** (> 99% de). Reaction of **15** with DIPHOS and I_2 at 0 °C[18] gave allylic iodide **16** in quantitative yield. The key alkylation of the lithium enolate of δ-lactone **7** with allylic iodide **16** in the presence of HMPA led to the required tetrasubstituted δ-lactone **17** in 85% yield after purification (Scheme 5).

Having created all the necessary asymmetric centres around the central δ-lactone core, the next goal was reduction to the analogous tetrahydropyran using a modification of the procedure described by Kraus *et al.*[19] Treatment of lactone **17** with



Scheme 5 *Reagents and conditions*: i, LDA, HMPA, −78 to 5 °C; ii, DIBAL-H, CH_2Cl_2, −78 °C; iii, Ac_2O, pyridine; iv, Et_3SiH, $BF_3{\cdot}Et_2O$, CH_2Cl_2, −78 °C; v, PDC, CH_2Cl_2 then MeMgBr, Et_2O, −5 °C then TPAP, NMO, CH_2Cl_2; vi, **22**, KHMDS, THF; viii, TBAF, THF.

DIBAL-H in CH_2Cl_2 at −78 °C gave lactol **18** which could be reduced directly to the tetrahydropyran with triethylsilane in the presence of $BF_3{\cdot}Et_2O$. However, an improved yield was obtained by acetylation to **19** prior to the triethylsilane reduction. The reaction conditions led to the concommitant selective removal of the TBS ether to unmask the primary alcohol **20** required for the next stage of the synthesis. Oxidation of **20** with PDC to the corresponding aldehyde, introduction of C-17 using MeMgBr and a second oxidation with TPAP then gave methyl ketone **21** in 74% yield from **20**.

The final carbon–carbon bond forming reaction was the Horner–Emmons coupling of ketone **21** with phosphonate **22** (prepared in 75% yield by the DCC/DMAP mediated coupling methyl 9-hydroxynonanoic acid with diethyl phosphonoacetic acid) giving the *E*-unsaturated ester **23**. Deprotection of the TBS ethers with TBAF gave methyl pseudomonate C **24**, with spectroscopic data in accord with those previously reported[7,20] and with $[\alpha]_D$ +10.0 (*c* 0.15, $CHCl_3$). Interestingly our literature search revealed no $[\alpha]_D$ value for methyl pseudomonate C derived from natural sources and only that for material prepared by total synthesis.[20] Hence a sample of pseudomonic acid C isolated from *Ps. fluorescens* was methylated giving ester **24** with $[\alpha]_D$ +10.7 (*c* 0.3, $CHCl_3$), in good agreement with the value obtained for our synthetic sample. The methyl ester may be hydrolysed[20] to pseudomonic acid C.

We are grateful to the EPSRC and SB for funding (to C. M.), Dr T. M. Peakman for NOE studies and to Ms K. M. Anderson and Professor A. G. Orpen for X-ray studies.

Mesomorphic phase transition of a cyclotetraphosphazene containing Schiff base moieties: comparison with the corresponding cyclotriphosphazene

Keiichi Moriya,*[a] Yasuyuki Kawanishi,[a] Shinichi Yano[a] and Meisetsu Kajiwara[b]

Received (in Oxford, UK) 13th January 2000, Accepted 10th May 2000
Published on the Web 8th June 2000

Newly prepared octakis{4-[*N*-(4′-heptyloxyphenyl)iminomethyl]phenoxy}cyclotetraphosphazene, consisting of a cyclotetraphosphazene ring backbone and Schiff base side-chain groups has been found to generate an enantiotropic smectic A phase; this is a first example of a mesomorphic cyclotetraphosphazene.

Cyclotetraphosphazenes are cyclic compounds of general formula $(PNX_2)_4$, in which tetracoordinated phosphorus atoms alternate regularly with the nitrogen atoms (Fig. 1). Several cyclotetraphosphazenes have been synthesized by introducing functional side chains into them.[1,2] Although some examples of mesomorphic transitions in cyclotriphosphazenes have been described[3–7] no liquid crystalline phases of cyclotetraphosphazenes have been observed.[5,7] In particular, in a previous paper, we reported our studies on phase transitions of cyclotetraphosphazenes and cyclotriphosphazenes with the same 4-octyloxybiphenyl mesogenic side groups.[5] We found no liquid crystalline phase for octakis[4-(4′-octyloxy)biphenoxy]-cyclotetraphosphazene **1** but an enantiotropic smectic C phase was observed for hexakis[4-(4′-octyloxy)biphenoxy]cyclotriphosphazene **2**. These results were interpreted in terms of the X-ray single crystal structure analyses of octakis(4-biphenoxy)-cyclotetraphosphazene (OBCP) and hexakis-(4-biphenoxy)cyclotriphosphazene (HBCP), which have shown the side chains lining-up randomly in the former but in a relatively regular fashion for the latter.[8] A similar situation might be assumed for compounds **1** and **2**. In tetramer **1**, the eight side chains are directed essentially randomly so preventing the formation of a mesomorphic layer structure. However, in trimer **2**, each of the three side chains of the cyclotriphosphazene molecules point almost perpendicularly upwards and downwards from the cyclotriphosphazene ring plane, which aids in the formation of a mesomorphic layer structure. The molecular structure of compound **2** assuming an all *trans* conformation for the octyloxy side chains based on the crystal structure of HBOP.[4] The architecture of the mesomorphic phase is reminiscent of arrangements of the mesomorphic phase in a cyclotetrasiloxane,[9] a dendric octasilsesquioxane,[10] and a fullerene derivative.[11]

Fig. 1 Chemical formulae of octakis{4-[*N*-(4′-heptyloxyphenyl)iminomethyl]phenoxy}cyclotetraphosphazene **3** and hexakis{4-[*N*-(4′-heptyloxyphenyl)iminomethyl]phenoxy}cyclotriposphazene **4**, octakis[4-(4′-octyloxy)biphenoxy]cyclotetraphosphazene **1** and hexakis[4-(4′-octyloxy)biphenoxy]cyclotriphosphazene **2**.

Schiff bases have a strong tendency to produce mesomophic phases.[6,12,13] Therefore, for attempted generation of liquid crystalline behavior, we synthesized octakis{4-[*N*-(4′-heptyloxyphenyl)iminomethyl]phenoxy}cyclotetraphosphazene **3** (Fig. 1), with side chains containing Schiff bases with long alkoxy tails, laterally linked to the cyclotetraphosphazene ring. We studied its phase transitions and mesogenicity using polarizing microscopy and DSC measurements, and the obtained results were compared with those for the cyclotriphosphazene, hexakis{4-[*N*-(4′-heptyloxyphenyl)iminomethyl]phenoxy}cyclotriphosphazene **4** with similar mesogenic side groups (Fig. 1). This paper presents the first evidence for the formation of a mesophase in cyclotetraphosphazenes.

Compound **1** was synthesized as follows. 4-Heptyloxyacetanilide **5** was prepared from 4-hydroxyacetanilide (25 g, 0.16 mol), bromoheptane (28.5 g, 0.16 mol) and KOH (11 g, 0.17 mol) in ethanol (200 ml) under reflux for 6 h. 4-Heptyloxyaniline **6** was synthesized from **5** (20 g, 83 mmol) and KOH (15 g, 0.23 mol) in ethanol (200 ml) under reflux for 24 h. Hexakis(4-formylphenoxy)cyclotetraphosphazene **7** was prepared from hexachlorocyclotetraphosphazene (5.0 g, 10.6 mmol) (Nihon Soda Co., Ltd.) and the sodium salt of 4-hydroxybenzaldehyde in THF (125 ml) under reflux for 3 h. The sodium salt was prepared from 4-hydroxybenzaldehyde (17.5 g, 0.143 mol) and NaH (5.73 g, 0.143 mol) in THF under reflux for 2 h. Finally, compound **3** was prepared by the reaction of **6** (2.7 g, 13 mmol) and **7** (1.0 g, 0.87 mmol) in benzene (50 ml) under reflux for 6 h. Water produced in the solution was removed by molecular sieves in a Dean–Stark tube. The obtained crude products were separated by filtration and recrystallized three times from benzene and once from THF–cyclohexane (1:1) after being separated by filtration. Compound **3** was characterized by ^{1}H and ^{31}P NMR, IR spectroscopy and elemental analysis.[14] Phase transitions were studied using Seiko DSC 210 and SSC 5500 systems from room temperature to above the melting point at heating/cooling rates of 5 K min^{-1}. The textures of the mesophase were observed using a polarizing microscope (Nikon, Optiphot-pol XTP-11) with a temperature controlled hot stage (Mettler, FP-80) at heating/cooling rates of 5 K min^{-1}.

The DSC thermograms of octakis{4-[*N*-(4′-heptyloxyphenyl)iminomethyl]phenoxy}cyclotetraphosphazene **3** for the first cooling (1c) and second heating (2h) processes are shown in Fig. 2. For the first cooling process, two exothermic peaks were observed at 429 and 422 K. According to polarizing microscopy, upon cooling from an isotropic liquid, batonnets were observed at 429 K which grew into a fan texture at *ca.* 428.8 K, suggesting the presence of a smectic A phase.[15] In the first heating process, two endothermic peaks were observed at 428 and 430 K. According to polarizing microscopy, melting of compound **3** was observed at 428 K and between 428 and 430 K a fan texture similar to that in the first cooling process was seen, which establishes the existence of the smectic A phase. The view become black at 430 K, which corresponds to the SmA–I phase transition. This is the first case of a mesomorphic phase in cyclotetraphosphazenes.

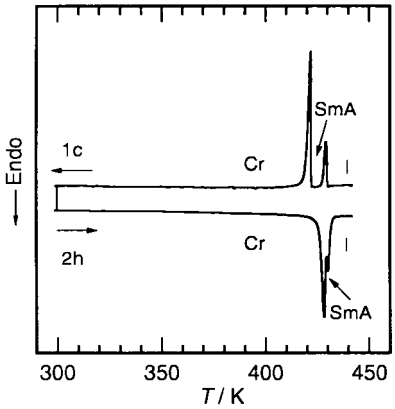

Fig. 2 DSC thermograms of octakis{4-[*N*-(4′-heptyloxyphenyl)iminomethyl]phenoxy}cyclotetraphosphazene **3** for the first cooling (1c) and second heating (2h) processes.

Table 1 shows a comparison of the phase transition temperatures, phase transition enthalpies and entropies for the pairs of tetramers (**1**, **3**) and trimers (**2**, **4**) bearing the same mesogenic substituents: octyloxybiphenoxy (**1**, **2**) and 4-{*N*-[4′-heptyloxyphenyl]iminomethyl}phenoxy groups (**3**, **4**). The thermodynamic values were obtained from the second heating process *via* DSC measurements. For the tetramers, the derivative **3** with substituents containing the Schiff base (compound **3**) has a narrow enantiotropic liquid crystalline phase with a temperature range of only 2 K, while no mesomorphic phase was observed for the derivative with octyloxybiphenoxy side chains (compound **1**).[5] The trimer with the Schiff base substituents (compound **4**) shows the enantiotropic mesomorphic phase transition sequence Cr–Sm1–SmC–SmA–I.[6] It displays a high SmA–I transition temperature (512 K) and wide mesomorphic phase transition region (ΔT = 52 K). By contrast, the trimer with octyloxybiphenoxy side chains (compound **2**) undergoes an enantiotropic mesomorphic phase transition, Cr–SmC–I.[3–5] The SmC phase was confirmed by X-ray photography under a magnetic field.[3] The SmC–I transition temperature (457 K) is lower, and the mesomorphic phase transition region (ΔT = 17 K) is narrower than those for the trimer with the Schiff base substituents (compound **4**). The compounds with the Schiff base side chains appear to have a higher thermal stability in the mesomorphic phase and higher mesomorphic phase generation ability than those with 4-octyloxybiphenoxy side chains. Two possible interpretations for the observed differences may be considered. In the first, the molecular structure of the tetramer with Schiff base side chains is assumed to differ significantly from that of the tetramer with octyloxybiphenoxy side chains. The other possible interpretation is that the intermolecular interactions might be much stronger for the Schiff base derivative **3** than for the octyloxybiphenoxy derivative **1** even if the molecular structures do not differ very much from each other. Based on this assumption, the mesomorphic ability of the compounds with Schiff base side chains would be high. Assuming this, and that compound **3** retains this molecular structure after melting, it would appear to be difficult to form a mesomorphic phase because of the random orientation of the side groups. Probably, the cyclotetraphosphazene rings would soften and the Schiff base side chains can form a smectic A layer structure. This behavior was observed in the SmA phase of the cyclotriphosphazene with dodecylbiphenoxy side groups, in which the local order parameter around the P atom obtained by ^{31}P NMR spectroscopy was *ca.* 0.44.[4] This value is lower than that in a typical sectic A phase and suggests the presence of disorder in the cyclotriphosphazene. The difference in the mesogenicity of tetramers and trimers is a result of their differing molecular structure.

In conclusion, we have introduced mesogenic side groups containing Schiff base functionalities onto the cyclotetraphosphazene ring and obtained the first N_4P_4 derivative capable of generating a mesomorphic smectic A phase. The liquid crystalline behavior results from assistance from the Schiff base to the formation of a layer structure due to the favorable intermolecular interactions of the laterally linked mesogenic units, which may override the formation of random orientations of the side chains typical in cyclotetraphosphazenes.

We are grateful to Nihon Soda Co., Ltd. for providing octachlorocyclotetraphosphazene.

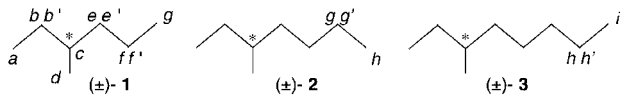
Natural abundance deuterium NMR spectroscopy in a chiral polypeptide liquid crystal solvent (PBLG) is used to successfully discriminate between chiral alkanes.

The enantiomeric differentiation of saturated chiral hydrocarbons is an interesting but difficult task using NMR spectroscopy. Among this class of compounds, 3-methylhexane **1**, -heptane **2** and -octane **3** are excellent illustrative examples.

Although the separation of 3-methylhexane by gas chromatography using undiluted cyclodextrin derivatives as a chiral stationary phase is noteworthy,[1] to the best of our knowledge, all isotropic NMR techniques have failed to discriminate between such chiral alkanes, as no successful results have been reported to date. This situation occurs mainly because these compounds do not possess any functional groups, making the derivatisation of the chiral molecule or the preparation *in situ* of specific complexation agents impossible.[2] Consequently, only NMR analytical approaches in which shape recognition plays an important role in the chiral discrimination mechanisms, compared with the electrostatic interaction contributions, are likely to produce successful results.

In this preliminary work, we demonstrate for the first time that enantiomeric discrimination of chiral alkanes is possible using natural abundance deuterium (NAD) NMR spectroscopy in a chiral polypeptide liquid-crystalline solvent composed of poly-γ-benzyl-L-glutamate (PBLG) dissolved in chloroform.[3,4]

Four different reasons justify the use of this unusual NMR tool. First, we have recently shown that the shape of solutes plays a important role in the differential orientation effect (DOE) of two enantiomers in the PBLG phase.[5,6] Second, since it may be expected that the difference in the interaction between the *R* and *S* isomers and the polypeptide helices will generate a rather small DOE, it is necessary to observe a very sensitive order-dependent NMR interaction, such as the quadrupolar interaction for deuterium ($I = 1$) nuclei.[3] Indeed, when the orientational difference between the *R* and *S* isomers is small, the relatively large magnitude of the deuterium quadrupolar coupling constant for a C–D bond (QCC ≈ 170 kHz)[7] can give a sufficiently large difference in their residual quadrupolar splittings ($\Delta\nu_Q^R - \Delta\nu_Q^S$), enabling their observation. Third, since the detection of rare spins such as deuterons in natural abundance is not an insurmountable obstacle in terms of sensitivity (*i.e.* detection using standard NMR equipment and reasonable experimental time), the site-specific labelling of the chiral molecules is not required, avoiding time-consuming synthetic work.[3] Finally, all possible deuterated sites of the molecule can be simultaneously probed, thus increasing the probability of observing a chiral differentiation.[3]



Proton-decoupled NAD NMR spectra in organic solutions of PBLG consist of the superposition of independent quadrupolar doublets, $\Delta\nu_{Q_i}$, corresponding to all non-equivalent deuterons in each of the two enantiomers.[3,4] Thus, in the case of (±)-**1**, (±)-**2**, and (±)-**3**, 20, 24 and 28 different chiral isotopomers exist in the mixture respectively, and a maximum of 20, 24 and 28 doublets, respectively, are expected to be detected if all deuterated sites show a chiral discrimination. Consequently, even if dipolar couplings between two rare atoms cannot be detected, the correlation between the two components for each quadrupolar doublet is not always simple, mainly due to overlapping of peaks, and requires the use of proton-decoupled deuterium 2D-NMR experiments.[4]

Fig. 1 reports the NAD 2D Q-COSY spectrum† of (±)-**1**‡ in the PBLG–$CHCl_3$ phase recorded at 298 K over 16 h at 61.4 MHz.[4] In this 2D spectrum, we can observe 12 different quadrupolar doublets. This result clearly indicates that two deuterons in the molecule are differentiated between, as only 10 doublets would be observed if no chiral separation occured. To confirm this result, we have recorded the NAD 2D Q-COSY spectrum of (±)-**1** in a racemic mixture of PBLG and PBDG (the enantiomer of PBLG) in $CHCl_3$.[6,8] In this mixture, the fast exchange between chiral solutes and the vicinity of PBLG and PBDG eliminates the chiral discrimination, hence only 10 quadrupolar doublets can be (and were) observed. The assignment of each doublet is non-trivial because all deuterons in methylene groups are diasteorotopic (non-equivalent),[3,4] and deuterium chemical shift dispersion in apolar alkanes is rather small. However, we can indirectly identify them from analysis of HMQC (^1H–^{13}C) and INADEQUATE (^{13}C–^{13}C) 2D spectra of (±)-**1** in an isotropic state, which enable a clear assignment of ^{13}C and ^1H signals. Assuming that deuteron chemical shifts in

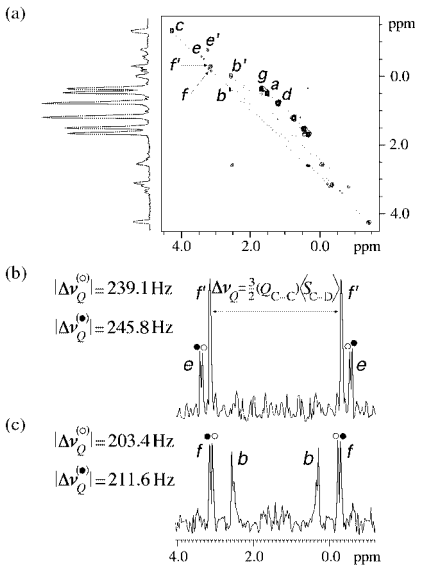


Fig. 1 2D contour plot of a NAD Q-COSY experiment obtained for (±)-**1** (a). The two columns extracted after tilting of the 2D spectrum show a chiral discrimination of the deuterons denoted *e*(b) and *f*(c). The doublet due to each enantiomer is arbitrarily labelled with (●) and (○). The chloroform doublet is not shown in the spectrum.

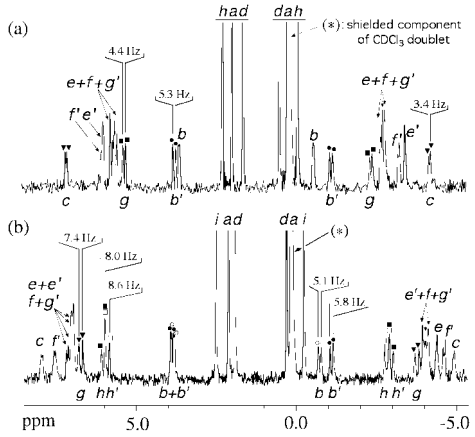

Fig. 2 NAD 1D spectra of (±)-**2** (a) and (±)-**3** (b). All clearly discriminated deuterons are labelled with different symbols.

PBLG are similar to those of protons measured in neat $CHCl_3$, it becomes possible to unambiguously assign almost all deuterium quadrupolar doublets. In addition, this assignment can be confirmed by measuring the proton–carbon dipolar couplings, $D_{C\text{-}H}$, in the carbon-13 spectrum of (±)-**1** in PBLG.[9] Since the ratio $|\Delta\nu_{Q_{C-D}}/D_{C-H}|$ can be quantified as 11.8 ± 0.2 (because $S_{C-D} = S_{C-H}$), we may *a priori* calculate the magnitude of $\Delta\nu_{Q_{C-D}}$ of the deuterons for a given assigned carbon and then compare with experimental values. Using this procedure, we were able to confirm that the deuterons *e* and *f* are discriminated between [Fig. 1(*b*) and (*c*)], while deuterons *b*, *b*' and *c* show broad peaks, indicating an unresolved chiral discrimination. In contrast, no chiral discrimination was detected between the methyl signals (*a*, *d*, *g*).

Fig. 2 reports the NAD 1D-NMR spectra† of (±)-**2**‡ and (±)-**3**‡ recorded at 298 K in the PBLG–$CHCl_3$ phase. Notably, we can unambiguously observe the doubling of numerous peaks, indicating that enantiomers of (±)-**2** and (±)-**3** are discriminated between in the PBLG–$CHCl_3$ phase. Here again, the assignment procedure previously described shows that the largest chiral separations are measured for the diastereotopic deuterons denoted *b*' and *g*, and *b*,*b*',*h*,*h*' and *g* for (±)-**2** and (±)-**3**, respectively. As for (±)-**1**, none of the methyl groups is discriminated between, but a small chiral separation has been observed on the deuteron attached to the asymmetric carbon on these compounds.

The successful enantiomeric differentiation of chiral flexible alkanes using deuterium NMR spectroscopy in PBLG is possible because the polypeptide helices are able to interact enantioselectively with non-functionalized enantiomers and because the sensitivity of the quadrupolar interaction to the DOE is sufficiently large to reveal small orientational differences. This result establishes the significant role of shape recognition in chiral discrimination mechanisms involved in the PBLG phase. An evaluation of the potential of this approach on a wide range of saturated and unsaturated chiral hydrocarbons is currently underway and will be extensively discussed in a subsequent publication.

We thank Professor Henri B. Kagan for stimulating discussions and Dr Claude Brevard from Bruker SA, France for the loan of a 5 mm selective ^2H probe with ^{19}F lock.

Notes and references

† NMR experiments: NMR experiments were performed on a Bruker DRX-400 using a 5 mm selective deuterium probe. The sample was not spun in the field and the temperature was controlled by the BVT 2000 system. Due to the good long term stability of the magnet, no field-frequency lock was used. The WALTZ-16 sequence was applied as broad-band proton decoupling. The 2D Q-COSY spectrum of (±)-**1** was recorded using 300 (t_1) × 1700 (t_2) data points. 400 transients for each t_1 increment were added, leading to a total of 120 000 scans. Gaussian filtering was applied in both dimensions. The 1D interferograms of (±)-**2** and (±)-**3** were acquired using a pulse angle of *ca*. 70°, a recycle delay of *ca*. 0.5 s and 1.7 k of data points, summing over 230 000 and 140 000 scans, respectively. No digital filtering was used.

‡ Sample composition: The liquid-crystalline NMR samples of (±)-**1**, (±)-**2**, (±)-**3** were prepared from 80, 50 and 60 mg of racemic material, 81 mg [degree of polymerisaton (DP) = 562(50%)+1078(50%)], 100 mg (DP = 562) and 100 mg (DP = 562) of PBLG (purchased from Sigma corp.) and 445, 400 and 400 mg of $CHCl_3$, respectively. For sample preparation, see refs. 4 and 5.

Low-temperature, clean catalytic combustion of N-bearing gasified biomass using a novel NH_3 trapping catalyst

Robert Burch and Barry W. L. Southward*

School of Chemistry, The Queen's University of Belfast, Belfast, UK BT9 5AG. E-mail: b.w.l.southward@qub.ac.uk

Received (in Cambridge, UK) 3rd April 2000, Accepted 11th May 2000
Published on the Web 8th June 2000

Substantially reduced NO_x emissions are obtained in the low temperature catalytic combustion of NH_3-bearing simulated biogas by use of a novel 1%Pt/20%CuO/Al_2O_3-trapping catalyst and cyclic operation between fuel lean and rich conditions.

The exploitation of renewable energy sources to both limit CO_2 emissions and extend fossil fuel reserves is a subject of considerable interest with the former aspiration being embodied in the landmark Kyoto agreement.[1] This interest is exemplified by the various attempts to harness biomass-derived fuels for combined heat and power generation.[2–7] However, during gasification, biogenic nitrogen, fixed during plant growth, is converted into significant quantities of NH_3 (600–4000 ppm) in addition to the main fuel components, CO (9.8–17.2%) and H_2 (9.8–13.2%) as well as CH_4, CO_2, H_2O and N_2.[2] The presence of this NH_3 is a particular obstacle to the exploitation of biogas as a fuel since its combustion in a conventional burner results in the formation of significant amounts of nitrogen oxides (NO_x) which are well-known atmospheric pollutants.[8]

Attempts to overcome this problem by catalytic combustion of the NH_3/fuel mix have met with limited success with N_2 yields of $< 70\%$ being typical.[3,4] In contrast, we have demonstrated substantially improved performance using either redox-acid catalysts, such as 12-tungstophosphoric acid which yield *ca*. 85% N_2,[5] or by use of a catalyst which can couple NH_3 oxidation and NO_x reduction using the fuel components of the biogas mixture[6] giving close to 100% N_2 selectivity. However, in order to achieve these high conversions of NH_3 to N_2, both catalysts must be operated at temperatures $\geqslant 600$ °C. We have now discovered for the first time a procedure for the selective oxidation of NH_3 to N_2 in simulated biogas, which can operate at temperatures as low as 200 °C.

The catalyst used was 1%Pt/20%CuO/Al_2O_3 (hereafter referred to as PtCu) prepared by sequential incipient wetness impregnation of Al_2O_3 (Criterion CK300, surface area 200 $m^2\ g^{-1}$). The dried Al_2O_3 (120 °C, 24 h) was first impregnated with $CuSO_4{\cdot}5H_2O$ (ex Aldrich 98%) dried (24 h at room temperature, 24 h at 120 °C), and calcined (500 °C, 24 h). The process was repeated for the addition of 1% Pt ($PtDNDA_{aq}$ ex Johnson Matthey, 2.28% Pt). The preparation of 1%Pt/Al_2O_3 was performed in an identical manner. Catalyst testing (60 mg) was performed in a standard quartz flow microreactor described previously[7] at a gas flow rate of 300 $cm^3\ min^{-1}$, (GHSV of *ca*. 240 000 h^{-1}). NO_x emissions and residual NH_3 levels were determined using an external NH_3 oxidation reactor (with independent oxygen supply) coupled to a NO_x chemiluminescence detector (Signal series 4000 with data logging at 1 s intervals using Signal SIGLOG). Switching between lean and rich fuel conditions was achieved using a pressure-balanced three-way valve immediately prior to the O_2 mass flow controller. This enabled the oxidant to be 'switched' from 20% O_2/He (lean conditions) to 1%O_2/He (rich conditions).

Fig. 1 illustrates both the lean steady state and switching activity of the PtCu for the oxidation of NH_3 under comparatively mild conditions (1000 ppm NH_3, 1.02% CO, 0.68% H_2). The steady-state N_2 yield was *ca*. 94%, already a significant improvement upon previous data[3,4] and is ascribed to the establishment of an *internal selective catalytic reduction* (*i*SCR) mechanism[5,7]

However, unlike previous metal and metal oxide systems for NH_3 oxidation, the PtCu catalyst is unique and may be considered to be a composite material with a strong synergy between two very specific but different active sites. Pt provides the first site whose function is the activation of NH_3, which has been shown to be the rate limiting step of the *i*SCR reaction.[7,9,10] The second site then resides on the Cu, which adsorbs NH_3 to produce an NH_x(ads) species (as shown by NH_3 TPD[11]) These NH_x(ads) species then react with the NO_x formed on the Pt to give N_2, consistent with the proposals of Janssen *et al*.[12]

The synergistic effect is particularly apparent when comparing the activity of the PtCu with both 10%Cu/Al_2O_3 and 1%Pt/Al_2O_3. 10%Cu/Al_2O_3 was found to require temperatures of *ca*. 400 °C to produce high yields of N_2 ($> 90\%$) while although 1%Pt/Al_2O_3 was active at lower temperatures it gave only a very low selectivity (*ca*. 29% N_2 at 200 °C).

The high N_2 yields of the PtCu were further improved by transient switching of the oxidant (15 s rich, 45 s lean). Indeed, by switching it was possible to obtain peak N_2 yields of 100% before N_2 production decreased over some 500 s to the values obtained under steady state conditions. This reflects the buffering of the system *via* the reservoir of NH_x(ads) species on the Cu. Under lean conditions these species are 'titrated' by *in situ* NO but in the absence of sufficient O_2 for full reaction the Cu accumulates an NH_x(ads) adsorbate layer, thus preventing NH_3 'slip'.

The importance of transient operation is seen even more clearly when we compare the activities of 1%Pt/Al_2O_3 with the PtCu catalyst in a more realistic feed stream containing high levels of the fuel components (5.1% CO and 3.4% H_2) (Fig. 2). In this case under lean conditions NH_3 conversion was again 100%, but in both cases NH_3 was predominantly converted into NO, reflecting an interception of any NO–NH_3 reaction. Moreover, as can be seen in Fig. 2 (filled diamonds) oxidant

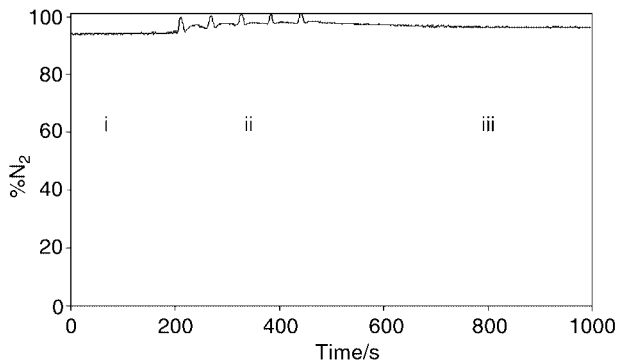

Fig. 1 N_2 production from the selective catalytic oxidation of NH_3/CO/H_2 over 1%Pt/20%CuO/Al_2O_3 at 200 °C (1000 ppm NH_3, 1.02% CO, 0.68% H_2, with either 2.1% O_2 (lean conditions) or 0.1% O_2 (rich conditions), balance He). Key: i, first 200 s of operation is under lean conditions; ii, cyclic operation 15 s rich/45 s lean for 300 s; iii, final 500 s operation is under lean conditions.

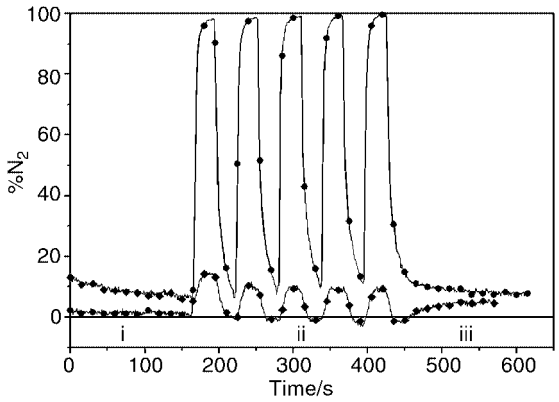

Fig. 2 N_2 production from the selective catalytic oxidation of $NH_3/CO/H_2$ over $1\%Pt/Al_2O_3$ and $1\%Pt/20\%CuO/Al_2O_3$ at 200 °C (1000 ppm NH_3, 5.1% CO, 3.4% H_2, 9.3% O_2 (lean conditions) or 0.5% O_2 (rich conditions), balance He). Key: i, first 180 s operation is lean; ii, cyclic operation 30 s rich/30 s lean for 300 s; iii, final operation under lean conditions. (◆) $1\%Pt/Al_2O_3$, (●) $1\%Pt/20\%CuO/Al_2O_3$.

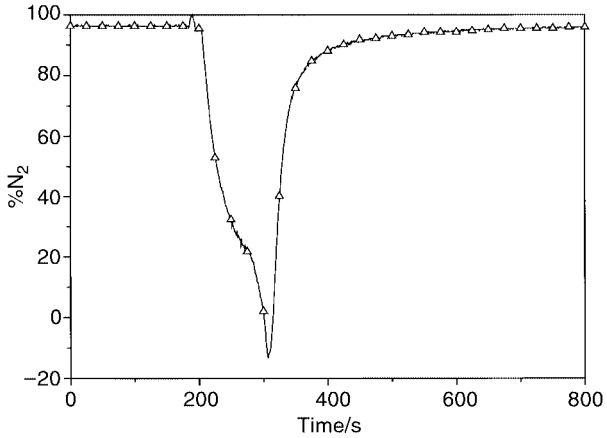

Fig. 3 N_2 production from the selective catalytic oxidation of $NH_3/CO/H_2$ over $1\%Pt/20\%CuO/Al_2O_3$ at 200 °C (1000 ppm NH_3, 1.02% CO, 0.68% H_2, with either 2.1% O_2 (lean conditions) or 0.1% O_2 (rich conditions), balance He). Key: i, first 180 s of operation is under lean conditions; ii, rich operation for 120 s; iii, final 500 s operation is under lean conditions.

cycling had a minimal effect on N_2 yields for the $1\%Pt/Al_2O_3$ catalyst. In contrast, with the PtCu catalyst (filled circles), under transient conditions there was a sudden and dramatic improvement in catalyst selectivity, with > 98% N_2 production being recorded.

These observations are entirely consistent with the proposed *i*SCR reaction, and may be rationalised as follows: in the case of the PtCu sample only, on switching to rich operation, the CuO was partially reduced by NH_3 to produce a reservoir of NH_x(ads). Then, on switching to lean conditions, all the gas phase NH_3 was again fully oxidised to NO on the Pt, but the NO formed is reduced to N_2 by NH_x(ads) on the Cu. However, this reduction process is limited by the concentration of NH_x(ads) and once these species are consumed excess NO is observed, in agreement with our experimental observations.

Further evidence of the trapping mechanism is found by examination of the effect of switching time on activity. Fig. 3 illustrates the activity of PtCu, under dilute fuel conditions at 200 °C when the rich phase is extended to 120 s. Again the initial increase in N_2 is observed (*cf.* Fig. 1). However, extending the period under rich conditions leads to a saturation of the trap and the breakthrough of NH_3/loss of N_2, clearly demonstrating the link between cyclic operation and high N_2 yields.

In conclusion, we have developed a potential strategy for the low-temperature removal of NH_3 from biomass-derived gases by the cyclic operation of a regenerable NH_3 trap catalyst which facilitates an *i*SCR-type reaction. Experiments have demonstrated that the concept is viable and provides a further novel method to overcome the environmental problems associated with the direct combustion of biogas. The strategy may be equally applicable to any comparable gasification gas derived from coal, or other renewable source. The concept is a further example of the advantages which may be gained by forcing catalysts to work harder by periodic perturbation of the reaction conditions.[13–15]

We are pleased to acknowledge the financial support of ABB-Alstom power, DTI, and EPSRC through the FORESIGHT Challenge initiative. Helpful discussions with colleagues at Lens (Dr M. Amblard), Cranfield University (Mr J. J. Witton, Professor B. Moss, Mr J. M. Przybylski and Dr E. Noordally) and at ABB-Alstom Power (Mr M. Cannon, G. J. Kelsall) are gratefully acknowledged.

Electrophilic halogenation of thioethers: 5-chloro- and 5,6-dichloro-5,6-dihydro-1,3-dithiolo[4,5-*b*][1,4]dithiine-2-one and an efficient synthesis of vinylenedithiotetrathiafulvalene (VDT-TTF)

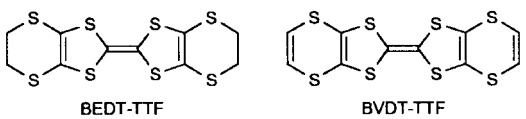
The SO_2Cl_2 chlorination of 5,6-dihydro-1,3-dithiolo[4,5-*b*]-[1,4]dithiine-2-one affords the corresponding mono- and *trans*-di-chloro derivatives which eliminate HCl upon treatment with KF/18-crown-6 or LiBr/HMPA, offering an easy route to the unsaturated vinylenedithiotetrathiafulvalene (VDT-TTF).

Halogen···halogen intermolecular interactions[1] have been recently used for the resolution of racemic bromoalkanes[2] and for the elaboration of novel organic conductors based on bromo- or iodo-tetrathiafulvalenes.[3,4] The strongly decreased donor ability of the analogous chlorinated TTFs prompted us to look for novel derivatives where the halogen atoms are not conjugated with the π-redox TTF core. Since the direct halogenation of the ethylenedithio moieties of the oxidation-sensitive bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) is not possible, we investigated the electrophilic halogenation of its precursor, *i.e.* 5,6-dihydro-1,3-dithiolo[4,5-*b*][1,4]dithiine-2-one[5] **1** and report here on the synthesis and reactivity of the mono- and dichloro derivatives of **1**.



The chlorination of **1** was efficiently performed with 1 equiv. of SO_2Cl_2 in refluxing CCl_4 to afford racemic (*R*,*S*)-**2** in 91% yield (Scheme 1).† With two equiv. of sulfuryl chloride, *trans*-5,6-dihydro-5,6-dichloro-1,3-dithiolo[4,5-*b*][1,4]dithiine-2-one **3** was obtained in 60% yield as a racemic mixture of (*R*,*R*) and (*S*,*S*) enantiomers without any (*R*,*S*) isomer, as confirmed by the presence of a single ^{1}H NMR signal and the X-ray crystal structure resolution of **3** (Fig. 1).‡ The molecule is located on an *mm*2 site in which the two chlorine atoms adopt axial positions while the carbon atoms are disordered, a consequence of the (*R*,*R*) and (*S*,*S*) racemic mixture. This *trans* addition, also observed in the dichlorination of 1,4-dithiane,[6] derives from the lowered nucleophilicity of the sulfur atom of **2**, α to the CHCl group (Scheme 2). The electrophilic reagent thus reacts on the second sulfur atom and the migration of the Cl^+ moiety occurs on the less hindered side, followed by HCl elimination to afford **3**. Note also that only traces of the trichloro derivative were obtained with an excess of chlorinating agent, while prolonged refluxing only led to product degradation.

In an attempt to obtain the corresponding mono- and difluoro derivatives of **1** by substitution of the chlorine atoms, **2** and **3** were reacted with KF/18-crown-6 as described, for example, in the reaction of $PhSCH_2Cl$ to give $PhSCH_2F$.[7] Under those conditions however, we observed that HCl elimination took place instead, affording in both cases the corresponding vinylic derivatives **4** and **5** in 50 and 60% yield, respectively (Scheme 1). This reaction thus provides easy access to the vinylic dithiolone **4**, otherwise prepared in low yield from the $dmit^{2-}$ dianion.[8,9] This is all the more appealing since **4** can be used as a starting material for a number of attractive target molecules, such as bisvinylenedithiotetrathiafulvalene (BVDT-TTF),[10] the unsymmetrically substituted vinylenedithiotetrathiafulvalene (VDT-TTF) as well as metal dithiolene complexes which can now be prepared from **4**.

A first illustration of this potential is given here by the chloro diester derivative **7**, obtained by $P(OMe)_3$ cross-coupling of **2** with **6**,[11] which directly affords VDT-TTF in 60% yield upon treatment with LiBr/HMPA in a one-pot reaction (Scheme 3) in which the two ester groups are hydrolysed and decarboxylated

while HCl is simultaneously eliminated under these basic conditions. Note that the reported synthesis of VDT-TTF involved the coupling of **4** with **6** in 8% yield and further decarboxylation in 18% yield.[12] Recrystallization from toluene afforded red crystals the X-ray crystal structure of which prove them to be isostructural with the saturated EDT-TTF analogue (Fig. 2).‡ Of particular note are the folding angles of the five- and six-membered rings along the S···S axes, 16.9(2) and 22.9(2)° in the dithiole rings along S2···S3 and S1···S4, respectively and 48.6(1)° along S5···S6 in the dithiine ring.[13] The availability of VDT-TTF will allow thorough investigations of its radical cation salts with various counter anions as well as reactivity studies, particularly in lithiation experiments where both types of vinylic hydrogen atoms of VDT-TTF might compete for metallation.

The efficient halogenation reactions described here, and the reactivity of the chlorinated species will prompt us to investigate the preparation of the corresponding halogenated tetrathiafulvalenes and their radical cation salts. Furthermore, other chlorinating agents are also being investigated with **1** for the synthesis of the tetrachloro derivative, while preliminary results on its direct fluorination showed the Selectfluor® reagent to be effective.

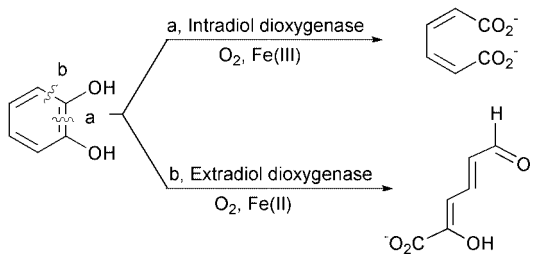
Received (in Liverpool, UK) 7th February 2000, Accepted 16th May 2000
Published on the Web 8th June 2000

A model reaction is described for extradiol catechol cleavage involving $FeCl_2$ or $FeCl_3$, 1,4,9-triazacyclononane (TACN), pyridine and dioxygen which shows similar cofactor and regio-selectivity to the extradiol catechol dioxygenases.

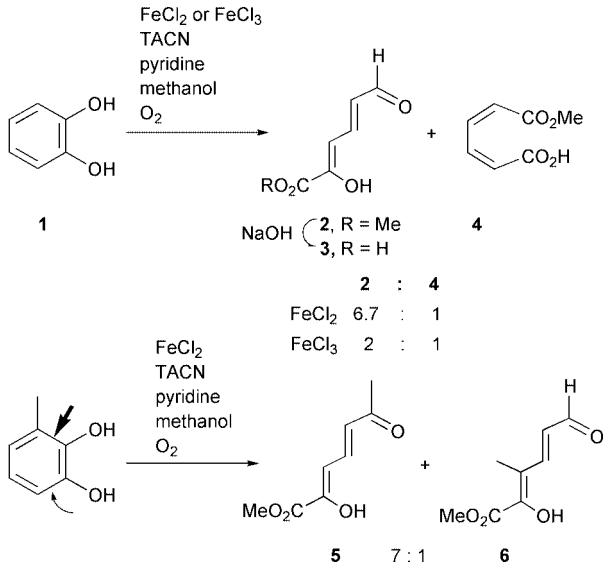
The oxidative cleavage of catechol and other dihydroxy aromatics is a key step in the biodegradation by soil bacteria of naturally occurring aromatic molecules and many aromatic environmental pollutants.[1]

The catechol dioxygenases are a class of non-haem iron enzymes that catalyse the oxidative cleavage of catechols. These enzymes can be divided into two subclasses (Scheme 1): the intradiol dioxygenases, which utilise a non-haem iron(III) cofactor, catalyse the cleavage of the carbon–carbon bond between the two catechol oxygens; and the extradiol dioxygenases, which utilise a non-haem iron(II) cofactor, catalyse the cleavage of the carbon–carbon bond adjacent to the catechol oxygens.[2]

The intradiol cleaving enzymes require non-haem Fe^{3+} to effect oxygen activation, which is ligated by two His and two Tyr moieties.[3] The extradiol cleaving enzymes require non-haem Fe^{2+} as an active site cofactor,[2,4] ligated by two His and one Glu ligands. Many attempts to model the catechol dioxygenases have been reported, but most catalysts give intradiol cleavage products.[5] However, there are three reported examples of extradiol cleavage by synthetic iron complexes. Funabiki *et al.*[6] found that $FeCl_2$ or $FeCl_3$ in THF–H_2O cleaves 3,5-di-*tert*-butylcatechol to substituted 2-pyrones, which were believed to derive from decarboxylation of the extradiol-cleavage intermediate α-keto lactone. Dei *et al.* found that the complex [Fe^{III}(TACN)Cl(dbc)] afforded 2-pyrone upon exposure to O_2 in 35% yield.[7] Ito and Que used the same complex to give an almost quantitative yield of 2-pyrone using a modified procedure.[8] However, none gave the authentic extradiol reaction product. Here, we report the first observation of extradiol ring fission product 2-hydroxymuconic aldehyde by an iron-dependent model reaction shown in Scheme 2. An investigation of the catalytic properties of $FeCl_2$ and $FeCl_3$ in the presence of a series of macrocyclic ligands, namely 1,4,7-triazacyclononane ([9]aneN_3, TACN), 1-oxo-4,7,10-triazacyclododecane ([12]aneN_3O), 1-oxo-4,7-diazacyclononane ([9]aneN_2O), 1,5,9-triazacyclododecane ([12]aneN_3), for extradiol catechol cleavage was carried out in methanol by UV–VIS spectroscopy (0.1 mM of catechol in methanol). Reaction of $FeCl_2$ or $FeCl_3$ in the presence of 1.0 equiv. TACN gave a new product absorbing at 315 nm. Upon addition of NaOH, the absorption maximum shifted immediately to 405 nm (Fig. 1), then over a



Scheme 1



Scheme 2

period of 2 h to 378 nm, the characteristic λ_{max} for the extradiol ring fission product. The free acid form **3** of ring fission product **2** is reported to show an absorption maximum shift from 322 nm (pH 3) to 378 nm (pH 8) on passing from the enol to the enolate form.[9] The UV–VIS data suggested that the initial product was the methyl ester enol **2**, which was converted into the corresponding enolate, then hydrolysed to give the disodium salt of acid **3**. Reaction of $FeCl_2$ or $FeCl_3$ in the presence of each of the other macrocyclic ligands gave no absorbance above 300 nm, indicating no extradiol cleavage.

To confirm the identity of the reaction product, a large scale model reaction of catechol with O_2 in the presence of $FeCl_2$ or $FeCl_3$, pyridine and TACN with a ratio of 1 : 1 : 3 : 1 (cat : Fe : py- : TACN) was carried out in methanol by bubbling dioxygen gas into the solution for 3 h (for $FeCl_2$) or 5 h (for $FeCl_3$).† The ^{1}H NMR spectrum of the reaction product displayed signals

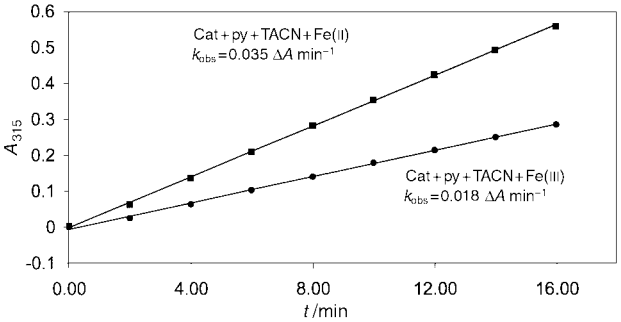

Fig. 2 Kinetic study of the reaction at 23 °C (0.1 mM catechol, 0.1 mM $FeCl_2$ or $FeCl_3$, 0.1 mM TACN, 0.3 mM pyridine in methanol). Absorbance at 315 nm was measured every 2 min for a total of 16 min.

corresponding to 2-hydroxymuconic semialdehyde methyl ester **2** as the major product, by comparison with NMR data for an enzymatic extradiol cleavage product,[11] and muconic acid monomethyl ester **4** as the minor product confirmed by comparison with authentic NMR spectral data (Scheme 2).[12]

This is the first reported reaction to give 2-hydroxymuconic semialdehyde as the major product from a biomimetic model reaction of extradiol dioxygenase. Its derivative 3,5-dibutyl-2-hydroxymuconic semialdehyde has been detected as a minor product previously from a reaction of 3,5-di-*tert*-butylcatechol, identified by Funabiki.[6] The extradiol cleavage product has also been generated using KO_2/DMSO.[10]

No ring fission was observed when either TACN, pyridine or Fe(II)/Fe(III) was omitted, indicating that all these reagents are essential for this reaction. The reaction was found to proceed using DBU in place of pyridine at a lower rate, but not using 2,6-lutidine or 4-dimethylaminopyridine. The absorption maximum at 315 nm was still observed using ethanol instead of methanol, but was not observed when the reaction was attempted in aqueous buffer. No activity was observed using $CuCl_2$, $CoCl_2$ or $MnCl_2$. Similarly, no activity was observed using $FeSO_4$ or $Fe(NH_4)_2(SO_4)_2$.

Interestingly, the reaction in the presence of $FeCl_2$ gave extradiol product **2** (50% yield by NMR spectroscopy using DMF as internal standard) and intradiol product **4** (7.5%) in a ratio of 6.7 : 1, while the reaction in the presence of $FeCl_3$ gave the products in a ratio of 2 : 1. Monitoring of A_{315} (corresponding to extradiol cleavage product only) revealed the reaction is twice as fast in the presence of 0.1 mM $FeCl_2$ (k_{obs} = 0.035 ΔA min^{-1}) than 0.1 mM $FeCl_3$ (k_{obs} = 0.018 ΔA min^{-1}) (Fig. 2). These observations imply that there is some intrinsically higher activity and specificity of Fe^{2+} for extradiol cleavage, which gives some insight into the fact that Fe^{2+} is the cofactor for the extradiol dioxygenase family.[2]

Furthermore, the treatment of 3-methylcatechol under the same conditions gave ketone **5** and aldehyde **6** in a ratio of 7 : 1 (only a trace amount of intradiol cleavage product) by NMR, which demonstrates that the model reaction also shows regioselectivity for the site of C–C cleavage. It is of interest that the model reaction shows the same selectivity as is found for extradiol dioxygenases which cleave 3-substituted catechols,[2] for example, 2,3-dihydroxyphenylpropionate 1,2-dioxygenase (MhpB) from *Escherichia coli*, which cleaves in the same way to give a ketone ring fission product whose ^{1}H NMR spectrum is almost identical to **5**.[11]

These observations raise the question of what the active iron-containing species during the reaction are. TACN has previously been shown to form a mononuclear, octahedral iron(III) complex with 3,5-di-*tert*-butylcatechol.[7] Monitoring of the $FeCl_3$-containing reaction at 0.4 mM TACN concentration by UV–VIS spectroscopy reveals the immediate formation of a complex (λ_{max} 456, 712 nm), which decays as product is formed, and whose UV–VIS spectrum matches that of the complex formed anaerobically between $FeCl_3$, TACN and catechol, indicating that an Fe(III)–TACN-catechol complex is formed. Monitoring of the $FeCl_2$-containing reaction at 0.4 mM TACN concentration by UV–VIS spectroscopy reveals immediate product formation at 315 nm, but only gradual formation of the Fe(III)–TACN-catechol complex, indicating that some oxidation of iron(II) is taking place during the reaction, but that a separate iron(II) complex is responsible for the majority of extradiol product formation. The formation of distinct iron(II) and iron(III) complexes, whose structures remain to be determined, would account for the different product distributions formed by $FeCl_2$ *cf.* $FeCl_3$.

In conclusion, this model reaction shows several features which closely mimic the extradiol dioxygenases. The extradiol ring fission product **2** is obtained as the major product; the reaction shows an inherent preference in extradiol selectivity for Fe^{2+} over Fe^{3+}, shows a similar regioselectivity to the extradiol dioxygenases, and demonstrates a selectivity for the TACN ligand which parallels the facial tridentate coordination found in the extradiol dioxygenase active site. It will be of interest to study the scope and the mechanism of this model reaction, and compare its properties with the enzyme-catalysed reaction.

High temperature calcination of boria-supported zirconia leads to highly selective and regenerable B_2O_3/ZrO_2 catalysts for the synthesis of ε-caprolactam by Beckmann rearrangement of cyclohexanone oxime.

The Beckmann rearrangement of cyclohexanone oxime is an important industrial reaction for the production of ε-caprolactam. The conventional technology makes use of fuming sulfuric acid as the catalyst in the liquid phase.[1] This technique is not environmentally friendly and is considered to be one of the most inefficient chemical processes, since it produces 2–5 equivalents of valueless by-product (ammonium sulfate) for every unit of the desired lactam product. It has long been hoped that this process could be replaced with one based on a solid acid catalyst.[2] However, the development of such a specific solid catalyst has proven to be a big challenge in heterogeneous catalysis. Borias supported on oxide supports are reported to be efficient catalysts for the Beckmann reaction.[3–7] The main obstacle to the practical use of these catalysts comes from the rapid deactivation and poor regeneration properties of these catalysts.[8,9] Since supported boria was believed to be volatile above 400 °C, the preparation of supported boria catalysts in the literature was deliberately developed in order to avoid using high calcination temperatures to activate the impregnated boria catalysts. Thus, calcination at 350 °C has become a 'standard' activation procedure for preparing supported boria catalysts.[3–7] Following the 'standard' preparation, we reported recently that boria supported on zirconia, B_2O_3/ZrO_2, was highly active and selective for lactam synthesis; the average lactam yield during a 6 h reaction over properly prepared B_2O_3/ZrO_2 catalyst was greater than 90%.[10,11] 'Pure' zirconia containing no boria showed very poor selectivity for the lactam synthesis.[11] Here, we show that activation of boria-loaded zirconia with high temperature (600–700 °C) calcinations produces highly selective (96–98%) catalysts for the Beckmann reaction. Although the loading of boria affects the catalyst activity and selectivity, deactivated catalysts can be regenerated, regardless of the boria loading, to their initial activity and selectivity by calcination at 600 °C.

Samples of B_2O_3/ZrO_2 were prepared by impregnation of the zirconia support with an aqueous solution of boric acid.[10,11] The boria loading in the catalyst was determined by ICP-MS analysis, and is expressed as a weight percentage of the catalyst sample. Zirconyl hydroxide, which was obtained by hydrolysis of $ZrOCl_2 \cdot 8H_2O$ with an aqueous solution of ammonia (25–28 wt% NH_3), was used as the precursor for the support. Before introduction of the boria, this support precursor was precalcined in air at various temperatures. After the support had been loaded with boria, the catalyst sample was activated by a further calcination at elevated temperatures in air. Both the calcination of the support and of the catalyst was carried out for 10 h. The Beckmann rearrangement reaction was performed on a down-flow fixed bed reactor at 300 °C with 10wt% cyclohexanone oxime in benzene (solvent), and with N_2 as the carrier gas. The weight hourly space velocity (WHSV) of the oxime reactant was 0.32 h^{-1}. Experimental details for the catalyst preparation and the gas-phase Beckmann reaction have been described elsewhere.[10,11] Regeneration of the deactivated catalyst was performed by calcination in air at 600 °C for 8 h.

The precalcination temperature (PCT) of the support precursor [$ZrO(OH)_2 \cdot xH_2O$] before loading with boria, the loading of boria, and the catalyst activation (calcination) temperature (CAT) after the loading are important parameters for catalyst preparation.[12,13] When the CAT is fixed for the preparation, the catalyst activity and selectivity at a fixed loading of boria can be significantly modified by changing the PCT. When the temperature for the catalyst activation is kept at or below 500 °C (CAT $\leqslant$ 500 °C), support precalcination at 300 °C (*i.e.* PCT = 300 °C) leads to the highest oxime conversion activities among 10% B_2O_3/ZrO_2 samples with various PCT histories.[13] Catalysts with PCT $\geqslant$300 °C also effectively reduce the formation of undesirable by-products when compared with samples prepared using lower PCTs.[13] In this work, the PCT is fixed at 300 °C for the catalyst samples to examine the effect of varying the CAT on the Beckmann reaction. A catalyst loaded with 9.5% B_2O_3 has been used for this prupose. This loading of boria is close to the optimum load with the 'standard' preparation (CAT = 350 °C) on a zirconia support precalcined at 500 °C (PCT = 500 °C).[11] Table 1 shows that oxime conversion and the selectivity and yield of the lactam are little affected over the entire period on an 8 h reaction time on stream (TOS) when the CAT is increased from the 'standard' activation temperature (350 °C) to 500 °C over this 9.5% B_2O_3/ZrO_2 catalyst. However, a further increase in the CAT to 600 °C results in dramatically improved selectivity and yield of the desired lactam; the selectivity increases from 70–80% to values greater than 95%, and the average lactam yield increases from *ca.* 70% to 92%. The last group of data at the bottom of the Table 1 gives the results of the reaction over a 'pure' zirconia support that was activated at 600 °C. Except at the very beginning of the reaction, the desired lactam product is basically not produced. This observation agrees with our conclusions from earlier work that the active catalytic sites for the Beckmann reaction are connected with boria in the sample.[13] ICP-MS analysis showed that the B_2O_3 loading in the three samples with CAT = 350, 500 and 600 °C are in the range 9.0–9.7%, which indicates that no significant loss of boron occurs during catalyst activation (calcination) with CAT > 400 °C. It is, therefore, clear that high temperature activation (calcination) is essential for the preparation of highly efficient B_2O_3/ZrO_2 catalysts. The ability of B_2O_3 to withstand the high temperature calcinations suggests a strong interaction between B_2O_3 and the support surface.

With CAT = 600 °C for the catalyst preparation, samples of B_2O_3/ZrO_2 catalysts were prepared with various loadings of boria. Fig. 1 presents the time course of the oxime conversion over two B_2O_3/ZrO_2 samples with 5 and 13.5% B_2O_3 by weight, respectively. While the oxime conversion decreases more or less with reaction time, no significant change (< 2%) in the lactam selectivity is observed over both catalysts; the lactam selectivity is 81–83% with the 5% B_2O_3/ZrO_2 sample and 96–97% with the 13.5% B_2O_3/ZrO_2 sample (not shown in the figure). Experiments were undertaken in order to ascertain the

reusability of the deactivated catalyst when regenerated by calcination in air at 600 °C for 8 h. Quantitative measurement of boron in the samples revealed that the difference in boria loading between the fresh and corresponding regenerated samples is less than 6% of the loading in the fresh sample.

It is evident from Fig. 1 that these two catalysts do not lose any activity for the Beckmann reaction, even after two repeated deactivation–regeneration cycles. Also, no meaningful change in the lactam selectivity was detected over these two catalysts in the deactivation–regeneration cycles. Very similar behavior was also observed with samples containing higher boria loadings, *e.g.* 20% B_2O_3. These observations may be very important, since complete restoration of catalyst activity and selectivity could prove attractive for industrial application. The effect of boria loading on the catalytic performance of 'fresh' B_2O_3/ZrO_2 catalysts has been a focus of discussion in other publications.[11,13]

For the 10% B_2O_3/ZrO_2 catalysts prepared with CAT = 600 °C, it has been shown that the precalcination temperature (PCT = 110–500 °C) of the support precursor has little effect on the catalytic efficiency for the lactam synthesis.[13] Attempts were therefore made to impregnate boric acid directly onto zirconyl hydroxide that had been dried at 110 °C, but with an even higher temperature (700 °C) used for the catalyst activation. This preparation produced even more efficient B_2O_3/ZrO_2 catalysts (boria loading 8–15%) that are able to yield 98% ε-caprolactam for longer than 10 h TOS, which further demonstrates that high temperature catalyst activation/calcination is beneficial for the production of highly efficient and regenerable solid acid catalysts based on supported boria. This conclusion could be important for the development of a practical boria catalyst for industrial application. Additionally, the discovery that zirconia-supported boria catalysts are able to withstand high temperature (600–700 °C) calcination seems of interest for fundamental research. Further study is required to understand the chemistry of the interaction between boria and the surface of the zirconia support.

The addition of isocyanides to ReS_4^-: [3 + 1] cycloaddition to S=M=S

Daniel E. Schwarz and Thomas B. Rauchfuss*

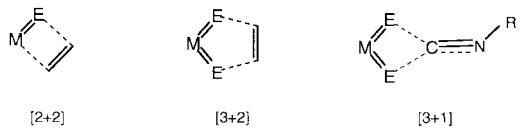
School of Chemical Sciences and the Frederick Seitz Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL 61801 USA. E-mail: rauchfuz@uiuc.edu

Received (in Irvine, CA, USA) 27th January 2000, Accepted 3rd May 2000
Published on the Web 8th June 2000

Isocyanides undergo [3 + 1] cycloadditions to ReS_4^- to give dithiocarboimidate derivatives, $Re(S)(S_4)(S_2CNR)^-$ and $Re_2S_5(S_2CNR)_2^{2-}$, which undergo S-atom transfer and, in the case of the monometallic species, *N*-alkylation.

Cycloadditions to oxo- and thio-metallates represent an important class of reactions related to atom transfer catalysis, *e.g.* by OsO_4.[1] In these transformations, the substrate adds wholly or in part to the main group atom, the metal playing a secondary role. Such cycloadditions to metal sulfides are relevant to catalyst–substrate interactions in hydrodesulfurization (HDS) catalysis.[2] Virtually all metal-based cycloadditions proceed *via* 2 + 2 or, more commonly, 3 + 2 pathways,[3,4] 3 + 1 pathways have not been observed.

Metal sulfides have been shown to catalyze the conversion of CO into thioesters and other biologically significant functionalities, although the mechanisms of such reactions are unclear.[5,6] The pathways for such reactions might be elucidated through studies on the interactions of isoelectronic analogues of CO with soluble metal sulfides under well defined conditions. Of all the soluble metal sulfides,[7] ReS_4^- **1** exhibits the greatest



reactivity toward alkenes and alkynes.[8–11] Compound **1** was therefore selected for an investigation of the reactions of metal sulfides with isocyanides, which are isoelectronic with CO.

With rigorous exclusion of light and adventitious oxidants, solutions of **1**, as its NEt_4^+ or PPh_4^+ salts, are unreactive towards MeNC. The reaction of MeNC and **1**, however, proceeds briskly when in the presence of elemental sulfur. Addition of 1–2 equivalents of elemental sulfur to solutions of (PPh_4)**1** and MeNC afforded brown microcrystalline **2** whose (−)ESI-MS spectrum shows molecular ions at *m/z* 372 ($z = 2-$) and 743 ($z = 1-$) corresponding to $Re_2S_9(CNMe)_2^{2-}$ (isolated yield: 35%).† The IR spectrum of **2** exhibits peaks at 1586 and 526 cm^{-1} for $\nu_{C=N}$ and $\nu_{Re=S}$, respectively. The ^1H NMR spectrum in CD_3CN shows a PPh_4^+/Me ratio of 1; a pair of equally intense Me signals (δ 3.25 and 3.274) is attributed to the unsymmetrical environment of the square-pyramidal Re centers such that the Me can be *trans* to persulfide or sulfide (Scheme 1). In part due to its low solubility, $(PPh_4)_2$ **2** was not obtained as X-ray quality crystals.

The addition of further equivalents of S_8 to MeCN slurries of **2** gave $(PPh_4)[Re(S)(S_4)(S_2CNMe)]$ **3a** over the course of several hours at room temperature. In this reaction, the two isomers of **2** are consumed at comparable, but not identical rates. The new species can be more easily prepared by treatment of **1** with MeNC in the presence of an excess of sulfur, the yields being *ca.* 60%. The poorly soluble side products in this reaction absorb at *ca.* 1580 cm^{-1} ($\nu_{C=N}$); (−)ESI-MS of these solids revealed ions corresponding to $[ReS_4]_m[MeNC]_n^{m-}$ (where *m* and *n* = 1 and 2). The structure of **3a** was established by single crystal X-ray diffraction (Fig. 1).‡ The rhenium atom is square pyramidal; the square base is defined by the tetrasulfido bridge and the dithiocarboimidate ($MeNCS_2^{2-}$) ligands, a terminal sulfur atom occupying the apical position. The rhenium atom lies 0.4570 Å out of the plane formed by the basal sulfur ligands. The C=N distance is 1.24 Å, which is consistent with a double bond, and resembling previously described dithiocarbodimidate complexes.[12,13]

Analogues of **3** were prepared using *tert*-butyl isocyanide (Bu^tNC) and cyclohexyl isocyanide (CyNC) to give the corresponding derivatives **3b** and **3c**, respectively.§ No RNC exchange was observed when solutions of **3a** were treated with an excess of Bu^tNC or solutions of **3b** were exposed to MeNC. Warm solutions of **3a** react with **1** and 1 equiv. of MeNC to give **2**, indicating that intermetallic S-atom transfer is facile.

Methylation of **3a** with MeOTf gave the dithiocarbamate $Re(S)(S_4)(S_2CNMe_2)$ **4**, confirming the relationship between dithiocarboimidate and the more familiar dithiocarbamate ligands. Dithiocarbamate complexes are usually prepared from preformed dithiocarbamates or thiuram disulfides,[14] not by *N*-alkylation routes.

The mechanism by which **2** and **3** arise involves generation of a reactive derivative by the addition of sulfur atoms to **1** followed by trapping with RNC. We have previously shown that such solutions bind nitriles (*via* a 3 + 2 cycloaddition process[9]). Further work is underway to identify this reactive intermediate.

The important conclusion is that isocyanides add across the S=M=S functionality[7] *via* an unprecedented 3 + 1 cycloaddition process. Isocyanides have been shown to add to μ-S ligands in binuclear molybdenum compounds.[15]

Received (in Cambridge, UK) 31st March 2000, Accepted 15th May 2000

A newly-synthesized 4′-[bis(diphenylphosphino)methane]–2,2′:6′,2″-terpyridine-based (dppm–terpy) ligand forms complexes by selective complexation of the terpy or diphos segment, respectively, with Fe(II) or Pd(II) salts; in the latter case, an X-ray structural analysis reveals the formation of a neutral square-planar complex assembled from the deprotonated ligands.

The 2,2′:6′,2″-terpyridine (terpy) molecule is widely used in transition metal chemistry as a meridionally coordinating and tridentate chelating ligand. Multiple applications have been found in the areas of analysis and the design of molecular electronic devices.[1] Phosphine-functionalized terpy entities, such as terpyPPh_2[2] and terpyPO_3H_2,[3] readily complex many different transition metals and bind strongly to certain semiconductors. We have shown recently that terpy$CH_2P(O)Ph_2$ can be deprotonated under mild conditions to produce a useful synthon for the preparation of carotenoid-based photoactive molecular-scale wires.[4] In light of the rich coordination chemistry of bis(diphenylphosphino)methane (dppm), a species well known in organometallic chemistry as a monodentate, bidentate or bridging ligand,[5] it was anticipated that the hitherto unreported terpy analogue (dppm–terpy) might be a valuable building block for the construction of multimetallic networks. Interest in such polynuclear assemblies is stimulated by the study of intramolecular electron or energy transfer processes[6] as well as by the coupling of luminophoric metal centers to photoactive catalytic sites.

We present here, the synthesis and coordination behaviour of a hybrid diphos/terpy ligand where the complexation behaviour is governed by the choice of the metal precursor. Ligand **L** is prepared in a stepwise fashion from the deprotonated monophosphine-terpy ligand **1**, followed by nucleophilic substitution with PPh_2Cl as illustrated in Scheme 1. The dppm–terpy ligand **L** is characterized by a ^{31}P NMR signal at δ −3.7 (singlet), compared to intermediate **1** which gives a singlet at δ −8.5. The corresponding phosphine oxide $\mathbf{L(O)_2}$, obtained under phase transfer conditions with $NaIO_4$ as oxidant, shows a ^{31}P NMR signal at δ 29.5, with the CH proton appearing as a triplet at δ = 5.00, J_{HP} 14.4 Hz. A strong IR absorption band is found at 1210 cm^{-1} ($\nu_{P=O}$).

The ambivalent reactivity of dppm–terpy is demonstrated by virtue of its interaction with Fe and Pd precursors. Thus, reaction of **L** with $Fe(ClO_4)_2{\cdot}6H_2O$ gives a deep-violet complex whose structure is assigned as $\mathbf{C^1}$.† Both the intense MLCT absorption band centred at 562 nm (ε = 20450 $dm^3\ mol^{-1}\ cm^{-1}$) and the slightly shifted singlet observed (δ 3.2 in $CDCl_3$) in the ^{31}P NMR spectrum are indicative of complexation at the terpy segment. Note that the related Fe(II) complex formed from $\mathbf{L(O)_2}$ gives a singlet at δ 30.0 (CD_3CN). In contrast, ligand **L** reacts with [Pd(acac)$_2$] (acac = acetylacetonate) to form a sparingly soluble, deep-yellow compound (λ_{max} = 407 nm, ε = 43450 $dm^3\ mol^{-1}\ cm^{-1}$) that lacks the signal characteristic of the CH fragment in the proton NMR spectrum but displays a ^{31}P NMR signal at δ −29.9 (singlet in CD_2Cl_2). The presence of uncomplexed terpy fragments within this latter complex, labelled as $\mathbf{C^2}$ in Scheme 2, was confirmed by an X-ray diffraction study (*vide infra*). The dppm–terpy ligands are deprotonated during the process so that the overall product is a neutral palladium(II) complex. It is likely that the acac anion operates as a buffer to deprotonate the ligand.[7]

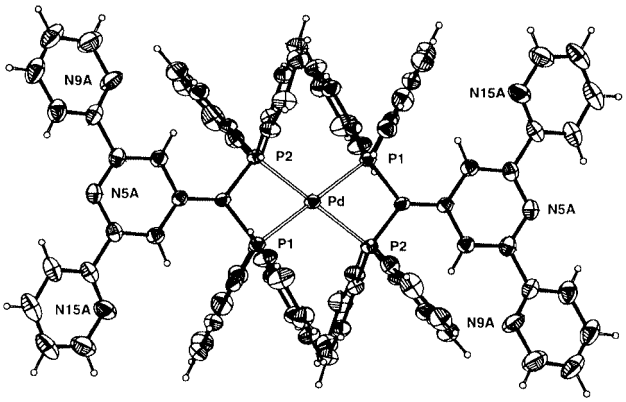

Fig. 1 ORTEP drawing of complex **C**[2] (Displacement ellipsoids are shown at the 50% probability level); Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Pd–P(1) 2.317(2), Pd–P(2) 2.315(2), P(1)–C(terpy) 1.756(4), P(1)–C(phenyl) 1.826(5), P(1)–C(phenyl) 1.822(5), P(2)–C(terpy) 1.764(4), P(2)–C(phenyl) 1.818(4), P(2)–C(phenyl) 1.823(5), P(2)*–Pd–P(2) 180.0, P(2)–Pd–P(1)* 109.09(5), P(2)–Pd–P(1) 70.91(5), P(1)–C(terpy)–P(2) 99.5(2).

The single-crystal X-ray analysis‡ (Fig. 1) indicates that the palladium atom is in a square-planar environment with the four P atoms coordinated to the metal centre and with two uncoordinated terpyridines. The crystals consist of discrete neutral centrosymmetric molecules, the Pd atom being located on an inversion centre. As expected, all six N-atoms are in a transoidal arrangment that minimizes electronic interactions.[8] An angle of 16.0(0)° between the planes defined by the two pyridine rings containing N(5A) and N(15A) and a dihedral angle of 16.8(0)° between the planes of the external rings containing N(15A) and N(9A) illustrate twisting about the interannular C–C bonds, as well as the slight distortion within the terpy subunit. Owing to the anionic nature of the coordinated diphos–terpy ligands the C–P bond distances (*ca*. 1.76 Å) are shorter than in related Pd(II)-phosphine complexes.[9] The bite angle P(1)–Pd–P(2) of 70.91(5)° and the twist of the phenyl rings around the P atom *versus* the plane defined by the square containing the palladium (71–75°) are in good agreement with values expected for a regular square-planar coordination polyhedron.

This mononuclear Pd(II) complex is of interest as a potential *metallo-synthon* for the construction of more elaborate molecular architectures in which the electronic interaction between both sites could, in principle, be tuned by the oxidation state of the central metal. In order to demonstrate this principle, we chose to complex the free terpy moieties with [Ru(terpy)(dmso)Cl_2][10] under mild conditions. The heterotrinuclear complex **C**[3] has a characteristic MLCT absoption band at 482 nm (ε = 43000 $dm^3\ mol^{-1}\ cm^{-1}$), and exhibits a singlet in the ^{31}P NMR spectra at δ −10.6 (CD_3CN). The MALDI-TOF mass spectra is in keeping with the proposed structure.†

The redox behaviour of these complexes was studied by cyclic voltammetry in MeCN (for **C**[1] and **C**[3]) or dichloromethane (for **C**[2]) containing $NBu^n_4PF_6$ (0.1 mol dm^{-3}) as supporting electrolyte. The Pd(II) complex **C**[2] exhibits two irreversible oxidation waves at $E_{pa}(1)$ = 0.69 and $E_{pa}(2)$ = 1.04 V *vs*. SCE using ferrocene as internal reference (Fc/Fc^+ = 0.41 V). No peaks are seen upon reductive scans, at least above −2.0 V *vs*. SCE. The oxidative processes can be ascribed to the successive oxidation of the anionic terpy–diphos ligands. Within the mixed Ru/Pd complex **C**[3], ligand-based oxidation steps are found at $E_{pa}(1)$ = 0.87 and $E_{pa}(2)$ = 1.06 V *vs* SCE. This complex also exhibits a single metal-based oxidation at 1.34 V *vs*. SCE (ΔE_p = 80 mV) and two irreversible terpy-based reductions at $E_{pc}(1)$ = −1.28 V and $E_{pa}(2)$ = −1.49 V. It is surmised that the unusual irreversibility of the ligand reduction is due to the strong electron density provided by the anionic Ph_2PCPPh_2 fragment appended to the terpy units. As expected, complex **C**[1] exhibits three well-defined and reversible redox processes; namely, a single oxidation at 1.26 V (ΔE_p = 70 mV) and two ligand-centered reductions at −1.20 V (ΔE_p = 74 mV) and −1.39 V *vs*. SCE (ΔE_p = 66 mV). The easier Fe(II) oxidation *vs*. Ru(II) in **C**[3] is in keeping with related unsubstituted terpy complexes.[11]

Preliminary steady-state emission studies show that complex **C**[2], in the solid state (0.5% dispersed in $MgSO_4$), exhibits an intense but structureless emission band at 590 nm when excited at 400 nm. This emission is not observed in deoxygenated acetonitrile solution. Additional photophysical measurements will be carried out in order to explore the photoreactivity of **C**[3].

In summary, we describe a simple strategy for the synthesis of hybrid ligands carrying hard and soft complexation centres. The diphos or the terpy part of the ligand can be complexed with good selectivity, using either Pd(II) or Fe(II), respectively. Further complexation of the free terpy centers with redox-active Ru(II) fragments facilitates preparation of linear heterotrinuclear complexes in a controlled manner. On-going experiments will study the chemistry of these novel multitopic systems.

Cyclodextrin-appended myoglobin as a tool for construction of a donor–sensitizer–acceptor triad on a protein surface

Itaru Hamachi,*†[a] Hiroshi Takashima,[a] Yi-Zhen Hu,[a] Seiji Shinkai[a] and Shigero Oishi[b]

[a] *Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, Fukuoka 812-8581, Japan. E-mail: itarutcm@mbox.nc.kyushu-u.ac.jp*

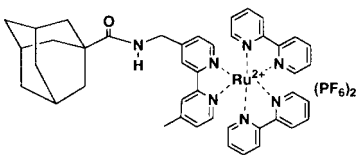
[b] *Department of Chemistry, School of Science, Kitasato University, Sagamihara, 228-8520, Japan*

Received (in Cambridge, UK) 13th March 2000, Accepted 18th May 2000

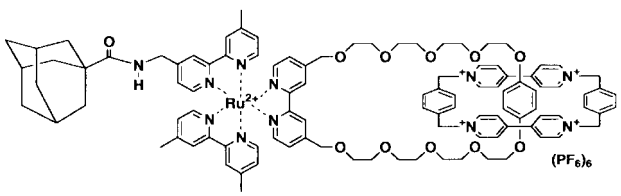
A protein-based and noncovalently-linked donor–sensitizer–acceptor triad has been prepared by self-assembly *via* mechanical linkages and hydrophobic interactions, and its photoinduced electron transfer properties have been studied.

Multi-step electron transfer (ET) in protein matrices is the key process of biological energy transduction in photosynthetic and mitochondrial respiratory systems.[1,2] A number of efforts have shown that model proteins suitably modified with an electron donor or acceptor are valuable for understanding such complicated ET mechanisms.[3] Most of the models reported so far, however, are simple donor–acceptor diads because of serious limitations for modifying native protein matrices. We recently reported a donor–sensitizer–acceptor triad attached to protein matrices using cofactor reconstitution methods.[4] Here, we describe a novel strategy for the construction of a triad by self-assembly. The protein-based triad, which consists of cyclodextrin(CD)–appended Zn–myoglobin (Zn-Mb-CD), an adamantane-modified $Ru(bpy)_3$ and a bis(viologen)cyclophane (BXV^{4+}), is noncovalently connected by elaborately employing mechanical linkages[5] and hydrophobic interactions.

The β-CD-modified protoporphyrins IX (**1a** and **1b**) were synthesized according to Scheme 1. Protoporphyrin IX (PP) mono-ethylester was condensed with 6-monoamino-peracetylated-β-CD in the presence of BOP to yield a CD-appended heme **2**. Subsequent metal insertion into the heme center followed by hydrolysis of the ester groups gave the target compound **1**. Tris-heteroleptic $Ru(bpy)_3$ derivatives (**3**, **4**) used



3



4

herein were synthesized according to the synthetic route reported previously by us.[4,5] All of the compounds were characterized by FT-IR, NMR, MALDI-TOF mass spectrometry, and elemental analysis.

Reconstitution of **1a** and **1b** with apo-Mb were carried out according to the literature reported by us.[4] The yield of Zn-Mb-CD and Fe(III)-Mb (Fe-Mb-CD) were 36% and 40%, respectively. The absorption and/or fluorescence spectra of Zn-Mb-CD and Fe-Mb-CD are very similar to those of their corresponding native forms, Zn-Mb and Fe-Mb.[6] Spectroscopic titration experiments clearly show that 1 equiv. of **1** is quantitatively complexed with apo-Mb (data not shown). In Fe-Mb-CD, the spectroscopic changes due to the ligand exchange and redox and oxygen-binding reactions were almost identical to native Mb.[6] These results undoubtedly imply that the heme unit of **1** is located in the natural heme crevice of Mb.

Binding of $Ru(bpy)_3$ derivatives bearing adamantane units to the CD-appended Mb's was monitored by emission quenching of $Ru(bpy)_3$ of **3** by Fe-Mb-CD. The emission lifetime of **3** was determined to be *ca*. 500 ns in the absence of Fe-Mb-CD. By addition of Fe-Mb-CD (10 μM) to a solution of **3** (1 : 1 ratio), we observed a faster decay (64%, the lifetime of 100 ns) of the emission at 600 nm, as well as the normal lifetime of 500 ns (36%). The shorter lifetime is attributable to the fraction of **3** bound to Fe-Mb-CD.[7] Based on these fractions, the binding constant of the adamantane unit of **3** with the CD unit of Fe-Mb-CD was estimated to be *ca*. 5×10^5 M^{-1}, suggesting that the

DOI: 10.1039/b001997f

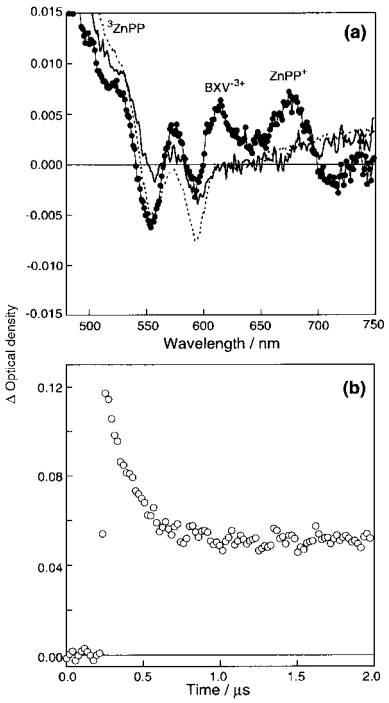

Fig. 1 (a) Transient absorption spectra observed after laser excitation of Zn-Mb-CD (10 μM)/**4** (20 μM) and Zn-Mb (10 μM)/**4** (20 μM) complexes in deaerated phosphate buffer (pH 7.0, 50 mM) solution at the delay time of 50 ns. (—●—) Zn-Mb-CD/**4**, λ_{ex} = 460 nm; (·····) Zn-Mb-CD/**4**, λ_{ex} = 596 nm; (——) Zn-Mb/**4**, λ_{ex} = 460 nm. (b) Time profile monitored at 670 nm in Zn-Mb-CD/**4** after laser excitation at 460 nm.

$Ru(bpy)_3$ derivatives **3** and **4** can form tight complexes with Zn-Mb-CD or Fe-Mb-CD.

Next, a donor–sensitizer–acceptor triad system was prepared by spontaneous assembly of Zn-Mb-CD with the $Ru(bpy)_3$-based diad **4**. Fig. 1a shows the transient absorption spectrum obtained by photoexcitation of an aqueous solution containing Zn-Mb-CD (10 μM)/**4** (20 μM) at 460 nm (MLCT band of $Ru(bpy)_3$; —●—) and 596 nm (Q-band of ZnPP; ·····): Photolysis at 460 nm led to the immediate appearance of absorption bands due to the viologen radical and the ZnPP radical at 610 nm and 670 nm, respectively, in addition to the ZnPP triplet absorption at 470 nm.[4,5,8] In contrast, the viologen and ZnPP radicals are not photo-produced in a mixture of native Zn-Mb and **4** (*i.e.* without CD; ——) under the same conditions. This is direct evidence for the formation of a pseudo intramolecular Zn-Mb-CD/**4** complex, in which a charge-separated (CS) state between ZnPP and cyclic viologen is generated by photolysis of the MLCT band of $Ru(bpy)_3$ (460 nm). Interestingly, the CS state was not observed by photoexcitation of Zn-Mb-CD/**4** at 596 nm excitation, indicating that a direct electron transfer from the excited ZnPP to cyclic viologen does not occur. Moreover, both the excited singlet and triplet states of the ZnPP unit of Zn-Mb-CD were not considerably quenched by **4**. This implies that an energy transfer from excited ZnPP to $Ru(bpy)_3$ does not take place in the Zn-Mb-CD/**4** complex. Conceivably, the CS is photogenerated by a stepwise electron transfer as shown in Fig. 2. Initial electron transfer occurs from the photo-excited $Ru^{II}(bpy)_3$ to the cyclic viologen,[5] followed by reduction of the produced $Ru^{III}(bpy)_3$ by ZnPP to yield the final CS state.[4] It is noteworthy that both ET steps occur in noncovalently linked donor–acceptor pairs.

The kinetic behavior of the CS state of Zn-Mb-CD/**4** was monitored at 670 nm. As shown in Fig. 1b, the absorbance at 670 nm appears within 50 ns, indicating that steps 2 and 3 of Fig. 2 proceed faster than 50 ns. Unfortunately, the precise rate constants for steps 2 and 3 have not been determined due to instrumental limitations. The lifetime of the CS state was determined to be *ca.* 640 ns from the decay process shown in Fig. 1b.[9] The quantum yield of the CS state was estimated to be 0.03 by using 5,10,15,20-tetraphenylporphyrin as a reference.[10]

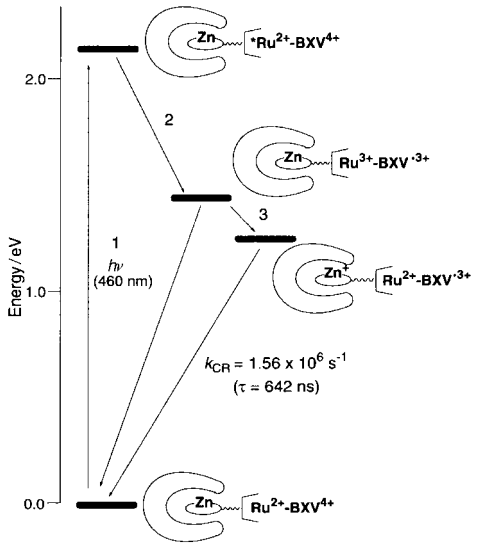

Fig. 2 Schematic energy diagram for the photoinduced reactions in the Zn-Mb-CD/**4** complex.

In conclusion, we have successfully prepared a noncovalently linked donor–sensitizer–acceptor triad on a myoglobin surface using a rational combination of mechanical bonding and hydrophobic interactions. The present approach may extend to the utilization of various kinds of donors and/or acceptors in semisynthetic systems, by which one can obtain valuable insight into ET events occurring in a protein matrix.

7 The emission of the $Ru(bpy)_3$ unit in the Fe-Mb-CD/**3** complex is quenched by intracomplex electron transfer from $Ru(bpy)_3$ to Fe-Mb. see: I. Hamachi, S. Tanaka, S. Tsukiji, S. Shinkai and S. Oishi, *Inorg. Chem.*, 1998, **37**, 4380.
8 The appearance of the ZnPP triplet absorption is due to the weak light absorption by the ZnPP moiety at 460 nm (*ca.* 10%) which decays with a lifetime of 2 ms. Since the emission of **3** was not quenched in the presence of Zn-Mb-CD, energy transfer from excited $Ru(bpy)_3$ to ZnPP can be ruled out.
9 On the time scale detected (2 μs), the decay curve in Fig. 1b does not reach zero because the ZnPP triplet state exhibits an absorption residue at 670 nm. The remaining fraction decays with a lifetime similar to that of the ZnPP triplet state of Zn-Mb-CD (*ca.* 2 ms).

ChemComm

Fluoride recognition in 'super-extended cavity' calix[4]pyrroles†

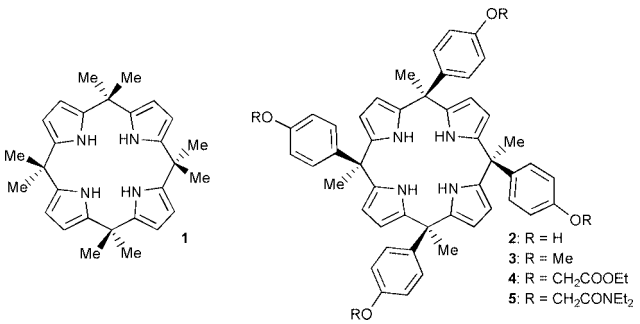
Salvatore Camiolo and Philip A. Gale*

Department of Chemistry, University of Southampton, Southampton, UK SO17 1BJ. E-mail: philip.gale@soton.ac.uk

Received (in Cambridge) 20th April 2000, Accepted 18th May 2000

Extended cavity ester (4) and amide (5) calix[4]pyrrole macrocycles have been synthesised and shown to bind fluoride exclusively in deuteriated DMSO solution.

The coordination chemistry of anionic species by abiotic receptor species is an area of supramolecular chemistry that continues to attract the attention of coordination chemists.[1] One of the major goals in molecular recognition is to produce receptors that are highly selective in their guest binding properties. The discovery that calix[4]pyrroles (such as *meso*-octamethylcalix[4]pyrrole (**1**)) are effective anion binding agents[2] in solution has led to the synthesis of a variety of new calixpyrrole macrocycles that have been used for anion binding,[3] sensing[4] and in new anion separation technologies.[5] Recently Sessler and co-workers[6] and Floriani and co-workers[7] have independently reported the syntheses of extended cavity calix[4]pyrroles derived from 4-hydroxyacetophenone. The αααα-isomer of this species (**2**) possesses an array of phenol moieties that resembles that present in lower-rim unfunctionalised calix[4]arenes in the cone conformation. Sessler and co-workers have studied the anion recognition properties of the isomers of **2** together with OMe derivatives (**3**) and found anion selectivity trends in line with those observed for other calix[4]pyrrole species.[6] We have modified the phenol groups of compound **2** with a variety of 'longer' and bulkier functional groups than methyl and have obtained tetra-ester (**4**) and -amide (**5**) macrocycles with 'super-extended cavities'. These macrocycles show interesting highly selective anion coordination properties in solution that are atypical of calix[4]pyrrole macrocycles.



Compound **4** was synthesised by reaction of compound **2** with ethylbromoacetate in dry acetone in the presence of K_2CO_3 with heating at reflux for 5 days. The tetra-ester derivative was isolated as a white powder in 76.5% yield. Compound **5** was synthesised by reaction of compound **2** with 2-chloro-*N*,*N*-diethylacetamide and potassium iodide in dry acetone with stirring for 5 days and was isolated in 50% yield. These compounds may be regarded as pyrrolic analogues of the lower-rim functionalised calix[4]arenes synthesised and studied in the 1980s by McKervey, Ungaro and co-workers.[8]

Solution binding properties of **4** and **5** were investigated using ^{1}H NMR titration techniques in deuteriated DMSO solution. Previous studies in deuteriated dichloromethane with compound **1**[2] and deuteriated acetonitrile with compounds **1**, **2** and **3**[6] have shown downfield shifts of the calix[4]pyrrole NH proton on addition of chloride and dihydrogen phosphate anions consistent with the formation of 1:1 receptor–anion solution complexed species. However, it was found that addition of 20 equivalents of Cl^-, Br^-, I^-, $H_2PO_4^-$ or HSO_4^- anions (as tetrabutylammonium salts) to deuteriated DMSO solutions of **4** and **5** caused *no changes* in the NMR spectra of these calixpyrroles.[9] Compounds **4** and **5** therefore *do not interact* with these putative anionic guests in DMSO solution. On the other hand, upon addition of fluoride anions, new resonances (for the N*H*, Ar*H*, pyrrole C*H* and ArOCH_2C protons) were observed in the ^{1}H NMR spectra of **4** and **5** corresponding to the formation of fluoride complexes with slow complexation/decomplexation kinetics relative to the NMR timescale (Fig. 1). In addition, coupling is observed between the NH protons of the calixpyrroles and the bound fluoride anions (confirmed by ^{19}F NMR spectroscopy) at room temperature (21 °C) with coupling constants of 47 Hz for both compounds **4** and **5**. This coordination coupling has only previously been observed in a

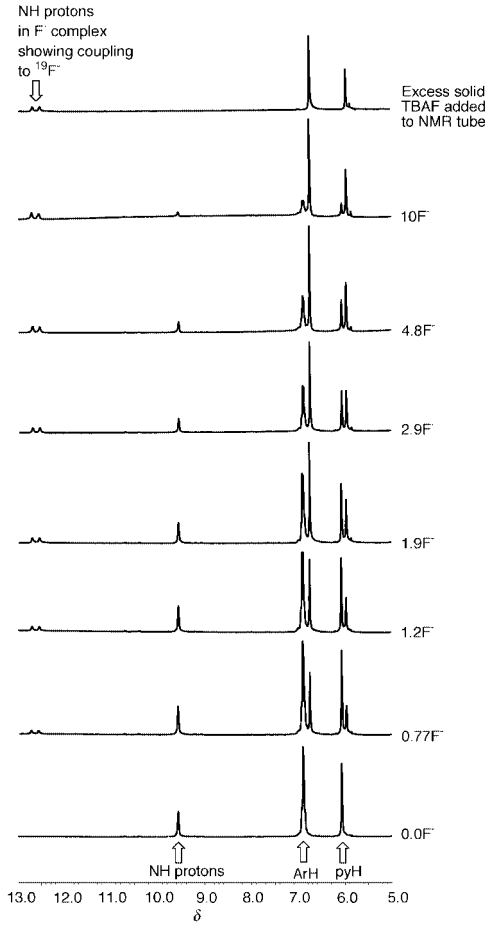


Fig. 1 NMR spectra of compound **5** in deuteriated DMSO solution on addition of aliquots of tetrabutylammonium fluoride. Proton resonances corresponding to the free receptor and fluoride complex can be seen in addition to coupling between the NH proton and $^{19}F^-$ nucleus.

† Electronic supplementary information (ESI) available: synthesis details, NMR and MS, and titration curves. See http://www.rsc.org/suppdata/cc/b0/b003229h/

DOI: 10.1039/b003229h

calix[4]pyrrole–fluoride complex at low temperature (193 K) in deuteriated dichloromethane solution.[10] The concentration profiles of compounds **4** and **5** and their fluoride complexes during the NMR titrations (calculated by integration of the relevant NH resonances in the NMR spectra) are shown in Fig. 2.

In order to compare the solution binding properties of **4** and **5** with *meso*-octamethylcalix[4]pyrrole **1** and the extended cavity calix[4]pyrrole **2**, titrations of these species with fluoride and chloride anions were conducted in deuteriated DMSO solution. In the case of compound **1**, upon addition of fluoride anions, a broadening of the 'free' NH resonance at 9.4 ppm occurred and the appearance of a new resonance at 12.8 ppm (after the addition of 1.4 equivalents of fluoride) was observed. Upon addition of chloride anions to solutions of **1** in the same solvent, shifts of the NH proton were observed with a maximum shift to 11.1 ppm after 3.3 equivalents of chloride. Least squares non-linear fitting of the titration results (pyrrole CH protons) with fluoride and chloride to a 1:1 anion/calixpyrrole binding model with the EQNMR computer program[11] afforded stability constants of 1060 and 1025 M^{-1} (errors estimated to be < 15%) with compound **1** and fluoride and chloride respectively. Similar behaviour was observed with compound **2** and chloride, however the shift of the NH proton was small (a downfield shift of 0.1 ppm after seven equivalents of chloride) and the binding profile did not reach a plateau. This suggests that only a weak interaction is occurring with chloride, making the accurate calculation of a stability constant difficult. The evolution of new resonances corresponding to a solution complexed species was observed upon addition of fluoride anions to compound **2** in deuteriated DMSO solution.

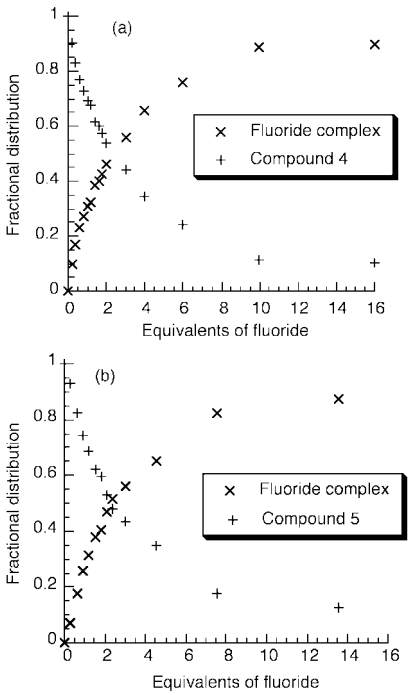

Fig. 2 Concentration profiles for (a) compound **4** and its fluoride complex and (b) compound **5** and its fluoride complex during ^{1}H NMR titrations in deuteriated DMSO solution at room temperature (21 °C).

Compounds **4** and **5** therefore show unique solution anion binding properties in that they *only bind fluoride* in deuteriated DMSO solution. These receptors do not interact with the other anions studied, behaviour not observed with other calix[4]pyrroles. It appears that the presence of an extended cavity in compound **2** and a 'super-extended' cavity in compounds **4** and **5** serves to decrease (**2**) and switch off (**4** and **5**) the affinity of this class of receptor for anions other than fluoride in DMSO solution. We are currently continuing to study the unusual coordination properties of these and other new calix[4]pyrroles in deuteriated DMSO. The results of this work will be reported in due course.

P. A. G. would like to thank the Royal Society for a University Research Fellowship and the EPSRC for a project studentship (to S. C.). Helpful discussions with Dr Pavel Anzenbacher, Jr. (present address: Bowling Green State University, Ohio, USA) are gratefully acknowledged.

9 Solubility problems prevented anion binding studies being conducted with compound **5** in deuteriated acetonitrile solution. It was therefore decided to conduct all binding studies in deuteriated DMSO (estimated water content approx. 0.02%) in order to give a consistent set of results and to minimise the chances of ion-pair formation in solution (which may occur with low polarity and poor donor/acceptor solvents such as dichloromethane). It should be noted however that ^{1}H NMR titrations of compound **4** with fluoride or chloride anions in deuteriated acetonitrile solution resulted in the appearance of new resonances corresponding to solution complexed species (slow exchange conditions in contrast to compound **2** which displays fast exchange with anions under these conditions (see ref. 6)).

Received (in Basel, Switzerland) 9th March 2000, Accepted 18th May 2000

Efficient oxidation of alkanes, including methane and ethane, with H_2O_2 in the presence of catalytic amount of an Os complex in MeCN (addition of nitrogen-containing heterocycles significantly enhances the yield of the products) or in $MeCO_2H$ gives the corresponding ketones and alcohols.

Unlike aromatic and olefinic hydrocarbons, alkanes are known to exhibit only negligible reactivity in reactions with a variety of normal reagents and the yields of the products are usually low, especially in the case of light saturated hydrocarbons (methane, ethane and propane).[1] Osmium compounds, particularly OsO_4, oxidize unsaturated hydrocarbons and some other organic compounds stoichiometrically and catalyse their oxygenations with various reagents.[2,3]

Here, we report that soluble osmium derivatives, especially $OsCl_3$, catalyse efficiently the oxygenation of saturated hydrocarbons with hydrogen peroxide. All reactions[4] were carried out at 80 °C. The oxidation of cycloheptane (0.4 mol dm^{-3}) in MeCN with H_2O_2 (1.0 mol dm^{-3}) in the presence of $OsCl_3$ (1.0×10^{-3} mol dm^{-3}) gave after 3 h cycloheptanol (0.05 mol dm^{-3}) and cycloheptanone (0.013 mol dm^{-3}), the total turnover number (TON) being 63. Addition of a small amount of pyridine (0.125 mol dm^{-3}) gave rise to a noticeable increase in the yield and to the predominant formation of the ketone (after 90 min: cycloheptanol, 0.020 mol dm^{-3}; cycloheptanone, 0.092 mol dm^{-3}; TON, 112). Other nitrogen-containing heterocycles also promote the oxidation: for example, the reaction with *n*-heptane in the presence of 3-methylpyrazole (Fig. 1) affords predominantly isomeric ketones (after 60 min total concentration 0.028 mol dm^{-3}) as well as isomeric alcohols (total 0.04 mol dm^{-3}). Heptanal has been detected only in negligible concentration. The reaction is accompanied by non-productive H_2O_2 decomposition to give molecular oxygen, and the oxidation decreases when hydrogen peroxide concentration becomes low (after approximately 1 h, as shown in Fig. 1). By varying the additive, it is possible to control the ketone/alcohol ratio (Table 1). Lower alkanes can be easily oxidized in MeCN, if pyridine is added to the reaction solution (Table 2). In contrast to methane which is the least reactive hydrocarbon in this reaction and affords methanol as the main product, ethane and propane give mainly carbonyl compounds and only smaller amounts of alcohols with TON values of 102 and 150, respectively.

The selectivities of the alkane oxidations catalysed by $OsCl_3$ are higher than those determined for analogous hydroxylations by the systems 'H_2O_2–*h*ν' and 'H_2O_2–$FeSO_4$' as well as 'H_2O_2–VO_3^-–pyrazinecarboxylic acid (PCA)'[7] which are believed to produce free hydroxyl radicals (Table 3). It is noteworthy that selectivities significantly increase when pyridine is added to the reaction solution. Moreover, while the oxidation of *cis*-decalin with H_2O_2–$OsCl_3$ in MeCN occurs without retention of the configuration (the *trans/cis* ratio of the products formed being more than unity), in the presence of

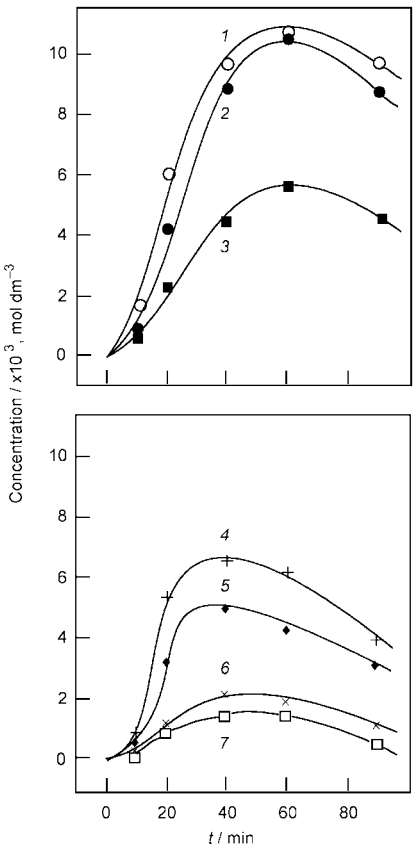

Fig. 1 Accumulation of heptan-2-one (*1*), heptan-3-one (*2*), heptan-4-one (*3*), heptan-2-ol (*4*), heptan-3-ol (*5*), heptan-4-ol (*6*) and heptan-1-ol (*7*) in the *n*-heptane (0.4 mol dm^{-3}) oxidation with H_2O_2 (1.0 mol dm^{-3}) catalysed by $OsCl_3$ (10^{-3} mol dm^{-3}) in MeCN in the presence of 3-methylpyrazole (0.12 mol dm^{-3}) at 80 °C.

Table 1 Oxidation of cycloheptane (0.4 mol dm^{-3}) with H_2O_2 (1.0 mol dm^{-3}) in MeCN (80 °C, 2 h)[4]

		Products/mol dm^{-3}		
Catalyst	Additive	Cyclo-heptanol (OL)	Cyclo-heptanone (ONE)	Ratio OL/ONE
$OsCl_3$	2,5-Dichloropyridine	0.076	0.014	5.4
$OsCl_3$	None	0.049	0.010	4.9
$OsCl_3$	2,2′-Bipyridine	0.059	0.026	2.3

Table 2 Oxygenation of lower alkanes (H_2O_2 = 1 mol dm^{-3}, $OsCl_3$ = 1 × 10^{-3} mol dm^{-3}, py = 0.125 mol dm^{-3}; MeCN 80 °C, 1.5 h)[4]

Alkane (pressure/bar)	Products/mol dm^{-3}
Methane (40)	CH_3OH (0.017); HCHO (3.0×10^{-5})
Ethane (20)	CH_3CHO (0.08); CH_3CH_2OH (0.022)
Propane (6)	CH_3CH_2CHO (0.034); CH_3COCH_3 (0.054); $CH_3CH(OH)CH_3$ (0.018); $CH_3CH_2CH_2OH$ (0.044)
n-Butane (2)	$CH_3CH_2CH_2CHO$ (0.011); $CH_3COCH_2CH_3$ (0.026); $CH_3CH(OH)CH_2CH_3$ (0.011); $CH_3CH_2CH_2CH_2OH$ (0.002)

Table 3 Selectivities of alkane oxidations by various systems

Substrate	System	Selectivity[a]
n-Heptane		C(1):C(2):C(3):C(4)
	H_2O_2–*hν* in MeCN	1.0:7.3:6.3:8.1
	H_2O_2–$FeSO_4$ in MeCN–H_2O	1.0:5.0:4.8:4.6
	H_2O_2–$OsCl_3$ in MeCN	1.0:11.8:9.8:3.5
2,2,4-Trimethyl-pentane		1°:2°:3°
	H_2O_2–*hν* in MeCN	1.0:1.75:6.2
	H_2O_2–$FeSO_4$ in MeCN–H_2O	1.0:2.75:6.0
	H_2O_2–Bu_4NVO_3–PCA in MeCN	1.0:3.0:4.8
	H_2O_2–$OsCl_3$ in MeCN	1.0:2.2:8.7
	H_2O_2–$OsCl_3$ in MeCN–py (0.125 mol dm^{-3})	1.0:2.1:18.3
cis-Decalin		*trans*/*cis*
	H_2O_2–*hν* in MeCN	1.3
	H_2O_2–*hν* in py	1.9
	H_2O_2–$FeSO_4$ in MeCN–H_2O	3.4
	H_2O_2–Bu_4NVO_3–PCA in MeCN	2.1
	H_2O_2–$OsCl_3$ in MeCN–py (0.125 mol dm^{-3})	1.2
	H_2O_2–$OsCl_3$ in MeCN–py (6.25 mol dm^{-3})	0.56
	H_2O_2–$OsCl_3$ in $MeCO_2H$	0.26

[a] Parameter C(1):C(2):C(3) is normalized (*i.e.* calculated taking into account the number of hydrogen atoms at each position) relative reactivities of hydrogens at carbon atoms 1, 2 and 3 of the alkane chain, respectively; parameter 1°:2°:3° is normalized relative reactivities of hydrogen atoms at primary, secondary and tertiary carbons, respectively; parameter *trans*/*cis* = [*trans*-decal-9-ol]/[*cis*-decal-9-ol], where [*trans*- and *cis*-decal-9-ol] are concentrations of *trans*- and *cis*-decal-9-ol formed in the oxidation, respectively.

pyridine the reaction becomes more selective, the *trans/cis* ratio decreasing with increasing pyridine concentration. It is important to note that in $MeCO_2H$ the reaction exhibits a high value of the *trans/cis* parameter (0.26) and the parameter RC_{cis} = $100(c_{cis} - c_{trans})/(c_{cis} + c_{trans})$ = 58%. The value of the *trans/cis* parameter for the system 'H_2O_2–$OsCl_3$' in $MeCO_2H$ is only slightly higher than that (*trans/cis* = 0.12) for the hydroxylation in MeCN by the system 'H_2O_2–$LMn^{IV}(O)_3$-$Mn^{IV}L^+$–$MeCO_2H$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane)' described recently.[8]

On the basis of the results obtained and especially taking into account the selectivity parameters, one may assume that oxidation by the system H_2O_2–$OsCl_3$ starts with hydrogen atom abstraction from the alkane by an oxo osmium complex, and the reaction occurs in a solvent cage. The alkyl radicals formed react then with dioxygen to generate the corresponding alkyl hydroperoxide which decomposes to afford the corresponding ketone and alcohol. The system described here can be considered as a model for the oxidations of C–H compounds catalysed by iron-containing enzymes, osmium being an iron homologue in the Periodic System. Indeed, oxidations with participation of cytochrome P-450, methane monooxygenase and chloroperoxidase are believed to begin with hydrogen atom abstraction by a high-valent iron oxo species.[1,9] Coordination of a nitrogen-containing heterocycle (and/or acetate) to osmium may produce a catalytically active oxo species surrounded with voluminous ligands, and the relatively high bond- and stereoselectivities of the alkane oxidation may be due in this case to the bulkiness of the ligands at the reaction centre.

We thank the Russian Basic Research Foundation and the Swiss National Science Foundation for support.

4 The oxidations of higher hydrocarbons were carried out in air in thermostated Pyrex cylindrical vessels with vigorous stirring. The total volume of the reaction solution was 5 or 10 mL. In a typical experiment, initially, a portion of 35% aqueous solution of hydrogen peroxide (Fluka) was added to the solution of the catalyst, substrate and heterocycle in acetonitrile (Fluka). The oxidations of lower alkanes were carried out in an stainless steel autoclave with intensive stirring (volume of the reaction solution was 5 mL and total volume of autoclave was 100 mL). Before the oxidation the autoclave was charged with the alkane under appropriate pressures. The reactions were stopped by cooling with ice and the reaction solution was analysed by GC (DANI-86.10; fused silica capillary column 25 m × 0.32 mm × 0.25 mm, CP-WAX52CB; integrator SP-4400). Comparison of the chromatograms of the reaction samples before and after their treatment with PPh_3 (for this method, see refs. 1(*a*),(*b*),5–8) demonstrated that concentrations of alkyl hydroperoxides were very low. The concentration of formaldehyde was measured spectrophotometrically after its transformation into 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine as described previously.[6]

Received (in Cambridge, UK) 28th April 2000, Accepted 19th May 2000

Aromatics with 6 to 9 carbon atoms can be converted catalytically with hydrogen on bifunctional zeolites, such as Pd/H-ZSM-5, into a high-quality steamcracker feed, thereby opening a direct route for the utilisation of surplus pyrolysis gasoline.

In view of the predicted over-supply of aromatics,[1] novel catalytic routes for their conversion into valuable products are urgently needed. One of the major sources of aromatics is so-called pyrolysis gasoline, a by-product of steamcracking in which ethylene and propylene are made from light hydrocarbons, such as straight-run naphtha,[2] LPG[3] or ethane. In a preceding communication[4] we have shown that cycloalkanes (which are readily obtained from aromatics by catalytic ring hydrogenation) can be converted on acidic zeolite catalysts, such as H-ZSM-5, into a high-quality steamcracker feed consisting mainly of ethane, propane and *n*-butane. Here, we demonstrate that, as an alternative to this two-stage route (ring hydrogenation followed by ring opening), aromatics can be *directly* converted with hydrogen into the same type of synthetic steamcracker feed, if *bifunctional* zeolite catalysts, *e.g.*, Pd/H-ZSM-5, are used. The literature on catalytic ring opening of aromatics in an excess of hydrogen is very scarce,[5–8] and on the catalysts used so far, the yields of *n*-alkanes with two or more carbon atoms, *i.e.* the most desirable hydrocarbons for a synthetic steamcracker feed, are reported to be low.

Results of the conversion of toluene[9] on 0.2Pd/H-ZSM-5[10] are displayed in Fig. 1. Whereas the conversion of toluene is 100% throughout the temperature range covered, the types of reaction occurring vary drastically: at 200 °C, hydrogenation to methylcyclohexane is the predominant reaction, and part of the methylcyclohexane is isomerised in consecutive reactions *via* the well known[11] bifunctional mechanism into ethylcyclopentane and dimethylcyclopentanes. With increasing temperature, more and more ring opening occurs. At 320 °C, virtually all cyclic hydrocarbons are converted into alkanes,[12] and increasing the temperature further brings about a diminution of the yield of isoalkanes which undergo secondary cracking reactions into propane and ethane. At 400 °C toluene is converted with a yield of 72.8% into C_{2+}-*n*-alkanes (*cf.* Table 1, column 4). It is noteworthy that no aromatics occur in the product under any reaction conditions, and very little methane is formed even at 400 °C. For various reasons (high hydrogen consumption and exothermicity, methane does not form ethylene or propylene in the steamcracker), methane is a very undesired product.

Upon increasing the palladium content of the catalyst from 0.2 to 0.5 and 1.0 wt.%, the yields at a reaction temperature of 400 °C do not change significantly. From this we conclude that, under the conditions applied in this work, ring opening and the formation of light alkanes proceed *via* the bifunctional hydrocracking mechanism[13] and Haag–Dessau cracking,[14] rather than *via* hydrogenolysis[15] on the noble metal.

Table 1 shows results obtained at 400 °C with different feed hydrocarbons. No products other than alkanes were found with any feed hydrocarbon under these conditions. The yields of methane are low throughout (around 3–4%, Table 1, entry 2). Interestingly, the yields of the desired C_{2+}-*n*-alkanes (Table 1, entry 7) do vary significantly with the nature of the aromatic

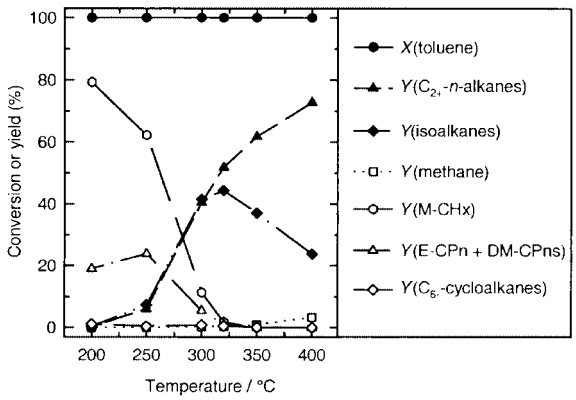

Fig. 1 Conversion of toluene on 0.2Pd/H-ZSM-5 at various temperatures (*X*: conversion; *Y*: yield; M-CHx: methylcyclohexane; E-CPn: ethylcyclopentane; DM-CPns: dimethylcyclopentanes).

Table 1 Conversion of aromatics on 0.2Pd/H-ZSM-5 at 400 °C

		Feed					
Entry		Benzene	Toluene	*o*-Xylene	*p*-Xylene	Ethylbenzene	1,2,4-Trimethylbenzene
1	X^a (%)	100	100	100	100	100	100

[a] *X* is the conversion of the aromatic feed hydrocarbon. [b] *Y* is the yield of the product indicated and defined in the usual manner, *e.g.*, $Y_{n\text{-butane}} = (4/7) \times (\dot{n}_{n\text{-butane, out}}/\dot{n}_{toluene, in})$, $\dot{n}$ being the molar flux. [c] Sum of entries 3 to 6.

DOI: 10.1039/b003422n

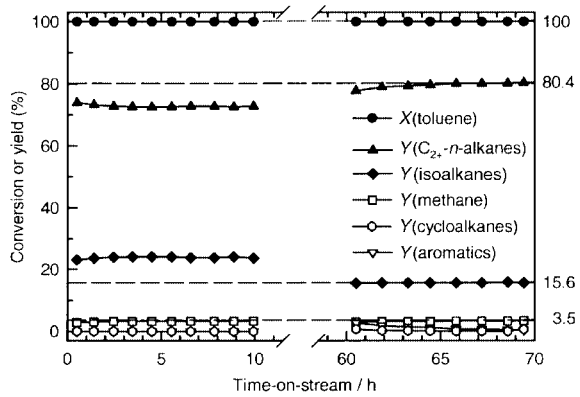

Fig. 2 Coke selectivation in the conversion of toluene on 0.2Pd/H-ZSM-5. (During the initial 10 h and from 60 to 70 h on-stream time, the reaction temperature was 400 °C. In the period between 10 h and 60 h, lower reaction temperatures in the range from 200 to 350 °C were applied; *X*: conversion; *Y*: yield.)

feed hydrocarbon. This yield is lowest for toluene and above 90% for both benzene and ethylbenzene. Note also that very large amounts of propane are formed from benzene (which can be rationalized in terms of a so-called type C β-scission[16,17] of hexyl cations), while an unusually high yield of ethane is observed in the product from ethylbenzene (which we tentatively ascribe to a deethylation reaction).

Regardless of the hydrocarbon used as feed, there was no significant change in the product yields with time-on-stream. In Fig. 2, results are shown which were obtained with toluene as feed on 0.2Pd/H-ZSM-5. During the initial 10 h, the yield of C_{2+}-*n*-alkanes amounted to *ca*. 73%. For the next 50 h (not shown in Fig. 2) toluene was converted on this catalyst sample at lower temperatures in the range 200–350 °C. Thereafter, the reaction temperature was again raised to 400 °C for 10 h. Significantly better yields of the desired C_{2+}-*n*-alkanes (*ca*. 80%) were attained than with the fresh catalyst. We interpret this selectivity gain in terms of a so-called coke selectivation, *i.e.* at the lower reaction temperatures between the two runs at 400 °C, some dimerization and/or disproportionation reactions of methylcyclohexane[18] or toluene inside the zeolite pores must have taken place, whereby larger product molecules were formed which ultimately led to some carbonaceous deposits with a concomitant narrowing of the pores. Similar effects have been observed by others, *e.g.* in the disproportionation of toluene on H-ZSM-5.[19]

In conclusion, we have demonstrated that aromatics can be *directly* converted with hydrogen into a high-quality steamcracker feed on bifunctional zeolite catalysts of the Pd/H-ZSM-5 type. This direct route will have to compete with the two-stage variant consisting of ring hydrogenation in the aromatics over a hydrogenation catalyst followed by ring opening of cycloalkanes on monofunctional zeolites.[4] The main technological advantage of the direct route described here is a single catalytic reactor for the manufacture of synthetic steamcracker feed from pyrolysis gasoline. On the other hand, advantageous features of the two-stage variant are (i) the possibility to optimise the ring hydrogenation of aromatics and the ring opening of the resulting cycloalkanes separately and (ii) the generation of the exothermic heat in two separate reactors and, hence easier removal of this heat. It remains to be seen whether the direct route or the two-stage variant is economically more attractive.

Estradiol binding synthetic polypeptides

G. Giraudi,* C. Giovannoli, C. Tozzi, C. Baggiani and L. Anfossi

Department of Analytical Chemistry, University of Torino, Via P. Giuria 5, 10125 Torino, Italy. E-mail: giraudi@ch.unito.it

Received (in Cambridge, UK) 14th December 1999, Accepted 19th May 2000

We have synthesised polypeptides that mimic the binding properties of natural receptors with high affinity and selectivity towards the steroid hormone estradiol, performing a template polymerisation in aqueous medium and without creating rigid structures.

Selective recognition systems are usually created in synthetic polymers obtaining a three-dimensional structure that has been shaped to match the template, after its removal. As a consequence, artificial systems of recognition are available for nucleotides,[1] inorganic ions,[2] amino acids[3,4] and herbicides.[5] We employed the template polymerisation method to synthesise oligopeptides that were templated with the steroid hormone estradiol. The application of this technique is completely new because until now the literature only gave examples on cross-linked organic macroporous polymers, whereas we performed the polymerisation in aqueous medium without the formation of rigid structures. The initial idea was that an amino acid mixture could generate polypeptidic systems, thus establishing non-covalent bonds with molecular species present in the polymerisation mixture. Polypeptides are structures that are well suited for the design of systems with molecular recognition properties, above all for the large structural heterogeneity in the amino acid lateral chain that gives rise to a great variety of chemical properties and non-covalent interactions useful in template polymerisation.

The amino acid composition of the mixtures that we polymerised is similar to bovine serum albumin. Two different amino acid mixtures were polymerised: the first—branched mixtures— contained branched monomers (Gly, Ala, Leu, Pro, Phe, Tyr, Trp, Ser, Met, Arg, His, Lys, Asp, Asn, Gln, Glu, Cys-Cys), the second—linear mixtures— contained the same amino acids apart from Lys, Asp, Glu, Cys-Cys and were richer in Leu and Gly. This enabled us to study the binding properties of both cross-linked and linear structures. Furthermore, for each mixture the polymerisation was performed in the presence (template mixtures) and in the absence (blank mixtures) of estradiol to compare the binding properties, and were performed for different reaction times (1, 3 and 30 h) to evaluate the influence of this variable on the binding constants.[6]

To remove the estradiol we used anion exchange chromatography on a DEAE-Sephacel column.[7]

The concentration of the oligopeptides was determined by spectrophotometric measurements, and the recoveries were between 94 and 97%.

After purification of the mixtures, we characterised the oligopeptides by determining the average molecular weights by HPLC using an Alltech Macrosphere GPC 60 A 7 μm (250 mm × 4.6 mm).[8] The average M_w was between 2000 and 6000 Da, increasing with the polymerisation time, and so, considering an average amino acid M_w of 130 Da, the degree of polymerisation was between 15 and 46, with an average value of 30.

The spectrophotometric titration of the template oligopeptides with estradiol performed at 274 nm shows that the stoichiometry of binding is close to 1 : 1, but an evaluation of the binding constant was not possible due to the absence of curvature in the equivalence region.

To evaluate the binding affinity of the oligopeptides we used immunocompetition where the oligopeptides competed with an immobilised anti-estradiol antibody for tritium labelled estradiol. The anti-estradiol antibody was immobilised into the wells of microtitre plates previously coated with goat anti-rabbit IgG antibodies, according to the literature.[9] The measurement of estradiol bound to the antibody in the presence of the oligopeptides allowed us to determine the binding constants K (by fitting a proper mathematical equation to the experimental data) of the oligopeptide mixtures. This defines the ratio between the binding of the tritium labelled estradiol with the antibody in the presence of the oligopeptides and without the oligopeptides, as a function of the binding constant of the antibodies for estradiol, the concentration of the solid phase, binding site antibodies, the tritium labelled estradiol concentration, the concentration of the oligopeptides and the binding constant of the oligopeptides for the estradiol. The first two parameters were determined in separate experiments as reported in the literature,[9] thus, knowing the tritium labelled estradiol concentration and the concentration of the oligopeptides we could obtain the binding constants of the oligopeptide mixtures for estradiol from the competition curves (Fig. 1). The binding constants are shown in Table 1.

As all these results could be affected by contributions from residual estradiol, we performed a template and blank polymer-

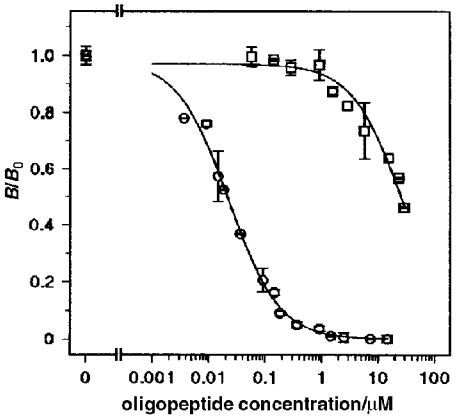

Fig. 1 Immunocompetition of branched mixtures polymerised for 1 hour. The plot of B/B_0, where B is the binding of the tritium labelled estradiol with the antibody in the presence of the oligopeptides and B_0 without the oligopeptides, *vs*. the oligopeptide concentration, gives competition curves from which the binding constant of the oligopeptides towards estradiol can be calculated. The branched template oligopeptides (○) and the branched blank oligopeptides (□) are shown.

Table 1 Binding constants of oligopeptide mixtures

Oligopeptide mixtures	Polymerisation time/h	Template K/M^{-1}	Blank K/M^{-1}
Branched	1	9.0×10^8	9.0×10^6
	3	1.2×10^9	1.5×10^7
	30	6.6×10^9	1.3×10^9
Linear	1	4.4×10^8	2.2×10^6
	3	5.8×10^8	2.8×10^6
	30	1.4×10^9	3.6×10^8

DOI: 10.1039/a909798h

isation in the presence of labelled estradiol.[10] After purification, the amount of bound estradiol was determined by this method, and only 3–4% of the template polypeptides contained bound estradiol. Control experiments were therefore carried out to investigate the effect of bound estradiol. Therefore, we corrected the mathematical equation, including a parameter that allowed us to take into account the presence of some residual estradiol. Fitting this last equation to the experimental data, we observed that the binding constants were essentially unchanged. So, the reported results are not affected by any contribution from residual estradiol, as the great excess of high affinity oligopeptides prevents the effective displacement of labelled estradiol from antibody binding sites by the residual template molecule.

To further verify the absence of artefacts in the evaluation of binding constants (due to the presence of residue template molecules), we performed some preliminary ultrafiltration experiments.[11] All values of binding constants obtained are about one order of magnitude lower than those obtained by competitive binding experiments, both for blank and template mixtures, but are affected by great imprecision. The reason for this is related to the partial adsorption of estradiol on the ultrafiltration membrane and also to the partial ultrafiltration of the oligopeptides, as determined in separate experiments with tritium labelled oligopeptides. The method is thus insensitive to residual estradiol but the partial ultrafiltration of oligopeptides leads to an underestimation of the binding. For these reasons we abandoned the ultrafiltration technique in favour of the competitive binding assay, which is simple to perform and gives better results.

In order to verify that there were no interactions between the rabbit anti-estradiol antibodies or the goat anti-rabbit γ-globulin antibodies and the oligopeptides, we checked the interactions of labelled oligopeptides (template and blank mixtures) with the immobilised antibodies.[12] In both cases we registered no significant binding to the solid phase. So, the inhibition of binding between labelled estradiol and its antibody is caused only by the binding properties of the oligopeptide mixtures that bind the steroid.

From the previously reported results, we note the very high affinity of the oligopeptides for the templating molecule. The difference between the binding constants of the template and blank mixtures shows the importance of the template effect on the amino acid mixtures and the efficacy of these systems as competitors of the antibodies themselves. For all mixtures the binding constants increase with the polymerisation time; this effect can be explained by the formation of more and more complex structures which are able to interact better with estradiol. The ratio between template and blank decreases when we increase the polymerisation time, probably because in the blank mixtures a longer reaction time increases the formation of more complex oligopeptide structures able to rearrange themselves around the steroid molecule to obtain a greater interaction. Instead, in the template mixtures this effect is less important as the binding properties are mainly due to the imprint.

An important parameter to consider is the specificity of binding. We performed an immunocompetition using the branched oligopeptides (1 h, 30 h) to evaluate the binding constant of this mixture for structural homologues, such as the steroids, testosterone and progesterone. The experimental procedure was similar to those used previously.[13] The results indicate that the oligopeptides do not have significant affinity for these molecules. For template branched oligopeptides (1 h) the binding constant for the testosterone is 1.2×10^5 M^{-1} *vs.* 9.0×10^8 M^{-1} for the estradiol, whereas for the blank ones K is 3.3×10^4 M^{-1} *vs.* 9.0×10^6 M^{-1}. The binding constants obtained for the branched oligopeptides polymerised for 30 h (template: 7.7×10^5 M^{-1}; blank: 4.8×10^6 M^{-1} for testosterone) confirm the hypothesis that longer reaction times can result in structures which can rearrange themselves to better match the steroid molecule without loss of selectivity (this remains unchanged), thus indicating that the imprinting effect is operative in all cases. For progesterone it is possible only to estimate an upper limit for the binding constant (1.0×10^4 M^{-1}). This is further evidence of the high affinity and high specificity of recognition toward the templating molecule. Moreover the template mixtures have selectivities similar not only to usual antisera, but also to the molecular imprinted polymers.[14]

6 The polymerisation was performed in mixed aqueous/organic media (carbonate buffer 0.2 M pH 9/DMF, 1 + 1) using carbodiimide as a condensing agent. The mixtures were shaken according to the different reaction times at room temperature in the dark. Then the oligopeptide mixtures were filtered on 0.45 μm sintered glass.
7 We washed the resin with carbonate buffer (20 mM, pH 8.5) until the absorbance had returned to the baseline. After reversing the direction of the flow, the elution was performed by running a phosphate buffer (50 mM phosphate, 1 M NaCl, 1 mM EDTA, pH 7).

9 G. Giraudi, I. Rosso, C. Baggiani and C. Giovannoli, *Anal. Chim. Acta*, 1999, **381**, 133.
10 Labelled estradiol (2.8×10^{-2} μM) was added to the estradiol and the amino acid mixtures before polymerisation. During the purification, we followed the absorbance of the oligopeptides with a spectrophotometric detector and the eluate was fractionated every 5 cm^3 to check the signal of the labelled estradiol.
11 We added the oligopeptides at increasing concentrations to a constant amount of labelled estradiol, and after centrifugation in an Amicon MPS-1 device, equipped with YM1 membranes (nominal molecular weight cut-off of 1000 Da), we measured the ultrafiltered estradiol in the filtrate. The fraction of estradiol in the retentate plotted *vs.* the oligopeptide concentration allowed us to estimate the value of binding constants.
12 For the synthesis of the labelled oligopeptides we added volumes of labelled Ser, Leu, Gly, Glu (each amino acid was 1.0 mCi cm^{-3}) to the amino acid solution, and then we performed the polymerisation as previously described. These quantities were proportional to the percentage of the corresponding amino acid in the polymerisation mixture and assured a significant measure of radioactivity. The small volumes added can be considered negligible in comparison to the volume of the whole polymerisation mixture.
13 We used antibodies directly against testosterone and tritium labelled testosterone for the affinity measurement of this steroid, and anti-progesterone antibodies and tritium labelled progesterone for the determination of the affinity for this one.

The unexpected head-to-head dimerisation of 1*H*-phosphirenes

Ngoc Hoa Tran Huy, Louis Ricard and François Mathey

Laboratoire "Hétéroéléments et Coordination" UMR CNRS 7653, DCPH, Ecole Polytechnique, 91128, Palaiseau Cedex, France. E-mail: dcph@poly.polytechnique.fr

Received (in Basel, Switzerland) 14th February 2000, Accepted 16th May 2000

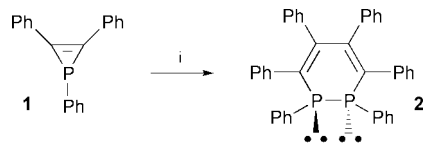
Both 1*H*-phosphirenes and their P-W(CO)$_5$ complexes readily dimerise in the presence of Ni(II) or Pd(0) catalysts to give the corresponding 1,2-dihydro-1,2-diphosphinines.

The ready dimerisation of borirenes into 1,4-diboracyclohexadienes is well documented and has been studied in some depth from a theoretical standpoint.[1] Similarly, silirenes readily give 1,4-disilacyclohexadienes in the presence of a palladium catalyst.[2] In both cases, no head-to-head dimers were detected. In the silicon case, although no mechanism was proposed for the dimerisation, the intermediacy of a 1-metalla-2-silacyclobutene appeared likely.[3] Since we knew from preceding experiments that both Pd(0) and Pt(0) readily insert into the P–C bonds of 1*H*-phosphirenes and phosphirene complexes,[4,5] it was tempting to explore the possible dimerisation of these phosphirenes in the presence of palladium catalysts.

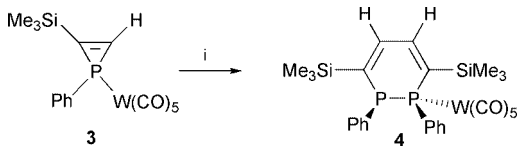
Preliminary experiments were carried out with 1,2,3-triphenylphosphirene[6] and its P-W(CO)$_5$ complex.[7] Heating 1,2,3-triphenylphosphirene with [Pd(PPh$_3$)$_4$] in toluene at 85 °C overnight led only to decomposition products. After several experiments, we finally found that clean dimerisation was achieved with a Ni(II) catalyst at room temperature (Scheme 1).

The structure of **2**† unexpectedly corresponds to a head-to-head dimer (Fig. 1).‡ The ring is highly distorted with two *trans* phosphorus lone pairs and some strain as indicated by the rather small P–P–C(ring) angles of 91.09(5) and 91.27(5)°. The P–P bond is short for a single bond at 2.193(2) Å. Compound **2** displays surprising instability. It decomposes completely upon heating at 65 °C for 20 min in toluene. Looking for more stable derivatives, we decided to investigate the dimerisation of phosphirene P-W(CO)$_5$ complexes. The complex of **1** appeared to be rather inert. We reasoned that a 1,2-disubstituted species would be more reactive. Accordingly, we prepared the (1-phenyl-2-trimethylsilylphosphirene)pentacarbonyltungsten complex **3**† by the usual technique[7] and studied its evolution in toluene at 85 °C in the presence of [Pd(PPh$_3$)$_4$]. Overnight we observed the formation of the head-to-head dimer **4**† which was isolated in 60% yield (Scheme 2).

The dimerisation is regio- and stereo-selective (Fig. 2).‡ The regioselectivity can be easily explained by a preferential insertion of Pd(0) into the less hindered P–CH intracyclic bond.



Scheme 1 *Reagents and conditions*: (i) 150 mg of **1**, 10 mg of [NiCl$_2$(Ph$_2$PCH$_2$CH$_2$PPh$_2$)], CH$_3$CN, 25 °C, 2 d, 70% yield.



Scheme 2 *Reagents and conditions*: (i) 530 mg of **3**, 30 mg of [Pd(PPh$_3$)$_4$], toluene, 85 °C, 16 h.

DOI: 10.1039/b001304h

The ring is almost undistorted. The intracyclic angles at phosphorus are normal at 101.3(1) (P_{III}) and 105.7° (P_W). The P–P bond is also in the normal range at 2.227 Å. In contrast to **2**, the stereochemistry at the phosphorus atoms is *cis* and **4** is quite stable.

At the moment, we have no precise explanation for this unexpected head-to-head dimerisation. The only argument which can be pointed out has a thermodynamic basis. The formation of one P–P and one C–C bond is more energetically favourable than the formation of two P–C bonds: 61 + 88 > 2 × 65 kcal mol^{-1}.[8] Unlike phosphorus, both silicon and boron have much lower electronegativities than carbon and the dimerisation of silirenes and borirenes is probably controlled by the polarity of the Si–C and B–C ring bonds. Whatever its origin, this head-to-head dimerisation of phosphirenes provides a direct access to the almost unknown 1,2-dihydro-1,2-diphosphinine ring. At the moment, only a 1,2-disulfide has appeared in the literature, prepared by a low-yield multi-step procedure.[9] The chemistry of this ring is now open for investigation.

Received (in Liverpool, UK) 29th March 2000, Accepted 23rd May 2000

A general photochemical synthesis of large thiohelicenes containing nine and eleven rings is discussed along with the organisation of racemic thiohelicenes in crystals: heterochiral assembling is dominant except in the nine-ring system where interactions involving terminal ring S atoms favour the segregation of close-packed homochiral molecules in planes.

Helicenes are intrinsically chiral helical molecules structurally characterised by *ortho*-fusion of aromatic rings. Nonracemic, appropriately substituted systems exhibit a spontaneous organisation in macroscopic fibrous structures in the solid state, while in concentrated solutions and thin films a gigantic rotation of the plane of polarised light was evidenced.[1–3] The polyconjugated chiral structure of helicenes makes them interesting candidates for optoelectronic applications[4] and molecular devices.[5] Higher carbohelicenes are endowed with an inherent propensity to homochiral molecular recognition.[6]

Some studies on lower heterohelicenes containing thiophene rings were published long ago.[7–9] Here, we report on a general synthetic approach we used to prepare a series of heterohelicenes formed by alternate thiophene and benzene rings: trithia[5]heterohelicene **4**, tetrathia[7]heterohelicene **7** and, for the first time, large molecules such as pentathia[9]heterohelicene **10** and esathia[11]heterohelicene **13.** We also investigated the electronic and self assembling properties of these systems with the aim of establishing whether the preference for heterochiral molecular aggregation shown by the racemic five- and seven-member thiaheterohelicenes in crystals[8,9] persists in higher members of the series, specifically with reference to the crystal structure of **10**.

Substituted helicenes are obtained in good yield by chemical synthesis both in racemic or enantiomeric form.[11,12] We obtained a series of unsubstituted thiohelicenes using a general procedure for the preparation of racemic molecules, shown in Scheme 1, where the photochemical cyclisation represents the final step. With this synthetic route it was possible to obtain molecules as large as the nine- and eleven-membered thiohelicenes.

Two approaches were in principle possible to synthesise large condensed systems. The first consists of the double photochemical ring closure of a molecule containing two 1,2-disubstituted ethylenes. In this case the bis-ethylene molecule needs only to contain a heteroaryl moiety that does not exceed three members and can be easily prepared. The second possibility, preferable in the case of higher thiohelicenes, consists of a single photochemical cyclisation of a 1,2-diheteroarylethylene and larger heteroaryl substituents, such as thio[5]heterohelicenes, are necessary.

The synthesis of thio[*n*]helicene (n = 7, 9 condensed rings) starts by reacting thio[$n - 4$]helicene with Vilsmeier reagent [$POCl_3$ and PhN(Me)CHO in boiling toluene] in order to obtain the corresponding 2-carbaldehyde. The phosphonium salt **5** is produced from the 2-carbaldehyde **2** with a sequence of reactions illustrated in Scheme 1 and described elsewhere.[13] The Wittig reaction between the phosphonium salt and the 2-carbaldehyde of the thio[$n - 4$]helicene gives a 1,2-diheteroarylethylene. The racemic thio[*n*]helicene can be easily obtained in high yield by the photoinduced cyclodehydrogenation of appropriate 1,2-diheteroarylethylenes.† The synthesis of the larger esathia[11]helicene **13** begins with the reaction between the 2-carbaldehyde-thio[5]helicene **8** and the phosphonium salt of the thio[5]helicene **11**, followed by photocyclisation of the 1,2-diheteroarylethylenes **12**.†

Electronic absorption spectra of the thiohelicene series in solution are shown in Fig. 1. Upon increasing the number of condensed rings, the absorption bands shift to lower energy owing to the lengthening of the π-conjugation in the helical

system. The photoluminescence spectra show a similar behaviour, with emissions that are red-shifted increasing the molecular size.‡

Fig. 2 and 3 show views of the packing of the nine ring helicene **10** as obtained by single crystal X-ray diffraction.§ The structure of the eleven ring system **13** will be presented elsewhere.[14] The tendency to stacking of antipodes[9] in interdigitated columnar structures is apparent (Fig. 2) for all of the thiohelicene racemic structures including **10**. The stacking interactions involve especially the third and/or the fourth rings (from the molecular ends) of enantiomeric pairs, and vary depending upon the particular molecule. In all the systems investigated specific interactions engaging sulfur[15,16] and hydrogen atoms at distances slightly shorter than the sum of the van der Waals radii (1.80 Å for S and 1.20 Å for H) were found. They always involve atoms of terminal rings and are quite probably attractive playing a role in molecular recognition and self assembly. The contacts are S···S 3.544 Å and S···H 2.89 Å in the case of the five- and seven-ring systems respectively. In the case of **10** S···H interactions§ at 2.87 Å appear a key feature of the microsegregation of homochiral, tubular molecules in planes parallel to the *ab* lattice plane (*ca*. Fig. 3). The helical axes of all molecules within a plane are parallel and form an angle of *ca*. 40° with *c*, while the twofold intramolecular axes are all parallel to *b*. The adopted *C*2/*c* space group corresponds to that predicted to yield best packing for racemic molecules preserving their C_2 symmetry in the crystal.[17]

We can conclude that for larger oligomers of thiohelicenes homochiral lateral aggregation of helices becomes more favourable. Interactions between terminal units are still important in the recognition pattern also for the nine- and eleven-ring systems. In the supermolecular tubular structures formed in racemic systems the two enantiomers alternate along a tube (Fig. 2). The role played by sulfur in the intermolecular interactions allows rationalisation of the different behaviour as compared to carbohelicenes. Attempts at optically resolving **10** and **13** are in progress to determine their chiroptical properties and characterise the self assembling properties of large homochiral thiohelicenes.

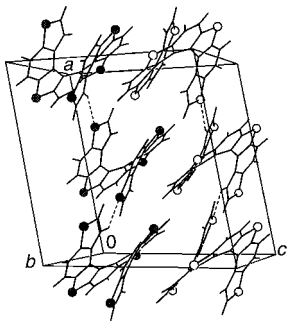

Fig. 2 Crystal packing of pentathia[9]heterohelicene evidencing both the stacking of enantiomers along the *c* axis direction and planes of isochiral molecules parallel to the *ab* plane. The molecular chirality is made apparent by the graphic codes of the sulfur atoms.

Synthesis of enantiopure isoprene epoxides from (*S*)-lactic acid *via* 'dispoke' intermediates

Daping Zhang,[a] Christine Bleasdale,[a] Bernard T. Golding*[a] and William P. Watson[b]†

[a] *Department of Chemistry, Bedson Building, University of Newcastle upon Tyne, Newcastle upon Tyne, UK NE1 7RU. E-mail: b.t.golding@ncl.ac.uk*

[b] *Shell International Chemicals BV, Shell Research and Technology Centre Amsterdam, Toxicology Department, PO Box 38000, 1030BN Amsterdam, The Netherlands*

Received (in Liverpool, UK) 14th March 2000, Accepted 9th May 2000

'Dispoke protected lactate' derived from (*S*)-lactic acid was converted into the enantiopure isoprene epoxides (*S*)-2-ethenyl-2-methyloxirane and (2*R*,2′*S*)-2-methylbioxirane.

The mechanistic toxicology of isoprene is a subject of considerable current importance.[1] In this context, samples of single enantiomers of isoprene epoxides are required for the preparation of reference standards of DNA adducts. We describe efficient syntheses of enantiomerically pure (*S*)-2-ethenyl-2-methyloxirane **1** and (2*R*,2′*S*)-2-methylbioxirane **2**, using as starting material the 'dispoke protected lactate' **3** derived from (*S*)-lactic acid.[2] An eight-step synthesis of (*S*)-2-(1-methylethenyl)oxirane (88% ee) from D-mannitol has been reported.[3] This was oxidised with MCPBA to a mixture of (2*S*,2′*R*)- and (2*R*,2′*R*)-2-methylbioxirane.

There is concern about the toxicology of isoprene because of its structural similarity to buta-1,3-diene, which is a multi-organ carcinogen in rodents.[4,5] This has raised the question of the effect of the methyl group in isoprene on its toxicity and carcinogenic potential. Studies with isoprene have shown that its carcinogenicity towards rodents is much lower than buta-1,3-diene.[6] It is therefore important to determine the significance of these findings for the cancer risk from human exposures to isoprene, which are unavoidable because isoprene is produced during normal metabolism.[7,8] Human exposures can also occur due to the presence of isoprene in tobacco smoke,[9] automobile exhaust gases,[9] emissions from plants and trees[10] and industrial sources.[11]

In vitro studies have shown that the mammalian metabolism of isoprene is similar to that of buta-1,3-diene and involves cytochrome P450 oxidation to mono- and then di-epoxides, which may be metabolites responsible for toxicity. It is important to clarify the influence of the stereochemistry of these epoxides on isoprene's toxicology, as well as determining the effect of the methyl group. We have previously shown stereochemical differences between rat, mouse and human in the formation of the mono-epoxides of isoprene by liver preparations *in vitro*.[13]

A key intermediate for the preparation of (*S*)-2-ethenyl-2-methyloxirane **1** is (*S*)-2-hydroxy-2-methylbutenoic acid **4**. Several approaches to prepare **4** in enantiopure form were tried using Evans' chiral oxazolidinone chemistry,[14] but none were successful. Furthermore, we were unable to resolve racemic 2-hydroxy-2-methylbutenoic acid, either *via* diastereoisomeric salts with optically active amines, or by lipase-catalysed hydrolysis of its esters. The failure of these approaches may be due to the similarity of the methyl and vinyl groups, which leads to diastereoisomers derived from 2-hydroxy-2-methylbutenoic acid having similar physical and chemical properties. However, (*S*)-2-hydroxy-2-methylbutenoic acid **4** could be readily prepared from the 'dispoke protected lactate' **3** (Scheme 1).‡ Ley and his coworkers[2] have shown that condensation with acetaldehyde of the carbanion derived by deprotonation of **3** with LDA gives predominately diastereoisomer **5**. We converted **5** into its triflate **6**, which underwent smooth DBU-induced elimination to **7**. Deprotection of **7** by treatment with 95% TFA gave (*S*)-2-hydroxy-2-methylbutenoic acid **4**. The synthesis of **1** was completed by reduction of **4** to (*S*)-2-methylbut-3-ene-1,2-diol **8**, tosylation of **8** to **9**, treatment of **9** with base and direct distillation of **1** from the reaction mixture in the manner described.[15] The high enantiomeric purity of **1** {$[\alpha]_D$ + 17.6 (*c* 6.2 g/100 ml in ethyl acetate at 19 °C)} was confirmed using ^{1}H NMR spectroscopy in conjunction with the chiral shift reagent europium tris[3-(heptafluoropropylhydroxymethylene)-(−)-camphorate] in deuterioacetonitrile.

(2*R*,2′*S*)-2-Methylbioxirane **2**, was also readily prepared from the 'dispoke protected lactate' **3**. Condensation of the carbanion derived by deprotonation of **3** with LDA with 2-(4-methoxybenzyloxy)acetaldehyde[16] gave predominately diastereoisomer **10**, which was converted into lactone **11** by treatment with 95% TFA. Reduction of **11** to tetraol **12** was

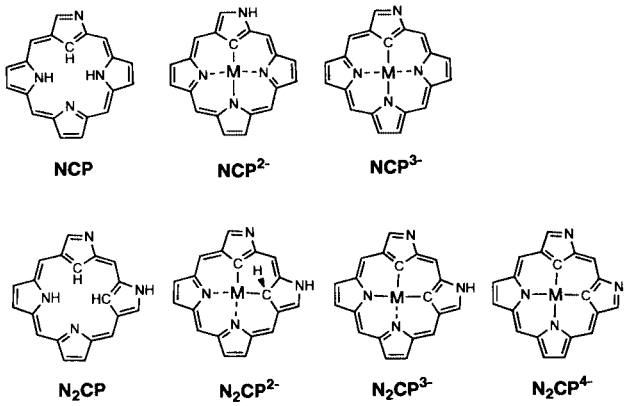
Received (in Cambridge, UK) 14th April 2000, Accepted 18th May 2000

An inner C-tolyl substituted Pd^{2+} complex of a doubly N-confused porphyrin (N_2CP) was obtained from the reaction of N_2CP and $Pd(OAc)_2$ in toluene and the structure was revealed by a single crystal X-ray analysis.

'N-Confused porphyrin' (NCP) or 'inverted porphyrin' is a porphyrin isomer wherein one of the pyrrolic rings is inverted.[1,2] Owing to the inner core carbon and outward pointing nitrogen, NCP coordination chemistry differs greatly from that of normal porphyrins.[3–5] For example, NCP can serve as both a



divalent (NCP^{2-}) and a trivalent (NCP^{3-}) ligand with d^8 metals such as Ni^{2+} and Ag^{3+}.[2,5] Recently, we have succeeded in synthesizing 'doubly N-confused porphyrin (N_2CP)' and disclosed its trivalent (N_2CP^{3-}) ligand nature in the complexation of Cu^{3+} and Ag^{3+}.[6] If the multi-valence property observed in NCP was common in all NCP families,[7] other valences, such as N_2CP^{2-} or N_2CP^{4-}, could be expected for divalent (M^{2+}) or tetravalent (M^{4+}) metal coordination. By keeping this point in mind, we have examined Pd complexation with N_2CP because square planar coordination of Pd^{2+} and/or Pd^{4+} is well known.[8] Interestingly, the synthesized complex was Pd^{2+}–N_2CP bearing a solvent molecule at an inner core carbon. In this communication, the X-ray structure and absorption spectrum of a novel Pd complex, Pd^{2+}–N_2CP–Tol (**2**), are reported.

When N_2CP, 2-ethoxy-5,10,15,20-tetrakis(pentafluorophenyl)-3,7-diaza-21,22-dicarbaporphyrin (**1**), [6] was treated with 2 equiv. of $Pd(OAc)_2$ in refluxing toluene for 5 h, a yellow-greenish product was obtained in 18% yield. A FABMS peak at *m/z* 1217.8 indicated the attachment of a tolyl group to the Pd–N_2CP complex. The ^1H NMR signals of the complex showed distinctly in the range from 11 to 1 ppm in CD_2Cl_2, which suggested that the Pd oxidation state of the complex was diamagnetic, either Pd^{2+} (d^8) or Pd^{4+} (d^6). The tolyl signals derived from the solvent were observed in the high field region (5.61–6.36 ppm), which indicated that the tolyl group was located on the porphyrin core, presumably at an inner carbon or nitrogen. The methyl groups on the tolyl substituent were found to occur at the *para* and *meta* positions in a 1 : 2 ratio. Moreover, an outer NH signal was observed at 10.37 ppm, which suggested N_2CP^{2-} type ligand formation, that is, Pd^{2+} coordination. Pd^{2+}–N_2CP–Tol (**2**) was isolated as a single product and the formation of neither Pd^{3+}–N_2CP nor Pd^{4+}–N_2CP was observed (Scheme 1). By using $CHCl_3$ or C_6H_6 as the solvent, the complexation reaction did not proceed and N_2CP (**1**) was recovered. However, in the presence of C_6H_6 and toluene (1/1 v/v), both C-phenyl and C-tolyl Pd–N_2CP complexes were formed. Furthermore, the formation of a C-arylated complex was observed in *m*-xylene but not in *p*-xylene in which the steric hindrance was significant.

The explicit structural details of the Pd^{2+}–N_2CP–Tol (**2**) complex was derived from a single crystal X-ray diffraction analysis (Fig. 1).[9] Surprisingly, a solvent tolyl group is bound to the inner carbon of a confused pyrrole ring which does not have an ethoxy group. The tolyl-substituted confused pyrrole ring is bent at 56.3° and the tolyl group stands almost vertically (88.6°) at the opposite side of a mean N_2C_2 plane consisting of core

nitrogens and carbons. The Pd–C bond distances are 1.97(1) and 2.202(9) Å, and the Pd–N distances are 2.09(1) and 2.056(8) Å.[10] Reflecting the tilting of the confused pyrrole ring and the different carbon atom types, sp^2 and sp^3, the two Pd–C bond distances differ greatly (0.23 Å). On the other hand, the Pd–N bond distances are slightly longer than in Pd^{2+}–tetraphenylporphyrin, 2.009 Å.[11] In the single crystal, the tolyl group was disordered and refinement of the structure was well performed with the assumption of a *para*:*meta* ratio of 2:3, in agreement with the ^{1}H NMR data. Similar structures, such as a perpendicular orientation of the C-substituted group and/or the strong tilting of the coordinating 5-membered ring, have been observed in N-alkylporphyrin and Pd–thiaporphyrin complexes.[4,12] The absorption spectrum of **2** displays three broad bands with peak maxima at 318.0, 410.0 and 662.0 nm indicating the distortion of the porphyrin ring (Fig. 2).

Mechanistically, it is not clear which Pd oxidation state, either Pd^{2+}, Pd^{3+} or Pd^{4+}, is formed before the tolyl group is incorporated at the inner carbon. One of the possible mechanisms is the initial formation of the unstable Pd^{3+}–N_2CP complex, like Ag^{3+} and Cu^{3+}, which is then attacked successively by a toluene molecule at either Pd or the Pd-connected carbon. As the Pd^{3+} (d^7) species is paramagnetic, a radical mechanism could be involved in the formation of **2** (Scheme 2).[13] Supporting this, the ratio of the obtained tolyl complex shows the statistical distribution, $p:m = 1:2$.[14] The H-radical derived from toluene would change to H^+ eventually, because

palladium black (Pd^0) is always associated with this reaction. It is reported that $Pd(OAc)_2$ causes the facile palladation of aromatic compounds to afford biaryls.[15,16] Although we have not detected bitolyl in this reaction, the other mechanism involving a tolyl–Pd complex before the formation of a Pd–carbon bond with the confused pyrrole can not be excluded. As this reaction implies the possibility of aromatic C–H activation, detailed study of the mechanism in addition to investigations with other group 10 metals is currently underway.[17]

Received (in Cambridge, UK) 4th April 2000, Accepted 19th May 2000

Thiol- and amino-functionalized SBA-15 silicas with uniform mesoporosities were prepared and employed for removing heavy metal ions from waste water; the thiolated SBA-15 adsorbent exhibited a higher complexation affinity for Hg^{2+}, while the other metal ions (Cu^{2+}, Zn^{2+}, Cr^{3+} and Ni^{2+}) showed exceptional binding ability with its aminated analogue.

To synthesize improved adsorbents for the removal of toxic heavy metal ions from waste water is a continuing research objective of environmental pollution control processes. Considerable efforts have been devoted to the preparation of mesoporous silica-based adsorbents due to their unique large surface area, well-defined pore size and pore shape and well-modified surface properties.[1–5] This application generally requires the materials to exhibit specific binding sites for heavy metal ions, but most mesoporous materials themselves do not have such surface properties. Accordingly, an efficient approach has been developed so that functional monolayers are chemically bonded to the surfaces of supports. The functionalized hybrid materials show great adsorption capacity and specificity for metal ions. For instance, a few metal ion adsorbents have been prepared by grafting thiol ligands onto the surface of a MCM-41 support, which are extremely efficient in removing mercury and other heavy metal ions.[1,2] The effectiveness of such adsorbents has been ascribed to the complexation chemistry of grafted ligands with metal ions. Continuing our efforts in synthesizing and improving the hydrothermal stability of mesoporous materials and in investigating their applications,[6–8] we prepared in this study two novel thiol- and amino-functionalized SBA-15 materials and investigated their complexation affinities for heavy metal ions. The more regular structure and much thicker silica walls of SBA-15 (31–64 Å) may impart significant hydrothermal stability in comparison to MCM-41. In addition, amino groups grafted on an SBA-15 support are expected to show considerably higher binding ability to relatively harder metal ions such as Cu^{2+}, Zn^{2+}, Cr^{3+} and Ni^{2+}.

Synthesis of the parent mesoporous SBA-15 was achieved by the use of a triblock copolymer surfactant in acidic media.[9] The calcined material has a surface area of 814 $m^2\ g^{-1}$ and an average pore size of 76 Å, as determined using the nitrogen adsorption technique and transmission electron microscopy (TEM). The X-ray powder diffraction pattern of this material shows a very intense peak (100) and two additional high order peaks with lower intensities, indicating a significant degree of long range ordering of the structure and well formed hexagonal pore arrays of the sample. SBA-15 functionalized with 3-mercaptopropyl groups [SBA-15(SH)] (5.6% C, S_{BET} 461 $m^2\ g^{-1}$ and V_t 0.66 $m^3\ g^{-1}$) and primary 3-aminopropyl groups [SBA-15(NH_2)] (9.5% C, S_{BET} 279 $m^2\ g^{-1}$ and V_t 0.45 $m^3\ g^{-1}$) were obtained through the treatment with chloroform solution of 3-mercaptopropyltriethoxysilane and 3-aminopropyltriethoxysilane, respectively. It was found that, upon functionalization, the surface area, total pore volume and pore size decreased significantly, revealing that the surface modification indeed occurred inside the primary mesopores of the SBA-15. However, the XRD analysis indicated that, in addition to a very intense peak (100), two higher order peaks were still observed. Therefore, the chemical bonding procedure did not diminish the structural ordering of SBA-15.

The ^{29}Si and ^{13}C NMR spectra and peak assignments for functionalized samples SBA-15(SH) and SBA-15(NH_2) are depicted in Fig. 1 and 2, respectively. In the ^{29}Si NMR spectrum of SBA-15(SH) (Fig. 1(a)), the three peaks at −113.8, −105.6 and −96.3 ppm are attributed to silicon in the siloxane binding environment without hydroxyl groups [$(SiO)_4Si$], isolated silanol groups [$(SiO)_3Si$-OH] and to geminal silanol groups [$(SiO)_2Si$-$(OH)_2$] of the silica support. In addition to these signals, two additional signals can be observed at −71.9 and −63.4 ppm, which correspond to two different environments for the siloxane groups in the functionalized monolayers:[10] (i)

	Hg	Cu	Zn	Cr	Ni
No treatment	10.1	5.21	10.1	5.21	10.2
After treatment with SBA-15	10.2	5.12	10.2	5.13	10.3
After treatment with SBA-15(SH)	0	3.18	9.91	4.72	5.10
After treatment with SBA-15(NH_2)	2.15	0.01	0	0	0

[a] 10 mL of waste solution was mixed with 100 mg of adsorbent at room temperature with agitation overnight. The remaining metal concentrations in solution were analyzed using inductively coupled plasma spectroscopy (ICP).

cross-linked groups bound to two neighboring siloxanes and (ii) isolated groups and terminal groups bound to only one neighboring siloxane. In the case of sample SBA-15(NH_2) (Fig. 1(b)), only two distinguishable peaks at −115.0 and −105.5 ppm were recorded for the silica support. An increase of the Q^4 peak intensity was also observed, along with a reduction in the signal intensity of the Q^3 site. In agreement with higher coverage of amino monolayers for SBA-15(NH_2) (9.5% C), these observations indicate that, compared with the mercaptopropyl groups in SBA-15(SH) (5.6% C), more aminopropyl groups have been grafted onto Si-OH groups of the silica support, and thus more Q^4 silica sites are subsequently formed. It should be noted that relative peak intensities in the ^{29}Si NMR spectra are not strictly quantifiable due to differences in relaxation behavior. In the ^{13}C NMR spectrum of SBA-15(SH) (Fig. 2(a)), the peak at 13.8 ppm is ascribed to the methylene carbon group C3 that is directly bonded to the silicon atom. The strong signal at 29.6 ppm is attributed to the other two methylene carbons (C2 and C1). However, for sample SBA-15(NH_2), three distinct peaks are clearly observed at 13.1, 24.9 and 45.6 ppm, which can be assigned to the carbons C3, C1 and C2, respectively. We believe that the better resolution of the peaks for the three carbons in SBA-15(NH_2) is associated with the higher ordering orientation of the carbon chains with respect to the silica surface.[1]

The functionalized materials exhibited unique selective affinity for binding heavy metal ions. Table 1 lists the ion concentrations of simulated waste water solutions before and after treatment with SBA-15(SH) and SBA-15(NH_2). It can be seen that a single treatment with SBA-15(SH) reduced the mercury concentration to below the detection limit, but it exhibited little or no affinity for other metal ions. On the other hand, the aminated SBA-15 adsorbent efficiently removed the metal ions from the waste solution with the exception of Hg^{2+}. Note that no significant concentration change for all metal ions was observed when unmodified SBA-15 was directly treated with the waste water solution under identical conditions. Thus, the concentration change is indeed attributed to the complexation reactions between metal ions with grafted ligands. It has been well recognized that softer transition metal ions are prone to forming stable complexes with ligands carrying softer donor atoms, and *vice versa*. Sulfur has been regarded as a softer donor atom compared with nitrogen, and therefore it is understandable that the thiolated adsorbent exhibited higher complexation affinity for the softer metal ion Hg^{2+}, while the other relatively harder metal ions (Cu^{2+}, Zn^{2+}, Cr^{3+} and Ni^{2+}) demonstrated considerably higher binding ability with its aminated analogue.

The hydrolytic stability was tested by treating mercury-loaded SBA-15(SH) and copper-loaded SBA-15(NH_2) in water at 70 °C for 12 h. Elemental analysis indicated that only a very small amount of metal was released during this process (0.5% Hg and 0.8% Cu were released from SBA-15(SH) and SBA-15(NH_2), respectively). To regenerate the used adsorbents, the metal-loaded functionalized SBA-15 adsorbents were washed with conc. HCl, resulting in complete removal of the loaded metal. The regenerated SBA-15(SH) and SBA-15(NH_2) materials were treated with $Hg(NO_3)_2$ and $Cu(NO_3)_2$ solutions, respectively. An Hg loading of 292 mg g(SBA-15(SH))$^{-1}$ and a Cu loading of 46 mg g(SBA-15(NH_2))$^{-1}$ were obtained, corresponding to about 60% of the original loading capacities. Similar results were obtained for a third regeneration and reuse cycle. These results indicated that both adsorbents remained effective even after extended regeneration and reuse cycles. In good agreement with the results, BET analyses of the regenerated adsorbents indicated that the surface area and pore volume for both adsorbents only slightly decreased (*ca*. 5% decrease), while the pore size essentially remained unchanged [68 Å for SBA-15(SH) and 63 Å for SBA-15(NH_2)]. IR spectra showed that the bonds corresponding to grafted ligands were still present. This result clearly demonstrates that both the mesoporous SBA-15 silica and the organic monolayers appear to essentially retain their structures even after extended use.

For the purpose of comparison, thiolated and aminated MCM-41 were also prepared and tested in this study. The effectiveness of these adsorbents is comparable to their SBA-15 analogues. However, the regeneration process resulted in a significant decrease in surface area and pore volume for both functionalized MCM-41 adsorbents: the surface area and pore volume of the regenerated MCM-41(SH) are 465 (665) $m^2\ g^{-1}$ and 0.41 (0.61) $cm^3\ g^{-1}$; for MCM-41(NH_2), 282 (460) $m^2\ g^{-1}$ and 0.26 (0.41) $cm^3\ g^{-1}$ (the corresponding original values are indicated in parentheses). This result is in good agreement with the report that SBA-15 is much more stable than MCM-41.[9] A great loss in adsorption capacity to heavy metal ions was observed accordingly: an Hg loading of 160 mg g(MCM-41(SH))$^{-1}$ and a Cu loading of 28 mg g(MCM-41(NH_2))$^{-1}$ were obtained, corresponding to about 35% of the original loading capacities.

Less attention has been focused on the synthesis and applications of SBA-15 mesoporous silica since it was discovered in 1998.[11–13] However, we believe that this unique mesoporous material can provide more possibilities for the design and synthesis of open pore structures because of its high surface area and easily controllable uniform pore size that may be extended to *ca*. 300 Å. In addition, compared with MCM-41, the more uniform pore structure and thicker silica walls of SBA-15 (31–64 Å) are shown to impart significant stability to the material under hydrothermal conditions.[9]

We are grateful to the National University of Singapore and the National Science and Technology Board of Singapore for the support of this research (Grant No. RP960608A).

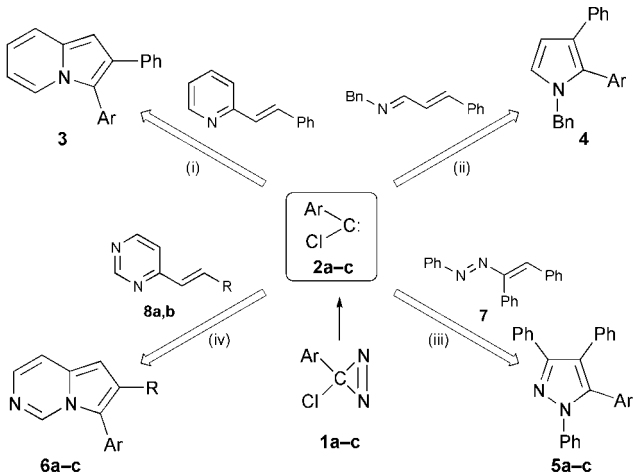
Received (in Corvallis, OR, USA) 10th April 2000, Accepted 10th May 2000

Substituted pyrazoles and pyrrolo[1,2-*c*]pyrimidines were prepared from the reaction of arylchlorocarbenes with 1,2-diazabuta-1,3-dienes and 4-vinylpyrimidines, respectively.

We recently reported the successful application of arylchlorocarbenes generated from arylchlorodiazirines to the synthesis of indolizines and pyrroles (Scheme 1, reactions (i) and (ii)).[1,2] The key step of the described approach produces a nitrogen ylide, followed by 1,5-intramolecular cyclization and HCl elimination. We now report further application of this methodology to the synthesis of a wider array of heterocycles containing two nitrogen atoms, such as pyrazoles and pyrrolo[1,2-*c*]pyrimidines (Scheme 1, reactions (iii) and (iv)). Pyrazoles have attracted the attention of many chemists because of their applications in organometallic chemistry as ligands, in synthesis, in particular of bioactive compounds, as well as their thermal reactions, spectroscopic applications and theoretical calculations.[3] Pyrrolo[1,2-*c*]pyrimidines, the aza analogues of indolizines, have attracted substantial interest because of their ability to facilitate easy ring cleavage, their variety of ring transformations and recyclizations,[4] and for their role as starting materials to N-bridged heteroaromatics.[5] However, the known synthetic routes to these compounds are lengthy and result in poor yields.[5,6] In this respect, these highly reactive carbenes have been harnessed and utilized to achieve difficult synthetic tasks which other reactive intermediates cannot easily perform.

The arylchlorocarbenes **2a–c** were generated from arylchlorodiazirines **1a–c**[7] by thermolysis. Phenylazostilbene **7** was prepared from acetoxydeoxybenzoin and phenylhydrazine.[8] Thermolysis of arylchlorodiazirines **1a–c** in the presence of phenylazostilbene **7** leads to 1,3,4,5-tetrasubstituted pyrazoles **5a-c** in good yield (74–83%). Attanasi and coworkers have developed an effective approach to pyrazoles based on a preliminary 1,4-addition of a nucleophilic reagent to the 1,2-diazabuta-1,3-diene substrates, which also gave a 70–80% product yield.[9] Vinylpyrimidines **8a,b** were prepared from 4-methylpyrimidine according to previously described procedures.[10,11] Thermolysis of arylchlorodiazirines **1a-c** in the presence of vinylpyrimidines **8a**,**b** leads to 6,7-disubstituted pyrrolo[1,2-*c*]pyrimidines **6a–c** in a 17–22% yield. The yields and physical data of obtained pyrazoles **5a–c** and pyrrolopyrimidines **6a–c** are given in ref. 12.†



1,2,5: **a** Ar = Ph, **b** Ar = *p*-MeC_6H_4, **c** Ar = *p*-ClC_6H_4

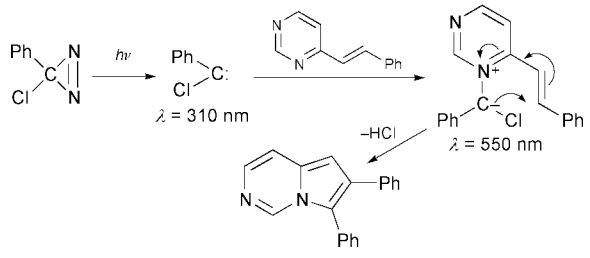
Scheme 1

In general, solutions of chlorodiazirine **1a–c** (2 mmol) and phenylazostilbene **7** or vinylpyrimidine **8a**,**b** (1 mmol) were refluxed in absolute benzene (10 mL) for 24 h. After workup, the pyrazoles **5a–c** were purified by column chromatography on silica gel with 10 : 1 hexane–diethyl ether eluent, followed by crystallization from propan-2-ol–hexane (1 : 3); pyrrolopyrimidines **6a–c** were purified by column chromatography on Al_2O_3 (basic) with 4 : 1 hexane–diethyl ether eluent.

Vinylpyrimidines **8a**,**b** are transparent at 351 nm, which is not the case for phenylazostilbene **7**. In order to learn whether the reaction of chlorodiazirines **1a–c** with vinylpyrimidines **8a**,**b** goes through an N-ylide intermediate, we undertook laser flash photolysis (LFP) studies[14] of this system to examine the kinetics of nitrogen ylide formation and the rate of 1,5-dipolar cyclization.

LFP irradiation at 351 nm of a solution of chlorophenyldiazirine **1a** in benzene (A = 1.0 at λ = 376, 392 nm) at 25 °C produces a transient absorption at 310 nm due to the formation of the chlorophenylcarbene **2a**, whose decay rate constant is 2.02×10^5 s^{-1}. In the presence of pyrimidine derivative **8b**, a new transient attributed to the pyrimidinium ylide appears at 550 nm. The plot of the observed pseudo-first-order rate constants for the growth of the absorption at 550 nm *vs.* concentration of **8b** is linear, and the rate constant for the reaction of chlorophenylcarbene **2a** and pyrimidine **8b** at 25 °C is $k_{ylide} = 3.24 \times 10^8$ $M^{-1}s.^{-1}$ The intercept of the straight line (2.78×10^5 s^{-1}) is the chlorophenylcarbene **2a** decay rate constant in the absence of **8b**, which is similar to that detected at 310 nm (2.02×10^5 s^{-1}). The pyrimidinium ylide (at 550 nm) decays in benzene with a lifetime equal to 102.2 μs at 22 °C, independent of the concentration of **8b**. Therefore, the rate constant for the 1,5-dipolar cyclization of pyrimidinium ylide is $k_{1,5\text{-cycl}} = 9.78 \times 10^3$ s^{-1}. The temperature dependence (0–55 °C) of the pyrimidinium ylide decay to form the



Scheme 2

DOI: 10.1039/b002940h

1,5-cyclization product yielded the following Arrhenius parameters: E_a = 10.0 kcal mol^{-1} and A = 2.36 × 10^{11} s^{-1}.

We have shown that chlorocarbenes can be successfully applied to the synthesis of 1,3,4,5-tetrasubstituted pyrazoles and 6,7-disubstituted pyrrolo[1,2-*c*]pyrimidines. This methodology is simple and effective. We have also demonstrated the existence of nitrogen ylides as intermediates in these reactions. The kinetics of the 1,5-dipolar cyclizations of pyrimidinium ylides to yield pyrrolo[1,2-*c*]pyrimidines are reminiscent of the cyclization of 2-vinylpyridinium ylides to indolizines[1] and azomethine ylides to pyrroles.[2]

Received (in Cambridge, UK) 12th April 2000, Accepted 8th May 2000

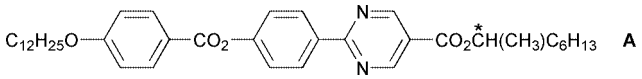
(*S*)-1-Methylheptyl 2-[4-(4-dodecyloxybenzoyloxy)phenyl]-pyrimidine-5-carboxylate and its racemic modification are synthesised; miscibility studies, investigations of defect textures, differential scanning calorimetry and electrical field studies show that this material exhibits an antiferroelectric twist grain boundary TGBC*$_A$ analogue of the Abrikosov flux phase found in superconductors.

The prediction[1,2] and discovery[3,4] of the twist grain boundary smectic A* (TGBA*) phase led to the unification of phase transition theory in liquid crystals with those of superconductors. Subsequent to these seminal contributions, TGB phases were found to be ubiquitous in the field of self-organising systems where they have been encountered at transitions from either the isotropic liquid or the chiral nematic (N*) phase to the lamellar, smectic (Sm) state.[5–7] At the normal chiral nematic to smectic transition, the helical ordering of the chiral nematic phase collapses to give the layered structure of the smectic phase. However, for strongly chiral systems, there can be competition between the need of the molecules, due to their chiral packing requirements, to form a helical macro-structure and the need for the formation of a lower energy layered structure. This frustration is relieved by the formation of a helical structure with its heli-axis parallel to the planes of the layers. The helix and lamellar structures are, however, incompatible with one another and cannot co-exist without the formation of defects. The co-existence is achieved by having small blocks/sheets of molecules, with a local smectic structure, which are rotated with respect to one another *via* sets of screw dislocations located at their interfaces, thereby giving a quasi-helical structure.[2] In this way the twist distortions are localised in defects that periodically punctuate the normal smectic state which is analogous to how lines of flux punctuate the Abrikosov vortex state in type II superconductors.

Frustrated equivalents of the smectic A* and C* phases have been found, with both having commensurable or incommensurable variants that are dependent on the rational number of smectic blocks/sheets with respect to the pitch of the phase.[8,9] For the TGBC modification a number of subphases have been discovered which are dependent on; (i) the presence (TGBC*) or expulsion (TGBC) of the local heli-axis of the smectic C* phase which is oriented perpendicular to the layers of molecules and to the heli-axis of the TGB phase; (ii) the direction of the local spontaneous polarization relative to the heli-axis (parallel or perpendicular); (iii) the inversion of the handedness of the helix in the TGBC phase as a function of temperature;[10] and (iv) the formation of a 2D modulated structure with respect to the tilt.[11]

Here we report on the liquid crystal properties of (*S*)-1-methylheptyl 2-[4-(4-dodecyloxybenzoyloxy)phenyl]pyrimidine-5-carboxylate **A**, and its racemic modification **B**. Through miscibility studies, investigations of defect textures, differential scanning calorimetry, and electrical field studies, we suggest this material exhibits the first example of a twist grain boundary (TGBC*$_A$) phase that has a local antiferroelectric structure.

The transition temperatures, and the associated enthalpies for each phase transition, for (*S*)-1-methylheptyl 2-[4-(4-dodecyloxybenzoyloxy)phenyl]pyrimidine-5-carboxylate **A**, and its racemate **B**, were determined by thermal polarized microscopy and differential scanning calorimetry, and are given together in Table 1. Firstly, we note from the Table 1 there are considerable differences in transition temperatures between the enantiomer and the racemate, however, we also emphasise that the purities of the materials were found to be better than 99.5%. Therefore the differences in temperatures are real, as are the variances in phase sequences and phase types, and both are associated with the effects of chirality on the self-organising processes. Importantly the isotropization temperature for the racemate is higher than that for the enantiomer, whereas the transition to a tilted smectic phase is lower, these results are at variance with problems associated with the effects of impurities.



Homogenous, homeotropic, uncovered droplets, and free-standing film specimens of **A** were examined by transmitted, polarized-light, thermal microscopy. The phase first formed from the isotropic liquid was iridescent and clearly helical. The phase did not exhibit either focal-conic, platelet or *schlieren* defect textures, and was not typical of either the TGBA or TGBC phase. Nevertheless, at lower temperatures the transition to and from the smectic C*$_A$ phase was characterised by the formation of filaments typical of a TGB phase.[12] A Grandjean plane texture, typical of a helical phase was obtained for **A** in a homogeneously aligned (perpendicularly oriented layers) cell with a *ca.* 5 μm spacing that had been antiparallel-buffed. The fact that the heli-axis forms normal to the glass substrates of the cell indicates that the twist is in the direction of the planes of the layers, *i.e.* typical of a TGB phase. The presence of filaments and a heli-axis in the plane of the layers confirm that the phase formed first on cooling the isotropic liquid of the enantiomer is a twist grain boundary phase, however, the lack of a characteristic texture suggested that the phase was not of the same class as those characterised so far.

Table 1 The transition temperatures (°C) and the associated enthalpies of transition [ΔH/kJ g^{-1}] for (*S*)-1-methylheptyl 2-[4-(4-dodecyloxybenzoyloxy)phenyl]pyrimidine-5-carboxylate **A** and its racemic modification **B**; * denotes the enthalpies that were too small to be evaluated.

DOI: 10.1039/b002941f

Comparing the results obtained for racemate **B** with those for enantiomer **A** yields some interesting and contrasting observations. The mesophase formed first on cooling the isotropic liquid of the racemic modification exhibits a focal-conic texture that is characterised by its elliptical and hyperbolic lines of optical discontinuity, and a homeotropic optically extinct texture. The presence of these defect textures characterises the mesophase as smectic A. Subsequent cooling leads to the homeotropic areas becoming *schlieren*, and the focal-conic domains becoming broken, both of these textures are characteristic of the formation of a smectic C phase. As the temperature is lowered there is the formation of a third phase, again characterised by the presence of a *schlieren* texture, but this time the focal-conic domains are not as broken as they were in the smectic C phase. These observations are in keeping with the third phase being an *anticlinic* smectic C_{alt} phase, where the tilt directions of the molecules alternate on passing from one layer to the next, *i.e.* the tilt direction rotates through an angle of 180° on passing from one layer to the next. Thus racemate **B** appears to exhibit a SmA, SmC, SmC_{alt} phase sequence, whereas the enantiomer **A** exhibits a TGB and SmC^*_A sequence.

Differential scanning calorimetry was used to investigate the nature of the phase transitions and to determine their associated enthalpy values, see Table 1. Fig. 1 shows the cooling scans for both the racemate and the enantiomer. For the racemate (dotted line) the smectic A phase forms first on cooling from the isotropic liquid at 96 °C. On further cooling a smectic C phase is formed at 90.5 °C, but as the transition is second order it is detected only as a baseline step in the DSC. As the temperature is lowered a weak first order transition is found for smectic C to smectic C_{alt} at 89.2 °C.

A, solid line in Fig. 1, shows strong pretransitional effects in the isotropic liquid just before the transition to the TGB phase. Transitional effects in the isotropic liquid are typical for systems that are about to form TGB phases and are associated, like those of superconductors, with entangled or disentangled flux phases, *i.e.* the amorphous liquid has some long range order associated with it.[13] The transition to the TGB phase is strongly first order, but the associated enthalpy is much lower than that obtained for the clearing point of the racemate. However, the enthalpy for the isotropic liquid to smectic A transition is approximately equal to the sum of the enthalpies associated with the pretransitional effect in the liquid and the isotropic liquid to TGB phase of the enantiomer.[3,4]

The magnitude of the spontaneous polarization for **A**, determined using the triangular wave method, was found to reach a maximum value of approximately 60 nC cm^{-2}. Examination of the current flow as a function of temperature and time showed that as the material is switched from one stable ferroelectric state to the other, two separate events occur which correspond to switching from one ferroelectric state to the antiferroelectric state and on to the other ferroelectric state. As

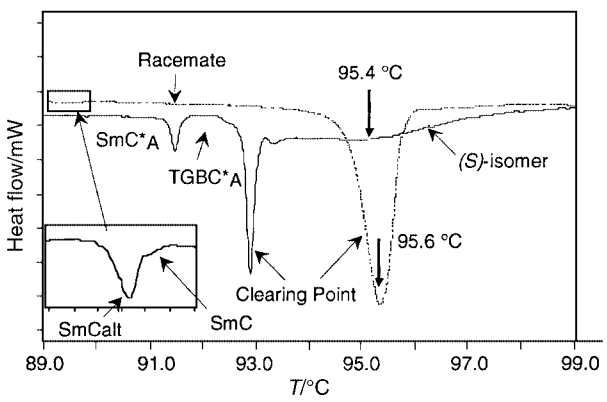

Fig. 1 Differential scanning thermograms obtained on cooling for the (*S*)-enantiomer, **A** (solid lines) and its racemic modification, **B** (dotted lines), the scan rate was 2 °C min^{-1}.

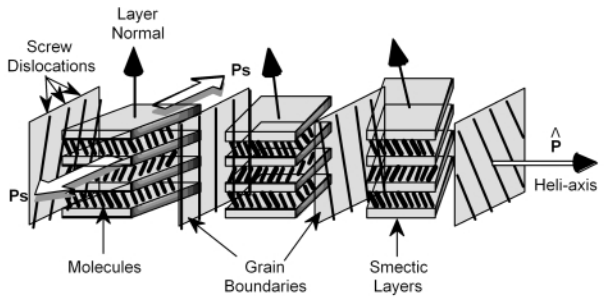

Fig. 2 A cartoon of the proposed structure of the antiferroelectric $TGBC^*_A$ phase.

the temperature is reduced, so the antiferroelectric state becomes more stable, which is probably reflected in a higher viscosity. At the transition to the TGB phase there is no appreciable change in the switching process indicating that the phase formed from the TGB phase on cooling is indeed antiferroelectric, confirming the observations made from the miscibility studies, *i.e.* that enantiomer **A** does not exhibit either a smectic A* or smectic C* phase that corresponds to the achiral phases of the racemate. It is also interesting to note the events that take place prior to and during the switching of the TGB phase. When the cell is filled from the isotropic liquid the homogeneous alignment causes the formation of a helical macrostructure, associated with the TGB phase, perpendicular to the glass substrates. As the field is applied the helix unwinds to give a bookshelf-like geometry, as the field is increased a helix, associated with an antiferroelectric phase, now forms perpendicular to the layers and parallel to the planes of the glass substrates. Increasing the field induces this phase to unwind to give a stable unwound antiferroelectric phase, which as the field is increased gives way to a stable switched ferroelectric phase. These investigations suggest that the polarization vector associated with the ferroelectric layers in the antiferroelectric phase lies perpendicular to the heli-axis as shown in Fig. 2.

In conclusion, we have demonstrated that (*S*)-1-methylheptyl 2-[4-(4′-dodecyloxybenzoyloxy)phenyl]pyrimidine-5-carboxylate exhibits a novel TGB which we believe to be antiferroelectric. This result represents the addition of a new frustrated state of matter to the family of twist grain boundary phases.

We thank the University of Hull Overseas Research Student Scheme, the Department of Chemistry, University of Hull, the EU TMR programme (Optical Research of Chiral Systems ORCHIS), and DERA for financial support.

Water-soluble platinum and palladium nanoparticles modified with thiolated β-cyclodextrin†

Julio Alvarez, Jian Liu, Esteban Román and Angel E. Kaifer*

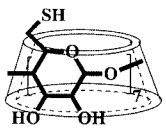
Center for Supramolecular Science and Department of Chemistry, University of Miami, Coral Gables, FL 33124-0431, USA. E-mail: akaifer@miami.edu

Received (in Columbia, MO, USA) 23rd March 2000, Accepted 17th May 2000

Pt and Pd nanoparticles can be modified with surface-attached cyclodextrin receptors leading to water-soluble materials that exhibit catalytic activity for the hydrogenation of allylamine.

The modification of metal[1] and semiconductor[2] nanoparticles with organic monolayers has become a very fruitful and active field of research in modern chemistry. An attractive aspect of recent developments in this area is that the final materials may exhibit combined properties from their inorganic nuclei and their organic surfaces. Our group is particularly interested in the modification of metal nanoparticles (metal clusters or colloids) with organic monolayers prepared with suitable, synthetic molecular hosts. We have recently reported several examples illustrating the use of cyclodextrins (CDs) for the modification of gold colloidal[3] or cluster[4] particles. In this report, we demonstrate the surface attachment of CDs to platinum and palladium nanoparticles that catalyze the hydrogenation of allylamine. As opposed to classical Pt and Pd catalytic materials, these novel nanocomposites are soluble in aqueous media and can be easily recovered by precipitation with ethanol.

Ulman and coworkers have recently reported the preparation of platinum nanoparticles protected with alkanethiol monolayers.[5] Inspired by this report, we decided to adapt our published procedure for the preparation of CD-modified gold clusters[4] to the synthesis of Pt and Pd nanoparticles derivatized with chemisorbed CD hosts. To this end, solutions of $PtCl_4^{2-}$ or $PdCl_4^{2-}$ sodium salts in DMSO–H_2O were readily reduced with BH_4^- in the presence of *per*-6-thio-β-cyclodextrin[6] (HS-β-CD, see structure below), leading to the isolation of dark precipitates.‡ These materials show FTIR spectra which are very similar to that exhibited by free HS-β-CD, indicating the



HS-β-CD

presence of the thiolated CD in the dark solids (ESI, Fig. S1†). Furthermore, close inspection of these IR spectra reveals that the weak S–H stretching peak at *ca*. 2560 cm^{-1}, which is clearly visible in the spectrum of free HS-β-CD, disappears in the spectrum of the dark precipitates collected from the reduced Pt and Pd complex solutions. This is consistent with the anticipated conversion of the H–S bonds in HS-β-CD to metal–thiolate bonds as the CD host chemisorbs on the surface of the metal nanoparticles.[3b] ^1H NMR spectroscopy also provides experimental evidence that supports the presence of HS-β-CD in the dark precipitates. However, the proton resonances from the CD receptors appear as broad peaks, a result of their relative proximity to the metal particles.[4,7] These spectroscopic features must result from the presence of HS-β-CD molecules attached to the metal nanoparticles, since any free HS-β-CD molecules were washed away before spectroscopic analysis.‡

TEM measurements recorded on the precipitates collected from the reduction of the Pt (or Pd) complex in the presence of HS-β-CD verified that these solids materials are composed of metal particles with dimensions in the nanometer range. Typical TEM images are shown in Fig. 1 and histograms showing the particle size distributions (obtained from individual measurements on at least 100 particles) are given as ESI (Fig. S2).† The average diameters were 14.1 ± 2.2 and 15.6 ± 1.3 nm for the Pt and Pd particles, respectively. Both the Pt and Pd nanoparticles exhibit limited polydispersity and their sizes fall clearly into the colloidal particle domain.

All these results clearly indicate that the derivatization of the Pt and Pd nanoparticles with surface-attached, thiolated β-CD receptors proceeds smoothly, yielding reasonably monodisperse, CD-modified Pt (or Pd) colloidal particles. Unlike modification with alkanethiols,[5] which passivates the particle surfaces and renders them catalytically inactive, we anticipated that these CD-covered Pt (and Pd) nanoparticles will exhibit catalytic activity. Therefore, in order to substantiate this hypothesis, we selected the hydrogenation of allylamine as a

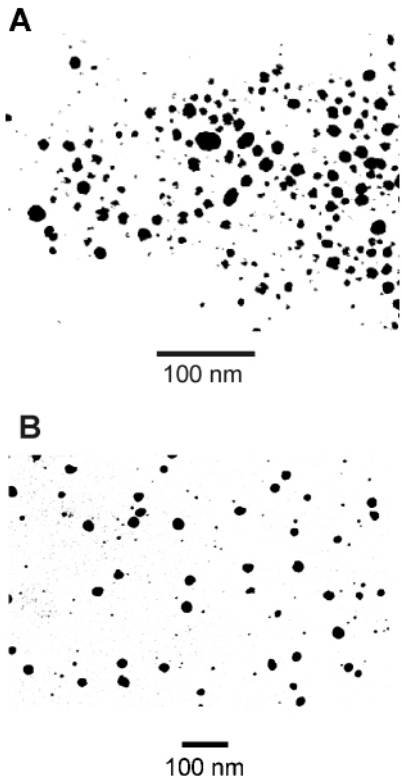


Fig. 1 TEM images of (a) CD-modified Pt nanoparticles and (b) CD-modified Pd nanoparticles.

Table 1 Percentage conversion from allylamine (1.8 mmol) to propylamine under 1.0 atm H_2(g) at room temperature in D_2O solution (2.0 mL)

Catalyst	Amount/mg	*t*/h	Conversion (%)
CD-mod. Pt	10	6	> 95
CD-mod. Pd	10	6	100
None	—	6	0
CD-mod. Pt	5	1	10
CD-mod. Pd	5	1	30

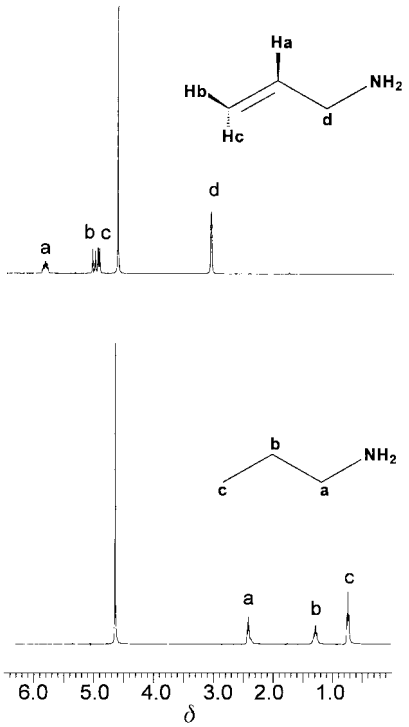

Fig. 2 ^{1}H NMR spectra of a 0.9 M solution of allylamine in D_2O containing 10 mg of CD-modified Pd colloids before (top) and after (bottom) 6 h of exposure to an H_2(g) atmosphere at 760 mm Hg.

straightforward test reaction. Our experimental results clearly verified the activity of these nanoparticles as 'homogeneous' catalysts[8] (Table 1). Under the surveyed reaction conditions,‡ both CD-modified Pt and Pd colloids catalyzed the hydrogenation of allylamine to propylamine. In a set of experiments, using 10 mg of each catalyst and 6 h reaction time, the surface modified Pt and Pd colloids achieved full conversion. In a second series of experiments, using 5 mg of each catalyst and a shorter reaction time of 1 h, the CD-modified Pd nanoparticles were more efficient than the CD-modified Pt nanoparticles. As an illustrative example, Fig. 2 shows the ^{1}H NMR spectra recorded before and after 6 h of hydrogenation catalyzed by 10 mg of the CD-modified Pd nanoparticles. We should note here that both types of CD-modified metal nanoparticles were soluble in the reaction medium and could be easily recovered at the end of the reaction by precipitation with ethanol.

In conclusion, we have demonstrated that the surface modified Pt and Pd colloidal particles reported in this work are active catalysts for the hydrogenation of allylamine in aqueous solution. These novel materials may find applications in 'green chemistry' and, perhaps, lead to 'selective' catalytic activity,[9] modulated by the molecular recognition properties of the surface-attached hosts. We are currently working towards this important goal.

We are grateful to the National Science Foundation for the support of this research work (to A. E. K., CHE-9982014). E. R. thanks the University of Miami for a graduate Maytag fellowship.

Notes and references

‡ *Preparation of modified metal colloids*: a DMSO–H_2O (1 : 4 v/v) solvent mixture was used to dissolve the metal complex. A sample of 0.125 mmol of Na_2PtCl_4 (or Na_2PdCl_4) was dissolved in 20 mL of the solvent mixture and placed in a 100 mL round bottom flask under vigorous stirring. Another 20 mL aliquot of solvent containing 12.5 mg (0.0096 mmol) of HS-β-CD and 75.5 mg (40 mmol) of $NaBH_4$ was prepared and carefully homogenized. The latter solution was added through an addition funnel to the metal complex solution, while maintaining the stirring rate. The reaction mixture was allowed to run its course overnight. After this, 10–15 mL of absolute ethanol was added to precipitate the metal particles. The dark precipitate was collected by centrifugation and washed several times, first with DMSO to remove free HS-β-CD and then with ethanol to remove the DMSO. Complete removal of the thiolated cyclodextrin was verified by thin layer chromatography (TLC). Once this was achieved, the sample was dried under vacuum at 60 °C during 24 h. The resulting dried powder was submitted for characterization by spectroscopic analysis or transmission electron microscopy (TEM) and used in the catalytic experiments.

Catalytic experiments: the CD-modified Pd and Pt colloids prepared in this work were tested for catalytic activity under identical reaction conditions. A solution of a measured amount of the catalyst in 2 mL of D_2O was stirred in a 5 mL peak-shaped flask and saturated with hydrogen gas for 10 min. Allylamine (136 μL, 1.8 mmol) was added with a microsyringe and a ^{1}H NMR spectrum was recorded just prior to the hydrogenation reaction. The flask was then sealed with a rubber septum under a hydrogen atmosphere (760 mm Hg) and left for the selected reaction time. At the end of this time, another ^{1}H NMR spectrum was recorded to monitor the extent of conversion from allylamine to propylamine.

Hydroxamic acids are nitric oxide donors. Facile formation of ruthenium(II)-nitrosyls and NO-mediated activation of guanylate cyclase by hydroxamic acids

Celine J. Marmion,[a] Terry Murphy,[a] James R. Docherty[b] and Kevin B. Nolan*[a]

Received (in Cambridge, UK) 29th February 2000, Accepted 18th May 2000

Hydroxamic acids are shown for the first time to be effective NO donors by their ability to readily form ruthenium(II)-nitrosyls, and to cause vascular relaxation of rat aorta by NO-mediated activation of the iron-containing guanylate cyclase.

Hydroxamic acids, a group of weak organic acids of general formula RC(O)N(R′)OH, fulfil a variety of roles in biology and medicine, for example, as siderophores for iron(III),[1] as potent and selective inhibitors of enzymes such as peroxidases,[2] ureases,[3] and matrix metalloproteinases,[4] and as hypotensive,[5] anti-cancer, anti-tuberculous and antifungal agents.[6] While some of these roles are undoubtedly due to the chelating ability of the hydroxamate group, others, such as the hypotensive effects (a known nitric oxide property), may be due to their ability to release nitric oxide, a view strengthened by the now established importance of NO in many physiological processes.[7] We report herein the first evidence that hydroxamic acids can indeed act as NO donors, as shown by the fact that they readily transfer NO to ruthenium(III) and cause vascular relaxation in rat aorta by activation of the iron-containing guanylate cyclase enzyme.

Reaction of K[Ru(Hedta)Cl]·2H_2O (200 mg, 0.40 mmol), with benzohydroxamic acid (177 mg, 1.29 mmol) in aqueous solution (30 cm^3) at room temperature resulted in an immediate colour change from straw-yellow to red. A brown product was obtained (*ca.* 55% yield without attempted optimisation) following purification on a Sephadex LH 20 column and removal of solvent. The unambiguous formation of a ruthenium nitrosyl complex was confirmed by microanalysis,† IR, mass and ^{1}H NMR spectra, which were consistent with the formulation K_2[Ru(edta)(NO)Cl], containing a linear, diamagnetic Ru^{2+}–NO^+ group[8] (IR: distinctive ν_{NO} at 1880 cm^{-1}, broad, strong ν_{CO} at 1660 cm^{-1}, no absorption at 1730 cm^{-1}, confirming fully depronated edta[9] and ν_{Ru-Cl} at 300 cm^{-1}; ESI-MS: mass peaks at 420 and 390 amu, corresponding to $[Ru(edta)(NO)]^-$ and $[Ru(edta)]^-$, respectively, with correct isotopic abundances; ^{1}H NMR: δ 3.6 due to ethylenic protons, 3.8, 4.1, 4.3 and 4.4 due to CH_2COO^- protons, in D_2O solution). This complex is similar to the previously reported six-coordinate Ru(H_2edta)(NO)Cl·2H_2O,[9] but contains fully deprotonated tetradentate edta with two pendant carboxylate groups. A related complex, $[Ru(edta)NO]^-$, is formed in solution by reaction of NO with K[Ru(Hedta)Cl].[10] Similar reactions of K[Ru(Hedta)Cl]·2H_2O with acetohydroxamic acid and salicylhydroxamic acid also gave the same product in high yields. The products of the denitrosylation reactions were shown to be the corresponding carboxylic acids by TLC, UV and ^{1}H NMR analysis.‡§ Reaction of $RuCl_3$·xH_2O with aceto-, benzo-, salicyl- and anthranilic hydroxamic acids in ethanol followed by purification on Sephadex LH 20 columns also gave ruthenium(II) nitrosyl complexes, all of which have very distinctive ν_{NO} bands at *ca.* 1885 cm^{-1}.¶

The ability of hydroxamic acids to release nitric oxide in simple biological systems was shown by vascular relaxation of endothelium-denuded rings of rat aorta.[11] These were set up in organ baths for isometric tension recording. Rings were contracted with the α_1-adrenoreceptor agonist phenylephrine (1 μM), and the ability of increasing concentrations of hydroxamic acid derivatives to produce relaxation was examined; the results are shown in Fig. 1. Of the hydroxamic acids investigated, benzohydroxamic acid proved most effective, causing approximately 45% relaxation of rat aorta at a concentration of 300 μM. Although this value is higher than that quoted for the well known NO donor 3-morpholinosydnonimine, SIN-1 (1 μM), it compares favourably with that of another NO donor 4-(3-butoxy-4-methoxybenzo)-2-imidazolidilone, Ro-20-1724 (100 μM).[12] Relaxation occurred by activation of the enzyme guanylate cyclase (a definitive receptor for NO),[13] as shown by the fact that methylene blue (10 μM), a known inhibitor of this enzyme,[14] prevented the relaxation (*e.g.* relaxation to 300 μM acetohydroxamic acid: vehicle (distilled water) treated, 31.4±10.9% relaxation; methylene blue treated, 6.4±3.1% relaxation, $n = 4$, $P < 0.05$).

In this work, we have shown conclusively that hydroxamic acids can act as effective NO donors by demonstrating that they can readily transfer NO to ruthenium(III), the first reported metal nitrosyl complexes formed from hydroxamic acids. Furthermore, hydroxamic acids can cause vascular relaxation in rat aorta by NO-mediated activation of the iron-containing enzyme guanylate cyclase, thus confirming the biological relevance of our novel results.

We thank Mr Brendan Harhen, Department of Clinical Pharmacology, RCSI, for mass spectra, The Microanalytical Laboratory, University College Dublin for the microanalysis, Dublin Institute of Technology for ^{1}H NMR and far IR spectra, and the Irish Government for financial support under its 'Programme for Research In Third Level Institutions' and EU COST D8.

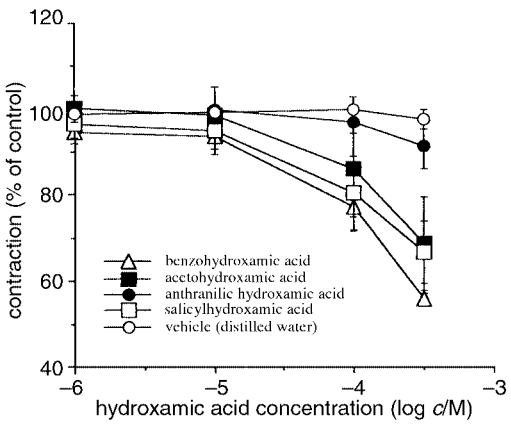

Fig. 1 The effects of hydroxamic acids on relaxation of rat aorta.

Notes and references

† Microanalysis: found: C, 21.03; H, 2.78; N, 7.51; Cl, 9.11. K_2[Ru(edta)-(NO)Cl]·0.5HCl·H_2O ($C_{10}H_{14.5}N_3O_{10}Cl_{1.5}K_2Ru$) requires C, 21.10; H, 2.57; N, 7.39; Cl, 9.34%.

‡ An aqueous mixture of benzohydroxamic acid and an excess of [Ru(Hedta)Cl]$^-$, after completion of the reaction, was analysed by TLC [silica plates and a toluene–ether–acetic acid–methanol (120:60:18:1) or ethanol–water–ammonia (8:1:1) solvent mixture] which confirmed the presence of benzoic acid and the absence of benzohydroxamic acid. The UV spectrum in H_2O has a band at 224 nm due to benzoic acid which is not present in the spectrum of the nitrosyl complex. The ^{1}H NMR spectrum of a D_2O solution containing [Ru(Hedta)Cl]$^-$ and a twofold excess of benzohydroxamic acid, to ensure complete removal of the paramagnetic ruthenium(III) complex, showed a signal at δ 8.01 which is characteristic of benzoic acid, but not of benzohydroxamic acid. The acid-catalysed hydrolysis of hydroxamic acids to carboxylic acids (half-life *ca*. 1 h at 88 °C) has previously been reported.[15]

§ A possible mechanism for the denitrosylation of the hydroxamic acid (RC(O)NHOH) involves aquation of [Ru(Hedta)Cl]$^-$, followed by nucleophilic attack by the hydroxo conjugate base ligand on the hydroxamic acid carbonyl group, giving an intermediate from which hydroxylamine is eliminated. Abstraction of NO from this causes displacement of the carboxylate ligand ($RCOO^-$) and this, together with displacement of coordinated edta carboxylate by chloride in the work up procedure, gives [Ru(edta)(NO)Cl]$^{2-}$.

¶ IR(Nujol mull): strong ν_{NO} at 1885 cm^{-1} (acetohydroxamate complex), 1885 cm^{-1} (benzohydroxamate), 1883 cm^{-1} (salicylhydroxamate) and 1885 cm^{-1} (anthranilic hydroxamate).

3-Bromobarekoxide, an unusual diterpene from *Laurencia luzonensis*

Masayuki Kuniyoshi,[a] Mong S. Marma,[a] Tatsuo Higa,[a] Gérald Bernardinelli[b] and Charles W. Jefford[b]*

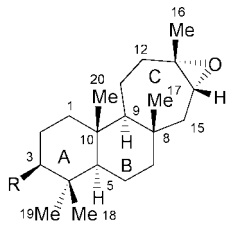
[a] *Department of Chemistry, Biology and Marine Science, University of the Ryukyus, Nishihara, Okinawa 903-0213, Japan*

[b] *Laboratory of Crystallography and Department of Organic Chemistry, University of Geneva, 1211 Geneva 4, Switzerland. E-mail: jefford@sc2a.unige.ch*

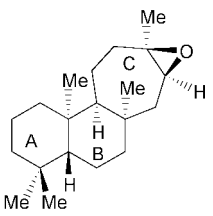
Received (in Liverpool, UK) 28th March 2000, Accepted 18th May 2000

A new, rare diterpene characterized by a cycloheptane ring *trans*-fused to a *trans*-decalin moiety was isolated from *Laurencia luzonensis* and its absolute structure determined by X-ray crystallography.

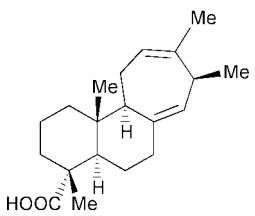
The red alga of the genus *Laurencia* and the sea hares that feed upon it have been a bountiful source of metabolites. So far more than 300 have been characterized, most of which are sesquiterpenes and C_{15} acetogenins. However a few di- and triterpenes have also been described.[1] We now report on a rare diterpene consisting of a seven-membered ring fused to decalin (**1**) which



1 R = Br
3 R = H



2



4

was obtained from the hitherto unexamined species *Laurencia luzonensis*.

A sample (3.5 kg), collected off the coast of Kudaka Island, Okinawa, in May 1998, was extracted by steeping with 95% ethanol. Concentration of the extracts and partitioning between water and ethyl acetate gave an oil (12.5 g). Successive chromatography over silica gel with solvent mixtures ranging from hexane, dichloromethane, and ethyl acetate afforded a fraction which was purified by HPLC (LiChrosorb Si60, hexane/AcOEt, 10:1). Subsequent recrystallization from CCl_4 furnished **1** (58.5 mg) as colorless crystals, mp 165 °C, $[\alpha]_D^{24}$ = 6.18 (*c* 0.3, $CHCl_3$).

The molecular formula $C_{20}H_{33}OBr$ was deduced from the ^{13}C NMR spectrum and LR EIMS. The monobrominated nature of the compound was immediately evident from the molecular ion peak which appeared as a doublet of equal intensity (*m/z* 368, 370). The absence of olefinic and carbonyl signals in the NMR spectrum suggested a tetracyclic entity. The carbon signals at δ 60.52 (s) and 60.45 (d) together with the proton signal at δ 2.70 (dd, *J* = 7.5, 7.5 Hz) indicated an epoxide (Table 1). Therefore the remaining three rings are carbocyclic. Analysis of the 1D and 2D NMR spectra (COSY, HMQC, HMBC, NOESY) led to a diterpene structure composed of *trans*-decalin and an epoxide fused to a common seven-membered ring. Comparison of the NMR data of **1** (Table 1) with those reported for barekoxide (**2**), a related terpene isolated from the sponge *Chelonaplysilla erecta*,[2] revealed good agreement apart from the obvious differences between the A rings. Therefore, we initially assumed that **1** was simply the 3β-bromo derivative of **2** in which the A/B and B/C junctions are *trans* and *cis*-fused respectively. However, as the absolute configuration of **2** was unknown, determining that of **1** would provide an convenient proof of structure for both molecules. Accordingly, a single crystal of **1** was submitted to X-ray analysis.† It is immediately seen that the decalin moiety is certainly *trans*, but that the B/C ring junction is *trans* as well (Fig. 1). Despite the *syn*-axially disposed methyl groups, the cyclohexane and cycloheptane rings adopt chair conformations. Evidently, the structure previously assigned to **2** is doubtful. Clarification was secured by treating **1** with tributyltin hydride and AIBN in DMSO.‡ Reductive debromination gave the parent hydrocarbon **3** as colorless crystals, mp 140 °C, $[\alpha]_D^{24}$ = 5.2 (*c* 0.256, $CHCl_3$). The ^1H and ^{13}C NMR spectra of **3** were essentially the same as those recorded for barekoxide (**2**).§ We therefore conclude that structure **2** is incorrect and should be revised to that of **3**. Furthermore, the sign of the specific rotation indicates that barekoxide of sponge origin¶ must have the same absolute configuration as the alga-derived product **3**.

5 X = Br or H

Scheme 1

The present findings correctly establish the absolute structure and confirm the novelty of the diterpene framework of the barekoxides. The tricyclic entity of *trans*-decalin fused to cycloheptane is extremely rare in nature and is only encountered in strobal[3] and strobic acid (**4**).[4] Significantly, the configuration of the C(5), C(9) and C(10) atoms in **1** and **3** is the same as in **4**. Clearly, all three metabolites arise by a similar stereoselective biogenetic pathway. Bromination or protonation of geranyllinalool (**5**) creates a steroid-like tetracyclic array affording **1** or **3**, whereas proton-initiated cyclization followed by oxidation of the C(19) methyl group, 1,3 methyl shift, and elimination accounts for **4** (Scheme 1).

Triphenylphosphine-mediated olefination of aldehydes with (*Z*)-(2-acetoxyalk-1-enyl)phenyl-λ³-iodanes: generation and reaction of (2-oxoalkyl)phenyl-λ³-iodanes

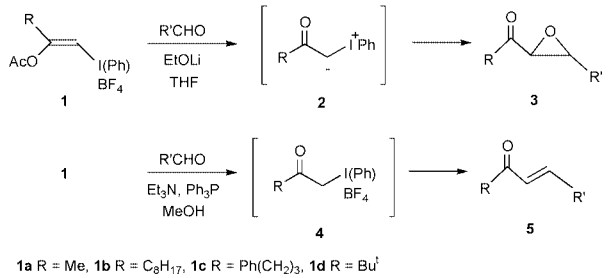
Received (in Cambridge, UK) 17th April 2000, Accepted 22nd May 2000

(*Z*)-(2-Acetoxyalk-1-enyl)phenyl-λ³-iodanes, on treatment with triethylamine in methanol in the presence of triphenylphosphine, undergo Wittig olefination with aldehydes, which involves the intermediacy of α-iodanyl ketones generated by *in situ* protonation of monocarbonyl iodonium ylides.

Recently, we reported that the ester exchange reaction of (*Z*)-(2-acetoxyalk-1-enyl)phenyl-λ³-iodanes **1** with EtOLi quantitatively generates the unstabilized monocarbonyl iodonium ylides **2** in THF at −78 °C with the liberation of ethyl acetate (Scheme 1).[1] In a marked contrast to the stable iodonium ylides derived from β-dicarbonyl compounds,[2] the monocarbonyl iodonium ylides **2** are moderately nucleophilic and undergo nucleophilic attack towards carbonyl compounds and activated imines. In general, ylides react with carbonyl compounds in either of two possible reaction modes, Wittig type reaction yielding alkenes and Corey type reaction leading to the formation of epoxides, depending on the nature of ylides and carbonyl compounds.[3] Because of the very high reductive nucleofugality of the λ³-phenyliodanyl groups,[4] monocarbonyl iodonium ylides **2** exclusively undergo alkylidene transfer reactions (Corey type) with aldehydes yielding epoxides:[1a] thus, the reaction of **1** with aldehydes in the presence of EtOLi gives α,β-epoxy ketones **3** in good yields with *trans*-isomers as the major product. No formation of the Wittig type olefination products **5** was observed in this reaction. The reaction course, however, was dramatically altered to the Wittig olefination pathway, when both the base and the solvent were changed to triethylamine and methanol, and the reaction was carried out in the presence of triphenylphosphine. We report herein triphenylphosphine-mediated Wittig olefination of aldehydes with (*Z*)-(2-acetoxyalk-1-enyl)phenyl-λ³-iodanes **1**, which involves an efficient generation of (2-oxoalkyl)phenyl-λ³-iodanes **4** under mild conditions.



1a R = Me, **1b** R = C_8H_{17}, **1c** R = $Ph(CH_2)_3$, **1d** R = Bu^t

Scheme 1

To a stirred solution of (*Z*)-2-acetoxydec-1-enyl(phenyl)-λ³-iodane **1b** and triphenylphosphine (2 equiv.) in MeOH was added triethylamine (1.3 equiv.) at room temperature under nitrogen and the mixture was stirred for 30 min. A solution of benzaldehyde (1.5 equiv.) in MeOH was added and the mixture was heated at 60 °C for 24 h. After usual workup, preparative TLC [hexane–ethyl acetate (10 : 1)] afforded a 98 : 2 mixture of (*E*)- and (*Z*)-1-phenylundec-1-en-3-one **5c** in 73% yield. No evidence for formation of the epoxide **3** (R = C_8H_{17}, R′ = Ph) was observed in this reaction. The results of the Wittig type reaction of aldehydes with the vinyl(phenyl)-λ³-iodanes **1** are summarized in Table 1. The vinyl-λ³-iodanes **1a**–**c** readily undergo Wittig olefinations with aromatic aldehydes containing electron-withdrawing or -donating substituents as well as with aliphatic aldehydes to give α,β-unsaturated ketones **5** with high *trans* selectivity. With α,β-unsaturated aldehydes, selective reaction at the carbonyl group was observed with no evidence for Michael addition yielding cyclopropanes (entries 9 and 16). With the use of the sterically demanding λ³-iodane, β-*tert*-butylvinyliodane **1d**, the Wittig olefination becomes sluggish (entry 17).

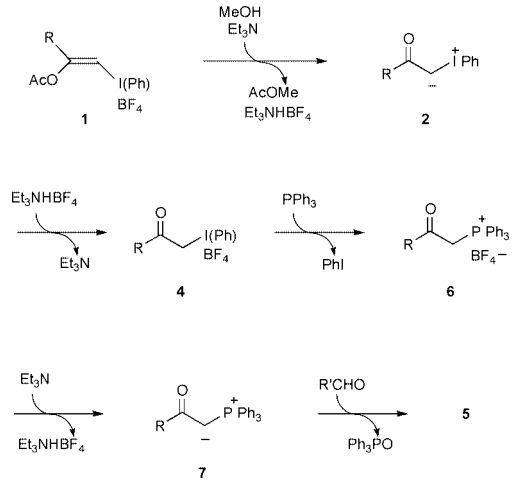
[a] Reactions were carried out at 60 °C under N_2. [b] Isolated yields. [c] *Trans* : *cis* ratio. [d] Reactions were carried out at 25 °C under N_2.

As illustrated in Scheme 2, a mechanism for the Wittig olefination of aldehydes upon reaction with (*Z*)-(2-acetoxyalk-1-enyl)-λ³-iodanes **1** in the presence of triethylamine and triphenylphosphine in MeOH might be assumed to involve the following key steps: (i) ester exchange of β-acetoxyvinyl-λ³-iodanes **1** with MeOH under basic conditions generating the monocarbonyl iodonium ylides **2** with the liberation of methyl acetate, (ii) formation of (2-oxoalkyl)-λ³-iodanes **4** *via* protonation of the ylides **2** with the resulting Et_3NHBF_4, (iii) bimolecular nucleophilic substitution of **4** with triphenylphosphine yielding (2-oxoalkyl)phosphonium salts **6**, and (iv) Wittig olefination of aldehydes with β-acylphosphonium ylides **7** produced from **6** by reaction with regenerated triethylamine. This mechanism involves the *in situ* generation and conversion of the monocarbonyl iodonium ylides **2** which undergo Corey type reaction to the monocarbonyl phosphonium ylides **7** which

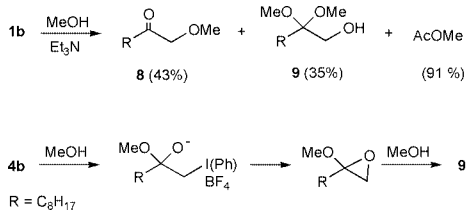
DOI: 10.1039/b003090m



Scheme 2

undergo Wittig olefination. Alternatively, the (2-oxoalkyl)iodanes **4** might be directly produced *via* triethylamine-mediated ester exchange of vinyliodanes **1** with MeOH.

Several experimental observations are in line with this proposed mechanism. Reaction of **1b** with triethylamine (1.1 equiv.) in MeOH (25 °C, 1 h) afforded a mixture of α-methoxy ketone **8** (43%), hydroxy dimethylacetal **9** (35%) and methyl acetate (91%) (Scheme 3). Without triethylamine, **1b** was recovered unchanged in MeOH. High yield formation of methyl acetate clearly indicates the intervention of the ester exchange between β-acetoxyvinyliodane **1b** and MeOH under basic conditions. Bimolecular nucleophilic substitution of (2-oxoalkyl)iodane **4b** with MeOH will produce the α-methoxy ketone **8**. Furthermore, formation of the hydroxy dimethylacetal **9** under basic conditions strongly suggests the intermediacy of the (2-oxoalkyl)iodane **4b** in this reaction (Scheme 3), as reported by Moriarty *et al.*[5] It has been reported that the presence of the λ^3-phenyliodanyl group raises the CH acidity of malonic esters



Scheme 3

by eight orders of magnitude.[6] Based on these data, the acidity (pK_a) of α-methylene protons of (2-oxoalkyl)iodanes **4** is estimated to be *ca.* 12. Therefore, it seems reasonable to assume that Et_3NHBF_4 with similar acidity (pK_a = 11.0),[7] undergoes proton transfer to the monocarbonyl iodonium ylides **2** yielding the (2-oxoalkyl)iodanes **4**.

It is possible to isolate the intermediate (2-oxoalkyl)phosphonium salts **6**: treatment of **1b** with triethylamine and triphenylphosphine in MeOH at room temperature, after acidification of the reaction mixture with 5% aqueous HBF_4 solution, afforded the phosphonium tetrafluoroborate **6b** in 89% yield. Without acid treatment, the monocarbonyl phosphonium ylide **7b** was obtained, thereby illustrating the occurrence of transylidation between iodonium and phosphonoim ylides under such conditions. The formation of phosphonium ylides **7** is compatible with the reported acidity of acetonyl(triphenyl)-phosphonium salt **6a** (R = Me, pK_a = 6.6), *i.e.* more acidic than Et_3NHBF_4.[8]

In conclusion, we have developed an efficient one-pot procedure for Wittig olefination of aldehydes with (*Z*)-(2-acetoxyalk-1-enyl)phenyl-λ^3-iodanes **1**. In addition to the reported Corey type alkylidene-transfer reaction of the monocarbonyl iodonium ylides to aldehydes, this new strategy developed here makes vinyl-λ^3-iodanes **1** valuable progenitors in monocarbonyl onium ylide chemistry.

Synthesis of highly ordered mesoporous silica materials using sodium silicate and amphiphilic block copolymers

Ji Man Kim and Galen D. Stucky*

Department of Chemistry, University of California at Santa Barbara, Santa Barbara, CA 93106, USA. E-mail: stucky@chem.ucsb.edu

Received (in Columbia, MO, USA) 22nd March 2000, Accepted 17th May 2000

A commercially important synthetic approach to highly ordered mesoporous silica materials (SBA-family) with 2-D hexagonal (*P6mm*), 3-D hexagonal (*P6*$_3$*/mmc*) and cubic (*Im3m* and *Pm3m*) structures, using sodium silicate as the silica source and amphiphilic block copolymers as the structure-directing agents is demonstrated.

It is well known that mesoporous silica materials are synthesised by synergistic self-assembly between surfactant and silica species to form mesoscopically ordered composites.[1,2] Generally, two types of surfactants are used for the formation of mesoporous silica materials: ionic surfactants such as alkyltrimethylammonium bromide[1,3] and nonionic surfactants such as alkylamine[4] and poly(ethylene oxide)-type copolymers.[5–7] The ionic surfactants interact electrostatically with inorganic species, whereas the nonionic surfactants result in the formation of mesocomposites through hydrogen bond or van der Waals interaction. The nonionic surfactants give commercially important advantages compared with the ionic surfactants. They are easily removable, nontoxic, biodegradable and relatively inexpensive. Pinnavaia and coworkers[6] have reported the synthesis of MSU-*X* mesoporous materials with several nonionic surfactants. These materials are composed of worm-like channels, which are disorderedly arrayed. Stucky and coworkers[7] have reported the synthesis of SBA mesoporous silica materials, which have well-ordered channel and cage structures, using amphiphilic di- and triblock copolymers as the structure directing agents at or below the isoelectric point (pH $\leqslant$ 3). However, these synthetic procedures using nonionic surfactants are not as commercially viable as they might be due to the use of tetraethyl orthosilicate (TEOS) as a silica source. Recently, Guth and coworkers[8] have pointed this out and reported the synthesis of mesoporous silica material using nonionic surfactant and sodium silicate in the pH range 3–10.5. However, the mesoporous materials thus obtained exhibit irregular or disordered channel connectivity and broad pore size distributions.

Here, we report the synthesis of highly ordered mesoporous silica materials that include 2-dimensional (2-D) hexagonal SBA-15 (*P6mm*), 3-dimensional (3-D) hexagonal SBA-12 (*P6*$_3$*/mmc*) and cubic SBA-16 and SBA-11 (*Im3m* and *Pm3m*) using sodium metasilicate as the silica source and nonionic amphiphilic block copolymers as the structure-directing agents.

Triblock copolymers such as Pluronic P123 ($EO_{20}PO_{70}EO_{20}$, M_{av} = 5800) and Pluronic P85 ($EO_{26}PO_{39}EO_{26}$, M_{av} = 4600) and diblock copolymer, $C_nH_{2n+1}(OCH_2CH_2)_xOH$ (C_nEO_x, n = 12–18, x = 9–23), were used as received from BASF, Aldrich and Sigma. Sodium metasilicate ($Na_2SiO_3{\cdot}9H_2O$) and concentrated hydrochloric acid (c-HCl, 37.6%) were obtained from Fisher Scientific. In a typical synthesis batch, 3.0 g of $C_{18}EO_{10}$ was dissolved in 57.4 g of distilled water and then 8.8 g of sodium metasilicate was added at room temperature with magnetic stirring, giving a clear solution. To this reaction mixture, 17.7 g of c-HCl was quickly added with vigorous magnetic stirring. The resulting gel mixture was stirred for 1 day at room temperature and subsequently heated for 1 day at 373 K in an oven to increase the degree of silanol group condensation. In the case of Pluronic triblock polymers, the reaction temperature was 313 K before heating to 373 K. The solid product was filtered off and dried at 373 K. The product was then slurried in ethanol–HCl mixture, filtered off, washed with ethanol, dried in an oven, and calcined in air under static conditions at 823 K. The product yield in a typical synthesis batch was above 90% on the basis of the silica recovery.

Fig. 1a–c show powder X-ray diffraction (XRD) patterns for SBA-15 materials, obtained from $C_{12}EO_9$, $EO_{26}PO_{39}EO_{26}$ and $EO_{20}PO_{70}EO_{20}$, after calcination. All exhibit XRD patterns with a very intense diffraction peak and two or more weak peaks, which are characteristic of a 2-D hexagonal (*P6mm*) structure.[1,5,7] The SBA-15 obtained from $EO_{20}PO_{70}EO_{20}$ shows (210) and (300) peaks, which indicates excellent textural uniformity of the material. There were no significant changes upon calcination, except for the expected increase in XRD peak intensity and lattice contraction (7–12%). Fig. 2a is a transmission electron microscopic (TEM) image for SBA-15 (Fig. 1c). The TEM image also indicates that the material has a highly ordered 2-D hexagonal structure, similar to that of SBA-15 obtained from TEOS.[7] Other 2-D hexagonal silica materials in Fig. 1a and b give similar TEM images except for their different channel sizes. The N_2 adsorption–desorption isotherms and pore size distribution curves for the present SBA-15 materials are essentially the same as those of SBA-3 and SBA-15.[3,7] Lattice parameters and pore sizes are listed in Table 1.

Fig. 1d and e show XRD patterns for the mesoporous silica materials obtained from $C_{12}EO_{23}$ and $C_{16}EO_{20}$, respectively. The XRD patterns can be indexed as cubic *Im3m* for Fig. 1d and cubic *Pm3m* for Fig. 1e.[7] It is interesting and important that cubic *Im3m* mesoporous silica (SBA-16) can be obtained using

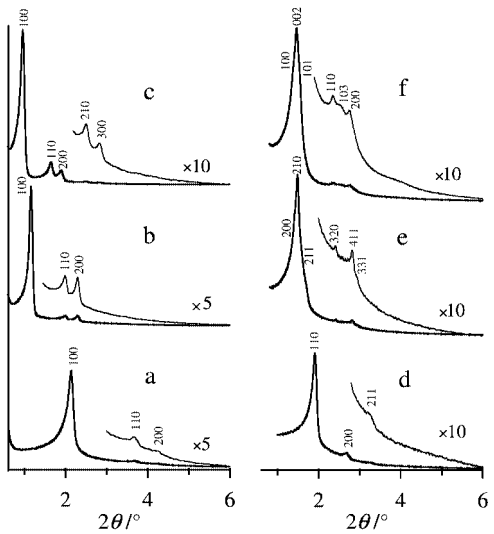

Fig. 1 XRD patterns for the mesoporous silicas obtained from (a) $C_{12}EO_9$, (b) $EO_{26}PO_{39}EO_{26}$, (c) $EO_{20}PO_{70}EO_{20}$, (d) $C_{12}EO_{23}$, (e) $C_{16}EO_{20}$ and (f) $C_{18}EO_{10}$. XRD patterns were collected with a Cu-Kα X-ray source using a Sintag X_2 instrument.

DOI: 10.1039/b002362k

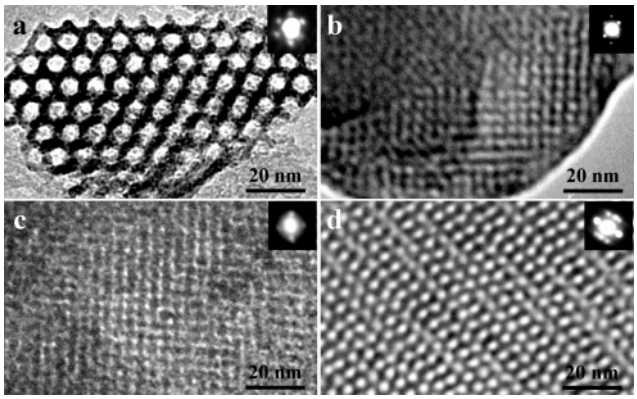

Fig. 2 TEM images and ED patterns for the calcined mesoporous silicas obtained from (a) $EO_{20}PO_{70}EO_{20}$, (b) $C_{12}EO_{23}$, (c) $C_{16}EO_{20}$ and (d) $C_{18}EO_{10}$. The TEM image was taken with a 2000 FX JEOL instrument operating at 200 kV.

Table 1 Lattice parameter, pore diameter and BET surface area of mesoporous silicas

Polymer	Mesophase	Cell parameter/nm[a]	Pore size nm[b]	Surface area/m^2 g^{-1}
$C_{12}EO_9$	2-D hexagonal	4.79	3.8	1055
$C_{12}EO_{23}$	cubic *Im*3*m*	6.70	3.5, 4.3[c]	701
$C_{16}EO_{20}$	cubic *Pm*3*m*	13.25	4.2, 5.0[c]	637
$C_{18}EO_{10}$	3-D hexagonal	7.43, 12.02[d]	4.5, 5.4[c]	572
$EO_{26}PO_{39}EO_{26}$	2-D hexagonal	8.83	5.6	849
$EO_{20}PO_{70}EO_{20}$	2-D hexagonal	10.68	7.6	600

[a] Lattice parameters calculated from *d* spacings in XRD patterns. [b] Pore size distribution obtained from N_2 adsorption–desorption isotherms following the BdB analysis with cylindrical and spherical models.[9,10] [c] Numbers denote pore opening size and largest diameter in spherical cage structure, respectively. [d] Numbers represent lattice parameters *a* and *c*, respectively.

the $C_{12}EO_{23}$ diblock copolymer as well as with the triblock copolymer $EO_{106}PO_{70}EO_{106}$ (Pluronic F127).[7] TEM images for the cubic materials are shown in Fig. 2b and c. The images show well-ordered structures viewed along the [001] direction, suggesting that both mesoporous silica materials have highly ordered cubic structures.

Fig. 1f and Fig. 2d are the XRD pattern and TEM image, respectively, for the mesoporous silica obtained from $C_{18}EO_{10}$. The XRD pattern can be indexed as a 3-D hexagonal ($P6_3/mmc$) structure with cell parameters a = 7.43, 12.03 nm. The cell parameter ratio (c/a) is 1.62, which is very similar to ideal ratio (1.633) for a typical hexagonal close-packed (hcp) phase and those of SBA-12[7] and SBA-2.[3] Fig. 3 shows N_2 adsorption–desorption isotherms and pore size distribution curves for the 3-D hexagonal material. The N_2 isotherm is of type IV with a H2 hysteresis loop, which indicates this material has bottle shaped pores similar to those of SBA-2.[3]

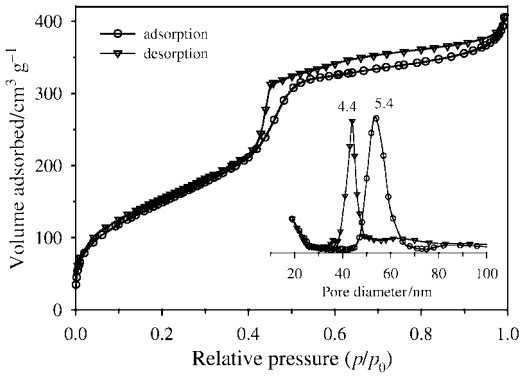

Fig. 3 N_2 adsorption–desorption isotherms for the mesoporous silica material obtained from $C_{18}EO_{10}$ and the corresponding pore size distribution curves. N_2 adsorption isotherms were obtained at liquid N_2 temperature using a Micromeritics ASAP 2000 instrument and pore size distributions were calculated by the BdB (Broekhoff and de Boer) method[9,10] with a spherical model.

In conclusion, we have developed a new synthetic method for highly ordered mesoporous silicas using sodium metasilicate as the silica source and amphiphilic block copolymers as the structure-directing agents. The replacement of TEOS by sodium metasilicate leads to the low cost production of mesoporous silica materials for practical applications. In addition, other substituents such as aluminium, titanium, *etc.* can be incorporated into the silica framework of the present SBA materials for applications such as catalysis and ion exchange.

Received (in Oxford, UK) 25th April 2000, Accepted 25th May 2000

The crystal structure of $AlPO_4$-14 in its calcined form was predicted using lattice energy minimisation and an initial model derived from its as-synthesised templated form, highlighting the possibility of using computational approaches for exploring thermodynamic stabilities of as-synthesised open-framework structures upon template extraction.

The evergrowing field of open-framework inorganic materials is in part related to the extensive development of synthetic routes involving organic amines.[1] The template molecules or structure-directing agents are incorporated in the final structure, acting as compensating charges or allowing the production of micropores with tailored size and shape. In a number of cases, for example aluminophosphates (AlPOs), the non-framework species may be removed, leaving behind an open-framework structure with potential adsorption or catalytic properties. However, the removal of the template is often a critical step and the production of the related stable open-framework compound cannot be easily anticipated.

In the recent years, computational tools have played a key role in the study of the structure and energetics of open-framework materials,[2] with the widespread use of energy minimisation techniques. For example, in the field of zeolites, energy minimisations have made it possible to locate extra-framework cations,[3] elucidate the adsorption sites of sorbate molecules[4] and to solve structures.[5] Also, the relative thermodynamic framework stabilities of various inorganic systems, such as silica polymorphs[6] and aluminophosphates,[7] have been successfully studied using appropriate forcefields.

Here we present an attempt to use energy minimisation to anticipate the calcined crystal structure of an as-synthesised aluminophosphate structure. Our main interest is to predict the stability and the crystal structure of the inorganic framework in the absence of the structure directing agent or template, starting from the knowledge of the as-synthesised structure only. We describe illustrative results for the $AlPO_4$-14 system, for which validating experimental structural data are available, both for the as-synthesised and calcined forms, from a synchrotron powder X-ray diffraction study.[8]

Diffraction results[8] show that the as-synthesised $AlPO_4$-14 structure comprises alternating Al and P atoms, linked by bridging oxygen atoms, with P atoms in a tetrahedral environment and the Al atoms possessing various coordinations (IV, V and VI) as a consequence of the extra-framework species becoming bonded. While two of the four inequivalent Al atoms are in tetrahedral coordination, one is in fivefold coordination and the other in octahedral coordination. The arrangement of AlO_x and PO_4 polyhedra constructs a three-dimensional 8-ring channel system in the *a* and *b* directions. The structure also contains hydroxy groups and non-framework species, *i.e.* protonated isopropylamine templating agents and water molecules. Each hydroxy group bridges three Al atoms: a five coordinate one and two six coordinate aluminium atoms. The isopropylamine template is protonated and balances the charge on the hydroxy group. Fig. 1 shows the above features in a selected view of the as-synthesised $AlPO_4$-14. The calcination of $AlPO_4$-14 leads to a zeotype open-framework structure where all Al and P atoms are in tetrahedral coordination, that retains the three-dimensional 8-ring channel system.

Our calculations were carried out using the lattice energy minimisation code GULP.[9] The interatomic potentials used were those developed by Gale and Henson using an empirical fit to the crystal structure plus elastic and dielectric properties of berlinite.[10] This formal charge shell model forcefield has been shown to reproduce the experimentally determined structures of aluminophosphates with good accuracy and to yield estimates of their relative framework stabilities that are consistent with thermodynamic data.[7]

The experimental crystal structure of the as-synthesised $AlPO_4$-14, $Al_8P_8O_{32}(OH)_2(C_3H_{10}N)_2(H_2O)_2$, proposed by Wilson *et al.*[8] was taken as a starting point for our calculations. This structure was then modified prior to energy minimisation as follows: atoms that are presumed to evacuate upon calcination, *i.e.* bridging hydroxy groups, isopropylamine templates and water molecules, were removed, leaving behind a neutral open-framework structure, namely, $Al_8P_8O_{32}$. This results in a structure where all four inequivalent Al atoms are in tetrahedral coordination, retaining two Al atoms in highly distorted environments (with O–Al–O angles ranging from 90 to 167°) that emanate from the two six-fold and five-fold coordinated Al atoms of the as-synthesised structure (see Fig. 2). In a final step, the modified structure was submitted to a constant pressure (*i.e.* allowing both cell parameters and fractional coordinates to relax) minimisation in space group *P*-1 since this was the space group of the as-synthesised structure.

In Fig. 3(*a*), we show the calcined structure of $AlPO_4$-14 as predicted by our energy minimisation. Clearly, the agreement with the observed calcined structure [Fig. 3(*b*)] proposed by Wilson *et al.*[8] is very good. In Table 1, we show a comparison

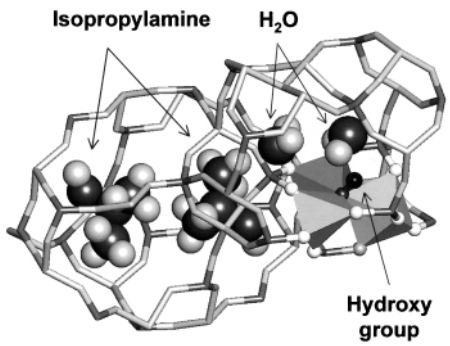

Fig. 1 Partial view of the as-synthesised $AlPO_4$-14 structure, $Al_8P_8O_{32}(OH)_2(C_3H_{10}N)_2(H_2O)_2$ from crystal data in ref. 7. Water molecules and organic template molecules are trapped in adjacent cages. A selection of three Al atoms with bipyramidal and sixfold coordination is represented with solid polyhedra, where the bridging hydroxy group participates in the coordination of all three Al atoms.

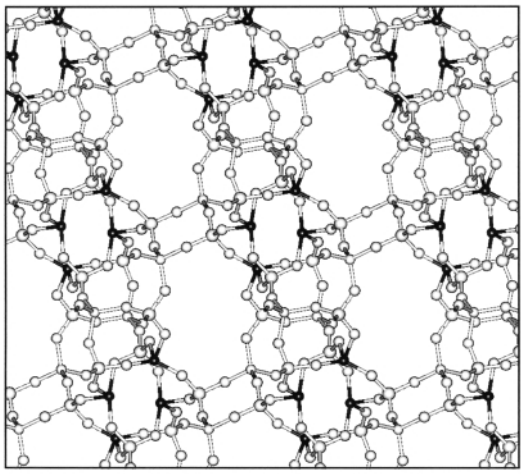

Fig. 2 Initial model for calcined $AlPO_4$-14, $Al_8P_8O_{32}$, used in our calculations and constructed from its as-synthesised form, removing the templating agent, water molecules and bridging hydroxy groups. The so-modified structure is left with Al atoms in highly distorded tetrahedral environment (shown in black).

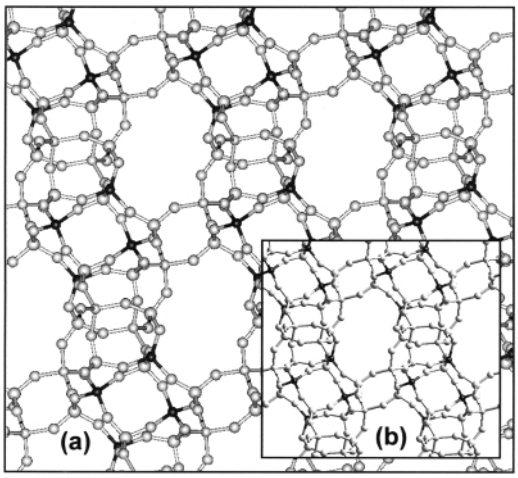

Fig. 3 (*a*) Predicted structure for calcined $AlPO_4$-14 from energy minimisation of the initial model, $Al_8P_8O_{32}$. (*b*) Observed structure of calcined $AlPO_4$-14 proposed by Wilson *et al*.[8]

[a] This work

of our calculated lattice parameters for the predicted calcined $AlPO_4$-14 with those of the observed structure. Interestingly, our initial model of calcined $AlPO_4$-14, with an initial lattice energy of 12374.8 kJ mol^{-1} per tetrahedral unit, converged rapidly towards the structure where all Al atoms are in regular tetrahedral environment, with a final lattice energy of 12924.9 kJ mol^{-1} per tetrahedral unit. This makes the structure of $AlPO_4$-14 11.7 kJ mol^{-1} less stable than α-berlinite per T site. For comparison, the work of Henson *et al.*[7] demonstrates that the most pure aluminophosphates are between 4 and 13 kJ mol^{-1} less stable than the thermodynamically favoured polymorph under ambient conditions, making $AlPO_4$-14 a relatively unstable structure. Our energy minimisation predicts the observed calcined structure of $AlPO_4$-14 remarkably well, especially as the initial model had large distorsions arising from the deletion of ligand atoms in the coordination spheres of the Al atoms from the as-synthesised form. Also, we checked that minimisations from both points, the initial model of calcined $AlPO_4$-14 or the observed calcined structure, lead to the same structure.

Another important use of potentials is that they can test space groups for possible lower symmetry distortions, as found for other AlPOs.[7] The phonon spectrum at the Γ point of the calcined structure of $AlPO_4$-14 was calculated to check the space group as *P*-1. The structure was found to be phonon stable in this space group verifying that the symmetry is at least *P*-1.

In summary, energy minimisation allows us to estimate the thermodynamic stability of calcined $AlPO_4$-14 and to predict its crystal structure, starting with the knowledge of the as-synthesised structure and anticipating the species removed during the calcination process. The further viability of this approach has been recently demonstrated through the prediction of the calcined form of a newly synthesised templated aluminophosphate, where atomic coordinates of the calcined form, which has a structure different from the as-synthesised form, were obtained from the simulation, allowing their direct use for future powder diffraction refinement.[11]

We are grateful to Dr T. Loiseau and C. Sassoye for helpful discussions.

First synthesis and characterization of vinylselenols and vinyltellurols

Jean-Claude Guillemin,* Asmae Bouayad and Dange Vijaykumar

Laboratoire de Synthèse et Activation de Biomolécules, UMR CNRS 6052, ENSCR, Avenue du Général Leclerc, 35700 Rennes, France. E-mail: jean.claude.guillemin@ensc-rennes.fr

Received (in Liverpool, UK) 11th April 2000, Accepted 24th May 2000

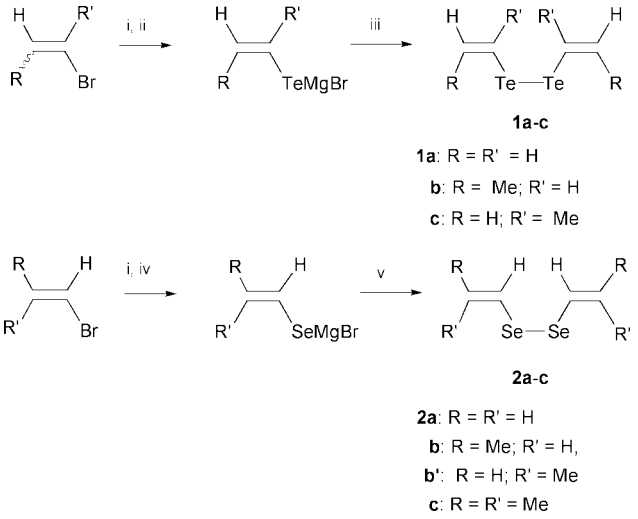
Vinylselenols and vinyltellurols have been prepared by slow addition of tributyltin hydride to the corresponding divinyldiselenide or divinylditelluride in tetraglyme.

Several α,β-unsaturated heterocompounds bearing one or several hydrogen atom(s) on the heteroatom exhibit interesting properties. For instance, base-induced keto–enol or imine–enamine tautomerism is a consequence of the high acidity of the hydrogen linked to the heteroatom.[1] Recently, evidence for a similar increase of acidity between saturated and α,β-unsaturated phosphines and arsines was provided by FT-ICR mass spectrometry and theoretical calculations.[2] From a synthetic viewpoint, the rearrangement of such α,β-unsaturated compounds provides an efficient method for the preparation or the chemical trapping of the corresponding carbon–heteroatom multiple bond derivatives.[3] Although primary α,β-unsaturated derivatives of mercury, silicon, germanium, tin, nitrogen, phosphorus, arsenic, antimony, oxygen and sulfur have been reported,[4] no primary α,β-unsaturated selenol or tellurol derivatives have been isolated so far.[5] Such compounds, which are probably unstable in a variety of experimental conditions, cannot be easily prepared by conventional approaches used for other heterocompounds.

Flash vacuum pyrolysis is an efficient technique to prepare derivatives of the elements of the first and second rows of the periodic table and vinylthiols have also been prepared by this method.[6] However, with the elements of subsequent rows, the energy of the carbon–heteroatom bond is often too low to withstand high temperatures. The preparation of thiols, selenols or tellurols *via* LAH or other reducing agents such as borohydrides requires an acidolysis of the resulting salt to isolate the free product.[7] Although quite stable compounds such as vinylthiols have been prepared in this manner,[8] such approaches are not viable for sensitive α,β-unsaturated derivatives of selenols and tellurols.

Since 1994, we have been involved in the synthesis of primary low boiling α,β- or β,γ-unsaturated phosphines, arsines, stibines, stannanes and mercury hydrides.[3,9–12] We have developed an efficient procedure for the preparation of these compounds using vacuum line techniques, *via* the reduction of the corresponding halo derivatives with excess tributyltin hydride. This approach cannot be used to prepare SH, SeH or TeH derivatives because these products would quickly react with the tin hydride to form the corresponding S–Sn, Se–Sn or Te–Sn derivatives. However, Crich *et al.* have recently shown that a selenol (PhSeH) can be detected for a short time by addition of Bu_3SnH to a solution of diphenyldiselenide.[13] By combining this approach with the experimental technique developed in our laboratory, we looked into the preparation of kinetically unstable selenols and tellurols. We now report here, the synthesis of low boiling vinylselenols and tellurols starting from the corresponding divinyldiselenides or ditellurides.

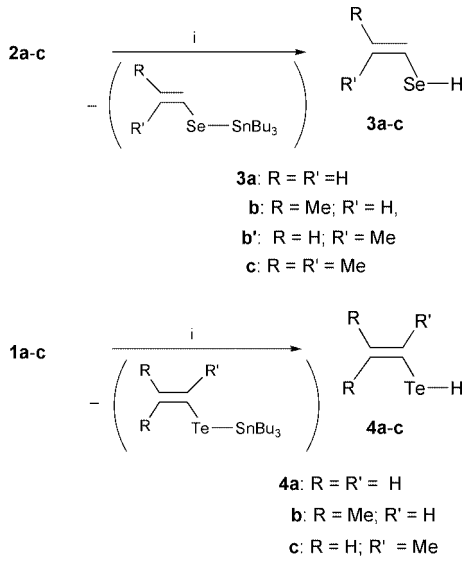
The synthesis of divinylditellurides has been reported by Dabdoub and Comasseto.[14] The arial oxidation of the product formed by insertion of tellurium in vinyl Grignard reagents led to compounds **1a**–**c** (Scheme 1). Starting from a mixture of *Z*- and *E*-isomers of 1-bromopropene, only the *Z*-dipropenylditelluride **1b** was obtained. The simple divinyldiselenides have never been reported before. We prepared the divinyldiselenides



Scheme 1 *Reagents and conditions*: i, Mg; ii, Te, reflux, 30 min; iii, air; iv, Se, room temp.; v, Br_2, −20 °C.

2a–**c** starting from selenium and vinyl Grignard reagents using dibromine as the oxidizing reagent (yields: 52–73%). Compounds **2a**–**c** have been unambiguously characterized by ^1H, ^{13}C, ^{77}Se NMR and high resolution mass spectrometry (HRMS). The ^{77}Se NMR signals were observed between δ 236 (**1c**) and δ 407 (**1b′**).[15]

The vinylselenols **3a**–**c** and vinyltellurols **4a**–**c** were prepared by slow addition of 1.5 equiv. of Bu_3SnH to a solution of **2a**–**c** or **1a**–**c**, respectively, in tetraglyme (Scheme 2).† The products were continuously distilled *in vacuo* from the reaction mixture and condensed in a cold trap. They were thus isolated before their reaction with the tin hydride. Vinylselenols **3a**–**c** were obtained in good yields (73–83%) but only moderate yields



Scheme 2 *Reagents*: i, Bu^n_3SnH.

[a] This work. [b] Ref. 16. [c] Ref. 15. [d] Yield not given, ref. 17. [e] Ref. 18. [f] Ref. 19. [g] Ref. 8. [h] Ref. 14.

(32–43%) were observed for the more reactive tellurols **4a**–**c**.‡

All compounds **3a**–**c**, **4a**–**c** were unambiguously characterized by ^{1}H, ^{13}C, ^{77}Se or ^{125}Te NMR spectroscopy and HRMS.§ In the ^{1}H NMR spectrum, the presence of an unsaturated group on a heteroatom usually leads to a downfield shift of the signals of hydrogen(s) attached to the heteroatom and an increase in the coupling constants.[9,11] In the ^{1}H NMR spectra of selenols **3a**–**c**, the signal of the hydrogen on the selenium atom was observed *ca*. 1.5 ppm downfield to that of the saturated derivative (Table 1). A similar downfield effect was observed for the tellurols. The $^1J_{SeH}$ and $^1J_{SeC}$ coupling constants of the unsaturated compounds **3a**–**c** are higher than those of the saturated compounds [$^1J_{SeC}$ (**3a**): 93.2 Hz, $^1J_{SeC}$ (EtSeH): 45.0 Hz]. This can be attributed to an increase of the s character of the Se–H and Se–C bonds. Although a similar increase was observed for the $^1J_{TeC}$ coupling constant of tellurols [$^1J_{TeC}$ (**4a**): 247.3 Hz, $^1J_{TeC}$ (EtTeH): 114.9 Hz], an opposite effect was observed for the $^1J_{TeH}$ coupling constants. To the best of our knowledge although a upfield signal has been observed for the proton on the mercury atom of the vinyl derivative,[12] such a decrease of a $^1J_{XH}$ coupling constant for a vinylic derivative has never been reported.

Vinylselenols and vinyltellurols exhibit a low stability at room temperature: the half-life of selenols **3a**–**c** diluted in $CDCl_3$ is *ca*. one day and *ca*. 60 min for the tellurols **4a**–**c**. Only insoluble black decomposition products were observed after a few days.

In conclusion, we have successfully prepared vinylselenols and tellurols by reaction of Bu_3SnH with the corresponding diselenide or ditelluride derivatives. By reaction with a hydride (Bu^n_3SnH), compounds bearing an acidic hydrogen (RSH, RSeH, RTeH) were prepared *via* a radical reaction thus providing a new route which is an alternative to the hydrolytic method. Further investigation into the synthesis of other unsaturated selenols and tellurols, and spectroscopic studies are currently under progress in our lab.

We thank the PNP (INSU-CNRS) and the CNES for financial support and Dr M. Davies for helpful suggestions in writing the paper.

Notes and references

† *Typical experimental procedure*: (**CAUTION:** *Selenols and tellurols are potentially highly toxic compounds and must be used with great care under a well-ventilated hood*). The apparatus already described for the reduction of dichlorostibines was used.[10] The flask containing the precursor [2 mmol of **1a**–**c** or **2a**–**c** diluted in tetraglyme (5 mL)] was fitted on a vacuum line and degassed. Bu^n_3SnH (3 mmol) was then slowly added (30 min) at room temperature with a syringe through the septum. During and after the addition, vinylselenols **3a**–**c** or tellurols **4a**–**c** was distilled off *in vacuo* (10^{-1} mbar) from the reaction mixture. A cold trap (−60 °C) removed selectively the less volatile products and compounds **3a**–**c**, **4a**–**c** were condensed on a cold finger (−196 °C) connected at the bottom to a flask or an NMR tube. A co-solvent can be added at this step. After disconnecting from the vacuum line by stopcocks, the apparatus was filled with dry nitrogen; liquid nitrogen was subsequently removed. The product was collected in a Schlenk flask or a NMR tube and kept at low temperature (< −50 °C) before analysis.

‡ Under these experimental conditions, we have also prepared alkylthiols (EtSH, yield: 96%), vinylthiols (MeCH=CHSH, yield: 91%), arylthiols (PhSH, yield: 77%), alkylselenols (EtSeH, yield: 89%) and alkyltellurols (EtTeH, yield: 83%). The reaction with EtSeSEt led to ethanethiol (yield: 92%) and traces of EtSeH suggesting that the ethylseleno group acts as a protecting group for the thiol.

Methyltrioxorhenium-catalyzed epoxidations in ionic liquids

Gregory S. Owens and Mahdi M. Abu-Omar*

Department of Chemistry and Biochemistry, University of California, Los Angeles, CA 90095-1569, USA. E-mail: mao@chem.ucla.edu

Received (in Irvine, CA, USA) 28th February 2000, Accepted 11th May 2000

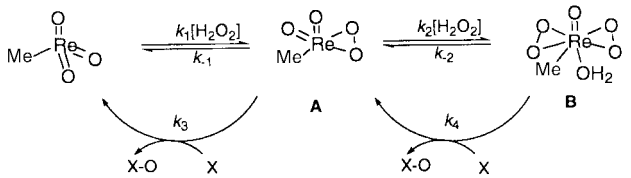
Alkenes and allylic alcohols have been epoxidized in an ambient-temperature ionic liquid for the first time using methyltrioxorhenium (MTO) and urea hydrogen peroxide; excellent conversions and selectivities for the epoxides of a wide number of substrates were observed.

One of the pressing issues for chemists in the twenty-first century is the pursuit of 'clean' or 'green' chemical transformations.[1] A particular source of chemical waste that is often taken for granted is the use of volatile molecular solvents.[2,3] The use of non-volatile ionic liquids, or molten salts, in chemical synthesis and catalysis has received attention in recent years;[2] however, the utility of these compounds remains largely unexplored. We report the first catalytic epoxidation system that makes use of a room-temperature ionic liquid as the solvent. Alkenes and allylic alcohols have been oxidized to their corresponding epoxides using the well studied methyltrioxorhenium (MTO) catalyst and urea hydrogen peroxide (UHP) with the ionic liquid 1-ethyl-3-methylimidazolium tetrafluoroborate, [emim]BF_4, as the solvent.

Numerous low-melting ionic salts are known, including chlorocuprates, halogenoaluminates, and alkylphosphonium, *N*-alkylpyridinium, alkylammonium, and *N*,*N*′-alkylimidazolium cations with various anions.[2] Chlorocuprates are not suitable for catalytic oxidations because of their oxygen sensitivity, and halogenoaluminates are difficult to work with because of their instability in the presence of water. We chose to use the 1-ethyl-3-methylimidazolium cation because: (i) its synthesis is facile,† and (ii) it is neither oxygen nor water sensitive (but is hygroscopic). Furthermore, with BF_4^- as the counteranion, the salt melts at 15 °C.[4]

The discovery by Herrmann in 1991 of MTO's ability to catalyze the epoxidation of olefins has led to a wealth of information regarding the efficiency and versatility of this catalyst.[5] This discovery has also fueled many efforts aimed at developing 'environmentally friendly' oxidation systems, as the only byproduct of the MTO–peroxide system is water. The creation of two active oxygen-transfer complexes, a monoperoxo- and a diperoxorhenium species, during the catalytic cycle has been well established, as have the mechanisms of oxygen transfer (Scheme 1). We refer the reader to the many reviews that have been written on the subject of MTO-catalyzed oxidations, for further information.[6–9]

Urea hydrogen peroxide has been shown to be a water-free peroxide source for MTO-catalyzed epoxidations.[10] The only disadvantage, thus far, to using UHP is that it is insoluble in organic solvents, such as chloroform, methylene chloride, and acetonitrile. Hence, the MTO–UHP system in organic media is heterogeneous.



Scheme 1

In this work, the advantageous properties of the MTO–UHP oxidation system and [emim]BF_4 have been combined to give an exceptionally clean environment for catalytic oxidations. One major advantage of this system is that both UHP and MTO are soluble in the ionic liquid, as are the peroxorhenium species. This gives an oxidation solution that is completely homogeneous. The formation of the peroxorhenium species is evident by the appearance of an intense yellow color in the solution; this color is attributable to the monoperoxo- and the diperoxorhenium intermediates. UV–Vis experiments have confirmed the presence of the diperoxorhenium complex, as indicated by its absorption maximum at 360 nm.

The results in Table 1 show that several different olefinic substrates have been oxidized to epoxides, with yields ranging from fair (in the case of 1-decene) to excellent. Aqueous hydrogen peroxide (30%) was used in one experiment (entry 4) to illustrate the ring-opening of sensitive epoxides in the presence of large amounts of water, as previously reported in molecular solvents.[5,11,12] In contrast, the reaction in entry 3 was performed with molecular sieves to ensure the complete removal of water from the system. As a result, only the epoxide

Table 1 Epoxidations of various substrates with MTO–peroxide in [emim]BF_4[a]

Entry	Substrate	Oxidant	Conversion (%)[b]	Epoxide yield (%)[b]
1		UHP	≥95	≥99
2		UHP	≥95	≥95
3		UHP	≥95	≥95
4		H_2O_2 (30%)	≥95	≤5[c]
5		UHP	>99	95[d]
6		UHP	95	≥95
7		UHP	≥95	≥95
8		UHP	≥95	≥95
9		UHP	>99	85[e]
10		UHP	46[f]	>99

[a] *Reaction conditions*: 0.5 mol substrate, 1.0 mol oxidant, 2% MTO, room temperature, 8 h. [b] Yields determinded by ^{1}H NMR and GC–MS. [c] The majority of the product is the diol. [d] Major products are 2,3-epoxycyclohexanol (62%) and 2,3-epoxycyclohexanone (32%). [e] This yield represents the diepoxide. The remainder of the product is the monoepoxide. The same results are obtained when 2.0 mol oxidant is used. [f] This conversion was obtained after 72 h.

DOI: 10.1039/b001661f

was obtained. It is also interesting to note the poor conversion in the reaction of 1-decene (entry 10). Better conversions for this reaction have been obtained with other MTO–peroxide epoxidation systems;[11–13] however, after 72 h, we observed that the reaction mixture was still intensely yellow, indicating that the catalyst is still active and, apparently, highly stable in this ionic medium. The poor conversion of 1-decene may be the result of heterogeneity in the solution; 1-decene was the least soluble substrate in the ionic liquid. The results in Table 1 also indicate that the time required for the epoxidation of these substrates is quite comparable to that required for previously reported results.[5,11,12] Additionally, as shown in previous work,[10] the use of UHP eliminates the epoxide ring-opening that is commonly observed when using aqueous hydrogen peroxide. This is because the urea that is produced during the consumption of UHP modulates the pH of the solution and prevents acid-catalyzed ring opening.

As shown in Table 1, two equivalents of UHP were used relative to the substrate. Although two equivalents of oxidant leads to faster epoxidation rates, only a single equivalent is required, as evidenced by experiments with 1,5-cyclooctadiene using one and two equivalents of UHP per double bond, which yield the same product distributions.

Remaining reactants and products are both easily removed from the reaction mixture *via* extraction with diethyl ether, which is immiscible with the ionic liquid used in this work. This method of removing reactants and products is also advantageous because MTO, the peroxorhenium species, and the urea byproduct are insoluble in diethyl ether. Careful evaporation of the ether extracts gives the reactant–product mixture, which can then be analyzed by NMR and GC–MS.

In summary, the advantages of this oxidation system are numerous: (i) urea hydrogen peroxide and MTO are completely soluble in [emim]BF_4, giving a homogeneous oxidation solution. (ii) The oxidation solution is nearly water-free, so conversion of the substrates yields only the epoxides and not the diols. (iii) Left-over reactants, if any, and products are easily separated from the oxidation solution by extraction with an immiscible solvent. (While it is true that molecular solvents have been used for isolation of the reactants/products in this work, one can easily imagine a large-scale system in which the reactants and products are distilled from the reaction mixture, thereby completely eliminating the use of organic solvents.) (iv) Most rates of epoxidation in this system are at least comparable to previously published data. Current work in progress includes the determination of equilibrium constants K_1 and K_2 (Scheme 1) in [emim]BF_4 and characterization of the kinetics. We also hope to expand the use of this oxidation solution to substrates other than olefins, such as amines, alcohols, hydrocarbons, and aromatics.

We are grateful to the National Science Foundation (CAREER Grant CHE-9874857), the Arnold and Mabel Beckman Foundation for a Young Investigator Award to M. M. A. O., and the University of California Toxic Substances Research and Teaching Program (UCTSR&TP) for financial support of this research. We would like to thank Professor Thomas Welton for helpful discussions.

Notes and references

† The 1-ethyl-3-methylimidazolium cation is readily synthesized from 1-methylimidazole and bromoethane. Subsequent metathesis with sodium tetrafluoroborate gives the desired ionic liquid, which is purified by passage through neutral alumina.[14] The conversion in the metathesis step is rather important, as bromide competes with alkenes for oxidation to hypobromite.[15]

A new and versatile diamide–diamine donor ligand set in early transition metal chemistry†

Michael E. G. Skinner, David A. Cowhig and Philip Mountford*

Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR.
E-mail: philip.mountford@chemistry.oxford.ac.uk

Received (in Cambridge, UK) 28th March 2000, Accepted 22nd May 2000

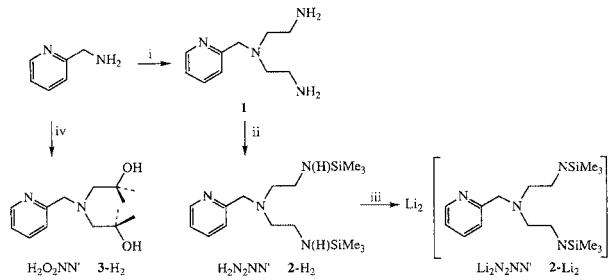
Straightforward, multigram synthesis of the new diamide–diamine proligand H_2N_2NN' [N_2NN' = (2-NC_5H_4)-$CH_2N(CH_2CH_2NSiMe_3)_2$] is described along with a preliminary survey of the five- and six-coordinate, neutral and cationic, single- and multiply-bonded complexes of groups 3, 4 and 5 that it can support; the related bis(alkoxide)–diamine proligand H_2O_2NN' is also described where H_2O_2NN' = (2-NC_5H_4)$CH_2N(CH_2CMe_2OH)_2$.

The bis(cyclopentadienyl) ligand set has been the dianionic environment *par excellence* for organotransition metal chemistry for *ca*. four decades.[1] Driven by the search for new fundamental and catalytic chemistry, the last ten years in particular have established the importance of polydentate di- and tri-anionic N-donor ligands as environments for early- to mid-transition metal coordination and organometallic complexes.[2]

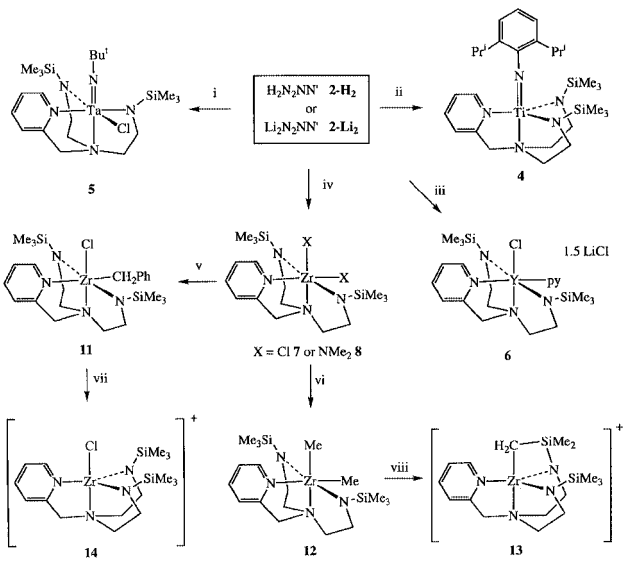
Among the tetradentate 'N_4' donor ligands, the porphyrins[2b] and tetraaza[14]annulenes[2c] are probably the best established *di*anionic ligands. They provide a really quite rigid, square-base donor environment. In contrast, the *tri*anionic triamidoamine 'tren' systems generally provide four vertices of a trigonal bipyramid or octahedron. Such ligands have been extremely successful in developing p-block, early-mid transition metal, lanthanide and actinide chemistry.[2d,3] Despite these successes, however, as a trianionic species the versatility of this ligand is hampered in certain regards for developing new lanthanide, and groups 3 and 4 chemistry in particular since there is only one (group 4) or no (lanthanide, group 3) metal electrons remaining for binding additional anionic ligands. Dianionic 'N_4' analogues of the tren systems will help advance early transition metal and lanthanide chemistry, and compliment the extensive studies of *tri*dentate diamido-donor systems.[2a] Indeed, it was recently reported that addition of an extra donor arm to bis(alkoxide)-donor systems can lead to enhanced ethylene polymerisation capability.[4]

The straightforward syntheses of the new proligands H_2N_2NN' **2**-H_2 and H_2O_2NN' **3**-H_2 are shown in Scheme 1.‡ The intermediate tetra-amine **1** has been previously described,[5] but we have found that the alternative synthesis shown from 2-aminomethylpyridine is more convenient on a large scale. The proligand **2**-H_2 is conveniently converted (Bu^nLi) to its lithiated derivative Li_2N_2NN' **2**-Li_2. The new proligands can all be prepared in multigram quantities: *e.g.* 5.4 g of **1** yields 7.1 g (75%) of **2**-H_2 and lithiation of this gives 4.2 g (57%) of Li_2N_2NN' **2**-Li_2.

The ready availability of H_2N_2NN' **2**-H_2 and Li_2N_2NN' **2**-Li_2 has allowed us to develop a representative range of new five- and six-coordinate, neutral and cationic, single- and multiply-bonded complexes of groups 3, 4 and 5 (Scheme 2). They are formed by salt- (for **4**–**6**), and alkane- or amine- (for **7** and **8**) elimination reactions; the applicability of a range of such protocols will clearly permit these new ligands to be incorporated into a wide range of transition, lanthanide and main group metal derivatives. Thus reaction of Li_2N_2NN' **2**-Li_2 with $[Ti(NAr)Cl_2(py)_3]$[6a] (Ar = $C_6H_3Pr^i_2$-2,6) or $[Ta(NBu^t)Cl_3(py)_2]$[6b] gives the five- and six-coordinate imides, $[Ti(NAr)(N_2NN')]$ **4** and $[Ta(NBu^t)Cl(N_2NN')]$ **5**, respectively. Transition metal imides continue to attract considerable interest,[7] and those of group 4 with π-donor coligands can have a particularly rich reaction chemistry.[2a,7,8] Reaction of **2**-Li_2 with YCl_3 in pyridine affords the 'ate' complex **6**, formulated as '$[YCl(N_2NN')(py)]\cdot 1.5LiCl$' on the basis of elemental analyses and ^{7}Li NMR spectroscopy. Nonetheless, preliminary reactivity studies of **6** show that it behaves as though it were simply $[YCl(N_2NN')(py)]$, and that it is a useful synthon with the Y-bound Cl ligand being readily substituted by bulky monoanionic donors.



Scheme 1 *Reagents and yields*: i, *N*-tosylaziridine (74% for this step) then conc. H_2SO_4 83% (61% overall); ii, 2 Me_3SiCl, 4 Et_3N, 75%; iii, 2.2 Bu^nLi, 57%; iv, 3-isobutylene oxide, 25%.



Scheme 2 *Reagents and yields*: i, (with **2**-Li_2) $[Ta(NBu^t)Cl_3(py)_2]$, 36 h, 29%; ii, (with **2**-Li_2) $[Ti(NC_6H_3Pr^i_2\text{-}2,6)Cl_2(py)_3]$, 58%; iii, (with **2**-$Li_2$) YCl_3, 71%; iv, (with **2**-H_2) for **7**: $[ZrCl_2(CH_2SiMe_3)_2\cdot 2Et_2O]$, 87%; for **8**: $[Zr(NMe_2)_4]$, 55%; v, $PhCH_2MgCl$, 87%; vi, LiMe (2 equiv.), 88%; vii, $B(C_6F_5)_3$, 61% [counter ion = $B(CH_2Ph)(C_6F_5)_3^-$]; viii, $B(C_6F_5)_3$, 60% [counter ion = $BMe(C_6F_5)_3^-$].

DOI: 10.1039/b002455o

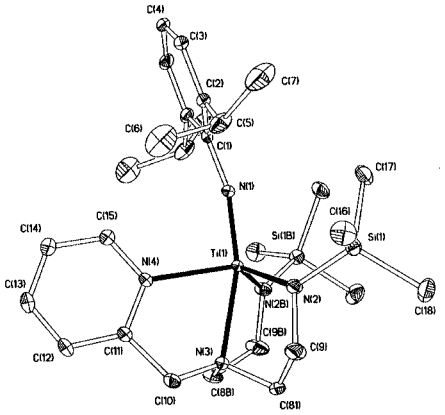

Fig. 1 Displacement ellipsoid plot of [Ti(N_2NN′)($NC_6H_3Pr^i_2$-2,6)] **4**.

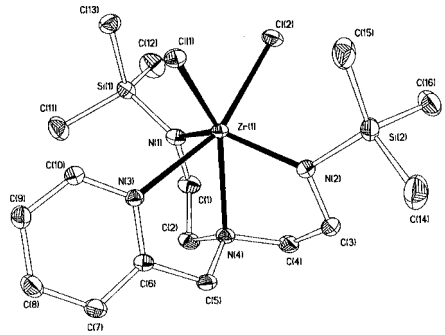

Fig. 2 Displacement ellipsoid plot of [Zr(N_2NN′)Cl_2] **7**.

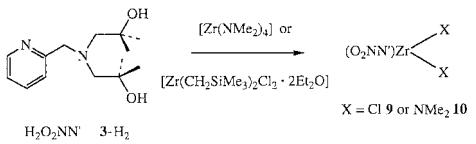
The group 4 compounds [Zr(X)$_2$(N_2NN′)] (X = Cl **7** or NMe_2 **8**) are readily obtained from **2**-H_2 and [Zr(CH_2SiMe_3)$_2Cl_2$·2Et_2O][9] or [Zr(NMe_2)$_4$], respectively. Such *cis*-X_2 complexes are of great importance in the study of new stoichiometric and catalytic group 4 reaction chemistry.[10] The bis(alkoxide) analogues of **7** and **8**, namely [Zr(X)$_2$(O_2NN′)] [X = Cl **9** or NMe_2 **10**, eqn. (1)] can be similarly prepared from



(1)

H_2O_2NN′ **3**-H_2. The compounds **9** and **10** will provide interesting comparisons with their more sterically-shielded tetraaza homologues **7** and **8**, and with very recent bis(phenoxide)–diamine ligands that are active ethylene polymerisation catalysts.[4]

We have structurally confirmed that the N_2NN′ ligand can readily accommodate both five- and six-coordinate metal centres. Views of the X-ray structures of [Ti(NAr)(N_2NN′] **4** and [$ZrCl_2$(N_2NN′)] **7** are shown in Fig. 1 and 2, respectively.§ The structure of **4** reveals an approximately trigonal bipyramidal geometry at the five-coordinate Ti centre. The structure of **7** reveals an approximately octahedral Zr centre; the chloride ligands are mutually *cis*. In both **4** and **7**, and indeed in all the derivatives to date of the N_2NN′ ligand, including the crowded bis(dimethylamide) complex **8**, the pyridyl donor is firmly bound to the metal centre and establishes a well defined coordination environment.

One or both chloride ligands in [$ZrCl_2$(N_2NN′)] **7** can be substituted using organo-magnesium or -lithium reagents forming the mono- and di-alkyl derivatives [Zr(CH_2Ph)Cl(N_2NN′)] **11** and [$ZrMe_2$(N_2NN′)] **12** in *ca*. 90% yield. There is no evidence in any of the reaction chemistry herein for metallation or other attack at the pyridyl donor group. *cis*-Dialkyl compounds such as **12** are potential precursors to Ziegler–Natta olefin polymerisation catalysts.[10] Treatment of **12** with $B(C_6F_5)_3$ or [CPh_3][$B(C_6F_5)_4$], however, affords the TMS-metallated cation **13** with counter anion [$MeB(C_6F_5)_3$]$^-$ or [$B(C_6F_5)_4$]$^-$; there is no evidence for interaction between **13** and the [$MeB(C_6F_5)_3$]$^-$ anion in solution. The [$MeB(C_6F_5)_3$]$^-$ salt of **13** is thermally stable at r.t. in both the solid state and CD_2Cl_2 solution, and has been fully characterised by NMR and elemental analysis. Cation **13** presumably forms *via* an intermediate cation [ZrMe(N_2NN′)]$^+$ (not observed) followed by σ-bond metathesis with one of the $SiMe_3$ C–H bonds. Similar reactions have been seen in group 4 triamidoamine chemistry,[11] but can, in principle, be circumvented by use of alternative amide N-substituents: such protocols are well established.[2a,12] Indirect evidence for a five-coordinate cationic intermediate comes from the formation of the cation [ZrCl(N_2NN′)]$^+$ **14** from the monobenzyl complex [Zr(CH_2Ph)Cl(N_2NN′)] **11** and $B(C_6F_5)_3$. Salts of the cation **13** react sluggishly with ethylene (1 atm), but work is in progress to develop analogues of H_2N_2NN′ with other, more robust amide N-substituents.

In summary, we have described the new diamido–diamine ligand H_2N_2NN′ and a survey of its versatile complexation chemistry.

This work was supported by the EPSRC and Royal Society. We thank Dr G. A. Vaughan (Exxon Chemical Co.) for a gift of [Zr(NMe_2)$_4$] and Dr D. J. Watkin for help with the X-ray data collection.

Formation of nanorods by self-assembly of alkyl-substituted polyphenylene dendrimers on graphite

Simona Loi,[a] Uwe-Martin Wiesler,[b] Hans-Jürgen Butt*[a] and Klaus Müllen[b]

Received (in Cambridge, UK) 17th April 2000, Accepted 11th May 2000

Alkyl-substituted polyphenylene dendrimers with a tetrahedral or disk-like shape form self-assembled monolayers on graphite (HOPG) which show complex supramolecular structures, such as parallel rods of 6 nm diameter or two-dimensional crystals.

The construction of supramolecular structures by self-assembly of molecules is a topic of great current interest in relation to the fabrication of new materials.[1–3] Dendrimers are attractive building blocks to form such materials because they are monodisperse macromolecules with well-defined shapes and dimensions.[4,5] In this paper, we report on the structure of self-assembled dendritic monolayers on the basal plane of graphite. Dendrimers binding to graphite are the ideal model system to study the adsorption of macromolecules to surfaces because adsorbant and adsorbent are well defined.

Different dodecyl-substituted polyphenylene dendrimers were synthesized (Fig. 1) and monolayers were formed by spontaneous adsorption from solution on the basal plane of graphite. The structure of these monolayers was imaged with an atomic force microscope (AFM). Formation of self-assembled dendritic monolayers is possible because the alkyl chains adsorb strongly to graphite; the adsorption energy is roughly 7 kJ mol^{-1} per methylene unit.[6,7] In addition, each phenylene subunit in close contact with the graphite surface is expected to contribute an adsorption energy of roughly 15 kJ mol^{-1}.[8]

Dendrimers **1** and **2** were prepared divergently *via* reiterative Diels–Alder cycloaddition according to the procedure described in ref. 9. The synthesis starts from a polyfunctional central building block, tetra(4-ethynylphenyl)methane for **1**, and 1,3,5-triethynylbenzene for **2**. To introduce dodecyl alkyl chains on the periphery of the dendrimer, tetraphenylcyclopentadienones alkylated with dodecyl chains were added by Diels–Alder cycloaddition as the last layer of the dendrimer. The dendrimers were characterized by MALDI-TOF mass spectrometry, NMR spectroscopy and GPC, and revealed that the products were pure. Due to the polyphenylene backbone and the high number of twisted, interlocked benzene rings, these dendrimers show a high shape persistence, with diameters of 5.5 and 3.8 nm for dendrimers **1** and **2**, respectively.[10] According to force field calculations and X-ray diffraction studies, dendrimer **1** shows a tetrahedric structure, whereas dendrimer **2** has a more planar propeller-like structure (Fig. 1).[11,12]

Dendrimer layers were prepared with the spin coating technique. A drop of solution was deposited on a freshly cleaved HOPG (highly oriented pyrolytic graphite) substrate and the

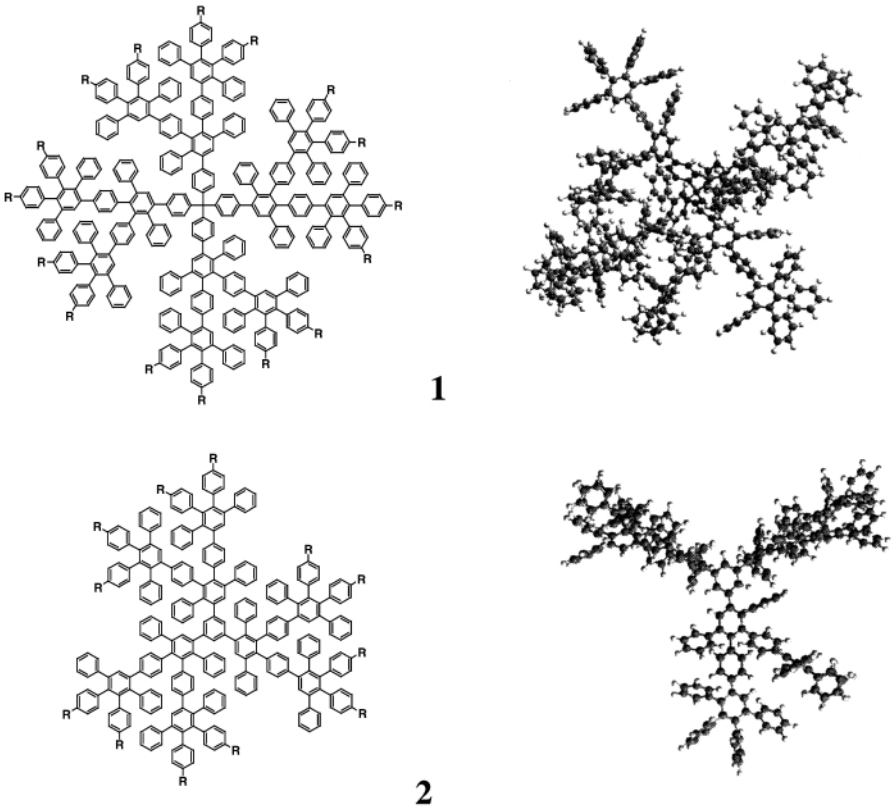

Fig. 1 2D- and 3D-structure (MM2 molecular mechanic simulation with CERIUS2 program package, Molecular Simulations Inc., Waltham, MA, USA) of the investigated alkyl-substituted polyphenylene dendrimers; R=$C_{12}H_{25}$.

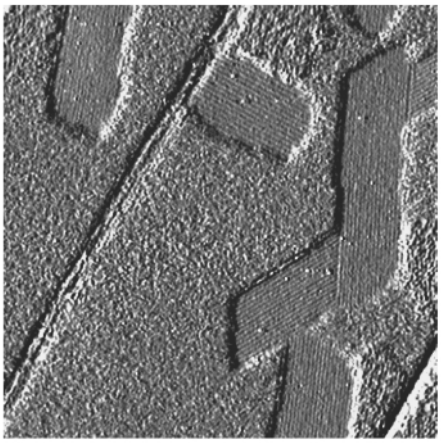

Fig. 2 AFM amplitude image (scan size 639 nm) of a dendrimer **1** layer on HOPG.

sample was rotated at 810 rpm for 10 s. Dendrimers were dissolved in dichloromethane at a concentration of 0.002 mg ml^{-1} ($2.7–4 \times 10^{-7}$ M). Samples were imaged at room temperature with a commercial AFM (Nanoscope III, Digital Instruments, Santa Barbara, California) in tapping mode using rectangular silicon cantilevers (Nanosensors, 125 μm long, 30 μm wide, 4 μm thick) with an integrated tip, a nominal spring constant of 42 N m^{-1}, and a resonance frequency of 330 kHz.

When preparing layers of dendrimer **1**, most of the graphite surface was covered with a diffuse layer. In addition, some distinct structures were observed. Some of the most remarkable structures were regions covered by parallel rows of 5.9 ± 0.7 nm spacing (Fig. 2). Typically, the regions were 50–100 nm wide and 70–800 nm long. Usually only a few percent of the total surface area was covered with a rod-like structure. However, in 2 out of 11 experiments, almost the whole surface was covered by rods. The rods were stable and could be imaged for several hours. Different rod-like regions were oriented parallel (0°) or at 60 or 120° with respect to each other. This indicates that the underlying graphite with its hexagonal structure determines the orientation of the dendrimer rods.

When forming monolayers from dendrimer **2**, in 4 out of 6 experiments, two-dimensional crystals (Fig. 3) were formed. The primitive unit cell can be described by the lattice constants $a = 10.2 \pm 0.3$, $b = 7.4 \pm 0.4$ nm and an angle of 122.8 ± 2°. Like the rod-like regions, these lattices were oriented parallel (0°) or at 60 or 120° with respect to each other, indicating that the underlying graphite determines their orientation. Each unit cell probably contains at least two molecules. This is indicated by the unit cell area of 63 nm^2. An upper limit for the area occupied by one dendrimer can be estimated from the extension of a polyphenylene chain with 10 phenylene rings plus two dodecyl chains, which is roughly 6 nm. When hexagonally close packed, circles of 6 nm diameter would occupy an area of 31 nm^2. In addition, each protrusion in a unit cell had an elongated, oval and not spherical shape. This shows that individual molecules do not form separate units, but that real supramolecular structures are formed. The two-dimensional crystals were stable and could be scanned many times. In one experiment we observed rod formation, as with dendrimer **1**. The spacing between the rods was again 6 nm. The rods were not stable and disappeared after scanning them few times.

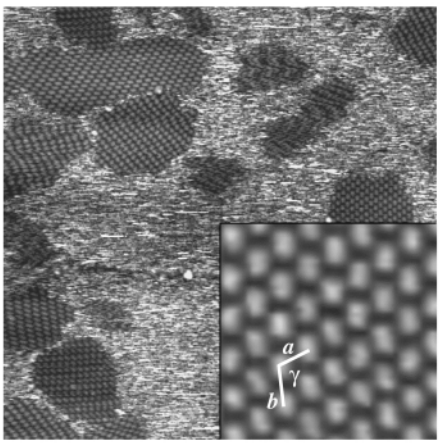

Fig. 3 AFM height image of a dendrimer **2** layer on HOPG showing a region with two-dimensional crystals (scan size 578 nm, 1 nm height). The insert shows details of a crystal. The lattice constants are indicated.

The formation of rods on surfaces has been observed from dendritic nanorods.[13] However, to the best of our knowledge, this is the first observation of rod formation from the self-assembly of dendrimers which are tetrahedral (dendrimer **1**) or shaped like a disc (dendrimer **2**) in solution.

Since it is a requirement for the formation of regular structures, it is ideally that single dendrimers on bare graphite are mobile. Hydrocarbon chains are strongly adsorbed to graphite and, once they are adsorbed, it is unlikely that they can leave the surface spontaneously. They can, however, diffuse laterally. Computer simulations of individual alkyl chains on graphite revealed negligible activation energy for translation along the chain.[6] The same is true for the polyphenylene subunits, because benzene molecules are able to diffuse laterally, even at temperatures of 85 K.[14] Hence, the dendrimers can probably diffuse on bare graphite. This explains why we were never able to image half-covered graphite. Either the surface was totally clean (this was the case when preparing layers from concentrations of < 0.002 mg ml^{-1}) or an almost complete monolayer was observed.

The requirement of high lateral mobility also explains why thiol-substituted dendrimers on gold do not form regular structures.[2] They bind to gold and remain at the point of first encounter, held by the strong localised thiol–gold bond. In contrast, dendrimers which form a monolayer at the air–water interface and which are laterally mobile also show two-dimensional crystalline packing.[15]

A new diastereoselective approach to simplified Dynemicin analogues

Giuseppe Guanti* and Renata Riva*

Università di Genova, Dipartimento di Chimica e Chimica Industriale, and C.N.R., CSCCCA, via Dodecaneso 31, I-16146 Genova, Italy. E-mail: guanti@chimica.unige.it, riva@chimica.unige.it

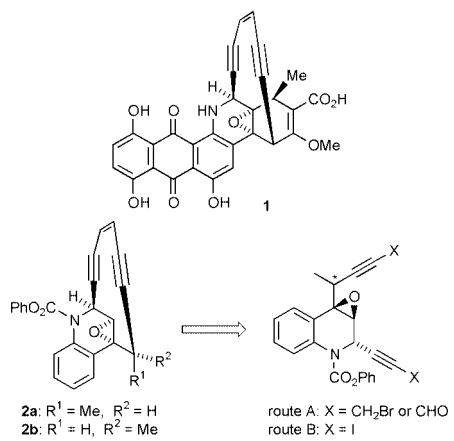
Received (in Liverpool, UK) 10th March 2000, Accepted 23rd May 2000

The stereoselective synthesis of new simplified Dynemicin analogues is reported: key steps of the sequence are the regio- and diastereo-selective functionalization of a quinoline nucleus, bearing a substituent with a stereogenic centre, and the formation of the 10-membered cyclic enediyne system by Pd-catalyzed Stille-like reaction.

Enediynes constitute an important family of recently discovered natural derivatives. Owing to their unusual molecular structure and strong cytotoxic activity, *via* unique double strand cleavage of DNA, in recent years these compounds have attracted the attention of many research groups. Dynemicin A **1** is certainly one of the most representative examples of this class of substances and the synthesis of this enediyne has been reported.[1] However, since its molecular structure is complex, many efforts have been made to synthesize simplified analogues, hopefully mimicking the activation mechanism.[2]

We recently performed a regio- and diastereo-selective nucleophilic addition of magnesium acetylides onto 2-(4-quinolyl)propan-1-ol and showed that the extent of induction was determined by the nature of the hydroxy protecting group.[3] Based on this methodology, compounds such as **5** and **6** (see Scheme 2) could be prepared in high chemical yield and moderate to good diastereomeric ratio.

Within our project in the enediyne field,[4] we planned to transform these adducts into enediynes **2a**,**b**, which are simplified analogues of **1** (Scheme 1). Although compounds with similar structure have been recently prepared by Isobe and coworkers,[5] we focused our attention on a completely different synthetic approach. The most critical step of our plan was undoubtedly the formation of the 10-membered cyclic enediyne system. For this purpose two different strategies were envisaged: (1) route A, in which the acyclic system already bears all the required ten carbon atoms; in this case the ring closure could be induced by the base-induced coupling of a bis(propargyl bromide)[6] or by an intramolecular pinacol coupling performed on a bis(aldehyde);[4b] (2) route B, in which the acyclic system, bearing only eight carbon atoms of the incoming enediyne, is coupled with a suitable two-carbon unit.[1a,7]



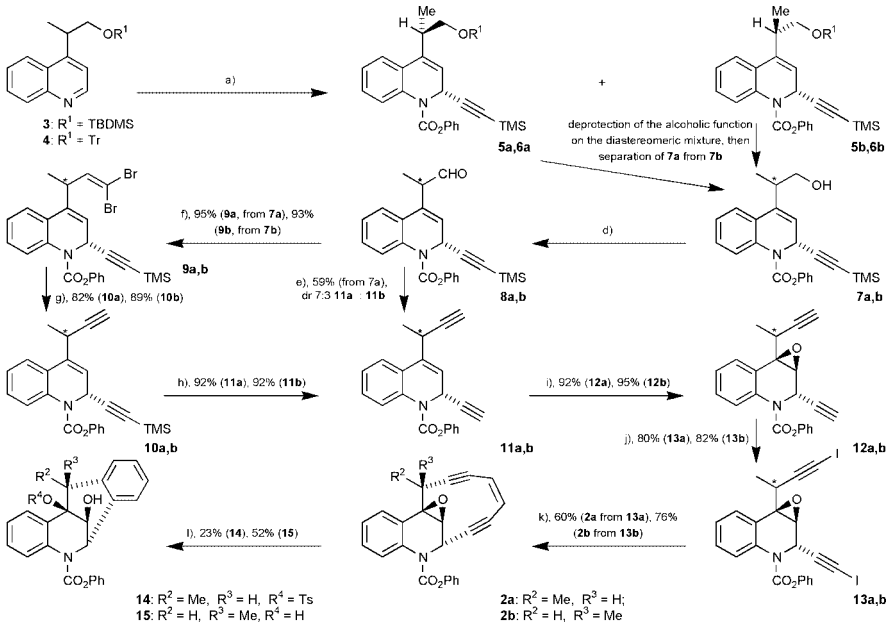
Scheme 1

We first explored route A. For this purpose, after deprotection of the alcoholic function of **5** (R^1 = TBDMS) and **6** (R^1 = triphenylmethyl (Tr)), obtained as 68:32 and 87:13 diastereomeric mixtures respectively, and chromatographic separation of the epimeric **7a** and **7b**, we separately transformed them into the diacetylenic intermediates **11** and **12**, following the procedure reported in Scheme 2. Owing to the propensity of **8a**,**b** to epimerize, the oxidation of the primary alcoholic function to the aldehyde was troublesome, either under Dess–Martin conditions, which were successfully used for the preparation of enediyne intermediates,[8] or under standard Swern conditions. Finally, we succeeded in performing the reaction under slightly modified Swern conditions[9] and **8a**,**b** were used just after aqueous work-up. The homologation of the aldehyde function of **8a** was first attempted through the one-pot sequence proposed by Ohira,[10] which directly allowed the preparation of **11a** in quite good yield (59%), but with extended epimerization, leading to a 7:3 mixture of **11a** and **11b**, probably due to the basic reaction conditions. We then examined the possibility to utilize the Corey–Fuchs[11] procedure. While the preparation of dibromides **9a**,**b** was realized without problems, the transformation of them to give alkyne moieties was more difficult than expected: after many attempts, in which all the possible factors affecting this transformation were examined, the optimal conditions were found to be treatment of **9a**,**b** with Bu^nLi for 15 min at low temperature under argon; on the other hand, working under nitrogen, the reaction was sluggish and the isolated yields of **10a**,**b** were never higher than 40%! C-Desilylation under basic conditions gave **11a**,**b**, and the overall chemical yield from **7a**,**b** was higher (72 and 76% respectively) than that obtained by the previously attempted one-step sequence and, most importantly, no epimerization was observed. Epoxidation of the double bond to give **12a**,**b** was straightforward and completely stereoselective, as expected from literature data.[5a]

With **10a**,**b**, **11a**,**b** and **12a**,**b** in hand, we tried to perform the homologation of the acetylenic functions. However, all attempts to substitute the acetylenic hydrogens with an alkoxymethyl moiety or a synthetic equivalent were unsuccessful.

At this point we turned our attention to route B and examined the possibility to build the enediynic system through a Stille double coupling reaction. This approach was not straightforward; indeed this methodology has been applied only in a few cases to generate cyclic 3-ene-1,5-diyne systems,[1a,7] but always on partially rigid systems, for which the ring closure should be easier than in our case. For this purpose we prepared the diastereomeric bis(iodides) **13a** and **13b** by simultaneous iodination with *N*-iodosuccinimide/$AgNO_3$[12] of both alkyne functions of **12a**,**b** and then performed the Pd(0)-catalyzed cross-coupling reaction with (*Z*)-bis(trimetylstannyl)ethylene. The first attempts were unsuccessful, but eventually, after a careful optimization of reaction conditions [solvent, temperature, choice of Pd(0) source, use of additives, high dilution in order to minimize intermolecular attack of tin reagent], we were able to obtain the epimeric enediynes **2a**,**b** in satisfactory yields. The different yields (60% for **2a** *cf.* 76% for **2b**)

DOI: 10.1039/b002031l



Scheme 2 *Reagents and conditions*: (a) TMS–C≡C–MgBr, $PhCO_2Cl$, THF, −78 °C, R^1 = TBDMS: 87%, 68 : 32 **5a** : **5b**, R^1 = Tr: 98%, 87 : 13 **6a** : **6b**; (b) R^1 = TBDMS: HF, MeCN, −20 → 10 °C, 91%; (c) R^1 = Tr: *p*-TSA, MeOH, 0 °C, 99%; (d) $(COCl)_2$, DMSO, Pr^1_2EtN, −78 °C; (e) $MeCOCN_2P(O)(OMe)_2$, K_2CO_3, MeOH, 0 °C; (f) CBr_4, PPh_3, THF, −78 → −50 °C; (g) Bu^nLi, toluene, −78 °C, Ar; (h) $NaHCO_3$, MeOH, 60 °C; (i) *m*-CPBA, CH_2Cl_2, 0 °C; (j) NIS, $AgNO_3$, THF, r.t., dark; (k) (*Z*)-$Me_3SnCH{=}CHSnMe_3$, $Pd(PPh_3)_4$, LiCl, DMF, 70 °C; (l) i, *p*-TSA (0.5 M sol. in THF), benzene, cyclohexa-1,4-diene, r.t., 30 min; ii, Et_3N, r.t., 24 h.

confirmed our expectations, based on molecular mechanics calculations performed with the CS Chem3D program (Cambridge Soft, Cambridge, MA, USA, version 4.0). For both iodides we found about eight further stable conformations with similar energy, as expected for systems which are not conformationally blocked. The distance between the two iodine bearing sp carbons is in the range 5.0–6.0 Å for **13a** and 4.1–4.4 Å for **13b**. As a result, **13b** is therefore best suited for the new C–C bond forming reaction, owing to the proximity of the two terminal sp carbons.

Finally, we tested the propensity of these compounds to undergo Bergman cycloaromatization, which is responsible for the biological activity of most enediyne derivatives. On Dynemicin and analogues, cycloaromatization usually takes place as soon as the epoxide is opened.[1,2,5*a*,7*a*,13] For this reason we submitted both **2a**,**b** to epoxide opening in the presence of *p*-toluenesulfonic acid.[5*a*,13*a*] To our surprise, after a reaction time of one day, we isolated two different compounds, the monotosylate **14** from **2a** and diol **15** from **2b**, for which the relative configuration at the benzylic carbon is only tentatively assigned based on literature data[5*a*,13*a*] and molecular mechanics studies. At the moment we do not have an explanation for the different behaviour of the two epimers during the acid-induced cycloaromatization process, although we think that different mechanisms could take place, probably due to a different conformation of the molecule in the two epimers.

From our results it seems clear that a relative configuration like that of **7b** seems to be preferable for the synthesis of the enediyne moiety, although this is not the preferred stereoisomer in the initial stereoselective addition step. However, we believe that this is not a real problem, since, thinking to extend our protocol on (*S*)-3-acetoxy-2-(4-quinolyl)propan-1-ol derivatives,[14] the enantiodivergency of this chiral synthon and the diastereodivergency of compounds analogous to **5** and **6** should be exploited to obtain the most useful diastereoisomer for the transformation into the corresponding enediyne. Studies in this field are still in progress in our laboratories.

We thank Ms Sara Perrozzi and Ms Dina Cavallo for their contribution to this work and C.N.R., University of Genova, and MURST (COFIN 98) for financial support.

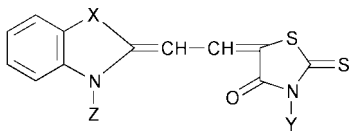
Received (in Cambridge, UK) 24th February 2000, Accepted 22nd May 2000

Porous TiO_2 electrodes sensitized using merocyanine dyes containing a carboxyl group and a long alkyl chain, in particular 3-carboxymethyl-5-[2-(3-alkyl-2-benzothiazolinyldene)ethylidene]-2-thioxo-4-thiazolidinone, showed remarkably high solar–energy efficiency (4.2%, AM-1.5, 100 mW cm^{-2}).

Since Grätzel *et al.* reported a highly efficient solar cell (incident solar light–power conversion efficiency, η_{sun} = 10%) based on a nanocrystalline TiO_2 semiconductor electrode sensitized by a Ru complex,[1,2] the studies on dye sensitization of porous oxide semiconductors have been actively investigated. Most papers on the Grätzel type solar cell so far have focused on metal complex dyes such as bipyridyl and porphyrin derivatives, and little attention has been shown to the use of organic dyes as photosensitizers. There are some early works on the spectral sensitization of non-porous semiconductors using organic dyes,[3] however, the efficiencies were quite low. It is worthwhile to develop highly efficient organic dye sensitizers from the standpoint of low cost, saving of limited precious metal resources and the easy handling for cell recycling without removal of metal, however, the efficiencies of Grätzel type cells sensitized by organic dyes were relatively low (η_{sun} < 1.3%).[4–10] Here we investigated various kinds of merocyanine organic dyes containing a carboxyl group as an anchor to attach the dye on the semiconductor surface. Merocyanine dyes have been studied on dye multi-layer photovoltaic cells based on a Shottky-type barrier at the metal/dye film contact,[11–13] but have been rarely investigated on Grätzel cells. We report here, for the first time, that some merocyanine dyes show excellent efficiencies up to η_{sun} = 4.2% on porous TiO_2 semiconductor electrodes, and also investigate the relationship between solar cell efficiency and the structure of the dyes.

All dyes were synthesized by Hayashibara Biochemical Laboratories Inc. The preparation of the porous TiO_2 film electrode on a conducting glass support (F-SnO_2,10 Ω sq^{-1}) was *via* the published procedure.[2] TiO_2 powder (Nihon Aerosil, P-25) was mainly used in order to prepare a TiO_2 paste for coating. Adsorption of a dye on the TiO_2 surface was carried out by soaking the TiO_2 electrode in a 220 mg dm^{-3} dry ethanol solution of the dye at 80 °C for 1 h, and the electrode was washed with ethanol. The dye-sensitized TiO_2 electrode was incorporated into a thin-layer sandwich-type solar cell with a Pt/conducting glass as counter electrode and electrolyte solution. To investigate the efficiency of dyes (Table 1), an Xe lamp with suitable band pass filters (3–4 mW cm^{-2}) and UV cut off filter was used as the light source. The incident solar light–electric energy conversion efficiency (η_{sun}) was measured with a solar simulator (AM-1.5, WACOM Co.).

We mainly investigated the photoelectrochemical properties of indole type [Ma, X = $C(CH_2)_2$] and benzothiazole type (Mb, X = S) merocyanines, a widely used merocyanine dye, as shown in Scheme 1. Both Ma(2)-N and Mb(2)-N dyes containing a carboxyl group adsorbed strongly on the TiO_2 surface, and showed significantly high efficiencies. On the other hand, the Mb(2)′ dye containing no carboxyl group scarcely adsorbed on TiO_2 and the cell efficiency was negligible, suggesting that the presence of anchoring groups to adsorb on the semiconductor surface is essential for efficient dye-sensitization. In the studies of solid photovoltaic cells using dye multi-layer electrodes without semiconductors,[11,13] various kinds of merocyanine dyes including Ma and Mb dyes were examined, and the carboxyl group was not essential in contrast to the dye-sensitized semiconductor cells studied here. The



Scheme 1 Structure of merocyanine dyes; for the identity of X, Y and Z see Table 1.

[a] TiO_2 film (thickness 7 μm, area 1 cm^2) prepared from P-25. The electrolyte solution was a mixture of tetrapropylammonium iodide (0.5 M) and iodine (0.05 M) in ethylene carbonate–dry acetonitrile (60:40 v/v). [b] In ethanol; values in parentheses were measured on TiO_2. [c] IPCE was measured by monochromatic light at near λ_{max} using band pass filters. [d] Under white light from an Xe lamp > 420 nm (80 mW cm^{-2}).

DOI: 10.1039/b001517m

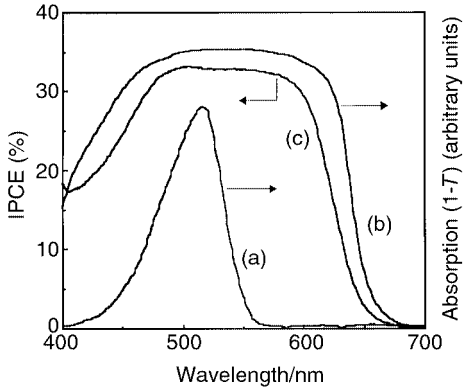

Fig. 1 Absorption spectra of Mb(2)-N in ethanol solution (a), Mb(2)-N on TiO_2 electrode (b) and IPCE action spectrum of the Mb(2)-N/TiO_2 cell (c). The TiO_2 electrode and the electrolyte were same as indicated in Table 1.

incident photon–current efficiencies (IPCE) of the dye-sensitized semiconductor cells in our study were superior to those of solid photovoltaic cells (IPCE < 22%).[11–13]

Fig. 1 shows the light absorption spectra of Mb(2)-N in ethanol solution (a) and Mb(2)-N on a TiO_2 electrode (b), in addition to the IPCE action spectrum of the Mb(2)-N/TiO_2 cell (c). The absorption peak maximum (λ_{max}) and the absorption threshold ($\lambda_{threshold}$) of various dyes in ethanol and on TiO_2 are also shown in Table 1. All merocyanine dyes had a narrow absorption band in ethanol solution, and the peak at around 500 nm was assigned to the monomer.[12] By adsorbing the dye on the TiO_2 electrode, a broadening of the absorption spectrum and a large red shift of the absorption threshold were observed in all electrodes. The IPCE action spectrum was as broad as the absorption spectrum on TiO_2. Similar broadening and red shifts have been reported on several merocyanine multi-layer electrodes without semiconductors.[11,12] Therefore, it is suggested that the interaction between neighboring dyes causes the red shift and the broadening of the absorption. The changes of absorption on the merocyanine multilayer electrode are explained on the basis of exciton phenomena, calculated from the molecular packing structure of the dye aggregate and the coupling of transition dipoles.[11] It was reported that a J-aggregate of Mb(2)-N, which showed a large red shift and a sharp absorption peak at 610 nm, was formed in the TiO_2 mesoporous network after aqueous solution treatment.[14] In our experiments, while a large red shift of the absorption was observed, no sharp absorption peak at *ca.* 610 nm was observed. Therefore, we speculate that small J-like aggregates were formed on the TiO_2, and that chemical anchoring on the TiO_2 surface restricted the formation of large and highly oriented J-aggregates.

We investigated the merocyanines [Mb(*m*)-N] with long straight alkyl chains (carbon number: m = 2, 5, 10 and 18) in detail, since it has been reported that the formation of J-aggregates is more facile with increasing length of alkyl chain in the study of dye multi-layer electrodes.[12,13] The peak maximum and threshold of absorption for Mb(*m*)-N on TiO_2 were slightly shifted to the longer wavelength with an increase in *m* (Table 1). In addition the rise of absorption at the threshold became sharp with increasing *m*. The IPCE of Mb(*m*)-N/TiO_2 cells at *ca.* 520 nm increased with an increase of *m*, and these electrodes had the same values of light harvesting efficiency at 520 nm. Therefore, it is suggested that the intrinsic sensitization efficiency, *i.e.* quantum efficiency, increased with the length of alkyl chain.

In discussing the relationship between the sensitization efficiency and the presence of long alkyl chains the electron injection process from the excited state of the dye to the TiO_2 generally competes with other undesirable processes, and photo-isomerization is one of the major decay pathways for merocyanine.[10] The presence of long alkyl chains and aggregate formation probably prevents isomerization by the restriction of rotation around the methine chain. Moreover, in the J-aggregate crystal structure of Mb(2)-N sodium salt octahydrate,[14] the alkyl chain is located at the opposite side of the carboxyl group, and the formation of single isomers and uniform orientation of the dye seem to be important factors for good J-aggregation. It is speculated that the repulsion between long alkyl chains and the TiO_2 surface might help form the predominant isomer, in which the alkyl chain lies far apart from the carboxyl group anchoring on the TiO_2 surface. Mb(2)-M, which has a carboxyl group at another position Z instead of position Y, showed almost same efficiency as Mb(2)-N. On the other hand, the photocurrent of Ma(2)-NM containing two carboxyl groups was very low compared with that of Ma(2)-N containing one carboxyl group. The configuration and aggregation of Ma(2)-NM on TiO_2 were very restricted by two anchors, and this might affect the photocurrent. From all the results, it is concluded that the control of configuration and aggregation of the merocyanine dye are very important factors in improving the solar cell efficiency.

Finally, we improved the efficiency of the Mb(18)-N/TiO_2 solar cell using thicker TiO_2 films (*ca.* 13 μm thickness) prepared by the alkoxide method using a different electrolyte solution consisting of a mixture of LiI (0.1 M), 1,2-dimethyl-3-propylimidazolium iodide (0.6 M), iodine (0.05 M), 4-*tert*-butylpyridine (1 M) and methoxyacetonitrile as solvent.[2,15] The maximum η_{sun} value under solar simulated light (100 mW cm^{-2}, AM-1.5, 0.25 cm^2) was *ca.* 4.2% (Isc: 9.7 mA cm^{-2}, Voc: 0.62 V, ff: 69%), the best value among organic dye systems reported so far.[3–10] The stability of these dyes in a sealed solar cell is now under investigation.

cis-[Ru(PMe$_3$)$_4$(H)$_2$] (1) reacts by two distinct photochemical pathways resulting in the formation of [Ru(PMe$_3$)$_4$] and [Ru(PMe$_3$)$_3$(H)$_2$]; derivatives of these intermediates are generated in the presence of CO and Ph$_2$SiH$_2$.

Photochemical loss of H_2 from *cis*-metal dihydride complexes is a general phenomenon widely employed to generate reactive unsaturated species.[1] We have demonstrated by laser flash photolysis, matrix isolation and steady state photolysis of the complexes [Ru(R$_2$PCH$_2$CH$_2$PR$_2$)$_2$H$_2$] (R = Me, Et, Ph, C$_2$F$_5$) that irradiation induces efficient loss of H_2 and formation of square-planar [Ru(R$_2$PCH$_2$CH$_2$PR$_2$)$_2$] intermediates.[2] It is therefore puzzling that UV irradiation of *cis*-[Ru(PMe$_3$)$_4$(H)$_2$] (**1**) in the presence of R$_3$SiH (R = Me, Ph) results in quantitative loss of PMe$_3$ and formation of [Ru(PMe$_3$)$_3$(SiR$_3$)(H)$_3$].[3,4] Here we present an investigation of the low-temperature matrix, transient-solution and steady-state photochemistry of **1**. We show that the reaction with R$_3$SiH creates the illusion of a single pathway. Our evidence reveals two photochemical pathways involving 16-electron intermediates, one gives rise to [Ru(PMe$_3$)$_4$] (**2**) and the other to [Ru(PMe$_3$)$_3$(H)$_2$] (**3**).

When **1** was irradiated under CO in [$^2H_6$]benzene (or [$^2H_8$]-toluene), two monocarbonyls *cis, mer*-[Ru(PMe$_3$)$_3$(CO)(H)$_2$] (**4**)[5] and [Ru(PMe$_3$)$_4$(CO)] (**5**)[6] and two dicarbonyls [Ru(PMe$_3$)$_2$(CO)$_2$(H)$_2$] (**6**)[7] and [Ru(PMe$_3$)$_3$(CO)$_2$] (**7**),[8,9] were identified by their characteristic ^{1}H and ^{31}P NMR as well as their solution IR spectra (ESI†). The number of CO groups in each species was counted *via* the ^{31}P NMR spectrum with ^{13}CO labelled material.[10] The identity of the products obtained by steady-state solution photolysis suggests the occurrence of photochemical loss of H_2 in competition with the loss of PMe$_3$ established previously.[3,4] In order to test this hypothesis, we turned to matrix isolation in conjunction with time-resolved spectroscopy in solution.

Complex **1** was isolated in an Ar matrix at 12 K.[11] After UV irradiation (17 min, 273 < λ < 400 nm), the originally colourless matrix turned purple and the area of the ν(Ru–H) bands (1820 cm^{-1}) decreased by 11%. A weak new band in the ν(Ru–H) region was observed at *ca*. 1790 cm^{-1}. The UV–VIS spectrum showed new bands at 543 and *ca*. 304 nm (Fig. 1). Subsequent selective photolysis (λ > 520 nm) depleted the principal initial photoproduct leaving bands of another species with λ_{max} = 503, *ca*. 610 nm. UV irradiation (273 < λ < 400 nm, 30 min) of **1** in an Ar + 1.5% CO matrix, resulted in new bands in the ν(CO) region assigned to **4**, **5** and **7** (Table 1, ESI†).

Laser flash photolysis (308 nm)[12] of **1** in cyclohexane solution under argon generated a transient within the instrumental response time, which decayed by second order kinetics ($k_2/\varepsilon l$ = 2.9 × 10^5 s^{-1}). The spectrum under 400 Torr of H_2 recorded by this method (λ_{max} = 550 ± 5 nm) greatly resembled the one obtained after photolysis in inert matrices (Fig. 1). The transient reacted with a variety of reagents giving pseudo-first order rate constants which varied linearly with the concentration of added quencher (Fig. S1, ESI†). The resulting second order rate constants are: k(CO) = (8.9 ± 0.4) × 10^8 > k(H$_2$) = (5.6 ± 0.4) × 10^8 > k(Et$_2$SiH$_2$) = (2.2 ± 0.1) × 10^7 > k(PMe$_3$) = (1.1 ± 0.1) × 10^6 > k(Et$_3$SiH) = (2.8 ± 0.1) × 10^5 > k(PEt$_3$) = (2.7 ± 0.8) × 10^5 > k(C$_2$H$_4$) = (1.8 ± 0.1) × 10^5 dm^3 mol^{-1} s^{-1}.[13]

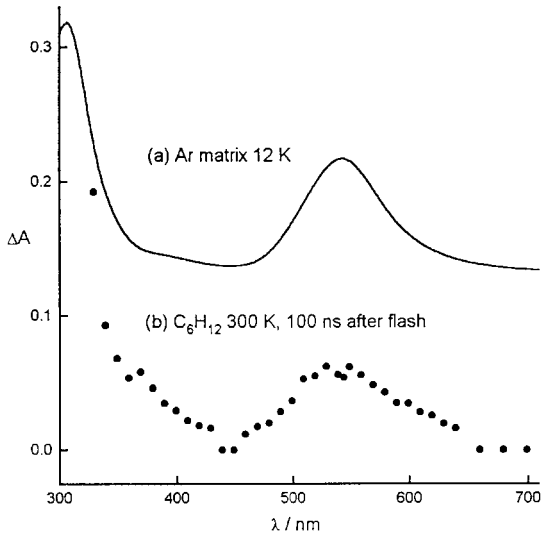

Fig. 1 (*a*) UV–VIS spectrum following photolysis of **1** in an argon matrix at 12 K (17 min, 273 < λ < 400 nm). (*b*) Point-by-point transient spectrum at 300 K measured 100 ns after laser flash photolysis (308 nm) of **1** in cyclohexane under 400 Torr H_2.

When the decay of the transient generated under H_2 was complete, no net change in absorbance was observed at any wavelength from 350 to 800 nm. In contrast, a high net change in absorbance at 350 nm in the presence of PMe$_3$ (< 0.1 mol dm^{-3}) implicated a longer-lived photoproduct.[14] This behaviour can be understood if the extinction coefficient in the visible region of **2** greatly exceeds that of **3**. The principal transient species observed by UV–VIS spectroscopy is then **2**. Reaction of **2** with H_2 would regenerate **1**, while treatment with PMe$_3$ would result in [Ru(PMe$_3$)$_5$] (probably unstable).

Further kinetic information was obtained by time-resolved infrared (TRIR) spectroscopy. A cyclohexane solution of **1** under CO was irradiated with a pulsed laser (266 nm) and the IR spectrum measured in a point-by-point fashion.[15] The TRIR spectrum showed a well-defined band at 1929 cm^{-1} due to **4** (Fig. 2). The second order rate constant for formation of **4** was determined [p(CO) = 150 to 760 Torr] as k_2 = (5.1 ± 0.6) × 10^7 dm^3 mol^{-1} s^{-1}. Since this value is about 17 times smaller than the rate constant for reaction of the UV–VIS transient with CO (see above), we postulate that **2** is the only transient *observable* by flash photolysis with UV–VIS detection.[16]

† Electronic supplementary information (ESI) available: IR spectral data for **4**–**7** (Table 1) and kinetic data (Fig. S1). See http://www.rsc.org/suppdata/cc/b0/b002297g/

DOI: 10.1039/b002297g

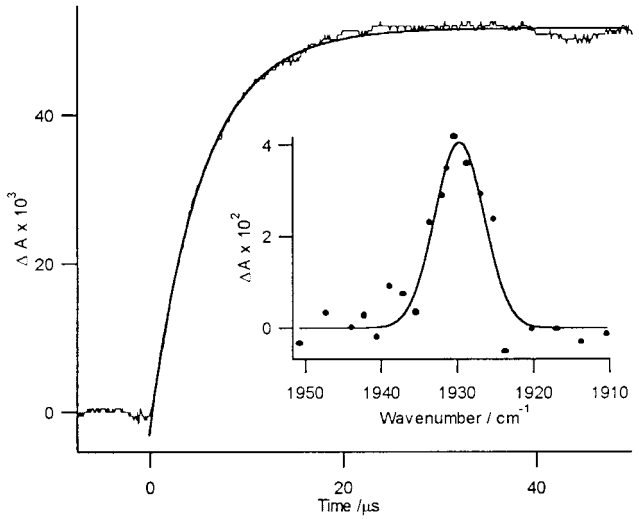

Fig. 2 Growth of ν(CO) band at 1929 cm^{-1} of **4** measured by TRIR spectroscopy after flash photolysis (266 nm) of **1** in cyclohexane under 300 Torr CO. Inset shows partial spectrum 23 μs after flash.

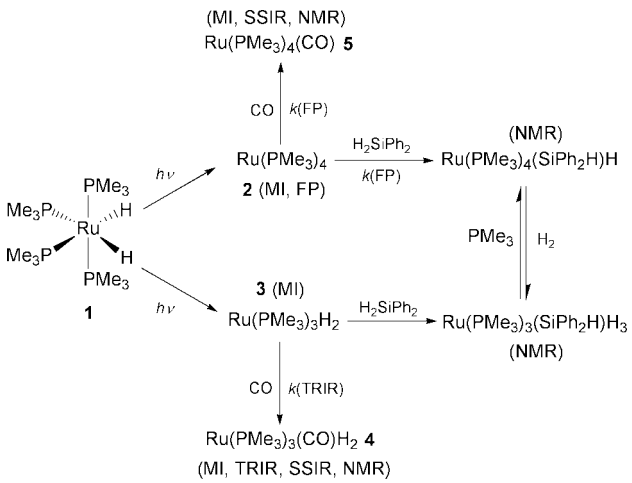
At this stage, we knew that laser flash photolysis of **1** generates **2** which reacts with Et_3SiH, presumably to give $[Ru(PMe_3)_4(SiEt_3)H]$. In apparent contradiction, steady state photolysis of **1** with Me_3SiH or Ph_3SiH only gives $[Ru(PMe_3)_3(SiR_3)(H)_3]$ (R = Me, Ph), derived from loss of PMe_3.[3,4] We therefore investigated the products of irradiating **1** with silanes by NMR spectroscopy. Low temperature photolysis in [$^2H_8$]toluene at 195 K in the presence of $HSiMe_3$ or $HSiEt_3$ generated the trihydrides but did not reveal the anticipated H_2-loss products. Reasoning that silanes with a smaller cone angle would stabilise $[Ru(PMe_3)_4(SiR_3)H]$, we irradiated **1** in the presence of dihydridosilanes. Photolysis of **1** with Ph_2SiH_2 yielded *cis*-$[Ru(PMe_3)_4(SiPh_2H)H]$ and $[Ru(PMe_3)_3(SiPh_2H)(H)_3]$[17] with an initial ratio of quantum yields of *ca.* 1:4.5 respectively.[18] Similar results were obtained with Et_2SiH_2, $HSi(OMe)_2$(allyl) and $HSiMe_2$(allyl).

Our evidence from a variety of methods now provides a consistent view of the photochemistry of **1** (Scheme 1). Two photochemical pathways act in competition: loss of PMe_3 occurs with a quantum yield *ca.* 4.5 times that for loss of H_2 in solution. We postulate that the H_2-loss products, *cis*-$[Ru(PMe_3)_4(SiR_3)H]$, are generated initially with all silanes, but if the silane is bulky (R = Me, Et, Ph), these products are labile and are converted to $[Ru(PMe_3)_3(SiR_3)(H)_3]$. Rapid displacement of PMe_3 by H_2 from *cis*-$[Ru(PMe_3)_4(SiR_3)H]$ has also been observed by Berry.[19] Competitive photodissociation of dihydrogen and phosphine has been encountered in the tetrahydride system $[Os(H)_4(PMe_2Ph)_3]$,[20] but H_2 photodissociation is the sole pathway in $[Ir(\eta^5\text{-}C_5Me_5)(PMe_3)(H)_2]$.[21]



Scheme 1 The photoreactivity of **1** showing the reactions of the primary photoproducts with CO and Ph_2SiH_2. The methods employed for detection are indicated: MI = matrix isolation, FP = flash photolysis, TRIR = time resolved IR, SSIR = IR spectroscopy following steady-state irradiation and NMR = NMR spectroscopy following steady-state irradiation.

We are grateful for support from CONACYT (México), ORS Awards, The British Council-Alliance Programme and to Professor D. H. Berry, Dr J. N. Moore and Dr S. B. Duckett for helpful discussions.

10 $^{31}P\{^1H\}$ NMR (121.5 MHz, [$^2H_8$]toluene, 300 K). $[Ru(PMe_3)_3(^{13}CO)(H)_2]$: δ 1.0 (dd, $^2J_{PP}$ 25.4 and $^2J_{PC}$ 10.5 Hz), δ −9.3 (td, $^2J_{PP}$ 24.7 and $^2J_{PC}$ 9 Hz); $[Ru(PMe_3)_2(^{13}CO)_2(H)_2]$: δ −0.8 (t, $^2J_{PC}$ 9.5 Hz); $[Ru(PMe_3)_3(^{13}CO)_2]$: δ −4.3 (t, $^2J_{PC}$ 8.4 Hz); $[Ru(PMe_3)_4(^{13}CO)]$: δ −9.8 (d, $^2J_{PC}$ 2.9 Hz).
11 Compound **1** was sublimed at 328 K and cocondensed with argon onto a window cooled to 20 K. The matrix was cooled to 12 K, see D. M. Haddleton, A. McCamley and R. N. Perutz, *J. Am. Chem. Soc.*, 1988 **110**, 1810.
12 Laser flash photolysis experiments were performed using a XeCl excimer laser (λ_{exc} = 308 nm, pulse width *ca.* 50 ns).[2]
13 E. Wilhelm and R. Battino, *Chem. Rev.*, 1973, **73**, 1. The solubilities of CO, H_2 and C_2H_4 in cyclohexane were taken as 9.3×10^{-3}, 3.8×10^{-3} and 1.4×10^{-1} mol dm^{-3} atm^{-1} respectively. Errors in rate constants are quoted to 95% confidence limits.
14 The rate constant for reaction with PMe_3 did not vary significantly with the wavelength of measurement.
15 Nd:YAG laser (λ_{exc} = 266 nm, detection with diode IR laser, CaF_2 windows, 1 mm pathlength), see M. W. George, M. Poliakoff and J. J. Turner, *Analyst*, 1994, **119**, 551.
16 The detection of the ν(CO) band of **5** by TRIR spectroscopy proved difficult due to overlap with the Ru–H stretching mode of **1** and its low IR extinction coefficient. To our surprise, bands were observed at 1828 and 1881 cm^{-1} (rise time < 1 μs) which correspond to the multiple substitution product **7** even when using an open-flow system. They were confirmed to result from a single-photon process. This species may be derived from hot **2** (full details will be published elsewhere).
17 Selected NMR data [$^2H_8$]toluene, 294 K. $[Ru(PMe_3)_4H(SiPh_2H)]$ ^1H NMR (400.1 MHz): δ −10.3 (dq, 1 H, $^2J_{HP}$ 67, 22.5 Hz, RuH), 5.9 (tt, 1H, $^3J_{PH}$ 14.6, 4.7 Hz, $SiPh_2H$). ^{31}P NMR (162 MHz): ABX_2 δ -0.1 (m, $^2J_{PP}$ 25, 23.7 Hz, X_2), −10.2 (m, $^2J_{PP}$ 25, 16 Hz, A) and −10.7 (m, $^2J_{PP}$ 25, 16 Hz, B. $[Ru(PMe_3)_3(H)_3(SiPh_2H)]$ ^1H NMR: δ −9.5 (m, 3 H, RuH_3), 6.7 (m, 1 H, $SiPh_2H$). ^{31}P NMR: δ −10.4 (br s) J_{SiH} by ^{29}Si filtered $^1H\{^{31}P\}$ spectroscopy: 64.5 Hz.
18 Relative quantum yields were calculated from the integrations of the dangling Si–H protons of both products in the ^1H NMR spectra recorded after short photolysis times in the presence of 3 equiv. of silane. On more prolonged photolysis, the ratio of the yields approaches unity, as a result of thermal/photochemical interconversion of the products.

Received (in Basel, Switzerland) 20th March 2000, Accepted 25th May 2000

$[(Bu^tN)_2Cr(CH_2Ph)_2]$ 1 and $[(NCMe_2CH_2CH_2CMe_2N)Cr(CH_2Ph)_2]$ 2 are robust single-component catalysts for the polymerisation of acrylonitrile, which afford high-molecular-weight PAN and also allow acrylonitrile–methyl methacrylate copolymerisation; owing to its strained seven-membered chelate ring, 2 exhibits exceptionally small imido bond angles.

The polymerisation of α-olefins by titanocene- and zirconocene-based catalysts is of great technological relevance.[1] Nevertheless, there is increasing interest in the development of novel non-metallocene catalysts for olefin polymerisation, since these may allow, *inter alia*, an even greater control over polymer properties. Several new catalyst families have been described in this context,[2] one of them being di(organoimido)-chromium(VI) complexes of the type $(RN)_2CrX_2$ (X = Cl, Me, CH_2Ph),[3] which have proved to be excellently suited to the polymerisation of ethylene in the presence of a cocatalyst.[4] Owing to their comparatively low Lewis acidity, catalysts based on group 6 metals may be more tolerant towards polar, functionalised olefins than group 4 metal systems. For example, complexes of the type $(RN)_2CrCl_2$ have been shown to tolerate ester groups in the cyclopropanation of olefins.[5] We report here on the polymerisation of acrylonitrile by di(organoimido)chromium(VI) complexes.

We have utilised $[(Bu^tN)_2Cr(CH_2Ph)_2]$[3a] **1** and the novel *ansa*-di(organoimido) complex $[(NCMe_2CH_2CH_2CMe_2N)Cr(CH_2Ph)_2]$ **2**‡ as catalysts. **2** bears an isolobal relationship to group 4 *ansa*-metallocene derivatives.[6] Its structure has been determined by single-crystal X-ray diffraction (Fig. 1)§ and resembles that of **1**.[3b] Both compounds contain an η^1- and an η^2-benzyl ligand. In solution, however, only one set of ^{1}H NMR resonances is observed for the two benzyl ligands even at low temperatures owing to rapid averaging. The most striking differences between **1** and **2** are due to the strained seven-membered chelate ring present in **2**, which causes exceptionally small imido bond angles (Table 1). A similar structural effect was recently observed in the chemistry of molybdenum.[6a] A variable-temperature ^{1}H NMR study (500.1 MHz, $[^2H_8]$toluene solvent) reveals that the chelate ring is moderately flexible in solution. At room temperature, a single, averaged signal at δ 1.82 is observed for the four protons of the CH_2CH_2 unit, which is compatible with an averaged C_{2v}-symmetric structure. The singlet shows coalescence at *ca.* −10 °C. At −70 °C two well separated signals (2 × 2 lines) are observed at δ 1.25 and 2.35, which is in agreement with the AA′BB′ spin system expected for a rigid C_2-symmetric ligand framework. $\Delta G^{\#}$ is *ca.* 48 kJ mol^{-1} for the ring inversion.

	1	**2**
Cr–N	162.5(2)/163.2(2)	163.1(3)/163.3(3)
N–Cr–N	116.09(8)	104.19(16)
Cr–N–C	166.07(13)/160.60(13)	146.8(3)/147.3(3)

Complexes **1** and **2** are active catalysts for the polymerisation of the polar, functionalised olefin acrylonitrile (AN). No cocatalyst is needed.¶ In all cases studied the polymerisation started immediately and continued for an extended period of time (Fig. 2). Initially, the polyacrylonitrile (PAN) yield increased linearly, and during the course of the reaction it approached an upper limit. After a while the clear solution became cloudy and a white precipitate was observed. At the same time the viscosity started to increase. The molecular weight reached remarkably high values, and the polydispersity (M_w/M_n) decreased slightly with the conversion (Fig. 2). The PAN produced by **1** and **2** had approximately the same tacticity (Table 2).[7] Copolymerisation experiments were performed with acrylonitrile and methyl methacrylate (MMA). The low glass

transition temperature T_g in comparison with T_g of the respective homopolymer PAN and PMMA indicates that the products obtained must be copolymers (Table 3).

The metal-catalysed polymerisation and copolymerisation of acrylonitrile is unprecedented. We are currently investigating the polymerisation mechanism. We note that with rigid ligand architectures of appropriate symmetry the formation of stereoregular functionalised polyolefins may be feasible, if the polymerisation mechanism is essentially metal-centered.

¶ *Experimental procedures*: polymerisations of acrylonitrile were carried out under argon in a 100 ml flask equipped with a magnetic stirrer and a cooling jacket. Typically, polymerisations were run with 0.012 mmol of **1** or **2** and 300 mmol of acrylonitrile in toluene solution (40 ml) at 20 °C. The reactions were carried out in the dark to exclude radical formation, since usually polyacrylonitrile is prepared by radical polymerisation. The reactions were quenched with methanol. The white fine powder which precipitated was filtered off and dried *in vacuo* at 60 °C for 12 h. Copolymerisation experiments with acrylonitrile and methyl methacrylate were made under essentially identical conditions, utilising 0.02 mmol of **1** or **2** in toluene solution.

α-LNA, locked nucleic acid with α-D-configuration

Poul Nielsen* and Jakob Kragh Dalskov

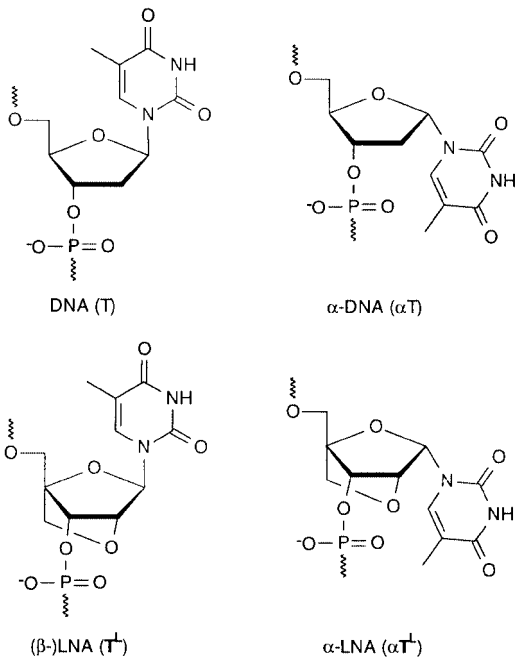
Department of Chemistry, University of Southern Denmark, Odense University, 5230 Odense M, Denmark. E-mail: pon@chem.sdu.dk

Received (in Cambridge, UK) 18th April 2000, Accepted 16th May 2000

The bicyclic thymine monomer of α-LNA (αT^L) was efficiently synthesised and used in the synthesis of α-LNA sequences: incorporation of single αT^L-monomers in α-configured oligothymidylates destabilises the affinity towards both complementary DNA and RNA, whereas a fully modified α-LNA sequence displays a very efficient recognition of complementary RNA.

Conformationally restricted oligonucleotide analogues have been intensively investigated for their abilities in high affinity nucleic acid recognition.[1] As a prime example, LNA (locked nucleic acid)† has recently been introduced as a nucleic acid analogue displaying unprecedented affinity towards DNA and RNA.[2] The anomeric inverted analogue of DNA (α-DNA) has been demonstrated to hybridise efficiently with complementary DNA and RNA with a parallel strand orientation, and to be highly resistant towards degradation by nucleases.[3] Chemically modified analogues of α-DNA have also been investigated,[4] including the introduction of α-configured bicyclic nucleoside monomers.[5]

The α-2′-deoxynucleoside monomers in α-DNA as well as the β-2′-deoxynucleoside monomers in DNA exist in an equilibrium between the two low-energy N- and S-type conformational ranges.[6,7] In none of the α-DNA analogues, investigated so far,[4,5] have the monomers been efficiently restricted towards N-type conformations. Hoping to obtain an unprecedented parallel nucleic acid recognition and, thereby, a new tool in the development of diagnostic probes and antisense therapeutics, we therefore decided to examine the incorporation into oligonucleotides of an α-nucleoside analogue which is conformationally locked in an N-type conformation, *i.e.* α-LNA.‡



In order to synthesise the α-LNA thymine monomer (αT^L, **4**, Scheme 1) we first investigated the coupling of thymine to appropriate bicyclic carbohydrate precursors.[9] However, this approach has never been optimised to give the target compound in a satisfactory yield, and we hereby introduce an alternative synthetic strategy. The starting methyl furanoside **1** was obtained, as described previously,[9] and used in a modified Vorbrüggen nucleobase coupling reaction (Scheme 1). After varying the reaction conditions, the best result in terms of yield and ratio of products was obtained by using *in situ* TMS-protection of both the 2′- hydroxy functionality in **1** and the thymine, followed by coupling by using TMS-triflate as the Lewis acid in refluxing acetonitrile for seven days. After desilylation, the mixture of nucleosides was reacted with sodium hydride to give the anomeric mixture **2** (α:β ≈ 1.3:1 according to ^{1}H NMR) in 57% overall yield. After removal of the benzyl groups by hydrogenation, the β- and α-LNA monomers (**3**[2] and **4**,[9] respectively) were obtained in 98% yield and separated. The configuration of **4** was confirmed by comparison of NMR data with its exact enantiomer[8d] and by NOE-difference spectra as mutual contacts were observed between H-1′ and H-3′ and between H-5″ and H-6, respectively. The αT^L monomer **4** was prepared for incorporation into oligonucleotide sequences by protection, by using the dimethoxytrityl (DMT) group to give **5**, followed by phosphitylation to give the phosphoramidite synthon **6**.§ This compound was used in automated solid phase synthesis of oligonucleotides by using the phosphoramidite approach.[10] In connection with the α-thymidine (αT) phosphoramidite, the α-LNA sequences were obtained (Table 1) by using tetrazole activation and 10 min coupling times giving > 98% stepwise coupling yields. The modified oligomers **8**–**10** and **12**, **13** were synthesised by using the DMT-*ON* mode on universal CPG-support (Biogenex), which allowed the synthesis of fully modified sequences after cleavage from the solid support by using LiCl in aqueous

[a] Melting temperatures (T_m) obtained from the maxima of the first derivatives of the melting curve (A_{260} *vs.* temperature) recorded in a buffer containing 10 mM Na_2HPO_4, 100 mM NaCl, 0.1 mM EDTA, pH 7.0 using 1.5 μM concentrations of the two complementary sequences, assuming identical extinction coefficients for all thymine nucleotides. [b] The change in T_m value per modification compared with the reference strand **8**. [c] Not determined. [d] No clear cooperative transition was seen. [e] Compared with **12**. [f] Compared with **11**.

ammonia. The oligomers were purified by using disposable reverse phase chromatography cartridges (Cruachem), which yielded products with > 90% purity, as judged from capillary gel electrophoresis. The compositions of α-LNA sequences were verified from MALDI-MS spectra.¶

The α-LNA sequences **9**, **10** and **13**, as well as their α-DNA counterparts **8** and **12**, were mixed with their DNA and RNA complements and the resulting hybridisation data are shown in Table 1. Compared to the unmodified sequence **7**, the affinity of the unmodified α-sequence **8** towards dA_{14} is, as expected,[3] similar. However, the introduction of one or four α-LNA monomers (**9** or **10**, respectively) results in strongly decreased affinities towards dA_{14}. Towards complementary RNA, rA_{14}, **8** has a higher affinity than **7** and the destabilising effect of one or four α-LNA monomers is even more pronounced. However, in both cases, the introduction of a block of α-LNA monomers diminishes the combined destabilising effect (comparing ΔT_m for **9** and **10**). This suggests that the N-type conformation α-LNA monomers do not have the ability to alter neighbouring nucleosides and, thereby, change the overall single strand conformation towards a form which is more preferable for duplex formation. As judged from NMR studies, this is an important feature of the original (β-)LNA.[11]

The fully modified α-LNA sequence **13** displays strong recognition of the complementary RNA-strand (ΔT_m = +1.2 °C per monomer compared to α-DNA **12** and +2.5 °C compared to the unmodified oligodeoxynucleotide sequence **11**). On the other hand, no clear cooperative transition was seen when **13** was mixed with dA_{14}. This indicates either that α-LNA is unable to recognise DNA and is thereby extraordinarily RNA-selective or, alternatively, that the two sequences might form a secondary structure not detectable by UV-spectroscopy at 260 nm. Thus, a broad non-cooperative transition at 40–45 °C is seen in the mixture, but a similar transition is also observed for **13** alone. Even though the possibility of self-melting has been described earlier for longer α-oligothymidylate sequences,[12] the broad transition and low hyperchromicity observed for **13** alone does not indicate the melting process of a duplex structure, but rather a transition between secondary forms of single strands. The presence of a duplex between **13** and rA_{14} was confirmed by the fact that a clear melting transition of a duplex between **13** and a mis-matching complementary sequence was observed with T_m decreased by 8 °C (Table 1). Furthermore, thermal stabilities measured at higher ionic concentrations (data not shown) were increased, as expected, for all the duplexes involving **11**–**13** and RNA-complements as well as **11** and **12** with dA_{14}, whereas no clear cooperative transitions at increased temperature were observed with **13**:dA_{14} or with **13** alone.

In conclusion, α-LNA is able to form a duplex with complementary RNA with a high thermal stability comparable to other stereoisomers of LNA,[8] even though the original (β)LNA still displays the highest affinity towards complementary nucleic acids. Nevertheless, α-LNA in the present oligothymidylate sequence displays the highest affinity towards RNA of any α-D-configured oligonucleotide analogue. However, from the sequences presented here we are not able to determine whether α-LNA prefers a parallel strand orientation upon hybridisation. This subject is under investigation in our laboratories *via* the synthesis of α-LNA sequences with mixed nucleobase compositions, in addition to further examination of the properties and applications of α-LNA.

The Danish Natural Science Research Council is thanked for financial support. Ms. Britta M. Dahl, Department of Chemistry, University of Copenhagen, is thanked for synthesising oligonucleotide sequences. Dr Henrik M. Pfundheller, Exiqon A/S, is thanked for recording MALDI-MS spectra.

Notes and references

† LNA is defined as an oligonucleotide containing one or more LNA monomers which are bicyclic nucleosides preorganized in N-type conformations. α-LNA is therefore defined as an oligonucleotide containing one or more monomeric α-D-LNA nucleosides in connection to unmodified α-D-nucleosides.

‡ Three other stereoisomers of LNA have been recently introduced[8] and their affinities towards both complementary RNA and the enantiomeric L-RNA have been investigated.[8c] In that sense, an α-LNA sequence has been examined in form of the duplex between its enantiomer α-L-LNA and L-RNA, but only as an (almost) fully modified sequence and only against RNA.[8c]

Received (in Basel, Switzerland) 13th April 2000, Accepted 24th May 2000

The iodide induced dimerisation of a dppm-/diphenylphosphido-bridged Pt_2^{2+} system leads to a 56 CVE Pt_4 butterfly cluster which is diprotonated by HO_3SCF_3 to give a 60 CVE rectangular Pt_4 cluster.

An electron count of 56 or 54 for tetranuclear platinum clusters in tetrahedral geometry with a latitudinal or longitudinal ligand arrangement is predicted by theoretical studies based on $Pt(PH_3)_2$ fragments.[1] 54-electron CVE clusters are proposed to be stabilised by bridging dppm or phosphido ligands, which might be able to retain the less favourable longitudinal ligand arrangement. Taking into account that two additional electrons lead to a butterfly geometry of the Pt_4 core, we report here on a ligand controlled stabilisation of an unusual cluster electron count: a Pt_4 butterfly cluster with the hitherto unknown valence electron count of 56 is readily accessible *via* dimerisation of the diplatinum(2+) system in a suitable ligand sphere. The protonation of the cluster is associated with a novel structural rearrangement of the cluster core to a rectangular 60 CVE Pt_4 skeleton.

Treatment of $[Pt_2(\mu\text{-dppm})(\mu\text{-}PPh_2)\{\eta^2\text{-bicyclo(2.2.1)hept-2-ene}\}_2](O_3SCF_3)_2$ **1**, (Scheme 1) with 1 mol equiv. of NBu_4I in toluene–dichloromethane (4/1) produces quantitatively the tetranuclear cluster $[Pt_4(\mu\text{-dppm})_2(\mu\text{-}PPh_2)_2I_2]$ **2** (Scheme 1, Fig. 1†) as dark red red crystals which are sparingly soluble in all common organic solvents. The reaction proceeds *via* the substitution of one bicyclo(2.2.1)hept-2-ene by iodide‡ which may in turn induce the dissociation of the remaining bicyclo-(2.2.1)hept-2-ene resulting in a reactive intermediate. The formation of **2** represents a ring opening dimerisation, the overall oxidation state of the platinum centres of +1 is maintained. We do not know whether the $Pt_2(\mu\text{-}PPh_2)$ or the $Pt_2(\mu\text{-dppm})$ ring is opened. The molecular structure of **2** exhibits a butterfly shaped Pt_4 skeleton. Complying with a crystallographically imposed C_2 symmetry, the two dppm and two diphenylphosphido ligands alternately bridge between the hinge and wingtip platinum atoms. One terminal iodide ligand is attached to each wingtip.

The wingtip to hinge Pt–Pt distances are 274.03(8) pm for the dppm-bridged and 287.40(8) pm for the diphenylphosphido-bridged platinum atoms. The distance between the two hinge Pt atoms of the butterfly framework amounts to 269.33(11) pm. The dihedral angle between the two wings [144.27(2)°] is substantially larger compared with other Pt_4 butterfly clusters

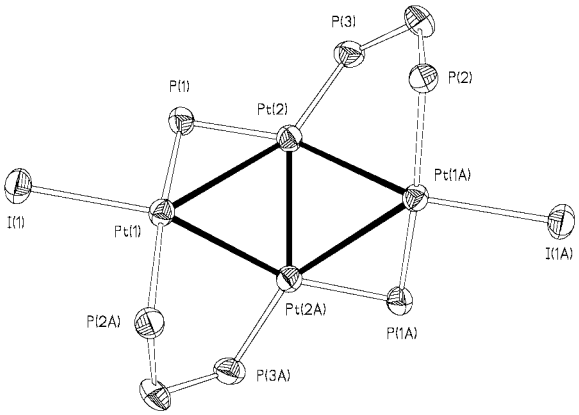

Fig. 1 Molecular structure of **2**. The phenyl groups have been omitted for clarity.

(83.7–96.8°).[3] The Pt_2P_2C rings formed by the dppm ligands adopt twist conformations. The structure seems to be retained in solution according to ^{31}P NMR spectroscopy.§

The protonation of **2** with 50% aqueous trifluoromethanesulfonic acid quantitatively produces the yellow tetranuclear dihydrido cluster $[Pt_4(\mu\text{-dppm})_2(\mu\text{-}PPh_2)_2(\mu_2\text{-}H)_2(\mu_2\text{-}I)_2](O_3SCF_3)_2$ **3** (Scheme 1, Fig. 2†) which is slightly soluble in CH_2Cl_2. The formation of **3** is accompanied by a rearrangement of the Pt_4 shape to a rectangle, a change of the geometry of the phosphido phosphorus relative to the dppm phosphorus atoms from *cis/trans* in **2** to *cis/cis* in **3** and a change to a bridging bonding mode of the iodide ligands. The phosphido bridged edges of the Pt_4 rectangle involve relatively short Pt–Pt distances [279.92(3) and 277.28(3) pm], whilst the distances of the dppm bridged platinum atoms [296.85(3) and 300.58(3) pm] indicate that the Pt–Pt interactions are weak. All sides are doubly bridged, either by dppm and iodide or by diphenylphosphido and hydride ligands making a 60-electron CVE. The hydride and iodide ligands are on the same side of the Pt_4 plane. The hydride ligands could be located *via* X-ray structure analysis and their position is confirmed by NMR spectroscopy:¶ the intensity of the hydride signal of the isotopomer containing one ^{195}Pt nucleus demonstrates a μ_2-H bonding. The P–H coupling constants involving the dppm and phosphido phospho-

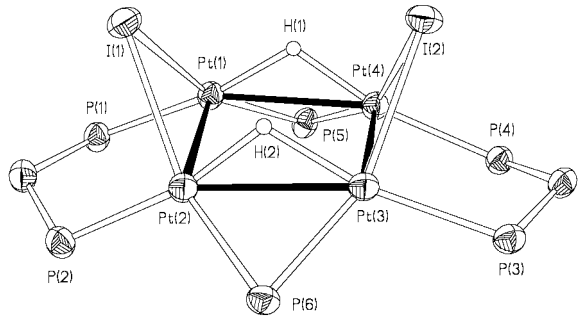

Fig. 2 Structure of the cation of **3**. The phenyl groups have been omitted for clarity.

rus atoms are 87.7 and 13.2 Hz respectively. This indicates the H–Pt–P_{dppm} angle to be distinctly larger compared with the H–Pt–$P_{phosphido}$ angle and this requires the hydride ligands to bridge the same edge as the phosphido ligands. The hydride ligands are kinetically stable on the NMR time scale at ambient temperature.

Dimerisation reactions related to the formation of **2** exist for the dipalladium(2+) system: the product of $[Pd_2(\mu\text{-dppm})_2Cl_2]$ and $NaBH_4$ was recently identified as $[Pd_4(\mu\text{-dppm})_4(\mu_4\text{-H})_2]^{2+}$ and the reaction with $[Cu(MeCN)_4]^+$ gave $[Pd_4(\mu\text{-dppm})_4(\mu_2\text{-Cl})_2]^{2+}$.[4,5] The X-ray structure of the latter product showed a rectangular Pd_4 skeleton [Pd–Pd 259.4(2) and 374.2(3) pm] consisting of two isolated Pd_2 moieties whereas no solid state structure of $[Pd_4(\mu\text{-dppm})_4(\mu_4\text{-H})_2]^{2+}$ is available. Analogous reactions of the platinum congener $[Pt_2(\mu\text{-dppm})_2Cl_2]$ leave the $[Pt_2(\mu\text{-dppm})_2]$ arrangement unchanged.[6] The different reactivities of the platinum and palladium $[M_2(\mu\text{-dppm})_2Cl_2]$ complexes have been attributed to different M–P bonding strengths. The reactivity of **1** in contrast to $[Pt_2(\mu\text{-dppm})_2Cl_2]$ is apparently due to the presence of both dppm and diphenylphosphido ligands.

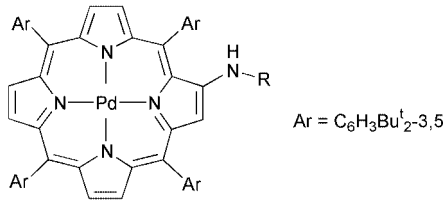
Received (in Cambridge, UK) 25th March 2000, Accepted 23rd May 2000

A palladium porphyrin has been covalently linked to a chiral lanthanide complex and effectively sensitises near-IR emission from Nd and Yb; sensitisation is enhanced in the absence of oxygen and in the presence of a nucleic acid.

The use of 'antennae' chromophores (such as substituted aryl,[1] bipyridyl[2] and phenanthridyl[3] groups) to sensitize lanthanide emission is now well established, particularly for lanthanide complexes which emit in the visible region of the spectrum, *e.g.* Eu(III) and Tb(III). The triplet energies of porphyrins (typically 12 000–17 000 cm^{-1}) render them suitable chromophores for sensitization of the relatively low-lying excited state(s) of lanthanide ions such as Yb(III) (10 200 cm^{-1}) and Nd(III) (11 360 cm^{-1}). Lanthanides with emission bands in the near-IR region of the spectrum have a variety of potential applications, including time-resolved luminescence imaging,[4] beyond the range of biological absorption or emission (*e.g.* from NADPH, haematoporphyrin). Previous work has demonstrated that Yb–porphyrin complexes possess rapid rates of energy transfer ($> 10^7$ s^{-1}) from the porphyrin antennae to the bound Yb ion[5] and the Yb emission intensity is primarily limited by quenching of the $^2F_{5/2}$ excited state involving vibrational energy transfer to bound OH oscillators.[6] In these cases, the Yb emission is insensitive to oxygen quenching of the intermediate excited porphyrin triplet. When an Yb ion is further away from the sensitising chromophore, the energy transfer step is less efficient and deactivation of the intermediate triplet state by oxygen may compete. Palladium porphyrin complexes possess particularly long-lived triplet states[7] and are subject to quite efficient oxygen quenching in polar media. Tetracationic Pd–porphyrins have been shown to bind to DNA[8] and the intercalation suppresses oxygen quenching, enhancing the phosphorescence by factors of up to 20.

With this background in mind, we have prepared a set of Pd–porphyrin conjugates which are linked to a well defined cationic, chiral lanthanide moiety. The strongly helical tetraamide complexes of Eu, Tb and Yb, incorporating an intercalating phenanthridinium moiety, have recently been shown to bind to DNA stereoselectively and with a factor of 50 in GC *vs.* AT base-pair differentiation.[9] The aim of the work described herein was to explore the sensitising ability of the proximate Pd–porphyrin chromophore for Nd and Yb emission and the effect of oxygen in the presence and absence of a simple oligonucleotide.

2-Aminoporphyrin **1** was prepared following the method described by Crossley and King.[10] Amide coupling of **1** with chloroacetic acid, using standard amide coupling conditions, followed by Pd complexation afforded the corresponding porphyrin chloroacetamide, which was then treated with an excess of KI in THF–MeCN to give the porphyrin iodoacetamide **2**. Reaction of **2** with an excess of cyclen in THF at 50 °C



1 R = H
2 R = $COCH_2I$

gave an almost quantitative yield of the monosubstituted-{Pd–porphyrin}-12-N_4. Introduction of the three chiral pendant arms onto the remaining ring nitrogens was carried out by reaction with either (*S*)- or (*R*)-2-chloro-*N*-(methylbenzyl)ethanamide to afford (*SSS*-*S*)-L^1 and the (*RRR*-*R*) isomer, respectively. Alkylation also occurred at the rather acidic amide NH position on the porphyrin periphery. Reaction of L^1 with lanthanide trifluromethanesulfonates (Yb, Nd, Gd) afforded cationic complexes which were purified by alumina preparative plate chromatography. Complexes gave ESMS, microanalyses and ^1H NMR spectra in accord with the proposed structures. For example, for $[YbL^1]^{3+}$, ESMS analysis revealed peaks at *m/z* 738 $[M]^{3+}$ and 1181 $[M + CF_3SO_3]^{2+}$ and the ^1H NMR spectrum in CD_3OD(293 K, 200 MHz) showed a single set of resonances (> 87%) for the most shifted ring axial proton for both stereoisomers at δ +100.8, 95.5, 78.2 and 72.9. Such chemical shift values are in a similar range to those observed for related tetraamide Yb complexes with a capping water molecule, in which the complex adopts a square antiprismatic coordination environment.[11]

The circular dichroism spectra for the (*RRR*)-$[NdL^1]^{3+}$, (*RRR*)-$[YbL^1]^{3+}$ and (*SSS*)-$[YbL^1]^{3+}$ complexes, in the visible range, are shown in Fig. 1. The CD spectra are dominated by the porphyrin chromophore, with the characteristic Soret band at *ca.* 422 nm (log ε = 5.36 M^{-1} cm^{-1}), and the α and β bands at 520 (log ε 4.37) and 560 nm (log ε 3.57), respectively (295 K, MeOH). The weak induced CD obtained for the (*RRR*)-Yb

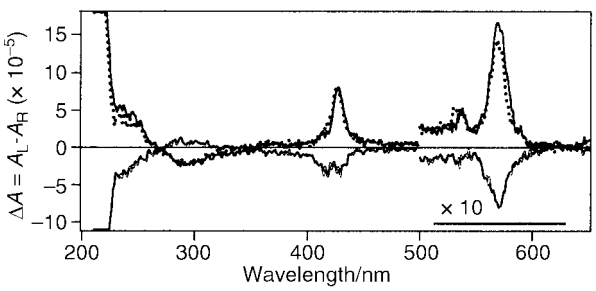


Fig. 1 CD spectra of (*RRR*-*R*)-YbL^1 (upper bold), (*RRR*-*R*)-NdL^1 (dashed) and (*SSS*-*S*)-YbL^1 (lower) (295 K, MeOH).

† Electronic supplementary information (ESI) available: emission spectra. See http://www.rsc.org/suppdata/cc/b0/b002452j/

DOI: 10.1039/b002452j

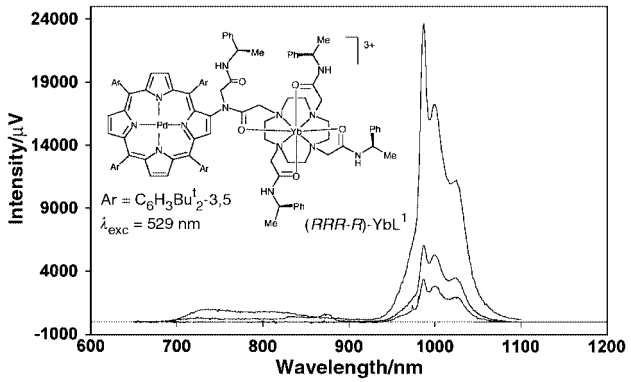

Fig. 2 Emission spectra for (*RRR*-*R*)-YbL[1] (295 K, 20% D_2O–CD_3OD, 5 μM) in degassed solution (top), in aerated solution (bottom) and in the presence of 0.1 mM $[(CG)_6]_2$.

complex resembles that of the Nd complex, with g_{abs} values of $+1.7 \times 10^{-4}$ (560 nm) and $+0.8 \times 10^{-4}$ (423 nm). Intriguingly the CD spectrum of the (*SSS*) stereoisomer showed a split Soret band (perhaps related to the change in the tertiary amide configuration in the two complexes, giving a different orientation of the porphyrin chromophore with respect to the Yb ion) and a reduced ICD at 420 and 566 nm. The chirality of the excited state of the lanthanide centre is conveniently probed using circularly polarised luminescence spectroscopy (CPL);[12] the first examples of CPL in the near-IR, following sensitised excitation in the near-UV, have only recently been reported.[13] With (*RRR*)-$[YbL^1]^{3+}$, weak CPL was observed following excitation at 529 nm, with $g_{em} = -0.04$ (985 nm) and $+0.05$ (963 nm) and a very similar spectrum, with the opposite polarisation was observed for the (*SSS*) complex. CPL spectra were also measured for the (*RRR*)-Nd complex and, for the first time, small, but measurable, CPL was observed for the $^4F_{3/2} - {}^4I_{9/2}$ transitions [*e.g.* $g_{em} = +0.015$ (884 nm)] and for the $^4F_{3/2}$–$^4I_{11/2}$ transition [$g_{em} = -0.006$ (1055 nm)].

The total emission spectra for the Yb and Nd porphyrin conjugates were measured in aerated and degassed MeOH and CD_3OD (Fig. 2), following excitation at 529 nm. Enhanced emission from the Ln ion was observed in the deuteriated solvent (a factor of 4 for Yb and 2.5 for Nd), reflecting the known sensitivity of the excited ion to quenching by OH oscillators.[6] In the absence of oxygen, the phosphorescence from the Pd–porphyrin appeared as a broad emission with maxima at *ca*. 735 and 800 nm, while that due to the lanthanide was also enhanced (a factor of 7 for Yb and 2 for Nd). The excitation spectra of degassed samples, observing the emission from Yb at 980 nm and Nd at 1064 or 870 nm, revealed the same spectrum which matched the porphyrin absorption spectrum of the separate complexes. Taken together such behaviour is consistent with competitive rates of energy transfer and triplet quenching by oxygen. The energy transfer to Nd is considerably more efficient than to Yb, as a consequence of the better spectral overlap integral (Nd: absorption maxima at 740, 794 and 865 nm (with ε values of 6, 9 and 3 $dm^3\ mol^{-1}\ cm^{-1}$, respectively) overlap well with the porphyrin emission band, but poorly with Yb at 980 nm (2 $M^{-1}\ cm^{-1}$). The absence of the porphyrin emission in aerated solution reflects the efficiency of the bimolecular quenching process (values of $k_q[O_2]$ of *ca*. 1×10^9 s^{-1} have been reported for palladium porphyrins).[8] In addition, the very presence of Ln emission is an indication that the rate of intramolecular energy transfer is relatively fast. The Yb emission from the stereoisomeric (*SSS*)-YbL[1] complex was identical in form but was 40% lower in intensity.

Preliminary time resolved studies have allowed the decay of the porphyrin triplet and the grow-in and decay of the Nd or Yb emission to be monitored. The rate constant for oxygen quenching was calculated to be $5 \times 10^8\ M^{-1}\ s^{-1}$ for the Nd complex. Complex decay profiles were observed consistent with the similar rates of decay of the Yb excited state and the rate of dissociative solvent exchange.[11] However, qualitative agreement between the rate of triplet decay and the rate of Ln 'grow-in' was observed, consistent with the conventional mechanism of triplet-mediated lanthanide sensitisation.[2,6]

In the presence of a 20 mol excess of $[(CG)_6]_2$ oligonucleotide or calf-thymus DNA, in aerated solution {20% D_2O–CD_3OD, 296 K, 5 μM (*RRR*)-$[YbL^1]^{3+}$, λ_{exc} 529 nm}, the porphyrin emission re-appeared to 30% of its value in deoxygenated media; the Yb emission also increased by a factor of 2, *i.e.* also to *ca*. 30% of the value in deoxygenated solution. Very similar behaviour was observed with the (*SSS*) stereoisomer. Evidently binding to the nucleic acid inhibits quenching of the porphyrin triplet by oxygen. That the porphyrin moiety might be interacting with the CG base pairs was suggested by the observation of a red-shift (9 nm) and a pronounced hypochromicity of the Soret band (40%) on binding.

The behaviour reported here is of interest with respect to time-resolved near-IR imaging studies. The sensitivity of the Nd and especially Yb emission to pO_2 may also be of interest in defining regions of low oxygen tension.

We thank EPSRC, the Royal Society, the Commissioners of the Exhibition of 1851 (L. J. G.), and BBSRC for support.

Received (in Basel, Switzerland) 17th April 2000, Accepted 22nd April 2000

For a diruthenium complex, charge migration between different moieties of a bridging ligand with extended conjugation is directly monitored for the first time by using time-resolved emission and absorption spectroscopy.

In recent years, luminescent Ru(II) complexes containing bpy-like polypyridine ligands with extended conjugation have received extensive attention because of their possible use as building blocks for multicomponent systems. These include stereochemically pure metallodendrimers,[1] molecular wires,[2–4] topologically controlled dyads and triads,[5] and compounds designed to behave as luminescent DNA probes.[6–11]

During the progress of these studies, some interesting and somewhat unexpected results have been obtained, in particular: (i) a dramatic effect of solvent or microenvironment on the luminescence properties of these species, which led to the so-called 'light-switching' behaviour of some of these species with respect to DNA interations;[6,7,10] (ii) a relatively small electronic coupling between metal-based chromophores connected by large and conjugated planar bridges,[1–4] implying relatively slow photoinduced electron and energy transfers across the bridges.

Recent investigations[1,10] pointed out that most of these results could be rationalised by taking into account the presence of multiple metal-to-ligand charge-transfer (MLCT) excited states (Fig. 1). According to this view, these states are localised on different moieties of the polypyridine ligands with extended conjugation, with their relative energy ordering and interconversion rates subject to the influence of the microenvironment. This assumption however relies on dynamics of interconversion between states which have been only marginally addressed.[10,11]

Here, we present direct evidence for the excited state interconversion between luminescent MLCT levels involving the tetrapyrido[3,2-*a*:2′,3′-*c*3″,2″-*h*:2‴,3‴-*j*]phenazine bridging ligand (tpphz). The interplay of these MLCT levels is responsible for the photophysical properties of the dinuclear complex $[(phen)_2Ru(\mu\text{-tpphz})Ru(phen)_2](PF_6)_4$ **1** (phen = 1,10-phenanthroline; the structural formula of **1** is shown in Fig. 2),[1] and the dynamics of the process are described on the basis of the results obtained from time-resolved absorption and luminescence spectroscopy.

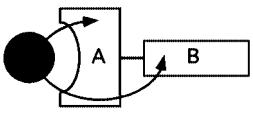

Fig. 1 Schematic representation of the MLCT transitions (arrows) from a metal M (solid circle) to a planar ligand A–B with extended conjugation, which give rise to multiple MLCT excited states. To underline the different localization of the two ligand orbitals involved in the transitions, the ligand A–B is represented as a segmented species, in which A and B are different moieties. Additional ligands and complex charges are neglected. M-to-A CT may convert into M-to-B CT by an A-to-B electron-transfer process.

The redox behavior, ground state absorption spectra, and steady-state luminescence spectra of **1** in acetonitrile fluid solution at room temperature and in a MeOH–EtOH (4:1, v/v) rigid matrix at 77 K have been previously reported.[1] The results are consistent with the following description. Direct irradiation first leads to population of the singlet Ru → tpphz CT state involving the phenanthroline moiety of the tpphz ligand, which very rapidly decays to the corresponding triplet state. At 77 K in rigid matrix, this latter state deactivates to the ground state, giving rise to a ^{3}MLCT luminescence peaking at 585 nm. By contrast, in fluid solution at room temperature a charge reorganization process occurs within the (formally) reduced tpphz bridging ligand. Here, the extra electron initially localized on the phen moiety migrates towards the central, pyrazine-based part of the bridge. Thus, the charge-reorganization process leads to population of a triplet Ru → tpphz CT state involving the pyrazine moiety of tpphz, which is the lowest energy excited state of **1**.[1] In turn, this level deactivates to the ground state (λ_{em}^{max} = 710 nm, τ = 100 ns; data in argon-purged acetonitrile).

In an attempt to study in further detail the dynamics of the excited-state interconversion taking place in **1**, we have performed time-resolved studies in different solvents.[12] In acetonitrile solution at room temperature the shape of the luminescence spectrum, as registered at the end of a 35 ps laser pulse, is constant in a time window of 7 ns, and essentially similar to that obtained from steady-state experiments. A possible explanation can be sought in the rate constant of the process, which could be faster than our experimental resolution time (30 ps). If this is the case, the interconversion process has to be slowed down to be detectable. For this reason, we decided to perform the experiments in dichloromethane because in this low-polarity solvent, CT levels are expected to be destabilized with respect to what happens in acetonitrile. Because of the different donor–acceptor separation in the two possible MLCT states involving the large bridging ligand, the extent of this effect should be larger for the final, lower-lying MLCT level (with reference to Fig. 1, this level could be described as a M-to-B CT state) than for the upper-lying MLCT state initially populated (which may be described as M-to-A CT, Fig. 1). As a consequence, in dichlomethane and with respect to acetonitrile, the lower-lying MLCT level should be destabilized (or less

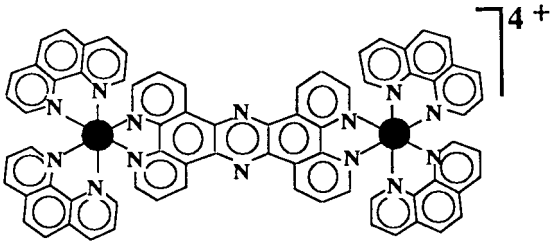

Fig. 2 Structural formula of **1**.

DOI: 10.1039/b004109m

stabilized) with respect to the upper-lying level, so that the driving force of the interconversion process between the two MLCT states is expected to be less favourable and the related rate constant slower and accessible to the time resolution of our equipment.

Actually, the luminescence properties of **1** are time-dependent in dichloromethane solution at room temperature (Fig. 3). In this solvent, the luminescence spectrum registered within the time gate 0–250 ps peaks at *ca.* 610 nm, while the spectrum registered within the time interval 1200–1450 ps is significantly red-shifted, peaking at *ca.* 630 nm (this spectrum is substantially similar to the steady-state emission spectrum in dichloromethane). These results suggest that at least two excited states contribute to the emission of **1** in dichloromethane at room temperature. The kinetic analysis of the streak image in the high- and low-energy wavelength regions of the emission spectra clearly indicates that the lower-energy emissive state is produced from the excited state responsible for the higher-energy emission. Actually, this latter emission decays with a lifetime of 220 ps, whereas the lower-energy emission exhibits a risetime of 200 ps, Fig. 3. Further evidence for the two-state interconversion comes from transient absorption spectroscopy, Fig. 4. Here we see that the absorption spectrum which is present at the end of the laser pulse, exhibiting a maximum around 625 nm, evolves to a new spectrum with a slightly blue shifted maximum, 620 nm, and a higher extinction coefficient. The rate of formation of the new species is 230 ps, see inset of Fig. 4, in good agreement with the luminescence results.

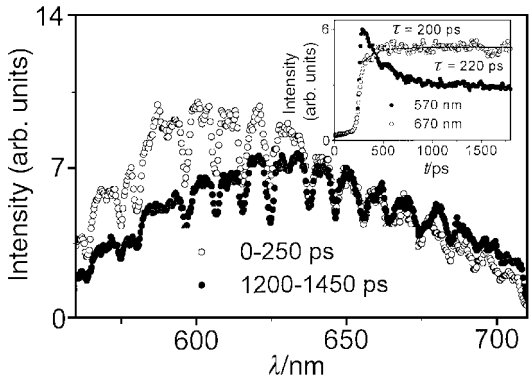

Fig. 3 Time-resolved luminescence spectra of **1** in CH_2Cl_2 following a 35 ps laser pulse (355 nm, 4 mJ); (○) integrated spectrum in the time interval 0–250 ps after the laser pulse; (●) integrated spectrum in the time interval 1200–1450 ps after the laser pulse. The inset shows the luminescence time profiles at 570 nm (●) and 670 nm (○) with the fitted exponential functions.

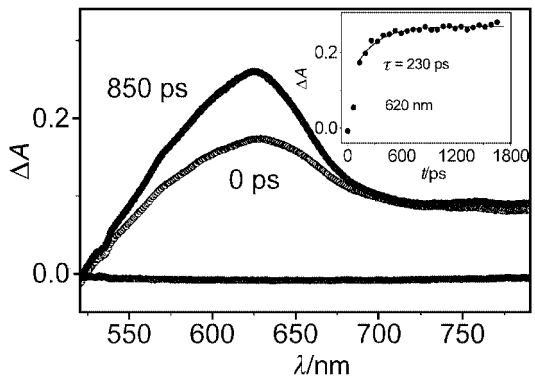

Fig. 4 Time resolved absorption spectra of **1** in CH_2Cl_2 following a 35 ps laser pulse (532 nm, 7 mJ); absorbance at the end of the laser pulse (○) and at 850 ps after the laser pulse (●). The inset shows the time evolution of the absorbance at 620 nm with the fitted exponential function.

On the basis of the spectroscopic results as observed for the time windows of Fig. 3 and 4, we assign the detected process to formation of the Ru → tpphz CT state involving the pyrazine moiety of the tpphz bridging ligand ($MLCT_0$) from the initially produced Ru → tpphz CT level involving the phenanthroline moiety of tpphz ($MLCT_1$). Over longer timescales, subsequent decay of the $MLCT_0$ state to the ground state takes place (not shown in the Figures). From the time evolution of the spectra the rate constant for the charge-migration process leading the interconversion from $MLCT_1$ to $MLCT_0$ is found to be 5×10^9 s^{-1}. Given that rate constants of the order of 10^{12}–10^{13} s^{-1} might be expected for an intramolecular conversion step between states of the same multiplicity, this suggests that a non-negligible energy barrier exists.

In conclusion, we have reported on the experimental observation of the interconversion dynamics of two MLCT excited states localised on the tpphz ligand, a bridge with an extended conjugation incorporated within a Ru(II) dinuclear species. We believe that our results may provide a useful basis for studies concerned with photoinduced intramolecular energy and electron transfer processes occurring in multinuclear species and across large-sized ligands.

Received (in Cambridge, UK) 17th April 2000, Accepted 23rd May 2000

A double helical architecture generated from a readily prepared ferrocenyl-containing bisthiosemicarbazone ligand is described together with its application to the self-assembly of novel supramolecular hydrogen-bonding cavities.

A theme of considerable interest in supramolecular chemistry is the spontaneous and selective formation of organized supramolecular architectures *via* self-assembly.[1] The double-helical structures generated by the complexation of two ligands around metal ions lying on the helical axis retain a unique fascination since life itself is encoded within a double-helical architecture. While the basic features of the design necessary to assemble a double helix are now fairly well established,[2,3] challenges in defining the precise topography or conformation of the helical superstructure remain.

Here, we introduce a ferrocene bridged bisthiosemicarbazone ligand (Fig. 1) to generate a double-helical zinc complex *via* self-assembly. The ferrocene group was chosen as a spacer to separate the two metal binding sites, not only because this spacer is suitable to assemble double-helices,[3] but also because host molecules containing metallocene units can accommodate metal ions at their coordination sites and undergo redox changes.[4]

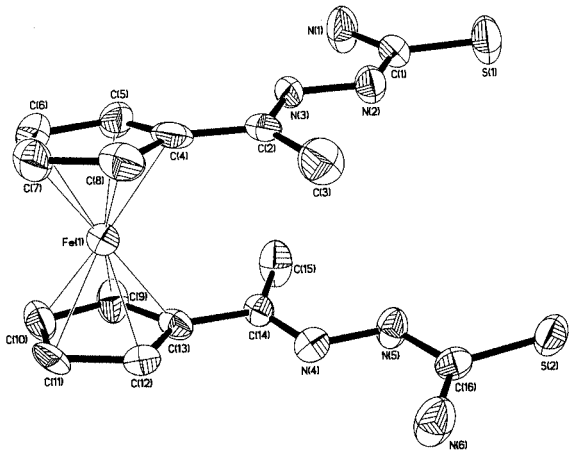

Fig. 1 ORTEP[8] plot of the ligand H_2L, showing the non-hydrogen atoms as 50% probability thermal ellipsoids. Selected bond lengths (Å): S(1)–C(1) 1.686(6), N(1)–C(1) 1.336(8), N(2)–C(1) 1.349(7), N(2)–N(3) 1.386(6), C(2)–C(3) 1.494(8), S(2)–C(16) 1.693(5), N(6)–C(16) 1.322(7), N(5)–C(16) 1.343(7), N(4)–N(5) 1.375(6).

Thiocarbazones and thiosemicarbazones have been used to assemble supramolecular architectures.[5] The hydrogen atoms attached to the amino nitrogen atoms of the thiosemicarbazone moiety have the ability to form donor hydrogen bonds. This kind of non-covalent bond has the potential to assemble smaller, simpler fragments into the desired cavities under favourable conditions, which is important in host–guest chemistry and has applications in chemistry, biology and materials science.[6]

When diacetylferrocene was treated with thiosemicarbazide in ethanol, a red crystalline solid formed readily.‡ Elemental analysis and crystal structure analysis‡ indicated the formation of a bisbidentate ligand $NH_2C(S)N(H)N{=}CMe(C_5H_4)$-$Fe(C_5H_4)CMe{=}NN(H)C(S)NH_2$ H_2L.† The ligand shows a *cis*-configuration with two thiosemicarbazone moieties positioned at the same side with the torsion angle C(2)–C(4)···C(13)–C(14) being −10.8°. Each thiosemicarbazone moiety is coplanar with the Cp ring to which it is attached (the mean deviation from the best plane is 0.09 Å on average). The C–S bond lengths of 1.69 Å agree well with those in related compounds, indicating that the Schiff-base compound H_2L remains as the *thione* tautomer. The two thiosemicarbazone moieties of the ligand adopt a configuration in which the hydrazone nitrogen atoms N(3) and N(6) are *trans* to S(1) and S(2), respectively. Rotation of the H_2NCS fragment by 180° about the C(1)–N(2) and C(16)–N(5) bonds places each pair of the sulfur atoms and the hydrazone nitrogen atoms on the same side, thus enabling H_2L to function as a double anionic N_2S_2 ligand.

Reaction of H_2L with $Zn(MeCO_2)_2{\cdot}2H_2O$ in methanol at reflux gives the binuclear neutral complex Zn_2L_2 **1** *via* self-assembly.† Complex **1** is a stable pale-orange precipitate which is insoluble in most organic solvents. Recrystallization of the compound from DMF by dichloromethane diffusion afforded X-ray quality crystals.‡ The structure of one of the two enantiomers is shown in Fig. 2 and confirms the formation of a double-helix composed of two anionic ligands L^{2-} wrapped around two Zn(II) ions which are separated by 7.74 Å. The complex possesses a crystallographic C_2 axis perpendicular to the helical Zn···Zn axis, with the four coplanar metal atoms forming a slightly distorted rhombus with sides of 5.0 Å and interior angles of 79 and 101°. Each zinc center occupies a four-

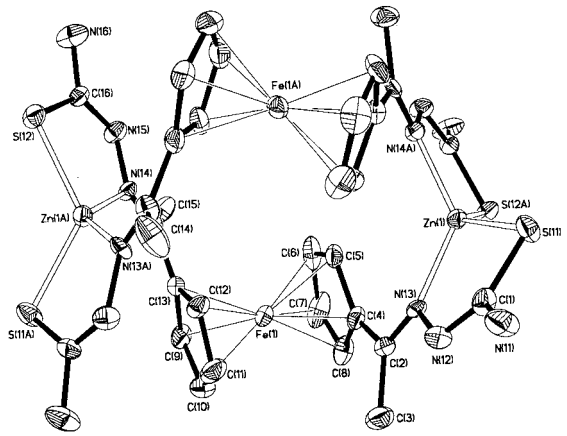

Fig. 2 ORTEP plot of the coordinated zinc(II) complex Zn_2L_2, showing the non–hydrogen atoms as 50% probability thermal ellipsoids. The solvent molecules and hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Zn(1)–N(13) 2.073(9), Zn(1)–S(11) 2.280(3), S(11)–C(1) 1.730(1), S(12)–C(16) 1.739(1), N(11)–C(1) 1.348(2), N(12)–C(1) 1.289(2), N(12)–N(13) 1.401(1), N(14)–N(15) 1.396(1), N(15)–C(16) 1.305(1), N(16)–C(16) 1.350(2); N(14A)–Zn(1)–N(13) 130.4(3), S(12A)–Zn(1)–S(11) 125.4(8), N(13)–Zn(1)–S(11) 86.6(3), N(14A)–Zn(1)–S(12A) 87.5(2), N(13)–Zn(1)–S(12A) 116.3(3), N(14A)–Zn(1)–S(11) 115.3(3), Symmetry code A: 1−*x*, *y*, 1−*z*.

DOI: 10.1039/b003072o

coordinated pseudo-tetrahedral environment bound to atoms S(1) and N(3) from one L^{2-} ligand, and S(2A) and N(4A) from a second ligand (Fig. 2). The dihedral angle between the two coordinated planes is 77°. The Zn–S distances of 2.266(3)–2.274(4) Å and Zn–N distances of 2.059(9)–2.068(9) Å agree well with those in related compounds. The thiosemicarbazone moieties are twisted by *ca*. 50° from the Cp rings to which they are attached with dihedral angles between the two thiosemicarbazone moieties of 73.5°. Coordination to the metal center also forces twisting between the two side chains with a torsion angle C(2)–C(4)···C(13)–C(14) of 128°. No significant deformation of the almost parallel Cp ring is observed. The measured C–S bond distances range from 1.736(11) to 1.748(11) Å and are within the normal range of a C–S single bond,[7] indicating that the thiosemicarbazone moieties L^{2-} adopt the *thiol* tautomeric form in acting as a doubly charged negative ligand. The C–N and N–N bond distances in L^{2-} are intermediate between formal single and double bonds, pointing to extensive electron delocalization over the entire molecular skeleton.

While both the dichloromethane molecules and water molecules lie outside the cavity of the helix, X-ray diffraction analysis of the complex reveals that helices of each enantiomer interact with each other through hydrogen bonds forming an infinite tube as shown in Fig. 3. The imino nitrogen atoms of the thiosemicarbazone moieties act as H-bond acceptors while the amino nitrogen atoms act as donors, these pair up with the corresponding imino and amino nitrogen atoms of a parallel helix forming hydrogen bonds. The N···N separations are 3.18(1) and 3.16(1) Å for N(11)···N(15B) (1−*x*, 1+*y*, 1−*z*) and N(16)···N(12C) (1−*x*, −1+*y*, 1−*z*), respectively, while N–H···N angles are 156(1) and 171° for N(11)–H(11B)···N(15B) and N(16)–H(16A)···N(12C), respectively. The one-dimensional tube contains alternate cavities and walls (the double-helix molecules) reminiscent of a train. Each 'coach' includes two hydrogen bonded dimeric water molecules with an O···O separation of *ca*. 2.93 Å. The O···O vector occupies a C_2 axis perpendicular to the helical Zn···Zn axis. No obvious hydrogen bonds are seen between the guest molecules and the host.

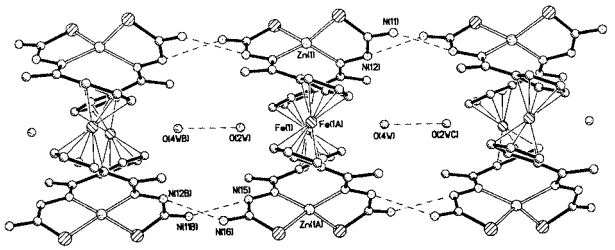

Fig. 3 View of the hydrogen-bonding one-dimensional tube with included water molecules. Symmetry code B: 1−*x*, 1+*y*, 1−*z*; C: 1−*x*, −1+*y*, 1–*z*.

The ferrocene-bridged double-helical complex derived here from an inexpensive and readily prepared bisthiosemicarbazone ligand and its novel hydrogen-bonding supramolecular 'train-like' system with each 'coach' of the train including two water molecules is interesting in that it provides an unusual example in metallo-supramolecular chemistry. This self-assembled nano-structure showing host–guest interactions shows potential for broadening the scope for further work in self-assembly. The development of new ligand systems containing the functional ferrocene group and application to assemble supramolecular cavities are in progress.

Unusually high *ortho*-selectivity in electrophilic aromatic substitution promoted by $GaCl_3$†

Received (in Cambridge, UK) 20th April 2000, Accepted 23rd May 2000

1,4-Bis(trimethylsilyl)buta-1,3-diyne in the presence of $GaCl_3$ reacts with aromatic hydrocarbons at −90 to −100 °C yielding 2-arylbut-1-en-3-ynes; the reactions exhibit an unusually high tendency to alkenylate the *o*-position of alkyl substituents; toluene, ethylbenzene and isopropylbenzene react predominantly to exclusively at the *o*-position while *o*-xylene and 1,2,3,4-tetrahydronaphthalene react at the 3 and 5-position, respectively.

Ortho–para selectivity in electrophilic aromatic substitution is an issue still not fully understood. Particularly, selective *o*-alkylation is rare, since a slight increase in the steric bulk of the substituent directs the reaction to the *p*-position.[1] Several benzene derivatives possessing heteroatom functionalities are known to exhibit such *o*-selectivity, which is ascribed to the interactions between the electrophile and the substituent.[2] Only modest levels of *o*-selectivity are observed in some reactions of toluene, where such an interaction is unavailable[3] while *o*-selectivity is rare for ethylbenzene or isopropylbenzene. Described here is an *o*-selective aromatic alkenylation reaction using $GaCl_3$ and 1,4-bis(trimethylsilyl)buta-1,3-diyne **1**. We previously reported the β-silylethenylation reaction of arenes with trimethylsilylethyne **2** in the presence of $GaCl_3$[4] involving C–C bond formation between an organogallium ethenyl cation and an arene exhibiting *para*-selectivity. By contrast, examination revealed that the electrophile derived from **1** shows an unusually high tendency to alkenylate the *o*-position of alkyl substituents.

Arene (5 mol equiv.) and **1** (1 mol equiv.) were reacted with $GaCl_3$ (2 mol equiv.) in CH_2Cl_2 at −90 to −100 °C for 1–2 h.‡ THF was then added, and the mixture stirred for 0.5 h at −90 to −100 °C. Aqueous workup gave (*Z*)-1,4-bis(trimethylsilyl)-2-arylbut-1-en-3-yne **3** and 4-trimethylsilyl-2-arylbut-1-en-3-yne **4** (method A) as shown in Scheme 1.[5] For some arenes such as *p*-xylene or *m*-xylene, addition of another portion of $GaCl_3$ (2 mol equiv.) increases the total yield (method B). The reaction can be carried out using an equimolar amount of *p*-xylene and **1** with only a slight decrease in the yield. Addition of THF prior to the water improves the yield of the products. The (*Z*)-stereochemistry of **3** was determined by NOE studies. The reaction sites of the arenes were confirmed unambiguously by spectroscopic methods. The isomer distribution of **3** is similar to that of **4**. The olefinic trimethylsilyl group of **3** can be removed producing **4** by careful treatment with CF_3CO_2H in a mixture of diethyl ether and water with the temperature gradually increased from −78 °C to room temperature. For example, (*Z*)-1,4-bis(trimethylsilyl)-2-(2,5-dimethylphenyl)-but-1-en-3-yne **7** was monodesilylated in 70% yield. Reactions of **1**, which is a stable alternative to buta-1,3-diyne, have attracted considerable attention in organic synthesis. For example, silicon substitution with electrophiles occurs in the presence of Lewis acids or methyllithium giving diyne compounds.[6] Organometal addition producing enynes has also been reported.[7] Electrophilic addition to **1** as well as to the parent buta-1,3-diyne has been little studied.[8]

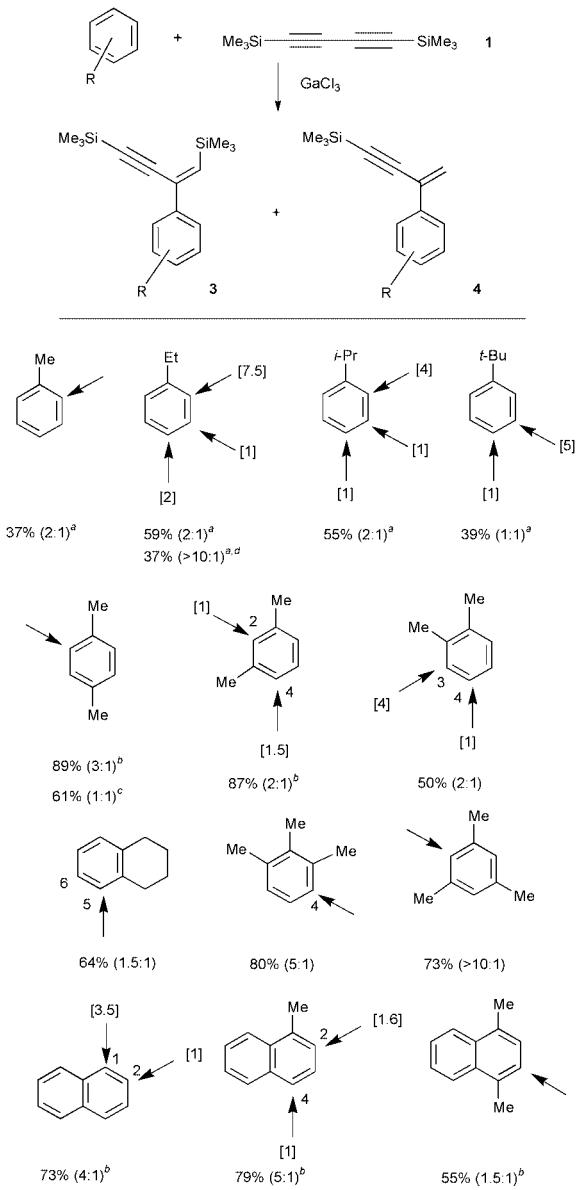
It may be reasonably assumed, based on the employment of similar reagents and reaction conditions, that the present reaction and the β-silylethenylation[4] involve similar electrophilic substitution mechanisms. However, several differences are noted. First, the orientation of these reactions differs considerably. The directing effect of the methyl group to its *o*-position is unusually high in the present reaction; indeed toluene



Scheme 1 Yield of **3** + **4** is shown. Figures in parentheses indicate the ratio of **3**:**4**. →: Reaction site. [ ]: Isomer ratio of **3**. [a] 20 mol equiv. of arene used. DOI: 10.1039/b003215h

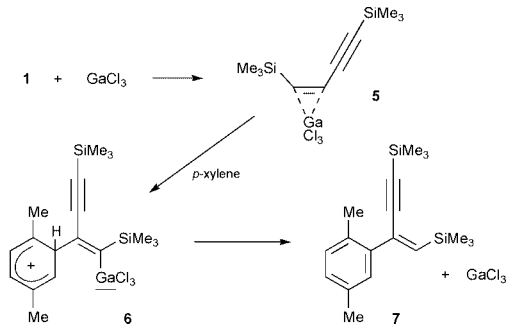
reacts exclusively at the *o*-position. This is in contrast to the observation that the β-silylethenylation predominantly occurs at the *p*-position.[4] Ethylbenzene and isopropylbenzene also predominantly react at the *o*-position. Notably, *tert*-butylbenzene gives the *m*-isomer as the major product. Disubstituted benzenes also show a tendency to react at positions adjacent to the alkyl substituents; *o*-xylene is predominantly alkenylated at the 3-position, 1,2,3,4-tetrahydronaphthalene exclusively reacts at the 5-position while a considerable proportion of *m*-xylene reacts at the 2-position. The dominant reaction sites in β-silylethenylation are at the 4-, 6- and 4-positions for these three substrates, respectively.[4] It is known from detritiation experiments that the *p*-position in toluene is about twice as reactive as the *o*-position.[9] Similarly, the 4-position of *o*-xylene, the 6-position of 1,2,3,4-tetrahydronaphthalene and the 4-position of *m*-xylene are more reactive than the others.[9] Detritiation is considered to reflect the reactivity of the aromatic sites excluding steric effects. The orientation of β-silylethenylation using **2**, therefore, can be understood by taking into account both electronic and steric effects. The orientation of the present reaction using **1** is unusual with reaction at the less reactive and more hindered sites predominating. The following examples also show the anomalous orientation of this reaction. 1-Methylnaphthalene predominantly reacts at the 2-position. While 1,3,5-trimethylbenzene is inert to β-silylethenylation, the reaction of **1** proceeds smoothly. The substituent on the silicon atom of **1** is not essential for *o*-selectivity, since 1,4-bis(triethylsilyl)buta-1,3-diyne reacts with ethylbenzene also at the *o*-position.

Second, a difference in the behavior of **1** and **2** is observed in deuteration experiments. When the reaction of *p*-xylene and **1** was quenched with D_2O, product **7** was not deuterated at the olefin moiety. Whereas β-silylethenylation using **2** produced a β-deuterated product.[4] Since the reaction of **1**, as for **2**, is likely to proceed *via* the organogallium electrophile **5**, an arenium cation **6** should be formed (Scheme 2). The above result of the deuteration experiment suggests that protodegallation of **6** takes place in the reaction mixture, regenerating $GaCl_3$. Unfortunately, 10 or 50 mol% of $GaCl_3$ does not effectively promote the catalytic reaction.§



Scheme 2

Third, the present reaction proceeds at a temperature lower than that for β-silylethenylation.[4] While the latter reaction does not take place at −90 °C, the former reaction occurs efficiently even at −100 °C. The electrophilic species derived from **1** appears to be more reactive than that from **2**.

A higher polyyne compound can also be used for alkenylation. Reaction of 1,8-bis(triethylsilyl)octa-1,3,5,7-tetrayne **8**[10] and toluene yields 2-aryloct-1-en-3,5,7-triyne **9** (Scheme 3). Since the *p*-product predominated here, the anomalous orientation in the reaction of **1** can be attributed, at least in part, to its diyne structure.

Notes and references

‡ *Typical procedure*: under an argon atmosphere, to a stirred solution of *p*-xylene (0.31 mL, 2.5 mmol) in CH_2Cl_2 (4 mL) was added dropwise a solution of $GaCl_3$ (1.0 M in methylcyclohexane, 1.0 mL) at −98 °C. To this mixture, **1** (97 mg, 0.5 mmol) in CH_2Cl_2 (1 mL) was added slowly, and stirring was continued for 1 h at this temperature. Then THF (3 mL) was added, and after 30 min water was added. A standard workup gave **7** (74 mg, 49%) and 4-trimethylsilyl-2-(2,5-dimethylphenyl)but-1-en-3-yne (10 mg, 9%).

§ There are lines of evidence for product inhibition: (i) When **7** (2 mol equiv.) was added to the reaction mixture of *m*-xylene (2 mol equiv.), **1** (2 mol equiv.) and $GaCl_3$ (1 mol equiv.) at −90 °C, alkenylation was totally inhibited with recovery of **7** in 84% yield. In contrast, 17% of the product derived from *m*-xylene was obtained in the absence of **7** under the same conditions. (ii) Compound **7** and $GaCl_3$ react to form an orange solution in methylcyclohexane at −100 °C, which fades on addition of THF. Reversible complex formation was also detected by *in situ* IR. **7**: IR (methylcyclohexane, −95 °C) 1248, 843 cm^{-1}. **7**•$GaCl_3$ complex: IR (methylcyclohexane, −95 °C) 1252, 839 cm^{-1}. For complex formation of $GaCl_3$ and aromatic hydrocarbons, see ref. 11.

Received (in Cambridge, UK) 17th April 2000, Accepted 19th May 2000

The formation of a transient Michael adduct, triggering an *in-situ* isomerization of the heterodiene, is postulated to explain the reversal of the diastereoselectivity of high pressure-promoted hetero-Diels–Alder reactions carried out in the presence of pyridine.

Application of high pressure in organic synthesis is a rapidly developing research area.[1] In particular, the use of these extreme conditions in [4+2] cycloadditions not only causes a marked acceleration of the reactions due to negative volumes of activation, but also often imposes efficient stereocontrol by favouring the more compact transition state, namely the *endo* state.[2]

Pursuing our work on the hetero-Diels–Alder reaction of α-phosphono-substituted heterodienes **1** [W = $(RO)_2P(O)$] with electron-rich dienophiles **2** (Scheme 1),[3] we recently observed an unexpected reversal of the diastereoselectivity of the resulting cycloadduct **3**, at high pressure, when the β-phenyl group of the diene was replaced by a pyridyl group.[4] Having postulated a possible *in situ* (*E*)- to (*Z*)-isomerization of the pyridyl-substituted diene, we decided to study, more generally, the possibility of modifying the selectivity of such high pressure-promoted cycloadditions by adding pyridine to the reaction mixture. We report here our first significant results (Table 1).

The synthesis of the phosphono-heterodienes (*E*)-**1a**–**c** were previously described.[3,4] The non-phosphonic diene **1d** was prepared according to a modification of the literature procedure,[5] giving a *ca.* 40:60 mixture of (*E*)/(*Z*)-isomers, which could be separated by HPLC. [6] Dienophiles **2a**,**b** are commercially available. The reactions of **1** with a ten-fold excess of **2** (acting also as solvent), at 20 °C and 11 kbar, led to the cycloadduct **3** as a mixture of two diastereomers, whose relative configuration was deduced from ^{1}H–^{1}H NOESY, ^{1}H and ^{13}C NMR spectra.[3,4] In the first set of experiments, we studied the reaction of the pair (*E*)-**1a**/**2a**. As we reported,[4] in the absence of pyridine the expected cycloadduct **3a** was obtained in very good yield after 72 h, with a predominent *trans*-diastereoselectivity (Table 1, entry 1), in agreement with the expectation of a preferred *endo*-transition state. In the presence of 1 equiv. of pyridine (entry 3), the reaction was complete after 24 h, giving **3a** in excellent yield, and with a high *cis*-selectivity (de = 82%), which was not altered by using an excess of pyridine (4 equiv., entry 4). However, with 0.5 equiv. of pyridine, the *cis*-selectivity of the cycloaddition dropped significantly (entry 2). At this stage, we checked that the 68/32 *t*-**3a**/*c*-**3a** mixture obtained in the first experiment was unchanged in the presence of 1 equiv. of pyridine for 48 h at 20 °C and 11 kbar. In addition, we verified that pure (*E*)-**1a** was configurationally stable at high pressure in the absence of pyridine, whereas we noticed that, in the presence of 1 equiv. of pyridine at 20 °C and 11 kbar for 48 h, it was partially isomerized into a 98:2 (*E*)-**1a**/(*Z*)-**1a** mixture. These accumulated results led us to think that the predominent *cis*-diastereoselectivity of the cycloaddition observed in the presence of pyridine was due to an equilibrated *in situ* isomerization of the (*E*)-heterodiene into its (*Z*)-isomer,[7] whose rate constant k_2 (reaction path b) should be higher, for steric reasons, than that (k_1) of its (*E*)-partner (reaction path a), *via* an *endo*-transition state assumed to be predominent in both cases (Scheme 2). We propose that such an unusual pyridine-promoted (*E*) ↔ (*Z*) isomerization[8] could take place through the formation, in hyperbaric conditions, of a transient adduct **4** resulting from a Michael-type addition of pyridine to (*E*)-**1a**.[9] The progressive decrease of the *trans*-selectivity from entry 1 to entries 3 and 4 seems to be in agreement with stoichiometric consumption of the (*E*)-heterodiene by the pyridine, to give the stabilized ionic adduct **4**, which likely decomposes into the (*Z*)-isomer by a retro-Michael release of pyridine, the overall process being equilibrated. Moreover, in order to account for the global selectivity of the cycloaddition, a minor contribution of the *exo*-approach mechanism (reaction paths c and d, in Scheme 2) could also be considered.

The results obtained in the following seem to agree with the mechanism proposed in Scheme 2 and illustrate the advantage and easiness of the method. In particular, the phosphono-heterodienes **1a**–**c**, for which only the (*E*)-isomers are available,[3,4] were efficiently transformed, as depicted in Scheme 1, into very interesting dihydro-pyrans or -thiopyrans **3**, usually obtained as their predominent *trans*-diastereoisomers, but often with a modest selectivity (Table 1, entries 1, 5, 7, 9 and 11).[10] The addition of 1 equiv. of pyridine to the reaction mixture, under the same conditions, allowed us to accelerate the reaction, as well as to reverse its selectivity, giving access to the less common *cis*-isomer (entries, 3, 6, 8, 10 and 12), occasionally with a diastereomeric excess up to 97% (entry 6).

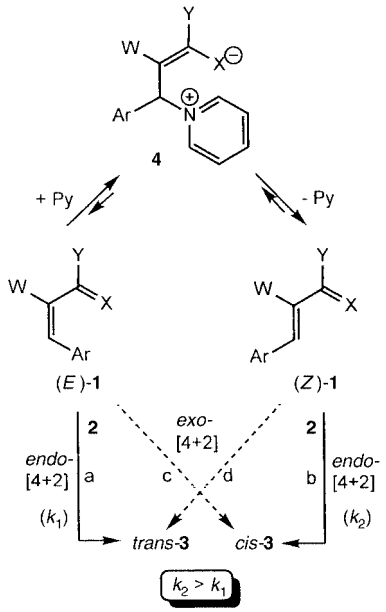

Scheme 2 Proposed mechanism for the pyridine-induced *cis*-diastereoselectivity of the [4+2] cycloaddition of **1** to **2**, at high pressure.

Finally, we report the cycloaddition of the cetoester **1d** with the dienophile **2a**, leading to the dihydropyran **3e** (entries 13–16). As observed above, in the absence of pyridine the diene (*E*)-**1d** gave **3e** with modest *trans*-diastereoselectivity (entry 13),[10] whereas in the presence of 1 equiv. (or an excess) of pyridine the *cis*-isomer became greatly predominant (entry 14). Interestingly, the same selectivity was obtained by using the diene (*Z*)-**1d** in the absence (entry 15) as well as in the presence of pyridine (entry 16). The remarkable similarity of these last three results suggests that in these three cases, and in particular for the first of them, the main reaction path was path b (Scheme 2). Moreover, we found that when pure diene (*E*)-**1d** was treated with 1 equiv. of pyridine in an inert solvent at 20 °C and 11 kbar for 48 h, it was isomerized into a 43:57 (*E*)-**1d**/(*Z*)-**1d** mixture. The same ratio was obtained when starting from pure (*Z*)-**1d**, indicative of a thermodynamic (*E*)/(*Z*) equilibration of **1d** at high pressure in the presence of pyridine.

In conclusion, this communication describes a straightforward method allowing, by addition of pyridine, the reversal of the diastereoselectivity of some high pressure-promoted hetero-Diels–Alder reactions, giving access, at room temperature, to unusual cycloadduct isomers. This method is especially useful when only the (*E*)-isomer of the heterodiene is available. In order to explain the observed results, a mechanism involving a transient Michael addition of pyridine to the starting (*E*)-diene,[11] and allowing the *in situ* formation of the more reactive (*Z*)-isomer, is proposed.

5 We prepared **1d** by condensing methyl acetoacetate with benzaldehyde bis(morpholino)aminal (following the procedure described in ref. 3), instead of benzaldehyde used by: C. A. Kingsbury, D. Draney, A. Sopchik, W. Rissler and D. Durham, *J. Org. Chem.*, 1976, **41**, 3863.

6 The separation of the isomers was achieved by using a Waters HPLC chromatograph, a Nova Pack (L = 10 cm, Φ = 0.8 cm) silica gel column and heptane/AcOEt (97:3) as eluent.

7 An example of light-promoted (*E*)/(*Z*)-heterodiene isomerization preceding the cycloaddition has been reported by: L. F. Tietze, T. Brumby, M. Pretor and G. Remberg, *J. Org. Chem.*, 1988, **53**, 810.

8 (*E*)-**1a** was configurationally stable in the presence of pyridine, at 20 °C and atmospheric pressure for several days.

9 High pressure-induced hetero-Michael additions of primary amines have been described in the literature [see for example: (*a*) J. d'Angelo and J. Maddaluno, *J. Am. Chem. Soc.*, 1986, **108**, 8112; (*b*) F. Dumas, B. Mezrhab, J. d'Angelo, C. Riche and A. Chiaroni, *J. Org. Chem.*, 1996, **61**, 2293], and are currently under study in our laboratories (A. Y. Rulev, J. Maddaluno, G. Plé, J. C. Plaquevent and L. Duhamel, *J. Chem. Soc., Perkin Trans. 1*, 1998, 1397, and work in preparation).

10 In each case, we verified, first, that the starting diene was configurationally stable at 11 kbar in the absence of pyridine, and secondly that the obtained cycloadduct mixture did not isomerize, at 11 kbar, in the presence of pyridine.

11 The postulated addition of the nucleophilic pyridine to the heterodiene is to be considered in relation to the first step of the Baylis–Hillman reaction, which is known to be very sensitive to pressure; see for instance: A. Gilbert, T. W. Heritage and N. S. Isaacs, *Tetrahedron: Asymmetry*, 1991, **2**, 969; I. E. Markó, P. R. Giles and N. J. Hindley, *Tetrahedron*, 1997, **53**, 1015.

Carbon parity affecting the packing state of azobenzene–urea monolayers

Toru Kobayashi, Takahiro Seki* and Kunihiro Ichimura

Photofunctional Chemistry Division, Chemical Resources Laboratory, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8503, Japan. E-mail: tseki@res.titech.ac.jp

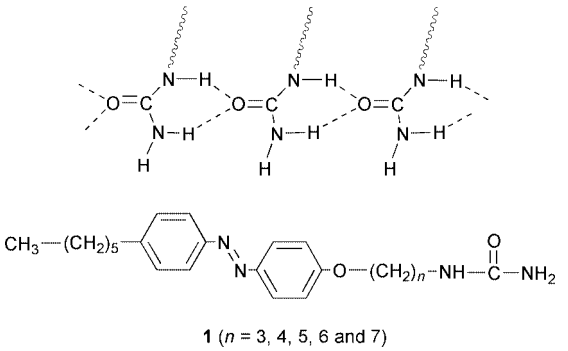
Received (in Cambridge, UK) 8th March 2000, Accepted 19th May 2000

The monolayers of azobenzene (Az)-containing urea amphiphiles show clear odd–even effects of the alkylene spacer length in respect of the spreading behavior on water and the packing state of the Az chromophore on a quartz substrate.

The urea moiety is very simple in structure but provides a particularly useful building block[1] in supramolecular chemistry.[2,3] Urea derivatives associate *via* intermolecular bifurcated NH···O=C hydrogen bonds (see Fig. 1) and these paired hydrogen bonds afford a robust and highly directional intermolecular joint. On the surface of water, the monolayers of long chain alkylureas are known to exhibit a unique thermally-induced area change.[4] The monolayer of alkylureas, unlike other amphiphiles, exhibits a sudden contraction at an intrinsic transition temperature on heating. It is assumed that the rupture of the bifurcated hydrogen bonds among the urea heads is responsible for this thermal change in the molecular packing.

Our recent work using an azobenzene (Az)-containing long chain urea showed that this monolayer on the surface of water adopts a characteristic packing structure in which the *trans*-to-*cis* photoisomerization is completely prevented.[5] More interestingly, when the monolayer is transferred onto a hydrophilic substrate, the atmospheric humidity change sharply switches the assembled state and hence the photoreactivity of Az in the assembly.[6] We report herein a new aspect of the molecular design of the Az–urea monolayer system. It is found here that the carbon parity (odd/even number) of the alkylene spacer connecting the urea and the Az unit obviously results in the alternation of the spreading behavior and the molecular packing nature. Examples of odd–even effects affecting the thermal properties in thermotropic liquid crystals are widely known.[7] In two dimensional monolayer or bilayer assembly systems, various surface-mediated phenomena, such as wetting of liquid,[8] ice nucleation,[9] liquid crystal alignment[10] and electrochemical properties[11] are altered by the carbon parity. This paper presents a new example involving the photochromic monolayer.

The family of Az–urea compounds, *N*-(5-{4-[(4-hexylphenyl)azo]phenoxy})alkylurea (**1**, n = 3–7), used in this work are shown in Fig. 1. These compounds were synthesized in a similar manner to that described in ref. 5 for n = 10. The corresponding Az-containing carboxylic acid derivatives, the starting compounds, were converted to isocyanates and then a subsequent reaction with ammonia gas was performed.[12] The spreading behavior of Az-containing monolayers was evaluated on pure water (Milli-Q grade, 18 MΩ cm^{-1}, pH = 5.8) using a Lauda FW1 film balance in subdued red light. After evaporation of the solvent, monolayers were compressed at a speed of 30 cm^2 min^{-1}, and the surface pressure was recorded *versus* the molecular area. The absorption spectra were taken on a JASCO MAC-1 spectrophotometer, which was principally designed for low absorbance measurements.



1 (n = 3, 4, 5, 6 and 7)

Fig. 1 Schematic representation of the bifurcated hydrogen bonds between the urea units (above), and the chemical structure of the Az–urea amphiphiles used in this study (below).

Surface pressure–area (π–A) isotherms of **1** (n = 3–7) in the *trans* form obtained at 20 ± 0.5 °C are shown in Fig. 2. As indicated, the limiting area per molecule, which was estimated by extrapolating the steepest slope to zero pressure, indicated systematic alternation with n (see Fig. 2 inset). For the compounds with an odd number of carbons in the spacer (n = 3, 5 and 7), the limiting area was in the range 0.29–0.30 nm^2. On the other hand, the monolayers of **1** having an even numbered spacer (n = 4 and 6) showed significant area expansions with higher compressibility. Since the cross section of vertically aligned Az is 0.25 nm^2, as estimated from the X-ray diffraction data of crystals,[13] it can be thus interpreted that the molecules in these monolayers are tilted with respect to the surface normal. The degree of molecular tilting for the even numbered carbon spacers should be greater than that of the odd numbered ones.

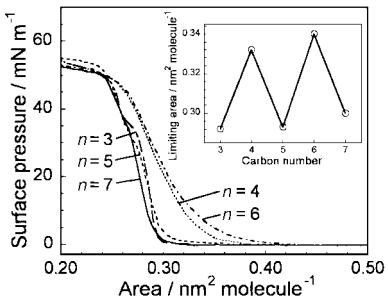


Fig. 2 Surface pressure–area isotherms of monolayers of **1** (n = 3–7) on pure water at 20 °C. In the inset, the limiting occupying area is plotted against the alkylene spacer length (n).

The shape of π–A curves also showed regular changes with n. The even numbered (n = 4 and 6) compounds gave a continuous smooth slope in the π–A curves. In contrast, monolayers of the odd carbon series (n = 3, 5 and 7) showed a sharper increase in the curve, indicative of lower compressibility. Furthermore, a characteristic inflecting region around 33 mN m^{-1} was observed for the odd numbered series only. We have not yet elucidated the process involved in this phase transition.

Single layers of **1** (n = 3–7) on water were deposited onto a clean quartz plate by the vertical lifting procedure at 20 mN m^{-1}. The transfer ratio was 1.0 ± 0.1 in all cases. Fig. 3 displays the transmission UV–vis absorption spectra of the monolayers of **1** on both sides of the quartz plate measured in the dry state. From these spectral features, the effect of the carbon parity of

DOI: 10.1039/b001867h

the spacer on the packing state of Az can be evaluated as follows.

Firstly, the aggregation state of Az was altered by the carbon number. The peak position of the π–π* band attributed to the long axis transition of Az (λ_{max}), which indicates the aggregation state of the chromophore,[14] showed a zigzag change with increasing *n* (open circles in Fig. 3 inset). The Az units in the transferred monolayers formed H-aggregates in all cases, judging from the considerable hyprochromic shifts of λ_{max} (317–327 nm) from the value in chloroform solution (352 nm).[5] As a general tendency, λ_{max} shifted to shorter wavelengths with increasing spacer length, indicating that a stronger H-type aggregation is formed in the monolayer with the longer spacers, due to stronger van der Waals interactions. Among these, λ_{max} for the odd numbered series showed significant hypsochromic shifts.

Secondly, the molecular orientation was altered. The absorption ratios of the two π–π* bands, *i.e.* the absorption intensity of the short-axis transition (peaking below 250 nm) relative to that of the long-axis transition (300–400 nm) (A_{short}/A_{long}), are plotted as a function of *n* (filled squares in Fig. 3 inset). The value of A_{short}/A_{long} was less than 1.0 for the even numbered series, whereas it exceeded 1.0 for the odd numbered series. This absorbance ratio can be related to the degree of molecular tilting. In the transmission mode measurements, the smaller value of A_{short}/A_{long} indicates a larger molecular tilt from the surface normal. Therefore, the monolayers of **1** with the even numbered spacers should be tilted to a greater extent than those of the odd numbered series. This observation is in good agreement with the above mentioned results of (i) the larger expansion in the spreading behavior on water (Fig. 2) and (ii) the less hypsochromic shifts of the π–π* band in the absorption spectrum (open circles in Fig. 3 inset) for the even numbered series.

We assume the origin of the odd–even effects observed here is as follows. The formation of the bifurcated hydrogen bonds fixes the head groups firmly and molecular motion is thereby strongly hindered. When the alkylene spacer chain takes the all-*trans* zigzag conformation, then the orientation of the Az moiety should be affected alternately by the carbon parity. A precise understanding of the packing state requires further exploration using techniques such as X-ray analysis, Fourier transform infrared spectroscopy and microscopy observations, which will be the subject of future investigations.

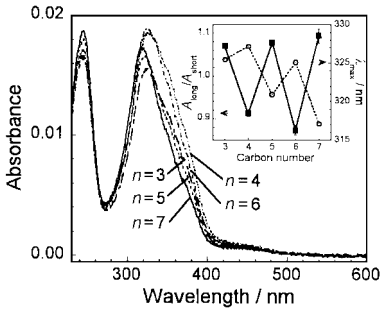

Fig. 3 UV–Vis absorption spectra of monolayers of **1** (n = 3–7) transferred at 20 mN m^{-1} onto both sides of a quartz plate. The inset shows λ_{max} (open circles) and A_{short}/A_{long} (filled squares, see text for definition) plotted against the alkylene spacer length (n).

In conclusion, this work revealed a new carbon parity effect observed in the packing state of photochromic Az units in a monolayer assembly. Since the packing state of Az governs the *trans*-to-*cis* photoisomerization behavior,[5] the findings observed here may have implications for the design of various photochromic functions.

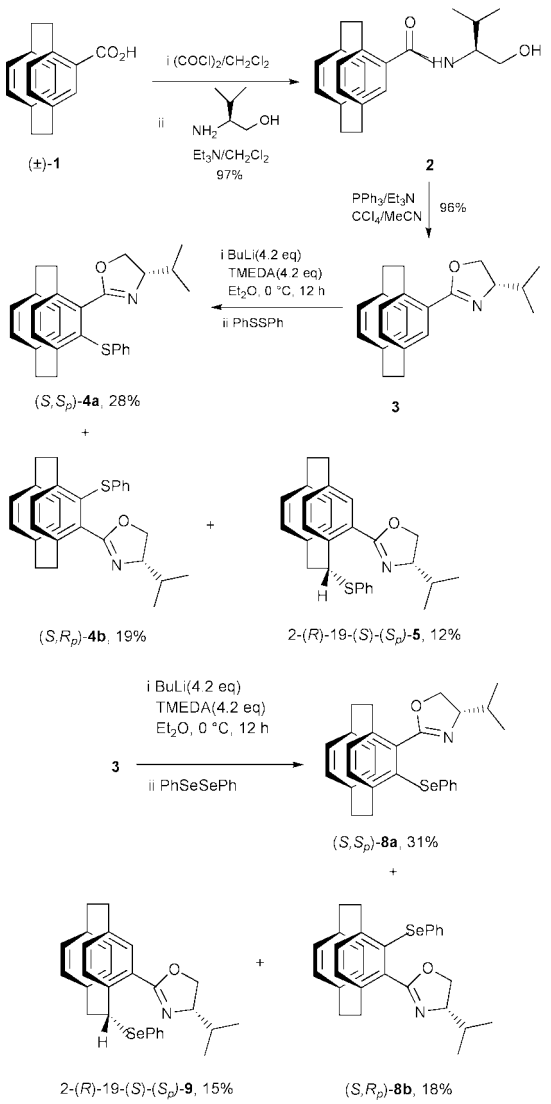
Received (in Cambridge, UK) 4th April 2000, Accepted 19th May 2000

Novel *N,S*- and *N,Se*-ligands with planar chirality derived from [2.2]paracyclophane have been synthesized and applied in palladium-catalyzed allylic alkylation reaction, in which ligands 5 and 9 with the two substituents at benzylic and benzene ring positions give the highest ee values.

The design and synthesis of new chiral ligands play a crucial role in transition metal catalyzed asymmetric reactions.[1] Recently, ligands possessing planar chirality have attracted greater interest amongst various chiral ligands in asymmetric catalysis. In comparison with ferrocene derivatives[2] and arene transition metal complexes,[3] little attention has been paid to ligands derived from [2.2]paracyclophane, a structural framework capable of introducing planar chirality, and only a limited number of reports have appeared on studies of chiral [2.2]paracyclophanes,[4] especially their uses in asymmetric catalysis,[4e–h,k] although these ligands are linearly chiral,[5] chemically stable[6] and undergo racemization only at relatively high temperature.[7] As part of a program aimed at the applications of planar chirality in asymmetric synthesis[8] we studied the role of [2.2]paracyclophane-type planar chirality in asymmetric induction. Herein we disclose our results on the synthesis of novel *N,S*- and *N,Se*-ligands with planar chirality and central chirality based on the [2.2]paracyclophane backbone and their use in the palladium-catalyzed allylic alkylation reaction.[9]

From racemic 4-carboxy[2.2]paracyclophane **1** as starting material[10] and by using literature procedures[11] oxazoline **3** was obtained as a mixture of two diastereoisomers. Direct *ortho*-lithiation of oxazoline **3** with Bu^{n}Li and an equimolar amount of TMEDA followed by quenching with PhSSPh gave rise to the expected products **4a** and **4b** (Scheme 1). To our surprise, a third product **5** was obtained in addition to the expected *ortho*-lithiation/electrophile quenching products **4a** and **4b**. The structure of **5** was determined by ^{1}H NMR spectroscopy and confirmed by X-ray crystallography.† The planar chirality of these three products were readily determined by comparison with that of products obtained by using optically pure **1a** and **1b**[10] as starting materials and repeating the same procedure. In addition, the absolute configuration of C-2 in **5** was assigned as (*R*) based on the (*S*)-configuration of C-19 in the oxazoline moiety (Fig. 1). Possibly the benzylic substituted cyclophane **5** was produced owing to the nonplanarity of benzene ring of the cyclophane[12] and the steric effect of isopropyl group of the oxazoline.[13]

To examine the efficiency of these planar chiral *N,S*-ligands in asymmetric synthesis, palladium-catalyzed allylic alkylation was chosen as the model reaction (Scheme 2). The experiment was carried out at r.t. in the presence of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ and the ligands. A nucleophile was generated from dimethyl malonate in the presence of *N,O*-bis(trimethylsilyl)acetamide (BSA) and a catalytic amount of salt. The results were summarized in Table 1. It was found that all ligands **4a**, **4b** and **5** can catalyze the reaction to afford the substitution product **7** in almost quantitative yields. In comparison with the results



Scheme 1

obtained by using benzene ring substituted compounds **4a** and **4b** as ligands, the reaction using the benzylic substituted cyclophane **5** provided far better enantioselectivity, and the reactivity of **5** was also much higher than that of **4a** and **4b** (entries 4, 5 *cf.* entry 6).

The structure of ligand **5** is unique in the planar chiral cyclophane family. Its enantioselectivity and reactivity are also notable. Therefore similar *N,Se*-ligands **8a**, **8b** and **9**, with the latter having the same skeleton as **5**, were prepared by using similar procedures from intermediate **3** (Scheme 1) and tested further for the efficiency of planar chiral ligands with the two

coordinating atoms at benzylic and benzene ring positions in asymmetric synthesis. It can be seen that a higher ee value was obtained for benzylic substituted ligand **9** relative to **8a** and **8b** (entry 9 *cf.* entries 7,8 in Table 1). As for the *N, S*-ligand, the reactivity of the benzylic derivative (**9**) as ligand is higher than that using ring-substituted cyclophanes **8a** and **8b** as ligands. These results clearly show that the ligand with the two coordinating atoms at benzylic and benzene ring-positions is more effective than that with both the coordinating atoms at benzene ring-positions. This is presumably due to the increased tether length between the donor atoms which coordinate palladium in **5** and **9**, bringing the asymmetric environment closer to the allyl species during the reaction.[15] Interestingly, **4a** and **8a** with the same S_p planar chirality afforded **7** in (*R*)-configuration, whereas **4b**, **8b** with R_p planar chirality gave rise to **7** in (*S*)-configuration, even though all of these ligands showed the same central chirality at the oxazoline. It seems that the central chirality is not a decisive factor in controlling the absolute configuration of the product in our reaction.[8b,e]

In summary, novel *N,S*- and *N,Se*-ligands bearing the two coordinating atoms at benzylic and benzene ring positions showed excellent enantioselectivity and reactivity in palladium-catalyzed allylic alkylation reaction. The synthesis of further similar ligands *via* introduction of other coordinating atoms at the benzylic position and further investigations on the role of these in asymmetric reactions in more detail are in progress.

Received (in Columbia, MO, USA) 4th April 2000, Accepted 23rd May 2000

Rich electrochemistry and strong electronic couplings across the carbon bridges are revealed for compounds composed of two tetra(μ-*N*,*N*′-2-anilinopyridinate)diruthenium(II,III) termini bridged by either butadiynediyl (1) or ethynediyl (2) ligands.

The proposal of constructing molecular wires from linear arrays of covalently-linked metal-complexes (M) and elemental carbon chain (C_m) has been inspired by the pioneering work of Nast[1] and Hagihara.[2] Extensive electronic delocalization along the $-(M-C_m)_\infty-$ backbone holds the promise for new generation electronic and optoelectronic materials.[3] Much of the work during this decade has focused on the M–C_m–M type molecular compounds.[4,5] The degree of delocalization between two equivalent termini M is gauged by the comproportionation constant K_{com} for the following equilibrium:

$$[M-C_m-M]+[M-C_m-M]^{2+} \overset{K_{com}}{\rightleftharpoons} 2[M-C_m-M]^{+} \quad (1)$$

K_{com} (= $\exp\{F[E_{1/2}(2+/1+)-E_{1/2}(1+/0)]/RT\}$) can be computed from the electrode potentials $E_{1/2}(2+/1+)$ and $E_{1/2}(1+/0)$.[6] Significant delocalization along the C_m-bridge (K_{com} *ca.* 10^8–10^{12}) has been achieved with termini of CpFe(P–P),[7] CpRe(P)(NO),[8] $CpRu(P)_2$[9] and $Mn(P–P)_2I$[10] (P and P–P are mono- and bi-dentate phosphines, respectively), all mononuclear transition metal complexes. We report the first examples of capping elemental carbon chains (C_2 and C_4) with a bimetallic terminus, $[Ru_2(\mu\text{-ap})_4]^+$ (ap = 2-anilinopyridinate), which is the valence-averaged (not mix-valence!) diruthenium species with a 2.5 Ru–Ru bond order.[11,12]

It has been established that the mono-capped complexes $[Ru_2](C{\equiv}CR)$ (**3**) with R as Ph, H (**3a**), $SiMe_3$ (**3a**) and CH_2OCH_3 (**3c**) can be obtained from the transmetalation reaction between $[Ru_2]Cl$ and $LiC{\equiv}CR$.[12,13] Similarly, treating $[Ru_2]Cl$ with either 0.5 equiv. of $LiC{\equiv}CC{\equiv}CLi$ or 1 equiv. of $LiC{\equiv}CLi$ yields **1** and **2**, respectively.† Formulation of $(C{\equiv}C)_n$-

bridged dimers was established by both the elemental analysis and FAB-mass spectrometry.† Further confirmation of $(C{\equiv}C)_n$-bridging structural motif is provided by an X-ray diffraction study of molecule **1**.‡ Asymmetric unit of the crystal **1** contains the halves of two independent molecules, and each is related to the other half *via* a crystallographic inversion center. Metric parameters of the two independent molecules are very similar, and the structural plot of one of them is presented in Fig. 1, where a linear array formed by the bridging C_4-chain and two $[Ru_2]$ termini is clear.

Compared with $[Ru_2](C{\equiv}CSiMe_3)$ (**3b**),[13] the 'half' molecule of **1**, the coordination geometry of the 2-anilionopyridinates around the Ru_2 core in **1** is essentially unchanged as evidenced by the averaged Ru(II)–N and Ru(III)–N bond lengths 2.050 and 2.095 Å in **1**, and 2.046 and 2.096 Å in **3b**. Room temperature effective magnetic moments of **1** and **2** are respectively 4.2 and

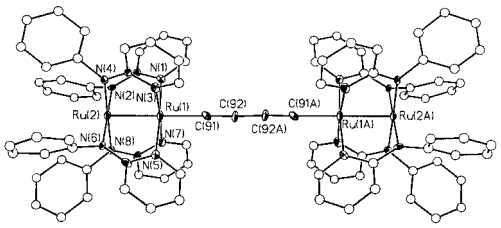

Fig. 1 ORTEP of **1** at 20% probability level. Selected bond lengths and angles: Ru(1)–C(91), 2.047(14) Å; C(91)–C(92), 1.258(16) Å; C(92)–C(92A), 1.33(2) Å; Ru(1)–Ru(2), 2.3311(15) Å; Ru(2)–Ru(1)–C(91), 179.5(4)°; Ru(1)–C(91)–C(92), 177.8(12)°; C(91)–C(92)–C(92A), 176.1(19)°.

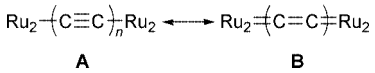
3.8 μ_B per $[Ru_2]$, indicating a S = 3/2 ground state that has been observed for many Ru_2(II,III) compounds including **3** and $[Ru_2]Cl$.[11–13] Hence, the termini of both **1** and **2** are globally isoelectronic with **3** and $[Ru_2]Cl$. Some small but notable differences, however, do exist between **1** and **3b**: the Ru–Ru (2.331(2) Å) and $C_\alpha{\equiv}C_\beta$ (1.258(16) Å) distances in **1** are elongated from that of **3b** (2.3162(5) and 1.207(6) Å), while the Ru–C_α distance is shortened (2.047(14) Å in **1** and 2.077(4) Å in **3b**). The C_β–$C_\beta{}'$ (≡C–C≡) distance, 1.33(2) Å, is identical to that found for the highly delocalized $[Mn(dmpe)_2I]_2(\mu\text{-}C_4)$,[10] but shorter than 1.367[9] Å found for *trans*-$[Pt(PPh_3)_2Cl]_2(\mu\text{-}C_8)$, a molecule lacking delocalization.[14] Although barely significant, all these changes are consistent with the strengthening of the Ru–C π interaction and concurrent weakening of the π(C≡C) bond. The valence structure of the $[Ru_2]_2(\mu\text{-}C_4)$ backbone may contain a significant contribution of cumulenic resonance structure **B** in addition to the predominant resonance structure **A** depicting the localized carbon–carbon triple bonds.



Cyclic voltammograms (CV) of **3** indicate two quasireversible redox processes (CV for **3a** shown in Fig. 2): an oxidation (**3a**$^+$/**3a**) around 462 mV and a reduction (**3a**/**3a**$^-$) around −873 mV and an irreversible couple at more positive potential (*ca.* 1300 mV). Upon a change from simple axial coordination of C≡CR to $(C{\equiv}C)_n$-bridge, both **1** and **2** undergo four quasireversible and one irreversible one-electron redox processes between −1600 and +1200 mV (Fig. 2). Therefore, there are six accessible oxidation states in both molecules **1** and **2**, surpassing the record of five established for $[CpRu(P)_2]_2(\mu\text{-}C_4)$.[9]

Based on the established electrochemistry of **3**,[13] the quasireversible redox couples in both **1** and **2** can be unambiguously assigned as:

Redox couples I and II correspond to the one electron reduction couple in **3**, and III and IV correspond to the oxidation couple in **3**. $\Delta E_{1/2}$(II/I) and $\Delta E_{1/2}$(IV/III), the differences in electrode

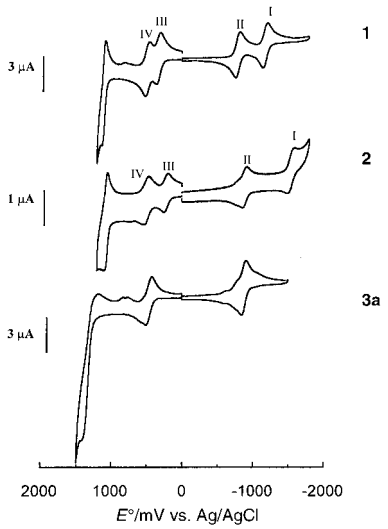


Fig. 2 Cyclic voltammograms of compounds **1**, **2** and **3a** recorded at a scan rate of 100 mV/s in 0.20 M $(Bu^n)_4NPF_6$ solution (THF, N_2-degassed) on a BAS CV-100W voltammetric analyzer with a glassy carbon working electrode, a Pt-wire auxiliary electrodes, and a Ag/AgCl reference electrode.

potentials, are respectively 389 and 157 mV in **1**, and 667 and 285 mV in **2**, which are undoubtedly the result of strong electronic coupling between two [Ru_2] termini mediated by the $(C{\equiv}C)_n$-bridges. Corresponding comproportionation constants K_{com}(red) and K_{com}(ox) are 3.8×10^6 and 506 for **1**, and 1.9×10^{11} and 6.6×10^4 for **2**, and K_{com}(red) for **2** is comparable to the largest K_{com} determined for other $(C{\equiv}C)_n$-bridged complexes with CpFe(P–P) (1.6×10^{12}),[7] CpRe(P)(NO) (1.1×10^9),[8] $CpRu(P)_2$ (1.5×10^{11}),[9] and $Mn(P–P)_2I$ (5.4×10^{10})[10] termini. Distance-dependence of the coupling is evident: K_{com} of C_4-bridged **1** is several orders of magnitude smaller than that of C_2-bridged **2**. Furthermore, K_{com}(red) is much larger than K_{com}(ox) in the same molecule, indicating that the Ru–C π-bonding is much stronger in the reduced form than in the oxidized form. Both linear and square arrays of bimetallic units covalently linked by dicarboxylates have been reported recently,[15] and K_{com} as high as 1.3×10^{12} was determined for $[W_2(O_2C^tBu)_3]_2$(μ-oxalate).

Effect of electronic delocalization over the C_m-bridge is also evident from the UV–VIS–NIR spectra (Fig. 3). The 'half' molecule **3a** absorbs strongly at 465 (**A**) and 745 nm (**B**), which may be respectively attributed to σ(Ru–C) to δ*(Ru_2) and π(Ru_2) to π*(Ru–N) transitions in analogy to the case of $Ru_2(O_2CR)_4Cl$.[16] Upon establishing the C_m bridge, each band is 'split' into two intensified bands (A1 and A2; B1 and B2), and the emergence of bands A2 and B2 accounts for the color change from the dark green for all $Ru_2(ap)_4(C{\equiv}CR)$ species[12,13] to the dark blue and red–purple colors for **1** and **2**, respectively. Clearly, the strong electronic coupling across the C_m bridge results in a significant orbital mixing between two [Ru_2] termini. The energy splitting of either the ground state or the excited state due to the mixing is sufficiently large that each of transitions **A** and **B** evolves into two bands.

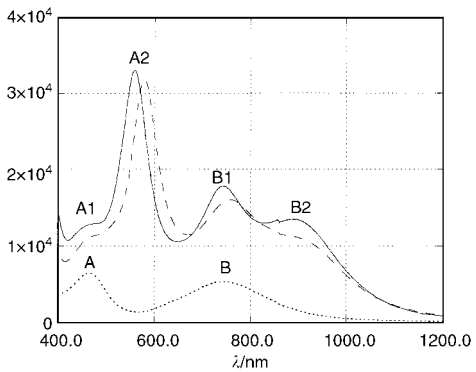

Fig. 3 UV–VIS spectra of compounds **1** (dash), **2** (solid) and **3a** (dot) recorded in THF.

The unprecedented number of accessible oxidation states in a C_m-bridged complex discovered for **1** and **2** clearly demonstrates the advantage of using bimetallic units as terminal electron reservoirs in constructing molecular conductors. The presence of multiple reversible redox couples in **1** and **2** may furthermore allow access to both the anionic (*e.g.* $\mathbf{1}^-$ and $\mathbf{1}^{2-}$) and cationic derivatives ($\mathbf{1}^+$ and $\mathbf{1}^{2+}$). Isolations of these derivatives and the analogs with longer C_m bridges are being explored in our laboratory.

Generous support from the University of Miami (Start-up fund, CCD-diffractometer fund, and General Research Award) is gratefully acknowledged. We also thank Professor A. Kaifer for the access of electrochemical apparatus.

Notes and references

† **1** and **2** were obtained by treating $Ru_2(ap)_4Cl$ with either LiCCCCLi (0.6 equiv.) or LiCCLi (1 equiv.) in THF at room temperature for 12 h under argon. After the mixture was washed with brine, the solvent was removed from the organic layer to yield a purple solid. Residual starting material was removed *via* rinsing with CH_2Cl_2 till the washings became colorless. Recrystallization in THF yield dark purple microcrystalline solids (53% for **1** and 42% for **2**). A chiral Eu^{3+}–thienoyltrifluoroacetone complex on an avidin tetramer: luminescence and CD studies on the supramolecular protein–metal chelate complex

Masumi Taki, Hiroshi Murakami and Masahiko Sisido*

Department of Bioscience and Biotechnology, Faculty of Engineering, Okayama University, 3-1-1 Tsushimanaka, Okayama 700-8530, Japan. E-mail: sisido@cc.okayama-u.ac.jp

Received (in Cambridge, UK) 8th March 2000, Accepted 23rd May 2000

A chiral Eu^{3+}–chelate complex was built into the biotin-binding sites of an avidin tetramer by the binding of biotin-linked thienoyltrifluoroacetones.

Eu^{3+}–β-diketone complexes are known to exhibit distinct luminescence when irradiated under UV light.[1] The emission properties have been intensively studied and have found a variety of chemical and biological applications, *e.g.* as sensitive fluorometric probes.[2] However, conventional bidentate β-diketone chelators form rather unstable complexes with Eu^{3+}, and their luminescence intensity is often very weak, especially in aqueous media. In order to overcome this problem, Matsumoto and coworkers synthesized a new type of Eu^{3+} chelate in which two bidentate β-diketone moieties are covalently linked.[3,4] The tetradentate ligand formed a very stable complex with Eu^{3+}, and the complex emitted strong luminescence.[4]

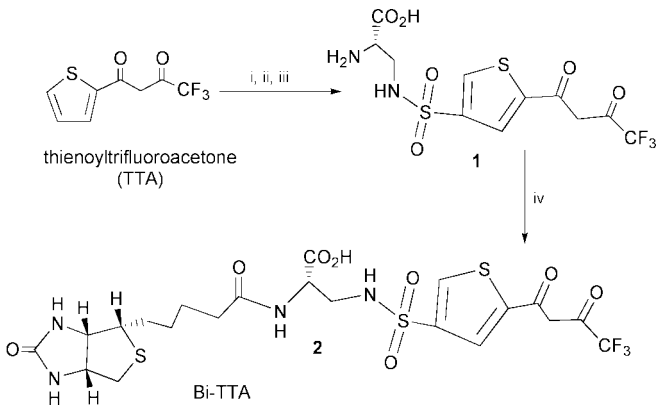
The finding of luminescence enhancement in the above tetradentate chelate motivated us to build a supramolecular Eu^{3+} complex of two bidentate ligand molecules arranged on a protein framework. A tetrameric avidin was chosen as the protein framework, since it strongly binds biotin[5] or biotin derivatives[6] through non-covalent interactions. The X-ray crystallographic data of the avidin tetramer[7] indicates that two of the four biotin-binding sites face one side of the tetramer and the two biotins in the binding sites take a right-handed screw configuration with a chirality factor of 0.90.[8] The dissymmetrically arranged biotin-binding pockets can be used to incorporate two biotin-labeled bidentate ligands in a chiral configuration. The structure and synthesis of the biotin-linked bidentate ligand **2** (Bi-TTA), are shown in Scheme 1.

Complexation of the Bi-TTA with avidin was confirmed by the fluorescence quenching of tryptophan in avidin. Fig. 1 shows the fluorescence spectra of avidin in the presence of different amounts of Bi-TTA. The peak position of tryptophan fluorescence shifted to a shorter wavelength[9] and decreased upon addition of Bi-TTA. The decrease stopped when the avidin units were saturated by the Bi-TTA molecules. The extent of fluorescence quenching was much larger than the quenching by biotin,[6] presumably owing to an energy transfer process from the singlet excited state of the tryptophan to the triplet state of the β-diketone group.

The formation of the Bi-TTA–Eu^{3+} complex on the protein framework was monitored by the increase of luminescence intensity of a solution of Bi-TTA and Eu^{3+} upon addition of avidin. As shown in Fig. 2, the narrow luminescence band at 613 nm increased with the addition of avidin, and the increase ceased after almost all the Bi-TTA molecules were bound to avidin. The luminescence intensity of the Bi-TTA–Eu^{3+} complex in the presence of avidin is 25 times larger than that of the free Bi-TTA and Eu^{3+} mixture in the absence of avidin. No luminescence band at 613 nm was observed for a mixture of Eu^{3+} and avidin in the absence of Bi-TTA.

When an excess of avidin was quickly added to a fresh mixture of Bi-TTA and Eu^{3+} up to a tetrameric avidin : Bi–TTA ratio of 5 : 1, the luminescence emission at 613 nm decreased to 17% of the intensity for the tetrameric avidin : Bi-TTA ratio of 1 : 4. The reduced Eu^{3+} emission in the presence of an excess of avidin suggests that the emission enhancement at 613 nm originates from interactions between the metal chelates on the avidin tetramer and Eu^{3+} that are most effective when the tetrameric avidin : Bi-TTA ratio is 1 : 4.

The ligand : Eu^{3+} ratio was determined to be 1 : 1 from the luminescence titration curve of the mixture of tetrameric avidin:Bi-TTA (1 : 4) with the addition of Eu^{3+}. The luminescence intensity at 613 nm increased with the addition of Eu^{3+}, and the increase ceased when the Eu^{3+} : Bi-TTA ratio reached



Scheme 1 *Reagents and conditions*: i, chlorosulfuric acid, 0 °C → room temp., 30%; ii, *N*-α-Boc-L-α,β-diaminopropionic acid, DMF, carbonate buffer (pH 9.3), r.t., 80%; iii, TFA, 0 °C, 100%; iv, *N*-hydroxysuccinimidobiotin, TEA, DMF, r.t., 100%.

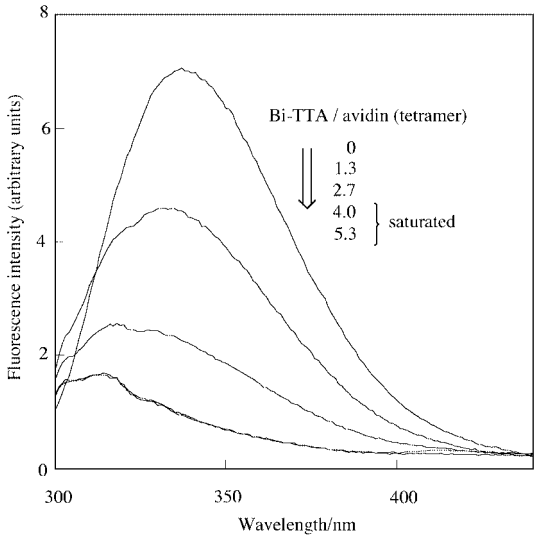


Fig. 1 Fluorescence spectra of avidin–Bi-TTA mixtures in PIPES–NaCl buffer at pH = 6.5. λ_{ex} = 290 nm. The molar ratios are indicated: [avidin (tetramer)] = 7.8×10^{-8} M.

DOI: 10.1039/b001908i

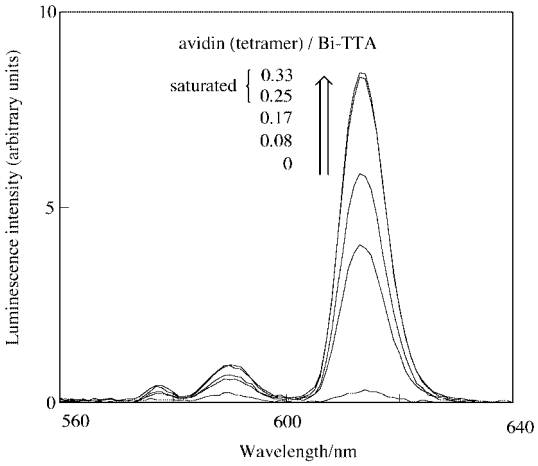

Fig. 2 Luminescence spectra of avidin–Bi-TTA mixtures in the presence of $EuCl_3$ in PIPES–NaCl buffer at pH = 6.5. The molar ratios of avidin (tetramer)/Bi-TTA are indicated: λ_{ex} = 343 nm. The TTA moiety is selectively excited under the conditions: [Bi-TTA] = 3.1×10^{-7} M, [$EuCl_3$] = 1.2×10^{-4} M.

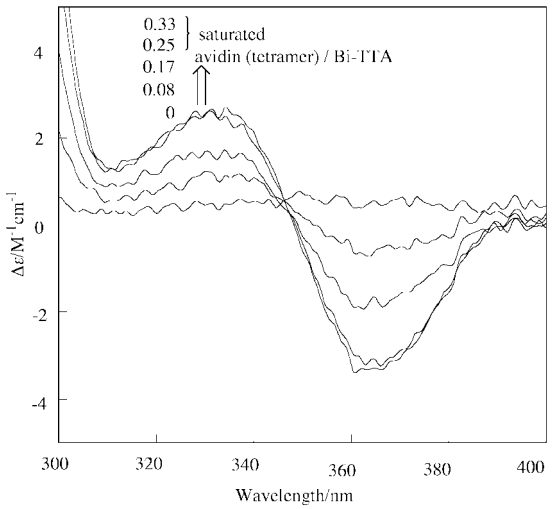

Fig. 3 CD spectra of Bi-TTA in the presence of $EuCl_3$ and different amounts of avidin in PIPES–NaCl buffer at pH = 6.5. The molar ratios are indicated; [Bi-TTA] = 4.0×10^{-4} M, [$EuCl_3$] = 3.0×10^{-3} M.

4:4. The Eu^{3+}:ligand ratio indicates that each TTA moiety binds a single Eu^{3+} ion, and the luminescence intensity increases when two TTA–Eu^{3+} complexes self-assemble on one side of the tetrameric avidin framework.

The formation of the two TTA–Eu^{3+} complexes was also confirmed from CD spectra. As shown in Fig. 3, a marked CD doublet appeared at 333 and 365 nm with the addition of avidin to a mixture of Bi-TTA and Eu^{3+}. The CD peak was saturated when all the Bi-TTA molecules were bound to avidin. No CD signal was observed in a tetrameric avidin:Bi-TTA (1:4) solution in the absence of Eu^{3+}. When Eu^{3+} was added to the latter solution, a similar CD spectrum as in Fig. 3 appeared, indicating the formation of the ligand–Eu^{3+} complex.

The luminescence and CD data indicate the formation of a chiral dimeric ligand–Eu^{3+} complex on the protein framework. The chiral lanthanide complex may find applications in enantioselective catalysis for the cleavage of nucleic acids[10] or proteins.[11]

A novel photocycloaddition of substituted pyridines with benzofuran†

Masami Sakamoto,*[a] Ai Kinbara,[a] Tadao Yagi,[a] Takashi Mino,[a] Kentaro Yamaguchi[b] and Tsutomu Fujita[a]

[a] *Department of Materials Technology, Faculty of Engineering, Chiba University, Yayoi-cho, Inage-ku, Chiba 263-8522, Japan. E-mail: saka@galaxy.tc.chiba-u.ac.jp*

[b] *Chemical Analysis Center, Chiba University, Yayoi-cho, Inage-ku, Chiba 263-8522, Japan*

Received (in Cambridge, UK) 27th March 2000, Accepted 23rd May 2000

Irradiation of a benzene solution containing 3-cyano-2-methoxypyridine (0.02 M) and benzofuran (0.5 M) resulted in the formation of stereo-isomeric 1:1 adducts, *endo* and *exo*-7-cyano-2-methoxy-4-methyl-9-oxa-3-aza-10,11-benzotricyclo[6.3.0.0^{4,7}]undeca-2,5-diene, accompanied by 5-cyano-2-methoxypyridine and a pyridine dimer; the structures of the adducts were established by X-ray structural analyses.

The photochemistry of heteroaromatics is an underdeveloped area compared with the carbon aromatics, such as benzene, naphthalene and anthracene derivatives, the photochemical behavior of which has been extensively studied from both mechanistic and synthetic perspectives.[1–7] In particular, the ring expansion or transformation of a pyridine ring with photochemical 4 + 4 or 2 + 2 cycloaddition is quite difficult.[8] We are interested in investigating the photochemical aspects of heteroaromatics and their utilization for the synthesis of new heterocycles. Recently, we reported that 2-alkoxy-3-cyanopyridines show comparatively high photochemical reactivity for promoting a variety of photochemical reactions, such as dimerization and 4 + 4 cycloaddition with furan.[9–11] The high reactivity of these pyridines compared with a simple pyridine is dependent on the polarization within the pyridine ring from the conjugate relationship of the cyano and alkoxy groups. We have identified a new photochemical 2 + 2 cycloaddition reaction between two heteroaromatics, pyridine and benzofuran.

When a benzene solution of 3-cyano-2-methoxy-6-methylpyridine **1a** (0.02 M) containing 0.05 M of benzofuran was irradiated with Pyrex filtered light, two types of 1 : 1 adducts of **1a** and benzofuran (**2a**, 32%; **3a**, 25%) were obtained, accompanied by **4a** and the pyridine dimer **5a**, in 7 and 33% yields, respectively, at 59% conversion (Table 1). The structures of the adducts, **2a** and **3a**, were determined on the basis of elemental analyses and the spectral data. Finally, the stereoisomeric structures were established by X-ray structural analyses (Fig. 1 and 2).‡ In the cases of the transpositional isomer **4a** and the dimer **5a**, we have already reported their formation by the direct irradiation of **1a**.[9] Irradiation of **1b** and **1c** also gave two stereoisomeric adducts as shown in Table 1, their structures were determined by comparison of the spectral data of **2a** and **3a**.

Usually, an electronically excited pyridine is not observed to undergo any radiative relaxation; however, this pyridine **1** shows strong emission of fluorescence at 310 nm. The emissive singlet excited state of pyridine reacts with the ground state of benzofuran, because the addition reaction was not quenched by triplet quenchers, such as 2,5-dimethylhexa-2,4-diene, penta-1,3-diene or stilbene, and also the sensitization by benzophenone or xanthone was quite inefficient. The formation of the adducts **2** and **3** is explainable in terms of the 2 + 2 cycloaddition taking place at the C-2 and C-3 positions of the singlet excited state of the pyridine ring with the C-3 and C-2 positions of benzofuran leading to **6** (Scheme 1). A subsequent ring-opening reaction gives cyclooctatriene **7**, which is followed by electrocyclization to the tricyclic adducts **2** and **3**.

The mechanism is also supported by Frontier-MO calculations using the PM3 Hamiltonian.[12] The orbital energies and coefficients of the singlet excited state for **1a** (HSOMO and LSOMO) and those of the ground state of benzofuran (LUMO and HOMO) were obtained (Fig 3). The energy gap (ΔE) between the LSOMO and HOMO is smaller than that between the HSOMO and LUMO, and this frontier orbital interaction is most important in this photocycloaddition. The coefficients at

the 3-position in the LSOMO of the singlet excited state of the pyridine ring and those at the 2-position of the HOMO in the ground state of furan are larger than those at any other positions. It is concluded that the initial bond formation occurs between the C2–C3 positions of pyridine and the C3–C2 positions of benzofuran, leading to **6**.

Gilbert and Heath reported the photochemical addition of 2-cyanoanisole to vinyl ether leading to a 2 + 2 adduct, and subsequently followed by ring-opening to a cylcooctatriene.[13]

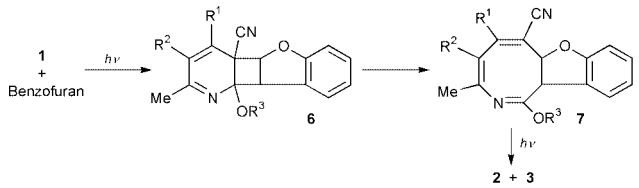

Scheme 1

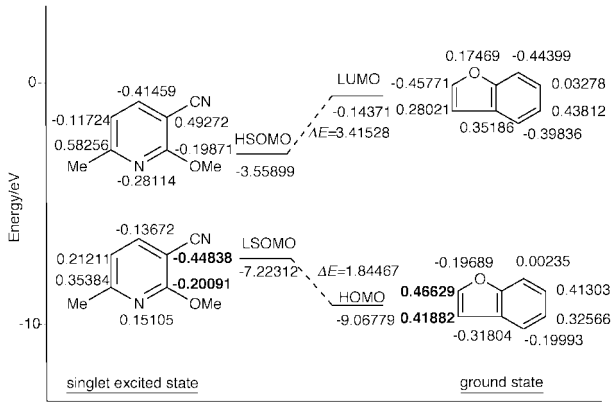

Fig. 3 Estimated energies and coefficients of 3-cyano-2-methoxy-6-methylpyridine **1a** and benzofuran obtained from the PM3 Hamiltonian contained within the MOPAC program.

The cyclooctatriene cyclizes to a secondary photoproduct, a bicyclo[4.2.0]octa-2,7-diene structure, upon irradiation. The reversibility of the photochemical reaction and the thermal conversion between the cyclooctatriene and the bicyclo-[4.2.0]octa-2,7-diene were confirmed. In our present reaction, the thermal and photochemical reactions of **2** and **3** were carried out to obtain further supporting information on the reaction. However, the pyrolysis and the photolysis at 254 nm of the photoadducts gave polymerized materials, furthermore, when the addition reaction was followed by ^{1}H NMR spectroscopy, primary cyclobutane **6** or cyclooctatriene **7** could not be detected on irradiation in an NMR tube. The high reactivity of **6** may be due to steric crowding or the bond-weakening character of the cyano and methoxy groups facilitates the ring opening to the cyclooctatriene, subsequently leading to **7**.[14]

In conclusion, we have detailed the first example of a photochemical reaction between two heteroaromatic compounds, a pyridine and benzofuran system, leading to 1:1 cycloadducts. Attempts at photoaddition with benzothiophene, indole or *N*-methylindole instead of benzofuran proved unsuccessful. We are continuing to explore the details and the scope of the photochemical reactions of heteroaromatics.

Facile construction of the oxaphenalene skeleton by *peri* ring closure. Formal synthesis of mansonone F

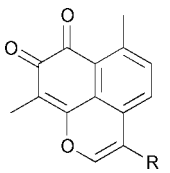
Young-Ger Suh,* Dong-Yun Shin, Kyung-Hoon Min, Soon-Sil Hyun, Jae-Kyung Jung and Seung-Yong Seo

College of Pharmacy, Seoul National University, San 56-1, Shinrim-Dong, Kwanak-Gu, Seoul 151-742, Korea. E-mail: YGSUH@plaza.snu.ac.kr

Received (in Cambridge, UK) 7th March 2000, Accepted 16th May 2000

A concise and divergent total synthesis of mansonone F has been accomplished *via* an efficient construction of the oxaphenalene skeleton by facile *peri* ring closure of the naphthol ether, and an effective preparation of the cyclization precursor starting from readily available 5-methoxy-1-tetralone by employing a palladium-induced aromatization of the naphthalinol.

Mansonone F (**1**) and biflorin, which are members of the naturally occurring *ortho*-naphthoquinone family, contain the unusual oxaphenalene skeleton.[1] Biflorin, the first oxaphenalene natural product, was found to have antibiotic properties.[2] More interestingly, mansonone F, a tricyclic sesquiterpenoid, has been reported as a phytoalexin[3–5] which is accumulated in the heartwood of the genus *Ulmus* in response to infections. Recently, mansonone F has also been isolated from the root bark of *Ulmus davidiana*, which has been traditionally used as a medicinal plant for treatment of infections in Korea. In addition, the highly potent anti-MRSA activity of mansonone F, comparable to that of vancomycin, has been studied in our laboratory.[6] However, the paucity of natural mansonone F, as well as its inherent structural constraint, has limited the optimization of its biological properties by structural modification and its therapeutic application. These reasons prompted us to develop a practical and divergent synthetic route to mansonone F, although an elegant synthesis of mansonone F employing intramolecular Diels–Alder addition of benzynes to furans has already been reported.[7] We report herein a concise and divergent synthesis of mansonone F starting from readily available 5-methoxy-1-tetralone.

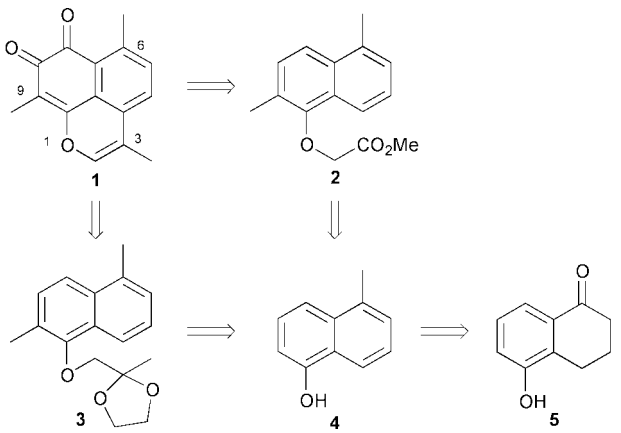


1 Mansonone F R=CH_3

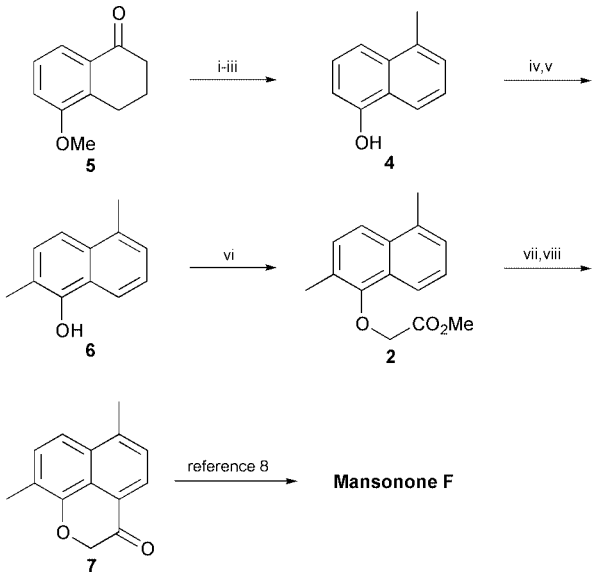
Biflorin R=$CH_2CH_2CHC(CH_3)_2$

Our synthetic strategy (Scheme 1) envisions a highly efficient construction of the tricyclic oxaphenalene skeleton *via peri* ring closure[8] by an intramolecular Friedel–Crafts acylation of the dimethylnaphthol ether **2** or **3**. The cyclization precursors **2** and **3** are readily accessible from the commercially available methoxytetralone **5** by sequential introduction of the alkyl substituents and an effective aromatization of the tetralinol intermediate.

Our synthesis (Scheme 2) commenced with preparation of the methylnaphthol **4**. The first methyl substituent, corresponding to the C6-methyl of mansonone F, was conveniently introduced by methyl Grignard addition to the carbonyl of the tetralone **5**. Aromatization[9] of the resulting carbinol by palladium-induced concurrent dehydration and dehydrogenation and then demethylation of the resulting methoxynaphthalene by boron tribromide provided the methylnaphthol **4**. The methylnaphthol **4** was transformed in a straightforward manner into the cyclization precursor **2** by a three step sequence. The second methyl substituent corresponding to the C9-methyl of mansonone F was effectively introduced by benzeneboronic acid-assisted hydroxymethylation[10] followed by hydrogenolysis of the resulting benzyl alcohol. *O*-alkylation of the naphthol **6** with bromoacetate afforded the dimethylnaphthol ether **2** as a cyclization precursor. The key tricyclic oxaphenalene skeleton of mansonone F was efficiently constructed by a facile *peri* ring closure[8] of the dimethylnaphthol ether **2**. Conversion of the ester **2** to an acid halide and then intramolecular Friedel–Crafts



Scheme 1 Synthetic strategy.



Scheme 2 First synthetic route to mansonone F. *Reagents and conditions*: i, MeMgI, Et_2O, reflux, 1 h; ii, 10% Pd/C, triglyme, reflux, 2 days; iii, BBr_3, CH_2Cl_2, −78 °C, then warm to room temp. (94% in 3 steps); iv, $PhB(OH)_2$, $(CHO)_n$, propionic acid, PhH, reflux, 1 h, then H_2O_2, THF; v, 10% Pd/C, H_2, MeOH, 5 h (63% in 2 steps); vi, $BrCH_2CO_2Me$, K_2CO_3, acetone, reflux (82%); vii, $LiOH·H_2O$, THF–H_2O, 10 min; viii, $(COCl)_2$, PhH, reflux, 1 h, then $AlCl_3$, CH_2Cl_2 (74% in 2 steps).

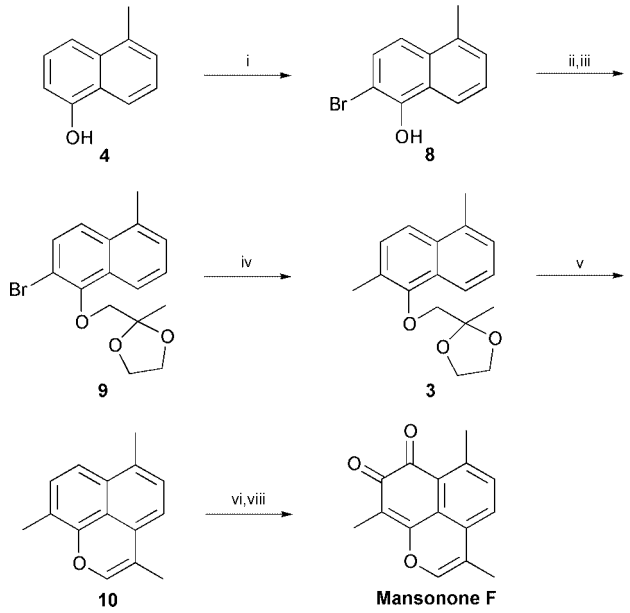

Scheme 3 Alternative synthetic route to mansonone F. *Reagents and conditions*: i, NBS, CH_2Cl_2, 0 °C (60–70%); ii, $BrCH_2COMe$, K_2CO_3, acetone, reflux (96%); iii, $(CH_2OH)_2$, PTSA, PhH, reflux (89%); iv, Bu^nLi, MeI, THF, −78 °C, then warm to room temp. (95%); v, PPA, 100 °C (87%); vi, $Cu(NO_3)_2{\cdot}xH_2O$, Ac_2O (83%); vii, 10% Pd/C, $NaBH_4$, MeOH, then Fremy's salt, 0.06 M NaH_2PO_4, acetone (41%).

acylation of the acid halide afforded the advanced intermediate **7**, which was transformed into mansonone F by a known procedure.[7]

Our alternative synthetic route for the transformation of methylnaphthol **4** into mansonone F is summarized in Scheme 3. The tether for *peri* ring closure was introduced to the bromonaphthol **8** by sequential *O*-alkylation with bromoacetone and carbonyl protection. Addition of the methyl substituent corresponding to the C9-methyl of mansonone F was achieved by halogen–metal exchange followed by methylation. Finally, construction of the oxaphenalene skeleton was executed by facile *peri* ring closure induced by polyphosphoric acid, to give the key intermediate **10**. In order to complete the synthesis, the ortho-quinone moiety of mansonone F was elaborated by application of the reported procedure.[7] The synthetic mansonone F was identical in all aspects to the naturally occuring compound.[1,10]

In summary, the total synthesis of mansonone F has been accomplished *via* a 10 step sequence, starting from the readily available 5-methoxy-1-tetralone (**5**). The key part of this synthesis involves the efficient preparation of 1,6-dimethyl-5-alkoxynaphthalene as a divergent cyclization precursor and its facile conversion to form the oxaphenalene skeleton by *peri* ring closure. This concise and practical synthetic procedure, providing a variety of substituents at the C3, C6 and C9 positions, offers a useful synthetic route to this important prospective anti-MRSA drug.

Generation of $C_{10}H_4$ species in a low-temperature argon matrix: consecutive photolysis of 1,2;5,6-naphthalenetetracarboxylic dianhydride†

Tadatake Sato, Hiroyuki Niino and Akira Yabe*

National Institute of Materials and Chemical Research (NIMC), Higashi 1-1, Tsukuba, Ibaraki 305-8565, Japan. E-mail: yabe@nimc.go.jp

Received (in Cambridge, UK) 30th March 2000, Accepted 30th May 2000

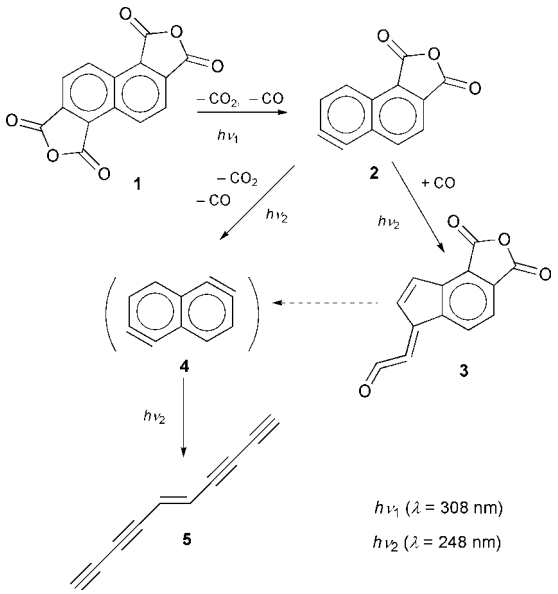
1,2;5,6-Naphthalenetetracarboxylic dianhydride has been consecutively photolyzed in a low-temperature argon matrix by wavelength-selective irradiation; dec-5-ene-1,3,7,9-tetrayne, which is the second $C_{10}H_4$ isomer, was generated as the final product.

Benzdiyne and naphthdiyne, in which two triple bonds are contained within one aromatic system, are challenging reactive intermediates. Recently, we reported the direct observation of a benzdiyne derivative by photolysis of 1,4-bis(trifluoromethyl)-2,3;5,6-benzenetetracarboxylic anhydride in a low-temperature argon matrix, which was the first finding that a benzdiyne could be trapped by the matrix isolation method.[1] However, we were unable to confirm the generation of parent benzdiynes (C_6H_2) by the consecutive photolysis of the corresponding precursors.[2–4] In a series of experiments, we confirmed the generation of hexa-1,3,5-triyne, the most stable C_6H_2 isomer, as a final photoproduct. This final product was formed by the ring opening of the benzdiynes.[4] Ring-opening reactions resulting in the generation of an acetylenic compound have also been reported in the case of benzyne.[5] These findings suggested that arynes containing diyne species are good precursors for acetylenic compounds, which are difficult to prepare by normal synthetic methods.

These acetylenic compounds, oligoynes and the compounds with a cross-conjugated π-system, have attracted much attention in the past. For example, Diederich *et al.* have thoroughly investigated such compounds in a series of research on molecular and polymeric carbon allotropes,[6,7] reporting the synthetic preparation of tetraethnylethene,[8] which is the only isomer with a $C_{10}H_4$ molecular formula identified so far. The acetylenic compounds are of interest as a building block for novel carbon networks.

Here, we report the consecutive photolysis of 1,2;5,6-naphthalenetetracarboxylic dianhydride **1**[9] in a low-temperature argon matrix (Scheme 1). The photolysis, which used several lasers, was carried out in an attempt to generate naphth-1,5-diyne. A novel acetylenic compound with a cross-conjugated π-system was observed as the final product, as well as stepwise-produced reactive intermediates.

Crystallites of **1** were vaporized at 145 °C and co-deposited with argon (99.9999%) onto a CsI or CaF_2 plate in a sample chamber whose pressure was kept at $< 10^{-5}$ Torr.[10] Precursor **1** was photolyzed using a XeCl excimer laser (308 nm, 5 Hz, *ca.* 10 mJ cm^{-2} $pulse^{-1}$). The photolysis was followed by FTIR and UV–VIS absorption spectroscopies. Upon irradiation, new IR bands ascribable to photogenerated species appeared, while the IR bands of **1** decreased. The appearance of IR bands arising from CO and CO_2 indicated that decarboxylation and decarbonylation of **1** were induced upon irradiation at 308 nm. This photolysis resulted in the generation of an intermediate having a naphthyne structure, **2**. Prolonged irradiation at 308 nm caused the formation of ketene species **3** by the addition of CO



Scheme 1

to **2**, which was confirmed by the appearance of the characteristic IR bands at 2082 and 2087 cm^{-1}.[11] The intermediates **2** and **3** were identified on the basis of their FTIR spectra being in good agreement with the theoretical IR spectra calculated by density functional theory (B3LYP/6-31G** level).[12] The obtained intermediate **2** was photolyzed upon irradiation at 248 nm (KrF excimer laser, 5 Hz, 8 mJ cm^{-2} $pulse^{-1}$). During the initial stage of irradiation, generation of **3** was the dominant process. However, upon prolonged irradiation, the generation of **3** was diminished and the generation of CO and CO_2 became the dominant process. Since the IR bands of **2** decreased upon irradiation, it was suggested that this process resulted in the formation of naphth-1,5-diyne ($C_{10}H_4$, **4**). However, IR bands ascribable to **4** were not observed. Upon irradiation, only two weak IR bands at 621 and 3323 cm^{-1} appeared, other than the increasing peaks of CO and CO_2. These weak bands were ascribable to the C–H bending and stretching modes of acetylenic compounds. Moreover, upon further irradiation at 248 nm, **3** was also photolyzed slowly. Even at this stage, increases in the IR bands of CO, CO_2 and the acetylenic species was still observed.

Taking into account benzyne[5] and benzdiynes,[2–4] it is plausible that acetylenic compounds may be generated by ring-opening of **4**. Certainly, the acetylenic C–H stretching band at 3323 cm^{-1} was observed at almost the same position as that of butadiyne (3324–6, 3340 cm^{-1}), hexatriyne (3324–7 cm^{-1}), or hex-1-ene-3,5-diyne (3324 cm^{-1}), which were formed by ring-opening reactions of benzyne[5] and/or benzdiynes[2–4] or the photo-decomposition of benzene.[13] It should be noted that several peaks were observed when several kinds of acetylenic compounds were formed simultaneously.[3,13] In our experiment, one C–H stretching peak accompanied by a shoulder on its higher wavenumber side was observed at 3323 cm^{-1} as shown in Fig. 1. Moreover, no peaks ascribable to other photo-

† Electronic supplementary information (ESI) available: synthesis of **1**, theoretically estimated IR data for *cis*- and *trans*-dec-5-ene-1,3,7,9-tetrayne and details of TD-DFT calculations. See http://www.rsc.org/suppdata/cc/b0/b002555k/

DOI: 10.1039/b002555k

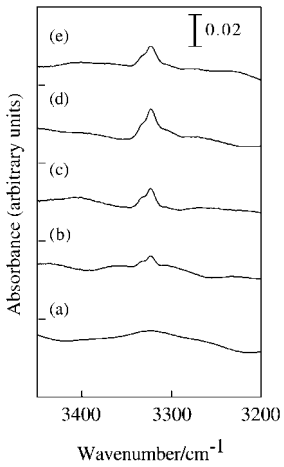


Fig. 1 FTIR spectra (C–H stretching band) upon photoirradiation of **1** with a KrF excimer laser: (a) before irradiation, (b) after 9000 pulses, (c) after 21000 pulses, (d) after 66000 pulses and (e) after 1800 pulse irradiation with the ArF excimer laser.

generated species were observed. Thus, the acetylenic $C_{10}H_4$ species was solely or dominantly generated: fragmentation of the $C_{10}H_4$ species can be excluded as a minor process. The species formed upon irradiation at 248 nm showed specific UV–VIS absorption bands as shown in Fig. 2. After irradiation by the XeCl excimer laser, absorption bands at 305, 296, 250 and 205 (broad) nm were observed. The bands at 250 and 205 nm were assigned to **2**, which was the major species existing upon irradiation at 308 nm and photolyzed upon irradiation at 248 nm. In contrast, the bands at 305 and 296 nm were assigned to **3**, since these bands also grew up in the initial irradiation at 248 nm. During this stage, increases in the bands at 372, 354, 338 and 305 nm were clearly observed, which were also assigned to **3**. Under prolonged irradiation, the absorption bands of **3** decreased slowly, and other bands emerged at 317, (296), 280, 213, 203 and 195 nm. These bands were assigned to the acetylenic $C_{10}H_4$ compound showing the C–H stretching band at 3323 cm^{-1}. Similar vibronic absorption bands have frequently been observed in acetylenic compounds.[14,15] As mentioned above, it was assumed that the acetylenic $C_{10}H_4$ compound was generated by ring-opening of **4**. Compound **4** has C_{2h} structure, in which two *o*-benzyne molecules are symmetrically fused. Considering that hex-1-ene-3,5-diyne was formed by ring-opening of benzyne,[5] we tentatively assigned the compound to dec-5-ene-1,3,7,9-tetrayne ($C_{10}H_4$, **5**), which has not been isolated before. This assignment was supported by the following discussions. The theoretical prediction shows two

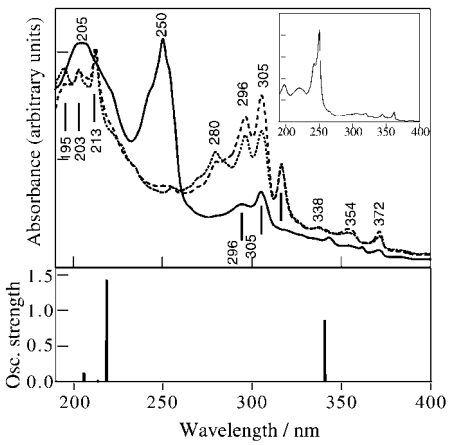

Fig. 2 (Top) UV spectra of the photolysis of **1** with a Nd:YAG laser (THG), XeCl and KrF excimer lasers in an argon matrix at 11 K: (——) after irradiation with Nd:YAG laser (THG) and XeCl excimer laser, (– – –) after successive irradiation with 3000 pulses and (····) 9000 pulses of the KrF excimer laser. Inset: UV spectra of **1** observed before irradiation in the argon matrix. (Bottom) transition energies and oscillator strengths of **5** calculated by the TD-DFT method.

C–H bending bands (581 and 587 cm^{-1}) and one C–H stretching band (3354 cm^{-1}) with intensities > 90 km mol^{-1}. On the other hand, the experimental results showed one C–H bending band (621 cm^{-1}) and one C–H stretching band (3323 cm^{-1}) with a shoulder as described above. Only one bending band would be ascribed to two neighboring bands and the appearance of the shoulder on the stretching band would be explained by matrix splitting.[16] Although tetraethynylethene, which is also a $C_{10}H_4$ species, would seem to be a possible candidate, it can be dismissed because it shows a quite different UV–VIS absorption spectrum.[8] The lowest transition band of the acetylenic $C_{10}H_4$ compound (317 nm) was seen in a longer wavelength region than that of hex-1-ene-3,5-diyne (275 nm in an Ne matrix).[5] This indicated that the π-conjugation system of the observed acetylenic compound was extended more than that of hex-1-ene-3,5-diyne. Electronic absorption spectra can be well described by time-dependent density functional theory (TD-DFT) calculations.[17] Transition energies and oscillator strengths of **5** calculated by the TD-DFT method are shown by bars in Fig. 2, which show favorable correspondences with the experimental result.[18] Thus, the observed acetylenic $C_{10}H_4$ compound was assigned to dec-5-ene-1,3,7,9-tetrayne.

In conclusion, the reactive intermediates **2** and **3** were identified on the basis of their FTIR spectra being in good agreement with calculated IR spectra. The aromatic $C_{10}H_4$ species, naphth-1,5-diyne, converted to a $C_{10}H_4$ species with acetylenic C–H moieties by ring-opening reactions. The acetylenic $C_{10}H_4$ species was dec-5-ene-1,3,7,9-tetrayne, the second $C_{10}H_4$ isomer, which has not previously been prepared.

16 In the results on DFT calculations for **5** (C_{2h} structure), another symmetrically forbidden C–H stretching mode (A_g 3354.6 cm^{-1}, 0 km mol^{-1}) was observed at higher wavenumber than that of the symmetrically allowed mode (B_u 3354.2 cm^{-1}, 341 km mol^{-1}). In the argon matrix, compound **5** may not be able to form an ideal symmetrical structure because it confined within a matrix cavity. In this case, the IR band corresponding to the A_g mode could be observed as a weak shoulder on the high wavenumber side of main C–H stretching band. As another possibility, we should consider the *trans*-confomer formed by *cis–trans* isomerization of the central C=C bond under photoirradiation (two acetylenic C–H stretching modes of the *trans*-conformer are predicted at higher wavenumbers: B_2 3355.2 cm^{-1}, 138 km mol^{-1}; A_1 3355.7 cm^{-1}, 120 km mol^{-1}).

The complexation of halide ions by a calix[6]pyrrole

Grazia Cafeo,[a] Franz H. Kohnke,*[a] Giovanna L. La Torre,[a] Andrew J. P. White[b] and David J. Williams*[b]

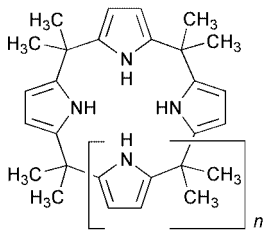
Received (in Cambridge) 20th March 2000, Accepted 23rd May 2000

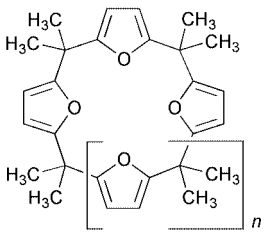
The X-ray crystal structures of the 1 : 1 complexes formed by calix[6]pyrrole 1b with Bu$^n_4$NCl and Bu$^n_4$NBr show the macrocycle to adopt D_{3d} symmetry and to encapsulate the halide ions within the macroring cavity *via* six N–H···X$^-$ hydrogen bonds; the macrocycle subtly adjusts its conformation to accommodate the differently sized anions; preliminary extraction experiments indicate that 1b is a dramatically stronger chloride ion complexing agent than its smaller analogue calix[4]pyrrole 1a.

Molecular receptors for cations and neutral guests have been extensively studied for many years.[1] In contrast, macrocycles capable of binding anions have attracted considerably less attention. However, because of the key role of anions in fundamental aspects of chemistry and biology, the search for novel and selective hosts for anions is a rapidly developing area of supramolecular chemistry.[2]

Significant progress in this field has been made by the discovery that, for example, pyrrole-based analogues of the calix[4]arenes such as **1a** are capable of binding fluoride and



n = 1 **1a** *n* = 3 **1b**



n = 3 **2**

chloride ions.[3–5] However, complexation occurs by means of a facial arrangement involving hydrogen bonding interactions between the four pyrrole N–H and the anions and not by inclusion within the macrocyclic cavity, which is too small for either the fluoride or the chloride ions.

These observations led us to synthesise[6] the larger calix[6]pyrrole **1b** from the known furan-based analogue **2**. This new synthesis provided a novel route to **1b** which, unlike its smaller analogue **1a**, is not readily isolated from the mixture of compounds obtained by the previously employed condensation reaction of pyrrole and acetone.[3b] We were thus able to investigate, for the first time, the behaviour of **1b** as a molecular receptor for halide ions. We expected **1b** to be an appreciably better complexing agent for the halide ions than **1a** both in terms of strength (it has the potential to form an additional two N–H···X$^-$ hydrogen bonds) and selectivity (owing to the possible inclusion of the ion within the larger macroring cavity—and hence achieve size-discrimination).

In order to estimate the improved binding of **1b** towards chloride and bromide with respect to that of **1a**, we compared the ability of the two macrocycles to complex and transfer these ions from a water phase to a lipophilic dichloromethane phase. The tests were extended to include also fluoride and iodide. In a series of extraction experiments, solutions of Bu$^n_4$NF, Bu$^n_4$NCl, Bu$^n_4$NBr and Bu$^n_4$NI in D_2O (10^{-2} M) were extracted with equal volumes of solutions containing **1a** or **1b** (10^{-2} M) in CD_2Cl_2 under identical conditions and temperature (16 °C). After separation of the two phases, the amount of anion transferred in each case was calculated from the ^{1}H NMR spectra of the CD_2Cl_2 solutions using the ratios between the integration values for the resonances of the protons of the macrocycles and those of the ammonium ion (which has to follow the halogen ion into the organic phase).† The values obtained were also confirmed by the corresponding decrease of the amount of salt in the D_2O phase which was measured by integration of ^{1}H NMR peak profiles with respect to a known amount of dioxane added as an internal standard.

In order to single out the contributions of the macrocycles to the phase transfer of the anions from other factors (halogen lipophilicity and phase transfer due to the Bu$^n_4$N$^+$ cation) the partition of these salts between the two phases was also determined in the absence of **1a** or **1b**. Macrocycles **1a** and **1b** are insoluble in water.

The results obtained (Table 1) indicate that the contribution of **1a** to the phase transfer of fluoride, chloride, bromide and iodide (if it exists) is marginal and its magnitude is at most within the experimental error. On the other hand, **1b** can effectively bind and transfer both chloride and bromide ions into a DCM phase and shows a *ca*. six-fold selectivity factor for chloride with respect to bromide.

The ^{1}H NMR spectra of **1b** in the presence of chloride and bromide (at the percentage concentration extracted) also show significant shifts of the pyrrole N–H resonances from its uncomplexed value of δ 7.67 towards higher values (up to δ 10.93 for chloride and δ 8.40 for bromide) which are certainly due to the involvement of the N–H protons in hydrogen bonding interactions with the halogen ions. A line broadening of the C–H resonances is also observed especially for the chloride complex.

Encouraged by these results, and to test the potential for inclusion as a function of the anion size, as well as to gain information on the mode of binding, we subjected 1 : 1 solutions of **1b** with Bu$^n_4$NCl and with Bu$^n_4$NBr in DCM to slow evaporation of the solvent to give, in each case, single crystals of 1 : 1 complexes suitable for X-ray analysis (mp 232–234 and 189–191 °C, respectively).

Table 1 Transfer of Bu$^n_4$NF, Bu$^n_4$NCl, Bu$^n_4$NBr and Bu$^n_4$NI (%) between D_2O and CD_2Cl_2 at 16 °C with and without **1a** and **1b**. The figures indicate the percentage variation in the concentration of salt in each phase after equilibration and were reproducible within a ±2% error

	Macrocycle					
	None		**1a**		**1b**	
	D_2O	CD_2Cl_2	D_2O	CD_2Cl_2	D_2O	CD_2Cl_2
Bu$^n_4$NF	[a]	[b]	[a]	[a]	[a]	[a]

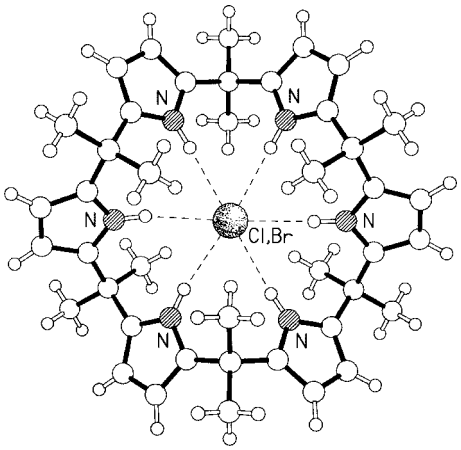

Fig. 1 Plan view of the X-ray structure of the 1:1 complexes formed between calix[6]pyrrole **1b** and Cl^- and Br^-. The hydrogen bonding geometries: N··X, H··X distances (Å), and N–H··X angles (°) are in the ranges 3.265(5)–3.305(5), 2.39–2.42 and 166–177 in the chloride and 3.344(5)–3.404(5), 2.46–2.51 and 170–178 in the bromide.

The X-ray analysis of the 1:1 complex‡ formed between the calix[6]pyrrole **1b** and chloride shows (Fig. 1), that to achieve binding, the host macrocycle undergoes a substantial conformational change from that observed for the 1:1 complex with water.[6] In the water complex the macrocycle adopts a tennis-ball-seam (D_{2d}) conformation whereas here with chloride the symmetry approximates closely to D_{3d}. The chloride anion is positioned centrally with respect to the six pyrrole nitrogen atoms (which are coplanar to within 0.02 Å) and displaced out of this plane by 0.37 Å along the molecular C_3 axis. Binding is *via* six N–H··Cl hydrogen bonds for which the N··Cl and H··Cl distances (Å) range between 3.265(5) and 3.305(5) [*cf.* a range of 3.264(7)–3.331(7) in the tetrapyrrole structure[7]], and 2.39 and 2.42 respectively; the N–H··Cl angles are in the range 166–177°. The small displacement of the chloride ion out of the plane of the six pyrrole nitrogens is accompanied by a slight 'flowering' of the macrocycle, the mean C··C separations between the inwardly directed methyl groups of the 'upper' and 'lower' set of isopropylidene groups being 5.25 and 4.40 Å, respectively.

The expectation that this 'flowering' in the case of the bromide complex would be more pronounced than in the chloride, owing to the larger anion size, was confirmed by X-ray analysis‡ (Fig. 2). Surprisingly, despite the inclusion in both structures of substantial amounts of disordered solvent, the structures are isomorphous. In the bromide complex the anion is again centrally positioned within the macrocycle which adopts a more distorted conformation but one which still approximates to D_{3d}. The bromide ion is bound by six N–H··Br hydrogen bonds with N··Br and H··Br distances ranging between 3.344(5) and 3.404(5), and 2.46 and 2.51 Å respectively; the N–H··Br angles are in the range 160–178°. Accompanying the increase in anion size (and lengthening of the hydrogen bonds) is an increase in the displacement of the anion (Br^-) from the plane of the six pyrrole nitrogen atoms (0.69 Å) and 'flowering' of the macrocycle, the Br^- adopting a 'perching' geometry analogous to that of, for example, ammonium ions with 18-crown-6. Here, the mean C··C separations (**a**–**f** in Fig. 2) between the inwardly directed methyl groups of the 'upper' and 'lower' set of isopropylidene groups are 5.62 and 4.31 Å, respectively. The anions, cations and solvent are, in both structures, well separated and there are no significant intermolecular interactions. The differences in the two solid state structures are consistent with the ability of **1b** to discriminate by size between the two halogen anions chloride and bromide.

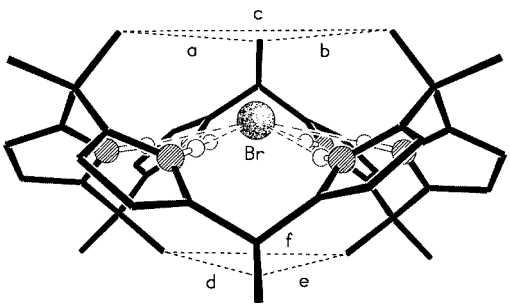

Fig. 2 Elevation of the X-ray structure of the 1:1 complex between calix[6]pyrrole **1b** and Br^- showing the 'perching' geometry of the hydrogen bonded Br^- ion within the 'flowered' macrocyclic conformation. The distances **a**–**c** and **d**–**f** between the inwardly directed isopropylidene methyl carbon atoms are in the ranges 5.46–5.72 and 4.26–4.38 Å respectively (*cf.* 5.11–5.37 and 4.34–4.48 Å respectively, in the chloride complex).

Work is in progress in our laboratory to determine the values of the association constants of **1b** with the halogen ions. Selectivity tests will include competitive binding experiments and transport across liquid membranes.

Notes and references

† The equilibrium of transfer between the two phases was always achieved within 10 min of vigorous stirring. The amount of $Bu^n_4N^+$ transferred between the two phases was not affected by the addition of NaOH to the water phase.

Oligomerization–transmetalation reactions of $Cp^*CrMe_2(PMe_3)$/methylaluminoxane catalysts

Jonathan S. Rogers and Guillermo C. Bazan*

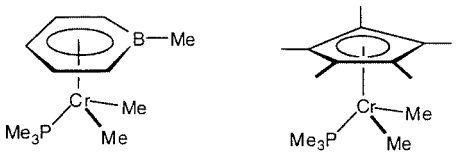
Department of Chemistry, University of California, Santa Barbara, CA 93106, USA. E-mail: bazan@ucsb.edu

Received (in Irvine, CA, USA) 15th March 2000, Accepted 18th May 2000

Chain growth in the reaction of ethylene with $Cp^*CrMe_2(PMe_3)$ activated with methylaluminoxane is restricted by a fast Cr/Al transmetalation process.

A range of metal ligand combinations exists for catalyzing the polymerization[1] and oligomerization[2] of olefins. The varying structures control the polymerization process to different extents and provide a means to tailor the polymer structure and the ensuing physical properties. The 'single site' technology is making a profound impact in the manufacture of this important class of commodity materials.[3]

Within this context, we recently reported that boratabenzene complexes of chromium(III), such as $(C_5H_5B–Me)CrMe_2(PMe_3)$ **1**, lead to active ethylene polymerization catalysts



upon activation with methylaluminoxane (MAO).[4] Since the reactivity of boratabenzene catalysts differs from the performance of their isoelectronic cyclopentadienyl-based counterparts,[5] it was of interest to compare **1**/MAO against $Cp^*CrMe_2(PMe_3)$/MAO (**2**/MAO). Compound **2** has been prepared previously and investigated because complexes of this type exhibit extreme ^1H and ^2H NMR parameters,[6] however little is known on its reactivity potential. In this contribution we show that the **2**/MAO catalysts react with ethylene to produce a distribution of low molecular weight oligomers with an *odd* number of carbon atoms.

Addition of a solution of **2** to MAO in toluene (50 μmol Cr; [Cr] = 1×10^{-3} M; Al/Cr = 1000, 23 °C) results in a color change from dark purple to red. Fast consumption of ethylene is observed when this solution is exposed to 1 atm of the monomer.[7] An activity of 87 kg[product]/(mol Cr h)$^{-1}$ was determined by measuring the amount of ethylene incorporated into the reaction vessel over a 30 min period. No precipitate was observed under these conditions. Using the same experimental setup, the Cp_2ZrCl_2/MAO catalyst system consumed 85 kg[ethylene]/(mol Zr h)$^{-1}$ to give high molecular weight polyethylene. Thus, under these conditions the affinity of **2**/MAO toward ethylene is comparable to those that characterize group 4 metallocene catalysts.

The mixture obtained from the **2**/MAO reaction was quenched with water and worked up with aqueous base. Analysis of the organic product by GCMS [Fig. 1(a)] reveals that the major product (*ca.* 98%) is a distribution of straight chain *n*-alkanes with an *odd* number of carbon atoms. The minor component corresponds to the homologous progression of *even* numbered alkanes.

Scheme 1 provides a plausible reaction pathway for the formation of the main product. In analogy to metallocene-type catalysts,[8] and taking into consideration the known reactivity of **1**[4] and the work of Theopold and coworkers,[9] it is likely that the

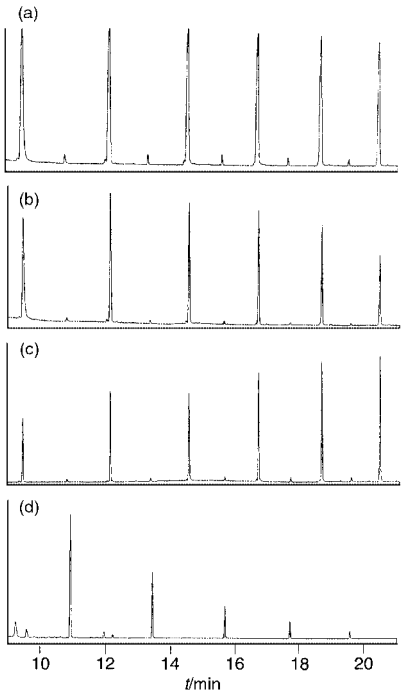


Fig. 1 GCMS analysis of C_{13} through to C_{23} products obtained from the following reactions: (a) **2**/MAO/C_2H_4; (b) **2**/MAO/C_2H_4 with 415 equiv. Al_2Me_6; (c) **2**/MAO/C_2H_4, after removal of volatiles from MAO *in vacuo*; (d) **2**/MAO/C_2H_4 with 830 equiv. '$AlEt_3$'. For all reactions: 50 μmol Cr; [Cr] = 1 X 10^{-3} M; Al/Cr = 1000; 1 atm C_2H_4.

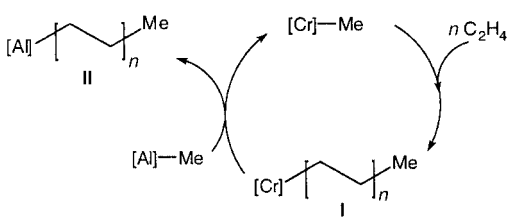
reaction between MAO and **2** leads to catalytic species of the type $[Cp^*(Me_3P)Cr–Me]^+$ ([Cr]–Me in Scheme 1). Insertion of ethylene leads to the propagating chain **I** in Scheme 1. Transfer to aluminium gives the aluminium alkyl **II** and regenerates $[Cp^*(Me_3P)Cr–Me]^+$. The reaction sequence shown in Scheme 1 provides odd carbon alkanes upon hydrolysis of **II**.

The chemical structure of '[Al]–Me' in Scheme 1 is not precise, in part because of the complex and poorly defined structure of MAO and because commercially available MAO contains varying amounts of trimethylaluminium. To explore the effect of increasing the concentration of '[Al]–Me' an additional 415 equiv. of Al_2Me_6 were added to the catalyst solution and the reactivity with ethylene measured. As shown by the GCMS chromatogram in Fig. 1(b), the additional Al_2Me_6



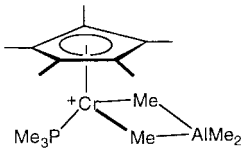
Scheme 1

DOI: 10.1039/b002146f

shifts the distribution in favor of the shorter alkanes, however the overall activity decreases to 34 kg[product]/(mol Cr h)$^{-1}$.

To examine the effect of reduced Al_2Me_6 concentration, the commercially available MAO solution was placed under vacuum for 16 h.[10] The resulting MAO solids were redissolved in toluene and the reaction with **2** and ethylene was carried out as before. Under these conditions, the activity was measured at 133 kg[product]/(mol Cr h)$^{-1}$ and polyethylene precipitates out of solution, accounting for *ca.* 85% of the product. The distribution of soluble alkanes gives a greater proportion of the heavier products [Fig. 1(c)]. Also relevant in this context is that only polyethylene is produced when **2** is activated by $B(C_6F_5)_3$.[4]

The overall trends illustrated in Fig. 1(a)–(c) are consistent with the mechanism proposed in Scheme 1. Additional Al_2Me_6 increases the rate of chain transfer to aluminium and gives rise to a distribution of shorter chain alkanes. The slower rate of ethylene consumption with the additional Al_2Me_6 may be due to the formation of bridging species such as **III**. It is anticipated



III

that the coordination of $AlMe_3$ to [Cr]–Me in **III** decreases the concentration of the active species thereby decreasing overall ethylene uptake. Removing free trimethylaluminium from MAO has the opposite effects—longer chains are obtained and more ethylene is consumed. Finally, we propose that the small fraction of even alkanes observed in the product results from a small fraction of ethyl and/or hydride found in the MAO.[11] When triethylaluminium is added (830 equiv. of '$AlEt_3$') to **2**/MAO (50 μmol Cr; [Cr] = 1×10^{-3} M; Al/Cr = 1000, 23 °C) the product is a homologous distribution of *n*-alkanes with an *even* number of carbon atoms [Fig. 1(d), activity = 97 kg[product]/(mol Cr h)$^{-1}$].

In summary, the **2**/MAO combination is an active catalyst for the oligomerization of olefins. Chain growth is limited by efficient Cr/Al transmetalation reactions.[12] After aqueous workup the product is a distribution of linear alkanes. The overall cycle shown in Scheme 1 reduces to the Cr-catalyzed insertion of ethylene into the Al–C bond.[13] It is also noteworthy that the isoelectronic boratabenzene–cyclopentadienyl substitution for the chromium catalysts (**1** *vs.* **2**), has a different effect than in zirconium catalysts. Under similar reaction conditions, the combination $Cp^*_2ZrCl_2$/MAO gives high molecular weight polyethylene, while $[C_5H_5B–OEt]_2ZrCl_2$/MAO[2b] produces low molecular weight 1-alkenes. In the zirconium case differences in reactivity stem from faster rates of β-hydride elimination for the boratabenzene complexes. For chromium, boratabenzene complexes exhibit slower rates of transmetalation with aluminium functionalities in MAO, leading to higher molecular weight polymer.

We are grateful to the Department of Energy for financial assistance.

7 *General polymerization procedure*: in a nitrogen filled glovebox, 50 μmol of **2** was weighed to the nearest 0.1 mg and dissolved in toluene. This solution was combined with the appropriate amount of MAO (10.3 wt% Al, 1.000 Al/Cr) and placed inside a 100 mL round bottom flask with a magnetic stir bar. Sufficient toluene was added to bring the total volume to 50 mL. The flask was fitted with a needle valve assembly and removed from the glovebox. The apparatus was weighed to the nearest 0.001 g and attached on a vacuum line. Vacuum was applied for 5 s and the flask was immersed in a water bath at room temperature. The flask was then exposed to an ethylene source which was vented to a mercury bubbler. After 30 min, the ethylene feed was stopped, the flask was cleaned, and weighed again to the nearest 0.001 g for activity determinations. The reaction was quenched using 3 mL of water and alumina salts were dissolved in aqueous base. The toluene layer was extracted to give the product.

ChemComm

The metal-directed self-assembly of three-dimensional porphyrin arrays†

Kelly Chichak and Neil R. Branda*

Department of Chemistry, University of Alberta, Edmonton, AB, Canada T6G 2G2. E-mail: neil.branda@ualberta.ca

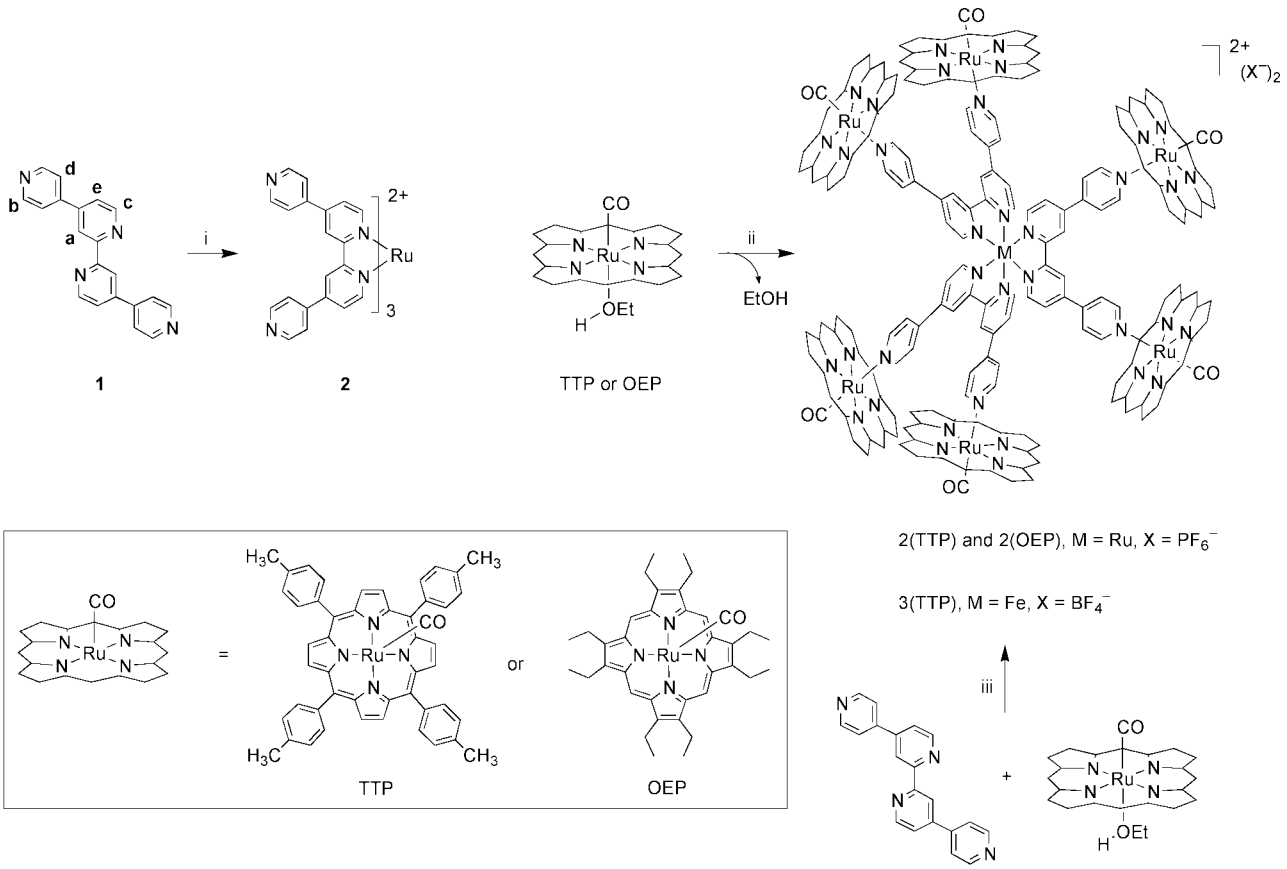
Received (in Columbia, MO, USA) 25th February 2000, Accepted 16th May 2000

Six metalloporphyrins spontaneously assemble into octahedral arrays through a metal-directed synthesis; ^{1}H NMR provides a convenient means for tracking the progress of the self-assembly process and highlights that the rates in which the octahedral complexes form are influenced by the steric demands of the building blocks.

The power of self-assembly synthesis lies in its ability to rapidly generate large and sophisticated molecular architectures from readily accessible building blocks with maximum efficiency. Extensive hands-on synthetic steps are minimized because the pathway to the formation of the assemblies is guided by the nature of the recognition surfaces programmed into the components. This provides access to high yields under thermodynamic control. Self-assembly synthesis has been applied to the area of coordination chemistry to produce a variety of elegant structures including helicates,[1] squares,[2] closed-shell capsules,[3] linear ribbons, two-dimensional nets and three-dimensional weaves.[4] We are taking advantage of this strategy to create molecular arrays with well-defined architectures based on metalloporphyrins and other transition metal complexes.[5] Porphyrins are particularly attractive supramolecular building blocks as they have rich photo- and redox properties and, to date, numerous polymolecular assemblies held together by covalent or non-covalent interactions have been used to model solar energy capture and transfer in naturally occurring photosystems, as well as to create artificial photoactive molecular devices.[6]

We recently reported the preparation of linear multicomponent porphyrin arrays in which a central metal atom positions two pyridyl Lewis bases that, in turn, axially coordinate to ruthenium-based metalloporphyrins.[5,7] The terpyridine scaffold, however, is restricted in its use. Only linear arrays can be conveniently synthesized. A ligand displaying multiple, divergent Lewis basic sites provides a means to extend the self-assembly strategy to three-dimensional metal-templated porphyrin arrays. The tetrapyridyl ligand [4,4′-di(4″-pyridyl)-2,2′-bipyridine, **1**][8] is ideal for this purpose. We report here the spontaneous assembly of three-dimensional ruthenium arrays **2**(TTP) and **2**(OEP) *via* axial coordination of ruthenium(II) porphyrin building blocks to a modified tris(bipyridine)ruthenium(II) metal template where the Lewis basic lone pair vectors are extensions of the octahedral geometry of the central metal–ligand complexes. We also describe a one-pot

† Electronic supplementary information (ESI) available: synthesis and spectral data for **2**, **2**(TTP), **2**(OEP) and **3**(TTP). See http://www.rsc.org/suppdata/cc/b0/b002562n/



Scheme 1 *Reagents and conditions*: i, $RuCl_3 \cdot xH_2O$, ethylene glycol, reflux, then excess NH_4PF_6; ii, **2**, acetone, room temp; iii, $FeBF_4 \cdot 6H_2O$, acetone–methylene chloride, room temp.

synthesis of an octahedral iron analog **3**(TTP) from its simplest molecular components.

Multigram quantities of ligand **1** can be conveniently prepared in one step by dehydrogenating 4,4′-bipyridine according to known methods.[8] The octahedral ruthenium core unit **2** was prepared by heating $RuCl_3 \cdot xH_2O$ with three molar equivalents of **1** and was isolated as its hexafluorophosphate salt (Scheme 1). Arrays **2**(TTP) and **2**(OEP) were synthesized by treating the core template with six equivalents of [Ru(TTP)(CO)(EtOH)] and [Ru(OEP)(CO)(EtOH)], respectively, in acetone with gentle heating (Scheme 1). Arrays **2**(TTP) and **2**(OEP) were isolated as air-stable red solids in yields greater than 95% and characterized by UV–VIS, IR and ^{1}H NMR spectroscopy, and mass spectrometry.†

All arrays exhibit significantly upfield-shifted signals in their ^{1}H NMR spectra, corresponding to the protons on the core unit which are completely surrounded by the shielding cones of as many as six porphyrin building blocks. The most significant shift corresponds to the protons directly adjacent to the axially directed nitrogen atoms ($\Delta\delta$ as much as 8.3 ppm upfield), as it is these hydrogen atoms that are buried deepest within each porphyrin's shielding cone and experience the greatest anisotropic effect.

The most notable feature of the self-assembly process arises from the steric bulk expressed by the porphyrinic building blocks and is highlighted by the different rates at which **2**(TTP) and **2**(OEP) form in solution. ^{1}H NMR studies of **2**(TTP) reveal that the self-assembling process is slow on the NMR time scale and sharp peaks for the statistical mixture of fully assembled and lower-generation arrays were clearly visible, even when six molar equivalents of [Ru(TTP)(CO)(EtOH)] were added [Fig. 1(b)]. Only upon heating to 45 °C did the spectrum simplify to signals that correspond to **2**(TTP) alone [Fig. 1(c)].‡ On the other hand, despite the fact that the ruthenium atom in the octaethylporphyrin is a weaker Lewis acid,[9] complex **2**(OEP) assembles at a significantly greater rate than **2**(TTP), as illustrated by the immediate appearance of major signals for the fully assembled array [Fig. 1(d)]. We attribute these phenomena to the relative steric bulk of the tolyl and ethyl groups. The need to input additional energy in the case of **2**(TTP) was not unexpected as the tetratolylporphyrin traces out a circle of a diameter that is significantly larger than that inscribed by the octaethyl analog (18.5 *vs.* 12.7 Å). The result is that the CH_3 groups on the tolyl overlap with those on adjacent porphyrin rings in **2**(TTP).

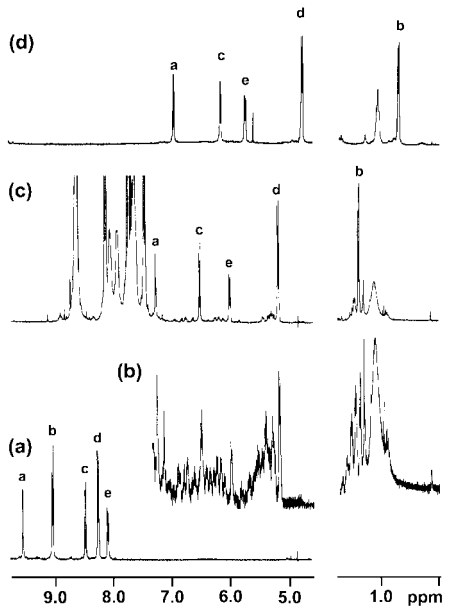


Fig. 1. ^{1}H NMR (300 MHz, acetone-d_6) spectra of (a) **2**, (b) **2** + 6 equiv. [Ru(TTP)(CO)(EtOH)] before and (c) after heating at 45 °C for 2 h, and (d) **2** + 6 equiv. [Ru(OEP)(CO)(EtOH)] at room temperature. Peak assignments correspond to the atom labels in Scheme 1.

The octahedral iron analog **3**(TTP) is readily synthesized in greater than 70% isolated yield in one step when a 1 : 2 mixture of solid **1** and solid [Ru(TTP)(CO)(EtOH)] is dissolved in a acetone-d_6/CD_2Cl_2 solution of $Fe(BF_4)_2 \cdot 6H_2O$ with gentle heating. This particular iron synthon was chosen for these studies because the highly labile nature of the metal's ligands allows for the rapid generation of the octahedral core fragment in high purity at room temperature, avoiding the harsh conditions required to form the ruthenate counterpart. Here, ten molecular species must organize and form twelve dative metal–ligand bonds in this assembly pathway. It is clear that, under these conditions, the self-assembly process results from the reading of both ruthenium and iron's inherent coordination algorithms and from the binding information stored in ligand **1**.

The absorption spectra in the UV–VIS region of **2**(TTP) and **2**(OEP) are essentially the sums of the spectra of the arrays' constituents. Initial steady-state emission spectra of these complexes, however, argue that there is a significant difference between the excited states of each array and their building blocks. Detailed results of the photophysical studies will be described elsewhere.

This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada and the University of Alberta.

Notes and references

‡ The spectra of both **2**(TTP) and **2**(OEP) generated *in situ* are identical to those of the corresponding isolated compounds.

ChemComm

Frameworks of amino acids: synthesis and characterization of two zinc phosphono-amino-carboxylates with extended structures

Stacy J. Hartman, Evgeny Todorov, Carlos Cruz and Slavi C. Sevov*†

Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556, USA. E-mail: ssevov@nd.edu

Received (in Columbia, MO, USA) 7th February 2000, Accepted 18th May 2000

Two α-amino acids, 3-phosphono-2-aminopropionic and 4-phosphono-2-aminobutyric, are used to link zinc atoms in three-dimensional structures where the three phosphonic and one of the carboxylic oxygen atoms coordinate to the metal, while the protonated amino groups and the second carboxylic oxygen atom are not coordinated and remain terminal in the voids of the framework.

Multifunctional ligands have attracted much interest in recent years mainly due to the possibility to build infinite frameworks by coordination to metal centers.[1] Such hybrid inorganic–organic compounds have the potential for use in shape recognition,[2] and more importantly, in stereoselectivity when chiral linkers are used.[3] Linkers with two or more different functional groups are even more interesting since they can provide different modes of coordination, different stability, and different structural dimensionality and motifs. Extended structures of such organic moieties with two different end groups that are both coordinated to the metal centers are actually quite rare. Known and structurally characterized are one such amino-phosphonate with a zeolite-like structure,[4] three carboxylate-phosphonates with layered structures,[5] and three of the latter type but with three-dimensional framework structures.[6] We have now taken one step further in the complexity, and have studied organic linkers with three different functional groups, *i.e.* species with an amino, carboxylic and phosphonic groups. Reported here are the structures and the IR and TGA characteristics of two framework compounds of zinc and phosphonated α-amino acids, $Zn(O_3PCH_2CH(NH_3)COO)$ (**1**) and $Zn(O_3PCH_2CH_2CH(NH_3)COO)$ (**2**), where the zinc atoms are coordinated by oxygen from the phosphonic and the carboxylic groups. Our ultimate goal is to achieve layered compounds with non-coordinated carboxylic and amino groups that are potential candidates for stereoselective intercalation due to the chiral α-carbon. In the pursuit of this same goal, layered inorganic compounds such as zirconium phosphate have been intercalated with amino acids where the latter interact electrostatically or van der Waals-like with the host.[7]

Compounds **1** and **2** were synthesized hydrothermally in autoclaves at 130 °C (2 d) from $Zn(NO_3)_2{\cdot}6H_2O$, and DL-2-amino-3-phosphonopropionic or DL-2-amino-4-phosphono-butyric acids (from Sigma), respectively, in molar ratio 1 : 4 and resulting pH of about 1.5. The latter is perhaps very near the isoelectric point of these very acidic amino acids, and as a result they exist as zwitterions in the product. The resulting solids were filtered, washed with water, ethanol and acetone, and were dried at room temperature. Compound **1** crystallizes as large polyhedral crystals, while the crystals of **2** are extremely small and very thin rectangular plates. Correspondingly, the structure of **1** was determined from X-ray diffraction data collected on a regular four-circle diffractometer, while a CCD area detector was used for the structure of **2**.†

The structure of compound **1** is a hybrid of alternating inorganic and organic layers (Fig. 1). The inorganic layers, made of oxygen-connected tetrahedra centered by phosphorus and zinc, are linked by the amino acid molecules. The connectivity is achieved *via* the carbon–phosphorus bond of the phosphonated amino acid and with the coordination of one of the carboxylic oxygens to Zn (Fig. 1 and in the TOC). The other oxygen of the latter is noncoordinated as is the protonated amino group of the amino acid. Thus, unlike other examples of bi-coordinated organic moieties such as diphosphonates or carboxylates-phosphonates and poly-carboxylates, the organic species here are highly functionalized with hydrophilic groups, *i.e.* with the $>C{=}O$ and NH_3^+ functionalities. These functional groups point toward the one-dimensional inter-linker apertures (4.36 Å O–O diameter) that exist along the *b* direction (Fig. 1), and are hydrogen bonded between themselves.

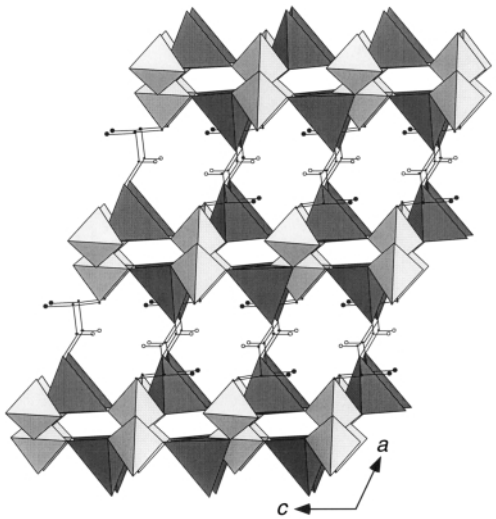

Fig. 1 A general view of the structure of compound **1**, $Zn(O_3PCH_2CH(NH_3)COO)$, along the *b* axis. The carbon and nitrogen atoms are shown as small and large black circles, respectively, while the non-coordinated oxygen of the carboxylic group is shown as an open circle. The darker and lighter shaded tetrahedra are centered by Zn and P, respectively.

The structure of compound **2** presents very similar features. Its carboxylic groups are also coordinated *via* only one oxygen atom, and therefore, the second one is terminal, and the amino groups are again protonated to $-NH_3^+$ (Fig. 2 and in the TOC). Crystallographically, there are two different phosphono-amino acids as well as zinc atoms in this structure but they are all nearly identical in coordination, bond distances and angles. Similar to **1**, the structure of **2** (Fig. 2) contains phosphonate–zinc inorganic layers that are grafted by the amino acid moieties. Nevertheless, there is an additional feature in this structure, inorganic chains of PO_3/ZnO_4 running along the *a* axis (the viewing direction of Fig. 2). The chains are positioned between the inorganic layers and are linked to the two neighboring layers by the amino acids. This leads to increased separation between the layers, 17.5 Å (half the *b* axis), since they are formally connected by amino acid–PO_3–ZnO_4–amino acid composite linker. These linkers are not perpendicular to the layers but are rather tilted, most likely due to the rigidity of the carbon angles, and give the impression that the layers are offset or shifted along the *c* direction with respect to each other. Long narrow gaps of about 19.3 Å (measured in O–O distance) are formed between

DOI: 10.1039/b001275k

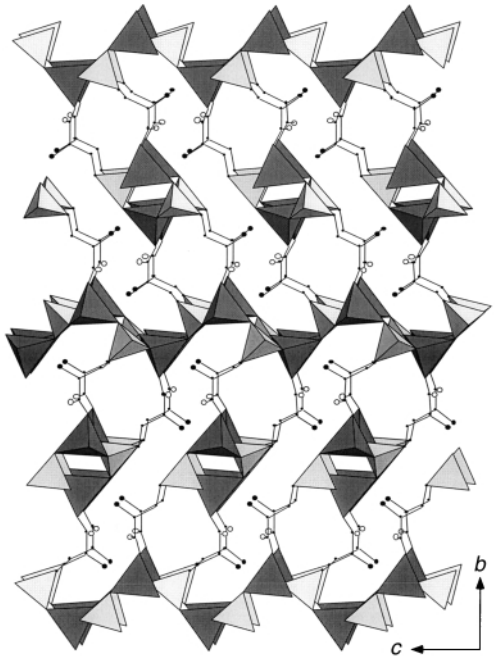

Fig. 2 A general view of the structure of compound **2**, $Zn(O_3PCH_2CH_2CH(NH_3)COO)$, along the *a* axis. The carbon and nitrogen atoms are shown as small and large black circles, respectively, while the non-coordinated oxygen of the carboxylic group is shown as an open circle. The darker and lighter shaded tetrahedra are centered by Zn and P, respectively.

the composite linkers. All pendant amino groups and carboxyl oxygen atoms point into these gaps and are extensively hydrogen bonded through that space (3 bonds per amino group and one bond per carboxylic oxygen). Both structures are centrosymmetric and contain racemic mixtures of the corresponding amino acids.

The compounds are thermally stable up to about 350 °C in a flow of air, according to TGA measurements. At this temperature, in a single sharp step, they lose the organic fraction in the form of CO_2, NH_3 and H_2O, and end up as $ZnHPO_4$. The IR spectra of the compounds (in KBr pressed pellets) show the antisymmetric and symmetric vibrations of the carboxylic groups. For compound **1** they are observed at 1627 and 1414 cm^{-1}, respectively, while doublets at 1636 and 1621 cm^{-1} for the antisymmetric and at 1446 and 1429 cm^{-1} for the symmetric vibrations are observed for compound **2**. The splitting is due to the two crystallographically different amino acids, *i.e.* the two slightly differently bonded carboxylic groups in the compound. The vibrations of the phosphonic groups are observed in the region 900–1200 cm^{-1}, as expected.

The existence of these framework compounds proves that it is possible sometimes to teach 'an old dog', the amino acids, 'new tricks'. The next step is to find a way to anchor only the phosphonic groups in a layer-type compound, and use the two functionalities COOH and NH_3, and the chiral α-carbon for a variety of intercalation and chiral molecular recognition reactions.

Such supported amino acids can be used for a number of organic reactions in the interlayer spacing, including formation of peptide bonds and longer chains of different residues. The two compounds presented here are not layered or microporous, and guest molecules can not access the inside of the structures, but they clearly have the right structural motifs and are on the right track towards more open frameworks.

We thank Chris Cahill for help with the data collection, and the National Science Foundation (DMR-9701550) for the financial support and for the Summer Program in Solid State Chemistry.

Notes and references

† *Crystal data* for $Zn(O_3PCH_2CH(NH_3)COO)$ **1**: Mw = 232.4, monoclinic, $P2_1/c$, Z = 4, a = 8.234(1), b = 9.768(2), c = 8.850(2) Å, β = 109.5(1)°, V = 670.9(2) Å^3, μ = 38.69 cm^{-1}. A hemisphere of data was collected on a CAD4 single crystal diffractometer with graphite-monochromated Mo-Kα radiation at room temperature (crystal size 0.35 × 0.25 × 0.20 mm, ω-2θ scans, $2\theta_{max}$ = 50°, 2328 and 1182° collected and independent reflections, respectively). *Crystal data* for $Zn(O_3PCH_2CH_2CH(NH_3)COO)$ **2**: Mw = 246.4, monoclinic, $P2_1/n$, Z = 8, a = 5.2022(6), b = 35.000(3), c = 8.1165(4) Å, β = 94.16(1)°, V = 1473.9(2) Å^3, μ = 35.30 cm^{-1}. Nearly a full sphere of data was collected on a Bruker SMART system with a CCD area detector (graphite-monochromated Mo-Kα radiation, room temperature, crystal size 0.16 × 0.06 × < 0.01 mm, 60 seconds/frame, $2\theta_{max}$ = 56.5°, 9719 and 3549 collected and independent reflections, respectively). The structures were solved by direct methods and refined with the aid of the SHELXTL-V5.1 package. XABS empirical absorption corrections were applied to the data of **2** after the structure was refined with isotropic thermal parameters. Final residual values: compound **1**, $R1/wR2$ = 4.74/14.30% for 968 reflections with $I \geqslant 2\sigma I$ and 99 refined parameters; compound **2**, $R1/wR2$ = 8.45/15.95% for 1092 reflections with $I \geqslant 2\sigma I$ and 225 refined parameters. The somewhat higher R-values for **2** are due to absorption problems resulting from the extremely anisotropic crystals (plates, 0.16 × 0.06 × < 0.01 mm). CCDC 182/1661. Received (in Cambridge, UK) 6th March 2000, Accepted 26th April 2000
Published on the Web 9th June 2000

In recent years, methods for the asymmetric epoxidation of electron-deficient olefins, particularly α,β-enones, have attracted widespread attention. A critical review is presented of these methods, which include epoxidations with chiral metal hydroperoxides, asymmetric phase-transfer methods, the use of polyamino acid catalysts and the use of chiral dioxiranes.

1. Introduction

Epoxidation holds a venerable place in the history of catalytic asymmetric synthesis. The development by Sharpless in the early 1980s of a system which can efficiently and predictably produce either enantiomer of an epoxide from an allylic alcohol using substoichiometric quantities of titanium and tartrate, paved the way for much of today's catalytic asymmetric synthesis.[1] Following this discovery, much progress has been made towards the asymmetric epoxidation of other classes of olefins; in particular the manganese–salen reagents of Jacobsen and Katsuki perform admirably in the asymmetric epoxidation of unfunctionalised, and particularly conjugated (*Z*)-disubstituted olefins.[2] More recently, the work of several groups has indicated that dioxiranes generated *in situ* from Oxone® and chiral ketones show great promise as asymmetric epoxidation reagents for a range of alkenes.[3]

On the other hand, no system for the asymmetric epoxidation of electron-deficient olefins has gained widespread popularity amongst synthetic organic chemists. Indeed, only recently have systems been described which allow the epoxidation of a wide range of enones with high enantioselectivity. This review introduces and compares the most significant and general of these epoxidation methods.

Most of the methods for the enantioselective epoxidation of electron-deficient alkenes are essentially asymmetric variants of the Weitz–Scheffer epoxidation[4] using alkaline H_2O_2; they are thus selective for electron-deficient alkenes in the presence of other olefins. A number of more general epoxidation methods have been applied to electron-poor olefins, and these are presented towards the end of this review.

As this survey is designed to cover those methods which may be generally applicable and synthetically useful for a range of olefins, we have chosen to exclude methods which rely on a different structural feature (such as an allylic alcohol) for the asymmetric epoxidation of an electron-deficient alkene.[5] In addition, isolated reports of epoxidations not developed with synthetic utility in mind, such as the isolation of a cell-free extract with quinone mono-oxygenase activity,[6] have been omitted.

2. Chiral ligand–metal peroxide systems

Several methods for the asymmetric epoxidation of electron-deficient alkenes rely on the use of a chiral ligand coordinated to the metal atom of a metal peroxide, which then executes a Weitz–Scheffer reaction. A number of metals, including zinc, lithium, magnesium and various lanthanides, have been used for this purpose and these methods are discussed in further detail below. In addition, Strukul and coworkers have described an asymmetric epoxidation process mediated by a platinum–diphosphine–peroxide complex, but the yields and enantioselectivities obtained in this reaction are moderate at best.[7]

a. Zinc-mediated asymmetric epoxidation

In 1996, Enders *et al*. disclosed that (*E*)-α,β-unsaturated ketones can be epoxidised in asymmetric fashion using stoichiometric quantities of diethylzinc and a chiral alcohol, under an oxygen atmosphere, to give *trans*-epoxides (Scheme 1).[8] Following screening of 35 optically active alcohols, (1*R*,2*R*)-*N*-methylpseudoephedrine (**1**) was selected as the alcohol which gave the best enantioselectivities. Furthermore, it was found that **1** could be recovered in almost quantitative yield from the reaction mixture.

More recently, Pu and coworkers have reported the use of a chiral polybinaphthyl **2** in similar reactions;[9] slightly in excess of 1 equivalent (based on the monomer binaphthyl unit) of **2** was necessary for the reaction to proceed.

As can be seen from Table 1, Enders' system gives excellent yields for several classes of enone for which the Pu conditions lead to much lower yields.[10] Furthermore, while the two methods are comparable in giving a moderate ee for the

Mike Porter was born in Harrogate, UK, in 1970. From 1988, he studied at Merton College, Oxford, where he received his BA degree in 1992. He remained in Oxford for his DPhil studies under the supervision of Professor Sir Jack Baldwin. Following postdoctoral positions at the University of Texas with Professor Philip Magnus and at the University of Liverpool with Professor Stan Roberts, he was appointed in 1999 to a lectureship at University College London. His research interests include the use of metal carbenes in synthesis, and the biomimetic synthesis of natural products.

John Skidmore was born in Macclesfield, UK, in 1972. He studied for his BA degree at St. Peter's College, Oxford, graduating in 1994. His DPhil studies were carried out under the supervision of Dr J. M. Peach in the Dyson Perrins Laboratory at Oxford. Since 1997 he has been investigating polyamino acid catalysed asymmetric reactions in collaboration with Professor Stan Roberts at the University of Liverpool, initially as a Senior Research Assistant and currently as a Principal Scientist funded by Degussa-Hüls AG.

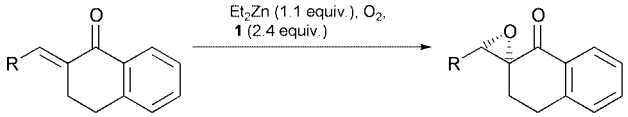
[a] A = **1** (2.4 equiv.), Et_2Zn (1.1 equiv.), O_2; B = **2** (1.1 equiv.), Et_2Zn (1.05 equiv.), O_2. [b] The predominant isomer was the enantiomer of that illustrated.

epoxidation of chalcone, Enders' system also shows high asymmetric induction for alkyl-substituted enones.

Enders' reagent has also been used for the asymmetric epoxidation of a series of β-alkylidene-α-tetralones (Scheme 2, Table 2).[8b] It appears that the enantioselectivity of the process generally increases as the substituent, R, increases in size. The reaction, however, fails for other α-substituted enones; it was surmised that this may be due to the requirement for an *s-cis* conformation of the enone moiety.



Scheme 2

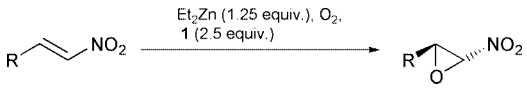
Ph	62	64

In addition to enones, the diethylzinc/oxygen/**1** system has been used for epoxidation of some (*E*)-nitroalkenes (Scheme 3, Table 3).[11] The absolute stereochemistry of the nitroepoxides was assumed by analogy with the enone substrates.



Scheme 3

Both Enders and Pu have proposed similar reaction pathways, based on the Weitz–Scheffer mechanism, for their

Table 3 Epoxidation of nitroalkenes using Enders' ligand[11]

R	Yield (%)	Ee (%)

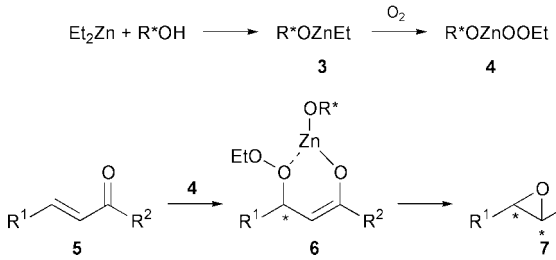
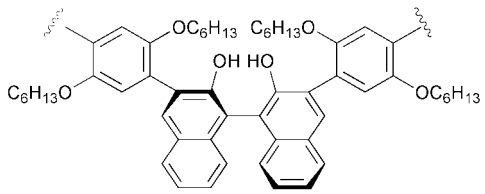
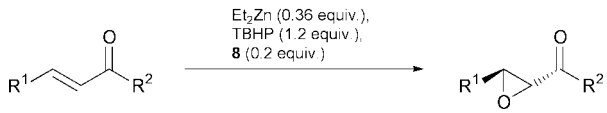
asymmetric epoxidations (Scheme 4). It is suggested that diethylzinc reacts with the chiral ligand (**1** or **2**) to give a zinc alkoxide **3**, with the loss of ethane. Reaction of **3** with molecular oxygen then gives rise to a chiral metal peroxide **4**. Stereoselective conjugate addition of this peroxide to an enone **5** affords intermediate zinc enolate **6**, which then collapses to the chiral epoxide **7** and a zinc dialkoxide.



Scheme 4

Improving upon the stoichiometric process described above, Pu and coworkers have developed a variant which is catalytic in zinc and ligand, using the modified polybinaphthyl **8**.[9] In this epoxidation process, oxygen is replaced as the stoichiometric oxidant by *tert*-butyl hydroperoxide (TBHP) (Scheme 5, Table 4). Under these adapted conditions, both chalcone derivatives and alkyl-substituted enones are epoxidised with high yields and acceptable levels of enantiocontrol.





Scheme 5

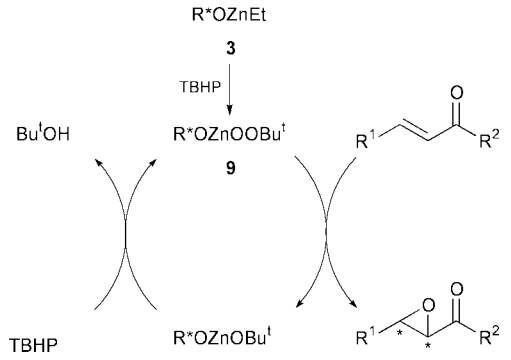
Table 4 Catalytic asymmetric epoxidation using Pu's ligand[9]

R^1	R^2	Yield (%)	Ee (%)
Ph	Ph	95	74
p-ClC_6H_4	Ph	81	79
Pr^i	Ph	94	81
Bu^t	Ph	67	64

For this catalytic process, a slight modification of the mechanism in Scheme 4 has been proposed (Scheme 6). In this case, the initially formed chiral zinc alkoxide **3** reacts with TBHP to give zinc peroxide species **9**, with the loss of a second ethane molecule. Following formation of the epoxide, ligand exchange of *tert*-butyl alcohol for a TBHP molecule regenerates the chiral zinc peroxide **9**.

b. Lanthanide-BINOL systems

Shibasaki *et al*. have developed a series of complexes of general form $LnM_3(BINOL)_3$, $AlM(BINOL)_2$ and $GaM(BINOL)_2$ (Ln

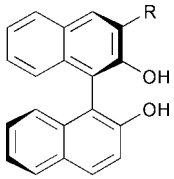


Scheme 6

= lanthanide, M = alkali metal) which have been shown to catalyse a range of transformations, such as Diels–Alder cyclisation, aldol condensation and Michael addition, in an asymmetric fashion.[12] It is believed that these bimetallic catalysts are effective owing to the presence of a Brønsted basic and a Lewis acidic site which serve to orientate the substrate and reagent in a chiral environment such that reaction may occur; Shibasaki compares this to the behaviour of some enzymes.

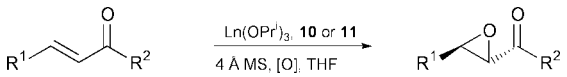
It was found that $LaNa_3[(R)\text{-BINOL}]_3$ catalyses the epoxidation of chalcone by *tert*-butyl hydroperoxide (TBHP) to afford (2*S*,3*R*)-epoxychalcone in 92% yield and 83% ee. Unfortunately, this epoxidation method did not prove to be generally applicable to other enones.[13*a*]

In the case of some Michael additions, Shibasaki and coworkers had previously found that alkali metal-free complexes were effective catalysts. Following this precedent, it was found that reaction of an equimolar mixture of (*R*)-BINOL **10** and $La(OPr^i)_3$ in the presence of 4 Å molecular sieves generates a complex capable of catalysing the asymmetric epoxidation of a range of (*E*)-enones. In this case, cumene hydroperoxide (CMHP) proved to be the most effective oxidant (*e.g.* chalcone was epoxidised in 93% yield and 83% ee). Alternative ligands were investigated and a substantial improvement in enantioselectivity was observed with 3-hydroxymethyl-BINOL **11**



10 R = H
11 R = CH_2OH

($Ln(OPr^i)_3$: **11** = 1:1.25). It was found that the optimum lanthanide was dependent on the nature of the enone; aryl ketones were more effectively epoxidised using a La–**11**–CMHP system whilst alkyl ketones responded better to Yb–**11**–TBHP (Scheme 7, Table 5, methods A and B).[13*a*] Recently, Shibasaki and coworkers used this method for a diastereoselective epoxidation as part of a synthesis of some prostaglandins.[13*b*]



Scheme 7

Shibasaki has made some interesting observations concerning the mode of action of these catalysts. He suggests (citing ^{13}C NMR evidence) that they adopt an oligomeric structure, allowing one Ln–BINOL moiety to act as a Brønsted base to deprotonate the hydroperoxide whilst a second Ln–BINOL unit

Table 5 Comparison of lanthanide–BINOL based epoxidation systems[13*a*,14,15]

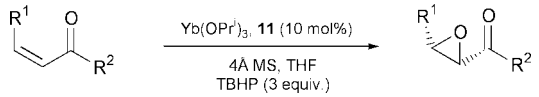
[a] A = ($La(OPr^i)_3$–**11**) (5 mol%), CMHP (1.5 equiv.), 4 Å sieves;[13*a*] B = ($Yb(OPr^i)_3$–**11**) (5–8 mol%), TBHP (1.5 equiv.), 4 Å sieves;[13*a*] C = ($Yb(OPr^i)_3$–**10**) (5 mol%), TBHP (1.5 equiv.), 4 Å sieves, water (22.5 mol%);[14] D = ($La(OPr^i)_3$–**10**) (5 mol%), TBHP (1.5 equiv.), 4 Å sieves, triphenylphosphine oxide (15 mol%).[15]

acts a Lewis acid, activating and controlling the orientation of the enone. A chiral amplification effect, whereby the ee of the product epoxide can exceed that of the ligand, was provided as evidence for this dual role.[13*a*]

More recently, Shibasaki and coworkers[14] have reported a method for improving the activity of the Yb–BINOL **10**–TBHP system allowing enantioselectivities to be attained which are comparable with the more expensive Yb–**11** catalyst. Addition of water (4.5 equivalents relative to $Yb(OPr^i)_3$) to a catalyst generated from $Yb(OPr^i)_3$: BINOL **10** (2 : 3) was found to give optimal results (Scheme 7, Table 5, method C). Surprisingly, it was found still to be necessary to add molecular sieves to this system in order to obtain effective catalysis. The catalysts generated from ligand **11** are not improved by the addition of water in an analogous manner and it should be noted that, as the above modification is of the ytterbium-based catalyst, ees are lower in the case of aryl ketones. Shibasaki has advanced an explanation for the effect of water, suggesting that it coordinates to ytterbium and controls the orientation of the hydroperoxides to form an appropriate asymmetric environment for the epoxidation.

Inanaga and coworkers have investigated the effect of a range of additives on Shibasaki's La–BINOL **10** catalyst. Comparison of lutidine-*N*-oxide, 1,3-dimethyl-2-imidazolidinone, tri-*n*-butylphosphine oxide, triphenylphosphine oxide, tri-*o*-tolylphosphine oxide, tri-*p*-tolylphosphine oxide and HMPA revealed that triphenylphosphine oxide is the most effective additive.[15] For the epoxidation of chalcone the addition of triphenylphosphine oxide (15 mol%) produced an improvement in ee from 73 to 96%. Similarly high ees were found for three alkyl ketones; unlike Shibasaki's lanthanum complexes, this catalytic system is applicable to alkyl and aryl enones (Scheme 7, Table 5, method D). It was suggested that the activation is due to the disruption of the oligomeric structure of the catalyst by coordination of the phosphorus-based ligand.

Shibasaki has shown that the unmodified Yb–**11** catalyst is also effective for the epoxidation of (*Z*)-enones to the corresponding *cis*-epoxides (Scheme 8, Table 6).[16] The trans-



Scheme 8

formation proceeds with good yields and high stereoselectivity for aliphatic enones. In the case of aromatic enones, the reaction is less effective owing to formation of substantial (up to 32%) amounts of the unwanted *trans*-epoxide. Interestingly the use of a given enantiomer of the BINOL derived ligand **11** generates

Table 6 Epoxidation of (*Z*)-olefins to afford *cis*-epoxides[16]

the opposite sense of stereochemistry at the β-carbon compared to the epoxidation of (*E*)-enones; thus the (*R*)-**11** catalyst converts (*Z*)-enones to the (2*S*,3*S*)-epoxides. The Yb–**11** catalyst also proved effective in the epoxidation of a trisubstituted enone, $Me_2C=CHCOPh$ being converted to the corresponding epoxide in 78% yield and 87% ee.[16]

c. Diethyl tartrate-metal peroxides

Jackson and coworkers have reported the epoxidation of enones using metal peroxides modified by chiral ligands.[17] Initial work investigated the effect of stoichiometric quantities of a range of chiral ligands on the addition of lithium *tert*-butyl peroxide (generated *in situ* from *tert*-butyl hydroperoxide (TBHP) and *n*-butyllithium) to chalcone. Diethyl tartrate (DET) was found to be the most effective ligand and an equivalent of lithium *tert*-butoxide was required for the reaction to proceed. The use of 1.1 equivalents of (+)-DET in a non-coordinating solvent, typically toluene, afforded the (2*R*,3*S*)-epoxide in 71–75% yield and 62% ee.

Attempts to use substoichiometric quantities of the ligand in this reaction were ineffective; however, replacement of *n*-butyllithium by dibutylmagnesium gave a system in which the use of only 11 mol% of DET and 10 mol% of the base was necessary for high levels of asymmetric induction on a range of chalcone-type enones (Scheme 9, Table 7). Interestingly the catalytic magnesium system generates epoxides antipodal with those obtained using the stoichiometric lithium system.

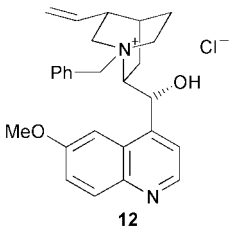
3. Phase-transfer catalysis

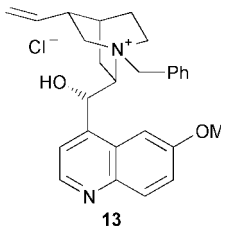
Phase-transfer catalysis, developed initially in the mid-1960s, typically uses an organic salt (such as a quaternary ammonium salt) to transport inorganic ions into an organic phase. By using chiral ammonium salts, it is possible to induce asymmetry in reactions such as enolate alkylations, Michael additions and Darzens reactions.[18]

The most common phase-transfer reagents used for the asymmetric epoxidation of enones are alkylated *Cinchona* alkaloids. A handful of papers using other chiral phase-transfer salts has appeared,[19] but ees for these epoxidations are low (≤37%).

The possibility of using a chiral phase-transfer salt in a biphasic Weitz–Scheffer epoxidation was first investigated by Wynberg and coworkers in the mid-1970s. A series of papers was published in which phase-transfer catalysts **12** and **13** were



12

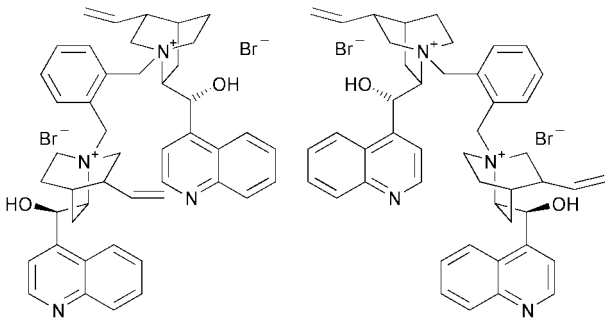


13

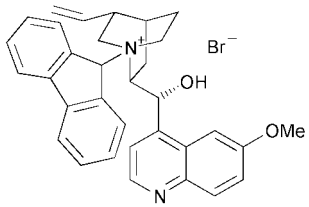
produced by *N*-benzylation of quinine and quinidine respectively.[20]

These compounds proved capable of catalysing the asymmetric epoxidation of a wide range of enones using aq. H_2O_2, *tert*-butyl hydroperoxide (TBHP) or sodium hypochlorite as oxidant; the ees obtained were in the range 0–54%. In an isolated example, an ee of 78% was obtained by Harigaya *et al.*, using **12** as the catalyst in the epoxidation of a 2-aryl naphthoquinone.[21]

Kawaguchi and coworkers have reported phase-transfer epoxidation using a related set of catalysts: a C_2-symmetrical pair, **14** and **15**, derived by reaction of the alkaloids cinchonidine and cinchonine respectively with α,α'-dibromo-*o*-xylene; and *N*-(9-fluorenyl)quininium bromide (**16**). These salts catalyse the epoxidation of cyclohexenone with ees up to 63%.[22]



14 **15**



16

More recently, **12** and similar phase-transfer catalysts based on *Cinchona* alkaloids have been utilised by Taylor and coworkers for the asymmetric synthesis of the manumycin class of natural products. Best results were obtained using *N*-benzylcinchonidinium chloride (**17**), which mediated the epoxidation of enone **18** in 32% yield and 89% ee (Scheme 10).[23]

Two recent reports have shown significant improvements in phase-transfer catalysed asymmetric epoxidation. In 1998, Lygo and Wainwright described the use of catalysts **20** and **21**, derived from cinchonidine and cinchonine respectively; these differ from catalysts of the Wynberg type (**12** and **13**) as they incorporate a 9-anthracenylmethyl group in place of the benzyl group on the quinuclidine nitrogen, and bear a benzyl group on the secondary alcohol. In the presence of sodium hypochlorite as stoichiometric oxidant, these catalysts mediate the epoxidation of a wide range of substituted chalcones and alkyl-substituted enones with complete diastereoselectivity and with ees in the range 69–90% (Scheme 11, Table 8, method A); **12** and **13** provide products with opposite senses, but similar magnitudes, of stereoinduction.[24]

[a] A = **20** (0.1 equiv.), NaOCl (2 equiv.), 25 °C; B = **20** (0.1 equiv.), KOCl (5 equiv.), −40 °C; C = **22** (0.05 equiv.), aq. H_2O_2 (10 equiv.), LiOH (3 equiv.), 4 °C.

More recently, Corey and Zhang have shown that the use of catalyst **20** with potassium hypochlorite as the stoichiometric oxidant and a reaction temperature of −40 °C, gives epoxidation of a range of enones with ees of 90–99% (Scheme 11, Table 8, method B).[25] Epoxidation of β-alkylidene-α-tetralones, however, gives ees of only 61 and 76%; Corey interprets this as an indication that a non-planar enone geometry is favoured in the epoxidation reaction (*vide infra*).

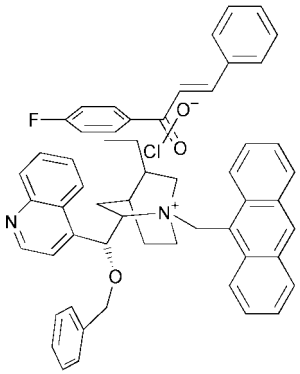

Fig. 1

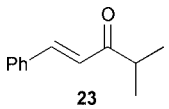
Further *Cinchona* catalysts have been developed by Arai *et al.*, who surveyed the alkylation of cinchonine with a range of substituted benzyl bromides.[26] Notably, *N*-(4-iodobenzyl)cinchoninium bromide (**22**) allows highly stereoselective oxidation of chalcone derivatives, although the ees are lower for alkyl-substituted enones (Scheme 11, Table 8, method C). Intriguingly, the epoxides obtained using this cinchonine-derived catalyst are generated with the opposite sense of stereoinduction to those from Lygo's cinchonine-derived catalyst **21**. The same authors also described a quinidine-based phase-transfer catalyst which was used to epoxidise substituted naphthoquinones and acyclic enones with ees ranging from 17 to 76%.[27]

Corey and Zhang[25] have posited a three-dimensional arrangement of ammonium cation **20**, benzal-4-fluoroacetophenone and hypochlorite ion to account for the observed stereoselectivity (Fig. 1). In this model, the fluorophenyl ring of the substrate is twisted out of conjugation with the carbonyl group and is wedged between the ethyl and quinoline substituents of the catalyst. The hypochlorite ion is contact ion-paired with the charged nitrogen and the carbonyl oxygen is placed as close to the N^+ as is permitted by van der Waals forces. This arrangement places the nucleophilic oxygen of the hypochlorite ion in proximity to the β-carbon of the enone, and positioned such that only one face of the enone is accessible.

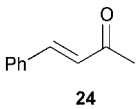
4. Polyamino acid catalysed epoxidation[28]

In 1980 Juliá *et al*. reported the poly-L-alanine catalysed asymmetric epoxidation of chalcone (Scheme 12).[29] The Juliá reaction conditions were triphasic, consisting of the insoluble polyamino acid catalyst, an aqueous solution of NaOH and H_2O_2 and a solution of chalcone in an organic solvent. The polyamino acid catalyst could readily be prepared from the corresponding amino acid *via* conversion to the *N*-carboxy-anhydride (NCA) and then treatment with an initiator such as water, a simple primary amine or a polystyrene-bonded amine.[30] It was found that enantioselectivity of the epoxidation increased as the average chain length increased from 10 to 30 residues. Over a series of papers the group of Juliá and Colonna investigated this method for the epoxidation of chalcone and simple analogues.[29,31] Their contribution to this field has recently been reviewed elsewhere.[28c] An important feature of the Juliá–Colonna epoxidation is that the insoluble catalyst may be readily separated from the reaction products, washed and reused. It was reported, however, that on reuse the catalyst frequently gave reduced enantioselectivity, a phenomenon ascribed to degradation of the catalyst under the strongly basic reaction conditions.[31c] A limitation of the Juliá-Colonna methodology is the length of reaction; even relatively reactive substrates such as chalcone and simple derivatives require 24 hours for complete conversion.[31a] Less reactive substrates

either generate products in low yield and ee or fail to form any epoxide. In particular enolisable substrates such as **23** (60% yield, 62% ee)[32] and **24** (decomposition)[33] are poor substrates for the triphasic reaction conditions.



23



24

Nonetheless, a reasonable range of epoxides has been prepared using the triphasic reaction conditions by Juliá and Colonna and by others (Scheme 12, Table 9).

[a] PLL = poly-L-leucine, PLA = poly-L-alanine; see references for examples using poly-D-amino acids.

The limitations of poor catalyst recycling and low reactivity have been overcome in modifications reported by Roberts and coworkers. Two biphasic procedures have been developed which reduce reaction times for chalcone to under 30 minutes. The first of these is essentially anhydrous in nature.[33,40] Peroxide is delivered in the form of an anhydrous complex, typically urea–H_2O_2. Such complexes are cheap, stable and easy to handle and are safer than concentrated solutions of H_2O_2 in organic or aqueous solvents.[41] The inorganic base employed by Juliá and Colonna is replaced with a strong amidine base, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and the reaction is performed in an organic solvent such as THF. Under these conditions enolisable substrates, such as simple alkyl ketones, can be readily epoxidised.[33] These biphasic conditions constitute the most widely tested and reliable of the new class of polyamino acid catalysed epoxidation systems (Scheme 14, Table 12, method A). Examples reported by Roberts and coworkers typically use polyleucine, however it has recently been disclosed that poly-L-neopentylglycine can offer advantages of increased reaction rate and enantioselectivity.[42]

In order to maximise both rate and stereoselectivity for the biphasic reaction it is necessary to activate the catalyst under conditions analogous to the triphasic procedure. This activation procedure consists of stirring the polyamino acid in a mixture of 4 M aq. NaOH and toluene for 1–5 days (the exact activation time appears to depend on the batch of catalyst), before filtering, washing and drying the catalyst.[43]

It has been demonstrated that the poly-L-leucine catalyst can readily be recycled under these conditions; for example it has been shown that for the epoxidation of chalcone, catalyst used for five previous reactions still afforded epoxide in 96% ee, albeit with increased reaction time. For less reactive substrates the activity of the catalyst was found to drop more rapidly with recycling, however it was found that the original activity could be recovered by submitting the recycled material to the activation procedure.[44]

A disadvantage of the aforementioned biphasic conditions is that they are rather more expensive than the triphasic conditions owing to the use of a more costly oxidant and of 1.5 equivalents of DBU (attempts to use substoichiometric quantities have proved unsuccessful); thus these conditions are not ideal for large-scale work. An alternative procedure employs inexpensive sodium percarbonate (NaPc) as both oxidant and base.[43] Screening of a range of solvent systems for this oxidant revealed that organic–water mixtures are most effective, in particular DME–water gives rates and enantioselectivities comparable with the urea–H_2O_2/THF/DBU system (Scheme 14, Table 12, method B). The non-catalysed background reaction under these conditions was found to be considerably slower than under the urea–H_2O_2/THF/DBU conditions; thus increased substrate to catalyst ratios may be employed with minimal reduction in ee (Table 10).

Table 10 Epoxidation of chalcone using poly-L-leucine[43]

	10 mol% catalyst[a]		2 mol% catalyst[a]

Urea–H_2O_2/DBU/THF	85	> 95	92	89
NaPc/DME/H_2O	—	96	87	94

[a] Based on a single polymer chain as the catalytic unit.

The sodium percarbonate–DME–water conditions have proved particularly useful for the diastereoselective epoxidation of enones with an oxy-substituted γ-chiral centre. Use of sodium percarbonate–DME–water at −3 to 0 °C gives reasonable selectivity for the epoxidation of such substrates in both the matched and mismatched sense (Scheme 13, Table 11).[45]

None	1:3.0	94	None
Poly-D-leucine	1:34	97	Matched
Poly-L-leucine	3.8:1	98	Mismatched

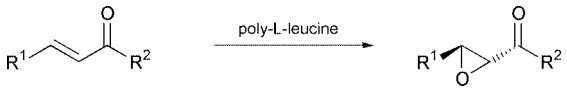
One further improvement reported by Roberts and coworkers is the introduction of a silica-supported polyamino acid catalyst.[46] It has been shown in the field of biotransformations that the immobilisation of enzymes on silica affords material

more active than the native enzyme when used in organic solvents. In addition, it has been found that this material is more readily recycled. Polyleucine was stirred as a suspension in THF with a range of solid supports and the properties of the resultant adsorbed materials were investigated. It was found that silica provided the best combination of improved activity and ease of filtration/recycling. Generally the silica-adsorbed material is active enough to allow as little as 2.5 mol% catalyst (based on 1 equivalent being a single polyamino acid chain) to be used without any reduction in enantioselectivity (Scheme 14, Table 12, method C).[46]

The polyleucine catalysed epoxidation shows some interesting selectivity. For example, the diene **28** is selectively epoxidised on the disubstituted double bond to afford the monoepoxide **29** in reasonable yield and good ee (Scheme 15).[48]

Generally α-substituted enones, such as α-methylchalcone are unreactive under polyleucine catalysed conditions. One exception to this is the case of cyclic enones derived from tetralone, indanone or benzosuberone (Scheme 16).[49] A similar explanation to that proposed by Enders *et al*., in which an *s-cis* conformation is required for epoxidation to occur, may account for this difference in reactivity.[8b]

Of all the epoxidation methods discussed in the current article the polyamino acid catalysed reaction is probably the one which is the least well understood from a mechanistic standpoint. A number of fundamental questions remain to be answered. The primary issues are the nature of the interaction between polyamino acid, substrate and/or oxidant and the relationship between the structure and the activity of the catalyst. Of these, the latter question is the more readily addressed. Studies by Juliá, Colonna and coworkers[31c] and by Roberts and coworkers[42] have found that polyleucine, polyalanine, polyisoleucine and poly(neopentylglycine) are effective catalysts. Of these the first two are known to favour an α-helical structure whilst polyisoleucine is reported to form a β-sheet. This seems to suggest that the secondary structure of the polyamino acid is not directly related to the catalysis. Less effective polyamino acids include polyvaline,[31c] polyphenylalanine[31c] and polyproline.[31d]



Scheme 14

Polyamino acids containing mixtures of L- and D-leucine have been prepared with a view to examining the importance of different regions of the polyamino acid chain. Investigation of material prepared by sequential polymerisation of D- and L-leucine *N*-carboxyanhydrides (NCAs) suggested that the amino terminal region plays a dominant role in determining which enantiomer of the product is generated.[50] In order to investigate this phenomenon further, Roberts and coworkers first demonstrated that a 20-mer of polyleucine prepared using a peptide synthesiser exhibits catalytic behaviour like that of the material prepared by NCA polymerisation. Such material is bound at the *C*-terminus *via* a hydroxymethyl phenoxyacetic acid linker and a polyethylene glycol graft to a polystyrene resin and is thus termed H-(L-Leu)$_{20}$-PEG-PS.[51] A series of oligopeptides of defined primary structure was then prepared and their behaviour as catalysts was examined.[52] It was shown that as few as five D-leucine residues at the *N*-terminus of a 20-mer of polyleucine is sufficient to overcome any catalytic effect of the 15 L-leucine residues which make up the rest of the polymer chain. Under the urea–H_2O_2/DBU/THF conditions the catalyst H-(D-Leu)$_5$-(L-Leu)$_{15}$-PEG-PS generated the epoxide corresponding to that afforded in the presence of poly-D-leucine in 52% ee. Moreover, the peptide H-(D-Leu)$_7$-(L-Leu)$_{13}$-PEG-PS catalysed formation of the same epoxide in 83% ee. In order to confirm that the bias towards the *N*-terminal region is not a reflection of the polymer support bound to the *C*-terminus the H-(D-Leu)$_5$-(L-Leu)$_{15}$-PEG-PS catalyst was cleaved from the support using TFA, recovered and tested again; although the ee was somewhat diminished by this procedure (21%), the major product was still the epoxide configured by a poly-D-leucine catalyst.

5. Bovine serum albumin catalysed epoxidation

In a series of papers, Colonna *et al*. have reported the use of bovine serum albumin (BSA) as an additive to Weitz–Scheffer

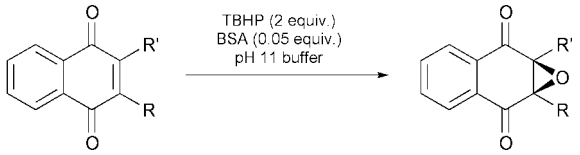
epoxidations of naphthoquinones.[53] Both the magnitude and the sense of enantioselectivity in the reaction were found to be strongly dependent on the nature of the side chains R and R′ (Scheme 17, Table 13). The best enantioselectivities were obtained using *tert*-butyl hydroperoxide (TBHP) as the oxidant,



Scheme 17

in an alkaline buffer solution (slightly higher ees were obtained in pH 9 buffer than in pH 11 buffer).[53b] Further improvements in enantioselectivity could be obtained by addition of small amounts of isooctane to the reaction mixture.[53c]

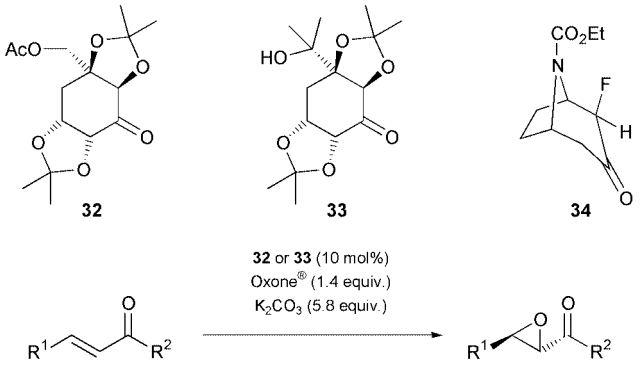
6. Epoxidation with chiral dioxiranes

The first attempts to effect asymmetric epoxidation using chiral dioxiranes were reported by Curci *et al.* in the mid-1980s.[54] It is only recently, however, that chiral ketones, the precursors of the corresponding dioxiranes, have been developed which will allow the epoxidation of a wide range of alkenes with good enantioselectivity.

While chiral dioxiranes can, in theory, epoxidise most classes of olefin, Baeyer–Villiger reaction of the chiral ketone from which the dioxirane is derived frequently competes with epoxidation for unreactive substrates. As a result, only a few chiral dioxiranes have been used successfully to epoxidise electron-deficient alkenes. In particular, the ketones **32** and **33**, derived from (−)-quinic acid, have been developed by Shi and coworkers; on treatment with Oxone® these are believed to generate chiral dioxiranes which then epoxidise the enones shown in Scheme 18 and Table 14, regenerating the chiral ketones.[3,55] An ester, ethyl cinnamate, was also epoxidised with good enantioselectivity, albeit in low yield.



32 **33** **34**

Scheme 18

Ph	OEt	**32**	34	86
		33	35	89

The tropinone derivative **34**, developed by Armstrong and Hayter[56] as a chiral dioxirane precursor, has also been applied to the epoxidation of an electron-deficient olefin; methyl cinnamate was epoxidised with 33% yield and 64% ee using this catalyst under conditions similar to those employed by Shi and coworkers.[3,55]

7. Miscellaneous methods

Among the numerous substrates which have been epoxidised using manganese–salen catalyst **35** are several electron-deficient alkenes. A series of (*Z*)-cinnamate esters has been studied by Jacobsen *et al.*; on epoxidation with sodium hypochlorite in the presence of **35**, both *cis*- (**36**) and *trans*-epoxides (**37**) are obtained (Scheme 19, Table 15).[57] Two general trends can be extracted from these data: the presence of electron-donating groups (R^1) on the aromatic ring minimises the extent of 'leakage' to the *trans*-epoxide **37**, but gives the lowest enantiopurity in the *cis*-product **36**; and for a given R^1, increasing the bulk of R^2 increases the enantioselectivity.

Furthermore, various isoflavones have been epoxidised by Lévai *et al.* using catalyst **35** and its enantiomer (Scheme 20, Table 16);[58] in this case, although good ees were obtained for certain substrates, the yields are disappointing.

An isolated report by Kumar and Bhakuni in 1996 outlined the use of MCPBA localised in a chiral liposomal bilayer as a reagent for asymmetric epoxidation.[59] Five electron-deficient olefins were oxidised with moderate to good enantioselectivity using this reagent, with esters displaying higher ees than ketones (Scheme 21, Table 17).

The groups of Colonna[60] and Takahashi[61] have both reported on the modification of Weitz–Scheffer conditions by the addition of cyclodextrins. Under Colonna's optimised conditions, the ees recorded for the epoxidation of a range of naphthoquinones and chalcone derivatives were below 48%; the highest ee observed by Takahashi and coworkers in the epoxidation of cinnamaldehyde was 2.5%.

In a related study, Sakuraba and Tanaka have shown that crystalline chalcone–cyclodextrin complexes, when dispersed in water, can be epoxidised by sodium hypochlorite with high yield and *ca.* 30% ee.[62]

8. Summary

It is clear from the above review that no single approach for the epoxidation of electron deficient olefins stands out from the methods discussed. The variation in selectivity observed between the different approaches means that they should all be considered as potential candidates for a given synthetic transformation. In order to aid this selection process Table 18 compares the effectiveness of the different methodologies for the epoxidation of various key classes of olefin. For the sake of clarity, it has not been possible to include all of the methods, and we have chosen to concentrate on a representative selection of the most general and effective. One caveat which should be borne in mind when consulting Table 18 is the tendency for a range of yields or ees to reflect unrepresentative, extreme results, particularly when a larger number of examples has been reported.

Despite the lack of a general method a number of high yielding and highly stereoselective methods exist; with judicious choice the chemist can epoxidise a wide range of electron deficient olefins. This fact, coupled with the potential of epoxides substituted with electron withdrawing groups as synthetic intermediates,[28c] should ensure that these methods gain increasing acceptance amongst the synthetic organic community. Moreover, it seems likely that we will witness many new and interesting developments in this field over the coming years. It remains to be seen, however, whether one single method will be developed to such an extent that it dominates epoxidation of enones in the way that the Sharpless reaction has become the pre-eminent method for the epoxidation of allylic alcohols.

Reaction of tris-arylgallium(III) with water: biaryl coupling *versus* Ga–C hydrolysis

Peter J. Nichols, Stavroula Papadopoulos and Colin L. Raston*

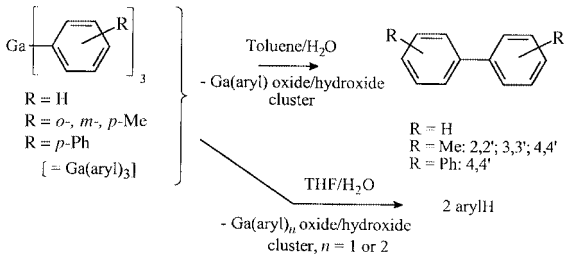
Reaction of toluene solutions of tris(aryl)gallium(III) compounds with water results in intra-molecular biaryl coupling (70% yield) and an oligomeric organogallium(III) hydroxide/oxide $[Ga_{12}O_{14}H_4(aryl)_{12}]$, whereas reaction in THF with water leads to hydrolysis, formation of arylH, and for aryl = Ph the trimeric THF hydrogen bonded trimer, $[Ph_2Ga(\mu\text{-}OH)]_3\cdot 3THF$.

Recent years have seen major developments in the synthesis and characterisation of galloxane (organogallium(III) oxide) and organogallium(III) hydroxide/oxide compounds.[1–13] Controlled hydrolysis reactions of organogallium(III) compounds, GaR_3, and reactions with excess water lead to the formation of hydroxide or mixed hydroxide/oxide species. These include (a) dimeric species, $[Ga(Mes)_2(\mu\text{-}OH)]_2$, Mes = 1,3,5-trimethylphenyl,[11] and $[Ga_2\{C(SiMe_3)_3\}_2Me_2(OH)(\mu\text{-}OH)(H_2O)]$,[8] (b) trimeric species, $[RR'Ga(\mu\text{-}OH)]_3$, R = R′ = Bu^t,[4,5] = Me,[6] and R = Me, R′ = $C(SiMe_3)_3$,[8] and (c) clusters, $[Ga_6(Mes)_6(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4]$,[7] $[Ga_{12}Bu^t_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)_2(\mu\text{-}OH)_4]$,[2] and $[Ga_4\{C(SiMe_3)_3\}_4(\mu\text{-}O)_2(\mu\text{-}OH)_4]$.[8] Thermolysis of $[Ga(Mes)_2(\mu\text{-}OH)]_2$ gives $[Ga_9(Mes)_9O_9]$ as a unique, structurally authenticated galloxane.[8]

All of the condensation reactions of GaR_3 with water arise from hydrolysis of one or more of the Ga–C bonds. We now show that treatment of tris-arylgallium(III) compounds, $Ga(aryl)_3$,† in toluene with water results in the formation of C–C bi-aryl coupled compounds and oligomeric arylgallium(III) hydroxide/oxide species. In contrast, treatment of the same compounds with excess water using tetrahydrofuran as a phase transfer reagent leads to Ga–C hydrolysis of one or two aryl groups with only a trace of the bi-aryl coupled compound being formed. These results are summarised in Scheme 1. The formation of bi-aryl coupled compounds has implications in organic synthesis, and is relevant to the actively pursued Suzuki aryl coupling reactions involving boronic acids and esters,[14,15] which require a transition metal catalyst in the presence of oxygen, unlike in the present reactions. Moreover, the reaction of organometallics with water is of interest in the search for environmentally benign synthetic protocols.[16]

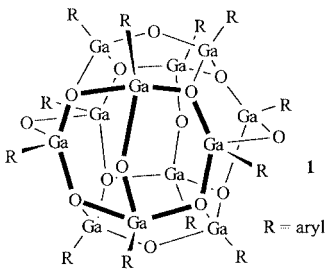
For the two phase toluene/water reactions the bi-aryl coupled compounds are isolated from the organic phase, and the gallium(III) hydroxide/oxide cluster compounds are isolated from the aqueous phase. The bi-aryls are formed in yields exceeding 70% (based on two aryl groups being converted to the bi-aryl) with a trace of the expected hydrolysis product, R = H, Me (*o*-, *m*-, *p*-), and *p*-Ph (GC). Conversely the single phase



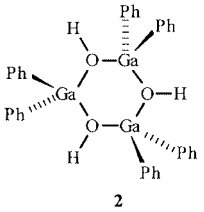
Scheme 1

reaction in THF gives mainly hydrolysis products and a trace of the bi-aryl product.

The metal containing by-products of these reactions were investigated as part of a detailed understanding of the mechanism of the reactions. Mass spectrometry (electrospray: methanol/methylene chloride) of the rapidly formed white micro-crystalline product obtained from the coupling reactions revealed the formation of singly and positively charged clusters of composition $[Ga_{12}O_{14}H_4(aryl)_{12}]$, **1**. The dominance of these



1



2

ions in the mass spectra shows the stability of the ions, and that the dominant species in solution is a single cluster. The same clusters are also formed in mildly acidic and basic solutions. A likely structure for these clusters is a central polyhedral core of twelve fused six-membered rings, **1**, as found in the structure of $[Ga_{12}Bu^t_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)(\mu\text{-}OH)_4]$,[2] albeit with the position of hydrogen atoms on the bridging hydroxy groups not defined. For the reaction of $GaPh_3$ with water in THF we were able to intercept and isolate some of the intermediate hydrolysis species, trimeric $[Ph_2Ga(\mu\text{-}OH)]_3$, **2**, the final product being **1**. Compound **2** was authenticated using X-ray diffraction data as the hydrogen bonded tris-THF adduct.‡ While bis-alkyl analogues of the trimer are known,[4–6,8] this is the first example of a bis-aryl system. $[Ph_2Ga(\mu\text{-}OH)]_3$ crystallises in the monoclinic space group *C*2/*c*, and consists of diphenylgallium bridged to two other diphenylgallium units *via* two μ-OH bridges with each gallium in a distorted tetrahedral geometry, Fig. 1. THF molecules are H-bonded to the OH bridges with two THF molecules related by a crystallographic C_2 symmetry axis disordered equally over two positions. Phenyl groups are close to being co-planar with an adjacent Ga–O bond and this allows maximum access to the OH groups for hydrogen bonding to THF.

As to the mechanism of the bi-aryl coupling reactions we have established that it is an intra-molecular process since hydrolysis of a mixture of the two compounds, $Ga(aryl)_3$, aryl = Ph or *p*-tolyl, in toluene gave exclusively the symmetrical bi-aryls. This also implies that $Ga(aryl)_3$ species themselves are non-labile and that the synthesis of mixed tris-arylgallium(III) species is possible which would be a route to unsymmetrical bi-aryl compounds on hydrolysis. Competition experiments, bi-aryl coupling *versus* hydrolysis, were investigated for the reaction of $Ga(C_6H_4Ph\text{-}p)_3$ in THF with excess water with increasing amounts of toluene relative to THF. The bi-aryl coupling diminishes dramatically only when the THF concentration is *ca.* 30% in toluene, even for two-phase reactions. Thus the THF plays an important role in initially coordinating to the

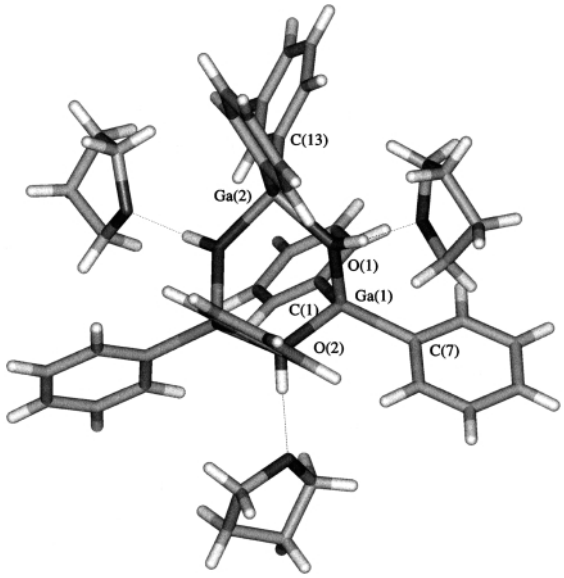


Fig. 1 Molecular structure of $[Ph_2Ga(\mu\text{-}OH)]_3\cdot 3THF$; important bond distances (Å) and angles (degrees): Ga(1)–O(1), 1.908(3); Ga(1)–O(2), 1.916(2); Ga(2)–O(1), 1.911(3); Ga(1)–C(1), 1.993(5); Ga(1)–C(7), 1.977(5); Ga(2)–C(13), 1.962(5); O(1)–Ga(1)–O(2), 97.9; O(1)–Ga(1)–C(7), 111.7; O(1)–Ga(1)–C(1), 110.8(2); C(1)–Ga(1)–C(7), 122.4(2). metal centre and/or hydrogen bonding to a water molecule on the metal centre as found in $[Ga(Mes)_3(OH_2)]\cdot 2THF$[11] and in the structure of **2**. The oxidant in the aryl coupling reactions is water with evolution of one equivalent of hydrogen gas (experimentally determined); note also that controlled experiments excluding oxygen afforded the same products. The hydrolysis reactions are rapid and under these conditions there would be insufficient oxygen delivered to account for the bi-aryl formation. The bi-aryl coupling is likely to proceed through a five coordinate bis-water adduct, $[Ga(aryl)_3(OH_2)]$, at the interface between the water and toluene, leading to a bis-hydroxide, $[Ga(aryl)(OH)_2]$, on elimination of the biphenyl, which then oligomerizes. However a reductive elimination of bi-aryl leading to a Ga(I) species which is then oxidized by water cannot be ruled out. In the presence of THF competition between complexation of THF and water would block such a bi-molecular water process.

Roesky *et al.*[11] have established that the controlled reaction of $[Ga(Mes)_3]$ in THF with water initially gives a four coordinate adduct of water, then a proposed five coordinate bis-adduct, followed by $[Ga(Mes)_2(\mu\text{-}OH)]_2$ then $[Ga_6(Mes)_6(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4]$, and that the latter compound is formed on reaction of $[Ga(Mes)_3]$ with water in toluene. The lack of aryl coupling here presumably relates to the steric impediment of two bulky aryl groups connecting at the metal centre and/or two water molecules coordinating to the metal centre necessary to effect a bimolecular water process for aryl coupling. Steric hindrance is also noteworthy in giving a smaller cluster, $[Ga_6(Mes)_6(\mu_3\text{-}O)(\mu_3\text{-}OH)_4]$,[7] either as an unstable hexa-tetrahydrofuran solvate[7] or its mono-tetrahydrofuran solvate which was isolated in the present study.§ We note that substitution of one of the *o*-positions of the aryl groups by Me still gives the biaryl, R = Me, Scheme 1. For *o*-OMe and *o*-Ph, however, the amount of coupling is reduced, 40 and 35% respectively. Substitution in both positions (aryl = mesitylene) gives arylH. This is consistent with some steric influence, including the formation of chelate rings in the gallium complex which may shut down the coupling reaction by blocking binding of two water molecules to the metal centre.

It is thus possible to prepare symmetrical bi-aryl compounds from tris-arylgallium(III) species. An inherent problem from the organic synthesis perspective, however, is the loss of one of the aryl groups to the gallium(III) hydroxide/oxide species. This aspect is being addressed along with developing the method for the synthesis of unsymmetrical bi-aryls.

We are grateful to the Australian Research Council for support of this work.

Notes and references

† Compounds $Ga(aryl)_3$, aryl = Ph, *o*-, *m*-, *p*-tolyl, were prepared by reacting the Grignard or lithium reagent of an arylbromide with $GaCl_3$ in diethyl ether (yields 65–80%), and melting points checked with the same compounds prepared from $Hg(aryl)_2$ and gallium metal.[17,18] $Ga(aryl)_3$, aryl = C_6H_4OMe-*o*, C_6H_4Ph-*o* and C_6H_4Ph-*p*, were similarly prepared from their corresponding lithium reagents but were difficult to obtain pure. The hydrolysis reactions involved addition of a $Ga(aryl)_3$ toluene solution at *ca.* 25 °C to excess water followed by stirring for 5 min. The two layers were separated and the respective products isolated; $Ga_{12}O_{10}(OH)_4(aryl)_{12}$, aryl = Ph, C_6H_4Me-*o*, -*m*, -*p*, from the aqueous layer, yields 30–40%, $M/2^+$ and M^+ (FTMS) 995.81, 1990.64, Ph; 1079.7, 2158.8, *o*-tolyl, *m*-tolyl, *p*-tolyl; 1175.6, 2350.7, C_6H_4OMe-*o*; M^+ 1549.0, C_6H_4Ph-*p*, C_6H_4Ph-*o*.

‡ *X-Ray crystallography*. A prismatic crystal of dimensions 0.15 × 0.15 × 0.1 mm was mounted under a stream of argon onto a glass capillary under oil. X-Ray data were collected at 123(1) K on an Enraf-Nonius KappaCCD single crystal diffractometer with Mo-Kα radiation (λ = 0.71073 Å). Data were corrected for Lorentzian and polarisation effects, but not absorption. The structure was solved using Fourier techniques with teXsan and refined by full matrix least-squares on *F* using teXsan: $[Ph_2Ga(\mu\text{-}OH)]_3\cdot 3THF$ $C_{48}H_{57}O_6Ga_3$, M_r = 939.13 g mol^{-1}, monoclinic, *C*2/*c* (no. 15), a = 16.3050(3), b = 17.6498(3), c = 15.9096(2) Å, β = 100.777(1)°, V = 4497.7(1) Å^3, ρ_{calc} = 1.387 g dm^{-3}, μ = 18.30 cm^{-1} (no correction), Z = 4, 33253 reflections were collected (6400 unique), $2\theta_{max}$ = 60.1° (4917 observed, $I > 3\sigma(I)$, R = 0.067, Rw = 0.082). The non-hydrogen atoms were refined anisotropically and hydrogen atoms were included at geometrically estimated positions but not refined. CCDC 182/1643. See http://www.rsc.org/suppdata/cc/b0/b002422h/ for crystallographic files in .cif format.

§ *Crystal structure* of $[Ga_6(Mes)_6(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4]\cdot THF$, the same cluster being previously authenticated as the hexakis-THF adduct;[7] crystals were obtained from THF: M_r = 1121.37 g mol^{-1}, trigonal $R\bar{3}$ (no. 148), a = 22.5232(2), c = 20.8835(2) Å, V = 9174.7(0.1) Å^3, ρ_{calc} = 1.218 g dm^{-3}, μ = 26.41 cm^{-1} (no correction), Z = 6, 45092 reflections, $2\theta_{max}$ = 60.1° (3576 observed, $I > 3\sigma(I)$, R = 0.061, Rw = 0.060). The THF molecule is disordered over two positions.

The origin of the 'spike' in the EPR spectrum of C_{60}^-

Parimal Paul,† Robert D. Bolskar,‡ Alex M. Clark and Christopher A. Reed*

Department of Chemistry, University of California, Riverside, California 92521-0403, USA. E-mail: chris.reed@ucr.edu

Received (in Cambridge, UK) 28th April 2000, Accepted 26th May 2000
Published on the Web 20th June 2000

The long-debated origin of the narrow line-width signal in the EPR spectrum of C_{60}^- is shown to be $C_{120}O^-$, arising from unavoidable $C_{120}O$ impurity in air-exposed samples of C_{60}.

A vexing problem in C_{60} chemistry has been the origin of a narrow line-width signal or "spike" superimposed on the broad EPR spectrum of C_{60}^- (Fig. 1). In the nine years since it was first observed, no fewer than six different hypotheses have been forwarded to explain its existence, but none has been confirmed. In a recent comprehensive review of the literature on this subject,[1] we concluded that the most likely explanation lies in $C_{120}O$, a recently discovered, inevitable impurity in air-exposed samples of C_{60}.[2] In this communication, we provide data that confirm this hypothesis.

If $C_{120}O$ impurity is the source of the sharp signal, three experiments of proof suggest themselves. (a) The EPR characteristics of pure $C_{120}O^-$ should match those reported for the narrow line-width signal. (b) Addition of an authentic sample of $C_{120}O$ to a standard sample of C_{60}^- should enhance the sharp signal at precisely the same g value and line width. (c) The preparation of high purity C_{60}, free of detectable $C_{120}O$, should allow a spike-free EPR spectrum of C_{60}^- to be obtained.

A sample of $C_{120}O$ was prepared by literature methods[3] and purified by standard HPLC methods.[2] One-electron reduction to $C_{120}O^-$ was achieved with <1 equiv. of cobaltocene in *o*-dichlorobenzene. As shown in Fig. 2, the EPR spectrum at 100 K is characterized by a sharp signal at $g = 2.0013$ and $\Delta H_{pp} = 1.42$ G (calibrated against DPPH). These parameters closely match those of the major signal observed when a two-electron electrochemical reduction of $C_{120}O$ is carried out in *o*-dichlorobenzene ($g = 2.0016$, $\Delta H_{pp} = 1.1$ G at 77 K).[4] This suggests that $C_{120}O^{2-}$ may be EPR silent (or weak) under these conditions and that the observed sharp signal results from $C_{120}O^-$, present because of the difficulty of carrying out a precise, quantitative two-electron reduction. The temperature dependence of the line width of the $C_{120}O^-$ signal is minimal, decreasing to 1.33 G at 225 K. The variation of signal parameters with solvent is also small. For example, in 2-methyltetrahydrofuran at 100 K, $g = 2.0005$ and $\Delta H_{pp} = 2.0$ G. In tetrahydrofuran at 100 K, the values are $g = 1.9988$ and $\Delta H_{pp} = 2.6$ G. The signal characteristics of $C_{120}O^-$ are clearly compatible with the 'spike' in C_{60}^- where, depending on conditions, g values are reported in the range 1.9995–2.0012 and $\Delta H_{pp} = 0.1$–3.5 G.[5]

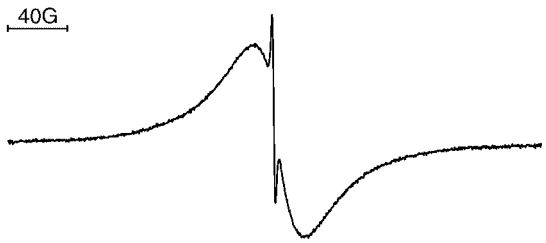

Fig. 1 Typical EPR spectrum of C_{60}^- prepared from off-the-shelf C_{60} showing the broad signal (major) and the sharp signal or 'spike' (minor). Conditions: $[Co(Cp)_2][C_{60}]$ in tetrahydrofuran at 140 K, microwave power 5.7 mW, modulation 5 G.

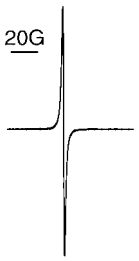

Fig. 2 EPR spectrum of $[Co(Cp)_2][C_{120}O]$ in *o*-dichlorobenzene at 100 K (microwave power 5.7 mW, modulation 1.25 G).

To explore whether this compatibility means identity, small additions of $[Co(Cp)_2^+][C_{120}O^-]$ were made to solutions of $[Co(Cp)_2^+][C_{60}^-]$ to ascertain whether the sharp signal increased relative to the broad signal. As shown in Fig. 3, this is exactly what happens. Moreover, the peak positions are *precisely* those of the spike. Experimental error and reproducibility variances are <0.08 G. The data in Fig. 3 provide

compelling evidence that the spike in C_{60}^- is due to $C_{120}O$ impurity.

Finally, we purified C_{60} by HPLC to try to obtain a spike-free EPR spectrum of C_{60}^-. Purification of C_{60} was carried out using a Cosmosil Buckyprep column with toluene as eluent. Double passage gave C_{60} with essentially undetectable quantities of $C_{120}O$ (monitoring at 330 nm) and a middle cut was collected anaerobically with exclusion of light. As shown in Fig. 4, the EPR spectrum of a cobaltocene-reduced sample of this material gave a spike-free spectrum at 100 K (g = 1.9963, ΔH_{pp} = 16.4 G). Interestingly, however, when we chose measurement conditions which optimized the observation of the sharp signal relative to the broad signal (higher temperatures where the broad signal becomes even broader and the use of the lowest possible microwave powers because the spike saturates more easily than the broad signal), traces of the $C_{120}O^-$ signal could still be detected as shoulders in the inflection region. This is partly a reflection of the extraordinary sensitivity of the EPR technique but it also shows how difficult it is to rid C_{60} entirely of $C_{120}O$. Traces of O_2 convert C_{60} to $C_{120}O$ with extraordinary ease.[2]

In summary, it now appears certain that all air-exposed samples of C_{60} contain $C_{120}O$ and that all EPR work using such samples has been compromised by its presence. It is likely that most (if not all) of the sharp signals observed in the EPR spectra of discrete C_{60}^{n-} fulleride ions (n = 1–4) arise from $C_{120}O^{n-}$ species (n = odd) or decomposition products therefrom. Further studies are in progress to investigate the full extent of the $C_{120}O$ influence in spectra of the more highly charged fulleride anions.

There have been a number of reports of sharp signals increasing significantly at the expense of broad signals upon aging of C_{60}^- salts.[1] We do not find this to be the case with the present samples. The solution of $[Co(Cp)_2][C_{60}]$ that gave rise to Fig. 1 was kept in a torch-sealed quartz EPR tube for several weeks. Its spectrum has remained essentially unchanged, even with exposure to laboratory light. It is likely that release of oxygen from the walls of containers or aerobic leakage are responsible for reports to the contrary. C_{60}^- would be preferentially oxidized (to EPR silent C_{60}) giving the *appearance* of an increase in $C_{120}O^-$ concentration. (The overlay of the two signals, and their very different line-widths, has typically precluded reliable measurements of absolute intensities). In the extreme (*i.e.* room temperature, low reduction levels, low signal-to-noise ratios) the observation of *only* a sharp signal[6,7] can be explained. Even the metal-intercalated fulleride materials such as A_3C_{60} (A = Na, K, *etc.*) are reported to have the sharp signal of an 'impurity phase' superimposed on the broad signal arising from conduction electrons.[8] Perhaps it also arises from $C_{120}O^{n-}$ defects (n = 5 or 7). Indeed, a number of complex explanations for multiple signals in fullerides[9] may have more straightforward interpretations.

We thank the US National Institutes of Health for financial support.

In the neutron diffraction study of the 1:1 adduct 2-methylpyridine–pentachlorophenol, a very short O–H···N hydrogen bond is found with a sharply defined proton position, and distances of O–H = 1.068(7), H···N = 1.535(7) and O···N = 2.588(3) Å; the bond order of H···N is about 0.24 valence units.

There is great current interest in the strongest types of hydrogen bonds, in particular in the context of chemical reactivity.[1] Whereas strong homonuclear hydrogen bonds O–H···O are today quite well investigated,[2] the experimental material on the very important heteronuclear N–H···O and O–H···N hydrogen bonds is still far from satisfactory. N–H···O and O–H···N hydrogen bonds are in most cases only of moderate strength, but can in some situations also become very strong. An interesting example are adducts of amines and phenols with suitably small values of ΔpK_a [$\Delta pK_a = pK_a(NH^+) - pK_a(OH)$].[3] In a certain 'critical' range of ΔpK_a, the systems can be found in crystals as molecular adducts linked by hydrogen bonds O–H···N, as ionic adducts linked by N^+–H···O^- interactions, or even as an equilibrium between the two.[4] In all these situations, hydrogen bond distances N···O can be < 2.6 Å. Strong intramolecular N–H···O and O–H···N hydrogen bonds have been described for resonance-assisted cases,[5] but they suffer from steric restrictions and have longer H···O separations than the more linear interactions in molecular adducts. Some of the most poorly described properties of strong heteronuclear hydrogen bonds are the distance characteristics at the H-atom, which cannot be deduced from X-ray diffraction data, but require neutron diffraction experiments. For strong O/N–H···N/O hydrogen bonds, not even one neutron diffraction study has been published as yet (for a survey, see ref. 6).

To perform a neutron diffraction study of a strong O–H···N hydrogen bond, we have selected as a model system the adduct of 2-methylpyridine and pentachlorophenol, **1**, which grows crystals of the large size that is required. X-Ray diffraction crystal structures of several related compounds have been published, as found surveyed in ref. 4. Neutron diffraction data on a single crystal of **1** were collected at 30 K at the instrument SXD of the ISIS facility.[7]† In the crystal, a molecular (not an ionic) adduct is formed, as is shown in Fig. 1. The hydrogen bond connecting the molecules has a geometry of O–H = 1.068(7), H···N1′ = 1.535(7), O···N1′ = 2.588(3) Å, O–H···N1′ = 167.5(6)°, and is directed almost ideally at the electron lone-pair of the pyridyl N-atom [H···N1′···C4′ = 172.7(3)°]. This is by far the shortest O-H···N bond for which neutron diffraction data are available. The H(O) atom is a relatively short distance from one of the methyl H-atoms, H···H72′ = 2.33(1) Å; this probably repulsive interaction might be responsible for a significant rotation of the methyl group out of the minimum energy conformation [torsion angle N1′–C2′–C7′–H72′ = 17.8(7)°; note that H and H72′ are displaced in opposite directions from the pyridyl plane, Fig. 1(b)]. Some further parameters of the molecular geometries are given in the legend of Fig. 1.

With very short hydrogen bonds, an important question is how sharply the hydrogen atom is located, and if there possibly is proton disorder. A look at Fig. 1 shows that the mean square displacement of the proton in the hydrogen bond is small, even smaller than those of the protons of the hydrogen atoms bonded to C. Numerically, its mean square displacement U_{eq} is 0.021(1) Å^2 compared to an average U_{eq} = 0.025(1) Å^2 of the C(sp^2)–H and 0.038(2) Å^2 of the methyl protons. This means that the proton in the hydrogen bond is very sharply located. To study the possibility of hydrogen atom disorder, O–H···N ↔ O^-···H–N^+, a hypothetical and partially occupied proton position at the N-atom was included in test refinements (compare the related

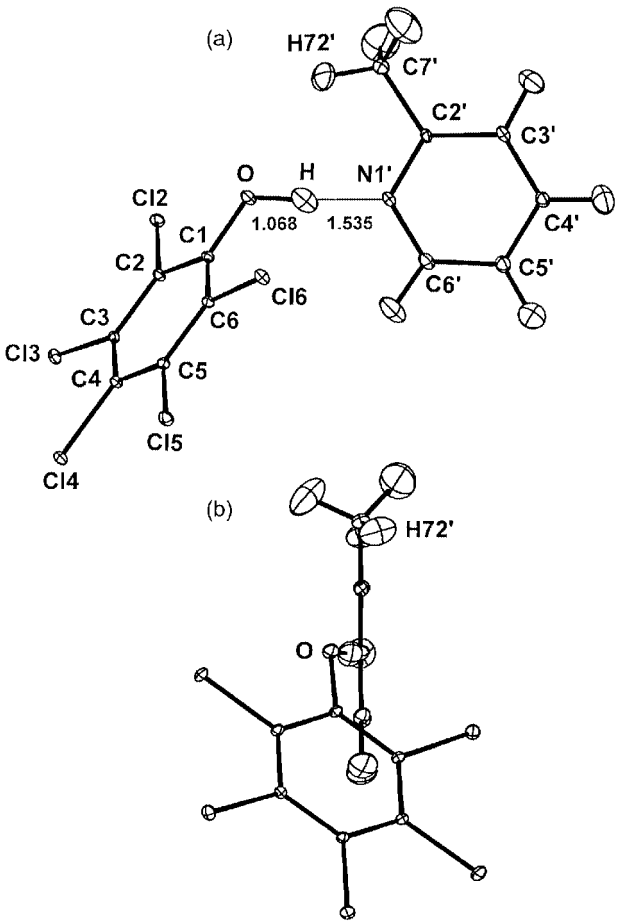

Fig. 1 Structure of **1** at 30 K, displacement ellipsoids are drawn at the 50% probability level. (a) View on the pyridine plane, (b) view perpendicular to the pyridine plane. Relevant geometrical parameters: O–H = 1.068(7), C1–O = 1.317(3) Å, C–O–H = 117.1(5), C2–C1–O–H = −140.3(6)°, N1′–C2′ = 1.338(3), N1′–C6′ = 1.335(4) Å, C2′–N1′–C6′ = 119.2(2)°, H···N1′ = 1.535(7), O···N1′ = 2.588(3) Å, O–H···N1′ = 167.5(6)°, H···Cl6 = 2.728(6), O···Cl6 = 2.963(3) Å, O–H···Cl6 = 91.9(4)°.

refinement of a disordered hydrogen bond in benzoic acid, ref. 8). In free refinement, the occupancy of the proton at the O-atom remained at 1.0, whereas that of the hypothetical proton at N dropped to −0.02. This means that an ionic adduct, if present in the crystal, at 30 K can only be populated spuriously.

An important general feature of X–H···Y hydrogen bonds is an elongation of the X–H bond compared to free X–H groups. This points at the hydrogen bond being an incipient proton transfer reaction.[9] In Fig. 2, the dependence of the O–H from the H···N distance is shown for all published neutron diffraction data (substances and references given in the Figure legend). The elongation of the O–H bond in **1** exceeds by far that in all previous studies, following trends that are much better studied in homonuclear hydrogen bonds.[9] If bond orders *s* of the O–H and H···N bonds are calculated from the distances using the Pauling approximation with the most recent set of numerical parameters,[6] one obtains $s_{OH} = 0.71$ and $s_{H\cdots N} = 0.24$. The rule of bond order conservation ($s_{OH} + s_{H\cdots N} = 1.0$) is not ideally fulfilled, indicating that the parameters in ref. 6 are only roughly valid for very short hydrogen bonds. Nevertheless, it becomes clear that the bond order of H···N is about ¼ of a valence unit, meaning that the 'incipient proton transfer' characterizing a hydrogen bond has reached already quite an advanced stage in **1**. This gives particular importance to the observation of a sharply located proton with a small vibration amplitude, and disfavours widespread concepts that in very short hydrogen bonds, the proton would oscillate in a potential that is deep but relatively flat at the bottom. Published views that heteronuclear hydrogen bonds cannot be very short (in H···X) by principle are disfavoured too, and it may be assumed that O–H···N hydrogen bonds can be made even shorter by suitably tuning the pK_a values of the donor and/or acceptor molecules.

† *Crystal data*: Single crystals of **1** ($C_6H_7N{\cdot}C_6HCl_5O$, M = 359.47) were obtained by slow evaporation of a CCl_4 solution of pentachlorophenol (Fluka) and an excess of 2-methylpyridine (Merck). A single crystal of dimensions 2.5 × 2 × 1 mm, *V ca.* 5 mm^3, was wrapped in aluminium foil and mounted on the time-of-flight Laue diffractometer SXD of the ISIS spallation neutron source.[7a] Crystals are sensitive to atmosphere of high humidity, requiring swift handling. Diffraction data were collected at 30(1) K, and reduced to 4303 independent structure factors[7b] (wavelength range 0.5–5.0 Å, total of 48 frames with a three weeks interruption after seven frames due to a failure of the source; because of continued cooling only 20% reduction in the sacttering after this delay). Unit cell dimensions at 30 K are a = 9.227(5), b = 11.668(6), c = 6.849(4) Å, α = 104.61(3), β = 105.06(3), γ = 99.87(3)°, U = 666.5(6) Å^3, with space group $P\bar{1}$ (no. 2). The structure was solved by molecular replacement methods,[10a] using the phenol and pyridine moieties in the related crystal structure of 4-methylpyridine–pentachlorophenol[11] as the search fragment. Anisotropic refinement with standard methods[10b] (245 parameters) proceeded smoothly, and converged at an R value of 0.0735 [$wR(F^2)$ = 0.1830].

Hydrogenated fullerenes derived from the Birch reduction and from hydrogen transfer reduction of [60]fullerene have been examined by matrix-assisted laser desorption ionization; applying 9-nitroanthracene as the matrix, it has been possible to desorb and ionise the samples with such a low degree of fragmentation as to enable the establishment of the amount of hydrogen bound to the fullerene; in contrast to the currently assumed polyhydrofullerene distribution featuring $C_{60}H_{36}$ only as a minor component, evidence has been obtained which re-establishes $C_{60}H_{36}$ as the major product of the Birch reduction.

The hydrogenation of fullerenes has been achieved by a large variety of synthetic methods including the Birch reduction,[1] transfer hydrogenation,[2] reactions with elemental hydrogen,[3] reduction in metal/acid systems[4] and others.[5] Thirty-six often represents a 'magic number' for the quantity of hydrogen attached to [60]fullerene. According to semiempirical and *ab initio* SCF calculations, the thermodynamically most stable structure of $C_{60}H_{36}$ possesses *T* symmetry.[6] This structure was initially suggested by Taylor[7] and is characterised by four isolated benzenoid rings located at the corners of a tetrahedron. A recent X-ray investigation provides evidence for the existence of the benzenoid rings in $C_{60}H_{36}$.[8] Two isomers in a ratio of 2 : 1 have been found applying ^{3}He NMR[9] and their structures have been proposed to exhibit C_3 and *T* symmetry. The coexistence of the C_3 isomer, which is thermodynamically less stable than the *T* isomer, probably indicates that kinetic factors play an important role in the hydrogenation of C_{60}. It seems reasonable to assume that variations in the way the reduction is achieved can lead to the formation of alternative structures of $C_{60}H_{36}$. It has even been proposed that in the case of the Birch reduction,[1] $C_{60}H_{36}$, which is commonly referred to as the first ever synthesised fullerene derivative, is only a minor product of the obtained distribution of hydrogenated [60]fullerenes of the type $C_{60}H_x$, with *x* ranging from 18 to 36.[10] These conclusions were derived from mass spectrometry-based experiments in which the reaction product resulting from the Birch reduction of C_{60} has been laser-desorbed into the gas phase to be in a second step, subsequently laser-ionised. A distribution of $C_{60}H_x^+$ ions was obtained which was centred at $x = 30$ and 32 with only a minor contribution attributed to $C_{60}H_{36}$. The fact that signals due to C_{60}^+ fragment ions were entirely absent was taken as evidence for the softness of the method revealing the true distribution of the hydrogenated [60]fullerenes. A similar distribution was obtained using liquid secondary ion mass spectrometry (LSIMS) and an almost perfect fit to a theoretical distribution based on Monte Carlo calculation supported the experimental findings. The comparison with other approaches for ionization, especially when electron impact (electron ionization, EI) was used, for which the sample had to be heated to achieve evaporation, revealed a clear shift in the observed $C_{60}H_x^+$ distribution towards $C_{60}H_{36}$. However, since C_{60}^+ was also prominently observed under these conditions, it was concluded that the excitation of the sample resulted in the dissociation of the initial $C_{60}H_x$ species with *x* being centred at around 30 and that the observed ions with a larger hydrogen content represent more stable species which resist dissociation. Interestingly, for the transfer hydrogenation of [60]fullerene by 9,10-dihydroanthracene (DHA), $C_{60}H_{36}$ has been established beyond any doubt as the major product utilising field desorption mass spectrometry.[2] Roger, Birkett and Campbell (RBC) have recently re-examined the hydrogenated product from transfer reduction of C_{60} with DHA by matrix-assisted laser desorption/ionization (MALDI) mass spectrometry.[11] A matrix combination of 5-methoxysalicylic acid and $NaBF_4$ was found to provide the softest conditions, and a spectrum was recorded which consisted almost entirely of only one signal arising from $C_{60}H_{35}^+$, which can be taken as direct evidence for the exclusive production of $C_{60}H_{36}$. The Birch reduction[1] and the hydrogen transfer reduction[2] differ in the actual reaction mechanism. The Birch reduction proceeds *via* anionic intermediates and the transfer reduction most probably involves neutral radicals, so that the findings by RBC[11] are not necessarily in conflict with those obtained by Banks *et al.*[10] In order to reveal whether or not the two reductions lead to different product distributions, we investigated the products derived from both reactions by MALDI time-of-flight mass spectrometry. In line with recently reported experiments by others,[12] our own initial efforts to apply the above mentioned matrix combination were unsuccessful, as the desorption/ionization process was always accompanied by efficient fragmentation. The reason for this has to be seen as due to slightly differing experimental conditions from those reported originally,[11] rather than in a failure of the method as such. RBC pointed out that the wavelength of the laser light, the laser fluence and the pulse duration were of crucial importance.[11] Employing a nitrogen laser of 337 nm wavelength with a variable laser fluence, the most pronounced difference in the present experiments is the pulse duration of 3 ns, which is two orders of magnitude longer and is probably the cause of the enhanced fragmentation. Unexpectedly, a much simpler approach was found to be more suitable for the present study. Using 9-nitroanthracene (9-NA) as the matrix (using a matrix : analyte ratio of 50 : 1) led to conditions which allow conclusive insight. Although there exists no comprehensive screening of matrices for the analysis of fullerene derivatives by MALDI, 9-NA has been used successfully in several earlier investigations involving related compounds.[13–17] The signals obtained at the threshold for ion formation from hydrogenated [60]fullerene, derived by transfer reduction[2] from DHA for which the synthetic details have been published elsewhere,[18] are depicted in Fig. 1(a). The base peak corresponds to $C_{60}H_{35}^+$ in line with the findings reported by RBC[11] and very little fragmentation is observed. The same experiment performed with the sample derived from the Birch reduction[1] gave rise to the spectrum shown in Fig. 1(b), which is almost identical to the

spectrum in Fig. 1(a). When the laser fluence is only slightly increased, the spectrum depicted in Fig. 1(c) results. Caused by enhanced fragmentation, a clear shift of the ion distribution is observed with $C_{60}H_{33}^+$ now prevailing. Fig. 1(d) shows the liquid secondary ion mass spectrum (LSIMS) of Birch-reduced C_{60} using 3-nitrobenzyl alcohol (3-NBA) as the matrix. With $C_{60}H_{35}^+$ as the major signal and no evident C_{60}^+ peak, LSIMS confirms the MALDI findings. In all spectra, small satellite peaks are observed, arising from oxygenated species. We assume that these are indicative of a partial oxidation of the hydrogenated samples, although we have recently established[19] that oxygen transfer from 9-NA to the analyte can be very pronounced during the desorption/ionization process in MALDI. The observation of these satellite peaks does not affect the interpretation of the present findings, as these species were also observed in the work performed by Banks *et al.*[10] In contrast to the assumption that $C_{60}H_{35}^+$ results under these conditions from protonation of $C_{60}H_{34}$,[10] RCB have provided evidence, that at least in the MALDI experiments, the $C_{60}H_{35}^+$ is directly formed from $C_{60}H_{36}$.[11] A comprehensive MALDI investigation on related, organic ligand-bearing fullerene derivatives confirms that protonation is not important for the ion formation in the present experiments.[19] The observed $C_{60}H_x^+$ ions (with *x* representing an odd number of hydrogen atoms) are thus indicative for the neutral $C_{60}H_{x+1}$ species. In contrast, the close match reported earlier[10] for the experimental distribution and the distribution derived from a Monte Carlo simulation was based on the assumption that the odd numbered $C_{60}H_x^+$ ions would represent $C_{60}H_{x-1}$ neutrals. On the basis of the present experiments it has to be concluded that the earlier experiments suffered from the partial dissociation of $C_{60}H_{36}$. Obviously, conditions were met by which a certain amount of hydrogen was readily evaporated from $C_{60}H_{36}$ without the complete loss of all attached hydrogen atoms, suggesting soft ionization conditions and leading to a distribution of ions which do not represent the neutrals which were initially present. In this context it is interesting to note that, in line with the assumptions made by Banks *et al.*,[10] fragment ions such as C_{60}^+ are primarily the result of neutral dissociation followed by ionization, rather than caused by fragmentation of energised ions. Recent investigations into the dissociation behaviour of size-selected, hydrogenated fullerene ions reveal that cage rupture efficiently competes with hydrogen losses in these cases.[20] This means the direct formation of C_{60}^+ from $C_{60}H_{36}^+$ is unlikely.

In summary, using 9-NA as the chosen matrix for the MALDI analysis of hydrogenated fullerenes creates desorption/ionization conditions which are sufficiently free of fragmentation to allow the establishment of the hydrogen content. These findings re-establish $C_{60}H_{36}$ as the major product derived by Birch reduction of C_{60}.

We report evidence from plane-wave (PW) pseudo-potential calculations, which suggests that neutral, molecular oxygen dissociates exothermically at bridging oxygen vacancies on the SnO_2 (110) surface, supporting recent experimental data.

Stannic oxide (SnO_2) is widely used industrially as a selective catalyst in oxidative dehydrogenation and is also a highly tuneable gas sensor, used in the detection of reducing gases. Although a wealth of experimental literature exists on SnO_2 reaction kinetics and profiles,[1,2] speculations on reaction mechanisms are a subject of contention. One such area of debate is the question of how oxygen gas effects the observed, substantial increase in surface conductivity. Of general interest is the need to establish how feasible homolysis of O_2 is at the surface. We have established previously that the adsorption energy of neutral oxygen at the surface is extremely small[3] (< 0.02 eV). Here, we describe a theoretical study to elucidate the thermodynamic viability of the dissociation of O_2 with the reduced (110) SnO_2 surface. On a reduced surface, the bridging oxygen vacancies can facilitate the first step in the Mars and van Krevelen[4] reaction, which underpins its catalytic and sensing properties.

Experiment[1] and previous calculations (including atomistic[5–7] and PW studies[8–10]) have shown the (110) surface to be energetically the most stable surface under ambient conditions. To generate a model for the surface, we first performed a constant pressure relaxation of the bulk unit cell using the VASP[11–13] code. We used an energy cut-off of 495 eV, an ultrasoft pseudo-potential for the Sn and O ions and the Ceperley–Alder expansion for local exchange. The resulting relaxed lattice parameters of $a = b = 4.725$ and $c = 3.180$ Å, are in excellent agreement with the experimentally measured values of 4.737 and 3.186 Å, respectively, and reproduce the experimental c/a ratio of 0.673. We then constructed a cell to describe the (110) surface, containing three cell layers forming a slab, comprising a total of 72 ions. We selected a vacuum width of 5.0 Å having verified complete convergence of the surface energy at 4.51 Å. Upon relaxation of the surface, we obtained a surface energy of 1.19 J m^{-2} in close agreement with previous atomistic[5–7] and PW studies.[8–10]

We verified the quality of the oxygen pseudo-potential by calculating the spin-polarised, relaxed bond length and binding energy for the molecular oxygen triplet. The oxygen bond length of 1.225 Å compares well with the measured value of 1.216 Å.[14] The binding energy (BE) of oxygen is overestimated at 7.0 eV compared with the experimental value of 5.1 eV;[14] this is a generic feature of LDA based methods. Although we would expect gradient corrections to improve the agreement with experiment for the molecular binding energy, we in fact obtained considerably poorer lattice constants for SnO_2 using GGA pseudo-potentials. Therefore, for methodological consistency, we have used LDA pseudo-potentials throughout.

Fig. 1 shows a schematic of the dissociation process. Light spheres indicate oxygen, dark spheres represent tin and black spheres signify dissociated oxygen. Site A is a bridging oxygen, whilst Site B is a five coordinate tin site and C is the oxygen vacancy. The first step in this process is the formation of a bridging oxygen vacancy; the second is the dissociation of oxygen at the vacancy with encapsulation of an oxygen atom in the vacancy, and the adsorption of the monoatom at a neighbouring five-fold Sn site.

Table 1 summarises the total energy of formation for the configurations calculated using an identical cell geometry.

The energy of dissociation can be expressed as the difference between the undissociated and dissociated surfaces, where the initial configuration is simply one where oxygen is non-interacting with the defective surface, *i.e.* the energy of the isolated oxygen molecule plus the energy of the defect-containing surface. Thus, the dissociation of oxygen is exothermic, releasing a net energy of 0.59 eV. In considering the equilibrium between molecular and atomised oxygen, we note that the energy of adsorption of the monoatom to the five-fold Sn site is −1.25 eV, whilst the vacancy formation energy is +2.84 eV. (We have assumed the vacating oxygen atom combines with another gaseous oxygen monoatom to form paramagnetic molecular oxygen). The monoatom is adsorbed 2.02 Å above the five-fold tin site, and its spin is reduced to a singlet.

Using these calculations, we can consider the end-points of dissociation for two other reactions; first that where oxygen dissociates to occupy two adjacent bridging oxygen vacancies

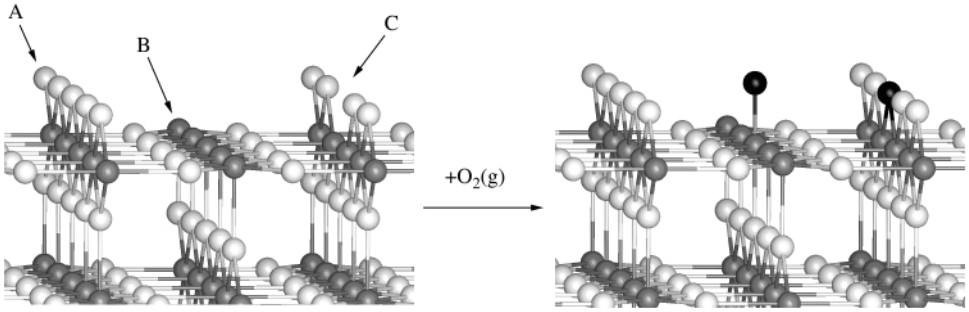

Fig. 1 Schematic oxygen dissociation process. The darker atoms in the final state come from the O_2 molecule: one atom fills the O vacancy (C), and the other is adsorbed on the five-coordinated Sn site (B).

DOI: 10.1039/b002039g

Table 1 Total energies of formation

Configuration	Energy/eV
SnO_2 perfect surface	−496.388
SnO_2 with bridging defect	−488.386
O_2 molecule	−10.332
O atom	−1.678
SnO_2 with bridging defect + dissociated O_2	−499.312

(A) and secondly, where two adjacent adatoms are formed (B) and compare with the main study here, where one bridging vacancy is occupied and one adatom is formed (C). Reactions A and C are exothermic; −5.68 and −0.59 eV, respectively, whereas reaction B is endothermic, +4.48 eV. Therefore, in the absence of specific activation barrier heights, we would expect reaction A to proceed more quickly than C and that reaction B will not occur at low temperatures.

The fact that the dissociation process is predicted to be exothermic for reaction C is our fundamental result, since this strongly supports the proposition that oxygen dissociates at bridging oxygen vacancies, filling the vacancy and producing an oxygen adatom. This evidence corroborates the recent postulate of Henderson and coworkers[15] who reported TPD (temperature programmed desorption) measurements with isotopically labelled oxygen. The authors suggested that below 600 K, oxygen on TiO_2 dissociates at bridging oxygen vacancy sites to fill oxygen vacancies and form adsorbed oxygen monoatoms at adjacent in-plane titanium sites on the TiO_2 (110) surface, a surface which is isostructural with the SnO_2 surface considered here. In addition, we have shown how two reactions (A and C) are concerted first steps in the generalised Mars and van Krevelen oxidative process.

We are grateful to EPSRC for providing time on the T3E facility at Manchester.

1-Butyl-3-methylimidazolium hexafluorophosphate, a room temperature ionic liquid, has been used as solvent for the copper(I) mediated living radical polymerisation of methyl methacrylate; the rate of reaction is enhanced and narrow polydispersity polymers are obtained which are easily isolated from the catalyst.

Transition metal mediated living radical polymerisation is rapidly developing as an efficacious new route for the controlled polymerisation of vinyl monomers.[1–3] We have been utilising a system based on $Cu^{I}X$ with alkylpyridylmethanimine ligands.[4,5] These Schiff base ligands are easily synthesised, and can be readily manipulated in order to vary the properties of the catalyst (*e.g.* solubility). One of the main constraints of this chemistry is the high level of catalyst required for acceptable rates of polymerisation, often equimolar with respect to initiator. This leads to contamination of products necessitating catalyst removal. Although this is relatively easily achieved in a laboratory, for most polymers, it would be advantageous for this extra process to be eliminated, especially with regards to exploitation of the technology. In order to achieve this we have been examining a number of routes including the use of solid supported catalysts[6,7] and fluorous biphasic conditions.[8]

Room temperature ionic liquids have been found to be excellent solvents for a number of chemical reactions, *e.g.* hydrogenation, alkylation, Diels–Alder reactions, *etc.*[9,10] However, the only polymerisation reactions reported in ionic liquids, to date, are the Ziegler–Natta polymerisation of ethylene,[11] the oligomerisation of butene[12] and the formation of conducting films by the electropolymerisation of arenes.[13] All of which have been carried out in water sensitive chloroaluminate(III) ionic liquids.

Imidazolium ionic liquids have been developed as air and water-stable reaction media which are tolerant to many functional groups.[14] This permits the use of a wide range of monomers in polymerisation reactions. As such it offers an excellent alternative method to address the problems of transition metal mediated living polymerisation. We have used the room temperature ionic liquid, 1-butyl-3-methylimidazolium hexafluorophosphate, [bmim][PF_6],[15] as a solvent for the Cu^{I} catalysed living radical polymerisation of methyl methacrylate (MMA). Our initial findings are reported which represent the first example of an ionic liquid being used for living radical polymerisation and indeed the first example of a new generation non-hygroscopic ionic liquid used as a polymerisation medium.

The addition of *N*-propyl-2-pyridylmethanimine to a deoxygenated suspension of $Cu^{I}Br$ in [bmim][PF_6] in a 1:1 molar ratio results in the formation of a dark brown homogenous solution at room temperature. Mixtures in toluene, the more normal solvent, only become homogeneous at, or near, reaction temperature (typically 90 °C). Polymerisation of MMA, with ethyl-2-bromoisobutyrate, as initiator, in this solution proceeds readily, reaching 87% conversion after 90 min at 70 °C (Table 1).† This is a fast reaction when compared to polymerisation in non-polar solvents. The increase in rate is manifested by a broadening of the polydispersity to 1.43, ascribed to free radical–free radical termination reactions. A similar increase in the rate has been observed with other polar/co-ordinating solvents, including water[16] and is thought to be due to co-ordination of the solvent to Cu^{I}. This is highly likely in the present case where only one equivalent of *N*-propyl-2-pyridylmethanimine with respect to copper is used precluding the exclusive presence of tetrahedral L_2Cu species. These observations led us to lower the reaction temperature, in an attempt to avoid excessive premature termination. Polymerisation proceeds efficiently at 50 and 30 °C reaching 45% conversion after 180 min at 30 °C.

Table 1 Final molecular mass and conversion data for PMMA synthesised in this work

Reaction[a]	Temperature/°C	Time/min	Conversion (%)[b]	M_n[c]	PDI[c]	k_p[pol*] × 10^4/s^{-1} [d]
1[e]	70	90	87	6440	1.43	5.67
2[e]	50	90	89	7390	1.41	4.13
3[e]	30	180	45	6420	1.30	0.56
4[f]	30	150	69	8390	1.36	1.36
5[g]	30	300	90	15 500	1.35	1.33

[a] All reactions carried were 50% v/v MMA in [bmim][PF_6]. [b] Conversion from integration of ^{1}H NMR. [c] Determined using SEC against pMMA standards. [d] From slope of first order kinetic plot. [MMA]–[$Cu^{I}Br$]–[Ligand]–[Initiator]: [e] = 50:1:1:1; [f] = 50:1:2:1; [g] 100:1:2:1.

Increasing the ratio of *N*-propyl-2-pyridylmethanimine to Cu^{I} to 2:1 (entries 4 and 5, Table 1) results in the rate of polymerisation approximately doubling indicating the reaction is approximately first order in ligand over this range. All reactions at 30 °C show very good first-order kinetic behaviour (Fig. 1) indicating a low amount of termination under these conditions. This taken together with the relatively low PDI values and low M_n of the products indicates that the polymerisation shows living characteristics as observed in more conventional organic solvents. When the [M]/[I] was doubled from 50 to 100 (reactions 4 and 5) an approximate doubling of the M_n is observed, as would be expected for a living polymerisation. Fig. 2 shows the evolution of the M_n as a function of conversion for reaction 4, which increases linearly again as would be expected for living polymerisation. Polymer produced at early stages in the reaction is of higher mass than

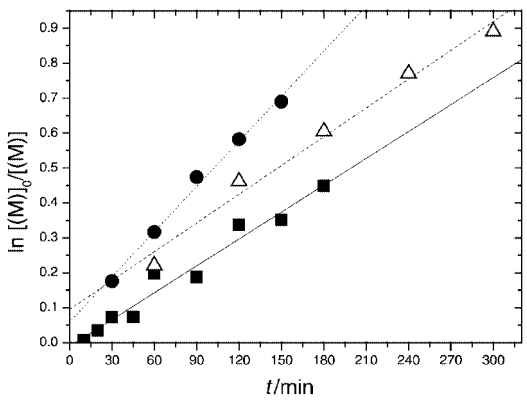

Fig. 1 First order rate plots for the polymerisation of MMA in [bmim][PF_6] at 30 °C. (■) reaction 3, (●) reaction 4 and (▲) reaction 5.

DOI: 10.1039/b003335i

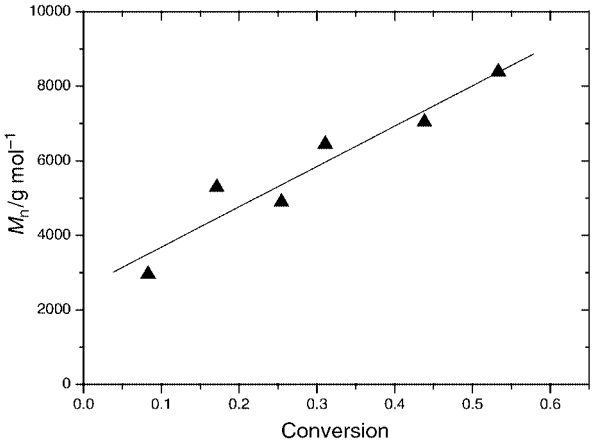

Fig. 2 Evolution of molar mass with conversion for reaction 4, line drawn is the linear regression fit through the data.

would be predicted which is ascribed to radical–radical coupling which occurs efficiently with low mass species as is often observed with living radical polymerisation.[5]

The Cu^{I} catalyst is very soluble in [bmim][PF_6], which in turn is immiscible with organic solvents, such as toluene. This allows the reaction solution to be washed with toluene so as to extract the poly(methyl methacrylate) (PMMA) product. The catalyst remains in the ionic liquid layer allowing isolation of the polymer product whilst leaving the catalyst solution for potential re-use. Analysis of the PMMA (reaction 4) for residual copper by ICP, shows a copper content of 3.4×10^{-3}% (2% expected if no copper is removed).

In summary, the room temperature ionic liquid [bmim][PF_6] has been demonstrated to be an excellent solvent for Cu^{I}–*N*-propyl-2-pyridylmethanimine mediated living radical polymerisation of MMA. Reactions are relatively fast as has been observed for other polar/co-ordinating solvents. The polymer is recovered essentially copper free by a simple solvent wash. Optimisation of this process and the potential to recycle the recovered ionic liquid–catalyst mixture are currently in progress.

Notes and references

† In a typical polymerisation reaction [bmim][PF_6] (10 cm^3) and Cu^{I}Br (0.142 g, 0.990 mmol) were placed in a Schlenk tube and degassed by pumping *in vacuo* for 30 min. MMA (5.34 cm^3, 49.9 mmol) was added and the mixture freeze–pump–thawed three times. *N*-Propyl-2-pyridylmethanimine ligand (0.309 cm^3, 1.98 mmol) was added to give a brown solution and a final freeze–pump–thaw cycle carried out. The Schlenk tube was immersed in a thermostated oil bath at 30 °C. When the contents stabilised at the reaction temperature, ethyl-2-bromoisobutyrate (0.146 cm^3, 0.995 mmol) was added *via* a degassed syringe. The polymerisation was sampled at suitable time periods throughout the reaction. Polymer for SEC analysis was obtained by an extraction of the reaction mixture with toluene followed by removal of the toluene *in vacuo*. Copper content of extracted polymer was obtained by ICP analysis at Warwick.

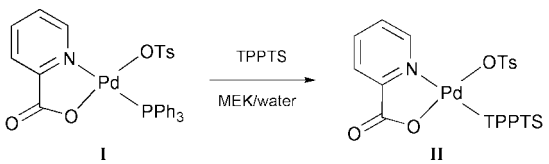
A novel water-soluble Pd complex containing pyridine carboxylate and TPPTS as ligands is a highly active catalyst for the carbonylation of vinyl aromatics under biphasic conditions and provides high regioselectivity to 2-arylpropionic acids.

Biphasic catalytic reactions using water-soluble transition metal complexes are of much current interest since they provide the unique advantages of homogeneous catalysis as well as facilitating the easy separation of the catalyst from the products.[1] While biphasic hydroformylation of olefins using water-soluble Rh catalysts has been practiced industrially,[2] the biphasic hydrocarboxylation of olefins is still at an exploratory stage, mainly due to the low catalytic activity and selectivity offered by most of the catalyst systems studied so far. An important application of hydrocarboxylation is in the synthesis of 2-arylpropionic acids, a class of non-steroidal anti-inflammatory agents, from the corresponding vinyl aromatic compounds[3] or aryl ethanols.[4] Biphasic carbonylation using *in situ* prepared $Pd(TPPTS)_3$ catalyst along with acidic promoters provided only very low catalytic activity (TOF = 1.5–50 h^{-1}) and 2-arylpropionic acid selectivity (50–70%) under mild reaction conditions of 60–120 °C and 40–60 bar.[5] A maximum regioselectivity of 90.2% was reported at higher CO pressure (140 bar), but with very low catalytic activity (TOF = 5 h^{-1}).[5a] Cationic water-soluble Pd complexes containing bidentate diphosphine 2,7-bis(SO_3Na)-Xantphos was reported recently to catalyse the hydrocarboxylation of olefins, which also provided low catalytic activity (TOF = 5 h^{-1}) and 2-arylpropionic acid (35%) selectivity.[6] Here we report for the first time a novel water-soluble Pd catalyst system for the biphasic carbonylation of vinyl aromatic compounds, which provides significantly improved turnovers and 2-arylpropionic acid regioselectivity.

Recently, we have reported a novel Pd^{II} complex containing pyridine carboxylate, PPh_3 and TsO^- ligands (**I**), which was found to be an efficient carbonylation catalyst under homogeneous conditions.[7] Here, we demonstrate that a novel water-soluble Pd catalyst prepared† by exchanging the PPh_3 ligand of complex **I** with TPPTS [tris(*m*-sulfophenyl)phosphine trisodium salt] (Scheme 1), is a highly active catalyst for the carbonylation of vinyl aromatics under biphasic conditions (Scheme 2). For instance, in the case of carbonylation of styrene, high catalytic activities (TOF) up to 550 h^{-1} (*ca.*10 times higher than the previously reported catalyst systems) were achieved with high regioselectivity to $CH_3CHPhCO_2H$ (up to 95%) at lower CO pressure (54 bar). The catalyst system $PdCl_2$–4TPPTS gave only a very low reaction rate (TOF = 34 h^{-1}) and $CH_3CHPhCO_2H$ selectivity (41%) under the present set of conditions. In a typical carbonylation experiment,‡ the aqueous catalyst, LiCl, TsOH and the substrate dissolved in toluene were charged to a stirred pressure reactor and the reaction was carried out at 54 bar of CO partial pressure at 115 °C under 1100 rpm for a specified time. The reaction mixture was analyzed by GC§ and the products were confirmed by GC-MS and NMR.

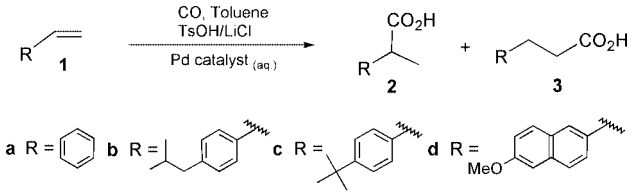


I II

Scheme 1 Synthesis of water-soluble Pd complex **II**.

An attempt was made to characterize the water-soluble Pd complex formed after the exchange of PPh_3 with TPPTS, by isolation from H_2O by precipitation using EtOHl.¶ The pale yellow complex obtained was stable in the solid state and in solution under Ar but its aqueous solution gradually decomposed to a red solution within 2–3 days on exposure to air. IR of the isolated complex showed C=O stretching vibrations at 1636 cm^{-1} and Pd–N vibrations at 524 cm^{-1}. ^{31}P NMR in D_2O showed a strong signal at 35.31 ppm and a weak signal at 36.13 ppm, which may be due to the *trans* (N *trans* to TPPTS) and *cis* (N *cis* to TPPTS) isomers respectively. ^1H NMR and elemental analysis were consistent with the structure of **II** given in Scheme 1.‖

The typical results of carbonylation of styrene are presented in Table 1. The best catalytic activity and selectivity was achieved with 2 equiv. of TPPTS to Pd, unlike the classical $PdCl_2$–TPPTS system where 4–6 equiv. TPPTS to Pd were required to obtain the highest catalytic activity. Further increase in TPPTS concentration lowered the catalytic activity as well as the $CH_3CHPhCO_2H$ selectivity significantly.



Scheme 2 Carbonylation of vinyl aromatics to 2-arylpropionic acids.

Table 1 Biphasic carbonylation of vinyl aromatics using the novel water-soluble Pd catalyst[a]

[a] *Conditions:* Pd (0.0629 mmol), TPPTS/Pd = 3, substrate (28.8 mmol), TsOH (11.2 mmol), LiCl (11.2 mmol), H_2O (6 ml), toluene (15.5 ml), P_{CO} (54 bar), *T* (388 K). [b] Traces of bis(α-methylbenzyl) ether was also detected. [c] TPPTS/Pd = 2. [d] TPPTS/Pd = 6. [e] Substrate (9.62 mmol). [f] Substrate (57.7 mmol). [g] Catalyst = $PdCl_2$–4TPPTS. [h] HCl instead of TsOH–LiCl. [i] In the absence of LiCl. [j] Substrate (16.67 mmol).

DOI: 10.1039/b002940o

Reaction rates were highly dependent on substrate concentration as well as promoters. The TOF increased steadily with styrene concentration of up to 32% (57.7 mmol), presumably due to the increase in concentration of styrene in the aqueous catalytic phase in equilibrium with organic phase. The concentration of promoters (TsOH–LiCl) also showed a significant effect on the reaction rates; at lower concentrations the TOF and yields being extremely low. In the absence of LiCl the catalytic activity and selectivity decreased considerably (see run 8, Table 1), suggesting a possible role of LiCl in the formation of phenylethyl chloride as the active carbonylation substrate. The formation of phenylethyl chloride was also confirmed by the analysis of intermediate organic phase samples. In addition, a small amount of phenylethyl alcohol was also detected in the intermediate samples, which may form by the acid catalyzed reversible hydration of the olefin. However, in the final reaction mixture only negligible amounts of the alcohol were detected.

Substituted vinyl aromatic compounds such as 4-isobutylstyrene (TOF = 147 h^{-1}), and 4-*tert*-butylstyrene (TOF = 273 h^{-1}) also gave good reaction rates though comparatively lower than that of styrene. 4-Isobutylstyrene gave high Ibuprofen selectivity of 98% while 6-methoxy-2-vinylnaphthalene gave 93% selectivity to Naproxen under these conditions (TOF = 10 h^{-1}). Since secondary arylethanols can be dehydrated to vinyl aromatic compounds under acidic reaction conditions, carbonylation of 1-(4-isobutylphenyl)ethanol (*p*-IBPE)[8] (**4b**) was also studied. TOF up to 18 h^{-1} was achieved with an Ibuprofen selectivity of 98%. Such a lower rate is expected considering the sluggish dehydration of IBPE to 4-isobutylstyrene under biphasic conditions.

In order to check whether the catalyst was reusable after the reaction, a few recycle experiments were carried out after phase separation. The recycle of catalyst after a reaction at 115 °C showed only very low catalytic activity (TOF = 25 h^{-1}). However, recycle experiments under lower temperatures (100–105 °C) showed only negligible loss in catalytic activity. In all these cases analysis of Pd content in the organic phase after a reaction showed only < 0.05–0.1 ppm of Pd indicating negligible leaching of Pd to the organic phase. The catalyst was efficiently reusable even at 115 °C when fresh styrene was added to the reaction mixture under CO atmosphere. The analysis of the organic layer for Pd content after two such recycles also showed only < 0.1 ppm of Pd. These observations indicate that the catalyst is stable during an experiment and efficient recycle of the catalyst can be carried out under CO. High conversions (91%) achieved even at higher substrate concentrations (32%, see run 5, Table 1) also support this argument. Traces of colloidal Pd formation were observed under certain conditions mainly at higher temperatures (> 115 °C). Since the reaction is passing through the Cl derivative as the active carbonylation substrate, either of the two catalytic cycles involving Pd^0/Pd^{II} or Pd^{II}/Pd^{IV} seems to be possible. However, further studies on the nature of catalytic species under reaction conditions are essential to understand the actual reaction mechanism, which are currently in progress at our laboratory.

In conclusion, we have demonstrated a novel water-soluble Pd catalyst system, which is highly active for the regioselective carbonylation of vinyl aromatics to 2-arylpropionic acids under biphasic conditions and provides significant improvement over the current state of art for the biphasic carbonylation of vinyl aromatics.

Notes and references

† **I** was dissolved in methyl ethyl ketone (MEK) (10 ml) and shaken vigorously with 2 or 3 equiv. of TPPTS in H_2O (6 ml). The yellow colour of the MEK layer disappears and the aqueous layer becomes yellow indicating the formation of **II** in water. For carbonylation reactions the aqueous layer was used after washing with pure MEK a few times (traces of MEK remain in the aqueous layer). All the solvents were degassed with Ar before use.

‡ The carbonylation reactions were carried out in a Parr Hastelloy C autoclave (50 ml). In a typical reaction, the substrate (28.8 mmol), catalyst (0.0629 mmol) (prepared as above) in 6 ml degassed water, LiCl–TsOH (11.2 mmol) and toluene (15.5 ml) (degassed) were charged to the autoclave. The contents were flushed a few times with N_2 followed by CO and heated to the desired temperature (115 °C). The autoclave was then pressurized with CO (54 bar) and the reaction was started by agitation (1100 rpm) and was continued for the specified time. TOF = Turnover Frequency = number of moles of carbonylation product formed per mole of Pd per hour.

§ The analysis of the liquid samples was carried out using a gas chromatograph (HP 5890) using a HP-FFAP capillary column.

¶ A yellow fine powder was precipitated as a suspension, which was allowed to settle, and the supernatant solution decanted. The precipitate was washed many times with EtOH and then with Et_2O and dried under vacuum. All the solvents used were degassed with Ar prior to use.

Photolysis of H_2Te in CO or 1% CO/Ar matrices at *ca.* 10 K results in the formation of carbonyl telluride; the assignment of the ν_{CO} modes of OCTe (1965.3 cm^{-1}), O^{13}CTe (1920.0 cm^{-1}) and ^{18}OCTe (1921.3 cm^{-1}) in neat CO matrices is confirmed by DFT calculations.

Carbonyl telluride (OCTe) is the only member of the carbonyl chalcogenides (apart from carbonyl polonide) that has not been spectroscopically identified or characterised, either in the solid, vapour or in cryogenic matrices. Reference to it in the chemical literature is very fleeting, including the first report of its preparation in 1944 which contained no experimental or characterisation details, but which did indicate that it was less stable than the analogous carbonyl selenide.[1] In 1993 Sonoda[2] reported that carbonyl telluride had not yet been identified, and we cannot find any subsequent reports. There are however, a couple of earlier papers containing predictions of its vibrational modes,[3] and calculations of its proton affinity and structural parameters.[4] As carbonyl selenide has been identified as the catalytic intermediate in the selenium assisted carbonylation of amines,[2] and it is also known that tellurium catalyses this reaction[5] we have initiated a study of the interaction of tellurium atoms with carbon monoxide to spectroscopically identify and characterise carbonyl telluride so that its presence in tellurium mediated organic transformations can be identified. One of the most common ways of stabilising reactive species is matrix isolation, but there is a distinct paucity of tellurium atom cryochemistry because the predominant vapour phase species above heated elemental tellurium are dimers, tetramers, *etc.*, and even when the vapour is superheated, the fraction of tellurium atoms remains low.[6] In this work we report the photolysis of H_2Te as an alternative source of tellurium atoms, and whilst this has been used previously to obtain tellurium atoms in argon matrices for Mössbauer experiments,[7] it has not been exploited as a cryochemical synthetic tool. In addition to being a source of atomic tellurium, Donovan *et al.*[8] have shown that when H_2Te is photolysed by UV light, some of the resultant Te atoms are in a $^1D_2$ excited state rather than the $^3P_2$ ground state expected from thermal evaporation, and this may result in lower activation barriers for subsequent reactions.

When H_2Te was matrix isolated in solid N_2 and photolysed with UV radiation,[9] the intensities of the three IR active bands at 2085.2 cm^{-1} (ν_1), 865.1 cm^{-1}(ν_2) and 2092.0 cm^{-1} (ν_3), (in good agreement with the previous high resolution[10] and nitrogen matrix[11] IR data) were reduced considerably, with no sign of the growth of any other bands. We have noted that this photobleaching is much more efficient using UV rather than visible irradiation, and that photolysis during deposition also increased the photobleaching of the H_2Te bands. In a neat CO ($^{12}C^{16}O$) matrix, the H_2Te stretching modes were obscured by the bands due to the various CO isotopomers. On UV photolysis in neat CO the ν_2 mode of H_2Te at 863.0 cm^{-1} decreased, and a new band (in the ν_{CO} region associated with carbonyl complexes) grew in at 1965.3 cm^{-1}, as well as features[12] due to HCO (*ca.* 1860 cm^{-1}) and H_2CO (*ca.* 1740 cm^{-1}) [Fig. 1(a)]. When ^{13}CO was used [Fig. 1(b)] the 1965.3 cm^{-1} band shifted to 1920.0 cm^{-1} and the use of ^{12}CO:^{13}CO ($\approx$1:1) mixed matrices [Fig. 1(c)] confirmed the presence of only one CO group in the moiety giving rise to these bands. With the use of $C^{18}O$ [Fig. 1(d)], the shift from a CO (1965.3 cm^{-1}) to a $C^{18}O$ matrix (1921.3 cm^{-1}) was less than that for a ^{13}CO matrix (1920.0 cm^{-1}). When H_2Te was trapped in a 1% CO/Ar matrix, the only band observed after photolysis in the 2000–1680 cm^{-1} region was at 1970.7 cm^{-1}, which is the counterpart of the 1965.3 cm^{-1} feature in the neat CO matrices, with no evidence of any HCO or H_2CO. When D_2Te was isolated and photolysed in a 1% CO/Ar matrix, the band at 1970.7 cm^{-1} was also present with no sign of any deuterated analogue, and photolysis of H_2Te in 1% ^{13}CO/Ar yielded a new feature at 1924.7 cm^{-1}.

The presence of HCO and H_2CO in the neat CO matrices confirms that the photolysis of H_2Te yields hydrogen and tellurium. The assignment of the features at 1965.3, 1920.0 and 1921.3 cm^{-1} in neat CO matrices to the ν_{CO} modes of the isotopomers of a monocarbonyl species is straightforward on the basis of the mixed CO:^{13}CO experiments, and the fact that in 1% CO/Ar matrices the 1970.7 cm^{-1} band is not affected by deuteration confirms the lack of hydrogen in the species giving rise to these features. As OCS is one of the products formed when H_2S is photolysed in solid CO,[12] it is reasonable to assign the features at 1965.3, 1920.0 and 1921.3 cm^{-1} to the ν_{CO} modes of OCTe, O^{13}CTe and ^{18}OCTe, respectively. The lack of bands other than these in the 1% CO/Ar matrices confirms this assignment as it has been noted previously that HCO is only observed in dilute CO/Ar matrices when vac-UV photolysis rather than UV–VIS photolysis is employed.[13] The isotopic ratios, in conjunction with the experimental data for the ν_{CO} modes of OCSe (OC^{80}Se, 2023.525064 cm^{-1}; O^{13}C^{80}Se,

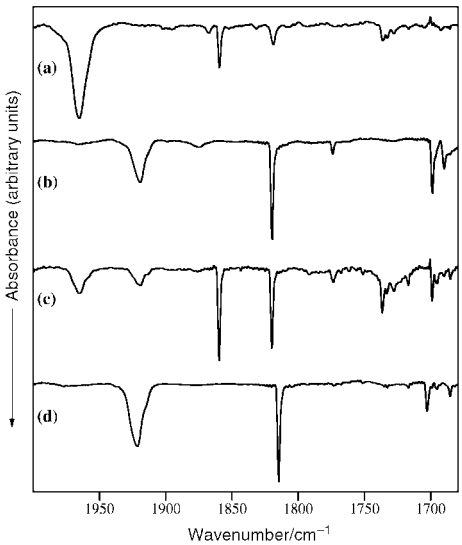

Fig. 1 Matrix isolation IR spectra of the photolysis products of H_2Te in neat CO matrices at *ca.* 10 K: (a) $^{12}C^{16}O$ (CO); (b) ^{13}CO; (c) CO:^{13}CO (~1:1); (d) $C^{18}O$.

1973.82425 cm^{-1}; ^{18}OC^{80}Se, 1983.54657 cm^{-1})[14] and our DFT calculated[15] frequencies of the ν_{CO} modes of OCTe (OCTe, 1981 cm^{-1}; O^{13}CTe, 1933 cm^{-1}; ^{18}OCTe, 1939 cm^{-1}), all reinforce the conclusion that these bands are the ν_{CO} modes of carbonyl telluride. The DFT calculations also indicated that the intensity of the ν_{CTe} and δ_{OCTe} modes would be too low to be observed in the experimental spectra.[16]

Our previous DFT calculations[17] have shown that the bonding between a main group metal and CO can be described in an analogous way to the synergic mechanism used for conventional transition metal carbonyls. In the case of OCTe the DFT calculations predict that the Te σ-accepts *ca.* 0.6 e$^-$ and π-backdonates *ca.* 0.7 e$^-$ to CO, resulting in a lengthening of the CO bond and a reduction of the CO bond order and ν_{CO} frequency. The Te–CO bond energy for OCTe with respect to Te(^{3}P) and CO($^1\Sigma^+$) was calculated to be −187 kJ mol^{-1}, and OCTe was favoured over the COTe isomer by 152 kJ mol^{-1} with markedly different values for ν_{CO} of 1981 and 1835 cm^{-1}, respectively. The linear dicarbonyl telluride [$(OC)_2Te$] was found to be 36 kJ mol^{-1} less stable than OCTe, and $(OC)_3Te$ was unstable with respect to decomposition.

Therefore, using the first spectroscopic identification and characterisation of carbonyl telluride, this work has demonstrated that the photolysis of hydrogen telluride is an excellent source of both hydrogen and tellurium atoms for use in cryochemical synthesis. The identification of the ν_{CO} modes of OCTe will be useful in identifying whether this is an intermediate in organic transformations.

We gratefully acknowledge the support of The University of Hull and the EPSRC for an award of a studentship (NH) and for equipment (GR/H 29117, GR/K 17514).

9 The H_2Te (D_2Te) was prepared by the addition of H_2O (D_2O) to powdered Al_2Te_3 (Strem) and was flushed out of the reaction vessel by N_2, through an ice-salt trap to remove residual moisture before condensation at 77 K and purification by vacuum sublimation and storage at either 77 or 195 K. During the matrix isolation experiments the H_2Te was kept at 147 K (methylcyclohexane slush) and the vapour condensed in an excess of matrix gas for *ca.* 1 h on a CsI plate maintained at *ca.* 10 K by an APD Cryogenic DE204SL Displex cryostat. IR spectra were acquired using a Bruker IFS66 FTIR spectrometer with a KBr beamsplitter and DTGS detector operating at 1 cm^{-1} resolution. The photolysis utilised an Oriel 200 W Hg–Xe lamp. The matrix gases were supplied and used as received from Distillers MG (N_2, 99.999%; CO, 99.997%), Cambridge Isotope Laboratories (^{13}CO, 99%) and Euroisotop (C^{18}O, 99%).

15 DFT calculations were carried out as described in ref. 17 using the DeFT code.[18] The detailed DFT calculation output is available as ESI.†
16 In addition to the bands assigned to OCTe, HCO and H_2CO in the neat CO matrices, there was a variable intensity band at 1819 cm^{-1} that shifted to 1774 cm^{-1} in ^{13}CO. In C^{18}O matrices, the band was of very very low intensity at 1773 cm^{-1}. In the 1% CO/Ar matrices these bands were absent. The isotopic behaviour in mixed CO:^{13}CO matrices was characteristic of a monocarbonyl species and the isotopic ratios are very similar to those of HCO, but different to both the observed and calculated isotopic shifts of OCTe. Therefore, we believe that these features are due to interaction between the formyl radicals and adventitious impurities in the matrix, for example, previous workers[19] have assigned bands at *ca.* 1820 cm^{-1} in neat O_2 matrices to the formylperoxy radical [HC(O)OO].

One-step synthesis of size tuned zinc selenide quantum dots *via* a temperature controlled molecular precursor approach

Young-wook Jun, Ja-Eung Koo and Jinwoo Cheon*

Department of Chemistry and School of Molecular Science – BK21, Korea Advanced Institute of Science and Technology (KAIST), Taejon 305-701, Korea. E-mail: jcheon@kaist.ac.kr

Received (in Cambridge, UK) 13th April 2000, Accepted 30th May 2000
Published on the Web 20th June 2000

One-step size-controlled synthesis of ZnSe quantum dots is studied and the obtained QDs are luminescent with the emission wavelength varying over a wide range (up to 100 nm) depending on the particle size; the single-molecular precursor is an air-stable bis(phenylselenolato)zinc *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) complex, which effectively affords different sizes of ZnSe QDs depending on growth temperatures.

Nanomaterials are of great interest owing to the novel optical, electronic and catalytic properties that arise from the quantum size effects and large surface areas that are characteristic of these species. In particular, quantum dots (QDs) of semiconducting materials have received special attention because their electronic band gaps can be tuned, thus varying their optical response from the IR to the UV depending on the size of the dots.[1–5] The tunability of the band gap makes QDs useful for many applications such as light emitting diodes[5] and as ultrasmall luminescent tags for biological studies.[6]

Bulk materials that absorb or emit in the blue to near-UV regions of the electromagnetic spectrum are being extensively studied owing to their potential uses in optical sensors and lasers.[7,8] The best known bulk semiconductors with band gaps in this region are GaN (E_{gap} = 3.4 eV) and ZnSe (E_{gap} = *ca.* 2.7 eV). Synthetic studies on QDs of these two materials with decent electronic band tunings, however, have been very limited.[9,10] For isolated colloidal ZnSe QDs, the use of a diselenocarbamate single-source precursor and a dual source precursor system are two successful demonstrations.[10]

One of the important current issues of nanomaterials research is the controlled synthesis of QDs. In many cases, however, successful nanostructured materials syntheses[1,11] with desired size and shape criteria, require multi-step processes and thus developing a simple and controlled method of synthesizing QDs is of particular interest.

Here we present a one-step synthesis of ZnSe QDs the sizes of which can be precisely tuned by simple temperature control. We demonstrate that these are luminescent in the blue region and that the emission wavelength varies over a very wide range (up to 100 nm) depending on the particle size. The key to this synthesis is the proper choice of a molecular precursor which has good solubility, adequate thermal stability, and simple ligand elimination processes that produce desired materials. Notably, our obtained QDs have a high monodispersity without size selective precipitation.

The compound bis(phenylselenolato)zinc, $Zn(SePh)_2$,[12] is polymeric and poorly soluble in organic solvents, and is thus not particularly convenient as a precursor for the synthesis of QDs. We observe, however, that the polymer reacts with *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) to form a soluble, air-stable, monomeric adduct of stoichiometry $Zn(SePh)_2$-(TMEDA) (Fig. 1).[13–15] As similarly observed by Yamamoto and Steigerwald in related work on alkyl- or phenyl-chalcogenolate ligand systems, this ligand is more thermally stable than other bulky selenolate ligands such as $SeSi(SiMe_3)_3$, and thermolysis of its complexes produces clean QDs with reduced contamination caused by undesired ligand fragmentation processes.[16]

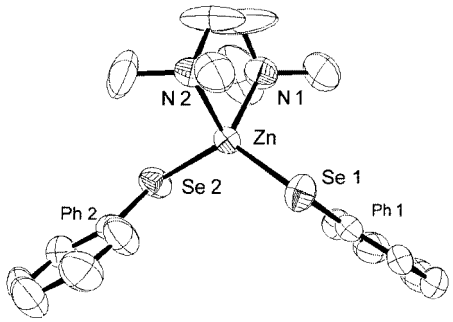

Fig. 1 ORTEP drawing of $Zn(SePh)_2$(TMEDA). Selected bond distances (Å) and angles (°): Se(1)–Zn(1) 2.398(2), Se(2)–Zn(1) 2.399(2), Zn(1)–N(1) 2.120(9), Zn(1)–N(2) 2.147(9); Se(1)–Zn–Se(2) 125.54(6), N(1)–Zn(1)–N(2) 86.3(3).

One-step size controlled synthesis of QDs was carried out by the thermolysis of $Zn(SePh)_2$(TMEDA) (eqn. 1).[17,18]

$$[Zn(SePh)_2][TMEDA] \xrightarrow{heat} ZnSe + TMEDA + Ph_2Se \quad (1)$$

In a typical QD synthesis, $Zn(SePh)_2$(TMEDA) (0.5 g, 0.101 mmol) was dissolved in trioctylphosphine (10 ml) and the resulting solution injected into hot trioctylphosphine oxide (3.92 g, 10.1 mmol). The latter solution is kept at one of four different temperatures: 320, 340, 367 or 385 °C. After 1 h, the resulting yellow solution was cooled to 80 °C and treated with an excess of methanol to generate a yellow flocculate, which is separated by centrifugation and washed with methanol. The resulting pale yellow powder was readily redispersed in toluene. No further size selection is carried out.

The QDs obtained are highly monodispersed with sizes that depend on the growth temperature. Relative to the position of the 460 nm (2.7 eV) absorption band edge for bulk ZnSe, the absorption band edges of the ZnSe QDs are blue-shifted. Larger shifts are seen for higher growth temperatures. Thus, the absorption band shifts are 0.95, 0.37, 0.29 and 0.17 eV for QDs grown at 385, 367, 340 and 320 °C, respectively. Similar blue shifts are also observed in the photoluminescence spectra: the band maxima are 387 (3.20 eV), 429 (2.89 eV), 443 (2.80 eV) and 451 nm (2.75 eV) for samples grown at 385, 367, 340 and 320 °C, respectively (Fig. 2). These results show that smaller quantum dots are obtained at higher growth temperatures where more nucleation sites are present and relatively less ZnSe material is available for each nucleus during growth kinetics. High resolution transmission electron micrographs show that the ZnSe QDs are roughly spherical and that the particles within a single sample have relatively uniform sizes (Fig. 3). The average sizes of the ZnSe QDs are 2.7 ± 0.2, 4.0 ± 0.35 nm, 4.4 ± 0.35 and 4.9 ± 0.29 nm for samples grown at 385, 367, 340, 320 °C, respectively (Fig. 2C). The ZnSe particles are in the cubic phase, as determined by X-ray diffraction and selected area electron diffraction.[18] Energy dispersive X-ray emission analysis of the QDs confirms that the particles have a 1 : 1 Zn : Se stoichiometry.

The results above demonstrate that monodispersed ZnSe QDs can be prepared by means of a simple and convenient one-pot

synthesis from an air-stable monomeric molecular precursor. The growth of QDs follows a simple ligand elimination reaction and by varying the growth temperature it is possible to control their size. The results constitute a good demonstration of controlling the size of semiconductor QDs with band gaps in the blue region of the electromagnetic spectrum. We believe that this strategy can be extended to facile size controlled synthesis of QDs of other materials that, at present, are difficult or complicated to prepare.

12 $Zn(SePh)_2$ was prepared according to a modification of literature procedure (M. Bochmann, G. Bwembya and K. J. Webb, *Inorg. Synth.*, 1997, **31,** 19). Selenophenol (2.14 g, 13.54 mmol) was slowly added to $Zn[N(SiMe_3)_2]_2$ (2.61 g, 6.76 mmol) in toluene (50 ml) for 30 min. A white precipitate began to form and the mixture was stirred at room temp. for 12 h, after which heptane (10 ml) was added. The precipitate was collected by filtration, washed with heptane (5 ml), and dried *in vacuo*, to give a white powder (2.32 g, 90%).
13 TMEDA (1.07 g, 9.17 mmol) was added to a suspension of $Zn(SePh)_2$ (1.81 g, 6.11 mmol) in toluene (50 ml). The mixture was stirred for 24 h to give a pale yellow solution, which was filtered, treated with pyridine (5 ml) and heptane (30 ml), and cooled to −24 °C to give colorless crystals (1.765 g, 59%), mp 137–138 °C. Anal. Calc. for $C_{18}H_{26}N_2Se_2Zn$: C, 43.8; H, 5.27; N, 5.67. Found: C, 43.1; H, 5.34; N, 5.37%. $\delta_H(CDCl_3$, 25 °C): 7.90 (t, 2H, J_{HH} 7 Hz, *o*-CH), 6.86 (*m*, 3H, *m*-CH and *p*-CH), 2.67 (s, 2H, NCH_2), 2.48 (s, 6H, NMe_2).
14 An X-ray crystallographic study of $Zn(SePh)_2$(TMEDA) (Fig. 1) shows that the zinc center adopts a distorted tetrahedral geometry with a large Se–Zn–Se angle of 125.55° and a small N–Zn–N angle of 86.33°. The Zn–Se and Zn–N bond lengths are 2.398 and 2.134 Å, respectively. The bond lengths and angles are similar to those seen for other zinc complexes with organochalcogen and amine ligands.[15] *Crystal data*: $C_{22}H_{16}N_2Se_2Zn$, M_r = 531.69, monoclinic, space group $P2_1/c$, a = 11.202(2), b = 12.7326(14), c = 15.125(3) Å, β = 107.050(18)°, U = 2062.5(6) Å^3, Z = 4, D_c = 1.340 g cm^{-3}, $F(000)$ = 1040, μ(Mo-Kα) = 47.2 cm^{-1}, R_1 = 0.0623, wR_2 = 0.1634. Palladium(II)-supported hydrotalcite as a catalyst for selective oxidation of alcohols using molecular oxygen

Takahiro Nishimura, Nobuyuki Kakiuchi, Masashi Inoue and Sakae Uemura*

Department of Energy and Hydrocarbon Chemistry, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan. E-mail: uemura@scl.kyoto-u.ac.jp

Received (in Cambridge, UK) 28th March 2000, Accepted 30th May 2000
Published on the Web 20th June 2000

Palladium(II)-supported hydrotalcite acts as a reusable catalyst for the oxidation of alcohols to aldehydes and ketones in the presence of pyridine under atmospheric pressure of oxygen.

Heterogeneous catalysts are currently receiving considerable attention from the standpoint of environmental and economical concerns because of their unique properties such as easy handling, simple separation and reusability.[1] Hydrotalcite [$Mg_6Al_2(OH)_{16}CO_3{\cdot}4H_2O$] is a naturally produced basic clay mineral which has a layered structure consisting of positively charged brucite-like layers and negatively charged counter ions located in the interlayers.[2] It has been used as a solid base catalyst in several reactions[3] and also some modified hydrotalcites have been prepared and used for aerobic oxidation of alcohols.[4] The utility of hydrotalcite as a support for transition metals has also been investigated[5] and further elaboration of its use in organic synthesis is awaited.

Recently we have reported the palladium-catalysed oxidation of alcohols to aldehydes and ketones using a catalytic amount of $Pd(OAc)_2$, pyridine and 3 Å molecular seives (MS3A) under atmospheric pressure of oxygen.[6] In order to construct a high-performance catalytic system, we have attempted heterogenization of this system to produce a reusable and efficient solid catalyst. Among several clay supports examined, we found that hydrotalcite was an effective support for Pd(II) in the oxidation of alcohols. We report here, the synthesis of a new heterogeneous catalyst, a palladium(II) salt supported hydrotalcite [Pd(II)-hydrotalcite] from commercially available reagents, and its application as a catalyst for aerobic oxidation of alcohols under oxygen.[7]

Pd(II)-hydrotalcite† (1.56 mmol g^{-1} Pd) was prepared by mixing $Pd(OAc)_2$, pyridine and hydrotalcite in toluene at 80 °C for 1 h, followed by filtration, washing and drying under reduced pressure at room temperature.[8] A residue was scarcely observed in the filtrate after removing solvents under reduced pressure, showing that virtually all of the $Pd(OAc)_2$ initially employed was adsorbed on hydrotalcite. The basal spacing (d_{003}) of the commercially available hydrotalcite was 7.8 Å as estimated by a sharp peak obtained from X-ray diffraction (XRD) analysis, while that of the prepared Pd(II)-hydrotalcite was essentially the same with no differences of peak pattern between hydrotalcite and Pd(II)-hydrotalcite being observed. This result suggests that the palladium salt is immobilised on the surface of hydrotalcite.[9]

Initially the catalytic oxidation of benzyl alcohol **1a** using Pd(II)-hydrotalcite‡ was performed (Scheme 1), and typical results are listed in Table 1. The oxidation of benzyl alcohol **1a** (1 mmol) in toluene at 80 °C for 2 h in the presence of 5 mol% Pd(II)-hydrotalcite (0.05 mmol Pd) under O_2 afforded benzaldehyde **2a** in 62% yield (Table 1, entry 1). By further addition of pyridine (0.2 mmol) in the reaction media, efficient oxidation proceeded to give a quantitative yield of **2a** (entry 2). The amount of the catalyst could be reduced to 1 mol%, although a longer reaction time was required to achieve the complete conversion of **1a** (entries 3 and 4). Other benzylic alcohols (**1b** and **1c**) were also smoothly oxidized to the corresponding aldehydes in high yields (entries 5 and 6). Non-activated primary and secondary aliphatic alcohols **3a–c** were easily transferred to the corresponding aldehydes and ketones in high yields (entries 7–9). In the latter case, however, the reaction was slower and an excess of pyridine (1.0 mmol) was required (entries 8 and 9). The reactions of alkenic alcohols using Pd(II)-hydrotalcite or $Pd(OAc)_2$/pyridine/MS3A (homogeneous catalytic system; abbreviated as MS-system)[6] were then carried out and compared, the results of which are summarized in Table 2. In the oxidation of geraniol **5** and nerol **7**, the presence of an excess of pyridine was required (entries 1–3). When the reaction of **5** was carried out using the MS-system, the yield of the corresponding aldehyde **6** was low (56%) even after long

[a] *Reaction conditions*: alcohol (1.0 mmol), pyridine (5.0 mmol), O_2, 80 °C. [b] Pd(II)-hydrotalcite (1.56 mmol g^{-1} Pd; 300 mg, 0.05 mmol Pd). [c] $Pd(OAc)_2$ (0.05 mmol), MS3A (500 mg). [d] The value in parentheses is the conversion of alcohol (%). *E*:*Z* ratio determined by ^{1}H NMR. [e] Pyridine (0.2 mmol) used.

reaction times and the *E*:*Z* ratio was seriously disturbed (*E*:*Z* = 63:37), while the Pd(II)-hydrotalcite catalysed reaction smoothly proceeded to give **6** in 91% isolated yield without geometrical isomerization (*E*:*Z* = 96:4, entry 2). Similarly, aldehyde **8** was obtained highly selectively from **7** in high yield using Pd(II)-hydrotalcite (89%, *E*:*Z* = 6:94), while both product yield and selectivity were low using the MS-system (entry 3).[10] Although the reason for this high catalytic activity and selectivity arising from immobilisation of a palladium(II) salt on hydrotalcite is not yet clear,[10] this catalyst is shown to be especially effective for the oxidation of unsaturated alcohols.

The catalyst could be easily separated from the reaction mixture by simple filtration and recycled. For example, Pd(II)-hydrotalcite could be recycled at least three times in the oxidation of benzyl alcohol **1a** although the catalytic activity decreased with the third use (1st: 98%, 2nd: 93%, 3rd: 77%).

In summary, we have demonstrated that a novel Pd(II)-supported hydrotalcite worked as an efficient catalyst for the oxidation of alcohols under oxygen. Especially, in the oxidation of geometrically isomerizable allylic alcohols such as geraniol and nerol, the corresponding aldehydes were obtained in high yield without any isomerization. The catalyst can be easily separated and recycled. Further characterization of this catalyst and application to other reactions are now in progress.

We gratefully thank Kyowa Chemical Ind., Ltd. for the gift of hydrotalcite [$Mg_6Al_2(OH)_{16}CO_3{\cdot}4H_2O$, brand name ALCAMAC < L > ®]. T. N. gratefully thanks a Fellowship of the Japan Society for the Promotion of Science for Young Scientists.

Notes and references

† *Procedure for the preparation of Pd(II)-hydrotalcite*: to a mixture of $Pd(OAc)_2$ (375 mg, 1.67 mmol) and toluene (100 mL) in a 200 mL two-necked flask was added pyridine (331 mg, 4.18 mmol) at 80 °C during which the brown suspension turned yellowish white. Then, hydrotalcite (ALCAMAC < L > ®, 10.0 g) was added and the mixture was stirred vigorously for 1 h at 80 °C. The obtained slurry was cooled to 0 °C, followed by filtration and washing with diethyl ether (20 mL × 2). The resulting solid was dried *in vacuo* at room temp. to give a yellowish white powder of Pd(II)-hydrotalcite. Elemental analysis; found: N, 0.35% [calc. N, 0.44% assuming that $Pd(OAc)_2{\cdot}2C_5H_5N$ formed *in situ* was completely adsorbed].

‡ *Procedure for Pd(II)-hydrotalcite catalysed oxidation of alcohols using molecular oxygen*: to a suspension of Pd(II)-hydrotalcite (300 mg, 0.05 mmol Pd) in toluene (6 mL) in a 20 mL two-necked flask was added pyridine (0.2–5.0 mmol) and the resulting mixture was stirred. Oxygen was then introduced into the flask from an O_2 balloon under atmospheric pressure and the mixture was heated to 80 °C for *ca.* 10 min with stirring. Then, an alcohol (1.0 mmol) in toluene (4 mL) was added and the mixture was stirred vigorously for 2 h (or appropriate time) at 80 °C under oxygen. After the reaction the catalyst was separated by filtration through a glass filter. Removal of the solvent from the filtrate under reduced pressure left an oily residue which was subjected to column chromatography (Merck silica gel 60; hexane–diethyl ether as eluent) to give the product.

8 The $Pd(OAc)_2(py)_2$ complex is formed by the reaction of $Pd(OAc)_2$ with pyridine, see: S. V. Kravtsova, I. P. Romm, A. I. Stash and V. K. Belsky, *Acta Crystallogr., Sect. C*, 1996, **52**, 2201; T. A. Stephenson, S. M. Morehouse, A. R. Powell, J. P. Heffer and G. Wilkinson, *J. Chem. Soc.*, 1965, 3632.
9 The presence of pyridine in Pd(II)-hydrotalcite was detected by TG/MS analysis, while desorption of pyridine was not observed from hydrotalcite which was treated with pyridine in toluene and washed by the same procedure as in the preparation of Pd(II)-hydrotalcite. We postulate that the Pd(II)-pyridine complex was adsorbed on the surface (not between layers) by ionic bonding between the Pd(II)-pyridine complex and hydroxy groups on the surface of the hydrotalcite.
10 Low catalytic activity of the MS-system might be due to strong complexation of palladium by the olefin. In Pd(II)-hydrotalcite, however, such complexation may be inhibited because of the steric bulk of hydrotalcite surface and this may be a reason for very low geometric isomerizations observed with the Pd(II)-hydrotalcite system.

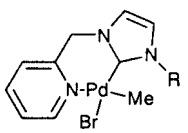
Received (in Basel, Switzerland) 28th March 2000, Accepted 26th May 2000
Published on the Web 20th June 2000

The pyridine functionalised N-heterocyclic carbene complexes (C–N)PdMeBr, C–N = 3-R-1-(2-picolyl)imidazolin-2-ylidene, (R = Bu^t 1a, R = mes 1b, mes = mesityl) are described; they are excellent catalysts for the Heck arylation; 1b is monomeric with a chelating C–N ligand; the product obtained by interaction of 1a with AgO_2CCF_3 shows a $[Pd(C–N)]_4$ framework with bridging C–N ligands.

N-heterocyclic carbenes have recently emerged as a new family of ligands with electronic characteristics similar to those of the phosphines.[1] The great interest in their complexes with transition metals has been stimulated by the realisation that they can act as catalysts or catalyst precursors to important transformations, such as Pd-catalysed Heck and Suzuki couplings, CO–ethylene copolymerisations, Ru-catalysed olefin metathesis and Rh catalysed hydrosilylations.[2] Furthermore, electronic and steric optimisation of the catalytic site should be achievable *via* ligand design. Recent reports on the synthesis of functionalised hemilabile N-heterocyclic carbene complexes[3,4] and their use as catalyst precursors prompted us to communicate our results describing the full characterisation of three novel pyridine functionalised N-heterocyclic carbene complexes of palladium, including two crystal structures and preliminary studies on their catalytic activities in Heck coupling and amination reactions.

The complexes (C–N)PdMeBr, C–N = 3-R-1-(2-picolyl)-imidazolin-2-ylidene, (R = Bu^t **1a**, R = mes **1b**, Scheme 1) were prepared in good yields by careful deprotonation at low temperatures of 3-R-1-(2-picolyl)imidazolium bromide, [H(C–N)] Br, (R = Bu^t, mes), with $LiNPr^i_2$ in THF, followed by trapping of the *in situ* formed carbene with (cod)PdMeBr. Complexes **1a**,**b** are air-stable solids and **1b** can be crystallised from CH_2Cl_2 by slow evaporation.† The structure of **1b** was determined by X-ray crystallography and is shown in Fig. 1.‡ The chelating ligand is coordinated to the square planar palladium centre with the carbene end disposed *trans* to the bromide. The carbene plane forms an angle of 64.2° with the square plane of the palladium. The resulting six-membered ring is puckered to release conformational strain.



R=Bu^t, **1a**; R=mes, **1b**

Scheme 1

Abstraction of the halide from **1a** by $Ag(O_2CCF_3)$ in acetonitrile results in isolation of complex **2**† the structure of which is shown in Fig. 2.‡ In this case the C–N ligand is bridging with carbene and pyridine ends occupying mutually *trans* positions. The four Pd atoms occupy the corners of a distorted tetrahedron and the ligands bridge four of the six sides in a way which leaves two opposite sites free.

Compounds analogous to **1** (R = Me) have recently been reported by McGuinness and Cavell,[4] however, they could not obtain crystallographic data. In the absence of such data for comparison, we note with interest that there are several other aspects of their paper, which point towards important differences between their complexes and the ones reported herein. Mention is made of the unselective reaction of bases with the precursor imidazolium salts, which precludes the use of the simple synthetic technique employed by us to synthesise the palladium complexes. They also note that their complexes once formed are unstable towards strong bases,which limits their use in amination catalysis. Both problems are believed to arise from

undesired deprotonation of the methylene protons linking the carbene to the heterocyclic donor, or even the methyl substituent of the carbene. We believe these initial observations may presage structure–property relationships in similar catalysts.

Complexes **1a** and **1b** are excellent precatalysts for the Heck coupling and show good activity for amination reactions (see Table 1). The activity of **1a** does not seem to decrease with time, implying high thermal stability under the reaction conditions. It is highest in *N*-methylpyrrolidone and *N*,*N*′-dimethylacetamide but is dependent on reaction temperature. The highest turnover frequencies are observed when triethylamine is used as base; other bases such as Na_2CO_3 or NaO_2CMe have also been used successfully but require longer reaction times. The results for the coupling of aryl iodides with acrylates are comparable to the best systems known.[5] Although the mechanism and the nature of the active species in the Heck reaction is far from clear,[6] our results show that (i) highly active palladium catalysts are obtained by using hemilabile carbene complexes, (ii) the presence of other labile ligands in the coordination sphere of the metal makes predictions of the nature of the catalytic species difficult and (iii) higher nuclearity complexes such as **2** may be precursors to the active catalyst which could be obtained by dissociation of the labile end of the ligand. Catalysis by higher nuclearity complexes, especially under Heck conditions, is less likely.

Studies on the reactivity of the new complexes, extension of the methodology to other transition metals and the synthesis of other functionalised N-heterocyclic carbene ligands with a variety of other donor functionalities is under way.

We are indebted to Ineos Acrylics, EPSRC and the University of Southampton for support.

Palladium catalysed Suzuki cross-coupling reactions have been conducted in the ambient temperature ionic liquid,1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]), exhibiting unprecedented reactivities in addition to easy product isolation and catalyst recycling.

The continuing depletion of natural resources and growing environmental awareness has necessitated changes in the practices of both the chemical industry and academia. One strategy that addresses these issues is the replacement of deleterious molecular solvents with environmentally more benign, reaction enhancing alternatives. Of the novel solvents that have emerged, ambient temperature ionic liquids consisting of 1,3-dialkylimidazolium cations have shown great promise (Fig. 1).[1] Their negligible vapour pressure, ease of handling and potential for recycling, circumvent many of the problems associated with volatile organic solvents. Furthermore, their high compatibility with transition metal catalysts and limited miscibility with common solvents, enables easy product and catalyst separation with the retention of the stabilised catalyst in the ionic phase. These and related ionic liquids have been successfully employed as the media in a number of reactions, which include hydrogenations,[2] alkene dimerizations,[3] Diels–Alder[4] and Friedel–Crafts[5] reactions.

The Suzuki[6] cross-coupling reaction is an extremely versatile methodology for the generation of new carbon–carbon bonds and is employed most successfully in the synthesis of biaryls.[7] The reaction, however, suffers from a number of drawbacks such as catalyst loss into the product, catalyst decomposition and poor reagent solubilities. We postulated that these problems might be resolved by the use of ionic liquids. Recently, the closely related Heck[8] and Trost–Tsuji[9] coupling reactions have been conducted in ionic liquids with great success. We report herein the first examples of the more complex palladium catalysed Suzuki cross-coupling reactions in the ambient temperature ionic liquid, [bmim][BF_4]. [bmim][BF_4] has a liquid range in the order of 300 °C, it is stable in air and is known to solubilize many organometallic compounds.[10] These properties, in addition to its controllable miscibility with water and immiscibility with ether, make [bmim][BF_4] a potential solvent for Suzuki reactions.

The reaction of 4-bromotoluene with phenylboronic acid in [bmim][BF_4] was initially investigated using the original Suzuki conditions.[11] This afforded 4-methylbiphenyl in a 30% yield after 6 h, with catalyst decomposition evidenced by the precipitation of a black solid (Table 1, entry 6). Further investigation revealed that modifying the original conditions significantly boosted yields of the desired products, enhanced reaction rates and prevented catalyst decomposition. The new conditions involved heating the catalyst with the arylhalide in [bmim][BF_4] at 110 °C with vigorous stirring until complete solution occurred. The catalytic solution is cooled to ambient temperature and the reaction started by the addition of the arylboronic acid and an aqueous solution of Na_2CO_3.[12] Adopting this procedure with a reduced catalyst concentration, $Pd(PPh_3)_4$ (1.2 mol%, based on arylhalide), afforded 4-methylbiphenyl in a 69% yield after 10 min, without catalyst decomposition (Table 1, entry 7). The reaction can also be achieved with one-tenth the catalyst concentration generally required, $Pd(PPh_3)_4$ (0.3 mol%, Table 1, entry 8). Once the catalytic solution has been generated the reaction can be conducted under air with analogous results and no catalyst decomposition (Table 1, entry 9).

The scope of the reaction in [bmim][BF_4] was investigated with electron-rich and electron-deficient arylhalides (Table 1). The reactivity exhibits dramatic enhancements over the conditions generally employed. For example, conducting the reaction of bromobenzene with phenylboronic acid under the original Suzuki conditions affords biphenyl with an 88% yield in 6 h (5 TON h^{-1}).[11] In [bmim][BF_4] a 93% yield is achieved in 10 min (455 TON h^{-1}, Table 1, entry 2), which is over 90 times the original reactivity. Notably, 4-methoxybiphenyl is afforded in a 40% yield in 6 h (2 TON h^{-1}) applying the original conditions.[11] In [bmim][BF_4] an 81% yield is afforded in

10 min (401 TON h^{-1}, Table 1, entry 10.1), which is in the order of 200 times the original reactivity. We are continuing to explore the generality of this result. Despite these enhancements, chlorobenzene was still inactive even after 3 h, with only a trace of biphenyl being detected, presumably due to *homo*-coupling of the arylboronic acid (Table 1, entry 3).[13]

The effect of the arylboronic acid partner on the Suzuki reactions in [bmim][BF_4] was also investigated (Table 2). The results of the functionalised arylboronic acids seem to parallel those obtained with the same functional groups on the arylhalide. This suggests that both the nature of the arylhalide and the arylboronic acid affect the reaction, apparently in an analogous manner. We are continuing to investigate these interesting results.

Isolation of the biaryl products from the [bmim][BF_4] reaction mixture can be achieved by extraction with diethyl ether, sublimation or precipitation by the addition of water, all without any apparent leaching of palladium species into the product. Extraction with diethyl ether was found to be a generally applicable method for all biaryls and led to the highest yields. Biphenyl, mono-, and di-functionalised biaryls can easily be sublimed from the reaction mixture by heating at 80 °C *in vacuo*. With water insoluble products, isolation and catalytic solution recovery and recycling was most effective with water. Typically, the reaction mixture was allowed to cool to *ca.* 60 °C, warm water was added and the mixture left to cool to ambient temperature whereupon the biaryl products crystallised out. These were collected by filtration and washed with cold water to afford the desired product with a purity > 98% (determined by GC). The only impurity being the *homo*-coupled product. The negligible amount of *homo*-coupled products detected in the reactions can be avoided by adding the phenylboronic acid to the reaction mixture over a period of an hour.

The by-products ($NaHCO_3$ and $Na[XB(OH)_2]$) generated in the reaction modify the miscibility of water with [bmim][BF_4] such that two phases are formed at ambient temperature. The by-products are preferentially soluble in the large excess of added water. This enables the removal of the by-products with the water, affording the cleaned, ionic liquid, catalytic solution. The ability to isolate product and recover the catalytic solution permits repetitive catalytic runs. The catalytic solution was re-used three times without loss of activity in the reaction of 4-bromoanisole with phenylboronic acid (Table 1, entries 10.2–10.4. Once the catalytic solution has been prepared in the first run, it can be re-used with no further modification. The product was extracted with diethyl ether and the catalytic solution washed with water after each run.

In summary, we have demonstrated that Suzuki cross-coupling reactions can be successfully conducted in the ambient temperature ionic liquid, [bmim][BF_4], with a number of advantages: (i) The reactions show a significant increase in reactivity at reduced catalyst concentration, especially with respect to non-activated arylbromides. (ii) Homo-coupled products can be eliminated, affording isolated products in high purity avoiding laborious purification procedures. (iii) The reactions can be performed under air without loss of yield or catalyst decomposition. (iv) The procedures developed permit repetitive catalytic runs without loss of catalyst activity. Further investigations concerning the nature of the active catalytic species and the mechanism of reaction are currently in progress.

This work was supported by EPRSC and a ZENECA CASE award (P. J. S.). We would like to thank Karsten Tonn (Imperial College) for performing GC-MS analysis and Dr Michael A. Carroll (Imperial College) for informative discussions. We would also like to thank Johnson Matthey for the kind loan of palladium.

11 The original Suzuki conditions employ: arylhalide (2.5 mmol, 1 equiv.); arylboronic acid (2.75 mmol, 1.1 equiv.); $Pd(PPh_3)_4$ (3 mol%, based on arylhalide); Na_2CO_3 (5.3 mmol, 2 equiv.) and toluene–H_2O–EtOH 4:2:1, heated at 110 °C for 6 hours. N. Miyaura, T. Yanagi and A. Suzuki, *Synth. Commun.*, 1981, **11**, 513.
12 Typical procedure for the Suzuki reaction in [bmim][BF_4]: aryl halide (2.5 mmol, 1 equiv.) was added to a suspension of $Pd(PPh_3)_4$ (34.7 mg, 0.03 mmol, 1.2 mol%) in degassed [bmim][BF_4] (5 cm^3) at ambient temperature under nitrogen. The mixture was slowly heated to 110 °C with vigorous stirring affording a yellow–orange solution. The solution was cooled to ambient temperature and the arylboronic acid (2.75 mmol, 1.1 equiv.) and a solution of Na_2CO_3 (560 mg, 5.28 mmol, 2.1 equiv.) in water (2.5 cm^3) was added. The mixture was reheated at 110 °C with vigorous stirring for a further 10 min, then cooled and extracted with diethyl ether (3 × 15 cm^3). The combined extracts were washed first by brine (2 × 10 cm^3), then water (2 × 10 cm^3) and dried ($MgSO_4$). Filtering through a silica pad and evaporation to dryness afforded the Suzuki biaryl product as characterised by GC-MS, ^{1}H-NMR and IR spectroscopy. The reaction mixture was washed with water (2 × 10 cm^3) and dried under *vacuo* to recover the catalytic solution.
13 The low reactivity of aryl chlorides in cross-coupling reactions is well documented. For discussions, see V. V. Grushin and H. Alper, *Chem. Rev.*, 1994, **94**, 1047.

A three-dimensional open-framework cadmium oxalate, $K[C_3N_2H_5][Cd(C_2O_4)_2]$, in which both the amine and the K^+ ion participate in the formation of the structure, has been synthesized and characterized for the first time.

Amongst the variety of open-framework inorganic materials, those of the metal carboxylates constitute a new family.[1–3] While the literature abounds in reports of the synthesis and characterization of aluminosilicates and metal phosphates with open architectures,[4] recent studies of metal carboxylates have also brought out certain novel structural features.[1,2] For example, OZn_4 clusters have been observed in zinc benzenedicarboxylates[2a] and Co–O–Co layers in a cobalt succinate.[1c] Metal oxalates synthesized hydrothermally in the presence of organic amines exhibit two- and three-dimensional architectures.[5,6] In the latter type of metal oxalates, the oxalate units lie in the plane of honeycomb-type layers and also provide the out-of-plane bridges to form the three-dimensional structure. The oxalate unit also plays a dual role in metal oxalate–phosphates where it forms an integral part of the layer structure predominantly constituted by the phosphate network and also acts as the link to create the third dimension.[7] Up to now open-framework metal oxalates synthesized in the presence of structure-directing amines have been restricted to those of Sn(II) and Zn. We have been exploring ways of preparing open-framework cadmium oxalates for some time. Here, we report the first successful synthesis and characterization of a Cd oxalate of the formula $K[C_3N_2H_5][Cd(C_2O_4)_2]$ **I**, with open architecture and possessing channels.

The cadmium oxalate **I** was synthesized by employing hydrothermal methods. Typically, 0.5 g of cadmium oxalate was dispersed in a mixture of 4.3 ml of butan-2-ol (BuOH) and 1.1 ml of water. To this, 0.328 ml of glacial acetic acid and 0.24 g of imidazole were added, followed by a small quantity of KCl (0.04 g). The approximate molar ratio of the reaction mixture was $5CdC_2O_4:KCl:5.5C_3N_2H_4:9MeCO_2H:75BuOH:100H_2O$. The mixture was homogenized for 30 min at room temperature (298 K), sealed in a 23 ml Teflon-lined acid digestion bomb and heated at 110 °C for 46 h. The product, a crop of tiny colorless diamond-shaped crystals, was recovered by suction filtration, washed with deionized water and dried at ambient temperature and conditions. Powder X-ray diffraction (XRD) indicated that the product was a new material, the pattern being entirely consistent with the structure determined by single crystal X-ray diffraction. Thermogravimetric analysis (TGA) under a nitrogen atmosphere (50 ml min^{-1}) from room temperature to 700 °C (heating rate = 10 °C min^{-1}) shows only one mass loss in the region 280–380 °C. The mass loss of 53.2% corresponds well with the loss of the oxalate and amine (calc. 55.6%). The powder X-ray diffraction pattern of the decomposed sample indicated that it was amorphous.

A suitable single crystal was carefully selected and subjected to X-ray diffraction using a Siemens SMART diffractometer with a CCD detector† and the structure was solved by direct methods. The asymmetric unit contains 20 independent non-hydrogen atoms. The structure of **I** consists of a network of cadmium and oxalate units forming an anionic framework with formula $[Cd(C_2O_4)_2]^{2-}$. Charge neutrality is achieved by the monoprotonated amine and potassium ions. Two K^+ ions occupy special positions with a site occupancy factor (SOF) of 0.5 per framework formula unit. The framework is built-up of four oxalate units, linked *via* the oxygens to the cadmium atoms with Cd–O distances in the range 2.327(3)–2.528(3) Å [$(Cd–O)_{av}$ = 2.422 Å] and O–Cd–O angles in the range 67.5(1)–151.3(1)° [$(O–Cd–O)_{av}$ = 88.6°]. The cadmium atoms are eight-coordinated with respect to oxygens forming a dodecahedral arrangement as shown in Fig. 1(a). The dodecahedral arrangement of oxygen atoms around the cadmium is of note since Cd atoms are generally octahedrally coordinated.

The complex framework structure of **I** can be understood in terms of simpler building units. Thus, the *in-plane* connectivity between the oxalate units [C(2)–C(3)O_4 and C(4)–C(4)O_4] and Cd results in the formation of honeycomb-like layers with twelve-membered apertures (six Cd and six oxalate units) along the [011] direction, as shown in Fig. 1(b). The remaining oxalate unit [C(1)–C(1)O_4] bridges (out-of-plane connection) these layers giving rise to one-dimensional elliptical channels (10.4 ×

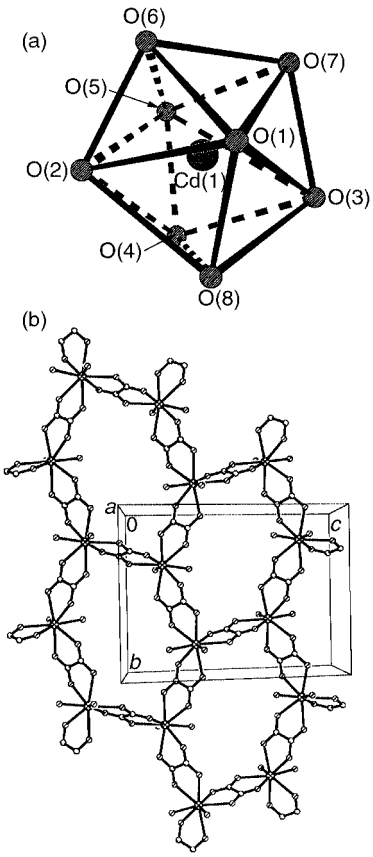

Fig. 1 (a) The environment of cadmium atoms in **I**. Note that the oxygen atoms form a dodecahedral arrangement around Cd. (b) In-plane connectivity between the oxalates and cadmium in **I**, along the *bc* plane, showing honeycomb-like layers.

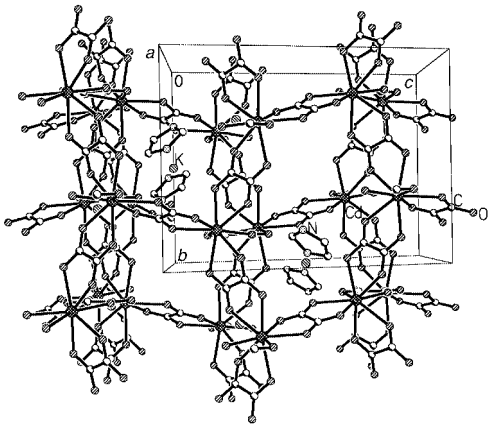

Fig. 2 Structure of $K[C_3N_2H_5][Cd(C_2O_4)_2]$ **I** along the *a* axis, showing one-dimensional channels. Note that both K^+ and imidazolium cations occupy the same channels.

7.2 Å, shortest atom–atom contact distances not including the van der Waals radii), along the *a* axis. The imidazolium and K^+ ions reside in these channels (Fig. 2). The linkages between $C(2)–C(3)O_4$ and $C(1)–C(1)O_4$ oxalates and Cd (in-plane) result in a layer with twelve-membered rectangular apertures, along the *ab* plane. These layers are pillared by the $C(4)–C(4)O_4$ oxalate units (out-of-plane) forming another one-dimensional channel of width (4.1 × 11.3 Å) along the *c* axis. To our knowledge, **I** is the first example of an open-framework cadmium oxalate possessing channels.

The structure of **I** shows close similarity to that of $[NH_4][Ti(C_2O_4)_2]·2H_2O$.[8] In the latter, the Ti atom is surrounded by eight oxygens forming a square antiprism. Connectivity between the Ti and oxalate units results in a three-dimensional structure with channels containing $[NH_4]^+$. Connectivity between Cd and the two oxalates in **I** leads to layers, which are then connected by another oxalate leading to three-dimensional connectivity.

In summary, the synthesis and structure of a novel open-framework cadmium oxalate **I** has been accomplished. It is likely that the formation of such an architecture is facilitated by the presence of two types of structure-directing species, the protonated organic amine and the alkali metal cation. The formation of channels in the presence of alkali metal cations is reminiscent of aluminosilicate zeolites,[9] and paves the way for possible ion-exchange and related studies. Since **I** is the first example of an open-framework cadmium oxalate it would be profitable to explore the formation of similar or related compounds by employing structure-directing agents. Work in this direction is in progress.

Notes and references

† *Crystal data* for **I**: $K[C_3N_2H_5][Cd(C_2O_4)_2]$, M = 396.6, crystal dimensions 0.2 × 0.2 × 0.16 mm, monoclinic, space group $C2/c$, a = 13.016(1), b = 11.291(1), c = 15.754(1) Å, β = 105.04(1)°, V = 2236.01(9) Å^3, Z = 8, D_c = 2.356 g cm^{-3}, μ(Mo-Kα) = 2.37 mm^{-1}, λ = 0.71073 Å. Structure solved by direct methods (SHELXTL-PLUS). A total of 4641 reflections were collected at 298 K in the θ range 2.42–23.25° and merged to give 1617 unique data (R_{int} = 0.033) of which 1463 with $I > 2\sigma(I)$ were considered to be observed. The structure was solved by direct methods with SHELXS-86[10] and difference Fourier synthesis. Final R_1 = 0.02 and wR_2 = 0.049 and S = 1.07 were obtained for 174 parameters. All the hydrogen atoms were located initially in the difference Fourier maps and for the final refinements, hydrogen atoms for the amine molecule were placed geometrically and held in the riding mode. Final Fourier map minimum and maximum: −0.664/0.359 e Å^{-3}. Full-matrix least-squares structure refinement against $|F^2|$ were carried out with SHELXTL-PLUS program package.[11]

Published on the Web 20th June 2000

Five novel peptide-based cationic *gemini* surfactants have been synthesised and their ability to transfect plasmid DNA containing the luciferase gene has been examined. Three of these detergents, differing in the number of positive charges per molecule at neutral pH, mediated transfection on their own. However, their efficiency increased markedly on the addition of a neutral colipid and a basic polypeptide.

Over the last ten years various cationic lipids have been synthesised for complexation with DNA and the *in vitro* delivery of genes to mammalian cells, leading to successful expression of the corresponding proteins.[1–3] The hydrophobic 'tails' of the majority of these cationic detergents consist of one or two saturated or mono-unsaturated hydrocarbon chains containing 16 to 18 carbon atoms; examples are cetyltrimethylammonium bromide (CTAB) and 2,3-dioleoyloxy-*N*-{2-[1,4-bis(3-aminopropymino)-2-butylcarboxamido]ethyl}-*N*,*N*-dimethyl-1-propylammonium bromide (DOSPA).[4]

The polar 'head-groups' of cationic lipid vectors have generally consisted of monovalent quaternary ammonium salts (as in CTAB and 1,2-dioleoyloxypropyl-*N*,*N*,*N*-trimethylammonium chloride, DOTAP). However, lipids such as DOSPA with a multivalent 'head-group' have been found to transfer genes *in vitro* more efficiently than the monovalent analogues.[5]

We report a novel class of non-viral gene-transfer vectors based on *gemini* surfactants (Fig. 1). Unlike several cationic lipids used in gene transfection studies, GS1 to GS5 *gemini* surfactants are solids, easy to handle and readily soluble in aqueous media over a wide range of pH. We use a thioether rather than the disulfide linkage for reasons of chemical stability. However, the amide linkages in the 'head-groups' and between the 'head-groups' and the hydrophobic alkyl chains confer a degree of biodegradability, reducing the potential cytotoxicity of these detergents.

Complexation of cationic lipids with DNA is a key design factor for these vehicles. The binding interaction between the cationic *gemini* molecules and DNA was confirmed by agarose gel electrophoresis studies (Fig. 2). Various concentrations of *gemini* surfactants were incubated with the pCMV-luciferase

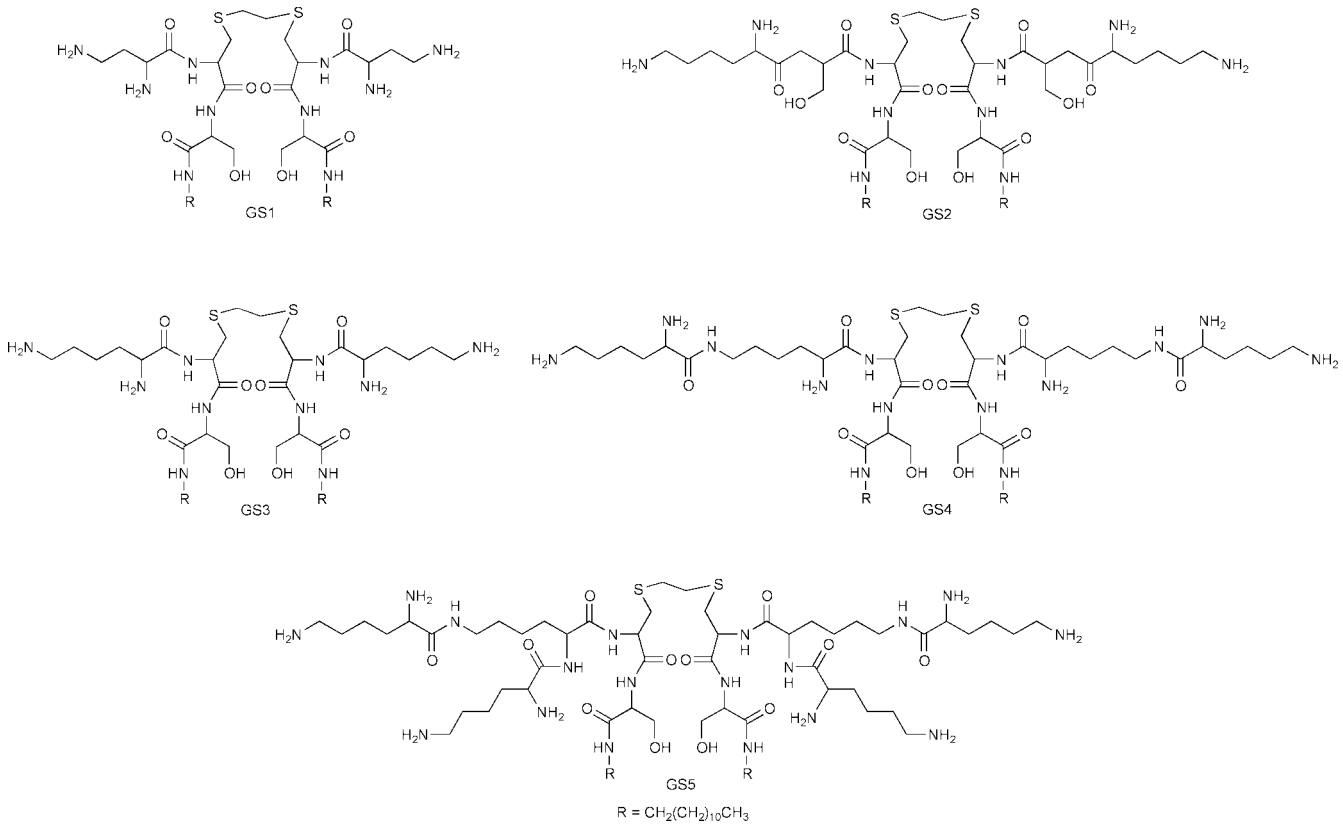

Fig. 1 Chemical structures of *gemini* surfactants GS1 to GS5. All details on the synthesis of these surfactants are provided in patent application, WO 99-29712 (SmithKline Beecham plc).

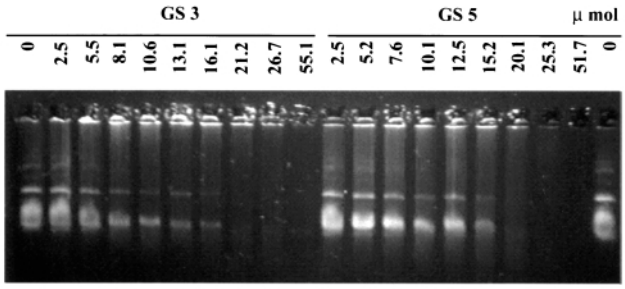

Fig. 2 Interaction of *gemini* surfactants with DNA in the presence of ethidium bromide. Agarose gel electrophoresis assay with GS3 and GS5.

plasmid DNA complexed with ethidium bromide.† These mixtures were then electrophoresed in agarose gel, and subsequently visualised under ultraviolet light. These experiments indicate that all five molecules were effective in releasing the nucleic acid from the DNA–ethidium bromide complex, consistent with binding of the cationic *gemini* to the DNA.

Relative transfection efficiencies for surfactants GS2, GS4 and GS5 are shown in Fig. 3. GS2 and GS5 are most efficient at about 10 μM, whereas for *gemini* GS4 the optimal concentration is slightly higher, at 13 μM. Concentrations used in the transfection experiments are well below the cmc values (0.3 ± 0.1 mM) so that the formation of micelles or liposomes (multilamellar forms) does not appear to be necessary for transfection to occur. Although the electrostatic nature of complex formation of these *gemini* molecules with DNA is likely to be important for complexation with DNA, it is not the only factor that influences gene transfection. Thus surfactants GS1 and GS3 complex with DNA, but do not mediate transfection. It may be that the complexes formed by these two surfactants are too strong to release DNA at a critical point, or that interactions other than electrostatic contribute to transfection efficiency.

It is well known that the DNA transfection efficiency of cationic lipids improves in the presence of a neutral colipid ('helper') and/or a basic polypeptide.[6,7] Thus LIPOFECTAMINE PLUS™ (Life Technologies), one of the leading commercial products for *in vitro* gene transfection, consists of a mixture of DOSPA, dioleoylphosphatidylethanolamine

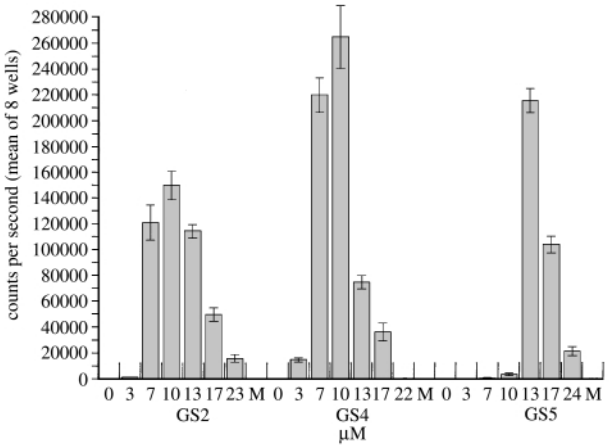

Fig. 3 Transfection experiment in CHO-K1 cells. The cells were incubated overnight at 37 °C with DNA and different concentrations of GS2, GS4 and GS5 or GS without DNA (M). Luciferase activity was measured using the stable light signal reporter gene assay and the counts per second from eight wells were averaged.

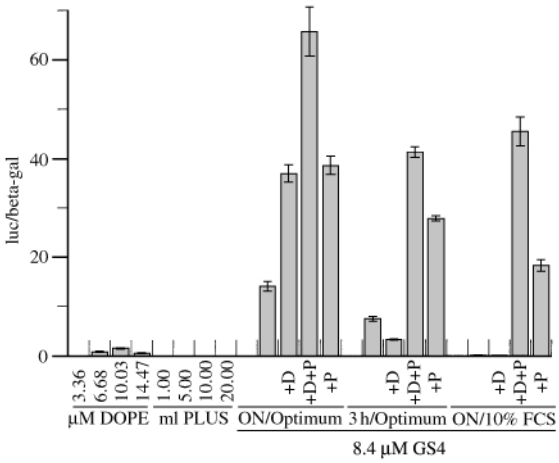

Fig. 4 Transfection experiment in CHO-K1 β-gal cells. The cells were incubated in Opti-MEM® or complete medium with the transfection mixtures overnight (ON) or 3 h at 37 °C. GS4 was used alone or in combination with DOPE (+D), with 'PLUS'-reagent (+P) or in a combination of both (+D+P). The luciferase activity of eight wells was normalized against the corresponding β-galactosidase activity. As controls, various amounts of DOPE and 'PLUS'-reagent alone were incubated with DNA and used for transfection (over night/Opti-MEM®).

(DOPE) and a basic peptide. The transfection efficiencies of GS4 alone and in the presence of (i) DOPE, (ii) the 'Plus' reagent (a basic peptide) and (iii) DOPE and the 'Plus' reagent is shown in Fig. 4. Addition of either the neutral lipid or the basic peptide increases transfection efficiency more than twofold. However, the biggest increase in efficiency occurs when both neutral lipid and basic peptide are added to GS4. It is remarkable that overnight incubation of the DNA with serum in the presence of GS4, DOPE and the 'Plus' reagent gave the maximum protection from degradation by serum nucleases. A similar result was reported recently for the transfection vehicle 3β-[*N*-(*N*′,*N*′-dimethylaminoethyl)carbamyl]cholesterol in the presence of polylysine.[7] In the majority of experiments, the observed expression level with GS4 was of the same order of magnitude as that with LIPOFECTAMINE PLUS™ (data not shown).

Practicable regiospecific bifunctionalization on the secondary face of α- and β-cyclodextrins†

Katsunori Teranishi

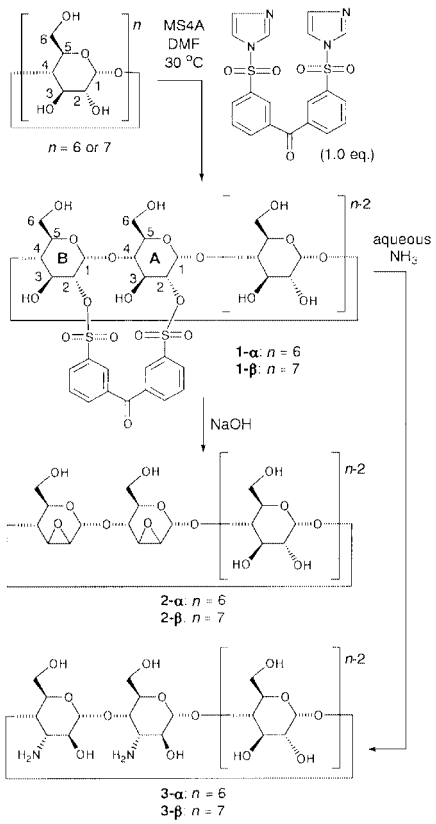
Received (in Cambridge, UK) 28th March 2000, Accepted 10th May 2000
Published on the Web 20th June 2000

Practicable regiospecific bifunctionalization onto the A,B-secondary hydroxyl face of α- and β-cyclodextrins, such as diepoxidation and diamination, has been made possible by staple-disulfonation with benzophenone-3,3′-disulfonyl imidazole and molecular sieves in DMF.

Regiospecific multifunctionalization techniques on the primary and secondary hydroxyl groups of cyclodextrins have been investigated in order to enhance the ability of cyclodextrins to act as acceptors or artificial enzymes. Several significant regiospecific disulfonations on the primary hydroxyl groups have been developed to modify the primary face[1] and, as a result, some elegant bifunctional catalyses have been achieved.[2] However, regioselective bifunctionalization on the secondary face has proven more difficult to accomplish.[3] Hence, no absolutely regioselective bifunctionalizations have, as yet, been developed. Two reported disulfonations on two secondary hydroxyl groups of α-, and β-cyclodextrins were not absolutely regiospecific, but afforded mixtures of the regioisomeric $2^A,2^B$-, $2^A,2^C$-, and $2^A,2^D$-disulfonates in extremely low yields.[4] Additionally, inconvenient separation techniques were necessary to isolate the products. Accordingly, an investigation into the bifunctionalization of the secondary hydroxyl groups was undertaken and led to the development of a very useful and efficient method for the exclusively regiospecific preparation of $2^A,2^B$-disulfonates of α- and β-cyclodextrins, with no $2^A,2^C$- and $2^A,2^D$-disulfonate isomers. This preliminary communication details the new method and shows that the $2^A,2^B$-disulfonates are effectively converted to the corresponding A,B-dimannoepoxido and $3^A,3^B$-diamino compounds, useful for the functionalization of cyclodextrins.

Recently, an interesting regiospecific monosulfonation on the secondary hydroxyl groups of cyclodextrins using a combination of sulfonyl imidazole and molecular sieves has been reported,[5] although the mechanism of the sulfonation is not yet clear. This method is extremely encouraging in practical cyclodextrin chemistry because the mild non-alkaline reaction conditions do not induce decomposition of the sulfonates. Furthermore, the reaction occurs independently of the nature of the sulfonyl groups. In this study, the use of benzophenone-3,3′-disulfonyl imidazole,† easily prepared from benzophenone-3,3′-disulfonyl chloride, imidazole and triethylamine,[6] as a $2^A,2^B$-disulfonation 'stapling' reagent (see Scheme 1) has been investigated. A mixture of α- or β-cyclodextrin (0.01 mol), benzophenone-3,3′-disulfonyl imidazole (0.01 mol), and freshly activated powdered molecular sieves 4 Å (10 g) in *N*,*N*-dimethylformamide (DMF) (200 ml) was stirred at 30 °C for 20 h. The molecular sieves were removed by filtration and the filtrate concentrated under reduced pressure. Warm 20% aqueous MeOH (400 ml) was added to the residue and the insoluble solid, containing a small amount of **1-α** or **1-β** and more complex sulfonated cyclodextrins, was removed by filtration. The filtrate was passed through a simple open reverse-phase chromatography column (50 × 120 mm, Fuji Silisia Chromatorex-ODS DM1020T). Elution with water and 10% aqueous MeOH removed the remaining unreacted cyclodextrin. Stepwise gradient elution to 50% aqueous MeOH gave pure 'staple-$2^A,2^B$-disulfonate' **1-α** and **1-β** in 30 and 33% yields, respectively. No other mono- or disulfonate isomers, such as staple-$2^A,2^C$-disulfonates, staple-$2^A,2^D$-disulfonates, 6-sulfonates or 3-sulfonates, resulting from the reaction were observed by HPLC analysis of the reaction mixture and ^{1}H NMR spectroscopy on the reaction products. The structural assignments of **1-α** and **1-β** were made from ^{1}H NMR, H–H COSY, ROESY, HOHAHA, ^{13}C NMR, H–C COSY, and FAB-MS spectra,† and by further derivatisations. The FAB-MS spectra of **1-α** and **1-β** indicated that the disulfonation of each cyclodextrin molecule was performed by a single benzophenone-3,3′-disulfonyl molecule. The ^{1}H NMR spectra, assigned from the H–H COSY experiments, exhibit an appreciable downfield shift of the resonances due to the H-1, H-2 and H-3 protons of the two glucose units of **1-α** and **1-β**, as shown in Fig. 1. In particular, the chemical shifts of the H-2 protons show a larger downfield shift than do the H-3 protons. The ^{13}C NMR spectra, assigned from the H–C COSY experiments, show an upfield shift of the C-1 and C-3 carbon resonances and a downfield shift of the C-2 carbon peaks of the two glucose units of **1-α** and **1-β**. These data show that the two sulfonyl groups of



Scheme 1

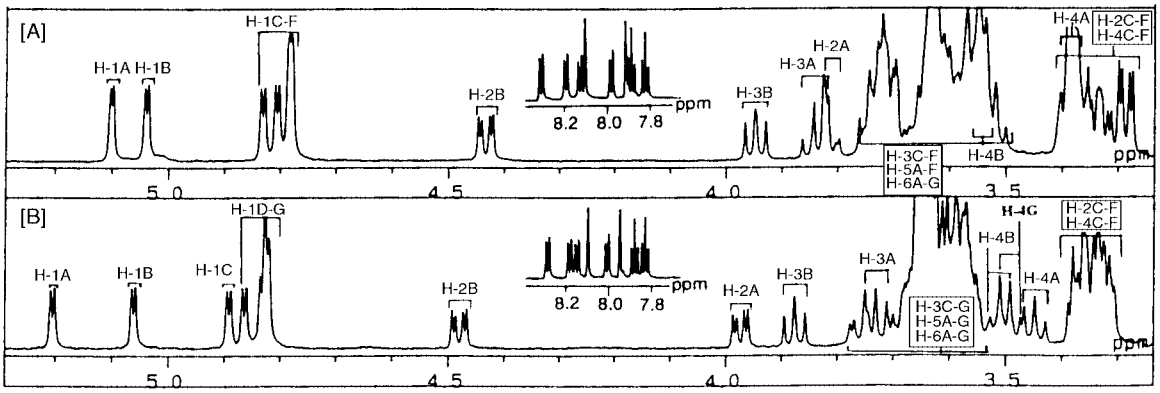

Fig. 1 [A] ^{1}H NMR spectrum of **1-α** [500 MHz, DMSO-d_6 containing 5% D_2O, 60 °C, ref. DMSO (δ 2.49)]. [B] ^{1}H NMR spectrum of **1-β** [500 MHz, DMSO-d_6 containing 5% D_2O, 80 °C, ref. DMSO (δ 2.49)]. The assigned signals are numbered according to the usual convention, shown in Scheme 1, and the glucose units are lettered A to F or G. The letters A and B refer to the sulfonated glucose units.

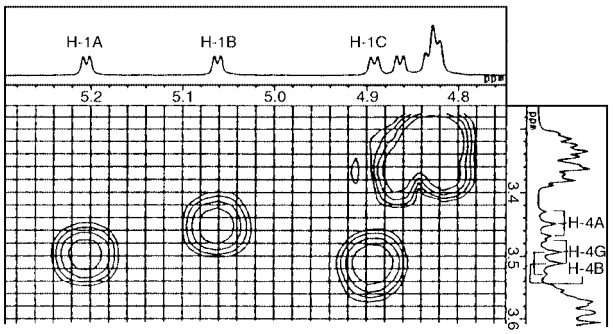

Fig. 2 Partial 2D ROESY NMR spectrum of **1-β** [500 MHz, DMSO-d_6 containing 5% D_2O, 80 °C, ref. DMSO (δ 2.49)].

the benzophenone-3,3′-disulfonyl molecule are located at the C-2 oxygen of the two glucose units. The regiochemistry of the disulfonyl groups of **1-β** was determined using a 2D ROESY NMR experiment (Fig. 2), whereas for **1-α**, this could not be done because the H-4 protons of the sulfonated glucose units and those of adjoining glucose units could not be assigned definitely (see Fig. 1[A]). The 2D ROESY NMR spectrum of **1-β** shows that the H-1B proton of one sulfonated glucose unit has a cross peak with the H-4A proton of another sulfonated glucose unit, indicating that the two units adjoin. Therefore, the structure of **1-β** is 2^A,2^B-disulfonated β-cyclodextrin, as shown in Scheme 1. Treatment of **1-α** and **1-β** with 0.1 mol l^{-1} aqueous NaOH (10 equiv.) at 20 °C for 1 h followed by simple open reverse-phase column chromatography afforded the corresponding pure di-2,3-manno-epoxides **2-α** and **2-β** in 87 and 90% yields, respectively. Their ^{1}H and ^{13}C NMR spectra were seen to be identical with published spectra for authentic A,B-di-2,3-mannoepoxides.[4] Hence **1-α** was assigned as 2^A,2^B-disulfonated α-cyclodextrin, as shown in Scheme 1, and furthermore, the structure of **1-β** was reconfirmed as 2^A,2^B-disulfonated β-cyclodextrin.

The conversion of the hydroxyl groups of cyclodextrins to amino groups is one of the important techniques for the modification of cyclodextrins. Hence, the transformation of 2-mono- or di-*O*-sulfonylcyclodextrins to 3-amino-3-deoxy-2(*S*),(3*R*)-cyclodextrins *via* 2,3-mannoepoxidocyclodextrins has been investigated.[7] However, a straightforward method for absolutely regiospecific A,B-diamination on the secondary face has never been reported.

Investigation into selective A,B-diamination on the secondary face showed that the staple-A,B-disulfonates prepared in the present study were very useful substrates for diamination. The treatment of **1-α** and **1-β** in 28% aqueous NH_3 at 37 °C for 5 days, followed by ion-exchange column chromatography (Sephadex CM-25) efficiently yielded the corresponding pure 3^A,3^B-diamino-3^A,3^B-dideoxy-(2*S*),(3*R*)-cyclodextrins **3-α** and **3-β** in 86 and 84% yields, respectively. The ^{1}H and ^{13}C NMR spectra of **3-α** were seen to be thoroughly identical with authentic published spectra[7b] and the structure of **3-β** was confirmed by ^{1}H and ^{13}C NMR and FAB mass spectroscopies (ESI†).

Studies on the scope and limitations of the present strategy for the absolutely regiospecific disulfonation are currently in progress.

The author thanks the Japanese Ministry of Education, Science, and Culture for a Grant-in-Aid for Scientific Research [(C) 10640520 and 11660106] and the Naito Foundation. The NMR instrument used in this research was installed at the Cooperative Research Center of Mie University.

Published on the Web 20th June 2000

Analysis of the inelastic neutron scattering rotational spectrum of sorbed dihydrogen in a cobalt aluminophosphate catalyst shows that dihydrogen molecules confined in the internal space of the CoAlPO behave as 1D rotors, rotating with the H–H axis aligned with the internal electric field, and as 2D rotors, rotating in a plane and bound sideways at surface sites.

As part of a continuing study[1] of the binding and activation of dihydrogen at catalytic centres and hydrogen atom spillover, we report the interaction of H_2 with the compound CoAlPO-18. The inelastic neutron scattering (INS) spectrum (energy loss vibrational spectrum) of the bound H_2 molecule enables us to observe and assign the H_2 rotational transitions and to describe the H_2 interactions. The H_2 molecule through its INS spectrum may be used as a local structural probe of a porous material.

Cobalt containing microporous materials are important selective oxidation catalysts in, for example, liquid phase oxidation of alkenes with dioxygen[2] and selective oxidation of cyclohexane to cyclohexanone.[3] The synthesis of the CoAlPO-18 catalyst is accomplished by standard hydrothermal sol–gel techniques.[4] Removal of the template is effected by calcination in oxygen; the cobalt(II) is oxidised to cobalt(III).[5] The catalyst is subsequently reduced in hydrogen to generate Brönsted acid sites. The interaction of the hydrogen molecule with the Co(III) centre is therefore crucial. The CoAlPO provided an opportunity to study the binding and activation of the H_2 molecule at a well defined site since the cobalt is known to reside in the framework before and after calcination and reduction. Here we report a study of the interaction of the dihydrogen molecule with the Co(III) site, both experimentally with inelastic neutron scattering (INS) on the TOSCA spectrometer at the Rutherford Appleton Laboratory, and theoretically with perturbation theory.

Inelastic Neutron Scattering Spectra (INS) measurements on the compound CoAlPO-18 were made on the TOSCA instrument at the ISIS Facility at the Rutherford Appleton Laboratory,[6] and cover the molecular vibrational range (16–4000 cm^{-1}) in one spectrum. A sample of CoAlPO-18 (15.7 g) was contained in a standard zirconium INS cell. This was heated in oxygen at 773 K to ensure conversion of Co to Co(III) and complete removal of the template. The sample was then dosed *in situ* with hydrogen at 20 K to a concentration of *ca.* 1 H_2 per cavity. When the CoAlPO-18 dosed with hydrogen was evacuated at 30 K the peaks at 58 and 168 cm^{-1} both disappeared. This is entirely consistent with them being associated with H_2 adsorbed on the same site.

The INS spectrum (0–250 cm^{-1}) after background subtraction (CoAlPO and the cell) is shown in Fig. 1. We observe sharp rotational transitions of the H_2 molecule and a broad recoil tail. The peaks have been fitted as Lorentzians.

In solid dihydrogen, the molecules rotate freely and have almost the same value for the rotational constant, B, as in the gas phase (B = 59.3 cm^{-1}). The energy level scheme is that of a linear rotor in three dimensional space [eqn. (1)].[7] For

$$E_J = J(J + 1)B \quad (1)$$

dihydrogen adsorbed on graphite the rotational states are slightly hindered but they can still be represented as perturbed three-dimensional rotor states.[8–10] The rotational ground state is nearly pure J = 0. The lowest band of excited states, nominally J = 1, is separated from the ground state by an average energy of $2BJ$ and is split by *ca.* 20.2–21.8 cm^{-1}. In our previously reported INS spectrum of H_2 on a Ru/C catalyst the lowest energy transition was seen as a sharp strong band at 120 cm^{-1} (B = 60 cm^{-1}).[1] This was the J(0–1) rotational transition (*para*- to *ortho*-H_2, allowed in INS although strongly forbidden in photon spectroscopy).[11] It is striking, however, that in the spectrum of H_2 adsorbed on CoAlPO-18 (Fig. 1) the *lowest* energy band is at 58.4 cm^{-1}, generally a featureless region of the spectrum. Clearly we cannot treat all our sorbed H_2 as an unconstrained rotor.

As the out-of-plane forces securing the H_2 to the surface increase in strength the molecule becomes more constrained. Ultimately these rotational states will, themselves, become hindered.[12] Here, however, we shall assume that translations and rotations parallel to the surface are unhindered; a potential that governs the rotational motion of the molecule is given by eqn. (2),[13] where θ is the angle between the H–H bond and the

$$V(\theta,\phi) = \sin^2(\theta)[a + b\cos(2\phi)] \quad (2)$$

preferred orientation in space (z axis), ϕ is the azimuthal angle in spherical coordinates, and a, b are constants. For $b \approx 0$, if a

DOI: 10.1039/b002587i

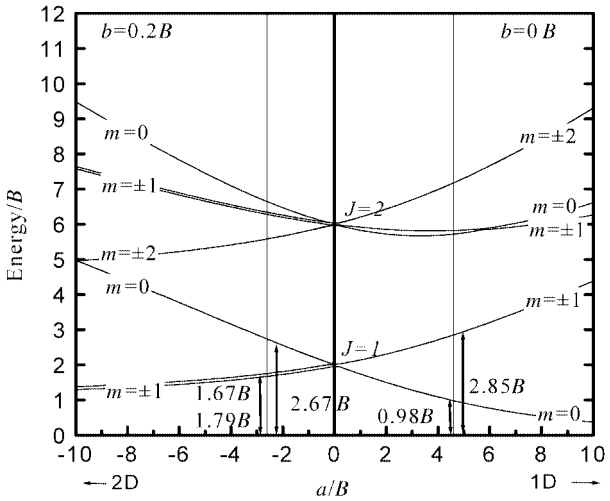

Fig. 2 Rotational states of constrained H_2: energy in units of the rotational constant B *vs.* the perturbation parameter a of Fig. 1 with $b = 0.2B$. Vertical arrows locate peaks in the INS spectrum.

> 0 the molecule will tend to align with the z axis (1D case) whereas if $a < 0$ the molecule will tend to lie in a plane perpendicular to that axis (2D case). Different values of b correspond to different hindrances to rotation within the plane perpendicular to the z axis. If the value of $a < 0$ is large enough, the rotor is effectively constrained to rotate in a plane, the so called two-dimensional rotor.[14] The energy levels are $E_J = J^2B$ and the lowest energy band appears at B. To obtain the transition energies from the ground state to excited rotational states, the Schrodinger equation for a quantum rotor in a potential given by eqn. (2) was solved numerically with a spherical harmonic basis set, $Y_{lm,}$ for values of the parameters a/B and b/B.[13] The parameters were evaluated by fitting to the INS spectrum.

Fig. 2 shows the behaviour of the rotational energy transitions from the ground state as a function of the value of a for $b = 0B$ and $0.2B$. For $a = 0$ we have the three-dimensional free rotor (3D rotor); negative values of a correspond with the 2D case and positive values with the 1D case. Transitions in agreement with the INS spectrum are shown by vertical arrows in Fig. 2 and assignments are given in Table 1. The fitted values of the parameters a and b [eqn. (2)] are for the 1D rotor ($a = 4.6B$ and $b = 0$), whereas for the the 2D rotor, $a = 2.8B$ and $b = 0.2B$.

Table 1 Assignment of the rotational modes in the INS spectrum of H_2 in CoAlPO-18

Peak					
cm^{-1}	B	Relative area	Width/ cm^{-1}	Transition	Assignment
58.4	0.985	0.125	2.77	$\|0,0\rangle \rightarrow \|1,0\rangle$	1D rotor
96.4	1.63	1.000	7.27	$\|0,0\rangle \rightarrow \|1,1\rangle$	2D rotor
110	1.86	0.896	11.4	$\|0,0\rangle \rightarrow \|1,-1\rangle$	2D rotor
134	2.26	0.055	2.28	$\|0,0\rangle \rightarrow \|1,0\rangle$	2D rotor
145	2.45	0.584	2.28	$\|0,0\rangle \rightarrow \|1,0\rangle$	2D rotor
168	2.83	0.116	7.59	$\|0,0\rangle \rightarrow \|1,1\rangle$	1D rotor

Finally we consider whether it is possible to associate features of the INS spectrum with particular components of the CoAlPO-18. We note that the intensity ratio of the 58 cm^{-1} peak to the 96 and 100 cm^{-1} peaks is *ca.* 1/17, the same as the Co/Al ratio if one Al^{3+} in each unit cell is replaced by one Co^{3+}. It is, therefore, possible that it is the Co^{3+} which aligns the H_2 molecule as the 1D rotor (58 cm^{-1} peak) (*cf.* the perpendicular orientation towards Co^{3+} of acetonitrile in CoAlPO-18).[15] The 2D rotor peaks then derive from H_2 molecules rotating in a plane and bound sideways at surface sites comprising Co^{3+} or framework AlPO. Density functional theory calculations are in hand to calculate the rotational frequencies of H_2 molecules bound at various sites of the CoAlPO-18.

We thank the EPSRC for funding (GR/M90627) and access to the ISIS neutron beam (GR/L13834); Professor Richard Catlow for his interest; Dr G. Sankar (Royal Institution) for helpful comments on the CoALPO structure and Dr J. Tomkinson (ISIS) on the hydrogen INS. Dr John Turner (Royal Institution) was involved in the initial planning of the project.

The prototype of an organometallic linear-rod building block incorporating the saturated σ-donating 16-TMC macrocycle, peripheral pyridine moieties for versatile ligation, and the π-conjugated *trans*-[Ru(C≡Cpy-4)$_2$] fragment along the molecular axis, is described and applied to the assembly of trimetallic arrays.

The development of molecular rods and wires[1,2] has gained importance in view of their potential applications in the emerging fields of molecular-scale electronics and devices.[3] An attractive pursuit in this area is the design of rigid building blocks with readily tuneable electronic, steric and photophysical characteristics.[4] In this context, we became interested in metal–acetylide units as components in organometallic supermolecules. The unique nature of the M–C≡CR interaction allows delocalisation of electron density in principle and has been harnessed in several active areas of material science,[5] but reports of supramolecular metal–acetylide systems are relatively sparse.[6]

We present the bis(σ-pyridylacetylide) derivative *trans*-Ru(16-TMC)(C≡Cpy-4)$_2$ (**Ru**, 16-TMC = 1,5,9,13-tetramethyl-1,5,9,13-tetraazacyclohexadecane) as a supramolecular bridging module for multinuclear rod-like assemblies.[7] The unique combination of properties that has been incorporated into the design of the neutral complex **Ru** include: (a) enhanced d_π(Ru) → π*(C≡Cpy) back-bonding due to the saturated σ-donating 16-TMC amine ligand, as observed for the arylacetylide analogues;[8] (b) versatile coordination to adjacent units by the pendant pyridine moieties, to yield multicomponent systems with well-defined structures; (c) the electronic effect conferred upon **Ru** by the 16-TMC macrocycle and the π-overlapping Ru–C≡Cpy interaction can afford anisotropic properties.

Reaction of a methanolic solution of [Ru(16-TMC)Cl$_2$]Cl with zinc amalgam, sodium methoxide and 4-ethynylpyridine yielded **Ru** as a yellow crystalline solid.‡ We suggest that the sterically bulky nature of the 16-TMC ligand leads to preferential ligation of acetylide groups at the Ru(II) centre rather than pyridyl moieties. Treatment of **Ru** with two equivalents of [Re(N–N)(CO)$_3$(MeCN)]OTf (OTf = CF_3SO_3) under reflux in THF afforded the trimetallic complexes [{Re(N–N)(CO)$_3$}$_2${μ-(4-pyC≡C)$_2$Ru(16-TMC)}](OTf)$_2$ (**[a–c]Re$_2$Ru**, see Fig. 1) as dark red solids in moderate yields (50–60%).‡ These derivatives are thermally stable > 200 °C (*e.g.* decomposition occurs at 220–222 °C for **Ru**; 207–210 °C for **[b]Re$_2$Ru**).

The IR spectrum of **Ru** displays an intense band at 1990 cm^{-1} for the asymmetric C≡C stretch. This value is slightly lower than that for the arylacetylide congeners (2002–2012 cm^{-1}),[8] and is one of the lowest ever reported for a simple metal bis(σ-acetylide) derivative.[5] The strongly electron-donating nature of 16-TMC is apparent, resulting in improved π back-bonding from the electron-rich Ru(II) core. The ν_{as}(C≡C) values for **[a–c]Re$_2$Ru** are shifted to 2028–2030 cm^{-1} upon coordination of Re(I) centres at the pyridyl sites. The FT Raman spectra of the trimetallic complexes show a symmetric C≡C stretch at 2010–2024 cm^{-1}. The electrospray mass spectra for **[a–c]Re$_2$Ru** are all dominated by two clusters of signals, the intensities of which correspond to the calculated isotope patterns of the $[M]^{2+}$ (peaks separated by 0.5 u) and $[M + OTf]^+$ species respectively. The ^{13}C NMR resonance for the α-acetylide carbon in **[a–c]Re$_2$Ru** (assigned by ^{1}H–^{13}C COSY, DEPT-135 and by comparison with precursors) appears at δ 155.4–156.7. This downfield shift compared to related Ru σ-acetylide complexes[5,7] again indicates strong ruthenium-to-acetylide π back-bonding. The cyclic voltammograms for **Ru** and **[a–c]Re$_2$Ru** all exhibit a well-defined reversible/quasi-reversible couple at −0.28 to −0.40 V *vs*. $Cp_2Fe^{0/+}$ (ΔE_p 50–130 mV), which is assigned to the Ru(III/II) couple.

While numerous multinuclear molecular rods have been described, structural elucidations are rarely provided. X-Ray crystallographic analyses have been performed on **Ru** and **[a]Re$_2$Ru**·Et$_2$O,§ and their molecular structures are shown in Fig. 2. The metal atoms in **Ru** and **[a]Re$_2$Ru** all reside in distorted octahedral environments. The salient features of these structures are their linearity along the molecular axis and the coplanarity of the pyridine ring systems. The former illustrates the potential application of **Ru** as a linear rigid-rod motif, while the latter implies that the π orbitals within the *trans*-[Ru(C≡Cpy-4)$_2$] fragment are able to undergo favourable overlap in the crystal lattice. For **[a]Re$_2$Ru**, a facial arrangement of the carbonyl ligands is observed, while the end-to-end Re···ReA distance is 19.1 Å. The Ru–C [**Ru**: 2.065(7) Å, **[a]Re$_2$Ru**: 2.040(10) Å] and C≡C [**Ru**: 1.20(1) Å, **[a]Re$_2$Ru**: 1.207(13) Å] bond lengths are comparable to those reported for related Ru(II) σ-acetylide[5] and σ-pyridylacetylide[7] derivatives.

The UV-Vis absorption spectrum of **Ru** in dichloromethane (Fig. 3) contains an intense absorption band at λ_{max} 430 nm (ε = 4.7 × 10^4 dm^3 mol^{-1} cm^{-1}). Because the saturated 16-TMC ligand is optically transparent in the UV-Vis spectral region, this absorption is assigned to a d_π(Ru)→π*(C≡Cpy) metal-to-ligand charge transfer (MLCT) transition. The trimetallic derivatives **[a–c]Re$_2$Ru** display characteristic UV-Vis absorptions at λ_{max} 355–430 (sh, $\varepsilon \approx 1 \times 10^4$ dm^3 mol^{-1} cm^{-1}) and 516 ($\varepsilon \approx 7 \times 10^4$ dm^3 mol^{-1} cm^{-1}) nm (Fig. 3 for **[a]Re$_2$Ru**). With

reference to previous spectroscopic studies on rhenium(I) diimine systems,[9] the former are attributed to d_π(Re) → π*(diimine) MLCT transitions. The highly intense 516 nm absorption band is tentatively assigned to be d_π(Ru)→π*(C≡Cpy) MLCT in nature. The observed red shift from **Ru** is in accordance with the Lewis acidity of the pyridine-bound Re(I) centres. Furthermore, the identical λ_{max} value of this band for $^{a-c}$**Re$_2$Ru** suggests that the transition concerned contains negligible contribution from the different diimine ligands. Complex **Ru** is non-emissive in solution or solid states. While [Re(diimine)(CO)$_3$(py)]$^+$ complexes are known to exhibit a long-lived Re→π*(diimine) MLCT excited state in solution at room temperature, this photoluminescence is quenched in the trinuclear arrays $^{a-c}$**Re$_2$Ru**. A possible mechanism for the quenching process involves fast intercomponent energy transfer (Re^{I*}–Ru^{II}–Re^{I} → Re^{I}–Ru^{II*}–Re^{I}), leading to a non-radiative Ru→π*(C≡Cpy) charge transfer excited state.[10]

We are grateful for financial support from The University of Hong Kong and the Research Grants Council of the Hong Kong SAR, China [HKU 501/96P]. We thank Prof. K. Y. Wong for assistance in electrochemical measurements.

Rapid and reversible olefin coordination to silver ions in $AgBF_4$–poly(vinyl methyl ketone) membrane has been characterized using FTIR and UV spectroscopy.

Olefin/paraffin separation by facilitated transport membrane using silver salts as carriers has been considered as a promising alternative to the conventional energy intensive distillation process.[1,2] The basis for the separation is the ability of silver ions to react reversibly with olefins forming silver–olefin complexes.[1–4] In general, facilitated transport phenomena have been mostly observed in supported liquid membranes and ion exchange membranes.[5] However, such membranes show facilitated olefin transport only in the presence of water, which is a serious drawback for practical application.[5] A solution to this problem is the development of dry polymer membranes in which silver ions can interact with olefins even in the absence of water.[6] Despite the extensive research on facilitated olefin transport phenomena in the water-free state, only a few dry polymer membranes have been developed. Accordingly, very little information has been obtained about phenomena occurring on the solid polymer membrane such as reversible interactions of silver salts with olefins and/or the polymer matrix, which is of pivotal importance in the development of high performance dry polymer membranes.[7]

It is well known that silver–olefin complexes are extremely unstable and lose olefin easily upon exposure to air.[8] Therefore, in order to characterize reversible olefin coordination to silver ions in a solid polymer membrane, the polymer matrix should contain some functional group(s) to stabilize the silver–olefin complexes to a certain extent. In addition, appropriate equipment should be used for the spectroscopic measurements in an inert or olefin atmosphere. Antonio and Tsou suggested that the stability of silver–olefin complexes could be enhanced by weak interaction between silver ions and oxygen atoms.[9] Among various oxygen-containing polymers, poly(vinyl methyl ketone) (PVMK) was chosen since it has a relatively simple structure and contains carbonyl functional groups the absorption peaks of which can be clearly seen by IR spectroscopy. A pressure cell is employed for the spectroscopic characterization of reversible interactions of silver salts with olefins and/or the polymer matrix in an inert or olefin atmosphere.[10]

We report the direct spectroscopic observation of rapid and reversible coordination of olefins to silver ions in dry PVMK membranes and of the interaction of silver ions with carbonyl groups in PVMK using FTIR and UV spectroscopy. We also report that the facilitated transport membrane consisting of $AgBF_4$ and PVMK exhibits excellent performance for olefin/paraffin separation.

All the samples for spectroscopic characterization[11] and permeation tests[12] were prepared in a dry box under argon to avoid contact with water. Spectroscopic characterization was carried out using a pressure cell equipped with two CaF_2 or quartz windows[10] and permeation tests were performed in a stainless steel separation module described elsewhere.[13]

The series of IR spectra in Fig. 1 demonstrate the solid state interaction of $AgBF_4$ with PVMK and reversible olefin coordination to silver ions dissolved in the solid $AgBF_4$–PVMK membranes. The peak at 1709 cm^{-1} in Fig. 1(a), associated with the C=O stretching frequency of uncoordinated PVMK, shifts to a lower frequency upon incorporation of $AgBF_4$, demonstrating the coordination of carbonyl groups to silver ions. The membrane with a molar ratio $AgBF_4$:PVMK = 1:4 shows a strong carbonyl absorption peak at 1681 cm^{-1} and a shoulder peak at *ca.* 1709 cm^{-1} which are assigned to coordinated and free carbonyl groups, respectively [Fig. 1(b)]. However, the membrane with a molar ratio of 1:2 shows a single absorption band implying that the maximum coordination number of silver ion by carbonyl groups is approximately two.

When the membrane ($AgBF_4$:PVMK = 1:2) was exposed to 30 psig of propylene and then purged with N_2, a new IR absorption peak at 1586 cm^{-1} appeared [Fig. 1(d)]. This new peak represents the C=C stretching vibration of coordinated propylene (*cf.* $\nu_{C=C}$ of free hex-1-ene = 1640 cm^{-1}).[7] It is interesting that the peak at 1586 cm^{-1} remains even after outgassing at 10^{-5} Torr for 4 h at room temperature. However, exposure of the propylene coordinated membrane to 30 psig of buta-1,3-diene and subsequent treatment with N_2 gives a new peak at 1558 cm^{-1} with concomitant disappearance of the peak at 1586 cm^{-1}. The peak at 1558 cm^{-1} can be assigned to the C=C stretching frequency of coordinated buta-1,3-diene [Fig. 1(e)]. The peak at 1558 cm^{-1} is replaced by a peak at 1586 cm^{-1} upon introduction of propylene into the gas cell containing the buta-1,3-diene-coordinated $AgBF_4$–PVMK

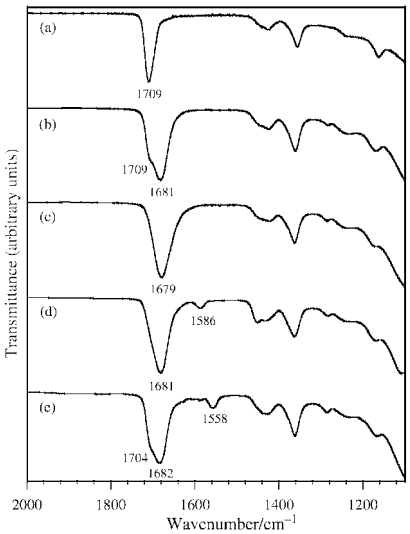

Fig. 1 IR spectra for the solid state interactions of $AgBF_4$ with PVMK and olefins: (a) PVMK, (b) $AgBF_4$:PVMK = 1:4, (c) $AgBF_4$:PVMK = 1:2, (d) propylene-coordinated membrane, (e) buta-1,3-diene-coordinated membrane.

DOI: 10.1039/b003373l

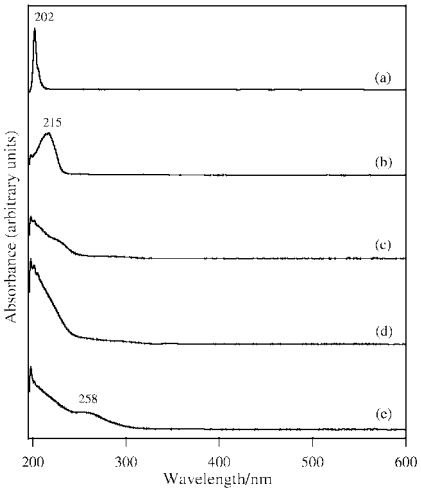

Fig. 2 UV spectra of olefin coordinated $AgBF_4$–PVMK membranes: (a) propylene, (b) buta-1,3-diene, (c) $AgBF_4$–PVMK ($AgBF_4$:PVMK = 1:2), (d) propylene-coordinated membrane, (e) buta-1,3-diene-coordinated membrane.

membrane. These results strongly indicate that the coordinated olefins are not rigidly held to silver ions in the membranes. Therefore, olefins can diffuse from the feed stream across the membrane to the permeate side thereby resulting in selective separation of olefins from the olefin/paraffin mixture.

The coordination of olefins to silver ions in the $AgBF_4$–PVMK membrane results in some significant changes in the absorption band of the coordinated carbonyl groups. As shown in Fig. 1(e), the IR spectrum of the buta-1,3-diene-coordinated membrane shows two carbonyl stretching bands at 1682 and *ca*. 1704 cm^{-1}. The shoulder peak at *ca*. 1704 cm^{-1} can be tentatively assigned to free carbonyl groups of PVMK, and this result strongly suggests that olefins and carbonyl groups compete with each other for coordination to silver ions.

Reversible olefin coordination was also observed by spectral changes in the UV absorption as shown in Fig. 2. Fig. 2(d) shows a strong and broad absorption band at 220–230 nm for propylene coordinated $AgBF_4$–PVMK ($AgBF_4$:PVMK = 1:2). When the propylene coordinated membrane was exposed to buta-1,3-diene atmosphere followed by an N_2 purge, the absorption band at 220–230 nm disappeared and a new band appeared at *ca*. 258 nm associated with coordinated buta-1,3-diene [Fig. 2(e)]. This result again indicates that co-ordinated propylene is labile enough to be readily replaced by other olefins. In the same manner, the absorption band of coordinated propylene at 220–230 nm reappeared when propylene was introduced into the cell containing the buta-1,3-diene coordinated membrane.

The separation of an olefin/paraffin mixture (1:1, v/v) was performed to evaluate the facilitated transport effect of silver ions in PVMK. Fig. 3 shows the effect of the molar ratio of $AgBF_4$/PVMK on the selectivity for olefins over paraffins. The selectivity for propylene (ethylene) over propane (ethane) increases with increasing molar ratio of $AgBF_4$:PVMK up to

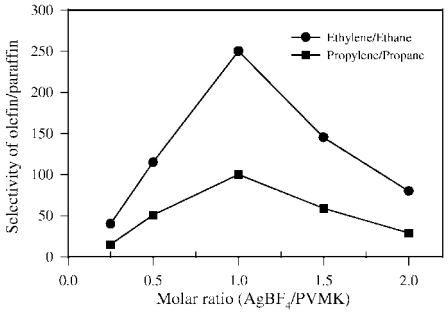

Fig. 3 Effect of molar ratio of $AgBF_4$/PVMK on the selectivity for olefins over paraffin selectivity.

1:1 and then decreases with further increases in the molar ratio. Such a selectivity dependence on the molar ratio of $AgBF_4$:PVMK implies that the coordination environment of silver ions in PVMK has a significant effect on the facilitated transport of olefins. The higher selectivity for ethylene/ethane in comparison with that for propylene/propane can be ascribed to the difference in diffusion rates of the mixture gas and/or to the difference in affinities for the olefins to silver ions in the membrane.

XPS analysis of $AgBF_4$–PVMK membranes is under way to characterize the chemical states of silver, carbon and oxygen atoms in $AgBF_4$–PVMK membranes.

Asymmetric synthesis of (+)-loline

Paul R. Blakemore, Volker K. Schulze and James D. White*

Department of Chemistry, Oregon State University, Corvallis, Oregon 97331-4003 USA. E-mail: james.white.orst.edu

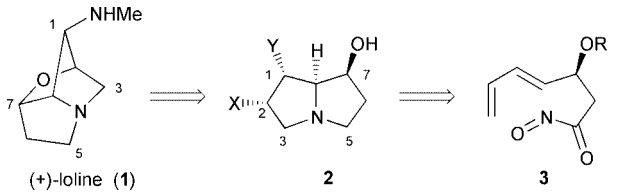
Received (in Cambridge, UK) 18th April 2000, Accepted 22nd May 2000
Published on the Web 22th June 2000

The first asymmetric synthesis of (+)-loline has been achieved in 20 steps from (−)-malic acid by a route incorporating intramolecular hetero-Diels–Alder cycloaddition of an acylnitrosodiene.

The lolium alkaloids comprise a small group of pyrrolizidine bases which possess a unique ether linkage bridging C2 and C7.[1] The principal member of the lolium group, (+)-loline **1**, was first isolated in 1955 from the rye grass *Lolium cuneatum* and its structure was initially misassigned.[2] Subsequently, lolium alkaloids were also found in the pasture grass tall fescue (*Festuca arundinacea*),[3] and most recently have been discovered in the roots of the tropical liana *Argyreia mollis*.[4] Acylated derivatives of loline are toxic to larvae of the horn fly (*Haematobia irritans*), an important arthopod ectoparasite of cattle.[5] A previous synthesis of (±)-loline **1** was reported in 1986 by Tufariello *et al.*[6]

Our plan for the synthesis of (+)-**1** envisioned formation of the bridging ether of loline at a late stage from a suitably functionalized pyrrolizidine core **2** (Scheme 1). Appropriate substituents X and Y could, in principle, be installed by oxidation of an unsaturated pyrrolizidine precursor. The latter was envisioned from a 3,6-dihydro-1,2-oxazine, itself accessible *via* intramolecular hetero-Diels–Alder cycloaddition of acylnitrosodiene **3**. Acylnitroso compounds are highly reactive dienophiles[7] and their cycloaddition chemistry has been exploited in several pyrrolizidine[8] and indolizidine[9] alkaloid syntheses.

The synthesis of a suitable precursor for **3**, hydroxamic acid **10**, began with (*S*)-(−)malic acid **4** (Scheme 2). Conversion of **4** to diene **7** was accomplished in six steps by modification of an existing route to the analogous (*R*)-benzyl ether.[10] Thus, reduction of **4** with $BH_3{\cdot}SMe_2$ was followed by acid catalyzed acetalization of the resulting triol to yield dioxane **5**, $[\alpha]_D^{23}$ + 9.9 (*c* 0.96, $CHCl_3$), as a single diastereoisomer in 64% overall yield. Swern oxidation of the remaining free hydroxy group yielded an unstable aldehyde which was immediately reacted with allylidene triphenylphosphorane to afford diene **6** (*E*:*Z* = 3:7) in 40% yield (two steps). Since only two isomers were observable in both the ^{1}H and ^{13}C NMR spectra of **6** it was concluded that no epimerization of the aldehyde had occurred during the Wittig reaction. Treatment of **6** with 5 equivalents of DIBAL-H selectively reduced the less hindered acetal C–O bond to yield a primary alcohol with concomitant formation of an internal *p*-methoxybenzyl ether. Subsequent iodine (1 mol%) catalyzed photoisomerization (medium pressure mercury lamp, no filter) yielded diene **7** (63% from **6**), $[\alpha]_D^{23}$ −60.3 (*c* 1.10, $CHCl_3$), with *E*:*Z* ≥ 95:5 by ^{1}H NMR analysis. A second Swern oxidation gave an aldehyde which was further oxidized to the carboxylic acid **8** with buffered sodium chlorite. The latter was converted to *O*-succinimidyl ester **9**, and the activated ester was then amidated with hydroxylamine to yield hydroxamic acid **10**, $[\alpha]_D^{23}$ −30.2 (*c* 0.97, $CHCl_3$), in 75% overall yield from **7**.[9a]



Scheme 1

Initial studies of the hetero-Diels–Alder reaction were carried out with the protected hydroxamic acid **12**, previously prepared from diacetone-D-glucose.[11] Oxidation of **12** with a periodate salt generates a highly reactive acylnitroso intermediate which is trapped by the pendant diene to afford a mixture of the diastereomeric oxazines, **13*c*** and **13*t***. A range of reaction conditions for **12** was surveyed in the hope that good selectivity for the desired *cis* oxazine **13*c*** could be achieved (Table 1). Initial results in non-polar solvents were encouraging (entries 1–3) in that **13*c*** was the major product of the cycloaddition; however, the yield and selectivity were only moderate. Changes in temperature generally had little effect, although carrying out the reaction in refluxing benzene (entry 4) improved the overall yield at the expense of *cis* selectivity. The latter conditions are similar to those employed in the dienophile transfer technique reported by Keck and Nickell,[8] which gave very similar results. More polar solvents (entries 5–7) afforded better yields, but the reaction was not selective. Addition of water to the reaction medium resulted in a preference for the unwanted *trans* oxazine **13*t*** (entry 8); the effect of water on selectivity in an analogous reaction was noted previously by Kibayashi and coworkers.[10] The most practical conditions for preparation of **13*c*** (entry 7), when applied to **10** (entry 9), gave a 57:43 mixture of **11*c***:**11*t***. The oxazines **11*c***, $[\alpha]_D^{23}$ + 86.0 (*c* 0.71, $CHCl_3$), and **11*t***, $[\alpha]_D^{23}$ −75.5 (*c* 2.45, $CHCl_3$), were readily separated by silica gel chromatography.

Conversion of oxazine **11*c*** into pyrrolizidine lactam **14** was readily accomplished in three steps (Scheme 3). Reductive scission of the N–O bond of **11*c*** with excess sodium amalgam afforded a monocyclic allylic alcohol in 91% yield. After quantitative mesylation of the hydroxy group, exposure to LDA resulted in smooth cyclization to bicycle **14** (88%), mp 55–56 °C, $[\alpha]_D^{23}$ −72.0 (*c* 0.50, $CHCl_3$), upon warming.

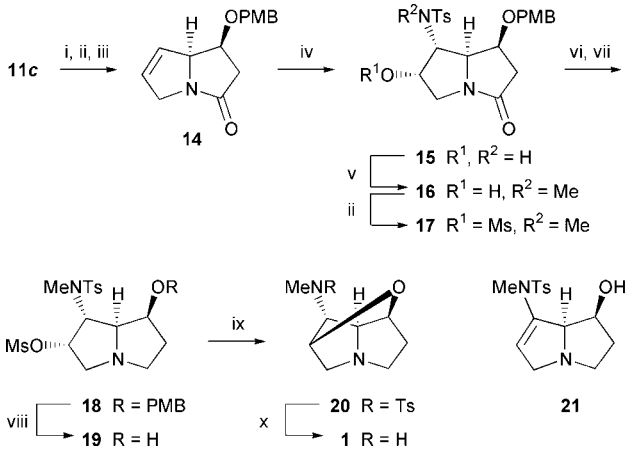
[a] The acylnitroso intermediate was generated *in situ* by slow addition of the hydroxamic acid (**10** or **12**) to a solution of $Bu^n_4NIO_4$ (2 equiv., *ca.* 0.03 M). [b] $NaIO_4$ used. [c] Isolated yield of oxazine products. [d] Determined by ^1H NMR integration of the mixture.



Scheme 3 *Reagents and conditions*: i, 6% Na(Hg), NaH_2PO_4, EtOH, 0 °C; ii, MsCl, Et_3N, CH_2Cl_2, 0 °C; iii, LDA, THF, −78 °C to r.t.; iv, $K_2OsO_2(OH)_4$, $(DHQD)_2PHAL$, chloramine-T, Bu^tOH-H_2O (1:1), r.t.; v, MeI, Bu^tOK, Bu^tOH, 50 °C; vi, $BH_3{\cdot}SMe_2$, THF, r.t.; vii, $Pd(OH)_2/C$, MeOH, r.t.; viii, DDQ, CH_2Cl_2–H_2O (20:1), r.t.; ix, *o*-$Cl_2C_6H_4$, 180 °C; x, sodium naphthalenide, DME, −60 °C.

Exploratory attempts to functionalize the olefinic bond of **14** led us to the discovery that **14** could be aminohydroxylated with the desired regioselectivity under the conditions used by Chang and Sharpless.[12] Thus, treatment of a mixture of **14** and chiral ligand $(DHQD)_2PHAL$ (25 mol%) in Bu^tOH–H_2O (1:1) with chloramine-T (2 equiv.), followed by portionwise addition of potassium osmate (1 mol% every 24 h for 3 days), afforded 40–52% of readily separated amino alcohols, **15** and its regioisomer, in a ratio of 3:1, respectively, together with 21% of a diol. All products were the result of oxidation of **14** from the *exo* face.

Selective methylation of the sulfonamide NH of **15** yielded 76% of **16**, $[\alpha]_D^{23}$ + 49.0 (*c* 0.55, $CHCl_3$); mesylation of the free alcohol then gave a 99% yield of the crystalline lactam **17**, mp 187–190 °C, $[\alpha]_D^{23}$ + 66.1 (*c* 0.70, $CHCl_3$). The latter was reduced with a large excess of $BH_3{\cdot}SMe_2$ (30 equiv.), and the resulting pyrrolizidine–borane complex was decomposed by the combined action of Pearlman's catalyst and methanol to give **18**, $[\alpha]_D^{23}$ + 73.3 (*c* 0.51, $CHCl_3$), in 73% overall yield. Oxidative removal of the PMB ether of **18** with DDQ was sluggish and required over 60 h to afford **19**, mp 175 °C (decomp.), $[\alpha]_D^{22}$ + 45.8 (*c* 0.28, $CHCl_3$), in 70% yield.

Unexpectedly, **19** failed to cyclize to the cage structure of loline under a variety of basic reaction conditions, giving only the elimination product **21** instead. In contrast, direct thermolysis of the hydroxy mesylate in the absence of a base afforded *N*-tosylloline **20**, $[\alpha]_D^{22}$ + 40.9 (*c* 0.11, $CHCl_3$), in 74% yield with no trace of **21**. *N*-Tosylloline prepared by tosylation of a sample of natural loline had $[\alpha]_D^{22}$ +38.0 (c 0.10, $CHCl_3$). Reductive removal of the tosyl substituent from **20** was effected with sodium naphthalenide and afforded (+)-loline **1**, isolated as its dihydrochloride salt in 48% yield. The ^1H and ^{13}C NMR spectra of synthetic material matched exactly those reported for the natural material.[13]

We are grateful to Professor Lowell P. Bush, University of Kentucky, for a sample of loline dihydrochloride and to Professor Joseph J. Tufariello, State University of New York at Buffalo, for the NMR spectra of (±)-loline and its dihydrochloride. One of us (V. K. S.) thanks the Deutsche Forschungsgemeinschaft for a Fellowship. Financial support was provided by the U.S. National Institutes of Health (GM58889).

A simple, general and robust function for equilibria in aqueous electrolyte solutions to high ionic strength and temperature†

Peter M. May

A novel function is proposed to calculate the conditional equilibrium constants of reactions in aqueous solution; two parameters characterise a non-electrolyte-specific response to increasing ionic strength (< 5 M) and temperature (< 250 °C).

How chemical equilibria in solution respond to changing experimental conditions is of considerable theoretical and practical importance. A good function is needed to model natural and industrial systems and to analyse the vast array of experimental data on which such models depend. Since electrolyte solutions depart strongly from ideality, this has proved elusive[1] and, consequently, many different functions have been employed.[2]

Among the most common approaches nowadays are the Pitzer,[3] the Brønsted–Guggenheim–Scatchard Specific Ion Interaction (SIT),[1] the Helgeson–Kirkham–Flowers (HKF)[4] and the Density[5] models. However, none is the obvious method of choice and, of the many tens of thousands of reactions of interest, only a small fraction have been characterised using these functions.[6]

The main problem with the Pitzer, SIT and HKF models lies in the numerical fitting of parameters that they use to describe individual chemical systems. Although very good agreement with experimental data can be achieved, many 'interaction coefficients' are typically involved. Predictions are then put in doubt because (a) the fitted parameters do not capture the essence (*i.e. only* the predominant factors) of the underlying *general* physicochemical behaviour and (b) unique characterisation becomes difficult, and extrapolations thwarted, by mathematical correlation (covariance).

In contrast, the parameters of the Density model are much fewer, are entirely fundamental and can be measured independently. The Density model thus provides an excellent means for assessing and predicting data under ideal conditions, *i.e.* at infinite dilution. It has been used extensively for these purposes at the U.S. Oak Ridge National Laboratories (ORNL),[8] whose results comprise by far the largest single body of reliable equilibrium constants in aqueous electrolyte solutions, especially at higher temperatures.[7]

Unfortunately, the Density model as described by Andersen *et al*.[5] does not deal directly with the effects of ionic strength. Extraneous and varied means are invoked to extrapolate measurements to infinite dilution, a notoriously difficult task even at ambient temperatures with plenty of data. A failure to record properly in databases the particular smoothing function used, and the parameters so obtained, exacerbates the problem. Sometimes more than ten fitting parameters are employed.

To extend the Density model to finite concentrations, I propose here, a novel function that calculates the conditional equilibrium constants of reactions in aqueous solution. The function is based on just two additional semi-empirical parameters that characterise the effects of increasing ionic strength and temperature in a non-electrolyte-specific manner. The need for, and magnitude of, specific interaction coefficients is thus much reduced.

The scientific description of the effect of ionic strength on equilibria in electrolyte solutions has recently been reviewed.[2] Soon after Debye and Hückel demonstrated the dominance in dilute solutions of coulombic interactions between ions, Hückel suggested that the expression for the mean ionic activity coefficient, $\gamma_{\pm}$, could be extended to higher concentrations by introducing a linear term, ascribed to 'ion-solvent interactions'. Guggenheim then proposed a formula for mixtures in which this linear term is expanded into a summation involving the so-called 'ion interaction coefficients'. This formula underpins the SIT model in current use today.

There is considerable experimental evidence showing that activity coefficients (and, hence, conditional equilibrium constants) vary in a way that accords with this linear behaviour. However, no theoretical explanation has prevailed, allowing the proliferation of correction functions described above.

An equation that works satisfactorily[8] at constant temperature (t) has the form

$$\log_{10} K' = \log_{10} K^0 + \left(\frac{-\Delta Z^2 A\sqrt{I}}{1+1.5\sqrt{I}} \right) + BI \qquad (1)$$

where K' is the conditional equilibrium constant at finite ionic strength, K^0 is the equilibrium constant (at infinite dilution), and A and ΔZ^2 are the usual Debye–Hückel factors. Both B and the factor in the denominator, shown here as 1.5 to accord with the SIT model,[1] must be nearly constant to maintain thermodynamic consistency but their exact values are somewhat arbitrary on account of the covariance between them.

The key observation of the present work is simply that the value of B itself changes linearly with temperature. To represent this behaviour in accord with the Density model (for which all parameters refer to a reference temperature) this variation is conveniently expressed as $B = G_C + G_M (t - 25)$, where the symbols G_C and G_M refer to the intercept and slope respectively of the Guggenheim factor B at 25 °C.

The linearity of the expression for B is important in the maintenance of thermodynamic consistency when the function is applied to reactions in general. Also important is the low correlation between the five parameters of the extended Density model (log K^0, ΔH^0, ΔC_p^0, G_C and G_M).

The new function has been applied in the characterisation of reaction data in the JESS Thermodynamic database.[6] Although much is still to be done, it is clear that in this way the vast majority of compiled equilibrium constants can be rationalised to well within their experimental error. Very few exceptions have been encountered and these exhibit no discernable pattern, leaving experimental error as their most likely explanation.

A very demanding test was provided by the ORNL data, comprising more than 700 equilibrium constants of unsurpassed precision and accuracy for over 30 reactions. All these chemical systems were fitted satisfactorily. The median deviations between observed and calculated data were typically better than 0.05 log K units and the worst rarely greater than 0.1 units.

† Electronic supplementary information: plots for 38 chemical systems of conditional equilibrium constants as a function of ionic stength and temperature. See http://www.rsc.org/suppdata/cc/b0/b003157g/

DOI: 10.1039/b003157g

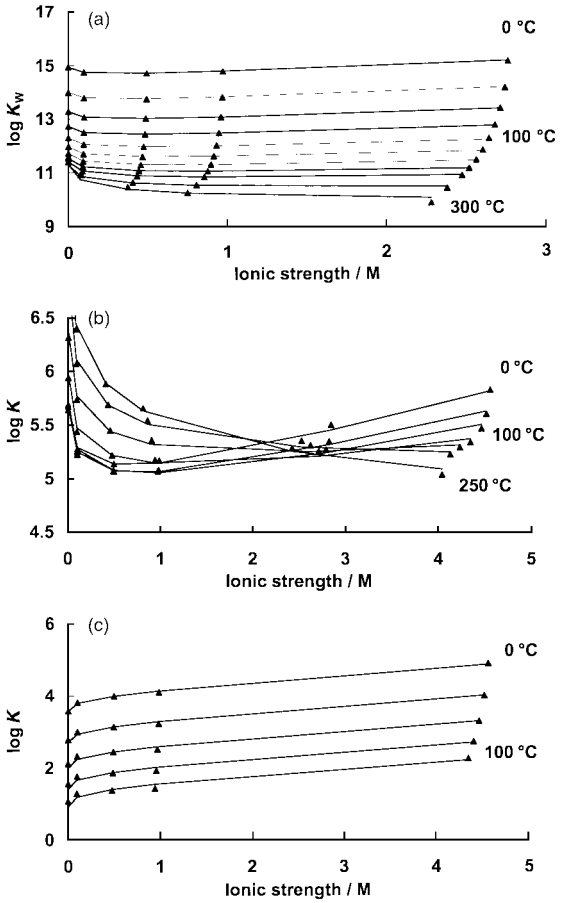

Fig. 1 Illustrative plots of observed and predicted values for conditional equilibrium constants as a function of ionic strength and temperature with three different types of chemical reaction: (a) the hydrolysis of water,[10] (b) the first protonation of succinate[11] and (c) the solubility of gibbsite.[12]

These differences are small compared to the changes in the measured equilibrium constants which over the intervals $0 \leqslant I \leqslant 5.0$ M and $0 \leqslant t \leqslant 250$ °C typically vary by as much as 3 log K units. It may even be possible to improve on these predictions for data at higher temperatures by taking account of density change in the electrolyte medium, but this remains to be done.

Three examples, representing quite different types of behaviour, are shown in Fig. 1. Plots for 38 chemical systems have been deposited as ESI.†

Despite the formal mathematical similarity between the function being proposed here and that of the SIT method, the two approaches differ diametrically. Whereas the (temperature-dependent) SIT parameters are many (one for each ion–counter ion, ion–neutral and neutral–neutral interaction[1]) and represent *specific* interactions, just two values, G_C and G_M, are used in this work to characterise the *non-specific* response of the reaction to changing conditions. It seems much better to attribute specific properties only to the *differences* in equilibrium constants observed in different background electrolytes at the same ionic strength and temperature: this isolates behaviour that is common to all electrolytes, such as caused by the general reduction in water activity with increasing concentration, and it keeps the magnitude of the specific factors to a minimum. The effects of individual electrolytes can then simply be described as a direct association between species (see *e.g.* ref. 9), which generally yields even better fits of the data.

The observed data are nonetheless modelled well, albeit not exactly, by the non-specific function on its own. This has all the flexibility needed to follow the main trends exhibited by equilibria to high concentrations (≈ 5 M) and high temperature (≈ 250 °C). It also possesses the three chief attributes necessary to rationalise diverse experimental data and to predict values beyond the range of parameterisation, namely it (a) appears applicable to all types of reaction, (b) involves only a few parameters and (c) offers a reasonable physicochemical basis for avoiding optimisation of values when this is not warranted by the data available.

Financial support from Murdoch University and from the Australian Government under its Cooperative Research Centres Program is gratefully acknowledged.

The hydrothermal crystallisation of barium titanate, $BaTiO_3$, has been studied for the first time by *in situ* time-resolved neutron powder diffraction; we deduce that $BaTiO_3$ is formed from solution by reaction between $[Ti(OH)_x]^{(4-x)+}_{(aq)}$ and $[Ba(OH)_x]^{(2-x)+}_{(aq)}$ species, rather than by a heterogeneous reaction between solid TiO_2 and $Ba^{2+}_{(aq)}$ ions.

Tetragonal barium titanate, t-$BaTiO_3$, finds widespread application in the electroceramics industry. The ferroelectric properties and high permittivity of t-$BaTiO_3$ are exploited in, for example, thermistors, capacitors, and electro-optic devices. Traditional routes to the synthesis of the material employ direct solid-state reaction between barium carbonate and titanium dioxide at elevated temperature (> 900 °C). Hydrothermal routes to $BaTiO_3$ have been the focus of much recent research as an efficient low temperature method for its manufacture (see, for example, refs. 1–3). The reaction of a number of barium and titanium sources in water at temperatures as low as 80 °C has enabled the production of t-$BaTiO_3$ and by varying reaction conditions and choice of starting materials it has proved possible to change the particle size and morphology of the material produced. Particular attention has been paid to the production of ultrafine (submicron) powders[1–4] and to the production of thin films[5–7] by the hydrothermal method. Such control of morphology is extremely desirable and has huge potential value, both in the manufacture of miniaturised devices[8,9] and in the production of dense fine-grained ceramics by sintering of the fine powders initially prepared.[10]

An understanding of the formation mechanism will be vital if controlled growth of t-$BaTiO_3$ is to be performed and the potential applications described above are to be exploited. Although the kinetics and mechanism of hydrothermal barium titanate production have been discussed by several authors,[11–14] no agreed description of its formation mechanism has been reached. Two extreme models have been postulated: one involving a homogenous solution phase reaction between titanium and barium hydroxy anions (the dissolution–precipitation mechanism) and another involving the reaction between solid TiO_2 and soluble barium species (the *in situ* heterogeneous transformation mechanism).[12] The data previously used to probe the kinetics of barium titanate crystallisation were derived entirely from quenching experiments, whereby material was removed from the reaction cell after given period of time and examined.

Because of the absorbing nature of the sample, we were unfortunately unable to probe the barium titanate crystallisation using *in situ* time-resolved synchrotron X-ray diffraction experiments, which are now well established.[15,16] Powder neutron diffraction, however, offers an alternative means of following the crystallisation. In recent months we have developed a gold coated, null-scattering (67.7 atom% Ti, 32.3 atom% Zr) environmental cell that enables us to record *in situ* high-resolution powder neutron diffraction patterns of highly reactive and/or corrosive materials reacting under hydrothermal conditions.[17] Only one previous report of the use of neutron diffraction to follow reactions under hydrothermal conditions appears in the literature, and this did not overcome the problem of significant scattering from the reaction vessel appearing in the diffraction patterns, which seriously limited the amount of quantitative and structural information that could potentially be extracted.[18] Here, we describe the first use of the Oxford-ISIS hydrothermal cell to study a hydrothermal synthesis using *in situ* neutron diffraction.

Fig. 1(a) shows the time-of-flight powder neutron diffraction patterns of the crystalline starting materials [TiO_2 (2.12 g) $Ba(OD)_2{\cdot}8D_2O$ (9.81 g), Ba : Ti ratio of 1.1 : 1] as a suspension in 10 ml D_2O in the hydrothermal cell before heating.† The cell was then heated to 125 °C and neutron diffraction patterns

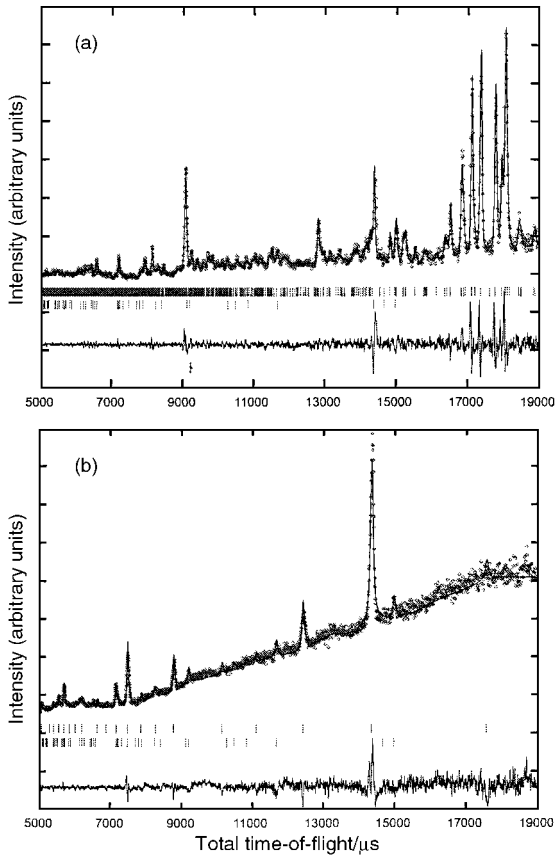

Fig. 1 Powder neutron diffraction data obtained from within the hydrothermal cell. for (a) $Ba(OD)_2{\cdot}8D_2O$ (upper tick marks) and TiO_2 (lower tick marks) in D_2O and (b) for the barium titanate produced by heating the mixture at 125 °C for 12 h (lower tick marks are unreacted TiO_2). The points are the experimental data, the full line the result of the whole pattern fitting, and the lower line the difference curve.

DOI: 10.1039/b003386n

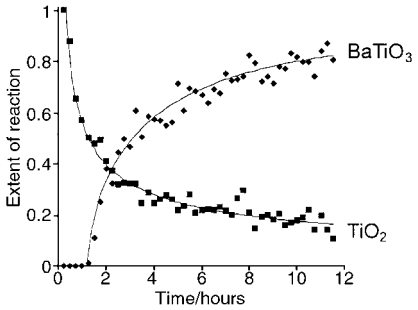

Fig. 2 Changes in integrated Bragg peak intensities for TiO_2 and $BaTiO_3$ during reaction at 125 °C. Line are guides to the eye and have no physical significance.

recorded every 15 min for a period of 12 h. Fig. 1(b) shows the sum of the four final diffraction patterns obtained, *i.e.* 1 h of data in total. These data can be successfully modelled as arising from cubic $BaTiO_3$. At 125 °C we would have expected t-$BaTiO_3$ to have formed since at temperatures below 130 °C the lower symmetry form is thermodynamically more stable. These synthesis conditions, however, produce submicron-sized particles of $BaTiO_3$ and as has previously been pointed out, it is very difficult to identify the $BaTiO_3$ polymorph using diffraction methods when the Bragg reflections are considerably broadened by the small particle size.[2,19]

Integrated intensities of the well resolved Bragg reflections were determined by Gaussian-fitting and this enabled decay and growth curves of both the starting materials and products to be quantitatively determined. Fig. 2 shows the extent of reaction ($\alpha = I/I_\infty$) curves *vs.* time derived from integrated intensities of TiO_2 and $BaTiO_3$ as a typical reaction mixture was heated at 125 °C. The growth curves for all the resolved Bragg reflections of $BaTiO_3$ were identical suggesting that crystal growth is isotropic, which is not unexpected given the spherical morphology of particles typically produced by this hydrothermal synthesis. We also have investigated the use of amorphous $TiO_2{\cdot}H_2O$ as a titanium source, which has recently been used to prepare submicron $BaTiO_3$ particles,[2] and confirmed that the rate of reaction is considerably more rapid compared to the crystalline source.

The neutron diffraction data clearly show that the crystalline barium source, barium deuteroxide octahydrate dissolves rapidly before any other changes in crystallinity are apparent in the reaction mixture; in all cases the Bragg reflections of $Ba(OD)_2{\cdot}8D_2O$ disappear in less than 1 h and always before the appearance of any $BaTiO_3$. All previously discussed mechanisms for the hydrothermal crystallisation of barium titanate suggest that the barium source is in solution and our *in situ* results provide clear evidence for this assumption. Most significantly, when crystalline TiO_2 is used as the titanium source its initial decay is rapid and more than 50% of the TiO_2 dissolves before the appearance of any of the $BaTiO_3$ product. This strongly suggests that a dissolution–precipitation mechanism is taking place, *i.e.* that barium titanate is formed by reaction between dissolved $Ba^{2+}_{(aq)}$ and $[Ti(OH)_x]^{(4-x)+}_{(aq)}$ species. If reaction between Ba^{2+} ions in solutions and solid TiO_2 particles was taking place, then we would expect the rate of formation of $BaTiO_3$ to mirror the decay of TiO_2. Some previous studies have assumed the latter *in situ* heterogeneous transformation mechanism,[11] but more recent studies using electron microscopy techniques find no evidence for this model; for example Pinceloup *et al.* examined the quenched material from barium titanate crystallisations after various periods of time and always observed distinct titania or barium titanate particles, and that there was no relationship between particle size distribution in the titanium oxide starting material and the barium titanate product.[14] Our study thus provides independent evidence for the dissolution–precipitation mechanism by a novel technique.

The kinetic crystallisation curves can be analysed quantitatively using the Avrami–Erofe'ev expression for a nucleation-growth mechanism.[20–23] We find that the power dependence (n) of the rate expression is 1.1 ± 0.5. A value of $n = 1$ suggests that the rate determining step of reaction is the reaction at the phase boundary, *i.e.* the chemical reaction taking place at the nucleation sites between solution Ba^{2+} and $[Ti(OH)_x]^{(4-x)+}$ anions. This study has thus provided a firm foundation on which to base a mechanism for the hydrothermal crystallisation of barium titanate.

In summary, we have demonstrated in this paper that neutron diffraction has the potential to be a powerful technique for the study of chemical processes under non-ambient conditions. It offers the potential for collecting new data not available using other sources and also data complementary to that available from analogous *in situ* synchrotron X-ray diffraction experiments. We believe with the ongoing improvements in available neutron flux and in detector technology it will be possible to collect data of higher quality in shorter time intervals from reaction vessels such as we have described.

We thank the EPSRC for financial support and provision of beam-time at the ISIS Facility.

Notes and references

† Neutron diffraction patterns presented were recorded in the high resolution backscattering detector bank [2θ(av.) = 45°] of the POLARIS diffractometer at the UK pulsed spallation neutron source ISIS, Rutherford Appleton Laboratory. The hydrothermal autoclave was loaded with TiO_2 (2.12 g), $Ba(OD)_2{\cdot}8D_2O$ (9.81 g) and D_2O (10 g) under a dry nitrogen atmosphere and rapidly heated under autogeneous pressure at 125 °C. The TiO_2 was purely in the anatase polymorph, and this was confirmed by the good fit achieved to the neutron diffraction data. The structure of barium hydroxide octahydrate has been determined using single crystal X-ray diffraction methods[24] and using the cell parameters previously found as a starting point for refinement against the neutron data allowed confirmation of the identity of the barium source [X-ray values: a = 9.274 Å, b = 9.260 Å, c = 11.817 Å, β = 98.95°,[24] neutron refined values: a = 9.3137(3) Å, b = 9.3043(3) Å, c = 11.860(8) Å, β = 98.995(3)°].

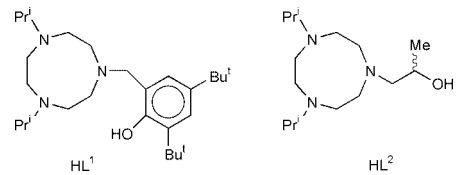
Reaction of $AlMe_3$ or [$AlMe_3$·py] with the pendant arm OH-funtionalised 1,4,7-triazacyclononane proligands, HL^1 or HL^2, affords the four- and five-coordinate derivatives [Al(L^1)Me_2] 1 or [$Al_2(L^2)_2Me_4$] 2 in which the pendant alkoxide O-donor and only *one* macrocycle N-donor is bound to Al; methyl anion abstraction from 1 yields cationic, pentacoordinate [Al(L^1)Me]$^+$ in which L^1 has a tetradentate coordination mode [L^1 = 1-(2-hydroxy-3,5-di-*tert*-butylbenzyl)-4,7-diisopropyl-1,4,7-triazacyclononane; L^2 = 1-(2-hydroxy-2-methylethyl)-4,7-diisopropyl-1,4,7-triazacyclononane].

Pendant-arm macrocycles offer the ability to modify and tune the electronic and stereochemical properties of a range of metal centres,[1] and may be regarded as potent protecting groups for catalytic reactions. We were therefore interested to explore the potential of pendant arm triazacyclononane ligands in neutral and cationic organoaluminium chemistry, for which there is no precedent in the literature, although several examples of compounds involving N-substituted 1,4,7-triazacyclononane ligands with the group 13 elements are known. Aluminium compounds in general are widely used as reagents or catalysts across a range of organic and inorganic chemistry, and cationic complexes, in particular, can lead to enhanced reactivity through more effective substrate coordination and activation.[2] We report herein preliminary results, including the first structurally authenticated examples of complexes having a triazacyclononane ligand coordinated through only *one* nitrogen, together with the first example of a cationic *p*-block organometallic complex of a triazacyclononane ligand.

Reaction of $AlMe_3$ or $AlMe_3$·py with HL^1 or HL^2 causes elimination of methane and affords the mono- or bi-nuclear



compounds [Al(L^1)Me_2] **1** and [$Al_2(L^2)_2Me_4$] **2** in good to fair yield (Scheme 1).†[3a] The molecular structures of **1** and **2** are shown in Figs. 1 and 2, respectively.‡ The compound [Al(L^1)Me_2] **1** possesses an approximately tetrahedral Al(III) centre [range of angles subtended at Al(1): 95.0(2)–119.8(2)°], the coordination sphere of which comprises two methyl groups, the oxygen atom of the pendant phenoxide group and only one N-donor of the triazacyclononane ligand. The compound [$Al_2(L^2)_2Me_4$] **2** features two approximately trigonal bipyramidal Al(III) centres [*e.g.* N(1)–Al(1)–O(28) 151.0(2)°; sum of the angles subtended at Al(1) by O(13), C(14), C(15) = 360.1°] with the pendant oxygen donors bridging them. The most important and highly unusual feature of **1** and **2** is that only *one* of the three macrocyclic N-donors binds to the Al(III) centre. That **2** forms a binuclear, μ-O-bridged complex is attributed to steric factors, the greater steric bulk of L^1 stabilising the mononuclear complex.

The low temperature, high-field NMR spectra of the highly fluxional compounds **1** and **2** are consistent with the solid state structures.† Of special note for both compounds is the presence of two low-field multiplets in the range δ 4–5 of the ^{1}H NMR spectra; these are assigned to two of the macrocylic ring methylene hydrogens. These shifts appear to be particularly diagnostic of the mono-N-coordinated mode of ligation of the ligands L^1 and L^2, as such features are absent from the ^{1}H NMR spectra of structurally authenticated tri-N-coordinated transition and main group metal complexes of pendant arm derivatives of triazacyclononanes.[3a,4]

The reaction of HL_2 or [$Al_2(L^2)_2Me_4$] **2** with 2 equiv. of $AlMe_3$ cleaves the dimer and gives binuclear [Al(L^2·AlMe_3)Me_2] **3** (Scheme 1) in which $AlMe_3$ is bound to the pendant alkoxide oxygen,‡§ rather than forming a product with the $AlMe_3$ bound to a nitrogen lone pair of L^2. As for **1** and **2**, the triazacyclononane ring in **3** binds through only one nitrogen, and the ^{1}H NMR spectrum shows a diagnostic pair of multiplets in the region δ 4–5. In contrast, [Al(L^1)Me_2] **1** does not react at all with $AlMe_3$, suggesting that neither the phenoxide oxygen nor the macrocycle nitrogen lone pairs are accessible.

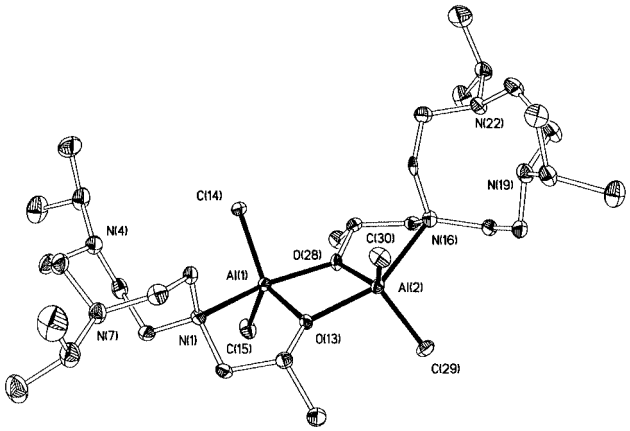

Fig. 2 Displacement ellipsoid plot of $[Al_2(L^2)_2Me_4]$ **2** Hydrogen atoms are omitted for clarity and displacement ellipsoids are drawn at the 40% probability level. Selected bond lengths (Å): Al(1)–O(13) 1.849(3), Al(1)–N(1) 2.245(4), Al(1)–C(14) 1.977(5), Al(1)–C(15) 1.972, Al(1)–O(28) 1.935(3), Al(2)–O(28) 1.845(3), Al(2)–N(16) 2.265(4), Al(2)–C(29) 1.966(5), Al(2)–C(30) 1.983(5), Al(2)–O(13) 1.946(3).

The mono-N-coordination modes for L^1 and L^2 in compounds **1**–**3** are unique in the now very extensive and important field of triazacyclononane ligand coordination (transition and main group metal) chemistry.[1,3] While there are a few examples of triazacyclononane ligands bonding through only two nitrogen ligands, these are found only for later transition metals where ligand field effects (*e.g.* those associated with d^8 square planar complexes) are particularly dominant.[5] Only one triazacyclononane complex of aluminium has been previously structurally characterised, namely six-coordinate [Al(L)] where L is the tris(pendant arm) ligand 1,4,7-$(O_2CCH_2)_3$[9]aneN_3.[6]

As mentioned above, there is considerable current interest in well defined, cationic organoaluminium compounds.[2c–g] Reaction of $[Al(L^1)Me_2]$ **1** with $B(C_6F_5)_3$ gives $[Al(L^1)Me][MeB(C_6F_5)_3]$ **4** (Scheme 1). We have not yet obtained diffraction-quality crystals of **4** and so this complex has been characterised by non-crystallographic techniques.† The ^1H and ^{19}F NMR data for the $[MeB(C_6F_5)_3]^-$ anion show that there is no interaction with the $[Al(L^1)Me]^+$ cation in which L^1 now bonds to Al through *all three* macrocyclic nitrogens.[7] This coordination mode is suggested by the *ca*. 0.3–0.9 ppm downfield ^1H NMR shifts of the NPr^i group resonances compared to those in **1**–**3** (consistent with bonding to a cationic metal centre) and the absence of any macrocyclic ring methylene resonances in the region δ 4–5 which would be expected for a mono-N-coordinated L^1. Analogous trigonal bipyramidal coordination modes have been reported for $[Zn(L^1)Cl]$ and its homologues.[3a]

Compound **4** is the first example of a cationic *p*-block organometallic complex of any triazacyclononane ligand. Moreover, the interconversion of coordination modes (mono-N-bound in **1** to tri-N-bound in **4**) has never before been observed for triazacyclononane complexes, and the current work suggests that the hemilability of functionalised [9]ane_3 ligands can be used to control and tune the reactivity of the Al centre. Preliminary studies of the reactions of other complexes $[Al(L)Me_2]$ (L = monopendant arm functionlised triazacyclononane) with $B(C_6F_5)_3$ show that other examples of organoaluminium cations related to **4** can be prepared, and reactivity studies of these cations towards organic substrates are in progress.

This work was supported by the EPSRC and Royal Society. We thank Dr N. A. H. Male for helpful discussions.

Notes and references

† Full spectroscopic data and elemental analyses have been obtained for all the new compounds which were prepared under dry, anaerobic conditions.

Impregnation of a mesoporous xerogel or of MCM-41 with an organic solution of the heterometallic cluster $[NEt_4][Co_3Ru(CO)_{12}]$, followed by thermal treatment under an inert atmosphere, leads to highly dispersed magnetic nanoparticles under milder conditions than when conventional metal salts are used as precursors.

The confinement of molecular clusters in the cavities of meso- or nano-porous inorganic matrices is attracting increasing interest as a way to stabilise highly dispersed metals in the form of atoms, clusters or colloids and prevent their coalescence into larger, ill defined aggregates. There are obvious implications for the fabrication of microelectronic devices[1] and for catalytic reactions whose selectivity will critically depend on the size and dispersion of the metal particles and also on the shape of the cavity in which they are embedded.[2] Numerous recent reports have emphasised the specific magnetic, optical, electrochemical, chemical and catalytic properties of nanostructures constructed from molecular clusters or colloids.[3] The sol–gel process is being increasingly applied to the design of new materials using functional building blocks[4] and it has already been used to incorporate mono- and bi-metallic species into inorganic matrices.[2c,5] Furthermore, solids with a template-based morphology control, such as zeolites and MCM-41, are currently attracting increasing attention as a way to stabilise highly dispersed metal particles endowed with unique properties (*e.g.* magnetic, catalytic, *etc.*).[6] A challenging development concerns the use of molecular mixed-metal clusters since microalloy particles could be obtained that would not be accessible by other, more conventional approaches.

With the aims of studying the influence of the structure of the inorganic matrix on the metal particles obtained after thermal treatment of confined molecular Ru/Co clusters, we have compared a mesoporous silica of the MCM-41 type with mesoporous silica xerogels.

A sample of MCM-41[7a] (pore diameter *ca.* 27 Å, specific surface area 1000 $m^2\ g^{-1}$) was impregnated with a dark red saturated THF solution of $[NEt_4][Co_3Ru(CO)_{12}]$,[8] resulting in a Co/Si molar ratio of 0.07 (EDX analysis). When a 1×10^{-3} M solution of the cluster was used, its discoloration from dark red to light red optically indicated adsorption of the cluster onto MCM-41. The solid was then rinsed with THF until the filtrate was colourless and drying under primary vacuum at room temperature (24 h) afforded an ochre powder which was kept under argon. The IR spectrum in the ν(CO) region contained the fingerprint absorptions of the molecular cluster.[8] X-Ray powder diffraction showed the absence of crystallised $[NEt_4][Co_3Ru(CO)_{12}]$, consistent with a high dispersion of the molecular cluster. The typical IR ν(CO) pattern was lost around 200 °C whereas the unsupported cluster decomposes at *ca.* 150 °C, which is consistent with a stabilising effect of the matrix. Furthermore, for the first time to our knowledge, the thermal evolution of the impregnated MCM-41 was followed by magnetic measurements in original lab-built equipment allowing heating of the sample under either reducing (H_2, N_2–5% H_2) or inert atmospheres (Ar). Magnetisation at 1 Tesla progressively increases above 250 °C to reach a maximum at *ca.* 550 °C [Fig. 1(a)]. Further heating results in a decrease of the magnetisation consistent with a Curie point at *ca.* 980 °C. In comparison, a similar experiment on the pure cluster showed an increase in the magnetisation by 180 °C and a Curie temperature around 650 °C. In both cases, the Curie temperature is lower than in pure bulk cobalt (*ca.* 1115 °C), which may be interpreted as resulting from the formation of Co/Ru alloys and/or from the small size of the particles. This will be further investigated by variable temperature XRD experiments under an inert atmosphere.

A crushed mesoporous xerogel[9] (pore diameter *ca.* 35 Å along with microporous domains, specific surface area 750 $m^2\ g^{-1}$) was impregnated, dried and thermally treated in the same manner. The Co/Si molar ratio was *ca.* 0.025 (EDX analysis). Magnetisation at 1 Tesla increases above 200 °C in a stepwise manner and reaches a maximum around 550 °C with a Curie temperature around 1000 °C [Fig. 1(b)]. For consistency, the magnetisation is expressed as per gram of cobalt to account for the different metal content in the samples.

Thermal treatments under argon were realised at 250, 350 and 500 °C on both materials. In all cases, TEM observations showed metal particles which for MCM-41 were well dispersed with a narrow size distribution (Table 1) whereas in the xerogels, the dispersion is less regular. At 500 °C, the small particles (*ca.* 30 Å) coalesce to form larger, ill defined aggregates (*ca.* 200 Å). This clearly points to a structural effect

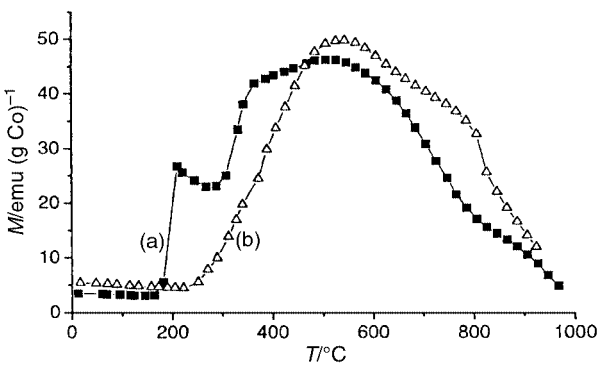

Fig. 1 Dynamic magnetic measurements under Ar of MCM-41 (a) and silica xerogels (b) impregnated with a saturated THF solution of $[NEt_4][Co_3Ru(CO)_{12}]$.

† Dedicated to the memory of Professor O. Kahn, who made so many brilliant contributions to inorganic chemistry.

Table 1 Sizes of the particles (Å) observed by TEM on MCM-41 and xerogels, after 1 h treatment under Ar at different temperatures

	T/°C		
	250	350	500
MCM-41	10	15	80
Xerogel	30	60	30/200

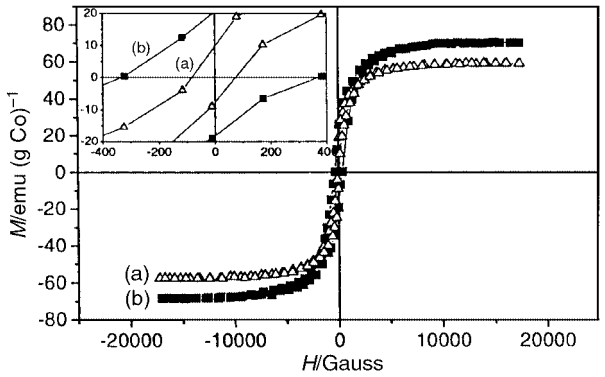

Fig. 2 Isothermal magnetic measurements at room temperature of MCM-41 (a) and silica xerogels (b) impregnated with a saturated THF solution of $[NEt_4][Co_3Ru(CO)_{12}]$, after 1 h treatment under Ar at 500 °C. Inset: expansion near zero shows an increase of the coercitivity for the monoliths.

of the inorganic matrix. Electron diffraction patterns performed on the particles observed after a thermal treatment at 500 °C show the presence of three different metallic phases: pure hexagonal cobalt, pure fcc cobalt, and pure hexagonal ruthenium; no alloy was formed at such low temperature. In contrast, X-ray diffraction after thermal treatment at 900 °C showed that a Co/Ru hexagonal alloy is also present besides pure metallic fcc cobalt and hexagonal ruthenium. Using Vegard's law, we have determined the composition of this alloy to be 86 atom% Co.

Hysteresis loops recorded at ambient temperature on the different samples are consistent with the particles sizes, since no open loop is observed for the doped MCM-41 treated below 350 °C. The xerogels show a ferromagnetic behaviour when treated at or above 350 °C (Fig. 2). In the other samples, superparamagnetic behaviour is observed. Particularly noteworthy is that, irrespective of the matrix, metal particles could be obtained at such a low temperature, without the use of a reductive atmosphere, which cannot be achieved when metal salts [*e.g.* cobalt(II) nitrate][10] are used since a hydrogen atmosphere is required to generate metallic behaviour. This is clearly due to the low oxidation state of the molecular precursor used.

Finally, the differences observed, on the one hand between the impregnated and the unsupported precursor and on the other, between the two impregnated materials, clearly indicate that the magnetic properties originate from particles inside the porous materials and not from intact molecular precursor or metal salts resulting from its decomposition, present at the external surface of the grains.

The approach presented here, which involves in the impregnation of well defined heterometallic, low oxidation-state, organometallic clusters into a given porous silica matrix, followed by thermal treatment under an inert atmosphere leads to the formation of magnetic metal particles at temperatures as low as 250 °C. The differences observed between the two kinds of materials concerning the repartition and sizes of the nanoparticles, as well as their magnetic behaviour highlights the structural effect of the inorganic matrix that should allow control of the particle size in the nanometer range and, accordingly, their magnetic properties.

We are grateful to Dr M. Drillon for valuable discussions and the Centre National de la Recherche Scientifique and the Région Alsace for support (Doctoral grant to F. S).

Nano-size stripes of self-assembled bolaform amphiphiles

Song Gao,[a] Bo Zou,[a] Lifeng Chi,[ab] Harald Fuchs,[b] Junqi Sun,[a] Xi Zhang*[a] and Jiacong Shen[a]

[a] *Key Lab of Supramolecular Structure and Spectroscopy, Department of Chemistry, Jilin University, Changchun 130023, P.R. China*

Received (in Cambridge, UK) 2nd May 2000, Accepted 6th June 2000
Published on the Web 26th June 2000

Self-assembled nano-sized stripes are obtained spontaneously by electrostatic adsorption of bolaform amphiphiles onto mica sheets. The ordered stripes are separated from each other by about 10 nm, and the ordered region can extend over macroscopic areas.

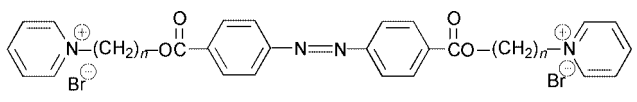
Amphiphiles at interfaces are a traditional but challenging topic in colloid chemistry, and now especially in supramolecular science.[1,2] Bolaform amphiphiles are molecules containing two hydrophilic moieties connected by a hydrophobic chain.[3] It is shown that bolaform amphiphiles have different aggregation behaviors,[4] and cationic bolaform amphiphiles can form a self-assembled monolayer on negatively charged substrates.[5,6] Surface patterning with microscopically defined structures is another rapidly developing topic.[7] Some interesting results have recently been reported concerning the regular packing of two-dimensional aggregates formed by amphiphilic molecules at the air–water interface and transferred onto solid substrates.[8,9] The self-assembled monolayer of the polyether dendron can lead to the formation of a patterned surface with nanometer-sized features and the nanostructure can be controlled by the size of the dendron.[10,11]

Combining the above two fields, we herein report not only the interfacing self-assembly of bolaform amphiphiles, but also an approach for creating ordered nano-sized surface structures. They are obtained spontaneously by electrostatic adsorption of bolaform amphiphiles containing rigid hydrophobic azobenzene groups and hydrophilic pyridinium head groups onto mica slides. The size of the structure is in the nanometer region and it is formed by molecular self-assembly at the liquid–solid interface. Our main interest is to establish a method for surface patterning and to understand how the experimental conditions or chemical structure influence the molecular packing in the self-assembled nano-structures.

The bolaform amphiphiles included in this work are azobenzene-4,4′-dicarboxylic acid bis(pyridiniohexyl ester) dibromide (**azo-11**), and azobenzene-4,4′-dicarboxylic acid bis(pyridinioundecyl ester) dibromide (**azo-6**) (Scheme 1). The syntheses of the substances are described elsewhere.[4] Scanning force microscopy (SFM) observation of the self-assembled nano-structures was carried with commercial instruments (Digital Instrument, Nanoscope III, Dimension 3000™ and Multimode™), operating in tapping mode.

To construct nano-sized stripes on mica a clean mica sheet was immersed into aqueous solution of **azo-11** (*c*. = 1.0×10^{-4} M, unless given otherwise). After adsorption for a certain time, the mica sheet was taken out and dried for about 30 min in a desiccator (P_2O_5). Except for the kinetics study, adsorbing time was 30 min for **azo-11** and **azo-6**.

Confocal Raman of the mica sheet after immersion in **azo-11** solution for 30 min confirmed that dicationic **azo-11** was



n = 6, **azo-6**; *n* = 11, **azo-11**

Scheme 1 Chemical structures of bolaform amphiphiles.

successfully adsorbed. We observed four peaks at 1403, 1457, 1497 and 1602 cm^{-1}, where the former two peaks corresponded to azo Fermi, and the latter two peaks were attributed to benzene.

The adsorption kinetics were studied by analyzing the film coverage from SFM images. This increases rapidly for **azo-11** with adsorption time initially. From SFM, within about 2 min, the film coverage reaches equilibrium and remains almost constant thereafter. It is conjectured that electrostatic attraction between the substrate and adsorbing molecules is the driving force for adsorbtion of cationic molecules onto the negatively charged surface.

SFM observation reveals that **azo-11** forms well-ordered stripes on a freshly cleaved mica sheet (Fig. 1A). The mean distance of ordered stripes is about 10 nm. They show a preferred orientation (Fig. 1B). The dark areas seen here are uncovered regions. The stripes are packed parallel to the elongated defects. The ordered regions with the same orientation can extend to large areas, up to centimeters. The nanometer size of the ordered stripes indicates that such an ordered structure is not formed by regular packing of single molecules but rather by molecular assemblies. Considering the fact that the **azo-11** concentration used for adsorption is above the critical micelle concentration (cmc), we speculate that the formation of the structure should be related to the micelle in the solution.

In order to confirm the above speculation, we varied the **azo-11** concentration systematically. We found that stripe structures are formed for concentrations of 5.0×10^{-5} M and above, even at 1.0×10^{-3} M, although the ordered structure shows a slight change at this concentration compared with the normal one. However, there is a critical concentration, 3.3×10^{-5} M, at which ordered structures and irregular aggregates co-exist (Fig. 1C). Below this, *e.g.* at 2.5×10^{-5} M, stripe structures may be completely lost. Instead, only irregular aggregates exist on the mica sheet (Fig. 1D). The cmc of **azo-11** was measured to be 3.4×10^{-5} M by the dramatic change of fluorescence with concentration.

Ourselves and others have used similar bolaform amphiphiles to fabricate the layer-by-layer assemblies previously, but no such nano-sized structure has been found. The reason could be that the concentration of bolaform amphiphile used for assemblies is often chosen to be lower than the critical concentration in order to avoid micelles and to ensure isotropic monomer deposition for multilayer construction.[5,6] Further evidence to support the above argument is given by UV/Vis irradiation experiments. After the **azo-11** solution was exposed to UV/Vis irradiation for up to 30 min, the film was prepared under the same conditions as above. Although mostly ordered regions were observed, we found that there are also some irregular regions. One possible reason is the *trans–cis* isomerization of azobenzene in between the bolaform amphiphile, which could partially destroy the structure of elongated micelles in solution. The UV/Vis absorption spectra support our assumption that the *trans–cis* isomerization can not be complete for the system, and some *cis–trans* mixture exists even after UV/Vis irradiation for 30 min.

For a similar bolaform amphiphile but with a shorter spacer, **azo-6**, we cannot find any similar structures even when we vary

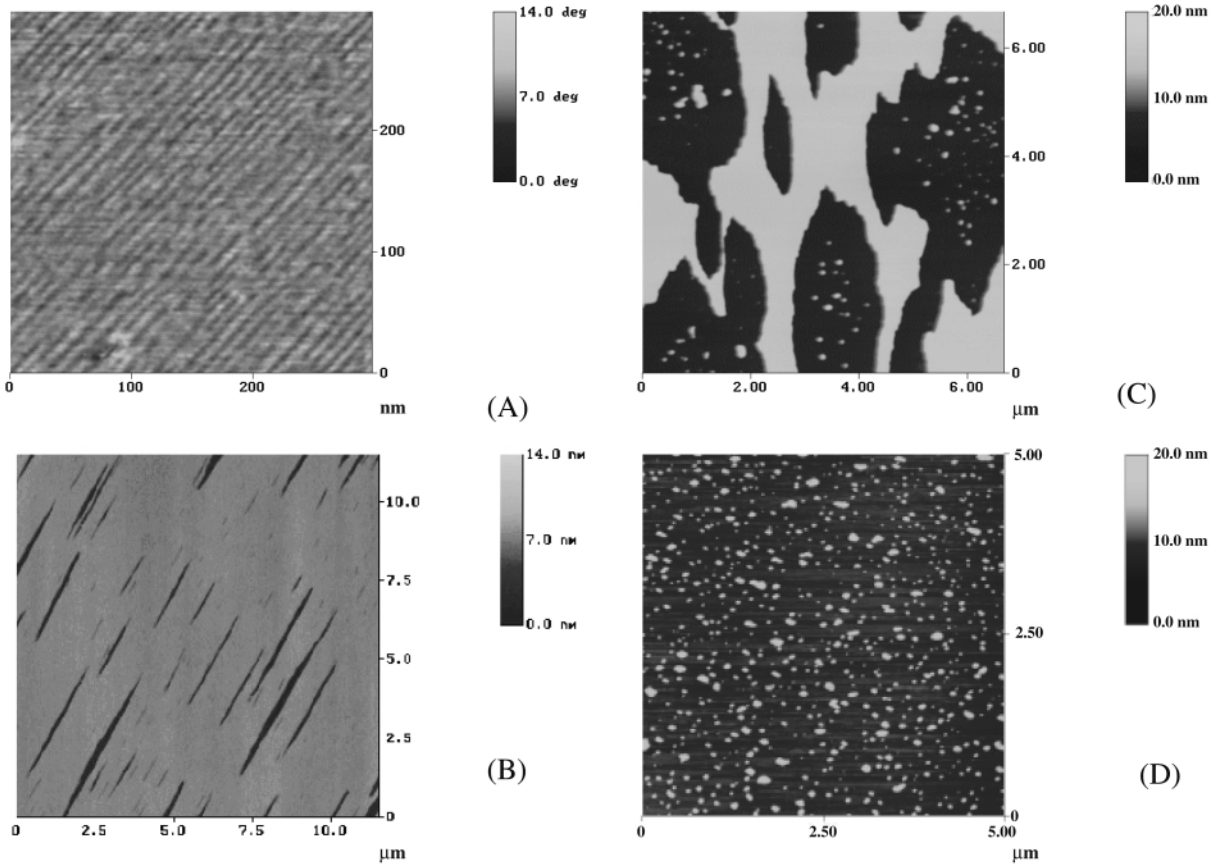


Fig. 1 SFM images of **azo-11** on a mica sheet. Self-assembled nano-sized stripes are formed by immersion of mica sheet into an aqueous solution of **azo-11** (*c.* 1.0×10^{-4} M), as shown in (A) in small areas and (B) in large areas. Ordered structures and irregular aggregates co-exist when the concentration of **azo-11** reaches a critical value, 3.3×10^{-5} M (C). Only irregular aggregates exist on mica sheet when the concentration of **azo-11** is as low as 2.5×10^{-5} M (D).

the concentration and prolong adsorbing time. It is inferred that the compromise between aggregation behavior of the compounds in solution, electrostatic interaction and van der Waals forces *etc*. plays an important role in molecular organization at the liquid–solid interface.

It is also found that the ordered packing of stripes could not form without a crystalline template *i.e*. a mica sheet. By depositing two layers of polyelectrolytes of diazo-resin and poly(sodium styrene sulfonate) alternately onto the mica sheet, a modified mica sheet with a negative charge but an amorphous surface was obtained. With this modified mica sheet, we repeated the previous experiments and found that the bolaform amphiphile **azo-11** can adsorb onto the negative charged surface. Unfortunately, no regular supramolecular structures were formed. Furthermore, by replacing the mica sheet by a glass slide, **azo-11** spread well onto the glass slide, but did not form any ordered structures.

In conclusion, we have demonstrated a very simple way to create ordered surface structures, based on the self-assembly of bolaform amphiphiles at the liquid–solid interface. As a result, it enhances many of the unique features of the ordered structure, like stability on a nanometer scale and over very large areas. Considering the great diversity of bolaform amphiphiles, we anticipate that this type of pattern fabricating method might open up other possibilities for surface modification.

The development of a new boron-based strategy for 'traceless' solid-phase synthesis of aromatic compounds is reported. A resin capture process can precede the cleavage step.

The combinatorial library approach is increasingly used for the discovery and development of new drugs, catalysts and materials.[1] Most of the organic chemical libraries reported to date have been constructed using solid-phase methods. A key aspect of these strategies is the linkage element, which acts as a tether to the polymeric support material. Typically, linkage to the polymeric support is based on a protecting group. However, after cleavage from the support, the presence of the functional group previously used for the attachment may have a negative effect on the biological or chemical properties of the target compounds. To overcome this disadvantage, alternative approaches were developed where linkage through a functional group can be excised efficiently, when desired, leaving behind no trace or 'memory' of the solid-phase synthesis (formation of a new C–H or C–C bond).

Only a few 'traceless' linkers have been reported so far for the synthesis of aromatic compounds, none of which are general.[2] As part of a program to develop new solid-phase synthetic methodologies, we became interested in exploring the use of polymer-supported arylboronates. We have prepared recently a macroporous support **1** which was found to be efficient in immobilizing a wide variety of arylboronic acids under mild and neutral conditions.[3,4] Since protonolysis of arylboranes is a well-documented reaction,[5] we planned to use the boronate functionality as a new traceless linker for the solid-phase synthesis of aromatic compounds. Furthermore, since the polymer **1** is extremely selective in its reactions with boronic acids, the boronate linker can be used in another strategy where the synthesis is initiated in solution and the material is subsequently captured by solid support before performing 'traceless' cleavage. In each approach, the cleavage step is associated with the regeneration of the resin **1** (Scheme 1).

In order to find an efficient procedure for the traceless cleavage of supported arylboronates, preliminary experiments have been performed on the resin-bound *m*-nitrophenylboronic acid (Table 1). Protodeboronation of arylboranes usually occurs under drastic hydrolytic conditions, catalysed by conc NaOH[6] or conc HCl.[7] Due to the incompatibility of these procedures with various acid or base sensitive functional groups, transition metal salts have attracted our attention as mild protonolysing reagents.[8] After some unsuccessful experiments, it was found that nitrobenzene can be obtained using an aqueous solution of $Ag(NH_3)_2NO_2$ in EtOH at rt (entry 1)[9] and that the use of THF instead of EtOH significantly improved the yield (entry 2). The optimized conditions required 10 equiv. of 0.5 M aq. $Ag(NH_3)_2NO_3$ in THF at 75–80 °C for 8 h (yield 75%, purity > 95%)(entry 4). The use of a gel-type glycerol-PS resin[10] led to < 50% of deboronation under the same conditions, clearly underlining the benefit of macroporous resin **1**. This cleavage was further examined with different aryl ring systems and the liberated products were isolated in moderate to good yields (entries 5–7).

The solutions obtained after filtration of the resin were evaporated to dryness, the residue was taken up in a mixture of EtOAc and H_2O, and, after separation of the layers, the organic solvent was evaporated. In all cases, the remaining products were > 85% pure as determined by GC or NMR.[11]

Of particular interest to combinatorial chemistry is the use of resin **1** to immobilize functionalized boronic acid templates and carry out different solid-phase transformations. As an example, butan-1-ol was coupled to resin-bound *p*-carboxyphenylboronic acid **2**, to afford the corresponding ester **3** in 56% after cleavage. Similarly, resin-bound *m*-aminophenylboronic acid **4** was

transformed into sulfonamide **5** upon treatment with *p*-methylphenylsulfonyl chloride (Scheme 2).

The exact mechanism of the silver ion catalyzed proto-deboronation has not been clearly demonstrated, but the hypothesis of an arylmetal intermediate is strongly favoured.[8] Note that, after washing (water, THF and Et_2O), the filtered slightly green resin can be reused for another attachment without requiring a regeneration step and with no apparent loss of activity.

The resin capture strategy is very promising for library generation since it combines the flexibility of solution synthesis with the purity of solid-phase products. In this regard, resin **1** could be very useful in capturing only organoboron products from complex reaction mixtures and, subsequently, to perform 'traceless' cleavage. For example, some transformations in the solution-phase of functionalized boronic acids have been realized using an excess of various reagents. *m*-Aminophenylboronic acid **6** was transformed into anilide by treatment with benzoyl chloride and *p*-formylphenylboronic acid **9** was subjected to a reductive amination with benzylamine. The crude products of these reactions were combined with resin **1** at reflux in THF to afford **7** and **10**. The desired products **8** and **11** were obtained in excellent purities and yields after cleavage. As another significant demonstration of the interest of such an approach, an UGI four-component condensation[12] was carried out with **12**, benzylamine, benzylisonitrile and isobutyraldehyde in MeOH at 60 °C for 12 h. After evaporation of the solvent, the crude product was treated with **1** to selectively afford **13**. After cleavage, the α-(acylamino) amide **14** was obtained in 57% yield and with a high purity (> 90%), as shown in Scheme 3. To the best of our knowledge, this constitutes the first example of resin capture which releases product with formation of a carbon–hydrogen bond in place of the resin attachment.

In conclusion, we have developed a new 'traceless' linker technology for solid-phase chemistry. The conditions of cleavage are compatible with the presence of functional groups such as amines, amides, esters, ethers and sulfonamides.[13] The boronate linker system is distinct from the existing alternatives by its ability to regenerate the polymer, and its use in a resin capture process. Other reactions of polymer-supported boronates in the formation of a new carbon–carbon bond instead of the initial boron–carbon bond are currently in progress in our laboratory.

We thank Dr B. Maillard (Université de Bordeaux 1) for fruitful discussions.

Received (in Cambridge) 7th April 2000, Accepted 17th May 2000

Rhodium complexes of unsymmetrical diphosphines of the type $Ph_2PCH_2CH_2PAr_2$ are catalysts for the carbonylation of methanol; several features of the catalysis are reminiscent of iridium carbonylation catalysts.

Methanol carbonylation (eqn. (1)) is one of the most successful industrial applications of homogeneous catalysis and is currently carried out on a scale of several million tonnes per annum.[1] The rhodium–iodide catalysed process gives acetic acid in better than 99% selectivity and the mechanism has been thoroughly reviewed by Maitlis *et al.*[2] The new *Cativa* process uses an iridium–iodide catalyst and offers many advantages over the rhodium system.[3] The conditions shown in eqn. (1) limit the use of phosphine modified catalysts because of the potential problem of quaternisation of the ligand.[1] Thus, while the rhodium complexes of P,O-, P,N- and P,S-donor ligands have all been reported[4–8] to be methanol carbonylation catalysts, either the conditions used were not the industrial conditions of eqn. (1) and therefore the process would not be viable,[4–6] or the catalysts were found to be unstable.[7,8] Here we report that rhodium complexes of unsymmetrical ethylene diphosphine ligands are more efficient catalysts than their symmetrical dppe analogues for methanol carbonylation and longer-lived than any previously reported ligand-modified catalysts under the harsh conditions of eqn. (1).[9]

$$\mathrm{MeOH} + \mathrm{CO} \xrightarrow[\text{[cat] / HI}]{\text{150-200 °C, 10-60 bar}} \mathrm{MeCOOH} \qquad (1)$$

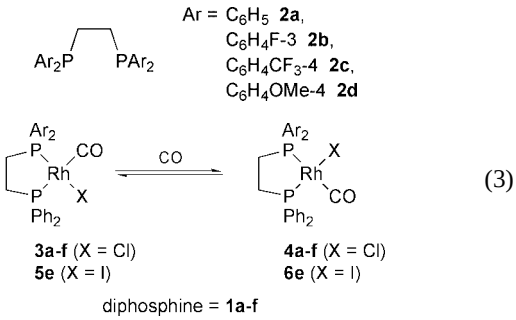
The diphosphines **1a–f**, some of which are known,[10,11] were made according to eqn. (2) and fully characterised. The

$$Ph_2P\!\!\smile\!\!PCl_2 \xrightarrow{\text{ArLi or ArMgBr}} Ph_2P\!\!\smile\!\!PAr_2 \qquad (2)$$

Ar = C_6H_4OMe-4 **1a**, C_6H_4F-3 **1b**, $C_6H_4CF_3$-3 **1c**, $C_6H_3F_2$-3,5 **1d**, $C_6H_2F_3$-3,4,5 **1e**, $C_6H_3(CF_3)_2$-3,5 **1f**

catalysts were prepared by addition of diphosphines **1a–f** or **2a–d** to $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ in methanol [eqn. (3)]. Under these conditions the complexes **3a–f** and **4a–f** are formed in approximately 1 : 1 ratio in each case; these isomeric mixtures have been isolated and fully characterised. Similarly the iodo analogues **5e** and **6e** have been prepared and characterised as a 1 : 1 mixture.

The carbonylation catalysis was carried out under the conditions given in eqn. (1) and the results are presented in Table 1.† In each case the conversion of methanol was greater than 98% and the selectivity for acetic acid was greater than 99%; the rates for the diphos systems (entries 1–11) were all lower than the commercial $[RhI_2(CO)_2]^-$ catalyst. The following observations suggest that the catalyst is a diphosphine–



(3)

rhodium complex throughout and not $[RhI_2(CO)_2]^-$. IR spectra obtained *in situ* during catalysis with ligand **1e** showed the absence of the intense ν(CO) bands for $[RhI_2(CO)_2]^-$ at 2059 and 1988 cm^{-1}. At the end of the catalysis, when the solution cooled, a homogeneous orange solution or red crystalline precipitate was present and ^{31}P NMR and IR spectra showed the presence of a mixture of diphosphine rhodium(III) carbonyl complexes (^1J(RhP) *ca.* 100 Hz, ν(CO) *ca.* 2090 cm^{-1}). The product *fac*-$[RhI_3(CO)$(**1b**)$]$ **7** was isolated from the reaction mixture using the catalyst derived from **1b** and the crystal structure of its pentane solvate was determined (see Fig. 1). The octahedral geometry at the rhodium(III) centre is somewhat distorted (iodine atoms I(1) and I(2) lie 0.140 and 0.184 Å respectively from the RhP_2 plane). The carbonyl ligand lies *cis* to the diphosphine phosphorus atoms, which show identical Rh–P bond lengths, any difference in the values being masked by the disorder.‡ The rate of catalysis is constant throughout a run and, after all the methanol was consumed, a second aliquot of methanol was injected and the rate was the same as in the first run. This final observation not only confirms the integrity of the

catalyst but also shows its longevity is greater than any previous rhodium–phosphine catalyst under these conditions[7] since it shows that all the diphosphine catalysts undergo over 500 turnovers without noticable diminution of activity.

In the following respects, the rhodium–diphosphine catalysts resemble the iridium *Cativa* catalysts. The main inefficiencies in traditional rhodium-catalysed methanol carbonylation are the water gas shift reaction and the formation of by-products such as MeCHO, EtI and $CH_3CH_2CO_2H$; this problem is much reduced with the iridium catalysts.[3] The amount of propionic acid reported in Table 1 for the diphosphine catalysts (entries 1–10) is significantly less than with $[RhI_2(CO)_2]^-$ as catalyst under these conditions (entry 12). ^{31}P NMR studies in CH_2Cl_2 show that oxidative addition of MeI to **5e**/**6e** is very rapid. The greater nucleophilicity of [RhI(CO)(diphosphine)] complexes[12] than $[RhI_2(CO)_2]^-$ may partly explain the similarities between the rhodium–diphosphine and the iridium catalysts.

Since the iridium catalysts are promoted by iodide-abstracting ruthenium complexes,[3] we investigated whether $[RuI_2(CO)_4]$ would also promote the rhodium catalyst from diphosphine **1b**; by comparing entries 7 and 2 in Table 1, it is clear that the addition of the Ru complex has more than doubled the rate.

From the data in Table 1, it can be deduced that the influence of the phosphorus substituents is complicated. The rate data are plotted in Fig. 2 as a function of the Hammett constants for the aryl substituents. The plot shows that increasing the electron-withdrawing power of the substituents on the aryl rings in the unsymmetrical diphosphines generally increases the catalyst activity up to a point, beyond which the rate decreases. The significance of the maximum in the curve might be interpreted in terms of a balance of σ-donor and π-acceptor qualities being required to optimise the rate. However entries 4 and 9 in Table 1 are with ligands **1d** and **2b** which would be expected to have similar overall donor/acceptor properties by virtue of the same number of *meta*-fluoro substituents and yet they show very different catalytic performance. In fact, all of the symmetrical diphosphines **2a**–**d** yield catalysts of similarly low activity (entries 8–11). Thus the *asymmetry* of the diphosphine is apparently crucial. Casey *et al.*[10] have shown that unsymmetrical diphosphines are superior to the symmetrical analogues for hydroformylation catalysis and associated this with a preference of the better σ-donor for the axial site in the trigonal bipyramidal intermediates. It is notable that P,O-, P,N- and P,S-donor ligands used previously[4–8] for methanol carbonylation are all unsymmetrical with one strong and one medium or weak donor. For the best one ($Ph_2PCH_2CH_2P(S)Ph_2$), Baker *et al.*[7] showed that only one isomer (with the S-donor *trans* to CO) is formed in the reaction of $[Rh_2I_2(CO)_4]$ with the ligand. By contrast, we find no such diastereoselectivity in the reaction of diphosphines **1a**–**f** with $[Rh_2X_2(CO)_4]$ (X = Cl or I). In the presence of CO, ^{31}P NMR spectroscopy shows that the diastereoisomers **3**/**4** and **5**/**6** interconvert rapidly (eqn. (3) and thus the *ca.* 1:1 mixtures observed represent the thermodynamic proportions. Hence there is little difference in the stability of the [RhI(CO)(diphos)] precursors under ambient conditions in CH_2Cl_2 but it is possible that under the radically different conditions of the catalysis, one of the isomers is preferred or one is significantly more reactive.

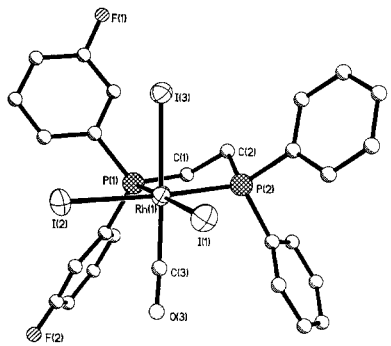

Fig. 1 The molecular structure of **7** showing one of the two orientations of the *meta*-C_6H_4F groups. Important molecular dimensions include: bond lengths (Å) Rh(1)–C(3) 1.885(6), Rh(1)–P(1) 2.335(2), Rh(1)–P(2) 2.3370(15), Rh(1)–I(1) 2.7337(7), Rh(1)–I(2) 2.7296(7), Rh(1)–I(3) 2.6869(6); bond angle (°) P(1)–Rh(1)–P(2) 86.03(6).

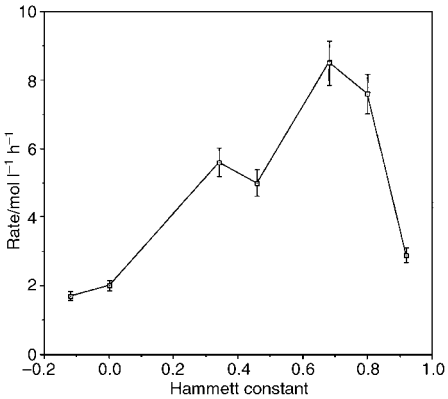

Fig. 2 Plot of the rate of methanol carbonylation (from Table 1) as a function of the Hammett substituent constant, σ for the Ar substituents in the ligands $Ph_2PCH_2CH_2PAr_2$. The error bars represent a 7.5% error in the rate measurement.

In conclusion we have established that unsymmetrical diphosphine–rhodium complexes are very active and selective catalysts for methanol carbonylation under industrially significant conditions and these catalysts have several features in common with the iridium *Cativa* catalysts.

Received (in Cambridge, UK) 26th April 2000, Accepted 2nd June 2000

A three-dimensional neutral framework of a novel decavanadate ion $[V^{IV}_8V^{V}_2O_{26}(\mu\text{-}H_2O)]$ containing an AsO_4 tetrahedral bridge has been synthesized hydrothermally and structurally characterized by X-ray diffraction.

One of the great challenges of modern chemistry is to create multifunctional structures which have well defined cavities and surfaces with sites or areas of different reactivity by linking preorganised robust building blocks.[1] Given the significance of transition metal oxide surfaces[2] and proven roles of polyoxometalates and their derivatives in catalysis and materials science,[3] it is conceivably valuable to attempt to design and prepare transition metal oxide based materials with desired and controllable properties by assembling metal oxide clusters which provide remarkably diverse and well defined building blocks.[4] Although the mechanism by which the assembly is organised remains elusive, a popular strategy in the realisation of materials engineering involves combined applications of the hydrothermal synthesis method and structure-directing templates.[5] On-going research has demonstrated that transition metal (*e.g.* Fe, Co, Ni, Cu, Zn and Mn) coordination complexes may serve as inorganic bridging ligands linking polyoxoanion clusters into one-, two- and three-dimensional networks.[6]

Owing to their exceptional ability to form mixed-valence compounds that exhibit rich electronic and magnetic properties, polyoxovanadates have been extensively studied with many structurally characterized examples now known.[7] Recently, a decavanadium cluster with a $[V^{V}_{10}O_{22}]^{6-}$ core has been reported, and an X-ray structural analysis shows that it is a discrete ion with a chiral framework formed by nine square-pyramidal VO_5 polyhedra surrounding one VO_4 tetrahedron linked through the vertices.[8] Although decavanadate ions as discrete entities are common, synthetically prepared examples of extended structures with decacavanadate ions are relatively rare. According to our literature search, only one example, $[Cu(en)_2]_2[V^{IV}_4V^{V}_6O_{25}]$, has been reported, which consists of $Cu(en)_2^{2+}$ groups linked through layered vanadium oxides into a three-dimensional network.[9] Khan *et al.* reported several three-dimensional frameworks which consist of spherical $[V_{18}O_{42}(XO_4)]$ clusters linked by bridging $[M(H_2O)_4]$ groups (X : V, S; M : Fe, Co, Mn, Zn).[10] Here, we report an entirely new type of mixed-valence decavanadate ion $[V^{IV}_8V^{V}_2O_{26}(H_2O)]$ as a building block which is bridged by AsO_4 tetrahedra leading to a three-dimensional neutral network $[AsV^{IV}_8V^{V}_2O_{26}(\mu\text{-}H_2O)]\cdot 8H_2O$ **1**. There are many structures reported in which AsO_4 terahedra are encapsulated in mixed-valence V^{IV}/V^{V} as well as V^{IV} polyoxoanions. To our knowledge, AsO_4 tetrahedra linking polyoxoanions in a bridging mode has not been described to date.

Compound **1** was prepared hydrothermally from a mixture of V_2O_5, H_3AsO_4, $H_2C_2O_4$, en and H_2O heated to 160 °C for three days.† The en is not incorporated into the structure of **1**, but is necessary to maintain the pH of the reaction. $H_2C_2O_4$ was employed as a reducing agent. The IR spectrum of the product exhibits characteristic bands at 972 and 958 cm^{-1} assigned to $\nu(V{=}O_t)$ and a number of bands in the range 750–900 cm^{-1} associated with ν(V–O–V) and ν(V–O–As).

The extended highly symmetrical structure of **1**‡ (Fig. 1), consists of a three-dimensional neutral network of $[V^{IV}_8V^{V}_2O_{27}]$ cages with crystallographic T_d symmetry, with each cage connected to four other neighboring units *via* AsO_4 bridging groups. This generates a network of $[-\{V_{10}O_{27}\}-AsO_4-\{V_{10}O_{27}\}-]_\infty$ arrays running along two mutually perpendicular directions. The building block units in the structure of **1** may be viewed as a 'rugby ball'-like $[V^{IV}_8V^{V}_2O_{26}]$ shell encapsulating a central water molecule which is covalently bonded to two V(1) atoms in a μ-bridging mode with a V(1)–O(6) distance of 2.450 Å. The symmetry at O(6) is 222. Indeed, an unusual property of reduced polyvandates is their tendency to form cages encapsulating a guest molecule.[11] Compound **1** represents a most unusual member of this class of clusters with the central bridging encapsulated water molecule.

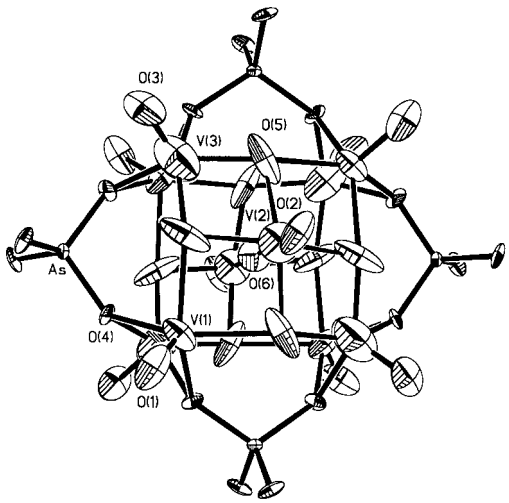

Fig. 1 Unit cell of structure **1** down the crystallographic *a* axis showing the rectangular channels parallel to this axis. Water molecules have been omitted for clarity.

The $[V^{IV}_8V^{V}_2O_{27}]$ unit is a new type of decavanadium ion. The vanadium exhibits two types of coordination: pyramidal [V(1) and V(3)] and octahedral [V(2)]. The octahedral geometry around vanadium V(2) is defined by a terminal oxo group [O(1)], four μ-oxygen atoms [O(5)] of the shell, and one μ-oxygen atom [O(6)]. The square-pyramidal geometry around V(1) and V(3) is formed by four basal μ_3-oxo [O(4), O(5)] groups from the shell and an apical terminal oxo groups. Two $V(1)O_5$ and two $V(3)O_5$ pyramids are corner-shared by a μ_3-O(5) atom to form a $[V_4O_{16}]$ ring. These vanadium atoms are all co-planar. Two such $[V_4O_{16}]$ rings are joined to each other by sharing edges in a parallel manner with two $V(2)O_6$ octahedra capping oppositely disposed faces of these two rings, respectively, forming a rugby ball-like structure. The surface of

DOI: 10.1039/b003359f

the cluster exhibits four open windows. Curiously, the four AsO_4 tetrahedra cap on the windows by edge-sharing through a μ_3-oxo group [O(4)] leading to a three-dimensional neutral network.

According to bond valence sum (BVS) calculations[12] and charge balance, compound **1** is formulated as $[AsV^{IV}{}_8V^{V}{}_2O_{26}(H_2O)]\cdot 8H_2O$. The assignment of oxidation state for the vanadium and arsenic atoms are consistent with their coordination geometries and are confirmed by valence sum calculations which gives values for V1, V2, V3 and As of 4.06, 5.06, 4.15 and 5.10, respectively. The valence sum calculations associated with O(6) (BVS = 0.28) identify it as a water molecule, a feature consistent with the significant lengthened bond distance.

It is noteworthy that the structure of **1** possesses large rectangular and hexagonal channels, which are filled with water molecules of crystallization (eight water molecules per unit cell) (Fig. 1 and 2). The rectangular channels run along all three crystallographic axes with mean diameters of 10.508 Å while hexagonal channels extend along the diagonal direction of the unit cell with a mean diameter of 11.986 Å. The arsenic atoms reside on a $\bar{4}$ axis. In addition, two perpendicular $\bar{4}$ axes pass through the center of the $[V_{10}O_{27}]$ unit. Owing to the crystallographically imposed $\bar{4}$ symmetry, these channels may be viewed as a cylinder, not observed previously in other metal oxide cluster frameworks. Whereas transition metal coordination complexes acting as bridges are well established, it is seen here that AsO_4 tetrahedra may play an important role in the assembly of a specific structural motif.

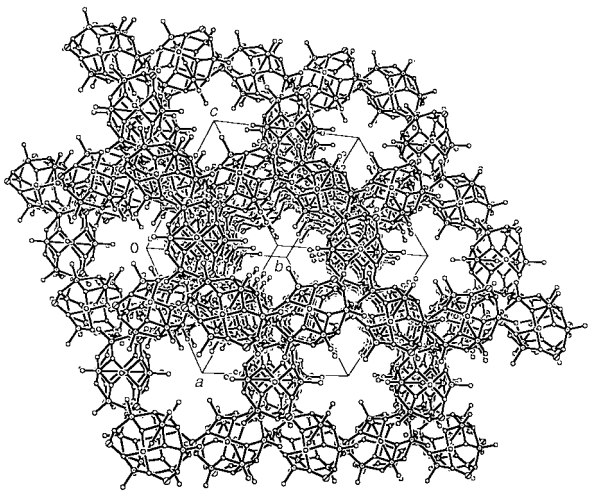

Fig. 2 The hexagonal channels viewed along the diagonal direction of the unit cell.

The room-temperature EPR spectrum of a crystalline sample of **1** consists of one signal (g 2.034), indicating the presence of V^{IV} centers. Although no hyperfine structure was observed, the linewidth was extremely narrow, which suggests significant exchange coupling.

The magnetic susceptibility χ_m of **1** was measured between 2 and 300 K. The value of $\chi_m T$ shows a gradual decrease as the temperature is decreased, indicative of weak antiferromagnetic exchange coupling. Because no suitable theoretical model is available in the literature[13] for such a complex system, detailed magnetic analyses were not performed for the present compound.

This work has important implications for the conversion of discrete cluster anions into three-dimensional networks[14] and demonstrates that the use of hydrothermal techniques is a vital tool for the realisation of materials design. This novel structure and building principle may provide further insight into designing new porous materials as well as other supramolecular architectures.

Received (in Cambridge, UK) 30th March 2000, Accepted 24th May 2000
Published on the Web 26th June 2000

A simple solid phase lipid synthesis (SPLS) is proposed for construction of an artificial glycolipid library; this method is so convenient and flexible that we have efficiently constructed a glycolipid library; some of these glycolipids formed into stable bilayer aggregates in aqueous solution, suggesting that the glycolipids obtained by SPLS are useful as a suitable model of naturally occurring glycolipids.

Recent development in the field of glycobiology has clearly established that naturally occurring glycolipids have various key functions in biological systems.[1] Despite such important roles, fundamental questions on the relationship of the functions to the molecular structures are poorly understood. This is partially due to the complicated and diverse structures of natural glycolipids. An appropriate model and synthetic scheme are now required.[2] We describe herein a simple and convenient strategy for synthesis of artificial glycolipids based on a solid phase method (SPLS). Using the present method we efficiently constructed a small glycolipid library.

Typical examples of the designed artificial glycolipids are shown in Fig 1. Since the artificial glycolipids can be divided into several structural modules to provide flexibility to SPLS,[3] we planned to combine these modules on a resin in sequence (Scheme 1). The Merrifield resin modified with a 3-hydoxymethyl-4-nitrophenoxy linker was employed as a solid support.[4] Initially, phenylisopropyl Fmoc-aspartate as a connector part is attached to the resin using a condensation reagent (DIC). After deprotection of the Fmoc group, succinic anhydride was reacted with the amine site to introduce succinic amide as a spacer, followed by condensation of dialkylamine with the remaining carboxylic acid site to form a hydrophobic tail.[5] Then, the phenylisopropyl group was cleaved by 2% TFA to afford a free β-carboxylic acid of the aspartic acid connector,[6] which was next connected with aminoethyl glycoside,[7, 8] a polar head group. Finally, the artificial glycolipid thus synthesized, was released from the solid support. Two distinct methods were used for the cleavage from the resin, (i) hydrazinolysis,[9] or (ii) photolysis followed by methanolysis.[4] In the hydrazinolysis, cationic lipids bearing a hydrazide were afforded,† whereas anionic lipids bearing a carboxylate were obtained in the photolysis sequence.† All glycolipids were purified by gel chromatography [Sephadex LH20, eluent : $CHCl_3$–MeOH (1/1)], and identified by MALDI-TOF mass and NMR spectroscopies.† The overall yield for the six or seven steps ranges from 33 to 91%. Using this SPLS method, a small library was prepared as summarized in Table 1.

In order to confirm the fundamental capability to form a lipid membrane, we next investigated aggregation properties of the artificial glycolipids using conventional physicochemical measurements. Glc-asp(NH_2)-$2C_2$ and Glc-asp(NH_2)-$2C_6$ were solu-

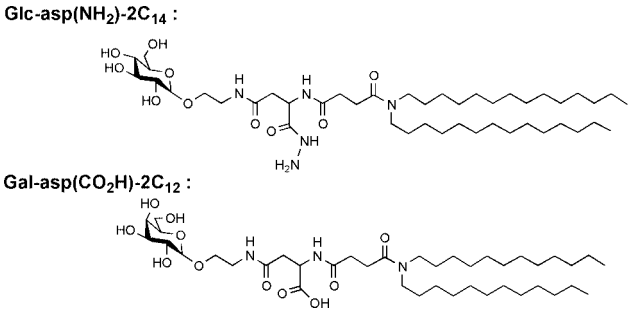

Fig. 1 Typical examples of artificial glycolipids. The glycolipids are abbreviated as 'sugar–connector(charge)–tail'. Sugar denotes the sugar head structure (Glc, Gal, Man), connector denotes the connection part of the lipid (asp), charge denotes the surface charge [NH_2 (cationic) or CO_2H (anionic)], and tail denotes the hydrophobic tail group ($2C_{12}$, $2C_{14}$, $2C_{16}$ *etc.*).

† Details of the release of Glc-asp(NH_2)-$2C_{12}$ from resin **5** and the synthesis of Glc-asp(CO_2H)-$2C_{12}$ are available as electronic supplementary information (ESI). See http://www.rsc.org/suppdata/cc/b0/b002545n/

Table 1 Yields and aggregation properties of artificial glycolipids synthesized by SPLS

Compound	Total yield (%)	Aggregation properties in water		
		Diameter[a]/nm	Morphology[b]	T_c[c]/°C
Gal-asp(CO_2H)-2C_{12}	39	40–350	Vesicles	< 0
Gal-asp(NH_2)-2C_{12}	67	120–690	Vesicles	< 0
Man-asp(NH_2)-2C_{12}	91	660–1230	Vesicles	< 0
Glc-asp(NH_2)-2C_2	49	< 5	No aggregates	Not measured
Glc-asp(NH_2)-2C_6	56	< 5	No aggregates	Not measured
Glc-asp(NH_2)-2C_{10}	68	170–810	Vesicles	< 0
Glc-asp(NH_2)-2C_{12}	81	50–90, 200–810	Vesicles	< 0
Glc-asp(NH_2)-2C_{14}	59	90–370	Vesicles, helical rods	4–5
Glc-asp(NH_2)-2C_{16}	60	140–430	Vesicles, helical rods, tubes	23–25
Glc-asp(NH_2)-2C_{18}	33	Not dispersed		

[a] The aggregates were assumed to be spherical in calculation of diameters. [b] All samples were negatively-stained with uranyl acetate. [c] Phase transition behaviors of the bilayer membrane were estimated by DSC.

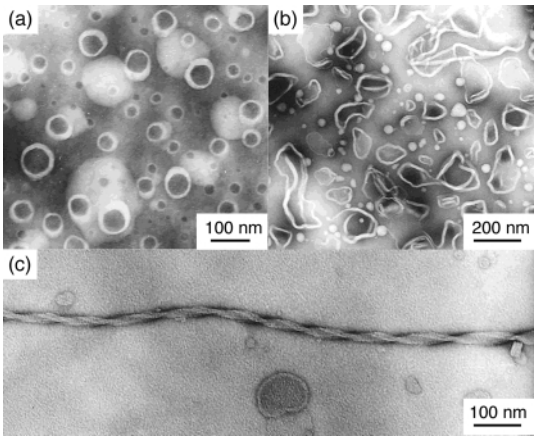

Fig. 2 TEM images of aggregates formed in 1.0 mM aqueous dispersions of artificial glycolipids. All samples were incubated at 35 °C for 12 h, followed by staining with uranyl acetate. The pH of the dispersed solution was *ca.* 6.2. (a) Gal-asp(NH_2)–2C_{12}, (b) Glc-asp(NH_2)–2C_{12}, (c) Glc-asp(NH_2)–2C_{14}.

ble in water without sonication whereas Glc-asp(NH_2)-2C_{18} was not dispersed even by prolonged sonication. Other glycolipids swelled in water, and then yielded a homogeneous dispersion displaying light-scattering properties upon sonication. The size distribution of the glycolipid aggregates in aqueous solution was studied by dynamic light scattering measurement (DLS, Otsuka DLS 7000). For Glc-asp(NH_2)-2C_2 and Glc-asp(NH_2)-2C_6, no or less than a few nm diameter of aggregates was determined, suggesting that these were dissolved as monomers or small micelles. DLS for the other lipids dispersed in aqueous solutions showed aggregate sizes is in the range 40–1230 nm.

Direct observation of these aggregates was conducted by transmission electron microscopy (TEM). No aggregates were observed for Glc-asp(NH_2)-2C_2 or Glc-asp(NH_2)-2C_6, consistent with data of their solubilities and DLS measurements. Fig. 2 shows typical TEM images of the artificial glycolipids. Both Glc-asp(NH_2)-2C_{12} and Glc-asp(CO_2H)-2C_{12} predominantly form into unilamellar vesicles. The layer width of these vesicles was roughly estimated to be 10 nm, which corresponds to the bimolecular length of Glc-asp(NH_2)-2C_{12}. Similarly, spherical vesicles were observed for Gal-asp(NH_2)-2C_{12} and Man-asp(NH_2)-2C_{12}, indicating that the morphology of these aggregates is not dependent on the head group structure of the monosaccharide. When the tail part becomes longer as for Glc-asp(NH_2)-2C_{14} and Glc-asp(NH_2)-2C_{16}, more developed structures such as helical rods and/or long tubes were observed, as well as vesicles.

Membrane fluidity of these aggregates was estimated by differential scanning calorimetry (DSC). The glycolipids bearing didodecylamine [Glc-asp(CO_2H)-2C_{12} and Glc-, Gal- or Man-asp(NH_2)-2C_{12}], do not show any endothermic peaks, suggesting that the phase transition temperature (T_c) is lower than 0 °C. Glc-asp(NH_2)-2C_{14} shows a rather broad peak at *ca.* 4–5 °C and the T_c of Glc-asp(NH_2)-2C_{16} was determined as 23–25 °C. The corresponding phase transition enthalpy (ΔH) was also determined to be 4–5 kcal mol^{-1} for Glc-asp(NH_2)-2C_{14} and 8–9 kcal mol^{-1} for Glc-asp(NH_2)-2C_{16}, comparable to that of typical natural phospholipids. It is clear that T_c gradually rises with an increase in the hydrophobic chain length, but these artificial glycolipids are still in the fluidic liquid crystal phase at room temperature.

In conclusion, we have developed a convenient SPLS method and successfully applied it to the construction of a small library of artificial glycolipids. All physicochemical data clearly demonstrated that some glycolipids form into stable aggregates consisting of bilayer membranes in aqueous solution. The proposed SPLS scheme is so flexible that we may envision a large library of glycolipids which confers valuable insights for the design of novel saccharide-based biomaterials, as well as elucidation of biological functions of natural glycolipids.

We are grateful to Professor K. Fukase (Osaka University) for his helpful comments on *O*-glycoside synthesis at the initial stage of this research. This research was financially supported by a Germinating Research grant (11878109) from the Ministry of Education, Science, Sports and Culture of Japan, and TERUMO life science foundation.

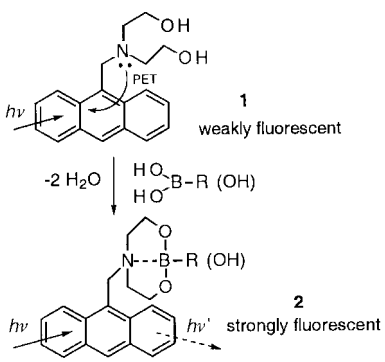
An anthracene-based PET sensor which uses a diethanolamine recognition site is selective for boronic and boric acids, showing up to a 19-fold fluorescent intensity enhancement upon binding.

Boronic acids and boric acid are ubiquitous compounds in chemistry and biology. Boronic acids are important organic intermediates that have been widely used in Suzuki cross-coupling reactions,[1] protection of diols,[2] Diels–Alder reactions[3] and asymmetric synthesis of amino acids.[4] In addition, this class of compounds has been used for the development of sensors for carbohydrates and amino acids;[5,6] selective transporters of nucleosides, saccharides and nucleotides;[7] inhibitors of proteases;[8] and therapeutic agents in boron neutron capture therapy (BNCT) of certain brain tumors.[9] Therefore, fluorescent sensors for boronic acids could be used for the analysis and detection of such compounds in a variety of applications. Boric acid plays an essential role in plant growth.[10] However, the cellular and molecular mechanisms through which boric acid functions in plant cells are far from clear. Appropriately designed sensors could be used for probing the detailed biological functions of boric acid at the cellular and molecular levels. To the best of our knowledge, no fluorescent sensors for either boronic or boric acids have been reported.

The design presented here takes advantage of the known high affinity binding of boronic and boric acid moieties with diethanolamine through boronate formation.[11] This boronate is stabilized by the donation of the nitrogen lone pair electrons to the open shell of the boron atom,[12] which allows for the formation of two five-membered rings (*e.g.* **2**, Scheme 1). Such binding has been used for the stabilization, purification and characterization of boronic acids.[13] Furthermore, it is known that the nitrogen lone pair electrons of 9-aminomethylanthracene can quench the fluorescence of the anthracene moiety through photoinduced electron transfer (PET).[5,6,14] Masking of the nitrogen lone pair electrons causes a suppression of this fluorescence quenching and, therefore, results in fluorescence intensity increases.[6,12] We envisioned that the diethanolamine recognition motif could be incorporated into an anthracene molecule so that its binding with boronic and boric acids would lead to the formation of boronate/borate **2**, which has a boron atom ideally positioned to accept, and therefore mask the nitrogen lone pair electrons. This masking of the nitrogen lone pair electrons could then lead to a fluorescence increase of the anthracene moiety. A fluorescent sensor, *N*-(9-anthrylmethyl)diethanolamine **1**, was designed, synthesized, and evaluated for its binding with boronic and boric acids (Scheme 1). In the absence of boronic and boric acids, the sensor displayed very weak fluorescence. However, upon addition of boronic or boric acid, the fluorescence intensity of the sensor increased by > 16-fold, at saturation concentrations (data not shown).



Scheme 1 The tight binding of boronic acid/boric acid with sensor **1**.

N-(9-Anthrylmethyl)diethanolamine **1** was readily synthesized from 9-(chloromethyl)anthracene through reaction with diethanolamine (6.0 equiv.) in the presence of K_2CO_3 (10.0 equiv.) and a catalytic amount of KI (0.3 equiv.) in a mixture of $CHCl_3$ and MeCN under reflux for 2.5 h (97% yield). In a typical binding experiment, the sensor was dissolved in methanol and was added to the solutions of different concentrations of boronic or boric acid in MeOH. The final concentration of the sensor was fixed at 10^{-5} M.

In the absence of boric or boronic acids, the sensor exhibited very low fluorescence owing to the quenching of the anthracene fluorescence through PET. For the boronic acid binding studies, phenylboronic acid was used as a model compound. Upon addition of phenylboronic acid, the sensor solution showed concentration-dependent fluorescence intensity increases from 34% at 10^{-6} M (Table 1, Fig. 1) to 16-fold at saturation (50 mM, data not shown). The sensor responded to boric acid with a 107% intensity increase at 10^{-7} M (Table 1, Fig. 1) and a 19-fold increase at saturation (500 mM, data not shown).

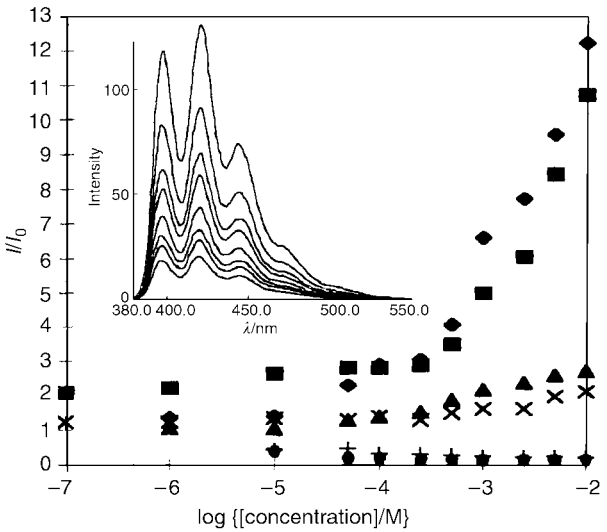


Fig. 1 Relative fluorescence intensity changes (I/I_0) as a function of log[boronic or boric acid] with **1** or **3** (1.0×10^{-5} M) in MeOH at room temperature, λ_{ex} = 370 nm, λ_{em} = 419 nm. $PhB(OH)_2$ with sensor **1** (◆); $B(OH)_3$ with sensor **1** (■); $PhB(OH)_2$ with control **3** (▲); $B(OH)_3$ with control **3** (×); $PhCO_2Na$ with sensor **1** (●); $PhOP(O)(ONa)_2$ with sensor **1** (+). *Inset:* a typical set of fluorescence emission spectra of sensor **1** (1.0×10^{-5} M) with $PhB(OH)_2$ in MeOH from 0 M to 1×10^{-3} M.

Table 1 The effect of $PhB(OH)_2/B(OH)_3$ on the fluorescent intensity of **1** and **3**

	I/I_0[a]			
	$PhB(OH)_2$[b]		$B(OH)_3$[b]	
Conc(M)	**1**	**3**	**1**	**3**
1.0×10^{-7}	—	—	2.07 ± 0.17	1.22 ± 0.10
1.0×10^{-6}	1.34 ± 0.17	1.05 ± 0.07	2.20 ± 0.29	1.23 ± 0.16
1.0×10^{-5}	1.38 ± 0.01	1.04 ± 0.02	2.63 ± 0.38	1.32 ± 0.06
5.0×10^{-5}	2.28 ± 0.22	1.28 ± 0.04	2.79 ± 0.37	1.28 ± 0.10
1.0×10^{-4}	2.88 ± 0.43	1.37 ± 0.14	2.79 ± 0.40	1.36 ± 0.13
2.5×10^{-4}	3.03 ± 0.31	1.50 ± 0.15	2.86 ± 0.33	1.27 ± 0.08

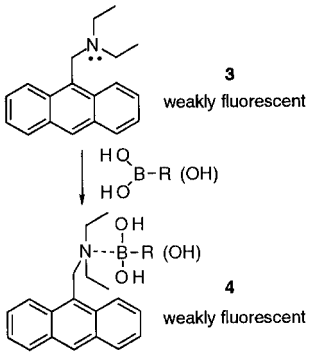
1.0×10^{-3}	6.58 ± 0.21	2.15 ± 0.08	4.96 ± 0.24	1.59 ± 0.25

[a] I_0: the intensity of **1** or **3** (1.0×10^{-5} M) in the absence of phenylboronic/boric acid; I the intensity of **1** or **3** (1.0×10^{-5} M) in the presence of phenylboronic/boric acid. [b] The ratio is listed as the average of three runs with the standard deviation.

It is well known that aminomethylanthracene-based fluorescent sensors are sensitive to pH changes.[15] Therefore, incidental changes in pH due to the addition of the boric or boronic acids were a possible contributing factor in the fluorescence intensity changes observed with sensor **1**, which could complicate the interpretation of the results. To examine whether the fluorescence intensity changes were due to unintended changes in the pH of the solution, we also synthesized compound **3** as a control by following the same procedure for the preparation of **1**. If incidental pH changes were not the reason for the fluorescence intensity changes observed with **1**, we would not expect **3** to be sensitive to boronic and boric acids because compound **3** lacks the two hydroxy groups (Scheme 2), which are critical for the formation of the tight complex of **1** with boronic and boric acids (Scheme 1). Indeed, it was found that compound **3** showed minimal fluorescence intensity changes upon addition of boric or boronic acids at concentrations up to 10^{-5} M (Fig. 1, Table 1). Even at 10 mM, the fluorescence intensity changes were small [1.6- to 2.2-fold *cf.* 5.0- to 6.0-fold with **1,** (Table 1)]. Such results indicate that the fluorescence intensity changes observed with sensor **1** are not primarily due to unintended changes in pH. Furthermore, the minor changes in the fluorescence intensity of **3** may be due to the non-specific weak complexation of the nitrogen atom of **3** with boronic or boric acid (**4**, Scheme 2).

To examine the selectivity of the sensor for boronic and boric acids in the presence of other anions, we also studied the effect of sodium benzoate and disodium phenyl phosphate on the fluorescence intensity of sensor **1**. These anions were not able to increase the fluorescence intensity of the sensor and actually caused a slight lowering of the intensity (Fig. 1). A ^{1}H NMR spectral comparison of the complexed and uncomplexed forms of sensor **1** shows that the sensor/analyte binding is in a 1:1 molar ratio for both phenylboronic acid and boric acid.



Scheme 2 The weak interaction of boronic acid/boric acid with control compound **3**.

In conclusion, the first fluorescent sensor **1** for boronic and boric acids shows high sensitivity and selectivity. Further work in this area may be beneficial to chemical process monitoring, impurity detection, examination of the intracellular functions of boric acid in plant cells, and biological analysis of medicinally useful boronic acid compounds.

Received (in Cambridge, UK) 9th May 2000, Accepted 1st June 2000

Reactions of butadiynediyldimetal complexes, Fp*–C≡C–C≡C–M(η^5-C_5R_5)$(CO)_2$ 1 [M = Fe, Ru; R = Me, H; Fp* = FeCp*$(CO)_2$], with group 8 metal carbonyls result in migration of a σ-bonded metal fragment along the C_4 rod to form novel highly conjugated polycarbon–metal systems; the zwitterionic μ-but-2-yn-1-ylidene-4-ylidyne complex $Ru_3(CO)_{10}$(μ_3-C–C≡C–μ-C)Fe_2Cp*$_2(CO)_3$ 2, and the dimerized product with a cumulenic μ-C_8 ligand $(Cp^*Fe)_4$-$Ru_2(CO)_{13}$[μ_6-C_8–C(=O)] 3, *via* 1,4-migration and the zwitterionic acetylide cluster-type product Fp*$^+$[$Cp(CO)_2$Ru-(η^2-C≡C)–(μ_3-C≡C)$Fe_3(CO)_9$]$^-$ 4, *via* 1,3-migration.

Increasing attention focused on polycarbon–transition metal complexes stems originally from their relevance to surface bound carbide intermediates[1] and recently from their intriguing chemical and physical properties which are potentially applicable to new molecular devices.[2] However, neither interaction modes nor synthetic methods have been thoroughly exploited. During the course of our synthetic study of polycarbon cluster compounds derived from polyynediyldimetal complexes M–$(C\equiv C)_n$–M [n = 1–6; M = Fe or Ru(η^5-C_5R_5)(CO_2)],[3] we observed formation of novel highly conjugated polycarbon–transition metal systems resulting from migration of a σ-bonded metal fragment along the carbon rod. Herein we report results of interaction of butadiynediyl complexes **1** (n = 2) with group 8 metal carbonyl species.

Reaction of the butadiynediyldiiron complex **1a** [Scheme 1, Fp* = FeCp*$(CO)_2$; Cp* = η^5-C_5Me_5][3b] with $Ru_3(CO)_{12}$ in refluxing CH_2Cl_2 gave a mixture of products, from which two compounds **2** and **3a** were isolated after TLC separation (silica gel). For the purple red product **2**,† the single Cp* NMR signal and the highly deshielded ^{13}C NMR signal (δ_C 347.1) suggested formation of a symmetrical cluster compound **2′** bearing a cumulenic >C=C=C=CFe_2 fragment but X-ray crystallography of its η^5-C_5Me_4Et derivative **2**#‡ [Fig. 1(a)] revealed a mirror symmetrical zwitterionic but-2-yne-1-ylidene-4-ylidyne structure[5] with (i) a C_4 bridge showing long–short–long bond alternation and (ii) μ_3-coordination of the C4 and C23 atoms. Contribution of the neutral butatrienetetrayl structure **2′**, however, is evident, since (i) the C_4 rod is slightly tilted toward Ru3 as indicated by the C3–C4–Ru bond angles and (ii) the C–C distances of the μ-C–C≡C–C moiety are averaged to some extent. It should be noted that the (μ-C_4)Fe_2Cp*$_2(CO)_3$ structure results from 1,4-migration of the iron fragment along the C_4 rod, *i.e.* the FeCp*$(CO)_n$ fragment is shifted from one end of the C_4 bridge to the other upon interaction with $Ru_3(CO)_{12}$. The NMR spectrum of the other deep purple red complex **3a**† contained four sets of Cp* signals indicating oligomerization of **1a**, and X-ray crystallography‡ [Fig. 1(b)] revealed a hexanuclear structure with a dimerized C_8 skeleton. Again, formation of the new C_8 carbon linkage involves 1,4-migration (C5 → C8) of the iron fragment. The migration induces a change of part of the polyyne structure into a cumulenic moiety (C8=C7=C6=C5) with similar C–C distances. Although the pentatetraenylidene structure **3a′** π-bonded to the two ruthenium atoms is a possible canonical structure of **3a**, the bent C5–

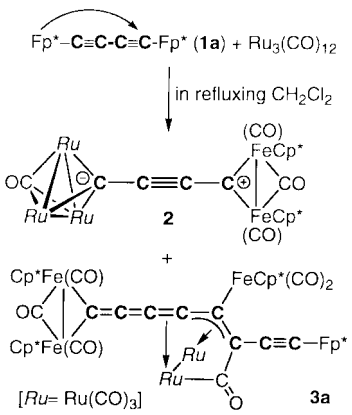

Scheme 1

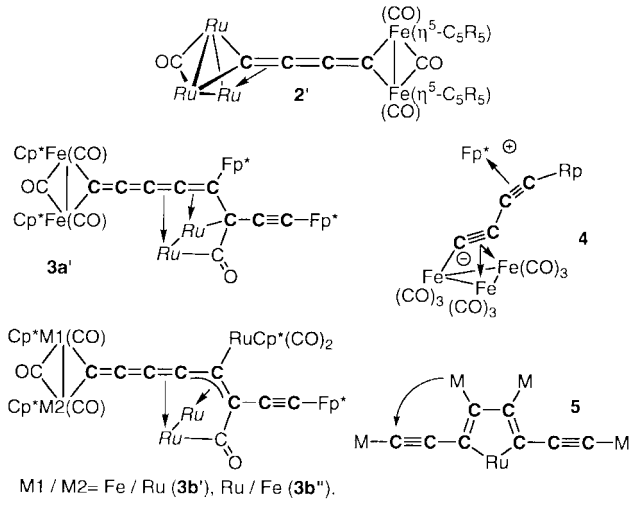

Chart 1

C4–C3 moiety with similar C–C and Ru2–C distances reveals η^3-allyl coordination to Ru2. The linear C3–C2–C1–Fe1 moiety is a normal η^1-acetylide structure. Coordination of the perpendicularly projected, adjacent cumulenic π orbitals of the C6–C5 and C5–C4 bonds to the two ruthenium atoms connected by a Ru–Ru bond[6] leads to strain, which is relieved by formation of a larger membered ring structure *via* CO-insertion [CO(9)]. The C_8 bridge was also characterized by ^{13}C NMR spectroscopy.† Except for the deshielded C8 signal (δ_C 254.7), the other signals appeared in a rather narrow range (δ_C 157–107).

The isostructural C_8 complex **3b**† was obtained from the Fe, Ru-mixed metal butadiynediyl complex, Fp*–C≡C–C≡C–RuCp*$(CO)_2$ **1b**,[4] upon treatment with $Ru_3(CO)_{12}$.§ Complex **3b** consisted of a mixture of two inseparable isomers, **3b′** and **3b″** (Chart 1), as indicated by NMR data containing two sets of signals as well as the successful X-ray structural analysis taking into account a disordered structure containing two components. It should be noted that no homometallic complexes (M1 = M2 = Ru or Fe) were detected by NMR and FD-MS analyses suggesting an intramolecular mechanism for the migration.

Another example of metal migration was observed for reaction of Fp*–C≡C–C≡C–RuCp$(CO)_2$ **1c** [Cp(η^5-C_5H_5) derivative of **1b**] with $Fe_2(CO)_9$, a group 8 metal carbonyl.§ The deshielded ^{13}C NMR signal (δ_C 193.7) of the resultant purple Fe_3-adduct **4** (Chart 1)† suggested formation of a μ-acetylide cluster compound,[7] and X-ray crystallography‡ revealed a pentanuclear structure consisting of a cationic dinuclear μ–η^1:η^2-acetylide complex part and an anionic trinuclear μ_3-acetylide cluster type structure. The structure of each component is normal, and the diamagnetic nature of **4** can be interpreted in terms of the zwitterionic structure, each metal center in which is coordinatively saturated.

In conclusion, interaction of the butadiynediyl complexes **1** with group 8 metal carbonyls results in the formation of novel highly conjugated polycarbon–metal cluster systems. The structures of **2** and **3** suggest the occurrence of stepwise metal migration along the carbon rod, and the C_8 linkage in **4** is formed *via* 1,4-migration on a ruthenacyclopentadiene intermediate **5** resulting from oxidative metallacyclization of **1** (Chart 1).[8] Noteworthy features of the present system are as follows. The formation of zwitterionic structures such as **2** and **4** are regarded as typical of electron transfer through unsaturated carbon rods. Another feature is the flexible coordination mode of the $C(sp)_n$ system. For example, in the case of interaction with trimetallic species, the C_4 ligand can behave as a three- (μ_3-η^1-C_4 like C4 in **2**) to seven-electron donor (μ-η^3-propargylidene-ketene).[3c] When combined with coordination of CO ligands, which can act as either one- or two-electron donors, various intermediates have many opportunities to attain coordinative saturation by switching coordination modes of the C_4 and/or CO ligands.

We are grateful to the Yamada Science Foundation for financial support of this research.

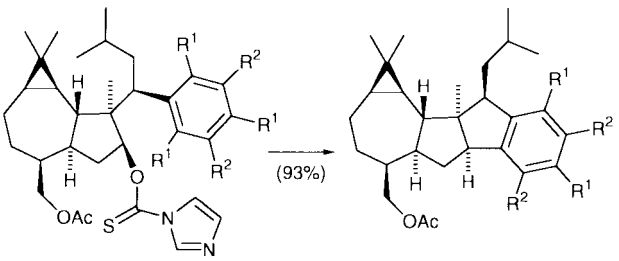
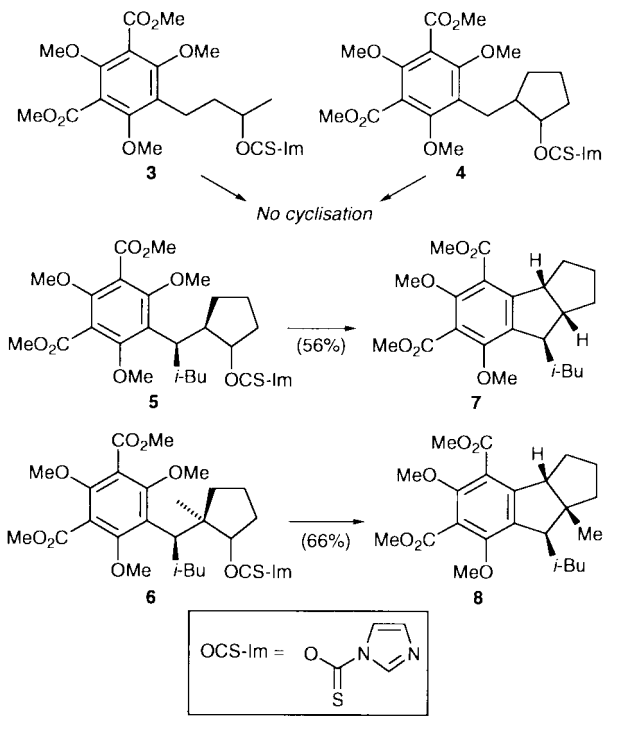
While conformationally favourable thiocarbamates bearing an aromatic methoxy group undergo intramolecular *ipso*-substitution of the methoxy group by treatment with tris(trimethylsilyl)silane (TTMSS) and AIBN, either conformationally flexible or favourable ketones easily cyclise into a five- or six-membered rings by treatment with SmI_2.

Radical cyclisation is one of the most useful methodologies for formation of a wide variety of carbon skeletons.[1] Particularly, the intramolecular reaction of the radical with an aryl group would provide an efficient synthetic route for constructing polycyclic systems containing an aromatic ring. During the course of our program directed toward the synthesis of macrocarpals,[2] we observed an unusual *ipso*-substitution of an aromatic methoxy group by treatment of the thiocarbamate **1** with TTMSS[3] and AIBN, yielding a cyclised product **2** (Scheme 1). A search of the literature revealed that there is no report describing the successful radical aromatic *ipso*-substitution of a methoxy group.[4] Accordingly, we undertook an investigation to identify the essential factor for the progress of this unusual cyclisation.[5]

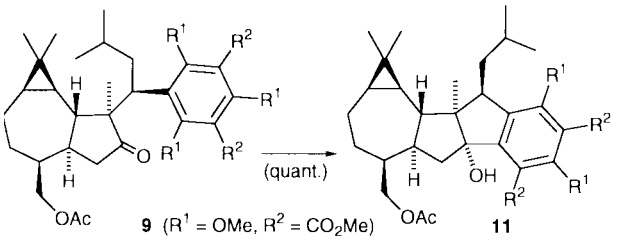
First, we prepared racemic thiocarbamates **3**–**6** bearing the substituted phenyl group, and exposed them to the radical cyclisation conditions described above. As shown in Scheme 2,

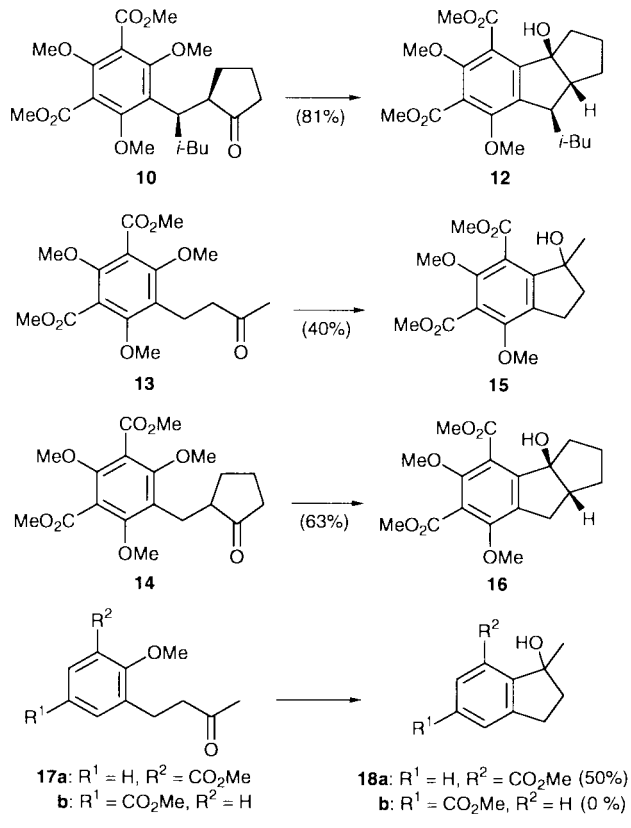


Scheme 1



Scheme 2





Scheme 3

DOI: 10.1039/b003742g

we observed no cyclisation by treatment of **3** or **4** with TTMSS–AIBN. However, conformationally more restricted thiocarbamates **5** and **6** gave the desired cyclised products **7** and **8**, respectively. In sharp contrast, the respective epimers of **5** and **6** at the benzylic position led to undesired reduction (deoxygenation or removal of thiocarbamate) under identical reaction conditions.

Based on these results, it is apparent that TTMSS-induced *ipso*-substitution is highly dependent on the steric nature of the starting thiocarbamates. Although the ground state and the reactive conformer are not necessarily the same, the conformation of radical intermediates, because of their low activation energy, is understood to have a significant effect on the course of the reaction. According to calculations,[6] the location of the alkyl radical generated from **5** and **6** is close to the reaction site (3.46 and 3.49 Å, respectively) in the most stable conformer.

This novel cyclisation is expected to be applicable to a wide range of substrates if the distance between the radical and aryl methoxy group could be shortened in some way. We then turned our attention to the strong chelating ability of samarium.[7] Since no information was available as to whether the aromatic methoxy group could be appropriately replaced by a ketyl radical, we initially explored SmI_2-induced cyclisation of the conformationally favoured ketones **9** and **10**. As shown in Scheme 3, these ketones were treated with 3.5 equivalents of SmI_2 in THF at room temperature, affording cyclised products **11** and **12**, respectively. Next, it was found that sterically more flexible ketones **13** and **14** could also be cyclised into **15** and **16** by exposure to SmI_2, as we expected. It should be clearly noted that in the TTMSS-induced reaction, we could obtain no cyclised products using the thiocarbamates **3** or **4** derived from the ketones **13** and **14** (Scheme 2). Interestingly, while **17a** gave the cyclised product **18a** in 50% yield, the ketone **17b** led to recovery of the unchanged starting material (64%) along with isolation of a small amount of the alcohol as a reduction product (22%).

Based on these observations, we propose the mechanism of chelation-induced cyclisation, as shown in Fig. 1. The ketyl radical intermediate **A**, generated by the reaction of the ketone **17a** with SmI_2, would be folded like **B** by the chelation of Sm(III) with the oxygen of both the methoxy and the ester group. Such chelation might attract the ketyl radical close to the reaction site, which enables the ketyl radical to attack the aromatic carbon. The resulting dienyl radical **C** was then reduced to the anionic species **D** by single electron transfer by SmI_2, followed by elimination of methoxide and hydrolysis to give **18a**.

In conclusion, we have developed a novel cyclisation reaction by radical *ipso*-substitution of an aromatic methoxy group. While TTMSS-induced cyclisation is highly dependent on the structure of the starting materials, SmI_2-mediated cyclisation was found to be applicable to conformationally flexible substrates. The scope and limitation of this novel cyclisation, and application to the synthesis of natural products are now being investigated in this laboratory.

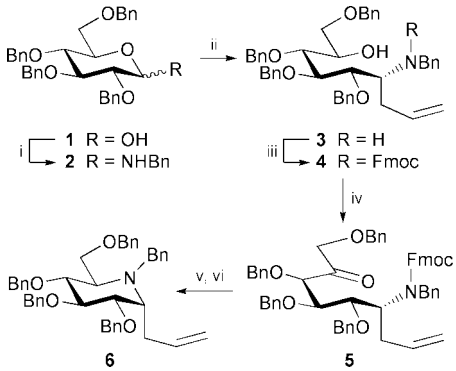
Reaction with allylmagnesium bromide of *N*,2,3,4,6-penta-benzyl-D-glucopyranosylamine 2, obtained from tetrabenzylglucose and benzylamine, afforded stereoselectively the open chain amino alcohol 3, which was converted into the *C*-glycoside of nojirimycin 6 by full protection of the amino function by Fmoc, oxidation of the free hydroxy group, hydrolysis of the Fmoc group and final intramolecular reductive amination with $NaBH(OAc)_3$; compound 6 was also converted into methyl ketone 7, by manipulation of the allylic appendage.

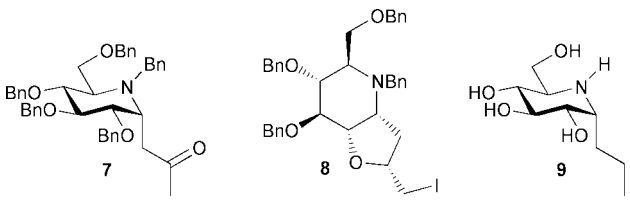
Deoxynojirimycin (1,5-dideoxy-1,5-imino-D-glucitol, DNJ) is a sugar-like plant alkaloid with inhibitory activity of a variety of glucosidases.[1] In particular, the capacity of deoxynojirimycin to inhibit trimming glucosidase I and II, interfering in N-linked oligosaccharide processing,[2] makes this molecule particularly attractive as a potential drug. It is well established that many pathological processes such as viral infections[3] and adhesion of tumour metastasis to endothelial cells,[4] involve complex N-linked oligosaccharides. Furthermore, inhibitors of glucosidases can find application in regulation of carbohydrate metabolic disorders.[5] In view of current interest in anti-HIV activity, the synthesis of DNJ derivatives and their analogues, which can reduce replication and infectivity of HIV, has attracted particular attention. Homologues,[6] deoxygenated,[7] *N*-alkylated,[7,9] *O*-glycosylated[7] and other DNJ derivatives have been synthesised by chemical[8] and enzymatic[9] methods. Investigation of their activity led to the interesting observation that short lipophylic appendages, *e.g.* a butyl group, at the N atom, strongly enhance the biological response.[10]

We wanted to find an efficient method for the introduction of a lipophylic substituent at position 1 of protected DNJ instead of at the N atom, particularly one affording stereoselectively the α-derivative, since the trimming α-glucosidases are the most interesting enzymes to be inhibited. We identified the allyl group as the substituent of choice, since its transformation into other functional groups, and its exploitation in the synthesis of neoglycoconjugates and *C*-disaccharides is widely described.[11]

Protected α-1-allyl-1-deoxynojirimycin has already been synthesised[12] from glucose through the key intermediate 1-fluoro-1-deoxynojirimycin, using a complex multistep sequence. We herein report an efficient approach allowing the stereoselective synthesis of protected α-1-allyl-1-deoxynojirimycin in 6 steps and 36% overall yield, using tetrabenzylglucose (**1**) as commercially available starting material (Scheme 1). This requires first the introduction of the amino function, secondly of the allylic appendage and finally the cyclisation to the desired piperidine derivative. From a stereochemical point of view, the allylation reaction and the cyclization are crucial to the effectiveness of the synthesis, and must be highly stereoselective. The amino group was introduced by reaction of **1** with benzylamine in CH_2Cl_2, in the presence of 4 Å molecular sieves and 1 equiv. of toluene-*p*-sulfonic acid. The resulting glycosylamine **2** (80% yield) was then treated with allylmagnesium bromide (10 equiv., Et_2O), in order to introduce stereoselectively the allylic appendage. The Grignard reaction occurs at the imino function, in equilibrium with the glycosylamine, *via* a Cram-chelated intermediate, affording stereoselectively the *threo* isomer **3** (81% yield, 90% de).[13] The cyclisation of **3** to the 'allyl-α-*C*-glycoside' of **6**, was accomplished by oxidation followed by reductive amination,[14] which turned out to be troublesome. Oxidation of the free –OH group of **3** with PCC resulted in over-oxidation and partial degradation of the product.[15] Swern oxidation with DMSO–Ac_2O provided the desired ketone with concomitant acetylation of the amine, and failed when Ac_2O was replaced with P_2O_5 or oxalyl chloride. These results clearly suggested that the amino group must be fully protected in order to perform a successful oxidation, and then deprotected to afford the cyclic azasugar by reductive amination. Both the protection/deprotection and the reductive amination reactions were difficult. Different protecting groups and reducing agents were tested. In terms of yields and stereoselection, the best results were obtained as follows: **3** was protected as **4** (FmocCl, Na_2CO_3, dioxane–H_2O, 89% yield), oxidised with PCC (CH_2Cl_2, 4 Å molecular sieves, 90% yield) to ketone **5**, then the amino group of **5** was deprotected with piperidine in DMF. Reductive amination of the crude product with $Na(OAc)_3BH$ (AcOH, dry Na_2SO_4, 1,2-dichloroethane, −35 °C) afforded **6**,† the protected allyl-α-*C*-glycoside of nojirimycin, in 78% yield and 90% de.‡ As an example of manipulation of the allylic appendage, **6** was treated with catalytic Na_2PdCl_4 (0.3 equiv.) and $CuCl_2$ (1 equiv.) in DMF–THF–H_2O (8/5/1) affording **7**§ in 50% yield. Alternatively, the allylic appendage can undergo a 5-*exo* iodocyclization–debenzylation, involving the benzyloxy group in the γ position.[16] Treatment of **6** with NIS in THF, afforded stereoselectively the bicyclic compound **8**¶ (2′*R*, determined by NOE experiments, as the only detected isomer) in 42% yield. Deprotection of **6** by



Scheme 1 *Reagents and conditions*: i, $PhCH_2NH_2$ 10 equiv., PTSA 1 equiv., CH_2Cl_2, 4 Å m.s., 80% yield, 5 days; ii, CH_2=$CHCH_2MgBr$ 10 equiv., dry Et_2O, 81% yield, 90% de; iii, FmocCl, dioxane–10% aq. Na_2CO_3, 89% yield; iv, PCC 3 equiv., CH_2Cl_2, 4 Å m.s., 90% yield; v, piperidine, DMF; vi, $NaHB(OAc)_3$, AcOH, dry Na_2SO_4, 1,2-dichloroethane, −35 °C, 78% yield, 90% de.



DOI: 10.1039/b003877f

hydrogenolysis [H_2, $Pd(OH)_2$, AcOH, AcOEt–EtOH 1:1] afforded **9**[12] in quantitative yield.

The procedure herein reported allows the synthesis of protected allyl-α-*C*-glycoside of nojirimycin through a highly stereoselective (80% de) and high yielding procedure (36%, 6 steps), from commercially available tetrabenzylglucose. The manipulation of the allylic appendage, widely reported in *C*-glycosides and to some extent also in iminosugars, allows the synthesis of a variety of functional groups and derivatives. The reported approach will be exploited in future projects devoted to the synthesis of imino-*C*-disaccharides.

We thank the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST) for financial support and Paolo Petroni for contributing to the experimental work.

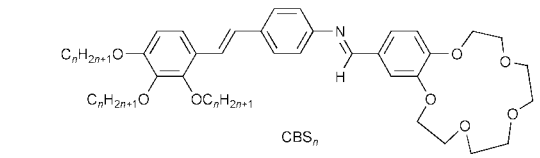
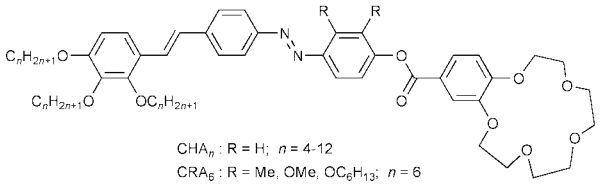
Thermotropic ionic nematics with moderate transition temperatures are obtained by dissolving alkali metal salts within nematogens bearing a crown ether moiety; in these media, the ions show a significant 'apparent ionic order' as measured by quadrupolar NMR spectroscopy.

Functionalized liquid crystals, which show the ordered structures of solids and the mobility of liquids, provide a combination of very innovative properties for numerous applications.[1] It is with this intent that grafting of poly(ethylene oxide)[2–6] or crown ether moieties has been already researched.[6–10] These segments are intriguing because they can dissolve organic molecules and ionic compounds.[11] However, when these polar units are linked to nematogen cores, microsegregation occurs between the different segments and leads to highly ordered self-organized phases.[12] The nematic phase is most suitable for NMR studies owing to its easy orientation in the magnetic field.

In this work we show that liquid crystals CBS_n, CHA_n and CRA_6 containing lateral chains and terminal crown ethers display a nematic phase at moderate temperatures over a wide temperature range, even when significant amounts of salt are dissolved within the phase. The cation binding ability of these new nematogens was analysed by thermal analysis and NMR studies. The three series of compounds were synthesized following standard steps which have already been reported.[4,13]





The transition temperatures of the compounds CBS_n and CHA_n are plotted in Fig. 1. The CBS_n compounds show monotropic behaviour while all compounds in the CHA_n and CRA_6 families show an enantiotropic nematophase over a wide temperature range. As expected, the mesogenic behaviour is very sensitive to the properties of the rigid core. The CBS_n series is based on three conjugated aromatic units. The balance between the mobility induced by the three alkoxy chains, the rigidity of the conjugated core and the relative rigidity of the crown ether leads to compounds presenting monotropic behaviour with a large temperature difference between the melting and the isotropic–nematic transitions.[13] Lenghtening of the rigid core in the CHA_n series leads to the formation of enantiotropic nematophases at fairly high temperatures relative to the CBS_n series.

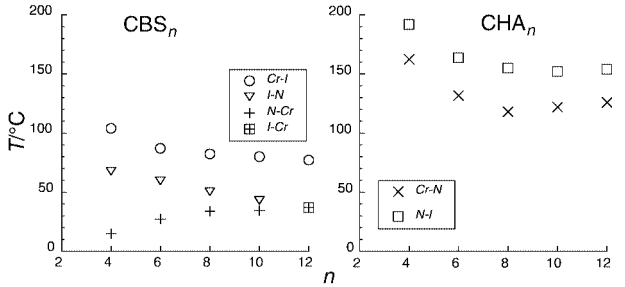


Fig. 1 Nematic range for CBS_n and CHA_n; transition temperatures measured by DSC (10 °C min^{-1}) (Cr: crystalline, N: nematic, I: isotropic).

To our knowledge, molecules of the CHA_n series are the first nematogens containing a crown ether moiety which show a large liquid crystalline range and reasonably low transition temperatures. This can be explained by the presence of three alkyl chains which increases the fraction of the mobile components which perturb the molecular cooperative packing by decreasing the segregation between aromatic, polyether and aliphatic fragments.[13] This effect has been also observed in polycatenar compounds.[14] In order to decrease the transition temperatures we have introduced lateral substituents. The liquid-crystalline properties of the CRA_6 compounds are listed in Table 1. As expected, the presence of lateral substituents substantially decreases the transition temperatures.

Crown ether derivatives are widely studied for their ability to dissolve salts by complexing cations leading to 'host–guest' entities.[11] Consequently, Li^+ and Na^+ salts were introduced inside the CHA_4 compound. Measured quantities of salt and nematogen were dissolved in $CHCl_3$–THF and heated for 1 h. Then the solvents were removed *in vacuo* and further dried (0.1 mm Hg, 70 °C, 3 h). The mixtures were then studied by DSC and polarizing microscopy. The phase diagrams are shown in Fig. 2 as a function of the molar ratio x (x = cation/crown ether moiety). CHA_4 mixed with $LiBF_4$ or $NaCF_3SO_3$ behave similarly with a nematic phase observed for x up to 0.5, and a more ordered smectic phase for higher values of x.

This molecule shows an unexpected nematic phase for a wide range of x, whereas molecules described elsewhere in the literature always show very ordered phases, even for low values of x. These ordered phases are generally explained by the

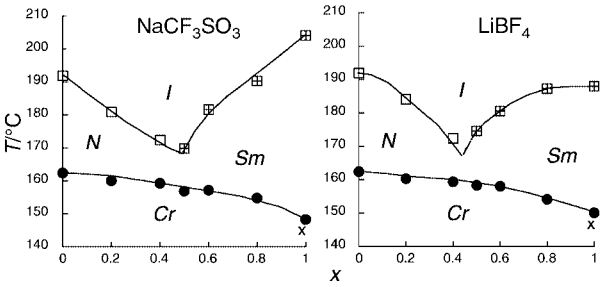

Fig. 2 Phase diagrams for CHA_4 alkali salt mixtures.

stacking of two molecules sharing one cation or by the segregation of the ionic motives in columnar mesostructures.[6] In these new systems, the observation of nematic phases over a large compositional range (x) can be explained by the three alkyl chains which prevent ionic interactions between cations, counter anions and molecules. The size of the crown cavity is larger than Li^+ but fits Na^+ ions well, while larger cations such as Cs^+ do not fit[11] and attempts to obtain mesogenic phases with this ion failed.

NMR of quadrupolar nuclei (*i.e.* with nuclear spin $I > \frac{1}{2}$) is a very sensitive method for probing the local anisotropy inside oriented media.[15] In isotropic solvents the averaged electric field gradient (*efg*) is zero and each non-equivalent nucleus gives a single line in the fast reorientation regime. In contrast, when ions are dissolved in anisotropic media, host–guest interactions may lead to the partial orientation of the dissolved entities and to a polarization of the electronic cloud, leading to a partially ordered *efg* of the cation which leads to $2I$ equally spaced lines. The existence of a quadrupolar splitting indicates that ions are effectively distorted and oriented inside anisotropic media. The measured quadrupolar splitting, $\Delta\nu_Q^{(ion)}$, represents the so-called 'apparent ionic order'.[16]

^7Li and ^{11}B ($I = \frac{3}{2}$) NMR spectra obtained for CRA_6 (R = Me) mixed with 0.2 equivalents of $LiBF_4$ [nematic range 136.6–152.4 °C (heating cycle) and down to 85 °C (cooling step)] are shown in Fig. 3. At 433 K, single lines are observed, thus showing the isotropy of the medium. Narrow linewidths were measured for both ions (*ca*. 20 Hz) which indicates their high mobility inside the fluid system. In the nematic state (400 K), triplets (intensities 3:4:3) were observed for both nuclei, indicating that both cations and anions experience the anisotropy of the media. The quadrupolar splittings, $\Delta\nu_Q^{(Li)}$ and $\Delta\nu_Q^{(B)}$ are ten times larger than those measured in swollen oriented DNA fibers[17] or lyotropic liquid crystals.[18] An enlargement of the ^{11}B central signal also indicates a quintet structure, which corresponds to the dipolar splitting $T_{B-F}^1 = 66$ Hz. An 'apparent ionic order' $S = 5 \times 10^{-3}$ was calculated for the anion inside these structures. This low value may be attributed to anisotropic tumbling and distortion of the anion from its initial T_d symmetry.[18]

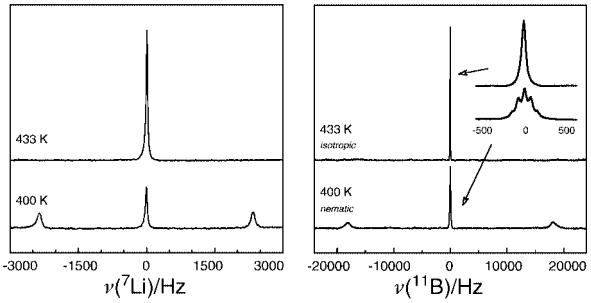

Fig. 3 ^7Li and ^{11}B NMR spectra of $LiBF_4$ (0.2 mol dm^{-3}) dissolved in $CMeA_6$, in the isotropic and nematic state. Spectra are shown to an absolute scale.

Further studies are in progress to understand the orientation inside these systems and to correlate these values with ion-crown complexation and ion-pairing.

Novel synthesis of alkali and quaternary onium hydroxides *via* liquid anion exchange; an alternative concept for the manufacture of KOH and other hydroxide salts

Gadi Rothenberg,† Harold Wiener, Zohar Lavie and Yoel Sasson*

Casali Institute of Applied Chemistry, Hebrew University of Jerusalem, 91904, Israel. E-mail: ysasson@vms.huji.ac.il

Received (in Cambridge, UK) 19th April 2000, Accepted 7th June 2000
Published on the Web 26th June 2000

Alcohols enhance the extraction of a basic potential through a liquid membrane in the presence of quaternary ammonium salts, thus enabling preparation of caustic solutions without direct transport of hydroxide ions.

Production of potassium hydroxide (KOH) in the US in 1993 was 276 kilotons.[1] It is used principally in the manufacturing of K_2CO_3 and $KMnO_4$, and for the production of pesticides, fertilizers, soaps and detergents.[1] Quaternary onium hydroxides are mainly used as phase-transfer catalysts and as templating agents in the synthesis of molecular sieves.[2]

Currently, KOH is produced industrially by the electrolysis of KCl, using diaphragm cells, mercury cells, or ion-exchange membrane cells. Because of high energy costs and product impurities associated with diaphragm cells, most of the KOH is produced using ion-exchange membrane cells or mercury cells. Obviously, environmental awareness is a prime concern in KOH plants employing the latter protocol. Other electrolytic and electrodialytic methods are known for the preparation of MOH-type salts[3,4] and quaternary onium hydroxides[5] on a small and medium scale, but all of these alternatives are capital and energy intensive, with product cost very sensitive to plant size.

We have previously shown that quaternary ammonium hydroxides could also be produced on a laboratory scale in a batch solid-liquid extraction process.[6] However, since it was necessary to use a methanolic solution, no phase separation was obtained, leading to a complicated protocol which precluded large-scale applications.‡

It is well known that direct liquid/liquid extraction of hydroxide anions using onium salts is practically impossible.[7] However, we have now discovered[8] that contacting a weak organic acid ($pK_a > 16$; *e.g.* an alcohol) with a quaternary onium halide in a hydrophobic medium, creates a liquid membrane that can selectively extract and release a basic potential between two aqueous solutions. This enables the preparation of various hydroxide salts, in good yields and purities, without physically transferring hydroxide ions through the membrane. The process requires only simple extraction equipment and utilises NaOH, the cheapest and most widely available caustic source.

Our process is based on two extraction stages. First, a concentrated aqueous solution of NaOH is contacted with a hydrophobic solvent which contains a quaternary onium halide QX (X = Cl, Br, I) and a lypophilic alcohol, ROH. The differences in lipophilicity between the alkoxide ion, RO^-, and the halide, result in the formation of QOR in the organic phase, with concurrent extraction of the halide into the aqueous phase [eqns. (1) and (2)].

$$NaOH_{(aq)} + ROH_{(org)} \overset{K_1}{\rightleftharpoons} NaOR_{(int)} + H_2O_{(aq)} \quad (1)$$

$$NaOR_{(int)} + QX_{(org)} \overset{K_2}{\rightleftharpoons} NaX_{(aq)} + QOR_{(org)} \quad (2)$$

In the second stage, the phases are separated, and the organic phase is contacted with an aqueous solution of the appropriate alkali (or alkali-earth or quaternary onium) halide salt. The basicity potential is extracted into the aqueous phase as the QOR moiety reacts with the *water* and MX to form ROH and QX in the organic phase and MOH in the aqueous phase [eqn. (3)]. The organic phase is then recycled, with no further treatment, back to stage 1.

$$QOR_{(org)} + MX_{(aq)} + H_2O \overset{K_3}{\rightleftharpoons} QX_{(org)} + ROH_{(org)} + MOH_{(aq)} \quad (3)$$

Successive extractions increase OH^-/X^- ratios in the product solution after each pass, depending on the total equilibrium constant for the above reactions (*i.e.* the extraction

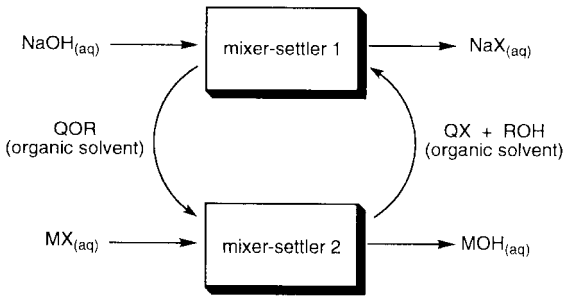

Scheme 1 Schematic representation of continuous MOH production.

is better for systems where K_1K_2 and K_3 are large). This can be explained by considering the selectivity constants§ of the various anions involved. Since the second extraction equilibrium is readily shifted to the right, the overall equilibrium constant ($K_1K_2K_3$) is determined by the selectivity constant of the alkoxide anion formed in the organic solvent. In the absence of the alcohol, the miniscule selectivity constants of the hydrophilic hydroxide anions lead to the relatively poor basicity extraction during the first extraction stage. However, the much higher selectivity constants of the alkoxide anions enhance the desired basicity extraction into the organic phase.[9,10]

The synthesis of KOH from KCl and NaOH, using different extracting agents, was chosen as a typical case study.¶ The results of extraction experiments under various conditions are summarized in Table 1. Repeated experiments showed that good yields of KOH were obtained from KCl using this method. 6–8 cycles were typically required to reach equilibrium. CsOH, LiOH and NMe_4OH, were similarly prepared from the corresponding chloride salts. Ammonium salt losses were typically $<2\%$ after 20 cycles, depending on solvent and concentration.

It can be seen that the extraction efficacy depends on the type of alcohol, in the order diols > primary alcohols > secondary alcohols. The high activity of diols may be attributed to possible formation of an intramolecular hydrogen-bonded complex.[10]

In conclusion, we present here a novel concept for the preparation of hydroxide salts, which is effected through a series of simple liquid anion exchange extractions. This concept may be conveniently adapted into a continuous process using mixer-settler techniques, as shown in Scheme 1, and may therefore constitute a practicable, cheap, and eco-friendly alternative to existing mercury-cell technologies.

Notes and references

‡ Lipophilic ammonium hydroxides (with at least two alkyl chains above C_8) may be obtained by extraction of hydroxide ions into an alcohol organic phase with lipophilic ammonium chlorides.[11] However, this method cannot be used for the manufacture of hydrophilic ammonium hydroxides.

§ For a given pair of anions Y^- and Z^-, the selectivity constant, $K^{sel}_{(Z/Y)}$ is defined as the equilibrium constant for the biphasic exchange reaction $QY_{(org)} + Z^-_{(aq)} \rightleftharpoons QZ_{(org)} + Y^-_{(aq)}$, *i.e.* $K^{sel}_{(Z/Y)} = \{[Y^-_{(aq)}][QZ_{(org)}]\}/\{[Z^-_{(aq)}][QY_{(org)}]\}$.[12]

¶ Representative experimental procedure: a source solution **A** was prepared by dissolving 50 g of NaOH in 50 g of water (50% w/w soln, 12.5 mol kg^{-1} NaOH). An extractant solution **B** was prepared by dissolving 40 g of Aliquat-336 and 12 g of pinacol in 48 g of hexane (1 mol kg^{-1} A-336 and pinacol). A destination solution **C** was prepared by dissolving 15 g of KCl in 85 g water (15% w/w soln, 2 mol kg^{-1} KCl). Solutions **A** and **B** were contacted at 25 °C, and, following phase separation, the organic (lighter) phase **B** was contacted with solution **C** at 25 °C. The phases were separated and solution **C** was analyzed for Cl^- and OH^- content by volumetric titration (HNO_3 0.01 mol kg^{-1} for titrating OH^- ions, using phenolphthalein as indicator; $AgNO_3$ 0.05 M for titrating chloride ions, using K_2CrO_4 as indicator). After the first cycle, the KCl solution contained 20 mol% KOH. The process was repeated until analysis of the chloride content of solution **C** showed that an equilibrium was reached (*ca.* 80 mol% KOH after eight cycles). Evaporation and filtration of the destination solution **C** precipitated the remaining KCl to yield up to >98% pure KOH soln.[13]

Phenol and resorcinol can be acetylated to the corresponding esters and ketones in aqueous and neat acetic acid at high temperature (250–300 °C) to substantial equilibrium conversion without any added acid catalyst.

Friedel–Crafts and other acylations generally require stoichiometric quantities of strong mineral acids, such as H_2SO_4, H_3PO_4, and HCl, or nonregenerable Lewis acids, such as $AlCl_3$.[1] These acids require neutralization and disposal, and disposal costs can be considerable. The conventional acylation of one mol of phenol with acetic acid consumes stoichiometric quantities of $AlCl_3$. Neutralizing this $AlCl_3$ requires land-filling several pounds of $Al(OH)_3$ salt for every pound of product produced.[2,3] In addition, many of these reactions require polar organic solvents, such as methylene chloride, that can simultaneously dissolve the reactants as well as the reactant–catalyst complex.[1,3]

Aromatic acylations have also been performed successfully without salt production over solid acids, such as zeolites,[4] as well as polymer supported alkyl sulfonic acid.[5] Heterogeneous catalysis of this type, however, generally requires the operating expense of vaporizing the reactant and the increased capital cost of the large vessels needed for solid–vapor contacting. In addition, the need for periodic regeneration or replacement of the rapidly deactivating zeolite catalysts may preclude their use in commercial applications where reactants readily form coke. Ghibaudi and Colassi attempted the Fries rearrangement of phenyl acetate at low pressure and very high temperatures (T > 675 °C) without catalyst, but only phenol and ketene were detected as products.[6] Photo-Fries rearrangements of phenyl acetate[7] and 2,5-dimethylphenyl acetate[8] have been run successfully to produce the corresponding ketones.

Another alternative to acid catalysts that require neutralization and disposal are polar-protic solvents at elevated temperature that can simultaneously act as the solvent, catalyst, and, in certain cases, the reactant. Liquid water (T_c = 374 °C) in the nearcritical region (250–300 °C) exhibits some beneficial properties that make it a good solvent and catalyst for acid-catalyzed organic reactions. As the temperature is increased from room temperature to 275 °C, the dieletric constant decreases from 80 to 20, and nearcritical water readily dissolves both organic and ionic compounds. Even non-polar organics, such as toluene, become miscible above 300 °C.[9–10] In addition, the dissociation constant of water increases by three orders of magnitude from room temperature to 275 °C, making it a source of hydronium and hydroxide ions that may catalyze reactions. Nearcritical water has been used as a solvent, catalyst, and reactant for a number of hydrolyses that require added mineral acid at ambient conditions.[9,12–15] It has also been successfully used for the Friedel–Crafts alkylation of phenol and *p*-cresol with *tert*-butyl alcohol.[16]

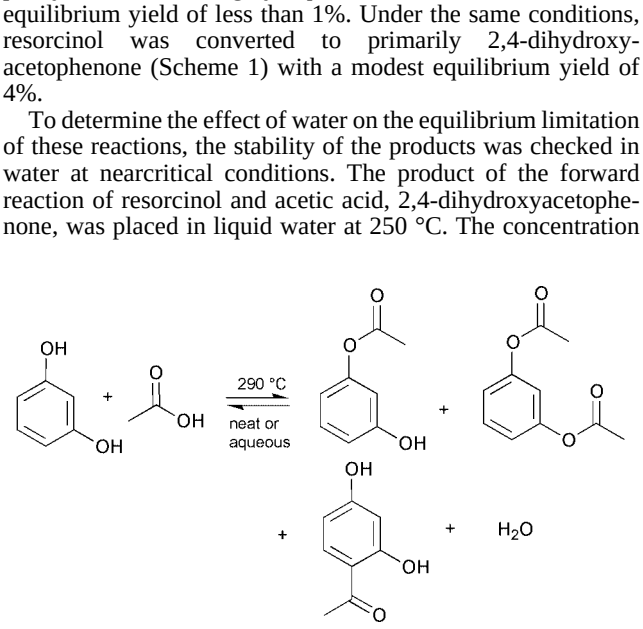
Nearcritical acetic acid (T_c = 319 °C) is another polar, protic solvent that may simulatenously act as the solvent, catalyst, and reactant in some reactions. Similar to nearcritical water, nearcritical acetic acid readily dissolves organics, and it has a higher acid strength and dissociation constant than water. Acetic acid can also be distilled from reaction products unlike other Lewis acid catalysts, such as $AlCl_3$, that require neutralization to salts and subsequent disposal.

We have successfully acetylated phenol and resorcinol in nearcritical water, as well as in neat acetic acid, in the temperature range 250–300 °C without any added acid catalyst or UV light. Performing Friedel–Crafts acylations and Fries-rearrangements in neat or aqueous acetic acid at elevated temperatures is also attractive as no additional organic solvent is required, and any unused acetic acid may be recycled for further reaction.

The reactions were performed in 3.2 ± 0.2 ml titanium batch vessels as described elsewhere.[16] Each vessel was loaded with phenol or resorcinol, an excess of acetic acid (Aldrich, HPLC grade), and, in certain experiments, deoxygenated water (Aldrich, HPLC grade). For reactions in neat acetic acid, the molar ratio of reactant to acetic acid was 1:50. For reactions in aqueous acetic acid, the molar ratio of reactant to acetic acid to water was 1 : 12 : 47, respectively. Products were identified by GC–MS (EI mode) and by comparison of the GC retention times and EI mass spectra to those of commercially available compounds. The composition of the each product mixture was quantified by GC-FID.

The Friedel–Crafts alkylations of phenol and *p*-cresol with *tert*-butyl alcohol in nearcritical water previously reported[16,17] were found to be reversible, with equilibrium yields of *ca.* 20 mol%. In this work, we report that the acetylations of phenol and resorcinol are also reversible at high temperature in the presence of water, but with less favorable equilibrium yields. These acylations are generally irreversible with traditional Friedel–Crafts catalysts due to the complexation of the acid catalyst with the carbonyl oxygen of the product. In this work, however, products were not stabilized by complexation with catalyst and were free to react back to starting material. In aqueous acetic acid at 290 °C, phenol was primarily converted to 2′-hydroxyacetophenone, 4′-hydroxyacetophenone, and phenyl acetate in roughly equal amounts, with a combined equilibrium yield of less than 1%. Under the same conditions, resorcinol was converted to primarily 2,4-dihydroxy-acetophenone (Scheme 1) with a modest equilibrium yield of 4%.

To determine the effect of water on the equilibrium limitation of these reactions, the stability of the products was checked in water at nearcritical conditions. The product of the forward reaction of resorcinol and acetic acid, 2,4-dihydroxyacetophenone, was placed in liquid water at 250 °C. The concentration



Scheme 1

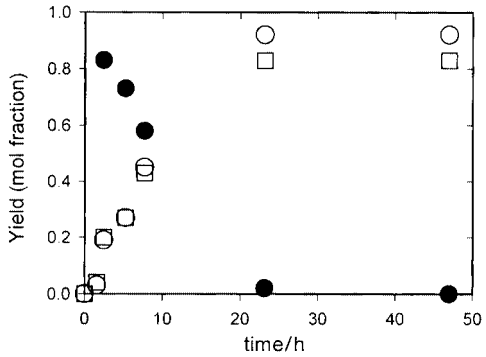


Fig. 1 Back reaction of 2,4-dihydroxyacetophenone (●) to resorcinol (□) and acetic acid (○) using water at 250 °C as solvent.

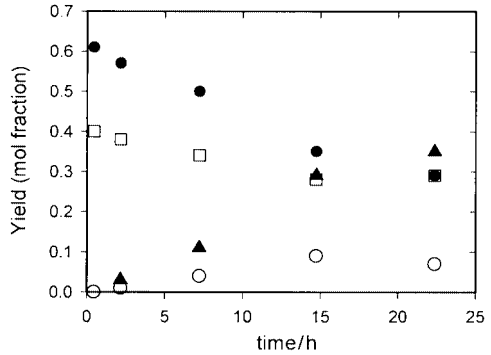

Fig. 2 Reaction of phenol (□) and acetic acid to phenyl acetate (●), 2′-hydroxyacetophenone + 4′-hydroxyacetophenone (○), and byproducts (▲) at 290 °C.

vs. time data of the almost complete conversion of 2,4-dihydroxyacetophenone back to the corresponding amounts of resorcinol and acetic acid are shown in Fig. 1. The products of the phenol acetylation, 2′-hydroxyacetophenone, 4′-hydroxyacetophenone, were also converted to phenol and acetic acid when high-temperature water was used as a solvent.

The tunable solvent properties of nearcritical water allow for the facile separation of products upon cooling, but excess water imposes too severe an equilibrium limitation on this reaction. To overcome the equilibrium limitation in the presence of excess water, the acetylations of phenol and resorcinol were run in neat acetic acid. Unlike water, acetic acid does not require elevated temperature to solubilize organics, so phenol was first refluxed in neat acetic acid for 24 h (*ca*. 117 °C). This resulted in an equilibrium conversion of 16% entirely to phenyl acetate with no detectable quantities of 2′-hydroxyacetophenone or 4′-hydroxyacetophenone. In neat acetic acid at 290 °C, however, phenol was converted to 2′-hydroxyacetophenone, 4′-hydroxyacetophenone, and phenyl acetate, with a combined equilibrium yield of 8 mol% (Fig. 2). Byproducts included 2-methyl chromone and 4-methyl coumarine. These same byproducts have been found in the Fries rearrangement of phenyl acetate over zeolites and are a result of the intramolecular reaction of 2-acetoxyacetophenone.[18] Under the same conditions, resorcinol was successfully converted to primarily 2,4-dihydroxyacetophenone, with an equilibrium yield of more than 50%, in less than 12 h. The yield of 2,4-dihydroxyacetophenone *vs*. time is shown in Fig. 3.

Although no water was added initially, the reactions in neat acetic acid remain equilibrium limited. In contrast to the Fries rearrangement of phenyl acetate, however, water is produced from the reaction of acetic acid and phenol or resorcinol. This implies that the water produced by the forward reactions in neat acetic acid may also promote the reverse reaction to phenol or

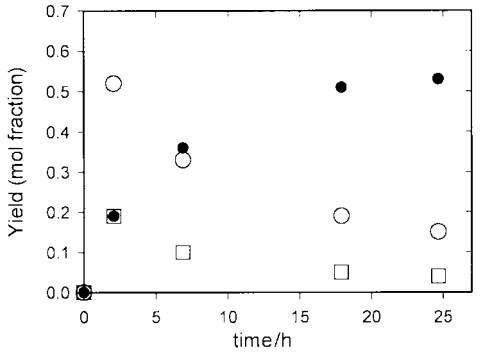

Fig. 3 Reaction of resorcinol and acetic acid to 2,4-dihydroxyacetophenone (●), resorcinol monoacetate (○), and resorcinol diacetate (□) at 290 °C.

resorcinol and acetic acid. The production of water could be avoided by starting the reaction with the corresponding monoesters of phenol and resorcinol.

In summary, Friedel–Crafts acylations of activated aromatic compounds can be run homogeneously at high temperature in nearcritical water without added Lewis acid catalysts, which have an undesirable environmental impact. While nearcritical water allows for subsequent separation of products upon cooling, it limits the reaction equilibrium yield of desired products when present in excess. Running the same reaction in neat acetic acid allows for a ten-fold increase in yield, while still avoiding the unwanted salt byproducts associated with strong mineral and Lewis acid catalysts.

We are grateful for the financial support of Kosa, Celanese, the Environmental Protection Agency, the National Science Foundation, and the Deutsche Forschungsgemeinschaft. We would like to thank Carla Moopenn, Griffin Smith, and Lee Suber for their help collecting data.

Received (in Cambridge, UK) 10th April 2000, Accepted 26th May 2000

The crystal structure of $\{[Cu(en)_2][KCr(CN)_6]\}_\infty$ reveals a novel three-dimensional porous framework in which $[Cu(en)_2]^{2+}$ acts as a template and K^+ as a connecting unit.

For years, chemists have devoted their efforts and have dreamt about the ability to assemble compounds, by using building units and connecting units in similar way that a bricklayer would erect a building. With the development of crystallography and synthesis chemistry, the assembly of polymer compounds[1] on the basis of simply adding building units and connecting them, is now achievable. Recently, a successful example of this process was construction of cyano bridged complexes[2] in which the cyanometallate anion behaves as the bridging moiety to build a multidimensional structure with a second coordination center and the resulting complexes demonstrated unique properties. These complexes are usually composed of a cyanometallate $[M(CN)_n]^{m-}$ (building unit), and a guest molecule and/or a complementary ligand. In general, the choice of the cyanometallate is limited, since the geometry of the complexes are restricted to, *e.g.* linear as in $[Ag(CN)_2]^-$,[2a] trigonal as in $[Cu(CN)_3]^{2-}$,[3] tetrahedral as in, $[Cd(CN)_4]^{2-}$,[4] square planar as in $[Ni(CN)_4]^{2-}$,[5] and octahedral $[M(CN)_6]^{3-}$.[2b,c] The second coordination center, however, can be almost any metal ion in the Periodic Table. Usually, the transition metal ion is selected because of the existence of a σ–π feedback bond between the selected metal ion and the cyano group which enables production of more stable complexes. The guest ion is often associated with organic molecules or other ions,[4,5] such as H_2O, unidentate aliphatic amines, ambidentate α,ω-diaminoalkanes, aromatic amines, pyrazine or piperazine. These compounds are necessary to fill up the void space so stabilizing the crystal structure.

We have recently prepared and structurally characterized a new polymeric supramolecular compound $\{[Cu(en)_2][KCr(CN)_6]\}_n$ **1**[9] (en = ethylenediamine) through a one-step self-assembly reaction of the complex $[Cu(en)_2](ClO_4)_2$ and $KCr(CN)_6$ in aqueous solution. The compound assembles itself *via* hexacyanochromium $\{[Cr(CN)_6]^{3-}\}$ as the building unit, and potassium cations as the connecting units. The copper(II) complex $[Cu(en)_2]^{2+}$ acts as the template/guest molecule. This is also a novel example where the potassium ion acts as a connecting unit to form a three-dimensional porous framework with the $[Cr(CN)_6]^{3-}$ ion. It is uncommon that the complex ion $[Cu(en)_2]^{2+}$ acts both as a special template, whose size, shape and charge match that of the cavity in the host lattice, and as a guest which stabiizes the crystal lattice. In fact, without $[Cu(en)_2]^{2+}$, $K_3[Cr(CN)_6]$ cannot form a three dimensional porous structure.

The IR spectra of complex **1** shows two sharp ν_{CN} bands at 2124 and 2111 cm^{-1} which are at lower wavenumber than that of the bridging cyano group (2150 cm^{-1} for the linear Cr–CN–Ni moiety[2c]) or a non-bridging cyano group {2128 cm^{-1} for the complex $K_3[Cr(CN)_6]$[6]} and indicates that these two cyano groups are neither linear bridging linked to two transition metals (Cr^{3+}, Cu^{2+}), nor non-bridging. Indeed the cyano group coordinates to potassium ions, as has been established by crystallography.

The asymmetric unit of **1** consists of a $[Cr(CN)_6]^{3-}$ ion, a K^+ and a $[Cu(en)_2]^{2+}$ ion and the structure is shown in Fig. 1. The geometry of the Cr^{3+} ion is octahedral with coordination of six carbon atoms of the cyano groups. The Cr–C bond lengths are 2.065(3), 2.080(2) and 2.085(2) Å, similar to values found in $K_3[Cr(CN)_6]$ (2.057, 2.075, 2.100 Å)[7] and $PPh_4[Ni(pn)_2][Cr(CN)_6]\cdot H_2O$ (pn = 1,3-propanediamine) (2.062, 2.083 and 2.087 Å).[2c] The six nitrogen atoms of the cyano groups coordinate to a potassium cation. According to the bond lengths (K–N) and bond angles (C–N–K) the six cyano groups can be divided into two groups. The first group is found in linear Cr–C–N–K chains, with K–N distances of 2.846 and 2.766 Å, and C–N–K bond angles of 172.3 and 178.6°. The

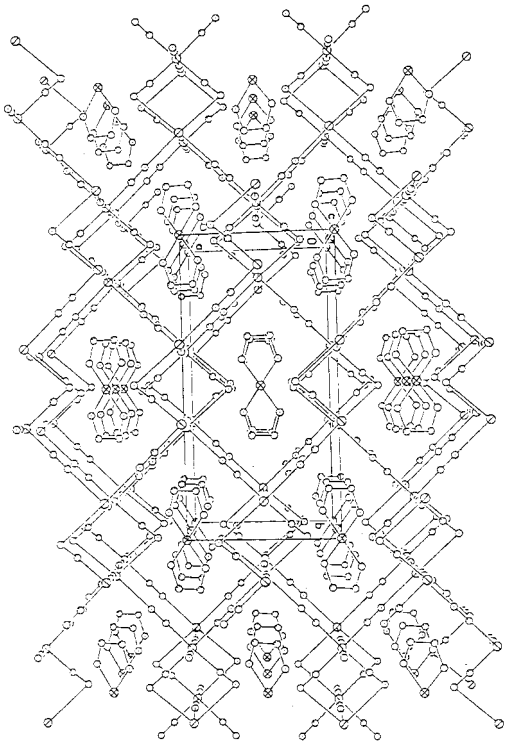

Fig. 1 Projection of the 3-D network structure of **1** in which the $[Cu(en)_2]^{2+}$ cations act as templates.

† Present address: Department of Welding and Material Engineering, East China Shipbuilding Institute, Zhengjiang 210093, P.R. China.

DOI: 10.1039/b002913k

second group comprises non-linear Cr–C–N–K chains with the CN group coordinating sideways,[8] with K–N distance of 3.229 Å, much longer than the linear bond distance. IR spectroscopy provides additional evidence with two ν_{CN} bands being observed with the intensity of the low wavenumber band at 2111 cm^{-1} being more intense than that of the high wavebumber band at 2124 cm^{-1}. The first band is due to the four σ bonded cyano groups linearly attached to a potassium cation while the second band results from the two cyano groups bonded sideways to potassium cations. This assignment is consistent with the molecular structure, in which four cyano groups donate their σ bonding electrons to the empty d^2sp^3 hybrid orbitals of the K^+ ions to form four σ-bonds which decreases the wavenumber, ν_{CN}. Another two cyano groups, which are part of the same hexacyanochromium ion, coordinate to K^+ ions sideways,[8] which owing to the orientation of the frontier orbitals, leads to poorer overlap. Consequently, the wavenumber of the cyano group is higher for the sideways coordination mode than for a linear σ bond.

The spontaneous assembly process of $Cu(en)_2(ClO_4)_2$ and $K_3[Cr(CN)_6]$ is a very specific one-step reaction. The $[Cu(en)_2]^{2+}$ ion acts both as a template and a guest while the structure of the host $\{[KCr(CN)_6]^{2-}\}_\infty$ is dependant upon the shape, size and charge of the guest ion. The cavity is very tight, and use of bulkier substituents $\{[Cu(nmen)_2]^{2+}$, $[Cu(dmen)_2]^{2+}$, $[Cu(tmen)_2]^{2+}$, $[Cu(pn)_2]^{2+}$; nmen = *N*-methylethylenediamine, dmen = *N*,*N*-dimethylethylenediamine, tmen = tetramethylethylenediamine, led to different types of complexes. In the self-assembly process of **1**, other than its shape, size and charge, the chemical properties of the $[Cu(en)_2]^{2+}$ ion is another important factor. Using $[Ni(en)_2]^{2+}$ (same symmetry) in place of $[Cu(en)_2]^{2+}$ ion, led to a different polymer complex $\{[Ni(en)_2]_3[Cr(CN)_6]\}_\infty$.

This work was supported by the National Nature Science Foundation of China for key project No. 29823001.

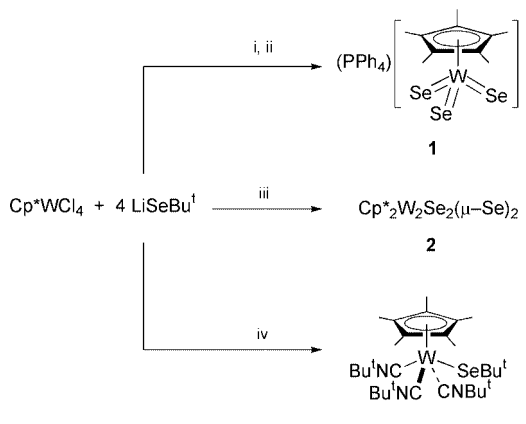
Received (in Cambridge, UK) 25th April 2000, Accepted 5th June 2000

The reaction of Cp^*WCl_4 with $LiSeBu^t$ in THF in the presence of Bu^tNC gave rise to $Cp^*W(SeBu^t)(CNBu^t)_3$ 3, while treatment of the $Cp^*WCl_4/LiSeBu^t$ reaction mixture with Li_2Se_2 followed by cation exchange with PPh_4Br in MeCN afforded $(PPh_4)[Cp^*WSe_3]$ 1.

The chemistry of terminal selenido complexes is much less developed than that of the familiar metal oxides and sulfides.[1] This is mainly because many of the traditional reagents used in metal oxo and sulfido chemistry are not simply transferable to their selenido congeners.[2] In the course of our studies of group 6 transition metal chalcogenido chemistry, we previously isolated the half-sandwich tri(sulfido) complexes $[Cp^*MS_3]^-$ (M = Mo, W).[3,4] Carbon–sulfur bond rupture of thiolato complexes gives ready access to thiolato/sulfido derivatives and eventually $[Cp^*MS_3]^-$. Here we report the synthesis of $(PPh_4)[Cp^*WSe_3]$ **1** *via* C–Se bond cleavage.

For the selenolation reagent, the readily accessible $LiSeBu^t$ was employed, which is prepared by the reaction of $LiBu^t$ with 1 equiv. of selenium in THF at −78 °C. We have reported facile C–S bond cleavage of *tert*-butylthiolato complexes of group 5 and 6 metals,[3] and C–Se bond activation was expected to occur for the analogous selenolato complexes. Addition of 4 equiv. of $LiSeBu^t$ to Cp^*WCl_4 in THF at −78 °C gave a red solution. After stirring for 30 min, the solution turned brown, from which $Cp^*_2W_2Se_2(\mu\text{-}Se)_2$ **2** was obtained in 40% yield (Scheme 1). Spectral data show that **2** is a mixture of *syn*- and *anti*-isomers. In a separate experiment, a freshly prepared $Cp^*WCl_4/LiSeBu^t$ mixture was quickly transferred into a THF solution of Li_2Se_2 to give a dark red suspension. Cation exchange with PPh_4Br in MeCN provided the intriguing tri(selenido) complex **1** as dark red crystals in 23% yield concomitant with **2** (14%).† This synthetic route to **1** is reminiscent of the preparation of $[Cp^*MoS_3]^-$ by the reaction of $Cp^*MoS_2(SBu^t)$ with Li_2S_2 and supports the generation of the hypothetical $Cp^*WSe_2(SeBu^t)$ intermediate in the $Cp^*WCl_4/LiSeBu^t$ reaction.[3] While the reaction of Cp^*WCl_4 with $LiSBu^t$ afforded $Cp^*W(SBu^t)_3$, $Cp^*WS_2(SBu^t)$, and $Cp^*_2W_2S_2(\mu\text{–}S)_2$, all attempts to isolate the expected Se analogues, such as $Cp^*W(SeBu^t)_3$ and $Cp^*WSe_2(SeBu^t)$, have failed.



Scheme 1 *Reagents and conditions:* i, Li_2Se_2, THF; ii, PPh_4Br, MeCN; iii, 30 min, −78 °C, THF; iv, Bu^tNC, THF.

Fig. 1 shows the three-legged piano-stool structure of the anion of **1**.‡ The average W–Se distance of 2.322 Å in **1** is similar to that of $(PPh_4)_2[WSe_4]$ [2.314(1) Å].[5] The IR spectrum of **1** shows the W=Se stretching frequency at 284 cm^{-1} comparable to that of $[WSe_4]^{2-}$.[6] The ^{77}Se NMR signal (δ 1437) lies in the range of chemical shifts for terminal selenido ligands.[7] The UV–VIS spectra of **2** and its sulfur congener $(PPh_4)[Cp^*WS_3]$ are similar, showing a strong absorption at 437 and 377 nm, respectively, assignable to charge-transfer transitions from selenium and sulfur to the vacant d orbital of tungsten. The red shift on going from sulfide to selenide (0.45 eV) compares well with the difference in the first ionization potentials of S and Se.[8]

In another experiment, we carried out the $Cp^*WCl_4/LiSeBu^t$ reaction in the presence of Bu^tNC, from which $Cp^*W(SeBu^t)(CNBu^t)_3$ **3** was isolated as brown crystals in 41% yield (Scheme 1).§ The X–ray structure of **3**‡ shows the metal surrounded in a distorted trigonal-bipyramidal geometry wherein the Se and C(20) atoms occupy axial positions, if the Cp* ligand is viewed as a monodentate ligand (Fig. 1). While two of the three Bu^tNC ligands are nearly linear [C–N–C = 175.8(8), 164.3(7)°], the other contains essentially an sp^2–type N atom with a C(15)–N(1)–C(16) angle of 128.7(6)° amongst the smallest of known bent isocyanides (122–156°).[9] The presence of the bent isocyanide is ascribed to extensive π–back donation from the electron-rich W(II) metal ion to the isocyanide. The bent isocyanide also has a shorter W–C bond [1.984(7) Å] and a longer C_{ipso}–N bond [1.220(9) Å] relative to the corresponding values in two linear isocyanides (mean 2.032 and 1.151 Å). This structural feature is consistent with the two N–C stretching frequencies at 2038 and 1813 cm^{-1} observed in the IR spectrum. The W–Se distance of 2.6271(7) Å is comparable to that of $CpW(CO)_3(SeCH_2Ph)$ [2.623(1) Å].[10] On the other hand, the ^1H NMR spectrum of **3** in C_6D_6 at room temperature shows three singlets assignable to *tert*-butyl groups in an intensity ratio of 2:1:1, indicating that the complex is fluxional in solution. Previously, we reported the isolation of

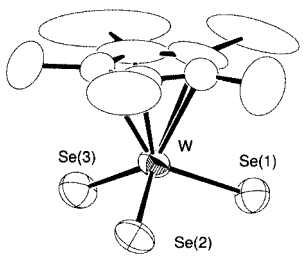


Fig. 1 Molecular structure of the anion of **1**. Selected bond lengths (Å) and angles (°): W–Se(1) 2.322(1), W–Se(2) 2.326(1), W–Se(3) 2.319(1); Se(1)–W–Se(2) 105.42(4), Se(1)–W–Se(3) 103.87(4), Se(2)–W–Se(3) 104.25(4).

the W(IV) thiolato complex $Cp^*W(SBu^t)_3(CNBu^t)$ from the Cp^*WCl_4/LiS^tBu reaction in the presence of Bu^tNC.[4] The isolation of a W(II) selenolato complex, **3**, is in accord with the tendency of selenolato complexes to favor lower oxidation states.

Notes and references

† All manipulations were carried out under an atmosphere of argon using solvents purified by standard methods. A mixture of $LiSeBu^t$ (7.60 mmol) and Cp^*WCl_4 (0.86 g, 1.87 mmol) in THF (50 mL) was quickly added to a slurry of Li_2Se_2 (1.40 mmol) in THF (20 mL) at −78 °C. The solution was warmed up to room temperature and stirred for 2 h. After centrifugation, the solution was evaporated to dryness. The residue was dissolved in MeCN (30 mL) to give a dark red solution and a brown solid. A solution of PPh_4Br (0.47 g, 1.12 mmol) in MeCN (20 mL) was added to the dark red supernatant. Concentration and cooling to −20 °C afforded 0.38 g of **1** as dark red crystals in 23% yield. The brown solid which was insoluble in MeCN was recrystallized from toluene to provide **2** in 14% yield. Data for **1**: ^{1}H NMR (500 MHz, $CDCl_3$), δ 2.20 (s, 15H, Cp*), 7.6–8.0 (m, 20H, PPh_4). ^{77}Se NMR (95.3 MHz, $CDCl_3$, Me_2Se), δ 1437. IR ν/cm^{-1}: 284m (W=Se). UV–VIS (MeCN): λ_{max}/nm(ε/M^{-1} cm^{-1}) 299 (19000), 350 (sh), 437 (38000), 530 (sh). Anal. calc.: C, 45.61, H, 3.94. Found: C, 45.57; H, 3.98%. Data for **2**: ^{1}H NMR (500 MHz, $CDCl_3$), δ 2.27 (s, Cp*), 2.33 (s, Cp*). IR ν/cm^{-1}: 315m, 298m (W=Se). FAB-MS: 954 (M^+). Anal. calc.: C, 25.18; H, 3.17. Found: C, 25.01; H, 3.30%.

‡ *Crystal data*: for **1**: $C_{34}H_{35}Se_3PW$, M = 895.35, orthorhombic, space group *Pbca*, a = 18.284(5), b = 20.171(7), c = 17.758(5) Å, V = 6549(2) Å^3, Z = 8, T = 293 K, μ(Mo-Kα) = 69.37 cm^{-1}, Rigaku-AFC7R, 6360 measured reflections ($2\theta_{max}$ = 50°). The structure was solved by Patterson methods and refined by full-matrix least squares. At convergence, R = 0.057, R_w = 0.058, and GOF = 1.44 for 352 variables refined against 4341 unique reflections [$I > 1\sigma(I)$].

For **3**: $C_{29}H_{51}N_3SeW$, M = 704.55, monoclinic, space group $P2_1/n$, a = 9.7349(8), b = 18.9776(5), c = 17.4477(3) Å, β = 97.1791(7) °, V = 3198.1(2) Å^3, Z = 4, T = 173 K, μ(Mo-Kα) = 47.74 cm^{-1}, Rigaku-AFC7 equipped with a MSC/ADSC Quantum1 CCD detector, 20472 measured reflections ($2\theta_{max}$ = 55°). The structure was solved by Patterson methods and refined by full-matrix least squares (TEXSAN). At convergence, R = 0.077, R_w = 0.063, and GOF = 1.47 for 307 variables refined against all 7147 unique reflections.

Unusual alkali metal α- or β-phenyl(trimethylsilyl)amides†‡

Floria Antolini, Peter B. Hitchcock, Michael F. Lappert* and Philippe Merle

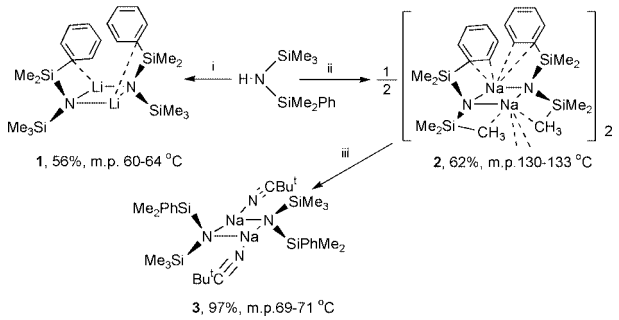
The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ. E-mail: m.f.lappert@sussex.ac.uk

Received (in Cambridge, UK) 19th April 2000, Accepted 24th May 2000

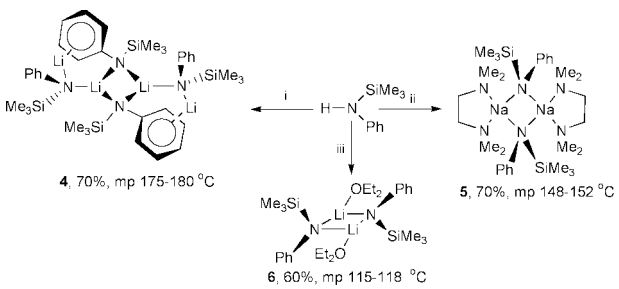
The synthesis (1–3 and 5) and structures (1–5) of the crystalline, hydrocarbon-soluble metal amides [M{μ-N(SiMe$_3$)(SiMe$_2$Ph)}(NCBu^t)$_n$]$_2$ [*n* = 0 and M = Li 1 (*cis*), M = Na 2 (*trans*) having intermolecular Na···C contacts, or *n* = 1 and M = Na (*cis*) 3], [Li{μ-N(SiMe$_3$)Ph}-*cis*]$_2$[μ-{N(SiMe$_3$)Ph}Li-*cis*]$_2$ 4 and *trans*-[Na{μ-N(SiMe$_3$)Ph}(tmen)] 5 are reported.

Bulky crystalline metal amides display a diversity of structures.[1] In the absence of a neutral coligand, they are polymers, *e.g.* [Na{μ-N(SiMe$_3$)$_2$}]$_\infty$, trimers, *e.g.* [M{μ-N(SiMe$_3$)$_2$}]$_3$ (M = Li or Na),[2] or, for [M{μ-NC(Me)$_2$(CH$_2$)$_3$CMe$_2$}]$_4$,[3] tetramers. Crystalline bis(trimethylsilyl)amides of the heavier alkali metals are dimers.[2] Addition of tmen to a bulky Li or Na amide results in its fragmentation into a crystalline mono- or binuclear compound, such as [Li{N(SiMe$_3$)$_2$}(tmen)],[4] *trans*-[Li{μ-N(Me)Ph}(tmen)]$_2$,[5] or *trans*-[Na{μ-N(Pr^i)C$_6$H$_{11}$-c}(tmen)]$_2$.[6]

We now report on the synthesis (**1**–**5**) (Schemes 1 and 2) and structures (**1**, **2** and **4**) of the crystalline Li and Na trimethylsilylamides having an additional α- or β-phenyl *N*-centered substituent: *cis*-[Li{μ-N(SiMe$_3$)(SiMe$_2$Ph)}]$_2$ **1**, *trans*-[Na{μ-N(SiMe$_3$)(SiMe$_2$Ph)}]$_2$ **2**, *trans*-[Na{μ-N(SiMe$_3$)(SiMe$_2$Ph)}(NCBu^t)]$_2$ **3**, [Li{μ-N(SiMe$_3$)Ph}-*cis*]$_2$[μ-{N(SiMe$_3$)Ph}Li-*cis*]$_2$ **4** and [Na{μ-N(SiMe$_3$)Ph}(tmen)]$_2$ **5**.



Scheme 1 Synthesis of the crystalline Li and Na amides **1**–**3** (yields are for crystals, from C_6H_6). *Reagents and conditions:* i, LiBu^n in C_6H_{14}, C_5H_{12}, −70 to 20 °C; ii, NaCH$_2$Ph, C_6H_{14}, −78 to 35 °C; iii, 2 Bu^{t}CN, C_5H_{12}, −78 to 20 °C.



Scheme 2 Synthesis of the crystalline Li and Na amides **4**–**6** (yields are for crystals, from PhMe **4**, C_5H_{12} for **5** and Et$_2$O for **6**). *Reagents and conditions:* i, LiBu^n, C_6H_{14}, 0 to 20 °C (*cf.* ref. 8); ii, NaN(SiMe$_3$)$_2$, Et$_2$O, 0 to 20 °C; then tmen to the precipitate in C_5H_{12}–PhMe; iii, LiBu^n, Et$_2$O, 0 to 20 °C.

Treatment of {phenyl(dimethyl)silyl}(trimethylsilyl)amine[7] with *n*-butyllithium or benzylsodium in pentane or hexane at low temperature yielded **1** or **2**, respectively. Addition of 2-cyano-2-methylpropane to **2** in pentane, irrespective of stoichiometry, afforded the 1 : 1 adduct **3**. Each of **1**–**3** furnished X-ray quality crystals from hexane for **1** and **3** or benzene for **2**.

Similar low temperature reactions between *N*-trimethylsilylaniline[8] and *n*-butyllithium in hexane or bis(trimethylsilyl)amidosodium in diethyl ether yielded **4**, or a white precipitate of the presumed sodium analogue which with tmen in pentane–toluene gave **5**. X-Ray quality crystals of **4** (from toluene) or **5** (from pentane) were obtained upon recrystallisation. Compound **4** had previously been made similarly[8] and used to make corresponding amides of Zn, Cd and Hg.[9] A material related to **4**, and believed to have been [Li{N(SiMe$_3$)Ph}]$_2$·OEt$_2$, was used *in situ* for the synthesis of [M′{N(SiMe$_3$)Ph}$_3$Cl] (M′ = Zr or Hf); it was obtained from aniline and successively LiBu^n, Me$_3$SiCl, LiBu^n and Et$_2$O.[10] In our hands, this procedure afforded *trans*-[Li{μ-N(SiMe$_3$)Ph}(OEt$_2$)]$_2$ **6**.

The new colourless (**1**–**4** and **6**) or pale pink (**5**), air-sensitive, benzene-soluble, compounds **1**–**3**, **5** and **6** gave satisfactory analyses and ambient temperature benzene solution multinuclear NMR spectra. Such data for **4** were similar to those in the literature,[10] but ^{29}Si and ^{7}Li spectral details are new (ESI†). The X-ray structures of each of **1**–**5** have been elucidated; those for **3** and **5** will be reported in the full paper.§

Numerous neutral donor-free lithium amide crystals structures are known; those for **1** and **4** display new features.

As for **1** (Fig. 1), only a single previous example of a dinuclear complex, albeit of opposite stereochemistry, *trans*-[Li{μ-N(SiMe$_3$)C$_6$H$_3$Pr$^i_2$-2,6}]$_2$ **7** was known.[11] Each Li atom in **1** and **7** has a close (< 2.45 Å) contact to its *ipso*-carbon, which is γ- in **1** but β- in **7**; in the latter there are two further more distant [2.76(2) Å] contacts to the γ- and δ- (*C*HMe$_2$) carbon atoms.[11] The LiNLiN core in **1**, unlike in **7**, deviates from a planar rhombus, the Li–N bonds ranging from 1.980(3) to 2.019(3) Å, the four atoms alternating above and below the plane by *ca.* 0.033 Å. The amide **1** has a two-fold symmetry axis; **7** is centrosymmetric.

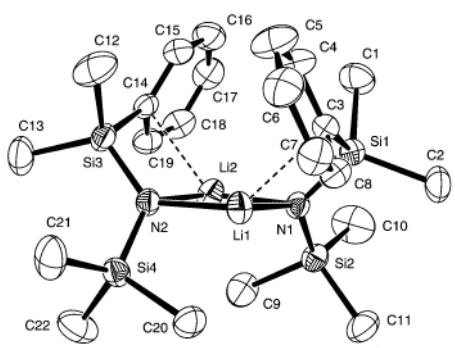


Fig. 1 Molecular structure (ORTEP) of **1** with atom labelling, H omitted for clarity.

† Electronic supplementary information (ESI) available: spectroscopic and analytical data, details of crystallography, and comparative data for **1**–**4**, **7** and **8**. See http://www.rsc.org/suppdata/cc/b0/b003169k/

DOI: 10.1039/b003169k

The tetranuclear, crystalline lithium amide **4** (Fig. 2) has an unprecedented structure. Unlike its only prior tetranuclear neutral donor-free complex, the planar octacyclic [L{μ-$\overline{NC(Me)_2(CH_2)_3CMe_2}$}]$_4$,[12] the centrosymmetric **4** has two distinct and different lithium atom environments. The four lithium atoms are arranged in a stair-like fashion, the central two, Li(1) and Li(2), are separated by 2.601(9) Å, while the two terminal, Li···Li(1 or 2) distances are longer at 3.121(9) Å, the Li–Li(1 or 2)–Li angles being 118(1)°. The atoms Li(1) and Li(2) are each bound to three nitrogen atoms at distances of 2.057(9) to 2.183(9) Å. Each of the terminal lithium atoms is bound slightly more tightly to a terminal nitrogen atom [Li(3 or 4)–N(3 or 4) 2.004(9) or 1.983(10) Å] and also has close η^6-contacts to the phenyl ring attached to a bridging nitrogen atom [av. Li(3 or 4)···M(1 or 2) 2.17(2) Å], the N–Li–M angle being 128.8(5) or 134.1(5)° at Li(3) or Li(4), respectively [M(1) and M(2) are the centroids of the phenyl rings attached to N(1) and N(2), respectively]. The Li(1)–N(1)–M(1) and Li(2)–N(2)–M(2) angles are 95.1 and 97.2°, respectively, compared with Li(1)–N(1)–C(1) and Li(2)–N(2)–C(10) angles of 95.6 and 98.0°, respectively; hence the Ph rings are essentially flat. The central $(LiN)_2$ ring is puckered, the torsion angle between the Li(1)N(1)Li(2) and Li(1)N(2)Li(2) planes being 14.6(4)°. The substituents at N(1) and N(2) are arranged in a *cis* fashion, while the two terminal {N(SiMe$_3$)Ph}Li(3 or 4) fragments attached to Li(1 or 2) also have the *cis*-orientation.

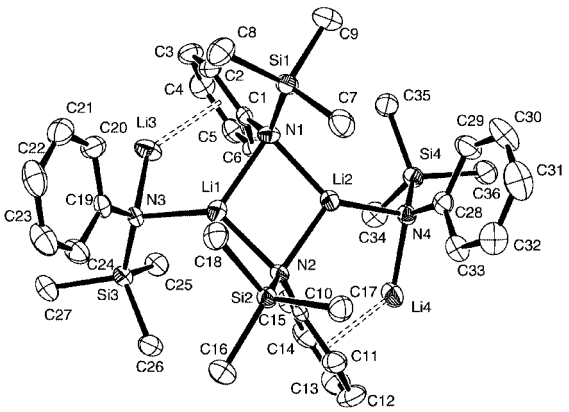

Fig. 2 Molecular structure (ORTEP) of **4** with atom labelling, H omitted for clarity.

The crystalline sodium amide **2** (Fig. 3) is a polymer made up of linked dinuclear units; each is attached to its neighbour by close intermolecular Na···C contacts. Neutral donor-free dinuclear Na amides are, we believe, unprecedented. Like its isoleptic complex **1**, each monomer unit of **2** has a two-fold rotation axis along Na(1)Na(2), but differs from **1** in having a *trans*-arrangement of the substituents at the N atoms and in having different environments for each of the alkali metal atoms. Each sodium atom has four additional Na···C close contacts: for Na(2) from the *ipso*-[2.686(1) Å] and one of the adjacent *ortho*-[2.884(2) Å] carbon atoms of the aromatic rings and for Na(1) from the C(1) carbon atoms of the *trans*-SiMe$_3$ groups [2.948(2) Å] and from the C(3) carbon atoms of an inversion centered related molecule [3.060(2) Å]. The Si–N–Si′ angle is slightly wider in **2** [av. 126.3(1)°] than in **1** [av. 123.9(5)°], but narrower than in its Bu^{t}CN complex **3** [129.9(1)°].[13] As for [Li{μ-N(SiMe$_3$)$_2$}(NCBu^t)]$_2$,[14] **3** may be regarded as a model MR′(NCR) intermediate for reaction of RCN with an organometallic compound MR′.

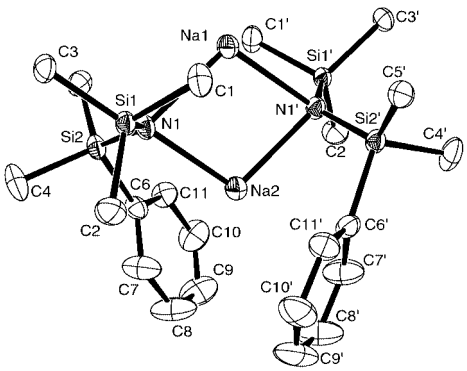

Fig. 3 Molecular structure (ORTEP) of **2** with atom labelling, H omitted for clarity.

The crystalline, dinuclear *trans*-sodium amide **5** is broadly similar to others, such as *trans*-[Na{μ-N(Pr^i)C$_6$H$_{11}$-c}-(tmen)]$_2$.[6] Comparative data on **1**–**4**, **7** and **8** are listed (ESI†).

The tetranuclear lithium amide **4** at 163 K in toluene-d$_8$ showed two ^{7}Li environments of equal intensity at δ 0.89 and −4.6, corresponding to the central and terminal lithium atoms in the crystal, whereas at higher temperatures various exchange processes (2D ^{7}Li EXSY) were observed.

The present results serve to highlight (*cf.* also ref. 1) the diversity of structural motifs available to alkali metal amides; the role of complexes **1**–**5** as reagents is being explored.

We thank the European Commission for the award of a Marie Curie fellowship for P. M. and the EPSRC for other support.

Received (in Oxford, UK) 8th May 2000, Accepted 31st May 2000

We report on the mapping of functional group distributions at flat, functionalised polymer surfaces with a sub-50 nm resolution by means of pH-dependent AFM force titration measurements using chemically modified tips.

The presence *and* spatial distribution of functional groups in polymer coatings or surface-treated bulk polymers play an important role in determining the interfacial properties of these materials.[1] While there are numerous techniques available which allow one to identify and analyse the functional groups introduced by, *e.g.* a surface modification reaction, the determination of the lateral spatial distribution of these functional groups, and the characterisation of their local environment on a sub-100 nm scale remains difficult to impossible with these techniques.[2,3]

As shown here for the first time, atomic force microscopy (AFM) with chemically functionalised tips was successfully applied to tackle this problem. The work described here combines the strategies of AFM tip modification[4] and *active* external control of tip–sample interactions in nanometer-scale AFM adhesion measurements on polymers which contain ionisable functional groups.[5–8] In particular, it is shown that pH-dependent force titration measurements allow one to map functional group distributions with a sub-50 nm resolution. The results obtained on three different polymer model systems, *i.e.* oxyfluorinated isotactic polypropylene (iPP),[9] plasma polymerised allylamine (PPAA),[10] and ammonia plasma modified polypropylene (PP), will be discussed.[11]

The interfacial properties of three different types of polymer surfaces were investigated in AFM force-distance measurements. The model surfaces differ in the type and local environment of the functional groups which are exposed at the free film surface. As shown in previous studies, PPAA contains amino groups,[10] oxyfluorinated iPP carboxylic acid groups,[12] and ammonia plasma modified PP basic (amino) groups.[11] The adhesion properties of these samples can be expected to differ strongly as a result of the different surface chemistry.

Gold-coated AFM tips were functionalised with ω-hydroxy-substituted thiols in order to adjust the interactions between tip and sample surface.[4,5,7–9,13] In an aqueous medium, hydroxy-terminated tips were previously shown to possess pH independent adhesion properties.[5] In these experiments the ionisation state of the exposed functional groups in the polymer films was varied systematically *in situ* by adjusting the pH of the aqueous medium while maintaining a constant ionic strength.[14]

Pull-off forces were evaluated from 100 force–distance curves for each pH.[15] Depending on the pH exclusively repulsive, both attractive and repulsive, or exclusively attractive interactions were detected.

The average pull-off force as a sum of attractive (van der Waals and dipolar) and repulsive (electrostatic) forces was calculated as peak maximum of a Gaussian distribution fitted to the corresponding histograms. The mean value found depended on the pH of the aqueous solution. As is shown in Fig. 1, the average pull-off forces exhibited a behaviour similar to conventional titration experiments. Force titration experiments have been performed previously by Lieber and coworkers[5] and van der Vegte and Hadziioannou,[7] without being accompanied by force volume imaging. For low pH values the PPAA and PP samples, which contain basic amino groups, showed negligible pull-off forces, while at pH >5 the adhesion was quite pronounced. An opposite trend was observed for the carboxylic acid-containing oxyfluorinated iPP, while the untreated iPP (without functional groups) showed no pH dependent pull-off forces.

The reduction of the pull-off forces as a result of repulsive interactions can be attributed to the presence of protonated amino groups for the PPAA and PP (low pH), and deprotonated

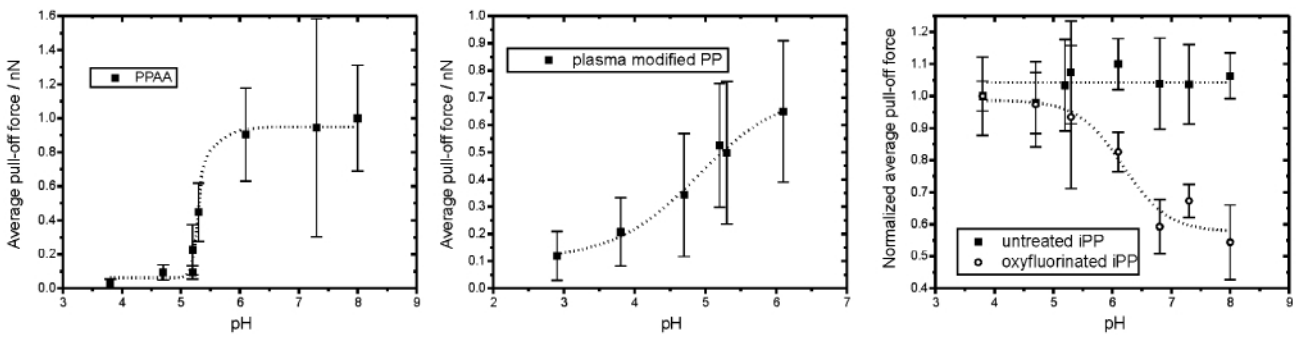

Fig. 1 Force titration data acquired with hydroxy-terminated tips for representative samples of the three model surfaces studied. For PPAA (left) and ammonia plasma modified PP (middle) the average pull-off forces are shown, for the untreated and oxyfluorinated iPP (right) the values were normalised to the values found for pH 3.8 (errors bars correspond to the standard deviation of the mean determined from the pull-off force distribution histograms). The dotted lines have been added to guide the eye.

DOI: 10.1039/b003756g

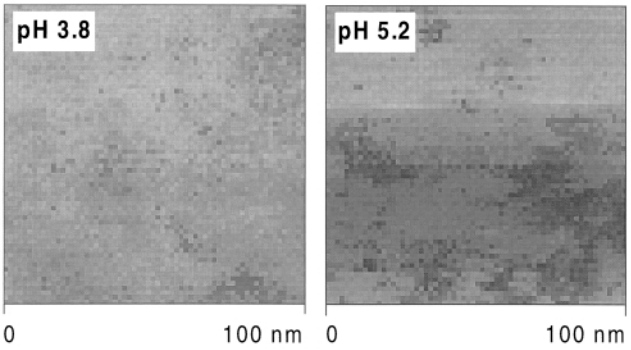

Fig. 2 Pull-off force images of a plasma polymerised allylamine film (peak power 175 W, duty cycle 10/10)[10] at different pH. In the force images dark regions indicates high adhesion (−0.1, −0.5 nN for pH 3.8 and 5.2, respectively), bright regions indicates low adhesion (*ca.* 0 and −0.1 nN for pH 3.8 and 5.2, respectively).

carboxylic acid groups in the iPP (high pH), respectively. The inflection points (force pK_a) are closely related to the thermodynamic surface pK_a values.[16] It is obvious that the force pK_a values are shifted relative to the known p*K*a values (in solution) for carboxylic acids and amino groups (acetic acid: pK_a 4.8; ethylamine: pK_a 10.7). The force pK_a values are shifted to a higher pH for the acidic groups, while for basic groups they are lower. Similar shifts were previously observed experimentally[5,17] and were related to the hydrophobicity of the local environment of the corresponding functional groups. This general interpretation is corroborated by recent simulations.[18] The more hydrophobic the local environment, the more difficult it becomes to create a charge due to the lower dielectric constant of the environment.

The shift of the force pK_a values observed in average force measurements can be used to differentiate between functional groups in different local environments. Depending on the hydrophobicity of the environment and on the local density of (electrostatically interacting) functional groups, these will either be ionised or neutral at pH values close to complete ionisation/neutrality. As indicated in the average adhesion measurements (*vide supra*) the adhesion properties are dramatically different for these two cases. Thus, by carefully adjusting the pH of the solution, areas where ionisation begins can be detected with a spatial resolution of 20 nm or better. This is shown in Fig. 2.

At pH 3.8 the amino groups of the PPAA are completely deprotonated which results in negligible adhesive forces. When the pH of the solution is adjusted to values close to the force pK_a, the spatial distribution of the pull-off forces is inhomogeneous. In the areas with pronounced adhesion the amino groups are neutral (dark patches in Fig. 2, right), while in the other areas repulsive or only weakly adhesive force are detected (bright areas in Fig. 2, right). The observed inhomogeneous distribution of amino groups at the surface of PPAA is most probably related to inhomogeneous temperature distribution in the plane of the film during the polymerization or different reaction pathways due to inhomogeneous initial coverage or *initially* deposited reaction products. This may lead to a heterogeneous restructuring of the polymer and the reorientation of the amino groups upon initial aging of the films in air similar to the processes observed previously.[19]

The data shown here constitute to our knowledge the first results on laterally resolved *imaging* of functional group distributions on polymers on a *sub*-50 nm level using scanning force microscopy with chemically modified tips ('chemical force microscopy'). pH-dependent pull-off force measurements carried out on various functional polymers using OH-functionalised tips revealed laterally inhomogeneous pull-off forces. These inhomogeneous forces can be related to variations of local 'pK_a' values and different local hydrophobicity, and thus to inhomogeneous distribution of the polar functional groups present at the polymer surface.

The oxyfluorinated iPP samples were kindly provided by SOLVAY S.A. and SOLVAY ALKOR-DRAKA Snc. The authors acknowledge financial support by the Council for Chemical Sciences of the Netherlands Organisation for Scientific Research (CW-NWO) in the priority program materials (PPM).

14 The data presented here were acquired at an ionic strength of 1.87×10^{-3}. Phosphate and acetate buffers were used. It should be noted that the force titration curves and the corresponding inflection points were found to be independent of the ionic strength (in the range of 2×10^{-1} to 2×10^{-4}).
15 Triangular shaped silicon nitride cantilevers with silicon nitride tips (Digital Instruments (DI), Santa Barbara, CA, USA), which were coated with 2 nm Ti and 75 nm Au in high vacuum (Balzers), were functionalised with 11-hydroxyundecanol following the procedures described in refs. 8 and 9. The SFM measurements were carried out with a NanoScope III multimode SFM (DI) with modified tips in buffered aqueous solutions of constant ionic strength utilising a liquid cell (DI). The force distance curves used for construction of force titration curves were obtained with at least 10 different positions for each sample. For laterally resolved pull-off force measurements the AFM was operated in the force volume (FV, DI) mode. Only subsequent up and down scans which showed the same force characteristics were considered.
16 A strict quantitative evaluation, such as described by Hu and Bard (K. Hu and A. J. Bard, *Langmuir*, 1997, **13**, 5114), is at this point not possible due to uncertainties of the tip shape (granular gold coating) and the unknown effect of the morphology of the polymer films.

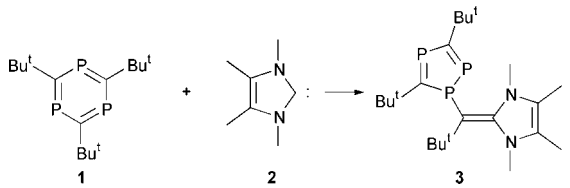
Received (in Cambridge, UK) 16th February 2000, Accepted 22nd May 2000

Treatment of 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene, $P_3C_3Bu^t_3$, with the stable carbene 1,3,4,5-tetramethylimidazol-2-ylidene affords the planar 1,2,4-triphosphole, $P_3C_2Bu^t_2CBu^t$(carbene), [carbene = C(N(Me)C(Me)=C(Me)N(Me))] which has been structurally characterised as its η^5- ligated $[Mo(CO)_3]$ complex; theoretical calculations are presented on the mechanism of this novel reaction.

The synthesis and ligating properties of compounds containing P–C multiple bonds is of considerable current interest.[1–4] The availability[5–7] of 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene $P_3C_3Bu^t_3$ **1** has enabled its chemistry to be developed and we recently described an unusual [1+4]-cycloadditon reaction with a stable silylene.[8] We now describe the remarkable reaction of **1** with the stable 'Arduengo' type carbene 1,3,4,5-tetramethylimidazol-2-ylidene **2**[9] which involves extrusion of a CBu^t fragment from the six-membered aromatic ring to quantitatively afford the 1,2,4-triphosphole, $P_3C_2Bu^t_2CBu^t$(carbene) **3** (carbene = 1,3,4,5-tetramethylimidazol-2-ylidene). (Scheme 1) This type of behaviour is unprecedented and has no parallel in conventional organic chemistry.



Scheme 1

To our knowledge, contractions from aromatic six-membered rings to aromatic five-membered rings are unknown in organic chemistry. In sulfur chemistry, reactions with electrophiles are known to cause six- to five-membered ring contractions in nonaromatic systems with S–S bond formation.[10,11] While ring expansion of arenes[12] and aromatic phosphabenzenes[13,14] are known to occur with carbenes, no ring contractions have been reported to date.

Thus, addition of the 1,3,5-triphosphabenzene **1** to the carbene **2** in solutions of benzene, toluene or THF immediately led to a deep red solution of the 1,2,4-triphosphole **3** which could be isolated as an air and moisture-sensitive red oil.‡ **3** is highly soluble in benzene, toluene, THF and diethyl ether but only sparingly soluble in saturated hydrocarbon solvents.

The structure of **3** was established by its mass spectrum and its characteristic ^{1}H, ^{13}C and ^{31}P NMR spectra, the latter exhibiting a very similar pattern of lines to that of the known, structurally characterised, triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$.[15] The ^{31}P NMR spectrum of the triphosphole **3** consists of three doublets of doublets in the unsaturated region at δ 209.2, 163.3 and 121.4 with the expected large ^1J(PP) coupling of 519.6 Hz, indicating a highly delocalised π-system, and the two smaller ^2J(PP) couplings of 40.3 and 27.2 Hz. While the ^{13}C and ^{1}H NMR specta are in good agreement with the proposed structure, several accidental coincidences should be noted. Though chemically inequivalent, in both the ^{13}C and ^{1}H NMR spectra, the two N-methyl groups and two carbene backbone methyl groups appear as singlets at their respective chemical shifts.

Confirmation of the proposed structure came from a single crystal X-ray diffraction study of the η^5-ligated molybdenum tricarbonyl complex **4** which was made by treatment of **3** with $[Mo(CO)_3$(cycloheptatriene)] at room temperature.‡ Crystals suitable for single crystal X-ray diffraction were grown at –25 °C from a saturated toluene solution layered with light petroleum (bp 40–60 °C).§

The molecular structure of **4**, shown in Fig. 1, reveals the following interesting features which are strongly indicative of a significantly delocalised system: (i) the sum of the bond angles at the tricoordinate phosphorus P(2) is 358.5°, (ii) the sum of the bond angles within the triphosphole ring is 539.97°, (iii) the C(14)=C(19) bond is 1.452(3) Å, (iv) the P(2)–C(14) bond outside the triphosphole ring is very short [1.7130(19) Å], (v) the P–C bond distances within the triphosphole ring are almost identical, [1.760(2), 1.7623(19), 1.763(2) and 1.774(2) Å, respectively].

The molybdenum tricarbonyl complex **4** was also characterised by ^{31}P, ^{13}C and ^{1}H NMR spectroscopy and mass

Fig. 1 Molecular structure of **4**. spectrometry. As was observed in the η^5-ligated $Mo(CO)_3$ complex of the triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$,[16] we observe a large upfield shift for the ring phosphorus resonances as well as an inversion in the chemical shifts of the two formally unsaturated P centres. Furthermore, the ^{13}C and ^1H NMR spectra of **4** revealed that the chemical shift coincidences of methyl groups in the parent triphosphole mentioned above, were no longer present.

We have investigated the mechanism of the above transformation of **1** to **3** by theoretical calculations[17] at the B3LYP/6-31+G* level. The parent 1,3,5-triphosphabenzene, $P_3C_3H_3$, and the diaminocarbene, $C(NH_2)_2$, were used initially to model the entire reaction path. In order to take the most important steric effects into account, additional new calculations were performed at all the minima (product and intermediates), to find the corresponding structures derivable from 2,4-dimethyl-6-*tert*-butyl-1,3,5-triphosphabenzene and 1,3-dimethylimidazol-2-ylidene. Since no significant changes were observed in the relative energies of the minima on the reaction path, apart from some destabilisation of the first intermediate, we consider that the transition structures are not significantly affected.

From the reaction of the diaminocarbene and the triphosphabenzene a complex **5** (Fig. 2) is obtained in which the charge of the carbon atom of the diaminocarbene unit becomes more positive by 0.6 than in the free diaminocarbene, while each of the three phosphorus ring atoms become more negative by *ca.* 0.2 electrons. Thus **5** can be described as an ylid in which the negative charge is delocalised over the PCPCP unit. Intermediate **7** is formed from **5** *via* the transition state **6TS** as a result of a ring closure and the product **9** is formed *via* transition state **8TS**. Despite a careful search, no transition state linking **5** directly to **9** was found. Furthermore, the Gibbs free energies of **5**, **6TS**, **7**, **8TS** and **9** are lowered by 4.4, 3.0, 6.6, 4.7 and 21.5 kcal mol^{-1}, respectively, from that of the reactants and since the transition structures lie just slightly higher in energy than the intermediates, the reaction should proceed smoothly.

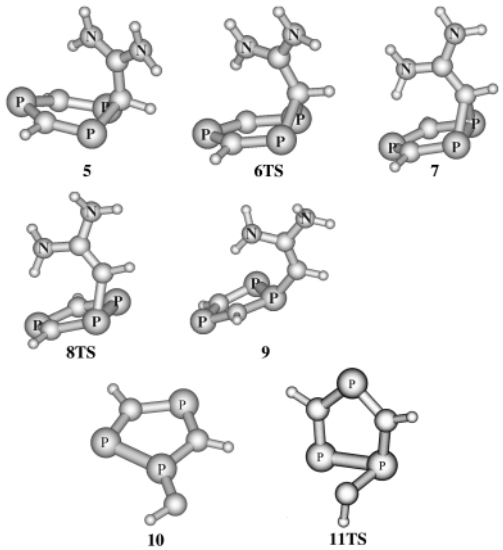

Fig. 2 B3LYP/6-31+G* level generated structures of intermediates and transition states generated in the transformation of **1** to **3**.

The structure of the experimentally observed **3** has also been optimised at the B3LYP/6-31G* level (neglecting the two β methyl groups on the imidazole ring). The calculated structural parameters are very similar to those obtained for the molybdenum complex **4**, except that the tricoordinate phosphorus atom is somewhat less planar (Σ bond angles 348.6 °). The calculated C(14)=C(19) bond length for the uncomplexed triphosphole system is 1.413 Å and the P(2)–C(14) bond length is 1.780 Å, while the remaining bonding distances are even closer to those obtained from the X-ray structure.

Finally, of special interest is the *reversible* nature of the triphosphabeneze–(triphosphole-carbene) interconversion. Thus treatment of **3** with $[PtCl_2(PR_3)]_2$ (PR_3 = PMe_3 or PMe_2Ph), at room temperature over 4 days leads to removal of the carbene, forming mixtures of the Pt(II) complexes *trans*-$[PtCl_2(PR_3)$(carbene)], *cis*-$[PtCl_2(PR_3)_2]$ and $[PtCl_2(carbene)_2]$ with simultaneous regeneration of the triphosphabenzene ring **1**, as the major product, as evidenced by ^{31}P NMR spectroscopy. Mechanistic information comes from theoretical calculations on the parent system which suggest that triphosphabenzene, $P_3C_3H_3$, which arises from loss of the carbene $C(NH_2)_2$ from **9** by metal complexation, results from the isomerisation of the planar compound **10** (Fig. 2), which has a singlet ground state and is less stable than triphosphabenzene by 59.3 kcal mol^{-1}. The Gibbs free energy of the transition state **11TS** for this reaction lies 17.5 kcal mol^{-1} higher than that of **10**.

We thank NSERC of Canada for a scholarship (for S. B. C.), the Royal Society and OTKA TO 26335 (for joint funding of J. F. N. and L. N.), EPSRC for their continuing support (to J. F. N.) for phospha-organometallic chemistry and Lisa Titcomb for the sample of 1,3,4,5-tetramethylimidazol-2-ylidene.

Received (in Cambridge, UK) 17th April 2000, Accepted 31st May 2000

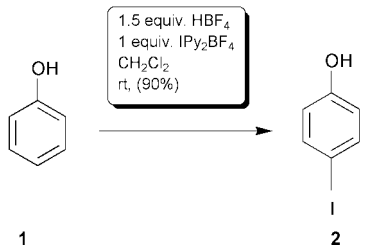
By using a slight molar excess of the IPy_2BF_4 reagent in an acid containing medium, activated aromatic residues on Tyr derivatives and peptides selectively react yielding, as major products, the monoiododerivatives; this level of reaction control cannot be achieved by other iodinating methods.

The methods available for either labeling complex biomolecules throughout radioiodination[1] or extending the reactivity of organic molecules by iodination[2] share similar problems. For most applications of iodinated aromatic compounds, monoiodination will be ideal, but known iodinating methods usually yield mixtures of mono-, diiodinated and unreacted species.[3] Accordingly, efficient control of the iodination of phenol-like compounds[4] at room temperature, that would result in a practical approach to monoiodinate target Tyr containing peptides still remains to be developed. The iodonium reagent IPy_2BF_4 that we are currently investigating[5] is very effective at iodinating aromatic functions of both simple organic molecules[6] and more complex polyfunctional peptides.[7] The performance of IPy_2BF_4 is dependent on factors such as reagent to substrate stoichiometry, the solvent and the presence of acid.[8]

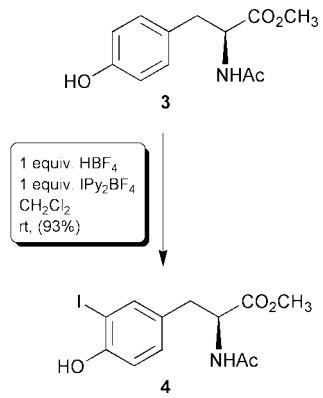
In searching for conditions for the selective and direct preparation of monoiodinated Tyr derivatives as new building blocks for use in combinatorial chemistry and Tyr containing peptides, starting from **1** we have established conditions for its regioselective conversion to **2** at rt, as outlined in Scheme 1. Thus, mixing HBF_4 with **1** in CH_2Cl_2 prior to the addition of stoichiometric amounts of IPy_2BF_4 results in the formation of **2** in 90% yield (the presence of minor amounts of the 2-regioisomer was noticed by ^1H NMR analysis of the crude reaction mixture). Next, we explored the iodination of **3** under the same conditions and **4** was obtained in 93% isolated yield (Scheme 2).

Then, we examined the reaction conditions shown in Table 1 on the protected Tyr derivative Fmoc-Tyr-OH **5**. As expected, if no acid was present, the sole reaction product was the diiodinated derivative when an excess of IPy_2BF_4 was added to a CH_3CN solution of Fmoc-Tyr-OH. Under the same conditions, stoichiometric amounts of the reagent produced mixtures of mono-, diioiodinated and unreacted species. However, addition of an equimolar quantity of HBF_4, in CH_3CN or CH_2Cl_2, or 10% TFA in CH_2Cl_2, and a slight excess of the reagent, the monoiodinated building block Fmoc-Tyr(3′-I)-OH **6** was the exclusive reaction product (Scheme 3).

For comparison to the traditional Chloramine T iodinating method,[9] Fmoc-Tyr-OH was reacted in CH_3CN with excess of both NaI and Chloramine T and the diiodinated derivative was produced. However, in conditions involving stoichiometric amounts of the iodinating reagents,[9c] low yields of Fmoc-Tyr(3′-I)-OH were obtained.



Scheme 1



Scheme 2

Table 1 Conditions assayed for the monoiodination of Fmoc-Tyr-OH

Entry	IPy_2BF_4 (equiv.)	Acid	Solvent
1	2.2	—	CH_3CN
2	1.1	—	CH_3CN
3	1.1	1 equiv. HBF_4	CH_3CN
4	1.1	1 equiv. HBF_4	CH_2Cl_2
5	1.5	10% TFA	CH_2Cl_2

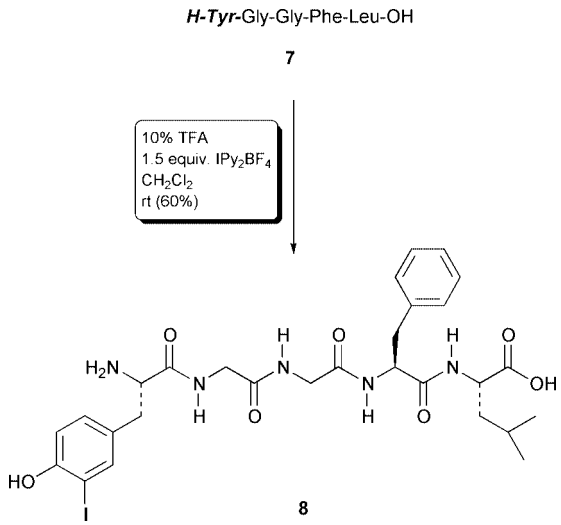
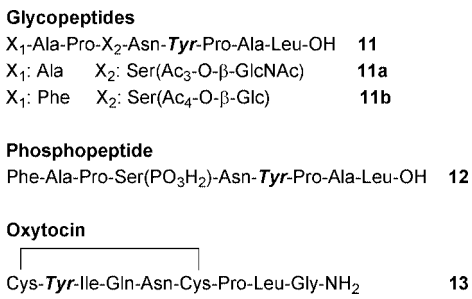
Scheme 4

The potential of this method was also explored on different peptides. The opioid pentapeptide (Leu-enkephalin: H-Tyr-Gly-Gly-Phe-Leu-OH **7**) provided a simple model, showing both Tyr and Phe residues with aromatic side chains that may react towards aromatic electrophilic iodination with our reagent in acidic conditions. To facilitate the identification of the possible iodination products, a series of reference peptides were synthesized from commercially available building blocks. Thus, peptides **8**, **9** and **10** (Scheme 4) were prepared and characterized by RP-HPLC, MALDI-TOF-MS and ^{1}H-NMR. Reaction of **7** in 10% TFA in CH_2Cl_2, which are conditions frequently applied in peptide chemistry, with 1.5 equiv. IPy_2BF_4, afforded the Tyr monoiodinated species **8** as a major product (Scheme 5). The monoiodinated derivative, with an approximate conversion of 60%, was isolated by RP-HPLC and was further characterized by MALDI-TOF-MS and ^{1}H-NMR. After HPLC and NMR data comparison with **8**, **9** and **10** (Scheme 4), no trace of iodination on Phe residues could be observed, which confirmed the selectivity of the reagent towards Tyr side chains.



Scheme 5

These reaction conditions were also successfully tested on biologically active peptides with acid labile post-translational modifications such as in the case of glyco- and phosphopeptides,[10] **11** and **12**, (containing *O*-glycosyl and phosphoseryl residues, respectively) (Scheme 6). This method may also be of potential application on larger and water-soluble peptides and proteins; preliminary evidence was gathered after assaying these iodination conditions on **13** in aqueous solution. Thus, oxytocin, which has only one Tyr residue in its sequence



Scheme 6

(Scheme 6), was reacted in 10% TFA aqueous media with 1.3 equiv. IPy_2BF_4 and the monoiodinated derivative was observed as a major product with 50% conversion. HPLC and MALDI-TOF-MS analysis confirmed the identity of this product, which holds its disulfide bridge in place.

In summary, a method for controlling iodination reactions on activated aromatic residues of peptides is proposed for the first time. The procedure can be carried out in aqueous media and reaction conditions are mild enough for application to acid-labile glyco- and phosphopeptides. Work is in progress to extend these procedures to protein chemistry.

[b] *Department of Chemistry, Nankai University, Tianjin 300071, P.R. China*

Received (in Cambridge, UK) 17th April 2000, Accepted 6th June 2000

Slow diffusion of $K_3[Fe(CN)_6]$ and $[NiL](ClO_4)_2$ (L = 3,10-diethyl-1,3,5,8,10,12-hexaazacyclotetradecane) yields a novel cyano-bridged 2D brick wall-like assembly which is ferromagnetically ordered below 9.1 K with considerably strong hard magnetic behaviour.

It is well known that the cyanide ion can coordinate to one metal ion through the carbon atom acting as a monodentate ligand or connect two metal ions as a bridging ligand through both the carbon and nitrogen atoms. Recently, magnetic interactions between paramagnetic metal ions through the cyanide bridge have been extensively investigated. In particular, the cyanide-bridged 3D bimetallic assemblies of Prussian Blue type, derived from $[M(CN)_6]^{3-}$ (M = Cr^{III}, Fe^{III}) and simple transition metal ions $[M']^{n+}$, have attracted great attention owing to the fact that many of them exhibit a considerably high magnetic critical (Curie) temperature.[1] However, the difficulty in obtaining single crystals suitable for X-ray diffraction analysis precludes the clarification of the magneto–structural correlation. Furthermore, the face-centred cubic structures (based on powder XRD results) they usually possess result in low or no magnetic anisotropy, which would give low or no magnetic coercivity.[1] To overcome these problems, hybrid Prussian Blue analogues have been synthesized by the reaction of coordinately unsaturated transition metal complexes $[M'L]^{m+}$ (L = polydentate ligand) with hexacyanometalate building blocks $[M(CN)_6]^{3-}$ (M = Fe, Cr or Mn).[2,3] Consequently, the introduction of organic ligands could lower the symmetry of the lattice, and afford various molecular structures.[2,3]

Most recently, stair-shaped 2D honeycomb networks, $[Ni(cyclam)]_3[Cr(CN)_6]_2\cdot 20H_2O$,[3a] $[Ni(cyclam)]_3[Fe(CN)_6]_2\cdot xH_2O$,[3b,c] $[NiL^1]_3[Fe(CN)_6]_2\cdot 9H_2O$[3d] and $[NiL^1]_3[Cr(CN)_5(NO)]_2\cdot 10H_2O$[3e] ($L^1$ = 3,10-dimethyl-1,3,6,8,10,12-hexaazacyclotetradecane 3,10-dimethyl-1,3,6,8,10,12-hexaazacyclotetradecane) have been reported. According to Mallah *et al.*, for Ni_3M_2 systems containing *trans* nickel macrocyclic complexes a meridional arrangement might lead to either a 2D flat brick wall-like layer or a double chain stair-like structure. However, this arrangement of five moieties [two $M(CN)_6$ and three Ni(macrocycle)] in a plane imposes a steric hindrance between the macrocycle ligands.[4] Therefore, only stair-shaped 2D honeycomb networks have been obtained so far. We have found, however, that the reaction between a bulky planar macrocyclic nickel(II) complex $[NiL](ClO_4)_2$[5] (L = 3,10-diethyl-1,3,5,8,10,12-hexaazacyclotetradecane) and $K_3[Fe(CN)_6]$ afforded a complex of similar formula, $[NiL]_3[Fe(CN)_6]_2\cdot 12H_2O$ **1**, which does have the flat brick wall-like structure.

Well shaped red–brown crystals of **1** for X-ray structure analysis† and magnetic measurements were grown at room temperature by the slow diffusion of an orange DMF solution (30 mL) of $[NiL](ClO_4)_2$ (0.15 mmol) and a yellow aqueous solution (30 mL) of $K_3[Fe(CN)_6]$ (0.15 mmol) in an H-tube.‡

The structure consists of neutral flat layers with slightly distorted rectangles. Unlike the honeycomb-like complexes mentioned above, in which three [Ni(cyclam)] or $[NiL^1]$ groups connect with three cyanide groups in a *fac* arrangement at an iron(III), chromium(II) or chromium(III) cation,[3] in the present complex each $[Fe(CN)_6]^{3-}$ unit uses three cyanide groups in a meridional arrangement to connect with three *trans*-$[NiL]^{2+}$ units [Fig. 1(a)]. This particular local molecular disposition extends to give rise to a brick wall-like structure [Fig. 1(b)], as predicted by Mallah *et al.*[4] The bridging cyanide ligands coordinate to the nickel(II) ions in a considerably bent fashion with Ni–N≡C bond angles of 148.5(9)° for C(1)–N(1)–Ni(2), 151.4(9)° for C(4)–N(4)–Ni(1) and 152.1(9)° for C(3)–N(3)–Ni(3), which prevents the steric hindrance of L. The coordination environment of the nickel ions can be described as axially elongated octahedral. Adjacent Fe···Ni distances are 5.003(2) Å for Fe···Ni(1), 4.987(2) Å for Fe···Ni(2) and 4.985(2) Å for Fe···Ni(3), respectively. In the crystal, the layers align along the

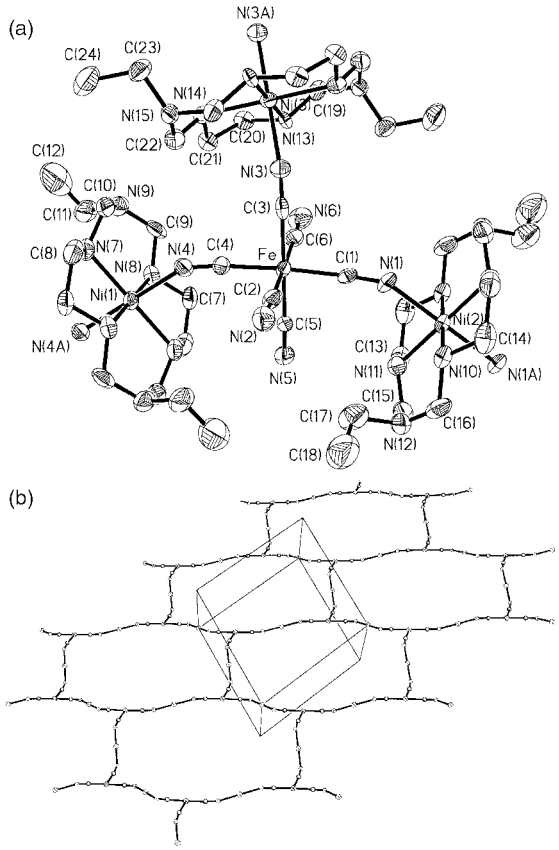

Fig. 1 (a) ORTEP plot of complex **1**. Selected bond distances (Å): Ni(2)–N(10) 2.050(9), Ni(2)–N(11) 2.053(9), Ni(2)–N(1) 2.126(8), Ni(3)–N(13) 2.064(8), Ni(3)–N(14) 2.066(8), Ni(3)–N(3) 2.111(9), Ni(1)–N(8) 2.072(10), Ni(1)–N(7) 2.074(8), Ni(1)–N(4) 2.139(10). (b) Projection along the *a* axis showing the brick wall-like backbone containing Fe_6Ni_6 rectangles.

DOI: 10.1039/b003089i

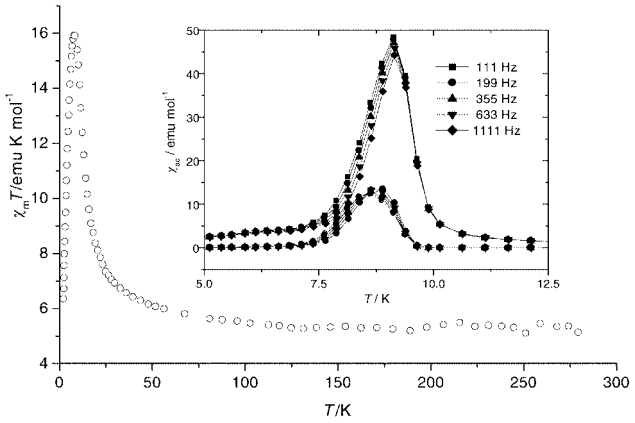

Fig. 2 Temperature dependence of $\chi_M T$ for **1**. Real (χ') and imaginary (χ'') ac magnetic susceptibilities in zero applied dc field and an ac field of 2 Oe at different frequencies for **1** are shown in the inset.

[110] direction with a separation of *ca*. 8.33 Å, and the nearest interlayer metal–metal distance is 8.53 Å for Ni(2)···Fe. Water molecules are positioned between the layers and are linked to the terminal CN^- ligands of $Fe(CN)_6^{3-}$ and other water molecules *via* hydrogen bonding.

The magnetic susceptibility of **1** has been measured on a crystalline sample confined within a gelatine capsule under a field of 10 kOe in the temperature range 2–280 K. A plot of $\chi_m T$ *vs*. T is shown in Fig. 2, where χ_m is the magnetic susceptibility per Ni_3Fe_2 unit. The $\chi_m T$ value at 280 K is *ca*. 5.3 emu K mol^{-1} (6.5 μ_B) which increases smoothly and then sharply with decreasing temperature, reaching a maximum value of 15.9 emu K mol^{-1} (11.3 μ_B) at 7.8 K, strongly suggestive of the occurrence of magnetic ordering. Below 7.8 K, $\chi_m T$ decreases rapidly, which may be due to interlayer antiferromagnetic interactions, a saturation effect and/or the zero-field splitting effect of nickel(II) ions in axially elongated octahedral surroundings. The magnetic susceptibility above 8.4 K obeys the Curie–Weiss law with a positive Weiss constant, θ, of +7.0 K.

The onset of a long-range magnetic phase transition is confirmed by the temperature dependence of the ac magnetic susceptibility displayed in the inset of Fig. 2. The real part of the ac magnetic susceptibility, χ', has a maximum at *ca*. 9.1 K for a frequency of 111 Hz, suggesting that T_c of complex **1** is *ca*. 9.1 K. The weak frequency dependence of χ_{ac}' and χ_{ac}'' suggests a degree of glassy behaviour.

The field dependence of the magnetization (0–50 kOe) measured at 1.6 K shows rapid saturation of magnetization reaching a value of 7.4 $N\beta$ at 50 kOe which is close to the expected $S = 4$ value of 8 $N\beta$ for a ferromagnetic Ni_3Fe_2 system. A hysteresis loop at 1.6 K was observed with a coercive field as large as 1500 Oe and a remnant magnetization of *ca*. 1.36 $N\beta$ per Ni_3Fe_2 unit, typical of a hard ferromagnet. To our knowledge, the coercivity in **1** is the highest measured for hybrid Prussian Blue analogues, probably due to the presence of the magnetic anisotropy of the paramagnetic ions, the grain size of the sample used and/or irreversible movements of the domain walls.[1a,2b,6] Magnetic studies on samples of different sizes should bring some insights into the origins of the large coercive field and remnant magnetization. Further work to this end is in progress in our laboratory.

In conclusion, we have obtained a hybrid Prussian Blue analogue with a unique brick wall-like molecular structure which serves as a new molecule-based ferromagnet showing hard magnetic behaviour.

Observations on the transition-metal catalysed oxidation of alkanes in trifluoroacetic acid: urea–hydrogen peroxide/TFA as a convenient method for the oxidation of unactivated C–H bonds

Christopher J. Moody and Jenny L. O'Connell

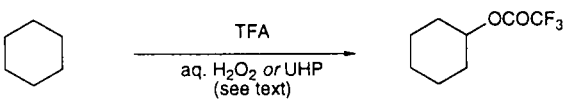
School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD. E-mail: c.j.moody@ex.ac.uk

Received (in Liverpool, UK) 17th April 2000, Accepted 22nd May 2000

Oxidation of cyclohexane in TFA using 30% aqueous H_2O_2 or urea–H_2O_2 (UHP) gives cyclohexyl trifluoroacetate in good yield, although the reaction is not accelerated by rhodium or ruthenium catalysts casting doubt on earlier claims on the role of transition-metals in oxidations in TFA.

The oxidation of unactivated C–H bonds in alkanes is often regarded as one of the Holy Grails of organic chemistry.[1] Whereas in Nature such oxidations are efficiently carried out by enzymes, there exists no single general laboratory or industrial method, despite the undoubted commercial importance of such a process. Nevertheless a number of methods have been developed which do effect the oxidation of unactivated C–H bonds: these include oxidations in superacid media,[2] using peroxide type reagents (including peracids, dioxiranes and oxaziridines),[3] ozone,[4] various cytochrome P450 models,[5] and a range of metal mediated oxidations,[6] including Gif chemistry.[7] Much of the current work in this area focuses on the use of transition-metal catalysed processes, and in view of our own interest in reactions catalysed by dirhodium(II) carboxylates,[8] we were intrigued to see a *Chemical Communication* in which dirhodium tetraacetate was reported to catalyse the oxidation of cyclohexane by hydrogen peroxide in TFA.[9] As a prelude to investigating the role of dirhodium(II) catalysts in other oxidation reactions, we have reinvestigated this original work, and report our results herein.

In their communication, Nomura and Uemura reported that a variety of rhodium salts (0.1–0.3 mol%) catalysed the oxidation of cyclohexane by 30% aqueous hydrogen peroxide in TFA. The yields of cyclohexyl trifluoroacetate were consistently 62–65% irrespective of the rhodium salt used, and the authors suggested a mechanism involving a highly reactive oxorhodium species.[9] The use of strongly acidic media is quite common in metal catalysed oxidations of hydrocarbons since (a) the conjugate base of a strong acid is a poor σ-donor and therefore enhances the electrophilicity of the metal ion, and (b) the esterification of the alcohol, the primary product of alkane oxidation, protects it from further oxidation.[10] However, it appears that the authors did not carry out a blank reaction in TFA in the absence of the rhodium salt.[9] This is somewhat surprising since many years earlier Deno and Messer also reported the oxidation of cyclohexane to cyclohexyl trifluoroacetate (73% yield) under more or less identical conditions (30% aqueous H_2O_2 in TFA) but in the *absence* of any metal salt.[11] Therefore our initial experiments were designed to investigate this apparent anomaly (Scheme 1). When cyclohexane (5 mmol) was treated with 30% aqueous H_2O_2 (15 mmol) in TFA (12 ml) in the presence of dirhodium tetraacetate (1 mol%) at room temperature, oxidation to cyclohexyl trifluoroacetate did indeed occur as evidenced by gas chromatographic analysis which clearly showed disappearance of the hydrocarbon and formation of the ester over 12 h (Fig. 1). When the blank experiment was run under identical conditions but in the absence of the rhodium complex a very similar plot was obtained (Fig. 1). The results show that this particular oxidation of cyclohexane clearly proceeds in the absence of the metal complex, and furthermore dirhodium tetraacetate does not catalyse the reaction.



Scheme 1

In order to obtain rate constants for the oxidation of cyclohexane in TFA, aqueous H_2O_2 was replaced by the urea hydrogen peroxide complex (UHP), a convenient solid source of anhydrous H_2O_2. This enabled the use of a large excess of peroxide to create pseudo-first order reaction conditions. Under these conditions (2.5 mmol cyclohexane in 2 ml CH_2Cl_2, 22 mmol UHP, 10 ml TFA), rates for the oxidation of cyclohexane in the presence ($k = 2.9 \times 10^{-5}$ M^{-1} s^{-1}) and absence ($k = 3.3 \times 10^{-5}$ M^{-1} s^{-1}) of dirhodium tetraacetate were readily obtained (Fig. 2). Given the error in the determination of rate constants (estimated as ±10%), the rates of these two reactions are clearly similar. In both the 30% aqueous H_2O_2–TFA and UHP–TFA oxidations, trace amounts of cyclohexanol were also observed. In a separate blank experiment it was shown that cyclohexanol is readily esterified in TFA, and therefore the alcohol is presumably the initial product of oxidation.

We also investigated the use of ruthenium catalysts based on the $RuCl_3$–TFA system reported by Murahashi *et al.*,[12] which was also thought to involve a metal oxo complex as the oxidant. Again it was evident that $RuCl_3$ also had no effect on the rate of cyclohexane oxidation in TFA ($k = 3.1 \times 10^{-5}$ M^{-1} s^{-1}). Therefore, we conclude that claims of transition-metal catalysed oxidations of hydrocarbons in peroxide–TFA systems should be viewed with caution in cases where the appropriate blank experiments have not been carried out. This view concurs with that of Hogan and Sen who have independently concluded that the role of the metal in C–H oxidation reactions carried out in TFA needs to be reassessed.[10,13]

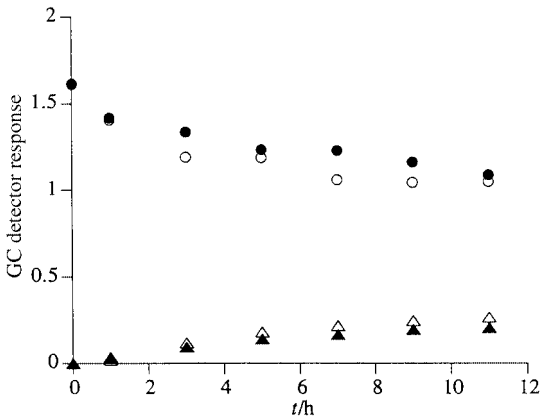


Fig. 1 Cyclohexane consumption and cyclohexyl trifluoroacetate formation *vs.* time in 30% aqueous hydrogen peroxide–TFA in the absence (○/△) or presence (●/▲) of dirhodium tetraacetate.

DOI: 10.1039/b003074k

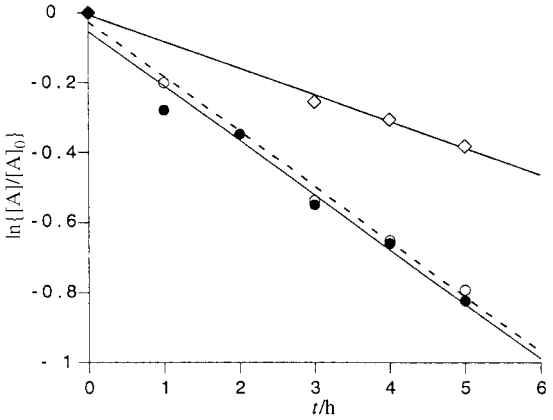

Fig. 2 Oxidation of cyclohexane by UHP–TFA in absence (○) or presence (●) (1 mol%) of dirhodium tetraacetate, and oxidation of cyclohexane-d_{12} (◇), where $[A]_0$ is the initial concentration of cyclohexane.

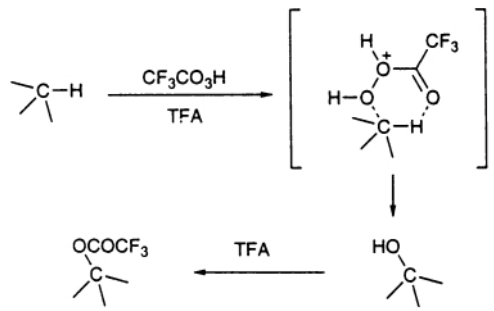
In the work of Deno *et al.* using 30% aqueous H_2O_2 in TFA,[11,14] it was assumed that the active oxidant was peroxytrifluoroacetic acid which participated in a concerted oxidation mechanism *via* a cyclic transition state, the electrophilic nature of the oxidant being further enhanced by protonation (Scheme 2). To shed further light on the mechanism of the UHP–TFA oxidation, we compared the rate of oxidation of cyclohexane with its perdeuterated analogue ($k = 1.4 \times 10^{-5}$ M^{-1} s^{-1}) (Fig. 2). The observed kinetic isotope effect of 2.3 ± 0.2 is in accord with previous studies using peracids as oxidants, and is possibly indicative of a concerted (*cf.* Scheme 2) or oxenoid type mechanism.[3a] Unfortunately alternative mechanisms involving radical hydrogen abstractions cannot be completely ruled out, since although such reactions usually exhibit a significantly larger deuterium isotope effect ($k_H/k_D \approx 4$–8),[15] the isotope effect can be as low as 1.[16]

The preparative oxidation of hydrocarbons was briefly investigated, and some illustrative examples are shown in Table 1. Cyclohexane, cycloheptane ($k = 6.4 \times 10^{-5}$ M^{-1} s^{-1}) and cyclooctane were all oxidized to the corresponding esters; norbornane gave the ester of *exo*-norborneol as the major product, and although adamantane was rapidly oxidized to the tertiary ester, with no sign of the secondary ester by GC, the product was unstable under the reaction conditions. *n*-Hexane gave a mixture of 2- and 3-hexyl trifluoroacetates (ratio = 47:53) with no evidence for oxidation at the terminal methyl group. Compounds containing aromatic rings (*n*-propylbenzene, cumene, tetralin) were completely decomposed in either 30% aqueous H_2O_2–TFA or in UHP–TFA.[17]

In summary, we have shown that UHP–TFA is a simple system for the oxidation of unactivated C–H bonds in alkanes; such reactions are not accelerated by rhodium or ruthenium catalysts, and therefore claims of metal catalysis of related reactions in TFA should be viewed with caution.



Scheme 2

Table 1 Preparative scale hydrocarbon oxidation using UHP–TFA

Alkane	Product	Yield (%)
		80
		78
		45[a]
		67[a,b]
		[c]

[a] GC yield; the reaction mixture is more complex. [b] Only the *exo*-product was observed. [c] Product not stable under reaction conditions; identified by GC by comparison with an authentic sample; 2-adamantyl trifluoroacetate was not present (GC).

Received (in Cambridge, UK) 25th April 2000, Accepted 9th June 2000

The 1,2,4-triphenylcyclopentadienyl ligand and the CHR carbene ligand, bound respectively to the Co and W atoms in [(η⁵-C_5H_5)W{μ-CBu^{t}CC(CO_2Me)=C(CO_2Me)CH}(μ-PPh_2)Co(η⁵-$C_5Ph_3H_2$)], are derived from the oligomerisation and cleavage of three molecules of phenylacetylene in the reaction of [(OC)(η⁵-C_5H_5)W{μ-C(CO_2Me)CC(C≡CBu^t)(OMe)O}(μ-PPh_2)Co($CO)_2$] with this acetylene.

The catalytic cyclo-oligomerisation of alkynes mediated by mononuclear, binuclear and polynuclear transition metal complexes to give organic compounds such as benzenes, fulvenes and cyclooctatetraenes has been well documented.[1–4] Sometimes stable organometallic complexes can be isolated in which the metal atom is ligated by the cyclised oligomer or is incorporated in a metallocyclic ring with the oligomeric moiety as in [(η⁴-Ph_4C_4)RhCl]$_2$ (from the dimerisation of diphenylacetylene),[5] [(η⁶-C_6Me_6)Co(η⁵-C_5H_5)] (from the trimerisation of dimethylacetylene)[6] or [$Co_2(CO)_4${μ-C(Bu^t)-CHCHCHCHC(Bu^t)}] (from the co-trimerisation of *tert*-butylacetylene and acetylene).[7] Reports of the oligomerisation and cleavage of an acetylene to give a C_5R_5-ring and CR unit (R = H, alkyl or aryl) are considerably more scarce. The few examples that have been reported all feature reactions of trinuclear or higher nuclearity homometallic cluster complexes and furnish organometallic products only in low[8] to very low yields.[9]

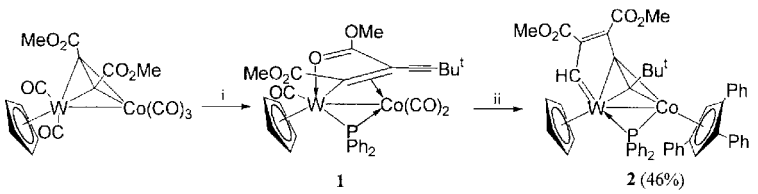
Recently, we have been interested in C–C coupling reactions of alkynes or acetylides on mixed-metal dinuclear transition metal centres. For example, the reaction of the alkyne-bridged complex [(OC)$_2$(η⁵-C_5H_5)W{μ-C(CO_2Me)C(CO_2Me)}Co-($CO)_3$] with PPh_2C≡CBu^t leads to [(OC)(η⁵-C_5H_5)W{μ-C-(CO_2Me)CC(C≡CBu^t)(OMe)O}(μ-PPh_2)Co($CO)_2$] **1** in which an acetylide fragment, generated from P–C bond cleavage within the PPh_2C≡CBu^t ligand, has coupled with the bridging alkyne.[10] Here, we report that phenylacetylene undergoes C≡C bond scission and oligomerisation on reaction with **1** to form a tungsten–cobalt complex containing an η⁵-bound triphenylcyclopentadienyl ligand and a terminal CHR carbene ligand (Scheme 1) both derived from phenylacetylene.

Treatment of **1** with excess phenylacetylene in toluene at 383 K for 6 h affords air stable [(η⁵-C_5H_5)W{μ-CBu^{t}CC(CO_2-Me)=C(CO_2Me)CH}(μ-PPh_2)Co(η⁵-$C_5Ph_3H_2$)] **2** as the sole product in 46% yield.† The product was isolated by TLC on silica [hexane–ethylacetate (3:1) as eluent] as a brown crystalline solid and characterised on the basis of ^{1}H, ^{13}C and ^{31}P NMR spectroscopy,‡ FAB-MS and X-ray diffraction.§

The molecular structure of compound **2** is depicted in Fig. 1. The molecule comprises a tungsten–cobalt core [W–Co 2.704(1) Å] with both metal atoms being bound terminally by mutually *cis* η⁵-cyclopentadienyl ligands [C_5H_5 on W and 1,2,4-$C_5Ph_3H_2$ on Co] and bridged by a PPh_2 group and a six-electron donor CBu^{t}CC(CO_2Me)=C(CO_2Me)CH ligand. The organic bridging ligand can be considered as a η^2:η$^{2\prime}$-bridging alkyne [*via* C(45) and C(46)] with one of the alkyne substituents being a Bu^t group and the other a C(CO_2Me)=C(CO_2Me)CH group. This latter group further coordinates to W *via* the CH carbene carbon atom [W=C(53) 2.000(7) Å]. The metallocyclopentadienyl ring so formed, [W(1)–C(46)–C(47)=C(50)–C(53)=], is almost planar [maximum deviation from plane 0.039 Å, C(46)] with the other end of the bridging alkyne [C(45)], sitting out of this plane. Both cyclopentadienyl groups are essentially planar with the phenyl rings in the 1,2,4-triphenylcyclopentadienyl ligand being located slightly out of the plane of the C_5 ring [C(11) elevation 0.243 Å, C(17) elevation 0.335 Å, C(23) elevation 0.297 Å] and tilted with torsion angles of 28.9° [C(24)–C(23)–C(9)–C(10)], 34.9° [C(12)–C(11)–C(6)–C(10)] and 49.9° [(C(18)–C(17)–C(7)–C(8)] with respect to the plane of the ring.

The key features of the structure of **2** are the presence of the 1,2,4-$C_5Ph_3H_2$ ligand and the W(1)=C(53) double bond. The formation of the carbene and the substituted cyclopentadienyl ring requires the cleavage of the C≡C triple bond in phenylacetylene to give PhC and CH fragments. The C_5 ring is formed by the linking of two unbroken phenylacetylene ligands with the C–Ph fragment, whereas the CH fragment inserts into the W–C bond of the bridging ligand in **1**, with resultant displacement of the coordinated vinyl and ester groups, to form a μ-CBu^{t}CC-(CO_2Me)=C(CO_2Me)CH ligand. Examples of crystallographically characterised homo- and hetero-bimetallic tungsten complexes containing a terminally bound carbene ligands are rare[11] with the W(1)=C(53) bond distance [2.000(7) Å] in **2** falling in the mid-range. It is noteworthy that the organic transformation mediated by **1** has resulted in the loss in **2** of all the terminal carbonyl groups in **1**.

The spectroscopic data for **2** is consistent with the solid state structure being maintained in solution. In the IR spectrum two weak bands at 1727 and 1698 cm^{-1} can be attributed to the ketonic carbonyls of the MeO_2CC=CCO_2Me unit. The ^{1}H NMR spectrum of **2** displays, in addition to phenyl and alkyl resonances, a downfield singlet at δ 11.8 which is assigned to the carbene CH proton. Similarly, a downfield shift is observed for the carbene carbon atom in the ^{13}C NMR spectrum at δ 234.3



Scheme 1 *Reagents and conditions*: i, Ph_2PC≡CBu^t, heat; ii, PhC≡CH, heat, 6 h.

Selected bond lengths (Å) and angles (°): W(1)–Co(1) 2.704(1), W(1)–C(53) 2.000(7), W(1)–C(46) 2.157(6), W(1)–C(45) 2.045(6), W(1)–P(1) 2.354(2), W(1)–$(C_5H_5)_{centroid}$ 2.053(6), Co(1)–C(46) 2.007(6), Co(1)–$(C_5Ph_5H_2)_{centroid}$ 1.739(6), Co(1)–C(45) 2.096(6), Co(1)–P(1) 2.187(2), C(45)–C(46) 1.443(8), C(46)–C(47) 1.429(8), C(47)–C(50) 1.383(8), C(50)–C(53) 1.431(9); Co(1)–P(1)–W(1) 72.98(5), C(53)–W(1)–Co(1) 120.1(2), C(45)–W(1)–Co(1) 50.1(2), C(46)–Co(1)–W(1) 52.0(2).

while the carbon atoms of the 1,2,4-substituted cyclopentadienyl ring are seen as upfield singlets at δ 106.7 (*C*–Ph) and 87.0 (C–H).

The mechanism by which the transformation of **1** to **2** occurs is uncertain but it is remarkable that only one product is formed in significant yield from such a complex reaction. A notable feature is that the acetylenic-based bridging ligand in **1** does not participate in the formation of the substituted cyclopentadienyl ligand.[12] Although the yield for the reaction of **1** to give **2** has not been fully optimised it still represents a considerable enhancement of the low yields previously obtained in the cluster-mediated formation of cyclopentadienyl and carbene ligands from acetylenes.[8,9,13] Further work is underway to assess the scope of the transformation and this will be the subject of a future publication.

We wish to thank the Cambridge Commonwealth Trust and Professor B. F. G. Johnson for funding (to K. S.).

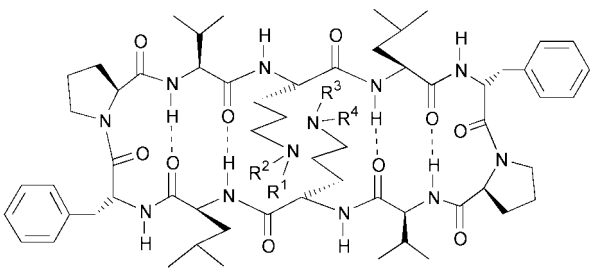
Received (in Cambridge, UK) 26th April 2000, Accepted 5th June 2000

A dinuclear Zn(II) complex of $N^{2\delta}$,$N^{2\delta}$,$N^{2'\delta}$,$N^{2'\delta}$-tetrakis(2-pyridylmethyl) derivative of cyclic peptide gramicidin S markedly accelerated the cleavage of the phosphodiester linkage of the RNA model substrate 2-hydroxypropyl *p*-nitrophenyl phosphate.

Rational design of functional molecules mimicking biologically important species such as enzymes is one of the most challenging fields in modern chemistry. Peptides and peptidomimetics are promising building blocks for the construction of such systems. While numerous studies using α-helical peptides as well-defined structural units were reported, functional molecules based on β-structured peptides were few. The cyclic decapeptide gramicidin S (GS, Fig. 1) possesses a stable antiparallel β-sheet conformation with two type II′ β-turns at the D-Phe-Pro sequences.[1] The amino groups of the two Orn residues of GS are located at one side of the β-sheet, and are suitable for the introduction of various functional groups.

It has been shown that the active sites of many enzymes contain two metal ions which operate cooperatively.[2] Artificial models for the dinuclear metalloenzymes were reported in which pyridine-containing ligand groups were linked to a molecular scaffold such as a calix[4]arene framework.[3] Since the dinuclear Zn(II) complex of the simple diamine derivative $[(PyCH_2)_2NCH_2]_2CHOH$ was shown to promote hydrolysis of the phosphodiester linkage of a diribonucleotide,[4] we have prepared a GS derivative containing two bis(2-pyridylmethyl) amino groups in place of free amino groups, namely [Orn$(PyCH_2)_2^{2,2'}$]GS (**1**). In the present study, the Zn(II) ion-chelating behavior of **1** and phosphodiester bond cleavage mediated by the dinuclear Zn(II) complex have been examined.

$N^{2\delta}$,$N^{2\delta}$,$N^{2'\delta}$,$N^{2'\delta}$-Tetrakis($PyCH_2$) derivative **1** was prepared from GS•2HCl in 57% yield by treatment with 2-PyCHO and $NaBH_3CN$ in MeOH.[5] For comparison, a GS derivative containing only one $(PyCH_2)_2N$ group, namely [Orn$(PyCH_2)_2^2$, Orn(Tfa)$^{2'}$]GS (**2**), was prepared in a similar manner from the singly protected [Orn(Tfa)^2]GS.[6] An alternative bis($PyCH_2$) derivative in which each Orn side chain carries a $PyCH_2NH$ group, namely [Orn$(PyCH_2)^{2,2'}$]GS (**3**), was also prepared by treatment of GS•2HCl with PyCHO followed by catalytic hydrogenation in 70% yield.



GS	$R^1 = R^2 = R^3 = R^4 = H$
1	$R^1 = R^2 = R^3 = R^4 = PyCH_2$
2	$R^1 = R^2 = PyCH_2$, R^3 = Tfa, $R^4 = H$
3	$R^1 = R^3 = PyCH_2$, $R^2 = R^4 = H$

Fig. 1 The structures of gramicidin S (GS) and the 2-pyridylmethyl ($PyCH_2$) derivatives **1**–**3**.

The pyridylmethyl derivatives **1**–**3** exhibited similar CD spectra to that of the parent GS, although the molecular ellipticity of **1** was slightly smaller than GS (Fig. 2a). The ^1H NMR spectral characteristics of **1** in DMSO-d_6 were also similar to those of GS, but the NH proton signal of the D-Phe residue of **1** (δ 8.59, d, J = 4.8) was more shielded, possessing a larger $N^{\alpha}H$–$C^{\alpha}H$ J value compared with the corresponding signal for GS (δ 9.04, d, J = 2.8). A similar spectral feature was observed for the GS derivatives lacking a main chain-side chain H-bonding interaction between $N^{\delta}H$(Orn) and C=O (D-Phe).[7,8] Therefore **1** was assumed to adopt essentially the same β-sheet conformation as that of GS, although the conformation was slightly distorted or disordered due to the absence of the H-bonding stabilization.

Zn(II) ion-binding properties of these pyridylmethyl derivatives were studied by spectrometric titrations. A CD spectral change between 245 and 280 nm upon the addition of aliquots of $ZnCl_2$ to the solution of **1** in MeOH as shown in Fig. 2b suggested stepwise formation of the 1:1 and 1:2 complexes between **1** and Zn^{2+}. A similar spectral change was also observed in buffered aqueous CH_3CN (pH 7.0) which was employed as the solvent for kinetic experiments described later. Formation of the stable dinuclear complex **1**•$(Zn^{2+})_2$ was further supported by UV spectroscopic titration. The CD spectrum of the dinuclear complex‡ in MeOH below 250 nm which was assumed to reflect the main chain conformation was similar to the CD spectral curve of unmodified GS (Fig. 2a). ^1H NMR analysis in DMSO-d_6 indicated a C_2 symmetrical structure for the dinuclear Zn(II) complex **1**•$(Zn^{2+})_2$. ROESY experiments revealed steric proximity of one of the pyridyl groups in each side chain of the Orn residues and the α-protons in the Pro-Val sequences. The NH proton of the D-Phe residue exhibited a similar signal (δ 9.06, d, J < 3.0) to that of natural GS. Taking into account these spectral characteristics the dinuclear complex was assumed to adopt the stable GS-type β-sheet conformation. Instead of the *i* to *i* + 2 type

Table 1 Pseudo-first-order rate constant of Zn(II) complex-mediated phosphodiester bond cleavage of HPNP[a]

Complex	k_{obs}/s^{-1}	Relative rate
None	0.51	1
1•$(Zn^{2+})_2$	3300	6500
2•Zn^{2+}	11	22
4•$(Zn^{2+})_2$	41	80

[a] Assays were carried out in 50% CH_3CN–20 mM HEPES buffer (pH 7.0) except **2**•Zn^{2+} (80% CH_3CN–20 mM HEPES buffer).

$N^{\delta}H$(Orn)··· C=O(D-Phe) H-bonding found in GS and its derivatives[8] the metal ions might play some role in the conformational stabilization. As expected, the bis($PyCH_2$) derivative **2** formed only the mononuclear 1 : 1 complex and no complex-forming tendency with Zn^{2+} was observed for the other derivative **3**.

Activity of the Zn(II) complexes of **1** and **2** for the cleavage of the linkage of 2-hydroxypropyl *p*-nitrophenyl hydrogen phosphate (HPNP) as an RNA model substrate was examined. For comparison, a dinuclear Zn(II) complex of the propanediamine derivative $[(PyCH_2)_2NCH_2]_2CH_2$ **4** lacking the peptide moiety was prepared and was also subjected to the kinetic study. The complexes were generated *in situ* in buffered aq. CH_3CN solution (pH 7.0) and the reaction progress was monitored by the absorbance at 400 nm due to the liberated *p*-nitrophenolate ion from HPNP.§ The obtained pseudo-first-order rate constants (k_{obs}) of the Zn(II) complex-mediated reaction are summarized in Table 1. The dinuclear complex **1**•$(Zn^{2+})_2$ was found to accelerate the reaction drastically. The effect of the mononuclear complex **2**•Zn^{2+} was much lower, indicating the importance of the cooperative participation of the two Zn(II) centers in the reaction process. Since the rate constant of the dinuclear complex **4**•$(Zn^{2+})_2$ lacking the peptide moiety was the same order as that of the mononuclear complex, the relative arrangement of the two Zn(II) centers linked to the rigid β-sheet framework by a moderately flexible trimethylene chain was considered to furnish a desirable reaction site enabling cooperative functioning of the two metal ions.

The pH dependence study of the reaction rate using **1**•$(Zn^{2+})_2$ demonstrated the optimal activity at pH 7.0. Metal ion-bound water in a hydrophobic environment is known to be highly acidic ($pK_a \approx 7$ to 8)[9] and in our case the Zn^{2+}–OH^- species generated near the antiparallel β-strands of GS moiety acts as a nucleophile, attacking the β-OH group of HPNP. As shown in Fig. 3 another Zn(II) ion was assumed to coordinate to phosphate oxygen, assisting the nucleophilic attack of the resulting anionic β-oxygen atom in HPNP to accomplish the intramolecular transesterification. The presence of the neighbouring hydroxy group was essential since the complex did not enhance the hydrolysis of di(*p*-nitrophenyl) hydrogen phosphate examined as a DNA model substrate.

In summary, we have demonstrated that the dinuclear Zn(II) complex **1**•$(Zn^{2+})_2$ possessing a β-sheet framework remarkably promoted phosphodiester bond cleavage of the RNA model substrate HPNP.¶ Very recently, Scrimin *et al.* reported transesterification of HPNP by a dinuclear Zn(II) catalyst based on water-soluble 3[10]-helical peptide.[10] A cyclodextrin-based dinuclear Cu(II) complex which hydrolyzes an amide bond was reported by Fujita's group.[11]

We are grateful to Dr Taka-aki Okamura (Department of Macromolecular Science, Osaka University) for mass spectral measurements and to Nikken Kagaku, Co. Ltd. for the supply of GS•2HCl. This work was supported by Grants-in-Aid from the Ministry of Education, Science, and Culture, Japan.

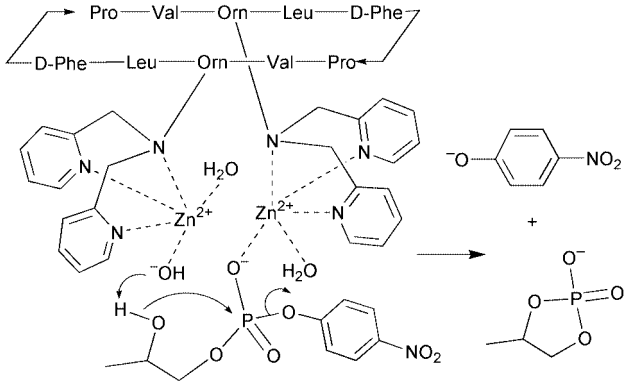

Fig. 3 A possible mechanism for the transesterification of HPNP mediated by the dinuclear Zn(II) complex of **1**.

Notes and references

† Present address: Faculty of Engineering, Gunma University, Kiryu 376-8515, Japan.

‡ **1**•$(Zn^{2+})_2$ was prepared from a MeOH solution of **1** (26 mg, 0.017 mmol) and $Zn(NO_3)_2$•$6H_2O$ (17 mM, 2 ml) by evaporating the solvent and lyophilization as a white solid (33 mg). ESI-MS: *m/z* 817.4 [**1** + 2Zn − 2H]$^{2+}$, $(C_{84}H_{111}N_{16}O_{10}Zn_2)^{2+}$ requires *m/z* 817.4. The complex thus obtained was water-soluble although **1** itself was almost insoluble in water.

§ A typical kinetic experiment was undertaken in 50% CH_3CN–20 mM HEPES buffer (pH 7.0) as follows: After mixing the solutions of **1** (0.5 mM, 3.0 ml) and $Zn(NO_3)_2$ (50 mM, 60 μl) for 1 min, HPNP (75 mM, 10 μl) was added and the pseudo-first-order rate constant k_{obs} was calculated by initial slope method using the absorbance at 400 nm.

¶ The corresponding D-Tyr analog of **1**, namely [Orn$(PyCH_2)_2^{2,2'}$, D-Tyr$^{4,4'}$]GS, possessing phenolic hydroxy groups to which a variety of functional groups (*e.g.* substrate binding sites) could be introduced was also prepared. The dinuclear Zn(II) complex exhibited similar activity to **1**•$(Zn^{2+})_2$ (k_{obs} = 2200 s^{-1}).

Received (in Cambridge, UK) 15th December 1999, Accepted 2nd May 2000
Published on the Web 13th June 2000

The novel organometallic cluster polymer of probable formula $[Ru_6C(CO)_{15}Ph_2PC_2PPh_2]_n$ (n = *ca.* 1000) 1 has been prepared and, on irradiation in an electron beam, forms first nanoparticle chains and then conducting wires.

The potential of simple organic and inorganic molecules as precursors in the formation of electronic devices by direct chemical synthesis is substantial. Well-studied examples include carbon nanotubes,[1] novel resists,[2] metal[3] and semiconducting colloids[4] and conducting and semiconducting polymers.[5] A wealth of physical phenomena have been observed for these examples varying from zero-dimensional electronic confinement[6] to a wide variety of field-effect transition (FET) structures.[7]

Here we report a further type of compound which offers considerable potential in its application to new electronic devices. Until recently, carbonyl clusters have received little attention in this connection, partly because of their relatively small size, and partly because of the difficulty in performing standard microelectronic fabrication. We now report that these difficulties may be largely overcome by the use of materials containing clusters bonded *within* a polymer backbone.

A number of organometallic polymers have been reported previously. These range from those with pendant organometallic fragments attached to polymeric organic backbones[8] to those with metallic species incorporated into the backbone.[9] A common method of incorporation of a metal as a pendant is by performing a polymerisation on a functionalised unit, *e.g.* the free radical polymerisation of vinylferrocene.[10] Other polymers in this class include rigid-rod transition metal–acetylide polymers which usually involve group 10 metals or gold; these polymers consist of metals linked by organic spacers with a minimum capacity to bend. This is achieved by using alkyne or aromatic groups alternately to form rigid rods. In these systems the metal has been shown to coordinate in a *trans* fashion.[11] The electrical and electrochemical properties of such materials have not been investigated in detail.

Here, we report: (i) the synthesis and characterisation of the first organometallic polymer with carbonyl clusters in the backbone formulated as $[Ru_6C(CO)_{15}Ph_2PC_2PPh_2]_n$ and (ii) the processing of this material by electron beam exposure into nanowires with tunable conduction characteristics.

The new cluster based polymer $[Ru_6C(CO)_{15}(Ph_2PC_2PPh_2)]_n$ was synthesised from the direct reaction of $[Ru_6C(CO)_{17}]$ with the alkyne linking reagent $[Ph_2PC_2PPh_2]$ in tetrahydrofuran under reflux. After 5 h, removal of the solvent, followed by precipitation from dichloromethane, hexane gives the polymeric derivative $[Ru_6C(CO)_{15}Ph_2PC_2PPh_2]_n$ **1** as a dark brown powder which is soluble in dichloromethane.† Other products **2**–**4** may also be separated from other reaction stoichiometries. These have been identified as $[Ru_6C(CO)_{16}PPh_2C_2PPh_2]$ **2**, $Ru_6C(CO)_{15}\{PPh_2C_2PPh_2\}_2]$ **3** and $[Ru_5C(CO)_{13}PPh_2C_2PPh_2]$ **4**.† Significantly, in a separate experiment, we have observed that compound **3** undergoes reaction with a stoichiometric amount of $[Ru_6C(CO)_{17}]$ to yield polymer **1**. We believe that the polymer consists of $[Ru_6C(CO)_{15}]$ units linked by $[Ph_2PCCPPh_2]$ ligands (Fig. 1). The polymer **1** has been identified by routine chemical analysis. Elemental analyses (C, H) are totally in accord with the proposed empirical formula, and the presence of phosphorus is further confirmed by the solid state ^{31}P NMR† which exhibits a broad band at $\delta -20$. In the IR spectrum a broad ν(CO) band is observed† consistent with a polymer containing a large number of bonded CO ligands. A molecular weight of 1000–1020 has been estimated from electon microscopy carried out on several samples. This technique has been developed from our TEM studies of other systems.[12] In brief, a monolayer of polymer was deposited from solution onto holey carbon microscopy grids. The images over

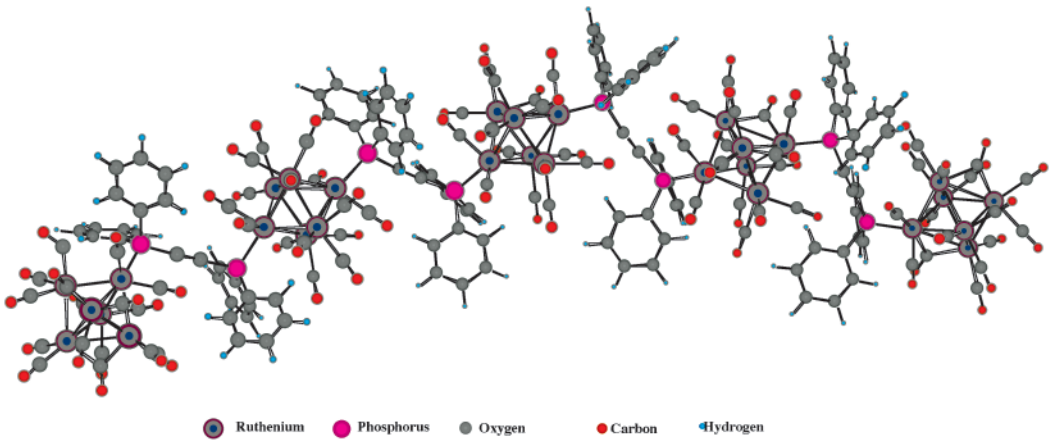

Fig. 1 The proposed structure of $[Ru_6C(CO)_{15}(Ph_2PC_2PPh_2)]_n$.

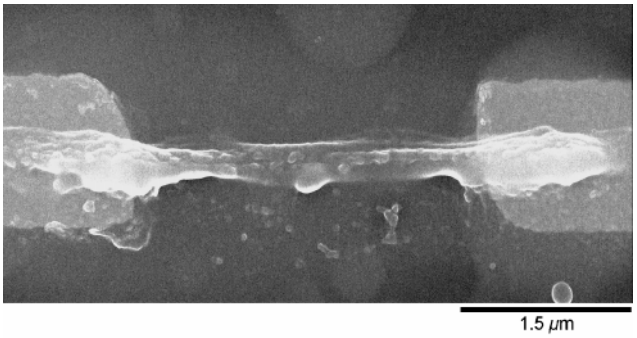

Fig. 2 SEM micrograph of a typical device. The polymeric nanowire (300 nm in width) lies on top of the gold contacts.

time showed that the polymer was very beam sensitive but from the initial images of chains of clusters an estimate of chain length could be determined. Further studies were made on the polymer supported on silica spheres (*ca.* 5 nm in diameter) to confirm and follow the nanoparticle growth induced by the electron beam (*vide infra*). This work will also be dealt with in a more detailed manner in a full paper.

Silicon substrates coated with 200 nm of high-quality oxide were prepared with micro-fabricated contacts composed of 10 nm Cr and 30 nm of Au (Fig. 2). The contacts defined a region for investigation of 4 × 5 μm, orientated with the shorter direction along the current path. A freshly prepared solution of polymer **1** in dichloromethane (200 mg ml^{-1}) was filtered through Teflon (200 nm pore size) and then spin-coated onto the substrate forming a layer *ca.* 120 nm thick. The layers were smooth and uniform and largely free from visible imperfections. Following preparation, exposures were performed on the samples in the usual way by electron-beam lithography (accelerating voltage 60 kV, current 1 nA, beam diameter *ca.* 250 nm). Exposures were conducted at 25 °C in a vacuum of 10^{-4} Pa or better. After development for 1 min, the polymeric material was observed to behave as a negative electron beam resist, with a sensitivity of 400 C m^{-2}. Atomic force microscopy (AFM) was used to determine the thickness of the material after development. At this stage the conductivity of the material was found to be immeasurably small. However, after more extensive electron beam exposures (accelerating voltage 60 kV, current 10 nA, beam diameter 1 μm at doses ranging from 10^3 to 4 × 10^6 C m^{-2}) the films showed conductivity increasing in a power law as a function of dose. The conduction mechanism was found to be variable range hopping in two dimensions[13] (Fig. 3). Using a finely focussed electron beam, it was possible to make wires as small as 100 nm in width. A typical device is shown in Fig. 2. The current–voltage characteristics near room temperature are well fitted by a hyperbolic sine, as predicted by variable-range hopping theory. However, at low temperatures, the current is strongly suppressed at low bias voltage.

We postulate that in the initially formed polymer the cluster units are surrounded by the non-conducting carbonyl sheath but that on initial irradiation with the electron-beam this sheath is lost to produce nanoparticle chains thus accounting for the observed contraction in volume. Weight loss as measured by tga tends to support this view. Further irradiation is then considered to bring about the fusion of groups of these particles into larger clusters, forming a conducting chain. We consider that this conductivity is brought about by an electron hopping process between nanoparticle groups rather than through the formation of a continuous metal wire. At low temperature, the device characteristics observed are consistent with charging-suppressed transport through these groups.

We thank the EPSRC and ICI for a CASE award (K. M. S.).

The reaction of cobalt(II) sulfate with 1,2-bis(4-pyridyl)-ethane gives a crystalline polymeric species comprised of chiral quintuple layers with five decks of linear chains rotated by 120° from level to level, that are perpendicularly joined *via* five-metal helical motifs; furthermore, each of these two-dimensional frames is catenated by the neighbouring layers to give an overall three-dimensional chiral nanoporous architecture.

There is much current interest for the crystal engineering of coordination frameworks,[1] not only because of their potential applications as zeolite-like materials, for molecular selection, ion exchange and catalysis, but also for their intriguing architectures, new topologies and intertwining *phenomena*. Some recent examples have shown that topological types unprecedented in inorganic chemistry and in minerals can be achieved within the area of networked coordination polymers.[2] Moreover, new types of supramolecular intertwinings of infinite motifs have been discovered, that open interesting perspectives in the study of these materials. Particularly attractive are polymeric systems sustained by supramolecular entanglements reminiscent of the mechanical bonds in molecular rotaxanes and catenanes, exhibiting constituent motifs of dimensionality lower than that of the resulting overall architecture. Known examples include polyrotaxanes[3] and polycatenated one-dimensional[4] and two-dimensional motifs.[5] Species like these are expected to be of comparable robustness but more flexible than the usual networks entirely based on coordinative bonds with similar ligands.[6] We report here on a new member of this class of polycatenated motifs, $[Co_5(bpe)_9(H_2O)_8(SO_4)_4](SO_4)\cdot 14H_2O$ [bpe = 1,2-bis(4-pyridyl)ethane] **1**, that presents a new remarkable chiral three-dimensional architecture sustained by the catenation of chiral five-fold decked layers.

Compound **1** forms as beautiful flat hexagonal pink crystals by slow evaporation of solutions obtained on mixing bpe in ethanol and Co(II) sulfate in water, with metal-to-ligand molar ratios from 1:1.7 to 1:2. The crystals are stable in the air at room temperature for an extended time but start to lose solvated water molecules when heated above *ca.* 40 °C. The powdered material obtained in good yields by fast evaporation of more concentrated solutions of the reagents corresponds to almost pure **1**, as confirmed by X-ray powder diffraction methods.

The crystal structure of **1**† shows the presence of multiple layers containing five levels of one-dimensional linear polymers, all lying perpendicular to the crystallographic *c* axis, that are formed by Co(II) ions joined by bpe ligands in a *trans* conformation (Co···Co distances of 13.69 Å). These polymers run on the five decks in different directions rotated by 120° about the *c* axis on passing from one level to the successive one, thus resulting in a *ABCAB* sequence. The decks are connected along the normal direction *via* five-metal helical motifs, illustrated in Fig. 1, all exhibiting homochirality (left handed chirality for the crystal examined). The resulting chiral multilayer thus formed is schematically shown in Fig. 2.

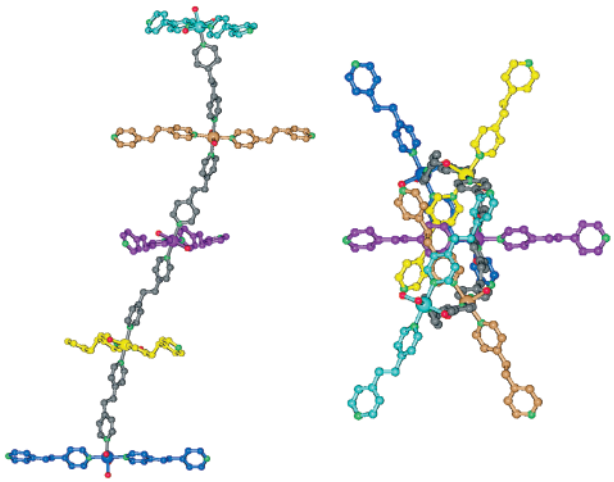

Fig. 1 A lateral (left) and a top (right) view of a single helical motif joining perpendicularly the quintuple layer (different colours are used to evidence the five decks). A two-fold axis passes through the central metal.

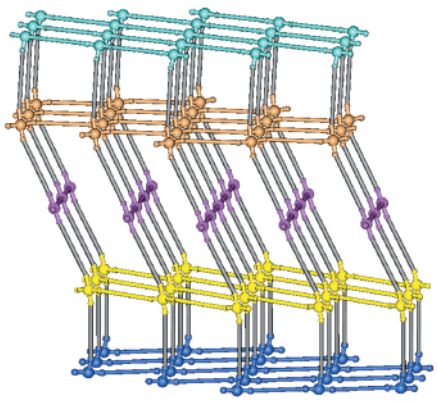

Fig. 2 A schematic view of a single five-decked layer with the same colours as in Fig. 1.

The cobalt ions of the two external levels are three-connected to bpe ligands (T-shaped geometry) while those of the three internal levels are four-connected to such ligands (square-planar geometry). The coordination spheres of the cobalt ions are completed by oxygen atoms of the sulfates and by water molecules (three *mer* H_2O for the two external Co, two sulfates for the central cobalt, one H_2O and one sulfate for the other two metal ions), resulting in all cases in distorted octahedral geometries. The five-metal helical chains are terminated at both ends by axial H_2O ligands, *i.e.* the external 'surfaces' of the multilayers are covered by coordinated water molecules. Though other examples of multiple layers are known within coordination polymers,[7] the two-dimensional motif of **1** is

unique in terms of topology, number of decks and thickness (see Fig. 2). To our knowledge, it is the largest two-dimensional coordination polymer ever reported.

We can rationalize this two-dimensional polymeric motif as a five-layer section of the chiral three-dimensional four-connected framework described by O'Keeffe as the 'dense' net.[8] This shows an *ABCABC* infinite sequence of levels and exhibits the unusual ($7^5 9$) topology. The first real example of this frame-work (three-fold interpenetrated) has been recently observed in a copper(II) polymeric species.[2a]

The stacking distance between two adjacent levels of each quintuple layer lies in the range 12.26–13.10 Å, so that the resulting overall height is as large as 50.5 Å. Identical layers are superimposed along the *c* crystallographic axis, with an interlayer gap of 13.4 Å (see Fig. 3). Two other sets of quintuple layers are generated by the 3_1 symmetry axis, exhibiting sequences of their five levels of the *BCABC* and *CABCA* type, respectively, resulting in an overall chiral packing. The three sets are entangled in such a way that each layer is catenated not only by the two nearest neighbouring (upper and lower) layers but also by the two second nearest neighbouring ones, as illustrated in Fig. 3. Thus each layer is intertwined in a 'parallel fashion'[1b] with the other four, to give a fascinating polycatenated array. Infinite catenation of polymeric motifs represents a type of supramolecular entanglement that is still quite uncommon. Known examples include polycatenated one-dimensional ladders that give two-dimensional[4b] or three-dimensional arrays,[4a,c] as well as two-dimensional simple,[5c] double[5a] and quadruple layers,[5b] resulting in three-dimensional architectures. We have very recently reported also on a catenated three-dimensional system based on different polymeric motifs, *i.e.* one-dimensional ribbons of rings and two-dimensional (4,4)-layers, that exhibits a peculiar sponge-like nanoporous behaviour.[6b]

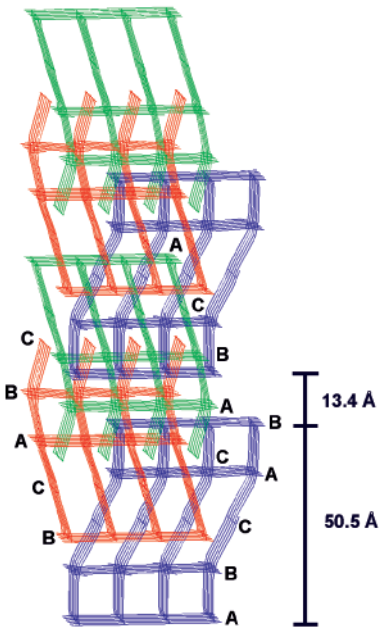

Fig. 3 The catenation of the two-dimensional quintuple layers. Three colours are used to evidence the different sets of layers generated by the 3_1 axis. Inside one layer the two interpenetrating nearest neighbours are also entangled between themselves (the inner red and blue layers inside the central green one).

The polycatenation in compound **1** is not sufficient to fill all the free voids, corresponding to *ca.* the 19.6% of the cell volume (calculated by neglecting the chlatrated H_2O molecules and the uncoordinated sulfates). These spaces are comprised of isolated cavities (three major cavities each of volume *ca.* 450 Å^3) containing solvated water molecules that can be removed by heating. Thermogravimetric analyses of **1**, under a nitrogen flux, show that both the solvated and the coordinated water molecules are completely lost in a continuous fashion in the range 40–120 °C. Above this point the product loses crystallinity and becomes unstable,‡ but if the samples are heated only up to *ca.* 80 °C the solvent loss (*ca.* 8% of the total weight, corresponding approximately to the solvated water molecules) can be regained by exposure to water vapour overnight, as confirmed by TGA and XRPD.

Since catenation of polymeric frameworks can allow a certain flexibility of the whole architecture, it can potentially favour solvent exchange processes, as observed in previous examples.[6] Compound **1** can be, therefore, considered as a model species for nanoporous arrays that present the additional features of non rigidity and chirality.

† *Crystal data* for compound **1**: $[Co_5(bpe)_9(H_2O)_8(SO_4)_4](SO_4)\cdot 14H_2O$, M = 2829.43, trigonal, $P3_121$ (no. 152), $a = b$ = 13.690(2), c = 63.880(9) Å, U = 10368(3) Å^3, Z = 3, D_c = 1.359 Mg m^{-3}, Mo-Kα radiation (λ = 0.71073 Å), μ(Mo-Kα) = 0.745 mm^{-1}, 61444 reflections measured, 9999 unique (R_{int} = 0.043), final $R1$ = 0.088 for 9343 independent reflections [$I > 2\sigma(I)$]. The data collection was performed at 293 K on an SMART-CCD Bruker diffractometer, by the ω-scan method, within the limits $2 < \theta < 24°$. The structure was solved by direct methods (SIR97) and refined by full-matrix least squares (SHELX97). The non coordinated sulfate anion is statistically distributed over two positions and was refined with half occupancy. One bpe ligand is statistically disordered by a two-fold axis passing through N1 and N2 and was refined using a half weight model. The handedness of the crystal was determined by testing the two enantiomeric models.

‡ Two other weight losses are observed. The first in the range 120–250 °C (*ca.* 19%) corresponds approximately to three ligand molecules. The corresponding XRPD spectrum shows a completely different pattern arising from a new violet anhydrous phase. The second weight loss (*ca.* 36–37%), occurs in the range 280–430 °C and leads to a final residue of $CoSO_4$, as evidenced by XRPD.

Published on the Web 26th June 2000

The hydrothermal reactions of Cu_2O, the appropriate polypyridine ligand, Na_3VO_4, H_3PO_4 and H_2O at 200 °C yield the two-dimensional material $[\{Cu(bpy)\}_2(VO)_3(PO_4)_2(HPO_4)_2]\cdot 2H_2O$ and the one-dimensional phosphate $[\{Cu(terpy)\}_2(VO_2)_3(PO_4)(HPO_4)_2]$, examples of the structure-directing role of secondary metal–ligand subunits on the architectures of vanadium phosphates.

One approach to the design of novel materials exploits the often dramatic influence of organic molecules on inorganic microstructures.[1,2] Zeolites,[3,4] mesoporous materials of the MCM-41 class,[5] and open framework metal phosphates[6,7] are examples of families of materials which incorporate organic cations as structure-directing agents. An alternative approach introduces the organic component as a ligand, linking metal sites into complex metal–organic scaffoldings.[8,9] A variant of this strategy as applied to molybdenum oxides employs secondary metal–ligand complex subunits, not only as charge-compensating and space-filling components, but also as intimate structural components of bimetallic oxide composite materials, exemplified by copper–molybdenum oxides such as [Cu(4,4′-bipyridylamine)MoO_4], [Cu(*o*-phen)MoO_4] and [Cu(tetraphenylporphyrin)$Cu_2Mo_3O_{11}$].[10–12] Since both the ligand geometry and spatial extension, as well as the coordination preferences of the secondary metal site can be manipulated, considerable flexibility may be achieved in the spatial transmission of the structural information inherent at the ligated metal site. The success of this approach in the evolution of a wealth of new materials in the molybdenum oxide family encouraged us to explore the structure-directing role of copper–organonitrogen subunits in the industrially significant oxovanadium phosphate family of materials. The coordination preferences of the copper and the consequences of increased ligand bulk and denticity are evident in the structure of two novel bimetallic oxide phosphate materials, two dimensional $[\{Cu(2,2'\text{-bipyridyl})\}_2(VO)_3(PO_4)_2(HPO_4)_2]\cdot 2H_2O$ (**1**) and one-dimensional $[\{Cu(terpyridyl)\}_2(VO_2)_3(PO_4)(HPO_4)_2]$ (**2**).

Compound **1** was prepared as dark green rhombi in 40% yield from the hydrothermal reaction of Cu_2O, 2,2′-bipyridine, Na_3VO_4, H_3PO_4 and H_2O at 200 °C for 95 h.† Substitution of terpyridine for bipyridine in the reaction mixture and heating at 200 °C for 50 h yielded **2** as emerald green rhombi in 50% yield. The infrared spectra of **1** and **2** exhibit strong bands in the 920–970 cm^{-1} range attributed to ν(V=O) and a series of bands characteristic of the phosphate group in the 1100–1600 cm^{-1} range.

As shown in Fig. 1, the structure of **1**‡ consists of copper–vanadium oxide–phosphate layers, decorated with 2,2′-bipyridyl groups projecting above and below into the interlamellar region. The network is constructed from the corner- and edge-sharing polyhedral connectivity of copper(II) square pyramids, vanadium(IV) octahedra and square pyramids and phosphate tetrahedra. The Cu(II) coordination geometry is defined by the nitrogen donors of the bpy ligand and three oxygen donors from each of two $\{PO_4\}^{3-}$ groups and the –OH group of the $\{HPO_4\}^{2-}$ unit. The Cu–O and P–O bond lengths of 2.35 and 1.61 Å, respectively, and valence sum calculations[13] establish this as the protonation site. The square pyramidal V(IV) site consists of a terminal apical oxo-group and four phosphate oxygen donors from each of four $\{PO_4\}^{3-}$ or $\{HPO_4\}^{2-}$ groups, while the octahedral V(IV) site features a terminal oxo-group and five oxygen donors from four $\{PO_4\}^{3-}$ groups. One phosphate group bridges three vanadium centers and a copper site, while the second bridges three vanadium and two copper sites, sharing two vertices with both vanadium and copper centers.

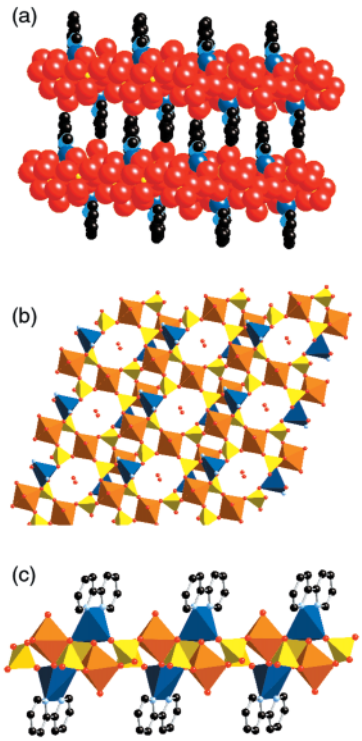

Fig. 1 (a) A space-filling view of the structure of **1**, parallel to the oxide layer. Red spheres, oxygen; dark blue spheres, copper; black spheres, carbon; light blue spheres, nitrogen. Hydrogen atoms have been omitted for clarity. (b) A view of the structure of **1**, normal to the plane of the bimetallic phosphate layer. The square pyramidal vanadium sites are represented as yellow polyhedra linking the $\{Cu_2(bpy)_2(VO)_2(PO_4)_2(HPO_4)_2\}$ chains with the vanadium octahedra in yellow, the copper sites in blue and the phosphate groups in violet. (c) A polyhedral representation of the $\{Cu_2(bpy)_2(VO)_2(PO_4)_2(HPO_4)_2\}$ chain. Selected bond lengths (Å): V1–O_t, 1.586(4); V1–$O_{phosphate}$, 1.964(3), av. of 4; V2–O_t, 1.607(2); V2–$O_{phosphate}$, 2.071(4), av. of 5; P–O, 1.531(4), av.; P–O(H), 1.605(2); Cu–O, 1.975(4), av; Cu–O(H), 2.349(2).

The structure of **1** may be best described as $\{Cu_2(bpy)_2(VO)_2(PO_4)_2(HPO_4)_2\}$ chains linked through square pyramidal $\{VO_5\}$ units into a 2-D network. Embedded within the chain are $\{Cu_2(bpy)_2(VO)_2(PO_4)_2\}$ clusters, constructed of a central ring of edge- and corner-sharing $\{VO_6\}$ octahedra and $\{PO_4\}$ tetrahedra capped by two $\{CuO_3N_2\}$ square pyramids. The phosphate groups of this cluster motif each link two copper and two vanadium sites, participating in edge-sharing with a

DOI: 10.1039/a909743k

vanadium polyhedron and contributing two triply-bridging oxygen donors. The fourth vertex of each of these phosphate groups serves to bridge to the square pyramidal vanadium site. The individual clusters are linked into the chain motif through four corner-sharing $\{PO_4\}$ tetrahedra. The fourth vertex of each of these phosphate sites again bridges to the square pyramidal vanadium center. One consequence of this unprecedented polyhedral connectivity is to generate eight polyhedral connect rings $[V_4P_4O_8]$ which create network cavities. The water molecules of crystallization are situated within these cavities and strongly hydrogen-bonded to the phosphate oxygens and the protonated phosphate oxygen. Since these intralamellar cavities are contained within hydrophobic regions defined by the bipyridyl groups, there is no facile pathway for removal of H_2O from the crystal. This observation is confirmed by the thermal gravimetric analysis of **1** which exhibits no weight loss below 250 °C, whereupon water is lost in two steps (250–275 °C and 310–375 °C). Ligand loss occurs above 400 °C to give an amorphous gray powder at 650 °C.

The structural consequences of increasing ligand bulk and denticity are apparent in the one-dimensional structure of **2**, shown in Fig. 2. The chain consists of exclusively corner-sharing vanadium(v) tetrahedra, square pyramids and trigonal bipyramids, copper square pyramids and $\{PO_4\}^{3-}$ and $\{HPO_4\}^{2-}$ tetrahedra. There are three distinct vanadium centers: an 'isolated' $\{VO_4\}$ tetrahedra site (*i.e.* no V–O–V linkages) and a binuclear site consisting of an oxo-bridged $\{VO_5\}$ trigonal bipyramid and $\{VO_5\}$ square pyramid. The $\{PO_4\}^{3-}$ group participates in corner-sharing to bridge the vanadium sites of the binuclear unit, the tetrahedral vanadium site and the copper. The remaining phosphate sites each bridge three metal centers and exhibit a pendant and protonated oxygen site. The terpy ligand occupies three coordination sites on the copper and introduces significant steric constraints, leaving two coordination sites available for linking to the oxovanadium phosphate chain. One copper site coordinates to two oxygen donors from two phosphorus tetrahedra, while the second bonds to a phosphorus oxygen and a bridging oxo-group of the trigonal bipyramidal vanadium site. The presence of three distinct vanadium polyhedra in **2** is a structurally unique feature for the oxovanadium phosphate family of materials.

Oxovanadium phosphates have received considerable attention as a result of their catalytic properties in organic oxidations[14,15] and their intercalation properties.[16] Significant activity has focused on structural modification and design of vanadyl phosphates through the introduction of organic substructures as templates and charge-compensating cations.[6,17] The approach to hybrid oxometal–phosphate/organic solids illustrated by the isolation of **1** and **2** employs secondary metal–organic ligand subunits as covalent linkers to the oxometal phosphate substructure. This strategy not only yields novel structural types, but appears to afford primitive control over the dimensionality of the solid through manipulation of the steric requirements and denticity of the ligand. The evolution of synthetic design in such solids appears inherent in the systematic variation of the secondary metal and its coordination preferences, the organic ligand, and the hydrothermal reaction conditions.

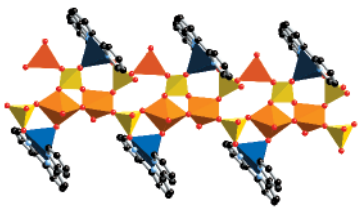

Fig. 2 A polyhedral representation of the structure of **2** using the same color scheme as for Fig. 1. Selected bond lengths (Å): tetrahedral vanadium: V1–O_t, 1.614(4) and 1.633(3); V1–O_b, 1.838(3) and 1.861(3); trigonal bipyramidal vanadium: V2–O_t, 1.594(4); V2–O_b(–Ve), 1.703(3); V2–$O_{phosphate}$, 1.956(5), av.; square pyramidal vanadium: V3–O_t, 1.620(3); V3–O_b(–Cu), 1.647(3); V3–O_b(–V2), 1.987(3); V3–$O_{phosphate}$, 1.985(4), av.; Cu1–$O_{phosphate}$, 1.923(3) and 2.099(3); Cu1–N, 2.052(6), av.; Cu2–O_b(–V3), 2.241(3); Cu2–$O_{phosphate}$, 1.921(4); Cu2–N, 1.993(6), av.

Received (in Liverpool, UK) 2nd May 2000, Accepted 12th June 2000

Reactions of aryl alkyl ketones with 1-fluoro-4-hydroxy-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate) (Accufluor™ NFTh) in methanol result in selective and almost quantitative formation of the corresponding α-fluoroketones, while in acetonitrile exclusive fluorofunctionalisation of the activated aromatic ring take place.

The strategic introduction of a fluorine atom into organic molecules has attracted considerable current interest in related fields of chemistry[1] since this element often induces beneficial changes in the physicochemical and biological properties[2] of organic compounds. The ever increasing application of these fluorofunctionalised compounds has given a strong impetus to the academic as well as the industrial evaluation of new reagents and methods for selective fluorination under mild reaction conditions. In the last decade the introduction of numerous organic molecules incorporating a reactive N–F bond as versatile, mild, electrophilic fluorinating reagents[3] has created new challenges and revolutionarily influenced achievements in this field of organic chemistry.

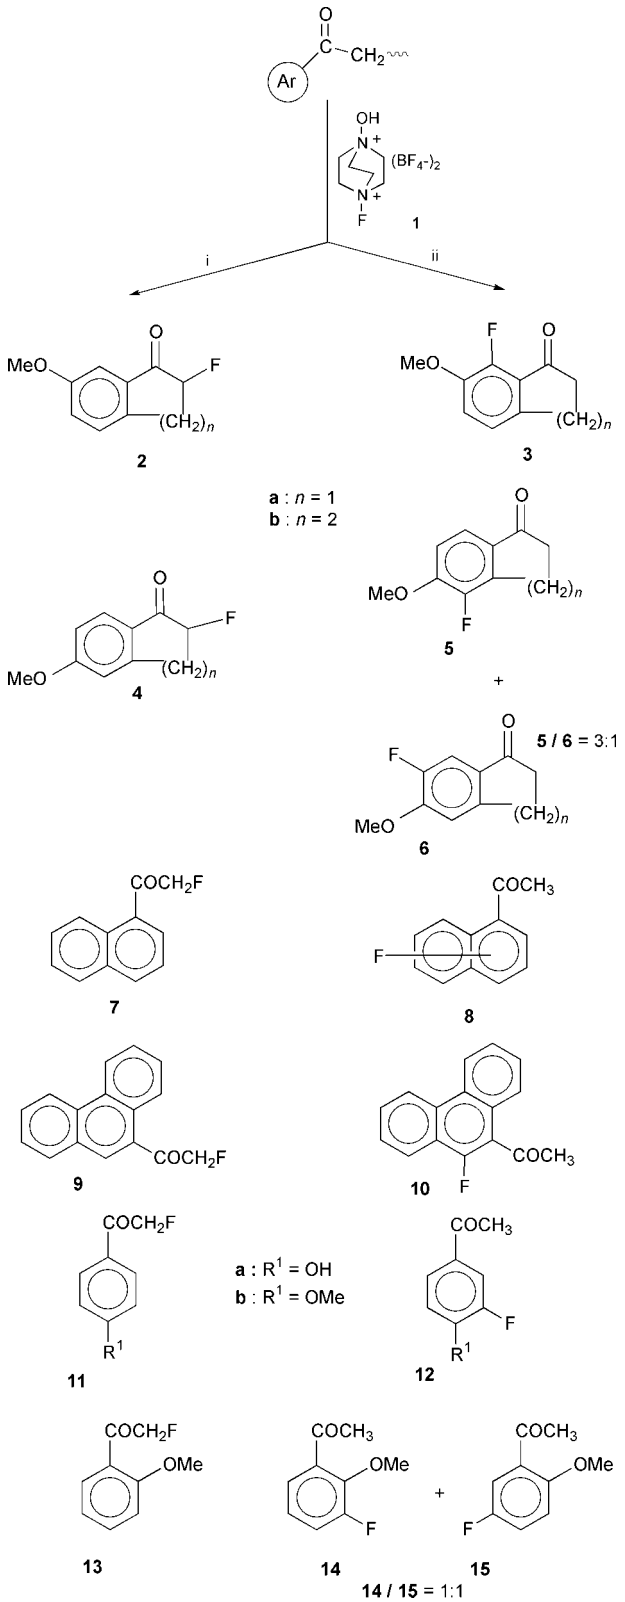
Fluorofunctionalisation of organic compounds bearing a carbonyl functional group has been of special interest,[1] since this reactive moiety is often present in bioactive molecules or in potentially valuable building blocks for the synthesis of more sophisticated organofluorine derivatives. The position α to the carbonyl seems to be the most strategic one for the introduction of fluorine,[4] but when using electrophilic fluorinating reagents prior activation through enolate anions or enol ethers is necessary, except for sufficiently activated 1,3-dicarbonyl substrates. The presence of other active sites, such as an activated aromatic ring, in a target molecule often provokes lower regioselectivity of fluorofunctionalisation, thus making the task considerably more difficult. We now report the reactions of 1-fluoro-4-hydroxy-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate) (Accufluor™ NFTh[5]) with alkyl aryl ketones bearing a strongly activated aromatic ring.

In a typical experiment we treated 6-methoxy-1-indanone with NFTh in acetonitrile solution under reflux and in the crude reaction mixture established a high yield (68%) of 7-fluoro-6-methoxyindan-1-one (**3a**, Scheme 1). The observed regioselectivity of the reaction was quite different from that in the case of the same reaction of unsubstituted indan-1-one where regiospecific fluorination of the α-carbonyl position was observed.[6] Although the result of this reaction was expected since the aromatic part of the substrate is strongly activated and suitable for fluorofunctionalisation,[3] we checked the effect of the solvent on the course of the reaction and found that by using methanol as the reaction medium, the regiochemistry of the fluorination process changed dramatically, leading the reaction towards quantitative formation of 2-fluoro-6-methoxyindan-1-one (**2a**, Scheme 1). Encouraged by the possibility that the regioselectivity of fluorination of these types of ketones could be regulated only by the solvent used, we further investigated the reactions of NFTh with a series of methoxy substituted benzocycloalkan-1-one derivatives‡ and found that in methanol 7-methoxy-3,4-dihydronaphthalen-1(2*H*)-one was transformed to 2-fluoro-7-methoxy-3,4-dihydronaphthalen-1(2*H*)-one (**2b**) in over 90% yield, while in acetonitrile the fluorofunctionalisation of the aromatic ring took place regioselectively at position 8, thus forming 8-fluoro-7-methoxy-3,4-dihydronaphthalen-1(2*H*)-one (**3b**). Solvent directed regioselective fluorination was also observed in the case of 5-methoxyindan-1-one or 6-methoxy-3,4-dihydronaphthalen-1(2*H*)-one: 2-fluoro derivatives **4** were exclusively formed in methanol, while in acetonitrile fluorination of the aromatic ring was again found to be favoured but not regiospecific and two isomers **5** and **6** in a relative ratio of 3:1 were isolated from the crude reaction mixture.

Direct fluorination of methyl aryl ketones in the α-carbonyl position was found to be considerably less effective than the corresponding functionalisation of dialkyl or alkyl aryl ketones,[6] but by using methanol as reaction medium the NFTh mediated transformation of acetophenone to fluoromethyl phenyl ketone was readily accomplished in over 80% yield. This fact encouraged us to also use the protocol described for the fluorofunctionalisation of methyl aryl ketones bearing an activated aryl part of the molecule. 1-Acetylnaphthalene was, following reaction with NFTh in methanol, thus effectively and regioselectively transformed to fluoromethyl 1-naphthyl ketone **7**, while the reaction in acetonitrile was in this case found to be unselective and up to six mono and difluoro isomers of the substrates were detected in the crude reaction mixture. On the other hand, the analoguous reaction of 9-acetylphenanthrene resulted in the formation of high yield fluoromethyl 9-phenanthryl ketone **9** if methanol was used as the solvent, while exclusive formation of 9-acetyl-10-fluorophenanthrene **10** was established when the reaction was performed in acetonitrile. We further found that strong electron donating substituents on the *para* position of acetophenone did not interfere with the effectiveness of the reactions. Fluorination of 4-hydroxy- or 4-methoxyacetophenone resulted in the high yield formation of the corresponding fluoromethylacetophenones **11** and 3-fluoro substituted derivatives **12**, respectively, depending on the solvent used. Similar results were also obtained with *ortho* substituted acetophenones: fluoromethyl-2-methoxyacetophenone **13** was formed in methanol and a 1:1 mixture of 3-fluoro- (**14**) and 5-fluoro-2-methoxyacetophenone (**15**) in acetonitrile mediated reactions. Unfortunately, derivatisation of acetophenone with an electron donating substituent at the *meta* position caused complete loss of the selectivity of the reaction, and in both solvents only a complex mixture of fluorinated products was observed.

Considering the results obtained, we can point out some important facts which in general facilitate the task of fluorofunctionalisation of ketones considerably. Using Accufluor™

† The results of characterisation of **2a**, **2b**, **3a**, **3b**, **4a**, **4b**, **5a**, **6a** and **9** are available as electronic supplementary information (ESI). See http://www.rsc.org/suppdata/cc/b0/b003488f/



Scheme 1 *Reaction conditions*: i, MeOH, reflux for 0.5–4 h, if necessary hydrolysis with 10% HCl in MeCN; ii, MeCN, reflux for 0.5–4 h.

NFTh direct and selective fluorination can be effectively achieved even of those ketones bearing an activated aromatic part of the molecule, while alkyl aryl regioselectivity of fluorofuctionalisation could be regulated by the solvent. When methanol is used as solvent the substrate is regioselectively fluorinated at the α-carbonyl position, while in acetonitrile medium the same molecule reacts as an activated aromatic substrate and fluorination of the aryl ring is favoured. In addition, reaction is also effective with methyl aryl ketones, which makes the method convenient for direct α-carbonyl fluorination of a comprehensive range of ketones. Mechanistic elucidation of these reactions is in progress and on the basis of preliminary results we can assume that a subtle interplay of keto–enol tautomerism of the studied ketones plays a crucial role on the course of these reactions. In methanol, the keto–enol equilibrium lies sufficiently on the side of an enol form and a substrate reacts with NFTh as an alkene, following the reaction pathway similar to our recent observations,[7] resulting in α-fluoroketones. This assumption is reasonable since we already established that in the case of fluorination with N–F reagents activated alkenes[7] are for several decades more reactive than activated aromatics.[8] In acetonitrile keto–enol equilibrium is less favourable and the activated aromatic ring became the most reactive part of the substrate.

The authors are grateful to the Ministry of Science and Technology of the Republic of Slovenia for financial support, and to T. Stipanovič and Professor B. Stanovnik for elemental combustion analysis.

Notes and references

‡ To a solution of 2 mmol of ketone in 20 mL of methanol or acetonitrile 1.35 g of Accufluor™ NFTh (2.1 mmol of active compound) was added and the suspension heated under reflux for 0.5 to 4 h until KI starch paper showed the consumption of the fluorinating reagent. The reaction solvent was removed under reduced pressure and the crude reaction mixture dissolved in CH_2Cl_2 (50 mL), insoluble material filtered off, the solution washed with water (50 mL), dried over Na_2SO_4 and the solvent evaporated. The isolated crude reaction mixtures were analysed by ^{1}H and ^{19}F NMR. The amounts of fluorinated products were determined from the ^{19}F NMR spectra of crude reaction mixtures using octafluoronaphthalene as an additional standard and yields between 90–95% for α-fluoro carbonyl products or 70–75% of fluoro aromatics (**3**, **5** + **6**, **10**, **12** and **14** + **15**) were obtained. Since crude α-fluoro carbonyl derivatives were often formed mainly in dimethylketal form, hydrolysis with 10% HCl solution in MeCN, followed by crystallisation of α-fluoro ketone was necessary in order to obtain pure products (75–85% yield) **2**, **4**, **7**, **9**, **11**, and **13**, while fluoro aromatic derivatives were purified by preparative TLC (SiO_2, CH_2Cl_2) and 55–65% yield of satisfactory pure products obtained. New compounds were fully characterised by NMR, MS, and IR spectroscopy and their purity verified by combustion analysis.†

Received (in Cambridge, UK) 10th May 2000, Accepted 12th June 2000

A single-crystal X-ray structure determination of the main isomer of $C_{60}F_{18}O$ shows it to be an intramolecular fullerene ether rather than an epoxide, and thus the first example of an oxa-homo[60]fullerene.

Formation of oxides is a major feature of fullerene chemistry. Hitherto, these oxides have been either characterised (*e.g.* $C_{60}O$,[1] $C_{70}O$,[2] $C_{60}O_2$,[3] $C_{60}O_3$,[4], $C_{60}O_n$,[5] $C_{60}Me_5O_2OH$[6]), or conjectured (*e.g.* $C_{60}Ph_4C_6H_4O_2$,[7] fluorofullerene oxides[8,9]) as epoxides. Strong circumstantial evidence for the epoxy form of fluorofullerene oxides was provided by identification of components in the moisture-induced reactions: $C_{60}F_n \rightarrow C_{60}F_{n-1}OH \rightarrow C_{60}F_{n-2}O$ (for various values of n), HF loss being manifest also in container etching. It was also notable that the isolated oxides were associated with precursors which possessed two additional fluorine atoms. A further indication of the presence of epoxides was the dramatic increase in oxide content when either fluoro[60]- or [70]fullerenes were reacted with aq. MeOH.[9]

Recently we described the isolation and ^{19}F NMR characterisation of the main isomer of $C_{60}F_{18}O$.[10] This has C_s symmetry, and the data were consistent with the presence of an in-plane epoxy oxygen atom (addition across a 6,6-double bond, **1**), but we also considered the possibility of insertion into various 6,5-single bonds. Insertion of oxygen into 6,6- and 6,5-bonds of [60]fullerene is predicted to be quasi-isoenergetic,[11] though no example of the latter has been observed; one of us conjectured that this was the first step in the spontaneous formation of $C_{60}Ph_8O_4$ from $C_{60}Ph_8$.[12]

However, three features seemed somewhat anomalous regarding the structure **1**. First, for the oxide to be an epoxide, there should be evidence of a precursor $C_{60}F_{20}$ molecule, and although traces of a component of this formula were seen, the amount was very small.[10] Secondly, the necessary precursor structure required the addition of two fluorine atoms remote from the rest, which contradicts the pattern for which we are finding increasing evidence (see *e.g.* ref. 13), that addition take places in a contiguous fashion. Thirdly, although traces of other oxides appeared to be present, there was no obvious energetic reason for **1** to be preferred; indeed, calculations indicated that an epoxide was not the structure of overall lowest energy for the formula.

We recently have scaled up our production of $C_{60}F_{18}$ (100–200 mg yield) and found that substantial quantities (*ca.* 50 mg) of the previously described isomer[10] of $C_{60}F_{18}O$ are also produced. This was separated by HPLC as described previously, but using a larger column of 10 mm diameter and 4.7 mol min^{-1} toluene flow rate. On standing, a toluene solution of this material deposited lemon-coloured plates, which single crystal X-ray characterisation† (Fig. 1) showed to be **2**.

This is thus the first intramolecular fullerene ether to be characterised and also the first having oxygen inserted into a 6,5-bond. The numbering of $C_{60}F_{18}$ is shown in **3** and hence this

ether is 1,2,3,4,8,9,10,16,17,18,22,23,24,36,37,38,39,40-octadecafluoro-1,2,3,4,8,9,10,16,17,18,22,23,24,36,37,38,39,40-octadecahydro-2a-oxa-2(3)a-homo[60]fullerene. This compound complements the homofullerenes and aza-homofullerenes, which have -CR_2- and -NR-, respectively, inserted into 5,6-bonds; these were first reported in 1991–1993[14] and numerous examples are now known.

The preference for this insertion may have a simple rationalisation. Recently we reported the single crystal X-ray structure for $C_{60}F_{18}$[15] which showed that the lengths (Å) of the FC–CF bonds in the molecule are: 1.557 (1,2); 1.672 (2,3); 1.623 (1,9); 1.558 (9,10). Semi-empirical calculations on this structure give the same ordering of bond lengths with the 2,3-bond at 1.69 Å (AM1), 1.71 Å (MNDO) exceeding the 1,9-bond by 0.4 Å (AM1), 0.3 Å (MNDO). Thus the 2,3-bond being the longest should also be the weakest, and hence the most amenable to oxygen insertion. In **2** the long (2,3) bond of $C_{60}F_{18}$ has opened out by 0.53 Å. The fact that oxides are major by-products of fullerene fluorination suggests that the reaction is also enhanced by electron withdrawal.

Previously, we compared the experimental results with semi-empirical calculations of the stability of C_s $C_{60}F_{18}O$ isomers involving incorporation of oxygen at various epoxide and ether sites. For the latter we considered only those bonds which connect carbons having no fluorine addends. These calculations (italicised data) are reproduced in Table 1.

One epoxide and one ether, involving addition to the central benzenoid ring, were clearly ruled out by their extremely low stabilities. The remaining data showed that the ethers should be the more stable, but each was ruled out by the ^{19}F NMR data (which consisted of 8×2 F + 2×1 F peaks, as follows: (i) one of the 2 F peaks was shifted substantially downfield (*ca.* 40 ppm) and this could not be accounted for by the remote oxygen in the 47,48-isomer. (ii) The 55,56-isomer required a downfield shift of one of the 1 F peaks, which was not observed. The data were however fully consistent with the 13,30-epoxide (**1**).

We have now calculated the heats of formation for all of the possible epoxides and ethers, including for the latter, insertion between carbons each or both of which are bonded to fluorine. The results (non-italicised) are given in Table 1 and it is very satisfying to see that of all the possible isomers, the one that is isolated in by far the largest yield is the one that is predicted to be the most stable. MNDO has a known tendency to favour ether over epoxide formation even in the bare [60]fullerene,[11] but the differences here should be more reliable indications of a real chemical preference, as they are much larger and stem from a clear geometric effect.

One unexpected feature however is the relatively small downfield shift for the resonances of the fluorines immediately adjacent to the oxygen. We have obtained significantly greater downfield shifts of some fluorine resonances in other fluorofullerene oxides, which may be attributable to differential electron withdrawal as a function of the number of sp^3 addend-bearing carbons. Further work on isolation and characterisation of oxides of fluorofullerenes is in hand.

Received (in Liverpool, UK) 30th March 2000, Accepted 5th June 2000

The enantio- and chemoselective hydrogenation of several 2,4-diketo acid derivatives to the corresponding 2-hydroxy compounds with cinchona modified Pt catalysts can be carried out with chemoselectivities of > 99% and enantioselectivities up to 86% (*R*) and 68% (*S*), respectively, and enrichment to > 98% ee was possible for several compounds by one crystallization, opening up an efficient technical synthesis of (*R*)-2-hydroxy-4-phenylbutyric acid ethyl ester, a building block for several ACE inhibitors.
