It is interesting to note that Regitz and co-workers[10] recently proposed, on the basis of $^{31}P\{^1H\}$ NMR spectroscopic data, the possible intermediacy of a 1,2,5-azadiphosphole ring system in the metal-mediated formation of azatetraquadricyclanes from phosphaalkynes. Complex **1**, which has a formal electron count of 18e, was found to be remarkably stable and column chromatography (silica gel, pentane) in air resulted in only very slight decomposition of the sample (1% loss), likewise attempts to displace the heterocycle from iridium by carbonylation of the metal centre proved unsuccessful.

R. S. and U. S. are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. F. G. N. C., J. F. N. and D. J. W. thank the EPSRC for their continuing support for phospha-organometallic chemistry.

Non-ionic surfactant assembly of ordered, very large pore molecular sieve silicas from water soluble silicates

Seong-Su Kim, Thomas R. Pauly and Thomas J. Pinnavaia*

Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, Michigan 48824, USA. E-mail: pinnavai@cem.msu.edu

Received (in Irvine, CA, USA) 4th April 2000, Accepted 26th June 2000

Very large pore hexagonal and cellular foam-like molecular sieve silicas with well cross-linked framework walls (denoted MSU-H and MSU-F, respectively), have been prepared from soluble silicate precursors under neutral pH conditions.

The supramolecular assembly of periodically ordered mesoporous molecular sieves, such as hexagonal MCM-41, is normally accomplished through an electrostatically mediated pathway involving ionic surfactants assemblies (S^+ or S^-) and inorganic reagents (I^+ or I^-).[1,2] Electrostatic assembly also is involved in the preparation of exceptionally large pore mesostructured silicas such as hexagonal SBA-15 and mesostructured cellular foams (MCF) in the presence of non-ionic surfactants (N^0) derived from triblock co-polymers of propylene and ethylene oxides.[3] These materials are assembled under strongly acidic conditions to allow for counter ion mediated interactions of the type $(N^0H^+)(X^-I^+)$, where X^- is the counter anion and I^+ is the protonated silicic acid derived from a silicon alkoxide reagent. Although the very large pore sizes (50 to 300 Å diameter) are attractive features for applications in large molecule reactions and separations, the high cost of silicon alkoxides and the strong acid reaction conditions, which can limit framework cross-linking and structural stability, are undesirable features of the preparative chemistry.

Mesoporous silica molecular sieves with wormhole framework structures, such as the MSU-X family of materials,[4] are also assembled from neutral surfactants and cost-intensive silicon alkoxides. In an effort to replace the costly alkoxides with sodium silicate, Guth and co-workers[5] reported the preparation of disordered mesostructures from sodium silicate solutions in the presence of a non-ionic surfactant. The complete removal of the surfactant by calcination at 600 °C, however, led to either the extensive restructuring of the silica framework or to the formation of a completely amorphous material. More recently, we achieved the high-yield synthesis of stable wormhole molecular sieve silicas from low-cost, water-soluble silicate precursors and non-ionic surfactants at near neutral pH.[6] In the present work we demonstrate that it is also possible to assemble from sodium silicate *highly ordered* mesoporous silica molecular sieves with very large framework pore structures analogous to both hexagonal SBA-15 and MCF, which we denote MSU-H and MSU-F, respectively.

In a typical synthesis the surfactant and an amount of acid equivalent to the hydroxide content of the sodium silicate solution (*e.g.* 27% SiO_2, 14% NaOH) were mixed at ambient temperature and then added to the sodium silicate to form a reactive silica in the presence of the structure directing surfactant. This allows for the assembly of the framework under neutral pH conditions. The assembly process for the preparation of a hexagonal mesostructure was carried out at molar ratios of H_2O/Si = 230 and N^0/Si = 0.008–0.017 and at a desired temperature for a period of 10–20 h. The surfactant was then removed from the washed, air-dried products either by solvent extraction with hot ethanol or by calcination in air at 600 °C.

Fig. 1 illustrates the powder X-ray diffraction patterns of as-synthesized and calcined (600 °C) forms of hexagonal MSU-H silica as prepared from Pluronic P123 ($EO_{20}PO_{70}EO_{20}$) as the surfactant at a synthesis temperature of 60 °C. The as-synthesized and calcined products exhibit resolved *hkl* reflections consistent with two-dimensional hexagonal symmetry and unit cell dimensions of 130 and 119 Å, respectively. We may conclude that MSU-H mesostructures are isostructural with SBA-15. However, the two classes of as-made silicates are readily distinguishable on the basis of framework connectivity. The ^{29}Si NMR spectra of as-synthesized MSU-H (not shown) typically exhibit three resonances corresponding to the Q^2 (93 ppm), Q^3 (100 ppm) and Q^4 (109 ppm) connectivities of the SiO_4 tetrahedra. The ratio of fully condensed (Q^4) silica sites to incompletely condensed Q^3 and Q^2 sites is 4.5, considerably higher than the value of 1.28 reported[3a] for conventional SBA-15. The neutral pH conditions of the present assembly pathway allow for a much higher degree of framework crosslinking, presumably, because there is little or no charge present on the silica framework walls under these conditions.

Further evidence for the hexagonal mesostructure of MSU-H silica is provided by the transmission electron micrograph (TEM) images shown in Fig. 2. In comparison to conventional SBA-15, which has a particle size in the micron range, MSU-H shows smaller particle sizes in the range 300–500 nm [Fig. 2(a)]. Fig. 2(b) unmistakably shows the highly ordered hexagonal arrays of mesopores and equidistant parallel lines related to the hexagonal repeat between tubules. Also evident are the small hexagonal domain sizes within the small particles.

Fig. 3 illustrates the N_2 adsorption–desorption isotherms and BJH pore size distribution plot (insert) calculated from the adsorption branch of the N_2 isotherms for calcined MSU-H. A typical, type IV adsorption isotherm with an irreversible H1 hysteresis loop is observed as expected for a large pore material.[7] The step-like uptake of N_2 in the range 0.7–0.9 P/P_0 corresponds to capillary condensation within framework pores with a BJH diameter of 98 Å. The pore volume is 1.24 $cm^3\ g^{-1}$, the BET surface area is 625 $m^2\ g^{-1}$ for this calcined MSU-H.

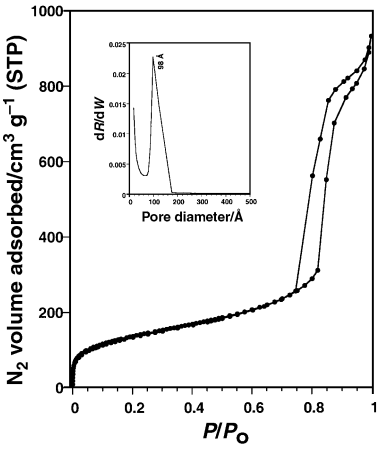

Fig. 3 N_2 adsorption–desorption isotherms for the calcined MSU-H silica molecular sieve. The insert provides the BJH pore size distribution calculated from the adsorption branch of the N_2 isotherm.

MSU-H silicas with (100) X-ray spacings in the range 99–108 Å and pore sizes between 82 and 110 Å have been synthesized with Pluronic P123 surfactant simply by varying the N^0/silica ratio or the synthesis temperature. More significantly, the addition of 1,3,5-trimethylbenzene (TMB) to expand the pore size of MSU-H leads instead to mesostructured cellular foams (denoted MSU-F) that are composed of large, uniform spherical cells, as shown in Fig. 4. This material has an average pore size of 225 Å, a BET surface area of 759 $m^2\ g^{-1}$, and a mesopore volume of 1.87 $cm^3\ g^{-1}$, very much like conventional MCF silicas[3b] formed from acidic TEOS mixtures in the presence of P123 and TMB (Fig. 5). The formation of a TMB/P123 microemulsion and the assembly of silica around the microemulsion droplets explain the phase transition from MSU-H to MSU-F.

The same chemistry described above for the preparation of MSU-H and MSU-F also applies to other non-ionic polyethylene oxide surfactants. For instance, molecular sieve silicas with two-dimensional hexagonal symmetry and BJH pore sizes of 32–53 Å, BET surface areas of 492–745 $m^2\ g^{-1}$ and pore volumes of 0.31–0.70 $cm^3\ g^{-1}$ were assembled from water-soluble silicate precursors using Brij 76 as the non-ionic surfactant at temperatures in the range 25–60 °C. Thus, the new assembly pathway reported here is general, as well as being especially suitable for the assembly of stable analogs of silica

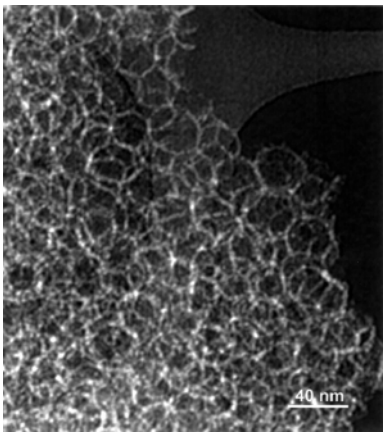

Fig. 4 TEM image of the calcined MSU-F silica formed from sodium silicate, TMB and Pluronic P123 under neutral pH conditions at 60 °C.

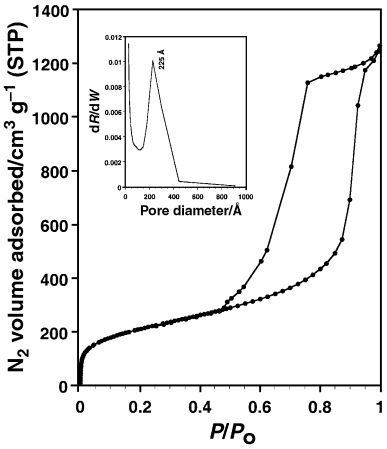

Fig. 5 N_2 adsorption–desorption isotherms for the calcined MSU-F silica. The insert provides the BJH pore size distribution calculated from the adsorption branch of the N_2 isotherm.

mesostructures with the largest of known framework pore sizes. The generality of the assembly pathway, together with the use of low-cost sodium silicate as the silica source, are attractive features for use in the commercial production of mesostructured silicas with framework pore sizes over the entire range from 20 to > 225 Å.

Note added in proof: The synthesis of SBA mesostructures from sodium metasilicate and non-ionic block copolymers as structure directing agents under strong acid conditions has recently been reported: J. M. Kim and G. D. Stucky, *Chem. Commun.*, 2000, 1159.

The support of this research by NSF-CRG grant CHE-9903706 is gratefully acknowledged.

Rationally designed improvement of the bis(phospholano)ethane ligand for asymmetric hydrogenation leads to a reappraisal of the factors governing the enantioselectivity of Duphos catalysts

Elena Fernandez,[a] Amy Gillon,[b] Katie Heslop,[b] Emily Horwood,[b] David J. Hyett,[b] A. Guy Orpen*[b] and Paul G. Pringle*[b]

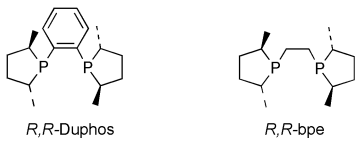
[a] *Universitat Rovira i Virgili, Departament de Química Física Inorgànica, Plaça Imperial Tàrraco, 1, Tarragona, Spain*

[b] *School of Chemistry, University of Bristol, Cantocks Close, Bristol, UK. E-mail: paul.pringle@bristol.ac.uk*

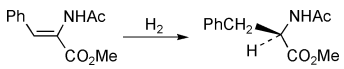
Received (in Cambridge, UK) 13th April 2000, Accepted 18th July 2000

Enhancement of enantioselectivity in hydrogenations catalysed by δ *vs.* λ rhodium chelate complexes of *trans*-1,2-bis(phospholano)cyclopentanes cannot be rationalised using the current quadrant model for Duphos ligands and therefore a new consistent model is suggested.

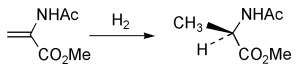
Diphosphines containing the 2,5-dialkylphospholane moiety (*e.g. R,R*-Duphos, *R,R*-bpe) are currently the most efficient



ancillary ligands for the asymmetric hydrogenation of many alkenes;[1–4] several of these catalytic processes are of commercial interest.[4] The enantioselectivity is a sensitive function of the ligand backbone.[1–7] For example, for the hydrogenations shown in eqns. (1) and (2), the enantioselectivity increases with

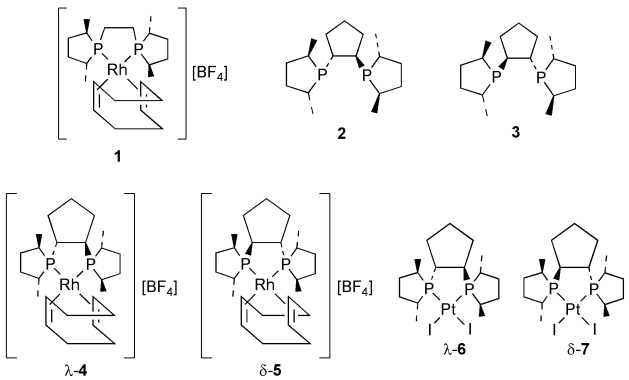


(1)

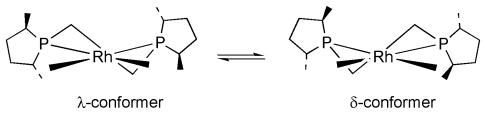


(2)

increasing rigidity of the ligand backbone. Here, we show an example of how the enantioselectivity for the bis(phospholane)-ethane complex **1** can be improved by rational design of the ligand backbone; our results challenge the currently accepted explanations for the selectivity of Duphos ligands.



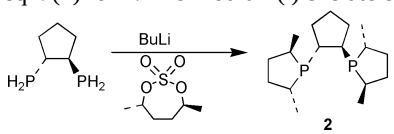
The chelate ring of the *R,R*-bpe complex **1** is flexible and an interconverting mixture of diastereomeric λ and δ chelate conformers would be anticipated [eqn. (3)]. It was predicted that



(3)

the λ conformer of **1** would give the higher enantioselectivity (see below)[3] and we reasoned that this hypothesis could be tested by comparing the optical yields obtained with **2** and **3**, the two diastereoisomers of *trans*-1,2-bis(*R,R*-phospholano)cyclopentane since **2** would give exclusively a λ-conformer chelate complex and **3** would give a δ-conformer.

The new ligands **2** and **3** were prepared from resolved *trans*-1,2-diphosphinocyclopentane[8] and the 1,4-diol cyclic sulfate[1] as shown in eqn. (4) for **2**. The rhodium(I) chelate complexes λ-



(4)

4 and δ-**5** have been synthesised and fully characterised but we have been unable to obtain crystals suitable for X-ray crystallography. However the crystal structures of the diiodoplatinum(II) complexes of **2** and **3**, λ-**6** and δ-**7** have been determined (Figs. 1 and 2).† These confirm the assignment of the chelate conformations. The bond lengths and angles around platinum in λ-**6** and δ-**7** are not substantially different (lengths differ by 0.01–0.02 Å and angles by 1–2°).[11] The principal effect of the change in backbone stereochemistry seems to be in the orientation of the phospholane rings. Changing the MP_2C_2 chelate conformation from λ to δ leads to a rotation about the M–P bond of *ca*. 30°, as measured by I–Pt–P–C torsions (see Figs. 1 and 2). As a consequence, the methyl groups are closer to the other ligands in the metal coordination plane (here iodine) in λ-**6** (I···CH_3 3.70 Å) than in δ-**7** (I···CH_3 4.11, 4.20 Å). Conversely the axial hydrogen atoms adjacent to the phosphorus are closer to the iodo ligands in δ-**7** (I···H 3.07, 3.00 Å) than

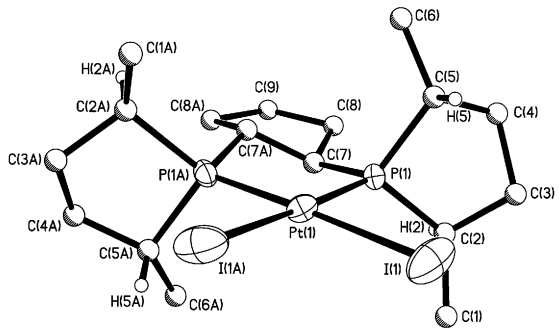


Fig. 1 Molecular structure and numbering scheme for λ-**6**. All but phospholane tertiary hydrogen atoms have been omitted for clarity. DOI: 10.1039/b002994g

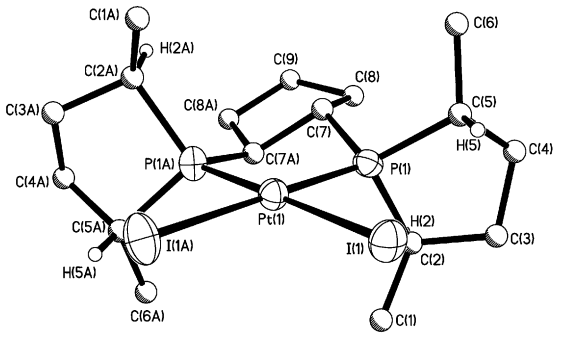

Fig. 2 Molecular structure and numbering scheme for δ-**7**. All but phospholane tertiary hydrogen atoms have been omitted for clarity. Important molecular dimensions include: bond lengths (Å) Pt(1)–P(1) 2.248(2), Pt(1)–P(1A) 2.258(2), Pt(1)–I(1) 2.6533(9), Pt(1)–I(1A) 2.6690(8); bond angle (°) P(1)–Pt(1)–P(1A) 86.44(9); torsion angles (°) I(1)–Pt(1)–P(1)–C(2) 78.4(2), I(1)–Pt(1)–P(1)–C(5) −38.3(2), I(1A)–Pt(1)–P(1A)–C(2A) 70.6(2), I(1A)–Pt(1)–P(1A)–C(5A) −47.5(2).

in λ-**6** (I···H 3.37 Å). The PC_4 rings in *R*-phospholanes have δ-conformations and so in δ-**7** the conformations are δδδ for the PC_4, PtP_2C_2 and PC_4 rings, respectively, while in λ-**6** these rings show δλδ conformations.

The results of the hydrogenations shown in eqns. (1) and (2) catalysed by the rhodium catalysts λ-**4**, δ-**5** and **1** are shown in Table 1. It is clear that the optical yields obtained with λ-**4** are inferior to **1** and those for δ-**5** are superior to **1**. The unequivocal conclusion is that the δ-chelate gives *higher* enantioselectivities than the λ-chelate, *i.e.* δ-**5** is the *matched* diastereomeric catalyst.[6] Since this is the opposite of what was predicted,[3] we decided to re-examine the basis of the current heuristic model for Duphos catalysts.[12]

Table 1 Optical yields for the hydrogenations of methyl-(*Z*)-2-acetamidocinnamate [eqn. (1)] and methyl-2-acetamidoacrylate [eqn. (2)][a]

Catalyst	Methyl-(*Z*)-2-acetamidocinnamate	Methyl-2-acetamidoacrylate
λ-**4**	77 (*R*)	73 (*R*)
1[b]	85 (*R*)	91 (*R*)
δ-**5**	98 (*R*)	95 (*R*)

[a] *Experimental conditions*: solvent MeOH, 2 atm H_2, 20–25 °C, 0.05–0.1% Rh catalyst, reaction time, 1–16 h. Conversions and enantiomeric excesses were determined by GC using a Hewlett-Packard 5800 A with a L-Chirasil-Val column. [b] Results from ref. 3.

In the stereochemical model of refs. 3, 6 and 12, it is assumed that the alkyl substituents of the phospholanes block the diagonal of quadrants shown in Fig. 3(a) for bis(*R*-phospholane) chelates. In turn this implies that the favoured, major, adduct diastereoisomer is that in which the enamide substrate is bound through its *si* face (see ref. 12 for explicit confirmation of this view).

Seminal mechanistic work[9] revealed that the major enantiomer formed in asymmetric hydrogenation by rhodium complexes of 'traditional' chiral diphosphines such as chiraphos was derived from the minor diastereoisomer of the prochiral alkene complex. Burk and coworkers showed[10] that, when the hydrogenation shown in eqn. (1) is catalysed by [Rh(*S*,*S*-Duphos)(cod)]$^+$, the major product enantiomer (having *S*-configuration) is derived, in Halpern-like manner, from the minor diastereoisomer of the substrate complex (which therefore must be *re*-face bound). Indeed they were able to confirm this assignment of adduct stereochemistry by NMR experiments and by analogy with iridium chemistry. By implication, for *R*,*R*-phospholanes, as here, the minor adduct is *si*-face bound (and the *R*-configuration product results from its Halpern-type hydrogenation). This directly contradicts the standard quadrant model prediction noted above.

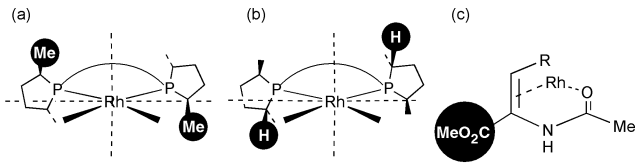

Fig. 3 (a) Quadrants that are reportedly[3,6,12] blocked by the methyl substituents in Rh(*R*,*R*-bpe) chelate; (b) quadrants that are proposed to be blocked by the axial hydrogens in a Rh(*R*,*R*-bpe) chelate; (c) *si*-face binding of substrate alkenes.

In λ-**6** the phospholane methyl groups are closer to the metal coordination plane than in δ-**7** and therefore would be expected to present more steric interaction at the sites where the alkene substrates would bind. However in δ-**7** (whose analogue δ-**5** is the more stereoselective catalyst) the axial hydrogen atoms are closer to the substrate binding site. This leads us to suggest an alternative stereochemical model for these phospholane ligands: it is the *axial* hydrogens rather than the equatorial methyls that offer the critical, diastereofacially-discriminating steric interactions with a prochiral substrate. The corollary of this suggestion is that the diagonal of blocked quadrants [Fig. 3(b)] is orthogonal to that currently accepted. The new quadrant diagram predicts (in accord with ref. 10) that the *less* stable (minor) diastereoisomer is formed when the substrate is *si*-face bound, Fig. 3c. A Halpern-type hydrogenation mechanism would then lead to the observed *R*-configuration of the product, again in accord with the results reported in ref. 10.

Hydrogenation of very bulky enamides (*e.g.* H_2C=CBu^{t}N-HAc) catalysed by *R*,*R*-Duphos complexes leads to a product of *S*-configuration. While this inversion of stereochemistry poses problems for any quadrant model, we note that it is possible that extreme bulk of the α-substituent may render the concentration of the minor adduct diastereoisomer effectively zero, thereby leading to no product from that pathway regardless of the rate of hydrogenation of the major (only) species.

Note added in proof: The quadrant models discussed in this paper implicitly assume that crowding in the plane of the metal–diphosphine moiety is important in enantioselection. A recent report (I. D. Gridnev, N. Higashi, K. Asakura and T. Imamoto, *J. Am. Chem. Soc.*, 2000, **122**, 7183) suggests that octahedral *cis*-dihydride species are critical.

We would like to thank Dr Guy Lloyd-Jones for useful discussions, EPSRC and Albright and Wilson for a CASE studentship (to E. L. H.), Acciones Integradas for a travel grant and Johnson-Matthey for a loan of precious metals.

Received (in Irvine, CA, USA) 22nd May 2000, Accepted 20th July 2000

Polycrystalline $LiAlH_4$ transforms into polycrystalline Li_3AlH_6 and Al during short time (5 min) ball-milling with 3 mol% $TiCl_4$ at room temperature; solid-state rearrangement of tetrahedral $[AlH_4]^-$ into octahedral $[AlH_6]^{3-}$ at ambient conditions was previously unknown; this transformation does not occur during ball-milling of pure $LiAlH_4$ or in the presence of 3 mol% $TiCl_4$ without mechanochemical treatment.

High capacity solid-state storage of hydrogen is becoming increasingly important as fuel cell power plants approach broad use in automotive and electrical utility applications. Overall hydrogen content of two alkali metal aluminohydrides, $LiAlH_4$ and $NaAlH_4$ (10.5 and 7.3 wt% H_2, respectively), is amongst the highest for about 70 known complex hydrides[1] reviving recent interest to them as potential ultra-high capacity hydrogen storage solids.[2–6] Temperature induced transformation of lithium aluminohydride ($LiAlH_4$) into lithium hexahydroaluminate (Li_3AlH_6) has been known for almost three decades.[7] However, the processes occurring in pure $LiAlH_4$ during its thermal decomposition were understood only recently.[8,9] According to results obtained by Bastide *et al.*[8] and Dymova *et al.*,[9] $LiAlH_4$ is quite stable in the solid state below its melting temperature but rapidly transforms in the melt, where rearrangement of the tetrahedral $[AlH_4]^-$ ion into the octahedral $[AlH_6]^{3-}$ ion[10,11] is easily achieved. The stability of the solid $LiAlH_4$ is, therefore, attributed to kinetic restrictions of the solid-state transformation process in the alumohydride anion rather than to thermodynamic reasons (ΔG of the reaction $LiAlH_4 = 1/3Li_3AlH_6 + 2/3Al + H_2$ is -27 kJ mol^{-1}).[12] Recently, a significant reduction of the decomposition temperatures of alkali metal aluminium hydrides doped with transition metal derivatives has been reported.[3–6] It is, however, unclear, whether transition metal dopants reduce melting points of complex aluminium hydrides or act as catalysts of solid-state transformations near the respective melting temperatures.

Here we report on the first observation of the rapid solid-state transformation of lithium aluminohydride into lithium hexahydroaluminate in the presence of a catalytic amount of titanium tetrachloride ($TiCl_4$) during mechanochemical activation at ambient conditions.† A reaction mixture containing 97 mol% $LiAlH_4$ and 3 mol% $TiCl_4$ was ball-milled in a Spex mill under helium for 5 min and then investigated using X-ray powder diffraction (XRD), differential thermal (DTA) and gas-volumetric analyses. According to XRD data, $LiAlH_4$ was completely transformed during the short mechanochemical treatment with a catalytic quantity of $TiCl_4$. Only Bragg peaks corresponding to the crystalline Li_3AlH_6,[13a] Al and LiCl are seen in the X-ray powder diffraction pattern of the reaction mixture (Fig. 1). The DTA trace of the reaction mixture in the temperature range between 380 and 500 K contains one broad endothermic peak between approximately 395 and 485 K with a minimum at 445 K (inset in Fig. 2). The endothermic process occurs at lower temperatures when compared to that observed in the pure mechanochemically prepared Li_3AlH_6[13a] (*ca.* 480–535 K, minimum at 505 K). This lowering of the hydrogen release temperature is, however, in good agreement with previously reported data on reduction of decomposition temperature of transition metal-doped alkali metal aluminohydrides.[3–5] The gas-volumetric analysis of the reaction mixture between 295 and 675 K in vacuum revealed a slow one-step hydrogen evolution at 395 ± 5 K (Fig. 2), *i.e.* at the onset temperature of the endothermic effect observed in the DTA experiment. The amount of released hydrogen, 2.08 wt%, agrees well with the decomposition of Li_3AlH_6 [eqn. (1)], which was formed according to eqn. (2) (the theoretical hydrogen content in the mixture is 2.1 wt%). The intensities of Bragg peaks (Fig. 1) are in quantitative agreement with the amounts of reaction products. Eqn. (2) summarizes transformations of $LiAlH_4$ and $TiCl_4$ during ball-milling [eqns. (3) and (4)]:

$$2Li_3AlH_6 = 6LiH + Al + 3H_2 \uparrow \quad (1)$$

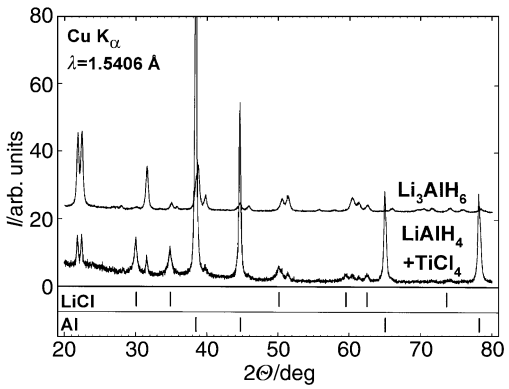

Fig. 1 The X-ray powder diffraction pattern of the reaction mixture obtained during 5 min ball-milling of 97 mol% $LiAlH_4$ and 3 mol% $TiCl_4$ compared with the X-ray powder diffraction pattern of Li_3AlH_6 prepared mechanochemically.[13] Vertical bars at the bottom of the chart indicate positions of Bragg peaks of pure LiCl and Al.

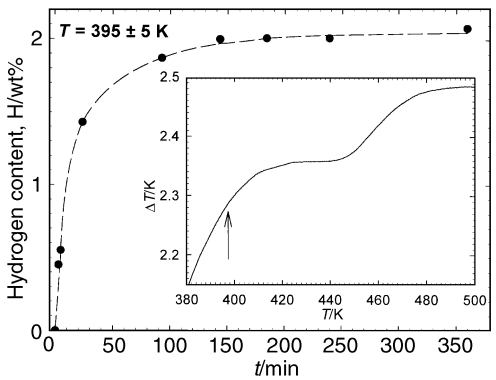

Fig. 2 The results of gas-volumetric analysis at 395 ± 5 K of the reaction mixture obtained during 5 min ball-milling of 97 mol% $LiAlH_4$ with 3 mol% $TiCl_4$. The inset shows the DTA trace of the same reaction mixture. The vertical arrow on the inset indicates the onset of the endothermic process.

DOI: 10.1039/b004144k

$$0.97LiAlH_4 + 0.03TiCl_4 = 0.283Li_3AlH_6 + 0.12LiCl + 0.687Al + 0.03[Ti] + 1.091H_2 \uparrow \quad (2)$$

$$4LiAlH_4 + TiCl_4 = 4LiCl + 4Al + [Ti] + 2H_2 \uparrow \quad (3)$$

$$3LiAlH_4 + [Ti] = Li_3AlH_6 + 2Al + [Ti] + 3H_2 \uparrow \quad (4)$$

The formation of lithium chloride, aluminium and a Ti-containing micro-crystalline phase with unknown composition during 5 min ball-milling of lithium aluminohydride and titanium tetrachloride was confirmed by mechanochemical treatment of stoichiometric amounts (4 : 1) of $LiAlH_4$ and $TiCl_4$ [eqn. (3)].[13b] No Bragg peaks corresponding to either $LiAlH_4$ or Li_3AlH_6 were detected from XRD data. Furthermore, the gas-volumetric analysis of the obtained reaction mixture [eqn. (3)] did not reveal observable hydrogen gas evolution up to 925 K.

To verify that the titanium catalyzed solid state transformation of $LiAlH_4$ into Li_3AlH_6 proceeds only during mechanochemical activation, the mixture containing 97 mol% of lithium aluminohydride and 3 mol% of titanium tetrachloride was thoroughly ground in a mortar under helium for 10 min. Although slight changes of the reaction mixture color from grayish-white to gray were observed, XRD did not indicate the formation of detectable amounts (*i.e.* 5 vol% or more) of Li_3AlH_6 during grinding. Weak Bragg peaks corresponding to polycrystalline LiCl and Al were found in the X-ray diffraction pattern of the reaction mixture after grinding, and therefore, the observed color changes were likely associated with the reduction of $TiCl_4$ by $LiAlH_4$ according to eqn. (3). Furthermore, our experiments with pure $LiAlH_4$ revealed that this complex hydride is stable during ball-milling without $TiCl_4$ for up to 35 h.

Currently, several different models describing the observed rapid solid-state rearrangement of $LiAlH_4$ (*i.e.* tetrahedral $[AlH_4]^-$ ion) into Li_3AlH_6 (*i.e.* octahedral $[AlH_6]^{3-}$ ion) in the presence of $TiCl_4$ during mechanochemical treatment at ambient conditions are being considered. One of the most likely mechanisms explaining the catalytic effect of $TiCl_4$ can be its reduction to a highly reactive nanocrystalline or amorphous titanium phase [eqn. (3)], which subsequently mechanically alloys into the crystal lattice of $LiAlH_4$. The following destabilization of the host crystal lattice caused by the presence of titanium leads to the formation of metastable 'melt-like' hydride phases, where the rearrangement of the tetrahedral $[AlH_4]^-$ ion into the octahedral $[AlH_6]^{3-}$ ion becomes kinetically possible. Although the nature of intermediate phase(s) is presently unclear, it is feasible that they are similar to the metastable high-pressure γ-$LiAlH_4$ with hexa-coordinated $[AlH_6]^{3-}$ ion,[10,15] and their formation becomes possible due to mechanically induced strain in the presence of titanium catalyst.

The Ames Laboratory is operated for the U.S. Department of Energy (DOE) by Iowa State University under contract No.W-7405-ENG-82. Different aspects of this work were supported by the Office of Basic Energy Sciences, Materials Sciences Division of the U.S. DOE and Iowa State University Carver Trust Grant.

Notes and references

† All experiments described in this communication were carried out in a glove box in a purified helium atmosphere and in a hardened-steel vial sealed under helium. The X-ray diffraction experiments were performed under helium in a sample holder covered by X-ray transparent polymer film. The differential thermal analysis was carried out in an argon atmosphere at ambient pressure using commercially available equipment. The heating rate during DTA measurements was 10 K min^{-1}. The gas-volumetric experiments were performed using a standard Sievert's type apparatus.

Received (in Cambridge, UK) 20th June 2000, Accepted 21st July 2000

The reaction of 1,2-bis(4-methylbenzylthio)benzene *s*-oxide with triflic anhydride in CH_3CN–CH_2Cl_2 in the presence of alkynes affords 1,4-benzodithiin derivatives and *N*-(4-methylbenzyl)acetamide after quenching with H_2O; this suggests the generation of benzodithiete or its equivalent.

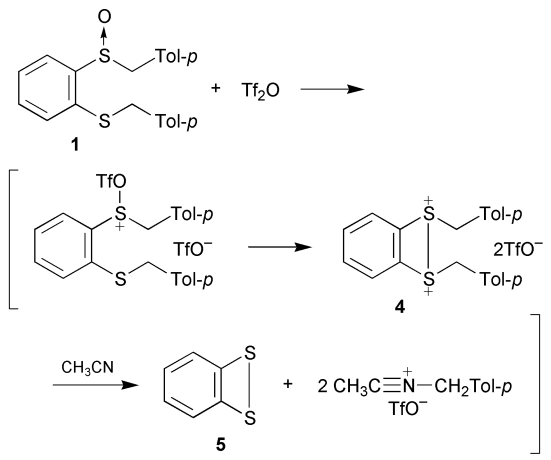
The development of new methodologies for the generation of reactive species is an important goal in organic chemistry. Benzodithiete **5** is a highly reactive transient species, which occurs in thermolysis[1–3] and photolysis[4–6] of appropriate precursors, and is trapped by alkynes to form 1,4-benzodithiin derivatives.[7,8] Benzodithiete **5** is estimated to be 17 kcal mol^{-1} more stable than *o*-dithiobenzoquinone by calculations at the MP2 level[9] and decomposed at more than −90 °C.[1] σ-Bonded dithia dications have attracted considerable attention in heteroatom chemistry from the viewpoint of structural interests.[10] The strained dication of 1,4-dithiane reacts with alkynes to give dithiabicyclo[2.2.2]octene derivatives.[11] Recently, we have demonstrated the facile dealkylation of dithia dications with a flexible conformation to afford thiasulfonium salts;[12] in particular, the dithia dication obtained from the reaction of 2,2′-bis(benzylthio)biphenyl *s*-oxide with triflic anhydride (Tf_2O) is decomposed even at −20 °C to afford biphenyl disulfide and a benzyl cation.[13] Herein we report the reactions of 1,2-bis(4-methylbenzylthio)benzene mono-*s*-oxide **1** with Tf_2O in the presence of alkynes **2** and alkenes **3**, which produce 1,4-benzodithiins **6** and 2,3-dihydro-1,4-benzodithins **7**, respectively. The key reaction for the generation of benzodithiete **5** or its equivalent is based on the dealkylation of **1** *via* a dithia dication **4** (Scheme 1).

The substrate **1** was prepared by the reaction of benzene-1,2-dithiol with 4-methylbenzyl chloride in the presence of KOH (86% yield) followed by the oxidation of the resulting bissulfide with MCPBA (73% yield).

The reaction of **1** with triflic anhydride (Tf_2O) was monitored by ^{1}H NMR spectroscopy. When 1 eq. of Tf_2O was added to a solution of **1** in CD_3CN-CD_2Cl_2 (v/v 1:1) at −75 °C, **1** immediately disappeared and a sole peak due to the *N*-benzyl–acetonitrile adduct appeared at δ 5.21 in the region of benzyl groups.[13] This result indicates that both benzyl groups of **1** are completely eliminated at −60 °C within a minute, although we have no direct evidence for the generation of dithia dication **4** and benzodithiete **5**. After warming up to rt, the reaction mixture gave a white precipitate. Treatment of the supernatant with H_2O afforded *N*-(4-methylbenzyl)acetamide (57% yield), and treatment of the white precipitate with $NaBH_4$ in THF followed by addition of iodomethane gave 1,2-bis(methylthio)-benzene (42% yield).

In order to elucidate the generation of benzodithiete **5** indirectly, the reaction of **1** with Tf_2O was carried out in the presence of alkynes **2** as a trapping reagent (Scheme 2).§¶ After complete dealkylation of **1** with Tf_2O in CH_3CN–CH_2Cl_2 (v/v 1:1) at −60 °C, **2** was added to the reaction mixture. From diarylacetylenes **2a**–**c**, 2,3-diaryl-1,4-benzodithiins **6a**–**c** were obtained in 44, 64, and 20% respective yields, and from arylacetylenes **2d**–**e**, 2-aryl-1,4-benzodithiins **6d**–**e** were produced in 18 and 21% respective yields. Thus, the formation of **6** strongly suggests the generation of **5** or its equivalent in the course of the reaction of **1** with Tf_2O. Diarylacetylenes serve as a more effective trapping reagent of **5** than arylacetylenes. However, dimethyl acetylenedicarboxylate[2,5] did not give 2,3-bis(methoxycarbonyl)-1,4-benzodithiin, although *N*-(4-methylbenzyl)acetamide and 1,2-bis(methylthio)benzene were obtained in 59 and 20% yields, respectively, after as treatment mentioned above. This result implies that a concerted mechanism may not be involved in the reaction of **5** or its equivalent with alkynes.

The reaction of **1** with Tf_2O in the presence of alkenes **3** was also conducted under the same conditions (Scheme 3).§¶ The stereochemistry of the product reflects the reaction mechanism. *trans*-Stilbene (*trans*-**3a**) gave *trans*-2,3-diphenyl-2,3-dihydro-1,4-benzodithiine (*trans*-**7a**) (29% yield), whereas *cis*-stilbene (*cis*)-**3a**) afforded a mixture of *trans*-**7a** (17% yield) and (*cis*)-**7a** (10% yield). The formation of two stereoisomers (*trans*)- and



Tf_2O = $(CF_3SO_2)_2O$, Tol-*p* = C_6H_4Me-*p*

(*cis*)-**7a**) from *cis*-**3a**, but not from (*trans*)-**3a**, suggests a stepwise addition mechanism of benzodithiete **5** or its equivalent to carbon–carbon multiple bonds such as an Ad_E path. Ethyl (*E*)-cinnamate (*trans*-**3b**) and 4-methylstyrene **3c** gave the corresponding (*trans*)-**7b** and **7c** in 19 and 32% yields, respectively.

The redox behavior of 1,4-benzodithiin derivatives has been studied extensively from the viewpoint of cationic π-conjugated systems.[7,14] Cyclic voltammetry of 1,4-benzodithiins **6** in CH_3CN with Bu_4NClO_4 (0.1 M) at rt showed two oxidation waves, where, in all cases, the first ones are reversible and the second ones are irreversible. The redox potentials of **6a**–**e** obtained here are summarized in Table 1. The first half-wave potentials are in the range of $E^1_{1/2}$ = +0.93– +1.02 V and the second oxidation potentials are in the range of E^2_{pa} = +1.26– +1.53 V *vs*. Fc/Fc$^+$. The first oxidation potentials of 1,4-benzodithiin derivatives are heightened with increasing the number of aromatic groups at the 2- and 3-positions owing to a π-conjugative effect: unsubstituted 1,4-benzodithiin[15] < **6d** (**6e**) < **6a** (**6b**). The oxidation potentials are lowered as the electron-donating ability of a substituent at the *para*-position of the aromatic ring is increased: **6a** > **6b** > **6c**. A good linear relationship between the first half-wave potentials and their σ_p^+ values was obtained with ρ = 0.12 and a correlation coefficient r = 0.98.

In conclusion, we have demonstrated the generation of benzodithiete **5** or its equivalent through the facile dealkylation of a 1,2-bis(benzylthio)benzene derivative **1** *via* a dithia dication **4**. The present study opens the way to the synthetic application of dithia dications.

Preparation and functionalization of hydride terminated porous germanium†

Hee Cheul Choi and Jillian M. Buriak*

Department of Chemistry, 1393 Brown Laboratories, Purdue University, West Lafayette, IN 47907-1393, USA. E-mail: buriak@purdue.edu

Received (in Irvine, CA, USA) 17th May 2000, Accepted 20th July 2000

Porous germanium (PG) is prepared by a novel bipolar electrochemical etching (BEE) technique; scanning electron microscopy (SEM) clearly reveals formation of a porous layer up to a few microns thick that is Ge–H_x terminated as indicated by FTIR spectroscopy; the hydride terminated PG material is quite resistant to oxidation, even under thermal conditions, but can be induced to undergo hydrogermylation reactions with alkenes and alkynes.

Porous semiconducting materials are a topic of intense interest because of their unique electronic,[1] optoelectronic,[2] and morphological[3] properties, and biocompatibility[4] characteristics. Up to now, the vast majority of research efforts have concentrated on porous silicon, although other materials such as porous GaAs, InP, SiC, Si_xGe_{1-x}, GaP, and GaN,[5] have also been investigated to a lesser extent. The unusual light emitting properties of porous silicon through photo-, electrochemi- and chemi-luminescence routes are a result of the highly complex nanoscale architecture. Embedded nanocrystallites and nanowires of silicon within the porous silicon matrix exhibit quantum confinement effects, and thus the material acts very differently from the bulk parent. There is a surprising dearth of knowledge about porous silicon's congener, porous germanium (PG), and thus any potentially important properties intrinsic to this material remain unknown. There are two published procedures[6,7] for preparation of PG involving an anodic etch with aqueous HF electrolytes, but in our hands yield an oxidized surface instead of hydride terminated germanium surface. Little morphological investigation and no chemical reactivity studies have been carried out on the reported PG surfaces prepared in this manner.[8,9] Here, we describe the formation of highly ordered PG with a nanoscale architecture, as determined from plan and cross-sectional views of the porous layer by scanning electron microscopy (SEM), utilizing a novel and reproducible etching technique, termed *bipolar* electrochemical etching (BEE), with an HCl-based etchant. Through transmission FTIR studies of the PG, we have determined that the surface is Ge–H_x terminated, and can undergo surface hydrogermylation reactions with alkynes and alkenes, yielding alkenyl and alkyl terminated interfaces respectively. Light emission upon UV irradiation is also observed at 77 K in air.

The porous germanium (PG) was prepared from polished single crystalline Ge(100) wafers, either n- or p-doped, using an ethanoic HCl solution (1 : 1.8 of 48% HCl : EtOH v/v) in air. A wide variety of conditions were examined, but only a bipolar electrochemical etching (BEE) procedure produced the desired results.‡ BEE was carried out in a homemade Teflon etching cell, identical to that used to prepare porous silicon.[10] Initially, the germanium surface is anodized at 350 mA cm^{-2} for 5 min, followed by cathodization for 1 min with a negative bias, at the same current density, as outlined in Fig. 1. Longer cathodization leads to surface damage due to electropolishing. Upon anodization, the surface turns visibly gray, and is believed to be composed of surface hydroxide or surface chloride, as suggested by the lack of Ge–H_x vibrations in the transmission FTIR spectrum and literature precedent.[11] Scanning electron microscopy indicates formation of a *ca*. 700 nm thick amorphous layer after 2 min anodization, which fully dissolves after 5 min, leaving no observable film on the surface of the bulk germanium within the resolution of the instrument (10 nm). Germanium oxide is soluble in aqueous solution, and thus appears to be formed transiently before dissolution under these conditions. The subsequent cathodization step is critical for formation of the porous layer and hydride termination. Presumably, the weak Ge–Ge bonds are protonated under the cathodic potential[11] which eventually leads to GeH_4 production, and dissolution of the bulk germanium, resulting in hydride termination and pore formation[12] (Fig. 1). Formation of thin porous layers on silicon has been reported under cathodic conditions.[13] Without the prior anodic step, only hydrogen evolution from the cathodic germanium electrode occurs. The PG layer shows false colors due to Fabry–Perot fringes, resulting from constructive and destructive interference of the reflected white light from the top and bottom of the thin porous layer, as is observed with thin porous silicon layers.[14,15]

Scanning electron microscopy (SEM) clearly reveals PG in both cross-sectional and plan views (Fig. 2) for both n- and p-type wafers. The porous layer of a PG sample prepared from n^+ Ge is *ca*. 15 μm thick (Figs. 2(*a*) and (*b*)), and features down to the resolution of the instrument, *ca*. 10 nm, can be discerned.

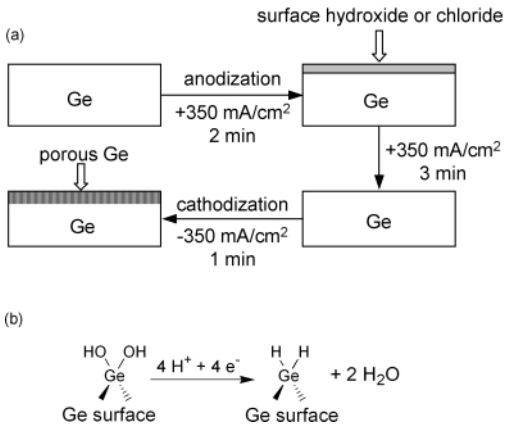

Fig. 1 (*a*) Schematic representation of the bipolar electrochemical etching (BEE) of Ge(100) wafers. (*b*) Surface electrochemical conversion of oxidized Ge(100) surfaces to hydride-terminated Ge(100) under cathodic bias in an acidic medium.[12]

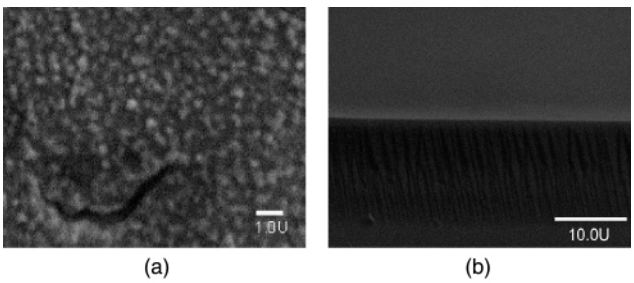

Fig. 2 Plan (*a*) and cross-sectional (*b*) views of n^+ type derived PG.

† Electronic supplementary information (ESI) available: FTIR thermal stability measurements and SEM images. See http://www.rsc.org/suppdata/cc/b0/b004011h/

The pores are tilted by 9° from the surface normal due to the 9° miscut of the starting wafers. The thickness of the porous layer can vary somewhat across an etched surface (1–15 μm), most likely due to heterogeneities in the electrical field during the etch as a result of the simplicity of our set-up. PG prepared from p-type Ge shows similar features, and is *ca.* 1.5 μm thick (Figs. 2(*c*) and (*d*)). Higher magnification of the surface layer in plan view of either n- or p-type samples reveals a highly porous top layer in the center of the 0.3 cm^2 etched area (Fig. 2(*a*) and (SI5†)), which progressively becomes populated by crystallites with an average size of 500 nm towards the edge.†

FTIR analysis of PG reveals a broad ν(Ge–H_x) vibration with features at 2044 cm^{-1} and 2015 cm^{-1}, as shown in Fig. 3(*a*), which appear at slightly lower energies than gas phase $Me_{4-x}GeH_x$.[16] Oxygen back-bonded Ge–H_x vibrations, expected at higher energies[11] are not observed. Because of the surface roughness and broad Ge–H_x stretching region, it is expected that the surface is terminated with mono-, di- and trihydrides, like porous silicon.[17] In order to definitively prove the formation of the Ge–H bonds, a deuterated surface (Ge–D_x) was made by same etching technique using deuterated ethanol and DCl solution. The resulting Ge–D_x stretching mode appears at 1455 cm^{-1}, as expected, with a very weak Ge–H_x band observed at 2020 cm^{-1} (Fig. 3(*b*)). The thermal stability of the hydride termination is surprising and is described in the ESI†.

In order to determine whether the hydride terminated PG surface could be functionalized, hydrogermylation of alkynes was examined. Refluxing a PG sample in a 20% 1-dodecene solution in mesitylene (v/v) for 2 h resulted in incorporation of surface-bound dodecyl moieties[18] (Fig. 3(*c*)). Application of other known reaction conditions for formation of Si–C bonds on porous and flat silicon to PG were unsuccessful, including Lewis acid[19] mediated hydrogermylation, and Ge–Ge bond attack with Grignard reagents.[20] The crystalline PG structure may be more sensitive to Lewis acids and nucleophilic attack under these conditions. In any case, the surface of PG may be tailored through thermally induced hydrogermylation reactions.

Homogeneous red photoluminescence is observed by eye across the entire PG surface at 77 K in a darkened room upon illumination with 365 nm irradiation, but is considerably weaker than that observed from porous silicon; the weak light emission, unfortunately, fell below the optical detection limit of our CCD set-up, and thus a λ_{max} could not be collected. Samples etched only anodically, as opposed to the bipolar etching procedure, on the other hand, emit yellow-white photoluminescence under 254 nm UV illumination at 77 K. Since there are no observable Ge–H_x bonds formed after anodization by FTIR, nor a porous layer by SEM, the source of the photoluminescence is believed to arise from germanium oxide layers, as opposed to germanium nanoparticles. This supposition is supported by the fact that all emission is eliminated after washing the sample with 25% aqueous HF, while the Ge–H_x terminated samples are unaffected. We propose that the weak red light emission observed from Ge–H_x terminated PG arises from Ge nanoparticles, whilst that from the anodically etched samples results from oxide.

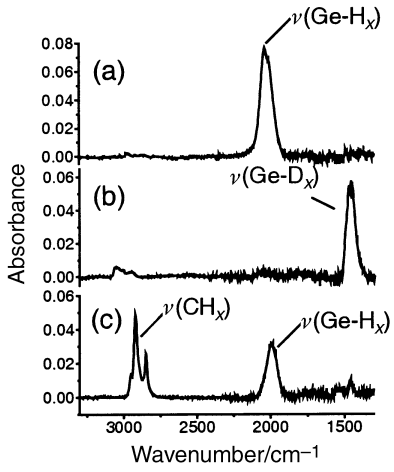

Fig. 3 FTIR spectrum of PG: (*a*) etched by BEE using ethanoic HCl, (*b*) using deuterated ethanol and DCl, and (*c*) thermally hydrogermylated using 1-dodecene.

To summarize, we report a new and highly reproducible etching procedure to produce hydride-terminated porous germanium. Through a bipolar HCl etch, porous layers up to 15 microns thick can be prepared and subsequently functionalized with alkyl monolayers through a thermally induced hydrogermylation reaction. Detailed mechanistic studies are presently underway in our laboratories to further elucidate the complex etching process. Optimization of the etching procedures through a better understanding of the PG formation process should permit us to improve the light emission from this material.

Notes and references

‡ *Experimental*: electrochemical etching of Ge was conducted using highly P doped (100) n-type (0.004–0.020 Ω cm) or Ga doped p-type (7–23 Ω cm) Ge wafers in a homemade Teflon etching cell equipped with an aluminium tongue in contact with the Ge wafer, and a Pt loop wire as a counter electrode, and ethanoic HCl (1 : 1.8 of 48% HCl : EtOH v/v) as the etchant/electrolyte. A Princeton Instruments 273 potentiostat was utilized as the current source. 350 mA cm^{-2} current density was applied for 5 min during anodization of n-type Ge followed by cathodization with the same current density. Light illumination was applied during cathodization for the p-type PG to harness the photocurrent, allowing for this high current density to pass. Thermal hydrogermylation of the PG was performed in a Schlenk flask with 20% 1-dodecyne in mesitylene solvent under nitrogen atmosphere, and was refluxed at 250 °C for 2 h. After completion of the reaction, the sample was washed with CH_2Cl_2, THF, ethanol and pentane, then dried under N_2 stream. All FTIR spectra were taken with a Nicolet Nexus FTIR spectrometer 670 equipped with a MCT detector cooled with liquid nitrogen. SEM images were taken using a JEOL JSM-35CF scanning electron microscope at an accelerating voltage of 10 kV.

Electrochemical deposition of macroporous platinum, palladium and cobalt films using polystyrene latex sphere templates

Philip N. Bartlett,* Peter R. Birkin and Mohamed A. Ghanem

Chemistry Department, University of Southampton, Highfield, Southampton, UK SO17 1BJ.
E-mail: P.N.Bartlett@soton.ac.uk

Received (in Cambridge, UK) 1st June 2000, Accepted 27th July 2000

Highly ordered macroporous films of platinum, palladium and cobalt with regular arrays of spherical pores with diameters of 0.40, 0.70 or 1 μm are prepared by electrochemical deposition into the interstitial spaces of a template formed by polystyrene latex spheres self-assembled on gold electrodes; after deposition of platinum, palladium or cobalt, the polystyrene spheres are fully removed by washing in toluene to leave a highly periodic, hexagonal close packed, interconnected network of monodisperse spherical pores within the metal film, the size of which is determined by the diameter of the polystyrene latex particles used to prepare the template.

The production of materials with micron and submicron scale structure in two and three dimensions is of importance in a range of applications, such as photonic materials,[1,2] high density magnetic data storage devices,[3] microchip reactors[4] and biosensors.[5] Several new templating techniques are being developed to achieve such macroporous solids with highly ordered structure and high surface area.[6–11] Highly ordered three-dimensional macroporous oxides with pore diameters of a few hundred nanometers have recently been prepared by the chemical hydrolysis of the corresponding metal alkoxide in the interstitial spaces of close packed arrays of polystyrene latex spheres as the template.[12–14] Macroporous titanium dioxide photonic crystals synthesised by a similar procedure have been shown to exhibit photonic band gaps.[15,16] In related studies other authors have described the synthesis of three-dimensional microporous films of semiconducting cadmium selenium (CdSe) by electrochemical deposition in the interstitial spaces in a close packed array of polystyrene latex spheres assembled on an indium tin oxide substrate surface.[17] Van Duyne *et al.*[18,19] have reported using monolayers or bilayers of polystyrene latex particles as masks for the deposition by evaporation of two-dimensional arrays of isolated silver nanoparticles on an insulating substrate.

Here we report the preparation of highly ordered macroporous metal films with pores of predetermined sizes. The preparation of the structured macroporous films was carried out by the electrochemical reduction of $[PtCl_6]^{2-}$, $[PdCl_4]^{2-}$, or $[Co(Ac)_2]$ complex ions in aqueous solution within the interstitial spaces of a close packed polystyrene latex sphere template, self-assembled on a gold surface. The thickness of the resulting films can be many multiples of the diameter of the polystyrene latex spheres used to prepare the template and is readily controlled by the amount of charge passed during deposition of the metal film.†

Most recently Xu *et al.* have described the electrochemical deposition of nanoscale Ni and Au meshes through templates made from close-packed silica sphere arrays (opal).[20] Although the two approaches give similar metal meshes there are several important differences between the method described in our work over that of Xu *et al.* First, the polystyrene latex particles we use are commercially available in a range of sizes; second, our close-packed templates can be prepared by evaporation in 2 d rather than by sedimentation over a period of several months; third, there is no need to sinter the template; fourth, the metal deposition is achieved in a few minutes rather than over 36 h; fifth, the template can be removed by dissolving the polystyrene in toluene rather than requiring the use of HF.

Scanning electron micrographs of cobalt films prepared by electrochemical deposition of cobalt at −0.90 V *vs.* SCE through a template formed from 0.40 and 1.0 μm diameter polystyrene latex spheres are shown in Figs. 1(*a*) and 1(*b*) respectively. The quantities of charge passed were −0.80 and −1.15 C cm^{-2} respectively. These values were chosen in order to grow films whose thickness corresponded to the radius of the template particles used in each case. Fig. 1(*a*) shows that the cobalt film made using the 0.40 μm polystyrene latex sphere template has a highly ordered two dimensional hexagonal network of monodisperse submicron voids each with a hemispherical shape. In the most ordered regions, the pores have a diameter of 380 ± 10 nm (n = 10) and pore to pore centre separation of 450 ± 10 nm (n = 30) The cobalt films made by using the larger, 1.00 μm, polystyrene latex spheres [Fig. 1(*b*)] have a pore diameter of 980 ± 10 nm (n = 10), however, this film shows less two-dimensional order. We attribute this to the fact that the larger latex spheres take a longer time to assemble into a highly ordered structure.[21]

Fig. 1(*c*) shows a scanning electron micrograph of a platinum film deposited into a template formed from 0.70 μm polystyrene latex spheres at a deposition potential of 0.10 V *vs.* SCE (total charge passed −1.20 C cm^{-2}). The image shows that the electrochemically deposited platinum film consists of a highly

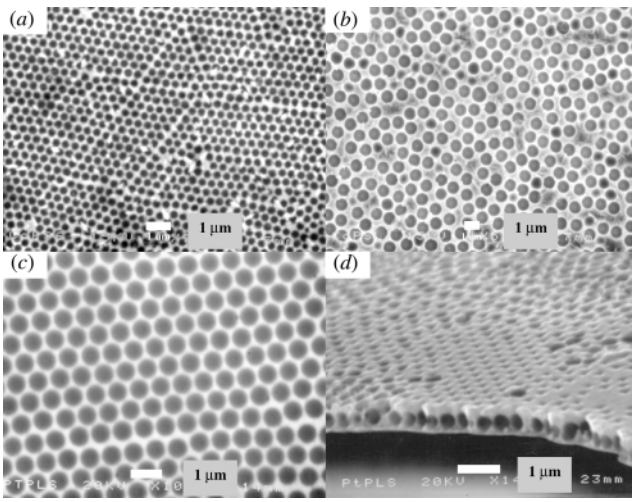

Fig. 1 Scanning electron micrographs of macroporous platinum and cobalt films electrochemically deposited, at 0.10 and −0.90 V *vs.* SCE respectively, through templates formed using polystyrene latex spheres pre-assembled on gold electrode surfaces. (*a*) Cobalt film, deposition charge −0.85 C cm^{-2}, polystyrene latex sphere diameter 0.40 μm; (*b*) cobalt film, deposition charge −1.15 C cm^{-2}, polystyrene latex sphere diameter 1.0 μm; (*c*) platinum film, deposition charge −1.20 C cm^{-2}, polystyrene latex sphere diameter 0.70 μm; (*d*) cross-sectional image of a platinum film, deposition charge −1.00 C cm^{-2}, polystyrene latex sphere diameter 0.40 μm.

DOI: 10.1039/b004398m

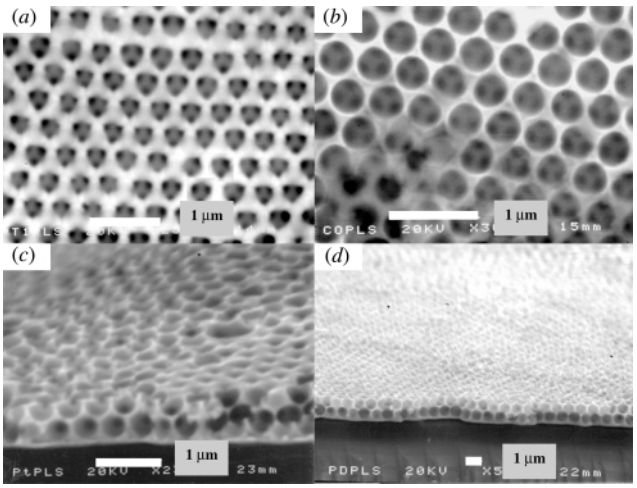

Fig. 2 Scanning electron micrographs of macroporous films of platinum, palladium and cobalt electrochemically deposited, at potentials of 0.10, 0.25 and −0.90 V *vs*. SCE respectively, through templates formed using polystyrene latex spheres pre-assembled on gold electrode surfaces. (*a*) Platinum film, deposition charge −2.00 C cm^{-2}, polystyrene latex sphere diameter 0.40 μm; (*b*) cobalt film, deposition charge −1.40 C cm^{-2}, polystyrene latex sphere diameter 0.40 μm; (*c*) cross-sectional image of a platinum film, deposition charge −1.50 C cm^{-2}, polystyrene latex sphere diameter 0.40 μm; (*d*) palladium film, deposition charge −1.15 C cm^{-2}, polystyrene latex sphere diameter 0.70 μm.

periodic hexagonal array of monodisperse pores. The pore to pore centre separation in this case was 770 ± 10 nm (n = 30). Fig. 1(*d*) shows a cross sectional image of a platinum film prepared by deposition of −1.00 C cm^{-2} through a template of 0.40 μm polystyrene latex spheres. The formation of a monolayer of spherical pores embedded in the platinum film (which in this case was grown to a thickness of approximately 0.4 μm) can be clearly seen.

Figs. 2(*a*) and 2(*b*) show scanning electron micrographs of thicker films of platinum and cobalt where sufficient charge has been passed to deposit films several multiples of the polystyrene latex sphere diameter in thickness. The micrographs show that the spherical pores left in the platinum or cobalt films after removal of the polystyrene latex spheres are arranged in a well ordered three dimensional hexagonal close packed structure. In addition, the connections between the spherical voids within the film, formed where the polystyrene latex spheres in one layer were in contact with those in the underlayer, can be seen as the three dark areas within each pore. In Fig. 2(*a*) the mouths of the pores have a rounded triangular shape. This appears to be a regular feature of films which are grown to a thickness corresponding to about (n + $\frac{3}{4}$) layers of spheres, where n = 0, 1, 2, …. Figs. 2(*c*) and 2(*d*) show cross-sectional images of platinum and palladium films prepared using templates formed from 0.40 and 0.70 μm polystyrene latex spheres. These micrographs also demonstrate the formation of three dimensional macroporous films with thickness of 1.5 or 2.0 times the pore diameters for the platinum and palladium films respectively. The spherical voids have a diameter determined by the diameter of the polystyrene latex spheres used for the template and are arranged as part of an hexagonal lattice, again indicating that the polystyrene latex particles were arranged in three-dimensional hexagonal close packed structure. This was also confirmed by scanning electron micrographs of the templates themselves before the deposition of the metal (not shown).

Our studies have shown that self-assembled layers of polystyrene latex particles formed on gold surfaces by slow evaporation of water from the latex suspension can be used as templates through which to electrochemically deposit metal films. In the resulting metal/polystyrene composite the polystyrene spheres are in contact and can be dissolved out of the metal to leave a regular array of interconnected spherical voids. The size of these voids is determined by the size of the polystyrene latex particles used. Since polystyrene latex particles of tightly controlled size distribution are readily commercially available in sizes from 0.05 to 90 μm the size of the voids can be readily controlled. Control over the quantity of charge passed in the electrochemical deposition of the film allows control over the final film thickness. Thus this method represents a simple route to the production of ordered macroporous films of metals, metal alloys, and polymers with potentially interesting and useful photonic, catalytic, magnetic, or other properties.

We thank the Embassy of the Arab Republic of Egypt, Educational and Cultural Bureau, London for their support of Mohamed A. Ghanem. We also thank Alastair Clark for assistance in obtaining the SEM images and manufacture of the gold substrates.

Notes and references

† *Experimental:* Cobalt acetate [$Co(Ac)_2{\cdot}4H_2O$, 99.5%] and potassium acetate (KAc, 99.4%) were obtained from Fluka. Hexachloroplatinic acid and diammonium tetrachloropalladate were obtained from Aldrich (purity 99.99%). 0.5 wt% suspensions of 0.40 and 1.00 μm diameter polystyrene latex spheres in water were obtained from Agar Scientific, 2.5 wt% suspensions of 0.70 μm diameter polystyrene latex spheres in water were obtained from Alfa Asear. The working electrodes were prepared by evaporating 10 nm of a chromium adhesion layer followed by 200 nm of gold onto thin glass microscope slides. A large area platinum gauze was used as the counter electrode and home made saturated calomel (SCE) as the reference electrode. Before use, the gold working electrodes were sonicated in propanol for 1 h and then rinsed with deionised water. A volume of *ca*. 0.3 cm^3 of the suspension of polystyrene latex spheres diluted with water to 0.5 wt% was spread over *ca*. 1 cm^2 area of the gold electrode and allowed to dry slowly over 2 d in a controlled humidity chamber. The working electrode, together with the adherent, dry, polystyrene latex bead template, was dipped in to the appropriate electrolyte solution to deposit the metal film. The deposition solutions were either 50 mmol dm^{-3} H_2PtCl_6, 40 mol dm^{-3} $(NH_4)_2PdCl_4$, or 0.1 mol dm^{-3} $Co(Ac)_2$ with 0.1 mol dm^{-3} KAc. The deposition was carried out potentiostatically at potentials of 0.10, 0.25 or −0.90 V *vs*. SCE for the electrochemical deposition of platinum, palladium, or cobalt. After deposition the polystyrene latex spheres were dissolved out of the metal films by soaking in toluene for 24 h.

Electrochemical synthesis of ammonia at atmospheric pressure and low temperature in a solid polymer electrolyte cell

V. Kordali, G. Kyriacou* and Ch. Lambrou

Department of Chemical Engineering, Aristotle University of Thessaloniki, Thessaloniki 54006, Greece. E-mail: kyriakou@vergina.eng.auth.gr

Received (in Cambridge, UK) 19th June 2000, Accepted 24th July 2000

The heterogeneous electrocatalytic synthesis of ammonia from nitrogen and water is carried out at Ru cathodes, using a Solid Polymer Electrolyte Cell (SPE), at atmospheric pressure and low temperature; the reduction rate increases with increase of temperature up to 100 °C, while with the increase of the negative potential a maximum is observed at −1.02 V *vs.* Ag/AgCl and gradually decreases in the hydrogen discharge region.

Industrially the synthesis of ammonia takes place by passing N_2 and H_2 over Fe or Ru surfaces at about 430–480 °C and 100 atm.[1] The synthesis of ammonia over these catalysts at ambient temperatures is a very difficult process because of the high energy barrier for the breaking of the N≡N bond which is about 1000 kJ mol^{-1} at 25 °C.

Numerous efforts have been reported so far on the conversion of nitrogen to ammonia at room temperature and atmospheric pressure using, photocatalytic,[2,3] electrochemical[4–11] or catalytic methods.[12] Recently, Marnellos and Stoukides studied the electrochemical synthesis of ammonia at Pd cathodes using a solid proton conductor at 570 °C and atmospheric pressure and pointed out that the thermodynamic demand for high pressure can be compensated by the use of an electrochemical reactor.[13] However, the operation temperature of that cell is high and ammonia undergoes decomposition at this temperature. The high electrical resistance of the electrolyte is an additional disadvantage of this method. The present study deals with the electrochemical synthesis of ammonia in a Solid Polymer Electrolyte (SPE) cell on Ru cathodes at atmospheric pressure and low temperature from nitrogen and water.

The reduction of nitrogen (99.999%) was performed in a two-compartment cell, as shown in Fig. 1. The cell was placed in a thermostated bath. Ruthenium was electrochemically deposited on a carbon felt (Electrosynthesis Corporation) from a 0.05 M $RuCl_3$ solution using a constant current of 25 mA cm^{-2} for 60 min. Consequently, it was washed with water to remove the chloride ions and it was finally placed into the electrolytic cell in contact with the Nafion membrane, where it was dried by a nitrogen stream for 24 h. The Nafion membrane was pretreated by heating in H_2O_2 5% solution at 80 °C for 1 h and in ultrapure water for another 1 h. The apparent surface area of the cathode was 2.35 cm^2. A 2 M KOH solution in ultra pure water was used as electrolyte in all experiments. The anode was in contact with the KOH solution (10 cm^3) and the anodic reaction was the oxygen evolution. A saturated Ag/AgCl electrode was used as a reference.

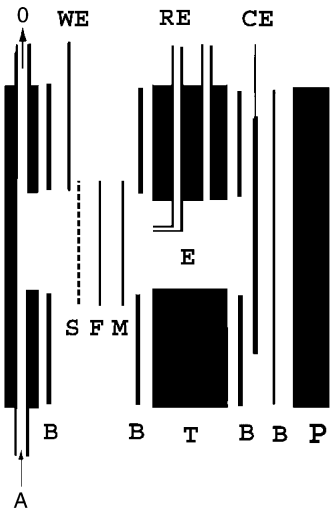

Fig. 1 Exploded view of the electrolysis cell: (A) gas inlet, (O) gas outlet, (T) polytetrafluoroethylene plate, (B) silicone gasket, (M) Nafion membrane, (F) carbon felt, (S) stainless steel screen 150 mesh, (E) electrolyte chamber, (P) stainless steel plate, (WE) working electrode, (RE) reference electrode, (CE) Pt anode.

A nitrogen steam with a constant flow rate withdrew the gaseous products from the cell. The NH_3, which was produced, was stripped by a 15 ml of 0.1 M H_3BO_3 solution. Ammonia was determined by Ion Chromatography using a CS15 column (Dionex Corp.) and a Dionex 4500i Chromatograph, as well as colorimetrically by using the phenate method.[14] Experiments have been conducted for the possible presence of hydrazine colorimetrically at 458 nm using the *p*-dimethylaminobenzaldehyde method.[15] Ammonia was the only product detected in the electrochemical reduction of nitrogen at 90 °C and at potential of −1.10 V, using ruthenium as cathode. Two control experiments were performed at 90 °C and for 24 h, in order to verify that the detected ammonia was a product of nitrogen reduction (i) Nitrogen gas was introduced into the cell at open-circuit (I = 0). (ii) Inert gas (Ar) was introduced into both compartments of the cell for 4 h, so that the air trapped within the carbon felt would be expelled. The flow of argon was continued and then a potential of −1.10 V was applied for 24 h. In both cases no ammonia was detected.

At all potential values examined, the amount of the produced ammonia is in an almost linear relationship with time, which confirms that ammonia was produced by an electrochemical reaction. The rate of ammonia formation remained constant even when the electrolysis was continued for another 100 h at a potential of −1.10 V. This implies that the electrode is not deactivated with time. Given this fact, the same electrode was used for all experiments.

The standard potential for the N_2 reduction to NH_3, as calculated from the Nernst equation, was found to be −0.67 V *vs.* NHE or −0.88 V *vs.* Ag/AgCl. The calculations were performed assuming that P_{N_2} = 0.99 atm. P_{NH_3} = 0.01 atm and pH = 14. The reduction of nitrogen in our experiments on Ru began at −0.96 V; a value which is slightly higher (0.08 V) than that anticipated from the thermodynamic calculations. The rate of ammonia formation, as is shown in Fig. 2, was increased with the negative potential until −1.02 V, where a maximum value was displayed and afterwards it was decreased. A similar behaviour was reported by Sclafani *et al.*,[11] in the electrochemical reduction of nitrogen at iron cathodes in the region of hydrogen discharge, which was attributed to the competitive adsorption of nitrogen and hydrogen species on the electrode surface. An explanation similar to this might be proposed for the observed behaviour at our ruthenium electrode.

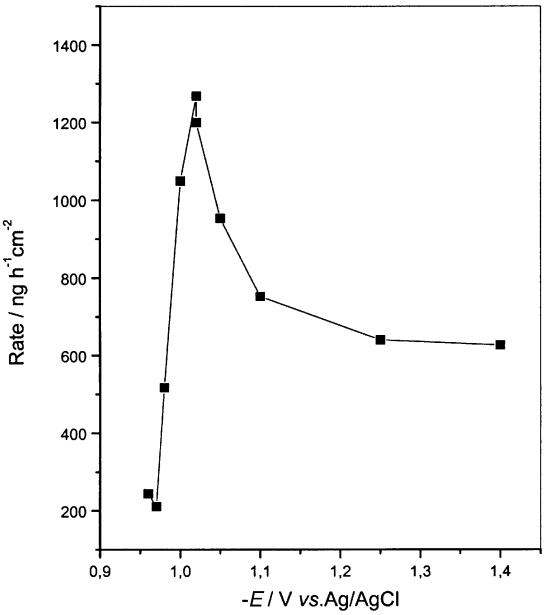

Fig. 2 The rate of formation of ammonia against negative cathodic potential, at 90 °C and an electrolysis time of 24 h.

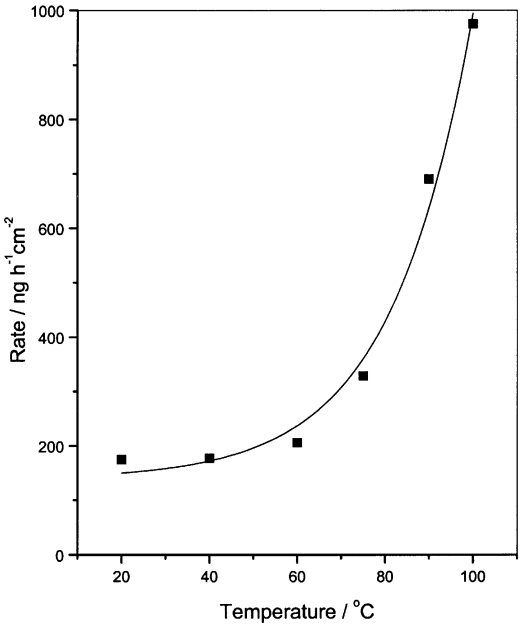

Fig. 3 Rate of formation of ammonia against temperature at −1.10 V and at an electrolysis time of 24 h.

Table 1 Rate and CE of ammonia formation at the Ru cathode at various experimental conditions

Potential/V	N_2 flow rate/ cm^3 min^{-1}	T/°C	Current[a]/mA	CE(%)	Rate of NH_3/μg h^{-1} cm^{-2}
−1.02	1	90	6.1	0.24	1.30
−1.02	10	90	5.8	0.23	1.20
−1.02	15	90	6.8	0.20	1.25
−0.96	25	90	0.3	0.92	0.25
−1.10	25	90	16.2	0.17	0.90
−1.10	25	20	8.2	0.28	0.21

[a] Average current.

The rate and the current efficiency (CE) of the process, as shown in Table 1, were quite low and in the best case they reached about 1.3 μg h^{-1} cm^{-2} at −1.02 V and 0.92% at −0.96 V respectively. This rate is about fifty times lower than that previously reported at 570 °C.[13]

Experiments were also conducted at −1.02 V and 90 °C and at various flow rates of 1, 10 and 15 cm^3 min^{-1}. Within the experimental error, no measurable effect was observed in the (CE) and at the rate of the reaction. This indicates that diffusion was not the rate determining step. Furthermore, the chemical yield (CY) of the reaction was 0.003% when the flow rate of nitrogen was 1 cm^3 min^{-1} and it was about inversely proportional to the flow rate of nitrogen. The chemical yield (CY) of the reaction can be increased with a different planning of the cell so that the retention time of N_2 will be increased. The rate displayed an exponential growth with temperature in accordance to the Arrhenius equation, as is shown in Fig. 3, and it was about 5 times higher at 100 than that at 20 °C. A corresponding increase of the reduction rate with temperature was previously observed in the reduction of nitrogen with hydrogen on Ru catalyst at ambient temperature.[12]

These results are in agreement with the recent work of Rod *et al.*,[16] who showed that it could be possible to produce ammonia at ambient temperature on Ru from nitrogen and hydrogen *via* a dissociative mechanism, by using density functional theory (DFT) calculations. Furthermore, the fact that hydrazine was not detected in any of our experiments, suggests the ammonia was produced *via* a dissociative mechanism, in a similar way to that in the gas phase.[17,18]

Examination of the crystal structure of the electrode (after electrolysis) by XRD indicated that the main reflections (101) and (100) of Ru had a ratio 100:10. It is known that the ammonia synthesis reaction is extremely structure sensitive and that the energy barrier for the dissociation of nitrogen depends strongly on the particle size and the crystal structure of Ru.[16,19] The Ru, which was used in our experiments, had planes with different activities and this fact led to the decrease of the number of active catalytic sites and therefore to a low reaction rate. Moreover, the competitive adsorption of hydrogen to that of nitrogen and the low number of sites, where a contact N_2/Ru/membane exists, are two additional reasons.

This is the first report regarding ammonia production at atmospheric pressure and low temperature. The main problems that exist at the present are the low rate of ammonia formation and the hydrogen evolution at the cathode. Further work to optimize these factors is in progress.

We are grateful to Professor M. Stoukides for his helpful suggestions concerning this work.

Direct formation of 1-vinyl-1*H*-isochromene derivatives *via* a palladium-catalysed coupling reaction

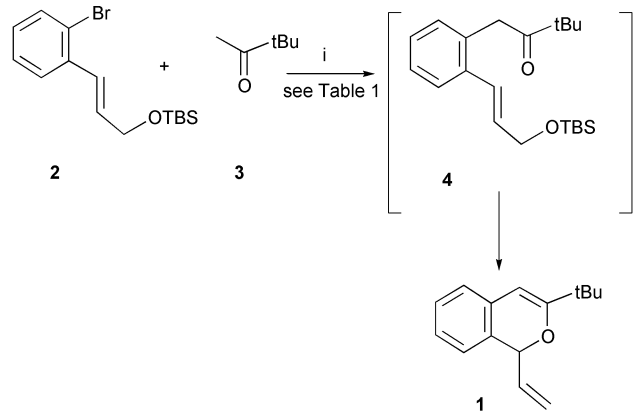
Roger Mutter, Eva M. Martin de la Neva† and Martin Wills*

Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL. E-mail: m.wills@warwick.ac.uk

Received (in Liverpool, UK) 6th July 2000, Accepted 26th July 2000

The palladium-catalysed reaction of the *tert*-butyldimethylsilyl ether of a 3-(*o*-bromophenyl)allylic alcohol with a methyl ketone leads directly to a 1-vinyl-1*H*-isochromene *via* a tandem ketone arylation–allylic cyclisation reaction.

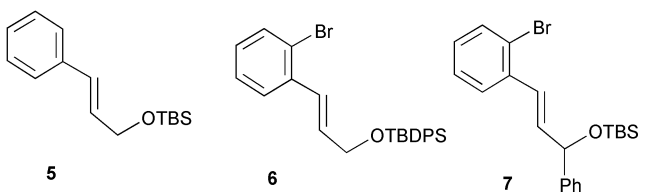
As a part of a wider project concerned with the synthesis of biologically active molecules, we wished to prepare 1-vinyl-1*H*-isochromenes **1**. We felt that we could achieve this end in two stages. The first stage (for the example shown in Scheme 1) would require the coupling reaction of an appropriate aryl



Scheme 1 Intramolecular cyclisation reaction to form 1-vinyl-1*H*-isochromenes. *Reagents and conditions*: (i) ligand, base, solvent, $[Pd_2(dba)_3]$, 85 °C (See Table 1).

bromide **2** with a ketone **3** to give **4**.[1] The second stage would involve replacement of the TBS with an acetyl group and subsequent cyclisation of the ketone enolate onto the allylic system. For the first step, we were confident that a palladium-catalysed ketone arylation reaction would be effective. The reason for the choice of a non-activating silyl group in **2** was simply to prevent the allylic substitution from outpacing the aryl coupling at the high reaction temperatures required (> 80 °C). Allylic acetates, for example, are known to react with ketones under palladium-catalysed reactions at rt.[2]

We first examined the coupling of the *tert*-butyldimethylsilyl-protected allylic alcohol substrate **2** with pinacolone (Scheme 1). Starting material **2** was prepared from readily available 2-bromobenzaldehyde in three steps in 90% overall yield following a literature procedure to the alcohol which was then silyated.[3] Initial attempts to couple **2** to pinacolone following the procedure of Hartwig *et al*.[1] (NaO*t*-Bu, Pd/DPPF, toluene, 100 °C) led mainly to the debrominated cinnamyl ether **5**; no coupling product was observed. Investigation of several



bases (NaO*t*-Bu, Na_2CO_3, Cs_2CO_3 LHMDS) gave none of the expected product **4**. In the case of LiHMDS, however, the 1*H*-isochromene **1**‡ was formed as the major product. Subsequent optimisation of this tandem arylation–allylic substitution reaction improved the yield of this product to 71%.§ As far as we are aware, this represents the first observation of such a tandem enolate arylation–allylic cyclisation reaction. Notable in this process is the involvement of a silyloxy leaving group, which would normally not be considered to be a suitable group for allylic activation. Presumably this reacts because of the high reaction temperature. Related intramolecular reactions of β-keto ester enolates and diketones have been reported to form five-membered rings in palladium-catalysed intramolecular cyclisations.[4]

During this work it appeared that a lithium base and a co-ordinating solvent must be employed to make the reaction work. Trost has reported a similar requirement for a lithium base in an allylic alkylation reaction.[2d] A series of phosphine ligands and ketones were also investigated (Table 1) and it was found that a

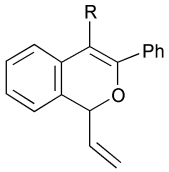
substantial amount of the intermediate **4** could be isolated when either tri-*tert*-butylphosphine or the bis(diazaphospholidine) ligand semi-ESPHOS[5] were used. This intermediate, **4**, was then exposed to the reaction conditions in the absence of palladium and ligands. No cyclisation occurred after several hours, indicating that the cyclisation step was also palladium catalysed. Tri-*o*-tolylphosphine also proved to be a good ligand for isochromene formation. The isolation of **4** from certain experiments suggests that it may be possible to 'tune' the reaction conditions towards the formation of either cyclic or acyclic products. We are currently investigating this issue.

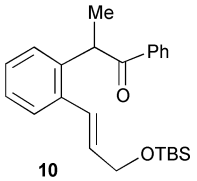
Changing the protecting group on the bromide in **2** from TBS- to the TBDPS- (*i.e.* **6**) did not effect the tandem reaction. Substitution at the allylic ether carbon with a phenyl group (*i.e.* **7**) led to an unreactive substrate. Aromatic ketones such as acetophenone and propiophenone also proved compatible with the reaction conditions. In each case the desired cyclic products **8** and **9** respectively were formed, although the non-optimised yields were low to moderate in both cases. In the case of propiophenone a small amount (6%) of non-cyclised material **10** was also formed.

We wished to confirm that the choice of a trialkylsilyloxy-allylic substrate was essential for a successful reaction. This was achieved through the attempted reaction of acetate **11** with both

DOI: 10.1039/b005519k

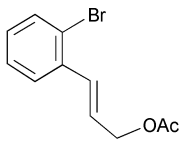


8 R = H
9 R = Me

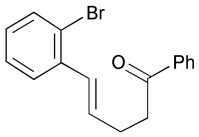


10

pinacolone and acetophenone under our reaction conditions for cyclisation. In the former case the result was a complex mixture, in the latter case the deacetylated alcohol was the major product of the reaction, together with a small amount of ketone **12**. The latter result serves to confirm the ability of the silyloxy group to delay the allylic reaction conveniently until after the arylation process has been completed.



11



12

In conclusion, we have demonstrated that, through the careful choice of ether protecting group, a tandem enolate-arylation–allylic cyclisation process may be 'fine-tuned' in order for the steps to take place in a desired order. The overall result is a convenient and rapid synthesis of vinyl-1*H*-isochromenes, which represent valuable synthetic building blocks for further reactions. The results of our studies on these products, together with further details of the coupling–cyclisation process, will be reported in full in due course.

We thank the CVCP for an Overseas Research Studentship (ORS) award (to R. M.) and Professor D. Games, Dr J. Ballantine and Dr B. Stein of the EPSRC Mass Spectrometry Service at Swansea for carrying out analyses of certain compounds.

§ General experimental procedure for the synthesis of 1-vinyl-3-*tert*-butyl-1*H*-isochromene 1. To a solution of LiHMDS (1 M in THF, 3 eq.) was slowly added a solution of the pinacolone (2 eq.) in solvent at 5 °C. A solution of $Pd_2(dba)_3$ (5% mol) and ligand (10% mol) in solvent was added at room temperature, followed by a solution of *tert*-butyldimethyl [3-(2-bromophenyl)allyloxy]silane **2** (1 eq.). The reaction mixture was heated to 100 °C overnight, allowed to cool and then quenched with 1 M HCl solution at room temperature. The mixture was twice extracted with dichloromethane and the combined organic layers were dried and the solvent was evaporated under reduced pressure yielding the crude product. The crude product was purified by flash chromatography.

Room temperature formation of rhodium nanoparticles on TiO_2[110] *via* MetalOrganic Chemical-Vapour Deposition (MOCVD) of $[Rh(CO)_2Cl]_2$

Mark A. Newton,*[a] Roger A. Bennett,*[b] Rupert D. Smith,[b] Michael Bowker[b] and John Evans[a]

Received (in Cambridge, UK) 11th May 2000, Accepted 25th July 2000

Room temperature adsorption of $[Rh(CO)_2Cl]_2$ on TiO_2[110] is investigated using Scanning Tunnelling Microscopy (STM) which reveals the formation of nanoparticles that coexist with the mono-disperse $Rh(CO)_2Cl$ species; the spatial distribution of these particles indicates that nanoparticle formation occurs principally at step edges.

Since the determination of the existence of mono-disperse $Rh^I(CO)_2$ species on supported Rh systems[1] a wealth of research has been directed at quantifying the role played by this species in Rh based catalysts, particularly with regards to NO_x removal processes.[2–9] CO may also oxidatively disrupt small metallic Rh clusters forming $Rh^I(CO)_2$.[10–13] A complete understanding of the behaviour of supported Rh systems must therefore include a detailed knowledge of how this species behaves under a variety of conditions.

Model supported $Rh^I(CO)_2$ systems can be created *via* two routes. Firstly, catalysts may be prepared from $RhCl_3$ which, after calcination and reduction, may be redispersed using CO to give an adsorbed layer of $Rh(CO)_2$ species.[1,7,14] Typically, however, this method is only viable for Rh loadings of < 2.5 wt%. A second approach is to use a volatile Rh organometallic which may be adsorbed to a prepared oxide surface to yield a $Rh(CO)_2$ adlayer directly.[15–17] As the $Rh^I(CO)_2$ is immediately present it has the perceived advantage of accessing higher Rh loadings whilst still producing a truly mono-disperse adlayer. The use of MetalOrganic Chemical-Vapour Deposition (MOCVD) of Rh organometallics has found particular favour in surface science studies of the chemistry of $Rh^I(CO)_2$ species[17] adsorbed on single crystal oxide surfaces. In these cases involatile inorganic salts, such as $RhCl_3$ may not be used, and the larger Rh clusters formed by Metal Vapour Deposition (MVD) may not be re-dispersed to yield a mono-disperse $Rh^I(CO)_2$ adlayer.[17]

Previous studies concerning the adsorption of $[Rh(CO)_2Cl]_2$ on both high area and [110] oriented single crystal rutile, have indicated that the dissociative adsorption of this species results in a uniform $Rh^I(CO)_2Cl$ adlayer.[15–17] However, there has been no determination of the local structures that result from the adsorption as no LEED structures[17] have been observed. Evidence for a molecular orientation with Rh–C–O bonds aligned in the $< 1\bar{1}0 >$ azimuth has however been demonstrated by Fourier Transform Reflection Absorption Infrared Spectroscopy.[18] We have therefore employed Scanning Tunnelling Microscopy (STM) to determine how the adsorbed $Rh^I(CO)_2Cl$ species interact with the surface and each other.

Experiments were carried out in a UHV chamber equipped with LEED/Auger, and variable temperature STM facilities.[19] The preparation of the rutile TiO_2[110](1 × 1)[20] surface, and the purification of the organometallic sample[17] have been described previously. Rh dosing was controlled *via* a fine leak valve and a line of sight tube doser permitting *in situ* STM measurements whilst the surface is being exposed the organometallic vapour. Unfortunately adsorption of carbonyl along the length of the tube precludes a sharp transition between 'on' and 'off' so considerable exposure of the surface continues after shutting the valve. All STM measurements were carried out with a positive sample bias and therefore unoccupied electronic states are imaged.

Fig. 1(*a*) shows a (97 × 97 Å) STM image of a freshly deposited $Rh(CO)_2Cl$ adlayer. The layer consists of elements showing some low level of local order. The average area per individual unit in Fig 1(*a*) is 40–50 Å^2 which places the coverage at *ca.* 0.2 ML where 1 ML is equivalent to the density of Ti in the surface (0.1 Ti Å^{-2}). Comparison of images taken before and after dosing indicate the features reside preferentially near the centre of the dark rows imaged on the clean TiO_2; *i.e.* on the rows of bridging oxygen. Lack of resolution precludes determination of the lateral position along the row.

Fig. 1(*b*) shows an area (198 × 198 Å) of the same adlayer *ca.* 40 minutes after initial deposition. The features now show a distinct ordering with the appearance of rows on the surface running in two rotationally related domains at ±42 ± 3° to the principal crystallographic directions. The apparent density of the species has increased within this more ordered adlayer and each feature now occupies 25–30 Å^2 corresponding to *ca.* 0.35–0.4 ML. This increased density is due to continued exposure from the dosing tube as mentioned above, and represents a saturation coverage of $Rh(CO)_2Cl$. Given the tunnelling conditions used (above), the size and density of the small features observed in Figs. 1(*a*) and (*b*), we associate these with the $4d_{x^2-y^2}$) orbital of individual, square planar coordinated Rh^I atoms. We believe that the Cl is intimately associated with the $Rh(CO)_2$ and not adsorbed as a separate species. Cl adsorbed upon TiO_2[110][21] appears as an anomalously large (*ca.* 6–8 Å diameter), immobile bright feature in STM: the features we observe do not show such character.

The adlayer in Fig 1(*b*) does show a LEED pattern. However, it is destroyed within *ca.* 2 seconds exposure to the LEED electron beam; the details of this structure will be discussed in a future communication. Also visible in Fig. 1(*b*) are two new

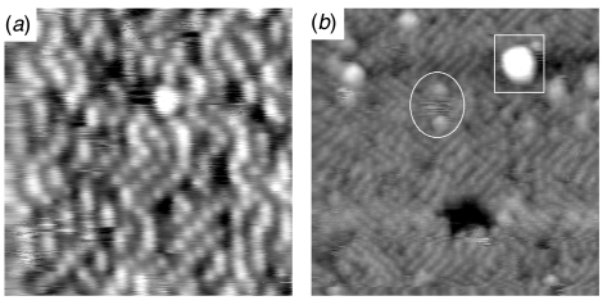

Fig. 1 (*a*) STM image (97 × 97 Å, 1 V, 0.3 nA) of a freshly prepared adlayer derived from room temperature adsorption of $[Rh(CO)_2Cl]_2$ to the TiO_2[110](1 × 1) surface approximately 3 minutes after dosing. (*b*) STM image (198 × 198 Å, 1 V, 0.3 nA) of the adlayer shown in Fig. 1(*a*) approximately 40 minutes after dosing. A large discrete particle is marked by the rectangle while an oval marks two of the smaller, less distinct, particles.

DOI: 10.1039/b003782f

types of feature: the first comprises small, indistinct particles with an apparent height slightly greater than the $Rh(CO)_2Cl$ adlayer; the second comprises discrete larger particles.

Fig. 2 shows a large area scan (998 × 998 Å) of the surface approximately 150 minutes after deposition. The large particles shown in Fig. 1(*b*) are found all over the surface preferentially residing at step edges of the underlying rutile. The particles co-exist with the $Rh(CO)_2Cl$ adlayer. Taking the width of the step region to be that of the largest particle we find large particle formation in the step region to be 5 times more probable than on the terrace on an area for area basis. This indicates that a regio-specific formation of Rh nanoparticles occurs alongside the production of domains of $Rh^I(CO)_2Cl$. Smaller particles are also observed but do not show a distribution that favours the step edges. This particulate formation is not an artefact due to the presence of the tip; moving the tip to new areas of the surface yields similar images.

Fig. 3 shows the particle size distributions derived from Fig. 2 in terms of particle heights, areas, volumes and perimeters. The distributions show two clear groups; a multitude of small particles, and long tail of large particles. An analysis of the height and volume data for the larger particles indicates that they contain up to a few hundred atoms at maximum. The total volume of these particles is *ca*. 435000 Å^3 giving an effective coverage of *ca*. 0.3 ML Rh in particulate form (assuming a bulk Rh lattice constant). It should also be noted, however, that

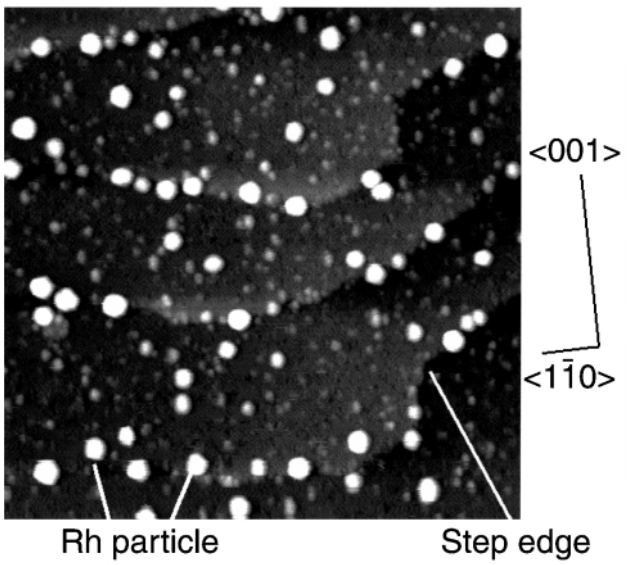

Fig. 2 Large area STM image (998 × 998 Å, 1 V, 0.1 nA) taken *ca*. 150 minutes after Rh deposition.

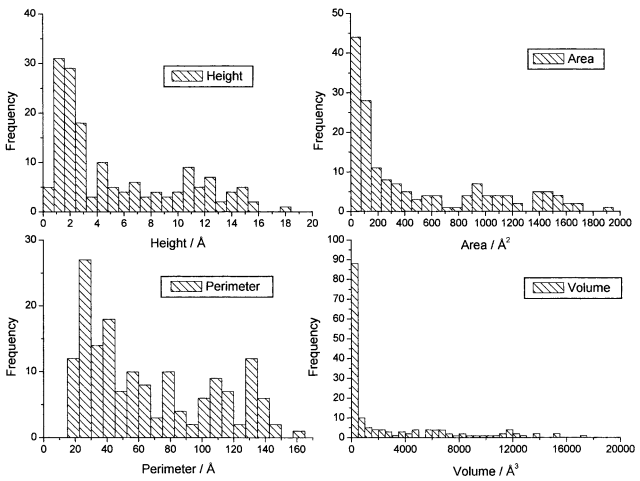

Fig. 3 Particle size distribution functions for Fig. 2. Area and perimeter are derived directly from the particles projected shape onto the surface, while volume and height are calculated from the apparent height and therefore may be influenced by electronic effects.

preliminary analysis of the scaling relationships of the measured parameters of Fig. 2 (*i.e.* volume, area, height *versus* perimeter) indicates that the particles have a well-defined shape despite the apparent lack of clear facets.

The spatial distribution of these particles is distinct from similar Rh particles grown *via* MVD which are reported to show no preferential decoration of step edges.[22] The reasons for this are as yet unclear, but this most probably relates to the need to activate the decomposition of the carbonyl in MOCVD, *versus* the surface diffusion limited growth in MVD.

In summary, and in contrast to a number of previous investigations,[15–17] we have shown that room temperature MOCVD of $[Rh(CO)_2Cl]_2$ does not necessarily lead to a uniform mono-disperse $Rh(CO)_2Cl$ adlayer. Adsorption of this species may initially result in formation of such a layer but this configuration is only metastable even at room temperature. Room temperature adsorption of $[Rh(CO)_2Cl]_2$ on vacuum reduced TiO_2[110] can result in the formation of Rh nano-particles that are distinct from similar sized particles grown *via* MVD, and that may coexist with an ordered layer of $Rh^I(CO)_2Cl$ species. The spatial distribution of these particles indicates that step edges on the rutile surface act as enhanced sites for nucleation of particulate Rh *via* the decomposition of the $Rh(CO)_2Cl$ species. Terraces show a much lower rate of particle formation. We have therefore demonstrated a previously unknown chemistry of TiO_2[110] step edges that produces the nanoparticles. Further, our results indicate that, in systems such as this, the time-scale of interrogation must be considered due to the possibility of changes in the phase of the adsorbed metal species.

We thank the EPSRC for post-doctoral funding to M. A. N. and R. A. B., and the EPSRC/Johnson Matthey PLC for funding a CASE award to R. D. S. We also thank A. J. Ramirez-Cuesta for development of the particle analysis software.

Michael addition of *N*-bonded enolato ligands to acrylonitrile in iron and ruthenium complexes†

Masafumi Hirano, Sayori Kiyota, Masataka Imoto and Sanshiro Komiya*

Department of Applied Chemistry, Tokyo University of Agriculture and Technology, 2-24-16 Nakacho, Koganei, Tokyo 184-8588, Japan. E-mail: komiya@cc.tuat.ac.jp

Received (in Cambridge, UK) 22nd May 2000, Accepted 26th July 2000

Treatment of the *N*-bonded enolatoiron(II) complex [M(H)(NCCHCO$_2$R)(L)$_2$] [1a, M = Fe, R = Me, L = depe {1,2-bis(diethylphosphino)ethane}; 1b, M = Fe, R = Et, L = depe; 2, M = Ru, L = dppe] with acrylonitrile results in mono-Michael addition to give [M(H)-{NCC(C$_2$H$_4$CN)CO$_2$R}(L)$_2$], which is found to be an active intermediate for the catalytic double-Michael reaction of cyanoacetate with acrylonitrile.

Transition-metal enolates have attracted considerable attention as key compounds in chemo-, regio- and stereospecific C–C bond forming reactions under neutral and mild conditions.[1] We previously reported the isolation of zwitterionic *N*-bonded enolate complexes of ruthenium[2] and rhenium[3] as active intermediates in catalytic Michael and Knöevenagel reactions. In these catalyses enhanced nucleophilicity of the enolato moiety by the zwitterionic structure was considered to be responsible for the driving force of the chemoselective C–C bond formations. Here we report the isolation of the mono-Michael adducts of the enolato-iron and -ruthenium complexes to acrylonitrile as active intermediates for the Michael reaction. The role of these adducts in the catalytic double-Michael reaction of cyanoacetate with acrylonitrile is also described.

The enolatoiron(II) complexes [Fe(H)(NCCHCO$_2$R)-(depe)$_2$]† (**1a**, R = Me; **1b**, R = Et) were newly prepared by the oxidative addition of cyanoacetate to a dinitrogen complex of iron(0) [Fe(N$_2$)(depe)$_2$][4] in 81 and 90% yields, respectively [eqn. (1)].

$$[Fe(N_2)(depe)_2] \xrightarrow{+\ NCCH_2CO_2R} [Fe(H)(NCCHCO_2R)(depe)_2] \quad (1)$$

1a R = Me
b R = Et

The molecular structure of **1b**[5] revealed that the structure of the enolato ligand is similar to those in other isolated enolato-ruthenium(II)[2] and -rhenium(I)[3] complexes, showing its delocalised zwitterionic character as suggested by the planarity of the O(1)–C(3)–C(2)–C(1) linkage [dihedral angle = 177.4(5)°] and linear structure of Fe(1)–N(1)–C(1)–C(2) [bond angles Fe–N(1)–C(1) = 173.3(4)°, N(1)–C(1)–C(2) = 178.6(5)°].

The ^{1}H and ^{31}P{^{1}H} NMR spectra of **1a** and **1b** indicate the presence of two isomers due to (*E*)- and (*Z*)-enolato ligands as observed for *N*-bonded ruthenium[2] and rhenium[3] enolates. The major : minor ratio for **1a** and **1b** at 23 °C was estimated as 4 : 1 and 3 : 1, respectively.

Treatment of **1b** with an equimolar amount of acrylonitrile in benzene in the absence of ethyl cyanoacetate at room temperature resulted in mono-Michael addition to the enolato ligand giving *trans*-[Fe(H){NCC(C$_2$H$_4$CN)CO$_2$Et}(depe)$_2$] (**3**) in 44% yield (Scheme 1).[6] The ^{1}H and ^{31}P{^{1}H} NMR spectra of **3** indicate the presence of two isomers (major : minor = 3 : 1 at 24 °C), probably due to (*E*)- and (*Z*)-isomerism of the enolato ligand. The ^{31}P{^{1}H} NMR spectrum of the major species shows two singlets at δ 84.3(s) and 89.4(s) and the ^{1}H NMR spectrum shows two quintets at δ − 25.70 and −25.61, suggesting that the hydrido and enolato ligands are *trans* to each other and all phosphorus atoms located in an equatorial plane. Methylene protons of the cyanoethyl group in **3** were observed as two multiplets at δ 2.4 (m, 2 H) and 2.5 (m, 2 H), as confirmed by COSY and homo-decoupling experiments.

We also carried out the reaction of the analogous enolato-ruthenium complex *trans*-[Ru(H)(NCCHCO$_2$Et)(dppe)$_2$][2a] (**2**) with acrylonitrile giving *trans*-[Ru(H){NCC(C$_2$H$_4$CN)-CO$_2$Et}(dppe)$_2$] (**4**) in quantitative yield.[7] The NMR spectra of **4** also show the presence of two isomers in 1 : 1 ratio, where the cyanoethyl group appears as a couple of A$_2$B$_2$ patterns at δ 1.84 (t, 2 H, J = 6 Hz) and 2.43 (t, 2 H, J = 6 Hz), and δ 2.28 (t, 2 H, J = 6 Hz) and 2.50 (t, 2 H, J = 6 Hz) in the same intensities.

The formation of these adducts **3** and **4** was further confirmed by the following chemical reactions. Acidolysis of **3** and **4** by excess dry HCl released the mono-Michael product NCCH(C$_2$H$_4$CN)CO$_2$Et in 48% and quantitative yields, respectively [eqn. (2)].

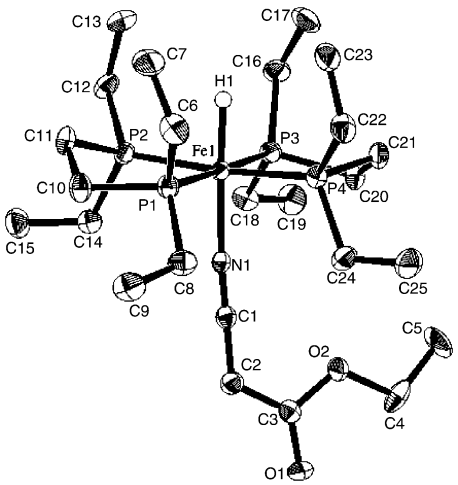

Fig. 1 Molecular structure of [Fe(H)(NCCHCO$_2$Et)(depe)$_2$] (**1b**). All hydrogen atoms except hydride and incorporated solvents are omitted for clarity. Ellipsoids represent 50% probability.

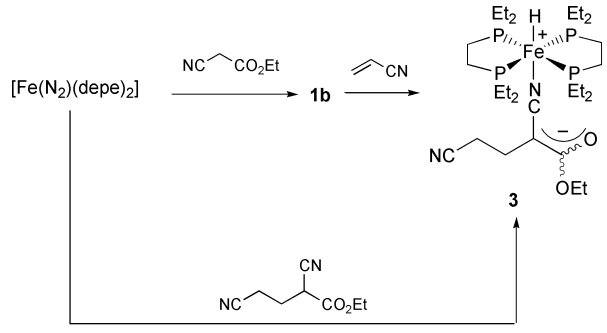
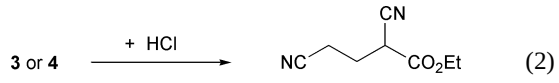


Scheme 1

† Electronic supplementary information (ESI) available: physical and spectroscopic data for **1a** and **1b**. See http://www.rsc.org/suppdata/cc/b0/b004099l/

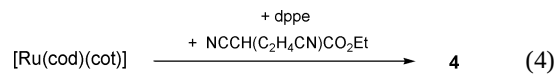
DOI: 10.1039/b004099l



(2)

Reactions of $NCCH(C_2H_4CN)CO_2Et$[8] with $[Fe(N_2)(depe)_2]$ and with [Ru(cod)(cot)]/dppe also gave **3** and **4** in 61 and 62% yields, respectively [eqns. (3) and (4)].

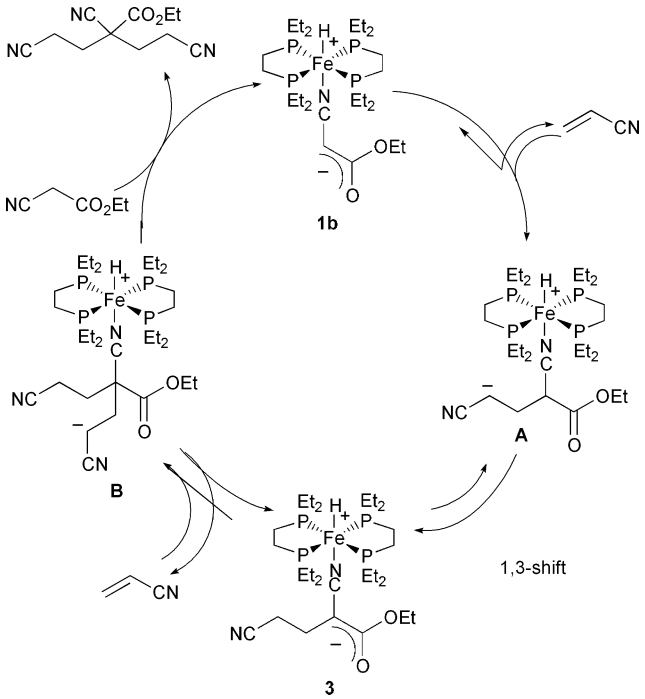
(3)



(4)

It is interesting to note that treatment of **3** (or **4**) with excess of either acrylonitrile or ethyl cyanoacetate resulted in no reaction, even at 50 °C, whilst the **3** (or **4**) catalysed double-Michael reaction of ethyl cyanoacetate with acrylonitrile exclusively gave ethyl 2,2-bis(cyanoethyl)cyanoacetate. Both enolate complexes **1b** and the mono-Michael adduct **3** (1.0 mol%) smoothly catalysed this double-Michael addition at room temperature for 36 h in 88 and 79% yields, respectively.[9] Similarly, complexes **2** and **4** also catalysed this reaction in 88 and 75% yields, respectively, under the same conditions.

By taking into account these facts, the possible reaction mechanism for the double-Michael reaction is illustrated in Scheme 2.



Scheme 2

The *N*-bonded enolate complex **1b** is nucleophilic enough to react with acrylonitrile to give **A**. The intermediate **A** rapidly converts to **3** by 1,3-proton migration. This process is probably driven by the high acidity of the methine proton in **A** and thermodynamic stability of the resulting oxo-π-allyl structure in **3**. This system exclusively affords the double-Michael product regardless of the amount of Michael acceptor and no trace of signals due to the mono-Michael product were detected by NMR. Thus, the direct formation of **1b** from **3** is negligible. Whereas compound **3** catalyses the double-Michael reaction, it remained unreacted with acrylonitrile or ethyl cyanoacetate. This fact suggests that the protonolysis of intermediate **B** took place by ethyl cyanoacetate to reproduce **1b**. When the isotopic labeled $FeD(NCCDCO_2Et)(depe)_2$ (**1b**-d_2) (45 atom% D for Fe–D) was employed in this reaction, the deuteride ligand in **1b**-d_2 remained intact during the catalytic Michael reaction of ethyl cyanoacetate with acrylonitrile (41 atom% D for Fe–D after TON = 3). This is good evidence for this double-Michael product being released from the catalyst, not by reductive elimination, but by protonation.

We are grateful to Proposal-based New Industry Creative Type Technology R&D Promotion Program from NEDO of Japan and the Ministry of Education, Science, Sports and Culture, Japan for financial support.

Received (in Irvine, CA, USA) 8th March 2000, Accepted 20th July 2000

Iridaoxetane 3 formed by oxidation of 1 with aqueous H_2O_2 is isolated and characterized, providing a rare example of formation of a metallaoxetane by direct oxidation of a metal–alkene complex.

Metallaoxetanes (1-metalla-2-oxacyclobutanes) have been invoked over the years as key intermediates in certain transition metal-mediated oxygen atom transfer reactions to olefins.[1,2] A number of metallaoxetanes of transition metals have been prepared by indirect methods,[3] but to our knowledge there is no example of isolation, or even spectroscopic detection, of a metallaoxetane from a catalytically oxidizing medium. Thus, their intermediacy has been the subject of much speculation and some debate over the past two decades.[2]

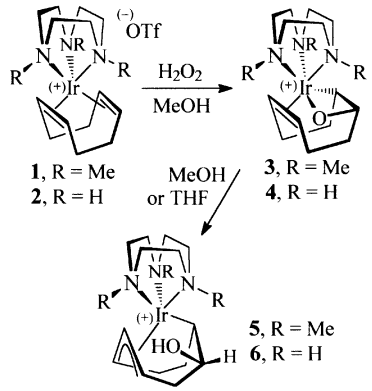
We are aware of only two reports of direct stoichiometric oxygenation of coordinated alkenes that result in formation of characterizable metallaoxetanes.[4,5] One of these is the recent elegant work of Gal and coworkers[5] on oxidation of olefins bonded to rhodium(I) bearing *fac*-coordinating triaza and tetraaza ligands. For example, $[(N_4)Rh(C_2H_4)]^+$ [N_4 = *N*,*N*,*N*-tris(2-pyridylmethyl)amine] and H_2O_2 gave a rhodaoxetane which was isolated and an X-ray crystal structure determination was completed.

Over the last several years we have been developing the synthetic organometallic chemistry of CnIr- and Cn*Ir-containing molecules,† and we have observed that Ir^{III} in these 'hard' coordination environments binds olefins very strongly. We decided to check the reactions of $[(Cn^*/Cn)Ir(cod)]^+$ (**1**/**2**) and $[(Cn^*/Cn)Ir(C_2H_4)_2]^+$ with H_2O_2 and other oxidants. Perhaps iridaoxetane 'intermediates' would be stable enough to detect or isolate before rearrangement to some other species. Ideally, the chemistry of iridium might depart substantially from that reported of rhodium.

[Cn*Ir(cod)]OTf **1** is obtained in up to 86% yield as a light yellow precipitate from reaction of Cn* with $[(cod)IrCl]_2$ in THF in the presence of NaOTf. Off-white [CnIr(cod)]OTf **2** is similarly prepared in up to 73% yield. [Cn*Ir(cod)]Cl can also be isolated in the absence of NaOTf, but the yield is very variable because of formation of a byproduct of stoichiometry $Cn^*Ir_2(cod)_2Cl_2$ and indeterminate structure. Both **1** and **2** are stable in the absence of air in DMSO, methanol or THF for days at 60 °C.

Treatment of **1** with an excess of aqueous H_2O_2 in methanol (Scheme 1), followed by precipitation with diethyl ether results in isolation of a pale-yellow solid. Various 1-D and 2-D NMR techniques were used to assign it iridaoxetane structure **3**.[6] The ^{13}C NMR spectrum contains 17 unique carbons, comprising of 3 CH_3, 10 CH_2 and 4 CH groups (DEPT). Despite considerable effort, X-ray quality crystals of **3** were not obtained.

After 2 days at 20 °C, a sample of **3** in MeOH-d_4 in a sealed NMR tube was unchanged. After 6 h at 60 °C, a new species, **5**, began to form, and after 24 h at 60 °C the conversion was quantitative. Since **5** is chiral (17 unique carbons) it cannot be the iridium analogue of the achiral rhodium product[5] $[Cn^*Rh(oxabicyclononadiyl)]^+$. Rearrangement of **3** was repeated on a synthetic scale in THF. Removal of solvent after



Scheme 1

16 h at reflux gave a beige powder for which DEPT NMR showed 3 CH_3, 9 CH_2 and 5 CH carbons. A ^1H–^{13}C correlation NMR experiment was consistent with the assignment of Ir(III) hydroxycyclooctenediyl species **5**.[7]

$[CnIr(cod)]^+$ **2** was also treated with aqueous H_2O_2 under conditions similar to those for **1**, but iridaoxetane **4** was not observed. Instead, the reaction proceeded directly to yield Ir(III)–hydroxycyclooctenediyl **6** in almost quantitative yield (Scheme 1). The structure was assigned by ^1H and ^{13}C 1-D and 2-D NMR. An X-ray diffraction study of a single crystal of **6** grown from THF–pentane confirms its structure (Fig. 1).[8] As expected, the hydroxy group is *endo* with respect to the iridium center, consistent with its origin in **4**. Formation of iridaoxetane intermediate **4** was established by low temperature NMR spectroscopy. A slight excess of aqueous H_2O_2 was added to **2** in MeOH-d_4 in an NMR tube immersed in liquid nitrogen. Reaction progress was monitored by NMR as the sample warmed. No change was seen below −20 °C, but at −10 °C formation of **4** was observed. After 10 min at −10 °C the resonances of iridaoxetane **4** had begun to be replaced by those of **6**, and conversion of **4** to **6** was rapid at 0 °C. Several attempts to isolate iridaoxetane **4** at low temperature were unsuccessful.

Complexes **1** and **2** were treated with other oxidants like pyridine *N*-oxide, iodosobenzene, and O_2 in aprotic solvents ($MeNO_2$, THF and CH_2Cl_2), all of which gave no reaction. *tert*-Butyl hydroperoxide and **2** generated **6**, but more slowly than H_2O_2. Dioxygen in methanol did form **3**, but the yield was much reduced and there was substantial decomposition during the reaction. We suspect that in the case of O_2 protic solvent is required to allow destructive oxidation of **1** and concomitant formation of H_2O_2 which then effects the usual oxidation of residual **1**. Treatment of $[CnIr(C_2H_4)_2]^+$ with H_2O_2 or Bu^tOOH in methanol or THF gave uncharacterizable mixtures, and its oxidation was not pursued further.

Overall, the oxidation of **2** to **4** is qualitatively faster than that of **1** to **3**, and clearly the rearrangement of **4** to **6** is much faster than **3** to **5**. The reason(s) for the faster reactions of **2** and **4** are not obvious. Since we would have expected the presumably

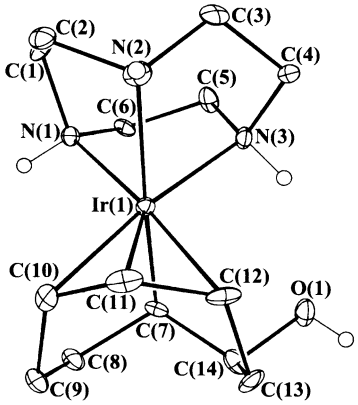

Fig. 1 Thermal ellipsoid plot (30% probability) of the cation of **6**. The OTf counter ion and hydrogen atoms, except H(1)–H(4) which were located, have been omitted for clarity. Selected bond lengths (Å) and angles (°): Ir(1)–N(1) 2.158(7), Ir(1)–N(2) 2.198(8), Ir(1)–N(3) 2.140(7), Ir(1)–C(7) 2.096(9), Ir(1)–C(10) 2.164(8), Ir(1)–C(11) 2.081(8), Ir(1)–C(12) 2.157(8); N(1)–Ir(1)–N(2) 80.0(3), N(2)–Ir(1)–N(3) 79.7(3), N(1)–Ir(1)–N(3) 79.4(3), N(1)–Ir(1)–C(12) 175.2(3), N(2)–Ir(1)–C(7) 171.5(3), N(3)–Ir(1)–C(10) 172.9(3), C(7)–Ir(1)–C(10) 81.3(4), C(7)–Ir(1)–C(12) 82.4(4).

more electron rich **1** to oxidize faster, steric differences may be the more likely explanation. Although we were not able to obtain X-ray quality crystals of either **3** or **4**, from the X-ray crystal structures of [CnIr(H)$_2$(η^2-cyclooctene)]OTf and [Cn*Ir(H)$_2$(η^2-cyclooctene)]Cl we have observed average Ir–N distances of 2.15 and 2.20 Å, respectively, so the methyl groups have only a small effect on the Ir–N distances. Thus, the *N*-methyl groups cause considerably more crowding around the equator of the complex than the N–H groups. It may be that the methyl groups restrict conformational mobility of the oxidized ligand in **3** relative to that in **4** leading to a larger barrier for the rearrangement. Similarly, the slower oxidation of **1** compared to **2** may result form steric hindrance to attack by peroxide on the metal or on the coordinated alkene.

It is interesting that in the three cases where metallaoxetane species have been isolated from oxidation of coordinated olefins, the complexes contain ancillary ligands which coordinate to the metal *via* the relatively non-polarizable atoms oxygen and nitrogen. There is too little information as yet to conclude if this observation is significant.

This work was funded by the US National Science Foundation.

Received (in Liverpool, UK) 6th June 2000, Accepted 3rd August 2000

Newly discovered non-isoprenoid dialkyl diglycerol tetraethers containing 13,16-di- or 5,13,16-trimethyloctacosanyl moieties have been identified in peats and coastal marine and lake sediments by HPLC–MS and high-field NMR spectroscopy.

Hyperthermophilic archaea thrive at temperatures > 60 °C and their ecological occurrence is, therefore, restricted to extreme environments such as waters near volcanic areas.[1] To meet the requirements posed by these hostile environments,[2] the membranes of these archaea (the third kingdom of life) are predominantly composed of isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs),[3] which are mainly comprised of acyclic (**1**)† or cyclic biphytane core lipids. Recently we reported a new technique for the direct analysis of intact GDGTs in extracts of archaeal cell material and sediments using high performance liquid chromatography–atmospheric pressure chemical ionization mass spectrometry.[4] Initial results indicated that GDGTs are widespread in low temperature environments, in contrast to the previous belief that GDGTs are restricted to hyperthermophilic archaea. Using this technique we also encountered unidentified GDGTs in extracts of peats. Here we report the identification of these abundant GDGTs as unprecedented, non-isoprenoid GDGTs.

The total ion current chromatogram of the HPLC–MS analysis revealed unknown components in the peat extracts, which possessed $[M + H]^+$ ions of 1050, 1036 and 1022 in order of increasing elution time (Fig. 1). Characteristic losses of $[M+H]^+$-18 and $[M+H]^+$-74 corresponding to loss of water and of a glycerol moiety (as $C_3H_6O_2$)[4] suggested these components to be GDGTs. Cleavage of ether bonds[5] with HI and subsequent reduction of the formed iodides with $LiAlH_4$, performed on a fraction of an extract of the Holocene Bargerveen peat (SE Drenthe, the Netherlands) containing these newly discovered GDGTs, produced two dominant branched hydrocarbons. The first eluting hydrocarbon was identified as 13,16-dimethyloctacosane by GC–MS analysis and co-elution with an authentic standard.[6] The second eluting isomer is a C_{31} alkane; its mass spectral characteristics indicate also a C_{28} linear alkyl chain with methyl branching at C-13, C-16 and C-5. Its relative retention time is consistent with this structure; the experimental Kovats index of 2912 compares favourably with the one calculated[7] (RI = 2914). The iodides formed upon HI treatment were also treated with $NaSCH_3$,[5] resulting in the formation of the α,ω-diSMe derivatives of the C_{30} and C_{31} branched alkanes. This established the number and positions by which these

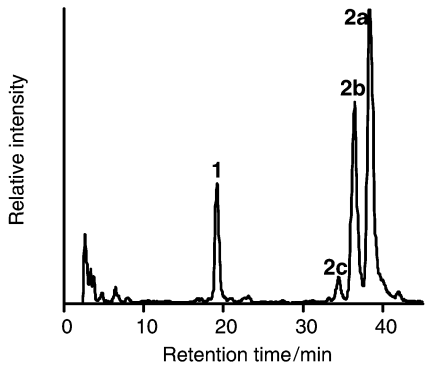

Fig. 1 Total ion current chromatogram of an extract of the Bargerveen peat revealing the abundance of GDGTs **1** and **2a**–**c**.

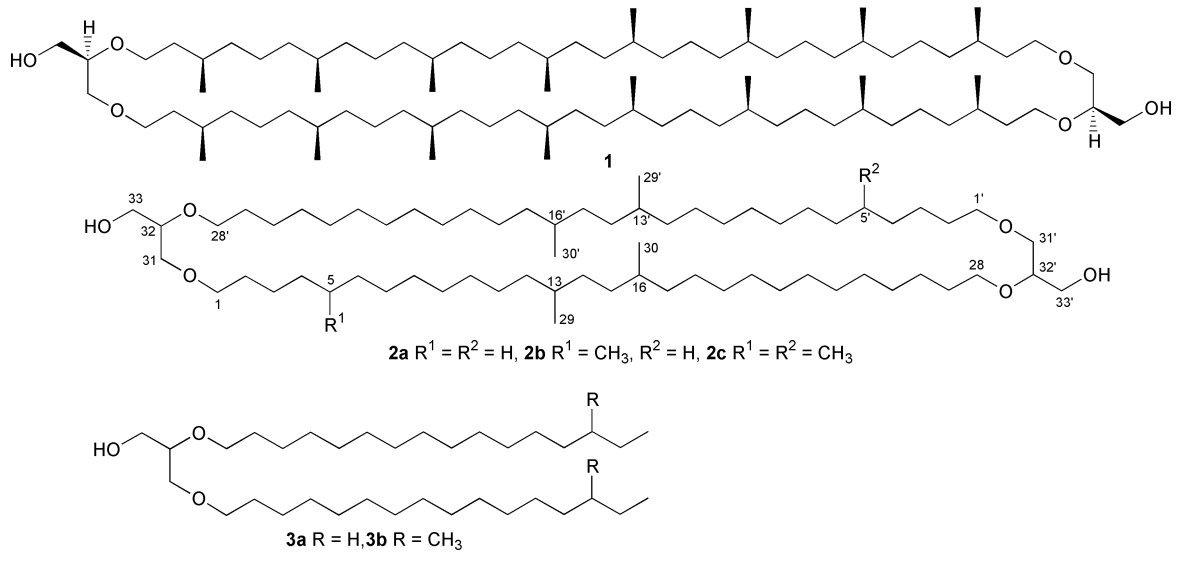

DOI: 10.1039/b004517i

skeletons are ether-bound. These data suggest that the new GDGTs comprise diether-linked di- or trimethyl branched C_{28} linear chains (**2a**–**c**), which fits with the determined molecular weights and indicates elemental compositions of $C_{66+n}H_{132+2n}O_6$ (n = 0–2).

These structural assignments were confirmed by high field ^{1}H and ^{13}C NMR‡ of GDGTs **2a** and **2b**, which were isolated from the peat extract by HPLC on a semi-preparative NH_2 Econosphere 10 × 250 mm column (Alltech) eluted with a linear gradient from 1 to 2% propanol in hexane in 55 min, yielding 1.6 and 1.1 mg per component, respectively. Both the ^{1}H and ^{13}C NMR gave substantial evidence for the presence of ether-bound glycerol units in **2a** and **2b**. The ^{13}C shifts of the carbon atoms of the glycerol moieties and the ether-bound CH_2 units of the alkyl moieties are in good agreement with those reported for GDGT **1**[3b] and commercially available 1,2-dihexadecylglycerol (**3a**). The remaining signals in the ^{13}C spectrum of **2a**, apart from a large suite of secondary C-atoms, indicated only 4 equivalent primary and 4 equivalent tertiary C-atoms, consistent with the proposed structure. The ^{13}C spectrum of **2b** is somewhat more complicated due to the additional methyl group in one of the branched alkyl chains. The shifts of the C-atoms around this additional methyl group are in good agreement with the proposed position for branching. A TOCSY experiment with **2b** indicated that the additional methyl group is present in the *O*-bound alkyl chain attached at the C-1 position of the glycerol moiety through a correlation between H-1 and the protons of the methyl group at C-5.

We have thus established a new type of GDGT not composed of isoprenoid but of branched alkyl core lipids. The new tetraethers all consist of a 64-membered ring with 6–8 stereocentres. Although the newly discovered GDGTs have been isolated from peat, they also occur in lake and coastal marine sediments. Their close structural similarity to **1** suggests that **2a**–**c** are also core membrane lipids, although they have not yet been identified in organisms. Branched dialkyl glycerol diethers (*e.g.* **3b**) have been reported in a thermophilic bacterium[8] and it may be that the GDGTs **2** represent 'dimers' of such lipids, in the same way as **1** is a dimer of the isoprenoid dialkyl glycerol ether, *sn*-2,3-diphytanylglycerol diether. This suggests that bacteria are more likely producers of these membrane lipids than archaea.

We would like to thank Dr P. Albrecht (University of Strasbourg) for his kind donation of a GC sample of the authentic standard of 13,16-dimethyloctacosane, Mr C. Erkelens (University of Leiden) for access to the 600 MHz NMR spectrometer, and Dr B. van Geel (University of Amsterdam) for peat samples. We acknowledge the Dutch Organisation for Scientific Research (NWO-ALW; grant number 809.33.001) for funding.

Notes and references

† Antiparallel arrangement of glycerol units is indicated and assumed for **2** but it has been shown for **1** that the parallel arrangement occurs in approximately equal amounts.[9]

Received (in Cambridge, UK) 25th April 2000, Accepted 27th July 2000

A novel 2D La–Cu heteronuclear coordination polymer, formed by the synergetic effect of Cl^- and ClO_4^-, possesses an irregular triangular lattice of copper ions, and shows unusual magnetic relaxation properties.

Ladder-like 2D copper arrays have attracted much attention in the last fifteen years owing to the key role of Cu–O layers in high temperature superconductors.[1] Meanwhile, the structure and magnetic behavior of many square-planar molecular compounds have been studied extensively, especially for the A_2CuX_4 series.[2,3] On the other hand, geometrically frustrated two-dimensional systems with triangular or kagome lattices have attracted continued interest both theoretically and experimentally.[4] However, genuine 2D copper molecular materials containing such lattices are surprisingly scarce. $Cu_2(OH)_3X$ may be a unique example of a triangular lattice, which shows a coexistence of long range ordering and spin glass-like behavior.[5] In 1998, we reported the 2D 4f–3d coordination polymers $Ln_2M_3(EDTA)_3(H_2O)_{11}\cdot 12H_2O$ (M = Co, Mn), in which the connection of the M ions led to a kagome lattice.[6] In continuation of this work, nitrilotriacetic acid (H_3NTA) was used as a multidentate bridging ligand, and two types of inorganic anions were introduced, which led to a novel 2D La–Cu assembly formulated as $[LaCuCl(NTA)(H_2O)_6]ClO_4\cdot H_2O$ **1**, in which the copper connections afforded an irregular triangular lattice. From the view point of synthetic chemistry, the template effect of inorganic anions has been well documented in the formation of some cluster compounds, for example, Cl^- for $[Eu_{15}Cl(\mu_3\text{-}Tyr)_{10}(\mu_3\text{-}OH)_{20}(\mu_2\text{-}H_2O)_5(OH)_{12}(H_2O)_8](ClO_4)_2\cdot 56H_2O$, μ_{12}-ClO_4^- in $[Ln_6Cu_{12}(OH)_{24}(H_2O)_{18}(pyb)_{12}ClO_4](ClO_4)_{17}\cdot nH_2O$ (pyb = pyridine betaine) (Ln = Nd, Sm, Gd and Y) and O^{2-} in $[Ln_6O(OH)_8(H_2O)_{24}](ClO_4)_8\cdot 6H_2O$.[7] In contrast, as monodentate ligands and counter ions, both Cl^- and ClO_4^- play a crucial role in the formation of compound **1**.

A mixture of $Cu(OH)_2$ (3 mmol) and H_3NTA (3 mmol) was dissolved in 30 ml H_2O, then $La(ClO_4)_3$ (1.5 mmol) and $LaCl_3$ (1.5 mmol) were added under vigorous stirring. The pH of the solution was adjusted carefully to 5.0. After being filtered, the solution was concentrated to 15 ml and left at room temperature. Blue rectangular crystals of **1** were deposited in *ca*. 40% yield after two weeks.†

X-Ray crystallography‡ has established that complex **1** adopts a two-dimensional honeycomb-like layer with nine-coordinate lanthanum and five-coordinate copper ions located at the apexes of each hexagon. As shown in Fig. 1(a), the NTA ligand coordinates to Cu in a tetradentate manner through three oxygen atoms (O1, O3, O5) of three different carboxyl groups and a nitrogen atom (N), forming three five-membered rings. The fifth coordination site of Cu is occupied by a chloride ion (Cl1). The remaining three carboxyl oxygen atoms (O2, O4, O6) of the NTA coordinate to three different adjacent lanthanum ions forming three *anti–anti* carboxylic bridges between Cu and La ions. For La, three oxygen atoms from three different NTA ligands (O2, O4A, O6B) occupy three coordination sites of La with three similar angles (O2–La–O4A 76.0°, O2–La–O6B 81.6° and O4A–La–O6B 78.5°). The remaining six coordination sites of La are taken up by six water molecules (O7–O12). The complex can be regarded as a polymer in which CuCl(NTA) units are linked to each other by $La(H_2O)_6$ bridges from three different directions, forming a two-dimensional metal-apex honeycomb [Fig. 1(b)], very different from the honeycomb of $[Ln_2M_3]$ found in $Ln_2(ox)[Cu(pba)]_3[Cu(H_2O)_5]\cdot 20H_2O$ [Ln = La–Gd, pba = 1,3-propylenebis(ox-

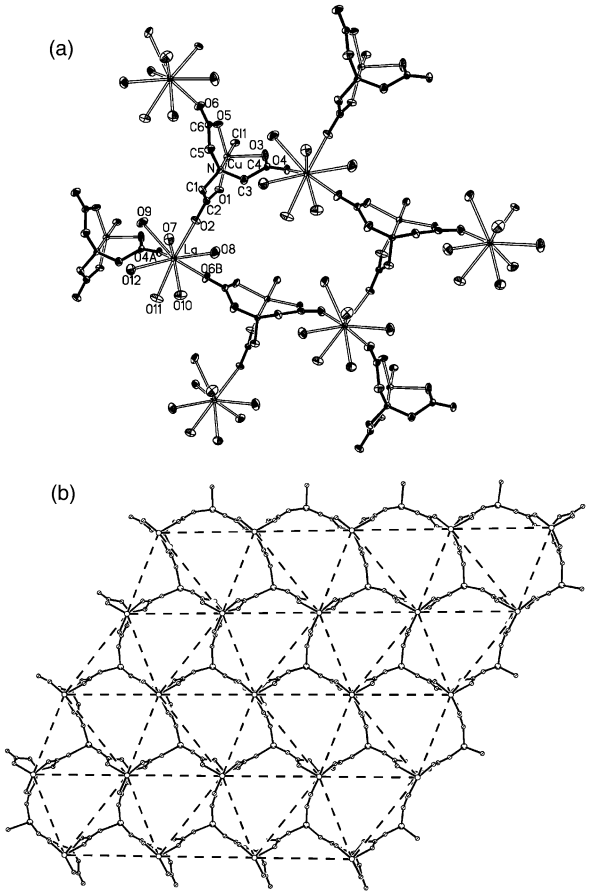

Fig. 1 (a) An ORTEP drawing of **1** showing the connections between La^{3+} and Cu^{2+}. Hydrogen atoms are omitted for clarity. Selected interatomic distances (Å) and angles (°): La–O6 2.466(5), La–O4 2.501(5), La–O2 2.541(6), La–O7 2.545(6), La–O10 2.566(6), La–O11 2.568(6), La–O8 2.579(6), La–O12 2.604(7), La–O9 2.622(6), Cu–O1 1.969(4), Cu–O5 1.988(5), Cu–N 2.010(6), Cu–Cl1 2.218(2), Cu–O3 2.222(5); O4A–La–O6B 78.47(19), O2–La–O6B 81.6(2), O2–La–O4A 75.97(19), O1–Cu–O5 151.9(2), O1–Cu–N 84.3(2), O5–Cu–N 85.1(2), O1–Cu–Cl1 95.90(17), O5–Cu–Cl1 95.13(16), N–Cu–Cl1 178.97(18), O1–Cu–O3 110.0(2), O5–Cu–O3 93.9(2), N–Cu–O3 81.2(2). DOI: 10.1039/b003293j

amato)][8] and $Ln_2M_3(edta)_3(H_2O)_{11}\cdot 12H_2O$,[6] where M ions occupy the center position of edges of hexagons. The intralayer La···Cu distances (6.34, 6.35 and 6.43 Å) are nearly equal but the distortion of the hexagon leads to neighboring intralayer Cu···Cu distances of 8.57, 9.30 and 10.11 Å, respectively; accordingly the connection of closest neighboring copper ions affords an irregular triangular lattice. It is also noted that the closest interlayer Cu···Cu separations are 7.44, 8.56 and 9.16 Å, comparable with those in the layer. In this sense, **1** is not an ideal 2D compound.

Experiments using only $La(ClO_4)_3$ or $LaCl_3$ did not give rise to this La–Cu complex, suggesting that both Cl^- and ClO_4^- have a synergetic effect in forming this heteronuclear complex. Compared with the Ln_{15} cluster which contains a central Cl^- ion as a template and ClO_4^- ions as counter ions,[7a] the Cl^- in complex **1** does not act as a template, but directly coordinates to Cu, and formation of **1** was impossible without Cl^-. The role of ClO_4^- as a counter ion in complex **1** may lie in it occupying the holes of the honeycomb and stabilizing the lattice. Since the volume of Cl^- is much smaller than that of ClO_4^-, the lattice might be destabilized if the counter ion is changed from ClO_4^- to Cl^-. These facts suggest that the formation of **1** is controlled by both Cl^- and ClO_4^-. Presumably, Cl^- and ClO_4^- could be replaced by other anions similar to them. For example, Cl^- may be replaced by Br^-, I^-, CN^-, OCN^- or even SCN^- , and ClO_4^- may be replaced by PF_6^-, BF_4^-, NO_3^- *etc.* The use of larger organic anions to explore the possibility of obtaining well separated 2D triangular compounds as well as replacement of La^{3+} by other lanthanide ions to yield chain complexes, will be reported elsewhere.

Preliminary magnetic investigations were made for **1**. The temperature dependence of the magnetic susceptibility in the temperature range 2–200 K at an applied field of 10 kOe is shown in Fig. 2(a). The value of $\chi_M T$ is 0.4 $cm^3\ mol^{-1}$ K at 200 K and increases very slowly to a maximum of 0.47 $cm^3\ mol^{-1}$ K between 13 and 6 K, then decreases upon further cooling. The data could not be fitted well using the Lines' model for a quadratic layer Heisenberg antiferromagnet,[9] but fitting the data to the Curie–Weiss law gave C = 0.398 $cm^3\ mol^{-1}$ K and θ = 2.6 K, indicative of weak ferromagnetic behavior. This might be considered as the result of frustration in the 2D triangular array of copper ions. If so, spin glass behavior should be expected for the geometrically frustrated system as for $Cu_2(OH)_3X$.[5b] However, zero field ac measurements did not give any peaks for either real χ' or imaginary χ'' as shown in Fig. 2(b) probably owing to weak coupling between Cu ions in **1** at zero field as a result of the large Cu···Cu separations. When a dc field (10 kOe) was applied, the antiferromagnetic (AF) interactions among Cu ions (including inter-layer) will be enhanced, and accordingly the frustration due to the AF interaction of triangularly arranged Cu ions may result in the very unusual magnetic relaxation shown in Fig. 2(b).[10] Peaks for χ' and χ'' are observed in the dc field, and are strongly frequency dependent. If we calculate the value of relative variation of peak temperature (T_p) per decade of frequency, $\varphi = \Delta T_p/[T_p\Delta(\log f)] = 1.2$, which is rather large and distinctly different from the behavior of normal spin glasses ($\varphi < 0.1$).[11] Further investigation on the mechanism of the unusual magnetic relaxation is under way.

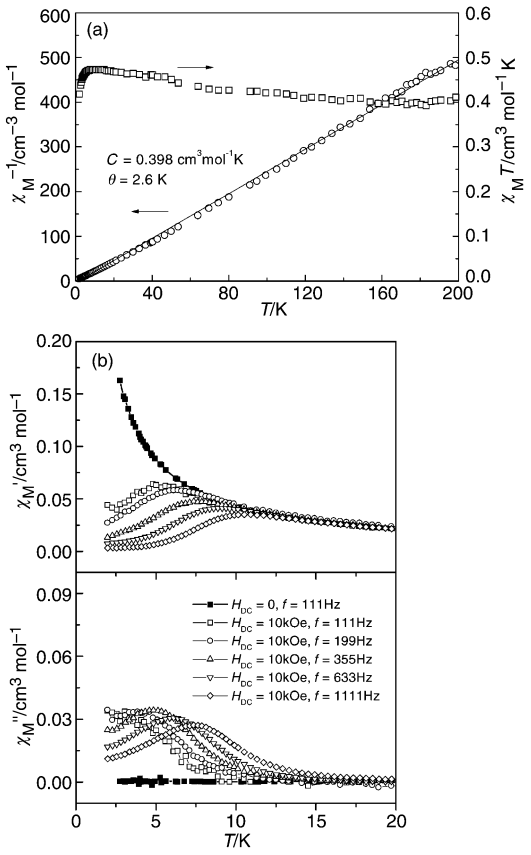

Fig. 2 (a) Temperature dependence of the dc susceptibility of **1** measured at a field of 10 kOe. (b) Temperature dependence of the ac susceptibility of **1** measured at zero dc bias field and at 10 kOe for different ac frequencies (top: real χ', bottom: imaginary χ'').

Anion recognition through hydrogen bonding: a simple, yet highly sensitive, luminescent metal-complex receptor

Shih-Sheng Sun and Alistair J. Lees*

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13902-6016, USA. E-mail: alees@binghamton.edu

Received (in Irvine, CA, USA) 5th June 2000, Accepted 26th July 2000

A new luminescent rhenium(I) polypyridyl-based receptor for a variety of inorganic anions has been designed and synthesized and this artificial receptor shows high affinities for halides, cyanide and acetate anions with binding constants as high as 10^4–10^5 M^{-1} and a detection limit as low as 10^{-8} M in CH_2Cl_2 solution.

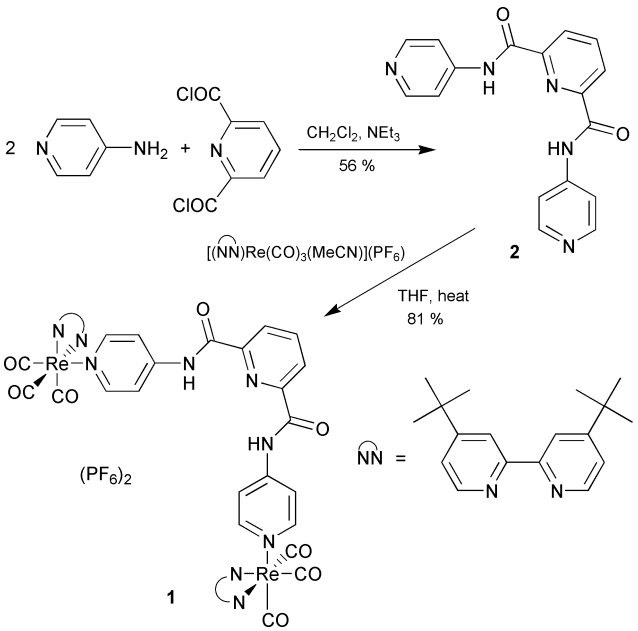
The design and synthesis of efficient artificial receptors for selective binding of biologically or environmentally important anionic species is an emerging field with many applications.[1,2] A variety of synthetic receptors have been designed and studied for their binding strength and selectivity toward different anions. These have included Lewis acids,[1] protonated polyammonium macrocycles,[1] pyrroles,[3] guanidiniums,[4] metalloreceptors[1] and amides.[1] However, many of these receptors have very elaborate structures that typically require multiple synthetic steps with relatively low overall yields which make it impractical to prepare them on a large scale. There are only a few structurally simple receptors exhibiting both sensitivity and selectivity. [5]

Nature provides many examples of proteins utilizing hydrogen bonding for binding substrates. The incorporation of luminescent chromophores into the receptor which are sensitive to interactions between the receptor and analytes has gained considerable attention due to their high sensitivity and detection limit.[6] Although there have been several literature reports concerning luminescence-based anion detection,[6,7] the highly sensitive luminescence-based halide and cyanide sensory systems are much rarer.[7] Thus, we embarked on designing a very simple and easily prepared luminescent metal complex integrated with an amide moiety functioning as a hydrogen bonding site. We report herein, the synthesis and binding properties of this highly sensitive and selective luminescent anion receptor, $[\{(Bu^t_2bpy)Re(CO)_3\}_2(\mu\text{-}L)](PF_6)_2$ **1**, (Bu^t_2bpy = 4,4′-di-*tert*-butylbipyridine).

The synthesis of L and complex **1** is shown in Scheme 1. The bridging ligand **2** was prepared in 56% yield from 2 equivalents of 4-aminopyridine and 2,6-pyridinedicarbonyl dichloride. Subsequent reaction of **2** and 2 equivalents of $[MeCN)(Bu^t_2bpy)Re(CO)_3](PF_6)$[8] in refluxing THF, followed by recrystallization from CH_2Cl_2–pentane, afforded a bright yellow crystalline solid **1**† in 81% yield.

The N–H protons of complex **1** exhibit a chemical shift δ 10.59 in $CDCl_3$. The very downfield chemical shift indicates the presence of strong intramolecular hydrogen bonding between the N–H protons and nitrogen in the central pyridine. This results in ligand **2** having an approximate right angle geometry[9,10] and the converged structure of complex **1** renders it as an effective anion receptor through hydrogen bonding. In deoxygenated CH_2Cl_2 solution, complex **1** exhibited intense absorption bands in the near UV to visible spectral region (λ_{max} = 254, 281 and 380 nm, ε_{max} = 63600, 61500 and 7700 M^{-1} cm^{-1}, respectively) and a very strong luminescence at 536 nm with quantum yield of 0.37 and lifetime of 0.48 μs.

Addition of different halides or inorganic polyatomic anions (as tetrabutylammonium salts) into a 1×10^{-5} M solution of complex **1** was observed to cause different degrees of quenching of the luminescence intensities.‡ The N–H protons in ^1H NMR spectra all showed significant downfield shifts (> 1.5 ppm), indicating the strong hydrogen bonding formation between the amide protons of complex **1** and the anions. Fig. 1



Scheme 1

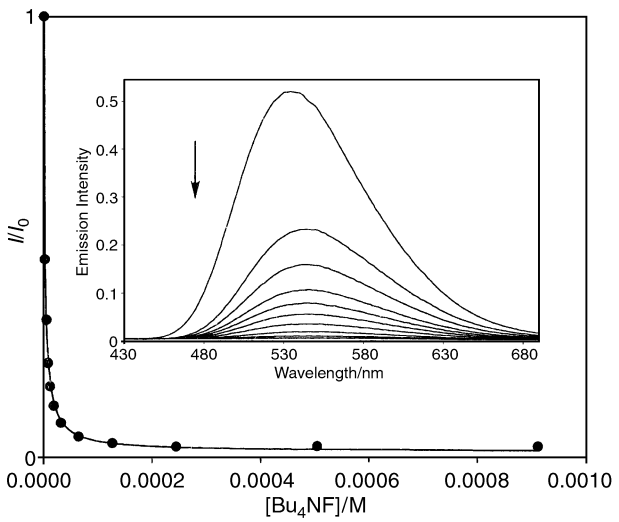


Fig. 1 Titration curve of the addition of F^- anion (as tetrabutylammonium salt). The inset shows the change of the emission intensity of complex **1** in CH_2Cl_2 solution upon addition of F^- anion. Excitation wavelength is 360 nm.

DOI: 10.1039/b004541l

Table 1 Binding constants K_b determined by luminescence titration in CH_2Cl_2 at 298 K

Anion	K_b/M^{-1}
CN^-	8.80×10^5
F^-	3.82×10^5
Cl^-	3.99×10^4
Br^-	3.90×10^4
I^-	1.49×10^5
OAc^-	3.41×10^4
$H_2PO_4^-$	1.47×10^2
NO_3^-	63.4
ClO_4^-	8.4

shows a typical titration curve for the luminescence intensity upon addition of F^- to a CH_2Cl_2 solution of **1**.§ The curve was determined to fit well to a 1 : 1 binding isotherm.[11] Concomitant with the quenching, the luminescence wavelength slightly red-shifted from 536 to 546 nm. Table 1 summarizes the binding constants measured for complex **1** toward different anions. Clearly, this molecule shows strong binding affinity toward halides, cyanide or acetate anions, only moderate binding affinity toward dihydrogen phosphate and very weak binding affinity to nitrate or perchlorate anions.

The overall order determined for binding affinity is: $CN^- > F^- > I^- > Cl^- \approx Br^- \approx OAc^- >> H_2PO_4^- > NO_3^- > ClO_4^-$. This finding is significant as it is not common for charged receptors to exhibit such outstanding selectivity for anion species.[12] In fact, the combination of interactions involving electrostatic force, hydrogen bonding strength and steric effects all apparently influence the binding affinities toward anions in complex **1**. Importantly, the sensitivity of complex **1** is so high that the emission intensity can be effectively quenched by as much as 10% even in the presence of only 10^{-8} M cyanide or fluoride anions.

The origin of the emission quenching upon addition of anions is not certain at this stage. The red shift of the emission band, however, indicates that the emission quenching is associated with a change in the energy of the excited state and, thus, the enhancement of nonradiative decay.

In summary, complex **1** represents a simple and easy to prepare luminescent anion sensory system. The strong binding affinity and high selectivity of complex **1** for certain anions also may make it a promising candidate for many other different applications besides sensors, such as homogeneous catalysis[13] and membrane transport.[14] Currently, we are working on anion binding studies in H-bonding competitive solvents such as MeCN as well as modifying the dipyridyl ligands so that the receptors will be soluble in aqueous solvents. These results are expected to be intriguing given the fact that most biologically and environmentally important anions are only soluble in aqueous environments.

We are grateful to the U. S. Department of Energy (Grant DE-FG02-89ER14039) for support of this research.

ChemComm

Synthesis and ligand substitution reactions of a homoleptic acetonitrile dipalladium(I) complex†

Tetsuro Murahashi,* Tomoki Nagai, Taketoshi Okuno, Teruo Matsutani and Hideo Kurosawa*

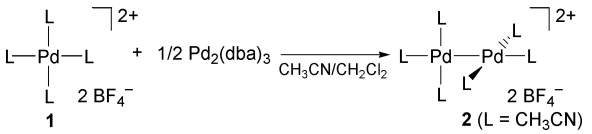
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565-0871, Japan

Received (in Cambridge, UK) 13th June 2000, Accepted 25th July 2000

The first homoleptic nitrile dipalladium(I) complex $[Pd_2(CH_3CN)_6][BF_4]_2$ is prepared; the CH_3CN ligand undergoes facile displacement by phosphine or bidentate nitrogen ligands while the Pd–Pd bond remains intact.

Homoleptic transition metal complexes containing weakly coordinated ligands have long been recognized as versatile sources of active catalysts or inorganic functional materials.[1] For example, the combination of an electrophilic Pd(II) complex $[Pd(CH_3CN)_4][BF_4]_2$ **1**[2] and appropriate auxiliary ligands has been frequently used as a pre-catalyst for olefin oligomerization, aromatic substitution, Wacker type oxidation, or alkyne hydroamination reaction.[3] While the corresponding homoleptic di- or multi-nuclear complexes of weakly coordinated ligands are relatively rare, several acetonitrile complexes of Mo≡Mo,[4] Tc≡Tc,[5] Re≡Re,[6] and Rh–Rh[7] have been prepared. Here, we report the first synthesis and reactivity of homoleptic acetonitrile dipalladium complex $[Pd_2(CH_3CN)_6][BF_4]_2$ **2**.

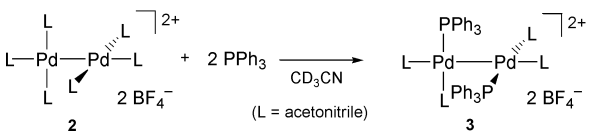
When **1** was treated with 0.5 equiv. of $Pd_2(dba)_3$ at room temperature in dry CH_3CN–CH_2Cl_2, the solution turned reddish-orange. Pouring this solution into Et_2O afforded an orange powder of **2** in 90% isolated yield [eqn. (1)].‡ Elemental



(1)

analysis supported the composition of **2**. UV–VIS spectra of **2** showed a σ–σ* transition at λ_{max} = 436 nm (ε = 1095 M^{-1} cm^{-1}). The homoleptic complex **2** was soluble in CD_3CN or CD_3OD. In CD_3OD, the coordinated acetonitrile protons appeared at δ 2.55, although gradual decomposition occurred with the formation of Pd black. When **2** was dissolved in H_2O, decomposition occurred within 10 min although it has been known that rather stable mononuclear aqua complexes are formed from **1** in H_2O.[3h] It should be mentioned that further addition of 0.5 equiv. of $Pd_2(dba)_3$ to **2** in CH_3CN–CH_2Cl_2 at room temperature resulted in decomposition instead of the desired formation of Pd_3 complexes such as $[Pd_3(CH_3CN)_8]^{2+}$.[8]

The dipalladium complex **2** underwent facile ligand-substitution reaction with the Pd–Pd bond remaining *intact* under moderate conditions. For example, addition of 2 equiv. of PPh_3 to **2** in CD_3CN afforded bisphosphine dipalladium complex $[Pd_2(CH_3CN)_4(PPh_3)_2][BF_4]_2$ **3**[9] quantitatively [eqn. (2)]. The reaction of **2** with >2 equiv. of PPh_3 afforded several



(2)

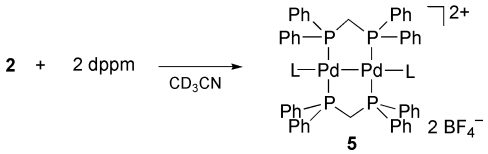
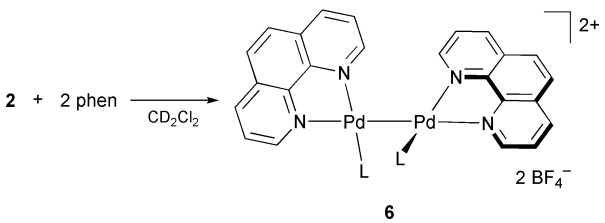
unidentified species. On the other hand, controlled addition of an equimolar amount of PPh_3 to a CH_2Cl_2 solution of **2** afforded monophosphine complex $[Pd_2(CH_3CN)_5(PPh_3)][BF_4]_2$ **4** which was detectable by ^{31}P NMR spectroscopy (δ 19.3). The position of PPh_3 ligand in **4** is suggested to be *cis* to the Pd–Pd bond by considering the relative *trans*-influence of PPh_3, CH_3CN and [Pd] ligands.[9] Further addition of PPh_3 (1 equiv.) afforded **3** quantitatively. The reaction of **2** with 2 equiv. of bidentate phosphine, dppm (diphenylphosphinomethane), in CD_3CN afforded a known complex $[Pd_2(dppm)_2(CH_3CN)_2][BF_4]_2$ **5**[10] quantitatively [eqn. (3)]. The reaction of **2** with 2 equiv. of



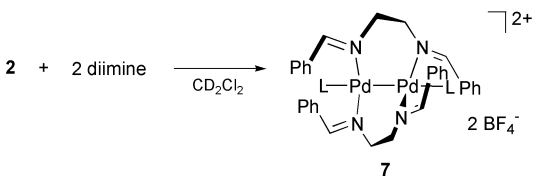
(3)

1,10-phenanthroline (phen) afforded $[Pd_2(phen)_2(CH_3CN)_2][BF_4]_2$ **6** [eqn. (4)].[11] ^1H NMR signals including non-



(4)

equivalent H^5 and $H^{5'}$ resonances showing H^5–$H^{5'}$ coupling (J 8.64 Hz). The coordination of CH_3CN in solution was confirmed by observation of a methyl resonance at δ 2.56. The reaction of **2** with *N*,*N*-ethylenebis(benzaldiimine) (diimine) afforded $[Pd_2(diimine)_2(CH_3CN)_2][BF_4]_2$ **7** [eqn. (5)].



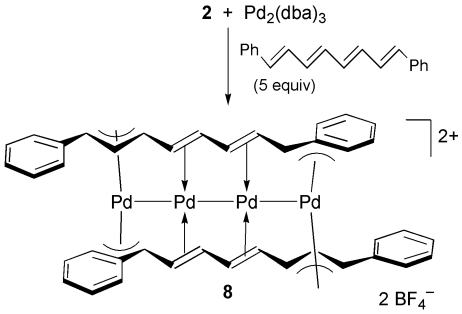
(5)

The observation of only one aldimine proton and carbon resonances suggests that the diimine ligands bridge over the Pd–Pd bond unlike phen in **6**. The ethylene proton resonances appearing as an AA′BB′ pattern suggest a chiral structure of **7** in solution arising from the non-planar Pd_2N_4 group.

Finally, to test the utility of the homoleptic acetonitrile dipalladium complex **2** as a 'naked' $[Pd–Pd]^{2+}$ building block of palladium clusters, we examined the preparation of palladium sandwich chains. Thus, the Pd_4 complex $[Pd_4(\mu\text{-}\eta^3:\eta^2:\eta^2:\eta^3\text{-}1,8\text{-diphenylocta-1,3,5,7-tetraene})_2][BF_4]_2$ **8**[12] was prepared

DOI: 10.1039/b004726k

(76% after recrystallization) [eqn. (6)] without formation of any



(6)

palladium black which was formed in considerable amounts in the previous method from **1**, 1.5 equiv. of $Pd_2(dba)_3$ and tetraene.

In summary, we have prepared the first homoleptic nitrile dipalladium(I) complex **2**. The nitrile ligands in **2** were proven to be substitutionally labile with the Pd–Pd bond remaining intact. Applications of **2** to catalysis as well as being a potential versatile building block towards palladium clusters are now under investigation.

Notes and references

‡ To a solution of $[Pd(CH_3CN)_4][BF_4]_2$ (1.00 g, 2.25 mmol) in CH_3CN (50 mL) was added $Pd_2(dba)_3{\cdot}CHCl_3$ (1.17 g, 1.13 mmol) and CH_2Cl_2 (50 mL). The mixture was stirred for 1 h at room temperature. The reaction mixture was filtered and poured into dry Et_2O to give an orange precipitate. After washing with Et_2O several times, **2** was obtained in 90% yield (1.28 g, 2.02 mmol). IR (Nujol): $\nu_{C\equiv N}$ 2331, 2307, 2282 cm^{-1}. Anal. Calc. (Found) for $Pd_2C_{12}H_{18}N_6B_2F_8$: C, 22.78 (22.65); H, 2.87 (2.92); N, 13.28 (13.03%).

A rearrangement-based approach to secondary difluorophosphonates

Afshan H. Butt, Jonathan M. Percy* and Neil S. Spencer

School of Chemistry, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT

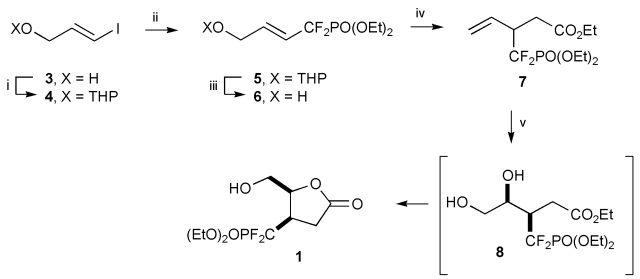
Received (in Liverpool, UK) 26th June 2000, Accepted 27th July 2000

[3,3]-Claisen rearrangements allowed the conversion of a readily available allylic difluorophosphonate to nucleic acid and inositol phosphate-related products *via* epoxide cyclisation or ring closing metathesis respectively.

Secondary hydroxy groups undergo phosphorylation in many of the key molecules of Nature. Inositols undergo phosphorylation and dephosphorylation events that are critical in intracellular signalling pathways while a phosphodiester linkage between primary 5′-hydroxy and secondary 3′-hydroxy groups provides the critical structural backbone of the nucleic acids. Oxygen atom replacement by a CF_2 centre has been used extensively as a mimetic strategy, replacing a scissile O–P bond with a non-scissile C–P bond, in the quest for enzyme inhibitors and molecular probes. A relatively limited range of target types has been synthesised; one of our major interests lies in expanding the range of species accessible using convenient methodology and starting materials. In this communication, we wish to show how a rearrangement-based route affords butyrolactone derivatives **1** (related to building blocks for nucleic acid analogues[1,2]) and cyclohexenone derivatives **2** (related to deoxyinositol phosphate analogues[3]). The approach complements our earlier conjugate addition[4,5] and cycloaddition[6] chemistry which was based upon chlorodifluoromethane as a feedstock.

Known alcohol **3** was prepared according to a modification of the published method[7] and protected as the THP ether **4**. Coupling under the Shibuya–Yokomatsu[8] conditions afforded a good yield of **5** which was deprotected smoothly to afford **6** (Scheme 1). Rearrangement under Johnson–Claisen conditions[9] was uneventful and alkenoate **7** could be isolated and purified rigorously. Overall, this sequence is synthetically equivalent to the selective addition at C_β of a difluoromethylphosphonate anion equivalent to an alkyl α,β,γ,δ-unsaturated dienoate.

To learn about the behaviour of the educt, dihydroxylation of **7** was attempted under a range of conditions, none of which were found to be satisfactory. Though starting material could be converted completely, apparently in a highly stereoselective manner, we were never able to isolate more than 11% of lactone **1**† formed *via* diol **8** (the configuration was inferred from that of **1**). The ^{19}F NMR spectrum of the crude product appeared to be that of a single diastereoisomer (as a racemic modification); the single product was identified as the 5-ring lactone **1** (by gradient HMBC) of *cis*-stereochemistry (by GOESY spectroscopy),



Scheme 1 *Reagents and conditions*: i, dihydropyran, Amberlyst-15, dry hexane, 86%; ii, $BrZnCF_2PO(OEt)_2$, CuBr, DMF, 96%; iii, MeOH, Amberlyst-15, hexane, 82%; iv, triethyl orthoacetate, propionic acid, hydroquinone, 140 °C, 86%; v, 10% OsO_4, 2.0 NMO, acetone–water (2 : 1), rt, 11%.

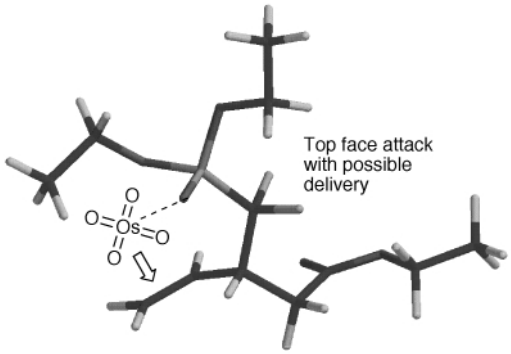


Fig. 1 Possible attack trajectory to explain the formation of lactone **1**.

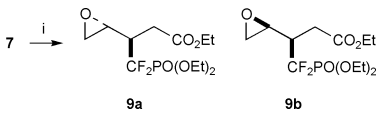
which showed a strong transfer of magnetisation from H-3 to H-4. Attack from the face occupied by the bulky (diethoxyphosphoryl)difluoromethyl group (Fig. 1) appears to have led to the observed product, suggesting a possible role for the phosphoryl P=O oxygen atom in delivering the reagent.[10]

We then tried to reverse the stereochemical relationship and obtain the *trans*-lactone by forming epoxide **9b** which would undergo nucleophilic ring-opening under acid catalysis, either intramolecularly with the ester carbonyl, or intermolecularly by traces of water in the medium (followed by cyclisation) to form the *trans*-lactone (Scheme 2).

Both reactions would involve a single inversion of configuration at the epoxide stereogenic centre. Epoxidation was very slow indeed under MCPBA or methyl trioxorhenium[11] conditions but the *in situ* dioxirane method of Yang[12] proved most effective and both epoxides **9a** and **9b** were obtained as an inseparable mixture in good (91%, **9a**:**9b** 1:2) yield.

However, treatment with Amberlyst-15 in dry dichloromethane[13] (Scheme 3) resulted in the isolation of only *cis*-lactone **1** in good (78%) yield.

A lower facial selectivity for oxidation with the smaller dioxirane reagent (which cannot coordinate to the phosphoryl oxygen either) was no surprise, but the convergence of the epoxides was unexpected. One epoxide (we believe **9a**) reacted considerably more quickly than the other and we were able to recover the less reactive species as a pure compound by careful ^{19}F NMR monitoring of the consumption of **9a**. The stereochemical convergence may involve neighbouring group participation by the phosphoryl oxygen in a double inversion mechanism *via* **10**; effectively, the all *cis*-epoxide **9b** must be opened with overall retention at the secondary carbon for the *cis*-lactone to form. Interestingly, an NMR sample of the less reactive epoxide in untreated $CDCl_3$ was converted to **1** and a trace of **11** upon standing. Neighbouring group participation by *thio*phosphoryl oxygen has been exploited to control glycosylation stereochemistry[14] but we are not aware of examples of a phosphoryl group exerting such an influence. Further under-



Scheme 2 *Reagents and conditions*: i, CF_3COCH_3, Oxone, $NaHCO_3$, Na_2EDTA, MeCN, H_2O, 91%.

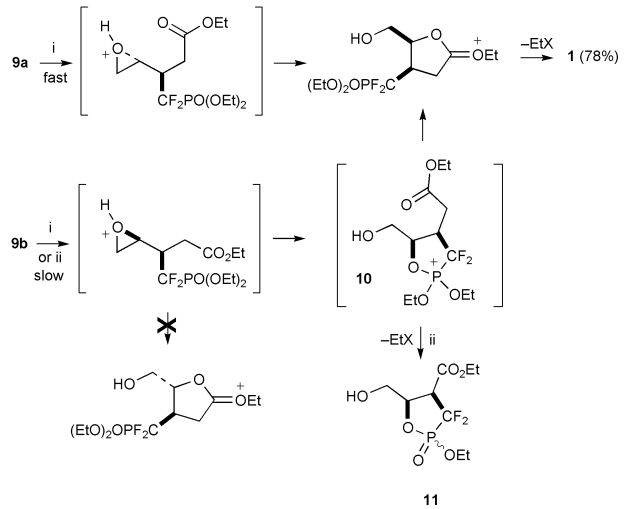
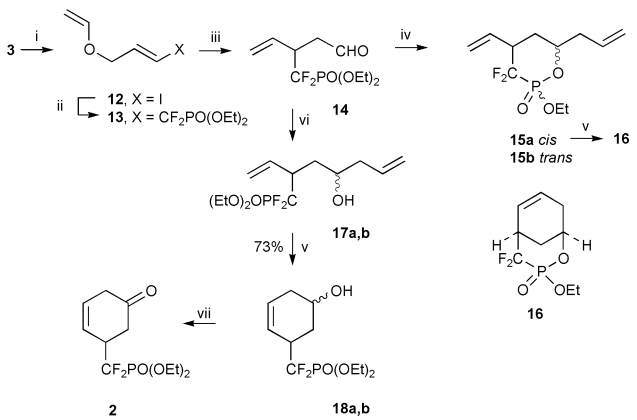


Scheme 3 *Reagents and conditions*: i, Amberlyst-15, dry DCM, rt; ii, $CDCl_3$, rt, 18 h.

standing of this process is sought currently, but clearly the direct cyclisation of **9b** *via* nucleophilic attack involving the ester carbonyl group is highly unfavourable.[15]

A change of tactics allowed access to an attractively functionalised cyclohexenone (Scheme 4); vinylation of **3** protected the hydroxy group as **12** for the Shibuya–Yokomatsu coupling allowing Dauben–Dietsche rearrangement[16] to proceed affording enal **14**.



Scheme 4 *Reagents and conditions*: i, ethyl vinyl ether, $Hg(OAc)_2$, reflux, 70%; ii, $BrZnCF_2PO(OEt)_2$, CuBr, DMF, 84%; iii, 140 °C, xylene, 75%; iv, allylmagnesium bromide, ethyl ether, 60% (1:1 ratio); v, Grubbs' catalyst, DCM, reflux, 48 h; vi, allyltrimethylsilane, $BF_3{\cdot}OEt_2$, DCM, rt, 83% (7:2 ratio); vii, PDC, DCM, rt.

Allylation under Grignard conditions afforded a pair (in a 1:1 ratio) of diastereoisomeric phosphodiesters **15a** and **15b**; slow (48 h) RCM under standard Grubbs' conditions[17] then closed the *cis* congener to yield **16** (64% by NMR) leaving the *trans* isomer **15b** unchanged. We inferred that cyclisation with loss of ethanol had occurred after Grignard addition. Boron trifluoride-catalysed (Sakurai) allylation with allyltrimethylsilane[18] afforded homoallyl alcohols **17a** and **17b** in a 7:2 ratio (unassigned) then RCM afforded a 7:2 mixture of cyclohexenols **18a** and **18b** which were converged by oxidation to **2**‡ with PDC. Enone **2** contains a pattern of functional groups from which four contiguous hydroxylated positions could be developed and we will explore its chemistry further.

The appeal of this strategy lies in the possibility of asymmetric catalysis of the [3,3] rearrangement controlling the absolute configuration of the mimetic-bearing carbon atom and the potential for a high degree of subsequent stereocontrol on the cyclohexene template. The products of this study are under evaluation as components for novel nucleoside and inositol phosphate analogues as we learn more about the steric and electronic effects of the mimetic group.

The authors wish to thank the Engineering and Physical Sciences Research Council of Great Britain for support (Quota Award to A. H. B).

Electrochemical reduction of oxygen on mesoporous platinum microelectrodes

Peter R. Birkin,* Joanne M. Elliott and Yvonne E. Watson

Department of Chemistry, University of Southampton, Southampton, UK SO17 1BJ. E-mail: prb2@soton.ac.uk

Received (in Cambridge, UK) 5th June 2000, Accepted 11th July 2000

The electrochemical reduction of oxygen is studied using electrochemically deposited mesoporous platinum microelectrodes, which exhibit efficient mass transfer of material to the electrode surface and accelerated reduction kinetics when compared to polished microelectrodes.

The reduction of molecular oxygen at the surface of an electrode is of considerable importance to many fields of research. Specific areas of interest include the quantitative analysis of oxygen concentration, the monitoring of enzymatic reactions and the conversion of chemical to electrical energy within a fuel cell. The mechanism for the reduction of molecular oxygen is known to be complex and dependent on the substrate employed.[1] In particular, two groups of substrates can be identified, those reducing oxygen to hydrogen peroxide through a 2 electron pathway[2,3] and those reducing oxygen to water through a 4 electron pathway.[4] In many instances it is desirable that the 4-electron pathway be selected. As an example, the reduction of molecular oxygen within a fuel cell is commonly achieved by a platinum-loaded high surface area cathode.[5] This choice is governed by platinum's superior catalytic activity. However, the performance of the platinum cathode is still limited at high potentials due to the formation of adsorbed species on the surface of the platinum metal.[1,6,7] These species inhibit oxygen reduction and reduce the operating potential of the electrode to around 0.8 V *vs.* RHE instead of the theoretical performance 1.229 V *vs.* RHE.[6,8] This limitation imposes a significant loss in the overall performance of the fuel cell, which has as yet to be fully addressed. It is reported here, for the first time, that Pt mesoporous modified microelectrodes have significantly altered oxygen reduction kinetics when compared to polished platinum microelectrodes of the same dimensions within the same solution.

Attard *et al.* first reported the use of a 'true liquid crystal templating technique' for the synthesis of mesoporous platinum powders (H_I-Pt) *via* the reduction of hexachloroplatinic acid (HCPA).[9]

Attard *et al.* also showed that it was possible to electrochemically produce mesoporous electrode materials and modified electrodes with a variety of nanostructures, for example, either hexagonal (H_I-ePt) or cubic (V_I-ePt) and that the dimensions of the mesoporosity could be finely tuned by varying the deposition conditions.[10–13]

Here we report the results of a study where the thickness of the mesoporous deposit is increased by controlling the deposition charge density. The results presented here are representative of a larger number of H_I-ePt modified microelectrodes studied. The subsequent effect on the mass transfer characteristics of the microelectrodes and electroreduction of molecular oxygen are now reported.

Electrodeposition was performed on a number of polished 25 μm diameter Pt microelectrodes sealed in glass. The platinum metal was deposited potentiostatically at a potential of −0.1 V *vs.* SCE from a template solution described previously.[10,12] Monitoring the charge passed during the deposition process enabled the amount of platinum metal deposited to be controlled. The control of the deposition conditions and charge enables the characteristics of the deposit to be chosen. Cyclic voltammograms of the H_I-ePt modified microelectrodes in 2 mol dm^{-3} sulfuric acid were performed and showed polycrystalline Pt characteristics as shown previously.[10,12] These voltammograms demonstrated that as the charge density is increased the surface area of the microelectrodes increases as expected. The voltammograms can be used to gain an estimate of the effective surface area of the Pt deposit by analysis of hydrogen UPD onto the surface.[10,13] Table 1 gives a summary of the effective surface roughness, R_f, of the deposit as a function of deposition charge within the template mixture. It can be seen that the surface area of the metal deposit scales approximately linearly with the charge density of the deposition process.

Microelectrodes were chosen for this project due to their unique properties which are related to their size.[14] Clearly as the electrodeposition proceeds the geometric characteristics could be altered by the H_I-ePt deposited. In order to test this we cycled the microelectrodes in a solution containing a suitable redox species. Fig. 1 shows the voltammetry of a series of microelectrodes within a solution containing $[Fe(CN)_6]^{3-}$ [16] and demonstrates that as the electrodeposition charge density was increased in the range 0 to 37.9 C cm^{-2} the reduction current for the redox species also increased. This indicates that the geometric area of the 25 μm Pt microelectrode has been effectively enlarged by the modification procedure. Further evidence for this change in geometric area is shown by the SEM image of one of the H_I-ePt modified microelectrodes (see insert in Fig. 1). This image shows that the deposit has spread over the surface of the glass insulator effectively increasing the geometric surface area. The SEM image also shows that the deposit is largely uniform and attached rigidly to the substrate surface. It is possible to calibrate the geometric surface area of the modified electrodes by comparing the average steady state current at −0.1 V *vs.* SCE for the electroreduction of $[Fe(CN)_6]^{3-}$ at a polished 25 μm Pt microelectrode and comparing this with the signal recorded with the H_I-ePt

Table 1 Measured parameters for the 25 μm diameter Pt microelectrodes investigated

Electrode	Deposition charge/μC	Real surface area/10^{-3} cm^2	R_f[a]	Effective diameter[a]/μm	$E_{1/2}$ O_2/mV[b]	n_{app}[c]
Polished (A)	—	0.01242	2.53	25	−422	2.36
H_I-ePt (B)	31	1.38	281	25.8	−219	3.82
H_I-ePt (C)	93	3.57	727	31.8	*ca.* −222	3.95
H_I-ePt (D)	186	5.69	1160	36.5	*ca.* −231	4.4

[a] R_f calculated by dividing the real surface area by the geometric area prior to modification. [b] vs. Hg/Hg_2SO_4. [c] The apparent number of electrons involved in the reduction of molecular oxygen, n_{app} was calculated from the current recorded at a potential of −0.5 V *vs.* Hg/Hg_2SO_4 for the H_I-ePt microelectrodes and −0.7 V *vs.* Hg/Hg_2SO_4 for the polished microelectrode (see Fig. 2).

DOI: 10.1039/b004468g

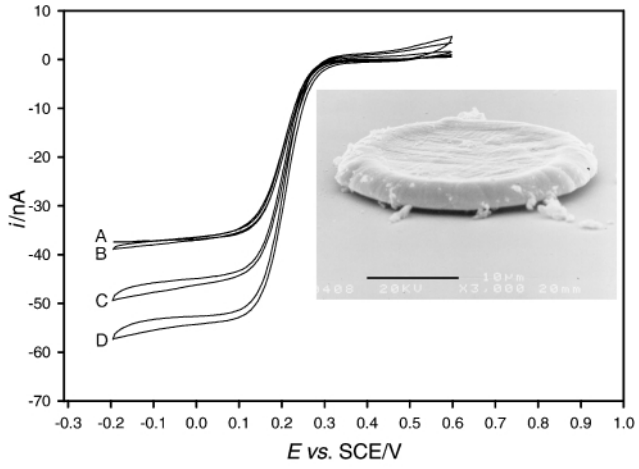

Fig. 1 Plot showing cyclic voltammograms recorded for a series of 25 μm Pt microelectrodes recorded at 2 mV s^{-1} in a solution containing 10 mmol dm^{-3} $K_3[Fe(CN)_6]$ in $Sr(NO_3)_2$ at 25 °C under anaerobic conditions; A, B, C, D as in Table 1. The insert in the figure shows a SEM image of the 93 μC H_I-ePt modified microelectrode recorded after the experiments were performed. The scale bar on the SEM represents 10 μm.

modified microelectrodes. This calibration shows that the effective geometric diameter changes in the range 25–37 μm for the thinnest and thickest film respectively. The actual values are shown in Table 1.

Turning to the activity of the H_I-ePt modified microelectrodes for oxygen electroreduction, a series of voltammograms were recorded in air-saturated pH 7 phosphate buffer. Fig. 2 shows the voltammetry recorded at 2 mV s^{-1} between +0.1 and −0.7 V *vs.* Hg/Hg_2SO_4. For comparison the electroreduction of oxygen under the same conditions on a polished 25 μm Pt microelectrode is included. A marked difference between the polished microelectrode and the H_I-ePt can clearly be seen. First, the plateau current for the H_I-ePt modified microelectrodes is consistently higher than at the polished microelectrode. It is possible to calculate the effective number of electrons involved in the reduction of oxygen on the polished Pt microelectrode as *ca.* 2 assuming an oxygen concentration[17] of 0.24 mmol dm^{-3} and a value for the diffusion coefficient of oxygen, *D*,[18] of 2.29×10^{-5} cm^2 s^{-1}. This is unusual for Pt, as normally the mechanism for electroreduction of molecular oxygen is stated as a 4 electron process. However, under the conditions employed in this study a consistent value of 2.36 electrons was obtained. The reason for this change is unclear but it is known that adsorption of ions[1,19,20] and high rates of mass transfer[18] can force the number of apparent electrons to fall below 4. Nevertheless the reduction

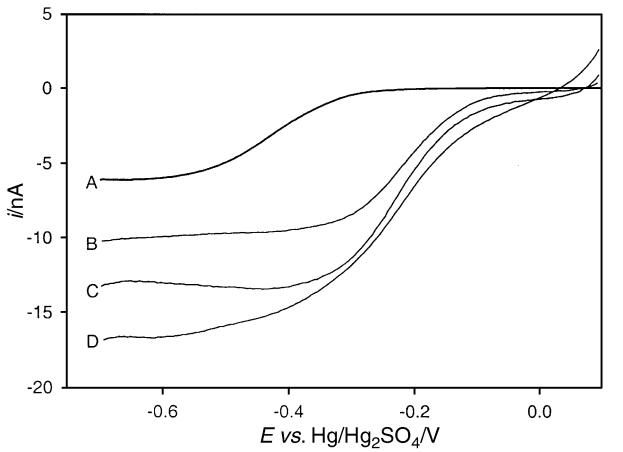

Fig. 2 Plot showing voltammograms recorded for a series of 25 μm Pt microelectrodes recorded at 2 mV s^{-1} in 0.2 mol dm^{-3} pH 7 phosphate at 25 °C under aerobic conditions; A, B, C, D as in Table 1.

of molecular oxygen on the H_I-ePt modified microelectrodes was associated with an increase in the plateau current to a value close to 4 electrons. Fig. 2 also shows that as the surface area of the deposit increased, the voltammogram became less well defined. This leads to some difficulty in accurately measuring the apparent number of electrons involved in the reaction for the thicker films studied. This distortion was attributed to the rising background signal associated with surface reactions on the increasingly large Pt surface. The anodic current supports the distortion, presumably due to oxide formation, above 0.0 V *vs.* Hg/Hg_2SO_4 for the larger surface area microelectrodes. Cyclic voltammograms (not shown) in the absence of oxygen also support these findings. Second, the reduction of molecular oxygen at the H_I-ePt proceeds at a considerably more positive potential *ca.* −219 mV *vs.* Hg/Hg_2SO_4 for the 31 μC H_I-ePt modified microelectrode compared to *ca.* −422 mV *vs.* Hg/Hg_2SO_4 for the polished microelectrode. However, increasing the surface area of the deposit further by increasing the deposition charge did not significantly shift the reduction wave to more positive potentials. In these cases the inhibition of oxygen reduction by adsorbed species is presumably still the predominant factor and increasing the surface area further has no beneficial kinetic effect. However, the increase in apparent number of electrons involved in the reaction and the improved kinetics of oxygen reduction, point to these materials being of potential use in either analytical chemistry or fuel cell technology. It is important to remember that these materials are electrodeposited onto the surface and as such are adherent and mechanically robust. Additionally the current densities, due to the unique mass transfer characteristics of microelectrodes, are of the order of 1.95 mA cm^{-2} for a catalyst loading calculated to be 1.29 mg cm^{-2} at 25 °C under stagnant conditions. This calculation assumed a maximum deposition efficiency of *ca.* 43%.[12]

Received (in Cambridge, UK) 3rd July 2000, Accepted 28th July 2000

Scandium(III) triflate catalysed Friedel–Crafts alkylation of aromatic compounds with alkenes proceeded readily in the hydrophobic ionic liquid solvents based on 1,3-dialkylimidazolium salts with easy catalyst/solvent recycling, whereas these reactions did not occur in common organic solvents, water or hydrophilic ionic liquids at all.

The Friedel–Crafts alkylation of aromatic compounds with alkenes is of great synthetic significance in view of laboratory synthesis and particularly industrial production.[1] For example, a number of important industrial processes for ethylbenzene, cumene and linear alkylbenzenes, *etc*. are based on this reaction. In general, this type of reaction is catalysed by $AlCl_3$, H_2SO_4, HF and other acid catalysts. However, a common problem, particularly in industrial processes, is that catalysts cannot be reused after the usual aqueous work-up.

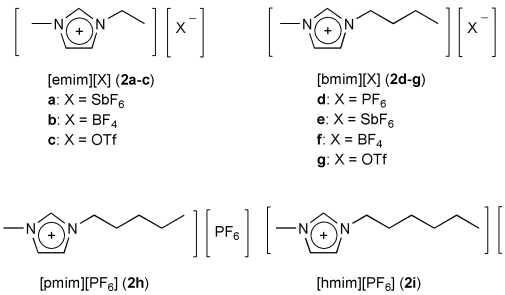
Recently, considerable attention has been focused on the catalytic use of rare earth(III) (RE) salts, especially, RE(III) trifluoromethanesulfonates [$RE(OTf)_3$] as water-tolerant and recyclable Lewis acid catalysts in carbon–carbon bond forming reactions.[2] The RE(III) compound-catalysed Friedel–Crafts alkylations of aromatic compounds using alcohols, mesylates, halides, aldehydes, acetals, *etc*. as alkylating agents have also been reported.[3] However, to the best of our knowledge, there has been no previous report on the use of $RE(OTf)_3$ for the Friedel–Crafts alkylation of aromatics using alkenes as alkylating agents.

We disclose here our preliminary results on the Friedel–Crafts alkylation of aromatics with alkenes using a novel and recyclable catalytic system, $Sc(OTf)_3$ immobilised in air and moisture-stable rt ionic liquids.[4]

To examine the catalytic effect of lanthanide trifluoromethanesulfonates, we first carried out the alkylation of benzene with hex-1-ene in the presence of 20 mol% of $Sc(OTf)_3$ in various organic solvents (none, CH_2Cl_2, acetonitrile, nitromethane and nitrobenzene) or H_2O at 20 °C for 12 h. However, in all cases neither alkylation nor olefin isomerisation took place at all (Table 1, entries 1–6). It is therefore not surprising that there has been no report on the use of $RE(OTf)_3$ for the Friedel–Crafts alkylation of aromatics using alkenes as alkylating agents so far.

Very interestingly, however, when the same reaction was carried out in air and moisture-stable rt ionic liquids consisting of 1,3-dialkylimidazolium cations and their counter anions **2**,[5] [emim][X] ([emim]$^+$ = 1-ethyl-3-methylimidazolium cation; X = SbF_6 (**2a**), BF_4 (**2b**), OTf (**2c**)), [bmim][X] ([bmim]$^+$ = 1-butyl-3-methylimidazolium cation; X = PF_6 (**2d**), SbF_6 (**2e**), BF_4 (**2f**)and OTf (**2g**)), [pmim][PF_6] ([hmim]$^+$ = 1-pentyl-3-methylimidazolium cation; **2h**) and [hmim][PF_6] ([hmim]$^+$ = 1-hexyl-3-methylimidazolium cation; **2i**), we obtained quite satisfactory results in some cases. In this reaction, the catalytic activity of $Sc(OTf)_3$ was strongly influenced by the nature of the anion [X].

When the hydrophobic ionic liquids such as the [emim][SbF_6] (**2a**), [bmim][PF_6] (**2d**), [bmim][SbF_6] (**2e**),



[pmim][PF_6] (**2h**) or [hmim][PF_6] (**2i**) were used, the desired alkylated products were obtained quantitatively, although $Sc(OTf)_3$ is only slightly soluble and thus exists as a suspended form in these ionic solvents (Table 1, entries 7, 10, 11, 14 and 15).† It is noteworthy here that the rearrangement of alkene takes place prior to the ring substitution, which indicates that the carbonium ion is formed first. Polarity of these ionic solvents leads to the stabilisation of the polar cationic intermediate. In sharp contrast to these results, in the hydrophilic ionic liquids, [emim][BF_4] (**2b**), [emim][OTf] (**2c**), [bmim][BF_4] (**2f**) or [bmim][OTf] (**2g**), the catalyst was highly soluble and thus totally immobilised in these ionic liquids, but the reaction did not occur at all (Table 1, entries 8, 9, 12 and 13). Thus, we next

[a] Reaction conditions: hex-1-ene (1 mmol), benzene (2 mL), $Sc(OTf)_3$ (0.2 mmol), solvent (1 mL), 20 °C, 12 h. [b] Conversions and yields based on hex-1-ene were determined by the internal standard method in GC.

DOI: 10.1039/b005335j

Table 2 $Sc(OTf)_3$ catalysed Friedel–Crafts alkylation of benzene with various alkenes in the ionic liquid **2e**[a]

Entry	Aromatic compound	Alkene	Product	Conversion[b] (%) of alkene	Yield[b] (%) of monoalkylated product
1	Benzene			>99	93[c]
2	Benzene			>99	84
3	Benzene			>99	90
4[d]	Benzene			>99	92
5[e]	Benzene			>99	92
6	Benzene			>99	65
7	Phenol			>99	93[f]
8	Anisole			>99	85[g]

[a] Reaction conditions: alkene (1 mmol), benzene (2 mL), $Sc(OTf)_3$ (0.2 mmol for entries 1–6 and 0.1 mmol for entries 7–8), the ionic liquid **2e** (1 mL), 20 °C, 12 h. [b] Conversions and yields based on alkene were determined using the internal standard method in GC. [c] **a**:**b** = 1.5:1. [d] Reaction was carried out with the ionic liquid **2e** containing $Sc(OTf)_3$ recovered from the reaction in entry 3. [e] Reaction was carried out with the ionic liquid **2e** containing $Sc(OTf)_3$ recovered from the reaction in entry 4. [f] The ratio of *ortho* to *para* product is *ca.* 2.5:1. [g] The ratio of *ortho* to *para* product is *ca.* 1.8:1.

examined Friedel–Crafts alkylation of other substrates only using the ionic liquid **2e**. As shown in Table 2, in all cases the reaction proceeded smoothly to furnish the corresponding alkylation products in quantitative yields. Moreover, the ionic liquid phase containing $Sc(OTf)_3$ was almost quantitatively recovered by simple decantation of the organic layer (the upper phase) after reaction. Second and third reactions of benzene with cyclohexene using the recovered ionic liquid **2e** containing catalyst afforded quantitative yield of cyclohexylbenzene (Table 2, entries 4 and 5).

In a typical reaction, the alkene and aromatic compound are added to the ionic liquid **2e** containing 20 mol% of $Sc(OTf)_3$ directly. Two phases are formed and the mixture is stirred at 20 °C for 12 h. The organic layer is separated to leave the ionic liquid phase containing the catalyst which can be reused.

In summary, Friedel–Crafts alkylation of aromatic compounds with alkenes using the novel reusable catalytic system, $Sc(OTf)_3$-ionic liquid, has been developed. The simple procedures, easy recovery and reuse of this novel catalytic system are expected to contribute to development of benign and waste-free chemical processes for Friedel–Crafts alkylation of aromatics with alkenes.

Notes and references

† $Y(OTf)_3$ (16%), $Ho(OTf)_3$ (16%), $Tm(OTf)_3$ (11%), $Lu(OTf)_3$ (64%) also catalysed the reaction of benzene with cyclohexene in the ionic liquid **2e**. However, the yields of the cyclohexylbenzene were significantly inferior to that with $Sc(OTf)_3$. All other lanthanide(III) triflates were inactive under the same reaction conditions. These results can be ascribed to the stronger Lewis acidity of $Sc(OTf)_3$ than that of lanthanide analogues.

Natural photosynthetic systems collect sunlight using a vast array of light-harvesting chromophores that channel the absorbed energy to a single reaction center. Recently, it has been realized that dendritic macromolecules can exhibit similar properties, though on a more modest scale. The preparation of dendritic structures and assemblies composed of numerous light-collecting chromophores that transfer their energy to a single energy 'sink' at the core has been achieved in a number of diverse and creative ways. These novel structures are being used as model systems in light-emitting diodes, signal amplifiers, fluorescent sensors, frequency converters, and other photonic devices.

Introduction

It has been estimated that the average yearly incidence of solar radiation at the earth's surface amounts to several orders of magnitude more energy than is consumed by its population.[1] Clearly, harnessing this energy is an important endeavor that will reduce our dependence on fossil fuels. Indeed, our own existence depends on light-harvesting by the plethora of photosynthetic organisms in the biosphere. These organisms have evolved intricate and extremely efficient mechanisms for the transduction of light into chemical energy in the form of ATP.[2] If we are to utilize sunlight in a similar fashion, it is not unreasonable to borrow some design concepts from structures that have evolved over billions of years.

To date, the most studied of all photosynthetic systems is probably that of purple bacteria.[3] The high resolution X-ray crystal structure of the photosynthetic unit (PSU) reveals a central reaction center (RC) that is surrounded by light-harvesting (LH) complexes (Fig. 1).[4] The LH1 complex is composed of a ring-shaped assembly of chlorophyll and carotenoid moieties embedded in a protein matrix that immediately surrounds the RC. Similar ring-shaped assemblies, somewhat further removed from the RC, make up the LH2 and LH3 complexes.[3] The role of these chlorophyll-containing assemblies is that of an antenna, absorbing photons that strike the relatively large surface area that they cover. Remarkably, the energy of any photon that strikes any of the several hundred chlorophylls within the extensive LH system is transferred to the RC with unit efficiency.[3]

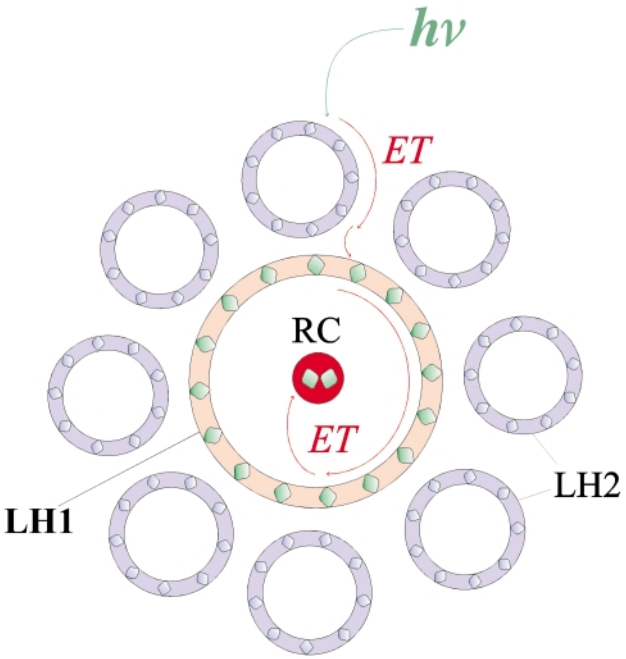

Fig. 1 Schematic representation of bacterial light-harvesting complexes (LH1 and LH2), showing the different protein-embedded light-absorbing porphyrins arranged in circles around the reaction center (RC). The path of energy transfer (ET) is indicated by arrows.

Dendrimers are perfectly branched synthetic macromolecules having numerous chain ends all emanating from a single core.[5–8] Their synthesis, first reported in 1985 by the groups of Tomalia[9] and Newkome,[10] involves a divergent iterative coupling and activation protocol[9–12] that results in the formation of concentric layers of building blocks terminated by a large number of reactive moieties. The convergent synthesis we introduced later[13] provides for growth through a single focal point, an approach that affords even better control over both the dendrimer backbone structure and the placement of functional groups within it. Overall, the accurate positioning of chromophores can be achieved, locating them at the core, focal point, periphery, or even at each branching point of the dendritic structure (Fig. 2). This schematic diagram of a dendrimer is reminiscent of the architecture of natural light-harvesting complexes, where antenna molecules surround the central RC. Although the appropriate placement of chromophores is

Alex Adronov was born in Kaunas, Lithuania in 1973 and moved to Windsor, Ontario, Canada in 1980 with his family. He received a BSc degree in Biological Chemistry from McMaster University in 1996. Currently, he is pursuing a PhD at the University of California, Berkeley, under the supervision of Professor Jean M. J. Fréchet.

Jean M. J. Fréchet obtained his first degree at the Institut de Chimie et Physique Industrielles (now CPE) in Lyon, France, and PhD degrees from the College of Environmental Sciences and Forestry and Syracuse University. Following academic appointments at the University of Ottawa (1973–86) and Cornell University (1987–96), he joined the Department of Chemistry at the University of California, Berkeley. J. Fréchet received both the American Chemical Society awards in Polymer Chemistry and in Applied Polymer Science; in 2000 he was elected a Fellow of the American Academy of Arts and Sciences, a member of the National Academy of Engineering, and a member of the National Academy of Science.

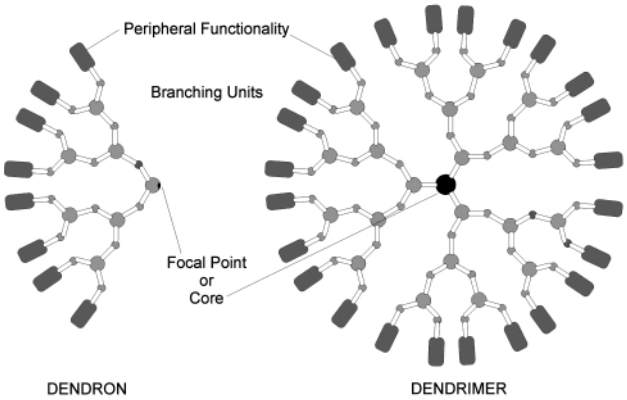

Fig. 2 Schematic diagram of the structure of a dendron and a dendrimer, highlighting the focal point or core (black) surrounded by rings of branching units (gray circles) and end-groups (rectangles).

important, judicious choices must be made both for the selection of the chromophores themselves, and for the design of each successive layer in order to maximize favorable energy transfer interactions.

Over the past several decades, there has been much work done on a number of synthetic light-harvesting complexes in which energy transfer is demonstrated. After a brief introduction to energy transfer, this article will focus on the more recent dendrimer-based light-harvesting structures.

Energy transfer and the choice of chromophores

In a bichromophoric system where one chromophore (the energy donor, D) is in its excited state and the other (the energy acceptor, A) is in its ground state, energy transfer can occur such that the donor returns to its ground state simultaneously with the promotion of the acceptor to its excited state (Fig. 3).[14] This

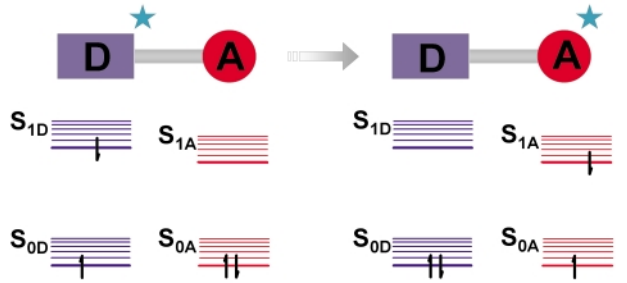

Fig. 3 The process of energy transfer involves the migration of excitation energy from an excited-state donor (D) to a nearby ground-state acceptor (A).

transfer can occur by either a through-bond[15] (Dexter) or through-space[16,17] (Förster) mechanism. In the former, an electron exchange occurs from the S_1 state of the donor to the S_1 state of the acceptor, with a simultaneous exchange of an S_0 electron from acceptor to donor (Fig. 3). This electron exchange requires strong D–A orbital overlap and is therefore a short-range (< 10 Å) interaction that diminishes exponentially with distance.[14] The rate constant for this process is described by eqn. (1):

$$k_{ET} = KJ\exp(-2R_{DA}/L) \quad (1)$$

where K is related to the specific orbital interactions, J is the spectral overlap integral (see below) normalized for the extinction coefficient of the acceptor, and R_{DA} is the donor–acceptor separation relative to their van der Waals radii, L.[14]

In contrast, the Förster mechanism does not require electron exchange and is rather a through-space dipole–dipole interaction.[18] In this case, D–A orbital overlap is not necessary, allowing the chromophores to be separated by a relatively large distance (10–100 Å). The Förster energy transfer rate constant is described by eqn. (2):

$$k_{ET} = \frac{9000(\ln 10)\kappa^2\phi_D J}{128\pi^5 n^4 N\tau_D R_{DA}^6} \quad (2)$$

where κ^2 is the orientation factor (related to the relative orientation of the donor and acceptor transition dipole moments), ϕ_D is the donor quantum yield in the absence of the acceptor, J is the overlap integral, n is the index of refraction of the solvent, N is Avogadro's number, τ_D is the donor lifetime in the absence of the acceptor, and R_{DA} is the inter-chromophoric distance in cm. The overlap integral J ($cm^6\ mol^{-1}$) is given by eqn. (3):

$$J = \int f_D(\nu)\varepsilon_A(\nu)\nu^{-4}d\nu \quad (3)$$

where $f_D(\nu)$ is the fluorescence intensity of the donor, $\varepsilon_A(\nu)$ is the molar extinction coefficient of the acceptor, and the integral is calculated over the whole spectrum with respect to the frequency expressed in wavenumbers. This integral represents the overlap between the donor emission spectrum and the acceptor absorption spectrum, and is closely related to the probability of energy transfer from the donor to the acceptor.

Unlike the Dexter interaction, where normalization of J diminishes its significance, Förster energy transfer is greatly influenced by this parameter.[14] In addition, the transition dipole moments of the interacting chromophores play a large role in the energy transfer efficiency of the through-space mechanism.[18] Hence, the bridging moiety plays a crucial role in Dexter energy transfer, where rigidity and conjugation are the key parameters, whereas the properties of the chromophores themselves (transition dipole moments and spectral overlap of donor emission and acceptor absorption) as well as the interchromophoric distance play the more important role in Förster energy transfer.

Within dendritic structures, practically all of the above parameters can be controlled and varied. Chromophore functionalization of the dendrimer can involve only the core and the end-groups, or it can involve the entire dendrimer backbone. The rigidity, conjugation, size, and polarity of the dendritic backbone all depend on the type of branched monomer that is utilized. Hence, the choice of the monomer will affect the overall properties and the energy transfer mechanism of the dendritic system. As the dendrimer generation increases, two competing factors become prevalent (Fig. 4). The number of

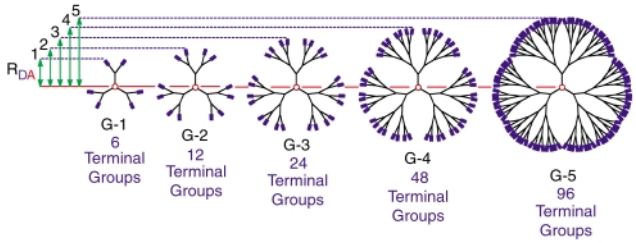

Fig. 4 As dendrimer generation increases, the number of terminal groups doubles, but the distance between the terminal groups (energy donors) and the core (energy acceptor) also increases.

monomer units, closely reflected by the number of end-groups surrounding the core, doubles with each successive generation, and the distance between the core and the end-groups increases. If each branching point or end-group acts as a chromophore, then increasing the generation allows for the harvesting of increasing amounts of light by the molecule. However, at a certain dendrimer generation, or size, it is expected that R_{DA} will become too large to sustain efficient energy transfer. It is thus necessary to reach a balance between the light-harvesting capacity of the dendritic shell, and the energy transfer efficiency to the core.

In the following paragraphs, some key examples of light-harvesting dendrimers will be highlighted.

Chromophoric dendrimer backbones and the role of an energy gradient

The initial reports of multichromophoric dendrimers undergoing intramolecular energy transfer were published by Balzani and coworkers in 1992.[19,20] Their 'complexes as metals/complexes as ligands' strategy provided a means of selectively incorporating different metal and ligand combinations into these low-generation dendrimers. Ru and Os were the metals of choice in this work owing to the ideal luminescence and redox properties of their polypyridine complexes.[20,21] The schematic representation of these molecules (Fig. 5) indicates the presence

	M_c	M_i	M_p
1	Ru	Ru	Ru
2	Os	Ru	Ru
3	Os	Ru	Os
4	Ru	Ru	Os

Fig. 5 (a) Schematic representation of metallodendrimers having branching ligands and different combinations and positions of Ru and Os metals. (b) Direction of energy transfer (indicated by arrows) in the different structures depicted in (a). ● = Ru, ■ = Os.

of three distinct metal-binding positions: a single core site; three intermediate sites; and six peripheral sites. In addition, it is well known that the oxidation potential of the metal ion in these polypyridyl complexes can depend on the nature of the coordinated ligands.[21] Hence, bandgap energies of the metal complexes located at the different sites (core, intermediate, and peripheral) within the dendrimer are controlled by both the nature of the metal (Ru complexes have larger bandgap energies than the corresponding Os complexes) and the nature of the surrounding ligands. Balzani and coworkers showed that metal complex bandgap energies depend on the ligands in the order dpp > biq > bpy.[22] Indeed, it was found that energy transfer in the all-Ru compounds (**1**) occurred from the internal higher energy units (dpp ligands) to the external lower energy units having bpy or biq ligands.[20] In the heterometallic complexes, energy migration predominantly occurred from the Ru-containing units to the Os-containing units. Hence, controlled energy migration from the internal units to the external units could be achieved by complexes **1** and **4**. Conversely, energy migration from the dendrimer periphery to the core was more difficult to achieve owing to the lower energy of the outermost complexes *vs*. the intermediate ones [Fig. 5(b)].

In all of these structures, energy transfer is dominated by the Dexter electron exchange mechanism,[20,23] which precludes long-range interactions between the periphery and the core. Indeed, in the third-generation structure having an Os core, it was again shown that energy migrates from the intermediate higher bandgap units to the lower bandgap units at either the periphery or the core.[24,25] Although the concept of intramolecular energy transfer within dendritic structures was clearly illustrated by these initial reports, the structures synthesized did not ideally function as photosynthetic mimics, where numerous peripheral light-harvesting chromophores channel absorbed energy in a unidirectional manner to a single, central, energy acceptor complex.

Efficient, unidirectional energy transfer from a dendritic framework to a single core chromophore was first reported in elegant work by Xu and Moore.[26] The robust, high-yielding synthesis of their phenylacetylene dendrimers allowed for the preparation of high-generation (G-*n*) molecules, up to G-6.[27,28] These cross-conjugated structures (Fig. 6) exhibit strong UV

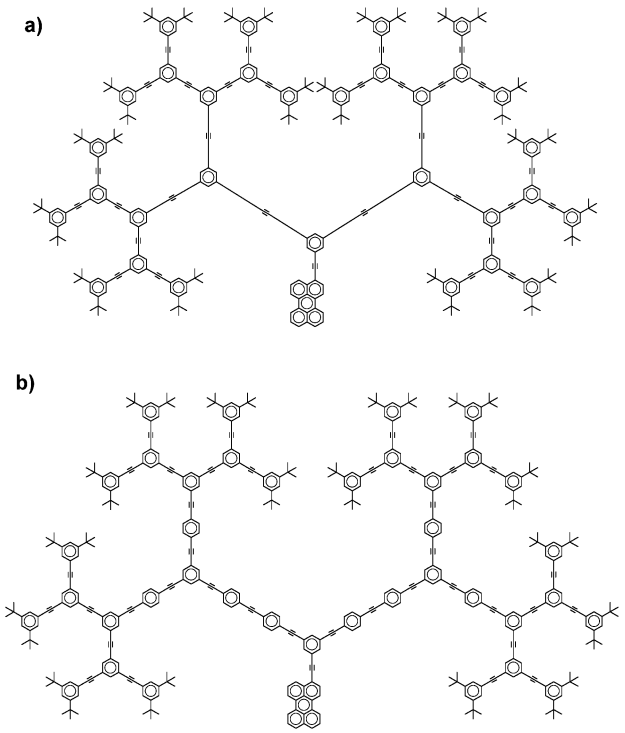

Fig. 6 Chemical structure of perylene-functionalized phenylacetylene dendrimers without (a) and with (b) an energy gradient.

absorption features in the 250–350 nm range that double in magnitude with increasing generation.[29] Additionally, it was found that these dendrimers act as luminescent chromophores that have an emission in the 350–450 nm range. By functionalizing the core of these structures with the lower bandgap perylene chromophore, the authors introduced an energy 'sink' into the system. Hence, the phenylacetylene monomer units act as the peripheral energy donors, and the perylene acts as the central energy acceptor. Excitation of the dendrimer backbone at 312 nm resulted in emission emanating solely from the perylene dye (450–600 nm), with nearly complete quenching of the dendrimer emission.[29]

Further, the versatile synthetic scheme allowed for the synthesis of dendrimers having a directional energy gradient, with the bandgap energy of each branch decreasing owing to increasing conjugation length [Fig. 6(b)].[30,31] Interestingly, it was found that this energy gradient dramatically increases (by two orders of magnitude) the energy transfer rate constant within the dendrimer.[29] Hence, the directional energy transfer from periphery to core must be greatly facilitated by the built-in energy gradient. Indeed, theoretical work by Klafter and coworkers afforded the same conclusion, suggesting that 'random walk' energy transfer from periphery to core, as in the former structures, is much less productive than the directional multi-step process.[32–34] These structures represent the first examples of effective photosynthetic mimics, and the latter molecules remain the *only* example of built-in multi-step energy gradients within dendritic macromolecules. However, the mechanism of energy transfer in these systems was difficult to ascertain. Owing to the cross-conjugated dendrimer backbone, orbital overlap contributions to the energy transfer cannot be ruled out. In addition, spectral overlap between donor emission and acceptor absorption is not very large in this case, and would

preclude the Förster mechanism alone from producing in the high energy transfer efficiencies that were observed.

Poly(benzyl ether) dendrimers and the 'antenna effect'

Several years ago our group studied the encapsulation of lanthanide ions (Ln^{3+}) by dendritic ligands in the context of a possible application for optical signal amplification. The impetus for this project originated from the self-quenching of fluorescence by lanthanide ions, such as erbium, when they are clustered together in the solid state. This self-quenching limits their effectiveness as signal amplifiers for optical fiber communications, since the poor solubility of Ln^{3+} ions in substrates such as silica leads to the formation of ion clusters.[35,36] Encapsulation of individual Er^{3+} and Tb^{3+} ions within a dendritic shell (Fig. 7) was expected to lead to their

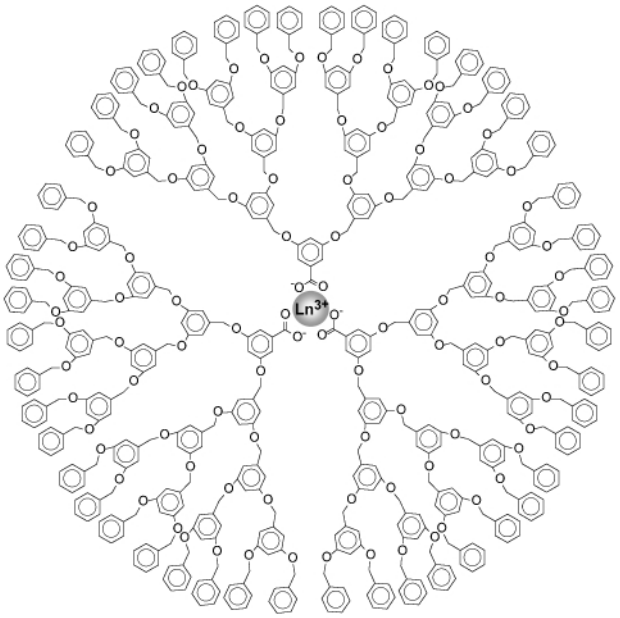

Fig. 7 Structure of a lanthanide-cored poly(benzyl ether) dendrimer.

site-isolation, thereby increasing interchromophoric distance and decreasing the self-quenching effect. Indeed, this site-isolation was realized by self-assembly of suitably functionalized carboxylate-cored dendrons around the lanthanide ion, and the resulting assemblies possessed all the characteristics desired for use in signal amplification. During the course of photophysical studies on these ionically bound supramolecular assemblies, it was found that irradiation at wavelengths where the dendrimer backbone absorbed (280–290 nm) resulted in strong luminescence from the lanthanide core.[37,38] Apparently, energy absorbed by the peripheral dendrimer shell was efficiently transferred to the luminescent Ln^{3+} at the focal point by a mechanism postulated to be of the Förster type. At these wavelengths, energy transfer to Tb^{3+} was found to be more efficient than in the case of Er^{3+}, likely due to the better overlap of dendrimer emission with Tb^{3+} absorption. This channeling of excitation energy from a dendrimer shell to a single core unit was termed the 'antenna effect'. Interestingly, it was also found that this energy transfer phenomenon was critically dependent on the substitution pattern within the dendritic shell. When the isomeric dendrons having 2,5- rather than 3,5-substitution at the focal aromatic ring were utilized, the energy transfer interaction practically disappeared.

Several other research groups have observed similar antenna effects while utilizing different luminescent cores. Jiang and Aida reported that singlet energy transfer could be observed from the same Fréchet-type poly(benzyl ether) dendrons to a core porphyrin ring (Fig. 8).[39] A variety of structures, differing

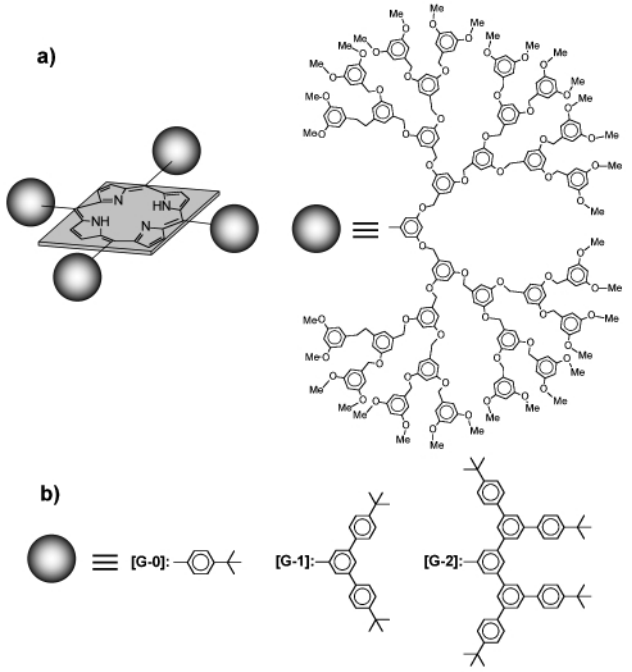

Fig. 8 Schematic representation of porphyrins encapsulated by (a) poly(benzyl ether) dendrimers, and (b) 1,3,5-phenylene-based dendrimers.

in the number of dendrons attached to the central porphyrin, as well as in the generation number of the dendrons, were prepared and studied. A small amount of overlap between the fluorescence spectrum of the dendrons and the Soret absorption of the porphyrin allows for some degree of energy transfer to occur. Indeed, excitation of the tetra-substituted dendritic porphyrin at 280 nm (dendrimer absorption) resulted in quenching of the dendrimer emission (310 nm), with most of the light being emitted by the porphyrin core (600–750 nm). The energy transfer efficiency in both the G-4 and G-5 analogs was calculated to be approximately 80%. However, if the porphyrin was only partially substituted, with one, two, or three G-5 dendrons instead of four, the energy transfer efficiency dropped dramatically, to 10, 20 and 32%, respectively. Similar phenomena were also observed when G-4 dendrons were used. Temperature-dependent effects indicated that increased flexibility and conformational freedom were responsible for the decreased energy transfer efficiency. Only the highly crowded molecule having four G-5 dendrons retained a constant level of energy transfer, even at high temperatures. It was also postulated that cooperativity between dendrons is necessary for efficient energy transfer, and this cooperativity appeared to decrease with increasing conformational mobility.

A slight variation of this work was recently published by Kimura *et al*., who synthesized low-generation (G-1 and G-2) 1,3,5-phenylene-based dendritic porphyrins [Fig. 8(b)].[40] Interestingly, the authors found that energy transfer between the dendrimer and the porphyrin was highly efficient at low generations. This seemingly contradictory result may be rationalized by the fact that the energy transfer mechanism may be different in these cross-conjugated molecules than for the dendrimers of Aida and coworkers.[39] Additionally, the authors point out that the spectral overlap between the emission of the dendrons and the absorption of the porphyrin core is larger in this case, which may also have a significant effect on the energy transfer efficiency.

In a more recent publication, Aida and coworkers reported the encapsulation of a poly(phenyleneethynylene) rigid-rod polymer by a poly(benzyl ether) Fréchet-type dendrimer shell.[41] The dendritic shell was again effective as both a steric 'bumper' preventing polymer chains from aggregating, and as a light-harvesting antenna. The authors showed that upon direct

excitation of the polymer backbone, the fluorescence quantum yield remained constant over a wide concentration range only if a large enough dendrimer envelope, composed of G-4 dendrons or higher, was utilized. Additionally, excitation of the dendritic shell at 278 nm resulted in complete quenching of dendrimer emission, and a high fluorescence intensity emanating from the conjugated polymer. It was found that this sensitized polymer fluorescence was greatly enhanced over the emission resulting from direct excitation of the polymer at 425 nm, again illustrating the dendrimer 'antenna effect'. Owing to the importance of such conjugated polymers in organic light-emitting diode (OLED) technology, these findings could have a significant impact on the future of LED devices.

In a separate report, Jiang and Aida have demonstrated an unusual acceleration of the *cis–trans* isomerization within an azobenzene moiety at the core of G-4 and G-5 poly(benzyl ether) dendrimers.[42] This acceleration was observed under low-flux IR irradiation of a stretching vibrational band of the aromatic rings at 1597 cm^{-1}. Interestingly, irradiation at different IR frequencies, such as 2500 or 1155 cm^{-1} resulted in no apparent acceleration above the thermal rate. Additionally, when low-generation dendrimers were utilized, the acceleration was not apparent. Any change in substitution, such as in the mono-dendritic analog (Fig. 9), also eliminated the acceleration.

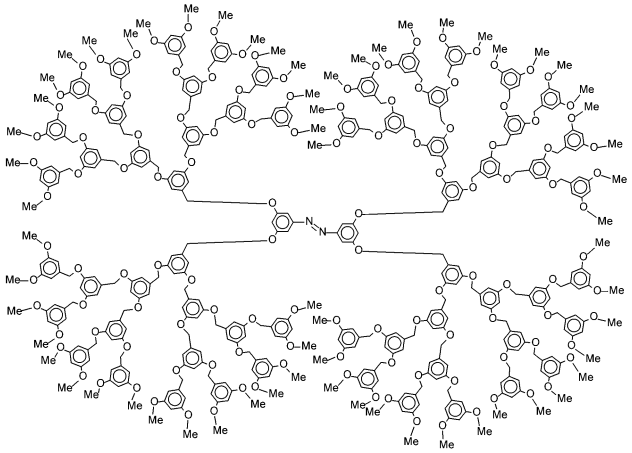

Fig. 9 Structure of a G-5 azobenzene-cored dendrimer.

This latter point is not surprising in light of our own work on encapsulated lanthanide ions (*vide supra*) in which the critical dependence of energy transfer on the substitution pattern of the focal aromatic ring was demonstrated. However, UV irradiation of the dendrons at 280 nm did result in a similar acceleration. In order to rationalize these observations, the authors proposed that the dendritic shell not only insulates the azobenzene core from collisional energy dissipation, but also acts as a photon-harvesting antenna. By comparison with thermally induced accelerations at 60 °C and by determining the dependence of the isomerization rate constant on the applied photon flux, it was found that the energy required for the observed rate acceleration required the simultaneous delivery of the energy of 4.9 IR photons to the azobenzene core. This calculation is consistent with the observed requirement of high-generation dendrons, since the simultaneous absorption of multiple photons from such weak photon sources could only be plausible in extremely large molecules.

Using a different approach, Stewart and Fox[43] utilized the known photoinduced electron transfer interaction between aryl chromophores (naphthyl or pyrenyl) and tertiary amines.[44] Since it is well known that excited states of aryl chromophores are quenched by electron donating amines, it was postulated that excitation of the periphery of dendrimers having naphthyl or pyrenyl groups at their chain ends and an amine at the core, would lead to intramolecular electron transfer through the dendrimer backbone (Fig. 10). Indeed, fluorescence quenching

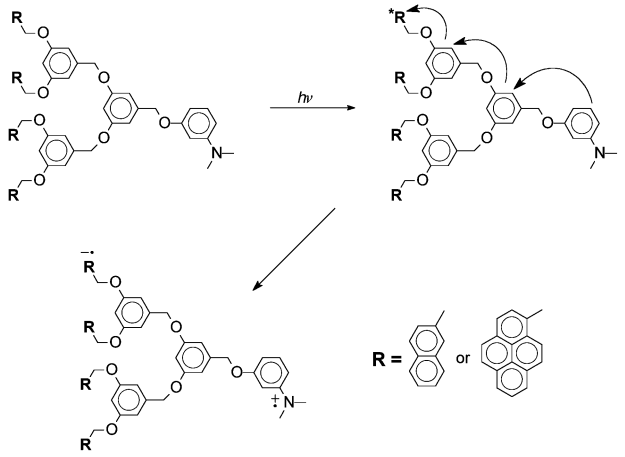

Fig. 10 Illustration of the electron transfer process occurring through the dendrimer backbone as a result of photoexcitation of the peripheral acceptor chromophores.

of the peripheral chromophores by the amine core was observed, but only in small dendrons (G-1 and G-2). At higher generations, the quenching efficiency decreased dramatically, probably as a result of the increased distance between periphery and core.

Dendrimer-independent energy transfer

In order to create a more versatile system in which the energy transfer between peripheral chromophores and core was not affected by the dendrimer backbone itself, we have designed dendrimers with photochemically silent building blocks. Since the energy transfer process with such structures requires a highly efficient through-space interaction between chromophores located at their focal point and periphery, chromophore selection must meet certain requirements.[45] Specifically, the chromophores should be suitable for Förster energy transfer, with a large spectral overlap between donor emission and acceptor absorption, high transition dipole moments, high extinction coefficients, and high quantum yields of fluorescence.[14] In addition to these photophysical requirements, the chosen chromophores should (i) be soluble in organic solvents—this is particularly important for the peripheral donor chromophores, since the solubility properties of dendrimers are known to be highly sensitive to the nature of the surface groups—and (ii) contain a functional 'handle' through which attachment to the dendritic structure could be achieved.

Amino-functionalized Coumarin-2 and acid-functionalized Coumarin-343 were selected as the donor and the acceptor, respectively (Fig. 11). The solubility of these chromophores was adequate for the preparation of dendrimers up to generation four using an AB_2 building block with orthogonal functionalities (Fig. 11).[46] The photophysical properties of these molecules were studied by steady-state and time-resolved absorption and emission spectroscopy.[47] Initially, steady-state data was collected for model compounds containing either the donor chromophores or the acceptor, but not both. These models showed that the large spectral overlap between donor emission and acceptor absorption is preserved after coupling of the chromophores to the dendritic architecture (Fig. 12). Additionally, exclusive excitation of either the donor or the acceptor was found to be possible, simplifying the analysis of fluorescence data for energy transfer calculations.

The steady-state absorption characteristics of the fully-labeled dendrimers showed the expected doubling of donor absorption as a function of dendrimer generation, indicating that no deleterious ground-state aggregation phenomena were occurring in this system [Fig. 13(a)]. The acceptor absorption was shown to remain relatively constant at each generation, with only slight solvatochromic shifts being evident due to the

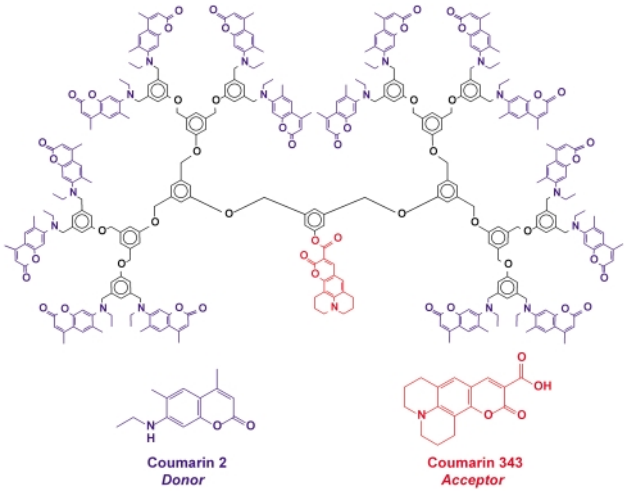

Fig. 11 Chemical structure of the Coumarin-2 donor, Coumarin-343 acceptor, and the fully chromophore-functionalized G-4 dendrimer.

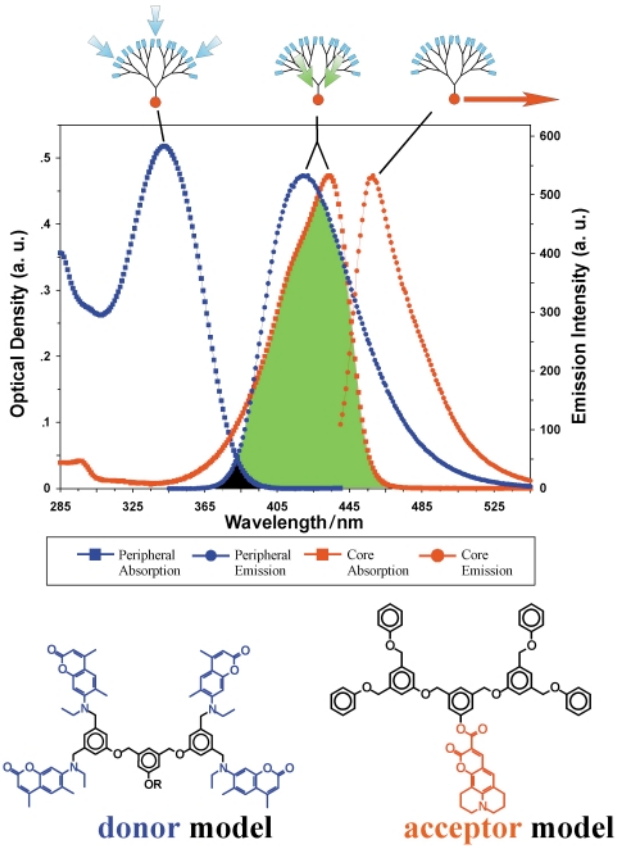

Fig. 12 Structures and spectral properties of donor and acceptor model compounds, indicating the strong overlap between donor emission and acceptor absorption.

increasing influence of the polar dendrimer shell around the focal chromophore. Upon irradiation of the donor absorption band, strong fluorescence was observed exclusively from the acceptor chromophore. The complete quenching of the donor chromophores attests to the highly efficient energy transfer occurring in these molecules. Additionally, a comparison of the emission intensity from sensitized acceptor excitation (λ_{ex} = 343 nm) to that from direct acceptor excitation (λ_{ex} = 440 nm) could be made [Fig. 13(b)]. It was found that in dendrimer generations beyond G-2, the emission intensity from sensitized excitation was greatly enhanced [Fig. 13(b), dotted curve], confirming that energy transfer efficiency is extremely high in these molecules. Time-resolved experiments indicated that energy migration from the periphery to the core occurred on extremely fast, sub-picosecond timescales. Using single-photon

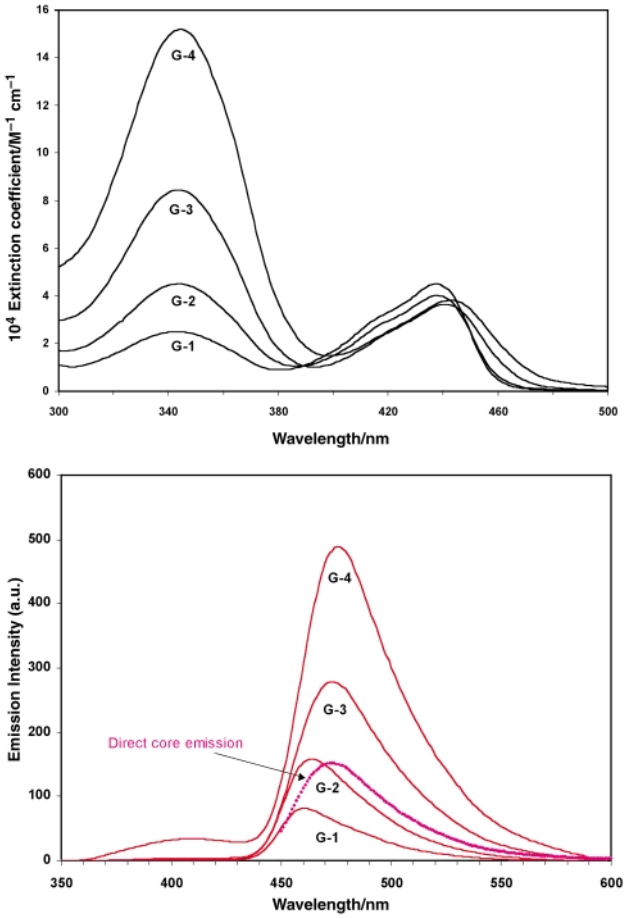

Fig. 13 UV–VIS absorption (top) and fluorescence emission (bottom) properties of the Coumarin-functionalized G-1 to G-4 series of dendrimers.

counting, it was not possible to resolve the rise-time of the core excitation upon irradiation of the periphery. Although these preliminary studies indicate that the Förster mechanism is the dominant energy transfer pathway, exact values for energy transfer rate constants must be ascertained before this claim can be fully substantiated. Further spectroscopic experiments with much faster time resolution will enable accurate measurements of the energy transfer rate constants and their quantitative comparison with theoretical calculations from Förster theory and molecular modeling.

Interesting insight into the relative rates of energy transfer *vs.* nonradiative relaxation of Coumarin-2 was provided by a study of the energy transfer dependence on solvent composition. When G-1 and G-2 donor model dendrons were dissolved in methanol (higher generation dendrimers were not soluble), it was found that the Coumarin-2 emission was completely quenched (Fig. 14). This was likely due to hydrogen bonding of the solvent with the tertiary amine lone pair, precluding optimal alignment of this lone pair orbital with the aromatic system of the chromophore. However, upon coupling of the acceptor chromophore to the focal point of these dendrons, excitation of the donors resulted in strong emission from the core. This indicates that, although fast nonradiative decay processes can compete with the nanosecond-scale donor fluorescence, the energy transfer process is much faster and still results in energy localization on the acceptor dye. The acceptor fluorescence is not quenched by the hydrogen bonding solvent presumably because the amine lone pair orbital is kept in conjugation by the two cyclohexyl rings (Fig. 11).

More recent work has shown that replacement of the Coumarin-343 acceptor by other chromophores can result in efficient energy transfer, as long as the absorption spectrum retains good overlap with the donor emission.[48] Oligothiophene

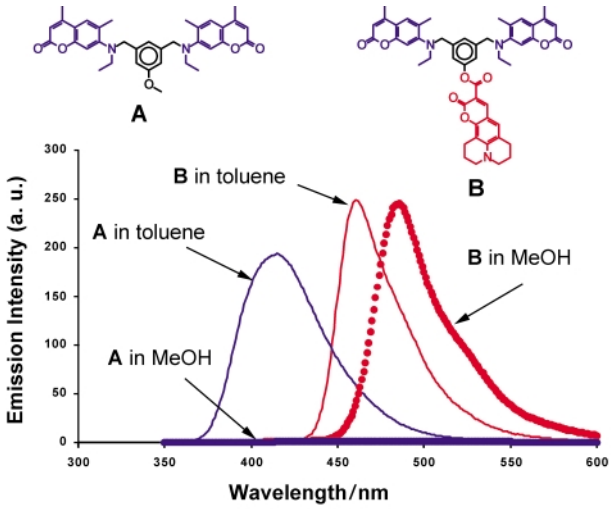

Fig. 14 Emission spectra of G-1 dendrons without (A) and with (B) the core acceptor chromophore in toluene (solid line) and methanol (dotted line).

chromophores proved ideal for this purpose, since it is possible to tune their absorption and emission properties by changing the degree of oligomerization. Two different oligothiophenes—a pentamer linked through its terminal ring, and a heptamer linked through its central ring—were chosen owing to their favorable absorption properties. Dendrimers up to the third generation were prepared, and it was shown that energy transfer was quantitative in all cases. Again, the emission intensity of the oligothiophenes, which have relatively low quantum yields of fluorescence (Φ_f = 0.15), was greatly enhanced by sensitized excitation upon irradiation of the peripheral light-harvesting antenna. This phenomenon may prove useful in the emission enhancement of photonic devices in which it is necessary to utilize components that have low fluorescence quantum yields. Interestingly, the oligothiophenes in this study had emission spectra that were strongly red-shifted from the emission of Coumarin-343. Hence, by simply changing the core functionality of the dendrimer, it is possible to tune the emission wavelengths across almost the entire visible spectrum, while irradiating at a single wavelength [Fig. 15(b)]. Molecules with this feature serve as ideal probes for experiments requiring simultaneous excitation and detection of several different targets, such as in the area of fluorescent conjugates for biological molecules.

Dendrimer-based light-emitting diodes

The findings made with the dendrimer antennas can be extended to the design of single-layer multichromophoric light-emitting diodes. The dendritic framework provides for both the energy transfer interaction and the site-isolation of different chromophores, enabling them to fluoresce simultaneously.[49–51] Separate emission from each dye is difficult to achieve in classical solid-state devices owing to intermolecular energy transfer to the chromophore with the smallest bandgap. By isolating the different chromophores within a dendritic shell, it should be possible to diminish or even eliminate this energy transfer in their mixture, and enable emission from each individual dye. Dendrimers peripherally-functionalized with hole-transporting triarylamines and core-functionalized with two different fluorescent chromophores were synthesized separately, and incorporated as a mixture into a single-layer light-emitting device (Fig. 16). These structures allowed the excitation energy to be changed from applied light to an applied voltage across two electrodes. Based on the solution work outlined above, the chosen fluorescent chromophores were Coumarin-343 and a pentathiophene, since their absorption bands overlap well with the emission band of the peripheral triarylamine. Our preliminary studies[49–51] indicate that it is possible to observe

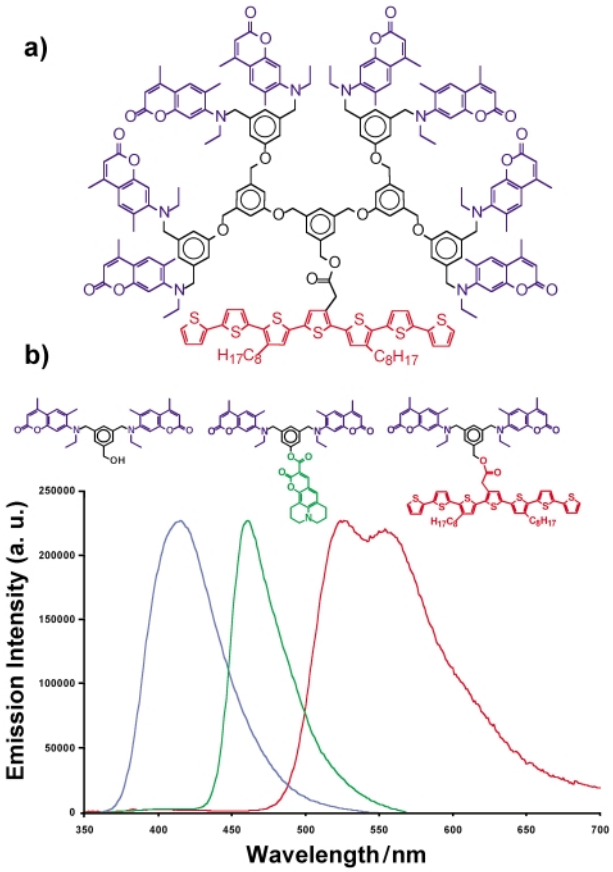

Fig. 15 (a) Structure of the G-3 heptathiophene (T-7) core-functionalized dendrimer. (b) Normalized emission spectra of G-1 dendrons having different moieties at the core: (i) no core chromophore; (ii) Coumarin-343; (iii) heptathiophene.

simultaneous emission from both chromophores when they are encapsulated in a dendrimer. In contrast, the light produced by mixtures of the free dyes originates solely from the lower bandgap oligothiophene.[49–51]

Dendrimer-based organic LEDs have also been reported by Moore and coworkers.[52] In this example, phenylacetylene dendrimers were prepared with peripheral triphenylamine groups for hole transport, and a core 9,10-bis(phenylethynyl)-anthracene as the light emitter. Unfortunately, thin films of these molecules exhibited only modest electroluminescence (EL) intensities. Solid-state aggregation of the rigid dendrimers and self-quenching by the low Stokes shift anthracene chromophores were the likely causes of diminished EL.

Light-harvesting in self-assembled monolayers

To further simplify the antenna concept without recourse to the tedious preparation of multichromophoric dendrimers, we studied the self-assembly of harvesting antennas and emitting components on silicon surfaces. Small Coumarin-2 functionalized donor dendrons and the Coumarin-343 acceptor chromophore (Fig. 17) were therefore functionalized with triethoxysilane moieties, which could then be adsorbed onto a silicon wafer to form self-assembled monolayers (SAMs).[53] The self-assembly process enables the use of a variety of donor–acceptor ratios by adjusting the adsorbate ratios in solution prior to SAM assembly. The photophysical properties of the monolayers were determined using front-face fluorescence techniques. As expected, variations in the donor–acceptor ratio on the surface had a large effect on the efficiency of energy transfer. Fig. 18(a) illustrates the normalized emission spectra from mixed monolayers of **6** and **8** having a 2:1 and a 3:1 ratio.[53] The larger average donor–acceptor distance obtained with a 3:1 ratio leads to a broader emission spectrum with contributions from both

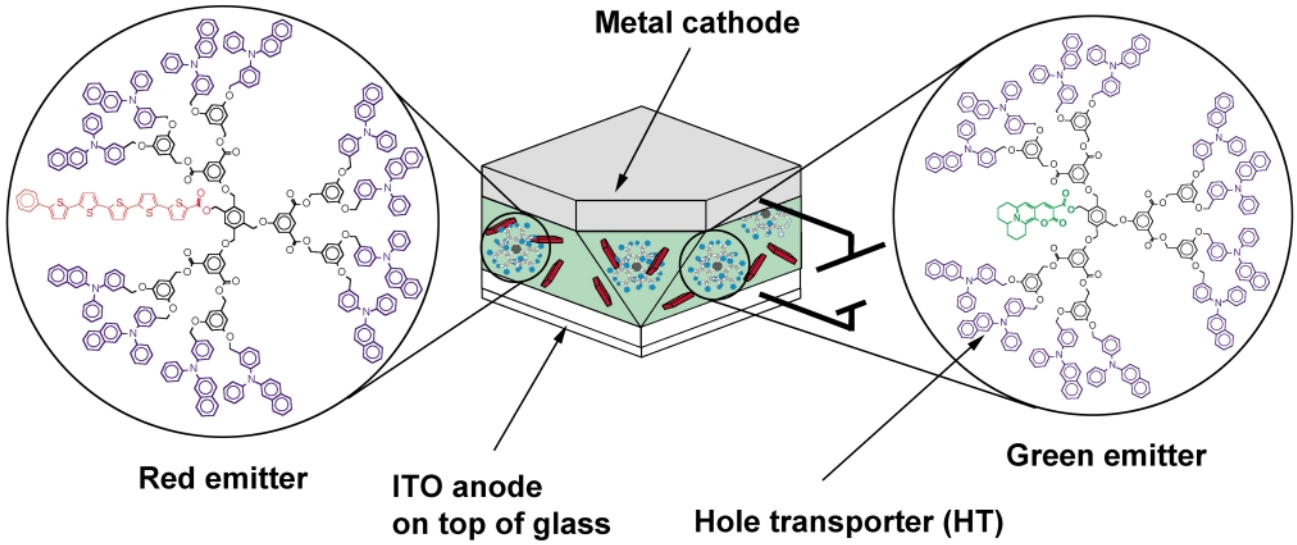

Fig. 16 Schematic diagram of an LED device incorporating hole-transporting dendrimers with pentathiophene (red emitter) and Coumarin-343 (green emitter) cores.

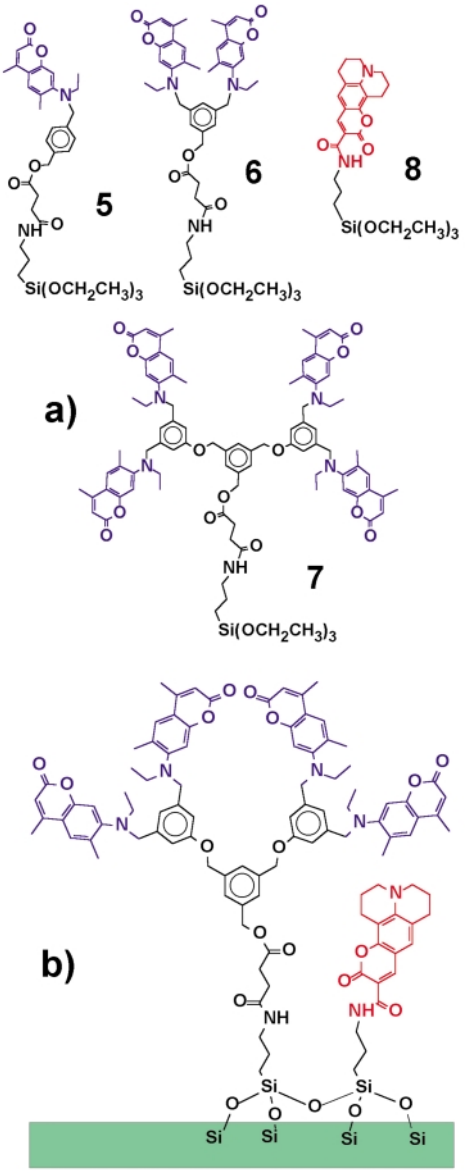

Fig. 17 (a) Structures of the triethoxysilane-functionalized donor and acceptor adsorbates. (b) Schematic representation of a mixed SAM of separate G-2 donor dendron and the Coumarin-343 acceptor on a silicon surface.

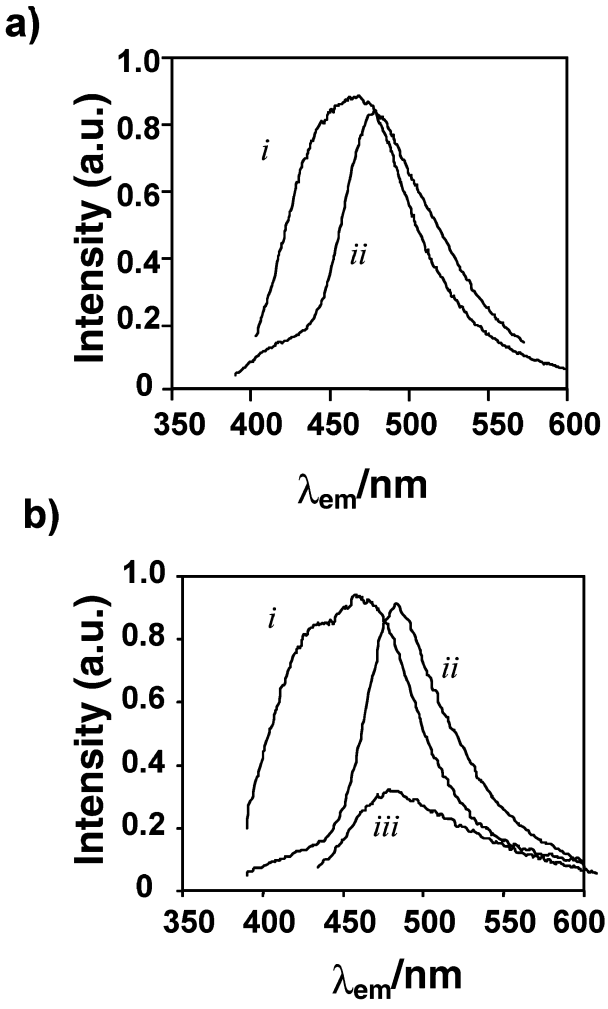

Fig. 18 (a) Normalized emission spectra from mixed monolayers of **6** and **8** having a 3:1 (i) and a 2:1 (ii) ratio. (b) Normalized emission spectra from mixed monolayers of a 4:1 ratio of adsorbates **5** and **8** (i), and a 1:1 ratio of adsorbates **7** and **8** (ii). Emission due to direct excitation of the acceptor at 420 nm is also illustrated (iii).

donor and acceptor as a result of inefficient energy transfer. In contrast, the emission spectrum of a SAM prepared with a 2:1 ratio of **6** to **8** is narrow, resulting purely from Coumarin-343 emission as energy transfer is highly efficient.

The importance of the dendritic character of donor chromophore **7** was confirmed in experiments involving adsorbate **5**

with its single Coumarin-2. The use of a 4 : 1 ratio of **5** to **8**, equivalent to the 1 : 1 ratio of **7** to **8**, led to incomplete energy transfer [Fig. 18(b)]. This illustrates the importance of the average inter-adsorbate distance in the energy transfer process as the dendritic nature of **7** facilitates the productive assembly of chromophores in the monolayer. Amplification of acceptor emission by sensitized excitation was clearly illustrated as the light output from the acceptor chromophore is significantly higher when it results from donor excitation at 350 nm than from its direct excitation at 420 nm.

Energy transfer in self-assembled dendritic structures of a different sort have recently been reported by Meijer and coworkers.[54] Poly(propylene imine) dendrimers were surface-modified with oligo(*p*-phenylene vinylene) (OPV) units affording amphiphilic structures that function as hosts capable of extracting water-soluble guests into the organic phase. Since the OPV-surface units are fluorescent, with an emission maximum at 492 nm when excited at 420 nm, it was speculated that energy transfer to a suitable chromophoric guest could occur. Using Sulforhodamine B as the energy-accepting guest (Fig. 19),

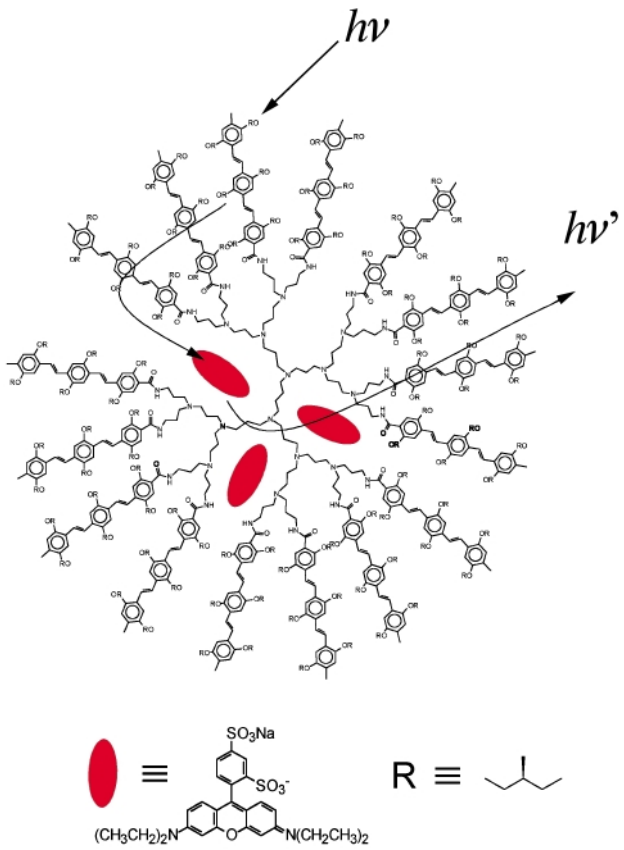

Fig. 19 Schematic representation of energy transfer from the peripheral OPV units to the encapsulated Sulforhodamine B guest within poly(propylene imine) dendrimers.

energy transfer was indeed observed with an efficiency of roughly 40% at maximal loading. This efficiency is significantly lower than achieved with dendrimers in which donor and acceptor are covalently linked, but this may be due, at least in part, to the poor overlap between donor emission and acceptor absorption.

Conclusions and outlook

In analogy to the natural photosynthetic systems, dendrimers, with their numerous branching units and chain ends uniformly surrounding a single core unit, seem ideally suited to function as light-harvesting structures. The examples illustrated in this article give testimony to our ability, through chemical manipulation, to create effective—if still very simple—mimics of natural photosystems. It is possible to vary the structural units in order to affect the physical properties of these molecules, while still maintaining a well defined, monodisperse macromolecule. Although it is unlikely that the current generation of light-harvesting dendrimers will be utilized in any but the most specialized applications owing to the somewhat tedious and expensive nature of their synthesis, they will prove to be effective model systems that will impact sensor technology, light-emitting diodes, fluorescent labeling of biological molecules, as well as a variety of photonic devices. It should be noted however that new routes to dendrimers[55] and less precise but nevertheless useful hyperbranched polymers[56] and dendritic hybrids are being developed, and some of these have already been applied to easily accessed multichromophoric systems.[57,58] In addition, it is envisioned that future work in this field will advance toward more complex mimics of natural photosynthetic systems, in which the energy absorbed at the dendrimer periphery will be employed to catalyze a chemical reaction. Nature utilizes the sun's energy to enable an electron transfer within the reaction complex, which eventually leads to the production of biologically important molecules such as ATP. Clearly, synthetic antennas have a long way to go as they aim to reach similar goals. The stakes of this research are high, as the development of novel synthetic photocatalysts and more efficient photovoltaic cells, such as the Grätzel cells,[59,60] would expand our ability to better utilize the sun's energy and decrease our dependency on fossil fuels.

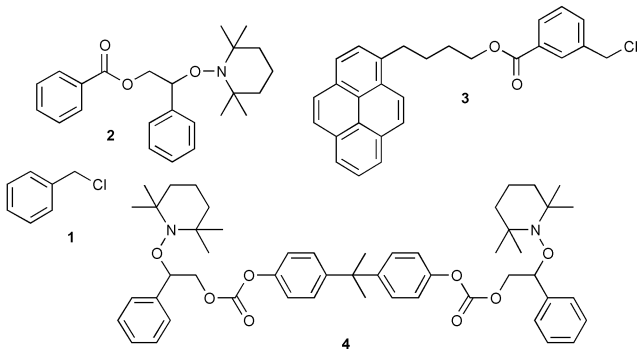
Equimolar mixtures of NMRP and ATRP initiators lead to polystyrene that is unimodal by GPC; the mechanism of action most consistent with the data suggests that under the reaction conditions, TEMPO and Cl end groups scramble rapidly relative to the propagation rate, and result in a single type of polymer chain.

Recent developments in controlled free radical polymerizations of vinyl monomers mediated by either Cu complexes (atom transfer radical polymerization, ATRP) or by TEMPO-derivatives (nitroxide mediated radical polymerizations, NMRP) have stimulated much research as they yield homopolymers and block copolymers with predictable MWs along with narrow polydispersities.[1]

While ATRP and NMRP are almost always used separately, we wondered whether the ATRP and NMRP initiators could each be used as the end groups on a single polymer chain. Critical to the success of this idea is whether the ATRP and NMRP end groups show crossover reactivity. If no crossover occurs, then the end groups of a one-pot mixed ATRP–NMRP initiator system should operate independently and grow polymers of different molecular weights if the rates of polymerization are different. If ATRP and NMRP end groups do exchange, however, then the structure of the resulting polymers will be sensitive to the relative rates of exchange and propagation.

To first address the issue of end group reactivity, four initiators (**1**–**4**) were used to synthesize polystyrene (PS): the monofunctional ATRP initiators benzyl chloride **1** and 4-(pyren-1-yl)butyl 3-chloromethylbenzoate **3**,[2] the monofunctional NMRP initiator 2-phenyl-2-(2,2,6,6-tetramethylpiperidin-1-yloxy)ethyl benzoate **2** and the symmetrical difunctional NMRP initiator bisphenol A bis[2-phenyl-2-(2,2,6,6-tetramethylpiperidin-1-yloxy)ethyl carbonate] **4**.

Polymerization conditions were chosen where both ATRP and NMRP mechanisms should be able to function, and were not varied during the study. Reaction solutions were first degassed with three freeze–pump–thaw cycles, and the polymerizations run at 135 °C under nitrogen (4 h), with equimolar amounts of initiator, CuCl, hexamethyltriethylenetetramine (N_4)[3] and acetic anhydride.[4] The results are listed in Table 1.



Prototypical ATRP and NMRP initiators were first tested separately as control reactions. Under exclusive ATRP conditions monofunctional initiator **1** (benzyl chloride) gave **PS-1a** (M_n = 36 000 g mol^{-1}, 70% conversion) and PDI of 1.89 (Table 1, entry **1a**). Polymerization of styrene using **1** under the modified ATRP–NMRP conditions (addition of acetic anhydride) also yielded PS with a broad MWM_n (distributions (MWD) PDI = 2) and polydispersity index, of 62 000 g mol^{-1} (42% conversion) (Table 1, entry **PS-1b**). Unlike typical ATRP conditions where the catalyst is a greenish colour, the modified reaction solution is deep blue.[5] Both experiments show that for **1**, the ATRP mechanism does not effectively control the polymerization under these conditions, and autopolymerization likely dominates. Polymerization of **3** under ATRP conditions is fast (100% conversion) and yields **PS-3** with a M_n of 28 000 g mol^{-1}, significantly closer to the theoretical M_n of 21 000 g mol^{-1}. The GPC chromatograms at 254 and 350 nm are both unimodal; the 350 nm trace is slightly shifted towards lower MW as expected for a chromophoric endgroup.[6] Polymerization of styrene with NMRP initiator **2** under exclusive NMRP conditions (no CuCl–N_4) was slow (14% conversion) and resulted in low molecular weight **PS-2** (M_n = 4600 g mol^{-1},

† The IUPAC name for a nitroxide is aminoxyl.

Table 1 MWD of PS obtained using modified NMRP–ATRP conditions

Entry	Initiator(s)	Reaction	$M_{n,\,calc.}$[a]/ g mol^{-1}	$M_{n,\,exp.}$ GPC[b]/ g mol^{-1}	PDI	Conversion[c] (%)
PS-1a	**1**	ATRP[d]	21 000	36 000	1.89	69
PS-1b	**1**	ATRP/Ac_2O[e]	21 000	62 000	1.97	42
PS-2	**2**	NMRP[d]	21 000	4 600	1.32	14
PS-3	**3**	ATRP[d]	21 000	28 000	1.52	100

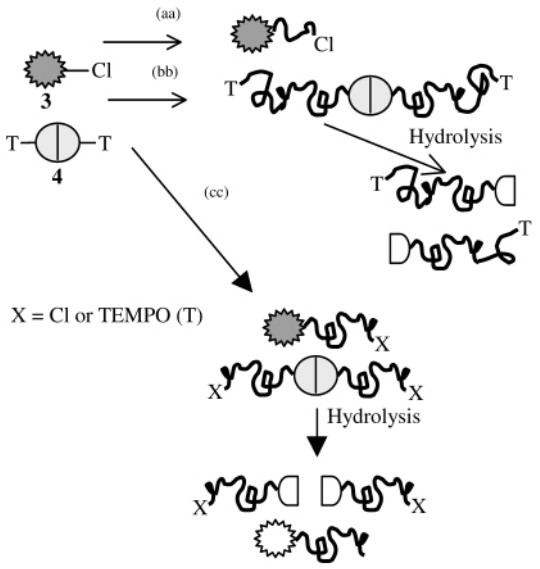
DOI: 10.1039/b004157m



Scheme 1 Scenarios (aa)–(cc) for the polymerisation of styrene in a one-pot mixture of ATRP and NMRP initiators **3** and **4**.

PDI = 1.32), which if extrapolated to 100% conversion results in M_n of 29 000 g mol^{-1}. Combining monofunctional ATRP and NMRP initiators **1** and **2**, respectively, together (one pot), obtains **PS-4** that was *monomodal* by GPC (M_n = 9000 g mol^{-1}, PDI = 1.29, 50% conversion). The monomodal distribution has several mechanistic interpretations: either (a) **1** or **2** initiates and propagates; or (b) **1** and **2** each initiate, but they propagate independently and at the same rate; or (c) the chlorine atom and nitroxide radicals exchange rapidly between end groups relative to propagation, *i.e*. the end groups don't remain unique.

To test for scenario (a) and to determine if the ATRP initiator led to polymer, UV-tagged **3** was employed together with **2**. The resulting polymer **PS-5** again was unimodal by GPC (M_n = 9000 g mol^{-1}, PDI = 1.46, 60% conversion), similar to **PS-4**. Most significantly, GPC traces recorded at 254 and 320 nm were superimposable and confirmed that initiation of at least the benzyl chloride functionality occurs in the mixture.

To similarly test if the NMRP initiator led to polymer, 0.5 equiv. of the difunctional initiator **4** was employed with one equiv. of **3**. This experiment allows three scenarios to be distinguished (see Scheme 1): (aa) if only **3** initiates and propagates, then a monomodal GPC trace with overlapping 254/350 nm GPC absorbances would result; (bb) if only compound **4** initiates and propagates, then no GPC trace would be observed at 350 nm and hydrolysis of the carbonate linkage would cut the resulting PS in half; (cc) if both types initiate and the end groups exchange more rapidly than propagation occurs, then a bimodal GPC trace would result with the low MW peak being UV-active at 350 nm. Hydrolysis of the carbonate linkage should halve the MW of the peak that doesn't absorb at 350 nm and return to an overlapping 254/350 nm GPC chromatogram.

This combination of **4** and **3** yielded **PS-6** (M_n = 18 500 g mol^{-1}, maximum peak at 30 000 g mol^{-1}, and PDI = 1.42, 73% conversion) that was *bimodal* at 254 nm and *unimodal* at 350 nm (Fig. 1). The 350 nm UV-active peak at M_n ~ 15 000 g mol^{-1} confirms that **3** has initiated and propagated in the presence of **4**, consistent with the experiment in entry **3**. A separate peak at ~ 30 000 g mol^{-1} in the 254 nm trace confirms that **4** also initiates and propagates in the presence of **3**. Since both initiators lead to polymer, these data eliminate scenarios (aa) and (bb) where only a single initiator leads to polymer.

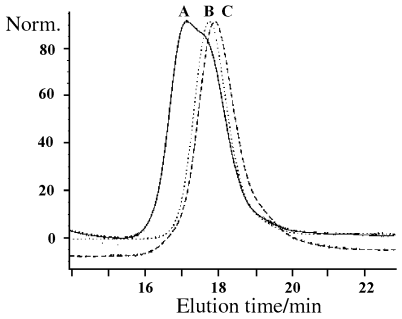


Fig. 1 GPC chromatogram of **PS-6** at 254 nm (A), 350 nm (B), and of **PS-7** at 254 nm (C).

Hydrolysis of **PS-6** yields **PS-7** that is *unimodal* at 254 nm (M_n = 15 000 g mol^{-1}, PDI = 1.25), and is now superimposable with the 350 nm GPC trace of **PS-5** (Fig. 1). Since all three PS blocks have the same MW, these data indicate that either the two propagation mechanisms form polymer at the same rate [*cf.* scenario (b)], or some process permutes the end groups rapidly enough to have a single propagation rate constant describe chain growth [scenario (c)].

From the productivity and MWD of the resulting PS as compared to the controls, it is clear that the modified reaction conditions affect both the ATRP and NMRP processes and most reasonably point to a common propagation mechanism for each of the two initiators in the reaction. For this to occur, Cl and nitroxide end groups must exchange rapidly relative to propagation. Crossover experiments in NMRP processes show that nitroxide end groups freely permute between growing polymer chains *via* indiscriminate nitroxide–radical recombinations,[7] and presumably do so in the present experiments as well. By homolysing the benzyl chloride end group, the ATRP mechanism similarly generates benzyl radicals and the opportunity to redeposit the Cl$^{\bullet}$ onto a nitroxide derived free radical. Thus, Cu^{I} amine complexes might reasonably catalyse the exchange between Cl and nitroxide end groups, and provide a mechanism for the global exchange of end groups.

In summary, the data presented herein indicate that under our reaction conditions, the NMRP and ATRP mechanisms do not operate independently and end group crossover occurs. Consequently, both initiators lead to polymers that grow at a common rate. However, the data don't distinguish if ATRP, NMRP, or both mechanisms are responsible for chain growth.

We thank the UNC Chapel Hill Curriculum in Applied Sciences, UNC Research Council, DuPont, 3M, and the Camille Dreyfus Foundation for partial support, and Ms Wendy Y. Mills for providing a sample of **4**.

Oriented growth of MCM-22 zeolite films

Mojie Cheng,* Dali Tan and Xinhe Bao

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian 116023, China. E-mail: mjcheng@ms.dicp.ac.cn

Received (in Cambridge, UK) 31st May 2000, Accepted 27th July 2000
First published as an Advance Article on the web 21st August 2000

MCM-22 zeolite films have been grown with layers vertical to the substrate under hydrothermal synthesis conditions, and characterized by X-ray diffraction and scanning electron microscopy.

In situ synthesis of zeolites and molecular sieves on various supports is of significant importance in utilizing the well defined intracrystalline pores for membrane separation, membrane catalysis and molecular sensing. A variety of zeolites and molecular sieves, *e.g.* ZSM-5 or silicalite-1,[1,2] zeolite A[3,4] and UTD-1,[5] have been grown into films and membranes. Most zeolite films and membranes are obtained with random crystal orientation, and better performances are expected for an oriented zeolite film or membrane.[6,7] Particularly for zeolites with one- or two-dimensional pore systems, the accessibility of zeolite pores in a film depends on crystal orientation. Zeolite MCM-22, which is a good catalyst in a variety of reactions,[8,9,11] has an unusual layered structure and dual two-dimensional pore systems.[10] Here we report the oriented growth of MCM-22 films under static hydrothermal synthesis conditions.

The synthesis mixture was prepared using silica sol (25wt% SiO_2), sodium aluminate, hexamethyleneimine (HMI), sodium hydroxide and deionized water. 0.8 g sodium hydroxide and 1.7 g sodium aluminate was dissolved in 135 g deionized water, then 10.3 g HMI and 50.2 g silica sol were added with stirring. The molar composition of the resultent mixture was $13.5Na_2O:5Al_2O_3:100SiO_2:4500H_2O:50HMI$. After stirring for 1 h at 303 K, the mixture was transferred into a Teflon-lined autoclave, and a glass plate was immersed vertically in the mixture. Crystallization was carried out at 423 K for 96 h. The powder product and the glass plate were separated, washed with deionized water, and then dried at 353 K. Calcination was carried out at 813 K for 10 h with a temperature ramping rate of 2 K min^{-1}. The products were characterized by X-ray diffraction (XRD) and scanning electron microscopy (SEM).

The XRD pattern of the as-synthesized powder sample [Fig. 1(a)], characterized by both sharp and broad peaks, agrees well with that of the as-synthesized MCM-22 sample, and the XRD pattern of the calcined powder sample [Fig. 1(b)], with only sharp peaks, is consistent with that of MCM-22.[12] Although the detailed structure of as-synthesized MCM-22 is unclear, it is clear that as-synthesized MCM-22 and the MCM-22 sample have the same *a*-parameter, but the *c*-parameter of MCM-22 is smaller than that of as-synthesized MCM-22. As-synthesized MCM-22 exhibits two separated XRD peaks at 2θ 6.5 and 7.2° for (002) and (100), respectively, whereas the two reflections overlap into one peak in MCM-22. Compared with the XRD patterns of as-synthesized MCM-22 and MCM-22 powder samples, no other phases except for as-synthesized MCM-22 and MCM-22 are present in the as-synthesized and calcined films [Fig. 1(c) and (d)]. The broad and sharp peaks of the as-synthesized film are unambiguously from as-synthesized MCM-22, and the sharp peaks of the calcined film are from MCM-22. The as-synthesized MCM-22 film gives an intense peak for (100) but very weak peaks for (001), (002), (101) and (102), which indicates that the MCM-22 crystals are grown with a preferred orientation. As the layers of MCM-22 are linked together along the [001] direction, the MCM-22 layers in the film are vertical to the substrate.

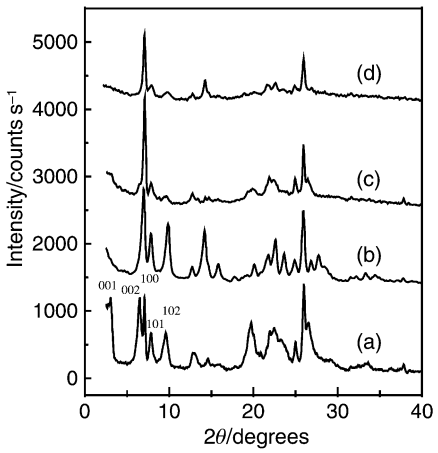

Fig. 1 XRD patterns of the as-synthesized MCM-22 powder (a), MCM-22 powder (b), as-synthesized MCM-22 film (c) and MCM-22 film (d).

SEM micrographs of MCM-22 crystals and the MCM-22 film are depicted in Fig. 2. MCM-22 crystals show stacked-thin-disk morphology. Most particles are aggregates of MCM-22 crystals intergrown in the [001] direction as illustrated in Fig. 2B. Sometimes intergrowth also occurs in the [100] direction. The MCM-22 film shows continuous intergrowth of MCM-22 crystals. The aligned-thin-sheet surface morphology, similar to that of MCM-22 crystals, further demonstrates that the MCM-22 layers are vertical to the substrate. The film has some cracks along the layer direction. Because as-synthesized MCM-22 lacks interlayer linkages and the *c*-parameter is larger than that of MCM-22, the formation of these cracks is ascribed to the contraction of the *c*-parameter during calcination. A cross-section micrograph (Fig. 2D) shows that the film has a thickness of *ca.* 5 μm. Only a monolayer of MCM-22 crystals is grown on the substrate and these crystals are largely normal to the substrate.

The formation of oriented zeolite films and membranes is closely related to the nucleation and crystal growth of zeolites. It has been demonstrated that completely oriented LTA-type zeolite films can be prepared by the intergrowth of oriented seed crystals.[6] Oriented zeolite films and membranes, *e.g.* of MFI-type[13,14] and AFI-type,[15] have also been prepared by direct hydrothermal syntheses. Zeolite crystals tend to orient with the largest crystal faces parallel to the smooth substrate, whereas crystal growth is preferred in the direction with the largest crystal growth rate vertical to the substrate. For thin disks, MCM-22 crystals would laterally lie on the smooth substrate. Thus, the vertical growth of MCM-22 film is not due to the orientation of the MCM-22 crystals. The high growth rate of the MCM-22 layer structure, indicated from the thin-disk-like crystal morphology, appears to be responsible for the vertical growth.

For MCM-22, shape-selective reactions occur in the channels and supercages, whereas the surface active sites can reduce the selectivity.[11] The low outer surface area vertically oriented MCM-22 film, for which the two pore systems are easily

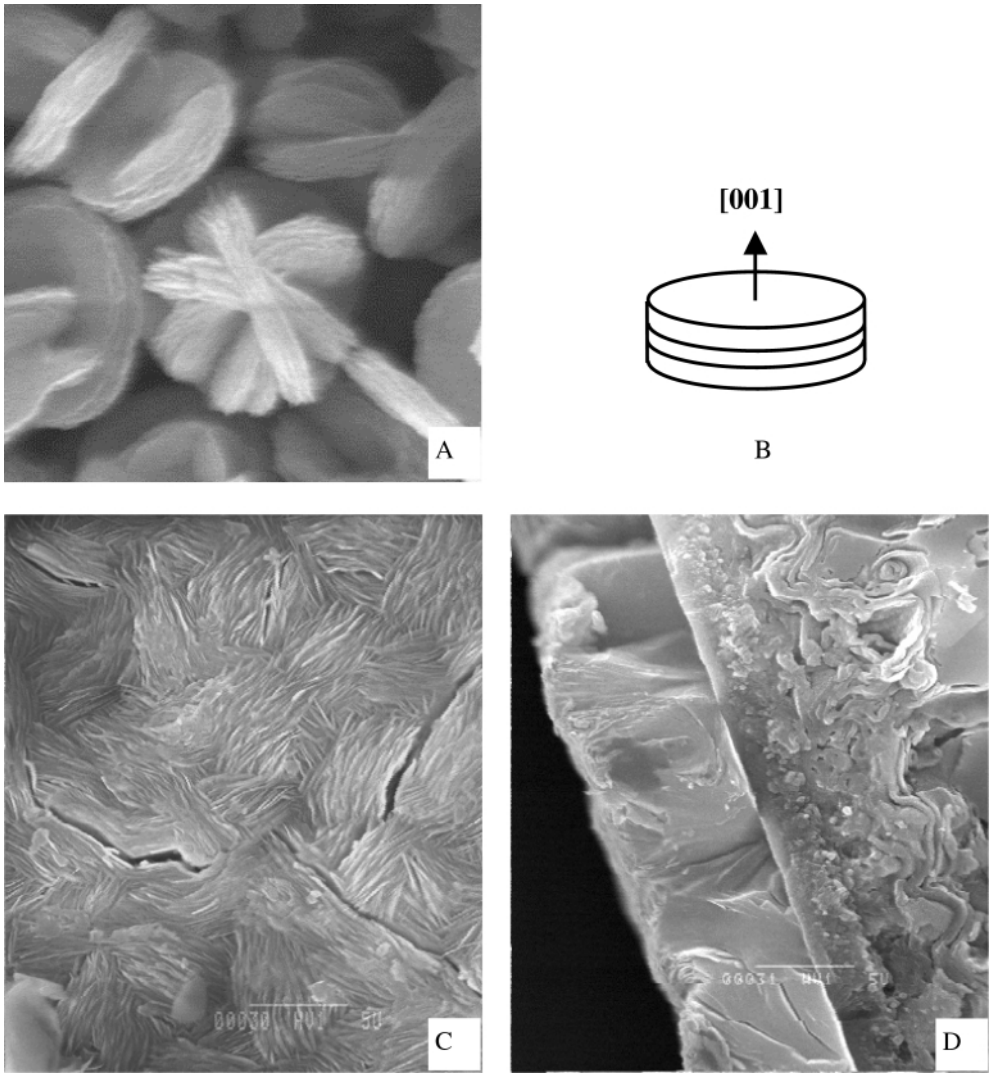

Fig. 2 SEM micrograph of the MCM-22 powder sample (A), the schematic intergrowth of MCM-22 crystals (B), and SEM photographs of the surface (C) and cross section (D) of the oriented MCM-22 film.

accessible to reactants may be a highly selective catalyst for some reactions.

Existence of a stable unconventional mesophase-like twist grain boundary smectic A (TGBA) phase was found in a wide temperature range for non-chiral α-(4′-propoxyphenylbenzyl-4-ylthio)-ω-(4′-butoxyphenylbenzyl-4-ylthio)-perfluorohexane (3BF6B4), which may be a consequence of the boomerang shape of the molecules.

Recently the generation and structure of TGB (twist grain boundary) phases have been investigated by several researchers[1–4] because of their unique packing structure. TGBA and TGBC phases can be regarded as smectic A and C variants composed of small SmA or SmC domains, respectively. The layer planes of the domains are arranged helically to form a macroscopic helical structure. Since the discovery of TGBA phases in (*R*)- or (*S*)-1-methylheptyl-4′-{[(4″-alkoxyphenyl)-propioloyl]oxy}biphenyl-4-carboxylate by Goodby *et al.*,[4] several liquid crystalline (LC) compounds exhibiting TGB phases have been reported, but, up to now, only chiral LC compounds were found to generate TGB phases, to our knowledge, with the chiral moiety causing a frustration of smectic ordering, so resulting in the helical ordering of the smectic domains. In this work, we have found unconventional layered mesophase-like TGBA (hereafter, simply denoted TGBA) phase in non-chiral α-(4′-propoxyphenylbenzyl-4-ylthio)-ω-(4′-butoxyphenylbenzyl-4-ylthio)perfluorohexane (3BF6B4, Fig. 1),† which is stabilized over a wide temperature range.

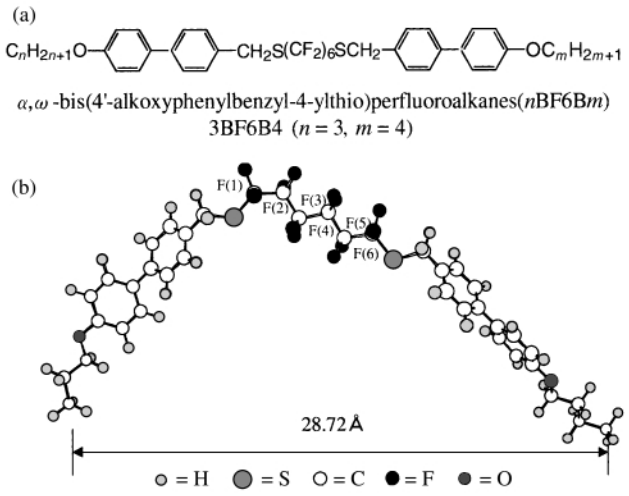

Fig. 1 Chemical structure of *n*BF*x*B*m* compounds (a) and the molecular model of 3BF6B4 obtained by PM3 calculation, where $–CF_2(1)–CF_2(2)–$ and $–CF_2(5)–CF_2(6)–$ bonds are in *gauche* and *trans* conformation, respectively (b).

Fig. 2(c) shows DSC curves of 3BF6B4.‡ For the first heating, the 3BF6B4 crystallites (Cr phase) melt to a TGBA state at 78.4 °C which changes into the isotropic liquid (I) phase at 99.4 °C. It is noted that the TGBA phase exists in the wide

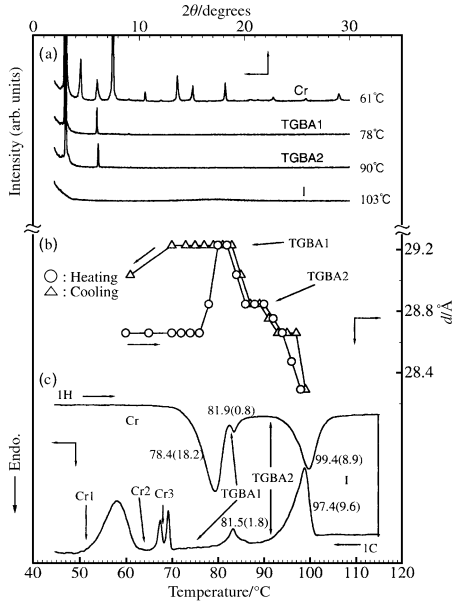

Fig. 2 X-Ray diffraction patterns of 3BF6B4 (a) and the temperature dependence of the spacing *d* (b) and DSC thermograms of 3BF6B4 (c). 1H: 1st heating, 1C: 1st cooling; Cr: crystalline state, I: isotropic phase. These figures in (c) denote the phase transition temperatures (°C) and enthalpy changes (kJ mol^{-1}).

temperature range from 78.4 to 99.4 °C. The identification of the TGBA phase was made from texture observations; Fig. 3 shows a cylindrical domain (CC) texture when the two glass plates are untreated [Fig. 3(a)] and a spiral filament texture when the two plates are rubbed parallel to the plane [Fig. 3(b)], this result indicating that the mesophase is a TGBA phase.[6] Moreover, we find an endothermic peak near 81.9 °C on heating of the DSC curve of Fig. 2(c), suggesting the presence of two TGBA phases, TGBA1 below 81.9 °C and TGBA2 above 81.9 °C; the TGBA textures of Fig. 3 were observed over the temperature range exhibiting the TGBA 1 and 2 phases and did not show any change between TGBA1 and TGBA2, hence it is believed that both phases essentially belong to the TGBA state. In Fig. 2(a), the X-ray scattering intensity (*I*) is plotted *vs.* the scattering angle (2θ) for 3BF6B4, as a function of temperature.‡ In the crystalline state (61 °C), the *I vs.* 2θ curve shows several sharp peaks, but only three peaks are seen at *ca.* 3.0, 6.0 and 9.0° for TGBA1 (78 °C) and at *ca.* 3.1, 6.1 and 9.2° for TGBA2 (90 °C). These three peaks are attributable to reflections from SmA layers of thickness 29.23 and 28.85 Å, respectively. A conformational structure was calculated for 3BF6B4, using PM3 (parametric method). As shown in Fig. 1(b), assuming a *gauche* conformation for $–CF_2(1)–CF_2(2)–$ a *trans* conformation for $–CF_2(5)–CF_2(6)–$, and a *trans* conformation for all the other bonds, the molecule is boomerang-shaped and the molecular length is estimated as 28.72 Å.[7] When the $–CF_2(1)–CF_2(2)–$ and $–CF_2(5)–CF_2(6)–$ bonds are in *trans* and *gauche*

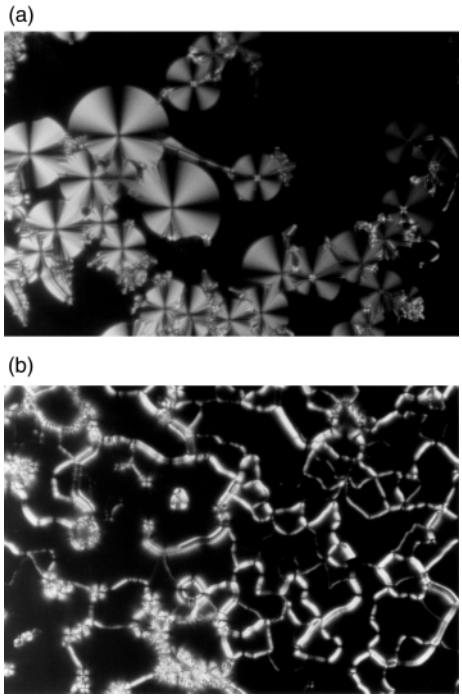

Fig. 3 The cylindrical domain (CC) texture of the TGBA phase at 92.5 °C (a) and spiral filament texture of the TGBA phase at 93.7 °C (b) in 3BF6B4 under a polarized microscope (magnification ×100).

conformation, respectively, the molecular length is estimated as 28.43 Å. Both molecular lengths are well consistent with the layer thickness obtained from the X-ray data.[8] From these results, both TGBA1 and TGBA2 phases can be tentatively concluded to be TGBA phases consisting of SmA domains. In Fig. 2(b), the spacing (*d*) is plotted *vs.* temperature. On heating, the value of *d* changes from 28.66 to 29.23 Å near the Cr–TGBA1 phase transition temperature, and suddenly decreases to 29.04 Å near the TGBA1–TGBA2 transition temperature, and rapidly decreases approaching the TGBA2–isotropic liquid (I) phase transition temperature. The decrease of *d* in the TGBA2 phase with increasing temperature may be caused by either the packing of 3BF6B4 molecules in the SmA layer being disturbed or the packing of the long molecular axes of 3BF6B4 molecules at a tilt angle to the layer normal (TGBC). At present, we infer that the former packings may be responsible for the appearance of TGBA2, since the texture of TGBA2 is similar to that in TGBA1.

In conclusion, this work has revealed the existence of a TGBA phase in non-chiral 3BF6B4, as a consequence of its boomerang-molecular shape, reminiscent of the generation of ferroelectricity in banana-shaped molecules.[9]

We are investigating the phase transition behaviors of *n*BF6B*m* homologues (Fig. 1), and at present, find the existence of TGBA phases in 3BF6B3, 3BF6B4 and 3BF6B5. Further studies will be published elsewhere in the near future.

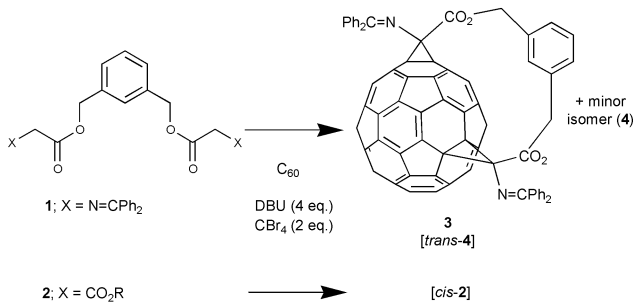
The structure of a novel tethered fullerene bis-adduct, of unexpected regiochemistry, has been unequivocally assigned using INADEQUATE 2D NMR experiments.

The regioselective, multifunctionalization of C_{60} is a continuing challenge in fullerene chemistry.[1] Bis- and tris-additions to fullerenes can generally be made regioselective through the use of tethered systems.[2] It is not clear, however, if the regiochemical outcome of tethered reactions is solely dependent upon the nature of the tether, or the stereoelectronic requirements of the reactive addend, or the mechanism of addition or some combination of these factors. An additional challenge for studies in this area is the development of methods for the unequivocal assignment of the structure of bis-tethered fullerene adducts. Earlier structural assignments of multiple adducts have relied on comparative methods (^{13}C NMR symmetry elements and UV-vis spectroscopy).[2e,3] However, as the production of higher order fullerene adducts increases, these methods will become less reliable, due to the decreasing symmetry of products and the lack of definitive structures for comparison. We report here the structure of a novel tethered fullerene bis-adduct of unexpected regiochemistry and the unequivocal assignment of its structure using INADEQUATE 2D NMR experiments.[4]

Earlier work has shown that tethered bis-malonate esters undergo regioselective bis-cyclopropanation reactions with C_{60} under Bingel conditions.[2e] For example, the *meta*-substituted bis-tethered system **2** gave exclusively the *cis*-**2** regioisomer as determined by UV-vis spectroscopy and from its symmetry, determined by 1D ^{13}C NMR spectroscopy. Interestingly, the *ortho*-isomer of **2** also gives a *cis*-**2** adduct, while the corresponding *para*-isomer gives predominantly the *trans*-**4** adduct. In contrast, we have found that treatment of C_{60} with the corresponding *meta*-substituted bis-imino-glycine tethered system **1** gives, under similar reaction conditions,[5] two regioisomeric adducts **3** and **4**[6] in a ratio of 80 : 20 from ^{1}H NMR analysis (Scheme 1). Compound **3** was obtained pure in 28% yield after separation by column chromatography and recrystallization. The ^{1}H NMR of **3** showed resonances for the two pairs of diastereotopic methylenes at δ 5.06 and 5.71 (AB q, J_{AB} 11.2 Hz), consistent with a tethered fullerene structure. Furthermore, the MALDI-TOF spectrum of **3** showed a characteristic parent molecular ion at *m/z* 1297. The UV-vis spectrum of **3** showed bands in the 400–800 nm region that suggested a *trans*-**4** structure but this conclusion was not definitive due to the lack of good reference compounds. Unequivocal evidence for the structure of **3** came from ^{13}C NMR and INADEQUATE experiments.[7]



Scheme 1

^{13}C NMR spectroscopy revealed 31 peaks associated with the fulleryl carbons in **3**. The resonance at δ 150.56 was shown to arise from the fortuitous overlap of one full-intensity peak and one half-intensity peak. Hence **3** has 32 unique fullerene carbons, four of which give half-intensity peaks (labelled as grey circles in Fig. 1), indicative of a dimethanofullerene with C_S symmetry. To distinguish between the 3 possible structural isomers, *cis*-**1**, *cis*-**2** and *trans*-**4**, INADEQUATE experiments were performed on a 10% ^{13}C enriched sample of **3**.[8,9]

The above three possible isomers would be expected to show 2, 1 and 3 bond separations respectively, between a fulleryl sp^3 hybridized carbon and its nearest carbon on the plane of symmetry (*i.e.* half-intensity peak). These experiments revealed a 3-bond connectivity (shown as grey lines in Fig. 1) between C1 (sp^3 carbon) and C19 (half-intensity peak) providing unequivocal evidence for its *trans*-**4** structure. Starting from C19, correlations were observed to the other half-intensity peak (C20) with a relatively large coupling constant ($^1J_{CC}$ = 66.8 Hz) typical for 6,6 ring fusion carbons and one to C5 with a smaller $^1J_{CC}$ (57.2 Hz) typical for 6,5 ring fusion carbons.[4] C5 showed correlations to C6 ($^1J_{CC}$ = 73.1 Hz) and C4 ($^1J_{CC}$ = 53.2 Hz), consistent with their 6,6 and 5,6 ring fusion positions, as well as to C19. C6 showed a correlation to the sp^3 carbon C1, unequivocally confirming the position of the cyclopropane ring to the plane of symmetry. Further corroborative evidence for this structure was the observation that C4 showed only 2 correlations (to C3 and C5) consistent with the magnetic

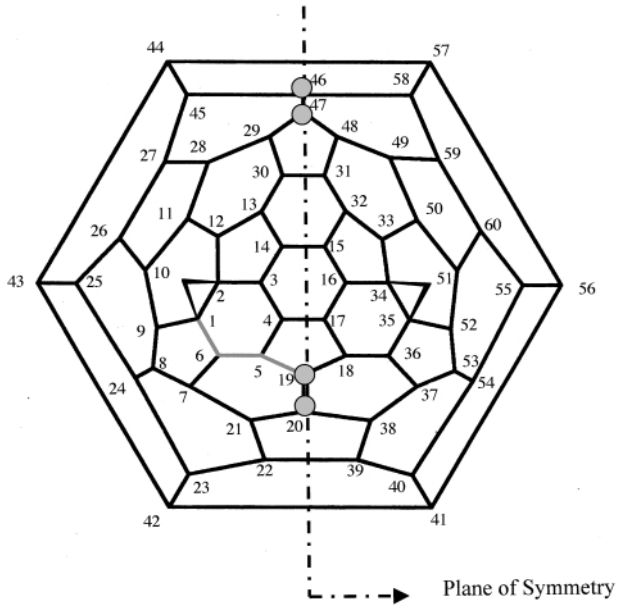


Fig. 1 Schlegel diagram of **3** (tether not shown) with carbons that lie on the plane of symmetry shown as grey circles.

[a] Denotes peak has two resonances, one full-intensity and one half-intensity. [b] Denotes coupling is not first order; peak positioning is consistent with structure model. [c] Denotes half-intensity peaks.

equivalence of C4 and C17 due to their positions relative to the plane of symmetry.

Using the above methods we have assigned all carbons in **3** and obtained information about the relative bond lengths from the measurement of $^1J_{CC}$ values (Table 1). These measured values were consistent with the radialene structure of **3**.

The regiochemical difference between our tethered reaction and that of **2** with C_{60} clearly demonstrates that much has yet to be understood about tethered fullerene reactions before generalizations on regiochemical outcomes can be made. These differences in regiochemistry may indicate that these reactions proceed *via* different mechanisms and experiments are in progress to help understand these differences.[10]

We thank the Australian Research Council for financial support and for a PhD scholarship to G. A. B.

6 The minor isomer **4** was obtained pure in 12% yield and has C_2 symmetry from ^{13}C NMR analysis which showed no half-intensity peaks and 30 sp^2 resonances. The possible structures for this molecule therefore are, *cis*-**3**, *trans*-**3** or *trans*-**2**. The *trans* isomers seem unlikely from PM3 calculations, leaving *cis*-**3** as the most likely structure.

7 The INADEQUATE experiment was performed on a Bruker DMX 600 spectrometer fitted with a Bruker TXI-XYZ ^{1}H/^{13}C/^{15}N probe. The sample (*ca*. 16 mg) was dissolved in CS_2–$CDCl_3$ 6:4 (*ca*. 250 μl) in a Shigemi tube and the spectrum was recorded at 288 K. A standard pure phase (States-TPPI) double quantum spectrum with power-gated proton decoupling was employed. A spectral width of 13020.8 Hz was used in both dimensions resulting in deliberate folding in f_1 which does not cause any ambiguity of peak assignments. 2048 × 8192 total points were collected in t_1 and t_2 respectively. A recycle delay of 9 s and 16 scans per increment were employed. The 90° pulse length was 11.6 μs.

8 ^{13}C enriched (10%) C_{60} purchased from Mer Fullerenes, Arizona.

9 To a solution of [60]fullerene, CBr_4 (0.54 g, 1.42 mmol) and **1** (0.47 g, 0.810 mmol) in PhCl (200 mL) was added DBU (0.43 g, 0.675 mmol), at room temperature and the solution was stirred for 2 h. The crude material was filtered through a short plug of silica, eluting first with toluene (to retrieve unreacted [60]fullerene) and then with CH_2Cl_2 (DCM). Column chromatography eluting with (90:10; DCM–light petroleum) and recrystallised from DCM–Et_2O provided **3** (0.245 g, 28%) and **4** (0.093 g, 12%). Two crystallographically distinct tetrahedral sites in zeolite merlinoite are identified by ^{29}Si MAS NMR and 2D ^{27}Al quadrupole nutation NMR spectroscopies.

Since the initial work of Lippmaa and Engelhardt in 1981,[1] the use of multi-nuclear solid-state NMR techniques in the characterization of zeolites and related materials has provided many new insights into the structure and chemistry of this important class of microporous solids, particularly in the short-range order. For instance, ^{29}Si MAS NMR can detect the relative populations of five distinct Si environments, *i.e.* $Si(OSi)_n(OAl)_{4-n}$ with n = 0–4.[2] When all tetrahedral atoms (T-atoms) in the zeolite framework are crystallographically equivalent with avoidance of Al–O–Al linkages, therefore, the quantitative framework Si/Al ratio can be easily calculated from the ^{29}Si resonance intensities. However, many of the already known zeolite structures contain two or more crystallographically distinct T-sites characterized by different T–O–T and O–T–O bond angles and T–O bond lengths. This allows the Si atoms situated in these sites to exhibit different ^{29}Si chemical shifts, even for the same $Si(OSi)_n(OAl)_{4-n}$ environments, making it difficult to accurately determine the framework Si/Al ratio from the spectra. When structurally distinct lines overlap heavily with one another, in particular, it is not possible to directly deconvolute the ^{29}Si NMR spectra.

Merlinoite (MER topology) is a small-pore, low-silica zeolite that is rarely found in nature.[3] Amongst the early zeolite discoveries, in addition, zeolites W and K-M are known to be synthetic counterparts of MER zeolite.[4,5] The structure of this zeolite is characterized by a three-dimensional pore system consisting of intersecting 8-ring channels.[6] To date, there are three reported ^{29}Si MAS NMR spectra of MER-type zeolites prepared *via* different synthetic routes.[7–9] In all cases, the interpretation and assignment of the spectra have been made based on the implicit assumption that only one crystallographically distinct T-site exists in the zeolite framework. A recurring question is the fact that the Si/Al ratios calculated from the ^{29}Si NMR spectra are not in reasonable agreement with those determined from elemental analysis. This implies that each line in the ^{29}Si MAS NMR spectra of MER zeolites previously reported may be misunderstood. Here we present the ^{29}Si MAS NMR and 2D ^{27}Al quadrupole nutation NMR results showing that two crystallographically distinct T-sites are present in the framework of MER-type zeolites.

An MER zeolite with Si/Al = 1.8 was prepared by heating an aluminosilicate gel with the oxide composition of $1.2Na_2O \cdot 4.8K_2O \cdot 1.0Al_2O_3 \cdot 10SiO_2 \cdot 150H_2O$ at 100 °C for 18 d. The powder XRD of MER zeolite prepared here reveals that the solid is a highly crystalline MER zeolite and no reflections other than those from MER are observed.[10] This pattern was indexed as orthorhombic with unit-cell dimensions of a = 14.13(1), b = 14.24(2) and c = 10.10(1) Å. A combination of elemental and thermal analyses of the as-synthesized Al-MER sample gives a unit cell composition of $K_{11.1}Na_{0.3}Al_{11.4}Si_{20.6}O_{64} \cdot 17.8H_2O$. The ^{27}Al MAS NMR spectrum of this zeolite exhibits only one line at 58.5 typical of tetrahedral Al sites in zeolites.

Fig. 1 shows the ^{29}Si MAS NMR spectrum of our MER zeolite together with the simulated spectrum and its deconvoluted components. Five well-resolved ^{29}Si lines at −85.1, −89.4, −94.0, −98.7 and −103.2 ppm are observed. The general feature of this spectrum is very similar to the case of zeolite structures having only one T-site such as LTA and FAU zeolites with high Al contents. As seen in Fig. 1, however, curve deconvolution reveals that there is an additional low-intensity shoulder around −108 ppm, reflecting the presence of more than one crystallographically distinct T-site in the framework of MER zeolite. This clearly shows that the ^{29}Si NMR spectra for Al-MER zeolites cannot be interpreted following the manner that the individual lines are implicitly regarded as single Si environments, which has been repeatedly employed in the literature.[7–9] Actually, an attempt to deconvolute the ^{29}Si NMR spectrum of our Al-MER material by assigning the first five lines to $Si(OSi)_n(OAl)_{4-n}$ species with n = 0–4 and by ignoring the presence of the high-field line, due to its low intensity, gave a $(Si/Al)_{NMR}$ value of 2.3 that is fairly larger than the bulk Si/Al

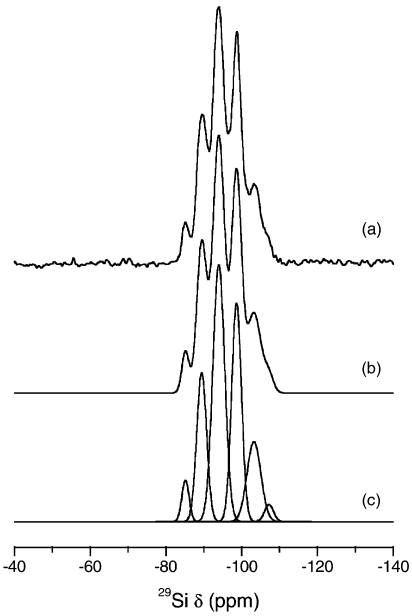

Fig. 1 ^{29}Si MAS NMR spectra of MER zeolite prepared: (*a*) experimental, (*b*) simulated and (*c*) deconvoluted components. Spectrum recorded on a Bruker DSX 400 at 12 kHz spinning rate, 60 s recycle delay, 79.459 MHz, 2.0 μs pulse length (π/5 rad), 1200 scans.

Table 1 Chemical shifts, intensities, and assignments of the ^{29}Si NMR resonances in MER zeolite prepared here

Chemical shift (ppm from TMS)	Relative intensity (%)	Assignment	Average T–O–T angle[11]	
			Si_I–O–T	Si_{II}–O–T
−85.1	3.6	$Si_I(OAl)_4$	142.1	
−89.4	17.8	$Si_I(OSi)(OAl)_3$ + $Si_{II}(OAl)_4$	140.3	148.8
−94.0	37.1	$Si_I(OSi)_2(OAl)_2$ + $Si_{II}(OSi)(OAl)_3$	139.0	147.2
−98.7	26.1	$Si_I(OSi)_3(OAl)$ + $Si_{II}(OSi)_2(OAl)_2$	137.8	145.7
−103.2	13.5	$Si_I(OSi)_4$ + $Si_{II}(OSi)_3(OAl)$	136.4	144.0
−107.5	1.9	$Si_{II}(OSi)_4$		142.1

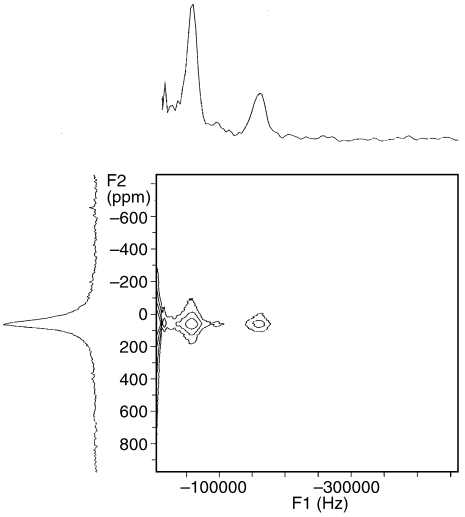

Fig. 2 1D and 2D ^{27}Al quadrupole nutation spectra of MER zeolite recorded on a Varian Unity Inova 200 with an ω_{rf} of 53 kHz. 512 data points were collected in the t_1 dimension in increments of 0.25 μs.

ratio (1.8) from chemical analysis. Although the topological symmetry for the MER framework was initially found to be the tetragonal subgroup *I*4/*mmm*, on the other hand, it has recently been shown that a better refinement is achieved from the orthorhombic subgroup *Immm*.[8,9] In this space group two crystallographically distinct sites T_1 and T_2 with 1 : 1 distribution exist in the unit cell. Considering that the average shift difference in the six ^{29}Si lines of Fig. 1 is 4.5 ppm, the shift effect due to site non-equivalence in the MER framework may be comparable in magnitude to the effect of Al substitution in the first tetrahedral coordination sphere of Si (*ca*. 5 ppm). If such is the case, structurally distinct lines should be superimposed upon one another and a deceptively simple spectrum could be observed as that in Fig. 1(a). A list of the positions, relative intensities, and assignments of the six deconvoluted components of the spectrum is given in Table 1, together with the average Si–O–T angles calculated using the relationship of Ramdas and Kinowski[11] for every resolved Si site. Based on the assignment in Table 1 and assuming a random Al distribution over the two T-sites with avoidance of Al–O–Al linkages, the Si/Al ratio derived from the intensities of the deconvoluted components of 1.9 was calculated to be very close to that from elemental analysis. This result supports the validity of our ^{29}Si NMR interpretation for MER-type zeolites based on the presence of two different T sites in this type of zeolites, which can be further evidenced by the fact that the average Si–O–T angle (142.6°) in our MER zeolite calculated from ^{29}Si MAS NMR data in Table 1 is in good agreement with the value (143.5°) in an MER zeolite with Si/Al = 2.1 from powder XRD Rietveld refinement.[8]

To obtain more firm evidence for the speculation given above, the static ^{27}Al quadrupole nutation NMR spectra[12] for MER zeolite prepared here have been measured with a radio-frequency field (ω_{rf}) of *ca*. 53 kHz, which was previously determined with an $Al(H_2O)_6^{3+}$ solution. Like the MAS spectrum, the 1D ^{27}Al static NMR spectrum exhibits one single line at 58 ppm with the full width at half-maximum of about 4 kHz. As seen in Fig. 2, however, the 2D nutation NMR spectrum consists of two distinct lines at 57 and 162 kHz along the axis F_1. Thus, the two lines corresponding to tetrahedral environments for Al atoms, which overlap in the ordinary MAS NMR spectrum, are further resolved by 2D quadrupole nutation. This reveals the presence of two different quadrupolar environments for framework Al atoms in the MER framework. The line at 57 kHz, which is similar to ω_{rf}, has a negligible quadrupolar interaction and can be attributed to framework Al atom at the site of spherical symmetry.[12] By contrast, the line at 162 kHz, which is about 3 times larger than ω_{rf}, has a quadrupole coupling constant (C_Q) of ≥ 12 MHz. Thus, it can be assgined to the Al site that is severely distorted from spherical symmetry. This clearly shows that the second Al site is crystallographically different from the first Al site. We believe that the asymmetric parameter (η) of the second Al site must be close to unity, since only one sharp peak is observed in the MAS and static ^{27}Al NMR spectra without any trace of a broad second order quadrupole powder pattern with several singularities typical for site with $C_Q \geqslant 12$ MHz and $\eta < 1$.[13] In parallel with the ^{29}Si MAS NMR evidence, in conclusion, it is clear that two crystallographically distinct T-sites are present in the framework of MER-type zeolites.

The results shown here clearly deomonstrate that if the Si/Al ratios calculated from the ^{29}Si MAS NMR spectra for zeolites, especially for novel materials, do not match well with those from elemental analysis, one must use caution in the interpertation of the spectra obtained. This is because we cannot rule out the possibility that structurally distinct lines are superimposed upon one another, yielding the deceptively simple spectra. In addition, the overall results of this study show that the ^{27}Al quadrupole nutation NMR technique can be very useful for determining the presence of crystallographically different T-sites in the zeolite framework, which is difficult to ascertain by other analytical methods.

^{1}H NMR nOe spectroscopic studies reveal that conformational control in the enolates of *N*-acyl-5,5-dimethyl-4-*iso*-propyloxazolidin-2-ones ensures that the stereodirecting effect of its 4-*iso*-propyl-5,5-dimethyl functional group affords superior levels of facial selectivity normally associated with enolates derived from *N*-acyl-4-*tert*-butyloxazolidin-2-ones.

The versatile oxazolidin-2-one based chiral auxiliary methodology first developed by Evans *et al.* has been widely used for the asymmetric synthesis of homochiral α-substituted carboxylic acids.[1] L-Valine derived 4-*iso*-propyloxazolidin-2-one **1a** is normally employed to control the asymmetric alkylation of enolates derived from the corresponding *N*-acyloxazolidin-2-ones, however it is known that the *tert*-leucine derived 4-*tert*-butyloxazolidin-2-one **1b** affords superior diastereoselectivities for this class of enolate alkylation. Thus, while methylation of the enolate of (*S*)-*N*-butyryl-4-*iso*-propyloxazolidin-2-one **2a** affords (4*S*,2′*S*)-**3a** in 82% de, methylation of the corresponding (*S*)-*N*-butyryl-4-*tert*-butyloxazolidin-2-one **2b** affords (4*S*,2′*S*)-**3b** in 97% de (Scheme 1).[2] However, the parent non-proteinogenic α-amino acid (*S*)-*tert*-leucine, from which **1b** is derived, is prohibitively expensive.[3]

We have recently reported on the development of a new family of SuperQuat 5,5-dimethyl-4-alkyloxazolidin-2-ones for asymmetric synthesis which fully address the troublesome endocyclic cleavage pathway associated with alkaline hydrolysis of *N*-acyloxazolidin-2-ones.[4] Whilst the primary function of the C(5)-*gem*-dimethyl group within *N*-acyl-5,5-dimethyl-4-alkyloxazolidin-2-ones is to completely suppress the endocyclic cleavage pathway, it was proposed on the basis of molecular modelling calculations (Fig. 1)[4] that the presence of this functionality might also serve a secondary function by enhancing the observed diastereofacial selectivity during enolate alkylation.[5,6]

As a consequence of this conformational preference, it was predicted that the facial selectivity observed for alkylation of 5,5-dimethyl-4-*iso*-propyl enolate **5c** would be significantly higher than that observed for alkylation of the corresponding enolate **5a** derived from 4-*iso*-propyloxazolidin-2-one **1a**. It follows therefore in terms of enolate alkylation that the *iso*-propyl group of the SuperQuat oxazolidin-2-ones mimics a *tert*-butyl group. In order to investigate this hypothesis, competitive enolate alkylations were carried out on the three enolates **5a**–**c** under identical conditions, *via* deprotonation of the corresponding *N*-acyloxazolidin-2-ones **4a**–**c** in THF at −78 °C, followed by warming to 0 °C, and addition of 1.1 equiv. MeI. These studies revealed that the diastereoselectivity for alkylation of enolate **5a** {(92% (4*S*,2′*S*)-**6a**: 8% (4*S*,2′*R*)-**7a**); 84% de} was significantly lower than that observed for both enolate **5b** {(98.5% (4*S*,2′*S*)-**6b**: 1.5% (4*S*,2′*R*)-**7b**); 97% de} and enolate **5c** {(97% (4*S*,2′*S*)-**6c**: 3% (4*S*,2′*R*)-**7c**); 94% de} (Scheme 2). These enolate alkylation reactions were then repeated under more precisely controlled conditions by carrying out the enolate methylation reactions on a 1:1 mixture of (*S*)-4-*iso*-propyl enolate **5a** and (*S*)-5,5-dimethyl-4-*iso*-propyl enolate **5c**, and a 1:1 mixture of (*S*)-4-*tert*-butyl enolate **5b** and enolate **5c**, in the same reaction vessel. These direct comparison studies reveal an identical trend to the separate enolate studies affording diastereoselectivities for (*S*)-4-*tert*-butyl enolate **5b** (97% de) > (*S*)-5,5-dimethyl-4-*iso*-propyl enolate **5c** (94% de) > (*S*)-4-*iso*-

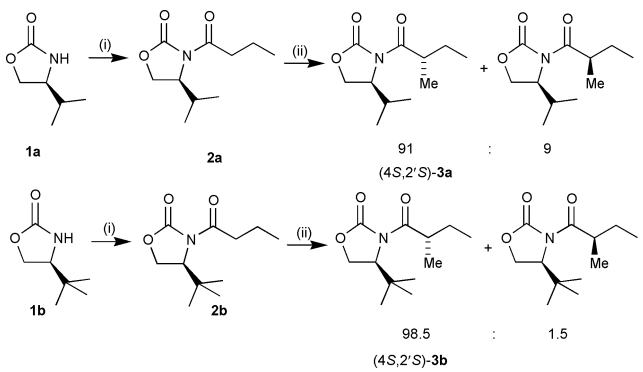
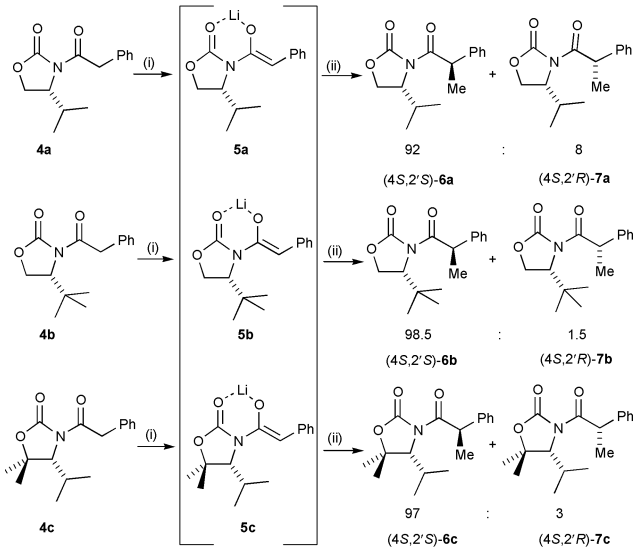


Scheme 1 *Reagents and conditions:* (i) *n*-BuLi, butyryl chloride, THF, −78 °C; (ii) LDA, MeI, THF, −30 °C.



Scheme 2 *Reagents and conditions:* (i) LHMDS, THF, −78 to 0 °C; (ii) 1.1 equiv. MeI.

propyl enolate **5a** (84% de). The diastereoselectivities for all of the enolate alkylation reactions investigated were calculated from integration of the resonances corresponding to both the major (4*S*,2′*S*)-diastereoisomers **6a**–**c** and minor (4*S*,2′*R*)-diastereoisomers **7a**–**c** in the ^{1}H NMR spectrum of each crude reaction mixture. Authentic pure samples of both the major (4*S*,2′*S*)-diastereoisomers **6a**–**c** and minor (4*S*,2′*R*)-diastereoisomers **7a**–**c** were obtained *via* chromatographic purification of the three pairs of diastereoisomers **6a**–**c** and **7a**–**c** obtained from *N*-acylation of the lithium anions of each of the parent oxazolidin-2-ones with racemic 2-phenylpropanoyl chloride, and fully characterised.

Having clearly demonstrated that methylation of the 5,5-dimethyl-4-*iso*-propyl enolate **5c** with MeI at 0 °C occurred in higher de than methylation of the corresponding 4-*iso*-propyl enolate **5a**, ^{1}H nOe NMR spectroscopic analysis on the enolates **5a** and **5c** was carried out in order to probe directly their conformation in solution. Enolates **5a** and **5c** were generated *via* treatment of **4a** and **4c** with 1 equiv. of LHMDS at −78 °C in d_8-THF, followed by warming the resulting solution to 0 °C. The ^{1}H NMR spectra of both **5a** and **5c** were entirely consistent with the proposed (*Z*)-enolate structures since enolate **5a** showed a singlet resonance at δ 4.58, while enolate **5c** exhibited a singlet resonance at δ 4.68, corresponding to the C(2′) vinylic proton of the enolate functionality in each case. Examination of the resonances corresponding to the *iso*-propyl C*H*(Me)$_2$ protons in the ^{1}H NMR spectrum of enolates **5a** and **5c** revealed small vicinal coupling constants of 3.2 and 2.3 Hz respectively between the *iso*-propyl C*H*(Me)$_2$ proton and the oxazolidin-2-one H(4) proton. This is consistent with both enolates **5a** and **5c** adopting conformations in which the C*H*(Me)$_2$ protons of their *iso*-propyl groups lie approximately syn- or anti-periplanar to the C(4)–C(5) bond of the oxazolidin-2-one ring, with both methyl groups of their *iso*-propyl units directed either towards, or away from the attached enolate fragment. Qualitative ^{1}H nOe NMR spectroscopic analysis of the 4-*iso*-propyl enolate **5a** in d_8-THF at 0 °C revealed a strong enhancement between the C(2′) vinylic proton of the enolate fragment and the oxazolidin-2-one *iso*-propyl C*H*(Me)$_2$ proton, with no nOe enhancement with either of the *iso*-propyl CH(C*H*$_3$)$_2$ groups. Further strong nOe enhancements were observed between the *pro*-(*S*) H(5) proton and both of the *iso*-propyl CH(C*H*$_3$)$_2$ methyl groups. These nOe enhancements are consistent with a major enolate conformer **5a** in which both of the *iso*-propyl methyl groups are directed away from the attached enolate fragment (Fig. 2). In contrast, qualitative ^{1}H nOe NMR spectroscopic analysis of enolate **5c** revealed both a medium and small enhancement between the C(2′) vinylic proton of the enolate fragment and each of the methyl groups of the *iso*-propyl CH(C*H*$_3$)$_2$ group. A further strong nOe enhancement was observed between the C*H*(Me)$_2$ proton and one of the C(5)-*gem*-dimethyl groups. These nOe enhancements are consistent with the proposed model for 5,5-dimethyl-4-*iso*-propyl enolate **5c** in which the major conformer in solution has both methyl groups of the stereocontrolling *iso*-propyl group directed towards the attached enolate fragment (Fig. 3). Importantly, both samples of enolates **5a** and **5c** in d_8-THF at 0 °C used in these ^{1}H NMR

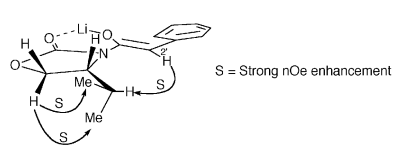


Fig. 2 nOe study on Evans' enolate **5a**. Other nOe enhancements omitted for clarity.

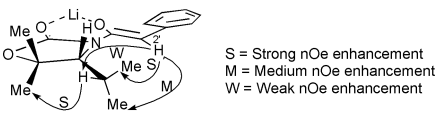

Fig. 3 nOe study on SuperQuat enolate **5c**. Other nOe enhancements omitted for clarity.

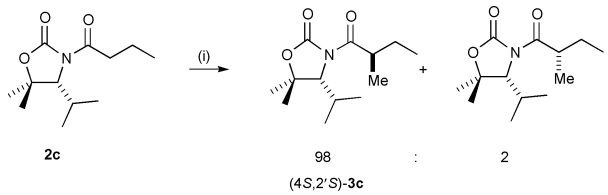

Scheme 3 *Reagents and conditions:* (i) LDA, MeI, THF, −30 °C.

studies were shown to be stable over the period of the experiment *via* subsequent treatment of both solutions of enolates **5a** and **5c** with MeI to afford the major diastereoisomers **6a** and **6c** with diastereoselectivites identical to those obtained previously.

In order to confirm the enhanced facial selectivity observed for alkylation of *N*-acyl-5,5-dimethyl-4-*iso*-propyl enolates, methylation of the enolate of *N*-butyryl-5,5-dimethyl-4-*iso*-propyloxazolidin-2-one **2c** was carried out under the original conditions described by Evans *et al.* for *N*-butyryloxazolidin-2-ones **2a** and **2b**. Thus, methylation of the enolate of **2c** gave the major diastereoisomer (4*S*,2′*S*)-**3c** in 96% de (Scheme 3), which is significantly higher than that obtained for methylation of the enolate of *N*-butyryl-4-*iso*-propyloxazolidin-2-one **3a** of 82% de, and compares favourably with that observed for methylation of the enolate of *N*-butyryl-4-*tert*-butyryloxazolidin-2-one **3b** of 97% de.

In conclusion, ^{1}H NMR nOe spectroscopic studies confirm that the superior enolate alkylation diastereoselectivities observed for (*S*)-5,5-dimethyl-4-*iso*-propyl enolate **5c** over (*S*)-4-*iso*-propyl enolate **5a** is a result of steric interactions between the C(5)-*gem*-dimethyl and the *iso*-propyl group of **5c** which direct both methyl groups of the *iso*-propyl stereocontrolling group towards the enolate fragment. We believe that the strategy outlined above of employing adjacent *gem*-dimethyl groups to control the conformation of an *iso*-propyl group such that it mimics a *tert*-butyl group is a general one, and we are currently investigating the development of a wide range of novel ligands and auxiliaries containing this structural motif, which is easily prepared from valine, as replacements for the corresponding *tert*-leucine derived analogues.[7]

We thank Dr Barbara Odell for her technical assistance with the qualitative ^{1}H nOe NMR spectroscopic studies on enolates **5a** and **5c**.

ChemComm

The first asymmetric Suzuki cross-coupling reaction

Andrew N. Cammidge* and Karen V. L. Crépy

Received (in Cambridge, UK) 6th June 2000, Accepted 27th July 2000
First published as an Advance Article on the web 22nd August 2000

The first asymmetric coupling reactions between aryl halides and aryl boronates (Suzuki coupling) are described to give binaphthalene derivatives in up to 85% ee.

Restricted rotation around the aryl–aryl bond in biaryls can lead to the phenomenon of atropisomerism (sometimes called helical chirality). Chiral binaphthalenes constitute an important class of such atropisomeric compounds, not least because they are amongst the most useful chiral ligands and auxiliaries employed in asymmetric synthesis.[1] Transition metal-catalysed cross-coupling between organometallic species and aryl halides (for example) is a powerful synthetic tool and represents one of the most straightforward methods for aryl–aryl carbon–carbon bond formation.

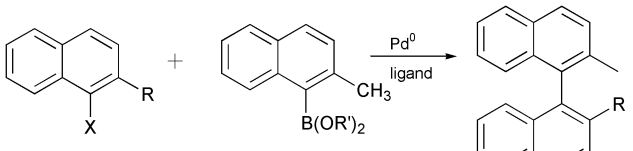
A small number of asymmetric biaryl syntheses have been reported. High selectivity has been achieved in the asymmetric synthesis of 2,2′-dimethyl-1,1′-binaphthalene **9** using chiral auxiliaries (chiral oxazoline[2,3] or a chiral leaving group[4]) or using chiral catalysts.[5] However, variable results have been reported depending on the nature of the catalyst used (*e.g.* Ni or Pd) and in all cases a Grignard reagent is used as the organometallic component.

Here we report the first examples of an *asymmetric* Suzuki coupling protocol for the construction of binaphthalenes.[6] The Suzuki coupling reaction has many inherent advantages over related Ni- and Pd-catalysed couplings and has found widespread application in the synthesis of simple and complex biaryls. The main advantage is its tolerance of a broad range of functional groups and its non-toxic by-products.[7] The organometallic partner in the Suzuki coupling (an organoboronic acid derivative) is thermally stable, inert to air and water (which allows its handling without special precautions) and unreactive to many of the electrophilic functional groups which cannot be employed (unprotected) in conjunction with Grignard reagents.

In our investigation of the asymmetric Suzuki reaction, we chose the synthesis of substituted binaphthalenes to allow comparison with previously reported methods (Scheme 1). Naphthyl halide starting materials **1**–**4** were obtained commercially or synthesised following standard procedures.[8] Boronic acid **5** was synthesised by converting the corresponding naphthyl bromide **3** into its Grignard reagent,[9] quenching with trimethylborate and aqueous acidic work-up. Boronic acid **5** was also converted to boronate esters **6** and **7** by treatment with pinacol and ethylene glycol respectively (Dean–Stark trap).

It is well known that use of sterically congested coupling partners can lead to poor yields in Suzuki reactions.[7,10] Racemic coupling was therefore first performed to optimise the reaction conditions (base–solvent combinations, heterogeneous *vs*. homogeneous conditions, boronic acid *vs*. boronate esters *etc*.) and selected results are summarised in Table 1. Both homogeneous and heterogeneous conditions were established to allow isolation of binaphthalenes **8** and **9** in acceptable yields. Optimum conditions typically involved treating aryl halides **1**–**4** with 1.1–2 mol eq. of boronic acid **5** or boronate esters **6**, **7** in the presence of 3 mol% $PdCl_2$/6 mol% PPh_3[11] and 1.5–2 mol eq. of base at elevated temperatures.[12] Competing deboronation was observed when the sterically congested boronic acids were reacted with hindered aryl halides and coupling was only observed in these cases when boronate esters were used. As expected, reactions with 1-iodonaphthalenes proved faster and led to greater yields than those reactions employing 1-bromonaphthalenes, especially with the combination $Ba(OH)_2$–DME–H_2O[12a] (Table 1, entries 1 and 4).

Our best conditions were then extended to investigation of the asymmetric Suzuki reaction using chiral ligands. Diamine ligands (*e.g.* **11**) gave racemic products but selectivity was



1 X = Br, R = H
2 X = I, R = H
3 X = Br, R = CH_3
4 X = I, R = CH_3

5 R' = H,H
6 R' = -$C(CH_3)_2$-$C(CH_3)_2$-
7 R' = -CH_2CH_2-

8 R = H
9 R = CH_3

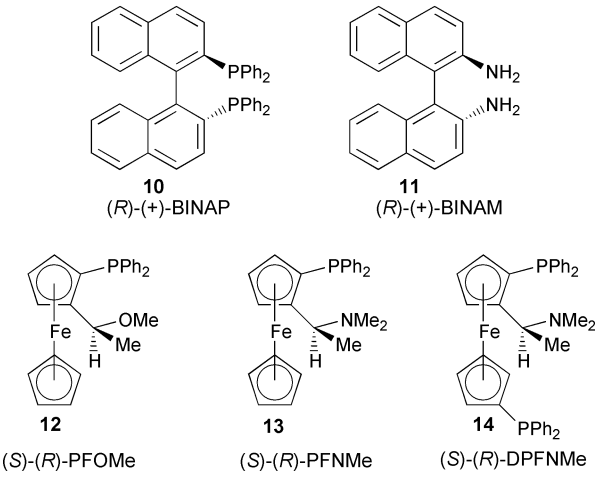
[a] Carried out with 1.1–2 eq. of boronic acid derivative in refluxing solvent using 3 mol% $PdCl_2$/6 mol% monophosphine chiral ligand or 3 mol% $PdCl_2$/3 mol% bidentate chiral ligand. [b] ee's were determined by optical rotation measurements[5b,13]. [c] Products isolated by column chromatography. To avoid fractionation, recrystallisation was not performed.



observed when phosphine ligands were employed. BINAP **10** led to modest ee's of 8–25% (summarised results are reported in Table 2). Furthermore, use of different boronate esters led to different selectivity (use of bulky pinacol ester **6** gave the opposite enantiomer to that observed when the boronic acid **5** or ethylene glycol ester **7** was employed (Table 2, entries 5, 12 and 13)) implying kinetic control. Highest selectivity was observed when a mono-phosphine ligand was employed. Diastereomeric ferrocene **12**, which has diphenyl phosphine and ether ligands gave disappointing ee's when **2** and **5** were coupled (**12** was found to be far superior to binaphthalene ligands in asymmetric couplings employing Grignard reagents[5b]). The related ligand **13**, in which a tertiary amine replaces the methoxide of **12**, was found to lead to the highest selectivity. With this ligand 2-methyl-1-1′-binaphthalene **8** could be synthesised in yields of 44–55% and ee's of 52–63%. The dimethyl derivative **9** gave the highest observed ee (85%) when boronate ester **7** was employed.

Our results obtained for the asymmetric Suzuki coupling can be compared to the nickel- and palladium-catalysed couplings of Grignard reagents with naphthyl halides. In the nickel-catalysed reaction, ligand **12** gives the highest ee and coupling reactions using **13** were ineffective. The selectivity in this reaction was suggested to arise through complexation of the magnesium ion of the Grignard reagent to the oxygen (methoxide) of the chiral ligand resulting in stereoselective delivery of the organometallic and kinetic control. Such complexation is not possible with a naphthylboronate so the observed low ee is perhaps not surprising. The high ee obtained with tertiary amine phosphine ligand **13** suggests that pre-complexation is arising between nitrogen and boron prior to transmetallation. Use of a bidentate phosphine ligand (**14**) resulted in a decrease in the observed selectivity which is similar to the results obtained with Grignard reagents.[5]

In summary, we have performed the first series of asymmetric Suzuki cross-coupling reactions to prepare chiral binaphthalenes with ee's up to 85%. The reaction permits the use of functional groups which are incompatible with Grignard reagents (the organometallic component used in all previously reported syntheses). The extension of this methodology to other biaryl systems is ongoing in our laboratories.

Support for this work from the School of Chemical Sciences (UEA) is gratefully acknowledged (K. V. L. C.).

ChemComm

Ultra fast and efficient synthesis of Ti-ITQ-7 and positive catalytic implications

Avelino Corma,* Ma José Díaz-Cabañas,[a] Marcelo E. Domine and Fernando Rey

Instituto de Tecnología Química, UPV-CSIC, Universidad Politécnica de Valencia, Avda. de los Naranjos, s/n, 46022 Valencia, Spain. E-mail: acorma@itq.upv.es

Received (in Oxford, UK) 24th May 2000, Accepted 27th July 2000
First published as an Advance Article on the web 22nd August 2000

Incorporation of germanium into a zeolite framework allows the synthesis of Ti-Ge-ITQ-7 without seeding in < 12 h, instead of 12 days when seeding or > 40 days without seeding for the Ge-free ITQ-7; the synthesis reported also increases the efficiency of Ti incorporation and allows the preparation of almost nanocrystaline Ti-ITQ-7 materials with a corresponding beneficial effect on the final catalytic activity.

The synthesis of zeolite containing framework transition metals has opened new catalytic possibilities for the use of such materials in the synthesis of chemicals and fine chemicals.[1] This is especially true for Ti zeolites, Ti-silicalite and Ti-beta being good examples of stable materials which can catalyse epoxidation of olefins, oxidation of alcohols, hydroxylation of phenol and sulfoxidation of sulfurs containing species among other reactions.[2] The potential applications of Ti-zeolites have been extended to bulkier reactants by the synthesis of mesoporous Ti-MCM-41[3,4] and delaminated Ti-zeolite ITQ-6.[5] The interest in Ti-zeolites is still high, but while the incorporation of Ti has been attempted in numerous structures very limited success has been observed. Indeed, isomorphic substitution of Ti in the framework of zeolites has been shown to occur in very few cases,[6–8] and in others[9] the introduction of Ti in the synthesis gel not only fails to lead to its incorporation in the final structure, but in many cases the presence of Ti slows down, or even prevents growth of the desired structure. This has also been the case in a recent publication on the synthesis of Ti-ITQ-7,[10] a zeolite with a three-directional system of large pore channels. When the synthesis was attempted in the absence of seeds and using a Si/Ti ratio of 30 in the synthesis gel, the crystallisation did not proceed to completion and stopped when the crystallinity reached *ca*. 30%. On the other hand, in the presence of seeds it was found that Ti-ITQ-7 grows much more slowly than the analogous pure silica zeolite; furthermore the efficiency in the incorporation of Ti is low and, also lower than that found for Ti-beta zeolite. These results seem to indicate that the presence of Ti slows the nucleation of ITQ-7 and can also severely affect the zeolite growth. We have carried out a theoretical study using *ab initio* methods with periodic systems on the effect of the incorporation of Ge in the framework of zeolites *viz-à-viz* the stabilisation of the Ti atoms in the framework structure.[11] It was found that substitution of Si atoms by Ge close to the Ti sites results in a stabilisation of the system owing to the additional framework flexibility provided by the less rigid GeO_4 units, similar to that occurring during the direct synthesis of Al-Ge-ITQ-7 catalysts.[12]

On this basis, we have attempted the synthesis of Ti-ITQ-7 by introducing Ge in the synthesis gel. Thus, a sample of Ti-Ge-ITQ-7 was synthesised in the following manner: 0.63 g of GeO_2 were dissolved in 34.31 g of a 0.97 M aqueous solution of 1,3,3-trimethyl-6-azoniumtricyclo[3.2.1.4^{6,6}]dodecane hydroxide (SDAOH). Then, 0.61 g of tetraethylorthotitanate and 12.61 g of tetraethylorthosilicate (TEOS) were hydrolysed in the above solution, and the reaction mixture was stirred until complete elimination of ethanol and water, to reach the desired gel composition. Finally, 1.38 g HF (48.1 wt%) were added and the mixture was transferred to a Teflon-lined stainless steel autoclave and left to crystallise under static conditions at 150 °C. An analogous synthesis was carried out without adding Ge to the synthesis gel. Different crystallisation times were considered in order to obtain the kinetic curves for the crystallisation of the zeolite (Fig. 1). The final compositions of the gels were: 0.90 SiO_2:0.10 GeO_2:*x* TiO_2:0.50 SDAOH:0.50 HF:3 H_2O and SiO_2:0.05 TiO_2:0.50 SDAOH:0.50 HF:3 H_2O, for the Ge and the Ge-free synthesis, respectively. The solids were recovered by filtration, and after exhaustive washing with distilled water, were dried at 100 °C, overnight. In all the syntheses, the yields of the solids recovered, in terms of oxides, were > 90% with respect to the initial gel composition.

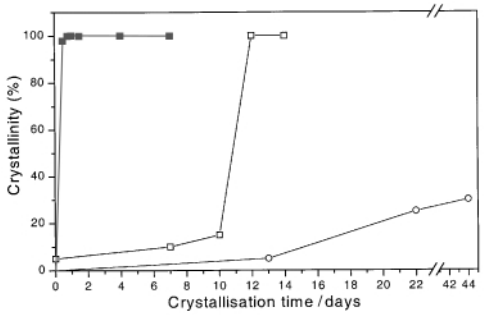

Fig. 1 Crystallization curves for the synthesis of Ti-Ge-ITQ-7 (■) and Ti-ITQ-7 with (□) and without seeds (○).

The XRD pattern (Fig. 2) of the Ti-Ge-ITQ-7 zeolite (sample D) shows a shift of the diffraction peaks to higher *d*-values when compared to the analogous Ti-ITQ-7 material (sample A) (*i.e.* without Ge and having a similar T^{IV}/Ti ratio in its composition) which indicates that the unit cell volume expands upon Ge incorporation in the zeolitic ITQ-7 framework. This result can be taken as unambiguous proof of the effective isomorphous substitution of Si by Ge in the Ti-Ge-ITQ-7 material.

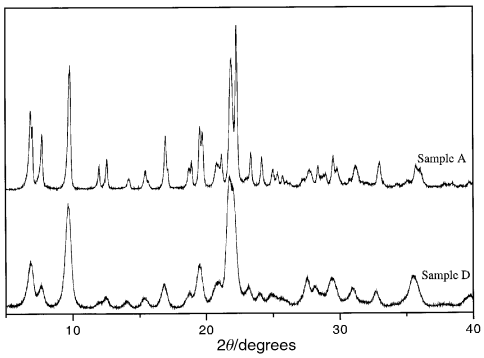

Fig. 2 XRD patterns of as-made samples: (a) Ti-ITQ-7 (sample A) and (b) Ti-Ge-ITQ-7 (sample D).

It was found (see Fig. 1) that when Ge is introduced on the synthesis gel, Ti-Ge-ITQ-7 is fully crystallised, even in the absence of seeds, in only 12 h (crystallinity measured in terms of the peak area between 2θ = 20.15 and 23.65° and referred to a sample arbitrarily assigned a value of 100%). Moreover, the nucleation period is strongly reduced with respect to the Ge-free

DOI: 10.1039/b004203j

Table 1 Efficiency for Ti incorporation as a function of gel composition

Sample	Si/Ge	F source	% TiO_2[a] (gel)	% TO_2 (solid)[b] SiO_2	GeO_2	TiO_2	% Ti incorporated
A[c]	∞	HF	6.64	98.86	—	1.14	17.2
B	10	HF	2.46	87.35	12.05	0.60	24.4
C	10	HF	5.01	85.67	12.93	1.40	28.0

E	10	HF	0	87.65	12.35	0	—

[a] % TiO_2 calculated as: $TiO_2 \times 100/(SiO_2 + GeO_2 + TiO_2)$. [b] Measured by atomic absorption; % SiO_2 is calculated as difference. [c] Samples used for catalytic activity testing.

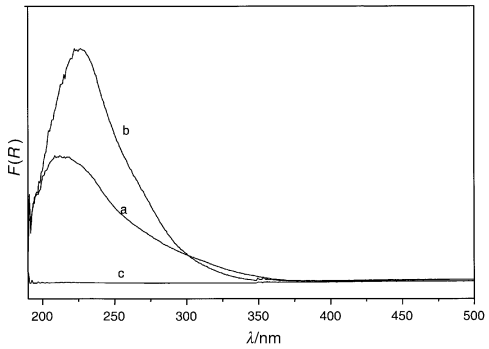

Fig. 3 Diffuse reflectance UV–VIS absorption spectra of calcined samples: (a) Ti-ITQ-7 (sample A), (b) Ti-Ge-ITQ-7 (sample D) and (c) Ge-ITQ-7 (sample E).

synthesis even if seeds were added to the synthesis gel. These facts, important in themselves, are even more impressive by considering that the efficiency of Ti incorporation is higher in the presence of Ge (Table 1), and more specifically when NH_4F is used instead of HF. In this case, the efficiency of the Ti incorporation is close to that found for Ti-beta zeolite. The high incorporation of Ti in the zeolite framework can be inferred from the UV–VIS band appearing at 220 nm (Fig. 3) which is much more intense than that of the Ge-free Ti-ITQ-7 synthesised by the previously reported procedure.[10] The higher intensity of the band is not due to the presence of Ge, since Ti-free Ge-ITQ-7 does not absorb in this region of the UV-visible spectrum (Fig. 3). Furthermore, anatase is not detected in the sample synthesised in the presence of Ge, either by UV–VIS (Fig. 3) or by Raman spectroscopy. By contrast some anatase formation was observed for Ge-free Ti-ITQ-7 samples[10] having similar Ti content as Ti-Ge-ITQ-7 catalysts described here.

The more efficient incorporation of Ti in the synthesis with Ge has an impact on the catalytic activity for the epoxidation of a linear olefin (*n*-octene) which can diffuse easily in the pores of ITQ-7 structure. The results presented in Table 2 show that a higher activity is observed for the Ti-Ge-ITQ-7 sample (D).

It is important to point out that the fast nucleation rate obtained in the presence of Ge produces much larger number of nuclei, giving Ti-Ge-ITQ-7 samples with a much smaller crystallite size (< 0.1 μm) than ITQ-7 synthesised by the previous method (1–2 μm).[9] This has important catalytic implications when reacting molecules diffuse slowly. Under these circumstances, a zeolite with smaller crystallite size is preferred in order to increase the number of Ti sites that can be reached by the reactants. We have proven this here by carrying out the epoxidation of dodec-1-ene with two Ti-ITQ-7 samples with different crystallite sizes. As seen before,[13,14] for Ti-silicalite and Ti-beta zeolites, a decrease in conversion occurs from oct-1-ene to dodec-1-ene owing to a decrease in the diffusion rate upon increasing the length of the hydrocarbon chain; this is also seen for Ti-ITQ-7. The results presented in Table 2 clearly show the increased activity of the smaller crystallites of Ti-Ge-ITQ-7 which results in a five fold increase in the turnover number with respect to the conventional Ti-ITQ-7 material.

Table 2 Catalytic activity of Ti-ITQ-7 for olefin epoxidation[a]

Olefin	Sample	X_{olefin}[b]	Selectivity to epoxide (%)	Selectivity to H_2O_2 (%)	TON[c]
Oct-1-ene	Ti-ITQ-7 (A)	14.9	98	55	27
	Ti-Ge-ITQ-7 (D)	25.9	100	52	41
Dodec-1-ene[d]	Ti-ITQ-7 (A)	0.8	100	17	3
	Ti-Ge-ITQ-7 (D)	4.8	100	43	16

[a] *Reaction conditions*: 16.5 mmol olefin; 11.8 g acetonitrile; 4.5 mmol H_2O_2 (slowly added); 200 mg of catalyst; 333 K, 3.5 h. [b] Conversion of olefin (mol% referred to the maximum possible). [c] TON = mol olefin converted/mol Ti. [d] 100 mg of catalyst.

In conclusion, we have found that it is possible to strongly increase the rate of nucleation and/or crystallisation of Ti-ITQ-7, to increase the efficiency of Ti incorporation in the framework and to produce an almost nanocrystalline zeolite, by introducing Ge to the ITQ-7 zeolite framework. All this has a clear beneficial effect on the catalytic activity of the resultant Ti-Ge-ITQ-7. It is remarkable that by a rigorous theoretical study, it was possible to predict that the incorporation of Ge should facilitate the synthesis of Ti-zeolites, as established here for Ti-ITQ-7.

Amphiphilic α-alkoxyalkyl hydroperoxide (α-AHP): a new oxidising reagent in aqueous media

Araki Masuyama,* Kazuyuki Fukuoka, Masanori Wakita and Masatomo Nojima

Department of Materials Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565-0871, Japan. E-mail: toratora@ap.chem.eng.osaka-u.ac.jp

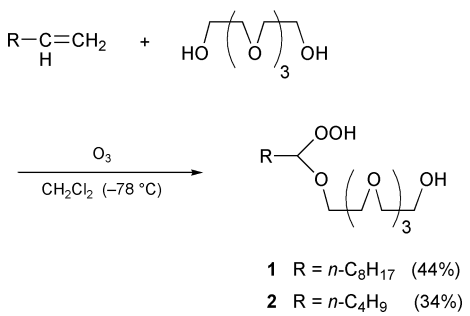
Received (in Cambridge, UK) 6th July 2000, Accepted 1st August 2000
First published as an Advance Article on the web 22nd August 2000

Effective oxidation of benzyl sulfide to the corresponding sulfoxide in water was achieved by using amphiphilic α-alkoxyalkyl hydroperoxide (α-AHP) in the presence of a catalytic amount of $MoO_2(acac)_2$ under mild conditions.

Exploration of organic reactions in aqueous media is now becoming important from the standpoint of environmentally benign processes.[1] One of the major problems in these reactions, however, is the poor solubility of most organic substrates in water. The application of micellar or vesicular systems made from amphiphilic molecules to organic reactions in water is an effective device to overcome this substantial problem.[2] For example, Jaeger *et al*. have studied in detail the rate and/or regioselectivities of certain reactions, such as monohalogenation of alkyl phenyl ethers or Diels–Alder reactions, in specially designed micellar or vesicular systems.[3] Kobayashi *et al.* have developed Lewis acid–surfactant combined catalysts and have applied micellar systems made from these functional surfactants to aldol or Mannich-type reactions.[4] A number of other papers concerning organic reactions in aqueous micellar systems have been published over the past decade.[5]

For oxidation reactions in aqueous media, commercially available 30–60% hydrogen peroxide has been used as an oxidising reagent because its oxygen efficiency is excellent and water is a resultant side product.[6] *tert*-Butyl hydroperoxide (TBHP) is another choice of reagent in aqueous media.[7] Because these hydroperoxides are potentially hazardous compounds, however, they must be handled with special care. With this in mind, we developed a unique amphiphilic α-alkoxyalkyl hydroperoxide (α-AHP) to act both as a micellar-forming reagent to solubilise organic substrates and as an oxidising reagent. The compounds designed for this work could be easily prepared by ozonation of α-olefins in the presence of oligo(ethylene glycol)s† (Scheme 1).

Fundamental surface-active properties of **1** were as follows: T_{cp} (cloud point at 1 wt%) = 40 °C; cmc = 3.1×10^{-3} mol dm^{-3}; γ_{cmc} (the surface tension at cmc, as an indication of the effectiveness of adsorption at the air/water interface)[8] = 30 mN m^{-1}; pC_{20} (the efficiency of adsorption)[8] = 3.7.‡ This cloud point means that **1** is soluble in water at rt and forms micelles at any concentration above its cmc. Compound **2** was additionally synthesised as a reference because it was freely soluble in water but showed no surface-active properties.



1 R = *n*-C_8H_{17} (44%)
2 R = *n*-C_4H_9 (34%)

Scheme 1

Differential thermal analyses (DTA/TG) of **1** and **2** were carried out.§ Both compounds were stable up to about 100 °C but gradually decomposed above that temperature. These results indicate that this type of α-AHP is moderately thermostable. Although careful treatment is still required, the α-AHP is easier to handle than TBHP. The ^{1}H and ^{13}C NMR spectra of a 5 wt% D_2O solution of **1** did not change at all after the solution was kept at 60 °C for 24 h.

Oxidation of benzyl sulfide was chosen to determine the effectiveness of α-AHP as an oxidising reagent in aqueous media. The reaction was run at rt and the reaction products were directly monitored by HPLC.¶ The oxidation reaction in each system was carried out at least three times to confirm its reproducibility. The results are summarised in Table 1 along with data for the same reaction conducted in dichloromethane.

It was confirmed that **1** certainly acted as an oxidising reagent in the presence of $MoO_2(acac)_2$ catalyst[9] under homogeneous conditions in dichloromethane (entry 8). In an aqueous system, too, **1** could oxidise water-insoluble benzyl sulfide very effectively (entries 1 and 2). The reaction proceeded cleanly. In no cases, were any compounds other than unreacted substrate, unreacted α-AHP, benzyl sulfoxide, (benzyl sulfone), alkyl aldehyde and tetra(ethylene glycol) detected in the reaction mixture after 24 h. Aldehyde and tetra(ethylene glycol) were fragements derived from the corresponding α-AHP through the oxidation reaction. Addition of a catalytic amount of $MoO_2(acac)_2$ to the aqueous micellar system promoted the reaction. In the presence of excess α-AHP, however, benzyl sulfone as well as benzyl sulfoxide was formed in quantity (entry 4). In contrast to the $MoO_2(acac)_2$ system, addition of $VO(acac)_2$[9] caused no acceleration of the reaction in aqueous media (entries 5 and 6). The conversion of the substrate was only 16% when **2** was employed as an oxidising reagent (entry 7). Compound **2** is water-soluble but does not form micelles in water. Evidently, a

DOI: 10.1039/b005414n

key feature of success in promotion of this oxidation in water is the formation of micelles.

When the concentration of **1** in water was 10 mmol dm^{-3}, the maximum conversion was only 72% (entry 3). It is surmised that the oxygen atom transfer from **1** to benzyle sulfide results in the formation of the corresponding hemiacetal, which in turn is easily decomposed into non-surface-active nonanal and tetra(ethylene glycol). Because the cmc of **1** is 3.1 mmol dm^{-3}, most of the micelles will disappear at the final stage of the reaction. This results in the loss of effective solubilisation of substrate in the system. The appearance of insoluble solids in the reaction system was actually observed after 18 h with the naked eye. However, when using excess **1** (20 mmol dm^{-3}) micelles were still present after 24 h, so that the conversion of substrate in each system was higher than in the corresponding system containing 10 mmol dm^{-3} of **1**.

The precise mechanism of these micellar oxidation systems has not yet been established, but it seems reasonable to surmise that benzyl sulfide solubilised within the α-AHP micelles will be oxidised effectively by hydroperoxy groups of α-AHP, which will exist in the vicinity of the solubilised site.

In summary, effective oxidation of benzyl sufide to the corresponding sulfoxide (and sulfone) in water has been achieved by using micellar α-AHP **1** in the presence of a catalytic amount of $MoO_2(acac)_2$ under very mild conditions. Studies on the preparation of a series of α-AHPs and their application to other oxidation reactions in these micellar systems are now in progress.

Notes and references

† Over a solution of 1-alkene (10 mmol) and tetra(ethylene glycol) (80 mmol) in dichloromethane (0.04 dm^3) was passed a slow stream of ozone (1.2 equiv.) at −78 °C. Then, the mixture was poured into aqueous $NaHCO_3$ and was extracted with ether. After evaporation of the solvent, the crude products were separated by column chromatography on silica gel. Elution with ether–methanol (95 : 5, v/v) gave the target α-AHP as an oil. *Selected data* for compound **1** (R = *n*-C_8H_{17}), δ_H(270 MHz; $CDCl_3$) 0.88 (t, 3H), 1.15–1.45 (m, 12H), 1.60–1.85 (m, 2H), 3.1 (s, 1H), 3.52–3.90 (m, 16H), 4.84 (t, 1H), 10.66 (s, 1H); δ_C(67.5 MHz) 13.98, 22.53, 24.71, 29.07, 29.23, 29.32, 31.05, 31.71, 61.49, 65.12, 69.95, 70.02, 70.19, 70.42, 70.92, 72.38, 107.00 (Calc. for $C_{17}H_{36}O_7$: C, 57.93; H, 10.30. Found: C, 58.12; H, 10.09%). For compound **2** (R = *n*-C_4H_9), similar NMR data were recorded (Calc. for $C_{13}H_{28}O_7$: C, 52.69; H, 9.52. Found: C, 52.39; H, 9.37%).

‡ Cmc, γ_{cmc} and pC_{20} values were obtained from a surface tension *vs.* concentration (on a log scale) curve measured by the Wilhelmy method (Kyowa CBVP-A3 model; platinum plate) at 20 °C.

§ DTA/TG measurements were performed in a stream of nitrogen at 2 °C min^{-1} of programming rate (Seiko DTA/TG30 model).

¶ Oxidation of benzyl sulfide in aqueous systems was conducted as follows: to a stirred aqueous solution of α-AHP (0.01 dm^3, 10 or 20 mmol dm^{-3}) in a 0.05 dm^3 sample vial equipped with a magnetic bar and a septum were added benzyl sulfide (0.1 mmol) and metal catalyst (3 mol%). The reaction mixture was stirred in dark at rt for 24 h. Then, acetonitrile (0.015 dm^3) was poured into the mixture and bromobenzene as an internal standard was added to the solution. The resultant solution was injected directly into the HPLC apparatus equipped with a TSKgel ODS-80Ts column (eluate: water–acetonitrile = 2/3, flow rate: 8×10^{-4} dm^3 min^{-1}). From the comparison with authentic samples, formation of nonanal (in the case of α-AHP **1**) or pentanal (in the case of compound **2**), and tetra(ethylene glycol) was confirmed in the reaction mixture.

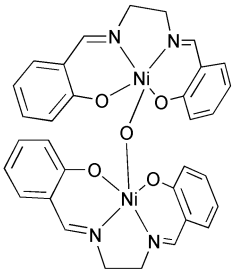
Received (in Cambridge, UK) 24th May 2000, Accepted 1st August 2000
First published as an Advance Article on the web 24th August 2000

A new thermally stable oxo-bridged dinuclear nickel(III) complex has been synthesised and its crystal structure showed two nickel(III) ions with distorted square pyramidal coordination geometry.

Complexes of Ni(III) are very significant for their participation in the catalytic action of hydrogenases.[1] Generally Ni(III) complexes are obtained by electrochemical oxidation of the corresponding Ni(II) species.[2] Although many homo- and hetero-metallic oxo-bridged complexes have been reported,[3,4] there are a limited number of high valent metal oxo-species that have been extensively characterised. Recently, structures of doubly oxo bridged dinuclear nickel(III) complexes were published.[5,6] However, both these species are thermally unstable. Usually M–O–M type complexes, where M has a d^n electronic configuration with $n > 5$, are unstable due to the presence of electrons in the higher level antibonding orbitals.[7]

We have synthesised and structurally characterised the stable oxo-bridged nickel(III) complex $[Ni(salen)]_2O$ **1**. The present



1

work provides the elemental analysis, X-ray structure analysis and magnetic studies of the complex and the results show that the two nickel ions in 3+ oxidation state are joined together by a bridging oxo group to form the dinuclear unit (Fig. 1).

The [Ni(salen)] complex was synthesised as reported earlier.[8] Pure oxygen gas was allowed to pass through a methanolic solution of [Ni(salen)], containing a few drops of NEt_3. On standing overnight, deep red crystals were obtained from the solution (yield 17%).† The crystals were thoroughly washed and air dried and one single crystal was selected for X-ray crystal structure analysis.‡

A perspective view of the molecule is shown in Fig. 1. As in most oxo-bridged complexes,[9] the Ni–O–Ni linkage is not linear [146.32(16)°]. Both the nickel(III) ions are five coordinate with distorted square pyramidal geometry. However, calculation of the geometrical factor τ shows that the degree of distortion in the two nickel centres is different [τ for Ni(1) is 0.15, for Ni(2), 0.33]. However the apical Ni–O(5) distance is 1.790(2) Å for both Ni centres.

The Ni–O distances are shorter here than in the doubly-bridged species [1.870(8), 1.841(7) Å]. The Ni–O distances found in closely related aqua species[6] are longer, typically by 0.1 Å and in the bridging hydroxo species,[5] longer still, by 0.2 Å.

The mean Ni–O and Ni–N salen distances are substantially longer [1.929(15) and 2.115(9) Å, respectively] than those

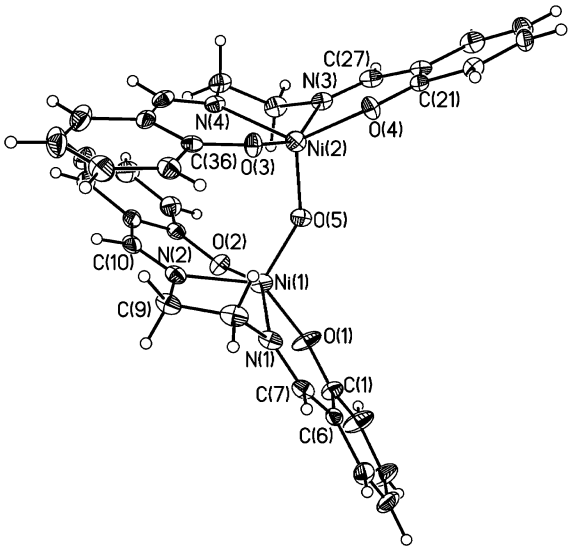


Fig. 1 Perspective view of **1** with displacement ellipsoids drawn at the 50% probability level. Selected distances (Å) and angles (°): Ni(2)–O(5) 1.790(2), Ni(2)–O(4) 1.918(2), Ni(2)–N(3) 2.108(3), Ni(2)–O(3) 1.949(2), Ni(2)–N(4) 2.116(3), Ni(1)–O(1) 1.912(2), Ni(1)–O(2) 1.938(2), Ni(1)–N(2) 2.130(3), Ni(1)–O(5) 1.790(2), Ni(1)–N(1) 2.108(3); O(2)–Ni(1)–O(1) 148.46(11), O(1)–Ni(1)–N(2) 139.37(12), Ni(1)–O(5)–Ni(2) 146.32(16).

found in a survey on Ni(II) salen species using the Cambridge Structural Database[10] where the mean Ni–N distance was found to be 1.858(32) Å and the mean Ni–O distance 1.849(15) Å. The standard deviations quoted are those of the population.

The thermally stable complex decomposed at 41 °C. The solid reflectance electronic spectrum of the complex exhibited two intense absorption bands at 390 and 320 nm which are assigned as salen-based bands, but there are no characteristic absorption bands due to d–d transitions of the nickel ions. The IR spectrum shows bands at 882 and 430 cm^{-1} assigned as ν_{as}(NiONi) and δ(NiONi) respectively and there is no characteristic band for ν(OH). An electrochemical study of the complex shows a reversible process ($E_{1/2}$ = 1.05 V *vs.* SCE in methanol). The spectroscopic and CV results strongly support an oxo-bridged Ni(III) complex with square pyramidal geometry. The presence of strong donating groups in the Schiff base ligand stabilises the nickel ion in the higher oxidation state.

The observed room temperature magnetic moment value for **1** is 6.16 μ_B, fairly close to the expected value of 5.5 μ_B for two high spin d^7 ions.

Complexes containing the heptadentate cogwheel C_7Me_7: synthesis and structural characterization of heptamethylcycloheptatrienyl (CHT*) tungsten complexes

Matthias Tamm,*[a] Bernd Dreßel,[a] Roland Fröhlich[b] and Klaus Bergander[b]

[a] *Anorganisch-Chemisches Institut, Westfälische Wilhelms-Universität, Wilhelm-Klemm-Straße 8, D-48149 Münster, Germany. E-mail: mtamm@uni-muenster.de*

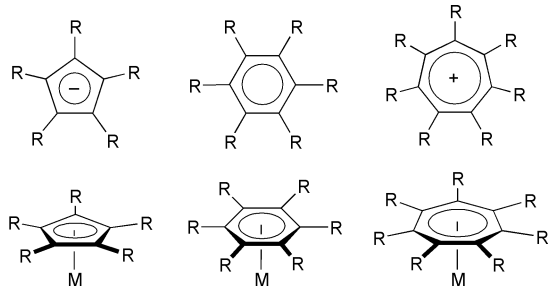
Received (in Cambridge, UK) 21st June 2000, Accepted 2nd August 2000
First published as an Advance Article on the web 22nd August 2000

The first heptamethylcycloheptatrienyl (CHT*) complexes $[(\eta^5\text{-}C_7Me_7)W(CO)_3(NCR)][BF_4]$ (R = Me, Et) and $[(\eta^5\text{-}C_7Me_7)W(CO)_3I]$ have been prepared from $[(C_7Me_7)BF_4]$.

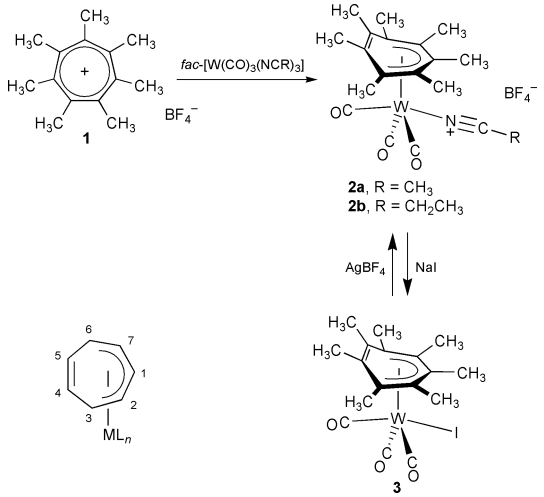
In contrast to complexes with sterically demanding peralkylated or perarylated cyclopentadienyl (η-C_5R_5) and arene (η-C_6R_6) groups (R ≠ H),[1] the corresponding cycloheptatrienyl complexes, (η-C_7R_7)M, are unknown despite the fact that the aromatic cycloheptatrienyl cations $C_7Me_7^+$ and $C_7Ph_7^+$ have been known for decades.[2,3] The molecular structures of $C_7Me_7^+$ and $C_7Ph_7^+$, however, have been determined only recently and represent the first structurally characterized cycloheptatrienyl cations with seven substituents to date.[4,5] Attempts to coordinate transition metals to the central seven-membered ring of these persubstituted π-perimeters have not been succesful so far.[6]



In continuation of our work on transition metal complexes with novel cycloheptatrienyl ligands,[7] we became interested in the synthesis of salts containing the heptamethylcycloheptatrienyl cation, $C_7Me_7^+$, and in the use of these compounds as ligands in organotransition metal chemistry. Thus, we have recently reported an improved protocol for the synthesis of heptamethylcycloheptatriene, C_7Me_7H, from hexamethylbenzene together with the synthesis and structural characterization of $[(C_7Me_7)BF_4]$ **1**,[4] which revealed a non-planar, boat-like geometry of the seven-membered ring owing to steric congestion caused by the seven methyl substituents. Consequently, we had stated that this strong distortion might impede applications of the C_7Me_7 ligand to the synthesis of organometallic derivatives. In the meantime, however, we have observed that coordination of this sterically demanding cation to transition metal centers is surprisingly easy, and with this contribution, we present the first transition metal complexes containing this molecular cogwheel.

The reaction of tropylium salts with complexes of the type *fac*-$[M(CO)_3(NCR)_3]$ (M = Mo, W; R = Me, Et) can result in the formation of cationic cycloheptatrienyl complexes $[(\eta^7\text{-}C_7R_7)M(CO)_3]^+$ by substitution of the three nitrile ligands,[8,9] *e.g.* 1,2,4,6-tetramethylcycloheptatrienyl hexafluorophosphate gives $[(\eta^7\text{-}1,2,4,6\text{-}C_7Me_4H_3)W(CO)_3][PF_6]$ upon treatment with *fac*-$[W(CO)_3(NCEt)_3]$ in the presence of a catalytic amount of ferricenium ion. This cationic tungsten complex reacts further with halides to form neutrally charged complexes $[(\eta^7\text{-}1,2,4,6\text{-}C_7Me_4H_3)W(CO)_2X]$ (X = Br, I),[9] which agrees with the reactivity observed for related cationic molybdenum and tungsten tricarbonyl complexes.[8,10]

In view of the observations described above, the reaction of $[(C_7Me_7)BF_4]$ **1** with *fac*-$[W(CO)_3(NCEt)_3]$ appeared to be a promising method for the preparation of the first CHT* complex (CHT* = C_7Me_7).[11] Hence, a thf–dichloromethane solution of **1** was treated with an equimolar amount of the nitrile complex in the presence of a catalytic quantity of $[Cp_2Fe][PF_6]$. After stirring for 2 h and evaporation of the solvents, the intermediate product (presumably **2b**, *vide infra*) was redissolved in acetone, and a large excess of sodium iodide was added (Scheme 1). Surpringly, no CO evolution could be observed, which is inconsistent with the formation of a complex $[(\eta^7\text{-}C_7Me_7)W(CO)_2I]$, which we had expected arguing from analogy with the 1,2,4,6-tetramethylcycloheptatrienyl system (*vide supra*). Instead, a stable, purple–red crystalline solid could easily be separated by column chromatography, of which the spectroscopic characterization indicated a C_7Me_7 ring not coordinated in a symmetric η^7-fashion. Its ^{1}H NMR spectrum exhibits four different resonances for the methyl protons in a 6:6:6:3 ratio. Consistently, in the ^{13}C NMR spectrum the methyl and the ring carbon atoms give rise to four resonances each, in addition to two signals for the carbonyl carbon atoms.† These results together with the observation of three carbonyl stretching frequencies in the IR spectrum suggest the formation of $[(\eta^5\text{-}C_7Me_7)W(CO)_3I]$ **3**, in which the C_7Me_7 ligand is only η^5-coordinated (Scheme 1).



Scheme 1

In order unambiguously to confirm this conclusion, the molecular structure of **3** was established by X-ray diffraction analysis.‡ The asymmetric unit contains two independent, almost identical molecules, and the structure of molecule A is

shown in Fig. 1. The complex is almost C_s symmetric with the pseudo mirror plane including I, W, C1, C15 and O1. The η^5-coordinated ring is strongly distorted from planarity and rather adopts a boat conformation with its uncoordinated part strongly bending back from the rest of the molecule.[12] Furthermore, the distance between the two uncoordinated carbon atoms [C4A–C5A 1.312(10) Å, C4B–C5B 1.310(10) Å] clearly corresponds to a C(sp^2)–C(sp^2) double bond, and hence the solid state structure of **3** is best described as a pentadienyl complex as shown in Scheme 1. In fact, the structural features compare well with those of other complexes containing 'true' pentadienyl ('open Cp')[13] or related cycloheptadienyl ligands.[14]

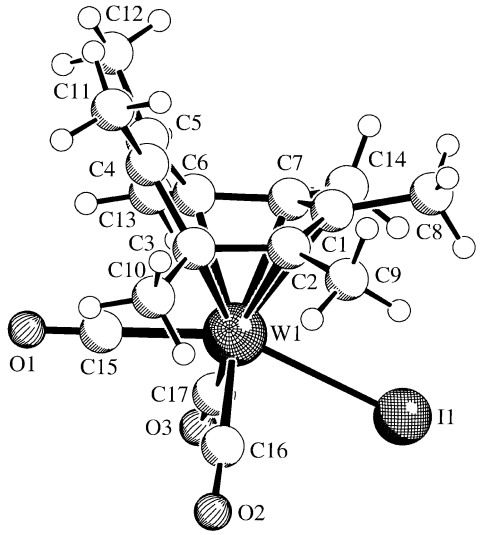


Fig. 1 Molecular structure of **3**. Selected bond lengths (Å) and angles (°): molecule A [molecule B] C1–C2 1,447(9) [1.428(9)], C1–C7 1.427(10) [1.432(10)], C2–C3 1.429(9) [1.451(9)], C3–C4 1.497(9) [1.503(9)], C4–C5 1.312(10) [1.310(10)], C5–C6 1.506(9) [1.496(9)], C6–C7 1.440(10) [1.442(9)], W1–I1 2.8425(6) [2.8659(5)], W1–C1 2.440(7) [2.425(6)], W1–C2 2.308(7) [2.303(7)], W1–C3 2.332(7) [2.335(6)], W1–C6 2.346(6) [2.329(6)], W–C7 2.323(6) [2.292(6)], W1–C15 2.008(10) [1.984(8)], W1–C16 1.988(8) [1.991(9)], W1–C17 2.000(8) [1.995(7)]; C15–W1–I1 153.2(2) [154.2(2)], C16–W1–C17 93.1(3) [93.7(3)].

Nevertheless, this η^5-bonding mode is quite unique for a cycloheptatrienyl ligand,[15] and only very few examples have been reported in the older literature[16] in addition to proposed intermediates containing an η^5-cycloheptatrienyl ring.[17] In contrast, the η^7–η^3 hapticity interconversion in cycloheptatrienyl complexes has been studied in great detail.[18] It appears that the constrained geometry of the uncoordinated heptamethylcycloheptatrienyl cation[4] accounts for the unusual reactivity observed here as the C_7Me_7 ring tries to retain its boat conformation.

In order to prove the intermediacy of **2b** in the formation of **3** from **1**, the iodine in **3** was removed by treatment of **3** with [$AgBF_4$] in acetonitrile solution. The IR and NMR spectroscopic characterization of the red crystalline compound reveals that the η^5-bound cycloheptatrienyl complex **2a** must have formed.† Even after one week in CD_2Cl_2 solution, the NMR spectrum gave no indication for a η^5–η^7 hapticity interconversion by intramolecular substitution of the coordinated acetonitrile by the pendent double bond. Thus, a η^7-C_7Me_7 complex still remains elusive.

With this contribution, we have demonstrated that η^5-bound heptamethylcycloheptatrienyl complexes are surprisingly stable and easy to prepare. These are very promising candidates for further reactions, *e.g.* for the preparation of bimetallic complexes[19] by specifically utilizing the pendant double bond for the coordination of an additional metal center. Future work in this area will also elucidate the possibility to prepare (η^7-C_7Me_7)M complexes which can be expected to be very reactive due to the permethylated ligand being in an 'entatic' state.

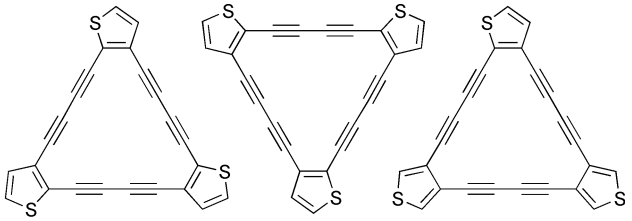
First published as an Advance Article on the web 25th August 2000

Use of a palladium/copper alkyne cross-coupling strategy provides access to three tris(thiophene-fused) dodecadehydro[18]annulenes, including examples of both highly symmetrical C_{3h} and unsymmetrical C_s structures.

We have been investigating dehydrobenzoannulenes with the aim of exploring diverse properties such as liquid crystalline behavior, solid state polymerization, and nonlinear optical activity.[1] Specifically, diacetylenic dehydrobenzoannulenes (DBAs) and related phenylacetylene macrocycles[2] have been shown to be useful precursors for a variety of carbon-rich polymeric systems, such as ladder polymers,[3] molecular tubes[4] and novel allotropes of carbon.[5] Recently, we described a simple yet versatile methodology for the preparation of site-specifically functionalized DBAs.[6] By applying a stepwise synthetic route, we were able to introduce donor and/or acceptor functional groups on the phenyl rings in a discrete manner, thereby permitting a detailed structure–property relationship study of this class of macrocycles and thus making advances toward molecular engineering.[7] In the course of further refining the design for our target annulenes, we planned to introduce thiophene rings in place of the phenyl moieties in the DBA skeleton. The choice of thiophene in our annulenes was inspired by factors such as the chemical and electrochemical polymerizability of thiophene, environmental stability of macrocycles containing thiophene, the ability to form two-dimensional π-systems useful for electronics and photonics, and interaction among the individual macrocycles due to the lone pairs present in the sulfur of thiophene rings.[8] Herein we report the preparation of three diacetylenic dehydrothieno[18]annulenes (**1**–**3**, DTAs), including the synthesis of **2** and **3** which possess unsymmetrical topologies.

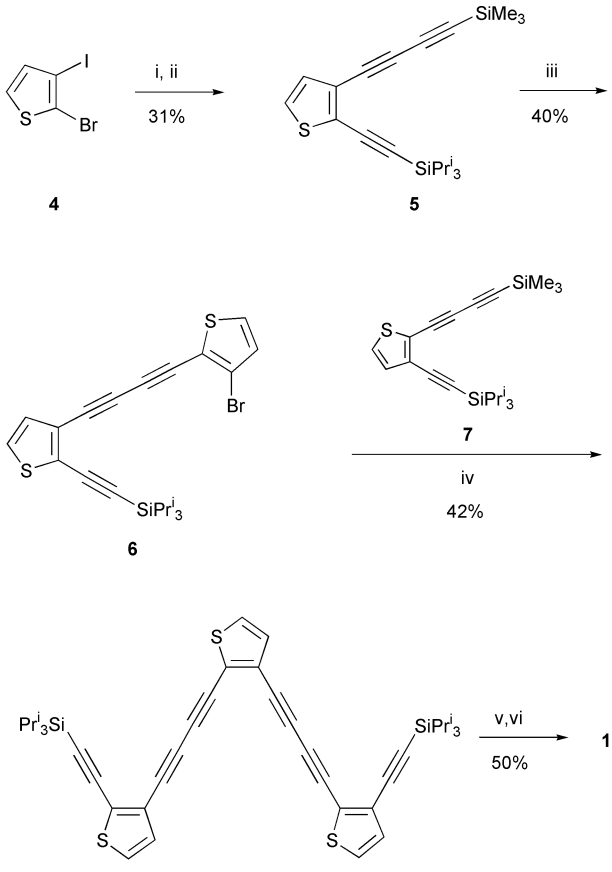


1 **2** **3**

Compounds **1**–**3** represent three of the seven possible regioisomers resulting from thiophene fusion to the [18]annulene core.[9] Other routes to thienoannulenes have relied on metal-mediated intermolecular couplings.[10] By virtue of the structure of the starting materials, only C_{nh}- and D_{nh}-symmetric macrocycles are produced. In order to probe the structure–property relationships among the various structural isomers, it is necessary to introduce the thiophene moieties in a stepwise manner to produce DTAs possessing lower symmetries (C_s), *i.e.* **2** and **3**.[11]

The synthesis of **1**, which illustrates the stepwise technique for DTA assembly, was accomplished as shown in Scheme 1. Sequential Sonogashira cross-coupling of 2-bromo-3-iodothiophene (**4**)[12] with 1-(trimethylsilyl)buta-1,3-diyne and (triisopropylsilyl)ethyne, respectively, gave triyne **5** in 31% yield. *In situ* protiodesilylation of **5** followed by Pd-catalyzed coupling[13] with an equimolar amount 3-bromo-2-iodothiophene[12] furnished bis-thiophene **6** as the major product in 40% yield. Attachment of triyne **7**, obtained in a reaction sequence similar to regioisomeric triyne **5** starting instead with 3-bromo-2-iodothiophene, provided the α,ω-bis-protected polyyne **8**. Removal of the TIPS groups with Bu_4NF in THF–EtOH and subsequent cyclization using CuCl–$Cu(OAc)_2$ in pyridine afforded **1**† in 50% yield. In an analogous manner, **2**† was prepared from **4** and two equivalents of triyne **5**, **3**† from **4** and two equivalents of the 3,4-regioisomeric triyne.[11]

In **1** and **2**, the thiophene moieties are fused at the 2,3-positions to the [18]annulene core, the sole difference between the macrocycles being the reversal of one thiophene ring. Therefore, the overall π-conjugation of **2** is expected to be similar to that of **1**. In **3**, two of the thiophene rings are fused to the macrocycle through the 3,4-positions. The C3–C4 bond in a thiophene ring is known to have less double bond character than the C2–C3 bond.[14] As a consequence, the overall conjugation of annulene **3** is expected to be lower than that in **1** or **2**. These arguments are supported by the electronic absorption spectra for



Scheme 1 *Reagents and conditions*: i, 1-(trimethylsilyl)buta-1,3-diyne, $PdCl_2(PPh_3)_2$, CuI, Et_3N, rt; ii, (triisopropylsilyl)ethyne, $PdCl_2(PPh_3)_2$, CuI, Et_3N, 120 °C; iii, 3-bromo-2-iodothiophene, aq. KOH, $PdCl_2(PPh_3)_2$, CuI, Et_3N, 60 °C; iv, **7**, aq. KOH, $PdCl_2(PPh_3)_2$, CuI, Et_3N, 60 °C; v, Bu_4NF, EtOH, rt; vi, CuCl, $Cu(OAc)_2$, pyridine, O_2, 60 °C.

DOI: 10.1039/b004962j

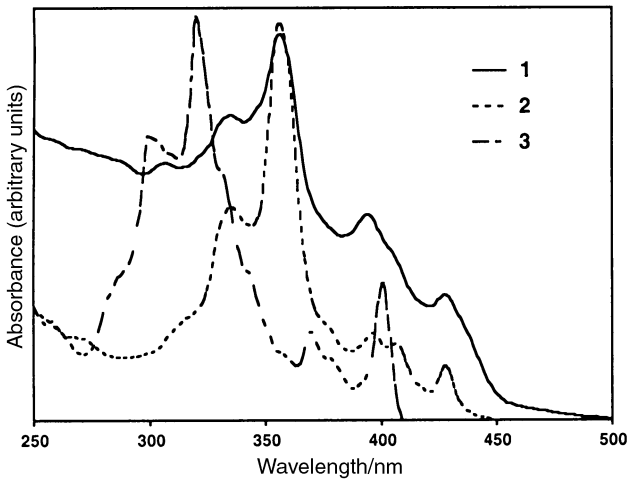


Fig. 1 Electronic absorption spectra for **1**–**3**.

1–**3** (Fig. 1). Quite expectedly, the spectra for **1** and **2** are essentially identical. Both molecules have λ_{max} at 428 nm; however, λ_{max} for **3** (401 nm) is significantly blue-shifted compared to **1** and **2**, thus indicating a lesser overall conjugation in **3**, as discussed above.

The thermal properties of **1**–**3** were studied using DSC and TGA scans. The macrocycles do not melt upon heating; instead, when heated above 150 °C, they are transformed into shiny black solids that are completely insoluble in common organic solvents. For example, DSC analysis of **1** showed a sharp exotherm at 168 °C. The TGA scan for **1** showed almost no weight loss ($< 5\%$) at the temperature range corresponding to the DSC exotherm. Therefore, the exotherm is most likely attributable to a polymerization reaction occurring in the solid state. Investigations to probe the polymerization reaction and the resultant products are in progress.

In summary, we have developed a versatile route for the synthesis of dehydrothieno[18]annulenes, including both symmetrically and unsymmetrically fused systems. A detailed structure–property relationship study of this class of macrocycles is currently underway.

We thank the National Science Foundation and the Camille and Henry Dreyfus Foundation for support of this work.

Diastereoselective synthesis of tetrahydrofuran-containing fragments by the permanganate oxidation of 1,5,9-trienes

Richard C. D. Brown,* Robert M. Hughes, John Keily and Anne Kenney

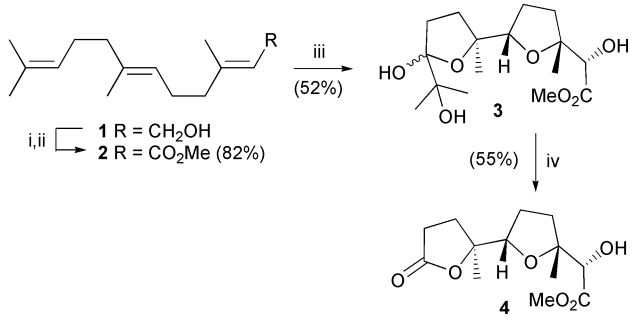
Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ. E-mail: rcb1@soton.ac.uk

Received (in Cambridge, UK) 31st May 2000, Accepted 4th August 2000
First published as an Advance Article on the web 25th August 2000

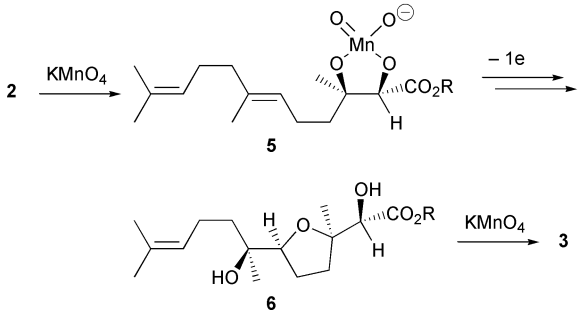
The permanganate oxidation of several readily accessible 1,5,9-trienes occurs regioselectively to provide very short diastereoselective routes to substituted octahydro-2,2′-bifuranyl systems.

Substituted tetrahydrofurans constitute important structural and functional sub-units of a variety of biologically active natural products including the polyether antibiotics and annonaceous acetogenins.[1,2] An attractive approach to the synthesis of *cis*-2,5-disubstituted tetrahydrofurans is the permanganate-promoted oxidative cyclisation of 1,5-dienes,[3–5] and there have been several elegant applications of oxidative cyclisation in the synthesis of polyether antibiotic fragments.[4,6,7] Unfortunately, modest yields and the non-availability of suitably functionalised isomerically pure 1,5-dienes have restricted more widespread application of oxidative cyclisation in natural product synthesis. Other metal oxo species have also been reported to effect oxidative cyclisation of 1,5-dienes,[8,9] although no overall advantage over the permanganate-promoted process is evident. Herein we report short diastereoselective syntheses of *cis*-2,5-disubstituted tetrahydrofuran-containing fragments that are suitably functionalised to permit further elaboration.

By exploiting the different reactivity of different types of olefin, regioselective oxidative cyclisation of certain 1,5,9-trienes can be achieved to provide rapid access to useful tetrahydrofuran building blocks. For example, oxidation of methyl (*E*,*E*)-farnesoate (**2**), obtained in 2 steps from (*E*,*E*)-farnesol (**1**),[10] by potassium permanganate in buffered aqueous acetone provides lactol **3** as an approximately 6:1 mixture of epimers (Scheme 1).[11] The formation of **3** can be explained by kinetically controlled attack at the C=C bond of the α,β-unsaturated ester,[12] leading to an intermediate hypomanganate diester **5**, which underwent extremely rapid oxidation to a manganate diester and cyclisation in line with the mechanism proposed by Baldwin (Scheme 2).[13] Independent oxidation of the remaining double bond present in **6** by permanganate afforded the observed product **3**. Lead tetraacetate cleavage of the vicinal diol completed the synthesis of the lactone **4** in an overall yield of 23% and in 4 steps from a commercial starting material.

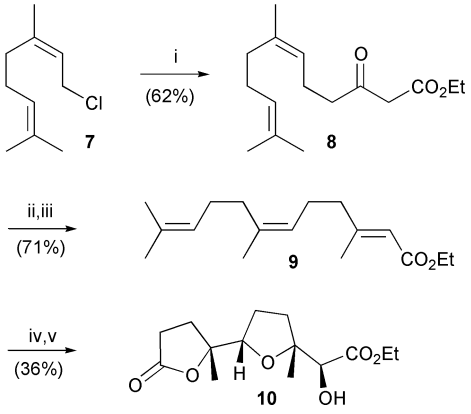


Scheme 1 *Reagents and conditions*: i, MnO_2, hexane; ii, MnO_4, KCN, AcOH, MeOH; iii, $KMnO_4$, AcOH, acetone, acetate buffer (pH 6.5); iv, $Pb(OAc)_4$, Na_2CO_3, CH_2Cl_2.



Scheme 2

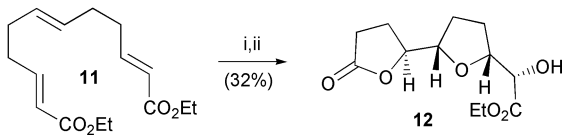
The scope of the triene oxidation is increased by the availability of other double bond isomers of ethyl farnesoate, which can be prepared conveniently using methodology developed by Weiler.[14] For example, the dianion of ethyl acetoacetate was alkylated with neryl chloride (**7**) to afford β-ketoester **8** (Scheme 3), which underwent stereoselective conversion to the corresponding (*Z*)-enolphosphate. Treatment of the enolphosphate with lithium dimethylcuprate† gave the desired triene **9** as a single isomer‡ in good overall yield. Permanganate oxidation of ethyl (2*E*,6*Z*)-farnesoate (**9**) under the usual conditions provided an epimeric mixture of lactols, which was cleanly converted to a single diastereomeric lactone **10** upon brief exposure to lead tetraacetate. In principle, all four possible diastereoisomers of lactones **4** and **10** could be prepared from geraniol or nerol using this approach.[15]



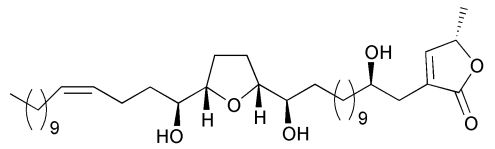
Scheme 3 *Reagents and conditions*: i, ethyl acetoacetate, NaH (1 eq.), n-BuLi (1 eq.); ii, LiHMDS, $(EtO)_2POCl$; iii, Me_2CuLi, Et_2O; iv, $KMnO_4$, AcOH, acetone, phosphate buffer (pH 6.2); v, $Pb(OAc)_4$, Na_2CO_3, CH_2Cl_2.

Our interest in the synthesis of annonaceous acetogenins such as Asiminenin A led us to consider use of the triene oxidation to generate a suitable lactone precursor **12** (Scheme 4). The requisite triene **11** was synthesised following a route described by Hoye.[16] Oxidation of **11** with potassium permanganate afforded an apparently complex mixture of products, from which compounds **13** (9%), **14** (23%) and unexpectedly **12**

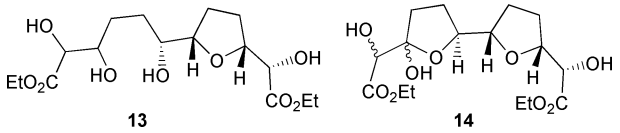
DOI: 10.1039/b004307i



Scheme 4 *Reagents and conditions*: i, $KMnO_4$, AcOH, phosphate buffer (pH 6.2), acetone; ii, $NaIO_4$, acetone, H_2O.



Asiminenin A



(10%) were identified. Rigorous assignment of the proton NMR spectra of the major component **14** was complicated by the presence of a number of isomers. Further indirect evidence for the structure of **14** came from its oxidative cleavage to yield the desired lactone **12** using sodium metaperiodate. Alternatively, the crude reaction mixture obtained from the permanganate oxidation of **11** could be treated with sodium metaperiodate to afford the lactone **12** in 32% yield over the two steps. The *cis*-relationship of the side chains on the tetrahydrofuran ring was confirmed by means of NOE experiments.

In summary, we have presented a very short diastereoselective synthesis of potentially useful tetrahydrofuran-containing fragments from readily accessible 1,5,9-trienes. The use of a chiral auxiliary in the oxidative cyclisations would provide the corresponding optically enriched tetrahydrofurans.[6,7] Future work will focus on the application of the oxidative cyclisation in the synthesis of the annonaceous acetogenin natural products and synthetic ionophores.

We wish to thank the Royal Society for a University Research Fellowship (R. C. D. B.), the EPSRC for MRes and PhD studentships (A. K. and J. K.), Pfizer Ltd. for a consumables grant and Mrs Joan Street and Mr Neil Wells for performing NMR experiments. We also wish to acknowledge the use of the EPSRC's Chemical Database Service at Daresbury.[17]

Notes and references

† We found it essential that methyllithium in ether was used in this reaction. On one occasion when a THF solution of methyllithium containing cumene was used a mixture of the desired product and the reduced *E*-disubstituted olefin was obtained (ratio of 5:1 estimated from the 300 MHz ^{1}H NMR spectrum).

‡ Only one isomer was observed in the 300 MHz ^{1}H NMR spectrum of **9**.

First published as an Advance Article on the web 25th August 2000

A practical synthetic route for the preparation of forskolin intermediate 20 is described. Previously reported lactone 3 was converted to 20 through intermediate 16. The main feature of this work lies in the formation and the cleavage of a tetracyclic intermediate for the stereochemical control in the formation of the tricyclic core of forskolin.

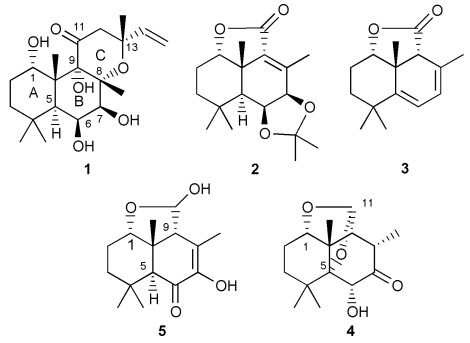
Forskolin **1**,[1] a labdane diterpene isolated from the roots of the Indian plant *Coleus forskolii*, has emerged as a highly attractive target for total[2] and partial[3] synthetic investigations. Besides the challenging structure of this natural product, its biological and therapeutic potential, mainly in the cardiovascular area,[4] has encouraged the efforts of numerous synthetic chemistry groups all over the world.

However, despite the diversity of the synthetic schemes used in the early steps of these studies, most of them have emphasized the so called 'Ziegler intermediate', **2** (Scheme 1), as the most versatile synthon for further synthetic strategies aimed at the formation of the tetrahydropyran ring of the target molecule.[5]

In preceding work, we designed several synthetic approaches toward the fully functionalized decalinic system of forskolin (A/B bicycle). Our approaches were mainly based either on the use of pericyclic reactions[6] or on the transformation of lactone **3**,[7] available in enantiomeric pure form.[8] This later methodology led to a highly efficient synthesis of the 'Ziegler intermediate'.[9]

The main original feature of this synthesis relies on the stereochemical control of the ring junction of the bicycle A/B through the formation, in the earlier steps of the synthetic scheme, of an intramolecular ketal **4** of the carbonyl group at C-11. This ketal links C-11 to C-1 and C-5 through an oxygen atom (Scheme 1). A base induced rearrangement of the tetracyclic system of **4** with fragmentation of the tetrahydrofuran ring produced the α-hydroxyketone **5** with complete stereocontrol of the asymetric centers C-1, C-5, C-9 and C-10 under thermodynamic conditions.

In order to design a more straightforward route to forskolin, we have investigated the possibility of formation of the tetrahydropyran ring C of **1** in an early stage of the synthesis, through introduction of the three missing carbon atoms as an allyl residue at the beginning of the synthetic sequence.



Scheme 1

Lactone **3** was first submitted to the previously described regioselective epoxidation procedure (MCPBA, CH_2Cl_2, 92%) to produce known epoxide **6**.[9a] Then the Grignard addition of allylmagnesium bromide stereoselectively produced hemiketal **7**, having the three required carbons. Hemiketal **7** was in turn converted into tetracyclic ketal **8** upon treatment with silica gel under sonication (Scheme 2, 86% from **6**) using our previously reported strategy.[9]

Epoxidation of both double bonds was then performed in a one-pot procedure using an excess of peracid; diepoxide **9a**,**b** was obtained in 76% yield (MCPBA, 4 eq., CH_2Cl_2, rt) as a mixture (1:1) of epimers at C-13. Then, reduction of **9** by lithium aluminium hydride led in high yield to the reductive opening of the more reactive 13,14-epoxide, while the basicity of the reaction conditions allowed a Payne-like rearrangement of the 8-hydroxy-6,7-epoxide and gave 6α-alcohol **10a**,**b**.

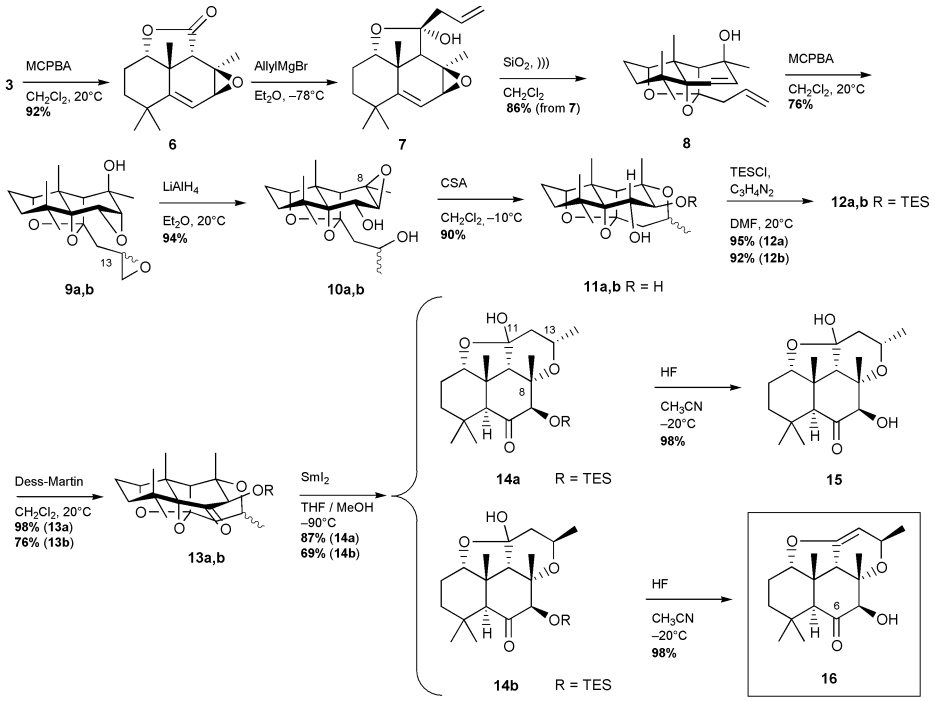
The key step in this sequence of reactions was the acid catalyzed formation of the tetrahydropyran ring C of the target molecule (camphorsulfonic acid, CH_2Cl_2, −10 °C, 90%), which resulted in a stereoselective inversion of the configuration at C-8 (Scheme 2), leading to the pentacyclic diols **11a**† and **11b** which can be separated by careful chromatography. The following steps were thus performed on both epimers separately. The two equatorial hydroxy groups at C-6 and C-7 were easily differentiated according to their steric hindrance: etherification with one eq. of chlorotriethylsilane (imidazole, DMF, 95%) yielded the formation of the mono-silyl ether at C-7 **12a** and **12b**. Then, **13a** and **13b** were synthesized through oxidation with Dess–Martin's periodinane (CH_2Cl_2, rt). Thereafter, extensive experimental investigations using various reaction conditions allowed the emergence of samarium(II) iodide as the best reducing agent to perform the desired cleavage of the C–O bond at C-5, thus leading to the formation of hemiketals **14a** and **14b** in 70% yield [5 eq. SmI_2, THF–MeOH (50:1) 13 mM, −90 °C, hydrolysis and extraction performed at pH 7.4, phosphate buffer].

At this stage of the synthesis, the synthetic aim was to reduce the carbonyl group at C-6 and to cleave the C-11 carbonyl ketal in order to complete the functional elaboration of ring C of forskolin.

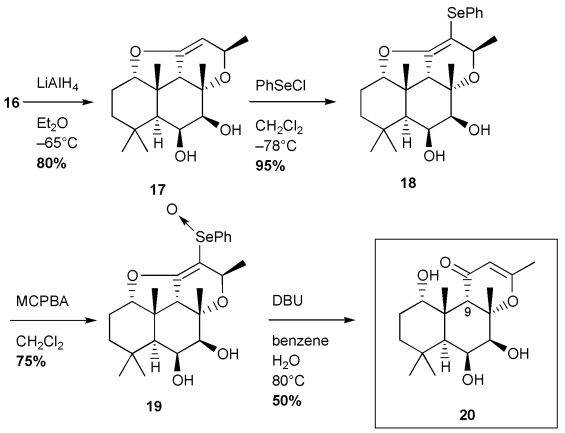
Treatment with hydrofluoric acid in acetonitrile of isomer **14a** cleanly gave the expected free alcohol **15** while isomer **14b**, under similar conditions, produced enol ether **16** in quantitative yield.

Taking advantage of this unexpected dehydration, we completed this approach by reduction of the carbonyl at C-6 ($LiAlH_4$, Et_2O, −65 °C, 85%) to give **17** with the correct diol configurations (Scheme 3). Thereafter, treatment of enol ether **17** with phenylselanyl chloride at low temperature resulted in addition of the phenylselenenyl group at C-12,[10] without cleaving the enol ether. This reaction was assumed to proceed through a two step procedure, consisting of the electrophilic addition of the phenylselanyl moiety, followed by hydrochloric acid elimination. Then, oxidation of the selenium and elimination of the resulting selenoxide under basic conditions led to the formation of the desired dehydro-γ-pyrone **20**.[11] Compound **20** is also the result of a two step reaction, involving hydroxide

DOI: 10.1039/b004515m



Scheme 2



Scheme 3

addition to the activated enol followed by phenylselenenic acid elimination.

In summary, we have developed a practical, stereoselective synthetic route to analogs of 9-deoxyforskolin and forskolin **1**, taking account of the previous reports dedicated to the introduction of the vinyl group at C-13 as a cuprate,[2c] and of the hydroxy group at C-9.[12]

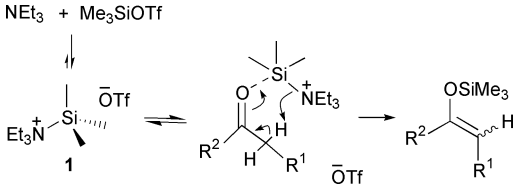
Received (in Cambridge, UK) 31st May 2000, Accepted 1st August 2000
First published as an Advance Article on the web 25th August 2000

An asymmetric intramolecular Michael–aldol reaction of a C_s symmetric ketone using chiral amine and silyl triflate is described as a new methodology of chiral induction; nonracemic tricyclic cyclobutanes were obtained from a 4-substituted cyclohexanone in high yields with moderate enantioselectivities in one step.

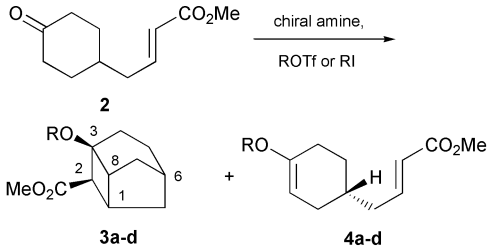
Carbon–carbon bond-forming reactions are among the most fundamental and important methodologies in organic transformations, and many of them have been focused and elaborated to give asymmetric products. Recently, the asymmetric C–C bond formations induced by the desymmetrization of C_s symmetric compounds have emerged as a powerful strategy for asymmetric synthesis.[1] For example, an asymmetric deprotonation of the prochiral ketones, followed by C–C bond formation (alkylation, aldol reaction, Michael reaction, *etc.*), can afford useful chiral intermediates.[2,3] Simpkins and Koga have elaborated the excellent desymmetrization process of C_s symmetric ketones by the use of chiral lithium amide bases to give enantiomerically enriched enolate equivalents with excellent enantioselectivities.[2–4]

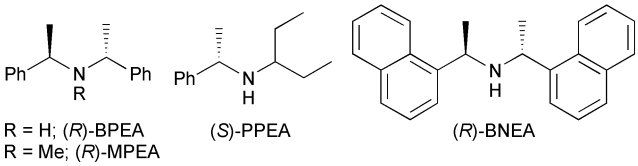
We have established the intramolecular Michael–aldol reaction as a new and efficient methodology to build polycyclic cyclobutanes.[5] The reaction of a C_s symmetric substrate, such as **2**, could form two bonds and five stereogenic centers with high stereoselectivity in a single operation. However, the use of lithium amides resulted in the termination of the reaction at the mono-Michael addition stage.[5b] The cascade reaction proceeded only under silyl triflate–amine, silyl iodide–hexamethyldisilazane (HMDS), or boron triflate–HMDS conditions. Simchen has shown that enol silylation using triethylamine in the presence of TMSOTf proceeds through the coordination of silyl ammonium complex **1** to carbonyl oxygen followed by deprotonation and silylation (Scheme 1).[6] Based on this mechanism, a chiral amine reagent in the presence of silyl triflate could be envisaged to effect an asymmetric induction in the Michael–aldol reaction. We herein report an enantioselective intramolecular Michael–aldol reaction of a prochiral substrate *via* asymmetric enol silylation as a new method of chiral induction.

We first examined suitable conditions for the intramolecular Michael–aldol reaction of **2** (Scheme 2). It was observed that more than 3 equiv. of amine and silyl triflate at temperatures higher than −30 °C were required for the production of **3** in high yield, whereas the use of 1.2 equiv. of the reagents gave the enol ether **4** quantitatively at −78 °C. The Michael–aldol reaction was typically performed as follows. To a solution of **2**



Scheme 1





Scheme 2

(0.26 mmol) in CH_2Cl_2 was added chiral amine (0.83 mmol) at room temperature. This solution was then cooled to −78 °C and silyl triflate (0.78 mol, −78 °C) was added dropwise. The whole was stirred for several hours at −78 °C, and further stirring was continued at −30 °C or at rt.[7] After the usual work up, the product **3** was purified by column chromatography (silica gel). The enantiomeric excess of **3** was determined, after its transformation into **5**, by HPLC analysis using a chiral column.[8] The asymmetric reaction using a variety of silyl Lewis acids with bis[(*R*)-1-phenylethyl]amine (BPEA) was investigated (Table 1). The reaction with TMSOTf afforded (−)-**3a** with 23% ee (run 1). Although no significant improvement was observed in the reaction with TMSI instead of triflate (run 2), the enantioselectivities were increased by the use of bulky silyl triflates such as TESOTf and TBDMSOTf (runs 3 and 4). However, the reaction with the bulkier triflate, TIPSOTf, furnished no Michael–aldol adduct **3d** but only the silyl enol ether **4d** (run 5). On the basis of the above observation, the following studies were carried out using TBDMSOTf as the silyl Lewis acid.

Results using various chiral amines under standard conditions are shown in Table 2. With bis[(*R*)-1-(1-naphthyl)ethyl]-

Table 1 Effect of silyl Lewis acids to the Michael–aldol reaction of **2** in the presence of (*R*)-BPEA[a]

Run	Reagent	Product	Yield (%)	ee (%)[b]	Yield of **4** (%)
1	TMSOTf	(−)-**3a**	58	23	6
2	TMSI	(−)-**3a**	39	24	Not isolated
3	TESOTf	(−)-**3b**	31	28	46
4	TBDMSOTf	(−)-**3c**	89	31	Trace
5	TIPSOTf	**3d**	0	—	73

[a] Reactions were carried out at −78 to −30 °C. [b] All enantiomeric excesses were determined, after transformation into **5**, through chiral HPLC analysis using a Chiracel OJ column.

DOI: 10.1039/b004320f

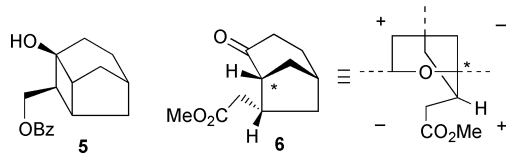
Table 2 Asymmetric Michael–aldol reactions using chiral amine and TBDMSOTf

			Yield (%)		ee (%)	
	Chiral amine	Temp./°C	**3c**	**4c**	**3c**[a]	**4c**[b,c]
1	(*R*)-BPEA	−78 to rt	85	14	32	nd
2	(*R*)-MPEA	−78 to rt	82	11	7	nd
3	(*S*)-PPEA	−78 to rt	87	8	8[d]	nd
4	(*R*)-BNEA	−78 to rt	88	12	36	35
5	(−)-sparteine	−78 to rt	77	9	8	nd
6	(*R*)-BPEA	rt	75	8	12	nd
7	(*R*)-BPEA	−78	0	88	—	31
8	(*R*)-BPEA	−90 to rt	85	13	42	nd

[a] All enantiomeric excesses were determined, after transformation into **5**, through chiral HPLC analysis using a Chiralcel OJ column. [b] Ees were determined in the same manner as **3c**, after conversion into (−)-**3c** by the treatment of (−)-**4c** with TBDMSOTf in the presence of NEt_3 at rt. [c] 'nd' means 'not determined'. [d] (+)-**3c** was obtained.

amine (BNEA) as chiral amine, (−)-**3c** and (−)-**4c** were obtained in 88 and 12% yield with 36 and 35% ee, respectively (run 4). Reactions in the presence of other amines, such as *N*-methylbis[(*R*)-1-phenylethyl]amine (MPEA), 3-pentyl-(*S*)-1-phenylethylamine (PPEA)[3a] and (−)-sparteine, afforded less than 10% ee of **3c** (runs 2, 3 and 5). The effect of temperature was as expected; higher enantioselectivities were observed at lower temperature (see runs 1, 6 and 8). The reaction, carried out at −90 °C to rt, resulted in 42% ee of **3c** (run 8). Note, quenching the reaction at −78 °C produced only the silyl enol ether **4c** having 31% ee (run 7).

The absolute configuration of (−)-**3c** was determined by circular dichroism of bicyclo[3.2.1]octanone **6** (24% ee; $[\theta]$ = +708, λ = 296 nm), which was obtained by treatment of (−)-**3c** (24% ee) with hydrogen fluoride–pyridine complex. The application of the octant rule[9] suggested (*R*)-configuration at the asterisked carbon of **6**. Accordingly, (−)-**3c** has a (1*S*,2*R*,3*S*,6*R*,8*R*)-tricyclo[4.2.1.0^{3,8}]nonane structure.



Some possibilities can be considered for the asymmetric induction of the above reaction. One is the desymmetrization of C_s symmetric substrate **1** by means of enantioselective enol silylation. Another possibility is that kinetic resolution is involved in the Michael–aldol reaction of silyl enol ether **4**. However the latter induction process could be ruled out by the observation that the treatment of isolated racemic **4c** with TBDMSOTf in the presence of (*R*)-BPEA at −78 °C to rt furnished only the racemate of **3c**. Hence, the asymmetric induction of the reaction occurs in the enol silylation step. To our knowledge this is the first demonstration of asymmetric enol silylation without the use of amide base.[10] The asymmetric intramolecular Michael–aldol reaction subsequently proceeds under the same conditions. It is worth noting that we have demonstrated the direct asymmetric C–C bond-forming reaction of a C_s ketone in a single operation, omitting the isolation of an enolate equivalent, to give a nonracemic tricyclo-[4.2.1.0^{3,8}]nonane compound. Further studies on the development and the application of this asymmetric process are in progress.

This work was partly supported by a Grants-in-Aid for Research on Priority Areas (Nos. 11119206 and 11147202) from the Ministry of Education, Science, Sports and Culture, Japan.

7 We found that **4a** was racemized at temperatures higher than −30 °C under the Michael–aldol conditions, but **4b**–**c** were not racemized even at room temperature. Consequently, the asymmetric Michael–aldol reaction with TMSX had to be carried out at −78 to −30 °C.

8 **5** was obtained from **3** in 3 steps. That is, the reduction of **3** by DIBAL-H, followed by desilylation and acylation with benzoyl chloride, gave the benzoate **5**.

9 The determination of the absolute configuration of some substituted bicyclo[3.2.1]octan-2-ones by means of circular dichroism was reported, see: W. Klyne, *Tetrahedron*, 1961, **13**, 29.

Noncovalent assembly of Zn^{II}–mesoporphyrin IX was accomplished by coordination to α-helical peptides (4–64 segments) based on polyamideamine dendrimer; the electron transfer functions were expressed more effectively with the growth of the dendrimer generation.

Assemblies of peptides or functional groups perform a significant role in nature, displaying highly efficient functions including energy transfer and electron transfer. For example, in photosynthetic bacteria, light-harvesting complexes (LH),[1] in which many bacteriochlorophylls are assembled and oriented with α-helix peptides, absorb light energy, and delocalize and transfer the energy to the reaction center where charge separation occurs. The development of an artificial system with native-like properties but without the complexity of the natural components, has been attempted using *de novo* designed peptides.[2,3] On the other hand, dendrimers have also attracted much attention in the field of polymer chemistry.[4–8] Some dendrimers have been investigated for electron transfer[6] and energy transfer[7] functions because of their morphological similarities to LH. Using dendrimers as templates in the *de novo* design proteins, the peptide assembly conditions and functionalization may be controlled precisely. In this study, designed amphiphilic α-helix peptides (4, 8, 16, 32 and 64 segments) were introduced at the end groups of polyamideamine dendrimers (PAMAMs)[4] (Fig. 1). Zn^{II}–Mesoporphyrin (Zn-MP) was coordinated between the 2α-helix peptides[3] to accomplish a multi-Zn-MP array so that electron transfer properties were expressed more effectively with the growth of the dendrimer generation.

Synthesis of peptide dendrimers was performed by a domain ligation strategy.[8] The 20-residual peptide (R-HL4) was designed to take an amphiphilic α-helical structure, which was stabilized by four sets of Glu–Lys salt bridges. As an axial ligand of metalloporphyrin, His was introduced to deploy a porphyrin parallel to the helix axis. Four Leu residues per α-helix were arranged to construct a hydrophobic pocket as a porphyrin-binding site.[3] Cys was used at the N-terminus of the peptide to ligate to the outer termini of the template dendrimer through the thioether linkage. Arg was introduced at the C-terminus of the peptide to form an electrostatic field at the outer shell of the peptide dendrimers. R-HL4 was synthesized by the solid-phase method using Fmoc-strategy and purified with reversed-phase (RP) HPLC. The peptide was identified by matrix assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS).[9] To conjugate the peptide with PAMAM [Starburst Dendrimer, G0, G1, G2, G3 and G4, from Aldrich], the chloroacetyl group was introduced at each amino terminal group of PAMAM, by treatment with *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline[10] and chloroacetic acid in MeOH. Perchloroacetylated (*n*-ClAc) PAMAMs were purified by size exclusion chromatography (SEC, Sephadex LH-60–MeOH) and RP-HPLC, and identified by MALDI-TOFMS.[11] R-HL4 and *n*-ClAc-PAMAM were combined by the ligation reaction[12] between the thiol side chain of Cys in R-HL4 and the chloroacetyl group of *n*-ClAc-PAMAM. The peptide dendrimers, *n*-(R-HL4)PAMAMs, were purified by SEC (Sephadex G-50–30% AcOH) and RP-HPLC, and identified by MALDI-TOFMS[13] or ultracentrifugation.[14]

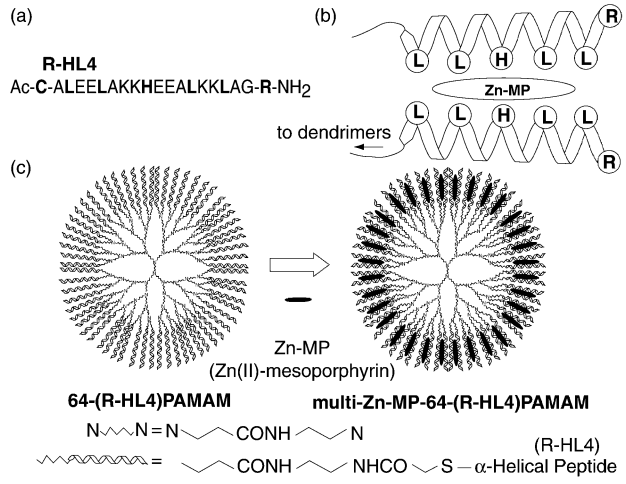

Fig. 1 Structure of the peptide dendrimers, (a) amino acid sequence of R-HL4; (b) schematic illustration of Zn-MP coordination to 2α-helix; and (c) 64-(R-HL4)PAMAM and multi-Zn-MP-64-(R-HL4)PAMAM.

Circular dichroism (CD) study revealed that *n*-(R-HL4)PAMAM, (*n* = 4, 8, 16, 32 and 64) showed a typical α-helical pattern in pH 7.4 buffer. The α-helicity[15] of the peptides in the dendrimers was estimated as *ca*. 50% (Table 1), indicating that *n*-(R-HL4)PAMAMs with different extents of dendrimer generation have similar α-helical properties. UV-Vis titration[3] of Zn-MP with *n*-(R-HL4)PAMAM showed an increase of the Soret band at 415 nm and decrease of the band at 403 nm of Zn-MP. The binding constant (K_a) was determined from the absorbance change at 415 nm using an equation assuming the 1/*n* (2α-helix in peptide dendrimer–Zn-MP) complexation (Table 1). The *n* values were found to be close to 1.0, indicating that Zn-MP bound to the peptide dendrimers almost equivalently per 2α-helix. The K_a values indicated that Zn-MP bound to the peptide dendrimers efficiently, and binding affinities to peptide dendrimers were almost identical. *n*-(R-HL4)PAMAM conjugated with multi-Zn-MP showed a strong induced CD

Table 1 Ellipticity at 222 nm and α-helicity of peptide dendrimers, and binding constant K_a and *n* value for peptide dendrimers with Zn-MP

n-(R-HL4) PAMAM	$[\theta]_{222}/10^4$ deg cm^2 dmol^{-1}	α-Helicity (%)	$K_a/10^5$ dm^3 mol^{-1}	*n* value
n = 4	−1.68	53	3.2	1.01
n = 8	−1.67	53	1.7	0.84
n = 16	−1.51	48	1.5	0.93
n = 32	−1.45	46	1.8	0.98
n = 64	−1.45	46	2.1	0.99

Ellipticity [θ] at 222 nm and α-helicity were estimated from the CD spectra. [*n*-(R-HL4)PAMAM] = 1.0×10^{-5} mol dm^{-3} (per 2α-helix), in 2.0×10^{-2} mol dm^{-3} Tris·HCl buffer (pH 7.4) at 25 °C. The binding constant K_a and *n* value were estimated by UV-Vis spectra titration, in pH 7.4 buffer at 25 °C. [Zn-MP] = 5.0×10^{-6} mol dm^{-3}.

DOI: 10.1039/b003786i

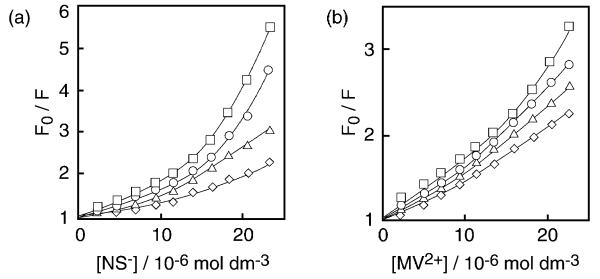

Fig. 2 Stern–Volmer plot for fluorescence quenching of Zn-MP (2.5×10^{-7} mol dm^{-3}) conjugated with *n*-(R-HL4)PAMAM (7.5×10^{-7} mol·dm^{-3} per 2α-helix) by quenchers. λ_{ex} = 415 nm, λ_{em} = 582 nm, in the buffer (pH. 7.4) at 25 °C. Electron acceptors = (a); NS^-, (b); MV^{2+}: □; *n* = 64, ○; *n* = 32, △; *n* = 16, ◇; *n* = 8 and 4.

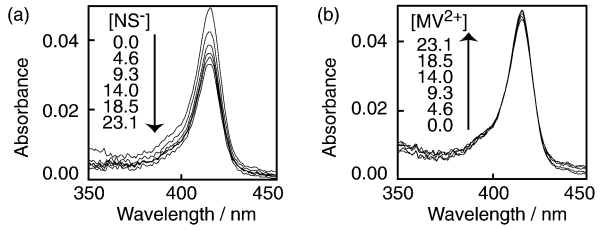

Fig. 3 UV-Vis spectra of Zn-MP (2.5×10^{-7} mol dm^{-3}) conjugated with 64-(R-HL4)PAMAM (7.5×10^{-7} mol dm^{-3} per 2α-helix) with increasing concentration (0, 4.6, 9.3, 14.0, 18.5, 23.1 $\times 10^{-6}$ mol dm^{-3}) of electron acceptors, (a); NS^-, (b); MV^{2+} in the buffer (pH. 7.4) at 25 °C.

peak at the Soret region,[16] suggesting that Zn-MP was coordinated in a regulated manner. In addition, the α-helicity was not changed by the binding with Zn-MP.

To examine electron transfer properties of multi-Zn-MP-conjugated *n*-(R-HL4)PAMAM, fluorescence quenching studies were performed by the addition of a negatively charged electron acceptor, naphthalene sulfonate[6] (NS^-), and a positively charged methylviologen[6] (MV^{2+}). Upon excitation at the Soret band, multi-Zn-MP–*n*-(R-HL4)PAMAM emitted fluorescence at 582 and 630 nm, which was quenched by the addition of NS^-. The Stern–Volmer plots (Fig. 2a) showed that the quenching occurred more strongly with increase in dendrimer generation. In each generation, the concentrations of 2α-helix and Zn-MP were constant. This result indicates that the positive charges of Arg residues were assembled more densely on the surface of the peptide dendrimer with the growth of each generation so that the negative charged NS^- was bound more effectively by the electrostatic force. Consequently, quenching was amplified with the growth of generation. On the other hand, when positively charged MV^{2+} was employed, the fluorescence quenching (Fig. 2b) was also observed to increase with the growth of the peptide dendrimer, although the charge repulsion became stronger with the generation growth. It was suggested that the quenching mechanism of MV^{2+} was different from that of NS^-. To examine these mechanisms, UV-Vis spectra on the addition of NS^- and MV^{2+} were measured (Fig. 3). In the case of NS^-, the Soret band decreased, supporting electrostatic binding between multi-Zn-MP–*n*-(R-HL4)PAMAM and NS^- in the ground state. By contrast, UV-Vis spectra were little changed by the addition of MV^{2+}, indicating that MV^{2+} does not have a strong influence on the ground state of Zn-MP. Table 2 shows the fluorescence lifetimes of multi-Zn-MP–*n*-(R-HL4)PAMAM. With the growth of generation, a percentage of the long-lived component (2.3–2.6 ns) increased. In 32- and 64-(R-HL4)PAMAM, the short-lived component (1.7–1.8 ns) disappeared. In the presence of NS^-, the fluorescence lifetime of multi-Zn-MP–64-(R-HL4)PAMAM was not changed (2.3 ns). This result supports the idea that NS^- causes electron transfer by a static mechanism.[17] By contrast, addition of MV^{2+} caused the fluorescence lifetime to be extremely shortened (0.5 ns, 88%). These results indicated that the electron was transferred mainly by a dynamic mechanism.[17]

Table 2 Fluorescence lifetime of multi-Zn-MP–*n*-(R-HL4)PAMAM

n-(R-HL4) PAMAM	Electron acceptors	τ_1/ns	A_1 (%)	τ_2/ns	A_2 (%)
n = 4	—	1.8	74.7	2.6	25.3
n = 8	—	1.8	73.8	2.6	26.2
n = 16	—	1.7	47.8	2.3	52.2
n = 32	—	—	—	2.4	100.0
n = 64	—	—	—	2.3	100.0
n = 64	NS^-	—	—	2.3	100.0
n = 64	MV^{2+}	0.5	88.0	2.3	12.0

Fluorescence lifetime was measured using Zn-MP (2.5×10^{-7} mol dm^{-3}) conjugated with *n*-(R-HL4)PAMAM (7.5×10^{-7} mol dm^{-3} per 2α-helix) at 25 °C. λ_{ex} = 415 nm, λ_{em} = 570–650 nm, electron acceptors, [NS^-] = [MV^{2+}] = 2.0×10^{-5} mol dm^{-3}. Decay profiles were analyzed by the double exponential equation, $I_f(t) = A_1\exp(t/\tau_1) + A_2\exp(t/\tau_2)$.

In conclusion, noncovalent Zn-MP assembly was accomplished by coordination to novel peptide dendrimers, and the electron transfer function was expressed more effectively with the growth of dendrimer generation. Dynamic quenching with viologen can be applied to the catalytic reactions. The nanoscale assembly of a system combining *de novo* designed peptides with dendrimers will be utilized in artificial photosynthesis.

We are grateful to Dr K. Aoi, Nagoya University, for valuable discussions on dendrimers, Dr F. Arisaka, Tokyo Institute of Technology, for ultracentrifugation analyses and Dr S. Sakamoto, Tokyo Institute of Technology, for valuable discussions on the *de novo* design.

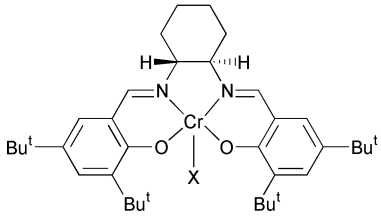
Cr(salen) catalysed asymmetric ring opening reactions of epoxides with $TMSN_3$ proceed readily in the room temperature ionic liquid 1-butyl-3-methylimidazolium salts ([bmim][X]) with easy catalyst/solvent recycling.

Optically pure β-amino alcohols are important structural elements in many biologically active molecules as well as the starting point in the design of many chiral ligands. Among many other methods, asymmetric ring opening reactions (ARO)[1] of epoxides with $TMSN_3$ catalysed by Cr(salen) complex **1** has been recognised as an attractive approach to the synthesis of optically pure β-amino alcohols.[2] Especially, the Cr(salen) catalyst exhibits indefinite stability under catalytic conditions which allows for its repeated recycling. Jacobsen reported that this reaction can be run without solvents and the catalyst can be recycled a number of times without loss of activity and enantioselectivity.[2a] However, this catalyst recycling procedure involves the potentially hazardous distillation of the neat liquid azides, which may prove a limitation for large scale applications.

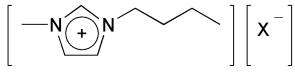


(*R*,*R*)-**1a**; X = Cl
(*R*,*R*)-**1b**; X = N_3

For catalyst recycling,[3] homogeneous chiral catalysts can be immobilised either by anchoring the catalyst on a solid support[3a] or by use of a two-phase system.[3b] All of these approaches are interesting but usually require additional modification of the catalyst. Moreover, such approaches frequently lead to partial loss of activity and/or enantioselectivity. Recently, a new approach has been adopted for catalyst separation and recycling in a few types of catalytic reaction involving the use of ionic liquids,[4] *i.e.* a salt mixture with a melting point below ambient temperature. Air and moisture stable room temperature ionic liquids consisting of 1,3-dialkylimidazolium cations and their counter anions, in particular, have attracted growing interest in the last few years.[5] In these solvents, catalysts having polar or ionic character can be immobilised and thus the ionic solutions containing the catalyst can be easily separated from reagents and products. For example, we reported recently a practical method for recycling a chiral Mn(salen) epoxidation catalyst by using this type of ionic liquid.[5g]

Herein we report a new and highly practical recycling procedure of Cr(salen) catalyst involving the use of air and moisture stable ionic liquids based on 1-butyl-3-methylimidazolium [bmim] salts **2a**–**d**.[6]

To compare the effect of ionic liquids on both reactivity and enantioselectivity, we first examined the asymmetric ring opening reactions of cyclopentene oxide with $TMSN_3$ which were carried out in the presence of 3 mol% of (*R*,*R*)-**1a** in four

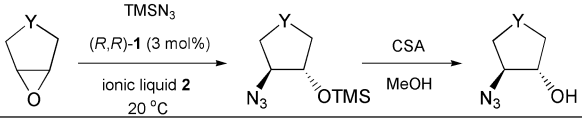


[bmim][X] (**2**); X = PF_6 (**2a**)
SbF_6 (**2b**)
BF_4 (**2c**)
OTf (**2d**)

different ionic liquids, [bmim][X] **2** {X = PF_6 (**2a**),[6a] SbF_6 (**2b**),[6b] BF_4 (**2c**)[6a] and OTf (**2d**)[6c]} at 20 °C. After completion of the reaction, hexane (15 mL in 2 mmol scale experiment) was added and the reaction mixture stirred for 10 min. The hexane phase (upper phase) was then separated from the ionic liquid phase containing the Cr(salen) complex (*R*,*R*)-**1b**[7] by simple decantation and analysed by chiral GC to determine ee values.† After removing the hexane under reduced pressure, methanol and camphorsulfonic acid were added to the residue, and the mixture was allowed to stir at room temperature for 30 min. The methanol was evaporated off and the residue was purified by column chromatography on silica gel with ethyl acetate–hexane to afford the pure azido alcohol.

As shown in Table 1 (entries 1–4), both reactivity and enantioselectivity were strongly influenced by the nature of the anion [X]. When the hydrophobic ionic liquid [bmim][PF_6] **2a** was used, the desired azido silyl ether was obtained with the same degree of yield and enantiomeric excess (94% ee) as those[2a] obtained under homogeneous conditions reported by Jacobsen *et al*. (Table 1, entry 1). Using the other hydrophobic ionic liquid [bmim][SbF_6] (**2b**), the reaction was run with similar conversion, although in slightly lower ee (Table 1, entry 2). In sharp contrast to these results, in the hydrophilic ionic liquids, [bmim][BF_4] (**2c**) or [bmim][OTf] (**2d**), the reaction hardly occurred (Table 1, entries 3 and 4). In the case of using the BF_4 salt (**2c**), only a 5% yield of product was obtained in nearly racemic form (3% ee). More dramatically, in the OTf salt **2d** the reaction did not proceed at all. Although this counter ion

Table 1 Enantioselective ring opening of *meso* epoxides in ionic liquids **2a–d**[a]

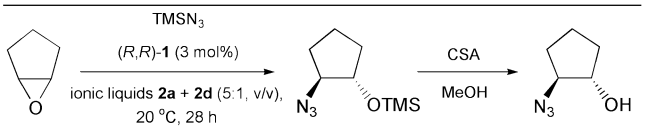


Entry	Substrate (Y)	Ionic liquid **2**	*t*/h	Yield[b] (%)	% ee[c]
1	CH_2	**a**	28	76	94
2	CH_2	**b**	28	75	87
3	CH_2	**c**	28	5	3
4	CH_2	**d**	28	trace	—
5	$(CH_2)_2$	**a**	18	86	85
6	O	**a**	18	74	97

[a] All reactions were run on 2 mmol scale of epoxide at 20 °C using 3 mol% of (*R*,*R*)-**1** in 1 mL of ionic liquid **2**. [b] Isolated yield of azido alcohol. [c] All ee's correspond to those of azido silyl ether and were determined by chiral GC: see footnote†.

effect can not be explained easily, it is apparent that the different hydrophobic character of **2** depending on the anion plays a decisive role in this reaction. Thus, we examined the ARO of other epoxides in the hydrophobic ionic liquid **2a**. All the yields and enantiomeric excesses were quite comparable to those[2a] obtained under homogeneous conditions (Table 1, entries 5 and 6). Although, as mentioned above, excellent results were achieved using the ionic liquid **2a**, the catalyst existed in a suspended form in the ionic liquid **2a** when hexane was added to the reaction mixture after reaction. On the other hand, although the reaction hardly occurred in the ionic liquids **2c** and **2d**, the catalyst was immobilised more efficiently in these solvents after reaction than in **2a**, and thus formed a clear red–brown solution phase, which can make its separation from the hexane phase more easy. We expected that a system combining the hydrophobic and hydrophilic ionic liquids might provide beneficial effects on the catalyst immobilisation. As we expected, in the mixture of **2a** and **2d** with a volume ratio of 5:1, the reaction proceeded with comparable yield and enantiomeric excess to those[2a] obtained under homogeneous conditions (Table 2, entry 1). Moreover, the catalyst could be much better immobilised in this mixture after reaction than in the ionic liquid **2a** alone, and thus the ionic liquid phase containing the catalyst was almost quantitatively recovered from the hexane phase.[8] The recovered ionic liquid phase containing the catalyst was reused several times without any loss of activity and enantioselectivity even after the fifth use (Table 2).

Table 2 Enantioselective ring opening of cyclopentene oxide with catalyst recycling using a mixture of ionic liquids **2a** and **2d**[a]



Entry	Recycle no.	Yield (%)	%ee
1	0	68	94
2	1	72	93
3	2	85	93
4	3	75	94
5	4	76	93

[a] All reactions were run on 2 mmol of epoxide at 20 °C using 3 mol% of (*R*,*R*)-**1** in 1.2 mL of the ionic liquid mixture (1 mL of **2a** and 0.2 mL of **2d**).

In summary, we have developed a new and highly practical recycling procedure of Cr(salen) catalyst by using the air and moisture stable ionic liquids **2**. This procedure does not include hazardous work-up stages such as distillation of the azide product, and moreover, provides not only simple recycling of catalyst but also the additional advantage that the catalyst can be used without any modification of the structure. The catalytic activity and enantioselectivity were strongly dependent on the nature of the anion [X] in the ionic liquids [bmim][X] **2**. Detailed studies for the optimisation of this process and the extension of this methodology to other ARO's are currently in progress.

This research was supported by a grant from the Korea Institute of Science and Technology.

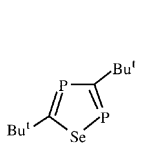
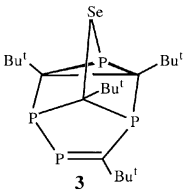
Received (in Cambridge, UK) 26th June 2000, Accepted 2nd August 2000
First published as an Advance Article on the web 29th August 2000

The novel cage compounds $P_3Se_3C_3Bu^t_3$ and $P_3Se_4C_3Bu^t_3$ are formed (together with the 1,2,4-selenadiphosphole $P_2SeC_2Bu^t_2$) from the reaction of the phosphaalkyne Bu^tCP with selenium; the $[PtCl_2(PMe_3)]$ fragment undergoes an unusual insertion reaction into the Se–Se bond of $P_3Se_4C_3Bu^t_3$.

There is current interest in the chemistry of (i) low-coordinate phosphorus compounds, (ii) phospholes containing additional heteroatoms and (iii) novel phosphorus containing cage compounds.[1–14] Regitz and coworkers have recently described[15] the facile, high-yield, synthesis of the previously known[8,9] 1,2,4-selenadiphosphole $P_2SeC_2Bu^t_2$ **1** by treatment of selenium with

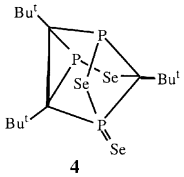


1

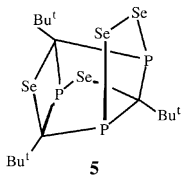


3

the phosphaalkyne Bu^tCP **2** in the presence of NEt_3. The ready [2 + 2 + 2] cycloaddition reaction of **1** with two further mol of **2** to yield the tetracyclic cage compound $P_4SeC_4Bu^t_4$ **3**, prompts us to describe the syntheses and structural characterisation of



4



5

two new cages $P_3Se_3C_3Bu^t_3$ **4** and $P_3Se_4C_3Bu^t_3$ **5**, both also derived from **1**. We also report an unusual oxidation of a Pt(II) complex to a Pt(IV) complex *via* insertion of the Pt(II) into the Se–Se bond of **5**.

Treatment of a suspension of a slight excess of selenium in toluene with **2** for 4 days at 75 °C, afforded **1** as the expected main product, which was removed by sublimation. The residue was chromatographed (Florisil/hexane) to give colourless crystals of $P_3Se_3C_3Bu^t_3$ **4** (5.3%) and red crystals of $P_3Se_4C_3Bu^t_3$ **5** (7%). ^1H, ^{31}P and ^{77}Se NMR data for **4** and **5** were entirely consistent with the proposed structures,† which were also confirmed by single crystal X-ray diffraction studies. The molecular structures of **4**‡ and **5**‡ are shown in Fig. 1 and 2. Both cages are most likely to have been derived from a common intermediate **6**, which would be formed *via* the initial [4 + 2] cycloaddition reaction of **1** with **2**.

Thus **4** probably arises from (i) insertion of Se, still present in the reaction mixture, into the weak P–P bond (resulting from the intramolecular [2 + 2] cycloaddition cage-formation step) of the intermediate **6** and (ii) a second exocyclic Se addition to one of these phosphorus atoms. Likewise, in an analogous way, the more symmetrical cage compound **5** would result from insertion of Se_2 into the P–P bond, as well as a separate single Se atom insertion into the C–C bond of the initially formed strained three-membered CPC ring. Compound **5** is noteworthy because

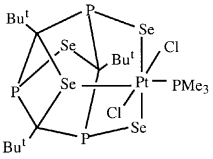
6

although homonuclear S–S bonds are common in monocyclic $(RP)_xS_y$ systems, analogous Se–Se bonded compounds are rare.[16]

Interestingly, the cage compound **5** undergoes an unexpected reaction with $[PtCl_2(PMe_3)]_2$. It was anticipated that simple η^1-coordination would occur, *via* either the P or Se lone pair electrons, however the platinum(II) fragment also unexpectedly inserts into the Se(1)–Se(2) bond of **5** as well as undergoing ligation to Se(3) of the four-membered P(3)C(3)Se(3)C(2) ring, to afford the novel deep-red Pt(IV) complex $[PtCl_2(PMe_3)P_3Se_4C_3Bu^t_3]$ **7** (55.8%).§



7

The latter was fully structurally characterised by a single crystal X-ray diffraction study‡ and its molecular structure is shown in Fig. 3.

Excited state interactions in phenol/olefin bichromophoric compounds: direct detection of an intramolecular exciplex

Francisco Galindo, M. Consuelo Jiménez, Miguel A. Miranda* and Rosa Tormos

Departamento de Química-Instituto de Tecnología Química UPV-CSIC, Universidad Politécnica de Valencia, Camino de Vera s/n, Apdo 22012, 46071 Valencia, Spain. E-mail: mmiranda@qim.upv.es

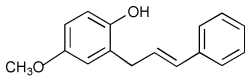
Received (in Liverpool, UK) 22nd June 2000, Accepted 2nd August 2000
First published as an Advance Article on the web 29th August 2000

The emission from an intramolecular exciplex detected in *trans*-4-methoxy-2-(3-phenyl-2-propenyl)phenol (1) is the first direct evidence for the excited state interchromophoric interaction in phenol–styrene systems.

Bichromophoric compounds have attracted considerable interest as models for the understanding of energy or electron transfer processes. They have also found application for mimicking some biological processes (*i.e.* photosynthesis) and for the development of new materials such as photoconducting polymers.[1]

trans-2-Cinnamylphenols are bichromophoric compounds containing phenol and styrene subunits connected by a methylene spacer. Upon the introduction of suitable substituents, these simple systems allow the reproduction at will of a wide range of intramolecular proton, electron or energy transfer processes.[2]

Previously, the photochemical reactivity of *trans*-2-cinnamylphenols and their relatively low fluorescence quantum yields, as compared with models containing the isolated chromophores, has been attributed to an intramolecular interaction in the excited state between the two chromophores.[3] However, no direct evidence has been provided in support of such interaction. In the present work, direct detection of an intramolecular exciplex has been achieved in the case of *trans*-4-methoxy-2-(3-phenyl-2-propenyl)phenol (**1**), by measuring the emission spectra in acetonitrile. To our knowledge, this is the first case of an intramolecular exciplex involving a phenol chromophore.



1

The emission properties of **1** are summarized in Table 1, together with those measured under the same conditions for the isolated 4-methoxyphenol chromophore. Thus, the fluorescence spectra of **1** in hexane displayed a single band with λ_{max} = 320 nm, clearly attributable to emission from the lowest lying phenolic singlet (compare trace B, Fig. 1a with trace A, Fig. 1b). The same result was obtained by exciting either at 250 nm (styrene) or at 290 nm (phenol), clearly due to efficient energy transfer between the excited singlets of both chromophores (Fig. 1c). By contrast, a completely different behaviour was observed in the more polar solvent acetonitrile. The most remarkable result was the presence of a much longer wavelength band centered at 420 nm and the concomitant disappearance of the phenolic emission at 320 nm (see Fig. 1b). This new band is clearly attributable to a charge-transfer

Table 1 Photophysical data of **1** and the reference compound 4-methoxyphenol in hexane and acetonitrile at room temperature[a]

Compound	Solvent	$\lambda_{emission}$/nm	ϕ_F	τ_F(ns)
1	Hexane	320	0.056	1.0
	Acetonitrile	420	0.051	5.1
4-Methoxyphenol	Hexane	320	0.143	1.9
	Acetonitrile	320	0.141	2.1

[a] $\lambda_{excitation}$ = 290 nm.

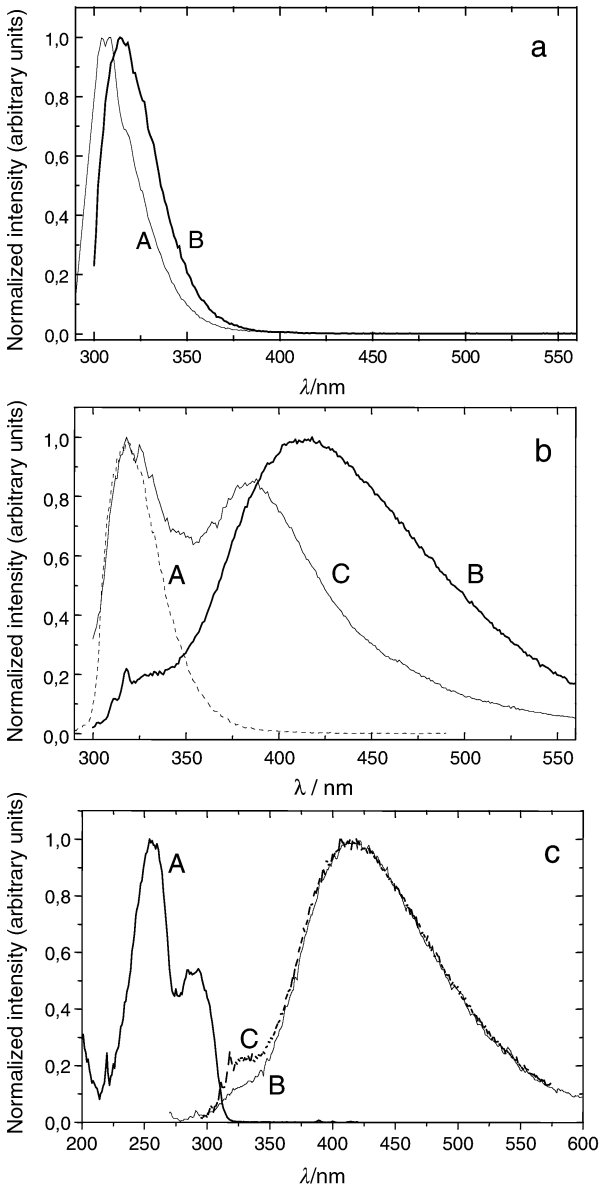


Fig. 1 Fluorescence spectra of: (a) the isolated β-methylstyrene (trace A) and 4-methoxyphenol (trace B); (b) **1** in hexane (trace A), in acetonitrile (trace B) and in a 9 : 1 dichloromethane–acetonitrile mixture (trace C); (c) **1** in acetonitrile; excitation spectrum (trace A), emission upon excitation at 250 nm (trace B) and emission upon excitation at 290 nm (trace C).

DOI: 10.1039/b005026l

exciplex, whose formation would be exergonic according to the Rehm–Weller eqn (1)[4]

$$\Delta G_f \text{ (kcal mol}^{-1}) = 23.06\,(E_{D/D^{+\cdot}} - E_{A/A^{-\cdot}}) - E^* \quad (1)$$

where $E_{D/D^{+\cdot}}$ and $E_{A/A^{-\cdot}}$ are the redox potentials of the donor and acceptor moieties, and E^* is the singlet energy of the phenolic chromophore. Using the excitation energy determined from the intersection between normalized excitation and emission spectra, together with the reported literature values for the redox potentials,[5] the resulting Gibbs free energy associated with exciplex formation would be *ca.* −25 kcal mol^{-1}. The emission spectra were also obtained for solutions of **1** in solvents of intermediate polarity and in a variety of solvent mixtures. For instance, using CH_2Cl_2–CH_3CN (9:1, v:v), both the monomer and the exciplex bands were observed (see trace C, Fig. 1b). As expected for a charge-transfer exciplex, the position of the longer wavelength band showed a clear dependence on the solvent polarity (see Fig. 2 for the Lippert–Mataga plot with the data obtained in pure solvents).[6]

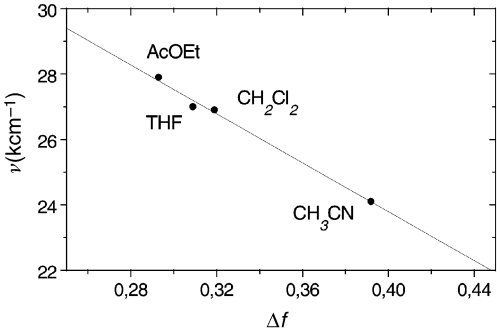

Fig. 2 Solvent polarity dependence of the exciplex emission maxima for **1**. Solvent parameter Δf has been calculated as follows: $\Delta f = (\varepsilon - 1)/(2\varepsilon + 1) - (n^2 - 1)/(4n^2 + 2)$ where ε is the dielectric constant and n is the refraction index of the solvent.

The quantum yield of emission at 420 nm was 0.05, and the lifetime was relatively long (5.1 ns), as compared with the monomer under the same conditions (1.0 ns). The exciplex was quenched by oxygen (k_q = 4.2 × 10^{10} M^{-1} s^{-1}) and by tetrabutylammonium hydrogensulfate (k_q = 3.3 × 10^9 M^{-1} s^{-1}). The Stern–Volmer plot for quenching by the ammonium salt is shown in Fig. 3. Similar salt effects have been observed for other exciplexes; they have been attributed to dissociation into radical ions, with the concomitant decrease of fluorescence.[7]

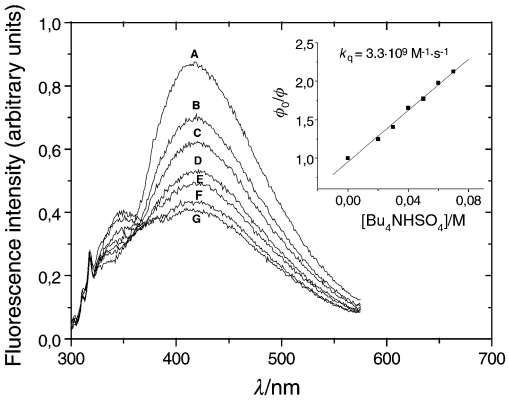

Fig. 3 Quenching of the exciplex fluorescence for **1** by [Bu_4NHSO_4] at different molar concentrations: curve A) 0.0 M; B) 0.02 M, C) 0.03 M, D) 0.04 M, E) 0.05 M, F) 0.06 M, G) 0.07 M.

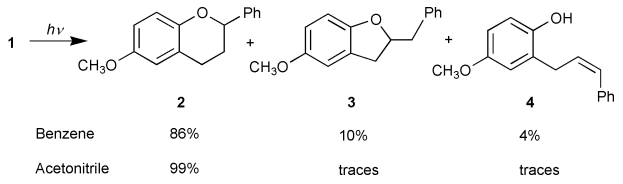
All the above data were obtained using 5 × 10^{-5} M solutions of **1**. To check whether the corresponding intermolecular exciplex is also observable, equimolar mixtures of 4-methoxyphenol and β-methylstyrene in acetonitrile (5 × 10^{-5} M each) were studied. The emission spectra consisted of the bands assignable to the isolated chromophores (either phenolic maximum at 320 nm, upon excitation at 290 nm, or styrenic maximum at 310 nm when exciting at 250 nm). However, using much higher concentrations of the partners (0.1 M), the exciplex emission at *ca*. 440 nm was clearly observable.



Scheme 1

After determining the photophysical properties of **1**, its preparative photochemistry was also investigated. Irradiation of **1** for 1 h in acetonitrile and benzene, with the Pyrex-filtered light of a medium pressure Hg lamp resulted in the almost complete (>95%) consumption of the starting material, accompanied by formation of the six-membered ring compound **2** as the major photoproduct. Minor amounts of the *cis*-isomer **4** and the five-membered ring product **3** were also obtained in benzene. These results are summarized in Scheme 1.

As the formation of six-membered ring product **2** is considered to be an indication for the involvement of intramolecular excited state electron transfer,[2] detection of a charge-transfer exciplex is compatible with the preparative photochemistry of **1**.

In summary, the intramolecular excited state interaction between phenol and styrene has been directly observed for the first time as an exciplex emission. This strongly supports the previous mechanistic proposals to explain the photochemistry of bichromophoric cinnamylphenols. Although such interaction is reported here for a single compound (**1**), preliminary data in hand show that other analogues with electron donating substituents at the phenolic ring [such as 4-methyl, 4,6-dimethyl- and 4,6-di-*tert*-butyl-2-(3-phenyl-2-propenyl)phenol] exhibit similar photophysical and photochemical properties.

Financial support by the DGICYT (PB 97-0339) is gratefully acknowledged. M. C. J. thanks the European Commision for a grant (MCFI-1999-00101). F. G. thanks Ministerio de Educación y Cultura for a grant.

Mesostructured iron sulfides

Jianquan Li and Linda F. Nazar*

Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada N21 3G1. E-mail: lfnazar@uwaterloo.ca

Received (in Bloomington, IN, USA) 6th July 1999, Revised manuscript received 1st May 2000, Accepted 14th June 2000
First published as an Advance Article on the web 29th August 2000

The synthesis and characterization of the first mesostructured iron sulfides are reported: the first is a disordered hexagonal structure prepared *via* a neutral template route; the other, formed using an ionic template, is a relatively ordered phase which represents the first hexagonal mesostructured transition metal sulfide.

Since the first synthesis of mesoporous silicates, much activity has focussed on self-assembled inorganic/surfactant composites[1–5] due to their potential applications as catalysts and absorbents. The best known member of this family, MCM-41, possesses a hexagonal array of channels while the atomic arrangement in the channel walls is disordered. Following this, many different types of surfactants have been used to prepare numerous mesostructured oxides, primarily in the silicate family. A liquid crystal templating mechanism[1] and a self-assembly process involving electrostatic interaction between the inorganic ions in solution and the charged surfactant head group[2,3] were proposed for the mechanism of formation. Using a neutral template, formation of a mesoporous silicate containing a disordered arrangement of channels was explained on the basis of hydrogen bonding and self-assembly between neutral primary amine micelles and neutral inorganic precursors.[4] Neutral surfactants have also been used to prepare mesoporous transition metal oxides with a high specific surface area.[5]

Compared with oxygen, sulfur has a far richer coordination chemistry due to its low-lying d orbitals. The lack of thermodynamic stability of sulfides in the presence of oxygen has made synthesis of mesostructured sulfides more difficult, however, and hence only a few have been reported. These include primarily the main group family, namely mesolamellar and pseudo-hexagonal phases of Group IV (Sn,[6] Ge[7]), and Group II (Cd,[8] Zn[9]). As metal sulfides are generally semiconductors, while many metal oxides are insulators, open-framework metal sulfides may be potentially useful for different applications. Iron sulfides are particularly interesting since they play an important role in life's beginning.[10] The catalytic formation of complex organic molecules from simple precursors is considered to take place on the surface of iron monosulfide or pyrite as a result of redox reactions between FeS and FeS_2.[11] Furthermore, bulk iron(II) and iron(III) sulfides have shown potential applications as cathodes,[12] high refractive index materials[13] and catalysts for coal liquefaction.[14] Herein we report the first mesostructured phases based on iron sulfides, prepared *via* different routes.

Mesostructured iron(II) sulfide [denoted DDA-FeS-M (DDA = dodecylamine)] was formed in the system dodecylamine–iron(II) sulfate–sodium sulfide–ethanol–H_2O at room temperature. Use of the two solvent system improved the solubility of dodecylamine. Fig. 1(*a*) shows the resulting XRD pattern: One peak is evident with a *d*-spacing of 33.8 Å, similar to the value observed for HMS.[4] The presence of a single broad peak is considered an indication of randomly ordered pores.[4,15] A very broad, low intensity line at about 20° (2θ), similar to that of MCM-41 and HMS-type materials, also observed in the XRD pattern, suggests that the inorganic wall is amorphous as expected.[1–4,15] We have found that DDA-FeS-M is formed at an optimum H_2O/ethanol ratio of 7.7: at lower ratios the material is not formed at all. An unknown impurity phase was found in the product when the ethanol was increased, or the amount of iron sulfate and sodium sulfide was increased in the reactant mixture. The impurity phase therefore is minimized under slightly acidic conditions.

The presence of DDA in the material was confirmed by thermal gravimetric analysis (TGA). The TGA curve (under N_2) shows an initial weight loss of about 3.6% below 135 °C due to the desorption of water. Weight loss (48.7%) above this temperature corresponds to the loss of organic material and also some sulfur species. The corresponding differential thermal analysis (DTA) curve in air shows two exothermic peaks at low temperature attributable to reaction with oxygen that result in a weight gain of about 4.4 wt%, evident from the TGA trace. Two exothermic peaks between 250 and 500 °C correspond to combustion of the surfactant. The total weight loss corresponding to the loss of surfactant and transformation from iron(II) sulfide to iron(III) oxide is about 61.5%, translating into an empirical composition of $FeS(DDA)_{0.6}{\cdot}0.4H_2O$. This material displayed a very disordered structure in its TEM image, similar to HMS.[4]

Employment of an ionic surfactant hexadecyltrimethylammonium hydroxide/chloride as a structure-directing agent,

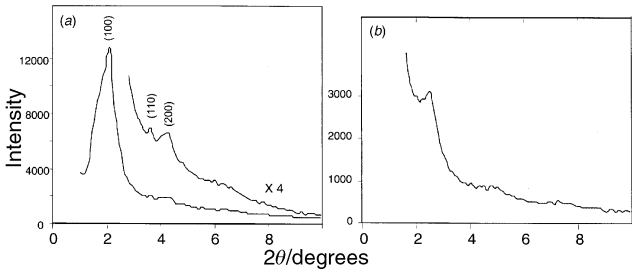

Fig. 1 (*a*) Powder X-ray diffraction patterns (Siemens D-500; Cu-Kα radiation) of DDA-FeS-M; (*b*) XRD pattern of C_{16}TMA-Fe_2S_3-M. Inset shows scale expansion of the 3–10° 2θ range showing the weak 110 and 200 reflections. Values for the experimental and calculated *d*-spacings, respectively for the hexagonal unit cell where a = 48.4 Å are (100), 41.92, 41.89 Å; (110), 24.25, 24.19 Å; (200), 20.59, 20.94 Å.

k	1.00	150	0.5	8.5	$C_{16}TMA$-Fe_2S_3-M
l	0.50	150	0.5 S[a]	24	$C_{16}TMA$-Fe_2S_3-M + Fe_2O_3

[a] Elemental sulfur was used in place of $(NH_4)_2S$

and an amorphous iron(III) sulfide,[16] as iron and sulfur sources yielded $C_{16}TMA$-Fe_2S_3-M after hydrothermal synthesis at 110 °C for 16 h. Fig. 1(*b*) shows the resultant XRD pattern in which three reflections are observed, consistent with diffraction from a poorly ordered hexagonal phase with a = 48.4 Å. Moreover, a broad peak at $2\theta \approx 20°$ is also evident in the XRD pattern, which indicates the inorganic wall is amorphous as previously described. The TEM image (Fig. 2) is in accord with the XRD pattern, in that a poorly organized phase is evident with no long range order apparent. The material is clearly not lamellar, however. The instability of the material in the beam precludes any further detailed TEM study.

Table 1 shows the influence of reaction composition on the products. The molar ratio of $H_2O/C_{16}TMA$ plays a key role in the formation of $C_{16}TMA$-Fe_2S_3-M, as it influences the basicity of the reactant mixture. For example, Fe_2O_3 was formed when the basicity was higher in the reactant mixture, while a mixture of Fe_2O_3 and FeS_2 was obtained when the basicity was lower. Our experiments also show that the addition of a small amount of ammonium sulfide in the reactant mixture can effectively prevent the formation of iron(III) oxide and result in formation of pure $C_{16}TMA$-Fe_2S_3-M. Addition of elemental sulfur cannot inhibit the formation of iron(III) oxide under the same conditions, however. Bulk chemical analysis results indicate that S/Fe molar ratio is about 1.5, with a C/N ratio close to 20.[17] This indicates that the inorganic component is amorphous iron(III) sulfide, and suggests the aliphatic surfactant chains remain intact during the formation of $C_{16}TMA$-Fe_2S_3-M.

Confirmation of the presence of intact surfactant was obtained by FT-IR. The spectrum of $C_{16}TMA$-Fe_2S_3-M shows several absorption bands, which may be assigned to occluded $[C_{16}H_{33}N(CH_3)_3]^+$ at: 2960(sh), $\nu_{as}(CH_3)$; 2920, $\nu_{as}(CH_3)$; 2850, $\nu_{as}(CH_2)$; 1467, $\delta_s(CH_2)$.[7a,18] The absorption band at 334 cm^{-1} is assigned to Fe–S.[19] The bands at about 3400 and 1635 cm^{-1} are due to water adsorbed in the pores of the material. Thermal gravimetric analysis confirms that surfactant is present in the material. The TGA curve under N_2 showed that physisorbed water was removed at about 40 °C, corresponding to a weight loss of 3.1%. The DTA curve in air revealed an exothermic peak at 85 °C and a corresponding weight gain in the TGA of 7.8%, assigned to an oxidation reaction. Subsequent weight loss between 150 and 700 °C, arising from the loss of H_2O and combustion of the surfactant was 71.3% corresponding to a composition of $C_{16}TMA$-Fe_2S_3-M as $0.8C_{16}TMA{\cdot}Fe_2S_3{\cdot}0.4H_2O$. The surfactant/inorganic element ratio of about 1/2 is in accord with previous reports for MCM-41 obtained at higher synthesis pH (CTMA/SiO_2 molar ratio = 0.44).[20] and mesoporous tin(IV) sulfide ($0.5\ C_{16}TMA{\cdot}SnS_2{\cdot}0.75\ H_2O$).[21] Similar to bulk iron(III) sulfide,[22] $C_{16}TMA$-Fe_2S_3-M is very unstable towards oxidation and therefore attempts to remove the surfactant were not successful.

Two probe electrical conductivity measurements indicated that whereas amorphous Fe_2S_3 is a poor semiconductor ($\sigma = 5.4 \times 10^{-8}$ S cm^{-1}), as-synthesized $C_{16}TMA$-Fe_2S_3-M is an insulator. This is probably the result of the large surfactant content and poor electronic transport along the confined dimensions of the amorphous wall. Other factors which would contribute to low conductivity include the possibility of incomplete polycondensation in the inorganic component which would lead to defects, and grain boundary effects.

In summary, two different synthetic routes provide new mesostructured iron sulfide phases, including the first hexagonal transition metal sulfide phase. Their lack of thermodynamic stability with respect to oxygen inhibits ready removal of the surfactant. Controlled oxidation of this material may provide a facile route to a hitherto unknown mesostructured or mesoporous iron oxide.

We gratefully acknowledge the financial support of the NSERC (Canada) through the Research Grants Program. Professor Jim Corbett (Physics, University of Waterloo) and Dr Jessie Zhou are thanked for their help in obtaining the TEM image.

Syntheses and structural characterization of novel luminescent heteronuclear rhenium(I)–zinc(II) and –cadmium(II) chalcogenolate complexes†

Vivian Wing-Wah Yam,* Yung-Lin Pui, Keith Man-Chung Wong and Kung-Kai Cheung

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong SAR, People's Republic of China. E-mail: wwyam@hku.hk

Received (in Cambridge, UK) 26th June 2000, Accepted 4th August 2000

Novel heteronuclear rhenium(I)–zinc(II) and –cadmium(II) complexes with chalcogenolate ligands have been synthesized and shown to exhibit rich luminescence properties; the X-ray crystal structures of [{(bpy)Re(CO)$_3$(μ-SC$_6$H$_4$Me-*p*)}$_2$Zn(bpy)](PF$_6$)$_2$ (2) and [{(bpy)Re(CO)$_3$(μ-SC$_6$H$_4$Me-*p*)}$_2$Cd(bpy)$_2$](PF$_6$)$_2$ (4) have been determined.

There has been a growing interest in luminescence studies of transition metal complexes, particularly with the increasing attention on the design of functional materials with unique properties.[1,2] The most widely studied and well-documented systems are those of the d^6 metal polypyridines[1–3] and very recently, the d^8 and d^{10} metal complexes.[4,5] Recently, a series of mono- and di-nuclear rhenium(I) diimine complexes with chalcogenolate ligands have been reported by us to show rich luminescence behaviour.[6] It is believed that extension of this work to heterometallic complex formation by using mononuclear rhenium(I) chalcogenolates as metalloligands, would give rise to a novel series of luminescent mixed-metal rhenium(I) complexes. In view of the known luminescence properties of zinc(II) and cadmium(II) thiolate systems[7] and our continuing interest in luminescent d^{10} metal complexes,[5] a series of trinuclear mixed-metal rhenium(I)–zinc(II) and –cadmium(II) chalcogenolate complexes have been synthesized and their luminescence behaviour studied. It is also envisaged that the attachment of zinc and cadmium moieties to the rhenium chalcogenolate would serve as an efficient method to perturb the excited state properties of the complexes. The X-ray crystal structures of [{(bpy)Re(CO)$_3$(μ-SC$_6$H$_4$Me-*p*)}$_2$Zn(bpy)](PF$_6$)$_2$ and [{(bpy)Re(CO)$_3$(μ-SC$_6$H$_4$Me-*p*)}$_2$Cd(bpy)$_2$](PF$_6$)$_2$ have been determined.‡

Reaction of [(bpy)Re(CO)$_3$(SC$_6$H$_4$R)][6b] with a mixture of Zn(NO$_3$)$_2$·6H$_2$O and 2,2′-bipyridine in a molar ratio of 2 : 1 : 1 in methanol under an inert atmosphere of nitrogen, followed by metathesis with NH$_4$PF$_6$ and subsequent recrystallization from MeCN–Et$_2$O, afforded [{(bpy)Re(CO)$_3$(μ-SC$_6$H$_4$R)}$_2$Zn(bpy)](PF$_6$)$_2$ (R = H **1**, Me-*p* **2**). Similar reactions of [(N–N)Re(CO)$_3$(μ-EC$_6$H$_4$R)] with Cd(NO$_3$)$_2$·4H$_2$O and 2,2′-bipyridine in a molar ratio of 2:1:2 gave [{(N–N)Re(CO)$_3$(μ-EC$_6$H$_4$R)}$_2$Cd(bpy)$_2$](PF$_6$)$_2$ (N–N = bpy, E = S, R = H **3**, Me-*p* **4**; N–N = bpy, E = Se, R = H **5**; N–N = Bu$^t_2$bpy, E = S, R = Me-*p* **6**). All the complexes have been characterized by ^{1}H NMR spectroscopy and positive ESI-MS and gave satisfactory elemental analyses.†

Fig. 1 and 2 show perspective drawings of the complex cations of **2** and **4** with atomic numbering, respectively. In **2**, the two Re centres adopt a distorted octahedral geometry with a S(1)–Re(1)–N(1) angle of 81.6(2)° and a S(2)–Re(2)–N(5) angle of 85.7(2)°. The zinc centre adopts a distorted tetrahedral geometry with a S(1)–Zn(1)–S(2) angle of 110.45(9)°. The angles Re(1)–S(1)–Zn(1) and Re(2)–S(2)–Zn(1) are 114.01(10) and 112.17(10)°, respectively. The average Re–S and Zn–S bond lengths are 2.523(2) and 2.285(8) Å, respectively, which are comparable to those observed in other related rhenium(I)[6,8] and zinc(II) thiolate complexes.[7c,9] In **4**, the two Re and the Cd centres adopt a distorted octahedral geometry with a S(1)–Re(1)–N(1) angle of 88.0(1)°, a S(1)–Cd(1)–S(1*) angle of 100.89(8)° and a Re(1)–S(1)–Cd(1) angle of 150.49(7)°. The average Re–S and Cd–S bond lengths are 2.523(2) and 2.713(2) Å, respectively, which are comparable to those found in related rhenium(I)[6,8] and cadmium(II) thiolate complexes.[7f,9,10]

The electronic absorption spectra of complexes **1**–**6** show absorption bands at *ca.* 350–380 nm with absorption shoulders at *ca.* 450–520 nm in MeCN. The photophysical data of the

[a] Absorption and emission wavelengths are reported to ±2 nm. [b] Ethanol–methanol (4:1 v/v) glass. [c] Excitation wavelength at 355 nm. Values in square brackets are λ_{em} with excitation wavelength at 450 nm.

complexes are summarized in Table 1. The former is tentatively assigned as $p_\pi(SR^-) \rightarrow \pi^*(\alpha,\alpha'$-diimine on Re^{I} or Zn^{II} or Cd^{II}) LLCT transitions as similar spectral assignments have been suggested in related zinc(II),[7a–c] cadmium(II)[7a,7f] and rhenium(I) systems,[6] while the latter is assigned as a $d_\pi(Re) \rightarrow \pi^*(\alpha,\alpha'$-diimine on Re) MLCT transition. Similar assignments have also been made in related Re(I) α,α'-diimine systems.[1–3,6] These have been further supported by the observation of an energy dependence on the nature of the chalcogenolate and the diimine ligands. The lower LLCT absorption energies in **2** compared to **1** and in **4** compared to **3** are in accordance with the presence of the more electron rich 4-methylthiophenolate ligand relative to thiophenolate. In view of the almost identical absorption patterns and energies for the Re^{I}–Zn^{II}–Re^{I} and Re^{I}–Cd^{II}–Re^{I} analogues, it is reasonable to assume that the transitions are dominated by the LLCT and MLCT transitions of the rhenium(I) diimine thiolate core, with minor contributions due to the zinc and cadmium moieties.

Upon excitation of complexes **1**–**6** at 350–450 nm, emission bands at *ca*. 520–630 nm were observed in the solid state, in 77 K glasses and in fluid solutions (Table 1). The close resemblance of the emission energies to those reported for the related dinuclear $[\{(N–N)Re(CO)_3\}_2(\mu\text{-}SR)]^+$ complexes[6a] is suggestive of a similar ^{3}MLCT $[d_\pi(Re) \rightarrow \pi^*(\alpha,\alpha'$-diimine)] emissive origin. Upon monitoring the emission at *ca*. 560–625 nm, bands at *ca*. 450–500 nm were observed in the excitation spectra, in regions close to the MLCT absorption. However, the broadness of the band as well as the dependence of the emission energy on the excitation wavelength may be suggestive of a dual luminescence. It is likely that the higher energy emission shoulder is derived from an ^{3}IL(diimine)/^{3}LLCT origin while the low-energy emission is dominated by a ^{3}MLCT origin. Similar to the trend observed in electronic absorption studies, the lower emission energy of **2** compared to **1** and **4** compared to **3** in the solid state, is in line with the electron donating ability of the substitutents on the thiophenolate ligand, giving rise to higher $d_\pi(Re)$ and/or $p_\pi(SR^-)$ orbital energies. The higher emission energy of **6** relative to that of **4** is also in line with a ^{3}MLCT origin, probably with some mixing of ^{3}LLCT $[p_\pi(ER^-) \rightarrow \pi^*(\alpha,\alpha'$-diimine)] character, since the presence of electron rich *tert*-butyl substituents on Bu$^t_2$bpy would raise the $\pi^*(\alpha,\alpha'$-diimine) orbital energy relative to that of bpy.

A thermally stable mesoporous TiO_2 with a crystalline framework and ordered large pores is synthesized using a block copolymer as a structure-directing agent through an N^0I^0 assembly pathway, followed by a hydrothermal process.

The synthesis of mesoporous silica with a high surface area and uniform cylindrical mesopores, which was designated as M41S, was first demonstrated in 1992.[1] Since then, the use of surfactants and amphiphilic block copolymers to organize mesoporous structures has been extended to the preparation of non-silica mesoporous metal oxides. Mesoporous MnO_2,[2] Al_2O_3,[3,4] TiO_2,[4,5] Nb_2O_5,[4,6] Ta_2O_5,[4,6] ZrO_2[4,7] and SnO_2[4,8] have been synthezied over the past few years. Among them, mesoporous TiO_2 is most attractive due to its excellent performance in photocatalytic reactions.[9] It is well known that the effectiveness of titania as a photocatalyst is very sensitive to its crystal phase, particle size and crystallinity, and the mesoporous TiO_2 prepared using phosphate surfactants has low photocatalytic activity because the amorphous titania channel walls afford low quantum yield for photocatalytic reactions.[10] Calcination of the as-synthesized mesoporous TiO_2 at high temperature is essential for the crystallization of titania in the channel wall.[4] However, damage to the integrity of the mesoporous structure will take place upon calcination at high temperature, thus only mesoporous TiO_2 with amorphous or semicrystallized channel walls have been reported till now. Here we present the first example of mesoporous TiO_2 with crystalline framework, prepared through an N^0I^0 assembly pathway using a triblock copolymer as a structure-directing agent and followed by a hydrothermal process.

The mesoporous titania with crystalline framework was prepared as follows: a calculated amount of titanium ethoxide $Ti(OC_2H_5)_4$ was dissolved in an ethanol solution containing triblock poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) ($EO_{20}PO_{70}EO_{20}$, Aldrich) and a very small amount of $CeCl_3$ which acts as a stabilizer in the syntheses.[11] After stirring for 1 h at ambient temperature, a water–ethanol mixture containing a 20% molar fraction of water was added dropwise. The molar composition of the reaction mixture was: 0.05 Ce^{3+} : 1.0 TEOT : 0.02 $EO_{20}PO_{70}EO_{20}$: 4.0 H_2O : 15.5 C_2H_5OH. The mixture was stirred at ambient temperature for another 48 h. In the hydrothermal process, a large amount of water was added to the resulting solution until the H_2O/TiO_2 molar ratio = 90. Then, the mother liquor containing the precipitate was transferred to a stainless steel autoclave, and heated at 80–180 °C for 24 h. The product obtained was filtered off, washed with distilled water, dried at 100 °C, and finally calcined in air at 350 °C or 500 °C for 4 h. The samples studied are denoted as TiO_2-*x*-*y*, where *x* and *y* represent the temperatures of hydrothermal aging and calcination, respectively. A mesoporous TiO_2 sample untreated hydrothermally was also prepared for comparison.

Fig. 1 shows the results of wide-angle X-ray diffraction studies performed on a Rigaku D/MAX-IIA diffractometer using Cu-Kα radiation of the hydrothermally treated mesoporous titania before and after calcination. No clear diffraction peaks are observed for as-synthesized mesoporous TiO_2 without hydrothermal treatment before calcination. After calcination weak and broad peaks, which can be indexed as the (101), (004), (200), (105) and (204) reflections of anatase crystalline phase, appear on the pattern, showing that the channel walls are semicrystallized and some anatase nanocrystallites are formed and embedded in the amorphous titania channel walls. In contrast, sharp diffraction peaks of anatase appear on the XRD patterns of samples hydrothermally treated at 80–180 °C even before calcination and the intensity of the peaks increases little after calcination, indicating that the channel walls of the mesoporous oxides can be successfully crystallized at the low hydrothermal treatment temperatures. The crystals in the TiO_2-120-350 and TiO_2-180-350 samples are estimated to be of size 10 and 15 nm, respectively, by applying the Scherrer formula on the (101) diffraction peaks. The degree of crystallization and the anatase crystal size increase as the hydrothermal treatment temperature is increased from 80 to 180 °C. A brookite peak at 31° (2θ) appears for samples treated at 180 °C. Calcination up to 500 °C does not have significant effects on the diffraction patterns of the samples, showing that the anatase crystal phase is retained at this temperature and no phase transformation has occurred.

Thermogravimetric experiments of the hydrothermally treated samples carried out in flowing air on a Rigaku Thermoflex instrument indicate that there are three endothermic processes in the TG/DTG/DTA curves at 20–120 °C, 120–320 °C and 320–420°C, corresponding to the release of adsorbed water, block copolymer and structural water, respectively. Therefore, the block copolymer template in this type of mesoporous TiO_2 samples can be completely removed upon calcination in air at 350 °C.

Transmission electron micrographs of the TiO_2-120-350 sample recorded on a Philips CM 200 FEG Microscope (Fig. 2) shows that the pore channel walls are not totally continuous and the mesostructure is spotted with a few micro-domains of less ordered worm-like pore symmetry. Selected-area electron diffraction patterns (Fig. 2 inset) recorded on the same sample

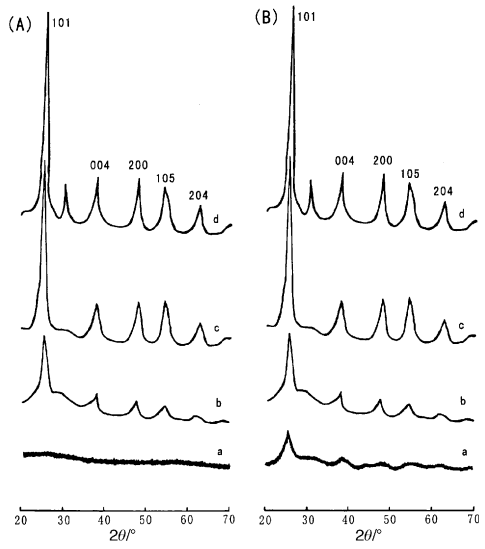

Fig. 1 XRD patterns of mesoporous TiO_2 before (A) and after (B) calcination. (a) TiO_2; (b) TiO_2-80-350; (c) TiO_2-120-350; (d) TiO_2-180-350.

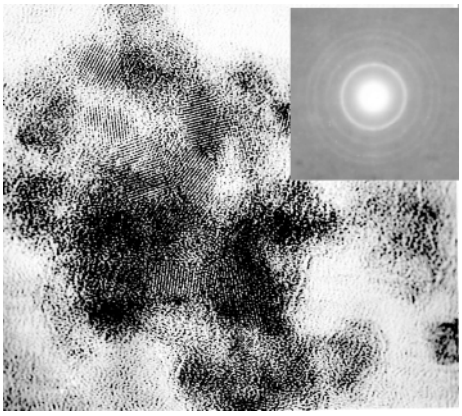

Fig. 2 TEM image and selected-area electron diffraction pattern (inset) of the TiO_2-120-350 sample

confirm that the channel walls are comprised of nanocrystalline anatase displaying characteristic diffuse electron diffraction rings.

Fig. 3 illustrates the N_2 adsorption/desorption isotherms of the TiO_2-120-350 sample measured using a Micromeritics ASAP 2000 system. A large H1-type hysteresis loop at high relative pressure is observed, which is related to the capillary condensation associated with large pore channels. BJH analysis of the desorption isotherm is shown in Fig. 3 (inset). The narrow gaussian pore size distribution curve implies that the material has very regular pore channels in the mesoporous region. The textural properties of all the hydrothermally treated samples are listed in Table 1 along with the data of the untreated samples. The pore size and volume of the hydrothermally treated samples are significantly greater than those of the untreated sample, whereas their specific surface areas are slightly lowered. The dramatic increase in pore size of the samples shows that the mesoporous TiO_2 could be restructured under hydrothermal treatment in the presence of the block copolymer template. The

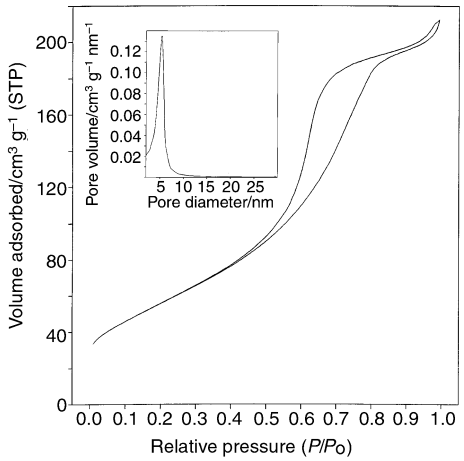

Fig. 3 N_2 adsorption/desorption isotherm and BJH pore size distribution plot (inset) of the TiO_2-120-350 sample at 77 K.

Table 1 Textural properties of mesoporous TiO_2 samples

Sample	Aging temperature/ °C	Calcination temperature/ °C	BET surface area/m^2 g^{-1}	Pore diameter/ nm	Pore volume/ cm^3 g^{-1}
TiO_2-80-350	80	350	201	4.4	0.271
TiO_2-80-500	80	500	150	5.2	0.249
TiO_2-120-350	120	350	204	5.5	0.315
TiO_2-120-500	120	500	157	6.2	0.302
TiO_2-180-350	180	350	159	7.0	0.366
TiO_2-180-500	180	500	134	8.0	0.336
TiO_2	none	350	242	2.2	0.156
TiO_2	none	500	191	2.0	0.130

pore sizes of TiO_2-180-350 and TiO_2-180-500 reach 7.0 and 8.0 nm, respectively, which are the largest reported for mesoporous titania until now.[4] The mesoporous TiO_2 materials with crystalline framework retain their structural integrity and mesoporosity when calcined at 500 °C.

This work shows that mesoporous TiO_2 materials with anatase crystalline framework can be successfully prepared using a templating procedure followed by hydrothermal treatment and calcination. Amorphous titania in the channel walls of the mesoporous structure is crystallized at low hydrothermal temperature without sacrificing porosity and pore regularity, and the template is removed at a relatively low calcination temperature to ensure the materials against structure degradation. The crystalline framework, high specific surface area, large pore size and high thermal stability of these new materials are expected to afford better activity toward photocatalytic reactions, in particular those concerned with bulky molecules and high space velocity.

Synthesis of the mixed lithium–magnesium, mixed amide (*R,R/S,S*)-[{LiMg(TMP)[$CH_2Si(Me)_2N(SiMe_3)$]}$_2$]: a conformationally-locked structure of five fused rings inducing two stereogenic nitrogen centres

Received (in Cambridge, UK) 31st May 2000, Accepted 2nd August 2000

Reaction of the magnesium amide $Mg(TMP)_2$ with the lithium amide LiHMDS is accompanied by an unexpected, sterically-promoted hydrogen transfer/amine elimination process, to yield the novel title compound which is the first such heterometallic composition to contain a heteroleptic amide ligand set.

Lithium amide compounds have been long-standing friends to the synthetic chemist, especially sterically encumbered types which find widespread use in regio-, stereo- and enantioselective deprotonation applications.[1] By comparison, magnesium amides are much more recent acquaintances, but they too are beginning to make an impression as specialist reagents,[2] most notably in the asymmetric arena.[3] While these mainstream homonuclear compounds have been commanding most attention, the effect of pairing a lithium (or another alkali metal) amide with a magnesium amide, in the same molecular package,[4] is also under scrutiny. Could this mixing promote a useful synergy, giving rise a new chemistry and novel structures, not known or not possible with the conventional homonuclear compounds? Studies directed towards answering this intriguing question are still at a preliminary stage; however, initial signs appear promising. For example, the idea of 'inverse crown ether' complexes was conceived from this heterobimetallic approach. These are eight-membered $(MNMgN)^{2+}$ rings (M = Li, Na or K)[5] which act as polymetallic hosts to oxygen-based O^{2-} or $(O_2)^{2-}$ dianions. Larger twelve-membered $(NaNMgNNaN)_2^{2+}$ or twenty four-membered $(KNMgN)_6^{2+}$ variants,[6,7] which function as single or multiple traps for larger arene-based anions, have also been introduced. In all of these mixed-metal macrocycles there is only one type of amido bridge, belonging to either 1,1,1,3,3,3-hexamethyldisilazide (HMDS) or 2,2,6,6-tetramethylpiperidide (TMP) ligands. Similarly, the few other mixed lithium–magnesium amides in the literature are also homoamido in composition. Therefore we set out to prepare the first mixed lithium–magnesium, mixed amide compound. As reported herein, while this aim has been achieved through the synthesis of [{LiMg(TMP)[$CH_2Si(Me)_2N(SiMe_3)$]}$_2$], **1**, which contains both TMP and HMDS ligands, surprisingly it is not an inverse crown ether and furthermore it is accompanied by an unexpected deprotonation of one of the Me groups attached to Si in the latter ligand. Interest is heightened by the fact that the molecular structure is chiral, as determined by X-ray crystallographic studies on representative crystals of **1**. This stereochemical outcome can be explained by an intramolecular hydrogen transfer, promoted by the sterically crowded, conformationally locked heteronuclear structure expected to form initially on mixing the component homonuclear amides.

We first observed **1** on attempting to prepare the homonuclear amides *in situ* by adding, in order, Bu^nLi (5 mmol) in hexane, HMDS(H) (5 mmol), Bu_2Mg (5 mmol) in heptane, and TMP(H) (10 mmol). The reaction mixture was subsequently heated to reflux for 90 min. A mutually coupled pair of doublets (^2J, 13.1 Hz) in the negative region of the ^{1}H NMR spectrum of a C_6D_6 solution of the product,† alerted us to the presence of the metal bound CHH′ group (a point later verified by X-ray crystallography). This surprising finding prompted us to try an alternative direct approach, preparing and isolating $Mg(TMP)_2$ (as an oil)[8] and LiHMDS (as a crystalline solid)[9] separately (to ensure all butyl anions had been consumed, a point confirmed by NMR studies), before adding them together in a 1:1 stoichiometry in hydrocarbon solution. Stirred and gently warmed for a few min but not heated to reflux, this solution also afforded pale yellow crystals of **1**.† Absolute yields could not be determined due to the high solubility of **1** which makes the low temperature filtration/isolation procedure problematical; however, in one attempt 30% was collected, though the true yield was considerably greater.

The molecular structure of **1** (Fig. 1)‡ is dimeric, composed of dinuclear (LiNMgN) monomeric fragments with pendant Me_2SiCH_2 arms which bind 'intramolecularly' through the methylene C atom to the Mg centre. Dimerisation is effected *via* 'intermolecular' bonds from the methylene C atom to the Mg centre of the other monomeric fragment. The Mg centres occupy distorted tetrahedral [80.80(10)–128.62(11)°] environments made up of two C and two N atoms. Formally occupying bent [104.3(2)°] geometries between two N atoms, each Li centre finds electronic relief through agostic interactions with one TMP [Li(1)···C(12), 2.565(6) Å; Li(2)···C(24), 2.585(6) Å] and one HMDS-Me group [Li(1)···C(4), 2.359(6) Å; Li(2)···C(28), 2.332(6) Å]. 'Intramolecular' Mg–C bonds are marginally longer than their 'intermolecular' counterparts (mean lengths, 2.320 and 2.258 Å, respectively). The $(MgC)_2$ ring they make, which represents the central component of a fivefold system of fused four-membered rings, is puckered

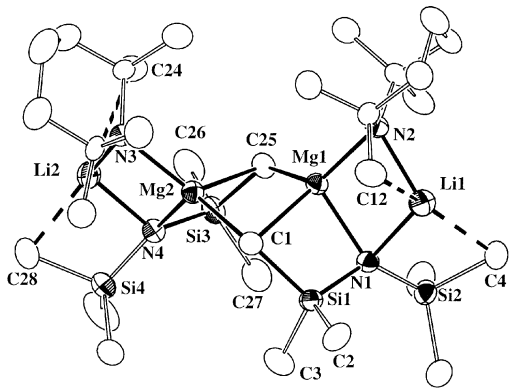

Fig. 1 Molecular structure of **1** showing agostic contacts as dashed lines. Hydrogen atoms are omitted for clarity. Scheme 1 Note that the stereochemistry shown here is idealized and not representative of that in **1**

(RMS deviation from planarity, 0.2138 Å). In contrast, the dinuclear (LiNMgN) rings at opposite ends of the structure are essentially planar. Mean Mg–N and Li–N bond lengths (2.104 and 2.000 Å, respectively) lie in the usual range for bonds of this type with the same connectivity. Also essentially planar, two (MgNSiC) rings complete the structure.

The most interesting aspect of the structure is the chiral nature of the HMDS N atoms N(1) and N(4). Each binds to one Li and one Mg centre, and to one $SiMe_3$ and one $SiMe_2CH_2$ group. Only the enantiomeric *R,R* and *S,S* pair has been observed. The *R,S* diastereoisomer has not been detected. Based on knowledge of related magnesium and mixed lithium–magnesium amide structures, it is possible to construct a structural pathway (Scheme 1) to rationalise the formation of **1**. Though not yet confirmed crystallographically, the structure of $Mg(TMP)_2$ is almost certainly either a monomer or a loosely-associated dimer. These two structural types co-exist in solutions of $Mg(HMDS)_2$,[10] so it is likely that solutions of $Mg(TMP)_2$ would contain an even more significant preponderance of monomer given the greater steric bulk of TMP. In the first step of the pathway, it is envisioned that a $Mg(TMP)_2$ monomer would approach a molecule of LiHMDS (formally a trimer in the solid state, but here shown as a monomer for simplicity). This should result in a heteronuclear arrangement, akin to that known for $LiMg(HMDS)_3$,[5a] but more sterically crowded and with a mixed TMP-HMDS bridge. A close contact between a C–H bond on the bridging $Me(SiMe_2)N$ group and the N atom of the terminal TMP ligand could then trigger hydrogen transfer and subsequent loss of TMPH. Concomitantly, a new Mg–C bond and fixed stereogenic N centre are formed. Relief of steric crowding around the Mg centre then allows dimerisation to proceed in the final step, thus increasing the coordination number of the Mg centre from 3 to 4. It is pertinent to note that no analogous pathway is possible in a homonuclear LiHMDS–LiTMP system, as from valency considerations no terminal TMP ligand would be available for subsequent displacement.

Though rare, it is known that certain transition metal (Ti,[11] V,[12] Zr[13]) HMDS-containing complexes can for steric reasons lose a hydrogen atom to generate $CH_2Si(Me)_2NSiMe_3$ ligands through direct metallation with a strong base (Bu^nLi, LiHMDS, NaHMDS), but these reactions afford only achiral products. A more interesting analogy is provided by a mixed Sb–Ga *geminal* organodimetallic complex[14] in which a $(2\text{-}C_5H_4N)C(SiMe_3)_2$ ligand is converted to $(2\text{-}C_5H_4N)C(SiMe_3)Si(Me)_2CH_2$ with generation of a new stereogenic C centre. Thermally induced *via* an intramolecular MeH elimination (*cf.*, the amine elimination here), this deprotonation is facilitated by a Me–Ga bond (*cf.*, the R_2N–Mg bond here) within the cyclic precursor.

Finally, given that **1** retains a bulky amide ligand within a conformationally-locked ring structure, as well as a bifunctional C, N-alkide, amide ligand, it will be of interest to ascertain whether it and similar heterometallic complexes have a future as companion reagents to the conventional homometallic bases and nucleophiles.

We thank Drs D. R. Armstrong and K. W. Henderson for many useful discussions and the EPSRC service at the University of Southampton for the X-ray crystallographic study.

Notes and references

'Inverse crown ether' complexes extended to group 12 through the syntheses of $[Na_2Zn_2(HMDS)_4(O)]$ and $[\{K_2Zn_2(HMDS)_4(O_2)_x(O)_y\}_\infty]$

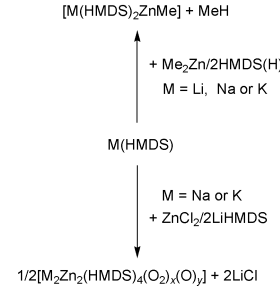
Received (in Cambridge, UK) 29th June 2000, Accepted 9th August 2000

The first sodium–zinc and potassium–zinc members of the inverse crown ether family, an emerging class of heterometallic macrocyclic amides previously limited to alkali metal–magnesium combinations, have been synthesised and crystallographically characterised.

The use of sterically hindered lithium amide bases, such as LDA, as selective deprotonating agents is widespread throughout organic chemistry.[1] Although these and other homometallic amides have been extensively studied, the possibility of fine-tuning the reactivity profiles of lithium amides by introducing a second metal centre has only recently been explored and has resulted in the characterisation of new structural types. We have described the formation of a new form of heterometallic macrocyclic amide, the inverse crown ether, which can be subdivided into two types. The first group consists of eight-membered $[MgNMN]_2$ rings (M = Li, N = HMDS or TMP;† M = Na or K, N = HMDS) which balance their 2+ charge by acting as oxygen scavengers and encapsulating oxide or peroxide dianions.[2–4] The second group consists of larger twelve-membered, $[NaNMgNNaN]_2$, and twenty-four-membered, $[MgNKN]_6$, rings (N = TMP) which encapsulate one dideprotonated or six monodeprotonated arene molecules, respectively, derived from the solvents used during the reaction.[5] This previous work encompasses a range of M^+ metals, of amide ligands and of guest anions, only the Mg^{2+} centre has remained constant. Substituting metals outside the s-block for magnesium would open new avenues for exploration. One intriguing possibility is that of performing redox chemistry on the guest anions by taking advantage of the range of easily accessible oxidation states displayed by many d-block metals. As a first step towards such compounds we sought to form mixed group 1 metal/zinc analogues. Zinc was chosen for these initial investigations owing to its similar size to magnesium, for its readiness to assume a trigonal-planar coordination geometry and for its stability in the +2 oxidation state, all of which fit the design criteria for inverse crown ether formation. As reported herein, this aim has been realised through the synthesis and crystallographic characterisation of the first sodium–zinc, $[Na_2Zn_2(HMDS)_4(O)]$ **1**, and potassium–zinc, $[\{K_2Zn_2(HMDS)_4(O_2)_x(O)_y\}_\infty]$ **2**, inverse crown ether complexes.

The magnesium containing macrocycles were formed on reacting mixtures of alkyl metal reagents with the appropriate amine;[2–4] however, following the same synthetic procedure with dimethylzinc and *n*-butyllithium did not give the expected macrocyclic product (Scheme 1). Instead one methyl group was retained and $[\{Li(\mu\text{-}HMDS)_2ZnMe\}_\infty]$ **3a**, was the only product isolated, forming in 39% yield as long, colourless needle crystals. The molecular structure of **3a**‡ was found to be based on planar four-membered ZnNLiN rings (Fig. 1) with the methyl group occupying a third (terminal) coordination site on Zn. The molecule has crystallographically imposed two-fold symmetry with Zn, Li and C1 lying on a rotation axis. The



Scheme 1

coordinatively unsaturated (with respect to N) Li attains a higher coordination number by forming a short, linear, intermolecular bridging contact with a neighbouring methyl group (Li···C1 2.435(12) Å, Zn–C1···Li 180°) thus giving rise to a relatively insoluble and structurally robust (*vide infra*) polymer. This is in marked contrast to $[Li(\mu\text{-}HMDS)_2Mg(HMDS)]^2$ **4**, where lithium attains a tetrahedral geometry by forming two intramolecular Li···C contacts [of length 2.294(10) and 2.320(9) Å] with methyl groups from the HMDS ligands. Despite the methyl group being shared between the two metal centres the Zn–C1 distance in **3a** of 1.957(7) Å is similar to those in comparable, but molecularly discrete, compounds.[6] The linear, CH_3 face-capping[7] nature of the methyl to lithium interaction in **1a** is unusual and contrasts strongly with the bent motifs found both in **4** and in other mixed Zn/Li species.[8]

Varying the reaction conditions by including a 4 h reflux or by initially preparing a separate '$Zn(HMDS)_2$' solution from $ZnMe_2$ and amine prior to addition of Li(HMDS) failed to dislodge the second methyl group and produced only **3a** as identified by ^{1}H NMR spectral data [C_5D_5N, δ 0.58 (s 12H, $SiMe_3$), −0.05 (s 1H, Me)]. Repeating the reaction with Bu^nNa or Bu^nK in place of Bu^nLi gave the equivalent sodium and potassium compounds, **3b** and **3c**, respectively, as assigned by comparison of their NMR spectra. To circumvent the retention of the methyl group, $Zn(HMDS)_2$ was prepared by a literature method[9] from $ZnCl_2$ and 2 equivalents of Li(HMDS), and subsequently purified by filtration and vacuum distillation. The pure zinc amide was then added to Na(HMDS) (in a 1 : 1 molar

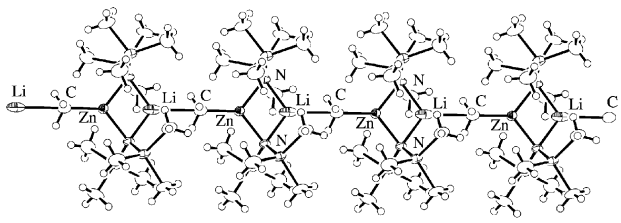


Fig. 1 Polymeric structure of **3a**. Selected geometric parameters (Å,°): Li–N 1.959(7); N–Zn–N* 102.0(2), C–Zn–N 129.0(1), Zn–N–Li 76.1(3), N–Li–C** 127.1(2), N–Li–N* 105.7(5). * = 1 − *x*, *y*, 1.5 − *z*, ** = *x*, 1 + *y*, *z*.

DOI: 10.1039/b005233g

ratio) in an arene solvent (which had previously had dry oxygen bubbled through it) and heated to reflux for 2 h. On cooling to room temperature, large colourless crystals were formed. These were found to be the desired product **1**.‡ Note that when 12-crown-4 is present during this reaction only the zincate $[Na(12\text{-crown-}4)_2][Zn(HMDS)_3]$ is obtained.[10] Repeating our reaction using K(HMDS) in place of Na(HMDS) gave crystals of peroxide rich **2** ($x = 0.82$, $y = 0.18$, for the crystal examined by X-ray diffraction). **2** is the first organoamido-group 12 metal peroxide to be crystallographically characterised, although relevant zinc oxides are known.[11] Compounds **1** and **2** are isomorphous with each other and with their magnesium containing analogues, **1a**[3] and **2a**.[4] Each consists of a near planar octagonal ring containing alternate metal and nitrogen centres (Figs. 2 and 3). Like metal atoms occupy transannular positions and all of them form a third attachment to the central oxide or peroxide guest. The Zn–N distances in **1** and **2** are essentially identical within each compound [mean 1.984(2) and 1.963(1) Å, respectively] and are shorter than that found for **3a** (2.010 Å), seemingly in line with the increasing electronegativity of the group 1 metal. Each Na or K atom forms one short and one long bond to an amide [Na–N 2.541(3), 2.597(2), K–N 2.797(1, 2.838(1) Å] and, unlike the smaller zinc atoms, are displaced both away from the centre of the ring and from the plane of the ring. This leaves both sodium and, more especially, potassium in relatively unfavoured low coordination states and with all their formal bonds on the same side of the coordination sphere. **2** compensates for this by forming short $K\cdots CH_3(SiMe_2)$ contacts. Each potassium forms one intermolecular contact [K··C 3.324(2) Å, K··C–Si 155.6(1)°], to give the linear polymer shown in Fig. 3, as well as several intramolecular contacts [range 3.309(2)–3.362(2) Å]. Note that, in contrast to **2a**, the intermolecular contact is no longer the shortest. It is of interest that the Na compounds display similar carbon contact distances but that these are normally disregarded due to the smaller size of Na. Preliminary results from a single crystal neutron diffraction study of **1** gave longer Na··H distances than those obtained from X-ray diffraction, which reinforces this view. Although the Zn–N distances are systematically 0.07–0.08 Å shorter than the Mg–N distances in **1a** and **2a**, the remaining ring bond lengths and angles are similar, giving essentially isostructural species and hence further encouragement for the future synthesis of larger heterometallic zinc macrocycles of the $[NaNZnNNaN]_2$ and $[KNZnN]_6$ types.

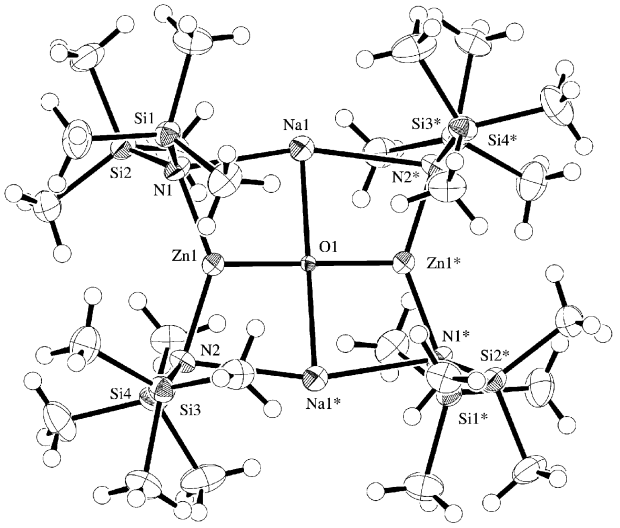

Fig. 2 Molecular structure of **1**. Selected geometric parameters (Å,°): Na1–O1 2.265(2), Zn1–N1 1.986(2), Zn1–N2 1.983(2), Zn1–O1 1.873(1); N1–Na1–N2* 158.96(8), N1–Zn1–N2 141.58(9), Na1–N1–Zn1 78.72(8), Na1*–N2–Zn1 79.78(8). * = $-x$, $-y$, $-z$.

Molecular amplification in a dynamic combinatorial library using non-covalent interactions

Ricardo L. E. Furlan, Graham R. L. Cousins and Jeremy K. M. Sanders*

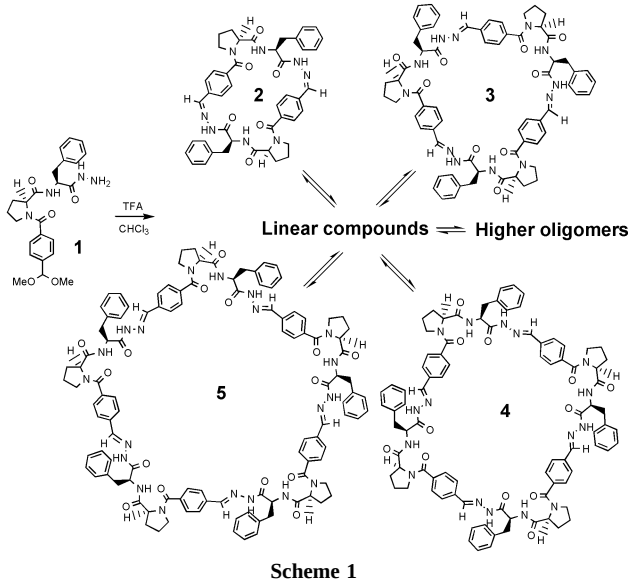
Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: jkms@cam.ac.uk

Received (in Cambridge, UK) 31st July 2000, Accepted 4th August 2000
First published as an Advance Article on the web 29th August 2000

A trace component within a dynamic combinatorial library of pseudo-peptide hydrazones has been dramatically amplified in a reversible manner through recognition by [18]crown-6.

Dynamic combinatorial libraries (DCLs) have attracted great interest because of their potential for the identification of new catalysts, enzyme inhibitors and host–guest systems.[1] Their successful implementation will hinge on our ability to effect control over the library composition using non-covalent interactions with a template: because of the dynamic equilibria established in a DCL, the stabilisation of any given member by molecular recognition will lead to its amplification by virtue of the Le Chatelier principle. In principle, even species which are present in only trace quantities should be able to be amplified, but since our original proposal of thermodynamic templating of 'living' mixtures in 1996,[2] only small changes in the product distribution of covalent DCLs induced by templates have been reported.[3,4] We now report that recognition by [18]crown-6 leads to dramatic amplification of a trace component within a pseudo-peptide DCL; we also show that this amplification is controllable and reversible.

Our group initially showed that DCLs generated by methoxide-catalysed transesterification of steroidal macrocycles can be influenced by the presence of NaI,[3b] but more recently we have sought to generate libraries using chemistry which offers exchange under milder conditions more suitable for supramolecular recognition such as transimination[5,6] and palladium-catalysed allyl transesterification.[7] A DCL of pseudo-peptide hydrazones can be prepared in chloroform from monomer **1** (5 mM) using TFA as catalyst (Scheme 1).[5a] Analysis of the library using ESI-MS† revealed the presence of 10 macrocyclic compounds ranging from dimer to undecamer. These major macrocyclic products must interconvert *via* at least 10 linear hydrazide species which are present in the DCL but at concentrations too low for detection by HPLC or ESI-MS. HPLC analysis of the library after 24 h showed as major products the dimer **2**, trimer **3**, tetramer **4**, pentamer **5** and higher cyclic oligomers (Fig. 1a). The products were identified using LC-MS.‡



Scheme 1

Unlike the cyclic members, the linear species present in the DCL contain a free hydrazide functionality, which under the acidic conditions used is likely to be protonated. As the affinity of [18]crown-6 for primary alkylammonium[8] and hydrazinium[9] ions is well known, similar behaviour could be expected for the closely related protonated hydrazides present in our system. Introduction of 4 eq. of [18]crown-6 to the reaction mixture shifted the equilibrium by formation of a hydrazide–crown ether complex. HPLC analysis showed a decrease in the concentration of the larger macrocycles and the presence of a new peak corresponding to **6** with a retention time of 3 min (Fig. 1b). At equilibrium, **6**, previously present in an undetectable amount, was the major component of the library (67%).§ As a control experiment, the library was prepared in the presence of [18]crown-6 by treating a solution of **1** and the crown ether with TFA, and the same distribution of products was achieved.

Compound **6** cannot be isolated as it reacts with itself to form hydrazones, but its UV spectrum was recorded using the diode array facility of the HPLC; it does not show the characteristic 288 nm absorption of the cyclic aromatic hydrazones but a band at 257 nm is observed which corresponds well with the spectrum of the model aldehyde **7**.¶ The ESI mass spectrum of the reaction mixture (Fig. 2) was dominated by a major peak at 673.4 corresponding to the **6**·[18]crown-6·H^+ complex, accompanied by small peaks for **6**H^+(409.4), cyclic dimer **2**H^+(781.6) and trimer **3**H^+(1171.7), as well as the complex of the protonated linear dimer **8** with [18]crown-6 (1063.5).

As the DCL contains a complex network of equilibria, it is important to show that kinetic traps have not been introduced

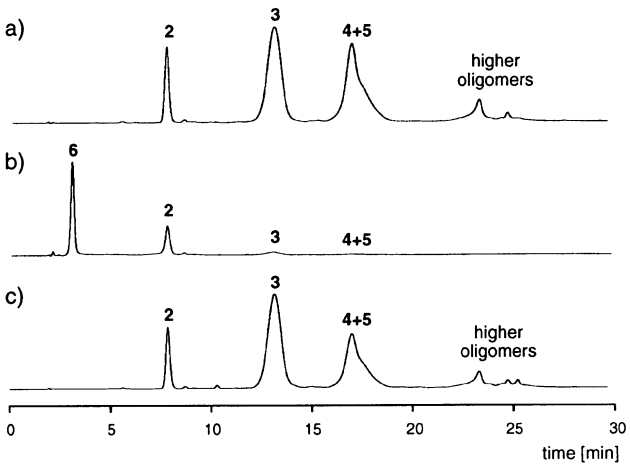


Fig. 1 (a) Chromatogram of the DCL at 24 h, (b) chromatogram of the DCL after addition of 18-crown-6, (c) chromatogram of the DCL showing the regeneration of the cyclic products by addition of 3 eq. of KBr with respect to the amount of [18]crown-6.

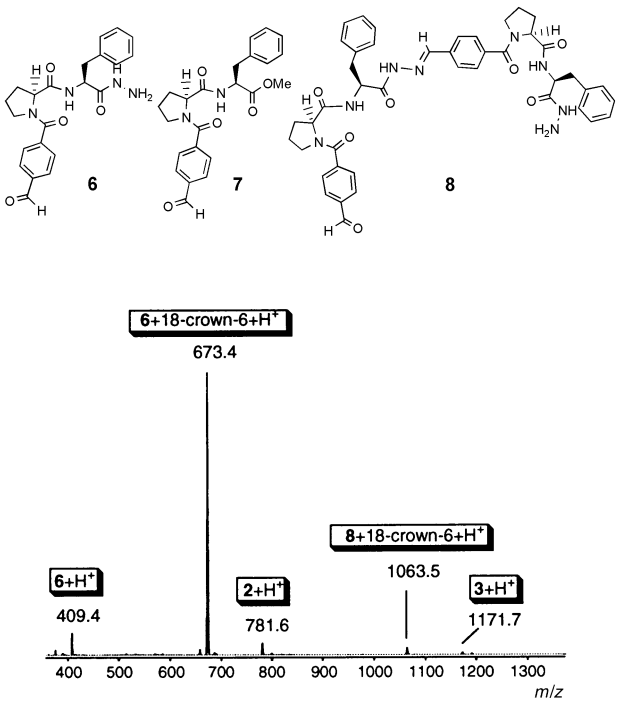

Fig. 2 ESI-MS of the library in presence of 4 eq. of [18]crown-6.

into the system. When KBr was added as a competitive guest that strongly interacts specifically with the crown ether, the original cyclic products were regenerated (Fig. 1c). In a control experiment, the same amount of KBr was added to the library in the absence of crown ether and no change in the composition was observed over 2 days.

Any variation in the strength or extent of hydrazide–crown ether binding should result in a corresponding change in the library composition. When the amount of added [18]crown-6 was varied in the range 0.4–5.0 eq., the proportion of peptide material present as **6** similarly ranged from 20–74%. When different crown ethers were introduced to the library the observed response from the system was related to the size of the ring. Within the series of unsubstituted crown ethers the amount of **6** increases with the size of the crown ether up to [18]crown-6; and in the series of the dibenzo crown ethers, the yield of **6** decreased with crown ethers larger than dibenzo [18]crown-6 (Fig. 3). These results are likely to be related to the affinity of the protonated hydrazide for the crown ethers. It is well known that [18]crown-6 possess the right size and shape to bind primary ammonium cations through three-point hydrogen bonds.[10]

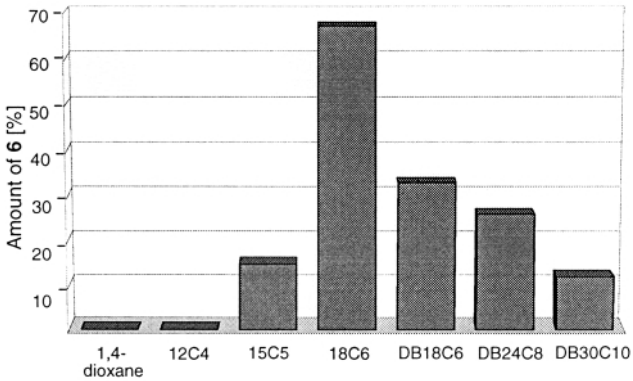

Fig. 3 Amount of **6** in the library when 4 eq. of differents crown ethers were added. 12C4 = [12]crown-4; 15C5 = [15]crown-5; 18C6 = [18]crown-6; DB18C6 = dibenzo [18]crown-6; DB24C8 = dibenzo [24]crown-8; DB30C10 = dibenzo [30]crown-10.

In summary, we have demonstrated that non-covalent interactions between a protonated hydrazide and [18]crown-6 can be used to generate a strong response from a hydrazone-based DCL. The response consists in the amplification of a member previously present in trace amounts to become the major constituent. That increase in concentration is achieved through the preferential consumption of all the unselected cyclic products. The amplification can be reversed by adding a competitive guest that specifically interacts with the crown ether, leading to the regeneration of the original macrocyclic products. To the best of our knowledge, this is the first example of a very substantial amplification in a covalent DCL.

The interaction between protonated hydrazide and crown ether can also be regarded as a *non-covalent* protection of the hydrazide, competing efficiently with the reaction between the hydrazide and an aldehyde to form new *covalent* bonds. Further exploration of the concept of non-covalent protection is under investigation in our laboratory.

We thank S. Otto and J.-C. Meillon for helpful discussions, and the BBSRC, the Ethyl Corporation, Fundacion Antorchas and Consejo Nacional de Investigaciones Cientificas y Tecnicas (Argentina) for financial support.

† Electrospray mass spectra were recorded on a Micromass Quattro-LC triple quadrupole apparatus fitted with a z-spray electrospray source. The electrospray source was heated to 100 °C and the sampling cone voltage was 65 V. Samples were introduced into the mass spectrometer source with an LC pump (Shimadzu LC-9A LC pump) at a rate of 4 μL min^{-1} of MeCN–H_2O (1:1).

‡ HPLC analysis was carried out using a Hewlett-Packard 1050 instrument, coupled to a HP 1050 DAD; data were analysed using HP ChemStation. LC-MS was carried out using an identical HPLC system containing a solvent splitter which diverted 1% of the eluant to a Micromass Platform MS operating in simultaneous positive and negative electrospray modes with a cone voltage of 30 V. The UV and MS data sets were analysed using a MassLynx software suite. Reverse phase HPLC separations were carried out using a 15 cm × 4.6 mm i.d. 3 μM particle size, Supelco ABZ+ C16 alkylamide column using acetonitrile and water gradients.

§ As the extinction coefficient of the new compound is different from that of a hydrazone, its concentration was indirectly determined by the absolute loss of signal intensity belonging to the macrocycles. Loss of hydrazone intensity was directly related to the increase in the signal due to the peak at 3 min.

¶ Aldehyde **7** was prepared from carboxybenzaldehyde dimethoxy acetal, Cbz-proline and phenylalanine methyl ester using standard peptide chemistry. Removal of the dimethoxy acetal was achieved with TFA.

Synthesis under reversible conditions of cyclic porphyrin dimers using palladium-catalysed allyl transesterification

Cyclic zinc-porphyrin dimers have been synthesised using reversible π-allyl palladium chemistry in the presence of bidentate pyridyl ligand templates.

Reversible covalent chemistry has the potential to be useful in the creation of diverse dynamic combinatorial libraries (DCLs)[1,2] and in the synthesis of specific supramolecular structures such as macrocycles and catenanes.[3] Examples of reversible reactions used to date include imine, hydrazone and disulfide exchange, olefin metathesis and metal–ligand interactions. However, there is always the need to expand the repertoire of available reactions and conditions. Here we report what we believe to be the first supramolecular application of π-allyl palladium-catalysed chemistry: furthermore, we demonstrate the use of a template to amplify an otherwise inaccessible synthetic target molecule from a complex mixture of interconverting oligomers.

We chose to apply π-allyl palladium chemistry to the synthesis of cyclic porphyrin dimers which might help our understanding of structure–activity relationships in the acceleration of a hetero Diels–Alder reaction.[4] Previously, such dimers have been prepared by intramolecular oxidative coupling of a linear porphyrin diester species (Fig. 1, route a)[4,5] since all attempts by our group to cyclise a linear dimer by irreversible esterification reactions (Fig. 1, route b) have failed; inevitably, these failures are unpublished. The attraction of route (b) using reversible π-allyl palladium chemistry is that, provided the product is thermodynamically accessible, its formation should be favoured by stabilisation through supramolecular complexation with an appropriate template. This is conceptually the inverse of the host-accelerated Diels–Alder reaction since the small guest is used to template the formation of the large host.

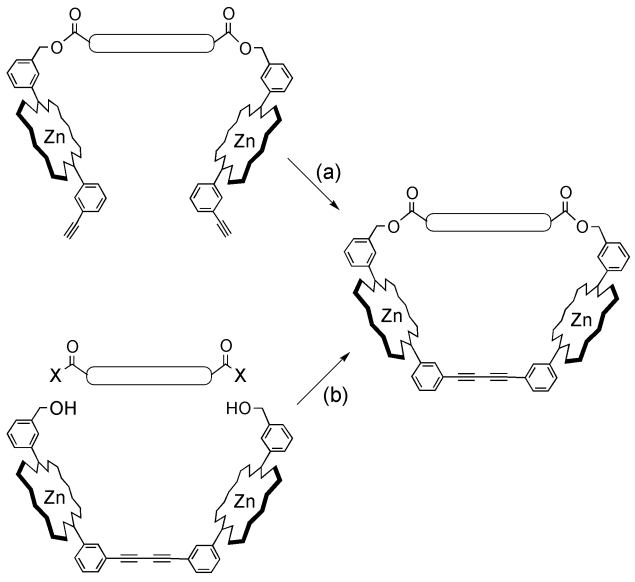

Fig. 1 Synthetic routes to capped porphyrin dimers.

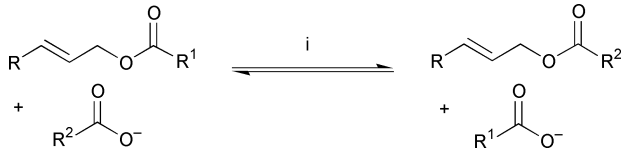
It is well known that π-allyl palladium complexes generally undergo reversible reactions (Scheme 1),[6] and Amatore and Jutand *et al.* have recently confirmed the reversibility of the reaction between allyl esters and palladium(0).[7] Carboxylates and phenolates represent an ideal class of functional groups for isoenergetic exchange *via* reversible π-allyl palladium chemistry since they can act as both nucleophiles and leaving groups. In order to confirm the feasibility of using allyl esters as substrates, a simple model system based on cinnamyl esters was set up (Scheme 1, R = phenyl and *o*-tolyl; $R^1 = CH_3$, R^2 = Et). Complete exchange of the ester groups was observed after 6 h at 50 °C: all 4 possible permutations were present in equal amounts independently of which starting combination was employed. The reaction conditions appeared to be mild enough to be employed in the capping reaction of linear porphyrin dimers. The scientific challenge was therefore to devise a system where, for the first time, a linear porphyrin dimer would undergo a multi-step ring-closing transesterification reaction catalysed by palladium(0).

The linear porphyrin dimer **1** (Scheme 2) was synthesised according to previously published procedures:[5] the asymmetric porphyrin synthesis was carried out in 25% yield, followed by a Glaser–Hay coupling of the deprotected porphyrin monomers to give the linear dimer (60% yield). The simple dipyridyl **2** was chosen as the template, its role being kinetically to preorganise the linear porphyrin dimer by restricting rotation about the butadiyne axis, or thermodynamically to favour capped dimers over linears.

For the initial exchange experiments, alkyl diacids were expected to be sufficiently flexible and nucleophilic, in contrast to aryl acids which are more rigid and less nucleophilic. In the first instance, succinic acid was chosen. To aid structural analysis of the cyclic porphyrin dimer by NMR methods, labelled 1,4-^{13}C succinic acid was used.† In a typical experiment the linear porphyrin dimer **1** (20 mg, 1 eq.) and the template **2** (1 eq.) were dissolved in chloroform (2 ml), succinic acid (8 eq.), triethylamine (40 eq.) and tetrakis(triphenylphosphine)palladium(0) (0.1 eq.) were added and the solution was stirred at 55 °C under an inert atmosphere for 6 h. The mixture was demetallated using trifluoroacetic acid to remove the template and then remetallated using zinc acetate. The different porphyrin fractions were separated by preparative thin layer chromatography and dissolved in a fixed amount of solvent. Quantitative analysis of the product fractions was carried out by UV–Vis spectroscopy, based on the assumption that the molar extinction coefficients of the linear and cyclic dimers were similar. The relative absorbance of the products was measured and values are given in arbitrary absorbance units. Due to the



Scheme 1 *Reagents and conditions*: i, concentration of cinnamyl esters 10 mM, $Pd(PPh_3)_4$ (0.1 eq.), R^1CO_2H (< 0.1 eq.), Et_3N, $CHCl_3$, 50 °C, 6 h.

DOI: 10.1039/b006151o

small quantities of the fractions, accurate determination of the weights of the product was not possible.

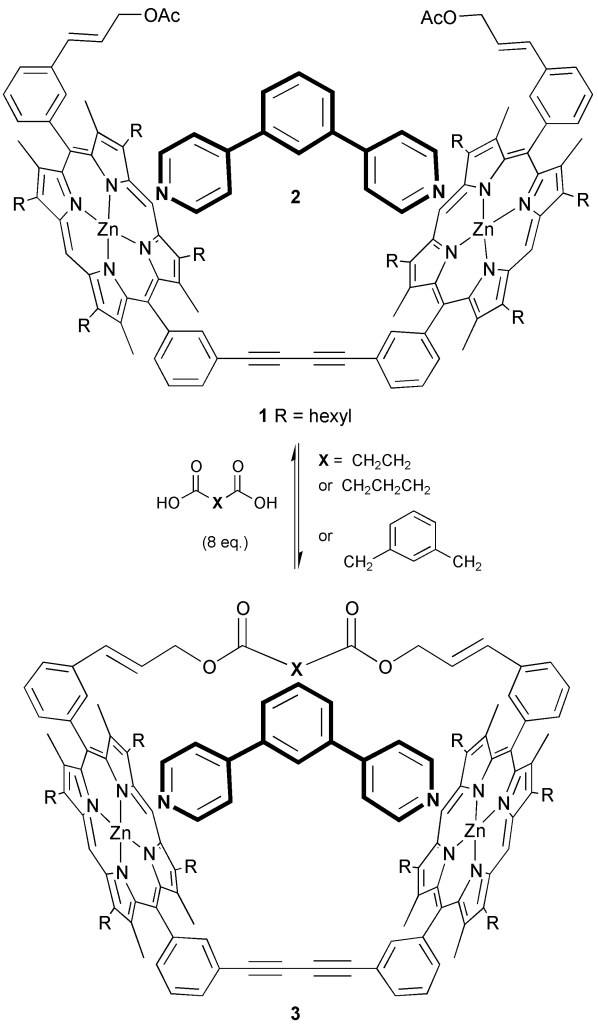
In the absence of the template only traces of the capped dimer could be isolated (0.009 au—absorbance unit; less than 2% yield). However, in the templated experiments the isolated yield of pure **3** increased 6-fold to approximately 10% (0.055 au). The structure of the ring-closed dimer was confirmed by HMBC-NMR showing a cross-peak for the single enriched ^{13}C signal (δ = 172.4 ppm) with the allylic CH_2 protons (δ = 4.63 ppm). This significant and reproducible increase in the yield confirms the templating effect of the bidentate ligand and represents the first thermodynamic capping of a linear porphyrin dimer using reversible π-allyl palladium chemistry. To test the generality of the reaction, and to illustrate the feasibility of utilising libraries of capping groups at a later stage, cyclic dimers containing glutaric and 1,3-phenylenediacetic acid as capping groups were also prepared in comparable yields. In addition to NMR characterisation, MALDI-TOF mass spectrometry was used to distinguish between linear and cyclic species.

The control experiments without template and those in the presence of pyridine (2 eq.) gave the same results. Pyridine is a monodentate equivalent of the template **2**, *i.e.* the pyridine units are not covalently linked as for the bidentate template. This result confirms that the dipyridyl compound **2** templates the formation of the cyclic dimer by stabilising it and that the pyridyl functionality of the template does not influence the outcome of the transesterification. The large binding constants of template **2** to the linear and cyclic dimers, 3×10^6 and 2×10^7 M^{-1} respectively, are consistent with the observed templating effect.[8] However, the relatively small increase in the binding constant upon cyclization highlights the flexibility of the host and rationalises the low yield of **3**, *i.e.* the equilibrium is shifted only slightly from oligomeric species towards the formation of **3**.‡

It was possible to identify mono- and disubstituted linear dimers as intermediates of the reaction by MALDI-TOF and ^1H NMR. However, the relative quantities of all intermediates could not be estimated accurately due to the low solubility of oligomers and disubstituted linear dimers with two free carboxylic acid groups.§ It should be noted that the solubility of the mixture was not problematic during the reaction itself as the triethylamine salts of all intermediates are soluble in chloroform.

In summary, we have shown the synthesis under reversible conditions of three cyclic porphyrin dimers using palladium-catalysed transesterification. The reaction was templated by a bidentate pyridyl ligand which improved the yield of the cyclic product 6-fold. To our best knowledge, this is the first supramolecular application of reversible π-allyl palladium chemistry; it is also one of the most effective examples yet reported of amplification of a specific product from an exchanging library of components.

We thank the BBSRC, AstraZeneca and the Cambridge European Trust for financial support and Dr Y.-F. Ng for recording some of the NMR spectra.



Scheme 2 *Reagents and conditions*: concentration of porphyrin dimer 5 mM, $Pd(PPh_3)_4$ (0.1 eq.), Et_3N, $CHCl_3$, 55 °C, 6 h.

Notes and references

† The molecular weights of linear dimer and unlabelled succinic capped dimer differ by only 2 a.m.u., precluding the use of MALDI-TOF mass spectrometry.

‡ This point is also apparent in the uniformity of yield from the three different capping acids of very different geometry.

§ The overall amount of isolated porphyrinic material was measured by UV–Vis spectroscopy and marked differences between the templated and non-templated reactions were observed. The overall recovery of soluble porphyrinic material was considerably lower for the non-templated reaction (0.1 au compared with 0.2 au for the templated reaction). This result implies that the template suppresses the formation of insoluble oligomers in addition to promoting the formation of cyclic product. The decrease in total oligomer formation is greater than the increase in cyclic dimer formation, suggesting that these are two separate effects, *i.e.* the dipyridyl compound **2** is a positive template for the cyclic dimer formation and a negative template for the oligomer formation.

Palladium catalyzed intramolecular nucleophilic addition of allylic species, generated from allene, to aryl aldehydes and ketones

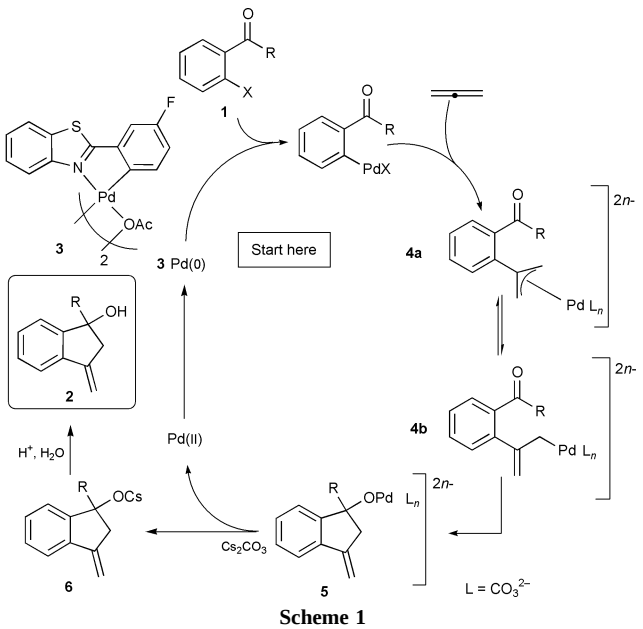
2-Haloaryl aldehydes and ketones react with allene (1 atm) in the presence of 2 mol% of a non-phosphine cyclopalladated catalyst to afford cyclopentenols and cyclohexenols *via* nucleophilic cyclisation of intermediate π-allylpalladium species. A possible mechanism for this unusual reactivity is suggested.

One of the major features of palladium catalysed processes is their tolerance of a wide range of functional groups. However, the versatility of palladium catalysts would be considerably enhanced if they incorporated, in a predictable way, reaction with functional groups heretofore immune to palladium catalysts. Arguably the most important 'immune' functional group is the carbonyl group. We[1,2] and others[3] have recently reported bimetallic Pd/In catalysis that permits both inter- and intramolecular allylation of carbonyl groups. Others have reported intramolecular vinylation and arylation of carbonyl groups[4] or nitriles[5] *via* undefined nucleophilic palladium species. In addition palladium(II)-catalysed aldol reactions have been reported.[6]

Allylation of carbonyl compounds is well known for the nucleophilic allyl derivatives of main group metals[7] whereas π-allylpalladium(II) species are usually electrophilic.[8] In order to explore the desired unusual reactivity of π-allylpalladium(II) species we elected to utilize a novel non-phosphine-containing palladacycle **3**[9] as catalyst and allene as the source of the π-allyl species (Scheme 1).

2-Iodo- and 2-bromobenzaldehyde **1a** and **1b** were found to react with allene (1 atm) in DMF at 80 °C over 18 h in the presence of 2 mol% **3** and Cs_2CO_3 (2 mol eq.) to afford the desired benzocyclopentenol **2a** (Table 1, entry 1). The iodoaldehyde **1a** was more reactive than bromoaldehyde **1b**. The reaction proved to be general for a range of substrates, **1b**–**1f** furnishing both 5-membered, **2a**–**2d**, and 6-membered, **2e**, **2f**, products. Arylalkyl ketones (Table 1, entry 2) and diaryl ketones (Table 1, entries 3,4) reacted to give the expected products with formation of 5-membered products proving more efficient than formation of 6-membered products for the limited examples surveyed thus far. 2-(2-Bromophenyl)indane-1, 3-dione **1f** gave **2f** (Table 1, entry 6), the product of dehydration of the expected cyclohexenol. The processes described herein occur under significantly milder conditions than the other reported examples of nucleophilic Pd^{II} species. Evidence to hand thus far[9] suggests that palladacycle **3** functions *via* controlled release of Pd^0 nanoparticles[11] and that Scheme 1 involves Pd^0/Pd^{II} rather than Pd^{II}/Pd^{IV}.[12]



Scheme 1

Cs_2CO_3 was the superior base of those (Cs_2CO_3, K_2CO_3, KOAc) tested. Possible mechanisms for the processes described herein and those reported previously[3–5] must account for the fact that only intramolecular processes forming 5- and 6-membered rings have been observed. A possible rationalization is shown in Scheme 1.

The key features of Scheme 1 are that coordination of the carbonate anions to Pd^{II} produces anionic η^3- and η^1-species **4a** and **4b**. The η^1-species **4b** is then postulated to undergo bond shift as depicted in **8** or **9**. The ability of carbonate to function as a mono- or hemilabile bidentate ligand might also be a factor. A common problem to both Scheme 1 and the previously reported nucleophilic vinyl and aryl palladium(II) species[4,5] is the mechanism by which Pd^{II} is reduced to Pd^0 to allow catalyst recycling. It is instructive that the reactions reported herein and the related work[4,5] all employ DMF as solvent. It is clear that DMF from certain sources contains formate impurities,[13] or that such impurities may be generated *in situ*, and these then react with Pd^{II} to produce HPdX which is then converted by base to Pd^0. In Yamamoto's examples, addition of 5 mol eq. of a primary alcohol is necessary. Although the role of the primary alcohol is not entirely clear it is not, apparently, active as a reductant for Pd^{II} to Pd^0.

The potentially bidentate CO_3^{2-} anion might be expected to be more effective in generating a carbon nucleophile perhaps *via* trace amounts of allyl anion **9** whose effective molarity[14] would be high, which would account for the failure to observe the analogous intermolecular reactions.

It seems likely that anionic Pd^{II} species may be important in the nucleophilic processes reported herein and those reported previously by Yamamoto.[4] Larock's nitrile–alkyne examples[5] do not employ inorganic bases but polyhalo anionic Pd^{II} species would appear to play a role in these phosphine free cases employing R_4NCl[14]. Although anionic Pd^{II} species have been detected in Heck reactions[14] they were not catalytically active in this reaction.

A further interesting and unresolved feature in many instances of Pd^0 nanoparticle catalysis is whether the catalytic processes occur on the surface of the nanoparticle at edges and/or vertices or in homogeneous solution by substrate leaching of the Pd^0.

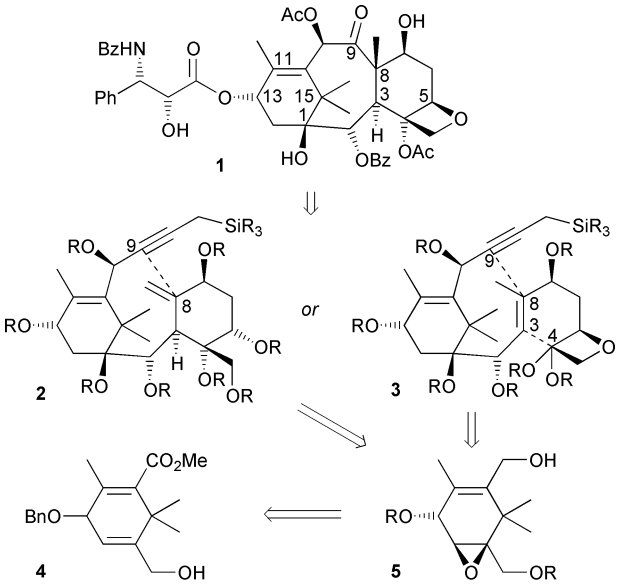
Highly substituted cyclohexenes corresponding to the A-ring of the anti-cancer diterpene natural product paclitaxel are synthesised using a Diels–Alder reaction and decarboxylative elimination as the key steps.

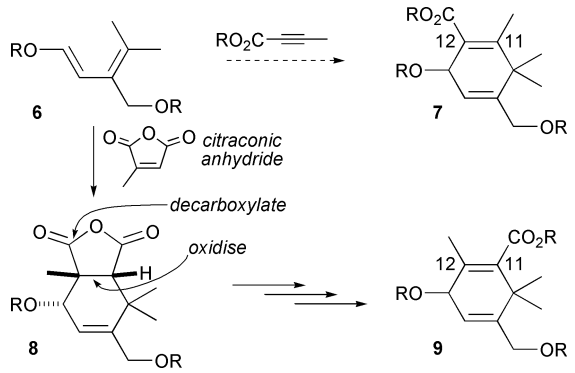
The paclitaxel family of molecules, exemplified by the parent paclitaxel (Taxol®) **1**[1] has commanded the attention of a significant number of organic chemistry research teams worldwide.[2] The strategies we are pursuing for the assembly of paclitaxel involve late-stage formation of the eight-membered B-ring by the joining together of C-9 and C-8 using radical- or carbocation-mediated cyclisation of a substrate **2**; in one of the approaches we intend to form the C-ring in the same step using a Lewis acid-induced carbocation-mediated cascade process starting from **3** in which the C-3–C-4 bond is formed as well. Both these sequences require a pre-formed A-ring fragment such as **5**, and this Communication reports the synthesis of key precursor **4** (Scheme 1).

In our synthetic plan for **4** we were keen to incorporate the required C-13 oxygenation directly using the Diels–Alder reaction rather than introducing it later by oxidation of C-13.[2a] This choice posed a strategic problem concerning Diels–Alder regiochemistry, in that [4+2] cycloaddition of **6** and a simple alkyne-containing dienophile such as a but-2-ynoate ester was likely to give a cycloadduct **7** bearing a C-12 rather than a C-11 ester substituent. Therefore it was decided to use citraconic anhydride as the dienophile,[3] since it was anticipated that the regiochemical orientation of the Diels–Alder reaction would be controlled by steric repulsion between the fully-substituted



Scheme 1

† Experimental details for **4**, **13**, **16**, **17**, **19**–**21** are available as supplementary data. For direct electronic access see http://www.rsc.org/suppdata/cc/b0/b005533f/



Scheme 2

diene and dienophile termini; subsequent selective decarboxylation and oxidation of adduct **8** would deliver the required C-11–C-12 unsaturation, as in **9** (Scheme 2).

The required diene was synthesised using the Julia procedure for the olefination step.‡ Thus, mono-protection of diol **10**[4] followed by oxidation using TPAP–NMO[5] gave enal **11**. Combination of **11** with the lithio-anion of benzyloxy(phenylsulfonyl)methane[6] and *in situ* trapping with benzoyl chloride gave a mixture of esters, which was exposed to samarium(II) iodide[7] to provide the required differentially protected diene **12**. Diels–Alder reaction of **12** with citraconic anhydride gave cycloadduct **13** as a single regio- and stereoisomer in 63% yield based on **12** (Scheme 3). The *endo* stereochemistry of **13** was inferred from the analogous reaction of **12** with maleic anhydride,[3] which had given a crystalline product amenable to X-ray structure determination.

With Diels–Alder adduct **13** in hand it was necessary to differentiate between the anhydride carbonyl groups. Treatment of **13** with dimethylamine gave an unstable§ half-amide as a

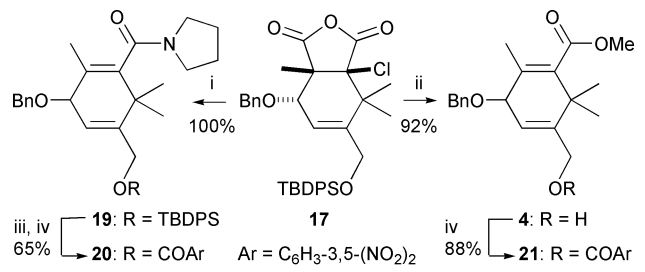
single regioisomer,¶ which was converted into the mixed anhydride **14** by addition of isobutyl chloroformate. Treatment of **14** with *N*–hydroxy-2-thiopyridone in CCl_4 under reflux[8] gave in low yield the product **15** of decarboxylation–chlorination. The stereochemistry of **15** was presumed on the basis of expected attack by CCl_4 on the less hindered face of the intermediate radical.‖ All attempts to effect base-mediated elimination of the elements of HCl from **15** resulted in the formation of the β,γ-unsaturated isomer **18**. In a modified approach, treatment of cycloadduct **13** with pyrrolidine gave a half-amide adduct which was considerably more stable than the dimethylamine-derived analogue. Surprisingly, subsequent exposure of this adduct to the mixed anhydride-forming conditions resulted in cyclodehydration, giving the cyclic *O*-acylketaminal **16** in virtually quantitative yield.** The desired oxidation at C-11 was now effected by treatment of **16** with NCS–aqueous THF, giving α-chloro anhydride **17** in high yield (Scheme 4). The difference in behaviour of the dimethylamino and pyrrolidino analogues under the carbonic anhydride-forming conditions is striking; the apparent greater nucleophilicity of the amide oxygen in the latter is consistent with greater delocalisation of the amide nitrogen lone pair into the carbonyl group, which in turn inhibits the reverse reaction during ring-opening of **13** with the secondary amine nucleophile.

The final part of the synthesis involved decarboxylation and introduction of the double bond, and again this depended on initial regioselective ring-opening to give a β-chloro carboxylic acid. In the event, treatment of **17** with a large excess of pyrrolidine gave amide **19** as a single regioisomer (Scheme 5). Interestingly, **19** existed in $CDCl_3$ and d_6-DMSO solutions as mixtures of rotamers. In similar fashion, treatment of **17** with benzyltrimethylammonium methoxide in large excess gave methyl ester **4**. Mechanistically, the presumed initial ring-opened half-amide and -ester either might form β-lactone intermediates which subsequently lose CO_2,[9] or might spontaneously undergo β-elimination with concerted loss of CO_2 and chloride ion.[10] Amide **19** was converted in high yield by desilylation and esterification into the 3,5-dinitrobenzoate **20**, which yielded crystals suitable for X-ray diffraction analysis. Similar treatment of **4** gave the crystalline ester **21**.††



Scheme 5 *Reagents and conditions*: i, pyrrolidine (50 eq.), DMSO–DMPU (5:3; 0.14 M), rt , 2 h; ii, $BnMe_3N^+OMe^-$ (50 eq.), MeCN–DMPU (0.14 M), rt, 27 h; iii, TBAF (1.1 eq.), THF (0.2 M), rt, 15 min; iv, ArCOCl (1.1 eq.), Et_3N (1.5 eq.), DMAP (0.2 eq.), CH_2Cl_2 (0.2 M), rt.

In summary, we have demonstrated that a highly substituted cyclohexa-1,4-diene may be accessed using a sequential Diels–Alder–decarboxylative olefination approach to introduce the C-11–C-12 unsaturation present in the paclitaxel A-ring. Ongoing studies in our laboratory seek to identify a direct [4+2] cycloaddition entry to **17**, and to develop ways of making the cycloaddition enantioselective. The results of these and related studies will be reported in due course.

We thank the EPSRC and Pfizer Central Research (CASE Studentships to C. A. L. L. and W. P. M.) and the Spanish Ministerio de Educacion y Ciencia (Studentship to S. C.) for financial support of this research.

Notes and references

‡ All yields reported herein refer to isolated, pure materials which had ^1H and ^{13}C NMR, IR and high-resolution MS characteristics in accord with the proposed structures.

§ The half-amide had a half-life in $CDCl_3$ of approximately 14 h.

¶ Treatment of this half-amide with ethyl chloroformate gave a mixed anhydride which was reduced using sodium borohydride to give a γ-lactone. The appearance of both lactone -CH_2- protons as simple doublets confirmed the absence of a vicinal proton, and therefore the complete regioselectivity of ring-opening of **13**.

‖ This assumption was later confirmed by single-crystal X-ray diffraction analysis of the product of one-pot epoxidation–debenzylation mediated by dimethyldioxirane.

Received (in Cambridge, UK) 25th May 2000, Accepted 4th August 2000
First published as an Advance Article on the web 31st August 2000

The reaction of PCl_3 with 3 equivalents of 2-methoxyaniline in THF/NEt_3, followed by metallation with Bu^{n}Li (2 equivalents) yields a complex $[Li_2P(H)(NR)_3]_2$ 1 (R = 2-methoxyphenyl), whose tris imido phosphonate anion is the imido analogue of the phosphite anion, $[HPO_3]^{2-}$.

The chemistry of main group imido complexes is relatively underdeveloped compared to the vast body of knowledge that has been accumulated on the related imido transition metal species.[1] Recently this imbalance has started to be redressed with the discovery of a diverse series of anionic imido complexes of the main group elements.[2–6] Our own interest in this area has focused on the study of imido analogues of phosphorus oxoanions. Recent studies on related P–N systems have revealed the beginnings of a family of these compounds. Alkali metal salts of the bis(imino)phosphinate anion, $[R_2P(NR')_2]^-$ have been prepared.[2] Niecke *et al.* have reported several structures that are imido analogues of kinetically unstable phosphorus oxoanions. This group described the planar tris(imino)metaphosphate anion, $[P(NR)_3]^-$ and the $[P(NR)_2]^-$ anion, isoelectronic with the kinetically unstable $[PO_3]^-$ and $[PO_2]^-$ anions respectively, but more importantly isoelectronic with the corresponding nitrate $[NO_3]^-$ and nitrite $[NO_2]^-$ anions.[3,4] Recently, we succeeded in synthesising the complex $[Li(THF)_4][(THF)_2Li(\mu\text{-}NR)_2P(\mu\text{-}NR)_2Li(THF)_2]$ from the reaction of P_2I_4 with 1-aminonaphthalene (1:4 equivalents) in THF/NEt_3, followed by metallation with Bu^{n}Li (4 equivalents). The $[P(NR)_4]^{3-}$ trianion of this complex is isoelectronic with the orthophosphate anion, $[PO_4]^{3-}$.[5] Related phosphorus–nitrogen complexes have recently found extensive uses as ligands to a range of metals, some of which have found application as polyolefin catalysts. This work has been reported and reviewed in several recent articles.[6]

Herein, we report the synthesis and structure of the imido analogue of the phosphite anion, $[HPO_3]^{2-}$. Reaction of PCl_3 with 3 equivalents of 2-methoxyaniline in THF/NEt_3, followed by addition of Bu^{n}Li (2 equivalents) and subsequent crystallisation from toluene gives $[Li_2P(H)(NR)_3]_2$ **1** (R = 2-methoxyphenyl.†

A low-temperature single-crystal X-ray diffraction study was performed on complex **1**.‡ The complex has an ion-contacted dimeric structure with a crystallographically imposed centre of symmetry wherein two $[HP(NR)_3]^{2-}$ anions sandwich four lithium cations. The $[HP(NR)_3]^{2-}$ dianion is formally the imido analogue of the phosphite dianion, $[HPO_3]^{2-}$.[7] The crystal structure of **1** is illustrated in Fig. 1.

Each of the phosphorus centres has a distorted tetrahedral geometry, being coordinated to three imido nitrogen atoms and one hydrogen atom. The phosphorus atoms are bound approximately equally to each imido nitrogen atom [with P–N distances ranging from 1.613(2) to 1.630(2) Å]. The shorter bond distances in **1** compared to those in the related imido analogue of the orthophosphate anion, $[P(NR)_4]^{3-}$ [1.645(4) Å][5] is perhaps due to the enhanced double bond character in **1** where formally, one P=N bond and two P–N bonds form a resonance hybrid, whereas in $[P(NR)_4]^{3-}$ the ratio is one P=N bond to three P–N bonds.

Within the core of **1** there are two distinct lithium environments. In one domain the lithium centre is complexed by one imido nitrogen centre from each $[HP(NR)_3]^{2-}$ unit and is additionally complexed by two methoxy sidearms of the corresponding methoxyanilido groups. The second lithium environment has the lithium centre complexed by two imido nitrogen atoms from one $[HP(NR)_3]^{2-}$ unit but by only one imido centre from the other $[HP(NR)_3]^{2-}$ unit. The methoxy sidearm of the latter unit completes the distorted tetrahedral geometries about these lithium centres.

The P–H proton could not be unequivocally located from the electron difference map, but its presence could be discerned from the ^{1}H and ^{31}P NMR spectra and from solution IR spectroscopy. Hence, the ^{1}H spectra in benzene-d_6, in addition to confirming the presence of 2-methoxyanilido ligands, show a

DOI: 10.1039/b004192k

doublet at δ 9.07 with a coupling constant of 436 Hz, consistent with the $^1J_{PH}$ coupling frequencies observed in related systems.[8] The corresponding doublet can be observed in the ^{31}P NMR spectra at δ 0.28. This bond can also be observed by IR spectroscopy with a band at 2266 cm^{-1} in THF solution being attributed to the P–H stretching frequency.

Although we have so far been unable to unequivocally identify the intermediates in the steps leading to complex **1**, it seems reasonable to postulate that the $[HP(NR)_3]^{2-}$ anion of **1** has resulted from a proton exchange from an amido centre to the phosphorus centre in addition to metallation of the remaining amido protons. Similar proton transfer from N to P in iminophosphoranes, R_2P–N(H)R′ has shown that the P–H tautomer is stabilised by both electron withdrawing amide groups (R′) and by bulky substituents on the P and N centres (R and R′).[9] Hence, N to P proton transfer accompanying metallation in the postulated $P\{N(H)R\}_3$ intermediate from the first step of our reaction system would yield complex **1**. It is interesting to note that phosphites (or rather phosphorous acid) can be produced by a similar route, *i.e.* hydrolysis of PCl_3.[10]

Asymmetric synthesis of 2-substituted 5-, 6- and 7-membered nitrogen heterocycles by oxime addition ring-closing metathesis

James C. A. Hunt, Pierre Laurent and Christopher J. Moody*

School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD

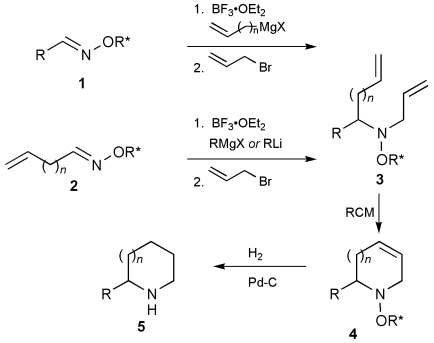
Received (in Liverpool, UK) 30th June 2000, Accepted 24th July 2000
First published as an Advance Article on the web 30th August 2000

Ring closing metathesis reactions of the dienes 6 and 9 leads to the nitrogen heterocycles 7 and 10, respectively, one of which 10c was converted into (*R*)-(−)-coniine.

The development of methods for the asymmetric synthesis of pyrrolidines and piperidines remains an area of current interest due to the presence of such saturated heterocyclic rings in a large number of biologically important compounds.[1] One possible approach to the synthesis of nitrogen heterocycles involves the ring-closing olefin metathesis (RCM) reaction. The RCM reaction is a powerful synthetic method and, with the development of practical and reliable catalysts by Grubbs and others,[2,3] has been widely used in a number of syntheses in the recent past,[4,5] including examples of nitrogen heterocycles.[6–14] In continuation of our interest in the asymmetric synthesis of saturated nitrogen heterocycles,[15] we decided to investigate the combination of the highly diastereoselective addition reactions of *O*-(1-phenylbutyl) aldoximes with the RCM reaction as a new route to this class of heterocycle. This combination of oxime addition–RCM is shown in outline in Scheme 1, and our preliminary results are described herein.

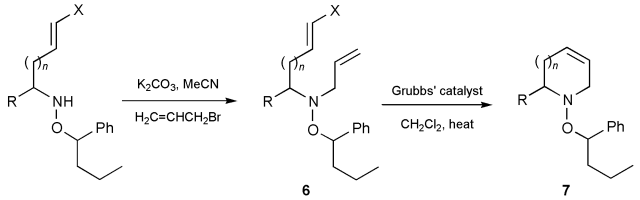
As outlined in Scheme 1, the substrates for the RCM reactions are the dienes **3**, accessible either by the addition of an alkene containing organometallic reagent to the aldoxime ether **1**, or by organometallic addition to an aldoxime **2** derived from an unsaturated aldehyde, followed in both cases by *N*-allylation of the resulting hydroxylamine. Both approaches were successful and a number of dienes **6** were prepared by the highly diastereoselective addition of organolithium reagents to the *O*-(1-phenylbutyl) oximes of cinnamaldehyde or allylmagnesium bromide to the oximes of butyraldehyde or benzaldehyde,[16,17] followed by reaction with allyl bromide in the presence of potassium carbonate (Table 1). The RCM reaction was carried out by heating the dienes **6** in dichloromethane in the presence of Grubbs' catalyst, and gave the required 5- and 6-membered rings **7** in modest to excellent yield (Table 1).

Although the above results indicate that basic or nucleophilic nitrogen atoms are tolerated in the RCM reaction of the hydroxylamine derived substrates, we also investigated the diene substrates **9** in which the nitrogen is rendered non-basic by protection as its benzyloxycarbonyl (Z) derivative. Thus a range of carbamates **8**, prepared as previously described,[16,17] or as indicated in Table 2, was converted into the corresponding *N*-allyl derivatives **9** by reaction with allyl bromide in the presence of sodium hydride. In the case of **8b**, these conditions caused migration of the double bond, and therefore the allyl group was introduced using the palladium catalysed reaction of allyl methyl carbonate.[18] Again the RCM reaction proceeded smoothly and gave the 5- and 6-membered nitrogen heterocycles **10a**–**10d** in good to excellent yield, with the yield of the 7-membered ring **10e** being slightly lower (Table 2).



Scheme 1 (R* = 1-phenylbutyl).

Table 1



(E)-Oxime[a]	Organometallic Addition	Yield (%) (de (%))	R	X	*n*	Diene	Yield (%)	Heterocycle (configuration at C-2)	Yield (%)
(*R*)-PhCH=CHCH=NOR*	MeLi[b]	[c](>95)	Me	Ph	0	**6a**	72[c]	**7a** (*R*)	87
(*R*)-PhCH=CHCH=NOR*	*n*-BuLi[b]	[c](>95)	*n*-Bu	Ph	0	**6b**	66[c]	**7b** (*R*)	78

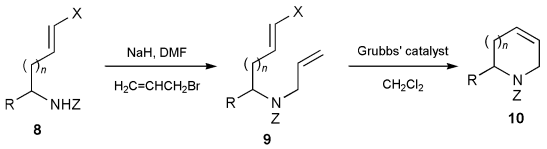
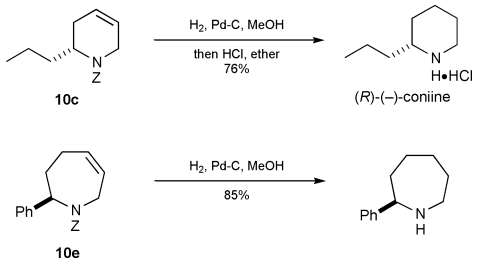
Table 2



Carbamate	Configuration (ee (%))	R	X	*n*	*N*-Allyl carbamate	Yield (%)	Heterocycle (configuration at C-2)	Yield (%)
8a[a]	*S* (89[b])	Me	Ph	0	**9a**	74	**10a** (*S*)	84
8b[c]	*R* (>95[d])	Ph	Ph	0	**9b**	63[e]	**10b** (*R*)	93
8c[f]	*R* (90)	*n*-Pr	H	1	**9c**	90	**10c** (*R*)	88
8d[g]	*S* (98)	4-MeO-C_6H_4	H	1	**9d**	97	**10d** (*S*)	91
8e[h]	*R* (90)	Ph	H	2	**9e**	90	**10e** (*R*)	65

[a] The preparation of the (*R*)-enantiomer is described in ref 15. [b] Enantiomeric excess (ee) of the *N*-allyl derivative **9a** not **8a**. [c] The preparation of the (*S*)-enantiomer is described in ref 15. [d] Refers to the diastereomeric excess (de) of the immediate precursor to **8b**. [e] Allylation using allyl bromide/base caused double bond migration; prepared using allyl methyl carbonate/Pd(0); see text. [f] Prepared by addition of allylmagnesium bromide to the oxime ether (Table 1), followed by cleavage of the N–O bond, and reaction with benzyl chloroformate. [g] Prepared as described in ref 16. [h] Prepared by addition of phenyllithium to the oxime ether, followed by cleavage of the N–O bond, and reaction with benzyl chloroformate.



Scheme 2

Finally two of the heterocycles prepared by the RCM reaction were converted into known compounds for confirmation of structure and configuration. Thus the 6- and 7-membered Z-protected compounds **10c** and **10e** were hydrogenated over palladium-on-charcoal to give (*R*)-(−)-coniine and the known 2-phenylazepane[19] respectively (Scheme 2).

We thank the EPSRC for support of this work.

Best design of heterogenized β-aminoalcohols for improvement of enantioselective addition of diethylzinc to benzaldehyde

Sébastien Abramson, Monique Laspéras,* Anne Galarneau, Delphine Desplantier-Giscard and Daniel Brunel

Laboratoire de Matériaux Catalytiques et Catalyse en Chimie Organique, UMR 5618 - CNRS - Ecole Nationale Supérieure de Chimie de Montpellier, 8, rue de l'Ecole Normale, 34296 Montpellier Cedex 5, France. E-mail: lasperas@cit.enscm.fr; Fax: +33 4 67 14 43 49

Received (in Cambridge, UK) 10th July 2000, Accepted 4th August 2000
First published as an Advance Article on the web 4th September 2000

Covalent immobilization of (1*R*,2*S*)-(−)-ephedrine, used as a model molecule of β-aminoalcohols, on the surface of MCM-41-type mesoporous aluminosilicates, performed by a new sol–gel method, leads to chiral auxiliaries which show greatly enhanced rates and ee's compared to those reported up to now in the enantioselective addition of diethylzinc to benzaldehyde.

Increasing interest has been devoted to the design of heterogeneous asymmetric catalysts.[1] One major method involves heterogenization of homogeneous catalysts by their immobilization on organic polymers or inorganic supports.[2] However, the efficiency of the catalysts of the heterogenized catalysts is different compared with their homogeneous counterparts. This is the case for chiral β-aminoalcohols used in the enantioselective addition of dialkylzincs to aldehydes[3] in C–C bond forming reactions. The efficiency of such catalysts depends mainly on the native of the support. Since the pioneering work of Frechet[4] who used polymer-bound chiral aminoalcohols, various authors have described such immobilization on organic polymers.[5,6] Ee's are high, and only slightly lower than those obtained in homogeneous conditions but rates are notably lower. On the other hand, immobilization on mineral surfaces has attracted little attention. Our first results using (−)-ephedrine supported on MCM-41-type mesoporous silicas[7] were in good agreement with precedent results of Soai *et al.*[8] using silica gel or alumina supported (−)-ephedrine. Lower rates, selectivities and enantioselectivities were obtained compared with homogeneous catalysis. Investigations involving changes in the pore size,[9] the composition[10] of the support, end-capping of the surface[9] and the dilution of the catalytic sites[9,10] failed to improve the ee's significantly. These results indicate significant activity of the naked surface towards the formation of racemic alcohols.

The aim of this work was to decrease the negative effects of the uncovered mineral surface by increasing the coverage by organics on the inner surface of the pores.[11] In this work, the synthesis of high surface densities of chloropropyl groups covalently grafted on mesoporous micelle templated aluminosilicates (Al-MTS) of various initial pore diameters is performed. The hybrid inorganic–organic materials resulting from halogen substitution by (−)-ephedrine are applied in the enantioselective addition of diethylzinc to benzaldehyde.

Two mesoporous aluminosilicates of the same composition (Si/Al = 27) and 3.6 (Al-MTS **1**, S = 833 m^2 g^{-1}, V = 0.76 mL g^{-1})[12] and 8.3 nm (Al-MTS **2**, S = 822 m^2 g^{-1}, V = 1.71 mL g^{-1})[13] mean initial pore diameter were used as supports, respectively. In order to remove the template, the as-synthesized solids were activated before surface modification at 550 °C for 12 h under a flow of synthetic air. Up to now, covalent anchorages have been performed in anhydrous conditions, by silylation (method **a**) with 3-chloropropyltrimethoxysilane (CPTMS) (Al-MTS-Cl **1a**) followed by the nucleophilic substitution of chlorine by the basic amino group of (−)-ephedrine (Al-MTS-Cl-E **1a**). Alternatively, grafting of the coupling CPTMS agent by the sol–gel method[11,14] (method **b**, Al-MTS-Cl **1b**, Al-MTS-Cl **2b**) and reaction with (−)-ephedrine leads to new hybrid materials (Al-MTS-Cl-E **1b**, Al-MTS-Cl-E **2b**) (Scheme 1).

Loadings of grafted chloroalkylsiloxanes (Al-MTS-Cl **1a**, **1b**, **2b**) or ephedrine moieties (Al-MTS-Cl-E **1a**, **1b**, **2b**) have been calculated from elemental and thermogravimetric analyses. They depend mainly on the grafting method used, the sol–gel method **b** leading to notably higher amounts of organics on the surface.

Textural properties are recorded in Table 1. Method **a** leads to conservation of the mesoporosity after modification by organics. As shown previously[7,9,10] textures are maintained after grafting of halogens and substitution by (−)-ephedrine. However, a decrease in the residual mesoporous volume is observed. In the case of method **b**, the porosity of hybrids Al-MTS-Cl **1b** and Al-MTS-Cl-E **1b** becomes a microporosity. Increasing the initial pore diameter allows high residual mesoporous volumes to be obtained even after immobilization of a high density of organic functions by method **b** (Al-MTS-Cl **2b**, Al-MTS-Cl-E **2b**, Table 1).

Enantioselective addition of diethylzinc to benzaldehyde conducted in the presence of these solid chiral auxiliaries leads to the formation of (*R*)- or (*S*)-1-phenylpropan-1-ol (Scheme 2). All experiments were performed at 0 °C using the same weight of solid chiral auxiliary (0.29 g) and 2.3 eq. of Et_2Zn to benzaldehyde.[9,10] Results are shown in Table 2.

Such chiral auxiliaries are efficient in the enantioselective transfer of an ethyl group to benzaldehyde. The best results are obtained using (−)-ephedrine anchored on the Al-MTS **2** support (entry 11) and it is worth noting that ee and activity are close to those obtained in homogeneous catalysis (entries 2 and 3). On the other hand, efficiency depends on the synthetic method and on the initial pore diameter of the support. The

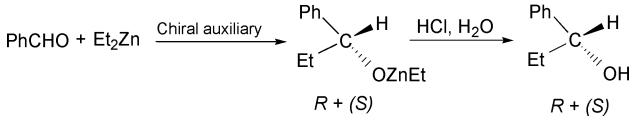
[a] Loadings are calculated relatively to the weight of dry initial silica content. [b] Densities are expressed by the ratio of the loading to the surface area of the naked support. [c] N_2 adsorption and desorption isotherms were collected on a Micromeritics ASAP 2000 apparatus at 77 K, after outgassing samples at 423 K for 8 h. Mean pore diameters are calculated by the $4V_{mp}/S_{BET}$ ratio. [d] BET equation used for the determination of surface area is inoperative.

Table 2 Alkylation of benzaldehyde with diethylzinc

Entry	Materials	(−)-Ephedrine (mol%)[a]	k^b_{obs}/h^{-1}	Selectivity[c] (%)	Ee[d] (%)
1	Without catalyst	—	$1.2\ 10^{-2}$	51	0
2	(−)-Ephedrine	8.5	0.53	98	65
3	(−)-*N*-Propylnorephedrine	8.5	0.68	98	76
4	Al-MTS **1**	—	0.17	84	0
5	Al-MTS-Cl **1a**	—	0.11	82	0
6	Al-MTS-Cl-E **1a**	13.6	0.17	93	47
7	Al-MTS-Cl **1b**	—	0.05	84	0
8	Al-MTS-Cl-E **1b**	15.4	0.11	94	54
9	Al-MTS **2**	—	0.26	87	0
10	Al-MTS-Cl **2b**	—	0.07	86	0
11	Al-MTS-Cl-E **2b**	16.8	0.55	98	64

[a] The number of catalytic sites is calculated relative to the total weight of hybrid material. [b] Fitting of BA (%) *versus* time (h) by an exponential regression leads to k_{obs} (h^{-1}). [c] % selectivity = 100 ([*R*] + [*S*])/([*R*] + [*S*] + [$PhCH_2OH$]). [d] (%) Ee = 100 ([*R*] − [*S*])/[*R*] + [*S*].



Scheme 2

inorganic surface of the support catalyzes the racemic alkyl transfer (entries 4 and 9) as shown by comparison with the uncatalyzed reaction (Table 2, entry 1) and the activity increases with the mesoporous volume (Table 1). Coverage of the surface by chloropropyl moieties leads to a decrease in the activity whatever the support (entries 4, 5 and 7 for Al-MTS **1**, entries 9 and 10 for Al-MTS **2**). The higher the coverage is, the lower the activity of the mineral surface. Solids derived from Al-MTS **1** show a slight increase in activity after modification by (−)-ephedrine; the activity of the high density solid (entry 8) is lower than that of the low density auxiliary (entry 6). Taking into account the low residual volume of the high density Al-MTS-Cl-E **1b**, we believe that accessibility to the catalytic sites is limited by diffusional constraints and that the reaction mainly proceeds on the external surface and at the pore opening. An increase in the mean pore diameter of the support allows the synthesis of high density hybrids with conservation of available mesoporous volumes. Hence, Al-MTS-Cl-E **2b** shows the highest activity obtained up to now, concomitant with good enantioselectivity related to the organic coverage of the mineral surface. It can be assumed that the catalytic sites located on the inner surface of the pores are active in the reaction. Bae *et al.*[15] reported recently the use of new chiral heterogeneous catalysts based on mesoporous silica, either MCM-41 or SBA-15 based catalysts. They attempted to improve ee's by using a more selective ligand than (−)-ephedrine and by addition of butyllithium as an extra metal reagent. It is worth noting that ee's were improved only in the latter case using a lithium salt in place of zinc alcoholate as the catalyst. Our approach based on the comprehension of the various effects led to the synthesis of the first inorganic–organic hybrid chiral auxiliaries, the efficiency of which can be compared with that obtained in homogeneous catalysis. Moreover, these catalysts may be reused three times without loss of enantioselectivity. In summary, two factors determine the design of new inorganic–organic chiral auxiliaries effective in C–C bond formation: firstly, the coverage of the surface by organics in order to suppress the activity towards the racemic reaction and secondly, the accessibility to the catalytic sites by using inorganic supports with large mesopore diameters.

The authors are grateful to F. Di Renzo, F. Fajula and P. Moreau for fruitful discussions.

Synthesis of unprecedented *oxygen-bridged* [*n*](2,5)pyridinophane dihydro-analogues

The development of new methods which allow the synthesis of [*n*]pyridinophanes and their dihydro-analogues is a major focus in supramolecular chemistry due to the many roles played by cyclophanes in biology and new technologies.[1] Pyridinophanes and their dihydro-analogues constituted the first examples of NADH models[2,3] capable of mimicking the diastereo-differentiating course of hydride exchange at pyridine dinucleotides under enzymatic conditions. In this way the asymmetric reduction of carbonyl substrates by optically active NADH model compounds has received wide attention.[3,4] Recently, crown ether annelated tetrathiafulvalenes were described as attractive components for sensor technology[5–7] and in some of these cases[6] pyridinophanes incorporating the tetrathiafulvalene (TTF) moiety have been studied as metal cations sensors.

In 1968 Gerlach and Huber[8] synthesized the first [*n*](2,5)pyridinophanes, *carbon-bridged* compounds, some *sulfur-bridged* [*n*](2,5)pyridinophanes were constructed and described as Vitamin B_6,[9] pyridoxal[10] and pyridoxamine[11] analogues; however, no synthetic procedure was reported to afford [*n*](2,5)pyridinophanes in which some methylene groups of the bridge were replaced by oxygen.

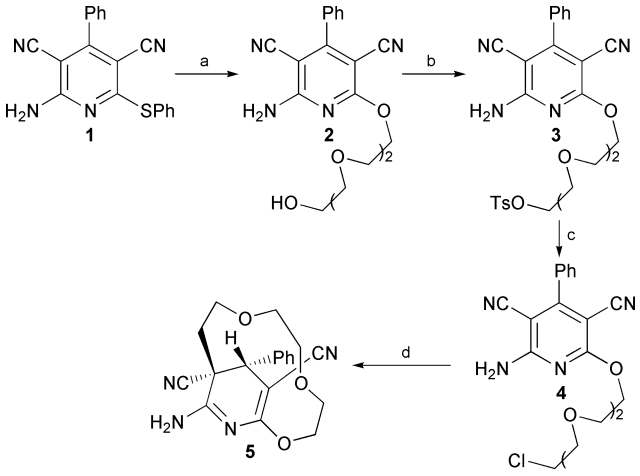
The synthesis of nearly all [*n*](2,5)pyridinophanes known has previously been accomplished using different synthetic strategies: (i) *via* the construction of the pyridine ring as happens in the acid-catalyzed cyclization of bis(β-aminovinyl)diketones[8] or (ii) by building the *ansa-chain* around the pyridine ring as in the thermal 1,6-Hofmann elimination from an intimate mixture of (4-methylbenzyl)trimethylammonium hydroxide and (5-methyl-2-picolinyl)trimethylammonium hydroxide.[12] *Sulfur-bridged* [*n*](2,5)pyridinophanes have been obtained through the Vögtle method by the condensation of dithiols with dihalogenopyridine compounds.[13]

Herein we present an unprecedented method for synthesis of dihydro-analogues of *oxygen-bridged* [*n*](2,5)pyridinophanes by a C–C bond formation between the pyridine ring and the ω-position of a chain. As a preliminary result we report here the synthesis and structural studies of the *oxygen-bridged* [9](2,5)pyridinophane‡ dihydro-analogues **5**.

Cyclic voltammetric data on the mercury cathode of the 2-amino-6-methoxy-4-phenylpyridine-3,5-dicarbonitrile[14] showed two peaks in the cathodic region at −1.88 and −2.20 V (*vs*. Ag/Ag^+),§ which make this compound susceptible to reduction by amalgam (Na·Hg).[15] On the basis of this behavior, we have developed a molecular system containing a latent nucleophilic pyridine ring moiety, switched on by electrochemical reduction, and an electrophilic center moiety linked by oxyethylene bridges. Pyridine derivative **4**, also having two reduction peaks at −1.88 and −2.20 V (*vs*. Ag/Ag^+),§ was chosen as a molecular model of this system. We have carried out its synthesis in multistep processes from pyridine **1**[16] as depicted in Scheme 1, *via* the substitution of the phenylthio group by triethylene glycol to afford **2** and followed by tosylation to **3** which could be converted in good yield to chloride **4**.

The synthesis of the *oxygen-bridged* [9](2,5)pyridinophane dihydro-analogues **5** was accomplished with an amalgam (Na·Hg) reduction of **4** in *N*,*N*-dimethylformamide under argon and required two eq. of Na per mol of **4**. The structure of **5** was well established by NMR spectroscopy,¶ X-ray diffraction study‖ and elemental analysis.

The structure of **5** can be clearly seen in the X-ray crystal structure (Fig. 1). Noteworthy structural features are the *trans* stereochemistry between the phenyl group on C15 and the *ansa-chain* bonding to the C11 atom, the very short distance C12–N20 (1.330 (4) Å) and sp^2 hybridization of N20.



Scheme 1 *Reagents and conditions*: (*a*) Under argon atmosphere, NaH (9 eq.), triethylene glycol (18 eq.), **1** (3 eq.), DMF, rt, 48 h, then poured on water, the precipitate was chromatographed (silica gel, CH_2Cl_2–EtOH, 25 : 1), 70%; (*b*) Under argon atmosphere, triethylamine (3.3 eq.), **2** (3 eq.) in dry CH_2Cl_2 (25 ml), 30 min, then toluene-*p*-sulfonyl chloride (3.3 eq.) in dry CH_2Cl_2 (10 ml) was added dropwise, rt, 12 h, then was neutralized with HCl (10%), solvent was removed *in vacuo* and the residue was chromatographed (silica gel, CH_2Cl_2–hexane, 25 : 1), 70%; (*c*) **3** (2 eq.), LiCl (8 eq.), dry MeOH (50 ml), reflux 4 d, purified by column chromatography (silica gel, CH_2Cl_2), 60%; (*d*) Under argon atmosphere, **4** (2 eq.), dry DMF (4 ml), amalgam (Na·Hg) (0.97% w.w. Na = 92 mg = 4 eq.), 0 °C, 24 h, then the solution was separated and evaporated to dryness and the residue was purified by column chromatography (neutral aluminium oxide, CH_2Cl_2–hexane, 20 : 1), 40%.

† Electronic supplementary information (ESI) available: 2D-J resolved ^1H spectra, 2D-COSY ^1H–^1H–^{13}C spectra of **5**. See http://www.rsc.org/suppdata/cc/b0/b004474l/

DOI: 10.1039/b004474l

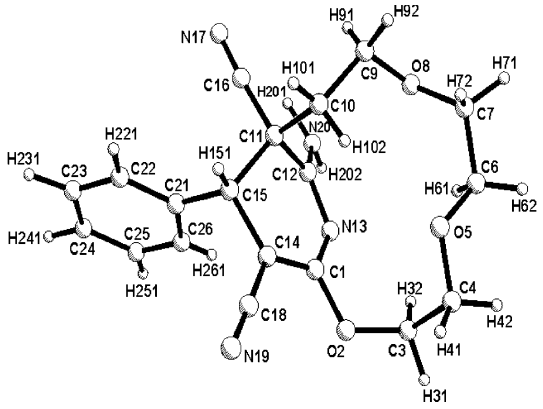


Fig. 1 View of the molecular structure of compound **5**. Selected bond lengths [Å] and angles [°]: C(1)–C(14) 1.343(5), C(1)–O(2) 1.352(4), C(1)–N(13) 1.369(4), C(11)–C(12) 1.524(5), C(11)–C(15) 1.564(4), C(12)–N(13) 1.298(4), C(12)–N(20) 1.330(4), C(14)–C(18) 1.411(5), C(14)–C(15) 1.523(4), C(15)–C(21) 1.517(4), N(13)–C(12)–N(20) 119.0(3), N(20)–C(12)–C(11) 119.0(3).

The ^{1}H NMR of **5**¶ shows two multiplets for the Ph ring, one singlet for the C15-H resonance and the three expected ABCD spin systems with typical values of SSCC for CH_2CH_2 groups of *ansa*-moiety, which were assigned by using the ^{1}H *J*-resolved, 2D-COSY ^{1}H–^{1}H and 2D-COSY ^{1}H–^{13}C spectra.† The observation of two unequivalent protons for the NH_2 group at δ = 8.5 and 7.8 ppm is due to very slow rotation around the C_{12}–N bond.

Received (in Irvine, CA, USA) 4th April 2000, Accepted 7th July 2000
First published as an Advance Article on the web 4th September 2000

Allylpalladium(II) compounds react readily in benzene with free phenyl and trityl radicals, generated from the thermal decomposition of phenylazotriphenylmethane, and with free cyclohexyl radicals, generated from the photolysis of (cyclohexyl)(pyridine)cobaloxime; the reactions appear to involve initial attack of the radicals at palladium, followed by secondary processes which convert the coordinated allyl ligands preferentially to terminal rather than internal alkenes.

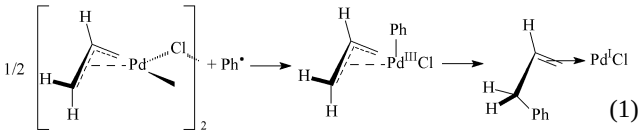
Free radicals have been invoked as reactive intermediates in a wide variety of reactions involving organotransition metal compounds, *e.g.* oxidative addition reactions,[1a] SmI_2 induced coupling of organic halides with carbonyl compounds,[1b] reduction of organic halides by complexes of chromium(II),[1c] and hydrogenation and hydrometallation of aromatic alkenes[1d] and conjugated dienes.[1e] Recent years have also seen increasing interest in free radicals as *reactants* with unsaturated organic ligands, *e.g.* with coordinated aromatic,[2a] allylic,[2b] carbenoid[2c] and alkenyne[2d] ligands although there is as yet no general understanding of the reactions of free radicals with coordinated ligands. We have therefore undertaken an investigation of reactions of a variety of free radicals with allylic palladium(II) compounds of the types $[(\eta^3\text{-allyl})PdCl]_2$, $(\eta^3\text{-allyl})PdCl(PPh_3)$ and $[(\eta^3\text{-allyl})Pd(PPh_3)_2]Cl$, the latter being of interest because the enhanced susceptibility of the allyl groups in these types of compounds to nucleophilic attack has proven very useful in synthetic organic methodology.[3]

Our initial studies have utilized triphenylmethyl (trityl) and phenyl radicals, derived *via* the thermal decomposition of phenylazotriphenylmethane ($PhN{=}NCPh_3$, PAT),[4] and cyclohexyl radicals, generated from visible light photolysis of (cyclohexyl)(pyridine)cobaloxime [*c*-$C_6H_{11}Co(DMG)_2(py)$].[5] Both procedures generate free radicals in good yields and under relatively mild conditions, and molar ratios of radical source to palladium of 2–3 : 1 ensured that reactions of the palladium substrates proceeded to completion.

Reaction of $[(\eta^3\text{-}C_3H_5)PdCl]_2$ with PAT in benzene or benzene-d_6 at 60 °C resulted in the formation of palladium metal, 3-phenylprop-1-ene, 1-phenylprop-1-ene, chlorotriphenylmethane (in high yield by GC) and a small amount of 4,4,4-triphenylbut-1-ene but no chlorobenzene. By monitoring the reaction products as a function of time, it was found that 3-phenylprop-1-ene was formed initially in *ca*. 90% yield (NMR) and that 1-phenylprop-1-ene was formed by subsequent isomerization of the kinetic product. Control experiments showed that this isomerization reaction is catalyzed by palladium metal, and thus the primary reaction involves the formation of 3-phenylprop-1-ene, $PhCH_2CH{=}CH_2$.

In contrast, the analogous reactions of $[(\eta^3\text{-}C_3H_5)PdCl]_2$ in the presence of either 1 or 2 equivalents of PPh_3 per palladium were found to produce 4,4,4-triphenylbut-1-ene (> 90% yield by NMR) and $[PdPh(\mu\text{-}Cl)(PPh_3)]_2$[6a] or *trans*-$PdPhCl(PPh_3)_2$,[6b,c] respectively. In addition, the reaction of $[(\eta^3\text{-2-methylallyl})PdCl]_2$ with PAT in the presence of PPh_3 produced *trans*-2-methyl-4,4,4-triphenylbut-1-ene and $PdPhCl(PPh_3)_2$, while the reaction of $[(\eta^3\text{-allyl})Pt(PPh_3)_2]^+Cl^-$ produced 4,4,4-triphenylbut-1-ene and *trans*-$PtPhCl(PPh_3)_2$.[6d]

Assuming a similar first step in all of these reactions, the results may be rationalized on the basis of initial attack of phenyl radical on palladium. In the absence of triphenylphosphine, it seems likely that initial phenyl radical coupling with the palladium to form a palladium(III) intermediate is followed by reductive coupling of the phenyl group with a terminal carbon atom of the allyl ligand to give an intermediate chloropalladium(I) complex [eqn. (1)]. In possibly a concerted



(1)

process, the chlorine atom is abstracted from the intermediate by free trityl radical to form chlorotriphenylmethane, palladium metal and free 3-phenylbut-1-ene.

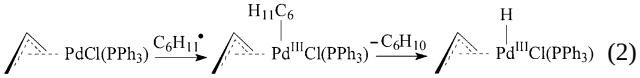
Initial abstraction of a chlorine atom from $[(\eta^3\text{-}C_3H_5)PdCl]_2$ by trityl radical can presumably be ruled out since no chlorobenzene was formed. Although one might anticipate that the initially formed trityl radical could react with $[(\eta^3\text{-}C_3H_5)PdCl]_2$ before significant amounts of the intrinsically more reactive phenyl radical are formed, in fact the relative rates of formation of the two radicals are very similar[4d] and pre-empting of any reactive site by the trityl radical seems unlikely. On the other hand, with analogous triphenylphosphine-containing phenylpalladium(III) intermediates such as $[(\eta^3\text{-}C_3H_5)Pd^{III}(Ph)Cl(PPh_3)]$ or $[(\eta^3\text{-}C_3H_5)Pd^{III}(Ph)(PPh_3)_2]^+$, steric hindrance by the bulky phosphine ligands may prevent attack on the coordinated chlorine atoms by the bulky trityl radical. Instead, the latter apparently couples in these cases with the sterically less congested allyl ligand to form 4,4,4-triphenylbut-1-ene, again possibly *via* a concerted process but not, presumably, *via* initial trityl radical attack as there is no obvious reason why at least *some* phenyl radical involvement to give 3-phenylprop-1-ene would not occur. Interestingly, in a control experiment, it was found that trityl radical, added as the corresponding dimer with which it is in equilibrium,[7] does react with $[(\eta^3\text{-}C_3H_5)PdCl]_2$ in the presence of PPh_3, the trityl and allyl groups combining to form exclusively 4,4,4-triphenylbut-1-ene. On the other hand, the formation of 4,4,4-triphenylbut-1-ene apparently does not involve trityl coupling with free allyl radicals as no hexa-1,5-diene, the product of allyl free radical coupling,[8] was formed.

In contrast to the above, photolysis of *c*-$C_6H_{11}Co(DMG)_2(py)$ with visible light in the presence of $[(\eta^3\text{-}C_3H_5)PdCl]_2$ (PPh_3 : Pd ratios 1 : 1, 2 : 1) in benzene or benzene-d_6 at 25 °C did not give 3-cyclohexylprop-1-ene and/or cyclohexyl–palladium complexes, but rather propene, cyclohexene and palladium(0) species. Similar reactions of $[(\eta^3\text{-1-methylallyl})PdCl]_2$, $[(\eta^3\text{-2-methylallyl})PdCl]_2$ and $[(\eta^3\text{-2-phenylallyl})PdCl]_2$ (PPh_3 : Pd ratios 1 : 1) resulted in the exclusive formation of but-1-ene, isobutene and 2-phenylprop-1-ene respectively, while reaction of $[(\eta^3\text{-1-phenylallyl})PdCl]_2$ (PPh_3 : Pd ratio 1 : 1) resulted in the formation of a mixture of 3-phenylprop-1-ene and 1-phenylprop-1-ene at 25 °C but only 3-phenylprop-1-ene at 5 °C if the PPh_3:Pd ratio were 2:1. The reaction of $[(\eta^3\text{-}C_3H_5)PdCl]_2$ with *c*-$C_6H_{11}Co(DMG)_2(py)$ gave propene and palladium metal while reaction of $[(\eta^3\text{-1-phenylallyl})PdCl]_2$ gave 1-phenylprop-1-ene and palladium metal; as above, isomerization of a terminal alkene kinetic product to internal alkene may be catalyzed by palladium metal. Control

DOI: 10.1039/b002851g

experiments showed that the allyl–palladium compounds are stable under the above conditions in the absence of *c*-$C_6H_{11}Co(DMG)_2(py)$.

Assuming a mechanism analogous to the above and considering the nature of the products, these reactions probably involve initial attack of the cyclohexyl radical at the metal to form a cyclohexyl–Pd(III) species, followed by β-hydrogen elimination of cyclohexene to form a hydrido–allylpalladium(III) complex [eqn. (2)]. Subsequent reductive elimination of propene could



(2)

result in the palladium(I) species $PdCl(PPh_3)$, which could undergo a second attack by a cyclohexyl radical to form the palladium(II) cyclohexyl compound $PdCl(C_6H_{11})(PPh_3)$, which could also undergo β-hydrogen elimination of cyclohexene to give the hydride $PdHCl(PPh_3)$.

Although cyclohexene is anticipated as a byproduct in these reactions, it is expected to be formed in any case as a product of the photolysis of *c*-$C_6H_{11}Co(DMG)_2(py)$[5] and we therefore cannot take its formation as evidence for the postulated mechanism. While neither the putative hydride $PdHCl(PPh_3)$ nor its dimer appear to have been reported, the ^1H NMR spectrum of a reaction mixture in benzene-d_6 exhibited a resonance at δ –13, indicative of a palladium hydride. This *same* resonance is also observed in reactions involving $[(\eta^3\text{-1-methylallyl})PdCl]_2$, $[(\eta^3\text{-2-methylallyl})PdCl]_2$, $[(\eta^3\text{-1-phenylallyl})PdCl]_2$ and $[(\eta^3\text{-2-phenylallyl})PdCl]_2$, consistent with the general mechanism proposed. Also consistent is an observation that the reaction of $[(\eta^3\text{-allyl})Pt(PPh_3)_2]Cl$ with $C_6H_{11}Co(DMG)_2(py)$ gives comparable amounts of propene and *trans*-$PtHCl(PPh_3)_2$, identified by comparison of its hydride resonance (δ −15.2) with that of an authentic sample,[9] in addition to cyclohexene.

Seemingly anomalous, however, is the exclusive formation of but-1-ene in the reaction of $[(\eta^3\text{-1-methylallyl})PdCl]_2$ and of 3-phenylprop-1-ene in the reaction of $[(\eta^3\text{-1-phenylallyl})PdCl]_2$. While these products are consistent with the reductive elimination step implied above, reductive elimination of alkenes from allylpalladium(II) hydrido complexes normally results in the formation of the thermodynamically preferred internal alkenes.[3b] Thus the fact that the reactions discussed here give solely terminal alkenes is perhaps evidence that the reactions do indeed involve allylpalladium(III) hydrido species, although it is not readily obvious why formation of the terminal alkenes should become kinetically preferred. A better understanding of these processes must await further labelling and stereochemical studies which are underway.

Although the mechanisms are as yet uncertain, the reactions lead in all cases to preferential conversion of the allylic ligands to terminal alkenes. Since compounds of the type $[(\eta^3\text{-1-}RC_3H_4)PdCl]_2$ (R = alkyl, aryl) are readily prepared from, *e.g.* alkenes $RCH{=}CHCH_3$[3a] and allylic acetates $RCH{=}CHCH_2OAc$,[3a] the chemistry involving hydrogen transfer from the cyclohexyl radical would seem in effect to provide a route for both the isomerization of the alkene or the hydrogenolysis of the allylic acetate, *via* η^3-allylpalladium compounds, to terminal alkenes $RCH_2CH{=}CH_2$. Both types of reactions have potential utility, as we note that hydrogenolysis of allylpalladium complexes by hydride sources normally results in the formation of internal alkenes unless the source is formate ion.[10]

First published as an Advance Article on the web 4th September 2000

Triols were prepared in enantiomerically enriched form by a short route that included a Sharpless asymmetric dihydroxylation; treatment of these triols with toluene *p*-sulfonic acid gave THFs as thermodynamic products.

Previously, we have reported the outcome of competitive cyclisations between two primary hydroxy groups at the end of separate or branched side chains (**1** and **2**, Fig. 1).[1,2] We then wished to investigate cyclisations of 2,4,5-triols (bearing a phenylsulfanyl group at C-1) with primary and secondary hydroxy groups in the same side-chain (Scheme 1). In each case two modes of cyclisation are possible: route (**A**) would result in tetrahydropyran (THP) formation, route (**B**) in tetrahydrofuran (THF) formation.

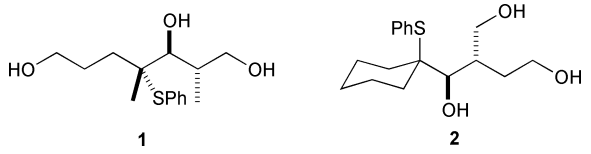

Fig. 1

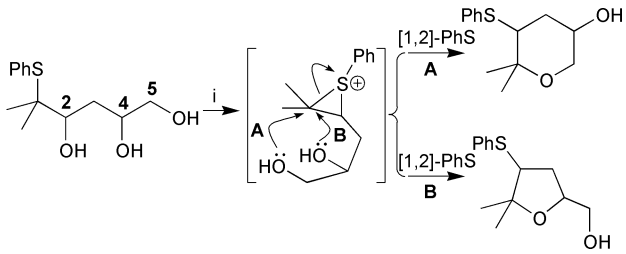
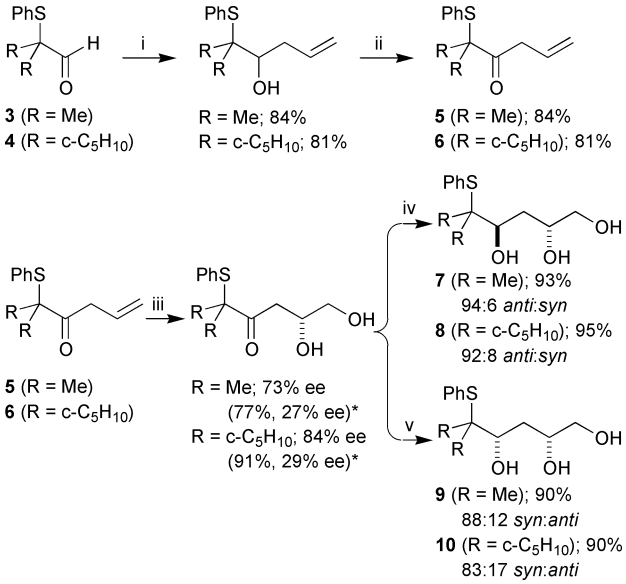


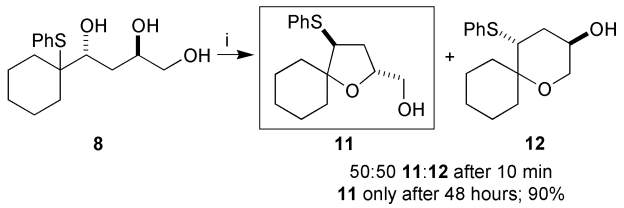
Scheme 1 *Reagents*: i, TsOH, CH_2Cl_2.



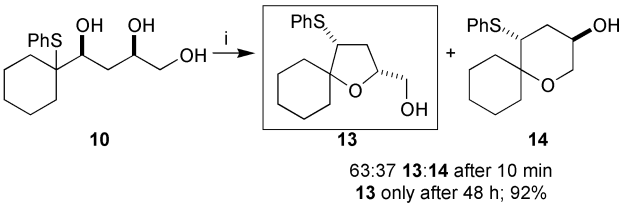
Scheme 2 *Reagents*: i, CH_2=$CHCH_2MgBr$, Et_2O, rt; ii, PCC, CH_2Cl_2, rt; iii, $K_2OsO_2(OH)_4$, $(DHQD)_2PYR$, K_2CO_3, $K_3Fe(CN)_6$, Bu^tOH–H_2O, 0 °C; iv, Me_4N^+ $BH(OAc)_3^-$, AcOH-MeCN, −20 °C, 7 days; v, Et_2BOMe, THF–MeOH, −78 °C then $NaBH_4$. * Yields and enantiomeric excesses in parentheses denote those obtained using AD-mix-β at 25 °C.

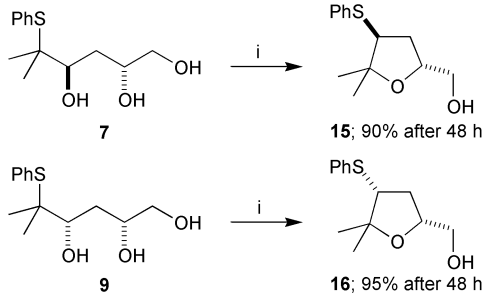
Two sets of diastereomeric triols were prepared for this study with different migration origins; for one pair (**7** and **9**) *gem*-dimethyl substitution was used and for the other (**8** and **10**) a cyclohexane ring was used (Scheme 2). The triols were readily synthesised starting from the aldehydes **3** and **4**. Grignard addition followed by oxidation gave the homoallylic ketones **5** and **6**. The asymmetric dihydroxylation reaction[3] gave optimum enantiomeric excess (73–84%) when Sharpless' PYR ligand was used.[4] Finally a 1,3-diastereocontrolled reduction gave either the 2,4-*anti*[5] (**7** and **8**) or 2,4-*syn*[6] diastereoisomers (**9** and **10**) of each triol.

Initially these compounds were subjected to our standard conditions for rearrangement: a 5 min reflux with 5 mol% toluene *p*-sulfonic acid in dichloromethane. To our initial disappointment, triol **8** gave a 50:50 mixture of THF **11** and THP **12** (Scheme 3).[7] Previously we have shown that these reaction are under thermodynamic control,[8,9] so resubmitting this mixture to the reaction conditions, or taking a fresh sample of the triol **8**, and heating to reflux in dichloromethane for 48 h led to the complete conversion into the spirocyclic THF **11** Scheme 3). Similarly the *syn*-triol **10** gave an initial product



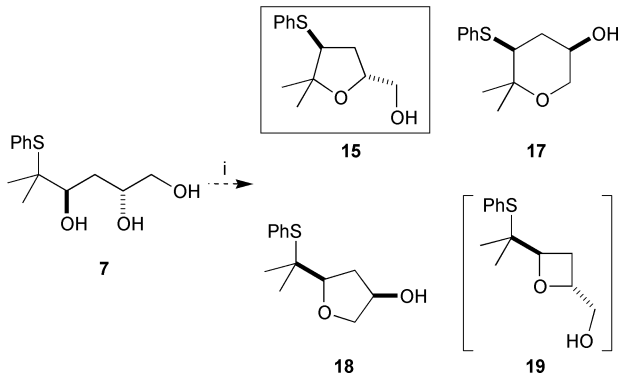
Scheme 3 *Reagents*: i, TsOH, CH_2Cl_2, 40 °C.





Scheme 4 *Reagents*: i, TsOH, CH_2Cl_2, 40 °C.

DOI: 10.1039/b005342m



Scheme 5 *Reagents*: i, TsOH, $CDCl_3$.

distribution of 63 : 37 THF **13** : THP **14**, but after a prolonged reflux (48 h) gave only THF **13** (Scheme 4). These results were followed by rearrangement of the structurally related triols **7** and **9**. Again, short reaction times led to THF–THP mixtures, but a longer reaction time (48 h) led to THFs **15** and **16** (Scheme 4).

In contrast to other systems we have studied,[1,2] ring-size has become more important than the relative stereochemistry. A 2,4-*syn* THF is preferred to the alternative 2,4-*anti* THP, where one of the two substituents would enter an axial environment. More interestingly though, the 2,4-*anti* THF is preferred to the 2,4-*syn* THP, where both groups could now be equatorial. We presume in this case that the factor governing the cyclisation outcome (the degree of substitution being equal for both rings) is the *gem*-disubstituted migration origin. In the THP one of the C–C bonds is forced to be axial; presumably the 1,3-diaxial interactions are too severe and the flatter THF ring is preferred.

The rearrangement of triol **7** was followed by 400 MHz ^{1}H NMR spectroscopy. By recording spectra at regular intervals it was possible to watch the initial formation of the heterocycles **15**, **17** and **18** and the subsequent equilibration of the mixture to the THF **15** (Scheme 5). Interestingly, the unrearranged[10] THF **18** was observed as a metastable product but none of the oxetane **19**, which would also be formed by attack on the less substituted end of the episulfonium ion, was detected.

In summary we have demonstrated further evidence that [1,2]-PhS rearrangements are under thermodynamic control and that for a simple class of triols **7**–**10** the most stable products are the THFs **11, 13, 15** and **16**. We believe that in this case the difference in product stability can be attributed to the *gem*-disubstituted migration origin. In other cases we have investigated[1,2] the relative stability of products may be dependent on ring-size, stereochemistry or a thermodynamic Thorpe–Ingold effect.

We thank the EPSRC and AstraZeneca for a grant to D. H.

7 The two types of heterocycle are readily distinguished by ^{1}H NMR spectroscopy: the hydrogen atom adjacent to the PhS group has a characteristic chemical shift in the range $3.0 < \delta_H < 3.5$ ppm. For the THPs this signal appears as a double doublet: for the THFs it is normally a triplet, or at least a double doublet with very similar coupling constants. Integration of these proton resonances provided an accurate means of assessing product ratios.

Asymmetric synthesis of tetrahydrofurans and tetrahydropyrans with competitive [1,2]-phenylsulfanyl (PhS) migration (II): synthesis of protected tetrahydropyrans

David J. Fox,[a] David House,[a] Fraser Kerr[b] and Stuart Warren*[a]

[a] *University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: sw134@cam.ac.uk*

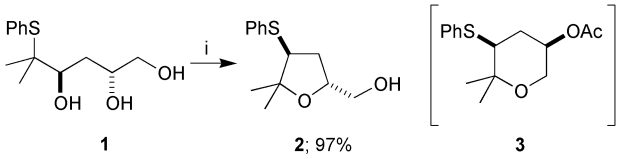
Received (in Cambridge, UK) 3rd July 2000, Accepted 2nd August 2000
First published as an Advance Article on the web 4th September 2000

Enantiomerically enriched triols were treated with trimethylorthoacetate and pyridinium toluene *p*-sulfonate to give a mixture of unrearranged THF and rearranged THP; treatment of the product mixture with toluene *p*-sulfonic acid equilibrated the mixture to the THP.

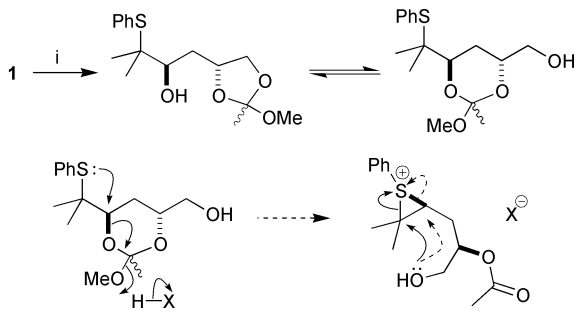
In the preceeding article[1] we reported the preparation of enantiomerically enriched triols (*e.g.* **1**) and their conversion to the thermodynamic tetrahydrofuran (THF) products (*e.g.* **2**) (Scheme 1). In this publication we disclose details of how the same cyclisation precursors can be converted to the complementary tetrahydropyran (THP) products (*e.g.* **3**).



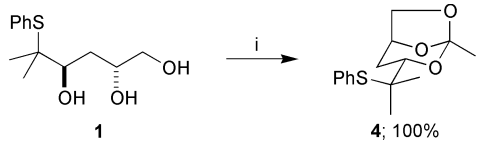
Scheme 1 *Reagents*: i, TsOH, CH_2Cl_2.

An obvious approach to the THPs would be an orthogonal protecting group strategy, which would leave the secondary hydroxy nucleophile protected and the primary hydroxy unprotected and available for cyclisation. Alternatively, we envisaged a situation where it would be possible to protect the secondary hydroxy nucleophile and simultaneously activate the other secondary hydroxy group to nucleophilic displacement. By using an orthoester in the appropriate conditions an exchange could be set up between a 5- and a 6-membered orthoester (Scheme 2). So long as the 5-membered orthoester was inert under these reaction conditions it would be possible to trigger the episulfonium ion formation and protect the secondary hydroxy group as its acetate.

Pyridinium *p*-toluenesulfonate (PPTS) (pK_a ~ 5.5) was chosen as the acid catalyst for this reaction because orthoesters exchange under general acid catalysis,[2] but we did not expect such a weak acid to promote direct formation of the episulfonium ion. Hence triol **1** was treated with 1 eq. of trimethylorthoacetate with PPTS as the acid catalyst. In the first instance the product was the orthoester **4** which is formed by exchange of all three molecules of MeOH (Scheme 3). However, with longer

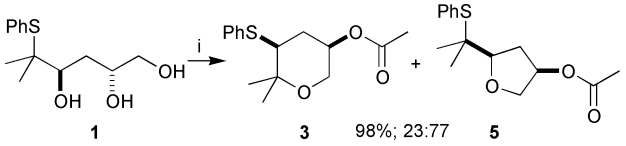


Scheme 2 *Reagents*: i, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-, CH_2Cl_2.



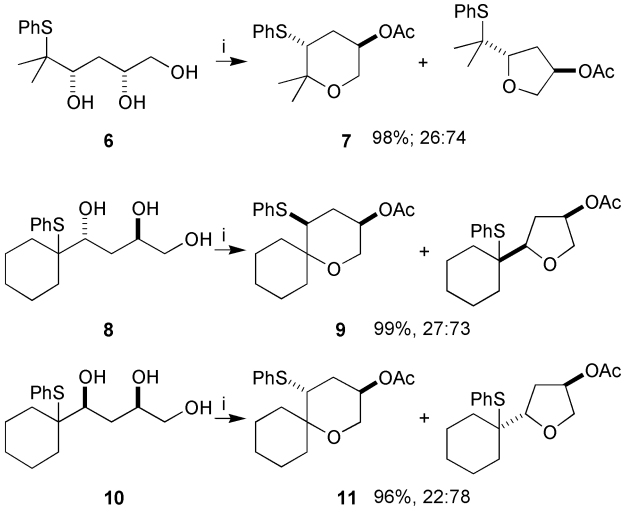
Scheme 3 *Reagents*: i, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-, CH_2Cl_2, rt, 2 min.

reaction times we obtained none of this orthoester but two heterocyclic products. The two heterocycles were the unrearranged[3] THF **5** and the rearranged[3] THP **3**: both products derive from cyclisation of the primary hydroxy nucleophile, but to different ends of the episulfonium ion intermediate (Schemes 2 and 4).

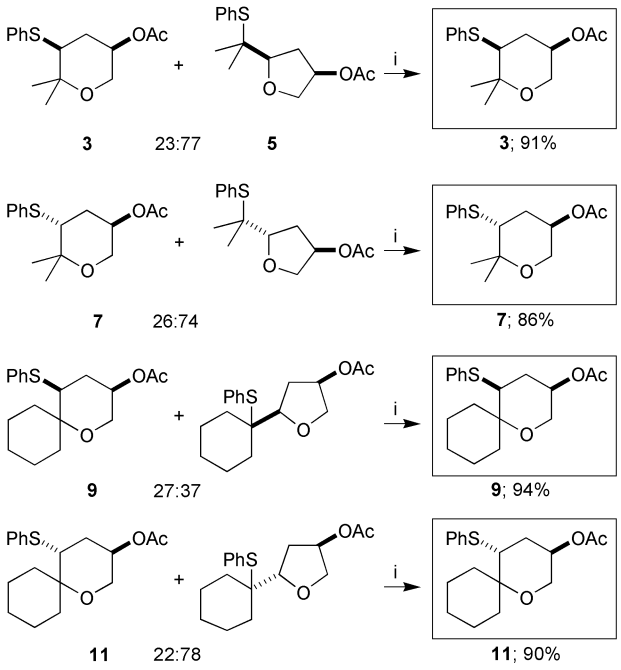


Scheme 4 *Reagents*: i, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-, CH_2Cl_2, rt, 24 h.

This result is important in the context of our research programme because it constitutes the first example of cyclisation on to the less substituted end of an episulfonium ion (where the alternative cyclisation would not give a 7-membered ring).[4] This raised the question of whether these reactions were therefore under kinetic control. (We have previously shown that cyclisations catalysed by toluene *p*-sulfonic acid are under thermodynamic control.[5,6]) To address this question we performed three control experiments. First we took a sample of the triol and treated it with PPTS, without adding trimethylorthoacetate, and showed that no reaction occurred. Secondly the 77:23 THF **5**: THP **3** mixture isolated from the cyclisation



Scheme 5 *Reagents*: i, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-, CH_2Cl_2, rt, 24 h.

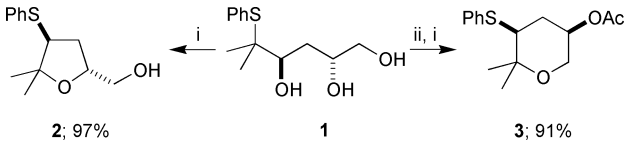


Scheme 6 *Reagents*: i, TsOH, CH_2Cl_2, 40 °C, 24 h.

reaction was resubmitted to the PPTS acid catalyst: no equilibration of the mixture occurred. Finally we confirmed the second experiment by showing that a pure sample of the unrearranged THF **5** was not converted to the THP **3** by PPTS. At this point we could conclude this orthoester-promoted cyclisation is in fact under kinetic control.

Following the reaction of triol **1**, we also cyclised triols **6** (the diastereoisomer of **1**), **8** and **10** under the same conditions and observed in each case that the unrearranged THF was the major product (Scheme 5). For the case of the 2,4-*syn* triols **6** and **10** none of the bicyclic orthoester intermediate could be isolated.

In order to exploit this interesting mechanistic observation synthetically we reasoned that treatment of the THF–THP mixtures with a strong acid, toluene *p*-sulfonic acid, should lead to equilibration of the mixture to the rearranged THPs. Indeed



Scheme 7 *Reagents*: i, TsOH, CH_2Cl_2; ii, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-.

this was observed in all four cases; complete equilibration occurred to give the THPs **3**, **7**, **9** and **11**, protected as their acetates (Scheme 6). Hence this two-step synthetic procedure can give the THP products (which are complementary to the THF products of the one-step toluene *p*-sulfonic acid cyclisation) without the need for any purification of the intervening mixture.

In summary, we have demonstrated a rapid approach to enantiomerically enriched THPs or THFs from a common triol precursor depending on the choice of reagent (Scheme 7). For THF synthesis the episulfonium ion is formed directly, under specific acid catalysis. Use of the orthoester route promotes episulfonium ion formation under general acid catalysis and results in THP–THF mixtures that can be equilibrated to THP.

We thank the EPSRC and AstraZeneca for a grant to DH and Martin Christlieb, David Hodgson and Adam Nelson for useful discussions.

Scope and limitation of the [1,2]-phenylsulfanyl (PhS) migration in the asymmetric synthesis of tetrahydrofurans and tetrahydropyrans from common triol precursors

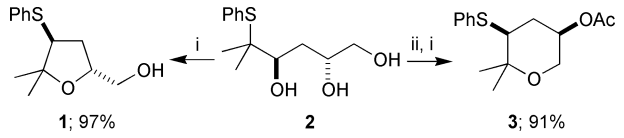
David House,[a] Fraser Kerr[b] and Stuart Warren*[a]

[a] *University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: sw134@cam.ac.uk*
[b] *AstraZeneca R&D Södertälje, Process R&D, S-151 85 Södertälje, Sweden*

Received (in Cambridge, UK) 3rd July 2000, Accepted 2nd August 2000
First published as an Advance Article on the web 4th September 2000

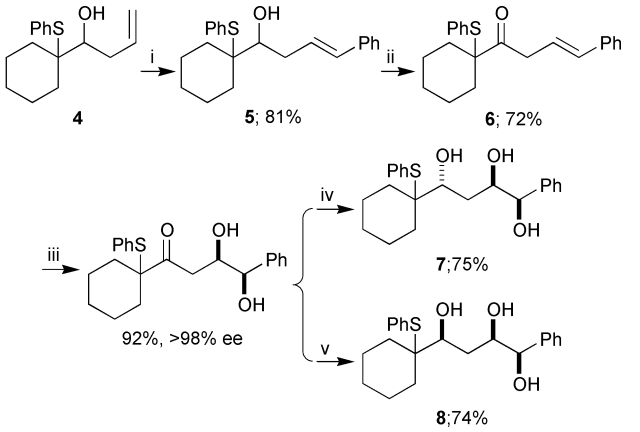
Triols containing three secondary hydroxy groups were reacted with either (i) toluene *p*-sulfonic acid or (ii) trimethylorthoacetate–pyridinium toluene *p*-sulfonate followed by toluene *p*-sulfonic acid.

In the previous two articles[1,2] we demonstrated how enantiomerically enriched triols (*e.g.* **2**) could be converted in a single step to THFs (*e.g.* **1**) (thermodynamic control) or in two steps to THPs (*e.g.* **3**) (kinetic control–equilibration sequence) (Scheme 1). The subject of the final communication in this series is our attempts to assess the generality of these reactions, particularly by replacement of the primary hydroxy in **2** with a secondary alcohol.

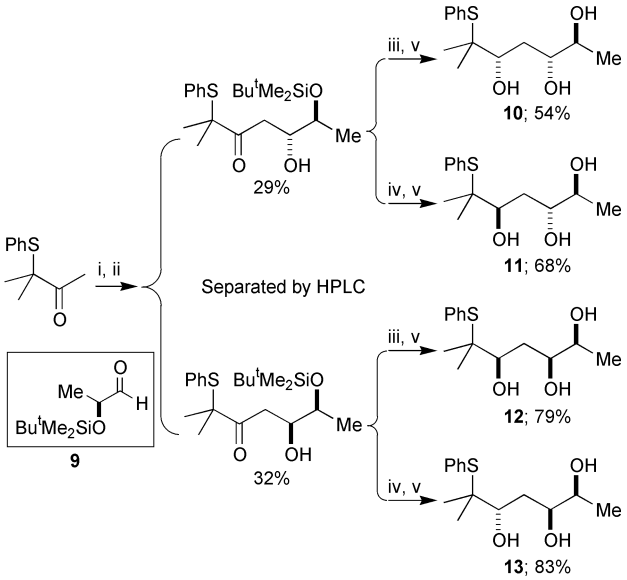


Scheme 1 *Reagents*: i, TsOH, CH_2Cl_2, 40 °C; ii, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-, CH_2Cl_2, rt.

Triols **7** and **8** were prepared by essentially the same method as used previously,[1] *i.e.* by Sharpless asymmetric dihydroxylation[3] of the styrene **6** and diastereoselective reduction of the β-hydroxyketones (Scheme 2).[4,5] Styrene **5** was derived from the homoallylic alcohol **4** by a Heck reaction with iodobenzene. The remaining triols **10**–**13** were prepared by an aldol reaction[6] of the lactic acid derived aldehyde **9**, followed by stereocontrolled reduction (Scheme 3). We were able to prepare all diastereoisomers of the triol target molecules since the aldol route gave poor diastereoselectivity and necessitated a difficult separation of the aldol products by preparative HPLC.

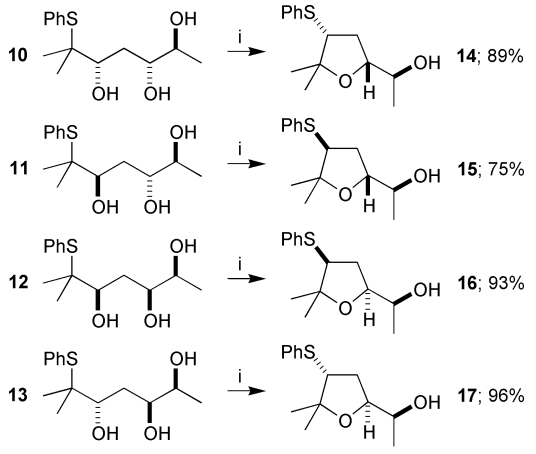


Scheme 2 *Reagents*: i, PhI, 5 mol% $Pd(OAc)_2$, 10 mol% Ph_3P, Et_3N, MeCN, 80 °C, 24 h; ii, PDC, CH_2Cl_2, rt; iii, AD-mix-β, $MeSO_2NH_2$, Bu^tOH–H_2O, rt; iv, Me_4N^+ $BH(OAc)_3^-$, AcOH–MeCN, −20 °C, 7 days; v, Et_2BOMe, THF–MeOH, −78 °C then $NaBH_4$.



Scheme 3 *Reagents*: i, LDA, THF, −78 °C; ii, aldehyde **9**; iii, Et_2BOMe, THF–MeOH, −78 °C then $NaBH_4$; iv, Me_4N^+ $BH(OAc)_3^-$, AcOH–MeCN, −20 °C, 7 days; v, $Bu^n_4N^+$ F^-, THF, rt.

The toluene *p*-sulfonic acid catalysed cyclisations are under thermodynamic control and so we used long reaction times to ensure equilibrium was established. The triols in the lactic acid series (*i.e.* triols **10**–**13**) all rearranged to give the THFs (**14**–**17**, respectively) as the major product (Scheme 4). We were particularly interested to establish the outcome of rearranging the ^{2,4}*anti*,^{4,5}*anti* triol **11**, since the THP **18** derived from this triol would have the maximum number of equatorial substituents (Fig. 1). Despite this 'favourable' arrangement of substituents in the THP product, the THF was still the major



Scheme 4 *Reagents*: i, TsOH, CH_2Cl_2, 40 °C.

DOI: 10.1039/b005336h

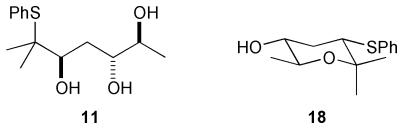


Fig. 1

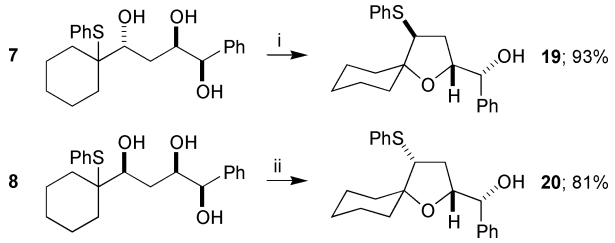
product, though THP **18** did account for 17% of the equilibrium.

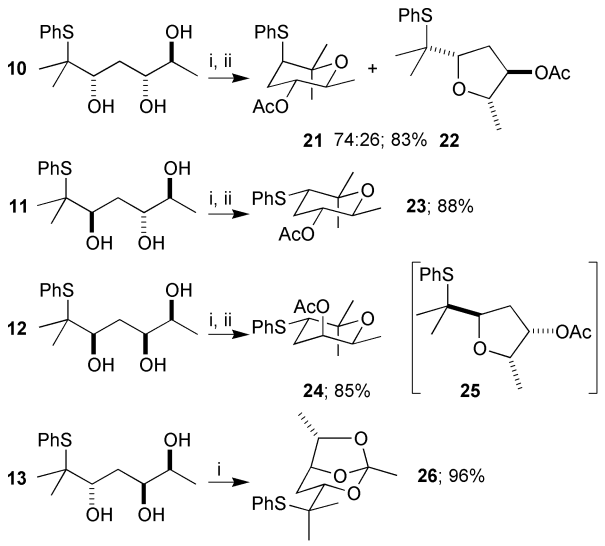
The rearrangement of the triols **7** and **8** required careful handling (presumably due to the benzylic hydroxy group). The ^{2,4}*anti*,^{4,5}*syn* triol **7** rearranged exclusively to THF **19** after being heated to reflux in dichloromethane for 24 h (Scheme 5). The ^{2,4}*syn*,^{4,5}*syn* triol **8**, however, had to be rearranged at rt (3 days) to avoid decomposition. Again, the THF **20** was the only isolated product.



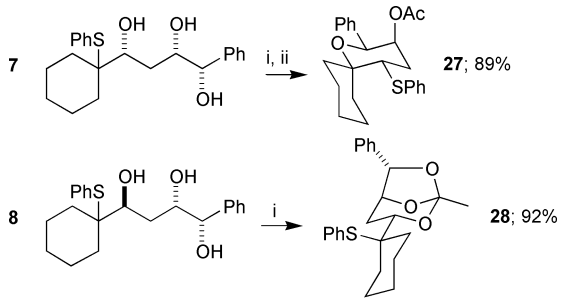
Scheme 5 *Reagents*: i, TsOH, CH_2Cl_2, 40 °C; ii, TsOH, CH_2Cl_2, rt.

The products of the kinetically controlled orthoester rearrangement reported in the preceding communication[2] were equilibrated with toluene *p*-sulfonic acid in dichloromethane with the aim of converting the unrearranged[7] THFs to THPs.

Reactions of the triols in the lactic acid series turned out to be very substrate dependent. Rearrangement of the ^{2,4}*syn*,^{4,5}*anti* triol **10** under kinetic conditions gave the unrearranged THF **22** as the major product (Scheme 6). Equilibration with toluene *p*-sulfonic acid gave only a 74:26 mixture of the rearranged THP **21** and unrearranged THF **22**. The inference here could be that it is unfavourable for the sulfur to occupy an axial position, indeed sufficiently unfavourable that it can partly overcome the driving force for 'downhill' migration.[8] The ^{2,4}*anti*,^{4,5}*anti*-triol **11** behaved quite differently; after equilibration of an initial THF–THP mixture the only product identified was the THP **23**, with methyl, acetoxy and phenylsulfanyl groups all occupying equatorial positions (Scheme 6). The ^{2,4}*syn*,^{4,5}*syn*-triol **12** gave,



Scheme 6 *Reagents*: i, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-, CH_2Cl_2, rt; ii, TsOH, CH_2Cl_2, 40 °C.



Scheme 7 *Reagents*: i, $(MeO)_3CMe$, $C_5H_6N^+$ TsO^-, CH_2Cl_2, rt; ii, TsOH, CH_2Cl_2, rt.

after the two-step reaction sequence, the THP **24** with an axial acetate (the alternative THF **25** contains an unfavourable 2,3-*syn* relationship) (Scheme 6). Finally, in this series of compounds, the ^{2,4}*anti*,^{4,5}*syn*-triol **13** gave a single product after treatment with trimethylorthoacetate and PPTS: the bicyclic orthoester **26**. Attempts to repeat the reaction at higher temperatures, or with longer reaction times, led only to decomposition products that were not characterised. It is interesting to note the stabilising effect of an *exo*-methyl group on these compounds. When triol **11** (with 2,4-*anti* stereochemistry) was reacted with the same reagent system no bicyclic orthoester intermediate was observed; presumably an *endo*-methyl group here destabilises the orthoester intermediate (if the corresponding orthoester forms at all).

The triols **7** and **8,** each containing a benzylic hydroxy group, behaved similarly to their analogues in the lactic acid series. Triol **7** was converted into the THP **27**, bearing an axial acetate, and triol **8** gave only the bicyclic orthoester **28**, which was not successfully transformed into the target heterocycles (Scheme 7).

In summary, we have demonstrated that for the general class of triols under investigation THFs are formed as thermodynamic products when toluene *p*-sulfonic acid is used as the catalyst. This is attributed to the 1,3-diaxial interactions which exist in the THPs when one of the C–C bonds of the tertiary migration origin is forced to enter an axial environment. The orthoester reaction was shown to be general apart from triols with ^{2,4}*anti*,^{4,5}*syn* stereochemistry in which case the intermediate bicyclic orthoester is overstabilised by a 6-*exo* substituent. The subsequent equilibration of the product mixture gives THPs as exclusive products in all cases except for triol precursors with ^{2,4}*syn*,^{4,5}*anti* stereochemistry.

We thank the EPSRC and AstraZeneca for a grant to D. H.

Received (in Liverpool, UK) 12th June 2000, Accepted 7th August 2000
First published as an Advance Article on the web 4th September 2000

The arylazo substituted salt 2 when treated with a base underwent a valence bond isomerization to yield a derivative of the heteroaromatic ring system, [1,2,3]triazolo[4,5-*d*]pyridazine (4).

Recently we have elaborated an easy synthetic pathway to some tricyclic zwitterionic fused pyridazo[1,2,4]triazines[1] (*e.g.* **1**) and have shown that these compounds readily undergo cycloadditions as well as Michael additions.[2] As a continuation of these studies the reactivity of the new zwitterions towards diazonium salts seemed of particular interest.

When the zwitterion **1** was treated with aryldiazonium salts at rt, the change of colour from green to bright red indicated that an azo coupling had taken place. Work-up of the reaction mixture led to the isolation of the stable brilliant red crystalline fluoroborate salt **2**.[3] This salt when treated with a base was converted into the neutral azo compound which decomposed upon storage at rt and a yellow component, as shown by tlc, appeared gradually. This decomposition could be accelerated by heating the suspension of **2** in toluene for a few minutes: a yellow crystalline substance was then formed in good yield. For the structure of this yellow compound the *peri* fused **3** was first anticipated. This could be easily rationalized by assuming attachment to the negatively and positively polarized nitrogen atoms (1,5-dipolar cyclization or 'pseudo-electrocyclization'[4]). Upon observation of some further transformations, however, this conclusion seemed ambiguous and structure **4** (*i.e.* a product of a possible thermal electrocycloreversion of **3**) had to be considered.[5] The ring closure (which might proceed *via* the intermediate *peri*-fused tetracycle **3**, or could also be formed from **2** in one single step) seems to represent a special case of a ring closure to [1,2,3]triazole starting from an azo compound.[6]

Comparison of the heats of formation of **3** (208.0 kcal mol^{-1}) and **4** (164.2 kcal mol^{-1}), calculated for a derivative unsubstituted at the triazole ring by the semiempirical PM3 method,[7] also revealed that the ring-opened form **4** is energetically more favourable (by 44 kcal mol^{-1}). A final decision on this structural problem was provided by an X-ray analysis of the product obtained from **2b** which showed that the isolated compound has in fact the ring-opened structure **4b**, as shown in Fig. 1.

The X-ray analytical data revealed that the bond distances and angles are normal.[8] The endocyclic bond angle at N2 is 116.2(2)°, at N1 and N3 102.5(2) and 102.7(2)°. The bond distances N1–N2 and N2–N3 are 1.336(2) and 1.345(2) Å, shorter than N5–N6 (1.364(2) Å).

The whole molecule is basically planar, with the exception of the pyridine moiety which is perpendicular to the mean molecular plane. A characteristic feature of the crystal packing is the infinite stacking with strong π ring interactions. The centroids of the nirophenyl ring at (*x*,*y*,*z*) and the pyridazine ring at (1 + *x*,*y*,*z*) are 3.52 Å apart (the dihedral angle is 0.81°).[9]

The Schiff base side-chain of **4** easily underwent hydrolysis in the presence of alumina at higher temperature (*i.e.* in boiling xylene) and gave rise to the triazolopyridazinone **5**,[10] a derivative of the heteroaromatic [1,2,3]triazolo[4,5-*d*]pyridazine ring system (saturated[11] and unsaturated derivatives[12,13] of this ring skeleton have been described elsewhere).

The 4-nitrophenyl substituted compounds (*i.e.* **4b** and **5b**) proved to be suitable for transformations to the derivatives containing an unsubstituted triazole moiety. Thus, these compounds when treated with sodium methylate in DMF underwent an *ipso* substitution and afforded the dearylated products **6**[14] and **7**.[15]

Our results reveal that this observed valence bond isomerization provides an easy access to a hitherto unexplored area of triazolopyridazines.

An electron-deficient iron porphyrin complex catalyzes the epoxidation of olefins by *tert*-alkyl hydroperoxides *via radical-free* oxidation reactions in aprotic solvent; the epoxidation reactions were markedly influenced by reaction temperature and high yields of epoxide products were obtained with retention of stereospecificity at low temperature.

The reactions of iron(III) complexes of porphyrin and non-porphyrin ligands with alkyl hydroperoxides have been extensively studied as biomimetic models for heme- and non-heme-containing enzymes.[1] It has been shown in a number of reports that oxidation of hydrocarbons by iron(III) porphyrin complexes and *tert*-alkyl hydroperoxides proceeds *via* O–O bond homolysis (*i.e. free* alkoxyl radical chemistry) in aprotic solvents.[1–3] In addition, Ingold and coworkers evidenced, using 2-methyl-1-phenyl-2-propyl hydroperoxide (MPPH) as a mechanistic probe to distinguish between *free* alkoxyl radical chemistry and *radical-free* chemistry, that O–O bond homolysis is a predominant pathway in non-porphyrin iron complex-catalyzed oxidation of hydrocarbons by *tert*-alkyl hydroperoxides.[1,4] Despite intensive study for the last two decades, it has rarely been observed that simple iron complexes of porphyrin and non-porphyrin ligands are able to catalyze the oxidation of hydrocarbons by alkyl hydroperoxides *via radical-free* chemistry in aprotic solvents.[5,6]† Since we found recently that a highly electron-deficient iron(III) porphyrin complex, $Fe(TF_4TMAP)(CF_3SO_3)_5$ [TF_4TMAP = *meso*-tetrakis(2,3,5,6-tetrafluoro-*N*,*N*,*N*-trimethyl-4-aniliniumyl)porphinato dianion], catalyzes the epoxidation and hydroxylation of hydrocarbons by H_2O_2 *via* radical-free oxidation reactions,[7] we attempted the epoxidation of olefins with the iron porphyrin complex and *tert*-alkyl hydroperoxides such as *tert*-butyl hydroperoxide (Bu^tOOH) and MPPH. Here we report that the epoxidation reactions were markedly influenced by reaction temperature and high yields of epoxide products with retention of stereospecificity were obtained at low temperature.

The catalytic epoxidation of cyclohexene by Bu^tOOH was carried out in the presence of $Fe(TF_4TMAP)^{5+}$ at various reaction temperatures under argon atmosphere in MeCN. As detailed in Table 1, the formation of cyclohexene oxide, cyclohexenol and *tert*-butyl cyclohexenyl peroxide (*c*-$C_6H_{11}OOBu^t$) was observed at room temperature, indicating that the cyclohexene oxidation proceeds *via* free alkoxyl radical chemistry (*i.e.* O–O bond homolysis of Bu^tOOH).[1,8] Interestingly, we found that the product distribution varied depending on reaction temperature. As the reaction temperature was lowered, the yields of cyclohexene oxide increased, while those of allylic oxidation products (*i.e.* cyclohexenol and *c*-$C_6H_{11}OOBu^t$) diminished (Table 1). These results indicate that the reaction of iron(III) porphyrin complex with Bu^tOOH is sensitive to reaction temperature and that two-electron epoxidation becomes a major pathway in the cyclohexene epoxidation at low temperature [Scheme 1(A), pathway A]. Further evidence that the epoxidation of olefins by $Fe(TF_4TMAP)^{5+}$ and Bu^tOOH at low temperature occurs *via* radical-free chemistry was obtained by analyzing products obtained in *cis*-stilbene epoxidation. *cis*-Stilbene was predominantly oxidized to *cis*-stilbene oxide [eqn. (1)],‡ demonstrating that the $Bu^tOO\cdot$ radical was not involved as an epoxidizing agent in the epoxidation reactions.[2,8]

The temperature effect on the reaction of $Fe(TF_4TMAP)^{5+}$ with alkyl hydroperoxides in MeCN was also observed when MPPH was used as an oxidant (Table 1). Only a small amount

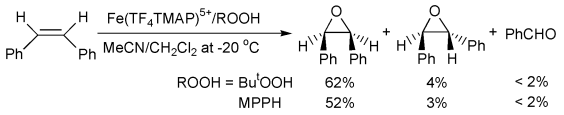
[a] MPPH[4] and *tert*-butyl cyclohexenyl peroxide (*c*-$C_6H_{11}OOBu^t$)[11] were prepared according to literature procedures. All reactions were run at least in triplicate, and the data represent the average of these reactions. [b] In a typical reaction, oxidant (2×10^{-2} mmol diluted in 80 μL of MeCN) was added to a reaction solution containing $Fe(TF_4TMAP)(CF_3SO_3)_5$ (1×10^{-3} mmol) and cyclohexene (0.3 mmol) in 0.3 mL MeCN at the given temperature under an inert atmosphere. After the reaction mixture was stirred for the given time, the reaction solution was directly analyzed by GC or GC–MS with known authentic sample. [c] Yields were based on oxidants added. [d] < 5% of cyclohexenone was formed in all of the reactions. [e] Since methanolysis of cyclohexene oxide took place under the reaction conditions, the yields of cyclohexene oxide were determined by summing the amounts of cyclohexene oxide and 2-methoxycyclohexanol.[12] [f] < 2% based on oxidant added was formed.

DOI: 10.1039/b005162o

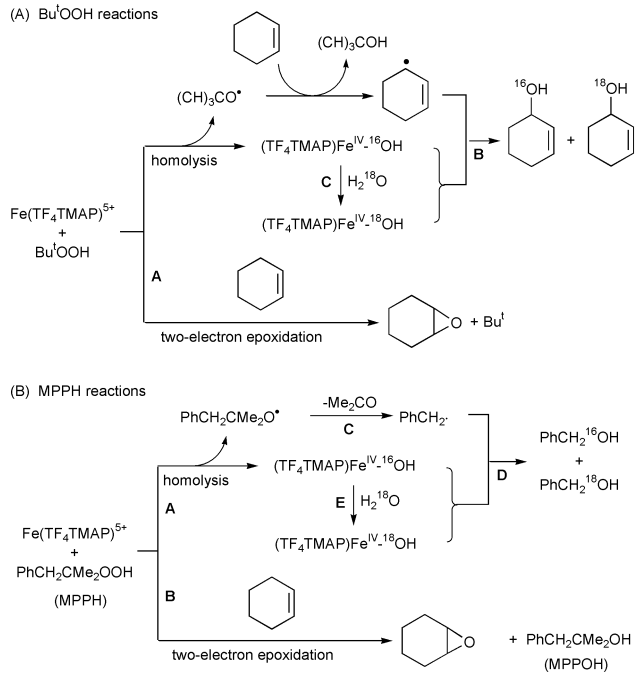


(1)

of cyclohexene oxide was formed and $PhCH_2OH$ was the major product derived from MPPH decomposition at room temperature. This result demonstrates that the reaction of $Fe(TF_4TMAP)^{5+}$ with MPPH occurs *via* O–O bond homolysis [Scheme 1(B), pathway A].[4] As the reaction temperature was lowered, the formation of cyclohexene oxide and $PhCH_2CMe_2OH$ (MPPOH) products increased, indicating that two-electron epoxidation takes place in the reaction of $Fe(TF_4TMAP)^{5+}$ and MPPH at low temperature [Scheme 1(B), pathway B]. When the epoxidation of *cis*-stilbene by $Fe(TF_4TMAP)^{5+}$ and MPPH was performed at low temperature, *cis*-stilbene oxide was obtained as a major product [eqn. (1)].‡ Also, MPPOH was the predominant product of MPPH decomposition (70% based on MPPH used). These results demonstrate unambiguously that the epoxidation of olefins by MPPH at low temperature occurs *via* radical-free chemistry.

Since it is known that methanol is a better solvent for iron porphyrin complex-catalyzed epoxidation of olefins by hydroperoxides,[5] the epoxidation of cyclohexene by Bu^tOOH and MPPH was carried out in a solvent mixture of MeOH and CH_2Cl_2 (3:1). As shown in Table 1, the yields of cyclohexene oxide formed in MeOH–CH_2Cl_2 were higher than those obtained in MeCN. In addition, as observed in the MeCN reactions, the oxide yields in the MPPH reactions increased as the reaction temperature was lowered. Interestingly, *ca.* 80% of MPPH was converted to MPPOH below −20 °C, and, to the best of our knowledge, this is the highest MPPOH formation in iron complex-mediated O–O bond cleavage of MPPH.[4]

We then studied ^{18}O-labeled water experiments in the epoxidation of cyclohexene by Bu^tOOH and MPPH,[9] in order to understand the source of oxygen atoms in cyclohexenol and benzyl alcohol products formed in the reactions of Bu^tOOH and MPPH, respectively.[4b,10] When the epoxidation reactions were carried out in the presence of $H_2{}^{18}O$ at room temperature,§ the percentages of ^{18}O incorporated from the labeled water into cyclohexenol and benzyl alcohol were 21 ± 2 and 14 ± 2%, respectively. The observation that some of the oxygen in the alcohol products came from $H_2{}^{18}O$ demonstrates unambiguously that cyclohexenyl and benzyl radicals were trapped by the $(TF_4TMAP)Fe^{IV}$–OH intermediate [pathway B in Scheme 1(A) and pathway D in Scheme 1(B)].[4b,9,10] The different and relatively small amounts of ^{18}O-incorporation into the cyclohexenol and benzyl alcohol products are ascribed to the fact that the oxygen exchange between the iron(IV)–OH intermediate and labeled water [pathway C in Scheme 1(A) and pathway E in Scheme 1(B)] is competing with the C–O bond-forming step between the intermediate and alkyl radicals [pathway B in Scheme 1(A) and pathway D in Scheme 1(B)].[3,9b]



Scheme 1

In conclusion, we have shown here that high yields of oxide products were formed *via* a *radical-free* mechanism in the epoxidation of olefins by *tert*-alkyl hydroperoxides at low temperature. The oxide yields were found to depend significantly on reaction temperature. In addition, it has been demonstrated unambiguously that alcohol products such as cyclohexenol and benzyl alcohol were formed by the trapping of alkyl radicals by $(TF_4TMAP)Fe^{IV}$–OH species. Future studies will focus on attempts to understand the temperature effect on the mechanism of hydroperoxide O–O bond activation by iron porphyrin complexes and to use the alkyl hydroperoxides in biomimetic alkane hydroxylation reactions.

Notes and references

† Traylor *et al.* reported that epoxidation of olefins by electron-deficient iron(III) porphyrin complexes and Bu^tOOH gives high yields of oxide products in protic solvents (*i.e.* MeOH).[5] We have shown that the reactions of water-soluble iron(III) porphyrins with *tert*-alkyl hydroperoxides epoxidize olefins to give the corresponding oxide products in aqueous solution.[6]

‡ *Reaction conditions*: oxidant (2×10^{-2} mmol, diluted in 80 μL of MeCN) was added to a reaction solution containing $Fe(TF_4TMAP)^{5+}$ (3×10^{-3} mmol) and *cis*-stilbene (0.3 mmol) in a solvent mixture (1 mL) of MeCN and CH_2Cl_2 (1:1) at −20 °C. After stirring for 4 h, the reaction solution was directly analyzed by HPLC.

§ ^{18}O-labeled water experiments with Bu^tOOH and MPPH were performed at 20 °C under the same reaction conditions as described in footnote a of Table 1 except that $H_2{}^{18}O$ (25 μL, 95% ^{18}O enriched) was present in the reaction media. The ^{16}O and ^{18}O compositions in cyclohexenol and benzyl alcohol were determined by the relative abundances of mass peaks at *m*/*z* 83 and 85 for cyclohexenol and at *m*/*z* 108 and 110 for benzyl alcohol.

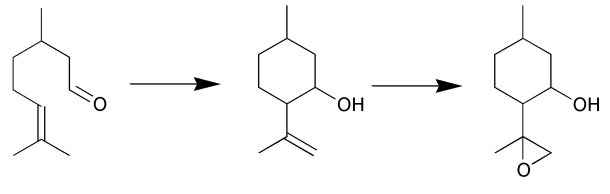
Received (in Liverpool, UK) 26th April 2000, Accepted 4th August 2000
First published as an Advance Article on the web 4th September 2000

Citronellal was converted into isopulegol epoxide in a one-pot two-step reaction achieving a 68% global yield on Ti-MCM-41 and designing a two-solvent catalytic system.

The push of environmental concerns makes bifunctional catalysts the object of growing interest as the tool to reduce the number of steps in a fine chemistry synthesis process.

In a programme aimed at the substitution of homogeneous with heterogeneous Lewis acids in organic synthesis, some of us reported that citronellal **1** (Scheme 1) can be easily cyclized to isopulegol **2** in the presence of acidic mixed oxides.[1] Likewise, we recently reported the epoxidation activity of Ti-containing MCM-41 materials, which easily transform **2** into isopulegol epoxide **3** using *tert*-butylhydroperoxide (TBHP).[2] The high selectivity observed in this reaction, together with the growing interest in isopulegol and related terpenic compounds for uses other than those for the flavour and cosmetic industry (*e.g.* isopulegol derivatives have been claimed to possess a high bactericidal and fungicidal activity[3] and a long-lasting insect repellent action[4]), prompted us to investigate the possibility of obtaining isopulegol epoxide **3** directly from citronellal **1** on the same catalyst.

Preliminary experiments, carried out starting from **1** in the presence of either in-framework or extra-framework Ti-containing MCM-41's, showed that Ti-MCM-41, obtained by grafting an organotitanium precursor onto the MCM-41 surface, leads to better catalytic features than other in-framework Ti-containing solids. This behaviour is also consistent with high conversion values recorded on this mesoporous material, when the epoxidation step is carried out separately (Table 1; tests 5 and 6).



1 **2** **3**

Scheme 1

As in other examples, where an epoxidation reaction is coupled to an acid-catalysed one,[5] the choice of the solvent is not trivial. In fact, while the cyclization reaction is easily carried out in apolar hydrocarbons, *i.e*. n-heptane or toluene (tests 1 and 2), the best results in the epoxidation reactions are achieved in aprotic polar solvents, *i.e.* acetonitrile or ethylacetate, which are bad solvents for the first-step reaction (tests 3 and 4). Therefore, the use of a unique solvent throughout the two-step reaction appeared to be hardly feasible. Moreover, to avoid the oxidation of the non-reacted citronellal **1** by TBHP, it is advisable to add the oxidant after the complete conversion of **1** into **2**. In fact, whenever TBHP is added at the beginning of the cyclization step, a plethora of products is registered, among which is menthone. So, during the first 6 h of reaction the intramolecular cyclization was performed in apolar hydrocarbon. After that time an equal volume of polar solvent was added together with the required TBHP aliquot.

Ti-MCM-41 has been prepared in the following way: MCM-41 was synthesized according to procedures developed by Mobil researchers.[6] Titanium was grafted onto the MCM-41 surface using titanocene dichloride as precursor following the procedure described by Maschmeyer *et al.*[7] Details about the preparation of the samples are reported in ref. 2. The Ti content, determined by ICP-atomic emission spectroscopy, of the Ti-MCM-41 sample was 1.88 wt.%. The specific surface area (BET), the total pore volume and the effective mean pore diameter of the solid were 860 m^2g^{-1}, 0.52 cm^3g^{-1} and 2.3 nm, respectively. The mesoporous solid was pretreated by heating at 773 K for 1 h in air. The catalytic reactions were carried out in a glass batch reactor at 363 K under anhydrous nitrogen using acetonitrile and toluene or n-heptane and ethyl acetate as solvents, anhydrous TBHP as oxidant (oxidant : substrate molar ratio = 1.1) and 15 wt.% catalyst with respect to the substrate citronellal **1**. The solvent : citronellal volume ratio is 25. The samples taken during the 24 h reaction were analysed by gas chromatography (FID detector; mesitylene as internal standard). The products were identified by GC-MS and NMR spectroscopy.

It is worth noting that pure MCM-41 (without titanium) was completely inactive, while some amorphous silica is able to catalyse the cyclization reaction.[1,8] This confirms that the Ti-

free mesoporous material is lacking in acidic sites and also that the presence of titanium(IV) in a siliceous matrix gives rise by itself to a material containing both redox and acidic properties.[9] Besides, the introduction of trivalent metal ion, although widely used in bifunctional catalysts,[10,11] appears to be redundant. The use of a MCM-41 sample containing both titanium (1.91 wt.% grafted from titanocene) and aluminium (0.59 wt.% inserted by isomorphous substitution for Si) did not lead to a remarkable improvement in catalytic features: the Al insertion shortens the first-step reaction time (cyclization is complete after 2 h), leaving the second-step reaction time and selectivity (74% conversion of **2** and 88% selectivity to **3** after 18 h in toluene + acetonitrile) practically unaffected.

Both toluene and n-heptane exhibit a complete and selective conversion of **1** into **2** within 6 h and this is consistent with the results obtained on amorphous mixed-oxide TiO_2–SiO_2.[1] The reaction time is rather longer, but is necessary to avoid the presence of unreacted citronellal in the second step.

In the epoxidation step, as in the tests on other terpenic unsaturated alcohols,[2] acetonitrile (test 7) showed better performances than ethyl acetate (test 8). This behaviour might be attributed to the weakly basic character of acetonitrile that inhibits the formation of acid-catalysed secondary products from isopulegol epoxide **3**.[12] The main by-product formed in the second-step reaction is isopulegone, *i.e.* 5-methyl-2-(1-methylethenyl)cyclohexanone.

With the purpose of obtaining a deeper insight about the heterogeneity of the system,[13] the reaction mixture was carefully filtered at *ca*. 50% conversion (2 h reaction) in the second step. Testing the colourless filtered solution for further reaction, no activity of the liquid mixture was observed. From this behaviour, the observed catalyst is presumably heterogeneous. Because of the intrinsic low chemical and mechanical stability of MCM-41-based materials,[14] work is in progress to verify whether or not the catalyst is stable and recyclable.

In summary, the best result for the one-pot conversion of citronellal into isopulegol epoxide with a *ca*. 68% global yield was achieved on Ti-MCM-41 as follows. Toluene was used as the solvent for the 6 h long cyclization step during which all the citronellal **1** was completely and selectively converted into isopulegol **2**. Then, after the addition of TBHP and acetonitrile, over the following 18 h isopulegol **2** was epoxidised to **3** with a 76% conversion and a 90% selectivity (test 7).

In this reaction, employing Ti-MCM-41 obviates the use of homogeneous catalysts in both steps, namely zinc halides in the first and transition metal complexes or peroxy acids in the second, thereby limiting the waste production to the work-up phase, when the TBHP in excess has to be quenched. Such bifunctional behaviour is to be attributed to the high dispersion of Ti^{IV} onto the surface of the mesoporous solid, which brings acidity into the silica matrix and causes the excellent activity in the epoxidation step.

The authors gratefully acknowledge the CNR-MURST for financial support through the 'Program Chemistry Law 95/95-I year'.

Generation of metalloenamines by carbon–carbon bond formation: ring opening reactions of 2-methyleneaziridines with organometallic reagents

Jerome F. Hayes,[a] Michael Shipman*[b] and Heather Twin[b]

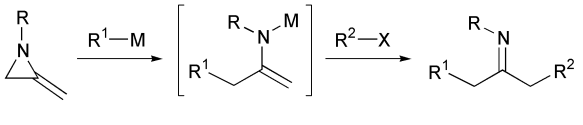
First published as an Advance Article on the web 4th September 2000

Ring opening of 2-methyleneaziridines with Grignard reagents in the presence of CuI yields metalloenamines in a regiospecific fashion which can be further reacted with electrophiles to produce functionalised ketones *via* a one-pot process.

Following their introduction independently by Stork[1] and by Wittig,[2] metalloenamines (metallated imines) have become established as one of the best methods of forming carbon–carbon bonds at the α-carbon atom of aldehydes and ketones.[3] Metalloenamines are known to be extremely reactive and undergo clean *C*-alkylation reactions with a wide range of electrophiles including primary and secondary alkyl halides, aldehydes, ketones, nitriles, epoxides and oxetanes. Consequently, alkylation reactions of these carbanions are widely used in organic synthesis. Metalloenamines are traditionally made by deprotonation of the corresponding imine using a strong base such as EtMgBr or LDA. One limitation with this method stems from the fact that regiochemical control in the enolisation process is not always possible when imines derived from unsymmetrical ketones are used, resulting in mixtures of alkylated products being formed.[4] Few alternative methods for the generation of metalloenamines have been developed, with the only notable contributions being made by Wender.[5] We imagined that ring opening of 2-methyleneaziridines with organometallic reagents might provide an alternative entry into metalloenamines, as depicted in Scheme 1. We felt that this conceptually new approach to metalloenamines might offer two significant advantages over the traditional route to such species by way of imine enolisation. Firstly, the overall transformation would result in the formation of two new carbon–carbon bonds and thus could be considered as an efficient and potentially highly flexible three-component coupling reaction. Secondly, the ring opening of the aziridine might be expected to provide the metalloenamine as a single regioisomer, circumventing problems associated with regioselectivity in the deprotonation of unsymmetrical imines. Here, we describe our preliminary results regarding the ring opening reactions of 2-methyleneaziridines with organometallic reagents and demonstrate their potential as metalloenamine precursors.

At the outset of this study, no ring opening reactions of methyleneaziridines using carbon based nucleophiles had been reported.[6,7] Initially, we chose to investigate the ring opening reactions of methyleneaziridine (±)-**1** (R = CHMePh) as it is very easy to prepare on a multigram scale.[8] Since Ganem has shown that simple *N*-alkylated aziridines can be ring opened with Gilman-type cuprates in the presence of boron trifluoride ethereate,[9] we anticipated that these conditions might effect ring opening of 2-methyleneaziridines. Gratifyingly, treatment of



where M = metal, X = leaving group

Scheme 1

methyleneaziridine **1** (R = CHMePh) with Bu_2CuLi (1.5 equiv.) and $BF_3{\cdot}OEt_2$ (1.5 equiv.) in THF (−78 → 0 °C) and subsequent hydrolysis with aqueous acid furnished heptan-2-one in 40% isolated yield after distillation. Further studies determined that this ring opening reaction can be accomplished more conveniently using BuMgCl in the presence of $BF_3{\cdot}OEt_2$ and a catalytic amount of CuI (Table 1, entry 1). The modest isolated yield observed for the formation of heptan-2-one is due to its volatility, as the chemical conversion is excellent as judged by GC analysis using an internal standard. The copper catalysed ring opening of methyleneaziridines with Grignard reagents appears general and we have used it to make a variety of methyl ketones **2** in moderate to good yields (Table 1).† Importantly, in control experiments, we have determined that at low temperatures, both CuI and the Lewis acid are essential for rapid ring opening to occur.

Our initial attempts to alkylate the presumed metalloenamine intermediate produced by ring opening of methyleneaziridine **1** (R = CHMePh) with BuMgCl, CuI and $BF_3{\cdot}OEt_2$ were entirely unsuccessful. Introduction of an electrophile such as BnCl into the vessel prior to aqueous hydrolysis did not result in the formation of any further alkylated products. Control experiments using a metalloenamine made by the traditional method of imine deprotonation using EtMgCl revealed that the presence of $BF_3{\cdot}OEt_2$ in the reaction mixture completely suppresses alkylation reactions of the metalloenamine. To overcome this problem, we sought conditions to effect the ring opening of 2-methyleneaziridines with organometallic reagents in the absence of an added Lewis acid. After further experimentation, we determined that the ring opening could be achieved using Grignard reagents in the presence of CuI (20 mol%) by warming the mixture to room temperature and stirring for an extended period (24 h) prior to introduction of the electrophile. Using these conditions, treatment of methyleneaziridine **1** (R = CHMePh) with BuMgCl then BnCl yielded alkylated ketone **4** in 78% isolated yield after imine hydrolysis and silica gel

chromatography (Scheme 2).‡ Significantly, the formation of metalloenamine **3** is highly regiospecific, and no trace of 3-benzylheptan-2-one could be detected in the crude reaction mixture.§

We have extended the scope of this method of metalloenamine generation to other Grignard reagents and electrophiles (Table 2).† Moderate to good yields of products are obtained in all cases and the method provides a flexible and efficient approach to functionalised ketones. The only notable limitation with this chemistry is the requirement to use excess Grignard reagent (3 equiv.) to drive the reaction to completion. Currently, we are searching for more active copper catalysts in an effort to address this problem. Future work will also be aimed at extending the scope of this method and to applying it in natural product synthesis.

[a] All reactions performed with 3 equiv. of Grignard reagent and 2 equiv. of electrophile unless otherwise stated. [b] Refers to yield of purified product after work-up and purification by silica gel chromatography. [c] Performed using 1.5 equiv. of electrophile.

We are grateful to the EPSRC and SmithKline Beecham Pharmaceuticals for their generous financial support of this work. We are indebted to Julie Ince and David Ennis for their assistance at the early stages of this project. We thank the EPSRC National Mass Spectrometry Centre for performing some of the mass spectral measurements and the EPSRC Chemical Database Service at Daresbury.[10]

Notes and references

† All new compounds were fully characterised using standard spectroscopic and analytical methods.

‡ *Typical procedure:* CuI (48 mg, 0.252 mmol) in a round-bottomed flask was heated under vacuum then purged with nitrogen (3 cycles performed). Freshly distilled THF (4 ml) was added and the mixture cooled to −30 °C whereupon BuMgCl (2.0 M in THF, 1.89 ml, 3.78 mmol) was added. After stirring for 10 min, *N*-(1-phenylethyl)-2-methyleneaziridine (200 mg, 1.26 mmol) in THF (2 ml) was added. The reaction mixture was allowed to warm up to room temperature and stirred for 24 h. The flask was then cooled to 0 °C and BnCl (218 μl, 1.89 mmol) added dropwise. A reflux condenser was fitted and the reaction mixture heated at 40 °C for 2 h then allowed to cool to room temperature and stirred overnight. Finally, 10% aq. HCl (3 ml) was added, and the mixture heated at 50 °C for 2 h (for all other entries in Table 2, imine hydrolysis was effected using 1 M AcOH–hexane at rt). Upon cooling, solid NaCl was added and the mixture extracted with Et_2O. The combined organic layers were washed with 0.5 M aq. HCl (2 × 15 ml), saturated NH_4Cl (2 × 20 ml), saturated $NaHCO_3$ (2 × 20 ml) and brine (2 × 20 ml). The organic layer was dried ($MgSO_4$) and the solvent removed *in vacuo*. Column chromatography on silica gel (2.5% EtOAc in hexane) gave 1-phenyloctan-3-one (201 mg, 78%) as a yellow oil. ν_{max} (thin film) 2947, 2931, 2856, 1713, 1450 cm^{-1}; δ_H (400 MHz, $CDCl_3$) 7.30–7.17 (5H, m, Ph), 2.89 (2H, m), 2.72 (2H, m), 2.37 (2H, t, *J* 7.6), 1.56 (2H, m), 1.30–1.21 (4H, m), 0.88 (3H, t, *J* 7.2); δ_C (100.9 MHz, $CDCl_3$) 210.5 (s), 141.2 (s), 128.5 (d), 128.3 (d), 126.1 (d), 44.3 (t), 43.0 (t), 31.4 (t), 29.8 (t), 23.5 (t), 22.5 (t), 13.9 (q); Observed 204.1519; $C_{14}H_{20}O$ requires 204.1514.

Organoimido-polyoxometalates as polymer pendants†

Aaron R. Moore, Haidoo Kwen, Alicia M. Beatty and Eric A. Maatta*

Department of Chemistry, Kansas State University, Manhattan, Kansas 66506-3701 USA. E-mail: eam@ksu.edu

Received (in Irvine, CA, USA) 20th June 2000, Accepted 2nd August 2000

The *p*-styrenyl substituent borne by the organoimido ligand in the Lindqvist derivative $[NBu_4]_2[Mo_6O_{18}(NC_6H_4CH{=}CH_2)]$ 1 allows the polyoxometalate complex to be introduced as a pendant group in polystyrene compositions *via* conventional free radical-induced copolymerization.

Research involving polyoxometalates[1]—the multimetallic oxo-anions formed by Mo, W, V and, to a lesser extent, Nb and Ta—continues to increase in scope and pace, driven by the goal of harnessing these species' remarkable and versatile attributes for catalytic, medical and imaging applications, and for use in magnetic and photo- and electro-chromic materials.[2] In their solid state applications, polyoxometalates generally are employed as components embedded heterogeneously within various matrices, rather than as covalently bound integral elements.[3] The covalent incorporation of polyoxometalates into conventional polymeric systems therefore may provide additional opportunities for their technological development.

There are few examples of polymers bearing covalently attached polyoxometalate species. Knoth[4] has described the 'all-inorganic' polymer $[(OC)_3CoGe_2W_{11}SiO_{40}^{5-}]_n$. Difunctional polyoxotungstates $[(RSiOSiR)W_{11}SiO_{39}]^{4-}$ have been homo-polymerized by Judeinstein[5] and incorporated into siloxane compositions by Katsoulis and Keryk.[6] Very recently, Mayer, Thouvenot *et al.*[7] have reported well characterized acrylamide and methacrylate networks cross-linked by the polyoxometalates $[\gamma\text{-}SiW_{10}O_{36}(RSiO)_4]^{4-}$ or $[\gamma\text{-}SiW_{10}O_{36}(RSiOSiR)]^{4-}$ [R = $C_3H_6OC(O)C(Me){=}CH_2$]. Here, we describe a different approach to organic polymers bearing polyoxometalate pendants, involving co-polymerization of the styrylimido ligand in the Lindqvist derivative $[NBu_4]_2[Mo_6O_{18}(NC_6H_4CH{=}CH_2)]$ **1**.

Reaction of $[NBu_4]_2[Mo_6O_{19}]$ with $Ph_3P{=}NC_6H_4CH{=}CH_2$ in pyridine solution at 90 °C produces $Ph_3P{=}O$ and the red styrylimido-hexamolybdate complex **1** in high yield (Scheme 1).‡ To our knowledge, **1** represents the first example of a styrylimido complex.[8] In MeCN solution, cyclic voltammetry of **1** reveals a one-electron reduction at $E_{1/2}$ = − 886 mV (*vs.* Ag/Ag^+); this value is more negative than that of the $[Mo_6O_{19}]^{2-}$ parent ($E_{1/2}$ = −707 mV) and is typical of other monosubstituted $[Mo_6O_{18}(NR)]^{2-}$ systems.[9] **1** is soluble in polar organic solvents such as 1,2-dichloroethane and its solutions display good hydrolytic stability: the deliberate addition of H_2O (*ca.* 15 equiv.) to a CD_3CN solution of **1** produced no detecable amount of 4-vinylaniline after 4 d at 25 °C as monitored by ^1H NMR spectroscopy.

Crystals of **1** were grown by diffusion of Et_2O vapor into an acetonitrile solution, and the molecular structure was determined by X-ray crystallography (Fig. 1).§ The styrylimido ligand occupies a terminal position on the hexamolybdate cage and its metrical parameters [Mo(1)–N(1) 1.728(7) Å, Mo(1)–N(1)–C(1) 159.9(7)°] indicate substantial [Mo≡NR] triple bond character. Along the Mo(1)–O(1)–Mo(5) axis, the central O(1) atom is substantially nearer to the imido-bearing Mo(1) site [2.223(5) Å] than to the *trans* oxo site Mo(5) [2.353(5) Å].

Co-polymerization of **1** (0.50 g, 0.34 mmol) and 4-methylstyrene (0.16 g, 1.34 mmol) initiated by AIBN [2,2′-azobis(2-methylpropionitrile), 0.010 g, 0.061 mmol] was conducted in 1,2-dichloroethane (5 mL) at 60 °C for 48 h, and led to the separation of an oily brown insoluble residue (0.435 g) from the brown solution. Dissolution of this residue in acetonitrile (10 mL), filtration to remove a small amount of gummy material, and evaporation to dryness afforded a green–brown solid **2**. In the IR spectrum of **2**, no bands were observed in the vinylic ν(C=C) region, and the presence of an imido-substituted hexamolybdate was confirmed by its characteristic 'doublet' pattern in the $\nu(Mo{-}O_t)$ stretching region [975(sh), 952s cm^{-1}]. The ^1H NMR spectrum of **2** taken in CD_3CN revealed features consistent with the formation of the expected co-polymer of **1** and 4-methylstyrene: the vinylic resonances of both precursors had disappeared; a pair of broadened aryl resonances were observed centered at δ *ca.* 7.0 and 6.5; a broad signal at δ 2.3 was assignable as the CH_3 resonance of the 4-methyl styrene component; the resonances of the $[NBu_4]^+$ cations were observed as virtually unbroadened signals in their characteristic regions; and broadened resonances assignable as the methine and methylene units of the polymer backbone were observed in the range δ 1.8–1.5 overlapped with the resonances of the interior CH_2 groups of the $[NBu_4]^+$ cations. A comparison of the relative intensities due to the aryl groups, the α-CH_2 groups of the $[NBu_4]^+$ cations, and the styrenic CH_3 group suggested a

composition for **2** of nearly three 4-methyl styrene units per unit of **1**, as indicated in Fig. 2. Elemental analysis of **2** is consistent with this formulation. Molecular weight determinations of **2** are in progress.[10]

This work demonstrates that the styrylimido ligand can be employed as a reactive site capable of delivering its metal complex into a conventional polymeric environment. Similar methodology should be broadly applicable to the synthesis of other new classes of hybrid inorganic/organic polymers which incorporate covalently attached organoimido-metal complexes as exploitable backbone substituents. Further characterization of the properties of **2** is underway, as are studies on a variety of other polymerizable organoimido systems.

We are grateful to the United States Department of Energy, Office of Basic Energy Sciences, for support of this work.

Department of Chemistry, Graduate School of Science, Hiroshima University, Kagamiyama, Higashi-Hiroshima 739-8526, Japan. E-mail: skojima@sci.hiroshima-u.ac.jp

Received (in Cambridge, UK) 2nd June 2000, Accepted 3rd August 2000
First published as an Advance Article on the web 4th September 2000

The Peterson reaction of triphenylsilylacetamide Ph_3Si-CH_2CONBn_2 with aromatic aldehydes and certain aliphatic aldehydes proceeded to give the corresponding *α,β*-unsaturated amide with high *Z* selectivity (up to *Z*:*E* = > 97 : < 3).

Geometry-defined olefins serve as good building blocks in organic synthesis. Of particular utility are olefins bearing electron-withdrawing groups, such as the ester group, since not only are these groups viable of further functionalization, but they also activate the olefin moiety for reactions such as Michael addition and pericyclic reactions. While it is rather facile to obtain disubstituted *E*-olefins bearing an electron-withdrawing group with high selectivity from aldehydes, only a few methods are available for moderate to highly selective preparation of the thermodynamically less stable *Z*-olefins, and so far they have been limited to the ester,[1–5] the cyano,[6,7] and the recently reported methyl ketone group.[8] For disubstituted *Z*-olefins bearing an amide group, it would be desirable to have a direct method of preparation from an aldehyde, especially for multifunctional carbonyl compounds. Peterson olefination with reagents bearing a trimethylsilyl (TMS) group has been widely utilized as a useful complementary reaction to that of Wittig type.[9] However, for disubstituted olefins with electron-withdrawing groups, the selectivity observed for this reaction is generally low (even for *E*-olefins) compared with its phosphorus counterpart. Previous amide formation with Peterson reagents bearing the TMS group is no exception.[10] Thus, based upon the notion that a more bulky and more electronegative silyl group would shift the selectivity towards the *Z*-olefin, we examined a reagent bearing the triphenylsilyl group, which had previously proved to be effective in combination with the cyano group.[6] In accordance with expectations, we have realized the first highly *Z*-selective preparation of α,β-unsaturated amides. Herein we describe our results.

The Peterson reagents **1a**,**b** examined for the reactions were prepared by treating the lithium enolate of *N*,*N*-dibenzylacetamide with Ph_3SiCl or Me_3SiCl, regioselectively giving the *C*-silylated products in moderate yield.[10,11] The results of using the triphenylsilyl reagent **1a** are given in Table 1. Since a countercation effect is usually observed for the analogous Horner–Wadsworth–Emmons (HWE) reaction, the examination of various metal-containing bases was first carried out in the reaction with benzaldehyde. The effect of the countercation proved to be quite significant as the ratio of *Z*-amide increased from 54 : 46 with *n*-BuLi to 80 : 20 with NaHMDS, and an exclusive > 97 : < 3 with KHMDS‡ (entry 1). In the case of *n*-BuLi, the reaction temperature was gradually raised from −78 to 0 °C in order to effect reaction. More common bases such as NaH and *t*-BuOK were found to be unsuitable. The reaction of **1a** and 3-phenylpropionaldehyde with KHMDS as base (entry 8) was also found to be *Z*-selective, although not quite as high as with benzaldehyde. In seeking a possible improvement in selectivity, an examination of solvents was carried out. However, neither a decrease (ether, 74 : 26, 15%) or increase (THF–HMPA mixture, 71 : 29, 64%) in polarity proved fruitful. Lowering of the reaction temperature to −95 °C led to a slight increase in selectivity to 94:6 but with a lower yield of 58%.

Table 1 Peterson reaction of $Ph_3SiCH_2CONBn_2$ (**1a**) with various aldehydes[a]

Entry	R	*Z*:*E*[b]	Yield (%)[c]
1	Ph	> 97 : < 3	88
2	*p*-$MeOC_6H_4$	> 97 : < 3	87
3	*o*-$MeOC_6H_4$	81 : 19	72
4	*p*-ClC_6H_4	88 : 12	91
5	2-Furyl	91 : 9	92
6	2-Pyridyl	59 : 41	47
7	(*E*)-PhCH = CH	81 : 19	99
8	$PhCH_2CH_2$	91 : 9	77
9	*c*-Hexyl	83 : 17	82

[a] All reactions were carried out in THF at −78 °C with KHMDS as base. [b] Determined by 500 MHz ^{1}H NMR measurement of crude mixture. [c] Combined isolated yield of *E* and *Z* olefins.

Under the standard conditions of using THF and KHMDS at −78 °C, other aldehydes were examined.§ For 4-substituted benzaldehyde derivatives, a drop-off in selectivity was observed with the electronegative Cl substituent (entry 4), but remained high with the electron-donating MeO group (entry 2). Although sterically hindered 2-substituted aromatic aldehydes are usually more *Z*-selective than their 4-substituted counterparts in HWE reactions, with the MeO group the Peterson reaction here gave lower selectivity (entry 3). With heterocyclic aldehydes, the highly electronegative pyridylaldehyde showed very low selectivity (entry 6), whereas that of furfural was highly *Z*-selective (entry 5). The conjugated *E*-cinnamaldehyde also furnished the *Z*-product as the predominant isomer (entry 7).

As for other aliphatic aldehydes, whereas α-branched 2-phenylpropionaldehyde did not react, the same α-branched cyclohexanecarboxyaldehyde did, giving the *Z*-olefin as the major product (entry 9). This indicates that with readily enolizable aldehydes, enolization is favoured over the olefination reaction. Apparently due to steric factors, pivalaldehyde was unreactive.

The 4-substituent effect observed with KHMDS as base was more profound upon using *n*-BuLi as base, with the *Z*-selectivity decreasing with increasing electron-withdrawing ability; from 69 : 31 with *p*-$MeOC_6H_4CHO$ to 54 : 46 with benzaldehyde and 43 : 57 with *p*-ClC_6H_4CHO.

The efficacy of the triphenylsilyl group was confirmed by making comparisons with reactions of trimethylsilyl reagent **1b**

using KHMDS as base, as shown in Table 2.[10] The reaction of **1b** with benzaldehyde resulted in a complete turnaround in selectivity, favouring *E*-olefin formation (entry 2) while that with 3-phenylpropionaldehyde gave no olefin product (entry 5). The effectiveness of the amide group for high *Z*-selectivity was exhibited by comparing corresponding reactions of an ester analogue **2**. The reaction of ethyl triphenylsilylacetate with benzaldehyde (entry 3) and 3-phenylpropionaldehyde (entry 6) with KHMDS as base gave the corresponding electron-deficient olefin as $Z:E$ = 71 : 29 and 77 : 23 mixtures, respectively, which are clearly inferior ratios compared with those of corresponding amide reactions (entries 1, 4). Thus, we have the general trend in which the larger the electron-donating ability of the group directly attached to the carbonyl group in both the aldehyde and the silyl reagent, the higher the *Z*-selectivity tends to be. Considering these electronic effects, the results we have obtained here fit in well with the generally accepted mechanism which involves an intermediate formed by rearrangement of the silyl group from a carbon to an oxygen atom, preceding olefin formation.[12]

In summary, we have developed a highly geometry-selective method of preparing *Z*-unsaturated amides based upon the Peterson reaction. Further examination of substituent effects are underway.

Notes and references

‡ Olefin geometries were determined by the coupling constants and chemical shifts of the olefinic protons, and were verified by NOE experiments for representative products.

§ The general procedure for the Peterson reaction is given as follows as the example of the reaction of benzaldehyde. To a solution of **1a** (206 mg, 0.415 mmol) in THF (4 mL) cooled to −78 °C was added KHMDS (0.5 M in toluene, 0.98 mL, 0.49 mmol). After stirring for 30 min at 0 °C, the solution was recooled to −78 °C. To this solution was added benzaldehyde (39.0 mg, 0.368 mmol) in THF (2.5 mL), and stirring was continued for 3 h. Water was then added to quench the solution, and extraction was carried out with ether. After the usual workup and chromatographic purification by preparative TLC (SiO_2; hexane : ethyl acetate = 5 : 1), (*Z*)-*N*,*N*-dibenzylcinnamamide (106 mg) was obtained as a viscous oil in 88% yield.

First published as an Advance Article on the web 4th September 2000

Non-covalent immobilization of [(*R*,*R*)-Me-(DuPHOS)Rh-(COD)]OTf by interaction of the triflate counter ion with surface silanols of silica supports leads to an active, stable, enantioselective, asymmetric hydrogenation catalyst.

We have found that cationic rhodium complexes containing chiral bidentate phosphines can be non-covalently immobilized on silica surfaces. This method, which should be general for ionic catalysts, enables the 'heterogenization' of readily available enantioselective catalysts, and avoids the tedious and often difficult task of ligand modification involved in numerous previously described covalent approaches for the immobilization of homogeneous catalysts on solid supports. We demonstrate this concept through the immobilization of [(*R*,*R*)-Me-(DuPHOS)Rh(COD)]$^+$ trifluoromethane sulfonate [Me-DuPHOS = 1,2-bis(2,5-dimethylphosphacyclopentyl)ethane] on mesoporous MCM-41 and silica gel which leads to a recyclable, non-leaching asymmetric hydrogenation catalyst with activity and selectivity equal to or greater than the homogeneous reaction. We also provide chemical and spectroscopic evidence for the mechanism of immobilization of these catalysts on silica surfaces.

The goal of heterogenization of homogeneous catalysts is to combine the superior activity and selectivity offered by homogeneous catalysts with the ease of separation and recycling of heterogeneous catalysts.[1–3] To date, the main approach for immobilizing homogeneous catalysts on solid supports involves covalent attachment of functionalized ligands or ligand–metal complexes which typically requires multistep syntheses.[4,5] Recently, hydrogen bonding between a sulfonated ligand and surface silanols has been demonstrated to lead to the immobilization of an achiral rhodium hydrogenation catalyst.[6] This approach requires the sulfonation of aryl phosphines, which, while possible, also requires multistep syntheses for chiral phosphine ligands.

Our studies focused on mesoporous silica, such as MCM-41, as a solid support due to the large, tailorable and well defined pore structure, high surface area and high area density of surface silanols found in this class of silicas.[3,7] Orange solutions of [(*R*,*R*)-Me-(DuPHOS)Rh(COD)]OTf **1**[8] (OTf = trifluoromethanesulfonate, triflate) in CH_2Cl_2 rapidly decolorized upon addition of MCM-41[9] and stirring. The powder X-ray diffraction pattern of the isolated orange powder (**2**) remains unchanged from the unfunctionalized MCM-41. Quantitative loading of the organometallic complex was demonstrated by thermal gravimetric analysis which showed 5.26% weight loss (calc. 5.29 wt%) and elemental analysis which gave 1.03 wt% Rh (calc. 0.96 wt%). The BET surface area was found to decrease from 953 $m^2\ g^{-1}$ in the unfunctionalized MCM-41 to 854 $m^2\ g^{-1}$ for composite **2** with a corresponding decrease in mesopore volume from 1.003 to 0.840 $cm^3\ g^{-1}$; this is consistent with partial mesopore filling by the organometallic catalyst.[10] While this work was in progress, Augustine and Tanielyan demonstrated that cationic rhodium complexes could be sorbed onto heteropolyacids to yield recyclable catalysts.[11a]

^{31}P and ^{19}F NMR spectra of the free and bound complexes (**1** and **2**) suggest that it is the triflate counter ion that interacts strongly with the support in **2**. The ^{31}P NMR spectrum (unlocked) of a slurry of **2** in CH_2Cl_2 shows a doublet at δ_P 76.6 (J_{RhP} 147 Hz) which is considerably broader [$\nu_{1/2}$ 130 Hz, Fig. 1(b)] than that for the free complex **1** in solution [$\nu_{1/2}$ 30 Hz, Fig. 1(a)]. The corresponding ^{19}F NMR spectra are shown in Fig. 2. The sharp singlet ($\nu_{1/2}$ 50 Hz) for the homogenous system [Fig. 2(a)] is broadened considerably ($\nu_{1/2}$ 575 Hz) in the spectrum of a slurry of **2**. The line broadening seen in both the ^{19}F and the ^{31}P NMR spectra of **2** is consistent with restricted mobility of the organometallic complex within MCM-41, as would be expected for a heterogenized molecule.[12]

The counter anion is very important for the successful immobilization of the catalyst onto MCM-41. Whereas the triflate DuPhos–Rh complex **1** was effectively immobilized, the analogous complex with the lipophilic BAr_F anion {BAr_F = $B[C_6H_3(CF_3)_2\text{-}3,5]_4$[13]} [(*R*,*R*)-Me-(DuPHOS)Rh(COD)]$^+$ BAr_F^- **3**, does not 'load' onto the support; solutions of **3** in CH_2Cl_2 remained orange upon addition of MCM-41. Indeed, addition of $NaBAr_F$ to a slurry of **2** in solvent caused the solvent to take on the characteristic orange color and ^{31}P NMR spectrum [$\nu_{1/2}$ 35 Hz, Fig. 1(c)] of dissolved [(*R*,*R*)-Me-(DuPHOS)Rh(COD)]$^+$, indicating release of the Rh cation from the support. The ^{19}F spectrum of the triflate ion, however, remains broad and unchanged [Fig. 2(c)] indicating the triflate is still immobilized on the support. The lack of immobilization of **3** onto the support, and the lack of exchange of bound triflate for BAr_F^- implies that triflate is strongly bound to the support and interacts with and binds the [(*R*,*R*)-Me-(DuPHOS)Rh-(COD)]$^+$ fragment to the MCM-41, a role BAr_F^- does not fulfill.[14] The mechanism of triflate binding is likely hydrogen bonding, similar to that demonstrated by Bianchini's group in the immobilization of an achiral sulfonated phosphine–rhodium

B	None	MeOH	R.T. (90 psi)	OTf	> 99	96.2
C	MCM-41	Hexane	R.T.	OTf	> 99	98
C	None	Hexane	R.T. (40 psi)	BAr_F[a]	26	85
C	None	MeOH	R.T. (90 psi)	OTf	99	96

[a] The lipophilic BAr_F^- anion is more soluble than OTf^- and provided more consistent results than the OTf salt. See also ref. 13.

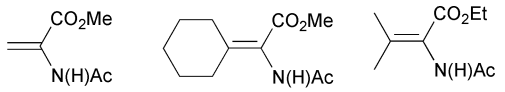

Fig. 3 Substrates utilized for catalytic hydrogenation studies.

complex to silica by hydrogen bonding.[6] Unfortunately, because of the low level of loading of the highly active catalyst (see below), we could not confirm the presence of hydrogen bonding using IR spectroscopy. Further work on other catalyst systems is underway. Other evidence that surface hydroxy groups may be involved in immobilization was found on studies of MCM-41 supports that were pretreated with trimethylsilyl chloride to protect the hydroxy groups. These supports were much less effective in immobilizing complex **1** (1.9 *vs*. 6.7 wt% based on Rh). We have found that other silica supports such as commercial silica gel, which are known to contain fewer surface silanols,[3] also led to significantly lower loadings of **1**.

The immobilized complex **2** was found to exhibit high catalytic activity, selectivity and recoverability for the hydrogenation of three prochiral α-enamide esters, used as test substrates. Hydrogenation of enamide **A** (Fig. 3) in hexane using **2** led to complete conversion with high enantioselectivity. As shown in Table 1, the immobilized catalyst **2** led to higher activity and selectivity than the homogeneous catalyst in hexane for the β,β-disubstituted substrates **B** and **C**,[15] and rivals the enantioselectivity reported in MeOH.[15] For example, **B** was hydrogenated with 98% ee with **2** as the catalyst in hexane while the optimized reaction with unsupported **3** gave 96% ee in MeOH and 93% ee in hexane.[15] Even more striking, the conversions for enamide **C** were significantly higher using the immobilized catalysts rather than the homogeneous analog in hexane, where conversion was only 26% (85% ee) with unsupported **3** in hexane after 22 h at 40 psi, while the reaction with **2** was complete (98% ee) after 16 h at 8 psi. Few reports[11] of such a positive influence on activity and selectivity for heterogenized catalysts exist. Other silica supports, including commercial silica gels, can be used to immobilize **1**; however, decreased loading (and therefore activity) was observed.

The recyclability of the immobilized catalyst was demonstrated using standard procedures. After completion of the initial hydrogenation of enamide **A**, the reaction mixture was filtered and the filtrate was tested for activity by adding more enamide; no further conversion was observed indicating the absence of highly active soluble catalyst leaching from the support. In a second set of recycling experiments, the materials were reacted under standard conditions for 30 min and the contents were then decanted leaving solid **1** in a small amount of solvent.[16] The bottle was recharged, and the reaction repeated four times, with the final run differing in that the catalyst was stored in hydrogen-free hexane for 16 h prior to the final reaction. Under these conditions, the catalyst remains active with no loss of conversion or enantioselectivity.

This work clearly shows that a chiral cationic rhodium catalyst can be simply and efficiently sorbed onto silicas without any ligand modification, a method that in principle could be applied to a wide variety of cationic catalysts. The surface-bound triflate counter ion immobilizes the cationic Rh complex onto the surface of the MCM-41 and the surface-sorbed complex is recyclable and stable to leaching from the surface in non-polar solvents. The results show that binding [(*R*,*R*)-Me-(DuPHOS)Rh]OTf to an MCM-41 surface has a beneficial effect on enantioselectivity and activity in the hydrogenation of prochiral enamides when compared to the homogeneous catalyst.

This work was carried out with Laboratory Directed Research and Development funds at Los Alamos National Laboratory, operated by the University of California for the U.S. Department of Energy under contract W-7405-ENG-36. R. D. B thanks the National Science Foundation (CAREER Award). We thank J. Rau, N. Clark, G. Brown and C. Hijar (all LANL) for materials synthesis and characterization.

Six-coordinate aluminium phosphinate

Y. Wang, S. Parkin and D. Atwood*

Department of Chemistry, University of Kentucky, Lexington, KY 40506-0055, USA. E-mail: datwood@pop.uky.edu

Received (in Cambridge, UK) 31st May 2000, Accepted 14th July 2000

Unique models of solid state aluminophosphate materials containing, for the first time, six-coordinate aluminium atoms, may be achieved in chelated phosphinate derivatives; the degree of aggregation of these species, specifically the remarkable transition from a dimeric molecule to a polymeric material, depends on just one methylene unit; thus, [(Bu$^t_4$salpen)Al{O_2P(H)Ph}]$_2$ 1 is dimeric while [(Bu$^t_4$salen)-Al{O_2P(H)Ph}]$_\infty$ 2, with one fewer methylene unit in the connection between the two nitrogens, is a polymeric material with the polymers aligned to form pores containing thf molecules.

Nanoporous or open-framework[1] group 13 phosphate materials have far-ranging applications in catalysis,[2] separations and many other areas.[3] There are a limited number of naturally occurring aluminophosphates (turquoise is one example). However, synthetic chemistry has dramatically expanded this class of compounds and is providing new[4,5] and unique[6] materials with a wide range of new applications.[7] In these materials the aluminium atom is often six-coordinate. Thus far, molecular models of these materials have contained four-coordinate aluminium,[8–11] while none have six-coordinate atoms found in many materials.[12,13] The present work demonstrates that six-coordinate aluminium may be achieved in chelated phosphinate derivatives, and that the degree of aggregation of these species, the transition from a dimeric molecule to a polymeric material, is dependent on just one methylene unit. Thus, [(Bu$^t_4$salpen)Al{O_2P(H)Ph}]$_2$ **1** is dimeric while [(Bu$^t_4$salen)Al{O_2P(H)Ph}]$_\infty$ **2** is a polymeric material.

The compounds are prepared by combining the chelated group 13 reagent with the phosphinic acid (Scheme 1).[14] Use of (Bu$^t_4$salpen)AlMe in this reaction leads to the dimeric compound [(Bu$^t_4$salpen)Al{O_2P(H)Ph}]$_2$ **1**. The dimeric nature of **1** is supported by the spectroscopic data and verified by a crystal structure (Fig. 1).[15] In the structure the aluminium atom is in an octahedral environment. The Al–O(ligand) distances, *ca.* 1.83 Å, are marginally shorter than the Al–O–P distances, *ca.* 1.93 Å. There are no known solid-state materials based on phosphinates [O_2P(H)R] but these bond distances are similar to that observed in an aluminium phenylphosphonate (O_3PR)[4] with Al–O distances in the range 1.786(6)–1.951(6) Å. By comparison, these distances are just slightly shorter in derivatives containing four-coordinate aluminium such as [$Me_2AlO_2P(OBu^t)_2$]$_2$ (Al–O ≈ 1.77 Å).[12] Aggregation of **1** is expected based upon previously reported compounds, including [$Me_2Al(O_2PPh_2)$]$_2$, first reported by Coates in 1964,[16] which are most commonly dimeric with four-coordinate aluminium atoms. Although the bonding within compound **1** is not unusual the compound still serves to demonstrate that molecular phosphinates of six-coordinate aluminium can be obtained.

Compound **2** differs from **1** in having one less methylene (CH_2) unit in the ligand 'backbone'. Surprisingly, this leads to a dramatic change in the structure of the resulting compound. Thus, [(Bu$^t_4$salen)Al{O_2P(H)Ph}]$_\infty$ **2**, is found to consist of polymeric chains of –[(Bu$^t_4$salen)Al(OP{(H)Ph}O]– units (Fig. 2). The –[O–Al–O–P]– backbone is not linear but curved at the O–P–O junctions with an angle of 119.1(3)°. The same angle in **1** is 116.81(8)°. The Al–O distances are also similar. Adjacent ligand Bu^t groups are arranged in a staggered configuration to reduce steric contacts. The effect of this arrangement is to make the polymers appear as columns in the packing diagram (Fig. 3). These columns are arranged so that the Bu^t groups point inwards towards channels containing thf molecules. In this manner the structure of **2** is similar to the structure of other inorganic phosphate solid state materials.[17] It is likely that many other materials like this should be accessible when using ligands that coordinate in a linear manner.

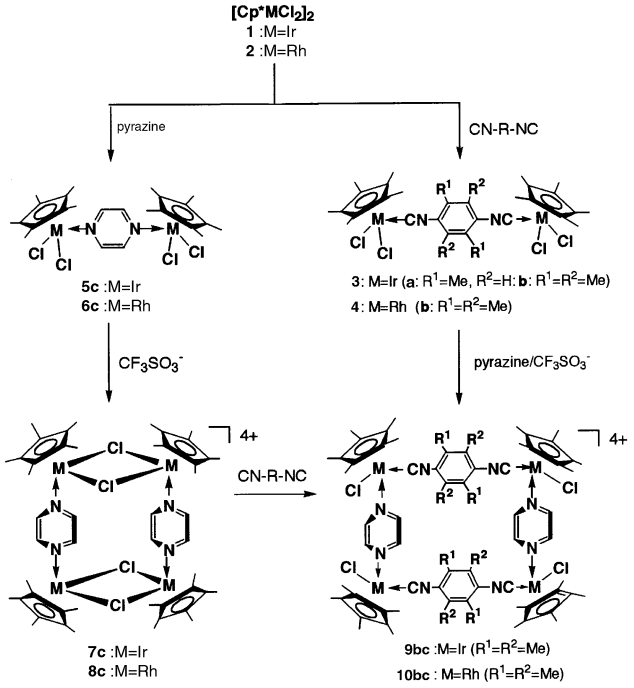
Received (in Cambridge, UK) 27th April 2000, Accepted 9th August 2000

Reactions of $[Cp^*MCl_2]_2$ (M = Rh, Ir) with bidentate ligand (L = pyrazine; L′ = diisocyanide) gave $[Cp^*MCl_2(L \text{ or } L')]_2$, which were converted into tetranuclear complexes $[Cp^*_2M_2Cl_2(L)(L')]_2(OTf)_4$ containing different ligands on treatment with Ag(OTf).

Metal-containing supramolecules and coordination polymers have attracted interest in recent years since there are many promising metal fragments which can be used for construction of novel supramolecular materials.[1] In particular, square planar complexes of platinum and palladium are attractive as building blocks which occupy vertices. For example, diphosphine and diamine derivatives as ligands in metallic building blocks have been used extensively by many groups.[2] We are interested in supramolecular complexes, based on quasi-octahedral geometries, bearing arene and cyclopentadienyl groups and their derivatives, since new types of supramolecular series would be developed by introduction of these organic moieties. Octahedral building blocks can be applied to form cubic or ladder-shaped structures. As our first report of this study, we report here, the stepwise assembly of tetranuclear rhodium and iridium supramolecules bearing pentamethylcyclopentadienyl and binary ligands. Complexes constructed here are novel because they contain 2-D architectures with two different ligand 'edges', *i.e.* molecular rectangles. Self-assembled supramolecules bearing pentamethylcyclopentadienyl groups, to our knowledge, have been reported only by Rauchfuss and coworkers;[3,4] $[Cp_4Cp^*_4Co_4Rh_4(CN)_{12}]^{4+}$, $[Cp^*_7Rh_7(CN)_{12}]^{2+}$ and $[Cp^*_7Rh_3Ir_4(CN)_{12}]^{2+}$ ($Cp^* = C_5Me_5$).

When bis[dicloro(pentamethylcyclopentadienyl)iridium] **1** was treated with 1,4-diisocyano-2,5-dimethylbenzene (**a**) or 1,4-diisocyano-2,3,4,5-tetramethylbenzene (**b**) in a 1:1 molar ratio at room temperature (Scheme 1), yellow crystals, formulated as $[Cp^*IrCl_2]_2[CN–R–NC]$ (**3a**: R = 2,5-$Me_2C_6H_2$; **3b**: R = 2,3,5,6-Me_4C_6) by FAB mass spectrometry, were formed in high yields.† Their IR spectra showed a strong band at *ca.* 2140 cm^{-1} owing to terminal isocyanide groups. In the ^1H NMR spectra two singlet resonances due to the Cp* and Me protons appeared at δ *ca.* 1.86 and 2.40. These spectroscopic data suggested dimeric structures for **3a** and **3b**, where the Ir centers are connected by a μ-diisocyanide ligand. X-Ray crystal analysis of **3a** confirmed the dimeric structure.‡ The Ir–C(11) and average Ir–Cl bond lengths are 1.96 and 2.401 Å, respectively, and the two Ir atoms are separated by 11.6 Å. The analogous rhodium compound $[Cp^*RhCl_2]_2$[μ-1,4-$(NC)_2$-2,3,5,6-Me_4C_6] **4b**, was prepared as orange crystals in 80% yield by the reaction of $[Cp^*RhCl_2]_2$ **2** with **b**.†

Treatment of **1** or **2** with pyrazine (**c**) also generated dinuclear complexes, $[(Cp^*MCl_2)_2(\mu\text{-}C_4H_4N_2)]$ (**5c**, M = Ir; **6c**, M = Rh), according to FAB mass spectrometry.† In the ^1H NMR spectra in dmso-d_6, two singlets appeared at δ *ca.* 1.62 and 8.65, due to the Cp* and pyrazine protons, respectively. When **6c** was reacted with AgOTf (Tf = CF_3SO_2) in a 1:2 ratio in CH_2Cl_2–MeCN at room temperature, reddish orange crystals of $[(Cp^*RhCl)_4(pyz)_2](OTf)_4$ **8c** (pyz = pyrazine) were produced,



Scheme 1 Reactions of $[Cp^*MCl_2]_2$ (**1**: R = Ir and **2**: M = Rh) with pyrazine or isocyanides.

and FAB mass spectrometry showed a peak at *m/z* 1254 ($[M + 1]^+$).† The ^1H NMR spectrum consists of two characteristic singlets at δ 1.61 and 8.65 in a 60:8 intensity ratio, suggesting a symmetric tetranuclear structure. Indeed, X-ray crystallographic analysis revealed that the complex cation has a rectangular structure bridged by four Cl atoms and pyrazine molecule with Rh···Rh separations of 3.68 and 7.02 Å (Fig. 1).‡ The crystal contains MeOH as crystal solvent. Both Rh(1)Rh(2)Cl(1)Cl(2) and pyrazine least-squares planes are perpendicular to the Rh(1)Rh*(1)Rh(2)Rh*(2) plane. The average Rh–N bond length is 2.413 Å. A tetranuclear iridium complex **7c** was obtained from **5c** and AgOTf in a similar manner to the rhodium analog.† The ^1H NMR spectrum showed two types of resonances for each of the Cp* and pyrazine ligands; at δ 1.58 and 1.74 for the former and at δ 8.84 and 8.97 for the latter, suggesting the presence of configurational isomers.

When μ-chloro-bridged complex **7c** was treated with 2 equiv. of **b**, the Cl bridges were replaced by **b** to produce yellow crystals formulated as $[(Cp^*IrCl)_4(pyz)_2\{1,4\text{-}(NC)_2\text{-}2,3,5,6\text{-}Me_4C_6\}_2](OTf)_4$ **9bc**.† This complex can also be obtained from the reaction between **3b** and pyrazine in the presence of Ag(OTf). In the IR spectrum, the CN band appeared at 2176 cm^{-1} while the ^1H NMR spectrum showed three singlets at δ 1.94, 2.42 and 8.65 in a 30:12:4 intensity ratio, due to Cp*, isocyanide and pyrazine protons, respectively. In addition, the

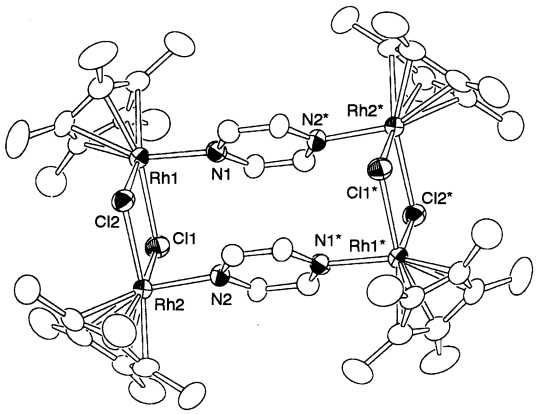

Fig. 1 Molecular structure of $[(Cp^*_4Rh_4Cl_4)(\mu\text{-}Cl)_4(\mu\text{-}pyz)_2](CF_3SO_3)_4$ **8c** (CF_3SO_3 anions omitted for clarity). Selected bond lengths (Å) and angles (°): Rh(1)–Cl(1) 2.466(3), Rh(1)–Cl(2) 2.467(2), Rh(1)–N(1) 2.133(7), Rh(2)–Cl(2) 2.474(3), Rh(2)–Cl(2) 2.459(2), Rh(2)–N(2) 2.153(8); Cl(1)–Rh(1)–Cl(2) 83.50(8), Cl(1)–Rh(1)–N(1) 88.0(2), Cl(2)–Rh(1)–N(1) 87.8(2), Cl(1)–Rh(2)–Cl(2) 83.47(8), Cl(1)–Rh(2)–N(2) 88.5(2), Cl(2)–Rh(2)–N(2) 88.5(2).

structure was determined by single crystal X-ray analysis (Fig. 2).‡ An asymmetric unit of the crystal of **9bc** consists of two halves of the molecules, each having a crystallographically imposed inversion center in the middle of the Ir···Ir* vector. Each iridium atom is surrounded by isocyanide, pyrazine, Cl and Cp*. The complex has a tetranuclear rectanglar structure with Ir···Ir* lengths of 6.986(1), 7.9145(9), 11.6459(9) and 11.668(1) Å. The dihedral angles between the Ir_4 plane and pyrazine are 49.44, 48.82° and those between Ir_4 plane and phenyl rings are 83.55, 83.58° and 75.75, 75.95°. The average Ir–C and Ir–Cl bond lengths are 1.97 and 2.388 Å, similar to

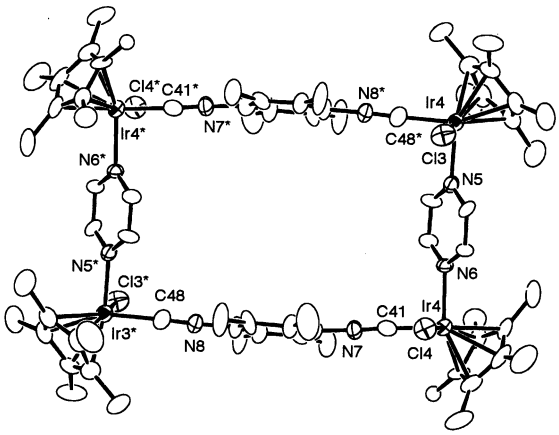

Fig. 2 Molecular structure of $[(Cp^*_4Ir_4Cl_4)\{\mu\text{-}1,4\text{-}(NC)_2\text{-}2,3,5,6\text{-}Me_4C_6\}_2(\mu\text{-}pyz)_2](CF_3SO_3)_4$ **9bc** (CF_3SO_3 anions omitted for clarity). Lithium atom exchange in solid *tert*-butyllithium

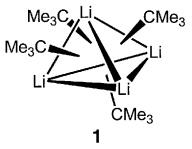
Glenn H. Penner* and Y. C. Phillis Chang

Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1. E-mail: gpenner@uoguelph.ca

Received (in Irvine, CA, USA) 11th April 2000, Accepted 2nd May 2000
First published as an Advance Article on the web 4th September 2000

Lithium-7 NMR spectral lineshapes and T_1 measurements show that the lithium atoms in the solid tetrameric form of *tert*-butyllithium are rapidly exchanging between the apical sites of a tetrahedron with activation energies of 23.8 ± 0.2 and 23.0 ± 0.6 kJ mol^{-1}, above and below a phase transition (310 ± 3 K), respectively.

Inter- and intra-molecular exchange in organolithium oligomers in solution is well documented.[1] An example of intramolecular exchange is the scrambling of the *tert*-butyl groups within the lithium-6 labelled[Bu^{t}Li]$_4$ tetramer **1** in cyclopentane solution.[2]



1

In this case the coupling $^1J(^{13}C^6Li)$ is observed between the α-carbon and all four ^{6}Li nuclei above 268 K. Below 251 K the exchange has stopped and coupling to only three ^{6}Li nuclei is observed. It has been shown that solid *tert*-butyllithium also exists as a tetramer.[3] These observations leads one to question whether a similar exchange process might occur in the solid state. Evidence for this comes from an early investigation of the ^{7}Li nuclear quadrupolar coupling constants (QCC) in solid methyllithium and ethyllithium where Lucken determined maximum values that were only a few kHz.[4] These values are unusually small and are much smaller than our calculated values for the [MeLi]$_4$ and [Bu^{t}Li]$_4$ tetramers.[5] Therefore it is expected that some kind of motional averaging might be responsible for the rather small QCC at ambient temperatures.

The ^{7}Li spectra of solid **1**, at various temperatures, are shown in Fig. 1.† At room temperature (293 K) we also observe a lineshape consistent with a ^{7}Li QCC of < 5 kHz. If an intramolecular exchange process is occurring, one should be able to observe changes in the spectral lineshapes as the temperature is reduced. This is indeed what happens between 200 and 150 K. Below 150 K the lineshape does not change and is consistent with a ^{7}Li QCC of 100 ± 3 kHz. The higher temperature lineshape shows that the quadrupolar interaction is nearly averaged to zero owing to either isotropic or pseudo-isotropic motion of the lithium atoms. Since the X-ray structure (at 180 K) shows lithium atoms occupying well defined sites located at the apices of a tetrahedron, pseudo-isotropic motion, *i.e.* exchange between tetrahedral sites, is the most likely averaging process. The lineshape changes indicate that the exchange rate is on the order of 10^5 s^{-1} in the temperature range 150–200 K, is $> 10^5$ s^{-1} above 200 K and $< 10^5$ s^{-1} below 150 K. In contrast the ^{1}H lineshape (not shown) changes very little in this temperature range. The relative temperature independence of the ^{1}H lineshape indicates that the *tert*-butyl groups are not exchanging, although rapid internal rotation of the methyl groups (about the C_α–C_β bonds) and the *tert*-butyl groups is expected to average the linewidth at these temperatures.

Another method for following molecular dynamics by NMR spectroscopy is through measurement of the spin–lattice relaxation time T_1. Fig. 2 shows a plot of the ^{7}Li T_1 as a function of temperature. It is quite clear that there is a well defined break in the T_1 curve at *ca.* 310 ± 3 K. We attribute this to a solid–solid phase transition. Above and below the phase transition temperature, the T_1 values are on the fast and slow motional side of the T_1 minimum, respectively. It would be informative to be able to discuss the lithium exchange process in terms of an exchange rate, *k*. This is possible if the spin–lattice relaxation rate can be described in terms of a single motional correlation time, τ_c, employing the commonly used BPP spectral density. Then the relaxation rate for a quadrupolar nucleus is given by eqn. (1)

$$R_1 = \frac{1}{T_1} = \frac{3\pi^2}{50}\frac{2I+3}{I^2(2I-1)}\chi^2\left[\frac{\tau_c}{1+(\omega_0\tau_c)^2}+\frac{4\tau_c}{1+(2\omega_0\tau_c)^2}\right] \quad (1)$$

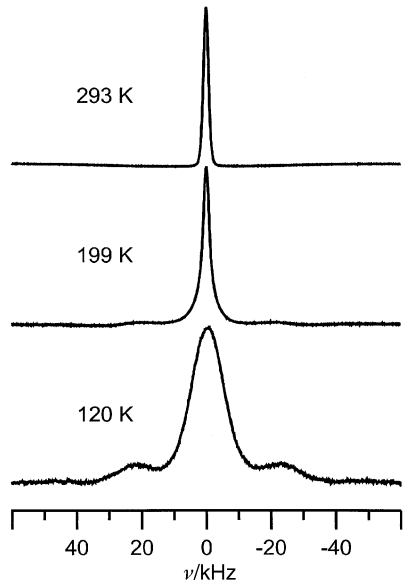


Fig. 1 The ^{7}Li spectra of solid *tert*-butyllithium at several temperatures.

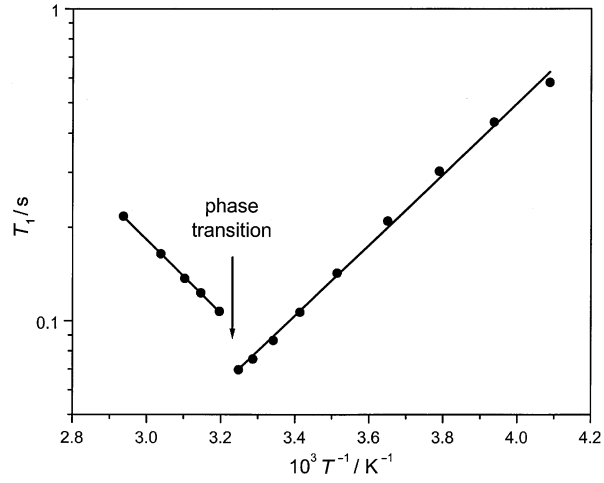

Fig. 2 Temperature dependence of the ^{7}Li T_1 for solid *tert*-butyllithium at a spectrometer frequency of 77.7 MHz.

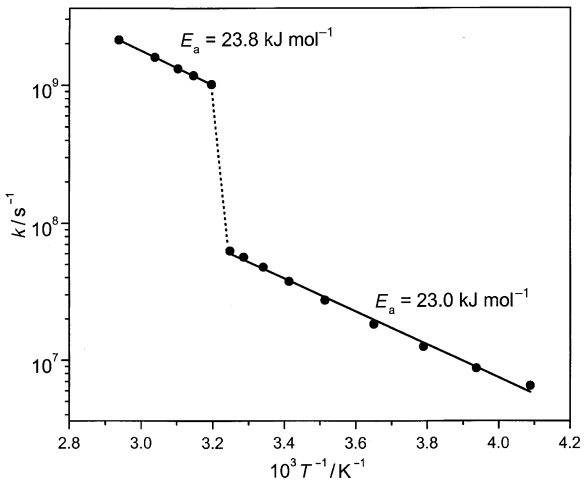

Fig. 3 Temperature dependence of the rate for lithium atom exchange in solid *tert*-butyllithium.

where I is the nuclear spin, χ is the nuclear QCC and ω_0 is the spectrometer (Larmor) frequency (in rad s^{-1}). If I, χ and ω_0 are known, τ_c values can be obtained from the T_1 measurements. The second assumption is that the lithium atoms are undergoing a 4-site exchange between equivalent tetrahedral sites. In that case the exchange rate is given as $k = 1/4\tau_c$.

Fig. 3 shows the temperature dependence of the lithium atom exchange rate. At the phase transition the rate changes by a factor of 16. The activation parameters for the exchange process are $E_a = 23.8 \pm 0.1$ kJ mol^{-1} and $k_\infty = 9.58 \pm 0.05 \times 10^{12}$ s^{-1} for the high temperature phase and $E_a = 23.0 \pm 0.6$ kJ mol^{-1} and $k_\infty = 4.85 \pm 0.33 \times 10^{11}$ s^{-1} for the low temperature phase. This analysis indicates that at 25 °C the lithium atoms in solid *tert*-butyllithium are exchanging at a rate of 8.5×10^8 s^{-1}!

Phase transitions are usually accompanied by changes in crystal and/or molecular structure. It would be of interest to compare a crystallographic study above 310 K with the earlier work at 180 K.[3]

Our calculated value of the ^{7}Li QCC for tetrameric **1** is 150 kHz.‡ This is larger than the observed value but does not take into account that the X-ray structure gives unrealistically short C–H bond lengths. Intermolecular effects are also not taken into account in this calculation. Details of our calculations and measurements of Li QCC values and chemical shift anisotropies in organolithium compounds will be published elsewhere.[5]

We are grateful to the Natural Sciences and Engineering Research Council (NSERC) of Canada for financial support. We are particularly indebted to Prof. Marcel Schlaf for the use of his inert atmosphere box and for help with sample preparation.

Notes and references

† Solid **1** was obtained by stripping the solvent from a 1.5 M pentane solution of *tert*-butyllithium (Aldrich) inside an inert atmosphere box under argon. About 1 g of the white powder was packed into a small airtight 10 mm o.d. container. A separate sample was prepared for magic angle spinning experiments (^{13}C, ^{6}Li and ^{7}Li) which showed that the solid sample was pure. In particular, the ^{6}Li MAS spectrum, which gave excellent signal-to-noise and a linewidth of only 0.09 ppm, showed a single small impurity peak (2.1% of total peak intensity). The non-spinning ^{7}Li spectra were obtained at a frequency of 77.7 MHz with a Bruker ASX-200 spectrometer using a single channel wideline probe. Single pulse experiments using 3 μs pulses and relaxation delays of 10 s were employed. Quadrupolar echo experiments at the lowest temperature were identical to the single pulse experiments. The T_1 experiments employed the inversion recovery pulse sequence, π–t_d–$\pi/2$ with 8 t_d values for each T_1 determination. The magnetization curves as a function of delay time showed mono-exponential decay.

‡ We performed a DFT calculation using the B3LYP functional and a 6-31G** basis set. We have found that this combination gives QCC values in good agreement with experiment. The crystal structure geometry of a single [Bu^{t}Li]$_4$ tetramer was used. Calculations were done with the Gaussian 98 software package.[6]

A new route to dilithio boraamidinates: formation and X-ray structures of the dimeric and trimeric clusters $\{Li_2[RB(NBu^t)_2]\}_x$ (R = Bu^n, x = 2 and R = Me, x = 3)

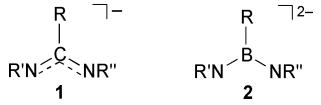
Justin K. Brask, Tristram Chivers* and Gabriele Schatte

Department of Chemistry, University of Calgary, 2500 University Dr. NW, Calgary, Alberta, Canada T2N 1N4. E-mail: chivers@ucalgary.ca

Received (in Cambridge, UK) 20th July 2000, Accepted 18th August 2000

The dilithio boraamidinate complexes $\{Li_2[RB(NBu^t)_2]\}_x$ (R = Bu^n, x = 2 and R = Me, x = 3), prepared unexpectedly by treating $B[N(H)Bu^t]_3$ with 3 equiv. LiR, represent the first structurally characterized s-block metal derivatives of the boraamidinate ion.

Amidinate ions $[RC(NR')(NR'')]^-$ **1** have been investigated extensively as ligands for both transition metal and main group element centers.[1] In the presence of Lewis bases, *e.g.* THF or HMPA, the lithium derivatives of these important reagents form dimeric step-shaped structures.[2,3] This structural motif is also evident in the lithio ligands of the lithium oxide complex $\{Li[Bu^nC(NBu^t)_2]\}_4{\cdot}Li_2O$.[4] By contrast, the isoelectronic boraamidinate ions $[RB(NR')(NR'')]^{2-}$ **2** have received little attention. The reagent $\{Li_2[PhB(NBu^t)_2]\}_n$, prepared by dilithiation of $PhB[N(H)Bu^t]_2$, has been used in metathetical reactions to generate several main group derivatives, *e.g.* $[PhB(\mu\text{-}NBu^t)_2]_2Te$[5] and $[PhB(\mu\text{-}NBu^t)_2Pb]_2$,[6] and the transition-metal derivative $[PhB(\mu\text{-}NBu^t)_2]_2Ti$.[7] The X-ray structures of these complexes were reported, but s-block metal derivatives of **2** have not been structurally characterized. We describe here



1 **2**

the unexpected formation and X-ray structures of dimeric and trimeric dilithio boraamidinates $\{Li_2[RB(NBu^t)_2]\}_x$ (**3**: R = Bu^n, x = 2; **4a**: R = Me, x = 3) from the reaction of $B[N(H)Bu^t]_3$ with LiR (R = Bu^n or Me, respectively).

Treatment of the trisaminoborane $B[N(H)Bu^t]_3$ with 3 equiv. $LiBu^n$ in *n*-hexane gives a 1:2 mixture of the dimer $\{Li_2[Bu^nB(NBu^t)_2]\}_2$ **3** and $LiN(H)Bu^t$ [eqn. (1)]. Complex **3** is the first product to crystallize from *n*-hexane at 0 °C and it can be isolated in 71% yield free from $LiN(H)Bu^t$.† The ^1H NMR spectrum of **3** in C_6D_6 consists of a single Bu^t resonance at δ 1.25 as well as resonances corresponding to a Bu^n group (Bu^n:Bu^t ≈ 1:2). The ^7Li and ^{11}B NMR spectra each exhibit single resonances at δ −0.63 and 36.6 ppm, respectively.

$$3\ LiR + B[N(H)Bu^t]_3 \rightarrow {}^1/_x\{Li_2[RB(NBu^t)_2]\}_x + LiN(H)Bu^t + 2\ RH$$

3: R = Bu^n, x = 2
4a: R = Me, x = 3
4b: R = Me, x = 2 (1)

X-Ray structure analysis revealed a 10-atom $Li_4B_2N_4$ cluster core for **3** (Fig. 1),‡ isostructural with the $Li_4Si_2N_4$ framework in $\{Li_2[(Me)_2Si(NBu^t)_2]\}_2$.[8] Although no crystallographic symmetry is imposed on the molecule, **3** displays near D_{2d} symmetry with the S_4-axis parallel to the B(1)–B(2) vector. This structure is consistent with the solution NMR data. The B–N distances for **3** [mean 1.458(4) Å, range 1.451(4)–1.464(4) Å] are similar to those found in $[PhB(\mu\text{-}NBu^t)_2]_2Ti$ [mean 1.464(10) Å, range 1.453(9)–1.475(10) Å],[7] while the Li–N distances [mean 2.037(6) Å, range 2.009(6)–2.091(5) Å] fall in the range for those of $\{Li_2[(Me)_2Si(NBu^t)_2]\}_2$ [mean 2.075(7) Å, range 2.003(6)–2.129(6) Å].[8] The distortion of the central Li_4N_4 cube along the S_4-axis [Li–N–Li: mean 75.42(20)°, range 68.30(18)–88.3(2)°; N–Li–N: mean 97.15(30)°, range 70.99(18)–110.8(2)°; Li(2)–N(1)–Li(1)–N(2) 46.16(18)°, Li(4)–N(4)–Li(3)–N(3) = 46.22(18)°] is attributed to the rigidity of the boraamidinate ions **2** (R = Bu^n, R′ = R″ = Bu^t). The geometry at the three-coordinate boron atoms of these dianions is essentially planar [Σ B(1) = Σ B(2) = 359.9(3)°]. The agostic C(–H)···Li contacts in **3** (mean 2.41 Å) are considerably shorter than those reported for the cluster complex $\{Li_3[Sb(NBu^t)_3]\}_2$ (mean 2.65 Å),[9] but longer than those observed for $\{Li_2[(Me)_2Si(NBu^t)_2]\}_2$ (mean 2.34 Å).[8]

The formation of **3** requires cleavage of a B–N bond in favor of a B–C bond. In effect, the added $LiBu^n$ functions as a base to deprotonate two $N(H)Bu^t$ groups per $B[N(H)Bu^t]_3$ molecule and as a nucleophile to displace the third $N(H)Bu^t$ group in the form of $LiN(H)Bu^t$. A similar displacement was observed in the reaction of $[(THF)_2Li]_2[Nb(NMes)_3(NHMes)]$ with 1 equiv. $LiBu^n$ to produce the alkyl complex $[(THF)_2Li]_2[Bu^nNb(NMes)_3]$ and LiN(H)Mes in a 1:1 molar ratio.[10] In order to gauge the versatility of this novel methodology for preparing dilithio boraamidinates, $B[N(H)Bu^t]_3$ was treated with 3 equiv. LiMe in diethyl ether. After removal of $LiN(H)Bu^t$, recrystallization of the product mixture from *n*-pentane gave $\{Li_2[MeB(NBu^t)_2]\}_3$ **4a** in 28% yield [eqn. (1)].†

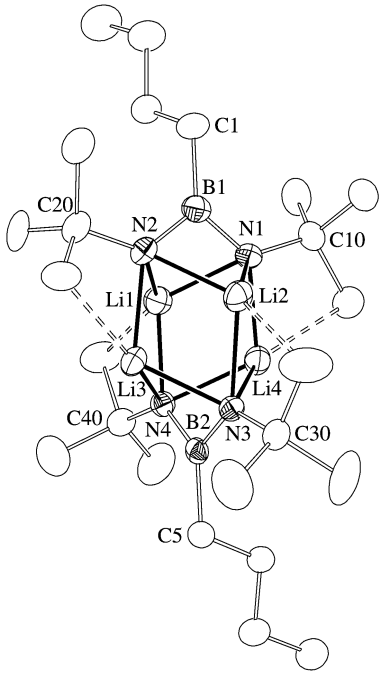


Fig. 1 Molecular structure of $\{Li_2[Bu^nB(NBu^t)_2]\}_2$ **3** (40% probability ellipsoids). For clarity, H atoms are omitted and only one orientation of the disordered Bu^t group centered at C(20) is shown. Relevant bond distances and bond angles are provided in the text.

DOI: 10.1039/b005852l

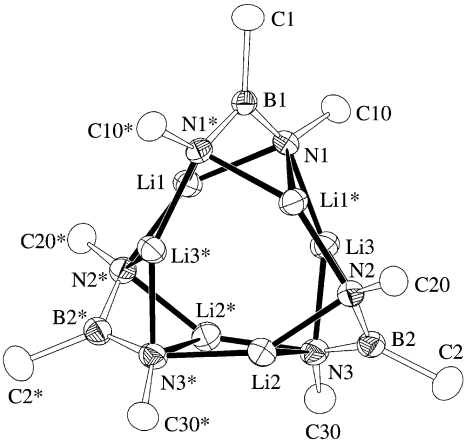

Fig. 2 Molecular structure of $\{Li_2[MeB(NBu^t)_2]\}_3$ **4a** (40% probability ellipsoids). For clarity, H atoms are omitted and only the α-carbon atoms of the Bu^t groups are shown. Starred atoms are related by the symmetry transformation: $-x+1, y, -z+{}^1/_2$. Selected bond distances (Å) and angles (°): B(1)–N(1) 1.452(3), B(1)–C(1) 1.604(4), B(2)–N(2) 1.456(3), B(2)–N(3) 1.451(3), B(2)–C(2) 1.608(3), Li–N [mean 2.051(4), range 2.001(4)–2.100(4)]; N(1)–B(1)–N(1*) 110.0(2), N(1)–B(1)–C(1) 125.02(12), N(2)–B(2)–N(3) 110.51(19), N(2)–B(2)–C(2) 124.4(2), N(3)–B(2)–C(2) 125.0(2).

The ^{1}H NMR spectrum of **4a** in C_6D_6 shows Bu^t and Me resonances at δ 1.29 and 0.85 in a 2 : 1 ratio, respectively. Single resonances are observed at δ −0.86 and 35.5 in the ^{7}Li and ^{11}B NMR spectra, respectively. A more soluble product, tentatively identified as the dimer $\{Li_2[MeB(NBu^t)_2]\}_2$ **4b**, was characterized by ^{1}H, ^{7}Li and ^{11}B NMR spectra.† The molar ratio of **4a**:**4b** was *ca.* 1:3 based on the integrated intensities of the resonances in the ^{1}H NMR spectrum of the mixture.

X-Ray structure analysis of **4a** disclosed a novel trimeric arrangement based on a severely distorted $Li_6(NBu^t)_6$ hexagonal prism, for which alternate Li_2N_2 rings are *N*,*N*′-capped by a BMe unit (Fig. 2).‡ The resulting 15-atom $Li_6B_3N_6$ core provides the first example of a tricapped hexagonal prismatic cluster. Although only a C_2-axis is imposed on the molecule crystallographically [through C(1), B(1) and the centre of the Li(2)N(3)Li(2*)N(3*) ring], **4a** displays near D_3 symmetry. The capped Li_2N_2 rings in **4a** deviate greatly from planarity [Li(1*)–N(1)–Li(1)–N(1*) = 44.99(16)°, Li(3)–N(2)–Li(2)–N(3) 45.14(13)°] as compared with their non-capped counterparts [Li(2*)–N(3)–Li(2)–N(3*) 10.9(2)°, Li(1*)–N(1)–Li(3)–N(2) −11.60(16)°], demonstrating the dominance of the dianion **2** in structure formation, *cf.* structural direction by the trianions $[Sb(NR)_3]^{3-}$.[11]

The reaction of readily accessible trisaminoboranes, $B[N(H)R]_3$ (R = alkyl or aryl),[12] with the appropriate organolithium reagent is a potentially versatile method for generating dianionic ligands **2** with variable steric requirements. Unlike the lithiation of bisaminoboranes $RB[N(H)R']_2$,[7] this new route to dilithio boraamidinates does not require the preparation of $RBCl_2$ reagents.

We thank Dr R. McDonald (University of Alberta) for assistance with the X-ray data collection for **3** and **4a** and NSERC (Canada) for financial support.

Received (in Cambridge, UK) 14th May 2000, Accepted 14th August 2000

Triols, formed as by-products from the titanium silicalite (TS-1) catalysed epoxidation of allylic alcohols, can cause leaching of Ti from the microporous framework.

The titanium(IV) silicalite known as TS-1 has been considered by many to be a unique redox molecular sieve since its discovery by Enichem researchers.[1,2] TS-1 has been shown to be an active heterogeneous catalyst for the epoxidation of alkenes[3] and allylic alcohols.[4] Two features are responsible for the uniqueness of TS-1. First, incorporation of Ti into the microporous silicate framework increases the hydrophobicity[5] and enables H_2O_2 to be used as an oxidant. Other redox molecular sieves are ineffective with H_2O_2 and require more active oxygen sources, *e.g. tert*-butyl hydroperoxide.[6] Secondly, TS-1 is considered very stable under the reaction conditions and to date, loss of Ti from the framework of TS-1 has not been studied in detail. These features have been emphasised recently by Sheldon *et al.*,[7] who also stress that most papers pay scant attention to the loss of framework transition metal ions from redox molecular sieves. Recently, it has been shown that other redox molecular sieves containing Cr and V leach these metal cations into solution during reaction, and therefore act as reservoirs for active homogeneous catalysts.[8,9] If leaching is common for transition metals incorporated into microporous frameworks, then it is surprising that this should not be the case for Ti in TS-1. We have now studied the stability of TS-1 with respect to loss of Ti during reaction and we demonstrate that by-product formation unfortunately can lead to the loss of Ti from titanium(IV) silicalite.

TS-1 (2.4 wt% Ti) was prepared according to the following method, which has been used in many previous studies. Titanium butoxide (3.4 g Aldrich) was added dropwise to tetraethyl orthosilicate (62.5 g Merck) and the resulting mixture stirred for 30 min. Tetrapropylammonium hydroxide (40 wt% in H_2O, 76.3 g Alfa) was added dropwise with stirring. The resulting mixture was then heated at 60 °C for 2 h to evaporate ethanol produced by the hydrolysis/condensation reactions between the silicon and titanium reagents. Water was then added to the synthesis gel to return the volume of the gel to that prior to the evaporation step. The gel was mixed thoroughly and autoclaved under autogeneous pressure at 175 °C for 48 h. The resulting solids were filtered off, washed and dried at 100 °C for 4 h. The materials were calcined at 550 °C in air for 16 h prior to use. The material was characterised by X-ray diffraction, scanning electron microscopy, FTIR and reflectance laser Raman spectroscopy. The data were found to be in agreement with literature data and the crystallites of TS-1 were found to be uniform, rhombohedral and 0.2 μm in diameter. The sample of TS-1 was used as a catalyst for the hydroxylation of phenol with H_2O_2 at 70 °C. After 75 min, the products formed were 49% catechol and 50% hydroquinone; this is in agreement with previous literature studies[10] confirming the quality of the TS-1.

The TS-1 was also shown to be an effective catalyst for the epoxidation of allylic alcohols [Fig. 1(a) and (b)]. In a typical reaction, crotyl alcohol (0.1 mol) was reacted with aqueous

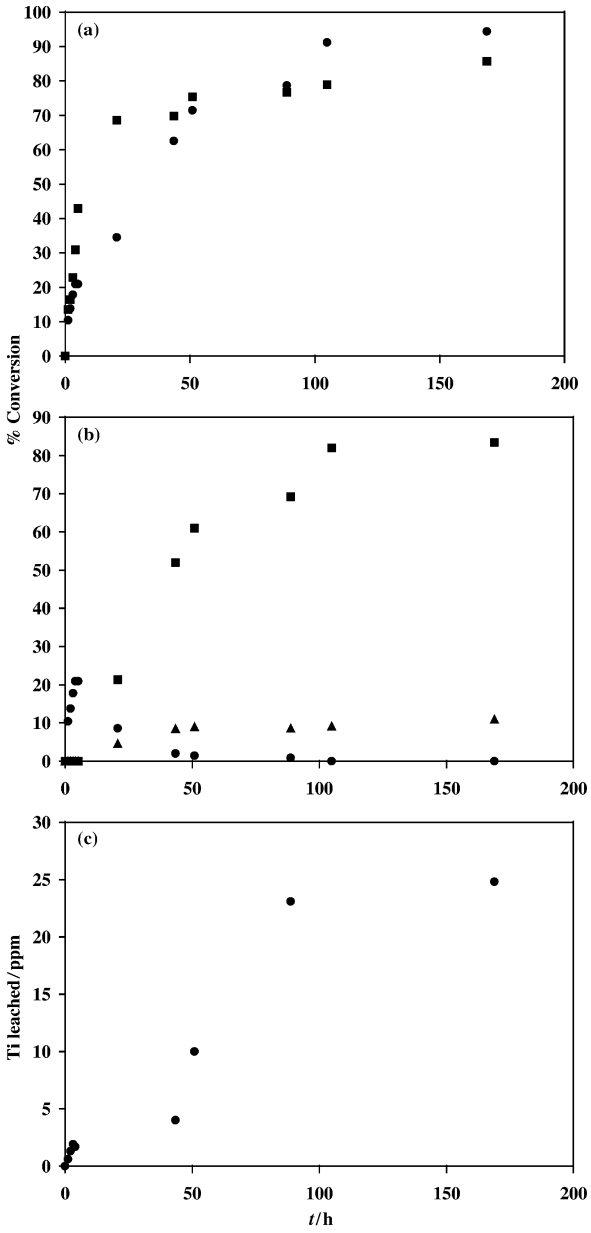

Fig. 1 Reaction of crotyl alcohol with H_2O_2 at 50 °C with TS-1 in methanol. (a) Conversion: (●) crotyl alcohol, (■) H_2O_2; (b) reaction products: (●) epoxide, (▲) ether diols, (■) triol; (c) Ti leaching.

DOI: 10.1039/b002055i

H_2O_2 (30% vol, 0.11 mol) at 50 °C with TS-1 (0.1 g) in methanol (10 ml) in a stirred flask fitted with a reflux condenser. Samples were withdrawn at various time intervals and the products analysed by GC using dimethyl sulfone as an internal standard. Samples were also filtered hot through a heated sinter funnel which contained a bed of Celite to remove small particles of zeolite. Blank experiments confirmed that this method was effective in removing any particulate Ti-containing material and, furthermore, that any titanium observed in solution did not originate from the Celite. The solutions were then analysed by ICPMS to determine the Ti content [Fig. 1(c)]. Initially, TS-1 is active and selective for the formation of the oxirane product and, at this stage, no Ti leaching is observed. However, in a sequential reaction the oxirane ring opens by nucleophilic attack by the solvent to form the triol (reaction with water) or ether diols (reaction with methanol). At this time, Ti is observed to leach from TS-1 and the pH of the reaction mixture decreases. These results clearly demonstrate that the structural integrity of TS-1 is not maintained in the presence of the secondary reaction products formed under typical reaction conditions.

In a further set of experiments, TS-1 (crystallisation period 2 d) was slurried with a range of reagents at 50 °C for 35 h. No Ti leaching was observed with hydrogen peroxide in methanol (30% by vol, < 3 ppm Ti), crotyl alcohol (< 0.3 ppm Ti), butane-2,3-diol (< 2 ppm Ti) or hydrochloric acid (1 M, < 0.7 ppm Ti). Several further experiments were conducted with glycerol as a model triol. No Ti leaching was observed with glycerol and hydrochloric acid (< 2 ppm Ti), or glycerol together with hydrochloric acid and methanol (< 1.3 ppm Ti). However, when TS-1 was slurried with glycerol and hydrogen peroxide using methanol as solvent, extensive leaching of Ti was observed (3571 ppm Ti) corresponding to removal of 16% of the Ti from TS-1. These model experiments confirm that the necessary condition for Ti-leaching from TS-1 is the combined presence of a triol together with hydrogen peroxide, and hence for the successful operation of TS-1 as a truly heterogeneous catalyst the formation of triols must be avoided.

It is interesting to comment on the mechanism by which Ti is removed from the framework of TS-1. Detailed UV–VIS spectroscopy[11] has shown that TS-1 contains four-coordinate Ti^{4+} in the absence of water. When TS-1 is suspended in water or water–H_2O_2 mixtures, the Ti^{4+} species becomes six co-ordinate, retaining three Ti–O–Si bonds, which are considered to anchor the Ti firmly within the microporous framework. The solvent molecules, in our case methanol, could be expected to displace one or more of the water molecules. We suggest that, when this site is exposed to triols, further Ti–O–Si bonds are broken and this leads to the irreversible loss of Ti from the structure (Fig. 2). Since triol by-product formation can be commonly observed in TS-1 catalysed reactions, we suggest that Ti leaching from TS-1 is probably more common than has previously been considered. It is also interesting to determine if the Ti that is leached during the catalytic reaction originates from the surface of the TS-1 crystallites. To determine if this is so, a further experiment was carried out in which the non-calcined TS-1 was silanised according to the method of Beck *et al.*[12] using trimethylsilyl chloride and hexamethyldisiloxane. As the non-calcined TS-1 retains the template within the intra-crystalline pores, this procedure effectively silanises just the exterior surface. On subsequent calcination (550 °C, 4 h), the template is removed and TS-1 crystallites covered on the external surface with silica are formed. Using this material as a catalyst for crotyl alcohol oxidation did not result in any significant leaching of Ti, yet the catalytic performance was essentially the same as that observed for the non-silanised sample [Fig. 1(a), (b)]. These data indicate that it is Ti located on the external surface of the TS-1 crystallites that is preferentially leached by the by-product triol.

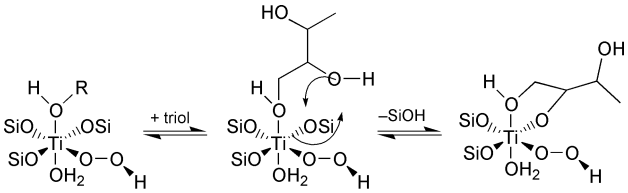

Fig. 2 Interaction of triols with the active site of TS-1.

We would like to thank Synetix, EPSRC, and the DTI/Link programme on asymmetric catalysis for financial support and the Department of Earth Sciences, Cardiff University for ICPMS results.

Cr(NAr)(O)(NPr$^i_2$)(Ar): a strongly-bent monoimido complex resulting from nitrosyl ligand cleavage

Eric W. Jandciu, Peter Legzdins,* W. Stephen McNeil, Brian O. Patrick and Kevin M. Smith†

Received (in Irvine, CA, USA) 26th May 2000, Accepted 31st July 2000

The molecular structure of Cr(NAr)(O)(NPr$^i_2$)(Ar) (Ar = 2-MeC$_6$H$_4$) is analysed by X-ray crystallographic and density functional theoretical techniques.

Tetrahedral imido complexes of the Group 6 metals are in the vanguard of applied organometallic chemistry.[1–4] In d^0 M(NR)(E)X$_2$ complexes (E = O, NR, CHR; X = OR, NR$_2$, CH$_2$R), the competition among the π-donor ligands for available metal orbitals is a critical component of their overall reactivity.[5] Here, we report the molecular structure of Cr(NAr)(O)(Ar)(NPr$^i_2$) (Ar = 2-MeC$_6$H$_4$), which contains a strongly-bent imido ligand.[6] Density functional theory (DFT) calculations have been employed to help analyse the π-bonding conflicts that underpin the experimentally observed geometry.

We recently reported that the alkylation of Cr(NO)(NPr$^i_2$)(O$_2$CPh)$_2$ with R$_2$Mg•*x*(dioxane) reagents yields unsaturated diamagnetic Cr(II) alkyl complexes (Scheme 1).[7] The structures of Cr(NO)(NPr$^i_2$)(CH$_2$SiMe$_3$)$_2$ and Cr(NO)(NPr$^i_2$)(CH$_2$Ph)$_2$ were confirmed by X-ray crystallography, and fluxional processes involving the amido and benzyl ligands were established by variable-temperature ^{1}H NMR spectroscopy.[7] However, the product resulting from treatment of Cr(NO)(NPr$^i_2$)(O$_2$CPh)$_2$ with Ar$_2$Mg•*x*(dioxane) has an anomalously sharp ^{1}H NMR spectrum with no indication of amido rotation. When the structure of this product was determined by X-ray crystallography, it was established that the original assignment as Cr(NO)(NPr$^i_2$)Ar$_2$ was incorrect; the complex is in fact Cr(NAr)(O)(NPr$^i_2$)(Ar) **1** (Fig. 1, Table 1).

The most remarkable feature of the structure of **1**[8] is the strikingly non-linear Cr1–N1–C1 angle of 146.2(3)°. The NAr ligand lies in the O–Cr–N(imido) plane, with the aryl substituent bent toward the oxo group. The Cr–N(amido) bond length, and the amido group planarity (sum of angles at N2 = 359.8°) and alignment are indicative of a Cr–N(amido) π-bonding interaction.[5] Similarly, the Cr–O bond length is consistent with maximum oxo-to-chromium π-donation. The O–Cr–N angles between the oxo and both the amido and imido groups are larger than the typical tetrahedral angle. The structure of complex **1** exhibits disorder in the Cr-bound aryl ligand. This ligand occupies two distinct orientations, in equal proportions, related by a roughly 180° rotation about the Cr–C8 bond. Each disordered fragment was modelled using rigid phenyl groups with isotropic thermal parameters.

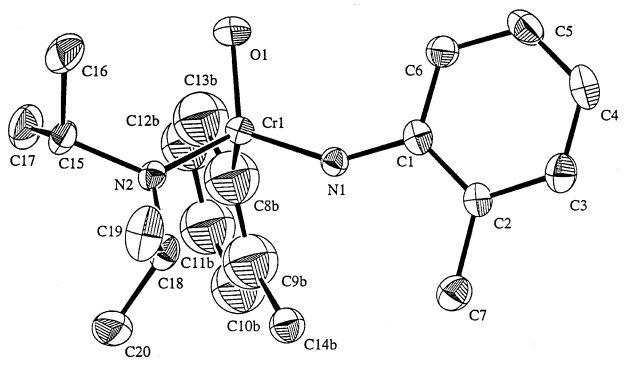

Fig. 1 Crystallographic structure of complex **1**.

Table 1 Comparison of experimental (**1**)[a] and calculated (**2**) bond lengths (Å) and angles (°) of Cr(NR)(O)(NR′$_2$)(R)[b]

Parameter	**1**	**2**
Cr–N1	1.670(2)	1.626
Cr–N2	1.801(3)	1.797
Cr–O	1.589(3)	1.592
Cr–C8a	2.103(6)	2.011
Cr–C8b	2.025(5)	
Cr–N1–C1	146.2(3)	149.0
O–Cr–N1	115.3(2)	115.2
O–Cr–N2	115.5(1)	115.4
O–Cr–C8a	112.6(2)	103.0
O–Cr–C8b	99.9(2)	
N1–Cr–N2	109.9(1)	110.8
N1–Cr–C8a	99.3(2)	101.8
N1–Cr–C8b	107.9(2)	
N2–Cr–C8a	102.3(2)	109.1
N2–Cr–C8b	107.9(2)	

[a] Parameters to C8 in **1** represent the two distinct orientations of the disordered aryl group. [b] **1**: R = 2-MeC$_6$H$_4$, R′ = Pr^i; **2**: R = R′ = Me.

DFT calculations[9] were performed on Cr(NMe)(O)(NMe$_2$)(Me) **2** to investigate the origin and relative importance of the imido angle in this unusual structure.[10] While the simplified model compound lacks the steric bulk present in **1**, the DFT-optimised geometry faithfully reproduces the pertinent structural features determined by X-ray crystallography (Fig. 2, Table 1). The Cr–N(imido)–C angle is calculated to be 149.0°, confirming that this distortion is electronic rather than steric in origin. Remarkably good agreement is attained for the Cr–O and Cr–N(amido) bond lengths and the O–Cr–N bond angles, which match the structural determination within experimental error. The parameters involving the Cr–C bond show poorer agreement, surely due to the disorder exhibited by the aryl group. Interestingly, the DFT-optimised structure has Cr–N(imido)

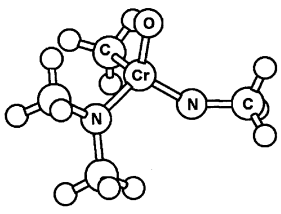

Fig. 2 Calculated structure of complex **2**.

DOI: 10.1039/b004340k

and N(imido)–C distances that are markedly shorter and longer, respectively, than the corresponding experimental bond lengths. This discrepancy may be due to the delocalisation of electron density from the N atom to the aromatic substituent, an electronic redistribution that is unavailable to the NMe ligand of the computational model.

Complex **1** is the most strongly-bent chromium imido complex observed to date, as confirmed by a search of the Cambridge Structural Database (October 1999 release), and is the *only* example of a chromium *mono*imido compound with a Cr–N–C angle $< 165°$.[11] While $Cr(NR)_2X_2$ compounds exhibit a wide range of Cr–N–C angles (typically 155 to 175°), none approaches the degree of bending observed in **1** unless the two imido groups are joined in a strained chelate ring.[3b] The evident π-donation of the NPr^i_2 group is not responsible for the Cr–N–Ar bending, in that amido π-bonding in the related $Cr(NR)_2(NHR)Cl$ complexes fails to disrupt the Cr–imido interaction.[12,13] The geometry of **1** is therefore attributed to the competition between the oxo and imido groups for available d_π orbitals.[14]

A series of single-point calculations were performed to see what variation of the overall energy of **2** would result from variation of the imido Cr–N–C angle. As shown in Fig. 3, this is a remarkably soft deformation mode, requiring < 18 kJ mol^{-1} to make the imido ligand perfectly linear. The relative ease of imido bending/straightening has been established theoretically,[15] spectroscopically[16] and structurally.[17]

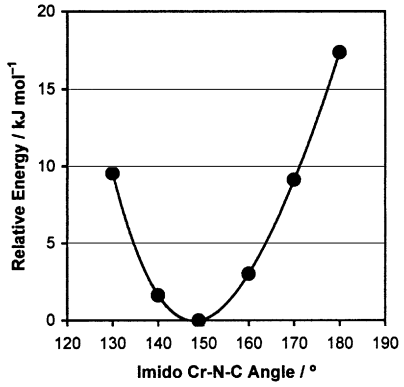

Fig. 3 Energy change with imido ligand angle in **2**.

As indicated in Scheme 1, $Cr(NO)(NPr^i_2)Ar_2$ is presumably an intermediate in the formation of complex **1**, though our attempts to trap or observe the diaryl precursor have thus far been unsuccessful. The relative instability of the putative diaryl compound with respect to nitrosyl bond cleavage may be related to the propensity of aryl (in contrast to alkyl) groups to undergo migration reactions to M=E linkages.[20] The cleavage of nitrosyl ligands is still relatively rare, but several examples of this reactivity are now known for unsaturated Group 6 complexes.[21] The transformation of R–Cr–NO to RN=Cr=O provides access to rare chromium d^0 monoimido species,[22] a potentially useful synthetic alternative to the chromyl chloride-derived $Cr(NR)_2X_2$ compounds that dominate Cr(VI) imido research.[12]

As established by DFT calculation, the strongly-bent imido angle of **1** clearly has an electronic origin, which we attribute to oxo–imido π-conflict, and which stands in contrast to the range of angles found in related bisimido structures. The calculations further reveal the soft nature of the distortion, in accord with experimentally determined examples of facile imido bending in Group 6 $M(NR)(E)X_2$ complexes. Given the influence of imido geometry on the reactivity of such complexes,[23] we feel the effect of these π-conflicts on imido-bending energy surfaces has been underappreciated. Further synthetic and theoretical studies to explore this phenomenon will undoubtedly aid in the rational design of catalysts for ROMP,[1] RCM[2] and olefin polymerisation[3] chemistries.

17 There exist cases where two independent imido compounds in the same unit cell exhibit highly disparate M–N–C angles, suggesting that such near-linear imido groups are susceptible to perturbation from intermolecular packing forces.[18] These angles are equally sensitive to *ortho* substitution; the classic structure of $Mo(NPh)_2(S_2CNEt_2)_2$ displays one linear and one bent imido ligand,[19a] while $Mo(NAr')_2(S_2CNEt_2)_2$ (Ar′ = 2,6-$Pr^i_2C_6H_3$) possesses two linear imido groups.[19b]

Preparation, characterization and condensation of novel metal chalcogenide/MCM-41 complexes

Collin Kowalchuk, John F. Corrigan* and Yining Huang*

Received (in Irvine, CA, USA) 16th March 2000, Accepted 2nd August 2000

Hexagonally ordered mesoporous MCM-41 with 3 nm pores has been impregnated with the metal chalcogenolate $Cu_6(TePh)_6(PPh_2Et)_5$ 1: the analysis and condensation of this material is a step toward the synthesis of semiconducting nanowires.

The ability of mesoporous materials to act as hosts for quantum structures has been the focus of numerous research efforts as exemplified with reports on the absorption and subsequent polymerization of analine,[1] the encapsulation of semiconducting Ge filaments,[2] the preparation of ferrocenophane polymer[3] and the fabrication of nanostructured Pt clusters and wires.[4]

The independent development of the chemistry of mesoporous materials and metal chalcogenide clusters over the past decade have seen dramatic growth.[5–7] The union of these two fields, the encapsulation of metal chalcogenide clusters and their subsequent condensation into size limited semiconductor particles, should provide novel one-directional nanostructures.

The copper–chalcogenolate cluster $Cu_6(TePh)_6(PPh_2Et)_5$ **1** can be accessed in high yields *via* the reaction of CuCl and $Te(Ph)SiMe_3$ with an excess of the phosphine PPh_2Et.[8] Cluster **1**, like many metal–tellurolate complexes[9] undergoes a series of condensation reactions *via* the photochemical elimination of $TePh_2$. For **1**, this yields the cluster $[Cu_{50}(TePh)_{20}Te_{17}(PEtPh_2)_8]^{4-}$.[8] Our efforts in this area are to exploit these facile condensation processes within the channels of nanoporous MCM-41. Pure silica MCM-41, prepared with cetyltrimethylammonium bromide, has a pore size easily large enough to accommodate clusters such as **1**.[10]

The synthesis of **1**/MCM-41† was achieved using sublimation techniques under an inert atmosphere. During impregnation, maintaining an inert atmosphere is extremely important since at these elevated temperatures rapid cluster decomposition is otherwise observed. However, after loading, these materials are stable under atmospheric conditions for an extended period of time.

TGA data provide important information about the loading features. Characteristic decomposition curves of **1** and **1**/MCM-41 are shown in Fig. 1. For pure **1** [Fig. 1(a)] a single decomposition is observed, produced by two distinct endothermic steps obtained by DTA. This decrease in mass results from the loss of 3 equivalents of $TePh_2$ and 5 equivalents of PPh_2Et per cluster molecule as determined by TGA and subsequent GC–MS analysis. The observed 70.5% weight loss is close to the calculated loss of 71.5%. Since no strong interaction between the outer surface of the host and copper cluster is expected, the thermal decomposition of **1** adsorbed onto the MCM-41 exterior surface should be very similar to that observed for pure **1**. The TGA of a sample **I** of MCM-41 combined with **1** (70 °C, 10^{-3} Torr) [Fig. 1(b)] displays a weight loss at low temperature (onset = 150 °C) due to **1** adsorbed on the external surface. A 150 °C onset decomposition temperature is consistently observed for externally adsorbed **1** on MCM-41 and is identical to that observed for pure **1**. The high temperature (250 °C) weight loss can thus be attributed to cluster loaded inside the MCM-41 channels. The TGA results indicate some impregnation at 70 °C (10^{-3} Torr), with cluster **1** being only partially loaded inside of MCM-41. In contrast, a sample of **1**/MCM-41 complex **II** prepared by heating at 110 °C (10^{-3} Torr) [Fig. 1(c)] displays only one, high temperature decomposition suggesting complete loading of **1** inside of the MCM-41 host.

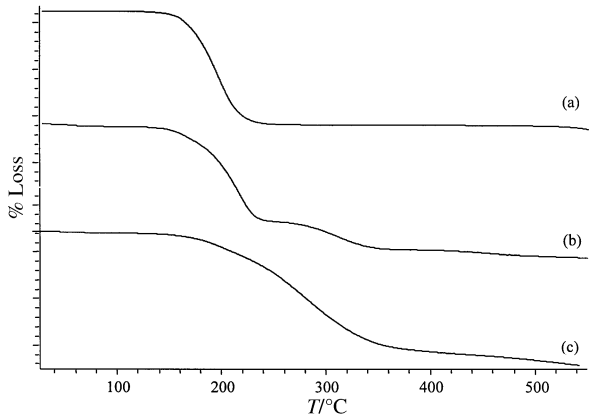

Fig. 1 TGA decomposition in the range 25–550 °C at a heating rate of 10 °C min^{-1}: (a) pure **1**; (b) **1**/MCM-41 treated at 70 °C at 10^{-3} Torr (sample **I**); (c) **1**/MCM-41 treated at 110 °C at 10^{-3} Torr (sample **II**).

The actual weight percent loading may be calculated from these curves. It is observed that loading is virtually time independent. Factors such as temperature and **1**/MCM-41 ratio affect the loading percent if loading is carried out for a minimum time of 12 h. For mechanical mixing under atmospheric conditions, a maximum of 5% loading is observed and can be attributed to a small quantity of cluster blocking the entrance to the pores. At 70 °C the loading increases to 11%. An increase in temperature leads to higher loading with a maximum of 34% achieved at 110 °C.

Nitrogen adsorption studies confirm that **1** is indeed loaded into the channels of MCM-41. The adsorption curve for pure MCM-41 [Fig. 2(a)] with a type IV isotherm and distinct capillary condensation characteristic of MCM-41 has a BET surface area of 1126 $m^2\ g^{-1}$. The BET surface area decreases to 272 $m^2\ g^{-1}$ for **II** [Fig. 2(b)]. No significant lattice contraction

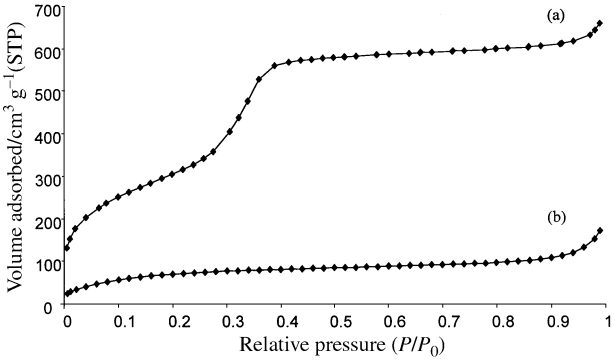

Fig. 2 Nitrogen adsorption curves: (a) MCM-41; (b) **1**/MCM-41 treated at 110 °C at 10^{-3} Torr (sample **II**).

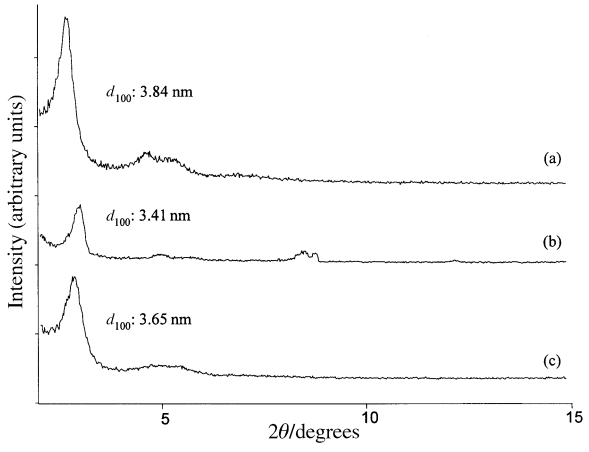

Fig. 3 PXRD patterns in the range 2θ = 2–15° (intensities normalized to the d_{100} reflection intensity of calcined MCM-41): (a) pure MCM-41; (b) **1**/MCM-41 treated at 70 °C at 10^{-3} Torr (sample **I**); (c) **1**/MCM-41 treated at 110 °C at 10^{-3} Torr (sample **II**).

was observed by powder X-ray diffraction (PXRD) and thus we conclude that this decrease in surface area is a result of the loaded cluster. The inflection point of the loaded sample becomes less sharp and shifts to lower relative pressure. This shift indicates the presence of smaller mesopores due to the impregnation of **1**. However the mesoporous structure is maintained as indicated by the overall shape of the isotherms and from PXRD.

The powder pattern of samples of MCM-41 has a characteristic diffraction pattern (h_{100}, h_{110}, h_{200}) with a calculated d_{100} of 4.4 nm.[10] The partial impregnation of **1** into MCM-41 [Fig. 3(b)] gives rise to diffraction patterns for host and guest species, with reflections of **1** due to crystallites of the cluster adsorbed on the external surface of MCM-41. With **II**, only the diffraction pattern of MCM-41 is observed [Fig. 3(c)]. We therefore conclude that the structural integrity of MCM-41 is maintained during impregnation and the clusters are dispersed within the channels with no long range ordering. A decrease in the intensity of the d_{100} diffraction and a smaller *d*-spacing are observed in both loaded samples **I** and **II**. The loading of **1** into the pores of MCM-41 causes a decrease in the mean electron density of silicate walls compared to the pores, thus decreasing the d_{100} diffraction.[11] The smaller *d*-spacing in Fig. 3(b) and (c) suggests the loading process slightly decreases the size of the pore walls.

The IR spectrum of **1**/MCM-41 in the ν(CH) stretching region suggests that cluster integrity is maintained during impregnation as the number of ν(CH) bands and their position of **II** are virtually identical to those for **1**. CP MAS ^{31}P NMR spectra of **II** display only a single peak at −11.8 ppm in close agreement with the observed solution shift (−10.4 ppm)[8] of the free cluster, as expected when the cluster is 'diluted' in the solid framework.

The photolysis of **1** and the **1**/MCM-41 complex provides evidence of cluster condensation, in agreement with its developed solution chemistry.[8] The UV–VIS spectra of non-photolysed **1**/MCM-41 in hexane show two distinct maxima at 210 and 249 nm.

Since **1** has low solubility in hexane, a slurry of **II** was prepared and the suspension was photolysed.‡ A darkening of the sample and a red shift is observed for both **1** and **II**. The observed red shift in the UV–VIS spectra suggests cluster condensation, as previously observed.[12] Increasing the irradiation time increases the red shift for both samples and yields a new absorbance at 440 nm for irradiated **1**. No further change is observed after 10 h of irradiation. Although identical condensation as that observed in solution, which results in the formation of $[Cu_{50}(TePh)_{20}Te_{17}(PEtPh_2)_8]^{4-}$, from **1** inside the pores of MCM-41 is unlikely, a condensation process is nonetheless occurring. Thermally activated condensation of **1** inside the pores of MCM-41 is also possible with complete loss of $TePh_2$ and PPh_2Et moieties with only copper telluride remaining as characterized by PXRD. We are currently perusing the characterization of the condensed materials and the general applicability of this method to metal chalcogenolate complexes.

We thank The University of Western Ontario, NSERC Canada and the Canada Foundation for Innovation for financial support. Dr L. Mercier (Laurentian University) is thanked for the nitrogen adsorption studies.

Notes and references

† 0.1 g of calcined MCM-41 was dehydrated at 130 °C under dynamic vacuum (10^{-3} Torr) for 3 h. Homogeneous samples of cluster:MCM-41 (weight ratios 1:4, 1:2) were prepared by mechanical mixing under atmospheric conditions producing a yellow microcrystalline powder. These samples were then heated at 70 or 110 °C under a static vacuum (10^{-3} Torr) for a minimum of 12 h.

‡ *Preparation* of UV–VIS samples: 0.05 g samples of **1** and **1**/MCM-41 (**II**) were charged in quartz UV cells with glass-distilled hexane and a stir bar to prepare a suspension. The samples were irradiated at room temperature with a low-pressure Hg lamp ($\lambda > 254$ nm).

Oxygen atom transfer from $Re^{V}O$ to tertiary diphosphines: spacer length and chemical differentiation of products

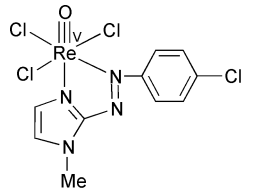
Sibaprasad Bhattacharyya, Indranil Chakraborty, Bimal Kumar Dirghangi and Animesh Chakravorty*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India. E-mail: icac@mahendra.iacs.res.in

Received (in Cambridge, UK) 7th June 2000, Accepted 16th August 2000

The reaction of *mer*-[ReL(O)Cl_3], [L = 2-(*p*-chlorophenylazo)-1-methylimidazole] with $Ph_2P(CH_2)_nPPh_2$ (abbreviated P*n*P) affords [ReL(OP1P)Cl_3] 2a, [ReL(OP1PO)Cl_3] 4 and [ReL(OP2P)Cl_3] 2b, [Cl_3LRe(OP2PO)ReLCl_3] 5, all having *mer* geometry; unlike 2b which is stable in solution, 2a spontaneously isomerizes to *fac*-[ReL(P1PO)Cl_3] *via* an associative pathway; the origin of the observed differentiation (2a *vs.* 2b and 4 *vs.* 5) is scrutinized in terms of structures and reaction models.

Tertiary phosphines are model oxygen atom acceptors from oxo moieties such as $Re^{V}O$.[1,2] Chelation by the π-acidic azoimidazole L as in **1**, facilitates the transfer process.[3] This work



1 *mer*-[ReL(O)Cl_3]

2a *mer*-[Re^{III}L(OP1P)Cl_3]
2b *mer*-[Re^{III}L(OP2P)Cl_3]
3 *fac*-[Re^{III}L(P1PO)Cl_3]
4 *mer*-[Re^{III}L(OP1PO)Cl_3]
5 *mer*-[Cl_3LRe^{III}(OP2PO)$Re^{III}LCl_3$]

concerns the species **2**–**5** formed from **1** and $Ph_2P(CH_2)_nPPh_2$ (abbreviated P*n*P, *n* = 1, 2)[4] directly or *via* subsequent transformations. The differentiation referred to in the title relates to the pairs **2a, 2b** and **4, 5** in which the length of the spacer –$(CH_2)_n$– varies.

With P*n*P in excess, stereoretentive one-atom transfer [eqn. (1)] afforded† **2a** and **2b** (Fig. 1).‡ Both are stable in the solid state and **2b** is also stable in solution. In contrast, **2a** undergoes spontaneous linkage-*cum*-geometrical isomerization [eqn. (2)] in solution furnishing† **3** (Fig. 2).‡

$$R{\equiv}O + PnP \rightarrow Re{-}OPnP \quad (1)$$

$$Re{-}OP1P \rightarrow Re{-}P1PO \quad (2)$$

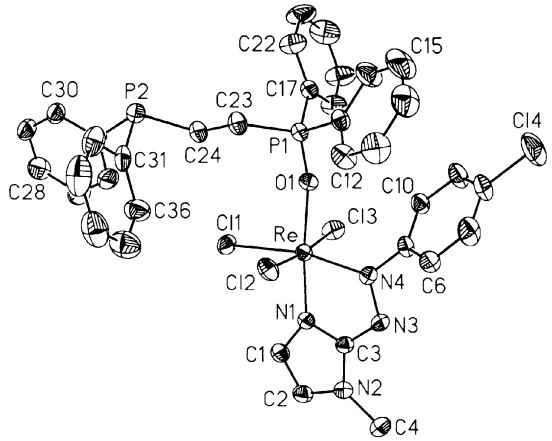


Fig. 1 Perspective view of *mer*-[Re^{III}L(OP2P)Cl_3] **2b**. $$\text{Re–OP1P} + \text{Re}\equiv\text{O} \rightarrow \text{Re–OP1PO} \quad (4)$$

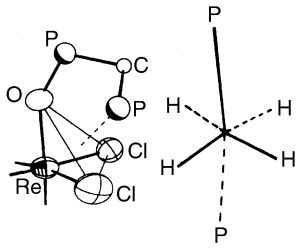
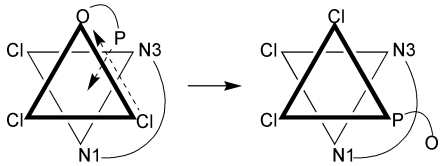
$$\text{Re–OP2P} + \text{Re}\equiv\text{O} \rightarrow \text{Re–OP2PO–Re} \quad (5)$$

The remarkable double isomerization of **2a** can be rationalized. **2a** did not afford single crystals but the structure of **4** provides a credible geometrical model in which the pendent P(1)C(23)P(2) fragment is positioned near the Cl(1)Cl(2)O(1) face. A simple rotation around the P(1)–C(23) bond brings the P(2) atom to within 2.6 Å of the face as in **6** which is a plausible



6 **7**

model for the associative transition state of the reaction. The attack by P(2) can progress *via* edge displacement[6] of a chloride ligand with concomitant Re–OP(1) bond cleavage leading to **3**, [eqn. (6)]. The *fac* geometry of **3** is sustained by concerted



2a **3** (6)

Re–L and Re–P back-bonding as in *fac*-[ReL(PPh$_3$)Cl$_3$].[3] In **2b** the PCH_2CH_2P fragment has the *anti* conformation **7**. The potentially reactive *gauche* conformation is not accessible due to the bulk of PPh_2, and accordingly **2b** fails to isomerize.

The conformation **7** is, however, ideally suited for sustaining binucleation as in **5**.[5] On the other hand only the dangling phosphine oxide function is preserved in **4** as a vestige of transient binucleation. The environment of the O(2) atom in **4** is crowded [O(2)···P(1) 3.57 Å, O(2)···C(11) 3.55 Å] and model building has confirmed that the $n = 1$ analog of **5** is not sterically viable.

In summary, there is a strong chemical differentiation between the $n = 1$ and 2 products formed in both one-atom (**2a**, **2b**) and two-atom (**4**, **5**) transfer from **1** to P*n*P. The applicability of the observed structural and dynamical features to other systems is under scrutiny.

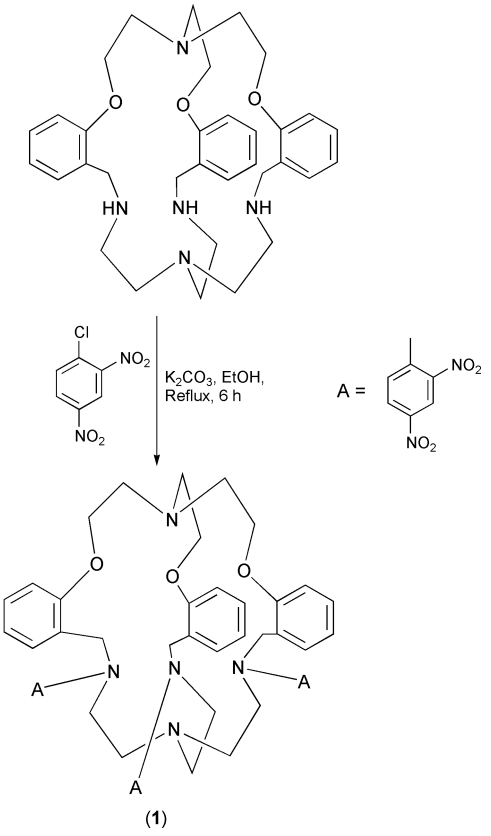
Received (in Cambridge, UK) 12th June 2000, Accepted 8th August 2000

The cryptand derivative has H-bond mediated trigonal network structure that leads to octupolar bulk nonlinearity

Optically nonlinear organic materials are of paramount importance for applications in optical signal processing and telecommunications.[1] We present here a new strategy for obtaining molecules with bulk optical nonlinearity by derivatizing a cryptand with three D–π–A units related by a 3-fold rotational symmetry. Thus, compound **1** (Scheme 1) is engineered with the ultimate aim of a trigonal network necessary for bulk octupolar nonlinearity. The classical molecular requirements for second-order nonlinear optical (NLO) effects have led to the development of strongly conjugated materials asymmetrized by interacting donor and acceptor groups.[2] Even though these molecules exhibit large hyperpolarizabilty, major drawbacks arise due to their anisotropic dipolar character, *e.g.* a high tendency towards unfavorable aggregation, difficult non-centrosymmetric crystallization, and small off-diagonal tensor components. To alleviate such problems, isotropic molecules with attached octupolar nonlinearities have been proposed, on the basis of group-theoretical and quantum-mechanical calculations.[3] Solution-phase studies by Hyper-Rayleigh Scattering (HRS) technique on crystal violet and tris(4-methoxyphenyl)cyclopropenylium bromide as octupoles have been reported.[4] However, assembly of octupolar molecules into an acentric bulk presents an arduous task. To-date, only 2,4,6-triamino-1,3,5-trinitrobenzene (TATB) (3 × urea),[5] substituted triazenes (0.1 × urea)[6] and cyclohexane-1,3,5-triamide derivative (0.06 × urea),[7] are the only octupolar organic materials reported to exhibit bulk NLO properties.



(1)

Scheme 1 Synthetic scheme for compound **1**.

No cryptand-based octupolar molecule having bulk NLO properties has been reported in the literature although cryptands are an important class of molecules having a 3-D cavity with proven recognition properties through supramolecular interactions.[8] Our principal motivation to use the cryptand as a central core stems from the following three assets: (i) a 3-fold rotational symmetry passing through the two bridgehead nitrogen atoms of the cryptand molecule, (ii) three phenyl rings as rigid segments would favor ordered structures and (iii) three easily functionalizable secondary nitrogen atoms would assist in grafting acceptor molecules of choice. We have chosen 2,4-dinitrobenzene as it has been shown to have adequate electronic asymmetry in methyl 2-(2,4-dinitroanilino)propanoate (MAP).[9] Besides, the nitro substitution at the *ortho* position would provide a more rounded-off shape to the molecules (Scheme 1), which would ease their packing in the crystal lattice.

Compound **1** was synthesized (Scheme 1) by refluxing the cryptand[10] with 3 equiv. of 2,4-dinitrochlorobenzene and anhydrous K_2CO_3 for 6 h in dry EtOH under N_2. The yellow–orange tri-substituted product was isolated in 92% yield.

Single crystals suitable for X-ray diffraction were grown by slow evaporation from pyridine solution. The compound afforded very large triangular crystals (~ 5 mm each side) in just two days. It crystallizes† in the desired non-centrosymmetric trigonal space group *P*3, containing three strands in the asymmetric unit. The C_3 symmetry generates the donor–acceptor substituted cryptand molecules **A**, **B** and **C** with the symmetry axis passing through the bridgehead nitrogens which also coincides with the triad axes of the lattice. Supramolecular assembly of these C_3 symmetric cryptand molecules generates an octupolar trigonal network. The molecules **A**, **B** and **C** vary considerably in their conformation. Three different forms of intramolecular forces are operational in the D–π–A substituted cryptand molecule: (i) aromatic π-stacking between the phenyl ring of one strand with the dinitro-substituted ring of the symmetry related strand in an edge-to-face fashion with a distance of 3.923 Å, (ii) CH···π interaction within the same strand of the molecule with a distance of 3.355 Å, and (iii) CH···O hydrogen bonding between the carbon atom of the benzylic amino group and the oxygen atom of the *ortho*-nitro group with a distance of 2.92 Å (Fig. 1).

The intermolecular interactions leading to the trigonal network structure involve each phenyl ring of the cryptand **B** stacked face-to-face[11] (3.328 Å) with a dinitrobenzene moiety of cryptand **C** while at the same time interacting with a phenyl ring of cryptand **C** in edge-to-face (3.585 Å) manner (Fig. 2). The intermolecular interactions also involve anti-parallel stacking of the dinitro-substituted rings of neighboring cryptands at a distance that ranges between 4.425–4.665 Å and that attenuates the bulk non-linear efficiency of **1** to some extent.

We performed Kurtz powder second-harmonic generation (SHG) measurements[12] on compound **1**. The non-centrosymmetric nature was confirmed by a visible SHG powder signal at

DOI: 10.1039/b004679p

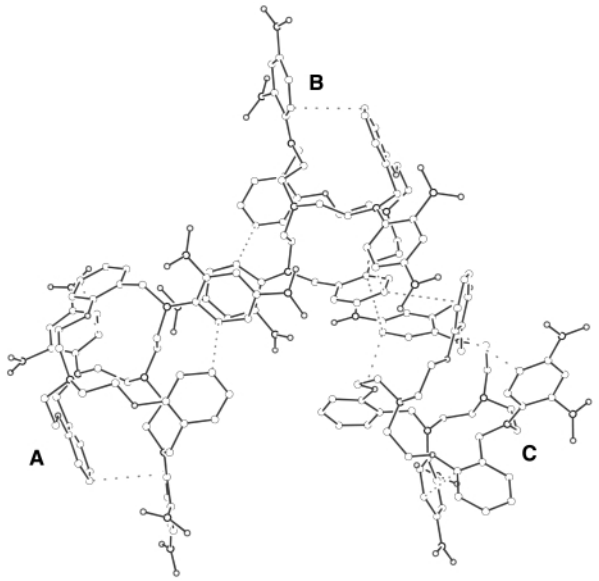

Fig. 2 A perspective view of **A**, **B** and **C** cryptand molecules showing both intra- and intermolecular H-bonding interactions.

1.064 μm of the order of 0.6 × urea and represents the first cryptand-based NLO-active bulk molecule. The non-linear $\sqrt{<\beta^2>}$ coefficient of **1** was determined by HRS technique[13] at 1.064 μm in $CHCl_3$ and gave a value of 16×10^{-30} esu. The corresponding $\sqrt{<\beta^2>}(0)$ static value was found to be 11×10^{-30} esu, which is comparable[6] to that of the classical dipolar PNA molecule under the same measurement conditions. Although powder efficiency of compound **1** is modest, it has a good transparency at the visible region of the spectrum (λ_{max} ~ 370 nm in $CHCl_3$). Most strikingly, compound **1** by virtue of its strong intermolecular interactions has a mp of 215 °C, which is the highest among all of the nitroaniline-based compounds reported[14] to have bulk NLO properties. This will make it potentially useful for further device applications. Furthermore, this work presents ample scope for modulating the NLO property through recognition of different metal ions in the cavity of the cryptand as well as by functionalizing the three amino groups with stronger acceptor units.

Hydrothermal synthesis and crystal structures of two bimetallic chain-like and cluster complexes $[\{Co(phen)_2\}_2V_6O_{17}]_n$ and $[\{Cu(phen)_2\}_4V_{10}O_{29}]\cdot 6H_2O$†

Xian-Ming Zhang, Ming-Liang Tong and Xiao-Ming Chen*‡

State Key Laboratory of Ultrafast Laser Spectroscopy and School of Chemistry & Chemical Engineering, Zhongshan University, Guangzhou, 510275, P.R. China

Received (in Cambridge, UK) 20th July 2000, Accepted 15th August 2000

Two complexes, $[\{Co(phen)_2\}_2V_6O_{17}]_n$ 1 and $[\{Cu(phen)_2\}_4V_{10}O_{29}]\cdot 6H_2O$ 2, have been hydrothermally synthesized; X-ray crystallography shows that 1 consists of one-dimensional stepped chains built up from covalently linked $\{V_6O_{17}\}_n^{4n-}$ chains and $[Co(phen)_2]^{2+}$ fragments while 2 is composed of a discrete $V_{10}O_{29}^{8-}$ cluster covalently attached to four $[Cu(phen)_2]^{2+}$ fragments.

There has been extensive interest in organic–inorganic hybrid vanadium oxides and polyvanadate clusters owing to their structural diversity and potential application in catalysis and material science.[1–5] An important advance in organic–inorganic vanadium oxides has recently been the study of solid state coordination chemistry, which is characterized by transition metal complexes or fragments covalently bonded to metal oxide framework or polyanion clusters. A variety of vanadium solid state complexes including discrete clusters, infinite chains and layer structures have been prepared by hydrothermal methods.[6–12] However, in terms of discrete organic–inorganic bimetallic clusters formulated as $[(ZnL_2)V_4O_{12}]$ [L = 2,2′-bipyridine (bpy) or 1,10-phenanthroline (phen)],[6] the vanadium clusters are limited to $V_4O_{12}^{4-}$, and in the metavanadate chain-like compounds formulated as $[(CuL_m)V_2O_6]_n$ (L = NH_3, ethylenediamine, bpy, diethylenetriamine; m = 1, 2) the vanadium oxide chains are limited to $\{V_2O_6\}_n^{2n-}$.[7–9] Herein, we report two interesting solid state vanadium(v) complexes $[\{Co(phen)_2\}_2V_6O_{17}]_n$ **1** and $[\{Cu(phen)_2\}_4V_{10}O_{29}]\cdot 6H_2O$ **2**, where the tetranuclear $V_4O_{12}^{4-}$ and dinuclear $V_2O_7^{4-}$ building units are unprecedentedly linked together by sharing oxygen atoms.

Complex **1** was synthesised as brown blocks in 80% yield based on vanadium by a hydrothermal method. A mixture of V_2O_5, $Co(OAc)_2\cdot 4H_2O$, phen and water in a molar ratio of 1:1:2:1100 was stirred for 20 min in air, before being transferred and sealed in a 23 cm^3 Teflon-lined reactor, which was heated to 140 °C and held at this temperature for 72 h. Complex **2** was synthesised as blue blocks in 40% yield under similar conditions to **1** using $Cu(OAc)_2\cdot 2H_2O$ in place of $Co(OAc)_2\cdot 4H_2O$. Both **1** and **2** are insoluble in water and common organic solvents. The IR spectra§ of **1** and **2** exhibit characteristic bands for both V=O and phen. Thermogravimetric analysis shows a weight loss of *ca*. 50% for **1** in the range 300–550 °C corresponding to the loss of phen. A weight loss of *ca*. 4% for **2** in the range 120–150 °C corresponds to removal of the lattice water molecules while a further weight loss of *ca*. 51% occurs in the range 300–550 °C consistent with the loss of phen.

The crystal structure of **1**¶ shows the presence of an unprecedented one-dimensional stepped chain constructed from $\{V_6O_{17}\}_n^{4n-}$ chains with $[Co(phen)_2]^{2+}$ fragments covalently attached *via* oxygen atoms, as shown in Fig. 1. The anionic chain in **1** is composed of alternate tetranuclear $V_4O_{12}^{4-}$ and dinuclear $V_2O_7^{4-}$ building units, which are linked by sharing oxygen atoms. All vanadium sites show VO_4 tetrahedral geometry, each of which has a terminal vanadyl (V=O) group and shares three corners with CoN_4O_2 octahedra and/or VO_4 tetrahedra. There are three crystallographically independent vanadium atoms in the anionic chain; V(1) and V(2) share oxygen atoms with one CoN_4O_2 octahedron and two VO_4 tetrahedra while V(3) only shares oxygen atoms with three VO_4 tetrahedra. The Co(II) atom, which is in a slightly distorted octahedral geometry, is ligated by two phen ligands, with the $[Co(phen)_2]^{2+}$ fragments further covalently bonded to the anionic chain through atoms O(1) and O(2) and their symmetry equivalents. Such a linking gives rise to three eight-membered rings, CoV_3O_4, V_4O_4 and CoV_3O_4, in chair-like configuration similar to that found in $[Cu(phen)MoO_4]$.[5] Although the empirical formula of **1** is similar to that of $[\{Zn(bpy)_2\}_2V_6O_{17}]$,[6] its architecture is different from the latter in which each VO_4 tetrahedron shares three corners with adjacent VO_4 tetrahedra forming layers rather than chains.

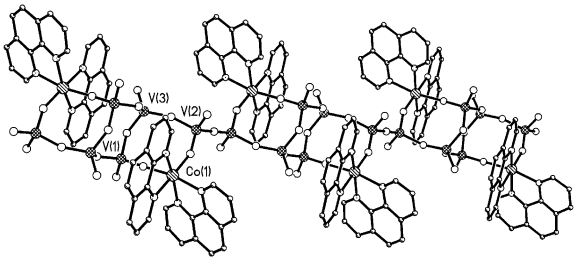

Fig. 1 Perspective view of the stepped chain of **1**.

The structure of **2** features a discrete tetradecanuclear heterometallic cluster built up from $V_{10}O_{29}^{8-}$ clusters and four $[Cu(phen)_2]^{2+}$ fragments (Fig. 2). The Cu(II) atoms, which are in a distorted square-pyramidal geometry, are attached to the vanadium cluster *via* O(6) and O(11) and their symmetry equivalents. In contrast to **1**, while the anionic vanadium cluster

also consists of corner-sharing VO_4 tetrahedra, all VO_4 tetrahedra in **2** have one [V(2)–V(4)] or two [V(1) and V(5)] terminal oxygen atom(s). The $V(1)O_4$ tetrahedron has two terminal oxygen atoms, which may be directly responsible for the formation of the cluster rather than a chain. Similarly to the anion in **1**, the $V_{10}O_{29}^{8-}$ cluster consists of a dinuclear $V_2O_7^{4-}$ and two tetranuclear $V_4O_{12}^{4-}$ fragments linked by sharing oxygen atoms. Although the $V_{10}O_{28}^{6-}$ cluster is common in solution and a chiral $V_{10}O_{22}$ cluster[13] has recently been synthesised, the $V_{10}O_{29}^{8-}$ cluster found in **2** has not been reported before. In addition, the coordination mode of V_4O_{12} fragments in both **1** and **2** is unprecedented, in contrast to all documented and proposed coordination modes of the $V_4O_{12}^{4-}$ cluster, in which each heterometallic atom is attached to two or four oxygen atoms of the $V_4O_{12}^{4-}$ cluster.[6]

It is of note that π–π stacking interaction between interchain or intermolecular phen groups plays a significant role in stabilisation of the structures of **1** and **2**. Adjacent phen groups in **1** or **2** are generally parallel and separated by 3.1–3.5 Å, which indicates strong π–π stacking interactions.[14] Therefore, the heterometallic stepped chains of **1** and discrete tetradecanuclear heterometallic clusters of **2** are further extended into interesting three-dimensional supramolecular arrays *via* π–π stacking interactions of phen groups (see Fig. 1S, 2S and 3S in ESI†). It should also be noted that while **1** and **2** were prepared under the same conditions, their structures differ significantly. This may originate from the nature of heterometallic atoms employed. Co(II) tends to adopt octahedral geometry whereas Cu(II) favours a square-planar or square-pyramidal geometry owing to the strong Jahn–Teller effect. Meanwhile, the steric effect of phen appears to play an important role in the formation of the unique structures of **1** and **2**. The large steric hindrance of phen prevents the formation of heterometallic layered structures.

Received (in Cambridge) 29th June 2000, Accepted 17th August 2000

Sequential reaction of $ZnMe_2$ with the (2-pyridyl)amines HN(2-C_5H_4N)R (R = Bz = benzyl 1, Me 2), Bu^tLi and oxygen affords species which demonstrate oxo-encapsulation {(μ$_4$-O)Zn_4[N(2-C_5H_4N)Bz]$_6$ 3}, and both encapsulation and insertion into a C–Li bond {Bu^t(μ$_3$-O)Li_3(μ$_6$-O)Zn_3[N(2-C_5H_4N)Me]$_6$ 4}; in the solid-state 4 has a new type of *fac*-isomeric (μ$_6$-O)$M_3M'_3$ octahedral core.

Current interest in the properties of lithium containing heterobimetallic species derives from their ability to effect organic transformations whose selectivity differs from those afforded by homometallic organolithium compounds. Hence, whereas organolithium reagents perform 1,2-addition across α,β-unsaturated ketones,[1] it has been reported lately that in the presence of group 13 Lewis acids 1,4-addition is preferred,[2] with the formation of a lithium aluminate recently being implicated in this process.[3] Also of use in such conjugate additions,[4] lithium organozincates find extensive employment in synthetic chemistry.[5] In spite of this utility, lithium zincate structural chemistry is not well understood, and of the few known structures two classes dominate. Ion-separated species are favoured by the presence of strongly coordinating Lewis bases[6] whereas in their absence ion-associated [Li(μ$_2$-C)$_2$]$_n$Zn (n = 1, 2)[7] motifs prevail. In the light of advances in the controlled oxygenation of heterobimetallic compounds[8] we report here on the incorporation of oxygen by mixed Li–Zn systems and detail the variable reactivity towards oxygen of the products afforded by sequentially treating (2-pyridyl)amines with organozinc and organolithium reagents (Scheme 1).

The reaction of a non-donor solution of HN(2-C_5H_4N)R (R = Bz = benzyl **1**) with $ZnMe_2$ and Bu^tLi was followed by treatment with air (pre-dried over P_2O_5) until the evolution of fumes subsided. Storage of the resultant solution afforded two crystalline compounds.‡ The characterisation of both species was made possible by their mechanical separation, with ^{1}H NMR spectroscopy verifying that one of these products was Bu^tOLi. The remaining compound was shown by X-ray crystallography§ to be the trigonal pyramidal complex (μ$_4$-O)Zn_4[N(2-C_5H_4N)Bz]$_6$ **3** [Fig. 1(a)] for which formulation there is a toluene molecule in the lattice. Of the two types of Zn centre in this species, three describe the pyramid base [Zn1A···Zn1B 3.130(2) Å] each non-bonding edge of which is spanned by a [N(2-C_5H_4N)Bz]$^-$ ligand [Zn–N(2-C_5H_4N) 2.069(7) Å, Zn–NBz 1.984(7) Å]. The final metal centre (Zn2) occupies the C_{3v} cluster apex and is stabilised by the pyridyl N-centres of the remaining three organic residues [Zn2–N(2-C_5H_4N) 2.045(7) Å], each of which spans one non-bonding Zn1···Zn2 [3.089(2) Å] pyramid edge [Zn1–NBz 2.002(7) Å]. At the core of the C_{3v} cluster is a nearly tetrahedral O^{2-} centre (mean Zn–O 1.903 Å, mean Zn–O–Zn 108.9°). It is noteworthy that previous examples of oxo-encapsulation by Zn_4-tetrahedra have resulted from the deliberate introduction of water[9,10] or

† Deceased.

carbon dioxide[11] whereas **3** is afforded by exposure to oxygen.

Significant structural modification was observed in the product of the analogous reaction for which R was the less sterically demanding Me group (**2**), this process affording **4**.‡ X-Ray crystallography§ reveals **4** to be the unique distorted octahedral oxo-encapuslation complex $Bu^t(\mu_3\text{-}O)Li_3(\mu_6\text{-}O)Zn_3[N(2\text{-}C_5H_4N)Me]_6$ [Fig. 1(b)] for which formulation there is one thf molecule in the lattice. That the Li_3 face is μ_3-capped by an OBu^t group points to an oxygen atom having inserted into a Li–C(Bu^t) bond [Li–O2 1.849(14) Å, Li–O2–Li 83.7(7)°].[12] The three lithium centres are less strongly bonded to the encapsulated μ_6-O centre [Li–O1 2.074(13) Å, Li–O1–Li 73.0(6)°] which in turn interacts with the three Zn centres [Zn–O1 1.944(4) Å, Zn–O1–Zn 101.4(3)°]. The result—a molecular *fac*-isomeric $(\mu_6\text{-}O)M_3M'_3$ octahedron—has not been seen before. Instead, existing examples of molecular μ_6-O heterobimetallic octahedra have either (MM'_5)[13] or $(M_2M'_4)$[14] formulations. The only previous report of a lithium containing heterobimetallic μ_6-O octahedral complex is that of $[RuH(SiHPh_2)(CO)X_2]_2{\cdot}[Li_2Ru_4OCl_8X_4]$ (X = PBu^t_2Me), which has a *trans*-isomeric $(\mu_6\text{-}O)Li_2Ru_4$ core;[15] all other examples of lithium containing μ_6-O octahedra have been homometallic.[16] The coordination spheres of both Li and Zn centres in **4** are completed by $[N(2\text{-}C_5H_4N)Me]^-$ ligands. Three of these residues span the 3.007(2) Å Zn···Zn non-bonding distances in the lower tier of the cluster [Zn–N1 2.038(7) Å, Zn–N2 2.050(7) Å]. The remaining organic residues circumscribe the non-bonding Li_3 [Li···Li 2.47(2) Å] upper tier but are orientated such that their N-pyridyl centres are precisely in the Li_3 plane while their NMe-groups span non-bonding heterobimetallic [Li···Zn 2.75(1) Å] octahedron edges [Zn1–N4 2.065(7) Å]. The sp^2-orbital on their deprotonated N-centres almost bisects the Li–N(Me)–Zn bond angle [N3–C11–N4–M torsional angles = 42.8° (M = Li1A), 45.4° (M = Zn1)] with the consequent mismatch in orientation of the NMe-centred lone-pairs with the Li^+ ions in the upper tier probably being responsible for the respective Li–N(2-C_5H_4N) and Li–NMe bond lengths of 2.071(14) and 2.160(13) Å. This variability in ligand coordination contrasts with the uniformly μ_2- or μ_3-bridging modes adopted by ligand heteroatoms in previously reported μ_6-O molecular heterobimetallic octahedra.[14]

Compounds **3** and **4** both incorporate six-membered MO-M′NCN rings by virtue of $[N(2\text{-}C_5H_4N)R]^-$ coordination [M = M′ = Zn (**3**); both M = M′ = Zn/Li and M = Li, M′ = Zn (**4**)]. Further, both species show almost identical $Zn_3[N(2\text{-}C_5H_4N)R]_3$ basal tiers [Fig. 1(a) and (b)], whilst the remaining three amide ligands exhibit significant variability between **3** and **4**. The orientation which they adopt in **3** results in their pyridyl N-centres bonding only to Zn2 which they render approximately tetrahedral, their deprotonated N-centres bonding only to Zn1. Conversely, in **4** the upper tier ligands are orientated such that the pyridyl N-centres lie in the Li_3 plane with the concomitant stabilisation of adjacent Li centres (by NMe groups) being accompanied by bridging to basal Zn atoms. Thus, **3** and **4** can be viewed as empirically incorporating a $\{(\mu_3\text{-}O)Zn_3[N(2\text{-}C_5H_4N)R]_6\}^{2-}$ ligand which is capable of acting either as a heptadentate donor to a C_{3v} cation [$(Bu^tOLi_3)^{2+}$ in **4**] or as a tetradentate donor to an R_3 cation (Zn^{2+} in **3**) by virtue of flexibility in the orientations demonstrated by the upper tier of $[N(2\text{-}C_5H_4N)R]^-$ ligands.

Attempts to elucidate the structural characteristics of the precursors to **3** and **4** are ongoing, as are studies into the nature of the competition between oxo-insertion (*cf.* the Bu^tO fragment in **4**) and oxo-encapsulation [*cf.* **3** and the $(\mu_6\text{-}O)Li_3Zn_3$ fragment in **4**]. Finally, the integrity of the $\{(\mu_3\text{-}O)Zn_3[(2\text{-}C_5H_4N)NR]_6\}^{2-}$ ligand is being investigated (by attempting to effect substitution reactions, *e.g.* the conversion of **4** to **3** by reaction with $ZnCl_2$).

We thank the UK EPSRC (D. J. L.) for a Studentship and St. Catharine's (R. P. D.) and Gonville & Caius (A. E. H. W.) Colleges for Research Fellowships.

Notes and references

‡ **3**: $ZnMe_2$ (0.5 ml, 1 mmol, 2 M in toluene) was added to a stirred −78 °C solution of 2-(benzylamino)pyridine (0.18 g, 1 mmol) in toluene (5 ml). After 30 min the mixture was warmed to −40 °C and Bu^tLi (0.59 ml, 1 mmol, 1.7 M in pentane) was added. Treatment of the room-temperature mixture with (P_2O_5) dry air (until observable reaction ceased after *ca.* 1 min) was followed by reflux and by storage at ambient temperature for 24 h whereupon needles of Bu^tOLi (by ^1H NMR) and blocks of **3** formed. Mechanical separation allowed the characterisation of **3**. Yield 42% (by **1** consumed), mp 140 °C (decomp.). Found: C, 64.96; H, 5.16; N, 11.34. The IMOMM method opens the way for the accurate calculation of "real" transition metal complexes

Feliu Maseras

First published as an Advance Article on the web 4th September 2000

The Integrated Molecular Orbital Molecular Mechanics (IMOMM) method is spearheading the entry of hybrid quantum mechanics/molecular mechanics (QM/MM) approaches in computational transition metal chemistry. The high ratio between quality of results and computer cost offered by these methods allows the introduction, for the first time, of the full experimental complexes, in accurate calculations. Several chemically relevant topics in this way become available to theoretical consideration. This article reviews a few representative examples of these applications.

Introduction

Computational chemistry has made huge progress in recent decades.[1] It has gone from the qualitative explanation of chemical trends to the accurate calculation of physical properties. This evolution has been made possible in good part because of the ever-increasing power of computers and because of the development of new methods. Progress has been even more dramatic in the field of computational transition metal chemistry.[2,3] The relatively cheap Hartree–Fock methods, which are sufficiently precise for a good deal of organic chemistry, providing at least a reasonable starting point into the properties and reactivity of small organic molecules, are usually too inaccurate for transition metal chemistry. Transition metal compounds often require the introduction of correlation energy and relativistic effects for a qualitatively acceptable description. Methods including these features have not been readily available for systems of large size until the last decade.

There is nevertheless still a new dimension to be gained in computational transition metal chemistry, namely the full introduction of the complete ligands. Most of the calculations have traditionally made use of model ligands, with only the atoms directly attached to the metal being described as such. Typical examples of this practice would be the replacement of any phosphine by PH_3, or of any cyclopentadienyl derivative by C_5H_5. This approach has been successful because it provides a reasonable description of the metal–ligand bonding. However, there are a number of chemical features that depend on the specific nature of the ligand, and cannot be reproduced by these simplified models.

A very promising method for the introduction of the real ligands in theoretical calculations is the use of hybrid quantum mechanics/molecular mechanics (QM/MM) methods. In these methods, the system is divided in different regions, each of them with a different computational description, as shown for a particular example in Fig. 1. In this way, the interactions related to the bulk of the ligands, mostly of steric nature, can be appropriately treated with the much more affordable molecular mechanics approach. A complementary approach, the use of pure molecular mechanics, requires the development of a specific force field for each compound, or family of compounds, that are to be studied, and will not be discussed here.[5]

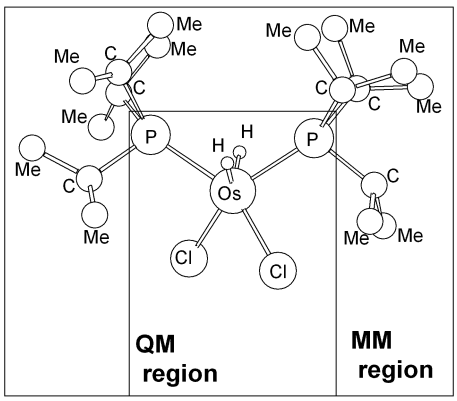

Fig. 1 Separation in QM and MM regions for an IMOMM calculation on $[OsCl_2H_2(PPr^i_3)_2]$.[4]

There are a variety of QM/MM methods proposed in the chemical literature, each with its particular methodological flavor.[6] This article will concentrate almost exclusively on the applications of one of them, Integrated Molecular Orbital Molecular Mechanics (IMOMM),[7] and of its derived forms.[8–10] This method has been so far the most widely applied to transition metal chemistry, mostly because of its robustness and simplicity. Precise descriptions of the method, and of its practical implementations can be found elsewhere.[7,11] Some aspects, like the mathematical treatment of the hydrogen bonds capping the dangling bonds in the QM region, which define the nature of different QM/MM methods, are still the subject of eventual improvement, but discussion of these aspects is outside the scope of this article,

There are nevertheless two characteristics of the IMOMM scheme that merit mention here because of their relevance in the

Feliu Maseras was born in 1962 in Martorelles, Catalonia. He studied at the Universitat Autònoma de Barcelona, where he obtained his B.Sc. in 1985 and his Ph.D. in 1991. He then spent two years as a postdoctoral fellow with Keiji Morokuma at the Institute for Molecular Science in Okazaki, Japan. After a two-year position as a CNRS Associate Researcher in the group of Odile Eisenstein in Montpellier, France, he took the position of Associate Professor at the Universitat Autònoma de Barcelona in 1998. His current research interests involve the development and application of theoretical methods to transition metal compounds, with special focus on the use of hybrid methods combining quantum mechanics and molecular mechanics for modeling species of experimental interest.

DOI: 10.1039/b006249i

interpretation and analysis of results. The first of these is that IMOMM is a full multistep method,[11] where the optimal geometry corresponds neither to the optimal QM arrangement nor to the optimal MM arrangement, but to the optimal, in a mathematical sense, compromise between both. The second defining characteristic of the IMOMM approach is that atoms in the MM region do not have a direct effect on the QM wavefunction, except through the distortions they induce in the geometry. Because of this, it can be stated that the IMOMM scheme introduces only the steric effects of the atoms in the MM region. On one hand, this supposes the introduction of an error, because the eventually important electronic contributions of these atoms are left out. On the other hand, this allows a straightforward separation between electronic and steric effects. The natural solution to the problem of electronic effects within the IMOMM scheme is the expansion of the QM region, which must include all electronic effects that are significant to the problem under study. As will be seen in the following sections, this can be used in some cases for the performance of computational experiments. Other QM/MM methods[6] introduce part of the electronic effects through the use of point charges. An alternative approach, available within the ONIOM scheme,[8] is the use of different quality QM descriptions for different regions of the systems.

A final methodological comment concerns the fact that the quality of IMOMM results, like that of any other QM/MM approach, depends critically on the appropriateness of the respective QM and MM methods to describe the interactions within the respective regions. Because of this, the quality of an IMOMM calculation is usually described in the form IMOMM(QM-method:MM-method), where the labels in parentheses describe the methods used in each of the two regions.

After this introduction, the current article focuses on a few selected applications of the IMOMM and related QM/MM methods to transition metal chemistry. The presentation does not intend to be exhaustive, but to be sufficiently general to show the possibilities of these methods to a general audience.

Structural studies

The most obvious feature of the application of hybrid QM/MM methods to transition metal chemistry is the possibility of introducing steric effects, and because of that a significant part of the published hybrid QM/MM calculations has been devoted to the analysis of how steric effects alter geometries and relative energies of transition metal complexes.

A representative study of how IMOMM calculations can be used in the identification of steric effects is provided by the joint experimental and theoretical study[12] on [Ir(biph)X(QR_3)$_2$] (biph = biphenyl-1,2-diyl; X = Cl, I; Q = P, As). These five-coordinate complexes have a distorted trigonal bipyramidal structure, as shown in Fig. 2. The phosphines (or arsines)

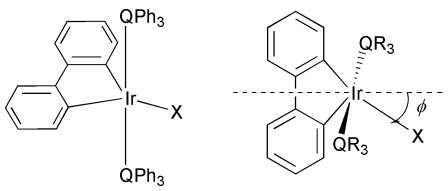

Fig. 2 Geometrical distortion of the equatorial X ligand in trigonal bipyramidal [Ir(biph)X(QR_3)$_2$] complexes.[12]

occupy the axial sites, and the halide and the chelating biph ligands are in the equatorial sites. A most intriguing feature of these compounds is the deviation that the halide presents from the symmetric arrangement between the two coordinating carbons of biph, a deviation characterized by values of φ (Fig. 2) different from zero. Previously reported calculations at the extended Hückel level suggested an electronic origin for the deviation. However, pure Becke3LYP calculations on the [Ir(biph)Cl(PH_3)$_2$] model system produced a symmetrical structure (φ = 0), making an electronic origin for the distortion unlikely.

The steric origin of the distortion was proved by IMOMM(Becke3LYP:MM3) calculations on the real system [Ir(biph)Cl(PPh_3)$_2$], which yielded a distortion angle φ of 11.4° (to be compared with the experimental value of 10.1°). The steric origin of the distortion shown by the hybrid QM/MM calculation was further confirmed by new experiments. In one of them, PPh_3 was replaced by $AsPh_3$, and in the other Cl was replaced by I. The logic behind these tests was that the modification of the size of the ligands should affect the importance of the steric effects, and therefore the value of the distortion angle. Values were merely indicative for [Ir(biph)Cl($AsPh_3$)$_2$] because of the presence of two different conformations of the arsine in the crystal structure, but clear for [Ir(biph)I(PPh_3)$_2$]. In this latter case the experimental value for the angle φ was 17.2°, 7.1° larger than for the parent compound, a trend reproduced by the corresponding IMOMM calculation. Therefore, the steric origin of the distortion from the electronically preferred symmetry was fully confirmed. Comparison of IMOMM and X-ray structures has allowed the characterization of steric effects also in [$ReH_5(PR_3)_2(SiR_3)_2$],[13] [$OsCl_2H_2(Pr^i_3)_2$],[4] and [Pd(P–N)($SiCl_3$)$_2$] (P–N = chiral chelating ligand).[14]

The application of hybrid QM/MM methods to structural problems is not restricted to the reproduction of crystal structures. A second block of structural studies has been centered in the evaluation of steric effects on the relative stabilities of two possible isomers. This type of work is well exemplified by the work on $Ru(CO)_2(PR_3)_3$,[15] where the study was centered in the comparison between the two isomers, *cis* and *trans*, as shown in Fig. 3. Both isomers have a trigonal

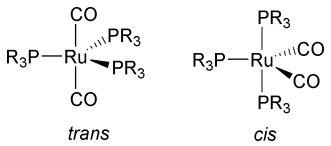

Fig. 3 The two isomers observed experimentally for $Ru(CO)_2(PR_3)_2$ complexes.[15]

bipyramidal geometry, and they are labeled following the arrangement of the two carbonyl ligands. The two forms have been observed experimentally[15,16] with different phosphine ligands PR_3. In particular, when PR_3 = PEt_3, the *cis* isomer is the species present in the crystal, with a C–Ru–C bond angle of 133.6°. When PR_3 = PPr^i_2Me, two independent molecules are present in the crystal, one of them of showing *trans* configuration (C–Ru–C 173.6°) and the other *cis* configuration (C–Ru–C 146.7°). IMOMM(MP2:MM3) calculations were carried out on these complexes using $Ru(CO)_2(PH_3)_3$ for the QM part. Both isomers, *cis* and *trans*, were found to be local minima for each complex. The computed C–Ru–C bond angles showed a clear separation between *trans* (178.2, 173.3°) and *cis* (136.7, 145.6°) forms, in good agreement with experimental data.

The most relevant part of this study was, however, comparison of the relative energies. For $Ru(CO)_2(PEt_3)_3$, the *cis* isomer, the only form existing in the crystal, was computed to be more stable than the *trans* isomer by 3.0 kcal mol^{-1}. The relationship between the two isomers is reversed for $Ru(CO)_2(Pr^i_2Me)_3$, the *trans* species being more stable by 2.8 kcal mol^{-1}. Electronic effects, represented by the QM energy, always favor the *cis* isomer, which has the two π-acceptor carbonyl ligands in equatorial positions. Steric effects, represented by the MM part, however, favor the *trans* isomer, with the three bulky phosphine ligands in equatorial positions. The

difference is that while electronic effects are similar for both PEt_3 and Pr^i_2Me, steric effects are significantly larger for the latter. As a result, the presence of the larger phosphine can invert the electronic preference for the *cis* isomer and make the *trans* isomer the most stable.

A similar IMOMM(Becke3LYP:MM3) study was carried out on $[MoO_2Cl_2(N–N)_2]$ (N–N = chelating ligand) complexes.[17] The nature of the adduct between $[OsHCl(CO)(PBu^t_2Me)_2]$ and $(CF_3)_2CHOH$ could also be clarified with the help of IMOMM(Becke3LYP:MM3) calculations.[18]

A final structural application of the IMOMM method to transition metal chemistry that will be analyzed in some more detail concerns the characterization of agostic interactions. An agostic interaction is the intramolecular interaction that takes place within one complex between the metal center and a C–H bond of one of the ligands.[19] Following their initial characterization, agostic interactions have been found to be very common in transition metal chemistry. They involve a three-center, two-electron bonding similar to that observed in main group Lewis acids such as diborane, and can also be viewed as an arrested state of the oxidative addition process of the C–H bond that would lead to the cyclometalated product. It follows that, from a molecular orbital point of view, the agostic interaction requires an empty orbital in the metal center, which must thus be unsaturated.

The steric repulsion associated with the presence of bulky ligands destabilizes high coordination numbers, also favoring unsaturated compounds. The coincidence of bulky ligands and agostic interactions in a number of complexes was therefore attributed mostly to its common association to unsaturated compounds. Recent hybrid QM/MM calculations have nevertheless proved a much more intimate relationship between steric influence and agostic interactions.[20–22]

A first proof of this relationship was obtained from the study, both experimental and theoretical, of the $Ir(H)_2(PBu^t)_2Ph)_2^+$ system (Fig. 4).[20] NMR and X-ray data showed the existence of

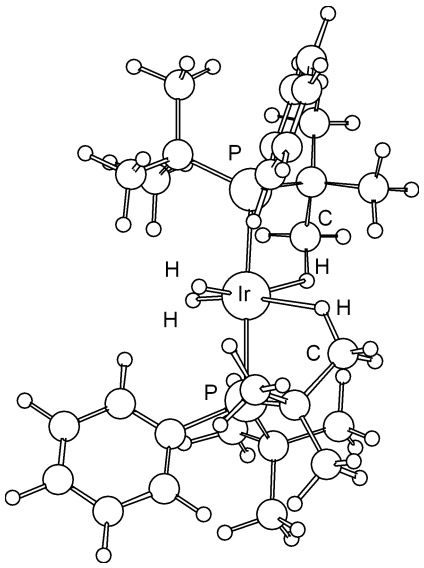

Fig. 4 IMOMM(Becke3LYP:MM3) optimized structure of $Ir(H)_2(PBu^t_2Ph)_2^+$.[20]

two agostic interactions in this complex, characterized geometrically by Ir–P–C angles of 97.0 and 99.0° (to be compared with Ir–P–C non-agostic angles of *ca.* 115°). Pure Becke3LYP calculations on $Ir(H)_2(PEtH_2)_2^+$ showed no agostic interactions at all (Ir–P–C angle of 118.4°). In contrast, IMOMM(Becke3LYP:MM3) calculations on the real complex using the same model for the QM part properly identified the agostic interactions (Ir–P–C angle of 101.7°). This result reveals two important consequences. The first is that the failure of the pure QM calculations on the model system means that the agostic interaction is intimately associated to the presence of the real ligands. The second consequence is that the success of the corresponding IMOMM calculation proves that the role of the ancillary substituents is steric in nature, and that the electronic contribution is at best minor.

While these first calculations on $Ir(H)_2(PBu^t_2Ph)_2^+$ clearly illustrated the importance of the introduction of the full ligand in the formation of the agostic interaction, they did not allow separation of the electronic and steric contributions to the steric distortion. This was accomplished within a systematic study of the steric influence on agostic interactions on a homologous series of Ir(III) complexes of general formula $Ir(H)_2(PR_3)_3^+$.[21] These complexes differ from that discussed above, with the presence of an extra phosphine, leading therefore to only one empty site in the coordination sphere, and one potential agostic interaction. In particular, the results for $Ir(H)_2(PCy_2Ph)_3^+$ are discussed. For this system, two different sets of partitioning of atoms between the QM and MM domains were applied in the IMOMM calculation (Fig. 5). In model I, all atoms not directly

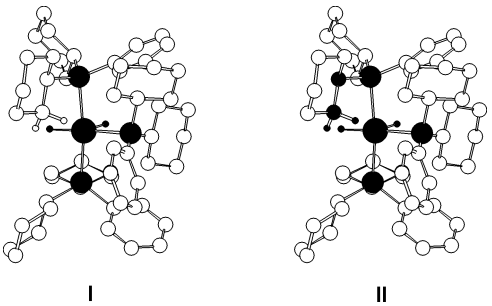

Fig. 5 The two different models used in IMOMM calculations on $Ir(H)_2(PR_3)_3^+$.[21] Atoms in the QM region are depicted in black.

bound to the metal were calculated at the MM level, the QM part being therefore $Ir(H)_2(PH_3)_3^+$. In model II, the QM part of the phosphine included the chain agostically distorted, the QM part thus being $Ir(H)_2(PEtH_2)_3^+$. The essential difference between each model is in the description of the potentially agostic C–H bond.

The geometry of $Ir(H)_2(PCy_2Ph)_3^+$ was fully optimized at four different computational levels, defined by the two different partitions and the use of MP2 and Becke3LYP methods for the QM part. Since IMOMM(MP2:MM3) led to slightly more accurate values, only these results will be discussed here. The IMOMM(MP2/I:MM3) calculation gave results essentially in agreement with the X-ray determined structure, with the largest discrepancy being in the value of 105.6° for the agostic Ir–P–C angle. This was larger than the experimental X-ray value of 100.9°, but already smaller than the computed average Ir–P–C value at this phosphorus center of 109.9°. This result is relevant because it proves that the bulk of the ligands alone is able to push one of the C–H bonds of the cyclohexyl group into the proximity of the metal atom even without any agostic orbital interaction. Use of the more elaborate model IMOMM(MP2/II:MM3), with the C–H bond in the QM part, led to results even closer to the X-ray values. The Ir–P–C bond angle improved to 99.8°, only 1.1° from the experimental value. This change proves that there is also an orbital contribution to the agostic interaction. The ability to determine the consequence of only one type of interaction is a strength of the hybrid method, which allows the execution of "computational experiments".

The accuracy of the hybrid QM/MM method in the characterization of this type of complex further proved by the calculation[21] on the isoelectronic $Ir(H)_2(PPr^i_2Ph)_3^+$ complex, with smaller phosphines, which is observed experimentally as non-agostic. This behavior is correctly reproduced by the IMOMM(MP2:MM3) calculation, which finds Ir–P–C bond angles of 115.7°. The successful application of the IMOMM method to the description of agostic interactions is not limited to late transition metals such as iridium, as proved by an

experimental and theoretical study[22] on $Tp^*Nb(Cl)(CHMe_2)$-(PhC≡CMe).

Homogeneous catalysis

The past two decades have witnessed the development of enantioselective catalysis both as a discipline and a production methodology in response to the increasing demand for enantiopure compounds for the pharmaceutical industry and the raising of environmental concerns.[23] Frequently, the key species in the catalytic cycle involves a metal atom chelated by a polyfunctional organic molecule. The role of the metal center is essential in offering neighbouring sites for coordination of the substrate and reagent molecules, and in providing a low energy pathway for their reaction. The selectivity of the reaction is however decided by the interactions involving enantiotopic groups in the polyfunctional organic ligand and the substrate, which give rise to energetically well differentiated diastereomeric transition states.

Homogeneous catalysis presents therefore two characteristics that make it especially appealing for hybrid QM/MM methods: the requirement of a high-level QM description for the metal center and its immediate environment, and the need to include in the calculation a large system that can only be introduced through an MM description. As a result, some of the more fruitful applications of the IMOMM method have been in the field of homogeneous catalysis.

Mechanisms for these processes are often complicated, and the interactions involved in enantioselectivity are often subtle. Because of this, and for the sake of the brevity of the article, the discussion will be concentrated on one of the reactions studied with the IMOMM method, the dihydroxylation of olefins by osmium tetroxide, with a brief mention made to other processes.

The osmium tetroxide-catalyzed dihydroxylation of olefins is a highly efficient method for the enantioselective introduction of chiral centers in organic substrates.[24] The reaction goes through an osmate ester intermediate containing a five-membered ring, and the stereoselectivity is decided in the formation of this intermediate after the initial interaction between catalyst and substrate. The mechanism for this part of the reaction has been the subject of intense discussion, and there seems to be finally an emerging consensus on the so-called [3 + 2] mechanism. A substantial role in the formation of this consensus has been provided by theoretical evidence from pure QM calculations on the $OsO_4(NH_3)$ + $H_2C{=}CH_2$ model system.[25]

Despite its relevance for the determination of the mechanism, calculations with the $OsO_4(NH_3)$ model cannot provide any explanation on the enantioselectivity of the reaction, because this property is related to the nature of the substituents in the NR_3 group, which are usually very bulky, as shown in the example presented in Fig. 6. A first preliminary IMOMM

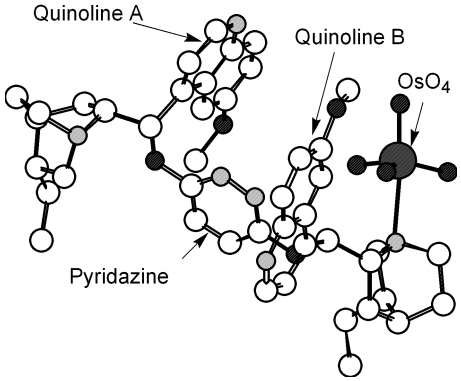

Fig. 6 Schematic presentation of the $(DHQD)_2PYDZ{\cdot}OsO_4$ catalyst.

study[26] on the subject consisted of the geometry optimization of the only two models of the catalyst where X-ray structures are available, namely $[OsO_4$(quinuclidine)] and [OsO_4\{(dimethylcarbamoyl)dihydroquinidine\}], and results showed an acceptable agreement with the experimental geometries.

The reaction of the catalyst with the olefin has been analyzed theoretically in detail in the case of the $(DHQD)_2PYDZ{\cdot}OsO_4$ [$(DHQD)_2PYDZ$ = 3,6-bis(dihydroquinidine)pyridazine] + $H_2C{=}CHPh$ system with the IMOMM(Becke3LYP:MM3) method using an $OsO_4(NH_3)$ + $H_2C{=}CH_2$ model for the QM part.[27,28] A first study[27] was concerned with the reaction profile of the formation of the osmate ester from the separated reactants. A likely reaction path leading to the experimentally observed *R* isomer was characterized though the location of the separate reactants, an intermediate, a transition state, and the product. Their relative energies, with respect to the reactants, were 0.0, −9.7, −3.3 and −34.3 kcal mol^{-1}, respectively. The geometries of both transition state and product were very similar to those obtained by pure QM calculations on the model system.[25] This proved the validity of the studies on the model system for the late stages of the reaction. The IMOMM study revealed nevertheless the presence of an intermediate that had not been located in the model system. The existence of this intermediate, shown in Fig. 7, is intimately associated to the

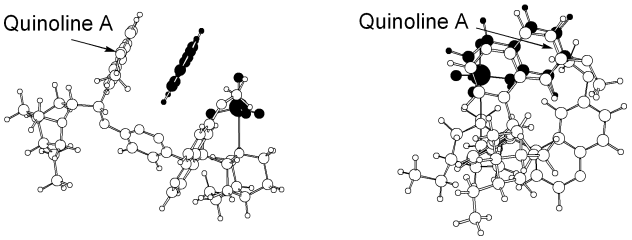

Fig. 7 IMOMM(Becke3LYP:MM3)-optimized[27] structure of the intermediate in the dihydroxylation of styrene catalyzed by $(DHQD)_2PYDZ{\cdot}OsO_4$.

interaction between the substrate and the bulky NR_3 ligand. The styrene substrate is sandwiched by two methoxyquinoline walls, with the parallel arrangement of the aromatic rings producing an attractive interaction. This interaction between substrate and catalyst has important implications on the reaction mechanism, because it is likely to be affected by the orientation of the catalyst. This point was clarified by the second study that is discussed below.

The second IMOMM(Becke3LYP:MM3) study[28] on the reaction of $(DHQD)_2PYDZ{\cdot}OsO_4$ with styrene was specifically focused on the origin of the enantioselectivity of the reaction. Because the selectivity is defined by the initial approach of the substrate to the catalyst, a number of possible pathways must be analyzed. There are twelve such paths, defined by the three possible regions (A, B and C) of approach of the substrate to the catalyst and the four possible orientations (I, II, III and IV) of the phenyl ring of the substrate within each region, as shown in Fig. 8. Each of these twelve possible pathways was theoretically

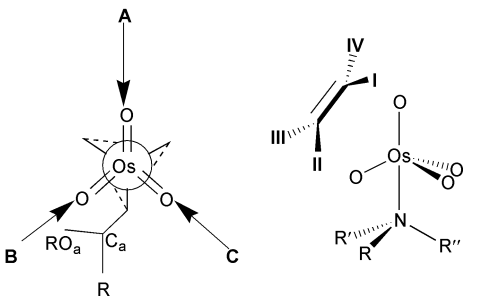

Fig. 8 Definition of the twelve possible reaction pathways in the reaction of $H_2C{=}CHPh$ with $(DHQD)_2PYDZ{\cdot}OsO_4$.

characterized through the location of the corresponding transition state, with its associated energy. The lowest energy saddle point, therefore the most likely transition state for the reaction, was B–I, followed closely by B–III and B–IV, 0.1 and 2.7 kcal mol^{-1} higher in energy. The next saddle point in energy,

A–IV, lies 4.7 kcal mol^{-1} above B–I. The fact that the three lowest energy saddle points correspond to region B, which is not the least sterically hindered (Fig. 8), is a clear indication that the non-bonding interactions between catalyst and substrate are of an attractive nature, in agreement with the existence of an intermediate.

The preference for paths B–I and B–III has an immediate consequence on the enantioselectivity of the reaction, because both lead to the *R* product. This is in excellent agreement with experimental data, that give a high enantiomeric excess of *R* product. In fact, all paths of type I and III go to the *R* product, while paths of type II and IV lead to the *S* product. The *S* product, which is a minor product of the reaction, must therefore come from path B–IV. Agreement with experiment reaches even to the value of the enantiomeric excess. If the ratio of products follows a Maxwell–Boltzmann distribution based on the internal energies of the transition states at 0 K, the theoretically computed enantiomeric excess would be 99%, close to the experimental value of 96%.

Application of hybrid QM/MM methods to the study of this reaction is not limited to the identification of the transition states and the reproduction of experimental data. It leads also to the analysis of the effect of the different regions of the catalyst on this enantioselectivity. The energy difference between the transition states, which is concentrated in the MM part of the calculation, can be further decomposed on a term by term basis. Grouping of the atoms in the regions of the catalyst according to the labels in Fig. 6 proves that the most decisive part in the selectivity (with a weight of *ca.* 50% of the interaction) is played by quinoline A, with significant, but smaller, contributions from quinoline B and pyridazine, and a very minor contribution from the OsO_4 unit.

The homogeneous catalysis process that has been the subject of more hybrid QM/MM calculations to date is however not dihydroxylation but olefin polymerization. This process had been traditionally carried out through heterogeneous catalysis, but several efficient homogeneous processes have gained importance in recent years.[29,30] Two major types of homogeneous catalysts are being used in this reaction, and both have been the subject of intense study through the IMOMM method. The most studied catalysts[31–33] have been those most recently developed, consisting of late transition metal complexes containing diimine ligands.[30] A typical QM/MM partition for these studies is shown in Fig. 9. The approach of the entering

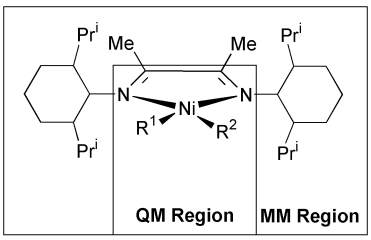

Fig. 9 Usual QM/MM partition applied in IMOMM calculations on the mechanism of olefin polymerization catalyzed by late transition metals.

monomer to the chain decides the general arrangement of the resulting polymer and, consequently, its physical properties. Calculations prove conclusively that this approach is controlled by the interactions of both fragments with the bulky substituents in the diimine group. It is worth mentioning that results of similar quality have been obtained in the application to related systems of different QM/MM combinations like IMOMM-(Becke3LYP:MM3),[31] IMOMM(BP:Amber)[32] and IMOMM(BP:CHARMM).[33] Apart from these studies on late-transition metal complexes, more traditional catalysts derived from bis-cyclopentadienyl complexes of early transition metals[29] have also been the subject of a number of IMOMM calculations.[34,35] All these calculations confirm that the tacticity and the chain length of the polymer are decided by steric interactions between substrate and catalyst. Both characteristics of the polymer depend on the relative values of the energy barriers for the insertion, branching and termination reactions. The values obtained for these processes from IMOMM calculations are in good agreement with experiment, and in an opposite order to that obtained in pure QM calculations on model systems.

A different catalytic process where hybrid QM/MM methods have made a recent entry is the enantioselective addition of diethylzinc to benzaldehyde promoted by chiral ligands.[36,37] Here, the RHF description is sufficient for the QM region, and the use of either UFF or MM3 descriptions in the MM region has provided satisfactory results. The IMOMM method has also been applied to the analysis of steric effects of bulky phosphine ligands on the mechanism of some particular reactions, such as the oxidative addition of hydrogen to $[Pt(PR_3)_2]$,[38] and the transformation of vinylidene to acetylene in the coordination sphere of $[RhCl(PPr^i_3)_2(C{=}CH_2)]$ complexes.[39]

Bioinorganic chemistry, heterogeneous catalysis, *etc*

The IMOMM method has found the most successful of its applications within transition metal chemistry in the two major fields described in the previous sections, where it is by far the most widely applied method. This notwithstanding, IMOMM and its modifications have also been applied to other areas of transition metal chemistry where other more elaborate QM/MM schemes have a well established tradition.

Biochemistry is probably the field where hybrid QM/MM schemes have found most of their applications. Proteins and nucleic acids have very large numbers of atoms, complicated folded structures, and both their structure and reactivities are heavily affected by the presence of water solvent molecules. The interaction with solvent molecules, which polarize the solute, is critical for a proper description of these systems, which consequently must introduce explicit polarization terms on the QM region.[6] Schemes like the original implementation of IMOMM,[7] where no polarization from the MM region is introduced in the QM region, are not adequate to the study of solvation problems, although the related ONIOM approach,[8] with a semiempirical description instead of MM should be appropriate.

The case of bioinorganic chemistry is however slightly different. There are a number of enzymes and proteins containing transition metals at their active center, with many atoms directly involved, and requiring the use of high level computational methods. The IMOMM method can be applied in this context to understand the properties of the active center, isolated from the rest of the protein. The analysis will be valid as far as the properties of the system are well reproduced in the isolated system, in a reasoning quite similar to that justifying experimental studies on biomimetic complexes. The performance of this approach can be seen in the example of IMOMM studies on complexes containing the heme group.

The heme group, constituted by an iron center and a porphyrin ring, occupies a prominent position in biochemistry as the active center of several relevant proteins and enzymes.[40] Although today computers allow calculation of the full heme group, the size of the system puts it at the limits of computer capacity, and hampers the performance of reactivity studies or very high level calibrations. An interesting alternative is the description of part of the porphyrin ring with an MM method.

The QM/MM partition used in the IMOMM calculations discussed here is presented in Fig. 10. In the QM part of the calculation the heme group is represented by $[Fe\{NH(CH)_3NH\}_2]$. The validity of the introduction of a QM/MM partition within the aromatic porphyrin ring is more arguable than in other topics previously discussed where the partition was across a single σ bond. One must however realize the fact that the four nitrogen donor atoms of the porphyrin are part of a large aromatic ring which has two different types of

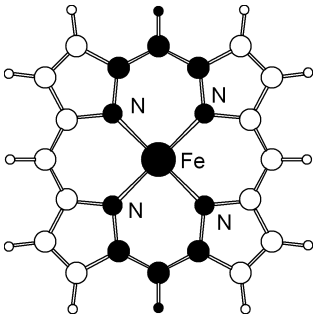

Fig. 10 QM/MM partition applied to the IMOMM calculation of iron porphyrin complexes. The QM atoms are depicted in black.

effects. One of those is the possibility that the aromatic ring has of acting as an electronic reservoir where occupied and empty orbitals are relatively close. This property is poorly reproduced in these IMOMM calculations. However, the other effect, the existence of a quite rigid framework, which precludes strong distortions out of planarity, is accurately described by the IMOMM calculation.

There was therefore a question on the reliability of this QM/MM modelization. This question was answered by a systematic set of calibrations,[41] where the results of the IMOMM calculation were compared with full *ab initio* and experimental data. Three different systems were analyzed, the four-coordinate [Fe(P)] (P = porphyrin) triplet system, the five-coordinate [Fe(P)(Im)] (Im = imidazole) quintet system, and the six-coordinate [Fe(P)(Im)(O_2)] singlet system. Computed IMOMM(Becke3LYP:MM3) geometries were always in reasonable agreement with those obtained from pure Becke3LYP calculations on the full systems, and with experimental X-ray crystal structure data on related species. The test was extended to the energy cost of the out of plane displacement of the iron atom. This factor, which ought to be ruled almost exclusively by electronic effects, *i.e.*, by the binding of the Fe center to the N atoms of the porphyrin ring, was examined with both pure Becke3LYP and IMOMM(Becke3LYP:MM3) calculations on the three different systems. The agreement of the values computed with both methods was good, with discrepancies smaller than 2 kcal mol^{-1} for displacements as large as 0.3 Å and as costly as 15 kcal mol^{-1}. Furthermore, the differences between the three different chemical systems were also well described, with the energy cost of a displacement of 0.3 Å being *ca.* 10 kcal mol^{-1} for the four-coordinate system, *ca.* 5 kcal mol^{-1} for the five-coordinate system and *ca.* 15 kcal mol^{-1} for the six-coordinate system. This QM/MM modeling of the heme group has been applied to the IMOMM(Becke3LYP:MM3) study[42] of the structural properties of [Fe(T_{piv}PP){1-Me(Im)}(O_2)], where T_{piv} is 5,10,15,20-tetrakis(α,α,α,α-*o*-pivalamidophenyl)porphyrin, a so-called picket-fence porphyrin.

A different example of application of IMOMM to bioinorganic problems is provided by the study of the catalytic mechanism of galactose oxidase.[43] In this case, the IMOMM method was used to introduce a backbone link between two residues attached to the copper center, a tyrosine and a histidine. The existence of the backbone is shown to affect the chemical nature of some reaction intermediates, but to have little effect on the overall energetics of the reaction.

Another field where QM/MM methods have been applied for a number of years is heterogeneous catalysis.[44,45] The simulation of a solid surface is much more affordable if one can describe at least part of it with an MM description. Some QM/MM methods have been specifically designed to deal with these chemical situations, and they have been applied with success to the case of zeolites.[44] Some success has also been obtained[46] in the application of IMOMM(Becke3LYP:MM3) calculations to the study of Cu atom deposition on SiO_2 surface defects. An IMOMM method that has been specifically designed for application to heterogeneous catalysis is the so-called SIMOMM (Surface IMOMM) method.[10] This method has been successfully applied to the description of the structure of the Si(001) surface[47] and to the cycloaddition reaction of cyclohexa-1,3-diene on this surface.[48] In this latter case, it has been shown that the presence of the bulk solid allows the possibility of a [2+2] reaction mechanism that was not available in gas phase studies on model reaction sites.

Concluding remarks

This article has shown how the IMOMM method, proposed only as recently as 1995, has already produced a significant amount of valuable theoretical contributions in transition metal chemistry. Its success has been logically concentrated in areas where the calculation of simplified models could not account for the experimental complexity, as in homogeneous catalysis and in structural issues associated with steric effects. Work in the area is nevertheless far from finished. There are many processes in transition metal chemistry where the bulk of the ligands seems crucial that have not as yet been tackled from a theoretical point of view. One must also expect developments from the methodological point of view. IMOMM is in fact a particular case of the more general ONIOM scheme,[8] which goes beyond the strict field of QM/MM methods by allowing the use of different QM descriptions, an approach that also has a role in transition metal chemistry.[49] Other developments in QM/MM methods will also find applications sooner or later to transition metal chemistry. In summary, the application of IMOMM and of other hybrid QM/MM methods to this field of chemistry looks very promising, and a sharp increase in the number of applications must be expected in forecoming years.

Acknowledgment

Profs. Keiji Morokuma (Emory), Odile Eisenstein (Montpellier) and Agustí Lledós (Barcelona) are thanked for helpful discussions throughout the years. Thanks must also be extended to the long list of graduate students and visitors in our group during recent years. Financial support from the Spanish DGES (Project No. PB98-0916-CO2-01) and DURSI (Generalitat de Catalunya) is acknowledged.

β-Glycosidase inhibitors mimicking the pyranoside boat conformation

Edwige Lorthiois, Muthuppalaniappan Meyyappan and Andrea Vasella*

Laboratorium für Organische Chemie, ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich, Switzerland. E-mail: vasella@sugar.org.chem.ethz.ch

Received (in Cambridge, UK) 17th July 2000, Accepted 14th August 2000
First published as an Advance Article on the web 11th September 2000

Polyhydroxylated isoquinuclidines mimicking the boat conformation of pyranosides are strong and selective inhibitors of a retaining β-mannosidase.

According to the principle of stereoelectronic control,[1] heterolytic cleavage of an acetal C–O bond requires an antiperiplanar orientation of a doubly occupied, non-bonding orbital. This antiperiplanar lone pair hypothesis (ALPH) means that hydrolysis of β-D-pyranosides involves a conformational change of the tetrahydropyran ring from a chair to a twist-boat or boat resulting in a pseudoaxial orientation of the aglycon (Fig. 1).[2] A

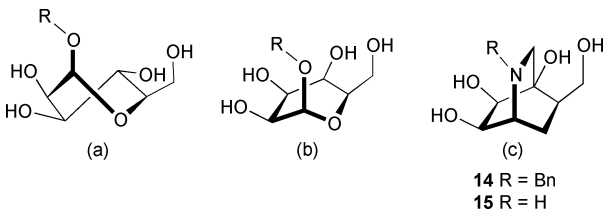

Fig. 1 Skew boat ($^1S_3$, a) and boat ($^{1,4}B$, b) conformers of a β-D-mannopyranoside and isoquinuclidines **14** and **15**.

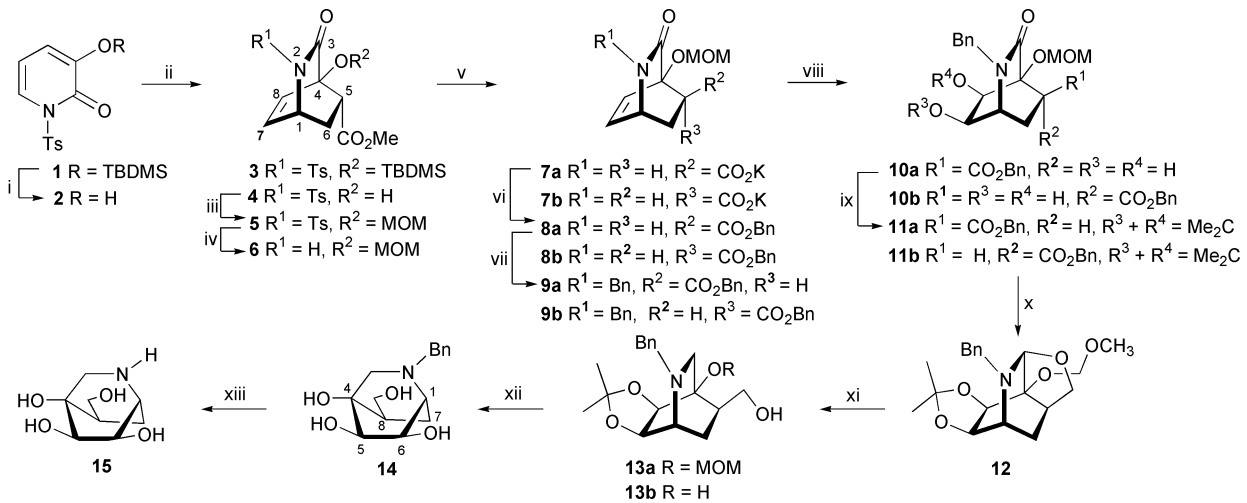
similar conformational change is required for nucleophilic assistance of the cleavage according to an intermediate S_N1/S_N2 mechanism. The relevance of ALPH for enzymic glycoside cleavage has met with strong scepticism,[2c] but crystal structures of three *endo*-glycosidases in complex with substrate analogues show a skew boat or a flattened boat conformation of the tetrahydropyran ring.[3] A skew boat or boat-like conformer with a pseudoaxial (elongated) C(1)–O bond may conceivably be closer to the transition state of an enzymic β-glycoside cleavage than a reactive intermediate of an oxycarbenium cation type. If so, inhibitors mimicking the boat-like conformation of a glycoside, the proper location of the 'glycosidic heteroatom' (*i.e.* the heteroatom attached to C(1) of the glycoside), and the correct orientation of its lone pairs may possess a more strongly pronounced character as transition state analogues than inhibitors mimicking the cationic reactive intermediate. Inhibitors mimicking the shape of an oxycarbenium cation appear indeed to be only partial transition state analogues.[4] Since the conformational change from a chair to a twist-boat or boat should be induced by all β-glycosidases, we wanted to synthesize and evaluate a mimic of such a conformer of a glycoside that is cleaved by an *exo*-glycosidase. The cyclohexane ring of **14** and **15** (Fig. 1) mimics the tetrahydropyran ring of a β-mannoside in a $^{1,4}B$ conformation; it is substituted by a pseudoaxial amino group that should allow lateral protonation.[5] Only one[6] of the known bicyclic glycosidase inhibitors[7] mimicks a tetrahydropran ring in a ($^{2,5}B$) boat conformation. It has been designed in another conceptual context, and was not tested against β-mannosidases; it is a poor inhibitor of other glycosidases.

The isoquinuclidines **14** and **15** were synthesised in 14 and 15 steps and in 6.6 and 5.4% overall yields, respectively, from 3-hydroxypyridone *via* the known tosylate **1**[8] as shown in Scheme 1. Notable features are the diastereoselective high yielding Michael addition and aldolisation of **2** to **4**, the epimerisation and hydrolysis (dealkylation?) of the ester **6** to **7a**, and the two step reduction of **11a** *via* **12** to **13**.†

Both **14**‡ (K_i = 0.17 μM; IC_{50} = 0.69 μM)§ and **15**¶ (K_i = 20 μM; IC_{50} = 29.4 μM) inhibit snail β-mannosidase competitively, as determined from a Lineweaver–Burk plot, **14** being about 120 times stronger than **15**. Jack bean α-mannosidase is inhibited *ca.* 10^4 times more weakly by **14** (IC_{50} = 9.6 mM) than snail β-mannosidase and about 700 times more weakly by **15** (IC_{50} = 20 mM). Both **14** (IC_{50} > 5.0 mM) and **15** (IC_{50} = 4.3 mM) are poor inhibitors of β-glucosidase from *Caldocellum saccharolyticum*. The value of IC_{50} for β-mannosidase dropped from 4.08 to 0.69 μM for **14** and from 183 to 29.4 μM for **15** as the preincubation was prolonged from 10



Scheme 1 *Reagents and conditions*: i, $BF_3{\cdot}Et_2O$, CH_2Cl_2, 98%; ii, CH_2=CH–CO_2Me, Et_3N, 92% from **2**; iii, $CH_2(OMe)_2$, P_2O_5, $CHCl_3$, 88%; iv, Na–$C_{10}H_8$, DME, −78 °C, 88% from **5**; v, K_2CO_3, MeOH, Δ; vi, BnBr, $NaHCO_3$, DMF, **8a**/**8b** 80:20 (49% from **6**), **9a**/**9b** 80:20 (18% from **6**); vii, NaH, BnBr, DMF, 89%; viii, OsO_4, acetone–H_2O, 89%; ix, $Me_2C(OMe)_2$, acetone, CSA, 94%; x, THF, Δ, **12** (57%), **13a** (17%), **13b** (8%); xi, $LiAlH_4$, dioxane, Δ, **13a** (67%); xii, TFA, H_2O, Δ, 84%; xiii, H_2/$Pd(OH)_2$/C, conc. HCl, MeOH/H_2O, 82%.

DOI: 10.1039/b005578f

min to 2 h. The inhibition by **14** and **15**, as represented by $1/IC_{50}$, shows a linear dependence on pH, revealing inhibition by the free amines rather than by the ammonium salts. The inhibition is *ca.* 4–6 times stronger at pH 5.6 than at pH 4.5 and again *ca*. 4–6 times weaker at pH 3.6.‖

Since **15** (pK_{HA} = 8.4) is a stronger base than **14** (pK_{HA} = 7.5), one expects **14** to be a stronger inhibitor than **15** at pH 4.5 by a factor of about 10. That **14** is 120 times stronger than **15** evidences a hydrophobic interaction of the benzyl group of **14** with the aglycon binding site. Such interactions are well precedented.[10,11]

The pH dependence of the inhibition by **14** and **15** evidences the essential interaction with the catalytic acid, and confirms its flexibility.[12] In contrast to the inhibition by the azole type inhibitors,[4,13–15] that is characterised by a cooperative interaction of the inhibitor with the catalytic acid and the catalytic nucleophile[2b] the interaction of **14** and **15** with the catalytic nucleophile appears to play at best a minor role. The inhibitory activity of **14** and **15** is in agreement with the postulate that a conformational change of the pyranose ring precedes or accompanies the enzymatic cleavage of β-glycosides.

Notes and references

† The esters **9a** and **9b** were isolated in yields of 41 and 10% from **5**. Selected ^{1}H-NMR data for **8a**: 4.00 (ddt, *J* = 5.6, 3.4, 2.1, H-C(1)), 2.93 (dd, *J* ≈ 10.5, 4.9, H-C(5)), 1.95 (ddd, *J* = 12.5, 5.0, 3.4, H_{exo}-C(6)), 1.79 (ddd, *J* = 12.5, 10.6, 2.2, H_{endo}-C(6)); selected ^{1}H-NMR data for **8b**: 4.05 (ddt, *J* ≈ 5.3, 3.6, 1.4, H-C(1)), 3.06 (ddd, *J* = 10.0, 5.1, 0.9, H-C(5)), 2.09 (ddd, *J* = 12.8, 10.0, 3.7, H_{exo}-C(6)), 1.56 (ddd, *J* = 12.5, 5.0, 1.6, H_{endo}-C(6)). The *exo* configuration of the diols **10** (*exo* refers to the face *syn* to the C(1)–N bond) was assigned on the basis that $J_{1,6}$ = 2.1 Hz (**10a** and **10b**) is smaller than $J_{1,7exo}$ = 3.6 (**10a**) and 4.4 Hz (**10b**) and closer to $J_{1,7endo}$ = 2.0 (**10a**) and 1.7 Hz (**10b**).[8] An attempt to reduce **11a** to **13** in one step was not successful.

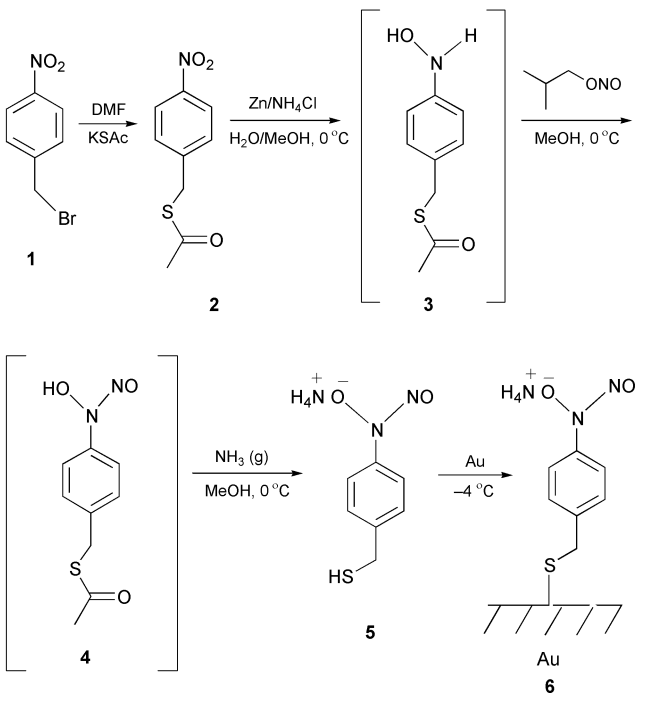
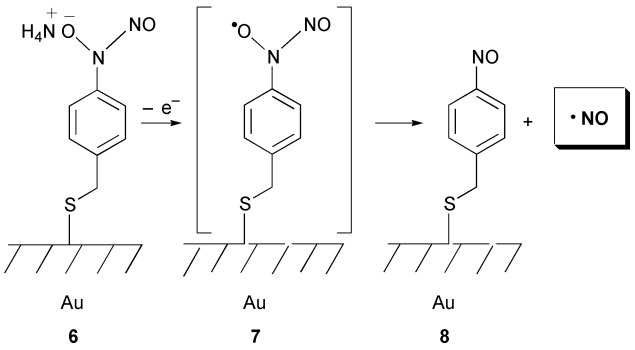
A SAM-modified gold electrode has been developed for the first time for quantitative NO generation of a nanomolar amount that is proportional to the surface area of the electrode.

Nitric oxide, a relatively unstable, potentially toxic gas, has been implicated in a wide variety of physiological and pathological processes.[1–4] Considering the numerous functions of NO in the human body, controlled delivery of a quantitative amount of NO to specific sites is most critical for biomedical applications of NO donor compounds.[5,6] On the other hand, extensive research on a variety of self-assembled monolayers (SAMs) on different metal electrodes has resulted in many biomedical applications during the past decade.[7–11] In our efforts to develop quantitative and site-specific NO donating compounds, we explored the possibility of using the self-assembled monolayer of an NO donor to achieve controlled NO release. Here we report the development of a novel SAM moiety **6** by attaching a thiol tail to the NO donor molecule and allowing it to self-assemble onto the surface of a thin gold electrode (Scheme 1). Upon applying an electric potential, the electrode achieves quantitative NO release on a nanomolar scale.

N-Nitroso-*N*-oxido-*p*-thiomethylbenzenamine ammonium salt **5** was synthesized according to Scheme 1. 4-Nitrobenzyl bromide (**1**) was reacted with potassium thioacetate to give compound **2**. Subsequent zinc reduction of the nitro group, nitrosation with isobutyl nitrite, and finally neutralization and spontaneous deacetylation afforded **5**.† Although compound **5** slowly decomposes at rt, successful preparation of the SAM gold electrode of compound **5** was achieved at −4 °C, leading to the formation of **6**. According to Lawless and others who have illustrated the oxidative electrochemical release of NO from cupferron‡ and its derivatives,[12,13] a similar mechanism is proposed to account for NO generation from the SAM donor **6** (Scheme 2). Upon applying an electric potential, **6** undergoes a one-electron electrochemical oxidation to form presumably the highly unstable free radical intermediate **7**, which spontaneously decomposes to release NO and form the nitroso SAM **8** as well.



Scheme 1 Synthesis of NO donor **5** and preparation of SAM **6**.



Scheme 2 Proposed NO releasing mechanism from the SAM modified gold electrodes.

An Osteryoung square wave voltammetry (OSWV) technique was employed to characterize the donor SAM **6**. Typical OSWV responses using a BAS-100B electroanalyzer were shown in Fig. 1. From 0 to 800 mV, the donor SAM modified gold electrode exhibited a single peak at a potential of 270 mV

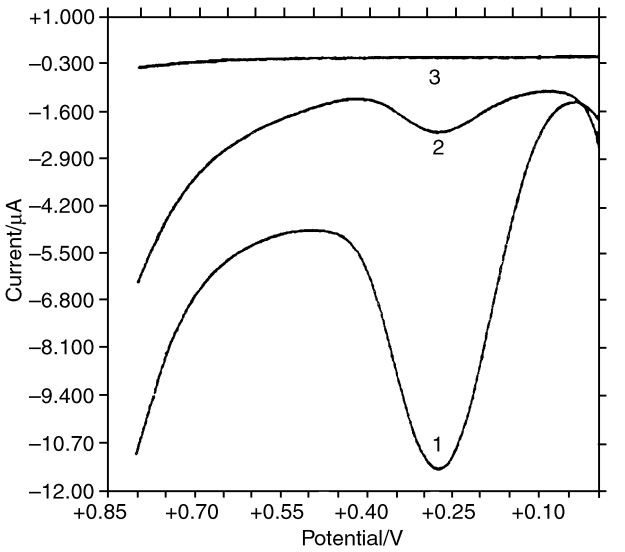


Fig. 1 Typical OSWV responses of SAM functionalized gold electrodes. Curve 1: first scan; curve 2: second scan; and curve 3: a 'real' background obtained after multiple scans.

DOI: 10.1039/b004159i

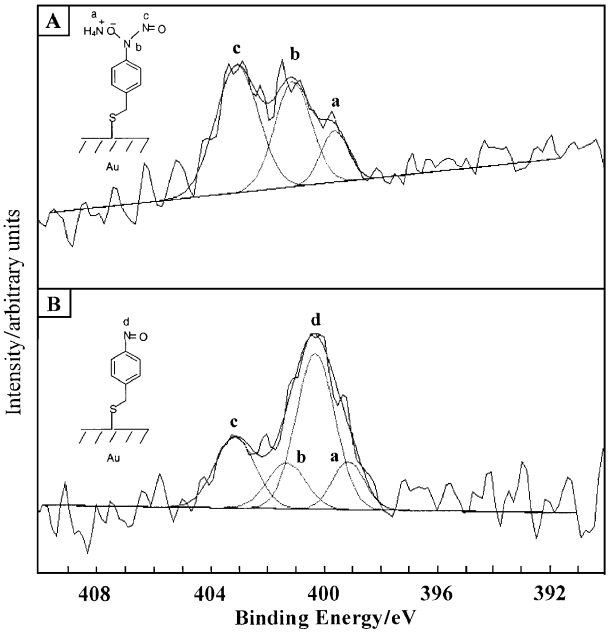

Fig. 2 XPS spectra of the SAM covered gold electrode prior to (A) and after (B) the electrolysis.

corresponding to an irreversible oxidation process (curve 1). A second continuous scan resulted in a lowered peak current (curve 2), indicating a reduced quantity of the donor compound **5** on the surface of the electrode. Upon multiple scans, the peak eventually disappeared and a 'real' background curve was obtained (curve 3), which represented the formation of **8**.

X-ray photoelectron spectroscopy (XPS) has proven to be a useful technique in characterizing SAM-functionalized metal surfaces by determining the oxidation state of nitrogen within SAM electrodes.[14] XPS specta in Fig. 2A are the results of three peaks that correspond to nitrogen atoms[15,16] in three different chemical environments in donor SAM **6** (binding energy of 399.66, 401.21 and 403.14 eV for $N_{1S}^{1/2}$, respectively). After electrolysis, the overall spectra changed with the appearance of a new peak with lower binding energy. The new spectrum (Fig. 2B) is best fitted for $N_{1S}^{1/2}$ peaks at binding energy of 399.33, 400.44, 401.38 and 403.22 eV, respectively. The new peak at 400.44 eV corresponds to the $N_{1S}^{1/2}$ intensity of the nitroso group in SAM **8**, which is consistent with the oxidation of the bulky terminal group in SAM **6**.

To directly monitor the generation of NO from the SAM functionalized gold electrode, a commercially available NO detector probe was inserted into the electrolysis cell through a bypass to the vicinity of a gold electrode at a fixed position. Due to the actual detection limit of the NO detector probe (~ 2 nM), the gold bead working electrode was replaced with a larger gold plate electrode (Au (111)) in order to generate a significant amount of NO for detection. NO generation was monitored simultaneously during a quantitative electrolysis process while the solution was vigorously stirred. The amount of NO released was determined by subtracting the highest point on the current plateau from the background current and converting the result into the corresponding quantities of NO using a standard calibration curve. It was shown that the amount of NO generated increased with the electrode potential during a bulk electrolysis process; however, no linear relationship appeared between the amount of NO released and the electrolysis potential.[13] Next, we carried out the electrolysis with various sizes of gold electrodes all having the same square geometry. Interestingly, a linear relationship between the amount of NO generated and the area of the electrode was established (Fig. 3),§ which indicates that controlled NO release could be achieved by selecting an appropriately sized surface area of the gold electrode.

In summary, this work demonstrates the principle and initial design of a gold electrode functionalized by a self-assembled

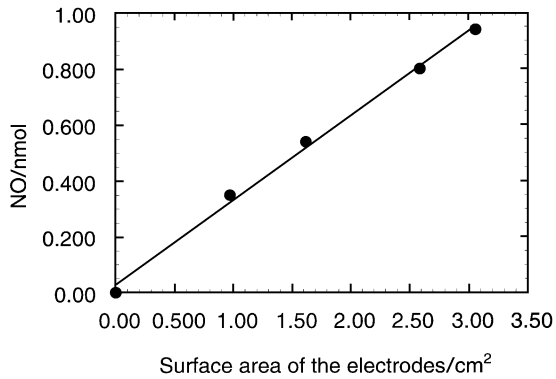

Fig. 3 A linear relationship between the amount of NO released and the surface area of the gold electrodes.

monolayer of NO donor compound. Upon electrolysis, such an electrode quantitatively generates NO at a nanomolar scale and the amount of NO produced can be controlled by changing the surface area of the gold electrode. It is thus envisioned that this type of electrode can be developed into practical NO generating micro electrode arrays for a variety of biochemical applications where a small but quantitative amount of NO can be targeted at specific sites.

DFT exploration of structural and magnetic properties of [*n*]annulene ring carbomers

Cyril Godard, Christine Lepetit and Remi Chauvin*

Laboratoire de Chimie de Coordination, UPR 8241 CNRS, 205 Route de Narbonne, 31077 Toulouse cedex 4 France. E-mail: chauvin@lcc-toulouse.fr

Received (in Cambridge, UK) 25th July 2000, Accepted 15th August 2000
First published as an Advance Article on the web 11th September 2000

DFT calculations of structural and magnetic properties of the ring carbomers of [*n*]annulenic species (*n* = 3–6), show that the aromatic *vs.* antiaromatic character of [*n*]annulenic species is qualitatively preserved by the carbomerisation process.

The constitutive, practical, and aesthetical importance of the carbon element in molecular chemistry[1] can be doubled with a formal function to expand the size of Dreiding (or ball-and-stick) models of molecules independently from other structural features. Indeed, by inserting an $(sp\text{-}C)_2$ unit into each bond of a Lewis structure, one constructs a so-called 'carbomer' structure of the former which has approximately a three-fold expanded size, and yet preserves the connectivity, the symmetry, the shape and π-electron resonance properties of its antecedent (Scheme 1).[2]

Scheme 1 Basic process in the definition of carbomers.

The general question to be addressed is whether the preservation/transformation of such essential characteristics of the chemical model entails preservation/transposition of physicochemical properties. The addition of two π-electron pairs per connection in the carbomerisation process makes a carbomer molecule *a priori* more reactive than the parent molecule. In order to correct this additive bond energy scheme and restore some stability in future synthetic targets, one here considers possible aromatic carbomer molecules: these molecules might simply be the carbomers of known aromatic molecules. This would allow us to test the way aromaticity, an intensively long debated concept,[3] is transposed by the carbomerisation process. In an exploratory study, we now consider the 'ring carbomers' of [*n*]annulenic species.[4]

Lewis structures of the ring carbomers ***n*b** of the lowest classical [*n*]annulenic molecules and ions ***n*a** (*n* = 3–6) are depicted in Scheme 2.[5] According to the simple VSEPR model, the structures should be planar and more or less symmetrical, depending on the electron delocalisation. Although none of these molecules are experimentally known,[6] substituted derivatives of the ring carbomer of benzene **6b** have been described.[7] In particular, the D_{6h} symmetry of the ring of the hexaphenyl derivative has been established by X-ray crystallography.[8] Since geometry optimisation of **6b** at the B3PW91/6-31G** level reproduced the experimental symmetry and bond lengths, this method was used for calculating the structures of all carbomers ***n*b** (Fig. 1).

As anticipated from the application of the basic Hückel rule to the sole π_z-electron systems,[9] the singlet $4m + 2$ π_z electron structures ***n*b** (*n* = 6, 5, 3) and the triplet $4m$ π_z-electron structure ***n*bT** (*n* = 4), exhibit D_{nh} symmetry just as their respective parent molecules ***n*a**. Likewise, the singlet $4m$ = 12 π_z-electron structure **4bS** possesses a lower D_{2h} symmetry just as its parent singlet cyclopentadiene **4aS** (Table 1). These results prove that structural aromaticity (resp. structural antiaromaticity) of a [*n*]annulenic species ***n*a** is preserved in its ring carbomer ***n*b**. Moreover, the application of the Hückel rule, early established for [*n*]annulenic molecules, is thus valid for their ring carbomers on the basis of a π_z electron count. The specific presence of in-plane π_{xy} electrons does not have a qualitative influence on the structural aromaticity of [*n*]annulene ring carbomers.

According to Katritsky's factor analysis, the aromaticity concept is two dimensional.[10] Whereas structural aromaticity (D_{nh} symmetry) can be regarded as a measure of the cyclic delocalisation of σ electrons,[11] magnetic aromaticity (ring current) is a measure of the cyclic delocalisation of the π electrons.[12] The Nucleus Independent Chemical Shift (NICS), propounded by Schleyer in 1996, proves to be a universal magnetic aromaticity measure revealing the existence of an overall diatropic ring current when negative, and an overall paratropic ring current when positive.[13] The NICS values of the optimised structures ***n*b** (*n* = 3–6) have been calculated at the ring center, at the B3LYP/6-31+G* level within the framework of GIAO formalism.[14] The data are compared with the NICS values of corresponding [*n*]annulenic species (Table 1):[15] ring

3b	D_{3h}	1,253	1.391	109.7°	155.1°	−22.3	**3a**	D_{3h}	1.365	−22.4

[a] Optimised geometries at the B3PW91/6-31G** level. Bond lengths are in Å units. [b] In ppm units. NICS were calculated at the centroids of the rings within the framework of the GIAO formalism at the B3LYP/6-31+G* level from the B3PW91/6-31G** optimised geometries.

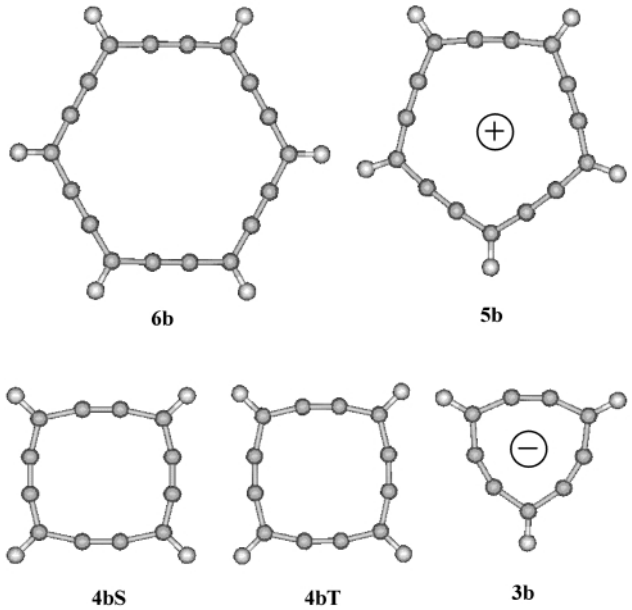

Fig. 1 Optimised geometries of ring carbomers ***nb*** at the B3PW91-6-31G** level.

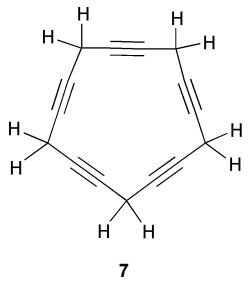
carbomers ***nb*** have the same NICS sign as their respective parent [*n*]annulenes ***na***. This shows that magnetic aromaticity is qualitatively preserved in the carbomerisation process. The high positive NICS value of singlet 12-π_z electron **4bS** must be emphasised: it is the signature of a rather strong paratropic ring current, as in singlet cyclobutadiene.

In order to bring out the specific influence of the out-of-plane π_z system *versus* that of the in-plane π_{xy} system in the ring carbomer structures ***nb***, the π_{xy} in-plane system is formally isolated in the corresponding [*n*]pericyclynes. For example, the ring center NICS value of [5]pericyclyne **7** (Scheme 3) in its optimised geometry has been calculated. The weak value found (NICS(**7**) = +0.6 ppm, at the HF/6-31+G* level) confirms the absence of homoaromaticity in **7** claimed by Schleyer *et al.*[16] The ring geometry of **7** is $\boldsymbol{D}_{5h}$ (with d(C≡C) = 1.208 and d(C–C) = 1.466 Å), similar to that of **5b**. Therefore, by



7

Scheme 3 [5]pericyclyne, assumed to have a π_{xy} system similar to that of **5b**.

resorting to the additive scheme NICS ≈ NICS(σ) + NICS(π_z) + NICS(π_{xy}),[17] it can be approximated that **7** and **5b** have similar NICS(σ) and NICS(π_{xy}) contributions: the high NICS value of **5b** is thus merely due to the NICS(π_z) component, while the in-plane π_{xy} system plays a minor role.

As for [*n*]annulenes, structural and magnetic aromaticity criteria correlate perfectly well together and with the Hückel rule applied to the sole π_z-electron system of [*n*]annulene ring carbomers. In conclusion, the preservation of aromaticity *vs.* antiaromaticity character during the carbomerisation process is clearly illustrated. This result encourages further efforts in the carbomeric comparison of physicochemical properties. In particular the transposition of energetic aromatic criteria going from ***na*** to ***nb*** will be reported shortly.[18]

The authors are grateful to Dr Guy Lavigne for encouraging discussions. We also wish to thank the Centre National de la Recherche Scientifique and the Ministère de l'Enseignement Supérieur de la Recherche et de la Technologie for financial support and IDRIS for computing facilities.

4 Since substituents generally exert a weak influence on the aromaticity of the benzene ring, peripheral C–H bonds are not required to undergo C_2-insertion. Therefore, in a preliminary study, the VSEPR symmetry of the Dreiding structures is preserved, but not the exact shape.
5 In order to satisfy the Hückel rule for **5b** and **6b**, one decides to define the carbomer of a charged species as the everywhere C_2-inserted structure with an opposite whole charge. In the case of non-covalent neutral structures, this is formally equivalent to a reversal of the charge separation.

Solid-phase synthesis of novel achiral hydantoin- and isoxazoline-substituted dispirocyclobutanoids†

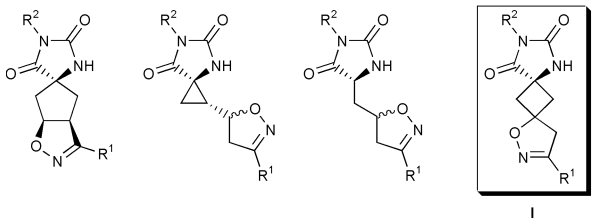
Kyung-Ho Park and Mark J. Kurth*

Department of Chemistry, University of California, One Shields Avenue, Davis, CA 95616 USA

Received (in Corvallis, OR, USA) 18th May 2000, Accepted 31st July 2000
First published as an Advance Article on the web 11th September 2000

A synthesis of novel achiral hydantoin- and isoxazoline-substituted dispirocyclobutanoids from solid-phase synthesis has been achieved. The facial and selective Boc-NH-mediated hydrogen-bond delivery of the nitrile oxide afforded 6 as the major compound.

In the field of drug discovery, considerable effort has been applied to the synthesis of hydantoin derivatives[1] using both solution- and solid-phase organic synthesis techniques. Many of the hydantoins reported to date are either racemic or diastereomeric mixtures. For example, we have synthesized a number of hydantoins.[1i–l]



I

The need to further diversify these compounds, together with recent reports regarding the biological activities of spirohydantoins[2] and spiroisoxazolines,[3] led us to explore development of a solid-phase synthetic strategy for the construction of hydantoin- and isoxazoline-containing heterocycle **I** with its central cyclobutane core. In this dispiro [4.1.4.1] system, the target molecule itself is achiral and thus avoids the formation of racemic mixtures—an important synthetic consideration when designing a potential drug scaffold.

Our solid-phase approach to **I** began with the coupling of Boc-protected amino acid **1**[4] with hydroxymethyl substituted polystyrene (1.1 mmol OH gram^{-1}) in the presence of 1,3-diisopropylcarbodiimide (DIC). A solid-phase 1,3-dipolar cycloaddition reaction[5] of the alkene moiety in **2** with a Mukaiyama-generated nitrile oxide[6] delivered resin **3**. Deprotection of the Boc moiety (TFA–CH_2Cl_2) and neutralization (Et_3N) of the resin delivered amino ester **4**. Treatment of this intermediate with isocyanates gave the urea ester intermediate **5** which released the achiral dispirohydantoins **6** and **7** by treatment with Et_3N (Scheme 1, Table 1). In previous studies,[1i–j] we discovered that urea-NH in cyclopentenyl amino acids can be a very effective stereocontrol element in solid-phase intermolecular nitrile oxide 1,3-dipolar cycloaddition reactions. With **2** now in hand, we were positioned to probe whether the Boc-NH moiety here would mediate similar stereoselectivity.

Indeed, the *exo*-methylenecyclobutane system realized some diastereoselectivity such that the H-bond directed product (*i.e.* **6**) was obtained with ≈3:1 selectivity relative to the non-H-bond directed product (*i.e.* **7**). X-ray crystallographic analysis of **6c**‡ (Fig. 1) verified the relative stereochemistries of **6**/**7**. This solid-phase stereoselectivity is in accord with our preliminary solution-phase studies where the ethyl ester equivalent of **2** (R^1 = C_6H_5–) undergoes 1,3-dipolar cycloaddition giving the ethyl ester equivalent of **3** with ≈3:1 stereoselectivity. Moreover, the solution-phase parallels of **2** → **3** → **4** → **5** → **6** (R^1 = C_6H_5–; R^2 = $C_6H_5CH_2$–) proceed in 52% overall yield (64, 89, 96, and 95%, respectively), while the solid-phase overall yield of **6** + **7** from hydroxymethyl substituted polystyrene (*i.e.* one additional step; **1** → **2**) is 45–56%. Thus, while solution- and solid-phase yields are comparable, the solid-phase protocol reported here enjoys the typical advantages of bead-based chemistry[7] and it allows for the easy manipulation of diastereomer mixtures with only end-product (*i.e.* **6** and **7**) separation.

Typical procedure for solid-phase synthesis of dispirohydantoins. A solution of DMAP (20 mg, 0.16 mmol) in DMF–CH_2Cl_2 (1 mL–4 mL) was prepared. Boc-protected amino acid **1** (0.37 g, 1.65 mmol) and DIC (0.21 g, 1.65 mmol) were dissolved in DMF–CH_2Cl_2 (1–4 mL) and this solution was added to the flask which contained the hydroxymethyl substituted polystyrene (0.5 g, 0.55 mmol, 1.1 mmol OH gram^{-1}). Finally the DMAP solution was added and the reaction mixture was stirred overnight at ambient temperature. The resin was washed with DMF, CH_2Cl_2, and ether, and dried to give the resin **2**. Resin **2** was swollen in THF (15 mL) and nitropropane (0.15 g, 1.65 mmol), phenylisocyanate (0.39 g, 3.3 mmol), and Et_3N (15 mg) were added. The reaction mixture was stirred at 60 °C overnight, then washed with DMF, CH_2Cl_2, and ether. This 1,3-dipolar cycloaddition step was repeated a second time. Drying *in vacuo* gave the resin **3** (R^1 = Et) which was treated

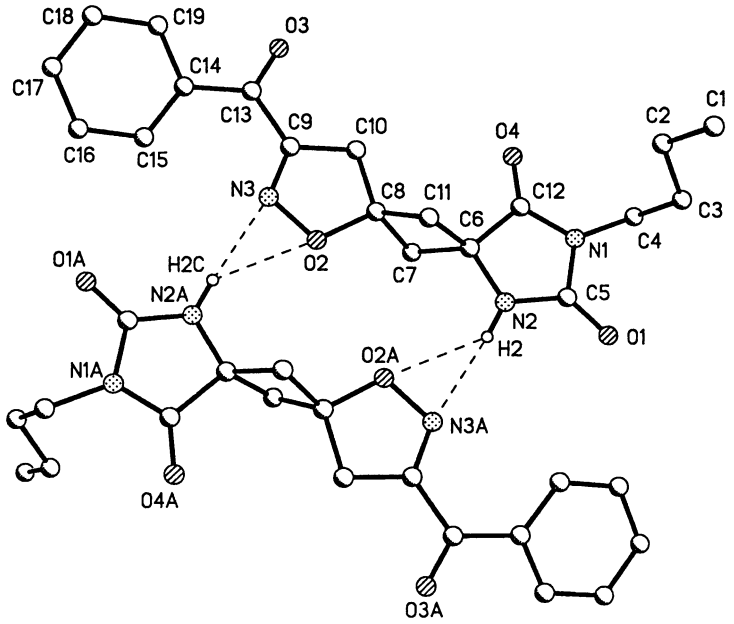

Fig. 1

with 50% TFA–CH_2Cl_2 (20 mL) at ambient temperature for 1 h. The resin was washed with DMF and CH_2Cl_2, followed by treatment with 10% Et_3N in CH_2Cl_2 (20 mL) for 1 h. The resulting resin was washed with DMF, CH_2Cl_2, and ether, and dried under vacuum to give resin-bound **4** with its free amine functional group. Resin **4** was treated with benzyl isocyanate (0.22 g, 1.65 mmol) in THF overnight at ambient temperature. The resin was washed with THF, DMF, and CH_2Cl_2 to afford the urea **5** (R^1 = Et–, R^2 = $C_6H_5CH_2$–). This resin was treated with Et_3N (0.33 g, 3.3 mmol) in DMF (20 mL) at 110 °C for 30 h to release the achiral dispirohydantoins as a mixture (**6b**:**7b** = 3:1), which was finally separated by column chromatography (ethyl acetate–hexane = 1:4) to give **6b** (62 mg, 0.2 mmol, 36% overall yield§) and **7b** (20 mg, 0.06 mmol, 11% overall yield§). **6b**: Mp 157 °C; FTIR (KBr) 3259, 2939, 1760, 1723, 1450 cm^{-1}; δ_H (300 MHz, $CDCl_3$) 7.37–7.23 (m, 5H), 7.11 (s, 1H), 4.62 (s, 2H), 3.32 (s, 2H), 2.95 (d, 2H, J = 13.8 Hz), 2.78 (d, 2H, J = 13.8 Hz), 2.34 (q, 2H, J = 7.4 Hz), 1.15 (t, 3H, J = 7.4 Hz); δ_C (75 MHz, $CDCl_3$) 176.8, 161.4, 155.7, 135.9, 128.6, 128.4, 127.8, 77.6, 53.4, 47.9, 46.6, 42.1, 21.3, 10.6; Anal. Calcd for $C_{17}H_{19}N_3O_3$: C, 65.16; H, 6.11; N, 13.41. Found: C, 65.11; H, 6.08; N, 13.27%. **7b**: Mp 194 °C; FTIR (KBr) 3196, 2934, 1778, 1714, 1431 cm^{-1}; δ_H (300 MHz, $CDCl_3$) 8.21 (s, 1H), 7.32–7.25 (m, 5H), 4.63 (s, 2H), 3.26–3.23 (m, 4H), 2.42–2.34 (m, 4H), 1.16 (t, 3H, J = 7.5 Hz); δ_C (75 MHz, $CDCl_3$) 174.2, 160.4, 158.0, 135.8, 128.6, 128.3, 128.0, 79.0, 54.8, 48.1, 46.6, 42.4, 21.4, 10.8; Anal. Calcd for $C_{17}H_{19}N_3O_3$: C, 65.16; H, 6.11; N, 13.41. Found: C, 65.36; H, 6.17; N, 13.41%.

In summary, we have developed a synthetic strategy for the preparation of novel heterocycles of generalized structure **I** from solid-phase. The work reported here secures this stage in a program aimed at the structural diversification of hydantoin- and isoxazoline-based pharmacophores. Combinatorial library production employing this general and expedient synthetic solid-phase methodology and subsequent biological evaluation are underway.

Palladium-catalysed cyclotrimerisation reactions of polycyclic alkenes under the Stille and Grigg coupling conditions

Antonio Paulon, Sergio Cossu, Ottorino De Lucchi* and Cristiano Zonta

Dipartimento di Chimica, Università Ca' Foscari di Venezia, Dorsoduro 2137, I-30123 Venezia, Italy

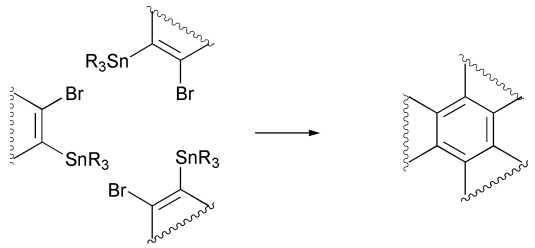
First published as an Advance Article on the web 11th September 2000

Preformed or *in situ* generated polycyclic bromostannylalkenes react under palladium catalysis under Stille or Grigg reaction conditions to afford cyclotrimerised adducts *via* a three-fold carbon–carbon coupling reaction.

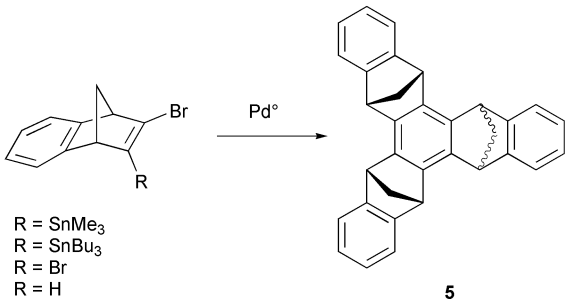
Due to their unusual electronic features, the class of molecules composed by trisannelated benzenes of polycyclic structures has attracted considerable interest in the past few years.[1] These molecules also have a peculiar cup-shaped structure that makes them suitable for use in molecular recognition as the component host.[2] Here we present a new and effective method of preparation of benzoannellated cyclotrimers which is based on the Stille coupling reaction.†[3] The cyclotrimerisation is accomplished by placing the metal center (the stannyl residue) and the leaving group (the bromine atom) (Scheme 1) at the two ends of the olefinic substrate.



Scheme 1

Bromostannylbenzonorborna-2,5-dienes‡ **1,2** were prepared by bromine–tin exchange from the dibromo derivative **3** or by LDA treatment of the bromobenzonorborna-2,5-diene **4** followed by quenching with trimethyltin chloride.[4] When **1** was heated at 70 °C for 24 h in DMF in the presence of palladium(II) acetate (10% mol eq.), triphenylphosphine (20% mol eq.) and LiCl a 4:1 mixture of *anti* and *syn* trimers **5** was obtained in 38% yield (Scheme 2). No detectable formation of dimers, as previously noticed in the reaction with copper nitrate, was observed.[4] Yields and *anti* to *syn* ratio are affected by temperature, solvent or by the changes to the other reaction conditions.

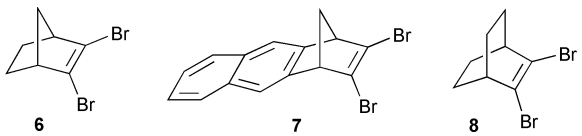
For example, the same reaction carried out in toluene at 120 °C affords, after 24 h, a 3:1 mixture of *anti* and *syn* isomers **5** in 30% yield. By comparison, in refluxing THF, the system is unreactive even after 94 h. The effect of co-catalysts has been considered. LiCl,[5] a well known Stille coupling activator, does not significally improve the yields of the reaction.



Scheme 2

Relevantly, the bromotributyltin derivative **2** treated with palladium(II) acetate (7% mol eq.) and triphenylphosphine (14% mol eq.) at 110 °C for 24 h in toluene leads to trimer **5** as only the *anti* isomer in 58% yield.

The toxic nature of tin compounds, which is especially crucial for the trimethyl derivative as well as the handling and storage of quantities of bromostannylalkenes, prompted us to test the feasability of the *in situ* reaction under the methodology developed by Grigg.[6] Accordingly, by heating a mixture of dibromobenzonorborna-2,5-diene **3**, palladium(II) acetate (10% mol eq.), triphenylphosphine (20% mol eq.) and hexamethylditin in refluxing toluene, cyclotrimer **5** is obtained in comparable yields with the Stille method (50%). In this case, however, only the *anti* isomer is formed. Remarkably the reaction can be achieved in much higher yields by using hexabutylditin, which besides being less toxic,[7] is less expensive than the methyl derivative. The latter reaction conditions, using hexabutylditin in place of hexamethylditin, gave **5** quantitatively, and were considered as the most convenient conditions for the desired transformation and were applied to other substrates for the determination of the scope of the method.§ All of the dibromoderivatives **6**–**8** afforded the respective trimer *anti*-**9**, *anti*-**10** and **11** in almost quantitative yields.¶[8]



The mechanism by which trimers are formed could be attractively envisaged as a 'head to tail' coupling amongst the tin and bromine termini of the double bonds. If this in indeed the case the cyclotrimerisation reaction of racemic **1** either preformed under the Stille reaction conditions or generated *in situ* with the Grigg method, should always afford a statistical 3:1 ratio of the *anti* and *syn* product.[1b] The formation of the *anti* product only suggests that the reaction occurs with the coupling of both antipods, while that derived from the coupling of the homochiral enantiomers does not form because of steric hindrance.[1b] Alternatively, the reaction may occur *via* an acetylene intermediate stabilised by complexation with palladium. However, no further data regarding the mechanism are available so far.

In conclusion we have reported the Stille reaction applied to an unusual bifunctional substrate that leads to a useful application and developed a method that, especially in the optimised Grigg variant, competes with the best method so far available for the cyclotrimerisation of polyclic alkenes both in terms of yields and safety.

Notes and references

† As reported in ref. 1*a*, 2-bromo-3-trimethyltinnorborna-2,5-diene does not undergo cyclotrimerisation under Stille-coupling conditions. The reason for this failure is assumed to be Pd complexation to the double bond between carbons 5 and 6 in this substrate.

‡ The IUPAC name for benzonorborna-2,5-diene is tricyclo[6.2.1.$0^{2,7}$]undeca-2,4,6,9-tetraene.

§ A mixture of 2,3-dibromobenzonorborna-2,5-diene (0.34 mmol), $Pd(OAc)_2$ (0.04 mmol), PPh_3 (0.08 mmol) and hexabutylditin (0.51 mmol) in dry toluene (3 mL) in a screw capped pyrex test tube was purged with argon, sealed and heated at reflux for 24 h. After cooling to rt, water (20 mL) was added and extracted with diethyl ether (3 × 30 mL), washed with brine, dried ($MgSO_4$) and concentrated at reduced pressure. The residue was purified by flash chromatography through a short silica gel column eluting with a hexane–dichloromethane gradient.

¶ It should be pointed out that the cyclotrimerisation reaction carried out on the boron derivative under Suzuki type reaction conditions afforded only a very moderate yield of cyclotrimer.

A novel synthetic route to peralkylated carborane anions, 1-H-$CB_9Me_9^-$ and 1-H-$CB_{11}R_{11}^-$ (R = Me, Et)

Chi-Wing Tsang and Zuowei Xie*

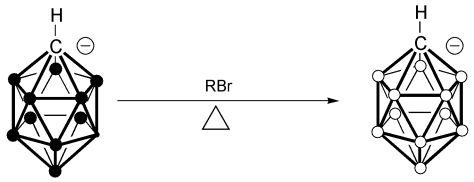
Received (in Cambridge, UK) 13th June 2000, Accepted 22nd August 2000
First published as an Advance Article on the web 11th September 2000

Treatment of carborane anions with excess RBr (R = Me, Et) in a sealed Pyrex tube at 200 °C gives peralkylated carborane anions in quantitative yields, which represents the most convenient and the most economic method so far reported in the literature for the preparation of peralkylcarborane anions.

As a class of the robust and weakly coordinating anions, carborane anions have found many applications in catalysis, metathesis, and oxidation chemistry as well as in stabilizing highly reactive cations.[1] Many derivatives of carborane anions have recently been reported; among these, the polymethylated species have received much attention.[2–7] Two main methods have been developed for the transformation of B–H or B–I vertices to B–C ones; they include palladium-catalyzed alkylation of B–I vertices of iodocarboranes with Grignard reagents,[2–5] and electrophilic substitution of B–H vertices by strong methylating reagents such as methyl triflate or trimethylaluminium/MeI.[6,7] These methods often involve complicated workup procedures, and sometimes a mixture of products, which lead to a lower yield. We report herein a very facile synthesis of peralkylated carborane anions.

Treatment of $[Me_3NH][1\text{-H-}CB_9H_9]$ or $[Me_3NH][1\text{-R-}CB_{11}H_{11}]$ with excess MeBr in a sealed Pyrex tube at 200 °C for 5 days gives permethylated products $[Me_3NH][1\text{-H-}CB_9Me_9]$ (**1**) or $[Me_3NH][1\text{-R-}CB_{11}Me_{11}]$ [R = H (**2**), CH_3 (**3**)] in almost quantitative yields.† The first perethylated carborane anion, $[Me_3NH][1\text{-H-}CB_{11}Et_{11}]$ (**4**), can also be prepared quantitatively in the same manner by using EtBr as a reagent [eqn. (1)].



(1)

No organic solvent is involved and no workup procedures are needed. After the reaction is complete, the Pyrex tube is opened and excess RBr is immediately evaporated leaving a pure product. These compounds have been fully characterized by ^1H, ^{13}C and ^{11}B NMR, MS and IR spectroscopy. The complete conversion of B–H vertices into B–R (R = Me, Et) vertices is indicated by the absence of the characteristic B–H absorption (*ca.* 2600 cm^{-1}) in the IR spectra and identical proton-coupled and proton-decoupled ^{11}B NMR spectra. The formation of the B–C bonds is also reflected in the broadening and upfield shifted carbon chemical shifts in their ^{13}C NMR spectra due to the close proximity of carbon nuclei to both ^{11}B and ^{10}B nuclei.[3,8]

Reaction of $[Me_3NH][1\text{-H-}CB_{11}H_{11}]$ with excess ^{i}PrBr under the same or more rigorous reaction conditions, however, affords a mixture of polyalkylated carboranes $[Me_3NH][1\text{-H-}CB_{11}H_{11-n}{}^i Pr_n]$ (n = 4–7) on the basis of MS analyses. The reasons for that are probably due to the steric effects of the isopropyl groups. It is noteworthy that no brown Br_2 is produced and only HBr gas is detected in the above-mentioned reactions. If the permethylation is carried out in a $(MeO)_3P(O)$ solution or the perethylation is performed in a $(EtO)_3P(O)$ solution, both the reaction temperature and reaction time are reduced.[9]

In contrast, reaction of $[Me_3NH][1\text{-H-}CB_{11}H_{11}]$ with excess MeI, under the same reaction condition, yields a mixture of products $[Me_3NH][1\text{-H-}CB_{11}Me_{11-n}I_n]$ (n = 3–5) on the basis of MS analyses, along with the formation of HI and purple I_2. These results indicate that MeI may undergo both heterolytic and homolytic reactions generating Me^+, $Me^{\cdot}$, I^- and $I^{\cdot}$. Coupling of $I^{\cdot}$ yields purple I_2. Both Me^+ and I_2 are electrophiles, which react with carborane to form a mixture of $[1\text{-H-}CB_{11}Me_{11-n}I_n]^-$.

In summary, a very facile and economic method has been developed for the first time for the synthesis of permethylated and perethylated carborane anions. Applications of this novel methodology to other carborane and borane molecules are under investigation.

We thank the Research Grants Council of the Hong Kong Special Administration Region (Project No. CUHK 4210/99P) for financial support.

† *Preparation* of **4***: Method A*. A thick-walled Pyrex tube was charged with $[Me_3NH][1\text{-H-}CB_{11}H_{11}]$ (0.10 g, 0.49 mmol) and ethyl bromide (0.5 mL, 6.70 mmol) at 0 °C. This tube was then cooled with liquid N_2, sealed under vacuum and placed in a furnace. The temperature of the furnace was gradually increased to 160 °C, and this temperature was maintained for 2 days. The temperature was then slowly raised to 220 °C, and this temperature was maintained for 3 days. The tube was opened and excess ethyl bromide was evaporated, leaving a pale yellow solid. The ^{11}B NMR showed that it is a pure compound. This pale yellow solid can be further recrystallized from a water/acetone solution to give **4** as a white crystalline solid (0.23 g, 92%). ^1H NMR (acetone-d_6): δ 2.96 [s, $(CH_3)_3NH$], 0.96 [br s, B-CH_2CH_3], 0.87 [br s, B-CH_2CH_3]; ^{13}C NMR (acetone-d_6): δ 45.48 [$(CH_3)_3NH$], 12.24 [s, B-CH_2CH_3(2–6)], 10.95 [s, B-CH_2CH_3(7–12)], 6.94 [br, B-CH_2CH_3(2–12)]; ^{11}B NMR (acetone-d_6): δ 2.95 (s, 1B), −4.05 (s, 5B), −7.78 (s, 5B); IR (cm^{-1}, KBr): ν 2953 (s), 2908 (s), 2874 (s), 1457 (m), 1156 (m), 1034 (w), 956 (m), 521(s); Negative-ion MALDI MS, *m/z* (isotopic abundance): calcd. for $[1\text{-H-}CB_{11}(CH_2CH_3)_{11}]^-$ 449(34), 450(70), 451(100), 452(90), 453(45); found 449(32), 450(67), 451(100), 452(91), 453(43).

Method B. A thick-walled Pyrex tube was charged with $[Me_3NH][1\text{-H-}CB_{11}H_{11}]$ (0.10 g, 0.49 mmol), ethyl bromide (0.5 mL, 6.70 mmol), and triethylphosphate (1.5 mL, 8.83 mmol) at 0 °C. This tube was then cooled with liquid N_2, sealed under vacuum and placed in a furnace. The temperature of the furnace was gradually increased to 180 °C, and this temperature was maintained for 3 days. The tube was opened and excess ethyl bromide was evaporated. The residue was dissolved in hot water and the precipitate formed was immediately filtered off. This solid was washed with CH_2Cl_2 and then hexane to give a white crystalline solid (0.21 g, 84%) that was identified as **4** by spectroscopic data.

Compounds **1**–**3** were prepared as white crystalline solids in the same manner in > 95% yield.

Spectroscopic data for **1**: ^1H NMR (acetone-d_6): δ 2.90 [s, $(CH_3)_3NH$], −0.29 [br s, B-CH_3(2–5)], −0.55 [br s, B-CH_3(6–10)]; ^{13}C NMR (acetone-

d_6): δ 52.62 [cage C], 45.00 [$(CH_3)_3NH$], −4.10 [br, CH_3(2–10)]; ^{11}B NMR (acetone-d_6): δ 37.04 (s, 1B), −4.19 (s, 4B), −8.24 (s, 4B); IR (cm^{-1}, KBr): ν 2919 (br s), 2863 (m), 1623 (m), 1456 (m), 1384 (s), 1093 (s), 1032 (s), 804 (w); these data are identical with those reported in the literature.[5]

Spectroscopic data for **2**: ^{1}H NMR (acetone-d_6): δ 3.08 [s, $(CH_3)_3NH$], −0.21 [s, B-CH_3(2–6)], −0.44 [s, B-CH_3(7–12)]; ^{13}C-NMR (acetone-d_6): δ 60.49 [cage C], 45.00 [$(CH_3)_3NH$], −3.05 [v br, B-CH_3(2–12)]; ^{11}B NMR (acetone-d_6): δ 4.24 (s, 1B), −3.91 (s, 5B), −7.36 (s, 5B); IR (cm^{-1}, KBr): ν 2927 (s), 2896 (s), 2831 (s), 1476 (m), 1458 (m), 1303 (m), 1226 (m), 1050 (s), 523 (m); Negative-ion MALDI MS, *m/z* (isotopic abundance): calcd. for [1-H-$CB_{11}(CH_3)_{11}$]$^-$ 294(12), 295(36), 296(74), 297(100), 298(87), 299(38), 300(24); found 294(28), 295(61), 296(91), 297(100), 298(92), 299(57), 300(23).

Spectroscopic data for **3**: ^{1}H NMR (acetone-d_6): δ 3.16 [s, $(CH_3)_3NH$], 0.80 [s, C-CH_3], −0.19 [s, B-CH_3(2–6)], −0.29 [s, B-CH_3(7–12)]; ^{13}C NMR (acetone-d_6): δ 45.00 [$(CH_3)_3NH$], 14.30 [C-CH_3], −2.67 [v br, B-CH_3(2–12)]; ^{11}B NMR (acetone-d_6): δ 0.53 (s, 1B), −8.86 (s, 5B), −10.85 (s, 5B); IR (cm^{-1}, KBr): ν 2953 (s), 2913 (s), 2848 (m), 1640 (w), 1476 (m), 980 (s), 937 (s), 774 (s), 512 (vs); these data are identical with those reported in the literature.[6]

Employing fast time-resolved infrared (TRIR) spectroscopy we have characterised $CpM(CO)_3(Xe)$ (M = Nb or Ta) at room temperature in supercritical Xe solution; $CpM(CO)_3(Xe)$ were found to exhibit a similar reactivity with CO to the corresponding alkane complexes, $CpM(CO)_3$(*n*-heptane) and we report a trend in reactivity of the early transition metal Xe complexes.

Organometallic noble gas complexes have a long history. More than 20 years ago Perutz and Turner used matrix isolation to show that photolysis of $M(CO)_6$ (M = Cr, Mo or W) in low temperature (12 K) matrices generated $M(CO)_5L$ (L = Ar, Kr, Xe or CH_4).[1] Matrix isolation has subsequently been used to characterise a wide range of organometallic noble gas complexes.[2–6] Although matrix isolation is a powerful technique for the characterisation of unstable species at low temperature, it does not provide any kinetic information quantifying the reactivity of these species at room temperature.

Organometallic noble gas complexes have been observed in solution. Simpson *et al*. characterised $Cr(CO)_5(Xe)$ in liquefied Xe (lXe) at −98 °C using conventional FTIR spectroscopy following UV photolysis of $Cr(CO)_6$.[7] Weiller extended this work, detecting $M(CO)_5L$ (M = Cr or W; L = Kr or Xe) in liquefied noble gas solution at low temperature using rapid-scan FTIR spectroscopy.[8] A similar approach was used to detect Cp*Rh(CO)L (L = Kr or Xe).[9–12] Organometallic noble gas complexes have also been observed in the gas phase at room temperature[13] and theoretical studies have predicted Au–Xe bond dissociation energies (BDEs) up to 127 kJ mol^{-1}.[14]

We have recently shown that organometallic noble gas complexes can be observed in fluid solution at room temperature following irradiation of transition metal carbonyls in supercritical fluids. Using fast TRIR spectroscopy we characterised $M(CO)_5L$ [M = Cr, Mo or W; L = Ar (W only), Kr or Xe][15] and $(\eta^5\text{-}C_5R_5)M(CO)_2L$ [M = Mn or Re; R = H, Me or Et (Mn only); L = Kr or Xe].[16,17] The reactivity of these complexes increases in the order Xe < Kr < Ar and Re ≤ W < Mo ≈ Cr ≈ Mn.

The comparison of reactivity between organometallic noble gas and alkane complexes is important. We reported $CpRe(CO)_2$(*n*-heptane) as being the longest lived alkane complex at room temperature[16] and this proved significant since Ball and Geftakis were subsequently able to characterise $CpRe(CO)_2$(cyclopentane) at low temperature using NMR spectroscopy.[18] $CpRe(CO)_2(Xe)$ was only twice as reactive towards CO in scXe compared to $CpRe(CO)_2$(*n*-heptane) in *n*-heptane solution.[16] Here, we investigate the photochemistry of the Group V complexes, $CpM(CO)_4$ (M = Nb or Ta) in supercritical Xe at room temperature, and report a trend in reactivity for the early transition metal noble gas complexes.

Fig. 1(a) shows the TRIR spectrum† obtained 80 ns following 355 nm excitation of $CpNb(CO)_4$ in scXe (1940 psi, 25 °C) in the presence of CO (100 psi). The parent *ν*(CO) IR absorptions at 2041 and 1936 cm^{-1} are bleached and new bands are produced at 1986 and 1885 cm^{-1} which can be assigned to $CpNb(CO)_3(Xe)$ by comparison with previous matrix isolation results[19] and the TRIR spectrum of the analogous *n*-heptane complex.[20] A similar experiment was performed with $CpTa(CO)_4$ dissolved in scXe (2070 psi, 25 °C) in the presence of CO (100 psi). The parent bands at 2037 and 1929 cm^{-1} were bleached and new absorptions at 1983, 1879(sh) and 1873 cm^{-1} were produced, which can be assigned to $CpTa(CO)_3(Xe)$ [Fig. 1(b)]. In the presence of CO, the formation of $CpNb(CO)_3(Xe)$ and $CpTa(CO)_3(Xe)$ in scXe is completely reversible with no observable secondary photoproducts. This reversibility is demonstrated more clearly in Fig. 2, which shows the relevant TRIR kinetic decay traces. Fig. 2 also shows that the decay of $CpNb(CO)_3(Xe)$ and $CpTa(CO)_3(Xe)$ in scXe depends linearly on CO concentration and from these plots we estimate the second order rate constants for the reaction of $CpNb(CO)_3(Xe)$ with CO [k_{CO} = 5.7 (± 0.6) × 10^6 dm^3 mol^{-1} s^{-1}] and for $CpTa(CO)_3(Xe)$ with CO [k_{CO} = 4.9 (± 0.5) × 10^6 dm^3 mol^{-1} s^{-1}] in scXe. $CpNb(CO)_3(Xe)$ and $CpTa(CO)_3(Xe)$ have similar reactivities towards CO in scXe compared to the analogous alkane complexes, $CpNb(CO)_2$(*n*-heptane) and $CpTa(CO)_3$(*n*-heptane) in *n*-heptane solution (Table 1).

The reactivities of early transition metal noble gas and alkane complexes show several trends. Thus far we have found that for a given metal/ligand combination the reactivity of organometallic noble gas complexes towards CO is very similar (≈× 2–3) to the reactivity of the corresponding alkane (*n*-heptane) complex.[15–17,21] In our previous studies we have found that the alkane complexes decrease in reactivity on moving down the Periodic Table and on moving from Group V to Group VII. The results reported here further demonstrate the similarity of the reactivity of early transition metal organometallic xenon complexes to that of their corresponding alkane complexes (Table 1). Preliminary results‡ obtained with $CpV(CO)_4$

[a] hep = *n*-heptane. [b] Ref. 20. [c] Ref. 23. [d] Ref. 15. [e] Ref. 24. [f] Ref. 17. [g] Ref. 16.

suggest that $CpV(CO)_3(Xe)$ also fits into this trend. The similarity between the reactivity of alkane and noble gas complexes towards CO is surprising since for a given metal/ligand system the BDE for a metal–xenon bond is expected to be significantly less than that of the corresponding metal–heptane bond. For example, the W–Xe BDE in $W(CO)_5(Xe)$ (34.3 kJ mol^{-1}) determined from gas phase studies[13] is significantly less than the W–heptane BDE in $W(CO)_5$(*n*-heptane) (62.8 kJ mol^{-1}) estimated from photoacoustic calorimetry measurements.[22] Detailed kinetic studies on Group VII xenon and alkane complexes[17,21] suggested that the early transition metal xenon complexes react with CO in scXe by a different mechanism than the early transition metal *n*-heptane complexes in *n*-heptane.

In conclusion, there is a general decrease in reactivity of the early transition metal xenon complexes, similar to that observed for the analogous alkane complexes, upon moving down the Periodic Table and on moving from Group V to Group VII, resulting in $CpRe(CO)_2(Xe)$ being the least reactive transition metal xenon complex reported so far. It is therefore hoped that the similar reactivity of $CpRe(CO)_2$(*n*-heptane) and $CpRe(CO)_2(Xe)$ will make the characterisation of an organometallic xenon complex by low temperature NMR a realistic possibility. There is clearly still much to learn about organometallic alkane and noble gas complexes and it is likely that TRIR spectroscopy will prove increasingly useful for this purpose.

Notes and references

† The TRIR experiments used a cw IR diode laser to monitor temporal changes in IR absorbance following 355 nm excitation by a Nd:YAG laser (Quanta-Ray GCR-12S, 7 ns pulse). IR spectra were built up on a 'point-by-point' basis by repeating this measurement at different IR frequencies. See: M. W. George and J. J. Turner, *Analyst*, 1994, **119**, 551 for further details.

‡ Initial TRIR kinetic decay studies on $CpV(CO)_3(Xe)$ in scXe show that $CpV(CO)_3(Xe)$ and $CpV(CO)_3$(*n*-heptane) have a similar reactivity towards CO. However we have not been able to obtain, to our satisfaction, a linear behaviour of the rate of decay of $CpV(CO)_3(Xe)$ with respect to CO concentration in scXe.

23 The previously reported values of k_{CO} were slightly higher than these (see ref. 20). The earlier values were calculated by measuring k_{obs} at only one concentration of CO and using the relationship, $k_{obs} = k_{CO}[CO] + k_{Ar}$ to obtain k_{CO}, where k_{Ar} is the observed rate constant in the absence of added CO. We have repeated the determination of these values by using a more accurate method in which k_{obs} is measured at a series of CO concentrations and k_{CO} is obtained from the slope of the resulting plot.

First published as an Advance Article on the web 11th September 2000

A flexible AM1/CHARMM treatment finds two distinct mechanistic pathways across the megadimensional energy hypersurface computed for lactate dehydrogenase catalysed reduction of pyruvate to lactate: these differ in the timing of the hydride transfer and proton transfer components of the reaction.

Current applications of hybrid quantum-mechanical/molecular-mechanical (QM/MM) approaches to modelling of enzyme reactivity commonly neglect flexibility in very large systems. Two recent independent studies of lactate dehydrogenase (LDH) catalysed interconversion of pyruvate and lactate, using similar QM/MM methods, yielded very different transition structures (TSs) and mechanisms.[1,2] We now report the simultaneous existence of two distinct mechanistic pathways across the megadimensional energy hypersurface for this system, and suggest that both earlier studies failed to explore its topography to a sufficient extent. To determine which mechanism is preferred will require use not only of a theoretical method giving reliable energies but also of statistical averaging over many configurations. Our finding is significant because it shows that a rigid approach to modelling of any complex system may easily miss an important feature of reaction mechanism.

The chemical step of the LDH cataysed reaction involves hydride transfer (HT) from the dihydronicotinamide ring of NADH to the carbonyl C atom of pyruvate and proton transfer (PT) to the carbonyl O atom of pyruvate from a protonated histidine residue (Fig. 1). The relative timing of the HT and PT is a matter of some interest in mechanistic enzymology. Ranganathan and Gready[2] (RG) found a mechanism (HT,PT) in which HT preceded PT in a stepwise manner, contrasting with the usual chemical and enzymatic arguments for HT processes and their own results from supermolecule calculations,[3] but in accord both with the assumption of an earlier empirical valence-bond study[4] and with the results of a later QM/MM study of the analogous malate dehydrogenase.[5] On the other hand, we (MTW) found a family of TSs (with differing relative dispositions of active site residues) corresponding to a concerted mechanism (PT/HT) with PT considerably more advanced than HT.[1]

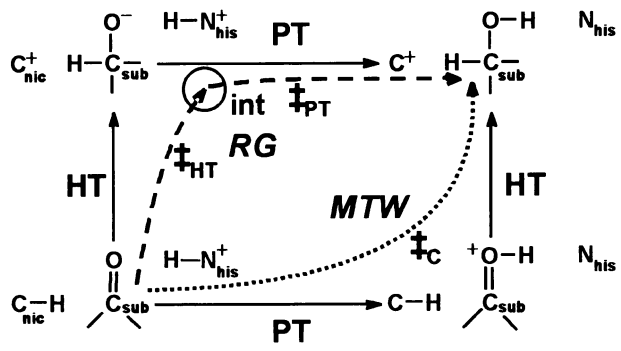

Fig. 1 Reaction map for LDH catalyzed reduction of pyruvate reactant (bottom left) to lactate product (top right); 'his' is histidine-195, 'nic' is nicotinamide, and 'sub' is substrate.

The RG and MTW studies both used the AM1 method[6] for the QM region. RG used the AMBER[7] MM method for the entire dogfish LDH sub-unit ternary complex, but with a relatively small number of atoms allowed to move. In contrast MTW used the CHARMM[8] force field for a truncated (1900 atom) *B. stearothermophilus* LDH but with a very large number of mobile atoms. The first important result of our recent studies is that these and other differences of detail (*e.g.* nature and location of QM/MM link atoms and QM/MM electronic coupling) are not primarily responsible for the different mechanisms found previously. We have now used a large-QM/full-MM model which includes all atoms (~5600) of the monomeric *B. stearothermophilus* LDH subunit,[9] plus NADH, pyruvate, and water molecules within a 20 Å radius ball of water centred on His-195.[10] All atoms were free to move in the optimisations and TS searches. A larger QM region (52 AM1atoms) containing also the ribose moiety was employed, as shown in Fig. 2. Schmidt and Gready have recently asserted that AM1 is likely to be adequate for modelling conformational preferences in QM/MM calculations for the LDH catalyzed reaction.[11]

Approximate saddle points were located by grid searches using constrained ABNR minimization of the CHARMM24b2[12] QM/MM energy.[13] TS refinement in GRACE[1b] employed an explicit hessian for the QM 'core' (Fig. 2) while the MM enzyme 'environment' was continually relaxed to a r.m.s. gradient < 10^{-3} kcal mol^{-1} Å^{-1}. TS optimisation in the core was continued until no element of the gradient vector of the entire system (core plus environment) was larger than 10^{-2} kcal mol^{-1} Å^{-1}. To characterise each saddle point, its hessian was recomputed for a total of 147 atoms (QM core + six amino acid residues in the active-site region) by central finite-differencing of the gradient vector: the single negative eigenvalue of the resultant hessian corresponded to the transition vector. The intrinsic reaction coordinate (IRC) was computed in both directions from each saddle point to confirm each as being the expected TS; energy minimisations from a point along each IRC path yielded structures for the reactant,

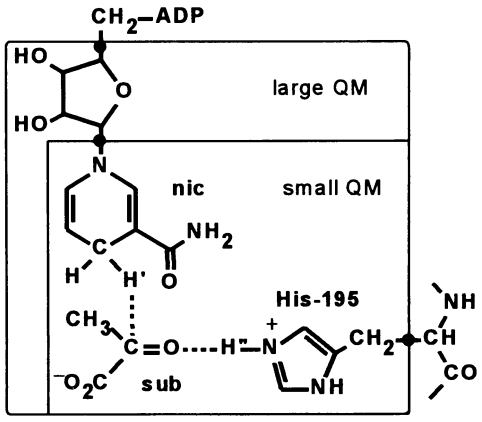

Fig. 2 Large and small QM regions in QM/MM models for LDH; link atoms are indicated as '●'.

intermediate, and product. Table 1 contains optimised bond lengths for the HT and PT components of LDH catalysed pyruvate reduction and energies for minima and TSs.

The second important result of this study is that we find reaction paths and TSs for *both* the stepwise HT,PT and the concerted PT/HT mechanisms for both the present large-QM/full-MM model and (results not shown here) small-QM/truncated-MM and small-QM/full-MM models. There is no fundamental disagreement between the MTW and RG results: the apparent discrepancy arose simply because different parts of the hypersurface had been explored in each of the earlier studies. Subtle but significant differences in many coordinates other than just HT and PT dictate whether a particular geometry for the QM region lies within that part of the overall hypersurface belonging to the HT,PT mechanism or else in that different part corresponding to the PT/HT mechanism. It is as if the hypersurface contains a watershed separating two distinct drainage basins: depending upon how a gentle breeze may gust at the crucial moment, a raindrop falling on the Andes watershed may flow to either the Atlantic or the Pacific. So it is with geometry optimisation in a very large and flexible system: two computational runs may start at very similar structures in the core region but be subtly influenced by small differences in their environments to follow separate courses to very different final structures. However, owing to the particular bias provided by the environment, optimisations initiated within the same basin may all tend to converge to the same mechanistic result, despite scanning of the key parameters within the core over adequate ranges of values. A difference in some detail of the QM/MM treatment may of itself generate only a trivial difference in energy for an initial structure but, as a consequence of small differences in the gradient and second derivatives, may cause an optimisation (or TS search) to proceed towards a significantly different stationary point.

The obvious question is which mechanism is preferred: HT,PT or PT/HT? Unfortunately, and perhaps surprisingly, there is no easy answer.[14] The order of the total energies ($E_{QM} + E_{QM/MM} + E_{MM}$) for the three TSs is $\ddagger_{HT} > \ddagger_C > \ddagger_{PT}$. This would suggest that the concerted PT/HT mechanism is preferred over the stepwise HT,PT mechanism, for which HT is the rate-determining step. If, however, only the energy of the QM core within the electrostatic environment of the MM atoms is considered ($E_{QM} + E_{QM/MM}$), then for both models the order of energies of the three TSs is $\ddagger_C > \ddagger_{HT} > \ddagger_{PT}$, favouring the HT,PT mechanism. If no MM atoms are allowed to move in the TS search, then $E_{MM} = 0$ and $E_{total} = E_{QM} + E_{QM/MM}$. However, as flexibility in the MM region is introduced, and the number of atoms contributing to E_{MM} is increased from zero to several thousand, it seems that the mechanistic preference changes. We are unable yet to make a definitive statement as to which mechanism is preferred, but are currently performing *ab initio* QM/MM calculations for this system with a view to obtaining more reliable energetics. We would also like to be able to describe the specific physical interactions within the MM region that favour each of the two mechanisms. Visual inspection of the two structures reveals no obvious significant differences, and as yet the origin of the change in E_{MM} responsible for the mechanistic shift eludes characterisation; we hope to report upon this important point in a full paper. It should be noted that, even for our smallest model, there are several thousand degrees of freedom in the MM region and the critical energetic difference is likely to be the sum of a large number of very small contributions.

Finally, our refined stationary points are not unique. The multiple minima issue has its counterpart for TSs: there exist multiple local saddle points differing in the conformation of the environment. Accurate determination of transition state properties will require statistical averaging over many configurations, each one individually being a transition structure.[1b] Free-energy calculations must not only sample representative configurations along an assumed *in vacuo* reaction path but also must consider the possibility of alternative mechanistic pathways.

We are grateful to the British Council/Acciones Integradas for a collaborative award and HEFCE/EPSRC JREI and Universitat Jaume I for provision of computer time.

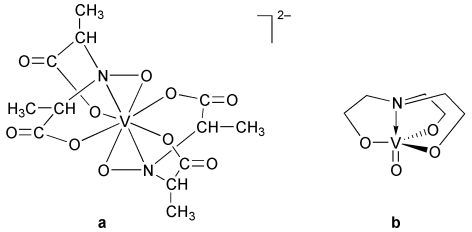
Received (in Cambridge, UK) 10th July 2000, Accepted 31st July 2000
First published as an Advance Article on the web 14th September 2000

Synthetic amavadine models, $[V(HIDPA)_2]^{2-}$ and $[V(HIDA)_2]^{2-}$ [where HIDPA and HIDA stand for the basic forms of 2,2′-(hydroxyimino)dipropionic and 2,2′-(hydroxyimino)diacetic acid, respectively], exhibit haloperoxidase- or peroxidase-type activities, and act as catalysts for the selective peroxidative monohalogenation, hydroxylation or oxo-functionalization of alkanes or aromatic compounds such as benzene and mesitylene at room temperature.

The roles of vanadium in biology have been the object of current and growing interest[1] from both biological and chemical perspectives. In particular, the biological role of amavadine, the natural bare octacoordinated vanadium(IV) complex $[V(HIDPA)_2]^{2-}$, [$HIDPA^{3-}$ = basic form of (*S*,*S*)-2,2′-(hydroxyimino)dipropionic acid][2] present in some *Amanita* fungi, is still an intriguing matter, although circumstantial evidence has started to emerge suggesting[3] that it can act either as a peroxidase which catalyses the oxidation of particular thiols to disulfide products, or as a catalase by promoting the decomposition of H_2O_2. Vanadium(V) haloperoxidases which have been found mainly in some brown and red marine algae have also raised much interest and their structures and functions have been investigated,[1] inorganic biomimetic reagents proposed and other vanadium complexes applied[4–6] to the peroxidative oxidation of alkenes and aromatic hydrocarbons. However, alkanes have been much less studied[6b,c,7] and only very rarely has a catalytic activity of vanadium been recognized for such reactions.

We now report that saturated (*e.g.* cyclohexane or cyclooctane) and aromatic (benzene or mesitylene) hydrocarbons can be oxidized catalytically, at room temperature, by a system composed of synthetic amavadine models and H_2O_2 in acidic medium, to give halo-, hydroxo- or oxo-functionalized compounds, thus suggesting a potential wider biological role for naturally occurring amavadine than that considered so far and demonstrating the capacity of a biogenic vanadium complex, much simpler than an enzyme, to catalyse, in mild conditions, the functionalization of alkanes, a challenging problem[8] in modern chemistry. Moreover, this complex constitutes, to our knowledge, the first reported vanadium catalyst for the peroxidative halogenation of alkanes.

In effect, we have observed that $Ca[V(HIDPA)_2]$ (the Ca^{2+} salt of synthetic amavadine) **a** or its model $Ca[V(HIDA)_2]$



a **b**

[HIDA = basic form of 2,2′-(hydroxyimino)diacetic acid], in a two-phase water–NCMe system also containing H_2O_2, KBr and HNO_3 (in high excess relative to the vanadium compound), catalyse at room temperature the peroxidative bromination of saturated and aromatic hydrocarbons, as shown in Tables 1 and 2 for typical experiments with cyclohexane and benzene to give bromocyclohexane and bromobenzene, respectively, according to the overall reaction (1). Catalytic chlorination (using KCl instead of KBr) also occurred for benzene and, in all the cases, only the mono-halogenated products were selectively obtained.

$$RH + Br^- + H_2O_2 + H^+ \xrightarrow{\text{Amavadine}} RBr + 2H_2O \quad (1)$$

The activity of the system increases with the amounts of H_2O_2 and of the acid, but beyond a limit (*e.g. ca.* 150 molar ratio for H_2O_2, relatively to vanadium, for the case of the bromination of cyclohexane) no further increase is observed and the activity can even decrease. Values of the turnover number (TON) are given in Tables 1 and 2 for typical essays (6 h reaction time) and indicate that both vanadium complexes have a comparable

[a] See footnotes to Table 1.

activity. Hence, *e.g.* TON *ca.* 10–15 for the molar ratios H_2O_2:V = 175 and HNO_3:V = 3610.

No activity was found for the free (hydroxyimino)dicarboxylic acids H_3·HIDPA or H_3·HIDA and the active species has the metal in the 5+ oxidation state (the starting blue V^{IV} complexes are oxidized by H_2O_2 to the corresponding red V^V forms, as observed by the immediate colour change of the reaction solution on addition of the peroxide). The presence of vanadium in the 5+ oxidation state has also been demonstrated in the vanadium-dependent bromoperoxidases and the formation of peroxo–vanadium complexes as active intermediate species has been proposed.[1a,b] In our system, the hydroxyimine(1−) groups, η^2-(O–N<), of the $HIDPA^{3-}$ or $HIDA^{3-}$ ligands that bind to the metal are isoelectronic with peroxide(2−) and therefore the oxidized complexes relate to bis(peroxo)-vanadium(V) species. Nevertheless, the presence of H_2O_2 is required for the detection of activity and the vanadium-promoted Br^- oxidation by H_2O_2 (to HOBr or a derivative thereof) occurs in the aqueous phase and the halogenation of the organic substrate in the organic phase (NCMe). The vanadium complexes are soluble in both solvents and the peroxidative halogenation occurs smoothly even without addition of a phase-transfer agent.

Apart from behaving as catalysts for the halo-functionalization of alkanes and aromatics, as shown above, synthetic amavadine and its model can also catalyse, at room temperature, the hydroxylation (reactions 2) and/or oxo-functionalization of these types of substrates. The reactions occur in homogeneous conditions (single-phase system), by treatment of an acetonitrile solution of the vanadium complex, in the presence of H_2O_2 and HNO_3, with the substrate (Tables 1 and 2).

$$RH + H_2O_2 \xrightarrow{\text{Amavadine}} ROH + H_2O \qquad (2)$$

The system does not require so high an acidic medium as for bromination, and the activity towards oxygenation of cyclohexane to cyclohexanol and cyclohexanone, which is already detected without added acid (overall TON = 4, 6 h reaction time), reaches a maximum (overall TON *ca.* 50 in the $[V(HIDA)_2]^{2-}$ system) for an acid:vanadium molar ratio of *ca.* 140 (for H_2O_2:V = 440). The alcohol is always the main product, but the ketone also forms. The selectivity is dependent on the experimental conditions, in particular the amounts of H_2O_2 and HNO_3, and *e.g.* for the above conditions, the obtained cyclohexanol/cyclohexanone molar ratio is 5.3, whereas a value of 9.2 is reached for HNO_3:V = 72 (also for H_2O_2:V = 440).

The selective oxidation to the alcohol, although less extensive, occurs for benzene (that forms exclusively phenol, TON = 16 or 6 for the corresponding $[V(HIDA)_2]^{2-}$ or $[V(HIDPA)_2]^{2-}$ systems), whereas mesitylene (1,3,5-trimethylbenzene) is oxidized to the aldehyde (3,5-dimethylbenzaldehyde) (TON = 13 or 7, respectively) rather than to the alcohol.

Attempts to characterize active intermediate vanadium species are under way, as well as the extension of the work to other substrates and to other amavadine models and related complexes. In particular, we have also observed catalytic activity towards the above reactions for various vanadium(V) complexes with other polydentate ligands with N,3O-donor atom sets such as triethanolaminate, *e.g.* $[VO\{N(CH_2CH_2O)_3\}]$ **b** (see Tables 1 and 2), aminocarboxylates, *etc.*

To the best of our knowledge, this study provides the first examples of vanadium catalysts for the peroxidative halogenation of alkanes, at room temperature. It might be expected that natural amavadine showed similar properties, *i.e.* the possibility to act as a haloperoxidase or a peroxidase, catalysing the peroxidative halogenation, hydroxylation and/or oxygenation of organic substrates, but we note that, since for the halogenation reactions the pH was very low, the results cannot be directly extrapolated to biological conditions. Curiously, the vanadium-dependent haloperoxidases, which probably developed later, since vanadium is in the oxidation state 5+, catalyse halogenation reactions at pH 5–6 to give products that appear to have defensive roles. On the basis of electrochemical studies[3] we have suggested that amavadine, which, as stated, is a simple complex, not an enzyme, may act as a kind of primitive peroxidase (towards thiols) or as a catalase (if substrates other than H_2O_2 are not present), behaving also as a protective agent against external microbial pathogens or host body damage. Halogenation of alkanes and aromatics which, as shown in this work, occur in the laboratory at room temperature but very low pH for the particular substrates studied, is unlikely to occur *in vivo* with the substrates studied but may eventually be viable in less extreme (even physiological) pH conditions for other more favourable substrates.

This work has been partially supported by the Fundação para a Ciência e a Tecnologia and the PRAXIS XXI programme, Portugal.

Received (in Columbia, MI, USA) 7th December 1999, Accepted 14th August 2000
First published as an Advance Article on the web 13th September 2000

Ultrathin films of an electrostatically-modified biotinylated polythiophene have shown interesting electrochemical properties which lead to the detection of femtomoles of the protein avidin in aqueous electrolytes.

Conjugated polymers (polyanilines, polythiophenes, polypyrroles, poly(phenylene vinylene)s, polyfluorenes, *etc.*) and related oligomers have become an important class of organic materials due to their unusual electrical and optical properties which lend themselves to the development of various devices in the areas of micro-electronics, electro-optics, photonics, sensors, genomics, *etc.*[1–7] In this respect, functionalized polythiophenes have been the subject of many investigations since some of them combine good processability and environmental stability with an ability to detect, transduce, and amplify various physical or chemical information into an electrical or optical signal.[5–7] These novel organic materials may serve in integrated sensory devices where the optical or electrical signal will not require any external tagging procedures but would come directly from the responsive polymeric supports. In order to achieve these goals, simple, specific, highly sensitive, and miniaturized polymeric devices must also be developed.

Along these lines, we have recently reported the easy preparation of electroactive thin films of functionalized polythiophenes through electrostatic interactions.[8] The deposition of ultrathin films (even monolayers) could be very important for solid-state biosensors since it is believed that the interaction between large biochemical molecules and the binding sites present within the electroactive materials will mainly occur at the interface. In the present study, we have electrochemically characterized the stability and the sensitivity of such simple polymeric assemblies for the future development of microarrays of polymeric sensors.

Following previously reported procedures,[8] ultrathin films of 50% pre-neutralized poly(2-(4-methyl-3-thienyloxy)ethanesulfonic acid) (PMTOES) have been easily transfered onto aminosilane-treated ITO electrodes.† Depending upon the nature of the side chains, various functionalized polythiophenes can be obtained but in the course of the present study, only biotinylated polythiophenes will be analyzed (see Fig. 1). As shown in Fig. 2, these electroactive ultrathin films have been characterized in an aqueous electrolyte (pH = 6–7) and have revealed a clear and reversible redox (related to a doping/undoping electrochemical process) process around 0.4 V *vs.* SCE. This quasi-reversible redox process occurs at a much lower potential than that previously reported in an organic electrolyte.[8] This could be related to the hydrophilic nature of the polymeric salt which allows very efficient wetting of the polymer in aqueous solutions. The good electrochemical activity of this polythiophene derivative in water opens the door to electrochemical detection in real biological systems. Various sizes (1 to 100 mm^2) of electrodes have been analyzed and a good correlation has been obtained between the surface of the electrode and the integrated charge exchanged during the redox process. On average the oxidative charge obtained by integration of the 0.44 V peak is 0.24 μC mm^{-2}. The number of electrons exchanged per repeat unit is difficult to assess but, on the basis of previous studies on electroactive polythiophenes,[9,10] it is reasonable to assume an exchange of one electron per three repeat units (*i.e.* a doping level of 33%). This rough estimate corresponds to a molecular density of 22 Å^2 per repeat unit. This value is in good agreement with recent results (21–23 Å^2) obtained with self-assembled polythiophene monolayers.[11]

The electrochemical responses of these biotinylated electrodes have been investigated upon addition of the protein avidin. This protein is built from four identical subunits (for a total M.W. = 68 000) and has a strong affinity for biotin.[12] This strong affinity between avidin and biotin is related to an exceptionally high binding constant of 10^{15} M^{-1}, which

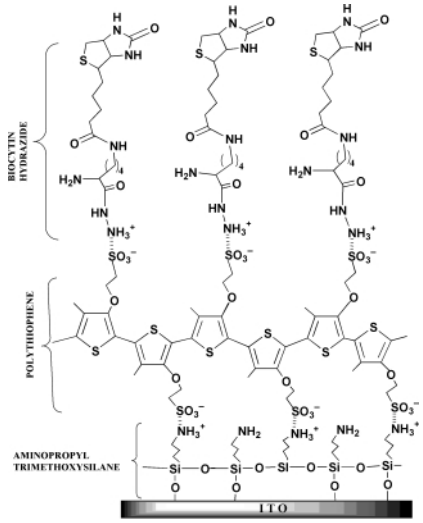

Fig. 1 Schematic and idealistic description of a biotinylated polythiophene electrode.

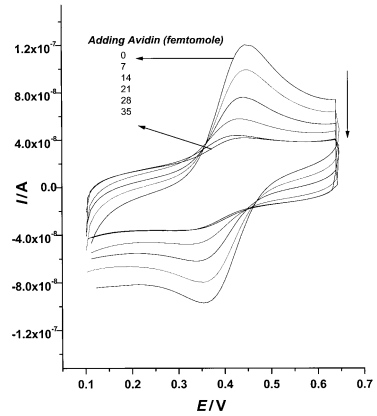

Fig. 2 Cyclic voltammogram of a 1 mm^2 biotinalyted polythiophene electrode in a 0.1 M KCl aqueous solution upon addition of aliquots of avidin, at room temperature. Scan rate of 20 mV s^{-1} *vs.* SCE.

DOI: 10.1039/a909744i

corresponds to a binding energy of 20 kcal mol^{-1}. For these reasons, the biotin/avidin couple has been extensively used in different types of biosensors[8,12–19] and is utilized here as a model compound for the future design of various types of sensors based on functionalized polythiophenes.

Interestingly a 1 mm^2 biotin-functionalized polythiophene electrode shows a clear modification of its cyclic voltammogram‡ (a decrease of the electrochemical activity) upon addition of as low as 7×10^{-15} mole of avidin in the aqueous electrolyte (Fig. 2 and 3). Saturation is almost obtained at 3.5×10^{-14} mole of avidin. Modified electrodes of area 1 cm^2 have shown similar electrochemical effects upon addition of aliquots of avidin but at concentrations multiplied by a factor of 100 (which corresponds to their surface ratio). A similar decrease of the electrochemical activity has been observed in nucleobase-functionalized polythiophenes[20] and could be explained by a decrease of the interfacial electron-transfer rates between the polymer and the electrode, due to the binding of the protein.[21] In other words, the bound avidin may shield the electroactive polymer and therefore affect the electronic exchanges between the electrode, the polymer and the electrolyte. First experiments on similar biotinylated electrodes in acetonitrile have revealed an increase of the redox potential[8] which had been explained by a twisting of the backbone upon complexation, but this mechanism does not seem to be dominant in aqueous electrolytes. Another explanation could be a release of the polymer from the electrode upon avidin binding. A similar mechanism was recently proposed for fluorescent conjugated polyelectrolytes.[22] It is clear that covalently-attached polythiophene derivatives would shed some light on the mechanism involved in the detection and these new polythiophene derivatives are currently being developed in our laboratory. It is also interesting to note that polythiophene-modified electrodes without biotin moieties (50% pre-neutralization of the sulfonic acid polymer with sodium hydroxide) do not show any significant modification of their electrochemical properties. These results also give clear evidence of the electrochemical and mechanical stability of such polymeric electrodes. Indeed, although these polythiophene derivatives are soluble in water, it seems that the multiple electrostatic interactions along the backbone are strong enough to avoid any significant release of the ultrathin polymeric film when immersed in aqueous electrolytes, the electrochemical activity being reproducible even after hours of immersion in the electrolyte.

From Fig. 3, it is also possible to assume that about 24% of the thiophene units are affected by the presence of 7×10^{-15} mole of avidin and that could mean that one avidin molecule affects about 250 repeat units. This amplification factor is similar to that calculated from biochromic measurements.[8] It is believed that the present amplification factor is more or less related to the difference in size between the protein avidin and one repeat thiophene unit. Indeed, as mentioned above, it is possible to determine that one thiophene unit occupies a surface of 22 $Å^2$, and from this amplification factor of 250 that could indicate that avidin occupies a surface of roughly 55 nm^2. These dimensions are in the same range as those determined by X-ray analyses for a parent protein (streptavidin, M.W. = 60 000 with dimensions of $4.5 \times 4.5 \times 5.8$ nm).[13]

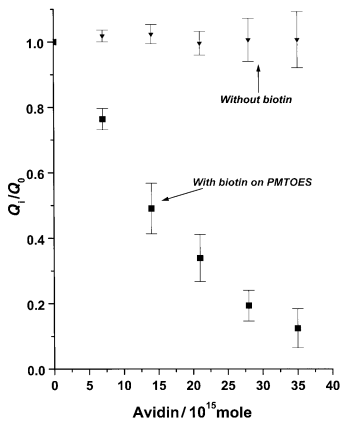

Fig. 3 Relative electroactivity (integrated charge exchanged during the oxidative 0.44 V peak) upon addition of avidin for a monolayer made of a 0.5:1 complex between sodium hydroxide and poly(2-(4-methyl-3-thienyloxy)ethanesulfonic acid) (▼) and a monolayer made of a 0.5:1 complex between biocytin hydrazide and poly(2-(4-methyl-3-thienyloxy)ethanesulfonic acid) (■).

In conclusion, this simple methodology, based on non-covalent interactions between water-soluble amine-bearing molecules and partially neutralized poly(2-(4-methyl-3-thienyloxy)ethanesulfonic acid), has allowed the efficient preparation of stable, highly sensitive, functionalized polythiophene electrodes and constitutes a promising platform for the future development of novel electrochemical biosensor arrays.

Notes and references

† Poly(2-(4-methyl-3-thienyloxy)ethanesulfonic acid) (PMTOES) was prepared following procedures described in previous publications.[8,23] 3-Aminopropyltrimethoxysilane (Aldrich), biocytin hydrazide and avidin (Pierce) were used as received. Amino-functionalized silanized ITO electrodes were prepared following well established procedures.[8,24,25] The electrostatic transfer of 50% pre-neutralized (performed with biocytin hydrazide or sodium hydroxide) poly(2-(4-methyl-3-thienyloxy)ethanesulfonic acid) was carried out by dipping the glass slides into 0.01–0.001 M aqueous solutions of the resulting polymer.

‡ Cyclic voltammograms were obtained with a Solartron 1287 potentiostat/galvanostat driven by Corrview software. The integrated charges during redox processes have been digitally calculated using this software. Satured calomel electrode (SCE) and a platinum plate were used as reference and auxiliary electrodes, respectively. Electrochemical measurements were performed at 20 mV s^{-1} in a 0.1 M KCl aqueous solution. All cyclic voltammograms shown in the present figures are the third ones in a series of three electrochemical cycles. Addition of aliquots of aqueous solutions of avidin were carried out directly in the electrolyte near the biotinylated electrodes. All reported electrochemical data are the averaged responses of five different electrodes.

Intramolecular carbometalation of functionalized terminal alkynes *via* low-valent titanium complexes

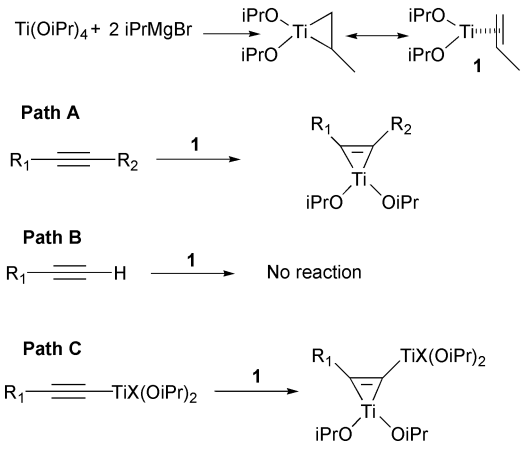
Natalia Morlender-Vais, Nicka Solodovnikova and Ilan Marek*

Department of Chemistry and Institute of Catalysis Science and Technology, Technion-Israel Institute of Technology, Technion City, Haifa 32 000 Israel. E-mail: chilanm@tx.technion.ac.il

Received (in Cambridge, UK) 20th June 2000, Accepted 20th July 2000
First published as an Advance Article on the web 14th September 2000

Treatment of δ- and γ-functionalized monosubstituted alkynes with diisopropoxy(η²-propene)titanium induces an intramolecular cyclisation to afford the 4- and 5-membered cycloalkanols in good overall yields.

Various disubstituted alkynes react with diisopropoxy(η²-propene)titanium **1**, readily generated by the reaction of $Ti(OiPr)_4$ with 2 eq. of iPrMgX (Sato's reagent), to give the corresponding titanacyclopropene derivatives as described in Scheme 1, path A.[1] However, as terminal alkynes failed to participate in the present reaction[1] (path B *vs.* path A), we have recently used the fact that a metalated alkyne can behave like a disubstituted alkyne to prepare the first titano–titanacyclopropene in good overall yield (Scheme 1, path C).[2]



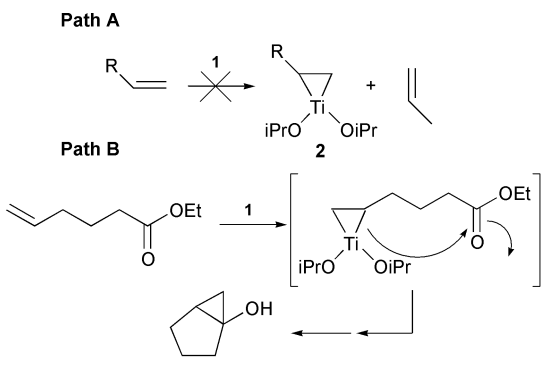
Scheme 1

On the other hand, when **1** is opposed to an *unactivated* olefin, the ligand exchange is not efficient and therefore the desired olefin–titanium complex **2** is not formed (Scheme 2, path A). Only activated olefins undergo this exchange as styrene,[3] conjugated dienes,[4] vinyl silane[5] or stannane.[6] However, the presence of an electrophile in the carbon skeleton (Scheme 2, path B) promotes this reaction since an intramolecular nucleophilic acyl substitution[7] reaction occurs in a second step to give the cyclopropanolate derivative[8] (known as the Kulinkovitch reaction).[9]

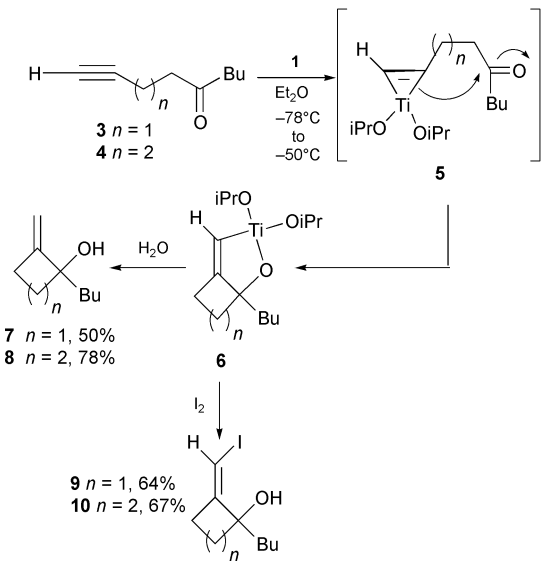
As part of our studies on the use of early transition metal complexes such as **1** for the carbometalation of unactivated alkynes,[10] we anticipated by analogy with the results described in Scheme 2 that the facile intramolecular nucleophilic acyl substitution reaction of a functionalized *terminal* alkyne (known to be totally unreactive,[1,11] Scheme 1, path B) might act as a driving force for shifting the equilibrium.[7] In this case, a transient monosubstituted titanacyclopropene will be formed as intermediate before the carbocyclisation reaction. Indeed, treatment of dec-9-yn-5-one **4** (n = 2) with a stoichiometric amount of $Ti(OiPr)_4$ and 2 eq. of iPrMgX at −78 °C leads to the cyclic product **8**, after hydrolysis, in 78% isolated yield (Scheme 3).

In order to probe the existence of a remaining carbon–titanium bond in the molecule, iodine was added at the end of the reaction. The vinyl iodide **10** (n = 2) was isolated in 67% yield as single isomer (the stereochemistry was determined by NOE). Interestingly, this reaction can be applied to the formation of more strained carbocycles such as 4-membered ring derivatives in a very easy and straightforward manner (**3**, n = 1, Scheme 3). Here again, the non-isolated terminal titanacyclopropene **5** (n = 1) reacts intramolecularly with the ketone to give the organometallic derivative **6** (n = 1). Hydrolysis of the reaction mixture leads to the *exo*-methylenecyclobutanol **7** in 50% isolated yield whereas the iodinolysis gives only the *Z*-isomer of the vinyl iodide **9** in good chemical yield.[12]

Although the reaction mechanism described in Scheme 3 seems plausible, we have not been able to isolate even in very small amounts the transient titanacyclopropene derivative **5**. So, we have also considered an alternative mechanistic pathway for the formation of **6**. Indeed, it is known that early transition metal



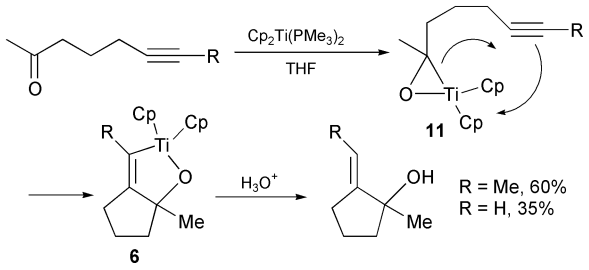
Scheme 2



Scheme 3

DOI: 10.1039/b005027j

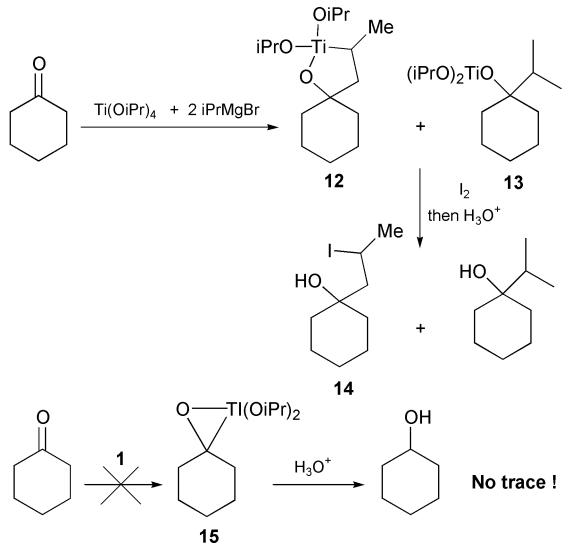
complexes can form some η^2-ketone complexes, **11**, (metalla-oxiranes)[13] which can further insert into an alkyne moiety to give the same oxatitanacyclopentene derivatives **6**. This mechanism was already reported for the reaction of δ-ynones with $[(C_5H_5)_2Ti(PMe_3)_2]$ to form 3-bis(cyclopentadienyl)-2-oxa-3-titanabicyclo[3.3.0]oct-4-ene in good overall yield.[14] Although the intramolecular addition to a substituted alkyne to form the unsaturated oxatitanacycle worked well, here again the reaction on a terminal alkyne gives a low isolated yield (35%) of the cyclic product after hydrolysis, as described in Scheme 4.



Scheme 4

So, in order to check if the first step of the reaction of **1** with **3** or **4** was a reaction at the alkynyl (Scheme 3) or at the carbonyl centers (Scheme 4), we decided to investigate the behavior of **1** with cyclohexanone as described in Scheme 5.

Treatment of 1 eq. of $Ti(OiPr)_4$ with 2 eq. of iPrMgX in the presence of 1 eq. of cyclohexanone leads to two products, **12** and **13**, in a respectively 5 to 1 ratio and in quantitative yields. The major product **12** results from the reaction of diisopropoxy(η^2-propene)titanium **1** with the carbonyl moiety which can further react with iodine to give **14** whereas **13** is formed from the direct attack of the Grignard reagent on the cyclohexanone.[15] No trace of cyclohexanol was detected after hydrolysis in the crude reaction mixture which clearly indicates that the reaction does not proceed through the oxametallacycle



Scheme 5

15. Thus, although **5** cannot be isolated, it is present as the first intermediate in the reaction before the nucleophilic attack on the carbonyl moiety occurs as described originally in Scheme 3.

In conclusion, the synthesis of *exo*-methylene-cyclopentane and -cyclobutane has been achieved in a one-pot sequence from readily available starting material with diisopropoxy(η^2-propene)titanium. The mechanism of this reaction has been investigated and is composed by a carbometalation reaction of the monosubstituted-unactivated alkyne followed by intramolecular nucleophilic acyl substitution.

Enantioselective conjugate addition of thiols to enones and enals catalyzed by chiral *N*-oxide–cadmium complex

Makoto Saito, Makoto Nakajima* and Shunichi Hashimoto

Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060-0812, Japan.

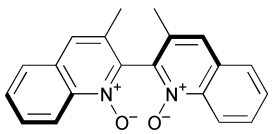
Received (in Cambridge, UK) 28h July 2000, Accepted 14th August 2000
First published as an Advance Article on the web 14th September 2000

A novel method of enantioselective conjugate addition of thiols to enones and enals produces sulfides with enantioselectivities up to 78% ee, employing a cadmium complex of (*S*)-3,3′-dimethyl-2,2′-biquinoline *N*,*N*′-dioxide 1 as a catalyst.

The development of enantioselective reactions requires the design of chiral ligands. Many recent studies have focused on the development of novel chiral ligands for use in metal-catalyzed reactions. Although *N*-oxide is a functional group possessing a unique electron-donating property, allowing it to form complexes with a variety of metals,[1] few attempts have been made to employ *N*-oxides as chiral ligands.[2,3] We recently reported an enantioselective allylation of aldehydes with allyltrichlorosilanes utilizing a chiral *N*,*N*′-dioxide **1** as a



1

catalyst, exploiting the electron-donating property of the *N*-oxide.[3c] Here, we describe an enantioselective conjugate addition of thiols to enones and enals catalyzed by a chiral *N*-oxide–cadmium complex.

Several chiral amine-catalyzed reactions have received considerable attention[4] since the first report on the enantioselective conjugate addition of thiols catalyzed by cinchona alkaloid.[4a] Due to their high efficacy, catalysis of enantioselective conjugate addition by lithium thiolate complexes of amino bisether,[5] heterobimetallic complexes,[6] and nickel oxazoline complexes[7] are of particular interest.

Recently, we described the optical resolution of **1** through the hydrogen-bonding of **1** and optically active binaphthol.[3a] We then hypothesized that thiophenol forms a hydrogen-bonding complex with **1**, controlling the nucleophilicity and steric accessibility of thiophenol to electron-deficient olefins in its enantioselective conjugate addition. We initially tested this hypothesis using 10 mol% of **1** as a catalyst in the conjugate addition of thiophenol to cyclohex-2-en-1-one in DCM. The reaction produced a significant yield of the corresponding sulfide, although the enantioselectivity was quite low (35%, 12% ee).

To enhance the reactivity and enantioselectivity, we used 10 mol% metal salt as an additive expected to coordinate with carbonyl oxygen. Among the various metal salts surveyed, addition of CdI_2 yielded the corresponding sulfide in high chemical quantity with moderate enantioselectivity (93%, 57% ee). Enantioselectivity increased up to 78% when the reaction was performed in toluene, whereas polar solvents decreased enantioselectivity substantially (THF: 99%, 0% ee; acetonitrile: 97%, 33% ee). Stoichiometric studies revealed that equimolar amounts of **1** and CdI_2 are sufficient for optimum enantioselectivity. The reaction was promoted by CdI_2 in the absence of *N*-oxide to produce the sulfide in 96% yield. These results suggest that a 1:1 complex of **1** and CdI_2[8] functions catalytically in this enantioselective addition. This is the first example of an enantioselective reaction utilizing a cadmium compound,[9] exhibiting a distinctive binding to *N*-oxide.

Table 1 summarizes the conjugate addition of various thiols to cyclic enones under optimized conditions.† Slight modifications of the substrate strongly influenced enantioselectivity. Cyclohept-2-en-1-one (entry 2) gave an enantioselectivity comparable to that of cyclohex-2-en-1-one (entry 3), while cyclopent-2-en-1-one (entry 1) demonstrated low selectivity. It is surprising that the reaction of 4-methylthiophenol (entry 5) gave low selectivity compared to that of thiophenol (entry 3).

Although acyclic conjugate ketones were unsuccessful (chalcone: 30%, 10% ee), the reaction of acyclic conjugate aldehydes gives the corresponding sulfides in high chemical yields with enantioselectivities up to 70% ee after conversion to the corresponding alcohol (Table 2). The mildness of the reaction conditions allows the enantioselective conjugate addition of thiols to enals, a reaction never previously reported due to the lability of aldehydes.

To determine the reaction mechanism, we investigated several additives to the reaction of cyclohex-2-en-1-one and thiophenol in toluene. Addition of cyclohexanone (1.0 eq.) influenced neither chemical yield nor enantioselectivity (92%, 74% ee) of the reaction. The addition of cyclohexene (1.0 eq.), however, dramatically reduced enantioselectivity (92%, 45% ee). These results suggest the importance of the coordination of the cadmium complex to the carbon–carbon double bond, though the detail is not clear.

We have demonstrated the effectiveness of a chiral *N*-oxide–cadmium iodide complex as a catalyst for enantioselective conjugate addition of thiols to cyclic enones and enals. The present reaction provides the first example of utilizing a cadmium complex in an enantioselective reaction. Mechanistic studies and the design of chiral *N*-oxides, currently in progress, will further enhance enantioselectivity.

Notes and references

† The conjugate addition of thiol to enone was performed as follows: Thiophenol (220 mg, 2.0 mmol) in toluene (1 mL) was added to a stirred solution of cyclohex-2-en-1-one (96 mg, 1.0 mmol), *N*-oxide **1** (3.2 mg, 10 μmol) and CdI_2 (3.6 mg, 10 μmol) in toluene (7 mL) and stirred for 6 h at rt. The reaction mixture was diluted in toluene and successively washed with aq. NaOH and brine. The solvent was evaporated and the residue was chromatographed on a silica gel column (eluent, toluene–AcOEt, 100 : 1) to afford 3-phenylthiocyclohexanone (198 mg, 96%) as an oil. *N*-Oxide **1** was recovered by elution with 10% EtOH in DCM without a loss of optical purity. The ee of the product was determined by chiral HPLC (Daicel Chiralpak AD, hexane–Pr^{i}OH, 9 : 1, 1.0 mL min^{-1}, t_R (*S*), 8.5 min; (*R*), 10.0 min).

Polypyrazolylborate copper(I) complexes as catalysts of the homogeneous and heterogeneous styrene epoxidation reaction

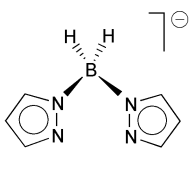
M. Mar Díaz-Requejo, Tomás R. Belderraín and Pedro J. Pérez*

Departamento de Química y Ciencia de Materiales, Universidad de Huelva Carretera de Palos de la Frontera, s/n, E-21819-Huelva, Spain. E-mail: perez@uhu.es

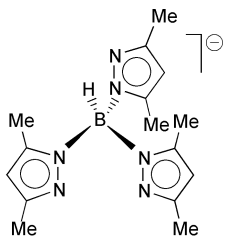
Received (in Liverpool, UK) 12th June 2000, Accepted 8th August 2000
First published as an Advance Article on the web 13th September 2000

The complexes BpCu (1) and Tp*Cu (2) catalyse the transformation of styrene into styrene oxide using Oxone as the oxidising agent; the use of silica gel-supported 1 or 2 as heterogeneous catalysts affords similar results, using water as the sole solvent.

Copper complexes have been extensively used as catalysts in metal-induced carbene transfer reactions to olefins to give cyclopropanes.[1] Their use in olefin aziridination reactions has also been frequently reported in the last decade.[1] By contrast, very few chemical systems based on this element are known to promote the oxidation of an olefin into the corresponding epoxide:[2–7] most of them have been developed with cyclic or strained olefins (thus avoiding undesired, side-reactions), and their catalytic capabilities are not as yet comparable to those of well-known catalysts based on manganese–salen or iron–porphyrin complexes.[8] For example, Cu(II) salicylaldehyde derivatives have been reported in the epoxidation of alkenes with molecular oxygen and 2-methylpropanal, the yields being found in the 22–40% range.[3] Murahashi and co-workers have reported the use of copper salts for a similar transformation, but in this case the yields were considerably higher (80–90%).[5] Cu(TPP) and Cu(cyclam)$^{2+}$ have also been used[2] in the epoxidation of cyclohexene with oxygen and aldehydes, with low to moderate yield, although the participation of metal-oxo intermediates in the epoxide formation pathway could not be established. In the last few years, we have focused our attention on the use of polypyrazolylborate[9] copper(I) complexes as catalysts for olefin cyclopropanation and aziridination reactions under homogeneous conditions,[10,11] and we have also developed their immobilization by supporting the catalyst precursors on silica gel, thus achieving the heterogenisation of the homogeneous system.[12] We have now studied the use of the complexes BpCu (**1**) and Tp*Cu (**2**) (Bp = dihydridobispyrazolylborate; Tp* = hydrotris(3,5-dimethylpyrazolyl)borate) as the catalyst precursors in the epoxidation reaction under both



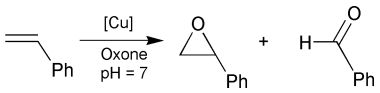
$H_2B(pz)_2$, Bp



$HB(pz^*)_3$, Tp*

homogeneous and heterogeneous conditions, and we have discovered that these Cu(I) complexes also display catalytic activity towards this transformation. Complex **1** was reported by Bruce as a 14-electron compound.[13] Although its solid state structure is unknown, molecular weight studies revealed the existence of discrete BpCu units in solution. Complex **2** was reported by Ibers and co-workers:[14] its solid state structure was determined by X-ray as a dimeric compound $[Tp^*Cu]_2$, but in solution the mononuclear species Tp*Cu prevailed. Thus, both complexes **1** and **2** seem to display monomeric structures when dissolved.

The addition of an aqueous solution of potassium peroxymonosulfate (Oxone = $2KHSO_5{\cdot}KHSO_4{\cdot}K_2SO_4$) neutralised



(1)

with $NaHCO_3$, to an acetonitrile solution containing the styrene and the catalyst precursors BpCu or Tp*Cu led to the conversion of the olefin into a mixture of mainly styrene oxide and benzaldehyde (eqn. 1, Table 1)†. The overall yield, based on oxidant, was nearly 70% for BpCu and 60% for Tp*Cu, of which at least 85–90% corresponded to styrene oxide (60 and 50% respectively, based on oxidant). Other minor products, including benzoic acid, accounted for *ca.* 5%. These conversion rates are clearly an improvement over most of those obtained with the copper-based epoxidation systems known to date.[2–5] In addition, no phase-transfer catalyst has been added to the biphasic reaction mixture, unlike the common procedure employed in related systems.[15]

The formation of benzaldehyde in metal-induced olefin oxidation was reported by Groves *et al.*[16] with an iron–porphyrin complex as catalyst. However, it is worth mentioning that control experiments have also shown the formation of benzaldehyde when reacting styrene oxide and Oxone in the absence of the copper complexes, as well as the oxidation of benzaldehyde to benzoic acid under the same conditions. This is in agreement with recent results from Corma and co-workers with Ti-zeolites as epoxidation catalysts,[17] in which benzoic acid and benzaldehyde were obtained along with the major product, the styrene oxide. Obviously, we have also checked the reaction between the olefin and Oxone in the absence of copper complexes but under otherwise identical reaction conditions: no epoxide nor any other oxidation products were observed.

As mentioned above, we have already reported the immobilization of complexes **1** and **2** in silica gel as well as their use as heterogeneous catalysts for the olefin cyclopropanation reaction.[12] Now, we have found that they also catalyse the styrene oxidation, using Oxone as the oxidant, to give a mixture of styrene oxide, 1-phenylethanediol, benzaldehyde and ben-

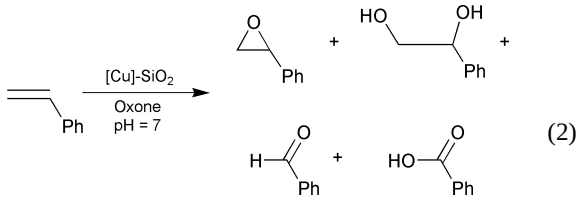
zoic acid, eqn. (2). Water is the sole solvent in this case. Table 2 displays the results of these heterogeneous experiments



(2)

(average of three cycles with the same reused catalyst). The yields, based on oxidant, are similar to those observed in the homogeneous case, although the reaction is faster in the former. The unique difference seems to be the appearance of the epoxide-opening product, the diol. This must be a consequence of the acidic nature of the solid support, the silica gel, since this transformation is usually acid-catalysed.[18] The epoxide and the diol account for 70–85% of the products (Table 2), very close to the 90% value obtained with the soluble catalysts. It is important to point out that the immobilisation of the catalyst does not seem to significantly alter the catalytic capabilities of this system, *i.e.*, it provides an excellent route to accomplish one of the permanent goals in catalysis: to heterogenise an homogeneous system without loss of the activity and/or selectivity of the latter, in order to achieve the well-known advantages of the heterogeneous system.

In conclusion, we have discovered that copper(I) complexes containing polypyrazolylborate ligands present catalytic activity towards the epoxidation reaction, as they did with the olefin cyclopropanation and aziridination reactions. These complexes can operate under both homogeneous and heterogeneous conditions, with no significant differences when moving from the former to the latter, thus achieving the well-known advantages of the recycling and reuse of the catalyst in the heterogeneous system. Moreover, the parallels between the epoxidation and the carbene and nitrene transfer reactions are reinforced since the same metal complexes assure those three catalytic conversions. Mechanistic, comparative studies for the three reactions are currently underway in this laboratory.

We thank the Universidad de Huelva (Plan Propio de Investigación) and the Ministerio de Educación y Ciencia (PB98-0958) for financial support. M. M. D.-R. also thanks the Junta de Andalucía for a research studentship. The Instituto de Investigaciones Químicas (CSIC-La Cartuja, Sevilla) is also thanked for the use of their NMR facilities.

Notes and references

† *Homogeneous catalytic experiment*: 0.05 mmol of the catalyst (**1** or **2**) was dissolved in 10 mL of acetonitrile and styrene (2 mmol) was added. An aqueous solution of Oxone (0.5 mmol, 1 mmol of $KHSO_5$, 10 mL H_2O) with three equiv. of sodium bicarbonate (1.5 mmol) was prepared and added to the catalyst-containing solution. The mixture turned greenish, and was stirred for 18 h. The products were quantified by GC, using acetophenone as an internal standard (added at the end of the reaction, immediately before quantification). The products were identified by NMR from experiments carried out in deuterated solvents, and by comparison with pure samples. The results are shown in Table 1.

Heterogeneous catalytic experiment: the copper complexes were supported as reported in ref. 12. One gram of silica-gel containing BpCu (0.02 mmol) or alternatively Tp*Cu (0.04 mmol) was suspended in 20 mL of H_2O along with 2 mmol of styrene. Neutralised Oxone (prepared as above) was added, and the mixture was stirred for 8 h. The solid was filtered off, and reused twice in an identical manner. Table 2 displays the average results of the three cycles.

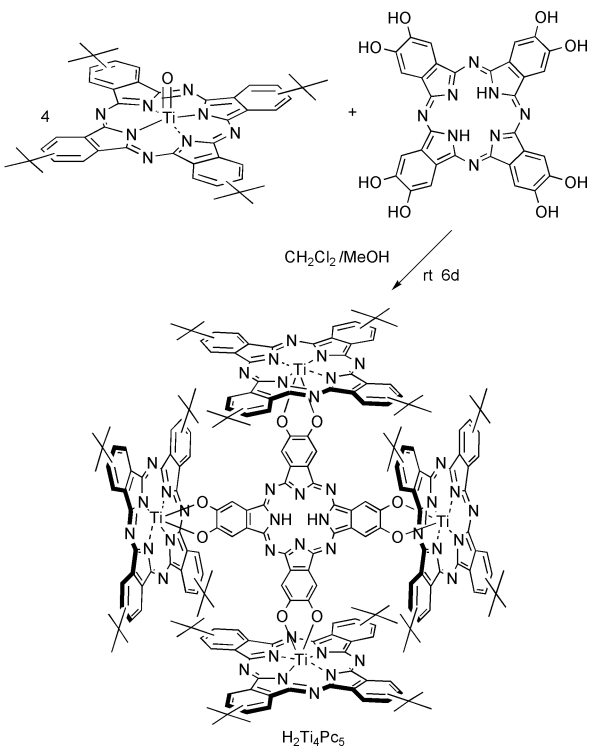
Received (in Cambridge, UK) 26th July 2000, Accepted 14th August 2000
First published as an Advance Article on the web 14th September 2000

A phthalocyanine pentamer consisting of mutually orthogonal Pc units has been prepared by a one-step reaction using oxo(phthalocyaninato)titanium(IV) and 2,3,9,10,16,17,23,24-octahydroxyphthalocyanine and characterized by mass, electronic absorption and magnetic circular dichroism spectroscopy and gel-permeation chromatography.

In contrast with the porphyrins, it is difficult to control steric interactions with the phthalocyanines (Pcs). Accordingly, most reported poly-Pc structures are limited to a few well-known types: one dimensional stacked μ-oxo SiPcs, liquid crystalline Pcs, cofacial rare earth sandwich Pcs, and planar dimers.[1] In addition, controlling the relative orientation of Pc units in Pc multimers is much more difficult than for porphyrins, since Pcs are generally obtained by template reactions and many peripheral substitution patterns are conceivable.[1] In this communication we report the first example of a Pc pentamer, in which four peripheral Pc units are covalently bound, and orthogonal to, a central Pc, **$H_2Ti_4Pc_5$** (Scheme 1).

In synthesizing **$H_2Ti_4Pc_5$**, we utilized the reactivity of the axial oxygen in TiOPc, which is readily displaced by *ortho*-phenolic OH groups, with the elimination of water, to produce two ether linkages.[2] Thus, an excess of tetra-*tert*-butyl TiOPc, obtained by a literature procedure,[3] was reacted with 2,3,9,10,16,17,23,24-octahydroxy H_2Pc[4] in dichloromethane at rt for several days (Scheme 1),[2b] and the mixture was imposed on a gel permeation column (Bio-beads SX-1, Bio-Rad), using the same solvent as eluent. The first green fraction was collected. Although this portion did not give a clear NMR spectrum due to poor solubility, satisfactory elemental analyses were obtained. Time-of-flight mass spectrometry showed *m/z* = 3774, which corresponds to the structure of **$H_2Ti_4Pc_5$** (calcd. for $C_{224}H_{202}N_{40}O_8Ti_4$ = 3773.46), together with cluster of peaks at *ca. m/z* = 2977, 2207, and 1495 (Fig. 1).[5] The difference between each peak corresponds to *ca.* one Pc unit. Since this mass spectrum could also be obtained from a mixture of compounds consisting of two to five Pc units, the elution time of **$H_2Ti_4Pc_5$** in gel-permeation chromatography was compared



Scheme 1

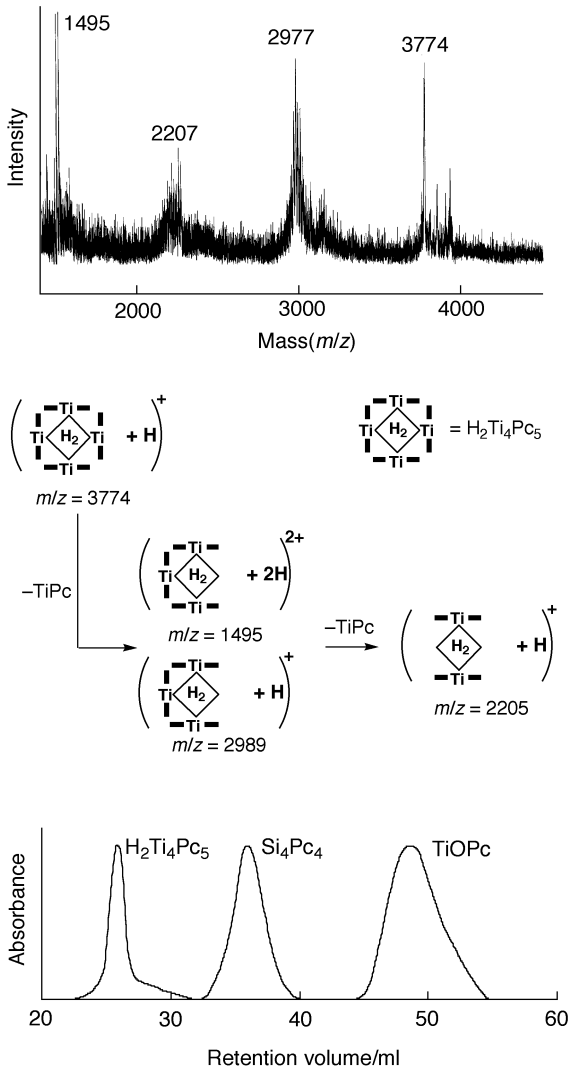


Fig. 1 MALDI-TOF Mass spectrum (top) of **$H_2Ti_4Pc_5$** and its anticipated fragment ions (middle) and gel-permeation chromatograms of **$H_2Ti_4Pc_5$**, Si4Pc4 and TiOPc (bottom). For mass measurements, dithranol (1,8,9-anthracenetriol) was used as a matrix. Chromatograms were obtained separately but superimposed.

DOI: 10.1039/b005969m

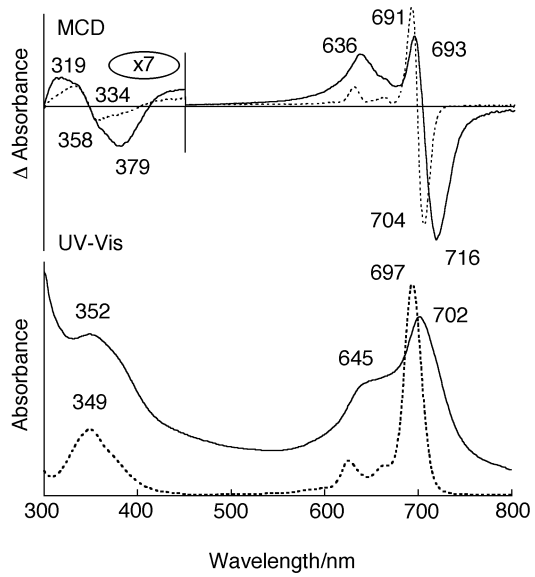

Fig. 2 Electronic absorption (bottom) and MCD (top) spectra of $\mathbf{H_2Ti_4Pc_5}$ (solid lines) and *tert*-butylated TiOPc (dotted lines) in dichloromethane.

with those of tetra-*tert*-butylated TiOPc and μ-oxo tetramer[6] of tetra-*tert*-butylated SiPc (*i.e.* Si_4Pc_4). $\mathbf{H_2Ti_4Pc_5}$ showed a single sharp peak, confirming the presence of a single compound. In addition, the shorter elution time of $\mathbf{H_2Ti_4Pc_5}$ (elution speed in column = 1.59 cm min^{-1}) indicated that $\mathbf{H_2Ti_4Pc_5}$ (Mw = 3773.89) is volumetrically larger than Si_4Pc_4 (Mw = 3142.21) (elution speed in column = 1.14 cm min^{-1}), in agreement with the proposed structure. The mass spectroscopy and gel-permeation chromatography results clearly indicate the formation of a pentamer, corresponding to $\mathbf{H_2Ti_4Pc_5}$. Although we have been unable to obtain crystals suitable for X-ray diffraction, an arrangement in which all Pc units are mutually orthogonal seems most likely, since only the Ti=O functionality can react with hydroxy groups of the octahydroxy H_2Pc to form the pentamer.

Fig. 2 shows electronic absorption and magnetic circular dichroism (MCD) spectra of tetra-*tert*-butylated TiOPc monomer and $\mathbf{H_2Ti_4Pc_5}$. Compared with the spectra of the monomer, those of $\mathbf{H_2Ti_4Pc_5}$ are shifted slightly to the red and broader. Excitonic interactions among mutually orthogonal chromophores are anticipated to be small.[7] However, our calculations[8] on the basis of an excitonic theory[7a] predict Q band transitions for $\mathbf{H_2Ti_4Pc_5}$ at 657, 689, 699 and 707 nm, and thus explain the broad and structureless Q band (the band at 689 nm corresponds to both in-plane and out-of-plane transitions and others are all in-plane transitions).

In conclusion, we have synthesized the first example of a well-defined mutually perpendicular phthalocyanine pentamer.

A one-pot synthesis of *N*-alkylaminobenzenes from nitroaromatics: reduction followed by reductive amination using $B_{10}H_{14}$

Jong Woo Bae, Young Jin Cho, Seung Hwan Lee, Choon-Ock Maing Yoon and Cheol Min Yoon*

Department of Life Science & Biotechnology, Graduate School of Biotechnology, Korea University, Seoul, South Korea. E-mail: cmyoon@tiger.korea.ac.kr; Fax: +82-2-3290-3433

Received (in Corvallis, OR, USA) 27th June 2000, Accepted 27th July 2000
First published as an Advance Article on the web 14th September 2000

_N_-Alkylaminobenzenes were prepared in a simple and efficient one-pot synthesis by reduction of nitrobenzenes followed by reductive amination with decaborane ($B_{10}H_{14}$) in the presence of 10% Pd/C.

Consecutive reactions[1] have received much attention because they give complex molecules efficiently from simple starting materials. In the first step of these reactions, the functional group necessary for the following transformation is formed. An ideal place for such consecutive reactions is in one-pot synthesis, in which all these processes occur consecutively by successive addition of reagents, without isolation of intermediates. Well known examples of one-pot processes are multicomponent condensations[2] and palladium-catalyzed reactions,[3] which are known to be useful owing to mild reaction conditions and stability against other functional groups.

Aromatic amines are important intermediates for dyes and agricultural and pharmaceutical chemicals. One popular method for the preparation of these amines is the reduction of nitroaromatics using various reagents and conditions.[4,5] One of the methods for the synthesis of secondary amines is the reductive amination of primary amines with carbonyls using a variety of reducing reagents.[6]

In the course of our work using decaborane as a mild and stable reducing agent,[7] we found that the reduction of

Table 1 Synthesis of *N*-alkylaminobenzenes

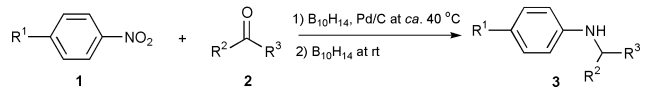
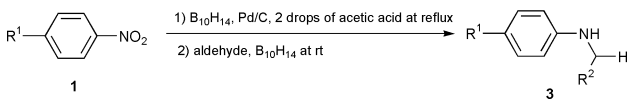


Scheme 1



Scheme 2

nitroaromatics using a decaborane–Pd/C system followed by reductive amination with carbonyls using decaborane gave a one-pot synthesis of *N*-alkylaminoaromatics in high isolated yield. To the best of our knowledge, this is the first example of a one-pot preparation of *N*-alkylaminoaromatics from nitroaromatics.

Decaborane was added in two batches in all of the examples.[8] 30 mol% of decaborane ($B_{10}H_{14}$) was added for the reduction of the nitro group in the first batch, and 20 or 30 mol%[9] was used for reductive amination in the second batch. When a ketone was used for the reductive amination (entries 1–7, Table 1), it was added to the reaction solution at the beginning of the reaction (Scheme 1). The reactions proceeded smoothly at 40 °C without addition of acetic acid. However, when aldehydes were used (entries 8 and 9, Table 1), they were added after the completion[10] of the nitro-group reduction to prevent reductive etherification[11] (Scheme 2). Under these conditions, the reactions were complete in several hours and gave the corresponding secondary amines chemoselectively and in high yields. Other functional groups such as esters (entries 1, 6 and 8), amides (entry 2), nitriles (entry 4) and hydroxy groups (entry 5) were intact under the reaction conditions.†

In conclusion, nitroaromatics were converted into *N*-alkylaminoaromatics in a single-pot synthesis using decaborane as a reducing agent in the presence of Pd/C in methanol. The reaction is efficient and chemoselective. Investigations of the scope of this one-pot synthesis are currently underway.

The authors wish to acknowledge the financial support of the Korea Research Foundation made in 2000.

† *Representative experimental procedures*: *Ketone (entry 3)*. To a solution of 4-nitrotoluene (50 mg, 0.364 mmol) in methanol (5 ml) was added butan-2-one (28.9 mg, 0.401 mmol), decaborane (13.4 mg, 0.109 mmol) and 10% Pd/C (15 mg). The resulting solution was stirred at *ca.* 40 °C under nitrogen for 1.5 h. The mixture was then cooled to rt and decaborane (8.9 mg, 0.073 mmol) was added to the mixture. The resulting solution was stirred at rt under nitrogen for 2 h. The mixture was concentrated under reduced pressure, chromatographed on a short pad of silica gel using a solution of ethyl acetate and *n*-hexane (1 : 8) and concentrated to give the product amine as a pale pink syrup. *Aldehyde (entry 8)*. To a solution of methyl 4-nitrobenzoate (50 mg, 0.276 mmol) in methanol (5 ml) was added two drops of acetic acid, decaborane (10 mg, 0.083 mmol) and 10% Pd/C (15 mg). The resulting solution was heated to reflux under nitrogen for 0.5 h and the mixture was cooled to rt. Propanal (17 mg, 0.303 mmol) and decaborane (6.7 mg, 0.052 mmol) were then added to the reaction mixture. The solution was stirred at rt under nitrogen for 2 h. The mixture was concentrated under reduced pressure, chromatographed on a short pad of silica gel using a solution of ethyl acetate and *n*-hexane (1 : 8), and concentrated to give the amine as a white solid.

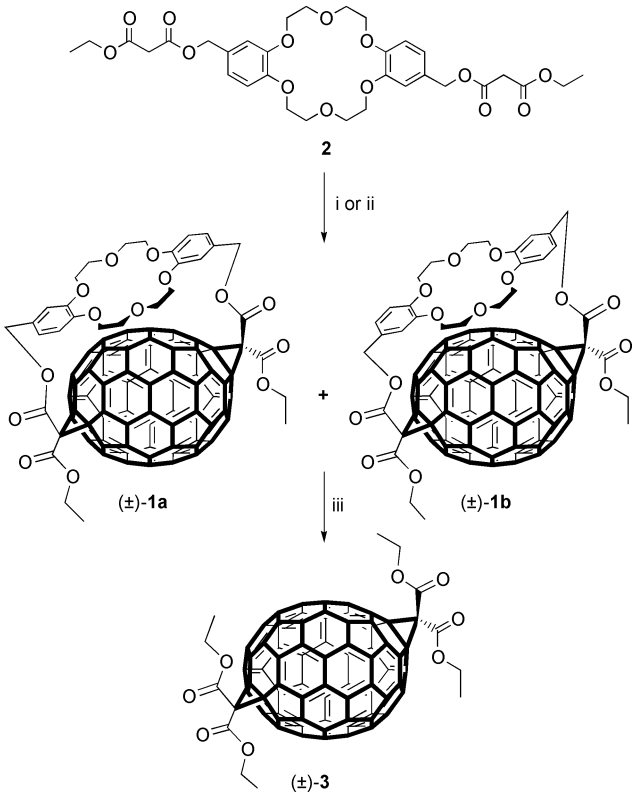
The covalently templated bis-functionalisation of C_{70}, employing a dibenzo-18-crown-6 tether, proceeds with complete regiospecificity and provides a bis-addition pattern which is disfavoured in sequential transformations.

Tether-directed remote functionalisation has proven to be a powerful tool for obtaining regiochemical control in multiple additions to buckminsterfullerene, C_{60}.[1–4] However, up until now, this approach had not been applicable to C_{70} or other higher fullerenes.

Double *Bingel* cyclopropanation of C_{70}[5] occurs on opposing hemispheres at the most curved α-type[6] 6–6 bonds (bonds at the junction between two six-membered rings) emanating from the two polar pentagons through which the C_5 symmetry axis of the higher fullerene passes. In a *Newman*-type projection looking down the C_5 axis onto the two polar pentagons, the two addends adopt a twelve, two and five o'clock geometrical relationship, respectively. Accordingly, the kinetically controlled *Bingel* bis-cyclopropanation with achiral dialkyl malonates provides three constitutional isomers, two of which (two and five o'clock) are pairs of enantiomers, in a ratio of 2.8:6.8:1.0, respectively (twelve, two and five o'clock orientation of the addends). Similar addition patterns were also obtained in other bis-functionalisation reactions, with the two o'clock geometric relationship being highly favored in each case.[7–10] Here we report the application of the tether-directed remote functionalisation to prepare C_{70} bis-adducts (±)-**1a** and (±)-**1b** with complete regioselectivity, featuring the kinetically disfavoured five o'clock addition pattern.

C_{70} was reacted with dibenzo-18-crown-6- (DB18C6) linked bis-malonate **2**[11] under modified *Bingel*-conditions (I_2, DBU, toluene) in the presence of KPF_6 (10 eq.), which was added as a template to rigidify the tether by complexation (Scheme 1). This afforded the two products (±)-**1a** and (±)-**1b** in a 56:44 ratio with an overall yield of 41%. Both compounds were separated by column chromatography (Silica-*H*; toluene–ethyl acetate (1:1)) and fully characterised (^{1}H and ^{13}C NMR, high-resolution MALDI-TOF-MS, IR and UV/Vis). Transesterfication of the crude product mixture of (±)-**1a** and (±)-**1b** (Cs_2CO_3, THF–EtOH (1:1)) afforded only one single C_2-symmetrical bis-adduct (±)-**3**. The spectroscopic data (^{1}H and ^{13}C NMR) revealed its identity with the C_{70} bis-adduct featuring diethyl malonate addends at the two polar C(1)–C(2) and C(67)–C(68) bonds (five o'clock addition pattern), which had previously been obtained by sequential double *Bingel* addition.[5,6b] This leads to the remarkable conclusion that reaction of C_{70} with **2** proceeds with complete regioselectivity to give the normally kinetically least favoured regioisomer. Surprisingly, the absence of KPF_6 in the *Bingel* macrocyclisation did not affect the regioselectivity at all, although the diastereoisomeric ratio changed slightly, providing (±)-**1a** and (±)-**1b** as the only products in a ratio of 37:63 with a substantial higher yield of 68%.

The presence of the inherently chiral five o'clock addition pattern and the *out–out* orientation of the EtOOC groups in



Scheme 1 *Reagents and conditions*: i, C_{70}, I_2, DBU, KPF_6 (10 equiv.), toluene, rt, 23% ((±)-**1a**), 18% ((±)-**1b**); ii, C_{70}, I_2, DBU, toluene, rt, 25% ((±)-**1a**), 43% ((±)-**1b**); iii, Cs_2CO_3, THF–MeOH (1:1), rt, 2 h.

(±)-**1a** was unequivocally established by X-ray crystallography (Fig. 1).† The fullerene core in this first crystal structure of a cyclopropanated C_{70} derivative has a spheroidal shape with a distance of 8.03 Å along the principal axis. As a consequence of cyclopropanation, the carbon atoms C(1), C(2), C(67) and C(68) are pulled out of the C_{70}-surface leading to a slightly longer distance along the main axis than observed for the complex (η^2-C_{70})Ir(CO)Cl(PPh_3)$_2$ (7.90 Å).[14] Distances from the carbon atoms at the equator to the center of the sphere range from 3.52–3.56 Å with a mean value of 3.54 Å. The bond lengths between the bridgehead atoms C(1)–C(2) and C(67)–C(68) of 1.605(9) and 1.596(10) Å, respectively, are strongly elongated compared to the analogous bonds reported for several η^2-transition metal C_{70}-complexes (1.512–1.523 Å).[8] However, they are similar to the lengths of the corresponding bonds reported for a *trans*-1 bis-cyclopropanated C_{60} crown ether conjugate (1.606–1.610 Å),[11b] and a Diels–Alder mono-adduct of C_{70} (1.603 Å).[15] Most geometrical features of **1a** are comparable to those of the latter Diels–Alder adduct.

The crown ether moiety exists in a conformation different from the four conformations reported so far in the literature for

DOI: 10.1039/b006066f

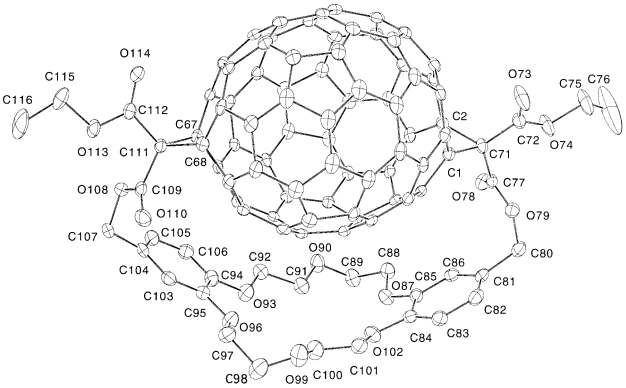


Fig. 1 Molecular structure of (±)-**1a** in the crystal. Atomic displacement parameters obtained at 233 K are drawn at the 30% probability level.

uncomplexed DB18C6.[16] In order to bridge the fullerene poles, it adopts an 'umbrella shaped' geometry with a distorted C_2-symmetry. The approximate dihedral angle between the two aromatic planes is about 124°. This is comparable to the value reported for DB18C6 complexes (128–102°),[11b,16b,c] but considerably larger than for uncomplexed C_{2v}-symmetrical DB18C6 (98.8°).[16c] Several close contacts between the DB18C6 tether and the fullerene surface are observed.

The structure of the other isomer ((±)-**1b**) was deduced from MM2-calculations,[17] which indicated that the *in–out* and *in–in* isomers are not feasible because of their much higher steric energy. Thus, (±)-**1a**, and (±)-**1b** are diastereoisomeric pairs of enantiomers, differing only in the orientation of the DB18C6 tether as a result of planar chirality.

To determine the effects of cation complexation on the redox properties of (±)-**1a** and (±)-**1b**, cyclic voltammetric (CV) studies were performed in toluene–MeCN (4 : 1) in the absence and presence of KPF_6 and $NaBF_4$ (Table 1). Based on the ΔE_{pp} values and the cathodic : anodic current ratio, the first reduction waves of (±)-**1a** and (±)-**1b** are electrochemically and chemically reversible. However, the second reduction is chemically irreversible as judged by an additional oxidation wave observed on the reverse scan. Consequently, ion binding effects were monitored only for the first reduction. Similar to the behavior of the previously reported C_{60}–DB18C6 conjugate,[11b] addition of sub-stoichiometric amounts of Na^+ ions to the solution of (±)-**1a** causes the appearance of a new poorly resolved, yet clearly discernible redox wave which is anodically shifted by 70 mV relative to that for the free compound.[11] This new redox couple, assigned to the cation complex, grows at the expense of the one for the uncomplexed species as the concentration of Na^+ ions increases. This was firmly established by the observation of isopotential points on both the forward and reverse scans. Addition of one eq. of Na^+ ions causes the redox wave of the free compound to disappear completely, and further addition causes no further observable changes in the voltammetry. This behavior implies strong complexation between the crown ether conjugate and one Na^+ ion.[18] The anodic shift must be attributed to the electrostatic effect of the Na^+ ion which is bound to the DB18C6 ionophore in close proximity to the fullerene surface. The behavior with K^+ ions was very similar (Table 1), and the same was observed for (±)-**1b** with either cation.

Microwave discharge-assisted catalytic conversion of NO to N_2

Junwang Tang, Tao Zhang,* Dongbai Liang, Changhai Xu, Xiaoying Sun and Liwu Lin

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian 116023, China. E-mail: taozhang@ms.dicp.ac.cn

Received (in Cambridge, UK) 2nd May 2000, Accepted 14th August 2000
First published as an Advance Article on the web 15th September 2000

By coupling microwave discharge with an Fe/HZSM-5 catalyst, novel effects have been observed for the conversion of NO to N_2 in the presence of excess oxygen with high efficiency.

The reduction of NO has been investigated for many years. Especially in the past decade, it has attracted much attention.[1] Recently, with the progress of advanced techniques, many papers have described the application of new methods in different branches of chemistry.[2] Among these techniques, microwave dielectric heating is a convenient and effective way of bringing about chemical reactions in the field of catalysis.[3] The use of microwave heating to stimulate catalytic reactions has provided some remarkable results,[4–6] Bond *et al*. and Wan and co-workers have investigated the effect of microwave heating on many catalytic reactions.[7] The reduction of NO by CH_4 by a microwave heating technique has also been reported by this laboratory.[8] Here, we report on a new process for the removal of NO by coupling the microwave discharge (not microwave heating) with the selective catalytic reduction (SCR) reaction by CH_4. We designate this kind of process as catalysis assisted by microwave discharge (CAMD).

A Fe/HZSM-5 catalyst was employed to demonstrate the effect of the CAMD of NO–CH_4. The Fe/HZSM-5 was prepared by impregnating HZSM-5 (SiO_2/Al_2O_3 = 25) in an aqueous $Fe(NO_3)_3$ solution (Fe in the catalyst was 10 wt%); all catalysts prepared were of 1.25–1.60 mm granule size. The flow rate of the feed, which consisted of 2000 ppm NO, 1600 ppm CH_4 and 2.0% O_2 (helium as a balance gas), was 60 ml min^{-1} (GHSV = 3600 h^{-1}).

A special quartz tubular reactor (i.d. 10 mm) was aligned vertically at the center of the microwave cavity. The catalyst bed was supported on a fused quartz frit of medium porosity. The gas composition was determined by an on-line NO_x-analyser and gas chromatograph (GC-8800 type, with 13X and PQ columns).

In this work, Fe/HZSM-5 was used not only as a catalyst, but also as a discharge igniter, by which discharge was achieved without any electrode at atmospheric pressure: after the microwaves were induced in the reactor, red discharge with weak sounds was observed among the catalyst granules.

Results obtained over the Fe/HZSM-5 in a conventional reaction mode (CRM) are presented in Table 1. From these data, it is apparent that the Fe/HZSM-5 was almost inactive for the reduction of NO with CH_4 in excess O_2 in the CRM. When CH_4 was wholly consumed, the conversion of NO to N_2 did not exceed 5%, which is almost in accordance with the results of Chen *et al*.[9] The results indicate that the activity of the Fe/HZSM-5 catalyst for CH_4–NO reaction is very low in the presence of excess O_2 in the CRM.

Results obtained over Fe/HZSM-5 in the CAMD process are presented in Table 2. It can be seen from these results that the conversion of NO to N_2 is increased to 44.5% in the presence of excess O_2, while at the same time the CH_4 consumption is 50.5%.

In order to confirm the enhancement of the catalytic activity by the microwave discharge, another microwave discharge experiment without any catalyst was conducted and the results are also given in Table 2. In this experiment, the average conversion of NO to N_2 was 18.2%. It can be noted that even the sum of the conversion of NO to N_2 in the microwave discharge mode without any catalyst and that in the CRM were still lower than that of NO to N_2 *via* CAMD.

From the above results it can be seen that, regardless of temperature, the Fe/HZSM-5 catalyst is inactive in the CRM for the CH_4–NO reaction (Table 1). However, when in the microwave discharge mode the conversion of NO to N_2 on Fe/HZSM-5 increases from *ca*. 5 to 44%. Apparently the catalytic activity of the Fe/HZSM-5 is enhanced remarkably by the microwave discharge. This increase in catalytic activity cannot be readily explained by an increase in reaction temperature, suggesting that microwave discharge can cause non-Arrhenius effects.

As we know, in the CRM all reactants gain energy by thermal conduction. In fact, the reaction of CH_4 with O_2 proceeds more rapidly than the reaction of CH_4 with NO at high temperatures so that a large portion of CH_4 is consumed by O_2, resulting in the restraint of the reaction rate for CH_4 with NO. Therefore, the conversion of NO to N_2 in the presence of excess O_2 is both very low and independent of temperature in the CRM. On the other hand, in the microwave discharge mode a high frequency electromagnetic field is formed easily in the reactor, and since the molecules in the gas phase are transparent to the electromagnetic field no interaction will take place between the electromagnetic field and the gaseous molecules. Our temperature-programmed desorption (TPD) experiments on Fe/HZSM-5 indicated that supported Fe_2O_3 is a good material for the adsorption of NO_x, which agrees well with the report of Otto and Shelef.[10] Moreover, it is known that the high frequency

Table 1 Activity of Fe/HZSM-5 catalyst in the conventional reaction mode[a]

T/°C	NO conversion (%)	CH_4 conversion (%)
300	0.7	2.0
400	4.5	4.5
500	5.0	7.3
600	4.4	9.0
650	3.0	27.3
700	3.3	81.3
740	2.1	100.0

DOI: 10.1039/b003499l

electromagnetic field is beneficial for the activation of polar molecules. So, it is speculated that the NO_x adsorbed on the Fe/HZSM-5 but not the O_2 in the gas phase, can be activated effectively by the high frequency electromagnetic field. This speculation agrees with the results of our previous paper.[8] Then again, microwave discharge can produce many active electrons with higher energy and higher temperature, and by the action of these electrons plenty of radicals, especially CH_x, can be produced. However, the average temperature of the gas feed is still very low in the microwave discharge mode, which is beneficial for lowering the energy consumption greatly and hence retarding the reaction of CH_4 with O_2. Under the same circumstances, the reaction between the activated NO_x adsorbed on the catalyst and the CH_x radicals is easily accelerated by the Fe/HZSM-5 catalyst so that the conversion of NO to N_2 can be enhanced greatly *via* CAMD on the Fe/HZSM-5. Although the mechanism of CAMD is not yet clear, it is likely that the reaction pathways in the CMR are different from those in the CAMD, and this may be the reason why the activity of the Fe/HZSM-5 catalyst varies significantly under the two modes.

In conclusion, the Fe/HZSM-5 catalyst exhibits a rather remarkable catalytic performance in the SCR of NO by CH_4 in the CAMD process, indicating that CAMD has a beneficial effect on the activation of reacting molecules.

The authors thank Professor Can Li, the director of State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, CAS, for helpful discussions.

First published as an Advance Article on the web

Using an *exo* ligand containing a pyridine unit as a monodentate coordination site and a PyS_2 moiety as a tridentate coordination pole, a directional 1-D coordination network has been obtained in the presence of $CoCl_2$ under self-assembly conditions; a single-crystal X-ray study revealed that in the crystalline phase the 1-D networks are packed in a centrosymmetric fashion.

The formation of coordination networks based on *exo* ligands (ligands with coordination sites outwardly oriented) and metal cations are currently attracting much attention.[1] The formation of such networks may take place in the crystalline phase through self-assembly processes based on the reversible coordination of metal cations by *exo* ligands. The iterative binding process leads to the assembling cores acting as structural nodes of the network. The dimensionality of coordination networks (1-, 2- or 3-D) is defined by the number of translations (1, 2 or 3) operating on the assembling core. The dimensionality depends, on one hand, on the topological and coordination features of the organic *exo* ligand and, on the other hand, on the stereochemical requirements of the metal. Although the majority of reported coordination networks are formed using bis-monodentate *exo* ligands based on 4,4′-bipyridine,[2] examples of coordination networks based on bis-bidentate[3,4] or tetrakis-monodentate[5,6] ligands have also been reported. However, dealing with bis-tridentate *exo* ligands, only a few structurally characterised networks have been published.[7–9]

At present, let us consider the formation of 1-D coordination networks based on a single translation of an assembling core. For such a network, owing to the fact that exploitation of directional physical properties requires vectorial arrangements of the building blocks, the control of directionality remains a challenging issue.

The design of ligands for the formation of 1-D networks using metals with linear coordination geometry is trivial and may only be based on bis-monodentate systems (one may use homo-L(*n*,*m*) and hetero-L(*n*,*m*) notation to design the *exo* ligand L composed of two coordination poles each containing *n* and *m* coordination sites of the same (homo) or different (hetero) nature: thus, bis-monodentate ligands may be described as homo- or hetero-L(1,1) and bis-bidentate ligands as homo- or hetero-L(2,2) *etc*.). For metal cations requiring four coordination sites arranged either in square planar or in tetrahedral coordination geometry, two different types of *exo* ligands based on either bis-bidentate (homo- or hetero-L(2,2)) or a combination of mono ($n = 1$) and tridentate ($m = 3$) (hetero-L(1,3) may be envisaged. For metal cations with octahedral coordination geometry, if all six coordination positions are taken into account, 1-D networks may be obtained using bis-tridentate *exo* ligands (homo- or hetero-L(3,3)). However, in the latter case, further design of the assembling core may be based on the use of four coordination positions located at the square planar base of the octahedron. In such a design the two axial positions would be occupied by two ligands acting as terminal coordinators and thus not participating in the formation of the network. Again, for such a strategy, one may use either homo- or hetero-L(2,2) or hetero-L(1,3) ligands. Whereas for symmetrical ligands of the homo-L(2,2) type no directional network may be formed, with hetero-L(2,2) or hetero-L(1,3) ligands the formation of directional 1-D networks may be envisaged.

In the present contribution we report the design and synthesis of a new hetero-L(1,3) *exo* ligand **1** and its self assembly in the crystalline phase into a 1-D directional network in the presence of $CoCl_2$.

The strategy that was followed for the design of 1-D directional networks was based on the self-assembly of the neutral hetero-L(1,3) *exo* ligand **1** and octahedral $CoCl_2$ complex. The design of **1** (Scheme 1) is based on a combination of two different coordination poles, one composed of a monodentate pyridine derivative and the other on a pyridine unit bearing at the 2 and 6 positions CH_2SCH_3 thioether fragments leading thus to a tridentate PyS_2 coordination system. The ethynyl spacer was chosen to interconnect the two coordination poles through the pyridine units at the 4 positions. The ethynyl spacer appeared as an interesting bridge since it should allow avoidance of possible steric effects which may alter the packing of 1-D networks in the solid state and based on its ability to permit possible electronic communication between the two pyridine rings.

The starting material for the synthesis of **1** was chelidamic acid **2**. Upon treatment of the latter with PBr_5 followed by EtOH, compound **3** was obtained in 61% yield.[10] The latter was reduced to **4** in 62% yield using $NaBH_4$ in dry EtOH.[11] Although the preparation of compound **5** from the diol **4** was reported using PBr_3,[11] it was found that bromination of **4** using 33% HBr/AcOH at 125 °C for 5 h was much more efficient and produced compound **5** in 89% yield. Treatment for 48 h at r.t. of **5** by NaSMe (2 eq.) in dry THF afforded **6** in 60% yield. The synthesis of the ligand **1** was achieved by coupling the bromopyridine derivative **6** with 4-ethynylpyridine **7** in the presence of $Pd(OAc)_2$ and Ph_3P in Et_3N under reflux for 48 h. The pure compound **1** was obtained in 94% yield as a colourless viscous oil after chromatography (SiO_2, CH_2Cl_2/MeOH 0–1%).

DOI: 10.1039/b006099m

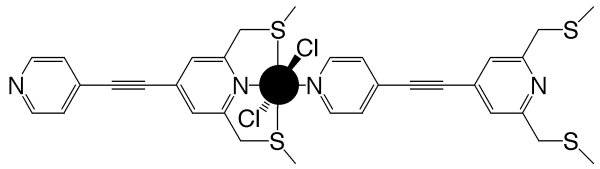

Fig. 1 Representation of the assembling core based on the coordination of $CoCl_2$ complex by two consecutive ligands **1** which by translation leads to the directional 1-D network.

Compound **7** was obtained in two steps upon treatment at r.t. of 4-bromopyridine hydrochloride by 2-methyl-3-butyn-2-ol in the presence of $(PPh_3)_2PdCl_2$ and CuI in diethylamine affording compound **8** and the removal of the protecting group by treatment under reflux with NaOH in toluene.[12]

Upon slow diffusion at r.t. of a MeOH solution containing $CoCl_2{\cdot}6H_2O$ (8 mg, 6.1 mmol) into a CH_2Cl_2 solution of compound **1** (8 mg, 3.3 mmol), purple crystals were obtained after three weeks. A single-crystal X-ray study† showed the following relevant features: the crystal (orthorhombic) was composed of **1**, $CoCl_2$ and MeOH molecules. As expected, a directional 1-D neutral network based on the interconnection of $CoCl_2$ units by the ligand **1** is observed. The assembling core is a distorted octahedral Co(II) complex for which the coordination sphere is composed of two Cl^- anions, two nitrogen and two sulfur atoms. The two Cl^- anions are located at axial positions with a Co–Cl distance of 2.425 Å and a Cl–Co–Cl angle of 178.8°. The square base of the octahedron is composed of one pyridine and one NS_2 coordination set belonging to the tridentate moiety of the ligand with Co–N and Co–S distances of 2.118 Å and 2.490 Å respectively. Whereas the ClCoS angle varies from 85° to 95°, the ClCoN angle is *ca.* 90° and the NCoN angle is 180.0°. Dealing with the ligand **1**, the two pyridine units are almost untilted and the CC triple bond distance is 1.207 Å (Fig. 1).

Owing to the unsymmetrical nature of the ligand **1** and, thus, the assembling core, upon a single translation a 1-D directional coordination network is indeed obtained. In the crystalline phase, in principle, a directional 1-D network may either be packed in centrosymmetric (Fig. 2a) or non-centrosymmetric modes (Fig. 2b). In the case reported here, the directional networks are positioned in a parallel fashion but oriented in opposite directions, thus generating centres of symmetry. Consequently, the overall system is non-directional (Fig. 3). This centrosymmetric packing may be due to cancellation of dipolar moments.

In conclusion, the unsymmetrical ligand **1** based on two different coordination poles was shown to form a directional 1-D coordination network in the presence of $CoCl_2$ demonstrating the viability of the approach. The network was structurally characterised by X-ray diffraction methods on single crystals.

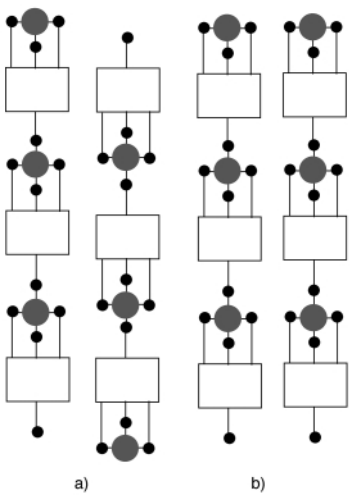

Fig. 2 Schematic representation of consecutive directional 1-D networks leading to symmetrical (a) or unsymmetrical (b) packing.

Fig. 3 A portion of the X-ray structure of the directional 1-D network showing the packing of consecutive networks in 'head to tail' fashion. H atoms and solvent molecules are not presented for clarity. For distances and angles see text.

However, the 1-D networks were packed parallel to each other with opposite orientation of linear arrays. The possibility of controlling the unsymmetrical packing of such 1-D coordination networks is currently under exploration using chiral analogues of the ligand **1**.

Proton-controlled photoisomerization: rhenium(I) tricarbonyl bipyridine linked to amine or azacrown ether groups by a styryl pyridine bridging ligand†

Jared D. Lewis, Robin N. Perutz and John N. Moore*

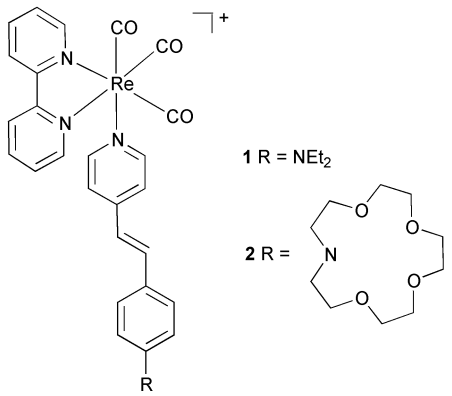
Received (in Cambridge, UK) 20th July 2000, Accepted 25th August 2000
First published as an Advance Article on the web 15th September 2000

Complexes in which *fac*-(bpy)Re(CO)$_3$ is linked by a styryl pyridine to an amine or an azacrown ether show no photoreaction in acetonitrile in the absence of acid, but they photoisomerize readily at the stilbene-like bridging ligand when the terminal amine or azacrown ether group is protonated because an intramolecular energy-transfer mechanism becomes available.

There is widespread interest in the design of molecular photodevices whose properties change on the addition of specific analytes.[1] Devices range from sensors where the analyte turns the emission on or off, to switches where the analyte controls the occurrence or route of a photochemical reaction. Photoinduced intramolecular electron or energy transfer often underlies the mechanism by which the sensing or switching effect occurs. Here we describe a molecular design in which protonation controls a photochemical switching reaction which is driven by intramolecular energy transfer.

We report two new complexes which combine three functional groups: (bpy)Re(CO)$_3$ is linked by a stilbene-like bridging ligand to either an *N*,*N*-diethylamine (**1**) or an aza-



15-crown-5 ether (**2**) group.‡ The (bpy)Re(CO)$_3$ chromophore is being used increasingly within molecular sensors and switches because it is luminescent, and its photophysics can be controlled by intramolecular electron and energy transfer.[2] Stilbene has been used as the basis for molecular photoswitches because its well-studied *trans–cis* photoisomerization reaction can be driven by excitation directly to the excited singlet state or indirectly by energy transfer to form the excited triplet state.[3] Crown ethers are attractive as receptors for analytes within many photodevices because cation binding at the crown generally modifies the absorption and emission properties of the attached group, and can control its photochemistry.[1] We report new complexes that combine all three of these groups in a photoswitchable device: photoisomerization at the styryl group is the switch, and proton binding at the amine or azacrown N-heteroatom controls the effect.

† Electronic supplementary information (ESI) available: UV/vis absorption spectra of **2**. See http://www.rsc.org/suppdata/cc/b0/b005889k/

The UV/vis absorption spectrum of *trans*-**1** in acetonitrile (Fig. 1) comprises an intense, solvatochromic band at 435 nm and weaker features at 240–350 nm. The 435 nm band is assigned to an intraligand charge-transfer (ILCT) transition localised on the py-DEAS ligand,§ in which charge is transferred from the amine N-atom donor to the pyridyl N-atom acceptor, and the weaker features at *ca.* 300 nm and *ca.* 250 nm are assigned to $\pi \rightarrow \pi^*$ transitions localised on the bpy and py-DEAS ligands, respectively. The $d\pi(Re) \rightarrow \pi^*(bpy)$ metal-to-ligand charge-transfer (MLCT) transition of (bpy)Re(CO)$_3$ complexes typically gives an absorption band at *ca.* 380 nm (absorption coefficient, $\varepsilon \approx 3500$ dm^3 mol^{-1} cm^{-1}), and excitation into this band gives MLCT emission at *ca.* 600 nm which is moderately intense in ambient temperature solution (emission quantum yield, $\Phi_{em} \approx 10^{-2}$).[4] The MLCT absorption band of *trans*-**1** underlies the intense ILCT feature (Fig. 1); excitation at 380 nm, or at any wavelength in the range 300–500 nm, resulted only in very weak MLCT emission, with $\Phi_{em} < 6 \times 10^{-4}$.

Addition of HCl to a solution of *trans*-**1** in acetonitrile resulted in a blue-shift of the ILCT absorption band to *ca.* 320 nm (Fig. 1): this change is attributed to the production of *trans*-**1**-H$^+$, in which protonation at the amine N-atom inhibits charge transfer and raises the energy of the ILCT state. Protonation would not be expected to cause a significant shift in the MLCT absorption band, which is revealed on the long-wavelength edge of the shifted ILCT feature. Excitation of *trans*-**1**-H$^+$ in the range 300–450 nm resulted in one extremely weak emission band at *ca.* 400 nm (excitation peak at *ca.* 330 nm) which is assigned to ILCT emission, and another slightly more intense band at 590 nm ($\Phi_{em} = 1 \times 10^{-3}$) which is assigned to MLCT emission. Excitation spectra recorded on monitoring the emission at ⩾590 nm were found to mirror the expected MLCT absorption profile (excitation peak at *ca.* 355 nm). Only MLCT emission was observed on excitation at >400 nm, confirming that irradiation at >400 nm excites *trans*-**1**-H$^+$ exclusively to the MLCT state.

Prolonged irradiation¶ of *trans*-**1** in acetonitrile at any wavelength in the range 350–450 nm, exciting to either ILCT or MLCT states, resulted in no change in the UV/vis absorption spectrum, indicating that there is no significant photoreaction.‖

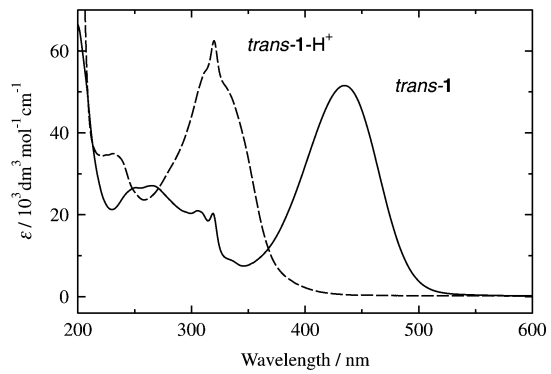


Fig. 1 UV/vis absorption spectrum of *trans*-**1** (2×10^{-5} mol dm^{-3}) in CH_3CN (—) and in CH_3CN on addition of excess HCl (---).

DOI: 10.1039/b005889k

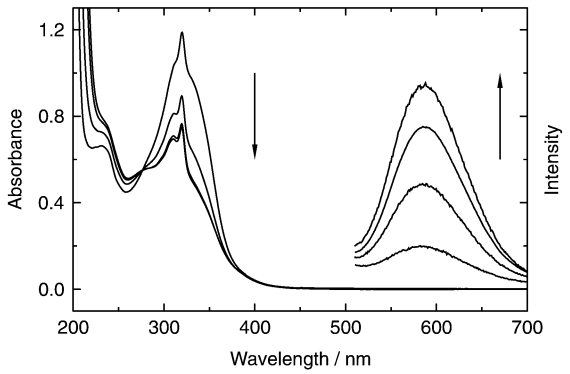

Fig. 2 UV/vis absorption spectra obtained from a solution of *trans*-**1** in CH_3CN (2×10^{-5} mol dm^{-3}), with excess HCl added, after arc-lamp irradiation at 406.7 nm (*ca.* 3 mW) for 0, 30, 120, and 180 min, along with corresponding emission spectra obtained on excitation at 380 nm; no distinct emission features were observed at < 500 nm following irradiation.

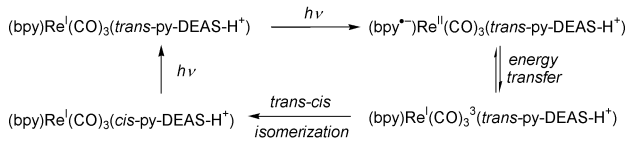
By contrast, irradiation of *trans*-**1**-H^+ at wavelengths in the range 400–430 nm, exciting exclusively to the MLCT state, resulted in pronounced changes in the absorption spectrum, and in a significant increase in the MLCT emission intensity (Fig. 2). The changes in the absorption spectrum of **1**-H^+ are consistent with *trans–cis* photoisomerization at the styryl –C=C– bond.[5] This interpretation was confirmed by ^1H NMR, which showed the production of new vinylic proton resonances characteristic of the *cis*-isomer;** integration of the *cis*- and *trans*-isomer peaks showed that the photostationary state reached on irradiation of *trans*-**1**-H^+ at 406.7 nm consisted of a *ca.* 50 : 50 *cis* : *trans* mixture. These results demonstrate that the photoisomerization of *trans*-**1** in acetonitrile is controlled by protonation.

The MLCT excited state of $(bpy)Re(CO)_3$ complexes typically decays back to the ground state in *ca.* 0.1 μs, by radiative and non-radiative routes, giving moderately intense MLCT emission in ambient temperature solution.[4] The extremely weak emission and the absence of any photochemical reaction for *trans*-**1** indicate that an additional non-radiative decay route that regenerates the ground state is available from the MLCT state of this complex. For complexes in which $(bpy)Re(CO)_3$ is linked to a dialkylamine by a saturated spacer, intramolecular electron transfer from the amine group to the Re centre in the MLCT state can result in the rapid (< 1 ns) formation of a charge-separated ligand-to-ligand charge-transfer (LLCT) state which decays non-radiatively back to the ground state.[2,6] Our observations are consistent with this mechanism for the decay of the MLCT state of *trans*-**1**.

The moderately weak emission observed from *trans*-**1**-H^+ indicates that, like *trans*-**1**, an additional non-radiative decay route is available from the MLCT state in comparison with typical $(bpy)Re(CO)_3$ complexes. The results of the irradiation experiments show that the mechanism is dependent on protonation, and that *trans–cis* photoisomerization occurs only for the protonated form, *trans*-**1**-H^+. Recent studies of complexes in which $(bpy)Re(CO)_3$ is attached to stilbene-like ligands have shown that the MLCT state can decay by intramolecular energy transfer to form a triplet excited state of stilbene from which *trans–cis* isomerization occurs.[7] We attribute the photoisomerization of *trans*-**1**-H^+ to this mechanism:



The increase in MLCT emission on irradiation (Fig. 2) can be attributed to the loss of this intramolecular energy-transfer decay route on isomerization to *cis*-**1**-H^+ because the energy of the styryl-centred triplet excited state is raised in the *cis*-isomer;[7] $\Phi_{em} \approx 10^{-2}$ is estimated for *cis*-**1**-H^+. The significant increase in the MLCT emission intensity on isomerization serves as an effective 'signal' that photoswitching has occurred.

The experiments described above for the diethylamino derivative **1** have been repeated for the azacrown ether derivative **2** (see ESI†). The spectra of these two complexes, and of the free styryl ligands, are similar under all of the conditions studied. As for *trans*-**1**, photoisomerization in acetonitrile was observed only on protonation at the azacrown to form *trans*-**2**-H^+.

In addition to describing these complexes as proton-controlled photoswitches, they can also be described as two-input photoionic signal-processing devices:[8] the presence of both protons (ionic input) and visible light (photonic input) is required to give a photonic output change, observed as an increase in the emission intensity.

In summary, we have demonstrated that protonation can be used to control the *trans–cis* photoisomerization reaction of a complex in which $(bpy)Re(CO)_3$ is linked by a stilbene-like bridging ligand to an amine or an azacrown ether. The effectiveness of this approach for the azacrown ether complex provides an opportunity to explore the use of cations within the crown to control the photoisomerization reaction, and such experiments are in progress.

Notes and references

‡ $(bpy)Re(CO)_3Cl$ was stirred with an excess of CF_3SO_3H at room temperature for 1 h to yield $(bpy)Re(CO)_3(CF_3SO_3)$, which was refluxed overnight in THF under N_2 with < 1 equiv of the appropriate styryl ligand, 4-(4-diethylaminostyryl)pyridine (py-DEAS) or 4-(4-aza-15-crown-5-styryl)pyridine (py-AZAS) (see ref. 9 for synthetic method for styryl ligands). The product was metathesized with NH_4PF_6 to yield $[(bpy)Re(CO)_3(py\text{-}DEAS)]PF_6$ (**1**) or $[(bpy)Re(CO)_3(py\text{-}AZAS)]PF_6$ (**2**), respectively. The complexes were purified by repeated recrystallization and column chromatography (5% MeOH–CH_2Cl_2 eluting on silica), and were characterized by IR, ES-MS and ^1H NMR, which showed that the *trans*-isomers were formed exclusively.

§ The absorption spectrum of the free *trans*-py-DEAS ligand in acetonitrile has a similar profile to that of *trans*-**1**, with an intense, solvatochromic absorption band at 375 nm and a weaker band at 250 nm.

¶ Samples were irradiated in a sealed 1 cm pathlength cell with the output from either a krypton ion laser (350.6 or 406.7 nm; 50 mW) or a xenon-arc lamp (monochromated to 5 nm bandpass; 1–3 mW).

‖ No changes were observed in the absorption spectrum of *trans*-**1** following arc-lamp irradiation at 406 nm (3 mW) for 180 min; these conditions are identical to those illustrated for *trans*-**1**-H^+ in Fig. 2 except the absorbance at 406 nm was 0.7 for *trans*-**1** (*versus* 0.03 for *trans*-**1**-H^+).

** The ^1H NMR spectrum showed vinylic proton resonances assigned to *trans*-**1**-H^+ (δ 6.95, 7.28; $J_{H\text{-}H}$ = 16 Hz) before irradiation, and to both *cis*-**1**-H^+ (δ 6.35, 6.70; $J_{H\text{-}H}$ = 12 Hz) and *trans*-**1**-H^+ after irradiation.

First published as an Advance Article on the web 15th September 2000

The homogeneously catalyzed reductive amination of aldehydes and ketones under smooth conditions is reported, showing for the first time, that Rh(I) catalysts based on chelating diphosphines and diphosphinites can be advantageously employed for this reaction, even for the production of chiral amino acid derivatives.

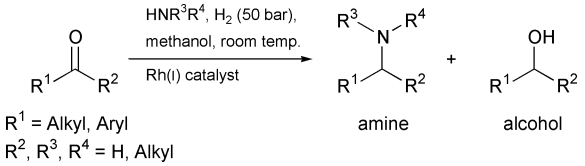
One-stage (or direct) reductive amination of aldehydes and ketones with amines affording higher alkylated amines is an interesting target in modern organic chemistry with great synthetic potential for application in academia and industry. Hitherto several chemical reducing agents, in particular borohydrides, have been shown to be valuable for this reaction giving rise to the alkylated amines in good yield.[1] However, from the ecological point of view and taking into account the demand for atom economy, more promising is the use of molecular hydrogen as a reducing agent. Indeed it was shown that reductive amination with hydrogen can be mediated by heterogeneous platinum, palladium, nickel or ruthenium metal catalysts.[2] Several amines have been prepared by this methodology even on an industrial scale.

Interestingly, only a few preliminary studies on the homogeneous version of this reaction can be found in the literature in spite of the tremendous progress which homogeneous catalysis has seen over the last decades.[3] For example, typical hydroformylation catalysts such as rhodium and cobalt carbonyls were tested, but were found to require rather severe reaction conditions (100–300 atm H_2, 100–200 °C).[4] The selectivity and efficiency of some glyoxyme Rh and Co complexes were studied in the reductive amination of cyclohexanone with ammonia.[5] A related cyanocobalt catalyst afforded only moderate yields of product amines.[6] More noteworthy is the unique reaction of a sterically hindered aniline with methoxyacetone in the presence of a chiral Ir–diphosphine catalyst.[7] Tandem hydroformylation–amination reactions (hydroaminomethylation) also contain a reductive amination step, however the range of products is limited owing to the use of olefins as starting material.[8]

Recently, we reported that cationic rhodium(I) complexes [Rh(dppb)(cod)]BF_4 **1** [dppb = 1,4-bis(diphenylphosphino)butane, cod = cycloocta-1,5-diene] and [Rh(dpoe)(cod)]BF_4 **2** [dpoe = 1,2-bis(diphenylphosphinito)ethane] are highly efficient precatalysts in the hydrogenation of imines[9] and enamines[10] under mild conditions (room temperature, 1–50 bar H_2 pressure). Usually these substrates are considered to be intermediates in some direct reductive amination reactions.[11]

Herein we demonstrate that complexes **1** and **2** are also useful for reductive amination (Scheme 1). For this reaction, besides the activity of the catalyst the selectivity for the formation of the desired amine is important. The production of the relevant alcohol by the competitive reduction of the carbonyl compound should be minimized.

Our results obtained with selected aldehydes and piperidine as the amine are listed in Table 1. Conversion with respect to the



Scheme 1 Reductive amination of aldehydes and ketones with Rh(I) catalysts.

starting carbonyl compound and selectivity in terms of produced amine/alcohol ratio in the final reaction mixtures were determined by ^{1}H NMR spectroscopy. As shown, cationic precatalysts **1** and **2** are efficient for reductive amination. It is of note that in all trials the desired amine and the corresponding alcohol were exclusively formed. Both complexes were more effective and selective than Wilkinson's complex $Rh(PPh_3)_3Cl$ (run 1, *cf.* runs 3 and 6; run 9, *cf.* runs 11 and 14). Also the hydroformylation precatalyst $Rh(PPh_3)_2(CO)Cl$ (run 10), frequently applied in hydroaminomethylation,[8] is inferior. Similar behavior was observed for the *in situ* prepared neutral complex $[Rh(dppb)Cl]_2$ (run 2). Although the conversion measured after 20 h was similar to that for precatalyst **1** the hydrogen uptake proceeded significantly more slowly.

Increasing concentrations of the amine had no pronounced effect on the selectivity, this applying for PhCHO (runs 3 and 4) as well as for PhCHMeCHO (runs 11 and 12) as substrate when precatalyst **1** was used. Application of precatalyst **2** in the

15	**2**[c]	1:1	>99	3.2

[a] *Reaction conditions*: 5 mmol aldehyde, 0.2 mol% precatalyst, 10 ml MeOH, 50 bar initial pressure of H_2, room temp. [b] Measured after 20 h. [c] $TsOH{\cdot}xH_2O$ added ($TsOH{\cdot}xH_2O$/Rh = 20).

DOI: 10.1039/b005777k

reductive amination of benzaldehyde led to a slight decrease in selectivity (runs 6 and 7). The absence of a significant dependence of the selectivity on the amine concentration is noteworthy. Obviously, the rate limiting step in the overall process is the reduction of the corresponding intermediates but not their formation. This assumption is also confirmed by the fact that preliminary heating of a mixture of PhCHO and piperidine in methanol had no effect on the selectivity.

It is interesting that both precatalysts exhibited approximately the same selectivity with PhCHO as carbonyl component (runs 3 and 6) while the selectivity observed in the reductive amination of PhCHMeCHO with **1** as a precatalyst was lower than with **2** (runs 11 and 14).

The effect of $TsOH{\cdot}xH_2O$ as additive is less clear. Thus, this additive slightly diminished the selectivity of precatalysts **1** and **2** in the reaction of benzaldehyde with piperidine (runs 3/5, 6/8). However, in the reaction with PhCHMeCHO the effect of the additive was dependent upon the precatalyst used (runs 11/13, 14/15). In general, in the presence of $TsOH{\cdot}xH_2O$, the rate of the hydrogen uptake was lowered.

We next investigated the reductive amination of aldehydes with a two-fold excess of piperidine as a function of the substitution pattern of the aldehyde using precatalyst **1** (Table 2). In the series of substituted benzaldehydes (runs 1–5) the beneficial effect of electron-withdrawing groups upon the selectivity is evident. The presence of a methyl group in an *ortho* position exhibited no steric effect on the selectivity (run 3). Unfortunately, NO_2- and CN-groups did not survive under the reaction conditions. An alkyl substituent α to the carbonyl group strongly affected the selectivity of amination (runs 6–8). The highest selectivity was observed with *n*-octanal (run 8).

Table 2 Comparison of the selectivity and the rate of amination of various aldehydes with piperidine using [Rh(dppb)(cod)]BF_4 **1** as a precatalyst[a]

Run	Aldehyde	Ratio produced amine/alcohol[b]
1	4-HOC_6H_4CHO	0.8
2	4-$MeOC_6H_4CHO$	0.9
3	2-MeC_6H_4CHO	1.0
4	PhCHO	1.5
5	4-ClC_6H_4CHO	1.9
6	PhCHMeCHO	1.9
7	EtCHMeCHO	2.4
8	*n*-$C_7H_{15}CHO$	12.0

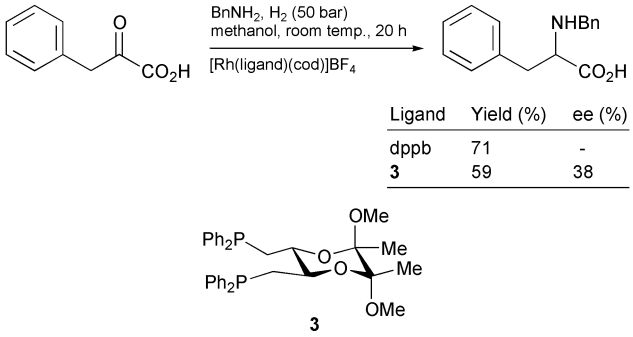
[a] For reaction conditions see Table 1. [b] After 20 h full conversion was observed in all reactions.

The results of reductive amination of PhCHO with various amines are summarized in Table 3. In general, good correlation between the selectivity of the reaction and the basicity of the amine was observed (runs 1–4). Apparently, steric effects can exert a strong influence. Thus, with 2-methylpiperidine as substrate, which has approximately the same basicity as piperidine but is sterically more hindered, only traces of the desired amine were formed (run 5).

Table 3 Comparison of reductive amination of PhCHO with various amines employing [Rh(dppb)(cod)]BF_4 **1** as a precatalyst[a]

Run	Amine	pK_a (amine)	Ratio produced amine/alcohol[b]
1	Pyrrolidine	11.27	2.30
2	Piperidine	11.02	1.50
3	Me_2NH	10.73	0.43
4	Et_2NH	10.49	0.07
5	2-Methylpiperidine	10.99	< 0.05

[a] *Reaction conditions*: 5 mmol aldehyde, 10 mmol amine, for other conditions see Table 1. [b] After 20 h full conversion was observed in all reactions.



Scheme 2 Preparation of racemic and enantiomerically enriched *N*-benzylphenylalanine.

In contrast to the reductive amination of PhCHO with piperidine, the reaction with $PhCH_2NH_2$ using precatalyst **1** was slow. After 20 h only 39% conversion was observed. However the high observed amine/alcohol ratio of 11 is remarkable.

Unexpectedly, reductive alkylation with α-keto acid derivatives afforded good yields of the desired amino acids. Thus, the industrially relevant reductive amination of $PhCH_2COCOH$ with benzyl amine gave *N*-benzylphenylalanine in a yield of 71% (Scheme 2). The product precipitated from the reaction mixture and the analytically pure compound could simply be isolated by filtration and subsequent washing with ethanol. In a preliminary investigation the reaction was also run with a catalyst bearing the chiral diphosphine **3**.[12] (*R*)-*N*-Benzylphenylalanine was obtained in 59% isolated yield and 38% ee.

In conclusion, Rh(I) complexes represent efficient homogeneous catalysts for reductive amination of aldehydes and ketones. The successful employment of chelating phosphorus ligands for this reaction opens up a broad field of modifications, whereby asymmetric reductive amination is one of the most challenging goals.

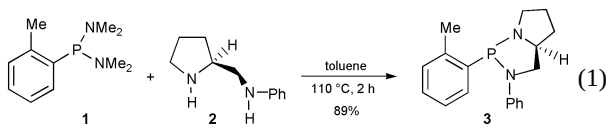
The synthesis and characterization of a new active P*-active phosphapalladacycle and its successful use in the asymmetric hydroarylation of norbornene with turnover numbers (TONs) of up to 10^{10} is described.

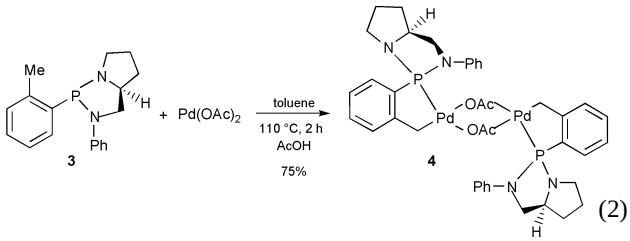
C–C coupling reactions using numerous transition metals are of fundamental interest in modern synthetic chemistry.[1] Thus, the arylation and vinylation of olefins catalyzed by Pd complexes (Heck reaction) has been extensively studied to achieve industrial scale technical application during the last decade.[2] In this area, Herrmann *et al.* discovered in 1995 highly efficient palladacycle catalysts in Heck and related reactions of aryl halides with catalyst turnover numbers (TONs)[3] up to 500 000.[4,5] On the other hand, because of the excellent control of regio- and stereo-selectivity in Heck reactions, intra- and inter-molecular asymmetric variations were developed.[6] Nevertheless, all of the results reported in the literature suffer from insufficient catalyst turnover frequencies (TOF < 10 h^{-1} and TON < 100) and are limited in the use of aryl triflates and aryl iodides as arylating agents.[7] Thus, few syntheses of chiral palladacycle catalysts have been envisioned and all these attempts failed.[8] To our knowledge, only Dunina *et al.* have successfully reported the synthesis of an optically active P*-chiral phosphapalladacycle *via* resolution of diastereomeric (*S*)-prolinate derivatives of the racemic dimer.[9] In the context of our studies, we have recently described the potentialities of oxaza- and diazaphospholidine ligands in various catalytic enantioselective reactions[10] as well as the synthesis of a new class of highly efficient new phosphapalladacycle catalysts for hydroarylation of norbornene with TON levels > 10^{10}.[14] Here, we report the synthesis and use of a new chiral phosphapalladacycle catalyst, as well as the isolation of an intermediate palladium complex involved in the hydroarylation of norbornene.

The synthesis of the chiral *o*-tolyldiazaphospholidine ligand **3** was readily achieved in 89% yield by an exchange reaction in refluxing toluene from bis(dimethylamino)(*o*-tolyl)phosphine **1** and (*S*)-anilinomethylpyrrolidine **2** (readily obtained from L-glutamic acid) [eqn. (1)].[15] The structure of this ligand was

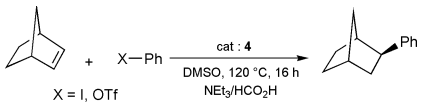


unambiguously established by ^{1}H, ^{13}C, ^{31}P NMR spectroscopy and also by X-ray structure analysis (Fig. SI 1, ESI†).[16]

Treatment of palladium(II) acetate with ligand **3** in refluxing toluene afforded the expected phosphapalladacycle complex **4** in 75% yield as a thermally, air and moisture stable yellow solid [eqn. (2)]. The structure of this cyclometallated compound,



resulting from simple C–H activation of *ortho*-methyl group in the aryl phosphine part, was established by NMR spectroscopy and elemental analysis. However, all attempts to crystallize this phosphapalladacycle complex have so far failed. This phosphapalladacycle catalyst mediates arylation of norbornene under reductive conditions (NEt_3/HCO_2H) [eqn. (3)] and the reactions



of phenyl triflate or iodobenzene with norbornene affording the corresponding *exo*-phenylnorbornane were investigated (ESI†).[17,18] Table 1 summarizes the results.

As already observed using achiral catalysts, an extraordinary high activity of complex **4** was observed at 120 °C in DMSO.[14] Consequently, exceptional turnover numbers up to 1.96×10^8 mol product (mol Pd)$^{-1}$ and yields of 98% were achieved (Table 1, entries 1–4). In addition, turnover frequencies up to 1.6×10^7 mol product (mol Pd h)$^{-1}$ were encountered. To our knowledge, these values are the highest TOF reported to date for palladium catalysis involving chiral palladacycle complexes. On the other hand, whatever the experimental conditions, low enantiomeric excesses (ee) up to 25% using phenyl triflate as arylating agent were observed (Table 1, entry 5). Nevertheless, these results constitute the first example of the use of an active chiral P*-phosphapalladacycle catalyst in an enantioselective hydroarylation reaction.

In the course of our investigations on the mechanism (Scheme 1) of this reaction,[19] we were able to isolate an intermediate Pd(IV) complex **5** which was fully characterized by X-ray structure analysis (Fig. 1).[16,20] Isolation of this inter-

mediate suggests a mechanism for the Heck reaction involving Pd^{II}–Pd^{IV} species and suggests that the first step of the catalytic cycle is oxidative addition of a haloarene to a palladium(II) compound to form a palladium(IV) species. In the next step, an alkene molecule is coordinated and inserts into the Pd–Ar bond. The insertion process occurs *via* a four-centered transition state which requires a planar assembly of the alkene and Pd–Ar bond. Hence, insertion proceeds in a *syn* manner to generate a σ-alkylpalladium complex. The formate anion reacts subsequently with the intermediate **7** producing the norbornyl palladium formate **8** from which *exo*-phenylnorbornane **9** is generated through decarboxylation and Pd(II) deinsertion.

In conclusion, we have described the synthesis of a new active P*-chiral phosphapalladacycle and its successful use in the asymmetric hydroarylation of norbornene, with TON up to 10^{10}. On the other hand, although the enantiomeric excesses are low (up to 25% ee) they constitute, to our knowledge, the first results in asymmetric catalysis using a chiral phosphapalladacycle catalyst. Further studies relating to structural modification of the chiral ligand are now underway and will be reported in due course.

20 It is noteworthy that the P, C and O atoms around the Pd center adopt a distorted tetrahedral arrangement with bond angles between 84.0 and 138.4°. The complexation of Pd occurs with retention of configuration at the P atom. The shortness of the P–N3 bond (1.662 *cf.* 1.701 Å in the free phosphine **3**) and of the P–N4 bond (1.662 *cf.* 1.73 Å) may be assigned to negative hyperconjugation due to electron donation from π_N to σ^*_{P-Pd} orbitals. Carbon nanofibers with a mean diameter of about 50 nm were successfully used as support for a palladium catalyst in the liquid phase selective hydrogenation of the C=C bond in an α,β-unsaturated molecule: a less critical problem of mass-transfer limitation led to the obtention of a highly active and chemo-selective catalyst compared to a commercial high surface area activated charcoal supported palladium catalyst.

Since their discovery at the beginning of the last decade,[1] carbon nanotubes and nanofibers seemed to be promising candidates for use as catalyst supports for heterogeneous catalytic reactions.[2–4] Such materials were expected to be efficient in liquid phase media due to their high external surfaces which can allow a significant decrease in critical mass transfer limitations,[5,6] also leading to an increase in the rate and the selectivity of the reactions.[7–10]

The aim of the present communication is to report the preparation of a highly dispersed palladium catalyst supported on carbon nanofibers, which is active and chemo-selective in the liquid phase hydrogenation of the C=C bond of cinnamaldehyde, at atmospheric pressure. The reaction rate and the product distribution are compared with those obtained on a commercially available activated charcoal supported palladium catalyst under the same reaction conditions.

The carbon nanofibers (CNF) were synthesized by a gas phase catalytic decomposition of a mixture of ethane and hydrogen over a high surface area alumina supported nickel catalyst at 650 °C. This nickel catalyst was prepared by incipient wetness impregnation of an alumina support with an aqueous solution of nickel nitrate containing 20 vol% of glycerol as viscous agent. After synthesis and sonication the carbon nanofibers were subsequently purified by acid treatment at 80 °C for 2 h in order to dissolve any residual nickel catalyst that they might have contained. The carbon nanofibers had a mean diameter of around 50 nm and lengths up to several micrometers and they were built with graphene planes in a herringbone pattern, sometimes connected in the middle of the fiber, forming a closed angle of about 75°. The distance between the planes was found to be 0.34 ± 0.01 nm.

The palladium deposition (5 wt%) onto the support was achieved by incipient wetness impregnation with an aqueous solution of palladium nitrate. The solid was dried overnight at 110 °C and subsequently reduced under flowing hydrogen at 350 °C for 2 h. Transmission Electron Microscopy (TEM) images evidenced the high and homogeneous dispersion of spheroidal palladium metal particles, with a narrow particle size distribution centered at around 3–5 nm diameter (Fig. 1). This homogeneous dispersion was attributed to a relatively strong metal-support interaction between the metal salt precursor and the graphite edges of the carbon nanofibers, increasing the resistance to the growth of the palladium particle. A similar observation has also been reported by Baker and co-workers[2–4] for graphite nanofibers supported on a nickel catalyst. However the distribution profile of the metal particles was relatively broad, ranging in size from 1.5 to 43.5 nm, with an average size of the metal particles of *ca.* 7–10 nm.

The hydrogenation of cinnamaldehyde was carried out at atmospheric pressure and low temperature, *i.e.* < 100 °C, with bubbling hydrogen. For the test, 10 ml of cinnamaldehyde (Athos, > 99.95 vol%) were dissolved in 40 ml of dioxane (RP, > 99.95 vol%). The catalyst (loading 1.05×10^{-3} g Pd) was added to the liquid under vigorous stirring (400 rpm) and subsequently, the reaction temperature was increased from rt to 80 °C, under continuous hydrogen bubbling through the liquid phase. The cinnamaldehyde concentration and the product distribution were followed by gas chromatography analysis (PONA capillary column equipped with a FID detector) of microsamples periodically withdrawn, and diluted with dioxane.

The catalytic results obtained over the Pd supported on carbon nanofibers and the commercial catalyst (Aldrich), are reported in Figs. 2 and 3. The superiority in terms of reaction rate of the nanofiber based catalyst was clear when the slopes of disappearance of CALD were compared. This performance was quite surprising as the literature reports that a relatively low surface area (45 m^2 g^{-1} instead of 900 m^2 g^{-1} for the

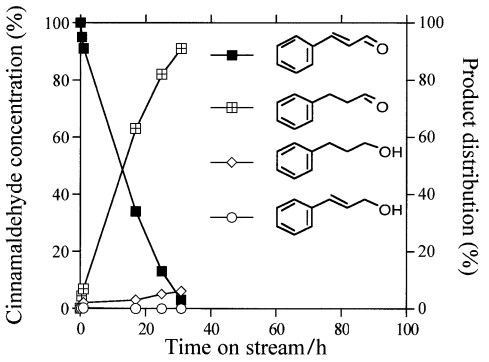

Fig. 2 Cinnamaldehyde conversion and product distribution as a function of time on stream obtained at 80 °C over the carbon nanofibers supported palladium catalyst. Cinnamaldehyde = CALD, cinnamyl alcohol = CALH, hydrocinnamaldehyde = HCALD and 3-phenylpropanol = PP.

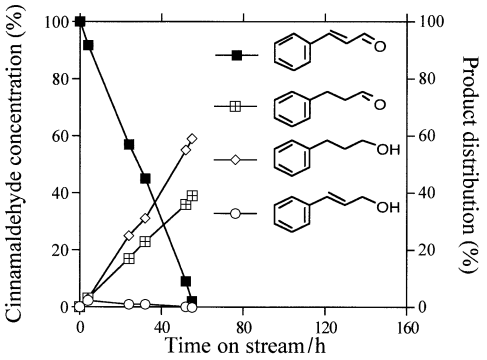

Fig. 3 Cinnamaldehyde conversion and product distribution as a function of time on stream obtained at 80 °C over the commercial activated charcoal supported palladium catalyst.

commercial catalyst) creates a major drawback for such an application.[4,11–13] Such behaviour is comparable to the results reported by Baker *et al.* over graphite nanofiber and alumina supported nickel catalysts.[4] This high catalytic activity was attributed to the high external surface area (high surface-to-volume ratio) of the carbon nanofibers compared to the charcoal grains (grains size *ca.* 50–100 μm) which improves the mass transfer during the reaction. In addition, the presence of a large amount of micropores (> 60% of the total surface area) in the commercial catalyst can be at the origin of diffusion phenomena, slowing down the apparent rate of the reaction. The total absence of microporosity in the nanofibers avoided such a drawback.

It is worth noting that only hydrocinnamaldehyde (HCALD) was detected and only trace amounts of C=O hydrogenated products (CALH or PP) were found over the carbon nanofiber catalyst, thus demonstrating a high selectivity for the C=C bond hydrogenation (98%), while a mixture of dihydrocinnamaldehyde (HCALD), cinnamyl alcohol (CALH) and 3-phenylpropanol (PP) was observed on the commercial catalyst (Fig. 3) and for related catalysts.[14–17] This could be explained both by the presence of microporosity and by some residual acidity on the activated charcoal surface which could favour the hydrogenation of the C=O bond in a consecutive reaction pathway.[4,14]

In conclusion, carbon nanofibers (mean diameter at *ca.* 50 nm) can be efficiently used as a catalyst support, for liquid phase reactions. The high external surface area of the catalyst inhibits the mass transfer limitation of the reactant to the active sites and leads to the obtention of an active and chemo-selective catalyst. Such performances can open routes for the design of new catalysts for liquid phase heterogeneous catalysis, and particularly for enantioselective allylic substitutions or ketone reductions.

Growth of ultrafine zeolite Y crystals on metakaolin microspheres

Mingcan Xu, Mojie Cheng and Xinhe Bao*

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian 116023, P.R. China. E-mail: xhbao@ms.dicp.ac.cn

Received (in Cambridge, UK) 18th July 2000, Accepted 17th August 2000
First published as an Advance Article on the web 18th September 2000

Ultrafine zeolite Y crystals (*ca.* 100–200 nm) have been successfully grown on metakaolin microspheres (< 100 μm) for which good hydrothermal stability was observed; products were characterized by powder X-ray diffraction, scanning electronic microscopy and transmission electronic microscopy.

Zeolite Y is the most widely used catalyst in petroleum cracking and reforming processes.[1] In order to increase the yield of diesel oil in FCC (fluid catalytic cracking), improve the catalytic selectivity and reduce coke formation,[2,3] fine and even ultrafine zeolite Y crystals are desirable. Although ultrafine zeolite Y crystals have been synthesized in the laboratory,[4,5] there are still two key problems remaining. One is the difficulty of production in large quantities for industry since separation of ultrafine crystals by centrifugation is not viable on such a scale. The other drawback of such crystals is their low hydrothermal stability.[5,6] *in situ* Crystallization of ultrafine zeolite Y on supports may solve these problems. In an early report zeolite Y was crystallized on shaped kaolin pellets.[7] Here, we report a method to grow ultrafine zeolite Y crystals on metakaolin microspheres. At the same time, better hydrothermal stability of the ultrafine crystals was observed after growth on the support.

The synthesis was performed under hydrothermal conditions. Initially, a clear aqueous solution with composition (molar ratio) of 16 : 16 : 283 : 1 (SiO_2 : Na_2O : H_2O : Al_2O_3) was prepared upon addition of NaOH, $Al_2(SO_4)_3 \cdot 18H_2O$ and deionized water to silica sol (30%). This solution was aged for 3 days at room temperature. Uniform metakaolin microspheres (GSS600) of *ca.* 40–100 μm diameter were prepared by flotation with deionized water from kaolin microspheres (GSS), and then calcined at 600 °C for 3 h. 2.8 g sodium citrate was then added to the above aged solution and stirred for 2 h until dissolution was complete. Then, 6 g GSS600 was added under strong stirring. After 6 h, aqueous sulfuric acid was added dropwise with agitation leading to a gel mixture with final composition (molar ratio) 1 : 16 : 7.8 : 400 (Al_2O_3 : SiO_2 : Na_2O : H_2O) excluding the kaolin microspheres. Finally the mixture was maintained at 100 °C for 10 h. Two products were separated by flotation, which were filtered off and washed. One product (KYAOLIN) consisted of spherical particles with a similar diameter as the kaolin microspheres while the other product (NNY) was a fine white powder. Both were dried at 120 °C.

The powder X-ray diffraction (XRD) pattern [Fig. 1(a)] of NNY is typical for zeolite Y, and no peaks from any other crystalline substances were present. Clearly NNY consists of zeolite Y crystals that did not grow on the metakaolin microspheres. This result suggests that zeolite Y is the only crystalline product present in this synthesis system. Fig. 1(b) shows the XRD pattern of GSS600; besides peaks attributed to mica and quartz impurities, only a broad background, characteristic of amorphous material, was observed. Kaolin-type clay is essentially an aggregation of book-shaped units of the clay mineral kaolinite.[8] Upon calcination at 600 °C GSS600 transformed into metakaolin[9] and all the kaolinite peaks disappeared. Fig. 1(c) shows the XRD pattern of KYAOLIN, which reveals a clear XRD pattern of zeolite Y above the background of the metakaolin microspheres (GSS600); no other crystalline peaks were identified. The above analysis of the XRD patterns undoubtedly indicates that zeolite Y crystals were synthesized on the metakaolin microspheres.

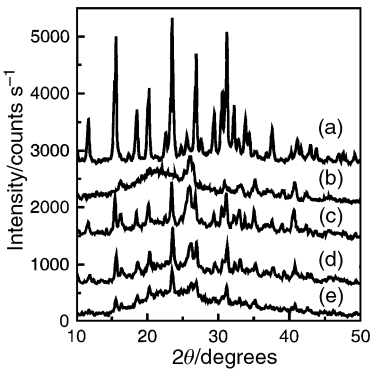

Fig. 1 XRD patterns of NNY (a), GSS600 (b), KYAOLIN (c), hydrothermally treated KYAOLIN (HKYAOLIN) (d) and hydrothermally treated NNY (HNNY) (e) obtained on a Rigaku D/MAX-γb diffractometer using Cu-Kα radiation.

On the surface of GSS600 [Fig. 2(a)], only irregular flakes can been seen. In comparison to GSS600, scanning electronic microscopy (SEM) of KYAOLIN [Fig. 2(b)] revealed many closely packed cubic crystals on the surface of the metakaolin microspheres. Fig. 3 shows a transmission electronic microscopy (TEM) image of a KYAOLIN section. The region shown

DOI: 10.1039/b005787h

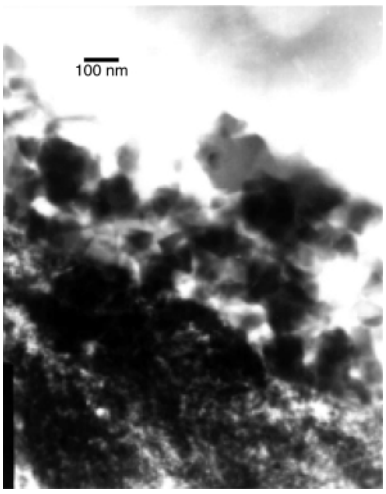

Fig. 3 TEM picture of a section (40–70 nm thickness) of KYAOLIN obtained on a JEM-2000EX, 100 kV instrument.

is part of a metakaolin microsphere section and was found to be homogeneous. A layer of cubic crystals, distinctly different from the metakaolin microspheres, were spread along the surface of the metakaolin microspheres. It is also observed that the crystals with sizes in the range 100–200 nm grow out of the metakaolin microspheres. The electronic microscope images and the XRD patterns unequivocally show that ultrafine zeolite Y crystals are grown on metakaolin microspheres.

HKYAOLIN [Fig. 1(d)] and HNNY [Fig. 1(e)] are, respectively, the products KYAOLIN and NNY treated with 100% water vapour at 650 °C for 2 h. In the XRD pattern of HKYAOLIN, clear peaks from the zeolite Y crystals are still present. Compared with KYAOLIN [Fig. 1(c)], the corresponding peaks from zeolite Y crystals in HKYAOLIN are somewhat broadened and reduced in intensity. This indicates that the crystalline structure of zeolite Y crystals grown on metakaolin microspheres are degraded to some extent during the hydrothermal treatment. As seen in Fig. 1(e), the intensities of peaks from zeolite Y crystals in HNNY are much weaker than those of the product NNY [Fig. 1(a)], and some amorphous substance was evident, *i.e.* during the hydrothermal treatment, the crystalline structure of the zeolite Y crystals is largely destroyed and changed into amorphous materials. The difference in decrease of the relative intensity of the HKYAOLIN and HNNY demonstrates that the hydrothermal stability of the ultrafine zeolite crystals is improved after growth on the metakaolin microspheres. The reasons for this improved hydrothermal stability upon growth on metakaolin spheres are, as yet, unclear, and require further investigation.

All the information obtained from XRD patterns, SEM and TEM images demonstrates that ultrafine zeolite Y crystals have been successfully grown on metakaolin microspheres and that they show good hydrothermal stability. The ultrafine zeolite Y crystals grown on metakaolin microspheres may have potential use in FCC processes.

First published as an Advance Article on the web 18th September 2000

Electrical current was flowed through indium oxide/tin oxide nanoparticles to create highly active catalysts for selective oxidation of methanol to H_2 and CO_2 with low concentrations of CO.

A new type of catalyst and catalyst activation procedure is presented for selective oxidation of methanol to H_2 and CO_2 at low temperatures. This catalyst is of interest as a way to use liquid methanol as a source of H_2 for fuel cells.[1–3] The catalyst was activated by passing electrical current through it while gas phase reactions took place.[4] The catalyst consists of a mixture of 90% In_2O_3 and 10% SnO_2 and will be referred to as indium tin oxide (ITO).

To prepare the catalyst, a mixed chloride was precipitated from an aqueous solution by adding NH_3(aq). The precipitate was filtered off, washed, and then calcined at 723 K. A mixture of 75% ITO (BET surface area 15.7 $m^2\ g^{-1}$) and 25% Al_2O_3 (surface area 61.7 $m^2\ g^{-1}$) nanoparticles was formed by milling the two powders together. The nanoparticles were deposited from a suspension onto porous (0.2–0.3 mm pores) honeycomb Al_2O_3 structures (3.8 × 1.3 × 0.6 cm). The two ends of the honeycomb were coated with a conductive paste, before the catalyst was deposited, so that electrical connections could be made. The honeycomb was placed in a circuit with a constant-current dc power supply. The deposited catalyst was reduced in 5–20% H_2 at 575 K; this lowered the resistance and changed the catalyst color to light blue. A chromel–alumel thermocouple (0.2 mm diameter) was inserted into a honeycomb pore near the center to record the temperature during reaction. The product and feed streams were analyzed by gas chromatography. The mass balances were checked by calculating the H/C and O/C atomic ratios for the products. Typical average deviation from the feed ratios were 5% for the H/C ratio and 9% for the O/C ratio.

Results presented here were obtained on several honeycomb structures. Methanol oxidation was carried out in three ways.

(1) The catalyst temperature was raised by thermally heating it with a small ceramic heating element directly attached to the honeycomb. No current passed through the catalyst.
(2) Electric current was passed through the catalyst, and ohmic heating raised the catalyst temperature.
(3) After the catalyst was used for reaction with the electrical current, the current was decreased to zero. The catalyst temperature was then increased using the attached ceramic heating element.

Fig. 1 shows the methanol conversion and selectivity for H_2 formation as a function of temperature during oxidation over an ITO catalyst honeycomb for the first two types of experiments. The selectivity for H_2 was defined as the molar ratio: $H_2/(H_2 + H_2O + CH_2O)$. These experiments used a 20% O_2/80% He gas feed and a $MeOH/O_2$ feed ratio of 1.3. When the reduced catalyst was heated by the ceramic heater alone, the reaction products were only detected above 473 K, and the same rates and selectivities were obtained when raising or lowering the temperature. The main products were H_2, CO_2, and H_2O. As the temperature increased, the rate of H_2 formation and the selectivity to H_2 both increased.

As shown in Fig. 1, the catalyst was much more active at a given temperature when an electrical current was passed through it.[4] At 373 K, methanol conversion was > 5%, and by 473 K, methanol conversion was 80%. The H_2 selectivity increased with temperature as the conversion increased, so that the rate of H_2 formation increased dramatically above 425 K. The H_2 production rate was higher at all temperatures with electrical current through the catalyst than for the thermally heated catalyst. At 525 K, the rate of H_2 production was 50 times higher than seen with thermal heating. As with thermal heating, H_2, CO_2 and H_2O were the main products. Only slightly more than 1% of the products were CO at 532 K, and a much smaller percentage were CH_2O. The percentage of H_2 in the reactor effluent at 500 K was 17.5% on a wet basis; the current was 0.15 A and the voltage was 95 V dc.

A turnover frequency (TOF, the number of molecules reacting per surface site per second) was estimated using the BET surface area of the ITO powder. At 450 K, where the conversion was *ca.* 50%, the TOF was 0.15 s^{-1}. Since the reaction was run for 30–60 min or longer at each temperature, this TOF shows that each site reacted with a large number of methanol molecules without deactivation.

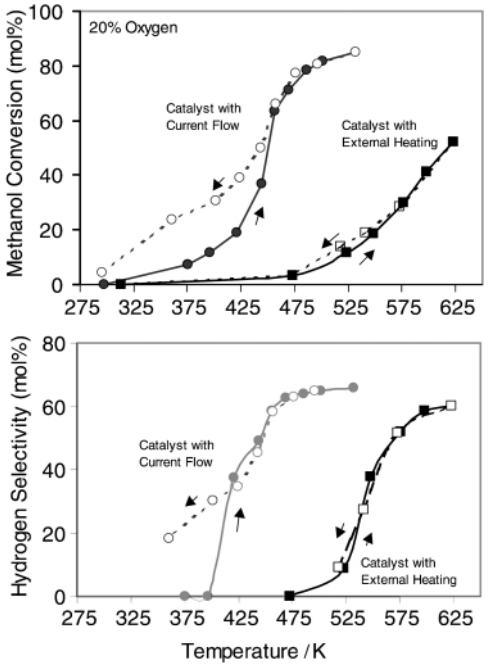

Fig. 1 (a) Percent methanol conversion and (b) selectivity [$H_2/(H_2 + H_2O + CH_2O)$] for H_2 formation *vs.* temperature for oxidation of methanol on an indium oxide/tin oxide catalyst. The results for thermal heating were obtained as the catalyst temperature was increased (—, ■) and decreased (-----, □). The results when an electrical current flowed through the catalyst were obtained as the current (and temperature) was increased (—, ●) and decreased (-----, ○).

DOI: 10.1039/b003920i

After the catalyst temperature had reached 525 K, the current was decreased in increments, and steady state measurements were made at several temperatures. Interestingly, the catalyst was more active at a given temperature during these measurements than when the current increased. That is, after the catalyst was exposed to the reaction mixture at 525 K with electrical current, it was more active at lower temperatures.

When 60% O_2/40% He was used as the gas feed instead of 20% O_2/80% He, the selectivity to H_2 was lower. After the catalyst had been exposed to the reaction mixture at 625 K with the electrical current, it was active for methanol oxidation even at 360 K with the current turned off. The percentage of H_2 in the reactor effluent was 12% on a wet basis with zero power. The reaction was reproducible and stable for at least 48 h, suggesting that this is not a transient artifact. When the electrically activated catalyst was heated thermally, it was much more active than when the original catalyst was heated thermally. Moreover, as shown in Fig. 2, the methanol conversion at low temperatures was higher for the activated catalyst (heated thermally) than for the catalyst with current flow. The selectivity to H_2 formation (Fig. 2) was higher at all temperatures after the catalyst had been activated by electrical current.

The products from electrically activated ITO catalysts were predominantly H_2, H_2O and CO_2. On 1% Pd/ZnO, Cubeiro and Fierro[5] reported selective oxidation of methanol to H_2 and CO_2 at 503–543 K, though more than 20% of their product was CO. On $Cu_{40}Zn_{55}Al_5$ catalysts, Alejo *et al.*[6] reported selective H_2 formation and low CO formation for MeOH oxidation near 500 K, but the O_2/MeOH feed ratio was only 0.06, so conversions were 20% or lower.

Previous studies have used electrical current to activate heterogeneous catalysts, but the present process is quite different. In the previous studies, a voltage applied across a solid electrolyte caused reversible increases in catalytic activity and dramatic changes in selectivity of metals supported on the electrolyte. These results have been explained using the non-Faradaic electrochemical modification of catalytic activity (NEMCA) effect.[7] For oxidation reactions, the rate increased by up to a factor of about 100 when an electrical current was applied. For most systems, NEMCA was attributed to electrochemically controlled back spillover of oxygen from a solid electrolyte such as yttrium-stabilized zirconia, and the rate enhancement depended dramatically whether the voltage was positive or negative. When the current was turned off, the NEMCA effect disappeared. The mechanism on the ITO catalyst appears to be quite different from the NEMCA effect for several reasons: (1) reversing the electrical leads to the catalyst did not change the reaction kinetics or selectivity, (2) when the current was shut off, the ITO catalyst was still active, and (3) reaction takes place on the ITO semiconductor oxide deposited on a porous insulating substrate and not on a metal deposited onto a solid ion conducting electrolyte.

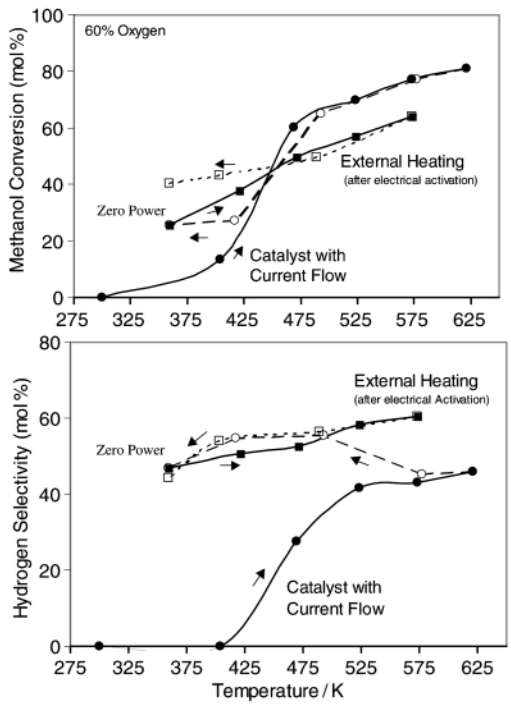

Fig. 2 (a) Percentage methanol conversion and (b) selectivity [$H_2/(H_2 + H_2O + CH_2O)$] for H_2 formation *vs.* temperature for oxidation of methanol in 60% O_2 on an indium oxide/tin oxide catalyst. The results were obtained when the current through the catalyst was increased (—, ●) and decreased (-----, ○). The point where the power was turned off is indicated. After the current was shut off, the catalyst temperature was raised thermally (—, ■) and then decreased again (-----, ○).

X-Ray photoelectron spectroscopy analysis was carried out on samples before and after reduction and after electrical activation in the methanol/air mixture. A reduced sample that was reacted in the methanol/air mixture at elevated temperature was also analyzed. A Physical Electronics Quantum 2000-1 system was used with electron and ion guns for charge neutralization. The reduced sample and the electrically activated sample had surface compositions that were 85–90% In and 10–15% Sn, and the sample reacted without electrical activation was 95% In. The bulk composition of the catalyst was 90% In, so surface enrichment does not appear to be responsible for the enhanced activity of the electrically activated catalyst. Small binding energy shifts (0.6 eV) toward more reduced states were observed for the indium peak on two out of three locations on the electrically activated catalyst, but the peak shifts could not be unambiguously assigned. Thus, the electrically activated catalyst may be reduced more than the H_2 pretreated catalyst.

The enhanced rate on the electrically activated catalyst could perhaps be due to reaction on local regions of the catalyst that were hotter than the temperature measured by the thermocouple. While we did not observe any hot spots on the visible external surfaces of the catalyst, such hot spots may exist internally. Alternatively, at contact points of the catalytic particles, the grain boundaries may be hot because of the ohmic heating. Given the nanostructured form of the catalysts, these microscopic hot spots may be localized. As shown in Fig. 1, the temperature to obtain 50% conversion is 200 K lower for the catalyst with current flow. If only a fraction of the catalyst is at a higher temperature than the average, then the temperature difference would have to be more than 200 K to yield the same conversion as when the entire catalyst was 200 K hotter. Since the ITO catalyst is expected to be a good thermal conductor (*e.g.* SnO_2 has a thermal conductivity similar to graphite) such large temperature differences over the short distances between particle contact points seems unlikely. Moreover, localized heating cannot explain why the conversion and selectivity are lower on raising the current than on lowering the current. Nor would localized heating explain why the catalyst was active when the current was off after electrical activation.

More extensive studies are necessary to determine the reasons for the enhanced activity, low carbon monoxide concentration in product gas, and other unusual effects observed when current is passed through the catalyst. The method of using electrical current to activate heterogeneous catalysts may be broadly useful to many other chemical reactions. In preliminary studies we have observed electrically activated ITO to catalyze methane reforming and the remediation of toluene and acetone.

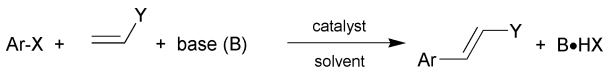
The application of the new cyclopalladated imine complexes of the Milstein-type 1d, 2a and 2b and the immobilised derivative 2c in the Heck reaction has provided evidence that these complexes are unstable and the active species is metallic palladium.

The palladium-catalysed reaction of organic halides with alkenes (the Heck reaction, Scheme 1) is a well-established method for carbon–carbon bond formation.[1] The reaction is usually carried out homogeneously in the presence of phosphine ligands and a base.



Scheme 1 The Heck reaction.

The need for relatively large amounts of catalyst and the early precipitation of palladium black are severe limitations that have so far prevented widespread industrial application of the Heck reaction. However, thermally robust cyclopalladated complexes offer a way to overcome these stability limitations. Specifically, in addition to the numerous examples that are based on palladated phosphines,[2] the cyclopalladated imine complexes **1a–c** were recently described.[3] Contrary to the ubiquitous application of palladium phosphine complexes as catalysts for the Heck reaction, the use of nitrogen-based catalysts is still very rare. However, these cyclopalladated imines form thermally and air-stable catalysts with high activities (turnover numbers {TON} $> 10^6$ were achieved).

In order to improve the recyclability, and thereby the applicability, of these highly active cyclopalladated imine catalysts, we attempted to immobilise one of these complexes. Among the numerous attempts to immobilise Pd catalysts on various supports,[4] there is only one example of an immobilisation *via* nitrogen-based tethers.[5] To avoid problems arising from the dimeric nature of catalysts **1a–c**, we utilised $Pd(hfac)_2$ instead of $Pd(OAc)_2$ as the source of Pd(II). The monomeric nature of cyclopalladated phosphine complexes bearing acac and hfac counterions has been reported.[2d] To guarantee comparability of results, we also synthesised the homogeneous model complexes **1d**, **2a** and **2b**. All these new palladacycles have been fully characterised.† Additionally, the monomeric nature of **2b** was verified by X-ray analysis (Fig. 1).‡

Utilising commercially available aminomethyl-functionalised polystyrene beads (AMPS, Fluka 81553), the catalyst **2c** was readily prepared in two steps (Scheme 2). A catalyst loading of 0.544 mmol g^{-1} was determined by XRF analysis. The characteristic imine C = N stretch vibration of 1661 cm^{-1} in the IR spectrum for the imine-functionalised support shifted to 1636 cm^{-1} in **2c**. The latter value is in good agreement with that of the homogeneous analogue **2b**.

The catalytic behaviour of the new palladacycles **1d** and **2a–c** was studied in the coupling reaction of iodobenzene with styrene in *N*-methylpyrrolidinone (NMP). *n*-Pr_3N was employed as the base in all experiments. In accordance with the results for **1a–c**, all experiments were performed in air. A

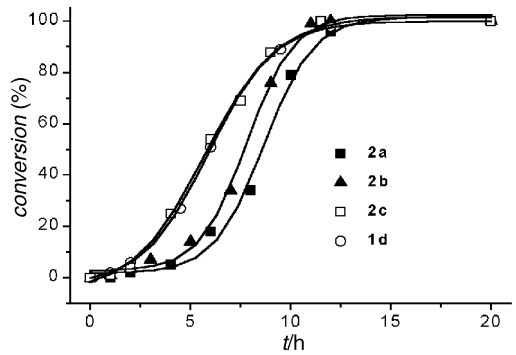

Fig. 2 Plot of conversion *versus* time for the Heck reaction of iodobenzene with styrene for the cyclopalladated catalysts **1d**, **2a–c** at 100 °C.

control experiment under N_2 with otherwise identical conditions showed no difference in catalyst activity. All catalysts were active under the employed conditions and pure stilbene (*trans*/*cis* = 6.8–7.4) was obtained (Table 1).

The immobilised catalyst **2c** showed a level of activity in the first run that is comparable to that of the three homogeneous analogues **1d**, **2a** and **2b** (Table 1, entries 1–3, 8). An increase of the reaction temperature from 100 to 140 °C led, as expected, to a rise of several orders of magnitude in TON (entry 2 *cf.* 4). An intriguing feature, which is exhibited by all the new catalysts in their first catalytic runs, is the presence of an induction period of about one hour (Fig. 2). Hence, the catalytically active species is not identical with the originally employed palladacycle, but is only formed during the course of the reaction. The gradual increase of the reaction rate after the initial induction period is indicative of a steady increase of catalyst concentration over the course of the reaction. Further evidence about the nature of the catalytically active species arises from the observation that the immobilised catalyst **2c**, recovered by filtration from an initial catalytic run at 140 °C (Table 1, entry 5), proved to be completely inactive in a consecutive run (entry 7). Instead, the filtrate of the initial run exhibited an undiminished level of activity upon addition of another equivalent of substrates and base (entry 6). Furthermore, the filtrate catalyses the Heck coupling without the occurrence of an induction period (Fig. 3). Therefore the catalytically active species has to be soluble. The imine ligand of the immobilised palladacycle in **2c** cannot be removed from the polystyrene support due to the firm C–C linkage. Hence, the catalytically active species must be formed under loss of this ligand. The liberation of the catalytic species from **2c** is slowed sufficiently at 100 °C to allow some of the catalyst precursor to remain on the support after the first run. Therefore some activity is maintained for a second, but not a third run. Accordingly, the

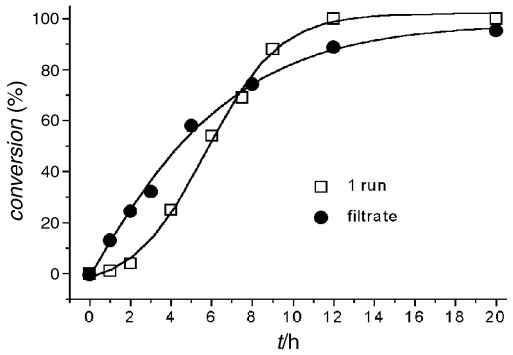

Fig. 3 Plot of conversion *versus* time for the Heck reaction of iodobenzene with styrene for **2c** in the first catalytic run at 100 °C and for the filtrate of the former after addition of a second equivalent of substrates and amine base.

filtrates of both the first and second runs exhibit high levels of activity (entry 8–12).

Contrary to the claim of high thermal stability of the cyclopalladated imine complexes **1a–c**, the catalyst precursors **2a–c** and especially **1d** proved to be thermally labile to such an extent that even moderate heating during the synthesis of these palladacycles caused precipitation of some palladium black. The particularly high lability of **1d** corresponds well with the relatively short induction period found in catalytic runs employing this complex (Fig. 2). The expected rapid decomposition of the palladacycles under the conditions of the Heck reaction was proven by the fact that heating **1d** in NMP to 140 °C for 2 h in the absence of substrates and amine base caused complete degradation under formation of Pd black. In accordance with recent observations by Reetz, who detected catalytically active, $R_4N^+X^-$-stabilised Pd colloids in comparable phosphine-free systems after a similar induction period,[6] we assume that finely divided palladium particles are also the true source of catalytic activity in our system. The stabilising role of $R_4N^+X^-$ may in our system be adopted by the *n*-$Pr_3NH^+I^-$ that is formed in the course of the catalytic cycle. The high activity of the examined cyclopalladated imine catalysts may be ascribed to the formation of Pd(0) nanoparticles in a particularly active form under the applied conditions.

First published as an Advance Article on the web 18th September 2000

A new type of force-field, based on the angular overlap model, has been developed in order to model compounds containing 'non-spherical' ions; the model has been successfully applied to $LaMnO_3$, with the Mn–O bond distances within the distorted MnO_6 octahedra and the lattice parameters being reproduced to within 0.33% of those determined experimentally.

There have been many successes over the last thirty years in the modelling of oxides using simple interatomic potentials based on the ionic model, particularly when ion polarisability is accounted for *via* the shell model.[1–3] Such calculations have typically used potentials comprising a Buckingham term to describe the short-range interaction between two ions along with the Coulomb term (evaluated *via* an Ewald sum) for the long-range interaction. Although potential parameters may be derived theoretically, particularly from fitting to *ab initio* energy surfaces, most have been obtained by empirical fitting to experimental data including structural and physical properties. However, the Coulomb and Buckingham potentials are purely radial, and consequently can only accurately model structures that contain spherical ions, representing a major limitation on the applicability of these methods to transition metal oxides. In order to extend the scope of structural modelling to include topical materials that contain 'non-spherical' (especially Jahn–Teller) ions, for example, manganates and cuprates which require accurate Mn^{3+}–O^{2-} and Cu^{2+}–O^{2-} potentials, we have developed a new short range potential. In this communication, we show that we are now able to model $LaMnO_3$, which contains the Jahn–Teller Mn^{3+}: $3d^4$ cation, which will clearly enable predictive computational chemistry to be applied to the area of colossal magnetoresistance (CMR) research. We expect the same basic method to be applicable in the case of Cu^{2+}: $3d^9$, and thus in the area of high T_c superconductivity.

The driving force for the distortions of the coordination sphere of Mn^{3+} and Cu^{2+} is associated with the Jahn–Teller effect, which removes a degeneracy in the electronic energies. In order to model the irregular coordination geometry associated with these 'non-spherical' ions, we chose to add a contribution to the lattice energy that corresponds to this energy-level splitting. Adding a ligand field stabilisation energy, and implementing numerical gradients, has previously proved[4] successful in the framework of molecular mechanics as applied to gas phase coordination complexes. Our model implements an adaptation of the angular overlap model (AOM).[5] The resulting parameterised interatomic energy term, E_{LF}, and its analytical gradients have been incorporated within the General Utility Lattice Program (GULP),[6,7] which is widely used for modelling ionic solids. One significant feature of our approach was to change the AOM formalism in order to introduce rotational invariance into the model, which is essential for application to energy minimisation studies. Thus, the GULP code creates a 5×5 overlap matrix for each transition metal ion,

$$H_{dd'} = \sum_{\text{ligands}} Ae^{-r/\rho}\Gamma_d\Gamma_{d'} \quad (1)$$

by taking the products of the angular contributions to the overlap integrals, Γ_d,[8] between the transition metal ion d-orbital and the orbitals of any surrounding ligand. A and ρ, which will subsequently be denoted with the subscript LF, are parameters that depend upon the transition metal and the ligand. From the eigenvalues of $H_{dd'}$, we can compute the approximate energy level diagram that results when the orbitals of the surrounding ligands overlap the d-orbitals of the transition metal ion *via* a σ-bonding interaction. In this way, we can calculate E_{LF}, for each transition metal ion, which is simply a weighted sum over these energy levels (eigenvalues). The second important modification of the AOM is the inclusion of an exponential distance dependence, rather than just inclusion of the nearest neighbour ions, such that a ligand that is further away makes a smaller contribution to E_{LF}. Moreover, the use of the exponential provides a way to decrease cut-off discontinuities and removes the need to specify which ligands belong to the first coordination sphere.

The mixing of the orbitals lowers the populated 'ligand' energy levels, creating a more stable environment. To conserve energy, the sum of the energy levels of the d-orbitals must increase. Because we do not explicitly consider the 'ligand' energy levels, the stabilising energy E_{LF} is calculated by summing up the energy levels of the unoccupied d-orbitals; thus, if there are 10 d-electrons there are no unoccupied states and no stabilisation energy. To avoid singularities (for example, when one or two electrons occupy d-orbitals that are three-fold degenerate) we have also allowed partial occupancies (or a non-zero probability that an electron can populate a higher energy state) through the use of a Fermi function. The Fermi energy, E_f, defined to be that which gives the required number of d-electrons, can only be expressed implicitly, and so it is calculated by an iterative method. Because we treat spin-up and spin-down separately, there are two Fermi energies, and E_{LF} for each transition metal ion is therefore a double summation over the weighted energy levels. The 'electronic temperature' of the Fermi function is fixed at room temperature in the present work.

Table 1 Buckingham parameters (B) for the interaction between the cations and the oxygen shells, O_s^{2-}, and the new force field parameters (LF) obtained for the Jahn–Teller interaction between the Mn^{3+} ion and the surrounding oxygen cores, O_c^{2-}. A cut-off radius of 10 Å was used for the cation–anion short-range potentials

To test the applicability of this new approach, we have parameterised a potential model including the AOM description for $LaMnO_3$. This material, which shows a substantial Jahn–Teller distortion of the MnO_6 octahedron, is of importance both for its relevance to CMR and for its use as the cathode material in solid oxide fuel cells. The total lattice energy is the sum of E_{LF} and the energy created by the two-body potential:

$$V = \frac{qq'}{r} + Ae^{-r/\rho} - \frac{C}{r^6} \quad (2)$$

where the first term represents the Coulomb interactions. The remaining terms constitute the Buckingham potential representing the anion–anion and cation–anion short-range interactions. We choose to use formal ionic charges for q and q', although the charge on the transition metal ion may not be quite as high,[9] as this leads to greater transferability. The potential parameters, A_B, ρ_B and C_B, together with A_{LF} and ρ_{LF} used in the formulation of the angular overlap model, may be derived using standard empirical fitting techniques.[6]

Our strategy was to perform a 'relaxed fit', whereby we minimise the square of the differences between the observed[10] and calculated lattice parameters and ionic positions. Initially only the Mn^{3+}–O^{2-} Buckingham parameter A_B was refined whilst we tested a range of trial parameter values (A_{LF} and ρ_{LF}) for our new force field. In these preliminary calculations we used an equivalent exponential dependence for both the Buckingham and 'AOM' interaction between Mn^{3+} and the surrounding O^{2-} ions (*i.e.* $\rho_B = \rho_{LF}$) and the Buckingham parameters for the La^{3+}–O^{2-} interaction were held at the values determined previously.[1] To help find suitable potential parameters, the data used in the least squares fit included the Mn–O bond distances within the MnO_6 octahedron. Once our calculated Mn–O bond distances were reasonable, we refined the cation–anion parameters A_B and ρ_B along with A_{LF} and ρ_{LF}, again using a relaxed fit but with the calculated structure constrained within the experimentally determined *Pnma* space group. To increase the transferability of our potential parameters, we used the O^{2-}–O^{2-} Buckingham parameters[1] that were previously refined to be consistent with a range of binary and ternary oxides.

In Table 1 we report the potential parameters obtained for the best fit to the structural properties of $LaMnO_3$. The structural parameters of $LaMnO_3$ obtained using our new force field are presented in Tables 2 and 3, along with those calculated from previously published force field parameters[2] and the observed values.[10] As shown in Table 3, after minimising the lattice energy, our calculated Mn–O bond distances within the distorted MnO_6 octahedron are within 0.006 Å of those observed, and the tilt of these octahedra is within 0.6° of that observed. Comparison with the bond lengths obtained when the previously published Buckingham potential parameters[2] were used to model $LaMnO_3$ shows quite clearly that that the Mn^{3+} ion cannot be represented as a spherical ion and emphasises the progress made in the present study.

In Table 3, we also present the energy levels and their respective occupancies. With an 'electronic' temperature within the Fermi function set to that of room temperature, we note that there is a small probability (0.007) of an electron being in the highest energy level. The splitting of these energy levels is of the correct order of magnitude (although possibly too small) compared to typical orbital splittings for first row transition metals with weak field ligands, although no constraint was placed on these energies during fitting. As expected, the energies of the three non-bonding t_{2g} orbitals do not change whereas there is a Jahn–Teller splitting ($\sim$0.25 eV) of the anti-bonding e_g energy levels.

To summarise, we have shown that we can model Jahn–Teller distortions within $LaMnO_3$, the parent compound of the manganese perovskites that display CMR. This is the first time that a code primarily based on the inter-atomic potentials has been able to reproduce the Jahn–Teller distortion within this material. Furthermore, we have subsequently shown that our potential parameters are transferable, in that they have been used to reproduce the structure of Mn_2O_3 (with the calculated lattice parameters coming within 0.4% of the experimental value). The basic strategy described above increases the range of compounds that can be modelled using computationally inexpensive methods to include some of the most technologically important inorganic compounds studied in the last twenty years.

We thank EPSRC for financial support (grant GR/K85216).

Selective ammoxidation of isobutane on a crystalline $SbRe_2O_6$ catalyst

Haichao Liu, Takafumi Shido and Yasuhiro Iwasawa*

Department of Chemistry, Graduate School of Science, The University of Tokyo, Hongo-7-3-1, Bunkyo-ku, Tokyo 113-0033, Japan. E-mail: Iwasawa@chem.s.u-tokyo.ac.jp

Received (in Cambridge, UK) 20th July 2000, Accepted 31st August 2000
First published as an Advance Article on the web 18th September 2000

The catalytic ammoxidation of isobutane to methacrylonitrile at 673 K proceeds on a new class of Re mixed-oxide $SbRe_2O_6$ with alternate $(Re_2O_6)^{3-}$ and $(SbO)^+$ layers, where ammonia is prerequisite for the C–H bond scission of isobutane.

Much attention has been devoted to selective ammoxidation of light alkanes from both fundamental and industrial interests. To date, a large number of multicomponent metal-oxide catalysts containing V, Mo, *etc*. have been explored to develop efficient catalytic systems for selective ammoxidation. However, owing to the inertness of light alkanes, very few catalysts have showed good performances that are comparable to those for the corresponding alkenes.[1–4] There is thus a clear need to develop new catalytic materials for the selective ammoxidation of light alkanes. Except for the oxidation of methanol and ethanol, compared with V, Mo and W there are limited uses of Re as a key element in selective ammoxidation/oxidation, in spite of Re having similar redox properties to those of V, Mo and W oxides.[5–7] Here, we report a first Re mixed-oxide catalyst (crystalline $SbRe_2O_6$) active for the selective ammoxidation of isobutane (i-C_4H_{10}) to methacrylonitrile (MAN) at 673 K, where NH_3 not only stabilizes the catalyst but also promotes the C–H bond scission of i-C_4H_{10}.

$SbOReO_4{\cdot}2H_2O$, $SbRe_2O_6$ and $Sb_4Re_2O_{13}$ were synthesized in the similar way to that reported previously.[6–12] The specific surface areas of the three samples were approximately 1 $m^2\ g^{-1}$. For comparison, Sb_2O_3-supported Re_2O_7 catalyst (Re_2O_7/Sb_2O_3; 10 wt% Re) was prepared by an impregnation method using an aqueous solution of NH_4ReO_4.[9] A coprecipitated $SbRe_2O_x$ catalyst (copr.$SbRe_2O_x$) was also prepared by a coprecipitation method using an ethanol solution of $ReCl_3$ and $SbCl_3$, followed by washing with water to eliminate the residual Cl ions from the sample. Ammoxidation reactions were carried out in a continuous-flow, fixed-bed reactor at 673 K under the conditions of 10% i-C_4H_{10}, 15% NH_3 and 25% O_2 balanced with He and a gas-hourly-space-velocity (GHSV) of 5000 h^{-1} at atmospheric pressure. Prior to each run, the catalysts (typically 0.3 g) were pretreated at 673 K under He for 1 h. The reactants and products were analyzed by two on-line gas chromatographs with Unibeads C, Gaskuropack 54 and VZ-10 columns. The conversion of NH_3 to N_2 and NO_x was < 10% under the present reaction conditions.

Table 1 presents the conversions, reaction rates and selectivities of the i-C_4H_{10} ammoxidation on the various Re–Sb–O catalysts and bulk ReO_x and SbO_x at 673 K. $SbOReO_4{\cdot}2H_2O$, $Sb_4Re_2O_{13}$ and Sb oxides such as Sb_2O_3 and Sb_2O_4 showed no activity. Bulk Re_2O_7 was active solely for i-C_4H_{10} combustion to CO_2. Bulk ReO_3 and ReO_2 produced MAN, but the selectivities were lower than 10% and the main product was CO_2. Re_2O_7/Sb_2O_3 or mechanically mixed $Re_2O_7{\cdot}Sb_2O_3$ samples showed almost no activity for the i-C_4H_{10} ammoxidation either. Copr.$SbRe_2O_x$ produced i-C_4H_8 (20.6% selectivity), but no formation of MAN was observed. Isobutane combustion was dominant also with this catalyst. Only the $SbRe_2O_6$ among these samples was active for the ammoxidation of i-C_4H_{10} to MAN. The selectivities to MAN and to the sum of MAN + i-C_4H_8 at the steady-state conversion of 4.4% were 44.9 and 84.3%, respectively. A decrease in the GHSV from 5000 to 2500 h^{-1} increased the conversion to 7.5% while keeping good selectivities to MAN and to MAN + i-C_4H_8, as shown in parentheses in Table 1.

The active $SbRe_2O_6$ compound consists of connected, alternate octahedral $(Re_2O_6)^{3-}$ and $(SbO)^+$ layers and grows as thin plate-like crystals preferably exposing the (100) plane.[12] The square basal (100) faces of $SbRe_2O_6$ crystals remained unchanged before and after the ammoxidation at 673 K as imaged by scanning electron microscopy. Further, neither change nor modification of the surface composition and crystallinity were observed by means of X-ray diffraction, X-ray photoelectron spectroscopy (XPS) and *in-situ* micro confocal laser Raman spectroscopy. The results indicate that the crystalline $SbRe_2O_6$ works as a promising catalyst for the ammoxidation. The fresh $SbOReO_4{\cdot}2H_2O$ and $Sb_4Re_2O_{13}$ possess Re^{7+} species, but the Re species were reduced to two valent states (possibly Re^{6+} and Re^{4+}) which exhibit XPS binding energies of 42.3 and 44.7 eV, and 45.1 and 47.5 eV for Re $4f_{7/2}$ and Re $4f_{5/2}$, respectively (compared to C 1s = 284.6 eV) under the ammoxidation conditions. These binding energies are similar to those for the $SbRe_2O_6$ surface after ammoxidation at 673 K. Thus, the difference in the catalytic performances of the crystalline Re–Sb–O catalysts may not be

[a] The data listed in parentheses were obtained at a GHSV of 2500 h^{-1}.

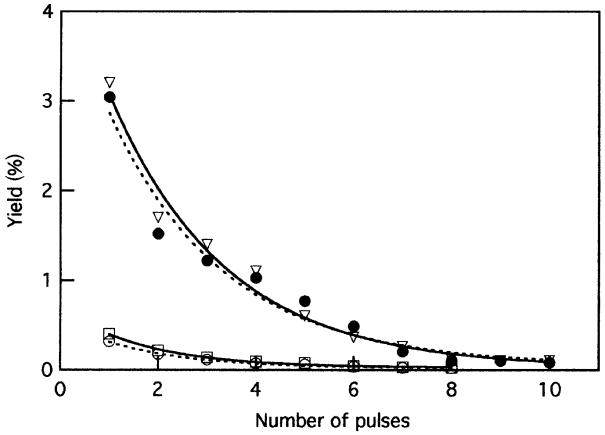

Fig. 1 Yields of MAN (∇, □) and i-C_4H_8 (●, ○) as a function of the number of pulses of i-C_4H_{10} alone (□, ○) and an i-C_4H_{10}–O_2 mixture (∇, ●) on an NH_3-preadsorbed $SbRe_2O_6$ catalyst at 673 K.

due to the difference in their surface Re oxidation states, but to the difference in their surface structures. This is entirely different from the finding in the selective oxidation of i-C_4H_{10} (773 K) and i-C_4H_8 (673 K) to methacrolein (MAL) that the activities of the three crystalline Re–Sb–O compounds are ascribed to a cooperation between Re_2O_7 and $Sb_4Re_2O_{13}$, both being formed by decomposition of the compounds under the oxidation conditions.[8–10] It is also different from the feature observed in the ammoxidation of i-C_4H_8 where the three Re–Sb–O compounds are more or less active at 673 K.[13]

It is to be noted that $SbRe_2O_6$ was inactive for i-C_4H_{10} selective oxidation as well as for the total oxidation at 673 K in the absence of NH_3, whereas it exhibited a good performance for i-C_4H_{10} ammoxidation at 673 K (Table 1). These results may indicate a promoting effect of NH_3 on the C–H activation in i-C_4H_{10}. To examine the role of NH_3, a series of pulse experiments were conducted on $SbRe_2O_6$ at 673 K in Fig. 1. No products were produced by pulsing i-C_4H_{10} alone or an i-C_4H_{10}–O_2 mixture on to the $SbRe_2O_6$ catalyst, which indicates that no C–H bond breaking in i-C_4H_{10} molecules occurs on the catalyst. However, when the catalyst was pretreated with an NH_3 pulse (the catalyst surface was saturated with NH_x), i-C_4H_{10} was converted to MAN and i-C_4H_8. The promotion effect of NH_3 pretreatment on the formation of MAN and i-C_4H_8 was more remarkable with the i-C_4H_{10}–O_2 pulse reaction as shown in Fig. 1. The formation of MAN and i-C_4H_8 decreased with the number of the i-C_4H_{10}–O_2 pulses. The pulse experiments show that adsorbed NH_x species are incorporated to the ammoxidation of i-C_4H_{10} to form MAN. These results demonstrate that NH_3 not only behaves as a reactant but also plays a crucial role in enhancing and/or generating the activity of $SbRe_2O_6$ for the dehydrogenation (C–H bond breaking) of i-C_4H_{10} to i-C_4H_8. Upon pulsing NH_3 on $SbRe_2O_6$, N_2 and H_2O were produced indicating the reaction of NH_3 with the lattice oxygen atoms of $SbRe_2O_6$ to form oxygen vacancies that may also be responsible for the C–H bond breaking. To our knowledge, $SbRe_2O_6$ is the first case where NH_3 changes an inactive catalyst to an active one for light alkane activation, although promoting effects of NH_3 have been documented.[14,15] Further study is necessary for depicting a detailed mechanism of the promoting effect of NH_3 on the $SbRe_2O_6$ selective catalysis.

In conclusion, a new class of Re mixed-oxide $SbRe_2O_6$ catalyzes the selective ammoxidation of i-C_4H_{10} to MAN. The activity of $SbRe_2O_6$ may be relevant partly to its specific crystal structure. The presence of ammonia is considered to be prerequisite, not only for maintaining the stable crystal structure of $SbRe_2O_6$, but also for promoting $SbRe_2O_6$ activity for C–H bond breaking in i-C_4H_{10} under the ammoxidation conditions.

This work has been supported by Core Research for Evolutional Science and Technology (CREST) of the Japan Science and Technology Corporation (JST). The authors acknowledge Professor H. Imoto, Utsunomiya University, for his helpful discussion on the preparation and structure of $SbRe_2O_6$.

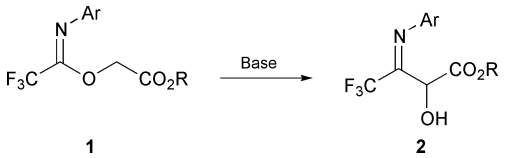
First published as an Advance Article on the web 18th September 2000

***tert*-Butyl 2-(difluoromethyl)-3-benzyl-6-methoxy-3,4-dihydro-4-quinazoline-4-carboxylic ester (4) and its related 6-substituted esters, precursors of a new type of cyclic amino acid, were synthesized *via* intramolecular defluorinative cyclization under basic conditions.**

The recent achievement of the synthesis of fluorinated isoserines[1] *via* Wittig rearrangement of **1** to **2** in Scheme 1, engaged us in exploration on the synthesis of other new heteroatom-substituted amino acids and their derivatives which are expected to be candidates for biologically important inhibitors.[2] Here, we report the discovery of a novel defluorinative cyclization (**3** → **4**) leading to the synthesis of difluoromethylated quinazolic derivatives.

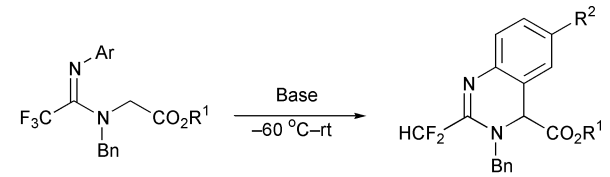


1 **2**

Scheme 1

Difluoromethylated amino acids are known to be important members of the family of fluorinated amino acids.[3] Introduction of difluoromethyl groups into nonfluorinated amino acids[4] or the synthesis of difluoromethyl-substituted amino acids from suitable fluorinated building blocks[5] is a great challenge in synthetic organofluorine chemistry. Selective defluorination from a trifluoromethyl moiety has been widely employed for promising construction of difluoromethylene moiety due to easy availability of trifluoromethyl compounds.[6] The present discovery of defluorinative cyclization of trifluoromethyl-substituted iminoamines **3**[7] provides a novel and efficient approach to the new *N*-heterocyclic *tert*-butyl 2-(difluoromethyl)-3-benzyl-6-methoxy-3,4-dihydro-4-quinazoline-4-carboxylic ester **4**[8] and the related 6-substituted esters (Scheme 2, Table 1), which is otherwise difficult.

The ester **3** was treated with LTMP (1.3 eq.) in THF at −60 °C for 10 min or *n*-BuLi (1.2 eq.) at 0 °C, and then the temperature was raised to 20 °C. The mixture was stirred for several hours (monitored by TLC) or 1 h, respectively.



3 **4**

Ar = 4-MeO-C_6H_4, 4-CH_3-C_6H_4, 3,4-Cl_2-C_6H_3, C_6H_5, Naphthyl

R^1 = *t*-Bu, Me; R^2 = OMe, Me, H.

Base = LTMP or *n*-BuLi LTMP = Lithium tetramethylpiperidide

Scheme 2

A sterically hindered base (LTMP) provided better yield (63%) of **4a** than LDA (47%). In the 3,4-dichloro-substituted iminoamine (entry 7 in Table 1), *n*-BuLi was found to be more useful than LTMP. Both electron-withdrawing and -donating substituents on the aromatic ring affected the formation of **4**. The 2,6-dimethylphenyl compound (entry 9) afforded no corresponding cyclized compound **4** and the starting substrate was recovered.

The quinazolic esters (**4a**–**f**) obtained in the reaction are liquids and their structures were elucidated by spectroscopic and elemental analyses, along with X-ray crystallographic structural analysis of its methyl ester (**4g**),[9] which are colorless needle crystals. Existence of both CHF_2 group and a 1,2,4-trisubstituted benzene ring in **4a** (entry 1 in Table 1, Ar = *p*-methoxyphenyl, R^1 = *t*-Bu) was rationalized by the observation of a doublet at δ = 45.8 ppm (J_{HF} = 53.6 Hz) in ^{19}F NMR (C_6F_6 as an internal standard) and a triplet at δ = 6.33 ppm (J_{HF} = 53.6 Hz) in ^{1}H NMR, and three sets of aromatic protons [δ = 6.52 (d, J = 2.8 Hz), 6.74 (dd, J = 8.7 Hz, 2.8 Hz), and 7.11 ppm (d, J = 8.7 Hz)], respectively.

A mechanism of this reaction is tentatively proposed as shown in Scheme 3.

No Stevens-type rearrangement[9] products **8** were observed although Wittig-type rearrangement is known in fluorinated imino ethers (**1** → **2**).[1] The generation of carbanions **5** by LTMP at lower temperature (−60 °C) was confirmed by the quantitative formation of deuterated product **6** on treating with D_2O. Intramolecular nucleophilic attack of the carbanion onto the imino carbon followed by nucleophilic ring opening of the aziridine type intermediate (**7** → **9**) and simultaneous defluorination would lead to the formation of the quinazoline intermediate **9**, which undergoes base-catalyzed proton migration to the quinazolic products **4**. The rate-determining intramolecular nucleophilic attack *via* intermediate **7** would make the equilibrium (**5** ⇄ **7**) proceed in the forward direction. Thus, the sterically hindered 2,6-dimethyl compound (Table 1, entry 9) was recovered entirely though an α-proton of the carboalkoxy group of **3** (Ar = 2,6-dimethylphenyl) was deuterated by quenching the reaction mixture with D_2O at −60 °C. The preference of path A over path B would arise from the poorer leaving ability of *N*-benzyl anion (Scheme 3) than alkoxide anion in Wittig rearrangement (**1** → **2**).

The authors are grateful to the Ministry of Education, Science, Sports, and Culture of Japan for the financial support

Table 1 Yield of **4** in the base-catalyzed rearrangement of **3**

Entry	Ar	R^1	Base (eq.)	Yield of **4** (%)

Synthesis of quinolines *via* ruthenium-catalysed amine exchange reaction between anilines and trialkylamines

Chan Sik Cho, Byoung Ho Oh, Joon Seok Kim, Tae-Jeong Kim and Sang Chul Shim*

Department of Industrial Chemistry, College of Engineering, Kyungpook National University, Taegu 702-701, Korea. E-mail: scshim@kyungpook.ac.kr

Received (in Cambridge, UK) 24th July 2000, Accepted 25th August 2000
First published as an Advance Article on the web 18th September 2000

Anilines react with an array of trialkylamines in the presence of a catalytic amount of $RuCl_3{\cdot}nH_2O$ and bis(diphenylphosphino)methane together with $SnCl_2{\cdot}2H_2O$ and hex-1-ene as hydrogen acceptor in dioxane at 180 °C to afford the corresponding 2,3-disubstituted quinolines in moderate to good yields.

It is well-known that the quinoline skeleton plays an important role as an intermediate for the design of antimalarial compounds. The structural core of quinolines has generally been synthesised by various conventional named routes such as Skraup, Döbner-von Miller, Conrad-Limpach, Friedlaender and Pfitzinger syntheses. In conjunction with the conventional syntheses, transition metal-catalysed versions utilising various substrates have also been attempted because of facility, efficiency and convenience for the formation of quinolines.[1–4] We recently developed and reported a novel ruthenium-catalysed synthetic approach for the formation of indoles[5] and quinolines[6] *via* a mechanistic amine exchange reaction between primary aromatic amines and functionalised aliphatic amines.[7] However, except for the aforementioned indoles and quinolines, a clear-cut example for the synthesis of N-heterocyclic compounds using the amine exchange reaction seems as yet to be limited to palladium-catalysed synthesis of pyrimidines and imidazoles.[7d] In the course of our continuing studies on ruthenium-catalysed synthesis of N-heterocyclic compounds using the amine exchange reaction, we now report another ruthenium-catalysed synthesis of quinolines from an array of primary aromatic amines and trialkylamines *via* an amine exchange reaction.

The results of several attempted ruthenium-catalysed cyclisations between aniline (**1**) and tripropylamine (**2**) are summarised in Table 1 (Scheme 1). Treatment of **1** with **2** in dioxane in the presence of a catalytic amount of $RuCl_3{\cdot}nH_2O$ (8 mol% based on **2**) and dppm (12 mol% based on **2**) together with $SnCl_2{\cdot}2H_2O$ and hex-1-ene as hydrogen acceptor at 180 °C for 20 h afforded 2-ethyl-3-methylquinoline (**3**) in 63% yield along with *N*-propylaniline (**4**) (28%). This reaction condition was eventually revealed to be the best for obtaining **3** (run 1). The absence of both $SnCl_2{\cdot}2H_2O$ and hex-1-ene stopped the reaction almost completely, but **4** was produced in a considerable yield by an alkyl group transfer between **1** and **2** (run 2). The addition of either $SnCl_2{\cdot}2H_2O$ or hex-1-ene was effective for the formation of quinoline **3** compared with the results in the absence of both $SnCl_2{\cdot}2H_2O$ and hex-1-ene (runs 3,4). Thus, the coexistence of $SnCl_2{\cdot}2H_2O$ and hex-1-ene was essential for the effective formation of **3**. Other hydrogen acceptors such as cyclohexene, hex-1-yne, acetone, and nitrobenzene were almost ineffective for the formation of **3** (runs 5–8).

Table 1 Ruthenium-catalysed reaction of **1** with **2** under various conditions[a]

Run	Hydrogen acceptor	Additive	GLC yield (%)[b] **3**	**4**

Scheme 1 *Reagents and conditions*: i, $RuCl_3{\cdot}nH_2O$, dppm, dioxane, 180 °C, 20 h.

From the heteroannulation between an array of anilines and trialkylamines under the described controlled reaction conditions above, the corresponding quinolines were also formed in good yields, and several representative results are summarised in Table 2.† The quinoline yield was not decisively affected by the position of the substituent on aniline. With chloroaniline having electron-withdrawing Cl substituent, the product yield

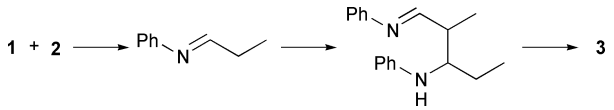
[a] All reactions were carried out with aniline (6 mmol), trialkylamine (1 mmol), $RuCl_3{\bullet}nH_2O$ (0.08 mmol), dppm (0.12 mmol), $SnCl_2{\bullet}sH_2O$ (1 mmol), and hex-1-ene (10 mmol) in dioxane (10 ml) at 180 °C for 20 h. [b] Isolated yield based on trialkylamine.

DOI: 10.1039/b005966h

was lower than that when anilines having electron-donating character were used. However, compared with the cases of anilines having electron-donating character, much more *N*-alkylaniline was produced. This result indicates that the reaction proceeds competitively between heteroannulation and *N*-alkylation and the electronic nature of the substituent on aniline determines relative rate. In the case of *m*-toluidine, the quinolines were obtained as a regioisomeric mixture, favoring predominantly the formation of the 7-substituted isomer.



Scheme 2

Although the details of the present reaction including the role of $SnCl_2{\cdot}2H_2O$ are not fully understood, the initial formation of imines by amine exchange reaction between anilines and trialkylamines seems to be a crucial step. Subsequent steps seem to be followed by the known Schiff-base dimerisation[8] and ruthenium-mediated heteroannulation (Scheme 2).[3c] However, one plausible role of $SnCl_2{\cdot}2H_2O$, as a ruthenium–tin complex formed by the insertion of tin(II) chloride into the ruthenium–chloride bond of $RuCl_3{\cdot}nH_2O$, seems to accelerate the initial amine exchange reaction between anilines and trialkylamines.[9] This can be rationalised by the result of Table 1 (runs 1–4). The statistical sum of **3** and **4** reveals the extent of amine exchange reaction between **1** and **2**.[10] Apparently, as shown in Table 1, the alkyl group transfer was effective for the reaction in the presence of $SnCl_2{\cdot}2H_2O$ (runs 1,3) as compared with the reaction in the absence of $SnCl_2{\cdot}2H_2O$ (runs 2,4).

In summary, we have demonstrated that quinolines can be synthesised by reaction of an array of anilines with easily available trialkylamines in the presence of a ruthenium catalyst. The present heteroannulation is a novel synthetic approach leading to quinolines *via* an amine exchange reaction.

Notes and references

† *General experimental procedure*: a mixture of aniline (6 mmol), trialkylamine (1 mmol), $RuCl_3{\cdot}nH_2O$ (0.08 mmol), dppm (0.12 mmol), hex-1-ene (10 mmol) and $SnCl_2{\cdot}2H_2O$ (1 mmol) in dioxane (10 ml) was placed in a pressure vessel. After the system was flushed with argon, the mixture was stirred at 180 °C for 20 h. The reaction mixture was passed through a short silica gel column ($CHCl_3$), poured into brine, extracted with $CHCl_3$ and dried over anhydrous Na_2SO_4. Removal of the solvent left an oil which was separated by column chromatography (silica gel, ethyl acetate–hexane mixture) to give quinolines.

First published as an Advance Article on the web 18th September 2000

gem-Difluoroolefins bearing homoallylic tosylamido, hydroxy, or mercapto groups undergo intramolecular nucleophilic substitution of the nitrogen, oxygen, or sulfur with loss of fluorine *via* a 5-*endo-trig* process, leading to 2-fluoro-2-pyrrolines, 5-fluoro-2,3-dihydrofurans, or -thiophenes in high yields.

5-*endo-trig* cyclization has long been considered to be a geometrically disfavored process in accord with Baldwin's rules.[1] Efficient examples of the cyclization, however, have been recently devised in radical-initiated[2] and electrophile-driven[3] ring closures. In contrast with these two types of 5-*endo-trig* cyclizations, the corresponding nucleophile-driven ring closure has still rarely been observed in synthetic chemistry.[4,5]

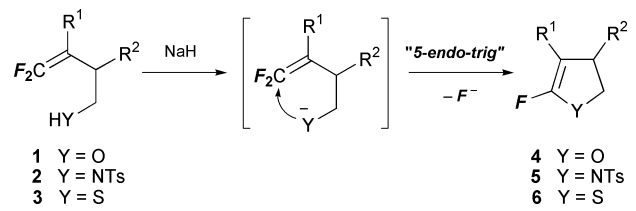
gem-Difluoroolefins possess remarkable reactivity toward nucleophilic substitution for their fluorine atoms *via* addition–elimination processes.[6] As one of its applications, we have recently disclosed that β,β-difluorostyrenes bearing *ortho*-nitrogen, oxygen, or sulfur heteroatoms readily undergo nucleophilic 5-*endo-trig* cyclization to provide ring-fluorinated heteroaromatics: 2-fluorinated indoles, benzo[*b*]furans, and benzo[*b*]thiophenes.[5] Such unique reactivity of *gem*-difluoroolefins is exerted presumably due to (i) the highly polarized C–C double bond (significant single bond character implied by ^{13}C NMR: *ca.* 150 and 90 ppm for CF_2=C), which would allow initial 5-membered ring formation, and (ii) the successive elimination of fluoride ion suppressing the reverse ring opening. In this ring-forming reaction the substrates had a benzene ring as an sp^2-carbon linker between the nucleophilic functional group and the difluoroolefin part.

In order to broaden the scope of this nucleophilic 5-*endo-trig* cyclization and rule out the possibility of an 6π-electrocyclization mechanism, we investigated the reaction of *gem*-difluoroolefins **1**–**3** bearing an *N*-, *O*-, or *S*-functional group which was linked by two sp^3 carbons to the olefinic carbon. Herein we report a facile synthesis of selectively ring-fluorinated pyrroline **5**, dihydrofuran **4**, and dihydrothiophene **6** (Scheme 1), which are difficult to access despite the potential uses of ring-fluorinated heterocycles as components of agrochemicals, pharmaceuticals, and dyestuffs.[7]

gem-Difluoroolefin substrates were designed to bear a nucleophilic nitrogen, oxygen, or sulfur atom at the homoallylic position suitable for substitution in a 5-*endo-trig* fashion. To introduce a functional group (HY) at the *gem*-difluoro-homoallylic position, we tried the regioselective hydroboration of 1,1-difluoro-1,3-dienes **7**, which were readily prepared from 2,2,2-trifluoroethyl toluene-*p*-sulfonate and vinyl halides in a one-pot operation according to our method.[8] The electron-rich, non-fluorinated double bond in **7** might be more reactive toward borane reagents. Treatment of difluorodienes **7** with 9-borabicyclo[3.3.1]nonane (9-BBN) under reflux in THF selectively promoted hydroboration as expected to generate difluorohomoallylboranes, and successive treatment with alkaline aqueous hydrogen peroxide gave *gem*-difluorohomoallyl alcohols **1a**–**c** in good yields (Scheme 2). The corresponding nitrogen- and sulfur-containing substrates **2a**–**e**, **3a**,**b** were easily obtained from **1** as shown in Scheme 2.

The cyclization of homoallyl alcohols **1a**,**b** was attempted by treatment with 1.2 eq. of NaH in several solvents. While the use DMPU or NMP gave no cyclized products, DMF, DMA, or DMSO successfully promoted the 5-*endo-trig* cyclization to afford 5-fluoro-2,3-dihydrofurans **4a**,**b** in good yields (Table 1, Entries 1,2).[9]† KH was less effective than NaH, and high-dilution conditions ([**1a**] = 0.03 mol L^{-1}) raised the yield by 10% compared to the case of [**1a**] = 0.2 mol L^{-1}.

Moreover, we examined the 5-*endo-trig* cyclization of the substrates with *N*-nucleophiles under similar conditions. Whereas *N*-unsubstituted and *N*-butylhomoallylamines **2c**,**d** did not cyclize, the *N*-phenyl substrate **2e** afforded 4-methyl-1-phenyl-3-(3-phenylpropyl)-2-pyrrolidone **8** *via* hydrolysis of



Scheme 1 Nucleophilic 5-*endo-trig* cyclization of *gem*-difluoroolefins **1**–**3**.

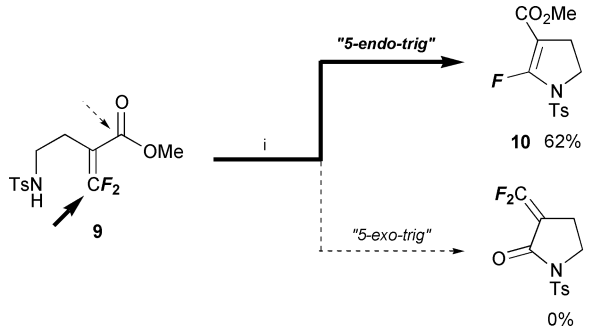
Table 1 Synthesis of ring-fluorinated dihydroheteroaromatics **4**–**6**[a]

Entry	YH	R^1	R^2	Substrate	Base (eq.)	Time	Product	Yield (%)[b]
1	OH	$CH_2CH(Me)Ph$	Me	**1a**[c]	NaH (1.2)	7 h	**4a**[c]	67
2	OH	Bu^n	CH_2Ph	**1b**	NaH (1.2)	11 h	**4b**	62
3	PhNH	$(CH_2)_3Ph$	Me	**2e**	NaH (1.1)	24 h	**8**	62
4	TsNH	$CH_2CH(Me)Ph$	Me	**2b**[c]	NaH (1.1)	4 d	**5**[c]	80
5	SH	$(CH_2)_3Ph$	Me	**3b**	NaH (1.1)	4 h	**6**	76
6	SC(O)Me	$(CH_2)_3Ph$	Me	**3a**	NaOMe (1.0)	8 h	**6**	69

[a] The reaction was conducted in DMF at 90 °C. [Substrate] = 0.02–0.03 mol L^{-1}. [b] Isolated yield. [c] 1:1 Diastereomer mixture.



Scheme 3 Competitive cyclization: 5-*endo-trig vs*. 5-*exo-trig Reagents and conditions*: i, NaH (1.1 eq.), DMF, 100 °C, 0.3 h.

the expected 2-fluoropyrroline (Entry 3). The *N*-4,4-difluorobut-3-enyltoluene-*p*-sulfonamide **2b** underwent the desired ring closure to give 2-fluorinated pyrroline **5** in 80% yield (Entry 4).[10]‡

As a further example of the cyclization, the intramolecular substitution of sulfur nucleophiles (which Baldwin's rules allow for the normally disfavored 5-*endo-trig* process) was also examined.[1b] The reaction of **3b** under similar conditions to those for **1** and **2** provided 5-fluorinated dihydrothiophene **6** in 76% yield (Entry 5).[11] In addition, treatment of thioacetic *S*-acid ester **3a** with sodium methoxide allowed the cyclization *via in situ* generated thiolate to give **6** (Entry 6).§

In order to demonstrate the favored nature of 5-*endo-trig* cyclization in *gem*-difluoroolefins, we tried the competitive reaction between 5-*endo-trig* and 5-*exo-trig* processes. The β,β-difluoro-α,β-unsaturated ester **9** bearing a 2-toluene-*p*-sulfonamidoethyl group was designed as a substrate which could undergo the Michael reaction and the transacylation *via* 5-*endo-trig* and 5-*exo-trig* processes, respectively. Compound **9** was prepared by the S_N2' reaction of methyl 2-(trifluoromethyl)propenoate[12] with benzyloxymethylcopper[13] and successive deprotection of the benzyl group, followed by the introduction of an NHTs group according to the same procedure for **2b**. On treatment of **9** with NaH in DMF, the 5-*endo-trig* cyclization proceeded to lead exclusively to the 2-fluorinated pyrroline derivative **10** as shown in Scheme 3.¶‖

In conclusion, normally 'disfavored' 5-*endo-trig* ring closures are successfully achieved in the intramolecular addition–elimination reaction of *gem*-difluoroolefins bearing nucleophilic heteroatoms linked by two sp^3 carbons to the vinylic carbon as well as two sp^2 carbons.[5] Thus, *gem*-difluorohomoallylamine, alcohol, and thiol derivatives open a new way to the syntheses of selectively ring-fluorinated heterocyclic compounds.

We gratefully acknowledge the financial support for this research by a grant from Central Glass Co., Ltd. to J. I. We also thank F-Tech, Inc. for a generous gift of 2-(trifluoromethyl)propenoic acid.

Silicalite membranes have been successfully synthesized onto mullite tubular supports by *in-situ* hydrothermal synthesis for only 8 h of crystallization, and showed high ethanol permselectivity for pervaporation of ethanol/water mixtures.

Zeolite membranes have strong potential applications for gas separation, pervaporation, and membrane reactors, especially MFI (silicalite and ZSM-5) membranes. On the other hand, less attention has been paid to pervaporation separation through zeolite membranes, even though zeolite A membranes are commercialized on a large scale by Mitsui Engineering Co. Ltd, in cooperation with Yamaguchi University, for dehydration of organic liquids. Silicalite membranes with hydrophobic properties exhibit preferentially selective permeation of organic components in contrast to zeolite A membranes. In 1994, Sano *et al.*[1] first reported that a separation factor of about 60 for ethanol (EtOH)/water mixtures was obtained for their silicalite membrane formed on a stainless steel disk with a crystal layer thickness of 400–500 μm, and further improved the separation factor up to 120 for 144 h crystallization in 1998.[2] They also prepared silicalite membranes on alumina disks, but their selectivity of 19 was much lower compared with that on the stainless steel support. Later, several groups tried to synthesize MFI membranes on tubular supports and made some progress. For example, separation factors of 11–44 were achieved.[3–5] However, the pervaporation performance of these membranes reported in the literature is still not good enough for industrial applications. Furthermore, various strategies have been successfully developed for the production of good quality zeolite membranes on various porous supports,[6–9] especially on flat discs. Considering practical applications, preparation of reproducible and high performance MFI zeolite membranes on cheaper porous tubular supports on a large scale, in which the cost greatly reduces, is still a challenge. In this paper, we report a simple and effective method to synthesize high performance silicalite membranes on mullite tubular supports for the shortest hydrothermal synthesis time among all the published papers.

A clear solution for the synthesis of silicalite membranes was prepared by mixing and stirring tetraethyl orthosilicate (TEOS, Aldrich), tetrapropylammonium hydroxide (TPAOH) and water at room temperature for 1 h. The resultant molar composition is SiO_2:0.17TPAOH:120H_2O. In such a Na-free medium, less gelation would affect the crystal growth onto the surface of a seeded support. A mullite porous tube with a pore size of 1 μm was chosen as the support because it is much cheaper than pure α-Al_2O_3 tubes, especially at pore sizes of less than 1 μm. Before *in-situ* hydrothermal synthesis, mullite tubes were simply rubbed with a slurry of H-ZSM-5 (Si/Al = ∞, Tosho Comp.). This seeding method was first used for the synthesis of zeolite A membranes by Kita *et al.*[10] which has been identified as an effective and reproducible seeding method.[11,12] The seeded support was vertically immersed in the synthesis solution. Crystallization was carried out at 175 °C or 185 °C for 8 h. After crystallization, the sample was taken out, washed carefully with hot distilled water, dried at 100 °C for several hours, and then calcined at 400 °C for 20–40 h at a heating rate of 1 °C min^{-1}.

The SEM surface view of the mullite support shown in Fig. 1 clearly indicates that the morphology is quite different from that of pure α-Al_2O_3. After hydrothermal treatment for 8 h at 175 °C, a well inter-grown silicalite crystal layer with a thickness of about 10 μm was formed on the seeded support, as shown in Fig. 2.

The pervaporation (PV) tests for EtOH/water mixtures were carried out at 60 °C. The effective membrane area was about 10 cm^2. The permeation side was kept under vacuum. The flux was calculated by weighing the condensed permeate. The separation factor was determined as $\alpha_{A/B} = (Y_A/Y_B)/(X_A/X_B)$, where X_A, X_B, Y_A, and Y_B denote the mass fractions of components A and B in the feed and permeate sides. The pervaporation results for the silicalite membranes synthesized at 175 °C and 185 °C for 8 h are listed in Table 1. Table 1 clearly shows that the pervaporation performance of our silicalite membranes was significantly improved compared with the previous results and also the membranes were prepared in a

DOI: 10.1039/b005180m

Table 1 Pervaporation performance through the silicalite membranes for EtOH/H_2O mixtures at 60 °C

Member No	Synthesis conditions		EtOH/H_2O (10 wt% EtOH)	
	T/°C	t/h	Flux/kg m^{-2} h^{-1}	Separation factor
Si-1	175	8	2.34	56
Si-2	175	8	2.55	72
Si-3	185	8	1.67	65
Si-4	185	8	1.58	64

highly reproducible manner. This suggests that silicalite membranes with both high flux and high separation factors can be prepared under suitable synthesis conditions, which has strong potential applications in the preferential separation of organic compounds from aqueous solutions. A systematic investigation of membrane preparation and membrane performance, including gas and vapor permeation, is under way.

Insertion of extra-framework Al into the framework of mesoporous MCM-41 aluminosilicates

Robert Mokaya

First published as an Advance Article on the web 18th September 2000

Virtually all octahedrally coordinated (extra-framework) Al in calcined Al-grafted MCM-41 materials can be inserted into (tetrahedral) framework positions upon treatment with an aqueous solution of NH_4OH; the insertion of Al into the framework is accompanied by an increase in (Brønsted) acidity and ion exchange capacity.

The recent synthesis of structurally well ordered mesoporous molecular sieves with uniform pores[1] has generated considerable research interest in the preparation and use of heteroatom containing mesoporous silicas as heterogeneous catalysts.[1,2] The incorporation of Al into mesoporous silicas is of particular interest as it gives rise to materials with solid acid and cation exchange properties. The acid and ion exchange sites are primarily associated with the presence of tetrahedrally coordinated Al in framework positions within the silica matrix. Al may be introduced into mesoporous silicas by direct synthesis[4,5] or by post-synthesis grafting methods.[6–8] Both methods, however tend to result in (calcined) materials with a significant proportion of extra-framework (octahedrally coordinated) Al.[4–8] It is desirable, with respect to acid catalysis and ion exchange properties, to maximise the proportion of Al in framework (tetrahedral) positions. So far no method has been described for modifying the siting of Al in calcined mesoporous aluminosilicates so as to maximise the amount (or proportion) of Al in framework positions. Reinsertion of extra-framework Al (EFAL) into framework positions has been previously described for dealuminated Y zeolites *via* hydrothermal treatment of the zeolite in an aqueous solution of KOH.[9] However, such treatment is not feasible for mesoporous aluminosilicates because it is too severe. The relatively fragile mesoporous frameworks would readily dissolve in the highly basic (pH = 13.5) KOH solution. Here we report a method *via* which virtually all octahedrally coordinated (extra-framework) Al in calcined Al-grafted MCM-41 materials can be inserted into (tetrahedral) framework positions. The method, which involves treatment of the mesoporous aluminosilicates with an aqueous solution of NH_4OH (pH $\approx$ 11.1), can be performed either at room temperature (30 °C) or at a range of temperatures up to 80 °C. NH_4OH was chosen due to the well known stability of Al-grafted MCM-41 materials at pH = 11,[10] and also because NH_4^+ is potentially an acid generating cation (and therefore no further ion exchange would be required to maintain Brønsted acidity). Our findings show that insertion of EFAL into the framework increases the proportion of tetrahedrally coordinated Al and is accompanied by an increase in acidity and ion exchange capacity. Although the Al insertion method described here is generally applicable to any mesoporous aluminosilicates, this preliminary report concentrates on Al-grafted materials because they offer distinct advantages over directly synthesised materials with respect to accessibility to active (Al) sites, structural ordering and stability.[6–8,10–13]

The purely siliceous MCM-41 from which the Al-grafted materials were derived was prepared using normal procedures. The Al-grafted materials were prepared *via* two methods.[13] In the first method, 2.0 g of pure silica MCM-41 were dispersed in 50 ml dry hexane and added to 150 ml dry hexane containing the appropriate amount of aluminium isopropoxide to give a grafting gel Si/Al ratio of 5. The resulting mixture was stirred for 10 min and allowed to react at room temperature for 30 h. The obtained powder was filtered off, washed with dry hexane, dried at room temperature and calcined at 550 °C for 4 h. The resulting material with a bulk Si/Al ratio of 4.6 was designated CAP5.[13] In the second method, pure silica MCM-41 was added to a 50 ml solution of 0.48 mol l^{-1} (w.r.t. Al) aluminium chlorhydrol at 80 °C and stirred for 2 h (at 80 °C). The resulting solid was otained by filtration and thoroughly washed with distilled water (until free of Cl^- ions), dried at room temperature and calcined in air at 550 °C for 4 h. To increase the amount of Al, the 'graft–wash–calcine' cycle was repeated once. The resulting material, designated CAH5, had a bulk Si/Al ratio of 4.7.[13] The calcined Al-grafted samples were then stirred in 1 M NH_4OH at a solution to solid ratio of 100 ml g^{-1}. At 30 °C, four 'stir–wash–dry' cycles were performed with each stirring lasting for 2 h. At 80 °C, the stirring was performed only once for 16 h. In both cases the NH_4OH-treated samples were thoroughly washed with distilled water and dried at 150 °C.

Fig. 1 shows the ^{27}Al MAS NMR spectra of CAP5 and CAH5 before and after treatment with NH_4OH. The untreated samples contain both tetrahedrally coordinated (δ 53) framework Al and octahedrally coordinated (δ 0) extra-framework Al. The proportion of tetrahedrally coordinated Al, calculated from the NMR spectra, is approximately 61% and 55% for CAP5 and CAH5 respectively. For both samples the proportion of tetrahedral Al increases significantly after treatment with NH_4OH. Indeed, after treatment with NH_4OH at 30 °C, virtually all (> 95%) of the Al is in tetrahedral coordination (Fig. 1b, e). Treatment in NH_4OH at 80 °C for 16 h appears to be slightly less effective in inserting the EFAL into framework positions probably due to its severity which affects structural integrity (see later). It is clear from Fig. 1 that the nature and environment of the Al in CAP5 and CAH5 is transformed by the relatively mild treatments in NH_4OH. Elemental analysis of the NH_4OH-

treated samples was performed in order to find out whether any preferential leaching of Si or Al occurred during the treatments. The Si/Al ratios of the NH_4OH-treated samples are given in Table 1. In all cases the elemental composition remained unchanged, *i.e.*, all the Si and Al was retained during NH_4OH treatment. This indicates that the increase in the tetrahedral/octahedral Al ratio observed from the MAS NMR spectra was due to insertion of EFAl into the framework rather than preferential dissolution of octahedral Al.

The acid contents of the Al-grafted samples and their NH_4OH-treated analogues are given in Table 1. The acid content was determined using thermally programmed desorption of cyclohexylamine.[13] Prior to analysis, the base (cyclohexylamine) containing samples were heated at 80 °C for 2 h. The acidity data indicate that an increase in the proportion of tetrahedral Al following NH_4OH treatment is accompanied by an increase in acid content. The increase is particularly remarkable for CAP5. Since the elemental composition remained unchanged (*i.e.* the amount of Al per gram of sample remained the same), the only explanation for the increased acidity is insertion of EFAL into acid generating framework sites. The insertion of EFAL into the framework is expected to specifically increase the proportion of Brønsted acid sites. Indeed, using FTIR spectroscopy of adsorbed pyridine (see ref. 17 for details) we observed a significant increase in the Brønsted acid content of NH_4OH-treated samples. For example, after evacuation at 100 °C,[14] the Brønsted acid content of CAH5 increased from 34 to 72 μmol g^{-1} and the Brønsted/Lewis acid ratio increased from 0.27 to 0.58. The same trend was observed after evacuation at 200 and 300 °C.[14] Furthermore, a preliminary check on ion exchange properties indicated that NH_4OH-treated samples exhibit substantially higher cation exchange capacities compared to the untreated samples; M^+/Al ratios of the Al-grafted materials (obtained following ion exchange) increased from *ca*. 0.4 to as high as 0.9 after treatment with NH_4OH at 30 °C. We were also able to observe Brønsted acid bridging OH groups in the FTIR spectra of NH_4OH-treated samples. These observations clearly point to the insertion of EFAL into framework positions rather than the formation of a separate alumina phase in which the Al is tetrahedrally coordinated.

The XRD patterns and sorption isotherms (obtained using a Coulter SA3100 Sorptometer after evacuating overnight at 200 °C) for CAP5 and its NH_4OH-treated analogues are shown in Fig. 2A. The insertion of Al into the framework (especially at 30 °C) does not appear to be detrimental to the structural ordering. CAP5 treated at 30 °C exhibits an XRD pattern and sorption isotherm comparable to that of the parent material. We note that CAP5 treated at 30 °C is very well ordered for an MCM-41 material with such a low (*ca*. 4.9) framework Si/Al ratio. Treatment at 80 °C results in rather more structural degradation; however, the resulting material still retains some hexagonal ordering and mesopore uniformity. The greater structural degradation for the 80 °C treated CAP5 may be the cause of the slightly less efficient insertion of Al into the framework observed from the MAS NMR spectra in Fig. 1. Table 1 shows the textural properties for the Al-grafted materials and their NH_4OH treated analogues. In general Al insertion results in a decrease in the surface area and pore volume. The decrease is modest at 30 °C but greater for materials treated at 80 °C. Note, however, that the effects of 80 °C NH_4OH treatment are reported here as an upper limit (with respect to severity of the treatment) and to show the versatility of the insertion method.

The mechanism for Al insertion most likely involves the dissolution of EFAL and the formation of aluminate ions that are inserted into the framework.[9] This is possible due to the amorphous nature of the pore walls and the presence of silanols (which may act as anchoring sites) on the pore wall surfaces. The pH of the basic solution used is important; a strongly basic solution dissolves both the EFAL and the mesoporous framework while a mildly basic solution does not dissolve the EFAL and is therefore not effective in Al insertion. Indeed when the strongly basic KOH solution (pH = 13.5) was used, the Al-grafted materials were destroyed. On the other hand, Al-grafted materials treated with KNO_3 (pH ≈ 8.8) remained virtually unchanged; neither structural ordering nor Al siting was affected. It appears therefore that NH_4OH (pH ≈ 11.1) is just right with respect to both the dissolution (and insertion) of EFAL into the framework and the preservation of structural integrity of the mesoporous framework. At the moment we have no evidence that the nature of the cation affects the insertion process.

The author is grateful to the EPSRC for an Advanced Fellowship. The assistance of Dr Y. Khimyak with NMR measurements is gratefully acknowledged.

FER (ferrierite) zeolite was hydrothermally crystallized in a gel system of sodium aluminosilicate with tetrahydrofuran (THF), a nitrogen-free organic compound, as the template; characterization by using TG/DTG/DTA and ^{13}C MAS NMR shows that THF is incorporated in the pores of the as-synthesized FER zeolite.

FER type zeolite is an aluminosilicate molecular sieve with medium pore openings. It has a variety of uses in catalytic processes, such as hydrocarbon cracking and isomerization. In particular, in recent years it has been found that FER zeolite possesses excellent shape selectivity for the isomerization of n-butene to isobutene. The latter is a raw material for manufacturing MTBE (methyl *tert*-butyl ether), an additive in lead-free gasoline.[1] What is more, it can be used as a catalyst for skeletal isomerization of n-olefins to iso-olefins.[2] Thus, the development of a novel method to synthesize FER zeolite in a cheap way will be a decisive step for the commercialization of these industrial processes.

FER zeolite can be prepared in an inorganic reactant system in the presence of Na^+ and K^+ simultaneously. However, the reaction temperature is usually high.[3] It is difficult to exchange K^+ in the zeolite synthesized from this system, leading to limited applications as catalysts and adsorbents. FER type zeolite was firstly synthesized by using an organic compound as the structure-directing reagent (template) in 1977.[4] Up to now more than 30 organic compounds have been employed as templates,[5] most of which are nitrogen-containing organic compounds, and some of which are large organic molecules, such as bis[*N*-methylpyridyl]ethylinium.[6]

Quite a lot of efforts have been made to synthesize various zeolites using oxygen-containing organic compounds. It is known that three types of organic compounds have been used as the templates: (1) ethers, such as 15-crown-5 and 16-crown-6;[7] (2) alkyl oxide compounds, such as trioxane and poly(ethylene oxides);[8] and (3) alcohols, such as ethanol and butan-1-ol.[9] Zeolites FAU, EMT, MAZ, MFI, TON, *etc*., have been synthesized in the presence of the above templates. One method was disclosed that FER zeolite can be prepared by using 2,4-diketones as the organic templates.[10] In this paper a novel process of using THF as the template[11] for the synthesis of FER zeolite is reported.

The process of synthesizing FER zeolite was as follows: 24.44 g of silica sol (SiO_2 = 25.07%, Na_2O = 0.27%, Qingdao Ocean Chemical Plant) was mixed with 6.94 g aqueous solution of aluminium sulfate (Al_2O_3 = 7.49%, H_2O = 74.9%, Shanghai Xinxing Material Corp.) to form a mixture in a plastic vessel. Then 1.69 g of NaOH and 13.25 g of deionized water were added to the mixture. A homogeneous gel of the reactant was formed after 3.71 g of THF (analytical grade, Shanghai Chemical Reagent Corp.) were added into the mixture with vigorous stirring. The molar composition of the reactant gel was $0.5THF:0.215Na_2O:SiO_2:0.05Al_2O_3:20H_2O$. The gel was sealed into a 30 ml stainless steel Teflon lined autoclave, and hydrothermally crystallized in an oven at 200 °C for 8–12 days under static conditions. The spontaneously crystallized product was washed with distilled water, filtered and then dried at 120 °C. A reactant with the same molar composition but without THF remained amorphous for a long time under the same conditions.

The XRD pattern (Cu-Kα radiation, Rigaku D-MAX/II A) indicates that the as-synthesized product is highly crystalline FER type zeolite without any impurity phase (Fig. 1). The cell composition of the as-synthesized FER zeolite is $Na_{3.42}[Al_{3.59}Si_{32.41}O_{72}]\cdot 1.05THF\cdot 6.19H_2O$ as determined by chemical analysis. The SEM photo (Shimadzu S-520) shows that the morphology of the zeolite is agglomerate with a shape like a spindle (Fig. 2).

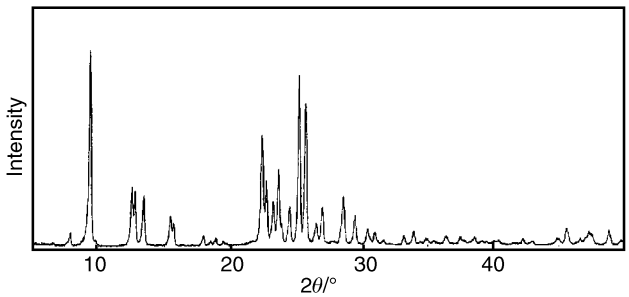

Fig. 1 XRD pattern of FER type zeolite synthesized in the reactant system with THF as the template.

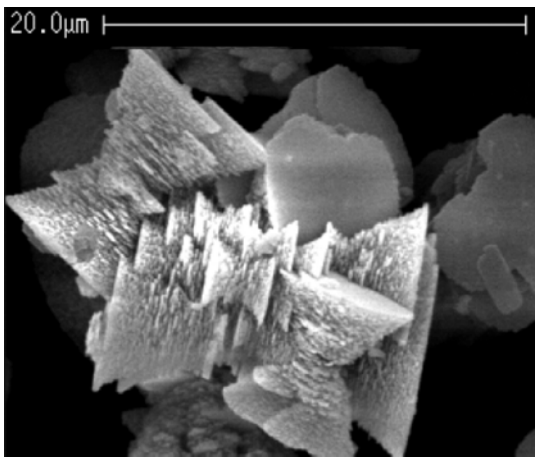

Fig. 2 SEM photograph of FER type zeolite synthesized in the reactant system with THF as the template.

The TG/DTG/DTA curves (PCT-10A thermal analyzer with a flow of air of 70 ml min^{-1} at a rate of 5 °C min^{-1} from room temperature to 600 °C) are displayed in Fig. 3. The weight loss below 350 °C is attributed to the loss of water incorporated into the pores of the as-synthesized FER zeolite. The weight loss in the temperature range of 350–550 °C is attributed to the loss of THF. The content of THF in the zeolite calculated from the weight loss is 3.12 wt.%. The maximum temperature in the DTG curve is 393 °C, and an obviously endothermal effect followed by an exothermal one are observed at 415 and 431 °C

respectively in the DTA curve (Fig. 3), indicating the escape of THF from the zeolite and the subsequent oxidation in air. This implies that THF is incorporated in the pores of the as-synthesized FER zeolite.

Fig. 4 shows the ^{13}C CP and HPDEC MAS NMR spectra (recorded at room temperature with a Bruker MSL-300 spectrometer, ^{13}C resonance frequency 78.468 MHz, rotor spun at 4.0 KHz, radiofrequency field 50 kHz, recycle time 2 s with an accumulation number of 2000–6000, contact time 2 ms for CP spectrum, decoupling power 50 kHz for HPDEC spectrum, adamantane was used as a second reference). Two peaks are observed in both the CP NMR and HPDEC ^{13}C NMR spectra of the as-synthesized FER zeolite compared with that of THF in the liquid phase. The chemical shifts of C_1 (-C-C_1-C_1-C-) and C_2 (-C_2-O-) are 23.99 and 66.09 ppm respectively for the THF molecules in the liquid state. In comparison, the chemical shifts of C_1 and C_2 in the CP spectrum move to 26.55 and 69.67 ppm respectively for the THF molecules trapped in the as-synthesized FER zeolite. The obvious shift to lower field is caused by

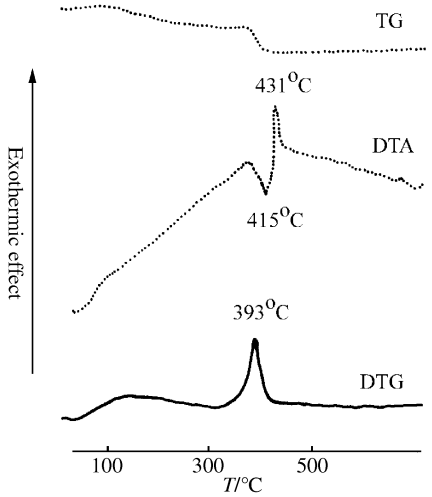

Fig. 3 TG/DTG/DTA curves of as-synthesized FER type zeolite in a flow of air.

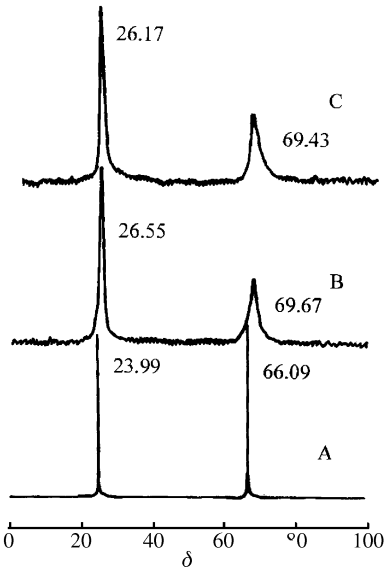

Fig. 4 ^{13}C MAS NMR spectra of THF (A) in liquid state, (B) CP spectrum of as-synthesized FER zeolite, (C) HPDEC spectrum of as-synthesized FER zeolite.

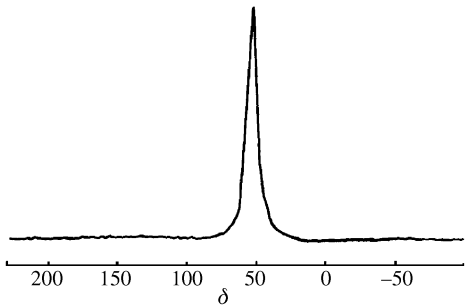

Fig. 5 ^{27}Al MAS NMR spectrum of FER type zeolite synthesized in the reactant system with THF as the template.

electronic deshielding effects of the framework oxygen atoms in the small cage formed by intersection of the 8-ring (0.48 × 0.34 nm) and 6-ring channels in the cell of FER zeolite. The deduction is consistent with our earlier observation of TMEDA (tetramethylethylenediamine) trapped in the cages of several as-synthesized zeolites, such as MTN, MON and FER.[12]

Fig. 5 shows ^{27}Al MAS NMR (resonance frequency 78.205 MHz, rotor spun at 3.5 kHz, frequency field 27.8 kHz, recycle time 500 ms, $AlCl_3(H_2O)_6$ as reference. The peak at 53 ppm in the ^{27}Al MAS NMR spectrum of the as-synthesized FER zeolite corresponds to tetrahedrally coordinated framework aluminium, indicating that the framework of the FER zeolite discussed herein does not include non-framework aluminium.

The nitrogen adsorption isotherm was measured (at 77.35 K using a Micromeritics ASAP 2000 instrument) on the sample of FER zeolite calcined to remove THF and treated by ion-exchange. The adsorption isotherm of N_2 belongs to the Langmuir type. The microporous volume was 0.15 ml g^{-1} calculated from the adsorption isotherm, which is consistent with the value determined for the FER zeolite synthesized by using TMEDA as the templete.[13]

This work was supported by the Doctoral Fund of the State Ministry of Education and the Institute of Beijing Yanshan Petrochemical Corporation.

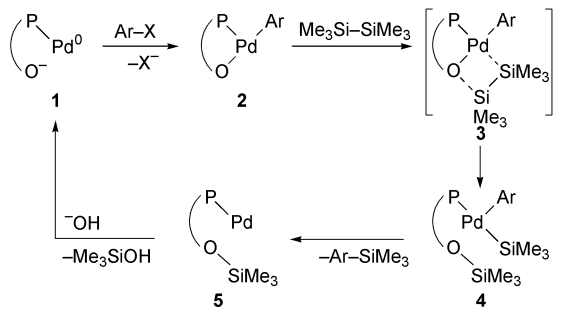
Received (in Cambridge, UK) 31st July 2000, Accepted 25th August 2000
First published as an Advance Article on the web 18th September 2000

Diphenylphosphinophenolate was found to be an effective ligand for the palladium-catalysed silylation of aryl halides, activating not only palladium but also silicon of a disilane, where aryl bromides and iodides having such substituents as methyl, methoxy, amino, ethoxycarbonyl, trifluoromethyl, formyl or phenyl are applicable to the reaction with hexamethyldisilane to give the corresponding trimethylsilylarenes.

The transition metal-catalysed silylation of aryl halides with disilanes should be one of the most straightforward and economical ways to arylsilanes,[1,2] which are versatile synthetic precursors especially for the palladium-catalysed cross-coupling reaction with organic electrophiles.[3] Although there have been many reports on the palladium-catalysed silylation using triphenylphosphine as a ligand,[1] the reaction requires drastic conditions to obtain arylsilanes in acceptable yields. Low reaction rate is ascribed to the low reactivity of a disilane toward a Pd(II) complex that is generated by oxidative addition of an aryl halide to a Pd(0) complex. In order to accelerate the rate-determining transmetalation step, two routes are possible in terms of electronic balance: one is to make the palladium(II) more electron-deficient and the other is to increase the electron density of the nucleophile. Ligands play significant roles for the former but not for the latter.

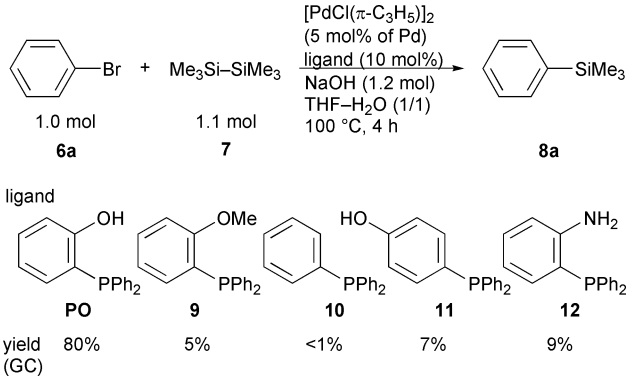
We envisaged that a phosphine having a phenolate group should not only serve as a bidentate ligand for palladium but also activate directly an incoming silyl nucleophile. Thus, in the palladium-catalysed silylation of aryl halides with disilanes, we considered that the phenolate anion in the ligand could coordinate to the silicon atom of a disilane and enhance its nucleophilicity in the transmetalation step in the catalytic cycle that we assumed to be working (Scheme 1). Here we report that a palladium complex coordinated by 2-(diphenylphosphino)-phenolate (PO)[4] efficiently catalyses the silylation of aryl halides using hexamethyldisilane.

We first compared the PO ligand in efficiency with other phosphines in the palladium-catalysed reaction of bromobenzene (**6a**) with hexamethyldisilane (**7**) (Scheme 2). Thus, **6a** (1.0 mol) was treated with **7** (1.1 mol) in the presence of a 1 : 2



The oxygen atom may coordinate on palladium in complex **1**, **4** and **5**.

Scheme 1



Scheme 2

mixture of $[PdCl(\pi\text{-}C_3H_5)]_2$–PO (5 mol% of Pd) and sodium hydroxide (1.2 mol) in a 1 : 1 mixture of THF and H_2O at 100 °C for 4 h to give trimethylsilylbenzene (**8a**) in 80% yield. Reduction of the amount of sodium hydroxide (0.1 mol, 9%; 0 mol, 0%), masking the hydroxy group of PO as **9**, or use of triphenylphosphine (**10**) in lieu of PO decisively reduced the yield, implying the significance of the phenolate moiety, whereas inefficiency of *p*-hydroxy derivative **11** revealed the importance of the *o*-phenolate anionic functionality. Aminophosphine **12** also was ineffective. These results clearly demonstrate that the catalytic cycle depicted in Scheme 1 is working smoothly with the Pd–PO catalyst.

The applicability of the catalytic system was proved by trimethylsilylation of various aryl bromides and iodides (Scheme 3 and Table 1). Trimethylsilylbenzene and 4-trimethylsilyltoluene were obtained in high yields from bromobenzene and 4-bromotoluene, respectively (Table 1, entries 1 and 2). Although an electron-donating substituent like methoxy or amino on the aryl bromide decreased the yield, as was the case with a triphenylphosphine ligand,[1a] use of a 1 : 1 mixture of toluene and H_2O as the solvent in combination with 10 mol% tetrabutylammonium bromide afforded the corresponding arylsilanes in yields over 90% (entries 3–6). The toluene/H_2O/Bu_4NBr system was effective also for the silylation of an aryl bromide having an ester moiety, preventing ester hydrolysis during the reaction (entries 7 and 8). Other aryl bromides with various substituents gave the corresponding arylsilanes in good yields (entries 9–12). Dibromo- or tribromobenzene also reacted smoothly to give bis(trimethylsilyl)- or tris(trimethylsilyl)benzene, respectively (entries 13 and 14). Aryl iodides also were found to be good substrates for this silylation reaction (entries 15–17). This is noteworthy, as iodobenzene is recorded not to react at all with a Pd–Ph_3P catalyst, the low efficiency of

[a] The reaction was carried out at 100 °C for 24 h using an aryl halide (0.40 mmol), hexamethyldisilane and sodium hydroxide (0.48 mmol) in the presence of $[PdCl(\pi\text{-}C_3H_5)]_2$ (0.01 mmol) and PO (0.04 mmol). A: THF(1 ml)–H_2O(1 ml); B: tetrabutylammonium bromide(0.04 mmol), toluene(1 ml)–H_2O(1 ml). [b] Isolated yields based on aryl halide are given. [c] The reaction was completed in 10 h.

the catalyst being attributed to the inertness of the oxidative adduct $PhPdI(Ph_3P)_2$.[1a,5] In our case the oxidative adduct **2** lacks a halide ligand which explains the results that the Pd–PO catalyst is free from the influence of the kind of halide.

In conclusion, we have demonstrated that a palladium catalyst coordinated by phosphinophenolate is efficient for the silylation of aryl halides using hexamethyldisilane. The protocol using a ligand that activates a transition metal and an incoming nucleophile simultaneously should be applicable to various transition metal-catalysed reactions. Studies on the details of the mechanism as well as application of the protocol are in progress in our laboratories.

Received (in Cambridge, UK) 4th July 2000, Accepted 22nd August 2000
First published as an Advance Article on the web

The first nonacoordinate bridging selenido ligand in a tricapped trigonal prismatic geometry, $Cu_{11}(\mu_9\text{-}Se)(\mu_3\text{-}Br)_3[Se_2P(OPr^i)_2]_6$, is prepared along with closed-shell ion-centered Cu^I_8 cubes, $Cu_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_6$ and $Cu_8(\mu_8\text{-}Br)[Se_2P(OPr^i)_2]_6(PF_6)$, from the reaction of $NH_4Se_2P(OPr^i)_2$, $Cu(CH_3CN)_4PF_6$, and Bu_4NBr in CH_2Br_2 at 0 °C.

One of the most commonly observed coordination geometries for a central atom which is surrounded by nine outer or ligand atoms is a tricapped trigonal prism.[1] Notable examples are lanthanide complexes,[2] $[ReH_9]^{2-}$ and its derivatives.[3] To the best of our knowledge this geometry has never been observed in any main group elements, though a main-group element in the cavity of a monocapped square antiprism is known in a couple of metal carbonyls.[4]

Molecular cubic clusters encapsulating main-group elements are particularly interesting from the general point of view of bonding.[5] To date two types of main-group element-centered transitional metal cubic clusters which include face-capped and edge-capped cubes have been characterized. While $Ni_8(\mu_8\text{-}As)(\mu_4\text{-}As)_6(PPh_3)_8$ is the only face-capped cube,[6] several edge-capped Cu^I_8 cubes centered by S^{2-},[7] Cl^- and Br^- [8] are known for dithiophosphate ligands. An unusual sulfide-centered, edge-capped mixed-metal cube, $[Mn_4Cu_4S(SPr^i)_{12}]^{2-}$, which is defined by two interpenetrating copper and manganese tetrahedra, is also accessible by reaction of $[Mn_2(SPr^i)_6]^{2-}$ with CuCl.[9] With the dialkyl diselenophosphate ligands (dsep), we uncovered the first selenide-centered edge-capped Cu^I_8 cubes.[10] Subsequently an exceptional co-crystallization with clusters, $Ag_8(\mu_8\text{-}Se)[Se_2P(OR)_2]_6$ and $Ag_6[Se_2P(OR)_2]_6$, superimposing on a trigonal lattice, was observed.[11] To extend our research efforts in centered cubic cluster synthesis, we focus on the halide ion and uncovered, besides selenide-centered Cu^I_8 cubes, **1**, a halide-centered Cu^I_8 cube, **3**, and a remarkable, undecanuclear copper cluster containing a selenide ion in the center of a pentacapped trigonal prism, $Cu_{11}(\mu_9\text{-}Se)(\mu_3\text{-}X)_3[Se_2P(OPr^i)_2]_6$, **2**. Cluster **2** is a novel example possessing not only a 3,3,4,4,4-pentacapped trigonal prismatic copper framework but also a nonacoordinate bridging selenido ligand in a tricapped trigonal prismatic geometry.

At least three clusters are produced from the reaction of $NH_4Se_2P(OPr^i)_2$ (1.2 g, 3.69 mmol), $Cu(CH_3CN)_4PF_6$ (0.917 g, 2.46 mmol) and Bu_4NBr (0.793 g, 2.46 mmol) in CH_2Br_2 (50 mL) at 0 °C for 24 hours. Both yellow clusters **1** and **2** dissolved in n-hexane are separated by column chromatography (eluent: ethyl acetate/hexane = 3/4) whereas the cationic species **3** is insoluble.† The formulation of **2** was confirmed by elemental analyses, positive FAB mass spectroscopy, ^1H and ^{31}P NMR spectroscopy. In the positive FAB mass spectrum of **2**, three major peaks which correspond to the intact molecule, an intact molecule with the loss of a bromide ion, $\{Cu_{11}(\mu_9\text{-}Se)(\mu_3\text{-}Br)_2[Se_2P(OPr^i)_2]_6\}^+$, and an intact molecule with the loss of a dsep ligand, $\{Cu_{11}(\mu_9\text{-}Se)(\mu_3\text{-}Br)_3[Se_2P(OPr^i)_2]_5\}^+$, respectively, were identified. These observed peaks are in agreement with the results of their respective, simulated isotopic patterns.

X-Ray analysis‡ of **2** reveals a $Cu_{11}Se$ core, stabilized by three bromide and six dsep ligands. The central core adopts a slightly distorted, fivefold capped trigonal prismatic copper framework, with an encapsulated selenium ion. Shown in Fig. 1 is the $SeCu_{11}$ core which displays an idealized D_{3h} symmetry. Both Cu(1) and Cu(2), each capping the triangular face of the prism, are located on the pseudo-three-fold axis, as is the encapsulated selenium ion Se(01). The Cu–Se(01) bond distances are noteworthy. Whereas two on the C_3 axis, 3.480 and 3.574 Å, are extremely long, the rest are in the range 2.519(2)–2.748(2) Å and are within the limits reported by Fenske and coworkers.[12] Consequently a novel nonacoordinate bridging selenido ligand in a tricapped trigonal primastic geometry is revealed in the title compound. The edges of the trigonal prism are in the range 3.431–3.588 Å while the heights (Cu7–Cu8, Cu6–Cu9, and Cu10–Cu11) are on average 3.103(2) Å. There exist a total of nine Cu_4 butterflies where the wing-tip positions are represented by five capping copper atoms with each edge and height of the trigonal prism being the hinges. Those Cu_4 butterflies comprising a copper atom on the C_3 axis are each connected by a dsep ligand having a tetrametallic

Selected bond lengths [Å]: Se(01)–Cu(3) 2.748(2), Se(01)–Cu(4) 2.739(2), Se(01)–Cu(5) 2.736(2), Se(01)–Cu(6) 2.568(2), Se(01)–Cu(7) 2.576(2), Se(01)–Cu(8) 2.580(2), Se(01)–Cu(9) 2.519(2), Se(01)–Cu(10) 2.551(2), Se(01)–Cu(11) 2.552(2), Cu(1)–Cu(10) 2.804(2), Cu(1)–Cu(7) 2.851(2), Cu(1)–Cu(6) 2.869(2), Cu(2)–Cu(9) 2.787(2), Cu(2)–Cu(8) 2.842(2), Cu(2)–Cu(11) 2.861(2), Cu(3)–Cu(9) 2.883(2), Cu(3)–Cu(6) 2.886(2), Cu(3)–Cu(11) 2.919(2), Cu(3)–Cu(10) 2.925(2), Cu(4)–Cu(6) 2.860(2), Cu(4)–Cu(9) 2.877(2), Cu(4)–Cu(7) 2.936(2), Cu(4)–Cu(8) 2.970(2), Cu(5)–Cu(10) 2.897(2), Cu(5)–Cu(7) 2.916(2), Cu(5)–Cu(8) 2.932(2), Cu(5)–Cu(11) 2.947(2), Cu(6)–Cu(9) 3.052(2), Cu(7)–Cu(8) 3.134(2), Cu(10)–Cu(11) 3.124(2).

DOI: 10.1039/b005366j

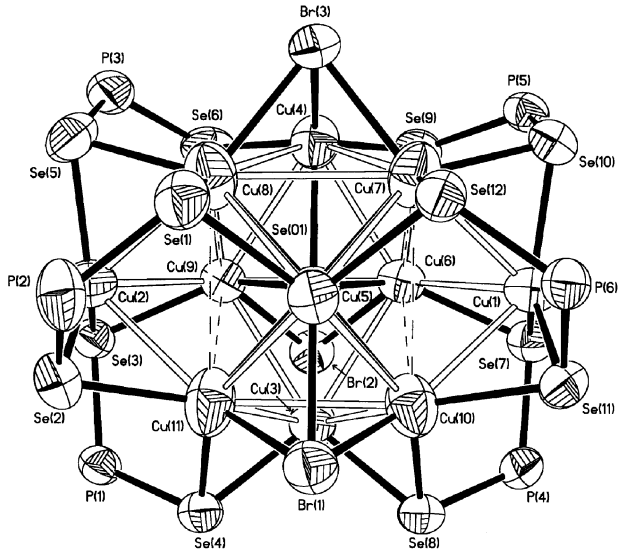

Fig. 2 The thermal ellipsoid drawing (50% probability) of **2**. The isopropoxy groups have been omitted for clarity. Selected bond lengths [Å]: Br(1)–Cu(5) 2.452(2), Br(1)–Cu(10) 2.565(2), Br(1)–Cu(11) 2.627(2), Br(2)–Cu(3) 2.451(2), Br(2)–Cu(6) 2.564(2), Br(2)–Cu(9) 2.622(2), Br(3)–Cu(4) 2.453(2), Br(3)–Cu(7) 2.539(2), Br(3)–Cu(8) 2.595(2), Cu–Se 2.350(2)–2.502(2).

tetraconnective (μ_2,μ_2)[13] coordination pattern (Fig. 2) The remaining three, where hinge positions are the heights of the prism, are each occupied by a triply bridging bromide atom over an alternating set of three of the six triangular faces. The Cu–Br bond distances are on average 2.541(2) Å. Two distinct coordination environments around copper atoms of the cluster are observed: two on the C_3 axis are coordinated by three selenium atoms of three different dsep ligands and the rest are surrounded by three selenium atoms and one bromine atom. Overall, owing to the existence of three, alternating triply bridging bromides, the D_{3h} symmetry depicted in Fig. 1 has been lowered to C_{3h}.

Compound **3** forms colorless crystals in the monoclinic space group *C*2/*c* and reveals a bromide-centered Cu^I_8 cube of which each edge of the cube is bridged by a selenium atom of the dsep ligand (Fig. 3). The averaged Cu–Cu bond length of 3.179(4) Å is about 0.25 Å longer than the corresponding Cu–Cu distance in the selenide-centered Cu^I_8 cube.[10] The averaged Cu–Br distance of 2.754(1) Å is comparable with those previously

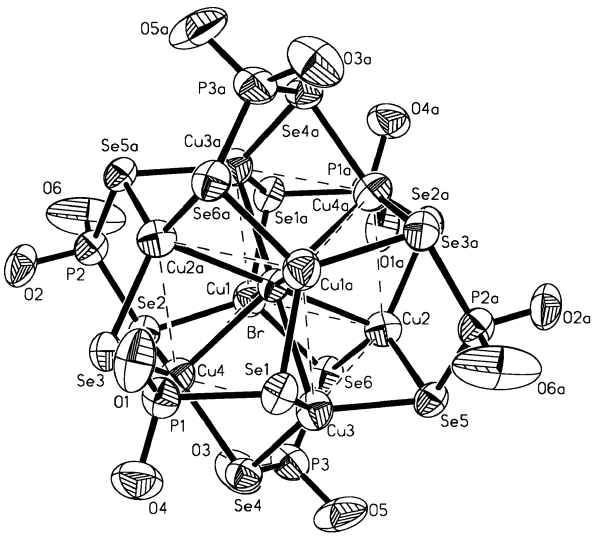

Fig. 3 The thermal ellipsoid drawing (50% probability) of the cation in **3**. The isopropyl groups have been omitted for clarity. Selected bond lengths [Å]: Cu–Se 2.374(1)–2.399(1), Cu–Br 2.732(1)–2.771(1), Se–P 2.169(3)–2.185(2).

reported in $[Cu_8(\mu_8\text{-}Br)(S_2P(OPr^i)_2)_6][PF_6]$[8] and significantly longer than those in **2**.

In summary, the first selenium atom surrounded by nine copper atoms in a tricapped trigonal prismatic geometry is identified along with a halide-centered Cu^I_8 cube containing dsep ligands during the preparation of closed-shell ion-centered cubic clusters. The silver analogues of **2** and **3** have been characterized structurally and details will be reported soon. This research was supported by the National Science Council of Taiwan (NSC 89-2113-M-033-004).

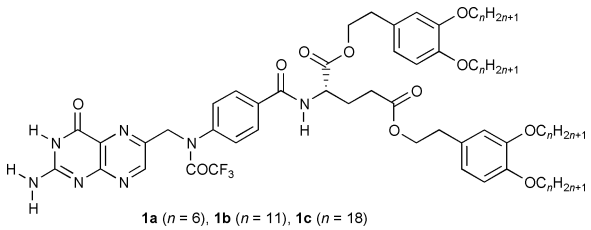
Thermotropic discotic and smectic liquid crystallinity can be induced for folic acid derivatives having octadecyl and undecyl substituents in wide temperatures ranges, respectively; the addition of sodium triflate to smectic liquid-crystalline folic acid leads to a change of the assembled structures from smectic to columnar phases.

Nanoscale molecular architectures formed by non-covalent interactions have been intensively studied because highly functional molecular materials can be obtained by self-organization processes.[1–4] For liquid-crystalline (LC) materials, the utilization of the molecular interactions such as hydrogen bonding has been shown to be quite useful.[4] The control of the patterns and the reversible self-assembling nature of hydrogen-bonded liquid crystals would lead to the preparation of a novel dynamically functional material. Our intention is to use self-organization behavior of biomolecules, which in many cases show lyotropic behavior, for the formation of new thermotropic LC materials.

In the present study, we have focused on the pterin ring of folic acid. Thermotropic LC folic acids have not yet been developed although the lyotropic mesomorphism through discotic tetramer formation of sodium folate in aqueous solution has been reported.[5] The induction of the thermotropic liquid crystallinity of this molecule may lead to the development of dynamically functional anisotropic systems.

We succeeded in inducing thermotropic liquid crystallinity for folic acid derivatives **1a–c** by incorporating 2-(3,4-dialkyloxyphenyl)ethyl groups into the glutamic acid moiety. Compound **1c** exhibited columnar mesophases, while smectic phases were seen for compounds **1a** and **1b** containing shorter alkyl chains.‡ The phase transition behavior of **1a–c** is summarized in Table 1.§



1a (n = 6), **1b** (n = 11), **1c** (n = 18)

X-Ray diffraction measurements showed that **1c** exhibited ordered and disordered discotic hexagonal columnar (D_{ho} and D_{hd}) phases (D_{ho} phase at 25 °C: d_{100} = 50.5, d_{110} = 29.2, d_{200} = 25.3, and the distance between disks = 4.1 Å; D_{hd} phase at 100 °C: d_{100} = 50.6, d_{110} = 29.2, and d_{200} = 25.3 Å). Only one sharp peak (small angle) and a broad halo were observed for the smectic phases of **1a** and **1b**. The layer spacings for **1a** and **1b** were 37.6 and 41.2 Å at 25 °C, respectively. It is noteworthy that the phase behavior of **1** was greatly dependent on the length of the alkyl chains. The textures observed for these compounds supported the difference of the phase structures.[6] The formation of the smectic and discotic phases can be attributed to the ribbon- and disk-like aggregation of pterin rings of **1**, respectively, as shown in Fig. 1.[7,8] The IR spectra of **1b** and **1c** also indicated the existence of the two types of the hydrogen-bonded structures.¶ The layer structure for **1a** and **1b** should be induced by the ribbon-like aggregation of the pterin ring (Fig. 1A).[7] In contrast, the induction of the discotic hexagonal columnar phase of **1c** was based on the disk-like aggregation of the pterin ring of **1c** (Fig. 1B).[8] For **1c**, the disordered alkyl chains can be closely packed in the discotic arrangement. The difference of these aggregated structures was due to the dynamic nature of the hydrogen bonding.

Table 1 Phase transition temperatures of **1**[a]

Compound	Phase transition temp./°C						
1a (n = 6)					S	238	Iso
1b (n = 11)			Cr	−13	S	240	Iso
1c (n = 18)	D_{ho}	62	D_{hd}	207	M	223	Iso

[a] Cr: crystalline; S: smectic; D_{ho}: ordered discotic hexagonal columnar; D_{hd}: disordered discotic hexagonal columnar; M: mesomorphic with low viscosity; Iso: isotropic.

The formation of columnar molecular assemblies has been a recent topic for the development of functional materials.[9,10] We were able to change the LC phase of **1b** from smectic to columnar by the addition of sodium triflate (NaOTf). The isotropization temperatures and the mesomorphic temperature

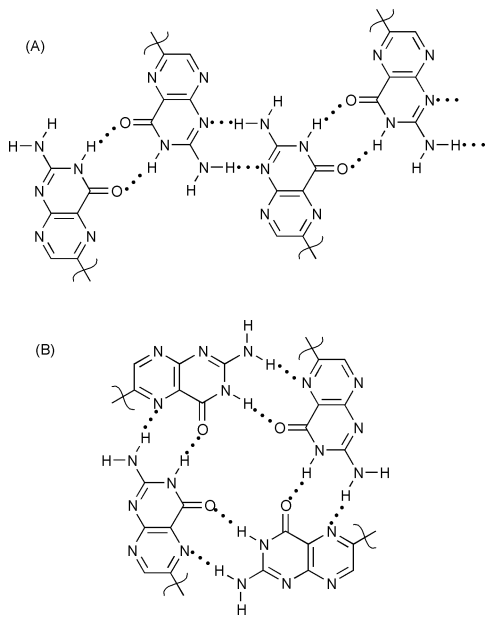


Fig. 1 Hydrogen-bonded self-assembled structures of the pterin rings of folic acid. (A) Linear ribbon-like aggregation style, (B) cyclic disk-like aggregation style.

† Electronic supplementary information (ESI) available: synthesis details and IR data. See http://www.rsc.org/suppdata/cc/b0/b004815l/

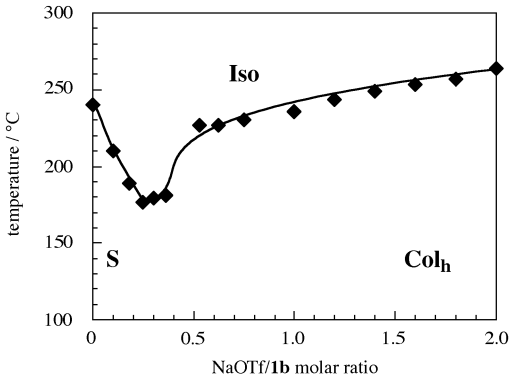

Fig. 2 Isotropization temperatures of the complexes of NaOTf and **1b**.

ranges of the resulting mixtures of **1b** and NaOTf on heating are summarized in Fig. 2.

The temperatures decrease drastically with the increase of the molar ratio of NaOTf to **1b** from 0 to 0.3. Further addition of NaOTf results in the increase of the clearing points. Fan-like textures characteristic of a hexagonal columnar phase (Col_h) were observed for the mixtures in the ratio of NaOTf to **1b** from 0.5 to 2.0. The addition of more than 2.5 mol of NaOTf led to the phase separation of the sodium salt from the mixture. The X-ray diffraction pattern of an equimolar complex of NaOTf and **1b** at 200 °C showed a sharp inner peak at 45.2 Å (d_{100}), small peaks at 26.0 and 22.6 Å (d_{110} and d_{200}, respectively), and a diffuse halo at 4.1 Å, which confirmed the formation of a disordered Col_h phase.

This phase transition behavior of the complexes can be explained as follows. The initial decrease of the temperatures was caused by the co-existence of hydrogen-bonded forms A and B (Fig. 1) in the smectic order. Further addition of NaOTf resulted in the formation of discotic aggregates leading to the induction of a hexagonal columnar order by ion–dipole interaction through sodium salts and the carbonyl oxygen of the pterin rings. These aggregates were further stabilized by the increase of the ion–dipole interactions. The formation of columnar phases by the complexation of covalently bonded cyclic molecules with metal salts has been reported.[11] However, to our knowledge, there has been no example of liquid crystals changing from smectic to columnar phases due to the change of hydrogen-bonding patterns by the effect of metals.

In summary, we have prepared, for the first time, thermotropic LC folic acid derivatives. In particular, for compound **1b**, the smectic phase can be changed to hexagonal columnar phases by the ion–dipole interactions. We are further exploring nanostructures formed by hydrogen-bonded aggregation of folic acid derivatives.

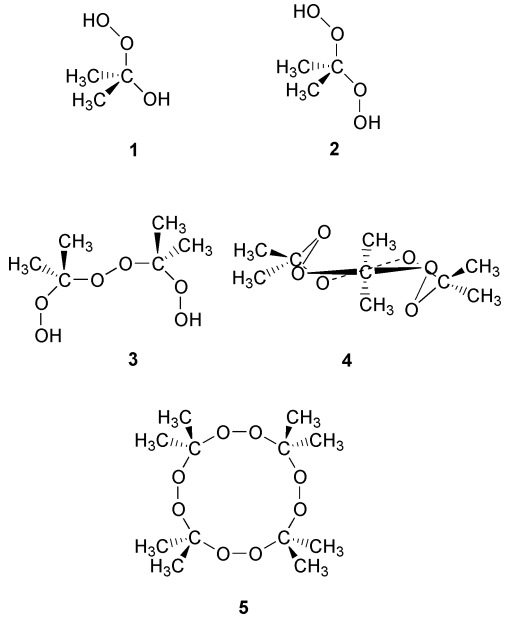
First published as an Advance Article on the web

By reaction of hydrogen peroxide and bis(diphenylphosphino)ethane in acetone, the 1 : 2 adduct (bis(diphenylphosphinoyl)ethane)·2(2,2-dihydroperoxypropane) ($dppeO_2$)·2[$Me_2C(OOH)_2$], stabilized by H-bonding between $Me_2C(OOH)_2$ and $dppeO_2$, was rapidly obtained in high yields in the presence of R_2SnCl_2 (R = Me or Bu^n).

Organic peroxides derived from acetone and hydrogen peroxide have been extensively studied.[1–5] The products identified to date in aqueous acetone–hydrogen peroxide solutions are 2-hydroxy-2-hydroperoxy propane **1**,[3] 2,2-dihydroperoxypropane **2**,[1,2] α,α′-bis(hydroperoxy)diisopropyl peroxide **3**[1,2] and 1,1,4,4,7,7-hexamethyl-1,4,7-cyclononatriperoxane **4**.[1,2,5]



Very recently a tetrameric species [1,1,4,4,7,7,9,9-octamethyl-1,4,7,9-tetraundecotetraperoxane) **5** has been isolated from an acetone–H_2O_2 solution containing $SnCl_4$·$5H_2O$ or $SnCl_2$·$2H_2O$. It has been hypothesized that tin(IV) salts catalyze the oxidation of acetone by hydrogen peroxide to tetrameric acetone peroxide at room temperature.[6] All the species **1**–**5** readily decompose. The structures of **1**–**3** and **5** have been hypothesized only on the basis of spectroscopic IR and NMR data, whereas the crystal structure of **4** was determined some years ago.[5] During our studies[7] on the interaction between tin(IV) acceptors and diphosphinoyl donors in acetone, using hydrogen peroxide as oxidizing agent for organic phosphines, we observed the formation of the crystalline adduct ($dppeO_2$)·2[$Me_2C(OOH)_2$] **6**.[8] Whereas the free 2,2-dihydroperoxypropane **2** decomposes rapidly due to its fast transformation into the more stable cyclic peroxo compounds **4** or **5**, **6** is very stable under the same conditions in both solid and solution states. The stabilization of dihydroperoxide **2** in the crystals of **6** can be explained by formation of H-bonds between the hydrogen atoms of $Me_2C(OOH)_2$ and the oxygen atoms of $dppeO_2$, which in this case acts as hydrogen acceptor. The energy of the hydrogen bond most likely prevents the oligomerization of the peroxide into the usual trimeric or tetrameric forms. The adduct **6** has a molecular structure[9] with two molecules of dihydroperoxide H-bonded to $dppeO_2$ (Fig. 1). The O–O distances in the peroxide (mean value 1.461 Å) are close to those in hydrogen peroxide (1.453 Å).[10] The bis(diphenylphosphinoyl)ethane molecule is stabilized in a staggered conformation. Each oxygen atom of $dppeO_2$ forms two H-bonds with a dihydroperoxide molecule (O(3)–H(3)···O(1) 2.758(2) Å, ∠O(3)–H(3)–O(1) 170(3)°; O(5)–H(5)···O(1) 2.824(3) Å, ∠O(5)–H(5)–O(1) 169(3)°).

When the reaction between dppe and H_2O_2–acetone was carried out in the absence of R_2SnCl_2 (R = Me or Bu^n) acceptors, compound **6** was obtained in only 40% yield after 10 days, whereas in the presence of tin acceptors the yield was much higher (90%) after only 24 h. This result is in accordance

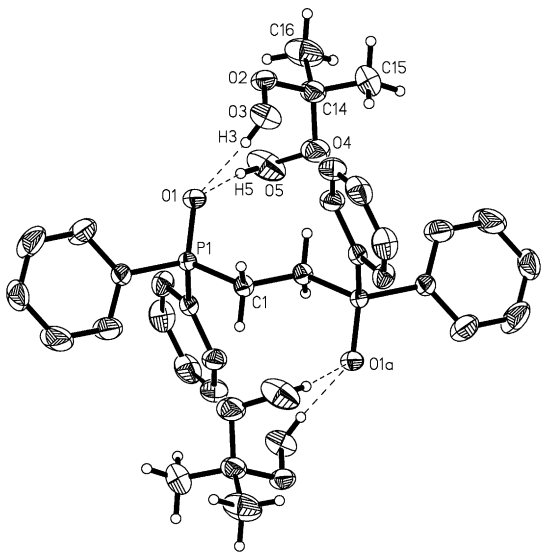


Fig. 1 Molecular structure of ($dppeO_2$)·2[$Me_2C(OOH)_2$] **6**. Selected bond distances (Å) and angles: P(1)–O(1) 1.511(1), P(1)–C(1) 1.805(2), P(1)–C(2) 1.795(2), P(1)–C(8) 1.812(2), C(14)–O(2) 1.425(3), O(2)–O(3) 1.464(2), C(14)–O(4) 1.428(2), O(4)–O(5) 1.457(3); ∠O(2)–C(14)–O(4) 110.2(2)°.

DOI: 10.1039/b005221n

with the recent work[6] on the oxidation of acetone by H_2O_2 catalysed by tin(IV) and tin(II) compounds.

When the reaction between dppe and H_2O_2–acetone was carried out in the presence of Ph_2SnCl_2, the derivative $Ph_2SnCl_2(dppeO_2)$[11] precipitated from the reaction mixture and no trace of **6** was detected after 48 h.

When **6** was reacted with Ph_2SnCl_2, the derivatives $Ph_2SnCl_2(dppeO_2)$,[11] **3** and **4** are afforded. In fact Ph_2SnCl_2 is a stronger Lewis acid than dialkyltin(IV) dihalides and it is able to substitute the dihydroperoxide in **6**, yielding the well known stable adduct $Ph_2SnCl_2(dppeO_2)$.[11] On the other hand, when R_2SnBr_2 (R = Me or Bu^n) were employed, **6** was obtained in 90% yields after 6 h. The substitution of chloride groups with the less electronegative bromide in diorganotins seems to accelerate the formation of **6**, in accordance with the weaker acceptor power of the corresponding Lewis acid.

Finally, when dppm, dppp (1,3-bis(diphenylphosphino)propane) or triphenylphosphine were employed, no dihydroperoxide adducts such as **6** were obtained, thus indicating that the methylene chain between the $–P(O)Ph_2$ units can be an important steric factor.

In summary, oxidized diphosphine ligand $dppeO_2$ is able to stabilize 2,2-dihydroperoxide formed by interaction of acetone with H_2O_2 and prevent cyclo-oligomerization. The formation of adduct **6** can be accelerated by R_2SnCl_2 (R = Me or Bu^n). Studies on the possibility of obtaining different dihydroperoxides by starting from different ketones, on the ability of other tin(IV) salts to catalyse the reaction between H_2O_2 and acetone, and finally on the importance of the diphosphine chain for the obtainment of compounds as **6**, are actually in progress.

A photosystem composed of colloidal $IrO_2 \cdot xH_2O$ stabilized by soluble Nafion, tris(2,2′-bipyridyl)ruthenium(II), and persulfate efficiently oxidizes water to oxygen under visible light.

Much effort has been applied to the development of photosystems for visible light cleavage of water into H_2 and O_2.[1–3] Although the reaction is thermodynamically possible with light of wavelength ⩽1000 nm, efficient water photolysis has not yet been reported. One of the key components of such photolysis systems is the catalyst that converts water into O_2.[4–8] As a four-electron redox process, the evolution of O_2 from water is more difficult than kinetically simpler processes, such as H_2 evolution. Recently, we have reported photocatalytic oxidation of water by a buffered $[Ru(bpy)_3]^{2+}$–colloidal $IrO_2 \cdot xH_2O$ system that uses $S_2O_8^{2-}$ as a sacrificial electron acceptor.[9] In this case, the quantum efficiency for O_2 evolution under optimized conditions is about 50%, and the turnover number with respect to the photosensitizer exceeds 200. The turnover rate is very fast compared with that of other $[Ru(bpy)_3]^{2+}$–catalyst–$S_2O_8^{2-}$ systems, but is still too slow to be coupled with a non-sacrificial hydrogen evolving system[10] for overall water photolysis.

Colloidal catalysts in these photosystems are stabilized by coordinating reagents such as citrate ions and polyethylene glycol. The colloid is negatively charged, and adsorbed cationic sensitizers take part in the water oxidation cycle. Interestingly, there is little or no activity at concentrations below that required to saturate the colloid with sensitizer molecules.[9] This suggests that colloidal catalysts stabilized by polyanions might exhibit a higher activity for O_2 evolution than conventional catalysts. In this paper, we report O_2 evolution from a $[Ru(bpy)_3]^{2+}$–Nafion-stabilized $IrO_2 \cdot xH_2O$–$S_2O_8^{2-}$ photosystem. Very stable colloids form in solutions containing soluble Nafion, and the $[Ru(bpy)_3]^{2+}$ photosystem incorporating these catalytic colloids has an appreciably higher quantum efficiency for water oxidation than conventional systems at moderate to high light intensity.

Nafion-stabilized and citrate-stabilized $IrO_2 \cdot xH_2O$ colloids (Nafion/IrO_2 and citrate/IrO_2) were compared as O_2 evolution catalysts. Citrate/IrO_2 was available from our earlier study, in which hexachloroiridate ions ($IrCl_6^{2-}$) were hydrolyzed in a citrate solution at pH 7.[9] Nafion/IrO_2 was prepared similarly in the presence of soluble Nafion perfluorinated ion-exchange resin.[11] The deep blue colloidal solution was stable over a period of three months. The UV–VIS spectrum of the solution had a broad absorption band in the range of 500–700 nm, signaling the formation of colloidal $IrO_2 \cdot xH_2O$,[7] which is apparently stabilized by interaction with the sulfonate groups of Nafion. A TEM image of Nafion/IrO_2 (0.05 g Nafion/0.030 g K_2IrCl_6) is shown in Fig. 1. Primary particles less than 10 nm in diameter form small aggregates that have diameters of 20–30 nm. The grouping of these aggregates into the micron-size patch shown in Fig. 1 is probably an artifact of TEM sample preparation, since the colloidal solutions are not turbid. Citrate/IrO_2 makes similar colloids, except that larger primary particles (10–15 nm) are observed.[9]

The photolysis reactions were carried out in 5 mL aqueous solutions containing $[Ru(bpy)_3]Cl_2 \cdot 6H_2O$, colloidal IrO_2, $Na_2S_2O_8$, Na_2SO_4 and Na_2SiF_6–$NaHCO_3$ buffer in a Pyrex test tube reactor. The concentrations of $Na_2S_2O_8$, Na_2SO_4 and Na_2SiF_6–$NaHCO_3$ buffer were 1.0×10^{-2}, 5.0×10^{-2} and 2.2×10^{-2}–2.8×10^{-2} M, respectively, and the constantly stirred solutions were irradiated with a Xe lamp of 300 W, equipped with a 450 ± 20 nm interference filter. Except as noted, the intensity of visible light reaching the solution was 18 mW cm^{-2}. The solutions were buffered at pH 5.4–5.7 during photolysis. The details are described elsewhere.[9]

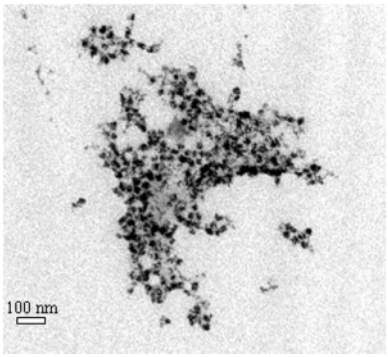

Fig. 1 TEM image of Nafion-stabilized IrO_2 colloid (prepared from 0.05 g Nafion/0.030 g K_2IrCl_6).

Fig. 2 shows the dependence of the sensitizer turnover number and initial O_2 evolution rate on concentration of the sensitizer for $[Ru(bpy)_3]$–Nafion/IrO_2 ([Ir] = 1.0×10^{-4} M) and $[Ru(bpy)_3]$–citrate/IrO_2 ([Ir] = 6.2×10^{-5} M). Nafion/IrO_2 colloids prepared from 0.05 g Nafion/0.030 g K_2IrCl_6 were used for these reactions. The rate of O_2 evolution plotted in this figure is that observed in the early stages of the reaction (5–10

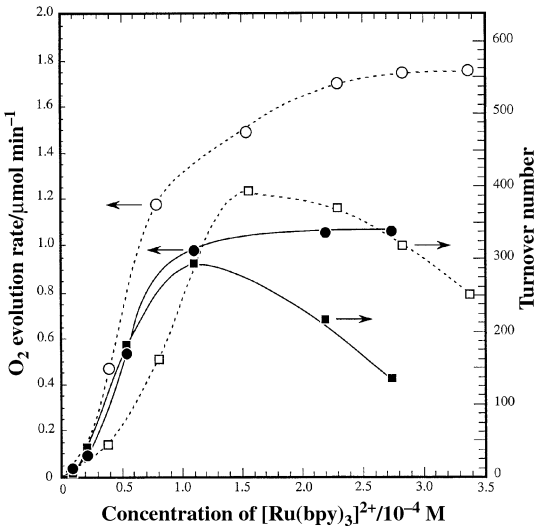

Fig. 2 Dependence of the initial rate of O_2 evolution and turnover number on the concentration of $[Ru(bpy)_3]^{2+}$. For $[Ru(bpy)_3]^{2+}$–Nafion/IrO_2–persulfate, initial rate of O_2 evolution (○), turnover number (□); $[Ru(bpy)_3]^{2+}$–citrate/IrO_2–persulfate, initial rate of O_2 evolution (●), turnover number (■). Nafion/IrO_2: [Ir] = 1.0×10^{-4} M; citrate/IrO_2: [Ir] = 6.2×10^{-5} M.

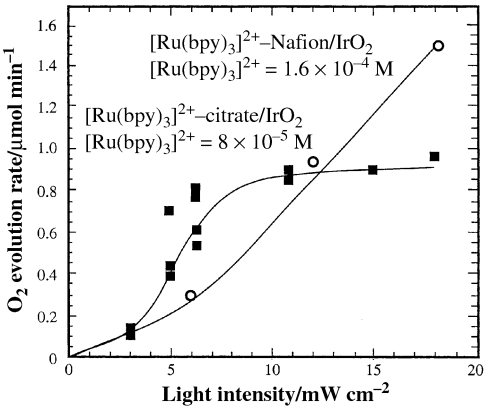

Fig. 3 Light intensity dependence of the initial rate of oxygen evolution for $[Ru(bpy)_3]^{2+}$–Nafion/IrO_2 and $[Ru(bpy)_3^{2+}$–citrate/IrO_2.

min) before significant decomposition of the sensitizer occurs. Each photosystem showed the highest O_2 evolution rate at the colloid concentration used in these experiments. Further addition of colloid to either system decreased both the turnover number and the O_2 evolution rate, because at high concentration the colloidal catalyst begins to quench the MLCT excited state of the sensitizer oxidatively.[6] In both systems, the turnover number reaches a maximum and the rate of O_2 evolution reaches a plateau at high sensitizer concentration. Beyond (1.1–1.5) $\times$ 10^{-4} M, the background decomposition rate of $[Ru(bpy)_3]^{3+}$ exceeds the rate of O_2 evolution and the turnover number decreases.[9] At high light intensity, $[Ru(bpy)_3]^{2+}$–Nafion/IrO_2 surpassed $[Ru(bpy)_3]^{2+}$–citrate/IrO_2 in the rate of O_2 evolution at all concentrations, and the difference in rate increased with increasing sensitizer concentration. The turnover number of the former system also exceeded that of the latter at high concentration. The highest quantum efficiencies for O_2 evolution, ϕO_2, with Nafion/IrO_2 and citrate/IrO_2 catalysts were 73% (2.8 $\times$ 10^{-4} M sensitizer) and 45% ($\geq$2.2 $\times$ 10^{-4} M), respectively.[12] The rate of O_2 evolution in the Nafion/IrO_2 system is light-limited up to the highest light intensity used (18 mW cm^{-2}), whereas that of citrate/IrO_2 is catalyst-limited above about 10 mW cm^{-2} (Fig. 3). This indicates that the turnover rate of the former catalyst is approximately twice that of the latter.

The effects of ionic strength and pH on the time course of O_2 evolution were determined by changing the concentration of buffer and ratio of Na_2SiF_6 to $NaHCO_3$. With buffer concentrations in the range (3.5–5.7) $\times$ 10^{-2} M, there was no noticeable effect of concentration on the time course of O_2 evolution. At lower concentrations, both the rate and turnover number decreased, but in this case the final pH was <4, so the loss in activity can be attributed to the failure of the dilute buffer to maintain the optimum pH (4–6). At initial pH >6.5 the rate also decreases, because the driving force for O_2 evolution decreases. An essentially identical pH dependence has been previously noted by Harriman and coworkers.[6–8]

Interestingly, both initial rate curves in Fig. 2 saturate in the manner of an adsorption isotherm, suggesting that O_2 evolution from these catalysts only occurs when sensitizer molecules are adsorbed on to the colloid.[9] In particular, the rate plot for citrate-stabilized IrO_2 resembles a Langmuir adsorption isotherm.[9] This behavior has also been observed in the $[Ru(bpy)_3]^{2+}$–colloidal RuO_2 system.[6] In contrast, the rate–concentration curve of $[Ru(bpy)_3]^{2+}$–Nafion/IrO_2 has a different shape, and appears to be the sum of two different kinds of isotherms. The turnover plot also peaks at higher $[Ru(bpy)_3]^{2+}$ concentration in this case. We tentatively attribute this behavior to the adsorption of more than a single monolayer of sensitizer on the Nafion polyanion-stabilized colloid.

In summary, colloidal IrO_2 can be stabilized using soluble Nafion, which promotes the photocatalytic oxidation of water through adsorption of sensitizer cations. Very high quantum yields and turnover numbers were achieved under optimized conditions. The high activity of these polyanion-stabilized colloids suggests that further rate enhancement may be possible using structured polyanion/polycation films or other organized assemblies. These possibilities are currently under investigation.

11 20 g Nafion–aliphatic alcohols–water solution (Aldrich, Nafion 5 wt%) was added to 300 mL deionized water. The solution was heated to 70–80 °C on a hot-plate until the total volume was reduced to 50 mL, and was then diluted to 300 mL. This procedure was repeated three times to remove aliphatic alcohols from the solution. The total volume of the final solution was adjusted to 100 mL. 0.030 g K_2IrCl_6 (6.2 $\times$ 10^{-5} mol) was added to 50 mL aqueous solutions containing 0.01–0.25 g dissolved Nafion, which were prepared from the Nafion stock solution described above. The resulting red-brown solution was adjusted to pH 5.0 with 0.25 M NaOH and was heated to 95 °C on the hot-plate with constant stirring. If less than 0.01 g dissolved Nafion was added, or if the pH was above 7, solid IrO_2 precipitated upon heating. After heating for 1 h, the deep blue solution was cooled to room temperature and NaOH solution was added to adjust the pH to the initial value. The solution was transferred to a round bottom flask with a reflux condenser and was kept at 95 °C for 2 h with O_2 bubbling through the solution. The pH was then adjusted to 5.0 with NaOH solution, and the solution was stirred with 10 mL of DOWEX 2X8-50 anion exchange resin to remove excess Nafion. After 30 min, the DOWEX resin was removed by filtration, and the final solution was diluted to 100 mL.
12 Quantum efficiencies (ϕO_2) were calculated using the following equation,[8] in which ϕO_2 (%) = $(2RO_2/I) \times 100$, where RO_2 and I represent the O_2 evolution rate (molecules min^{-1}) and the rate of absorption of incident photons (photons min^{-1}), respectively. The factor of two arises because two photons produce one O_2 molecule when persulfate is used as the sacrificial electron acceptor.

Amine guest size and hydrogen-bonding influence the structures of *p-tert*-butylcalix[4]arene inclusions†

A novel structure involving a 2(*p-tert*-butylcalix[4]arene)·3.5(1,4-butanediamine) inclusion compound shows amine sites both *exo* and *endo* to the cavity, with the amine hydrogen-bonding to itself as well as to the host hydroxyl groups; for bulky amines with large pK_a values, steric factors are more important than basicity, and the formation of a 1:1, high-symmetry host–guest structure is preferred over a low-symmetry hydrogen-bonded structure.

The upper and lower rims of the *p-tert*-butylcalix[4]arene **1** basket-shaped cavity have been extensively derivatised in order to tailor supramolecular behaviour,[1] and almost all modifications at the lower (OH-bonded) rim have been covalent. We report the modification of the cavity's lower rim *via* H-bonding with amines, giving a non-covalent elaboration of the calixarene in the solid state. A delicate balance between amine size and basicity in forming H-bonded structures is observed. The molecular structure changes upon the induction of dynamics or guest loss for at least one of the amine guests in the 2(*p-tert*-butylcalix[4]arene)·3.5(1,4-butanediamine) compound **2**.

In general, interactions between amines and calixarenes in solution depend on the steric nature of the amine. If not too bulky the amine can abstract a proton from a calixarene hydroxyl group *via* a proton-transfer mechanism, forming an ion pair in which the guest occupies the host cavity in an *endo* arrangement.[2] Bulkier amines appear to interact with the host so that the amine is outside (*exo*) the host cavity.[3] Thermodynamic and conductance measurements of alkylamines and **1** in solution indicate H-bonding or ion-pair interactions between calixarene and amine.[4] A theoretical study of amine salts of the anion of **1** shows the preference for amine *endo* and *exo* positions to be solvent-dependent.[5] Amine interaction with the calix phenolic hydroxyl group forms the basis of sensors that change colour upon molecular recognition.[6]

Structures of several calixarene–amine complexes show that the amine interacts with the calixarene phenol in both *endo* and *exo* positions,[7] and structures of calixarenes with alkyl ammonium cations indicate cation inclusions, but no interactions between the guest and the H-bonded OH groups of the host.[8]

Solid-state ^{13}C NMR spectra of **1**·guest inclusion compounds provide a rapid means to determine symmetry elements.[9] An inclusion compound in which the host molecule has an axis of 4-fold symmetry gives a single resonance for each chemically distinct carbon of the *p-tert*-butylphenol repeat unit.[10] Lowering the symmetry element increases the multiplicity of each carbon resonance, as the four repeat units are no longer equivalent symmetrically. The ^{13}C CP-MAS NMR spectrum of **2** [Fig. 1(a)] indicates that the structure has very few, if any, symmetry elements. In particular, the δ 135–160 region shows the signals from the H1 and H4 aromatic carbons of the host. Whereas a high-symmetry structure gives only two host signals in this region, and three in the aliphatic region (δ 22–48),[9] the present spectrum shows 14 resolved lines over the region δ 135–160 and 11 lines (host and guest) in the aliphatic region. Peaks at 39.8 and 42.2 ppm arise from guest methylene carbons attached to the amine nitrogen, and are broadened due to coupling to the ^{14}N quadrupole or because of dynamic effects. The extent to which the aromatic carbon signals are spread out, the multiplicity, and the signal intensity distribution all contrast to the comparable features seen for nitrobenzene inclusion in the same host.[11] Clearly, the structure of **2** shows low symmetry, and is distinct from other low-symmetry structures such as **1**·nitrobenzene.

The existence of a significantly distorted host cavity is confirmed by the X-ray diffraction structure.‡ The asymmetric unit contains two crystallographically inequivalent host molecules, each without any element of symmetry. Each host molecule has two ordered and two disordered Bu^t groups: the *C*-host has the disordered groups positioned *cis* and the *T*-host has the disordered groups positioned *trans*. Unlike other structures of **1**, there is no clear correlation between the disorder in the host Bu^t groups and the disorder in the guest. The two Bu^t groups in the *C*-host are disordered over two positions each, while those in the *T*-host are disordered over two and four positions. There are 3.5 molecules of 1,4-butanediamine in the asymmetric unit (which contains two host molecules). Each *C*- and *T*-cavity contains one *endo* guest molecule, and that in the *T*-cavity is disordered over two positions. There are two, fully occupied *exo* guest sites outside the host cavities; one is on the inversion centre thus giving the fractional stoichiometry.

The structure possesses two independent groupings of H-bonded guests, one a finite trimer and the other an infinite chain. The trimer involves the *endo* guest of the *C*-host cavity (Fig. 2). This fully ordered guest adopts a curled ⊂-conformation in which the guest is H-bonded to itself ($d_{N–N}$ 2.72 Å), to one hydroxyl group of a *T*-host ($d_{N–O}$ 2.80 Å), and an amine group of the *exo* guest on the inversion centre ($d_{N–N}$ 2.77 Å). The *exo* amine group also interacts weakly with a second hydroxyl group of the same *T*-host ($d_{N–O}$ 3.3 Å); this hydroxyl group is

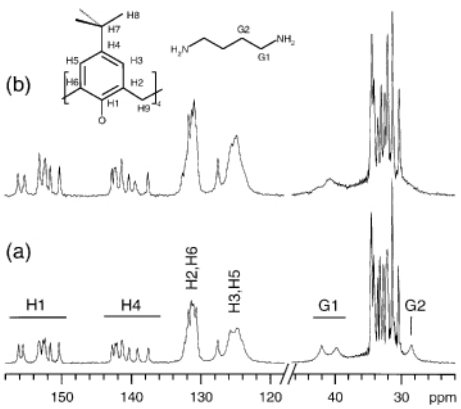

Fig. 1 Partial 75.48 MHz ^{13}C-{^{1}H} CP-MAS spectra: (a) **2**, (b) **2** after stirring in *n*-hexane. The aromatic host carbons are assigned; the aliphatic host carbons (H7, H8, H9) occur in the δ 27–36 region. Experimental details: 5.3 kHz spinning speed, 1600 transients, 3.4 μs 90° pulse, 50 kHz ^{1}H-decoupling field, 3.5 ms contact time, 1.5 s recycle delay, 40 kHz spectral width, 4 K data points collected and zero-filled to 16 K points.

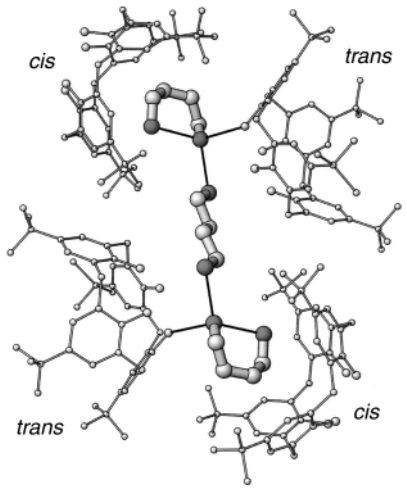

Fig. 2 Geometry of **2** indicating the finite hydrogen-bonding trimer involving the *endo* amine guest in the *C*-host cavity and the *exo* amine on the inversion centre.

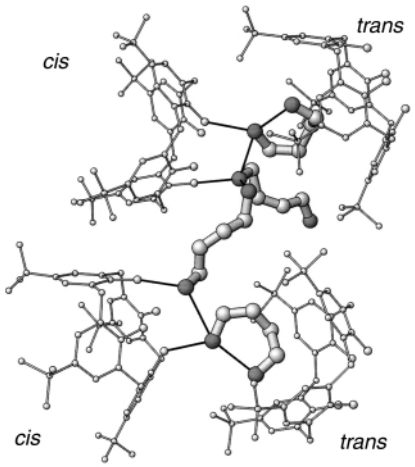

Fig. 3 Geometry of **2** indicating the infinite hydrogen-bonding chain involving the *endo* amine guest in the *T*-host cavity and the *exo* amine in the general position.

located *trans* to the first H-bonded hydroxyl group. The infinite chain involves the *endo* guest of the *T*-host cavity (Fig. 3); this guest is disordered over two positions. It is similarly curled and H-bonds to itself ($d_{N–N}$ 2.77 Å), to one hydroxyl group of a *C*-host ($d_{N–O}$ 3.01 Å), and an amine group of the second *exo* guest ($d_{N–N}$ 2.70 Å). This second *exo* guest further H-bonds with a symmetrically equivalent *exo* guest ($d_{N–N}$ 2.70 Å) and two adjacent hydroxyl groups of the *C*-host ($d_{N–O}$ 2.70 Å, $d_{N–O}$ 2.70 Å).

Hydrogen-bond formation is expected to depend primarily on the acidity of the host hydroxyl group (pK_a = 19.33 in benzonitrile)[4] and the amine basicity. Several amines have been used to form inclusion compounds of **1**, and the solid-state ^{13}C NMR spectra indicate the presence or absence of H-bonded structures.§ While amines with pK_a > 9 appear to favour H-bonded structures, the *sec*- and *tert*-butylamine compounds indicate that the amine basicity does not appear to direct the symmetry of the resultant structures, which show NMR spectra of the high-symmetry 1 : 1 host–guest inclusions.[9] Inclusion and orientation of these two guests in the host cavity are dominated by steric factors. It is intriguing to consider an amine guest in which the basicity and steric factors are so closely balanced that slight changes in conditions (*P*, *T*) cause the structural motifs in the inclusion compound to switch.

Finally, we report preliminary findings on the structural modifications of compound **2** that result from stirring in *n*-hexane.¶ The ^{13}C NMR spectrum in [Fig. 1(b)] shows a single guest amine G1 carbon signal (δ 41.0) whereas in **2**, there were two signals (δ 39.8 and 42.2). This feature indicates that *n*-hexane induces dynamic changes in the guest that may result from exchange of two rigid G1 carbons and/or loss of one of the guests from the lattice. Changes in the aromatic host carbon signals, though subtle, are well enough defined as slight differences in chemical shifts and intensities. Both NMR observations indicate that the structural modifications lie primarily with the guest, and that the affected guest likely occupies an interstitial or *exo* site, due to its longer intermolecular hydrogen bonds relative to the *endo* guests.

Selective β-polynitration of Zn–5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin, Zn(TDCPP), is achieved by controlled titration with the HNO_3–CF_3SO_3H–$(CF_3SO_2)_2O$ system, and affords a full series of Zn porphyrins bearing one through to eight β-nitro groups in high yield and exhibiting a wide range of reduction potentials (from −920 to +155 mV *vs.* SCE); an X-ray structure of the first reported β-pernitrated Zn porphyrin Zn(TDCPN$_8$P)(EtOH)$_2$·2EtOH confirms the synthetic methodology.

Iron and manganese meso-tetraaryl porphyrins bearing electron-withdrawing β-substituents have been shown to be efficient catalysts for cytochrome P450-mimetic oxygenations of hydrocarbons.[1] In an effort to obtain metalloporphyrins with significantly altered redox potentials and unusual reactivities, we have attempted to synthesize metalloporphyrins bearing as many electron-withdrawing β-nitro substituents as possible.[2] Nitration of TDCPPH$_2$[3] with red fuming HNO_3 led us to mixtures of β-pentanitro- and β-hexanitro-TDCPPH$_2$.[2a] More recently, we reported that a more powerful nitrating agent, consisting of a mixture of HNO_3 and $(CH_3CO)_2O$ in the presence of K10 montmorillonite, reacted with Zn(TDCPP) to afford the corresponding β-heptanitroporphyrin, Zn(TDCPN$_7$P), in 50% yield.[2b] However all the nitrating systems that we have used so far suffered from two main drawbacks, (i) they did not pernitrate the porphyrin to the β-octanitro level, and (ii) they did not act as general nitrating agents to produce all the desired β-polynitroporphyrins, Zn(TDCPN$_x$P) (x = 1–8), as the number of nitrating equivalents was increased. Indeed, selective formation of any one TDCPN$_x$P porphyrin required a different nitrating system[2] for each value of x.

We have now developed a nitrating system based on HNO_3 and the superacid CF_3SO_3H in the presence of $(CF_3SO_2)_2O$ that acts as a general nitrating agent for the selective synthesis of the full TDCPN$_x$P series. We describe here the successful use of this nitrating procedure to prepare all eight members of the Zn(TDCPN$_x$P) series in high yield, present the first X-ray structure of a β-pernitroporphyrin, Zn(TDCPN$_8$P), prepared by this method, and report the strikingly wide range of redox potentials now accessible *via* the eight members of the Zn(TDCPN$_x$P) series.

Titration of Zn(TDCPP) with 1, 2, 3, 4 or 6 equiv. of red fuming HNO_3 and CF_3SO_3H (1:1)[4] selectively led to Zn(TDCPN$_x$P) with x = 1, 2, 3, 4 or 6, respectively with yields between 50 and 70% (Table 1). However, the use of 5 equiv. of HNO_3–CF_3SO_3H led to a complex mixture of Zn(TDCPN$_x$P) with x = 4, 5 and 6. Moreover, low yields of Zn(TDCPN$_8$P) were obtained (*ca.* 25%, Table 1) when using the same system.

A slightly modified system consisting of red fuming HNO_3 in the presence of < 1 equiv. of CF_3SO_3H and $(CF_3SO_2)_2O$, in order to limit side reactions [demetallation and destruction of Zn(TDCPP)], allowed us to prepare each compound of the Zn(TDCPN$_x$P) series in much higher yields. Thus, titration of Zn(TDCPP) with increasing amounts of the HNO_3–CF_3SO_3H–$(CF_3SO_2)_2O$ (1:0.12:0.06) mixture selectively led to each compound of the Zn(TDCPN$_x$P) series (x = 1–7) with yields between 78 and 95%. Formation of the desired porphyrin was followed by thin-layer chromatography and addition of the nitrating agent was stopped after complete formation of the target product. The pernitrated Zn(TDCPN$_8$P) was selectively obtained with a satisfactory 50% yield by the same method under the conditions described in Table 1. The full range of β-nitro products obtained with this system contrasts sharply with

the classical nitrating HNO_3–H_2SO_4 system which was found to be efficient only for the preparation of the first four members of the $Zn(TDCPN_xP)$ series (yield *ca.* 80%).

All the $Zn(TDCPN_xP)$ compounds (x = 1–8) were completely characterized by elemental analysis and UV–VIS, ^1H NMR spectroscopy and mass spectrometry. Additional details of the syntheses and full characterizations will be presented elsewhere. It is of note that Zn(TDCPNP), $Zn(TDCPN_7P)$ and $Zn(TDCPN_8P)$ are single pure compounds while the other members of the $Zn(TDCPN_xP)$ series are mixtures of regioisomers with different relative positions of the β-nitro substituents.

The molecular structure of the first β-pernitrated porphyrin to be reported, $Zn(TDCPN_8P)(EtOH)_2$ **1**, was confirmed by an X-ray crystallographic study of **1**·2EtOH obtained by crystallization from CH_2Cl_2–EtOH.[5] As shown in Fig. 1, the Zn is axially coordinated by two molecules of EtOH with Zn–O distances of 2.272(10) Å and average Zn–N distances to the pyrrole nitrogens of 2.075(8) Å. The Zn–O and Zn–N distances are, respectively, the shortest and longest bond distances reported to date for hexacoordinated Zn porphyrins with oxygen donor axial ligands.[6] The tight axial bonds and the expanded porphyrin core are readily attributable to the multiple electron-withdrawing groups of **1**. In spite of the 12 peripheral substituents, which generally result in severe skeletal distortions,[7] the macrocycle of **1** is essentially planar with an average deviation from the 24-atom porphyrin plane of only 0.035 Å, and maximum displacements of only 0.08 and 0.07 Å at any one β or meso carbon, respectively. Macrocycle planarity is achieved by orienting all the peripheral substituents nearly orthogonal to the porphyrin plane: the two crystallographically independent phenyl rings align at 80 and 90° to the porphyrin plane whereas the four independent nitro groups subtend angles of 76, 82, 87, 77° to the same plane.

As established by cyclic voltammetry, all eight $Zn(TDCPN_xP)$ undergo a reversible one-electron reduction leading to the formation of π-anion radicals. Formation of such radicals[8] is confirmed by controlled-potential electrolysis of $Zn(TDCPN_8P)$ at 0 V *vs.* SCE in CH_2Cl_2 which yields a species that exhibits new absorption bands centered at 900 nm and a singlet EPR spectrum centered at g = 2.00.[9] Table 1 compares the reduction potentials of each ZnP/ZnP^- couple for all eight nitro derivatives. The potentials increase in a linear manner, the introduction of each additional β nitro group causing a shift of *ca.* +150 mV. Thus, the incorporation of eight β-nitro groups in Zn(TDCPP) leads to a strikingly large positive shift of *ca.* 1.4 V of the reduction potential and thus readily explains why the π-anion radical of $Zn(TDCPN_8P)$ forms under such mild reducing conditions, even in the presence of O_2.

In conclusion, we have developed a new general method for selective β-polynitration of Zn(TDCPP) in high yield based on controlled titration of the starting porphyrin with HNO_3–CF_3SO_3H–$(CF_3SO_2)_2O$. The method leads to a complete series of porphyrins bearing 1–8 β-nitro groups with a wide span of reduction potentials that range from −920 to +155 mV. Similar results were obtained with Ni(TDCPP) and methods for selective demetallation of the Zn and Ni polynitroporphyrins have been recently developed. Use of metallo–β-polynitroporphyrins in catalysis, and application of the nitration method to other polyaromatic molecules are under investigation.

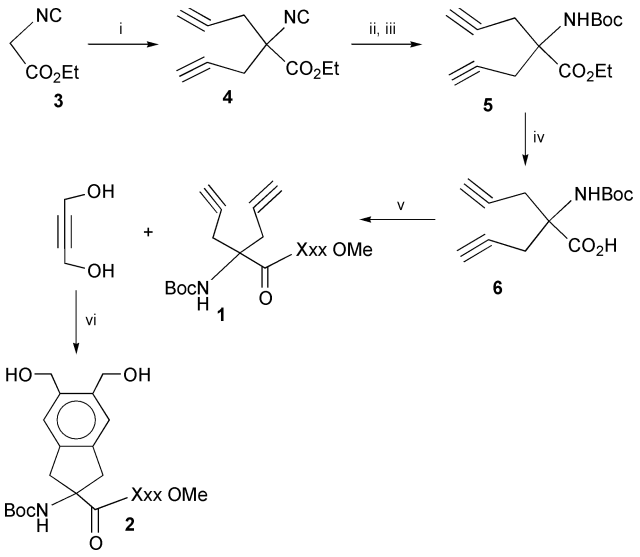
Peptide modification potentially valuable for peptidomimetic and combinatorial chemistry applications is described involving a [2+2+2]-cycloaddition reaction leading to conformationally constrained phenylalanyl peptides.

Aromatic amino acids like phenylalanine and tyrosine are often important elements of peptide pharmacophores. Novel methods to generate conformationally restrained analogs from suitable precursor peptides evoke interest,[1–3] particularly for combinatorial chemistry applications. A variety of benzenoid molecules are accessible through [2+2+2] or [4+2]-cycloaddition reactions.[4] Applied to suitable peptide precursors, the reaction may provide an approach to conformationally constrained aryl amino acid residues *in situ*. Artificial amino acids with olefin, diene, allene or acetylene groups in the side chain have been described[5] and could be useful synthons for conformationally constrained aryl amino acid residues approachable in a [2+2+2]-type cycloaddition reaction. Conversion of a suitable diacetylenic dipeptide precursor **1** into a constrained phenylalanyl peptide **2** in a [2+2+2]-cycloaddition reaction catalyzed by Wilkinson's catalyst[6] is illustrated in Scheme 1.† The reaction conditions are mild enough to be compatible with the acid and base labile protecting groups that are normally required for peptide synthesis.

The precursor peptide **1** could be easily made in a standard peptide synthesis protocol starting from the dipropargyl glycine **6** as the specific building block amino acid. The Boc-protected form of **6** was easily made from ethyl isocyanoacetate **3** serving as the glycine synthon.[7] Dipropargylation in refluxing acetonitrile–K_2CO_3 in the presence of tetrabutylammonium hydrogen sulfate as the phase transfer catalyst furnished the isonitrile derivative **4** in good yield (69%). Acid catalysed hydrolysis, followed by Boc-protection gave **5**. Saponification of **5** furnished the Boc protected amino acid **6**.



Scheme 1 *Reagents*: (i) K_2CO_3, propargyl bromide, $^nBu_4NHSO_4$; (ii) HCl, EtOH; (iii) $CHCl_3$, $(Boc)_2O$; (iv) aq NaOH, MeOH; (v) HCl H_2N Xxx CO_2Me, HOBt, THF, NMM; (vi) $(Ph_3P)_3RhCl$, EtOH, reflux.

Table 1 Representative constrained phenylalanyl peptides

Starting peptide	[2+2+2]-Cycloaddition product	Yield (%)[a]
 1a	 2a	66
 1b	 2b	54
 1c	 2c	75
 1d	 2d	70
 1e	 2e	65

[a] Yields refers to [2+2+2]-cycloaddition product

Condensation of the Boc-protected building block amino acid **6** with various amino acid ester derivatives in a standard DCC-mediated peptide procedure[8] furnished the dipeptide (*e.g.*) **1a** or longer peptides Boc-Dprg-Xxx-OMe (with Xxx = L-Leu, D-Val, D-Leu, D-Val-L-Leu, L-Leu-L-Ala, L-Leu-D-Val-L-Leu). Treatment with five-fold excess of but-2-yn-1,4-diol, a model monoyne so chosen as to avoid the formation of diastereomers, furnished representative constrained phenylalanyl peptides shown in Table 1.

The additional methylene bridge connecting the α-carbon with the aromatic ring not only restrains the phenylalanyl moiety but also the backbone, restricting its conformational freedom, and this has potential to influence the pharmacological profile[9] of the parent Phe or Tyr peptide variant. Additional structural variations are feasible and can add to the versatility of the combinatorial chemistry approaches. For instance, the diol functionality in the product peptides here is a useful site for possible further molecular manipulations.

In summary, a peptide modification capable of generating constrained phenylalanyl peptide variants in a [2+2+2]-cycloaddition reaction is reported and could be potentially useful for both peptidomimetic and combinatorial chemistry applications.

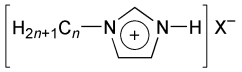
Easily accessible liquid crystals of 1-alkylimidazolium salts having a bilayer structure, are good solvents providing a partially ordered reaction environment.

Molecular thermotropic liquid crystals, which have been extensively studied and documented, are usually molecules composed of an extended rigid aromatic core and terminal flexible alkyl chains. Ionic liquid crystals (ILCs), which have been less well studied[1–6] in comparison to neutral LCs, are amphiphiles having a hydrophilic cationic or anionic head group and hydrophobic long alkyl chains. A classic example of an ILC is an alkali metal soap, in which the anion possesses a negatively charged head group with a long alkyl chain. However, ILCs with positively charged mesomorphic cations, such as alkylammonium,[1] alkyl phosphonium,[1b,d,2] *N*-alkylpyridinium[3] and *N*,*N*-dialkylimidazolium[3a,b,4] salts have also been reported. These cationic amphiphiles have many interesting properties and are potentially useful as synthetic membranes,[5] antimicrobial agents,[6] gellators[7,1b,d] NLO[8] and surfactants,[9] to name a few.

Recently rt ionic liquids (ILs) have been considered as a new generation of green solvents for organic reactions.[10] ILs not only provide solvent properties different from any other organic solvent, but can also be recycled very easily. Furthermore, ILs possessing liquid crystal properties further provide a partially ordered environment and may give a better selectivity for organic reactions. A few examples of liquid crystalline ionic liquids of imidazolium salts have been reported.[4,3b,c] In this paper we report the mesomorphic behavior of a new series of 1-alkylimidazolium salts prepared simply by the addition of acids to 1-alkylimidazoles (Scheme 1). In order to appraise the usefulness of this system as a solvent, we have begun a study of the Diels–Alder condensation. A stereoselectivity different from that of the known reactions has been found.

1-Alkylimidazoles‡ were synthesized according to the literature methods.[11] 1-Alkylimidazolium salts (n = 10, 12, 14, 16, 18) were prepared by adding a slight excess of concentrated acids dropwise to the 1-alkylimidazoles. Salts with the formula [R-imH][NO_3], [R-imH]Cl·H_2O and [R-imH][BF_4] were obtained after recrystallization from THF or CH_2Cl_2–hexane. Anhydrous chloride salts were obtained by heating the hydrated samples at 140 °C under vacuum for 3 h. Under such conditions, no decomposition has been observed as evidenced by ^{1}H NMR spectroscopy. The completeness of the dehydration has been confirmed by thermal gravimetric analysis. The chemical shift of the NH proton depends on the anion. With an alkyl chain length of n = 14, the chloride salt has the lowest chemical shift at 16.0 ppm, the nitrate salt has 15.5 ppm and the $[BF_4]^-$ salt has the highest chemical shift at 12.3 ppm. A similar trend is observed for the 2-CH protons (Cl^-, 9.4; $[NO_3]^-$, 9.2; $[BF_4]^-$, 8.7 ppm). These trends may reflect the strength of the H-bonding between the respective protons and anions and have been reported.[12]



X = NO_3^-, Cl^-, BF_4^-; n = 10, 12, 14, 16, 18

Scheme 1 *N*-alkylimidazolium salts.

In research on the packing of charged surfactant molecules, studies of the crystal structures of imidazolium based salts are rare.[3b,4a] Therefore, the molecular structure of [$C_{14}H_{29}$-imH][NO_3] was determined by single crystal X-ray diffraction and is shown in Fig. 1. 1-Alkyl chains are parallel to the imidazole planes. The nitrate planes are also parallel to the imidazole planes. Interdigitation of alkyl chains forms a bilayer lamellae with a repeating layer distance of 16.9 Å. Each bilayer is further linked with anions through hydrogen bonds.

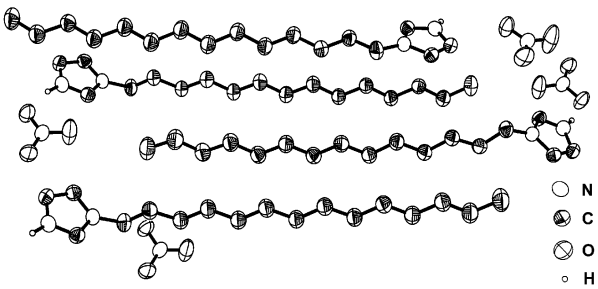


Fig. 1 ORTEP drawing of [$C_{14}H_{29}$-imH][NO_3] (50% thermal ellipsolids), hydrogens being omitted for clarity (except for N–H).

The liquid crystal properties of 1-alkylimidazolium salts were examined by optical polarized microscopy and differential scanning calorimetry. The nitrate salts with n = 14, 16 and 18 exhibit liquid crystal behavior. Characteristic focal conic fan and oily streak textures with spontaneous homeotropic phenomena are observed during the process of heating and cooling, suggesting a lamellar SmA mesophase (Fig. 2). The chloride and tetrafluoroborate salts also show SmA mesophases. The Cl^- salt of n = 10 is a rt ILC and for the salt of n = 12, the process of crystallization needs several days when cooling to rt. The $[BF_4]^-$ salt with n = 12 exhibits monotropic liquid crystal properties. In general, the temperature range of mesophase increases with increasing chain length (Fig. 3). Among the three different anions of [C_nH_{2n+1}-imH]X (X = Cl^-, $[NO_3]^-$,

Fig. 2 The fan texture of the mesophase of [$C_{14}H_{29}$-imH][NO_3] at 70 °C.

DOI: 10.1039/b004462h

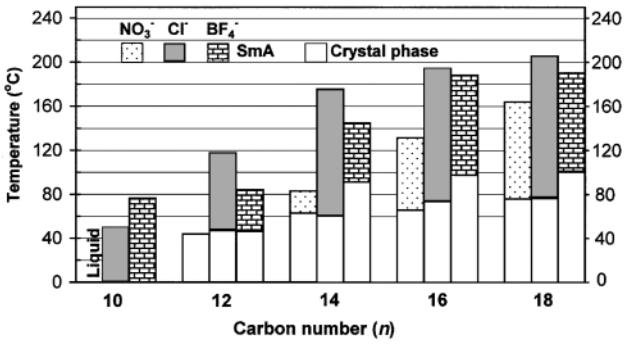

Fig. 3 The phase transition diagram of $[C_nH_{2n+1}$-imH]X from DSC at 10 °C min^{-1}. (X = Cl, BF_4, second heating step; X = NO_3, first heating step; X = BF_4, monotropic; X = Cl, n = 10 and X = NO_3, n = 14 from POM). For clarity the crystal to crystal phase transitions are not shown.

$[BF_4]^-$), the chloride salts have the widest temperature range of mesophase. This result may reflect the strength of H-bonding between the cation and the chloride anion. The nitrate salt of n = 12 and chloride salts of n = 10, 12, 14 exhibit lyotropic behavior in water, acidic water and THF. For example, both the nitrate and chloride salts of n = 12 in H_2O (> 20% by weight concentration) are liquid crystals having a fan texture with a spontaneous homeotropic behavior at rt.

To demonstrate the effect of the lamellar phase on the stereoselectivity of Diels–Alder reactions, a preliminary condensation reaction[13] of cyclopentadiene (0.063 g, 0.3 mmol) with diethyl maleate (0.024 g, 0.3 mmol) in an ionic liquid crystalline solvent system (a mixture of 0.42 g of $C_{12}H_{25}$-im and 0.15 mL of 12 M HCl) at rt was examined. Optical observation indicated that under these reaction conditions the reaction mixture retained the lamellar mesophase structure. The selectivity of *exo/endo* product was 54 : 46. A parallel reaction carried out in EtOH, gave an *exo/endo* ratio of 12 : 88. This preference for *exo* over *endo* product in the ionic liquid crystalline solvent is different from that observed when the reaction is carried out it EtOH and, in those earlier studies, simple ionic liquids,[13c,d] water[13a–c] or organic solvents.[13a–c] This result indicates that the lamellar mesophase has a strong influence on the selectivity of the reaction product.

In summary, we prepared a new series of thermotropic liquid crystalline 1-alkyl-substituted imidazolium salts. The chloride salts of n = 10, 12, 14 and the nitrate salts of n = 12 also exhibit lyotropic properties. The thermotropic and special lyotropic properties possessed by this series of ILCs make them alternative solvents for organic reactions, such as Diels–Alder condensations, and metal-catalyzed reactions.

We thank the National Science Council of Taiwan, R. O. C. (NSC90-2113-M-030-001) for the support of this work.

‡ 1-Alkylimidazolium nitrates (n = 10, 12, 14, 16, 18) were prepared by adding a slight excess of concentrated nitric acid dropwise to the 1-alkylimidazoles at 0 °C in ether. Immediate white precipitates formed when n = 12, 14, 16 ,18. The nitrate salt with n = 10 is a liquid, which was purified by successive washing with ether followed by vacuum drying. Chloride salts (n = 10, 12, 14, 16, 18) were prepared by using concentrated hydrochloric acid as the acid source. Tetrafluoroborate salts (n = 10, 12, 14, 16, 18) were prepared by adding excess of tetrafluoroboric acid (32% in water) to 1-alkylimidazoles in water–THF.

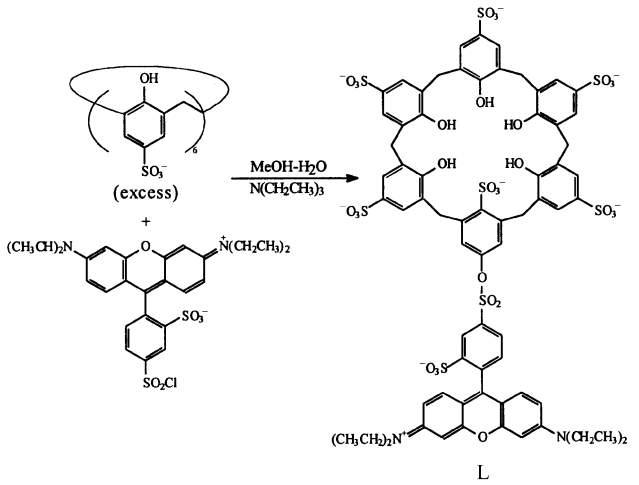
4-Sulfonic calix[6]arene is derivatized with lissamine rhodamine B to give a fluorescent ligand, L, which is applied to a capillary electrophoresis microchip for the selective detection of uranium(VI).

Environmental concerns associated with the remediation of radioactive waste sites have generated considerable interest in the development of a portable, rapid and selective monitor for radioactive contaminants, such as uranium. This need has been prompted by the costly and time-consuming delays which have resulted from submitting samples to external laboratories for analytical characterization before, during and after the application of remediation methodologies to contaminated groundwater or structural materials encountered at these sites. In this communication, we report the application of a derivative of the 'super-uranophile', 4-sulfonic calix[6]arene, which has been tagged with a long wavelength fluorophore, lissamine rhodamine B, for the selective detection of uranyl ion, UO_2^{2+}, on a glass microchip. The experimental design employed here combines the superior selectivity of 4-sulfonic calix[6]arene for the UO_2^{2+} ion,[1] the high sensitivity and diminished overlap of impurity fluorescence inherent with utilizing long wavelength fluorescence detection,[2] and the numerous advantages associated with performing glass microchip separations, including short analysis times, minimal sample consumption and waste generation, and portable instrumentation.[3]

The calixarene derivative, **L**, was synthesized through the coupling reaction of 4-sulfonic calix[6]arene with lissamine rhodamine B sulfonyl chloride in a mixed solvent of methanol and water in the presence of excess 4-sulfonic calix[6]arene (Scheme 1). The mono-derivatized product, **L**, was isolated by column chromatography (methanol/ethyl acetate) and verified by electrospray mass spectrometry.[4] Excitation of **L** at 532 nm gives an intense fluorescence peak at 593 nm in water, differing only slightly from the parent fluorophore, lissamine rhodamine B sulfonyl chloride, at 583 nm.



Scheme 1 Synthetic coupling of lissamine rhodamine B to 4-sulfonic calix[6]arene.

The microchips utilized for performing the separation were microfabricated in Borofloat glass to contain a simple cross pattern, lithographically etched into the glass substrate (20 μm deep × 50 μm wide) to define the sample loading and separation microchannels (see Fig. 1).[5] A glass cover plate pre-drilled to contain four access holes was thermally bonded to the microfabricated glass plate. Sample, buffer, and waste reservoirs were constructed by inserting pipette tips into these holes. The lengths of the loading and separation channels were 10 and 85 mm, respectively, with an effective separation length of 80 mm. Through computer control of the potentials applied to the different reservoirs, sample analyte was loaded into the intersection of the two channels and subsequently separated down the length of the separation channel. The separation was monitored by focussing light from a compact, 15 mW Nd/YAG laser (532 nm) onto the end of the separation channel, collecting the fluorescent light with a microscope objective (20×) positioned at 90°, and directing the light onto a miniature, red-shifted photomultiplier tube (Hamamatsu).

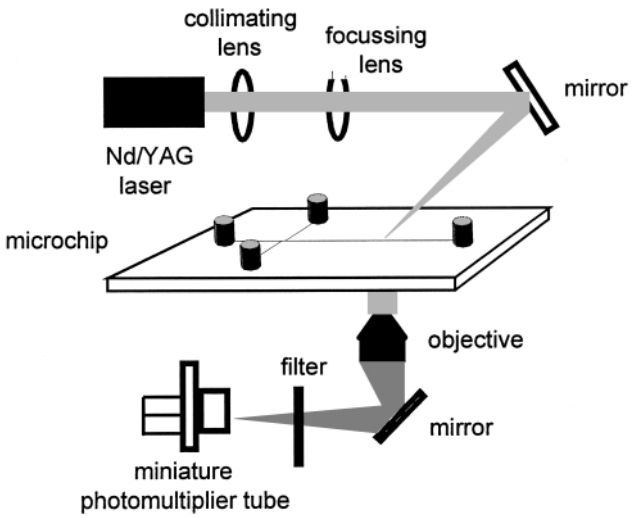


Fig. 1 Instrumental layout for performing microchip separations.

Microchip separations were performed using a buffer solution containing 10 mM sodium borate, 50 mM boric acid, and 2 mM $MgCl_2$ (pH = 8.3). Under this pH condition, in addition to the complete deprotonation of the six sulfonic groups of ligand **L**, previous studies establish that two of the five phenol groups will also likely be deprotonated to give $\mathbf{L}^{8-}$.[6] In experiments run without the addition of $MgCl_2$ in the buffer solution, **L** was detected under positive polarity (+1000 V cm^{-1}) with long migration times (over 100 s) and poor peak shapes. Furthermore, following the addition of UO_2^{2+} to the analyte reservoir, the resolution obtained on the microchip was insufficient to separate the uranyl bound ligand from the free ligand, **L**. The addition of 2 mM $MgCl_2$, however, allowed **L**

and its uranyl ion complex to be completely resolved under negative polarity (−1000 V cm^{-1}) with significantly reduced migration times and improved peak shape (Fig. 2a, b). A similar enhancement in the resolution was reported for the capillary electrophoretic separation of *p*-sulfonated calixarenes following the addition of Mg^{2+} to the background supporting electrolyte.[7] The uranyl complex formed with **L** is believed to further deprotonate the remaining three phenols, giving a planar complex, $[\mathbf{L}\cdot UO_2]^{9-}$, which is more negatively charged than the parent molecule, $\mathbf{L}^{8-}$. This observation helps explain the shorter retention time obtained for the uranyl complex, $[\mathbf{L}\cdot UO_2]^{9-}$, due to its enhanced electrophoretic mobility under the applied electric field. Microchip evaluations of the electroosmotic flow using the neutral marker, rhodamine B, demonstrate that the electroosmotic flow was significantly reduced by the addition of $MgCl_2$, but not reversed. The detection limit for UO_2^{2+} under these conditions was 4.2 μM.

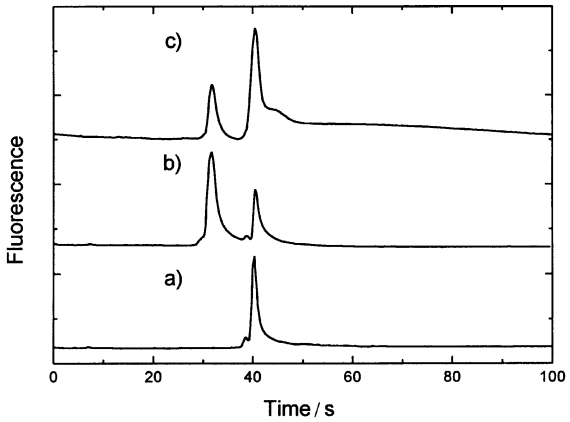

Fig. 2 Microchip separations obtained using 10^{-4} M **L** in a buffer solution containing 10 mM sodium borate, 50 mM boric acid and 2 mM $MgCl_2$ (pH = 8.3), (a) 0 mg L^{-1} UO_2^{2+}; (b) 10 mg L^{-1} UO_2^{2+}; (c) 10 mg L^{-1} UO_2^{2+}, Cu^{2+}, Pb^{2+}, Cd^{2+}, Th^{4+} and Nd^{3+}.

The effective detection of UO_2^{2+} on the microchip requires a pre-complexation step between the ligand, **L**, and uranyl ion. In general, the binding rates of UO_2^{2+} by calixarenes are relatively slow, due to the geometric rearrangement requirements imposed on the calixarene for conforming to the pseudoplanar geometry which permits binding of the uranyl ion in a hexacoordinate structure. The half-life of the binding reaction between the super-uranophile, 4-sulfonic calix[6]arene, and UO_2^{2+} is about an hour.[1b] The high thermodynamic stability constant and slow dissociation kinetics of the uranyl ion complex, $[\mathbf{L}\cdot UO_2]^{9-}$, however, explain why the complex does not dissociate and become undetectable as it travels down the separation column, a problem which plagues the majority of capillary electrophoresis separations of strongly complexed metal ions when the complexing ligand is absent from the separation buffer.[8]

Studies were performed on the detection of UO_2^{2+} in the presence of six competing metal ions, Cu^{2+}, Zn^{2+}, Pb^{2+}, Cd^{2+}, Th^{4+}, and Nd^{3+}, each at a concentration of 10 mg L^{-1}. Introduction of these six impurity metal ions to **L** in the absence of UO_2^{2+} resulted in no change to the electropherogram recorded for **L**. The subsequent addition of UO_2^{2+}, however, gave the electropherogram shown in Fig. 2c, indicating the capability for **L** to selectively complex UO_2^{2+} despite the presence of a matrix of six impurity metal ions. The underivatized form of the ligand utilized here, 4-sulfonic calix[6]arene, has been termed a super-uranophile, due to the extremely large selectivity factors, 10^{12-17}, determined for the binding of uranyl ion in the presence of competing Ni^{2+}, Zn^{2+}, and Cu^{2+} ions.[1] The selective binding of UO_2^{2+} ion by **L** in the presence of other metal ions results from the fact that **L** provides a pseudoplanar, hexacoordinate geometry which suits UO_2^{2+} uniquely. Any weakly bound metal complexes and/or complexes bearing fast dissociation kinetics will be unresolved due to their rapid dissociation from the fluorescent ligand as the complexes travel down the separation column.

In conclusion, by synthetically coupling the super-uranophile, 4-sulfonic calix[6]arene, to the long wavelength, fluorescent dye, lissamine rhodamine B, we have developed a new ligand, **L**, which is ideally suited for selectively detecting uranium on a glass microchip platform. **L** has a coordination site which is highly selective for binding UO_2^{2+} ion in the presence of numerous impurity metal ions, and a fluorescent tag whose red shifted emission wavelength enables a compact, portable laser to be utilized, minimizing any background fluorescence arising from impurities apparent in real samples. The results of this study have exciting implications with respect to methods for preparing molecular and metal recognition molecules for application to the burgeoning field of microchip capillary electrophoresis.

The authors gratefully acknowledge the Environmental Management Science Program of the Department of Energy for funding support of this study.

4 Compound **L** was verified by NMR and electrospary mass spectrometry. The negative ion mode of the mass spectrometer yielded three major clusters of peaks, corresponding to doubly, triply and quadruply charged species. The most abundant cluster of peaks corresponded to the following species: $[M - 2H]^{2-}$, *m/z* 828.1; $[M - 3H + Na]^{2-}$, *m/z* 839.1; $[M - 4H + 2Na]^{2-}$, *m/z* 850.1; $[M - 5H + 3Na]^{2-}$, *m/z* 861.1; $[M - 6H + 4Na]^{2-}$, *m/z* 872.1. A second cluster of peaks, corresponding to triply charged ions, was observed at the following *m/z* ratios: $[M - 3H]^{3-}$, *m/z* 551.7; $[M - 4H + Na]^{3-}$, *m/z* 559.0; $[M - 5H + 2Na]^{3-}$, *m/z* 566.4; $[M - 6H + 3Na]^{3-}$, *m/z* 573.7. The cluster of quadruply charged ions was observed at the following *m/z* ratios: $[M - 4H]^{4-}$, *m/z* 413.5; $[M - 5H + Na]^{4-}$, *m/z* 419.0; $[M - 6H + 2Na]^{4-}$, *m/z* 424.5. Mass assignments were confirmed to 0.1 u using a high resolution scanning mode.

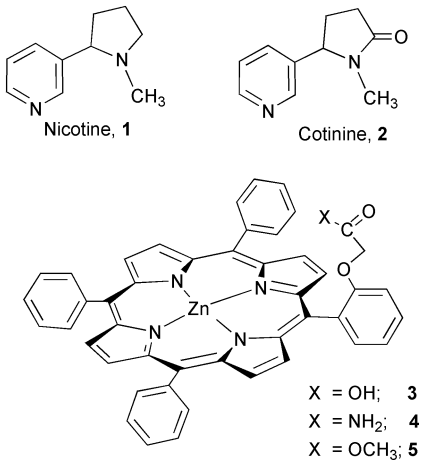
The first example of a metalloporphyrin based fluorescent chemosensor for selective detection of dinitrogen alkaloids such as nicotine and cotinine in solution by using a 'two-point' binding strategy and a modified fluorescence analysis procedure is reported.

Nicotine, a dinitrogen alkaloid is a major drug of abuse, acting as a potent agonist of the nicotinic acetylcholine receptor (*n*AChR). Recently, nicotinic agonists and antagonists have been considered as promising therapeutic agents for a variety of conditions including the treatment of pain, cognitive and attention deficits, Parkinson's disease, Tourette's syndrome, and anxiety.[1] Nicotine is also the most abundant and potent pharmacological agent in tobacco and tobacco smoke, hence, it is of considerable interest to medicine and society.[2] Several methods using HPLC, GC-MS or capillary electrophoresis are available for quantification of nicotine in tobacco, tobacco smoke, pharmaceutical agents, atmospheric air (an issue related to passive smoking), and in urine samples (involves cotinine, a metabolic product of nicotine).[3] Though these methods offer good detection sensitivity, they often suffer from low selectivity. Hence, a selective method for sensitive detection of nicotine and cotinine is highly desirable.

The development of sensors/biosensors for selective detection of analytes and improved transduction methods for higher detection sensitivity is considered to be a challenge in modern chemistry.[4] Among the different techniques utilized for developing chemical sensors, molecular fluorescence is an important one because of its high sensitivity of detection down to a single molecule, recognition and/or self-assembly directed selectivity, on–off switchability, sub-nanometer spatial resolution with sub-micron visualization, and sub-millisecond temporal resolution.[5] Among the different fluorophores that could be utilized to develop fluorescent sensors/chemosensors, porphyrins are attractive candidates because of their relatively high fluorescence quantum yields and the many different established synthetic procedures of functionalization.[6] In porphyrin based chemosensors, sensing is often achieved either by having suitable receptors at the ring periphery, by metal axial ligation, or a combination of both.[6] In the present study, we have successfully designed a porphyrin based fluorescence chemosensor for selective detection of nicotine and cotinine in solution. Our approach utilizes: (i) a 'two-point' binding mechanism which involves axial ligation of the nicotine pyridine entity through the zinc ion of the porphyrin cavity, and, hydrogen bonding of the pyrrolidine ring nitrogen to a carboxylic acid or amide group located on one of the phenyl rings of a tetraphenylporphyrinatozinc macrocycle and (ii) a modified porphyrin fluorescence data analysis procedure.

The binding of the dinitrogen alkaloid, **1** or **2**, to the newly synthesized, receptor porphyrin,† **3** or **4** was studied by ^{1}H NMR and UV-visible absorption spectral methods. Fig. 1 depicts ^{1}H NMR spectra of **1**, **3**, and, a mixture of **1** and **3** in $CDCl_3$. Upon binding to **3**, the *o*-pyridyl protons of **1** experience a shielding up to 5 ppm while the *m*- and *p*-pyridyl protons and the pyrrolidine ring protons of **1** experience less shielding (1–2 ppm). The protons of the substituted phenyl ring of **3** experience



a deshielding effect (up to 0.5 ppm) upon binding to **1**. Control experiments performed using *meso*-tetraphenylporphyrinatozinc, (TPP)Zn, (a compound without the side pendant arm) or compound **5**, bearing a methyl ester group at the substituted phenyl ring, reveal similar large deshielding of pyridyl protons of **1** indicating that the pyridyl group of **1** binds to the central zinc.[9]

The UV-visible absorption spectral studies reveal red shifted Soret and visible bands upon addition of **1** to a solution of the investigated receptor porphyrins confirming that the pyridyl entity of **1** binds to the central zinc.[10] The formation constant *K*

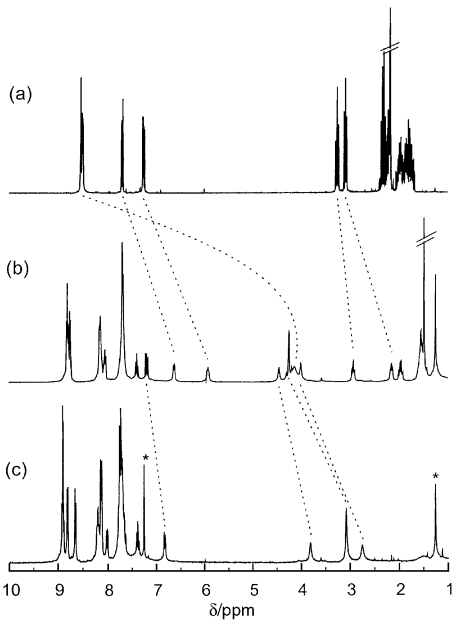


Fig. 1 ^{1}H NMR spectrum of (a) nicotine, **1** (31 mM), (b) **1** (31 mM) + porphyrin, **3** (27 mM), and (c), **3** (12 mM) in $CDCl_3$ at 298 K.

Table 1 Formation constant, *K*, and the thermodynamic parameters for zinc porphyrin–alkaloid complexes in toluene

Porphyrin	Alkaloid	K_a, M^{-1} [a]	ΔG, KJ mol^{-1} [a]	ΔH, KJ mol^{-1}	ΔS, J K^{-1} mol^{-1}
3	**1**	455.6×10^3	−32.28	−65.75	−112.31
	2	42.3×10^3	−26.39	−47.21	−69.87
4	**1**	63.1×10^3	−27.38	−49.12	−72.96
	2	17.5×10^3	−24.21	−40.25	−53.83
5	**1**	6.4×10^3	−21.69	−26.13	−14.89
	2	7.0×10^3	−21.92	−26.44	−15.17
(TPP)Zn	**1**	6.9×10^3	−21.91	−26.34	−14.87
	2	7.0×10^3	−21.93	−26.33	−14.77

[a] At 298 K.

calculated from the Scatchard method[11] of UV-visible absorption titration curves, is listed in Table 1. The binding constants for (TPP)Zn binding to alkaloids under these solution conditions is also given for comparison. The *K* values for **1** binding to **3** is found to be nearly two orders of magnitude higher than that observed for binding of either **1** to **5** or **1** to (TPP)Zn. The binding of alkaloids, **1** or **2** to porphyrins **3** or **4** are stronger as revealed by the *K* values and this effect could be attributed to the 'two-point' mode of binding. As expected, the *K* values for binding of **1** or **2** to **5** are comparable to that observed for alkaloid binding to (TPP)Zn indicating the absence of any hydrogen bonding between the methyl ester group of **5** with the pyrrolidine ring nitrogen of either **1** or **2**. The calculated thermodynamic parameters from the Van't Hoff plots of ln*K vs.* T^{-1} for **5** or (TPP)Zn binding to **1** or **2** also draw similar conclusions. Interestingly, both ΔH and ΔS decrease upon binding to **3** or **4** as compared to that observed for binding to **5** or (TPP)Zn. These results indicate that the enthalpy change is a main factor responsible for the observed higher stability of the 'two-point' bound porphyrin–alkaloid systems.

Fig. 2 shows the fluorescence emission spectra of porphyrin **3** in the presence of various amounts of **1** in toluene. The zinc porphyrin emission bands located at 605 and 650 nm decrease in intensity with the appearance of an isosbestic point at 670 nm indicating the presence of only one equilibrium in solution. It is observed that the decrease in intensity of the 650 nm band is much more than the 605 nm band.‡ Similar spectral features are observed for porphyrin **3** or **4** binding with either compound **1** or **2**.

In order to quantitate these results, we monitored the intensity ratio of these two bands as a function of alkaloid concentration.

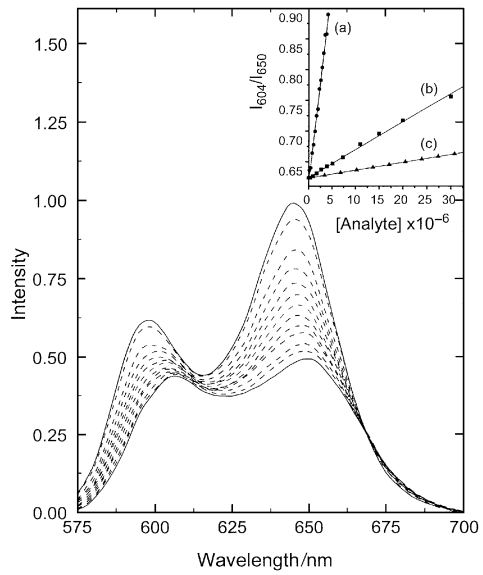

Fig. 2 Fluorescence emission spectrum of **3** (3.8 μM) in the presence of various amounts of **1** in toluene (λ_{ex} = 420 nm). The inset figure shows the relationship between the intensity ratio of the emission bands, I_{604}/I_{650} of **3** in the presence of (a) nicotine, (b) cotinine and, (c) pyridine substrates.

The inset in Fig. 2 shows such plots obtained for nicotine and cotinine binding. A linear relationship is obtained for the emission peak intensity ratio against the alkaloid concentration. This procedure is found to work well in non-coordinating solvents such as toluene, *o*-dichlorobenzene or acetonitrile. These plots offer the much-needed selectivity with respect to the presence of other axially coordinating nitrogenous bases. As shown in the inset of Fig. 2, the intensity ratio of the emission bands for a strongly coordinating ligand such as pyridine does not change significantly in the employed concentration range. These results along with the higher binding constants suggest that the present 'two-point' binding and fluorescence analysis procedure offers the much-needed selectivity for dinitrogen alkaloid detection. Further studies to expand this novel approach of employing a 'two-point' binding and modified fluorescence analysis procedure for developing porphyrin chemosensors for selective detection of compounds of biological and societal importance are in progress.

The authors are thankful to the donors of the Petroleum Research Fund, administered by the American Chemical Society, and Wichita State University for financial help.

Notes and references

† Free-base forms of porphyrins **3**–**5** were synthesized by reacting stoichiometric amounts of pyrrole, benzaldehyde and the appropriate *ortho* substituted benzaldehyde in propionic acid followed by column chromatography purification on either basic alumina or silica gel. The *ortho* substituted benzaldehydes, (2-formylphenoxy)acetic acid and (2-formylphenoxy)acetamide were synthesized according to the literature procedure given in ref. 7*a* and 7*b*, respectively. Zinc insertion was carried out according to the standard procedure (ref. 8). The molecular integrity of all the synthesized free-base and zinc porphyrins was established from FAB mass, elemental analysis and ^{1}H NMR studies (see Fig. 1 and text for ^{1}H NMR results).

‡ The details of the fluorescence quenching mechanism will be published elsewhere.

Received (in Corvallis, OR, USA) 10th July 2000, Accepted 23rd August 2000
First published as an Advance Article on the web 18th September 2000

The increasing α-effect observed in MeCN–H_2O solvent mixtures, which contrasts with the previously found bell-shaped dependence on solvent composition in the DMSO–H_2O system, is attributed to the differential solvent effect on basicities of the α- and normal nucleophiles in the former case.

Among the possible causes of the α-effect, that is the enhanced reactivity of nucleophiles having an unshared pair of electrons adjacent to the nucleophilic centre,[1] the effect of solvent has been particularly controversial.[2–9] As one possible approach to the problem, in 1986 we examined the reactivities of an α-nucleophile, butane-2,3-dione monoximate (Ox^-), and a normal nucleophile, *p*-chlorophenoxide ($ClPhO^-$) with *p*-nitrophenyl acetate (PNPA) in dimethyl sulfoxide (DMSO)–H_2O mixtures,[7a] due to the unique properties of this solvent system.[10] Unexpectedly, we observed a bell-shaped profile for the dependence of the α-effect on solvent composition, with a maximum at *ca*. 50 mol % DMSO.[7a] More recently, we observed a similar bell-shaped α-effect trend for the corresponding reactions of *p*-nitrophenyl diphenyl phosphinate (PNPDPP).[7b] However, a contrary result was reported for the reaction of PNPA with *O*-iodosylbenzoate (IBO^-) and $ClPhO^-$: the α-effect showed no maximum but decreased steadily as the DMSO content in the reaction medium increased.[9] Clearly, more work is called for in order to understand the effect of solvent on the α-effect.

We have now extended our study to a different solvent system, acetonitrile (MeCN)–H_2O mixtures, and have found a new type of solvent effect on the α-effect, namely an increasing α-effect. A plausible cause of this trend for the reaction of PNPA with Ox^- and $ClPhO^-$ (eqn. 1) in MeCN–H_2O mixtures is herein presented.

$$CH_3C(O)OC_6H_4NO_2\text{-}p + Nu^- \rightarrow CH_3C(O)\text{-}Nu + p\text{-}NO_2C_6H_4O^-$$
$$Nu^- = CH_3C(O)C(CH_3)=NO^- (Ox^-), \text{ an } \alpha\text{-nucleophile}$$
$$p\text{-}ClC_6H_4O^- (ClPhO^-), \text{ a normal nucleophile} \quad (1)$$

Kinetic studies were performed spectrophotometrically under pseudo-first-order conditions with the nucleophile in excess. Pseudo-first-order rate constants (k_{obs}) were obtained from linear plots of ln ($A_\infty - A_t$) *vs*. *t*. Second-order rate constants (k^{Ox-} and k^{ClPhO-}) were calculated from the slope of the linear plot of k_{obs} *vs.* nucleophile concentration. As shown in Fig. 1, the magnitude of the α-effect (k^{Ox-}/k^{ClPhO-}) increases as the mol % MeCN in the medium increases, from *ca.* 100 in H_2O to 500 in 90 mol % MeCN. Recently, we found a decreasing α-effect trend for the reaction of PNPA with hydroxamates in MeCN–H_2O mixtures, and a shift in equilibrium from an OH acid to an NH acid upon addition of MeCN to H_2O was attributed as responsible for the observed α-effect trend.[8b]

Transition-state stabilization is one possible cause of the α-effect[11] and recently the bell-shaped α-effect trend observed for the reaction of PNPA in DMSO–H_2O mixtures has been explained through a dissection of ground-state and transition-state contributions.[7c] In that system the basicities of the α-Nu (Ox^-) and normal-Nu ($ClPhO^-$) exhibit a parallel dependence on the DMSO–H_2O composition.[7]

The addition of MeCN to H_2O could influence not only the reaction rate but also the basicity of the anionic nucleophiles. Although the pK_a values for some phenols, carboxylic acids and amines in pure MeCN are available,[12a,b] very few pK_a data have been reported for MeCN–H_2O mixtures.[8b] Therefore, we have measured the relative basicity of Ox^- and $ClPhO^-$ in MeCN–H_2O mixtures using piperazine as a reference base. One can define ΔpK_a as the pK_a difference between the conjugate acids of the nucleophile (Ox^- or $ClPhO^-$) and piperazine, *i.e.* ΔpK_a = pK_a of the conjugate acid of the nucleophile (Ox^- or $ClPhO^-$) − pK_a of the conjugate acid of the reference base (piperazine). Hence, the magnitude of ΔpK_a represents the relative basicities of these nucleophiles. We determined ΔpK_a values spectrophotometrically using the relationship: $\Delta pK_a = \log [HA]_{eq}[B]_{eq}/[A^-]_{eq}^2$, in which $[HA]_{eq}$ represents the equilibrium concentration of the conjugate acid of the nucleophile, and $[B]_{eq}$ and $[A^-]_{eq}$ represent the equilibrium concentration of the reference base (piperazine) and the nucleophile, respectively. The ΔpK_a values thus determined in MeCN–H_2O mixtures are summarized in Table 1. As shown in the table, the ΔpK_a values of Ox^- and $ClPhO^-$ in H_2O are −0.38 and −0.44, respectively. The pK_a values of the conjugate acids of Ox^-, $ClPhO^-$ and piperazine in H_2O at 25 °C, have been reported to be 9.44,[7b] 9.38[12c] and 9.82,[12c] respectively, *i.e.* the ΔpK_a data determined in H_2O in the present study are identical to the literature values. It is also noted that Ox^- and $ClPhO^-$ are less basic than piperazine in H_2O but appear to be more basic upon addition of MeCN. This is consistent with the report that the increase in pK_a values upon changing medium from H_2O to MeCN is more significant for phenols than for amines: the pK_a enhancements were reported to be 12–17 and 7–8 in pK_a units for phenols and for the conjugate acids of alicyclic secondary

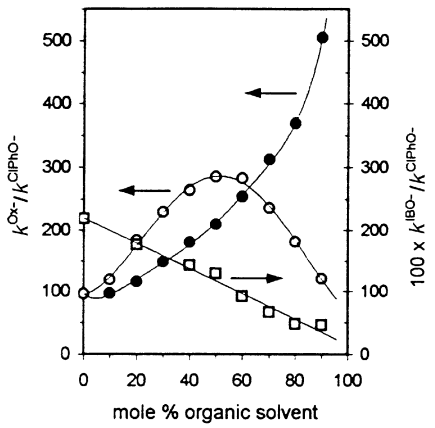

Fig. 1 Plots showing the effect of solvent on the α-effect ($k^{\alpha-Nu}/k^{normal-Nu}$) for the reaction of PNPA at 25.0 °C: k^{Ox-}/k^{ClPhO-} in MeCN–H_2O (●); k^{Ox-}/k^{ClPhO-} in DMSO–H_2O (○);[7b] k^{IBO-}/k^{ClPhO-} in DMSO–H_2O (□).[9]

† Electronic supplementary information (ESI) is available: second-order rate constants for the reaction of *p*-nitrophenyl acetate with butane-2,3-dione monoximate and *p*-chlorophenoxide in MeCN–H_2O mixtures at 25 °C. See http://www.rsc.org/suppdata/cc/b0/b005610n/

Table 1 Summary of the relative basicity of the nucleophile (ΔpK_a = pK_a of the conjugate acid of the nucleophile—pK_a of the conjugate acid of the reference base, piperazine) in MeCN–H_2O mixtures of varying compositions at 25.0 ± 0.1 °C[a]

Mol % MeCN	ΔpK_a (Ox^-)	ΔpK_a ($ClPhO^-$)	$\Delta\Delta pK_a$[b]
0	−0.38	−0.44	0.06
10	0.58	0.43	0.15
20	1.17	0.90	0.27
30	1.80	1.44	0.36
40	2.32	1.89	0.43
50	2.69	2.19	0.50
60	3.43	2.84	0.59
70	3.90	3.20	0.70
80	4.96	4.18	0.78
90	5.85	4.90	0.95

[a] The uncertainty in ΔpK_a values is estimated to be less than ±0.03 pK_a units. [b] $\Delta\Delta pK_a$ = ΔpK_a (Ox^-) − ΔpK_a ($ClPhO^-$).

amines (*e.g.* piperidine and morpholine), respectively, upon solvent change from H_2O to MeCN.[12a,b]

The difference in the relative basicity between Ox^- and $ClPhO^-$ can be expressed as $\Delta\Delta pK_a$, *i.e.* $\Delta\Delta pK_a$ = $\Delta pK_a(Ox^-)$ − ΔpK_a ($ClPhO^-$). As shown in Table 1, $\Delta\Delta pK_a$ increases as the mol % MeCN in the medium increases, *i.e.* Ox^- is more basic than $ClPhO^-$ by 0.06, 0.50 and 0.95 pK_a units in H_2O, 50 and 90 mol % MeCN, respectively, which contrasts with the situation, noted above, for DMSO–H_2O mixtures. We propose therefore, that the differential solvent effect on the basicity of these nucleophiles is the cause of the contrasting α-effect trends observed for the reaction of PNPA with Ox^- and $ClPhO^-$ in DMSO–H_2O and in MeCN–H_2O mixtures.

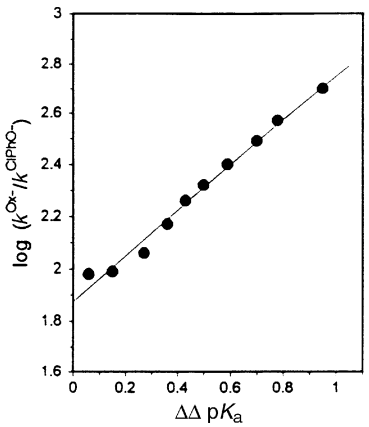

Fig. 2 Plot of log k^{Ox-}/k^{ClPhO-} *vs.* $\Delta\Delta pK_a$ for the reaction of PNPA with Ox^- and $ClPhO^-$ in MeCN–H_2O mixtures at 25.0 ± 0.1 °C.

Furthermore, it is found that a plot of log k^{Ox-}/k^{ClPhO-} against $\Delta\Delta pK_a$ is linear with a slope of 0.85 (Fig. 2). This provides evidence that the increase in the $\Delta\Delta pK_a$ values is almost fully reflected in the increase in the α-effect for the reaction of PNPA with Ox^- and $ClPhO^-$ upon addition of MeCN into the reaction medium.

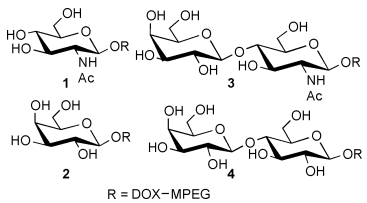
By combination of glycosidase-catalyzed transglycosylation with polyethylene glycol ω-monomethyl ether (MPEG; mw 5000) based solution phase synthesis, various terminally sialylated di- and trisaccharides were synthesized.

Sialyl oligosaccharides are involved in many diseases and function as the receptor determinants for viruses, lectins, toxins and certain tumor-specific antibodies.[1,2] To further investigate the biological functions of these components efficient methodologies for their synthesis are needed.

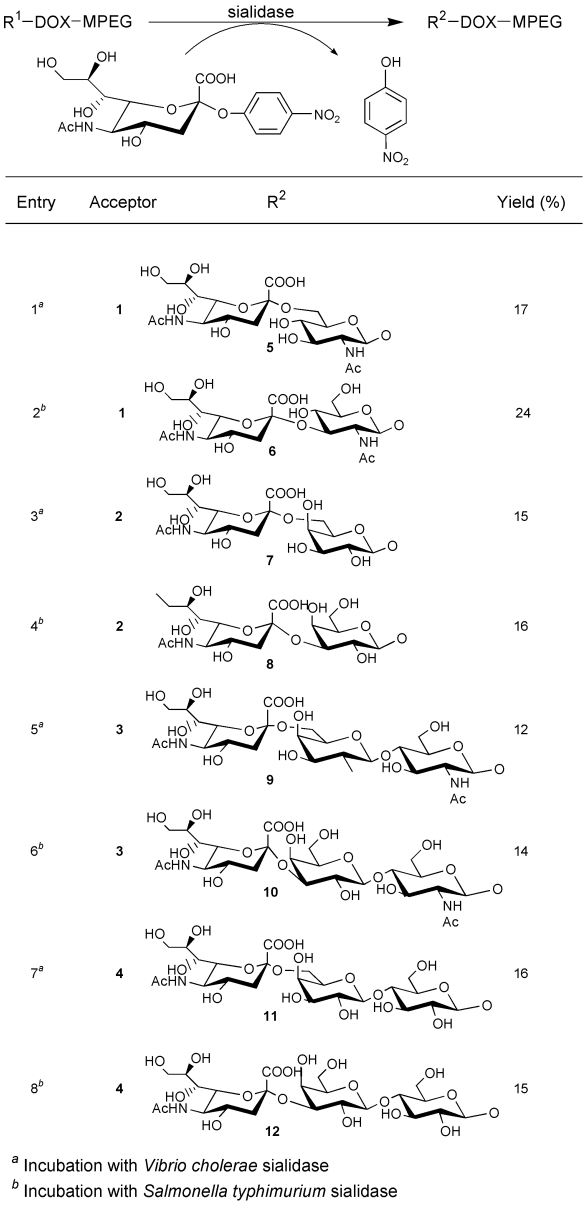
It has been demonstrated that sialidases are effective sialylation tools[3–5] supplying the stereoselective efficiency of a sialyltransferase while avoiding its complex donor-regeneration cycles and the need for intermediate protection and deprotection sequences of classical chemical procedures. Limitations in efficiency of classical chemical and enzymatic glycosylation methods resulting from time-consuming work-up and purification procedures after each glycosylation step can be overcome by application of polymer-supported solution-phase techniques which previously have been shown to be powerful tools in classical chemical synthesis.[6] Whereas solid-phase techniques suffer from various problems due to the heterogenous nature of reactions on the insoluble resin, soluble polymer supports enable standard solution-based reaction conditions to be used while preserving the possibility of exploiting the macromolecular properties of the resin in the purification steps. Combining the glycosidase-catalyzed transglycosylation technique with solid-phase supported work-up procedures, the terminally α(2-3)- and α(2-6)-sialylated oligosaccharides **5**–**12** (Scheme 1) were synthesized from the precursors **1**–**4** employing MPEG as polymeric support using a procedure based on the solubility of the polymer under reaction conditions and its insolubility during work-up in various ethers.[7]† In order to facilitate final cleavage, an α,α′-dioxyxylyl linker (DOX) is introduced.[8] Thus, glycosylation can be performed in the aqueous solution phase whereas work-up is performed in the solid phase.



Essentially, all reactions proceed following the same sequence: TRANSSIALYLATION → CODISTILLATION (with toluene) → REDISSOLUTION (in dichloromethane) → PRECIPITATION (with *tert*-butyl methyl ether) → FILTRATION → RECRYSTALLIZATION (from ethanol).

Employing incubation conditions broadly identical to standard procedures for transsialylation the oligosaccharides **5**–**12** were obtained in yields corresponding to non-polymer-supported acceptor molecules.[5]

As sialidases can display a variety of regioselectivities depending on their biological source, extreme care has to be taken in order to achieve product formation of a single regioisomer. Among a variety of sialidases that not only display the necessary regioselectivity but are also commercially available in sufficient quantitity and purity the sialidases from *Vibrio cholerae* and *Salmonella typhimurium* proved to be the most suitable transsialylation catalysts.§ While the sialidase



Scheme 1 Chemoenzymatic transsialylation of **1**–**4** using *Vibrio cholerae* and *Salmonella typhimurium* sialidase.

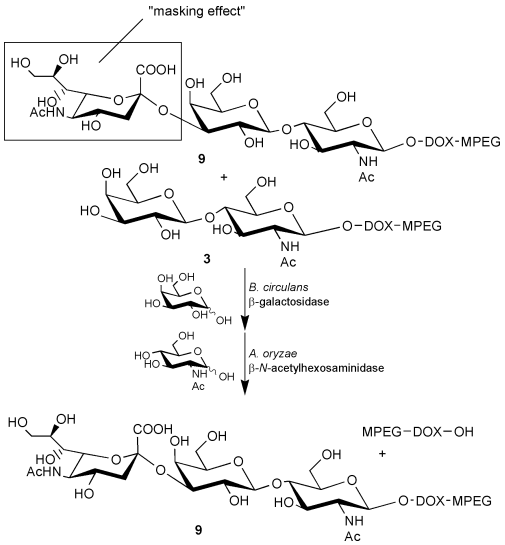
† Electronic supplementary information (ESI) available: Further experimental data. See http://www.rsc.org/suppdata/cc/b0/b003943h/

from *V. cholerae* preferentially catalyzes transsialylation in the α(2-6)-position the sialidase from *S. typhimurium* displays a pronounced regioselectivity for the α(2-3)-directed sialylation.

Sialylation of the monosaccharide acceptors **1** and **2** afforded slightly higher yields than the respective disaccharide conjugates **3** and **4**. The relatively high yield of 24% for **6** was achieved by twofold repetition of the transsialylation after intermediate work-up, giving **6** in 13% after the first and 21% yield after the second cycle. Unfortunately, only in this one case could the yield be raised considerably. Increases in yields of 2–3% after renewed incubation did not justify repeated transsialylation cycles for the other acceptor molecules. Instead it proved to be more profitable to run the same reaction in several small batches. The reactions could be scaled up to 100 μmol of product oligosaccharide without great loss in yields. In all instances described, a completely regiospecific transfer of *N*-acetylneuraminic acid could be achieved by careful monitoring of the reaction course by ^{1}H NMR spectroscopy. Regioisomeric transfer ratios were determined on-resin by integration of the axial and equatorial H-3 protons of neuraminic acid, applying the structural-reporter group concept.[9] The shifts of the *N*-acetylneuraminic acid H-3 protons are not only located outside the bulk signal region but also contain characteristic information about the type and linkage position of the glycosidically coupled saccharide. In some cases incubations had to be interrupted before maximum overall product formation was achieved in order to obtain a single regioisomer.

Even with an acceptor turnover rate of 10–25%, 75–90% of unreacted polymer-bound acceptor is still present. Cleavage from the resin at this stage would require an additional chromatographic step. This can be avoided by exploiting the capability of *exo*-glycosidases to stereoselectively hydrolyze specific terminal glycosyl units while leaving internal ones intact. Treatment of **9** with β-galactosidase from *Bacillus circulans* and β-*N*-acetylhexosaminidase from *Aspergillus oryzae* using standard incubation protocols yields MPEG-bound sialyllactosamine while free galactose and *N*-acetylglucosamine are removed as above by precipitation and filtration (Scheme 2). Owing to similar incubation conditions, the reaction in this case can be carried out as a one-pot reaction.

Prior to the cleavage of the product from the polymer, the carboxy function of the sialyl unit is protected by a methyl ester using standard procedures. Final cleavage of the product is achieved by application of a recently published method using scandium(III) trifluoromethanesulfonate and acetic anhydride,[10] which results in cleavage of the C–O bond between the dioxyxylyl unit and the terminal oxygen of the MPEG. Furthermore, all free hydroxy groups of the oligosaccharide are acetylated, which facilitates chromatographic purification of the product by flash chromatography.



Scheme 2 Down-trimming of the polymer.

In conclusion, we have demonstrated for the first time a combination of glycosidase-catalyzed transglycosylation methodology with polymer-supported solution-phase techniques and have been able to synthesize various terminally α(2-3)- and α(2-6)-sialylated di- and trisaccharides, thus, providing a simple and useful method for the synthesis of heterooligosaccharides.

‡ *Transsialylation assay using V. cholerae sialidase.* Solutions of *p*Np-Neu5Ac (21 mg, 50 μmol) and acceptor (120–160 mg, 25 μmol, donor–acceptor ratio 2 : 1) in degassed incubation buffer (150 μl, 0.1 M NaOAc, 0.5 mM $CaCl_2$, pH5.5) are incubated with *V. cholerae* sialidase (1 U) at 30 °C. Compounds **5** (24 mg, 17%), **7** (21 mg, 15 %), **9** (17 mg, 12 %) and **11** (22 mg, 16%) were obtained as white powders. The amounts refer to the calculated absolute amounts of polymer-bound product, whereas the percentages are relative to polymer-bound acceptor units.

Transsialylation assay using S. typhimurium sialidase. Solutions of *p*Np-Neu5Ac (21 mg, 50 μmol) and acceptor (110–150 mg, 20 μmol, donor–acceptor ratio 2.5 : 1) in degassed incubation buffer (150 μl, 0.1 M NaOAc, pH 5.1) are incubated with *S. typhimurium* sialidase (1 U) at 30 °C. Compounds **6** (34 mg, 24%), **8** (23 mg, 16%), **10** (21 mg, 14%) and **12** (23 mg, 15%) were obtained as amorphous solids.

General procedure. The course of the reaction is followed photometrically at 400 nm and by TLC (EtOH–1 M ammonium acetate (pH 7.4) 5 : 1) using resorcinol spraying reagent for *N*-acetylneuraminic acid detection. The incubation is terminated by addition of 0.1 M Na_2CO_3 (1 ml) followed by ultrasonification for 3 min. The mixture is acidified to pH 6.8 with Dowex 50WX8 H^+ cation exchanger and centrifuged. The supernatant is decanted and codistilled twice with toluene (10 ml). The residue is taken up in dry dichloromethane (10 ml) and precipitated with *tert*-butyl methyl ether (200 ml). The precipitate is filtered, rinsed with *tert*-butyl methyl ether (50 ml) and recrystallized from EtOH.

Cleavage of the product from the resin exemplified for compound **3**. 160 mg of polymer-bound trisaccharide **11** (0.032 mmol) is dissolved in dry dichloromethane (1.5 ml). Acetic anhydride (1.5 ml) and scandium(III) trifluoromethanesulfonate [$Sc(OTf)_3$, 10 mg, 0.02 mmol] are added sequentially. After stirring under argon for 6 h the mixture is cooled to 0 °C in an ice bath and *tert*-butyl methyl ether (150 ml) is added to precipitate the cleaved polymer. The filtrate is concentrated to dryness. The residue is suspended in dry MeOH (10 ml) and 100 mg cation exchange resin (DOWEX 50W-X8 H^+) is added. After stirring for 6 h at rt the resin is filtered off. The filtrate is concentrated and purified by flash chromatography (petrol ether–ethyl acetate 3 : 1 to 1 : 1) to yield *p*-*O*-acetyl-[DOX]yl [methyl(5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-D-*glycero*-α-D-*galacto*-2-nonulopyranosyl)onate]-(2-3)-*O*-(2,3,4-tri-*O*-acetyl-β-D-galactopyranosyl)-(1-4)-*O*-2,3,6-tri-*O*-acetyl-*β*-D-glucopyranoside (1.8 mg, 14% relative to polymer bound **4**, 88% relative to **11**).

§ Sialidase (E.C. 3.2.1.18) from *V. cholerae* was a kind gift from Chiron Behring GmbH, Germany. Recombinant sialidase (E.C.3.2.1.18) from *S. typhimurium* was purchased from New England Biolabs GmbH, Germany. 2-*O*-(*p*-Nitrophenyl)-5-acetamido-3,5-dideoxy-D-*glycero*-α-D-*galacto*-nonulopyranusonic acid (*p*Np-Neu5Ac) was prepared by the method of Rothermel *et al.*[11] Acceptor **1** was prepared by a procedure developed by Hodosi *et al.*[12]

Received (in Cambridge, UK) 27th July 2000, Accepted 21st August 2000
First published as an Advance Article on the web

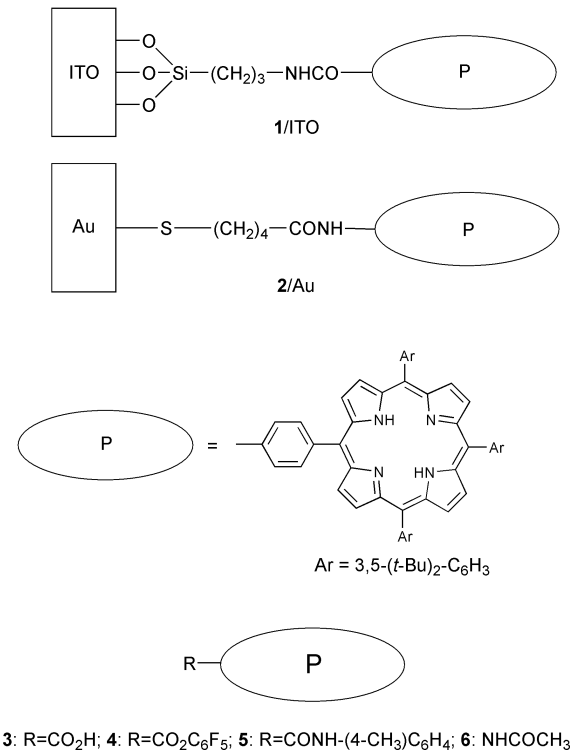
Quantum yield of the photocurrent generation by an ITO electrode modified with a self-assembled monolayer of porphyrin was remarkably enhanced by a factor of *ca.* 280, as compared to that of the corresponding porphyrin monolayer on a gold electrode.

In recent years organized assemblies of porphyrins have attracted much attention directed toward the development of photovoltaic devices, catalysis, and sensors.[1] In particular, formation of self-assembled monolayers (SAMs)[2] of porphyrins on the material surface is a potential approach for fabricating highly ordered functional thin films. In this context, we[3–5] and others[6] have reported the photoelectrochemical properties of porphyrin and porphyrin-containing donor–acceptor SAMs on gold electrodes. However, the photocurrent generation, initiated from the porphyrin excited singlet state ($^1P^*$) in the porphyrin SAMs on the gold electrodes, has been hampered by the competing energy transfer (EN) quenching of $^1P^*$ by the gold surface. Such an undesirable EN process may be avoided by employing semiconductor electrodes such as indium tin oxide (ITO) instead of metal electrodes.[7,8] However, there has so far been no report on the photoelectrochemical properties of porphyrin-containing donor–acceptor SAMs on conductive ITO support, although porphyrin SAMs on oxide surfaces or gold nanoparticles have been extensively studied.[9–12] As such, no quantitative comparison of such quenching effect has ever been reported for porphyrin SAMs on semiconductor and metal electrodes.

We report herein the first quantitative comparison of photocurrent generation in porphyrin SAMs on ITO and gold electrodes. A remarkable 280-fold enhancement of photocurrent generation has been observed in the porphyrin SAM on the ITO, as compared to the corresponding porphyrin SAM on the gold surface. The present study thereby provides valuable information for the construction of highly efficient photovoltaic cells.

In order to evaluate the EN quenching effect accurately, we designed porphyrin SAMs where the porphyrin is tethered to ITO (denoted as **1**/ITO) and gold electrodes (denoted as **2**/Au) with a spacer of the same number of atoms, respectively, as shown in Fig. 1. Bulky *tert*-butyl groups were introduced into the *meta*-positions of the *meso*-phenyl groups on the porphyrin to preclude self-quenching of the $^1P^*$ due to the porphyrin aggregation.[4,13] The general strategy employed for synthesizing the SAMs is summarized in Scheme 1. ITO electrodes (1900–2000 Å ITO on transparent glass slides) were treated with aminopropyltrimethoxysilane by refluxing for 3 h in toluene.[11] Activated porphyrin **4**, prepared from porphyrin carboxylic acid **3** and pentafluorophenol,[11] was coupled to the aminopropylsilylated glass by refluxing for 3 h in toluene to give **1**/ITO.[11] **2**/Au was prepared by following the same procedures as described previously.[4]‡ Porphyrin references **5** and **6**[4] were also synthesized.

Fig. 2 displays absorption spectra of **1**/ITO and reference **5** in $CHCl_3$. The Soret band of **1**/ITO becomes broader than that of reference **5** in $CHCl_3$. The λ_{max} value of the Soret band of **1**/ITO is nearly identical to that of **5** in $CHCl_3$, whereas the λ_{max} value of **2**/Au was reported to be red-shifted (4 nm) as compared to that of reference **6** in $CHCl_3$.[4] This indicates that the porphyrin environment of **1**/ITO is less perturbed than that of **2**/Au.



3: R=CO_2H; **4**: R=$CO_2C_6F_5$; **5**: R=CONH-(4-CH_3)C_6H_4; **6**: $NHCOCH_3$

† Electronic supplementary information (ESI) available: Fig. A cyclic voltammograms of **1**/ITO and **2**/Au. See http://www.rsc.org/suppdata/cc/b0/b006108p/

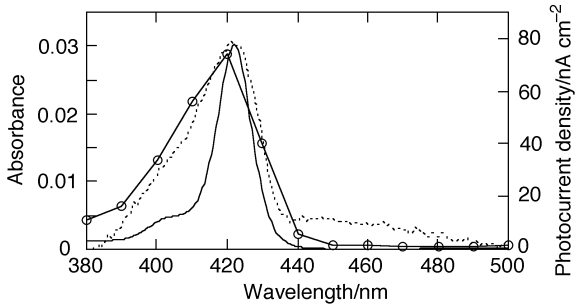

Fig. 2 UV-visible absorption spectra of **1**/ITO (dotted line) and **5** in $CHCl_3$ (solid line) and action spectrum of the ITO/**1**/TEA/Pt cell (solid line with circles); 100 μW cm^{-2}, +400 mV *vs*. Ag/AgCl, an argon-saturated 0.1 M Na_2SO_4 aqueous solution containing 50 mM TEA. The spectra are normalized at the Soret band for comparison.

A cyclic voltammetric experiment using **1**/ITO (electrode area, 0.48 cm^2) in CH_2Cl_2 containing 0.2 M $Bu^n_4NPF_6$ electrolyte with a sweep rate of 0.1 V s^{-1} was performed to estimate the surface coverage.[4,5]‡ The adsorbed amount of the porphyrin on **1**/ITO was calculated from the anodic peak of the porphyrin as 2.4×10^{-10} mol cm^{-2} (69 Å^2). Assuming that packing densities of the porphyrins are similar in **1**/ITO and **2**/Au (1.0×10^{-10} mol cm^{-2}, 170 Å^2),[4] the roughness factor of ITO is estimated as 2.5.

Photoelectrochemical measurements were carried out in an argon-saturated 0.1 M Na_2SO_4 aqueous solution containing 50 mM triethanolamine (TEA) as an electron sacrificer using **1**/ITO or **2**/Au as the working electrode, Pt counter electrode, and Ag/AgCl (sat. KCl) reference electrode (hereafter represented by ITO/**1**/TEA/Pt and Au/**2**/TEA/Pt, respectively, where / denotes an interface).[4,5] A stable anodic photocurrent from the electrolyte to the ITO appeared immediately upon irradiation of the ITO electrode with $\lambda = 419.5 \pm 5.3$ nm light with 100 μW cm^{-2}. The photocurrent fell down instantly when the illumination was cut off. In the absence of TEA, the anodic photocurrent was negligible under otherwise the same experimental conditions. The anodic photocurrent increases monotonically with increasing positive bias to the ITO electrode (−0.2–+0.4 V), whereas the dark current remains constant, as shown in Fig. 3. This demonstrates that photocurrent flows from the electrolyte to the ITO electrode *via* the porphyrin SAM. The agreement of the action spectrum with absorption spectrum of **1**/ITO from 380–500 nm (Fig. 1) demonstrates clearly that the porphyrin is the photoactive species.

The photocurrent generation efficiency becomes much lower when the ITO/**1**/TEA/Pt cell was replaced by the Au/**2**/TEA/Pt cell under the same experimental conditions. The quantum yield (3.4%) of the ITO/**1**/TEA/Pt cell determined under the optimized conditions ($\lambda = 419.5 \pm 5.3$ nm light with 100 μW cm^{-2} and at +0.4 V *vs*. Ag/AgCl)§ is *ca*. 280 times higher than the value (0.012%) for the Au/**2**/TEA/Pt cell.

Time-resolved, single-photon counting fluorescence studies were made for **1**/ITO and **2**/Au as well as **5** and **6** in solutions with the excitation wavelength at 435 nm. In each case the decay of the fluorescence intensity due to the $^1P^*$ was monitored at 655 nm. The decay curve could be fitted as a single exponential except for the case of **1**/ITO. The fluorescence lifetimes of **1**/ITO (1.0 (74%) and 3.7 ns (26%))¶ are significantly longer than that of **2**/Au (15 ps), although the lifetimes are shorter than those of **5** (7.7 ns) and **6** (7.6 ns) in $CHCl_3$.[4] This clearly indicates that the EN quenching efficiency of $^1P^*$ on the ITO is much suppressed as compared to that on the gold surface. Based on the electrochemical data, it is concluded that an electron transfer takes place from TEA (+0.61 V)[15] to the singlet excited state $^1P^*$ (+0.62 V *vs*. Ag/AgCl)[14] rather than the excited triplet state $^3P^*$ (+0.12 V *vs*. Ag/AgCl),[14] yielding the porphyrin radical anion ($P^{\bullet -}$). The formation efficiency of $P^{\bullet -}$ in **1**/ITO should become much larger than that in **2**/Au as observed experimentally because of the suppression of undesirable EN quenching of $^1P^*$ by the electrode as compared to the **2**/Au system. The resulting $P^{\bullet -}$ (−1.28 V *vs*. Ag/AgCl) gives an electron to the ITO electrode, resulting in the anodic photocurrent generation.

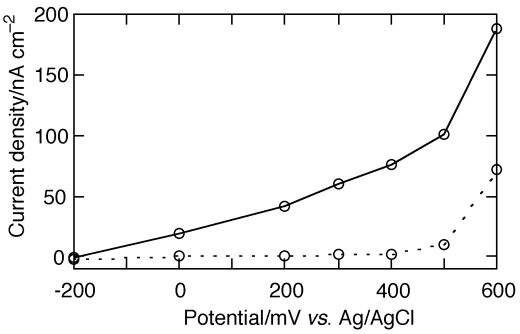

Fig. 3 Photocurrent *vs*. applied potential curves for the ITO/**1**/TEA/Pt cell (solid line with open circles): $\lambda = 419.5$ nm (100 μW cm^{-2}), an argon-saturated 0.1M Na_2SO_4 aqueous solution containing 50 mM TEA. The dark current is shown as a dotted line with open circles.

In conclusion, we have successfully demonstrated that the quantum yield of photocurrent generation for the porphyrin SAM cell on ITO becomes 280 times larger as compared to the quantum yield on the gold electrode due to the suppression of undesirable EN quenching of $^1P^*$ by the electrode.

Three 1,3,4-oxadiazole derivatives with an amine and an alkyl tail were designed and synthesized as novel electroluminescent materials; it was found that the length of alkyl tail and the structure of the amine strongly affect the phase structure of the oxadiazole derivatives.

Functional organic materials have been the subject of recent research work in relation to their optical and electronic properties as well as their industrial applications in many fields such as electroluminescent (EL) devices, transistors, batteries, sensors, photoreceptors and displays.[1] However, practical products made of organic compounds are solely photoreceptors and displays. Thus, the advantages of organic compounds are not sufficiently utilized in practical materials and devices.

Liquid-crystalline (LC) phases and amorphous states of organic materials have been known to show unique morphology. LC materials are quite attractive in terms of possessing both self-organizing capability and fluidity. On the other hand, amorphous materials are promising in terms of their excellent processability, flexibility, transparency, non-existence of grain boundaries and isotropic properties. Recently, much attention has been paid to low-molecular-weight materials which form stable amorphous glasses above rt.[2] It is of interest and of significance to develop photo- and electroactive amorphous molecular materials, which consist of π-electron systems and have glass transition temperature (T_g) higher than rt, for use in electronic devices.

In 1990, it was found that 2-(biphenyl-4-yl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD) functioned very well as an excellent electron transport material (ETM) in an organic multilayer EL diode.[3] After this report, many researchers began to use various kinds of oxadiazole molecules to obtain high EL performances. Furthermore, in recent studies of polymer light-emitting diodes, the oxadiazole moieties were demonstrated to possess high potential for electron transport.[4]

Introduction of the oxadiazole moieties to polymer main chains and to mesogens of LC compounds is expected to tune EL efficiencies and electron transport properties. EL polymers with *p*–*n* diblock structures were reported, in which thiophene and 1,3,4-oxadiazole moieties connected alternately to form fully conjugated rigid-rod polymers: one has been successfully used to fabricate single layer EL devices showing blue emission.[5] Likewise, LC compounds containing oxadiazole moieties were reported to exhibit a high electron transport capability and blue EL emission.[6]

In this study, we report the synthesis and properties of a novel class of oxadiazole derivatives for photo- and electroactive materials, emphasizing that the length and structure of the introduced moieties strongly affect the phase structure of the oxadiazole derivatives.

The oxadiazole derivatives in this study were prepared starting from 4-(4-*n*-alkylphenyl)benzoic acid by the synthetic route shown in Scheme 1. 4-(4-*n*-Alkylphenyl)benzoic acid was reacted with an excess of thionyl chloride. The resulting 4-(4-*n*-alkylphenyl)benzoyl chloride was reacted with aminophenyltetrazole derivatives in dry pyridine at 135 °C, yielding the products: 2-(4′-propylbiphenyl-4-yl)-5-(4-*N*,*N*-dimethylaminophenyl)-1,3,4-oxadiazole (**3-OXD-Me**), 2-(4′-heptylbiphenyl-4-yl)-5-(4-*N*,*N*-dimethylaminophenyl)-1,3,4-oxadiazole (**7-OXD-Me**) and 2-(4′-heptylbiphenyl-4-yl)-5-(4-*N*,*N*-diphenylaminophenyl)-1,3,4-oxadiazole (**7-OXD-Ph**).[7] These products were purified by column chromatography on silica gel, followed by recrystallization from toluene–ethanol. The overall yields were about 55%. The oxadiazole derivatives were characterized as obtained by FT-IR, ^{1}H NMR and elemental analysis.

Thermotropic and LC behaviors were evaluated by means of DSC (heating and cooling rate: 2 °C min^{-1}) and polarizing microscopy. Fig. 1 shows DSC thermograms of **3-OXD-Me** and **7-OXD-Me** on the third cooling. It was found that **3-OXD-Me** showed only a sharp exothermic peak corresponding to a melting point (T_m) at 174 °C. By contrast, **7-OXD-Me** exhibited two exothermic peaks at 143 and 138 °C. It seems that the peak at 143 °C is due to isotropic (I)-nematic (N) phase transition and another peak at 138 °C is due to N-crystal phase transition. Fig. 2 shows the textures observed with a polarizing microscope at 140 and 100 °C, respectively. Referring to the Schlieren texture, the phase could be assigned to an N phase at 140 °C, and then a typical crystal texture was observed at 100 °C. As **7-OXD-Me** showed no LC phase on heating but an N phase on cooling, it seems to be a monotropic LC material.

DSC thermograms of **7-OXD-Ph** on the first and the second heating are shown in Fig. 3. When the crystalline sample of **7-OXD-Ph** obtained by recrystallization from ethanol–toluene was heated, **7-OXD-Ph** exhibited T_m at 166 °C to give an I phase. **7-OXD-Ph** in the I phase was then cooled by standing in

air, and it formed spontaneously the supercooled liquid state, which changed into the amorphous glassy state. On the second heating, T_g was observed at 27 °C, and then the first exothermic peak owing to crystallization appeared at around 60 °C. Subsequently, another crystallization occurred at 87 °C and the crystal melted at 166 °C. These phenomena of crystallization from the melt were confirmed with a polarizing microscope, however, the structure of each crystal was beyond identification.

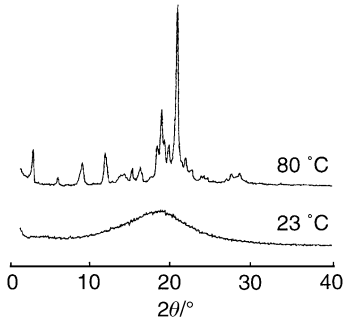

Fig. 4 X-Ray diffraction patterns of **7-OXD-Ph** at 23 and 80 °C.

The formation of an amorphous glass was evidenced in the X-ray diffraction patterns of **7-OXD-Ph** at rt (23 °C) and 80 °C, as exhibited in Fig. 4. **7-OXD-Ph** showed no sharp signals but only broad halos, when cooled from an I state to 23 °C, indicating that **7-OXD-Ph** is in an amorphous state. On the other hand, several sharp signals appeared at 80 °C, suggesting that **7-OXD-Ph** is in a crystalline state. **7-OXD-Ph** did not show an LC phase but an amorphous state; steric hindrance between two clusters of benzene rings of **7-OXD-Ph** may contribute to formation of the amorphous glass.

All materials investigated in this work emitted strong blue fluorescence with high quantum yields (0.81–0.91); emission peaks of **3-OXD-Me** and **7-OXD-Me** were 420 nm, and that of **7-OXD-Ph** was 436 nm. It is assumed that these compounds show an excellent EL performance. The present study will enable us to perform molecular design of various compounds based on oxadiazole for developing photo- and electroactive materials. These materials are expected to find potential application as functional materials, *e.g.* charge transport and luminescent materials for photoreceptors and electroluminescent devices.

In summary, 1,3,4-oxadiazole derivatives with amine and alkyl tails were designed and prepared as novel EL materials: the phase structures and optical properties of the oxadiazole derivatives were investigated in this study. We found that the length of the alkyl tail and the structure of the amine strongly affected the phase structure of the oxadiazole derivatives.

A chiral catalyst derived from 1,1′-bis(diphenylphosphino)-ferrocene and anchored within MCM-41 displays remarkable increases in both enantioselectivity and activity, in the hydrogenation of ethyl nicotinate to ethyl nipecotinate, when compared to an analogous homogeneous model compound.

It is acknowledged that, in view of their biological activity, the enantioselective synthesis of chiral saturated ring systems involving piperidine or cyclohexane is of considerable practical interest. Previously, efforts to hydrogenate enantioselectively an aromatic ring such as that in ethyl nicotinate (Scheme 1) have resulted in values of enantiomeric excess (ee) that are less than 6%.[1] However, very recently, a two-step process, involving initial hydrogenation in high yield to the comparatively stable 1,4,5,6-tetrahydronicotinate, followed by subsequent hydrogenation in the presence of a dihydrocinchonidine modified noble metal catalyst, yielded a quite high ee of the nipecotinate. The best activity reported by Blazer *et al.* [using a Pd on carbon (plus cinchonidine) catalyst for step (ii)] was 19% ee at 12% conversion.[2] Using the principle, first conceived five years ago,[3] of chirally constraining a designed active centre attached to a chiral ligand and tethered to the inner walls of mesoporous silica, as schematized in Fig. 1, we have produced an effective enantioselective catalyst for the direct hydrogenation of ethyl nicotinate to ethyl nipecotinate, with an ee of 17% and conversions in excess of 50%.

We have previously demonstrated that in the allylic amination of cinnamyl acetate, the enantiomeric excess achieved by the spatially confined (tethered) catalyst, which is derived from 1,1′-bis(diphenylphosphino)ferrocene (dppf), far exceeds that attained with the same active site when it is unconfined.[4] Mesoporous silica of the M41S type (used earlier as the support for several high performance catalysts[5]) was used to confine the designed catalyst, thereby creating the chiral space. The confinement is a crucial feature of the enantioselectivity of our catalyst. When an alkyl silsesquioxane with the same tethered, designed catalyst is subjected to identical conditions, degrees of conversion are appreciably lower and the catalyst exhibits no enantiodiscrimination.

Our approach in the synthesis of the heterogeneous catalyst was to design a homogeneous, metal-containing ferrocenyl precursor which possessed a functionality capable of reacting directly with a silica surface. This precursor could be characterized in detail using solution spectroscopic techniques, and then anchored to the surface of the mesoporous silica support in a one-step reaction. The synthetic strategy involved the reaction between (*S*)-1-[(*R*)-1,2′-bis(diphenylphosphino)ferrocenyl]-ethyl acetate[6,7] and 3-(methylamino)propyltrimethoxysilane to form a silane functionalised ferrocenyl ligand (**1**), the incorporation of palladium dichloride to which forms the target ferrocenyl precursor (**2**) (Scheme 2). The ferrocenyl precursor **2** was then reacted with the mesoporous silane MCM-41, the outer walls of which were previously deactivated *via* treatment with [Ph_2SiCl_2], a method which we have already shown to be applicable in this situation.[8]

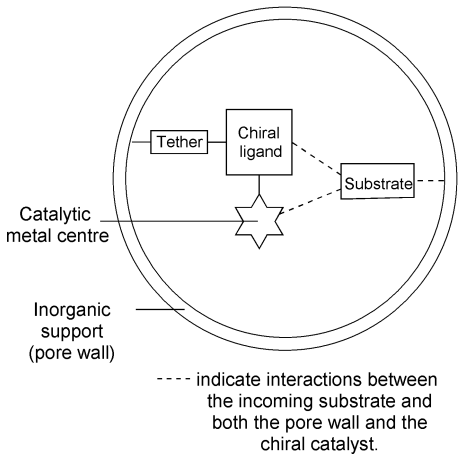

Fig. 1 Schematic diagram of the chiral catalyst constrained within a mesopore.

The anchored catalyst was characterised using ^{13}C and ^{31}P MAS NMR spectroscopy (ESI†). The ^{13}C spectrum was fully assignable when compared to that of (*S*)-1-[(*R*)-1,2′-bis(diphenylphosphino)ferrocenyl]ethylallylamine palladium dichlor-

† Electronic supplementary information (ESI) available: ^{1}H, ^{13}C and ^{31}P NMR spectroscopic data for the ferrocenyl precursor **2**, the anchored heterogeneous catalyst and the silsesquioxane-bound homogeneous catalyst. See http://www.rsc.org/suppdata/cc/b0/b005689h/

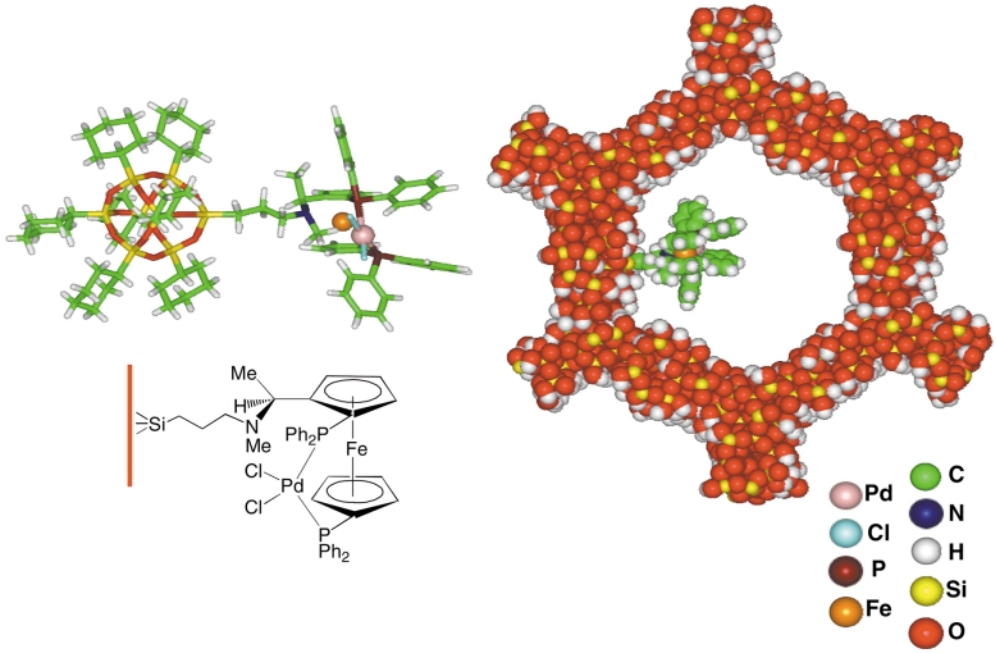

Fig. 2 Depiction of the catalytically active centre attached to a soluble silsesquioxane moiety and bound in a constrained manner inside mesoporous silica.

ide.[9] The spectrum showed two broad peaks centred at δ 135 and 75 which may be attributed to the phenyl and cyclopentadienyl rings, respectively. There is a peak at δ 12 which may be assigned to the methyl group bound to the chiral carbon and the carbon bound to the silicon. The central carbon in the propyl tether may be assigned to the peak at δ 22, whilst the final carbon of the tether, that bound to the nitrogen, can be attributed to the peak at δ 52. The final peaks in the spectrum are at δ 41 and 58 and may be assigned to the methyl group of the amine and the chiral carbon, respectively. The ^{31}P MAS NMR spectrum revealed a broad, split signal centred around δ 30, which is comparable to that observed with the ferrocenyl precursor **2**.

The ferrocenyl precursor **2** was also reacted with an incompletely condensed silsesquioxane cube,[10] to form a homogeneous model of the anchored heterogeneous catalyst. Solution ^{1}H NMR spectroscopy in C_4D_8O was used to characterise the model compound (ESI†), and the absence of the peaks for the hydroxy protons of the box at δ 6.97 and the methoxy protons of **2** at δ 3.47, are diagnostic in this regard. The MCM-41 bound catalyst and the silsesquioxane catalyst are illustrated in Fig 2.

The two catalysts were tested in the one-step hydrogenation of ethyl nicotinate to ethyl nipecotinate.‡ The catalysis was performed under mild conditions (20 bar H_2, 40 °C) and in both cases proceeded with the formation of the desired nipecotinate. However, analysis of the products revealed that the MCM-41 anchored species catalysed the reaction with a 17% ee whilst the use of the homogeneous silsesquioxane complex resulted in a racemic product. This remarkable change in stereoselectivity demonstrates the profound importance of confinement in the catalysis. The free catalyst shows no enantioselectivity whilst chiral confinement results in a catalyst that shows greater selectivity by almost a *threefold* margin than any other reported.[1] The confined catalyst also displayed a higher degree of activity (TON = 291) compared to the homogeneous form (TON = 98), after a reaction time of 72 h, and is remarkably stable. The reaction mixture of the anchored catalyst contained less than 3 ppb of metal (by ICP analysis), thereby ruling out the possibility of any leaching.

These results show the considerable potential that this type of catalyst offers, and how, by careful design of an active centre, a heterogeneous catalyst may be engineered, the performance of which is far superior than its free, homogeneous analogue.

We thank EPSRC for a rolling grant to J. M. T. and an award to B. F. G. J. We also wish to thank ICI for a case studentship to S. A. R. M.S.I. Inc. is gratefully acknowledged for the molecular modelling software. We are also grateful for assistance from Professor L. F. Gladden.

Notes and references

‡ The catalytic testing was performed in a high-pressure stainless steel reactor (Cambridge Reactor Design) lined with PEEK (polyether ether ketone). The catalyst (250 mg MCM-anchored, 100 mg box) was added to 5 g of ethyl nicotinate in 100 ml solvent (90 ml THF, 10 ml methanol). The vessel was pressurised to 20 bar with hydrogen and heated to 40 °C, whilst stirring was maintained at 400 rpm. During the reaction small aliquots were removed, using a mini-robot autosampler, to enable the kinetics to be studied. The products of the reaction were analysed by gas chromatograpy (GC, Varian, Model 3400 CX) employing a BPX5 capillary column (25 m × 0.32 mm) and flame ionisation detector. The ee was determined on the same machine *via* the conversion of the nipecotinate to a diastereomeric amide using (*R*)-(−)-Mosher's acid chloride.[2]

First published as an Advance Article on the web

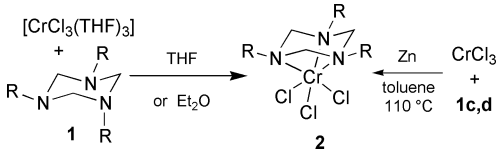
MAO activated 1,3,5-triazacyclohexane complexes of chromium(III) are highly active ethene polymerisation catalysts that resemble the Phillips catalyst in many important properties and may represent the first good homogeneous model system.

The heterogeneous Phillips catalysts[1] based on CrO_3/SiO_2 for the polymerisation of ethene without co-catalysts produce a large fraction of the world production of HDPE (>7 M ton a^{-1}).[2] The molecular weight of the polymer depends on the reaction temperature. When activated with metal alkyls the Phillips catalyst can also trimerise ethene to 1-hexene (as well as some dimers) which is *in-situ* co-polymerised giving a polymer with butyl side chains and other unusual end groups including additional methyl groups, vinylidene and some internal olefinic groups. In contrast to the Ziegler–Natta systems, the nature of the active species and the origin of the end groups is still a matter of debate. Many homogeneous model systems[3] show only limited activity[4] and most of them fail to reproduce the properties of the Phillips catalyst and a true model has yet to be found.

For several years we have been investigating the coordination chemistry of 1,3,5-triazacyclohexanes **1**.[5] The results suggest that it should be possible to generate cationic alkyl chromium complexes with low steric demand due to the small N–Cr–N angle which may be able to catalyse ethene polymerisation. Indeed, complex **2a** reacts with methylaluminoxane (MAO) to give a highly active catalyst. However, good solubility of the complexes is crucial to achieve high productivities. This solubility problem is solved by introducing longer alkyl chains as substituents in **2b**–**d** according to Scheme 1. The solubility increases dramatically and **2c** and especially **2d** become highly soluble in toluene. Complexes **2c** and **2d** can be prepared from $CrCl_3$ (stored under air), **1**, toluene and zinc powder by simple heating under a stream of argon.[6]

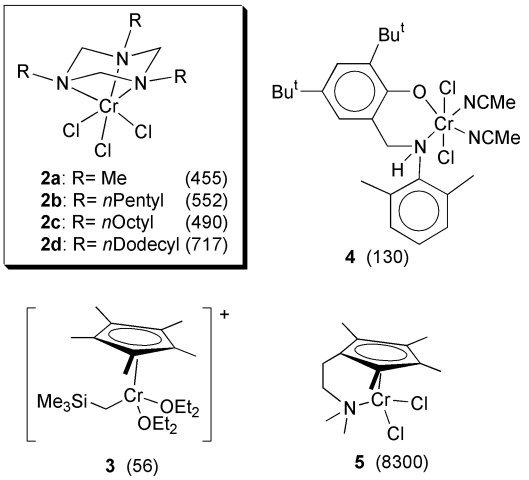
Since the ligands **1c**,**d** can also be prepared by heating the corresponding primary amine and paraformaldehyde in toluene a simple one-pot synthesis of **2** is possible.

The systems **2**/MAO have much higher activity than the best co-catalyst free complex **3**[7] and the best non-Cp system **4**/MAO[8] (Scheme 2). The activity is comparable to



Scheme 1 Syntheses of the complexes **2**.

† Electronic supplementary information (ESI) available: synthetic, spectroscopic and analytical details of new compounds and the ethene polymerisation experiments. See http://www.rsc.org/suppdata/cc/b0/b005842o/
‡ Dedicated to Prof. H. Schumann on the occasion of his 65th birthday.
§ Chemistry of 1,3,5-triazacyclohexane complexes, Part 8. [Part 7, is ref. 5(*a*)].



Scheme 2 Chromium complexes in ethene polymerisation (comparison of activity in [kg (mol Cr)$^{-1}$ h^{-1}]) (**2** at 40 °C and 1 bar ethene in toluene over 1 h).

$[(nBuCp)_2ZrCl_2]$/MAO under the same condition (650 kg (mol Cr)$^{-1}$ h^{-1}) and the only more active chromium system is **5**/MAO from Jolly *et al*.[4]

Maximum activity is reached at MAO : Cr $\approx$ 300. Activation of **2** can also be achieved with 1.6 eq. DMAB (dimethylanilinium tetrakis(pentafluorophenyl)borate) and 20–50 eq. $Al(iBu)_3$, giving similar activity (590 for **2a** and 390 for **2d**).

The molecular weights of the polymers under these conditions are around 40 000 (M_w) with M_w/M_n = 2–4 which is typical for a single-site catalyst.

End group analysis of the polymers (IR, ^{13}C NMR) shows more methyl groups than expected and additional vinylidene and some internal olefin as well as the expected vinyl end groups in a distribution that is typical for end groups produced by the Phillips catalyst. Since the molecular weights of the polymers differ, the end groups are best compared relative to the total number of olefinic groups (set to 100%) (Table 1).

In addition, 1-hexene as the trimer of ethene and some decenes as 'co-trimers' of 1-hexene and ethene can be found in the solution, and butyl side chains in the polyethene are indicative of some 1-hexene built into the polymer. Thus, our system is also able to reproduce the selectivity for trimerisation.[9] Interestingly, analysis of the decene isomers by NMR

Table 1 Relative end group distribution with the sum of olefinic groups set to 100%

End group	CH_2=CHR	CH_2=CR_2	RHC=CHR	Me
PE (Phillips)[a]	84–92%	7–13%	1–4%	150–300%
PE (**2d**)	82%	12%	6%	240%
decenes (**2d**)	87%	8%	5%	200%

[a] IR analyses of commercially available (BASF) Phillips HDPE products. Typical range under various conditions.

DOI: 10.1039/b005842o

shows an end group distribution similar to the polymers (Table 1). Addition of 1-hexene to the solution increases the content of butyl side chains substantially and a co-polymer can be obtained. Similar to the Phillips catalyst, activated **2** gives molecular weights of polyethene that are highly dependent on the reaction temperature.

Thus, activated **2** represents the first true homogeneous model for the Phillips catalyst that can reproduce many important properties and the results indicate that the typical end group distribution may be closely linked to a required trimerisation activity. A comprehensive discussion of substituent effects and the link between trimerisation and polymerisation activity will follow in separate publications.

Atomic absorption spectroscopy of the ionic liquid 1-ethyl-3-methylimidazolium ethanoate ($[emim]_2[O_2CMe]$), prepared according to International Patent WO 96/18459, showed it to contain large amounts of lead impurity: (*ca.* 0.5 M): $[emim]_2[Pb(O_2CMe)_4]$ was isolated and shown crystallographically to contain the first known example of a monomeric, homoleptic pentacoordinate lead(II) carboxylate complex, with a stereochemically active lone-pair.

Ionic liquids are well-established media for clean synthesis,[1,2] and consequently an essential requirement is their purity. In particular, heavy metal and halide impurities pose problems with regard to human and environmental health, catalysis and corrosion. Thus it is important to develop routes that yield pure products. A number of methods for the synthesis of ionic liquids have been cited in the literature.[2,3] As part of our general work in this area, we have examined a BP Chemicals patent that describes the use of lead(II) salts in the synthesis of ionic liquids.[4] It is claimed that the ionic liquid 1-ethyl-3-methylimidazolium ethanoate ($[emim][O_2CMe]$) could be synthesised *via* the metathesis of lead(II) ethanoate and [emim]Cl or [emim]Br. Analysis by atomic absorption spectroscopy of the ionic liquid thus obtained showed that large amounts of lead remained in the product (*ca.* 0.5 M). Crystals of the dissolved lead complex were obtained from the $[emim][O_2CMe]$ produced *via* a modification of this method that precludes the addition of water.†

A review of BIDS[5] and the Cambridge Structural Database[6] for lead(II) carboxylate complexes identified a total of 25 structures: 18 were polymeric with the carboxylate moiety acting as a bridging ligand; three others that, although monomeric, contained either the sterically demanding $[edta]^{2-}$ ligand or bulky crown ethers; and one containing hexanuclear units.[7] The remaining three compounds, $Pb(C_8H_{11}N_4S)(O_2CMe)$,[8] $[Pb(C_{16}H_{36}N_4)(O_2CMe)][O_2CMe]\cdot 2H_2O$[9] and $Pb(C_{12}H_{10}N_3SO)(O_2CMe)$,[10] are compared and contrasted with $[emim]_2[Pb(O_2CMe)_4]$ below.

The data for $[emim]_2[Pb(O_2CMe)_4]$ were collected using our usual methodology.‡ The asymmetric unit consists of one $[Pb(O_2CMe)_4]^{2-}$ unit and two $[emim]^+$ cations. The four ethanoate anions are involved in two different bonding modes: three are bonded *via* one oxygen atom, and one is chelating, Fig. 1. The three non-coordinated oxygen atoms are involved in C–H···O hydrogen bonds with the cations, and extend towards the void associated with the lead(II) centre, Fig. 2. Two $[emim]^+$ cations lie either side of this void and act as spacers between the $[Pb(O_2CMe)_4]^{2-}$ units. The large void in the coordination sphere around the lead(II) centre is indicative of a stereochemically active lone-pair, the existence of which is usually attributed to the '*inert-pair effect*'. The $[Pb(O_2CMe)_4]^{2-}$ units in $[emim]_2[Pb(O_2CMe)_4]$ are hydrogen bonded to four cations forming an infinite chain *via* C–H···O interactions in the $<0\,0\,1>$ plane, Fig. 2.

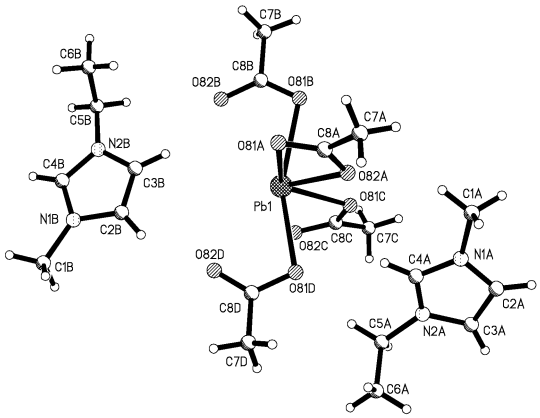

Fig. 1 Atomic numbering scheme for $[emim]_2[Pb(O_2CMe)_4]$ emphasising the void created by the stereochemically active lone-pair on the lead(II) centre.

Although the term '*inert-pair effect*' is the subject of some controversy, the structural consequences of the $6s^2$ lone-pair are well documented. Shimoni-Livny *et al.*[11] identified some conditions in which the lone-pair is likely to be stereochemically active; namely, hard donor atoms, a low coordination number and attractive interactions between ligands. The structure of $[emim]_2[Pb(O_2CMe)_4]$ fits well with these findings and the criteria are satisfied.

DOI: 10.1039/b005095o

The dominant feature of the three monomeric lead complexes obtained from the CSD is the presence of a rigid organic ligand, which restricts the possible geometries available to the metal centres. In $Pb(C_8H_{11}N_4S)(O_2CMe)$[8] and $[Pb(C_{16}H_{36}N_4)(O_2CMe)][O_2CMe]\cdot 2H_2O$[9] this leads to the orientation of the inert lone-pairs associated with adjacent lead atoms towards one another with Pb···Pb contacts of 3.905 and 4.165 Å, respectively: they essentially exist as dinuclear complexes. As with $[emim]_2[Pb(O_2CMe)_4]$, the ethanoate ions are monodentate with the free oxygen atoms extending towards the void associated with the lone-pair. In $Pb(C_{12}H_{10}N_3SO)(O_2CMe)$[10] the use of a rigid ligand still influences the coordination geometry of the lead(II) centres. However, the distance between the metal centres is much longer which suggests that they are not associated with each other (Pb···Pb distance 4.822 Å). Again, the ethanoate ions are monodentate with the free oxygen atoms associated with the void. Moreover, these free oxygen atoms are also associated with the lead centre of the adjacent molecule (Pb···O distance 3.001 Å). The only common feature of these compounds and $[emim]_2[Pb(O_2CMe)_4]$ is that the monodentate ethanoate ligands are associated with the lone-pair on the metal centre. Unlike the previous complexes, the lead centres in $[emim]_2[Pb(O_2CMe)_4]$ do not show any lone-pair orientation effects and $[emim]_2[Pb(O_2CMe)_4]$ can be considered mononuclear.

A recent study by Hall *et al.*[12] on lead(II) complexes containing aromatic ligands highlighted the difficulties of determining the presence or absence of a stereochemically active lone-pair. They found that in many of the materials the so-called '*lone-pair*' regions were either (a) associated with longer contacts with the oxygen atoms from anions (*e.g.* $[ClO_4]^-$, $[NO_3]^-$), leading to polynuclear motifs with consequent orientation of the lone-pairs towards each other as above, or (b) associated with inter-ring interactions between the aromatic ligands which occupied the void region. In $[emim]_2[Pb(O_2CMe)_4]$, although the cations are associated with this lone-pair region and are involved in C–H···O hydrogen bonds with the ethanoate anions, the emim cations do not occupy the void associated with the '*inert lone-pair*'.

Furthermore, the presence or absence of a stereochemically active lone-pair has implications for the design of new materials using the Group 14 elements. The use of hydrogen-bond donor cations, in conjunction with hydrogen-bond acceptors on the coordination complex anions, results in '*capping*' of the voids, which may be a useful generic strategy for the rational design of materials containing these elements. The possible application of this approach to crystal engineering is illustrated by the isolation of $[emim]_2[Pb(O_2CMe)_4]$.

In conclusion, we have isolated and structurally characterised a new and novel lead(II) homoleptic complex. Preliminary XAFS data§ show that this unusual (for lead) metal coordination environment is stable even at moderate temperature (*ca.* 373 K), which will be the subject of a further communication. This, and the previously reported $[SbCl_3][AlCl_4]$,[13] also indicates that ionic liquids may be useful media for the stabilisation and study of unusual metal coordination environments; more specifically those metals that contain stereochemically active lone-pairs.

Furthermore, the presence of this lead(II) complex, which was produced in an attempted preparation of an ionic liquid, highlights the problems inherent in the use of metathetic reactions of metal salts as a preparative methodology for ionic liquids in general. We are currently critically examining the extant methods and developing more general procedures for ionic liquid production.

† *Preparation*: [emim]Cl and $Pb(O_2CMe)_2\cdot 3H_2O$ (Aldrich) were separately dissolved in solutions of methanol–water (4:1 v/v). Upon mixing the two solutions a precipitate of $PbCl_2$ was produced which was removed by filtration after cooling at −20 °C overnight. The solvent was removed from the filtrate by rotary evaporation. Analysis by ^{1}H NMR spectroscopy showed that this was insufficient to remove the water, and this was accomplished after heating at *ca.* 130 °C under vacuum for 24 h. The product was a viscous liquid, pale yellow in colour before drying and pale brown in colour after drying. In order to eliminate the need for drying, the above method was modified slightly to eliminate the use of water. This was achieved by placing the lead ethanoate in a Soxhlet extractor. The product obtained was a mixture of crystalline solid and viscous liquid. Single crystal X-ray analysis showed the crystalline material to be the salt $[emim]_2[Pb(O_2CMe)_4]$.

‡ *Crystallographic data* were collected on a Siemens P4 diffractometer using omega scans. A crystal was sealed into a Lindemann tube under an inert atmosphere and then mounted on to the diffractometer at room temperature. The structure was solved using direct methods using the SHELX program packages.[14] *Crystal data* for $[emim]_2[Pb(O_2CMe)_4]$: M = 665.70, triclinic, space group $P\bar{1}$, a = 7.9761(9), b = 10.4439(9), c = 16.8872(15) Å, α = 100.222(7), β = 99.228(9), γ = 94.712(9), U = 1357.6(2) Å^{-3}, Z = 2, μ = 0.117 mm^{-1}, R_{int} = 0.0607. A total of 3743 reflections were measured for the angle range $4 < 2\theta < 50$ and 3455 independent reflections were used in the refinement. Final parameters were wR_2 = 0.1815 and R_1 = 0.0556 [$I > 2\sigma(I)$].

First published as an Advance Article on the web

A polystyrene-resin supported Pt catalyst displays higher conversion, remarkably improved selectivity and excellent recyclability relative to Speier's catalyst in the room temperature solvent-less hydrosilylation of oct-1-ene using trichlorosilane.

Alkene hydrosilylation is an important reaction both on a laboratory and an industrial scale. Though many metal complexes have been reported as useful catalysts,[1] since the discovery by Speier *et al.* in 1957 that hexachloroplatinic acid is a potent catalyst even under ambient conditions,[2] Pt complexes have become the catalysts of choice. The remarkable turnover frequencies displayed by Pt-based species, and the fact that they can be used not only with alkyl and alkoxysilanes but also with chlorosilanes, explain their dominance in industrial processes. Paradoxically, however, these high activities coupled with the exothermicity of alk-l-ene hydrosilylation can lead to a rapid temperature rise in reactions, and the occurrence of a significant level of alkene isomerisation. The so-formed internal alkenes react much more slowly, and in any event limit the conversion of alk-l-enes to useful terminally silylated products.

There has been significant earlier work on the immobilisation of Pt-based catalysts using both inorganic and polymer supports, aimed at producing experimentally and technologically convenient analogues of soluble catalysts.[3,4] Likewise Rh-based species,[5] and recently Mn-based catalysts,[6] have been examined in this context. While these reports have demonstrated active heterogeneous catalysts, data on the activity and selectivity with prolonged use are rare, particularly with the more difficult chlorosilane reactants, and equally importantly meticulous evaluation of the contribution from leached soluble catalyst has generally been absent. We now make a preliminary report on our studies of in-house prepared polystyrene and polymethacrylate resin-supported Pt catalysts in the hydrosilylation of oct-l-ene using trichlorosilane in the absence of any solvent, and at ambient temperature.

Precursor resins (PR1–PR5) were prepared by suspension polymerisation[7] using the comonomer mixtures shown in Table 1. The functional group content [–CH_2Cl from vinylbenzyl chloride (VBC) or epoxide from glycidyl methacrylate (GMA)] and surface area of the resultant resins are also shown in Table 1. PR1–PR5 were aminated by treatment with excess trimethylethylene diamine/NaH in THF at 60 °C for 48 h to yield AFRI–AFR5 (Table 2), and finally each of these was loaded with Pt by treatment with an excess of K_2PtCl_4 in water to yield polymer catalysts C1–C5 (Scheme 1, Table 2). The activity and selectivity of C1–C5 were assessed in the reaction of oct-l-ene (20 mmol) and trichlorosilane (10 mmol) in 8 cm^3 sealed Pyrex vials in the absence of any solvent at room temperature. Polymer catalysts containing 10^{-3} mmol of Pt were employed

Table 2 Analytical data for catalyst resins

	Amine functionalised resin		Pt catalyst resin	
Precursor resin	Code	Diamine content[a]/ mmol g^{-1}	Code	Pt content[b]/ mmol g^{-1}
PR1	AFR1	2.85	C1	1.4

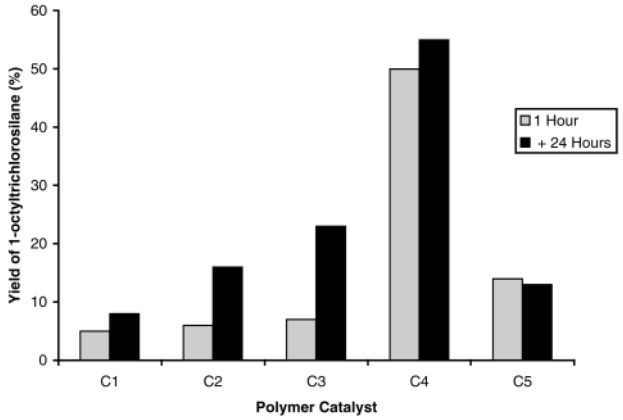

Fig. 2 Yield of 1-octyltrichlorosilane from oct-l-ene and trichlorosilane catalysed by C1–C5 with the heterogeneous catalyst removed after 1 h.

and compared to the performance of soluble Speier's catalyst (5 wt% H_2 $PtCl_6 \cdot 6H_2O$ in isopropyl alcohol using 10^{-3} mmol Pt). The appearance of l-octyltrichlorosilane and octene isomers (oct-2-, -3- and -4-enes as a non-resolved group) was monitored by GC analysis using nonane as an internal standard. The mole ratio of oct-l-ene: trichlorosilane of 2 : 1 was chosen to highlight any isomerisation induced by the catalyst while minimising competition from the hydrosilylation reaction, *i.e.* isomerisation was deliberately given a competitive advantage. In addition, to demonstrate the high activity and stability of the polymer catalysts (identified in preliminary ligand screening experiments) each sample reported here was utilised in four previous reactions, *i.e.* the data here refer to the fifth cycle of use in each case. Data for Speier's catalyst refer to its first use. No attempt was made to recover and re-use this homogeneous species.

The results of the catalytic studies are summarised in Fig. 1. The behaviour of the homogeneous catalyst is as expected from the literature. The conversion of trichlorosilane to l-octyltrichlorosilane reached *ca.* 75% in *ca.* 1 h. However, simultaneously the isomerisation of oct-l-ene to internal alkenes was *ca.* 60%. (Note initial mole ratio oct-l-ene : trichlorosilane is 2 : 1.) The performance of the polymer catalysts varies considerably. Catalyst C1 shows very low activity. Since this is a polar gel-type methacrylate-based resin, it would not be expected to swell in the non-polar reaction mixture and presumably therefore catalytic Pt sites are accessed only very inefficiently as a result of poor mass transport. Likewise though catalyst C5 is a non-polar styrene-based resin, and is nominally macroporous, in fact the surface area of this species is very low (*ca.* 30 $m^2\ g^{-1}$), and we believe the morphology is substantially collapsed.[8] Catalysts C2 and C3 perform well yielding *ca.* 70% l-octyltrichlorosilane after *ca.* 6 h. Though these are polar methacrylate-based resins, they have permanent macroporous morphologies with good surface area (*ca.* 110–120 $m^2\ g^{-1}$). Catalyst C4 is significantly the most active yielding *ca.* 70% l-octyltrichlorosilane after 2 h, and ultimately delivering *ca.* 90%. In this respect it performs better than Speier's catalyst. C4 is a non-polar styrene-based resin and is macroporous with a good surface area (*ca.* 100 $m^2\ g^{-1}$). It clearly offers no significant mass transfer limitations. Furthermore with C4 the level of oct-l-ene isomerisation is only *ca.* 9%, and indeed less than *ca.* 4% with the other polymer catalysts. C4 therefore is also significantly more selective in favour of hydrosilylation than Speier's catalyst. These results are even more remarkable when it is borne in mind that these data refer to the fifth cycle of use of this sample of C4.

Overall it is tempting to conclude that the heterogenised Pt complexes are highly selective in favour of the hydrosilylation reaction, and the low level of alkene isomerisation observed may be due to very low levels of leached Pt species acting as a less selective homogeneous catalyst.

Some assessment of the level of Pt leaching with C1–C5 was obtained from a sixth cycle of use of these samples in which hydrosilylations were run as before for 1 h, and then the reaction mixtures decanted from the resin beads, and the mixtures monitored for a further 24 h. The results are shown in Fig. 2. The left-hand bar in each case shows the percentage of 1-octyltrichlorosilane formed after 1 h in the presence of polymer catalysts, and the right-hand bar the conversion after a further 24 h in the absence of polymer catalysts. Though some increase in l-octyltrichlorosilane is seen, particularly with C2 and C3 (presumably reflecting the presence of some soluble catalytic species), the effect is not large. With C4 the small additional conversion seen after 24 h is within the analytical experimental error. In addition no measurable increase in the amount of isomerised alkene is observed, which remains very low. Thus it seems that the level of Pt leached is itself very low, or any species in solution is inactive as a catalyst either in hydrosilylation or in isomerisation.

Thus we have succeeded in producing a polymer-supported Pt alkene hydrosilylation catalyst (C4) with activity comparable to that of Speier's catalyst, with greatly enhanced selectivity in terms of minimising concurrent alkene isomerisation, and with considerable long term recycling stability along with minimal Pt leaching characteristics. The catalyst performs well with trichlorosilane as the silylating agent and displays considerable potential for both small- and large-scale application. We are currently undertaking a more detailed investigation to improve our understanding of this catalyst system.

R. D. and S. J. T. acknowledge the receipt of studentships from Dow Corning. The gift of vinylbenzyl chloride from the Dow Chemical Company is appreciated. The useful discussions with Z. M. Michalska are warmly acknowledged.

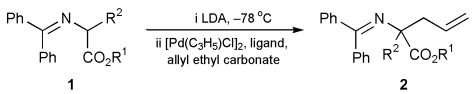
Several derivatives of ferrocene ligands with planar chirality were investigated in palladium-catalysed asymmetric allylic alkylation of iminoesters, in which bis-ferrocene ligand 7 containing a chiral pocket showed good enantiocontrol in this reaction; the products having a quaternary chiral center were obtained with up to 75.3% ee.

Chiral α,α-dialkyl-α-amino acids are an important class of non-coded amino acids and have attracted an ever growing interest in biological and pharmacological problems.[1] The quaternary chiral center leads to many of the desirable properties associated with this class of amino acid, but offers a significant challenge with respect to asymmetric synthesis.[2] Many methods reported to date involve either the use of chiral auxiliaries or strategies that utilize self-regeneration of stereocenters.[3] The catalytic asymmetric hydrogenation of dehydroamino acids is not applicable to synthesis of quaternary amino acids.[4] Thus, the procedure of their catalytic asymmetric synthesis remains to be established. Imino esters as nucleophiles in Pd-catalyzed asymmetric allylic alkylation reactions give chiral α-mono-alkylated amino acids,[5,6] however, the ee was not high when simple allyl acetate was used. Though a significant improvement of the asymmetric alkylation of a glycine Schiff's base under PTC conditions has been reported, an amino acid with a quaternary chiral centre could not be easily constructed in general.[7] Recently, Trost and Ariza reported the asymmetric synthesis of α-alkylated amino acids by using their chiral pocket strategy in catalytic asymmetric allylic alkylation and good to excellent results were obtained when substituted allyl acetates were used—for the simplest member of this family, the allyl acetate, only 40% ee value was provided.[8]

In the course of studying the synthesis and applications of ferrocenyl derivatives with planar chirality in metal-catalysed asymmetric reactions,[9] we investigated the role of planar chirality and found that the enantioselectivity could be affected by planar chirality, and that high enantioselectivity would be reached when the ligand contained a pair of matched chiralities. Combining these results and Trost's chiral pocket concept[10] we designed new planar chiral ligands **7** and **8** and used them in a synthesis of α-alkylated amino ester derivatives with a quaternary chiral carbon center through catalytic asymmetric allylic alkylation. Herein we would like to report our preliminary results.

The reaction of imino esters **1** with allyl ethyl carbonate in the presence of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ and ligands **3**–**8** was carried out [eqn. (1)]† and results were summarized in Table 1.



1 **2** (1)

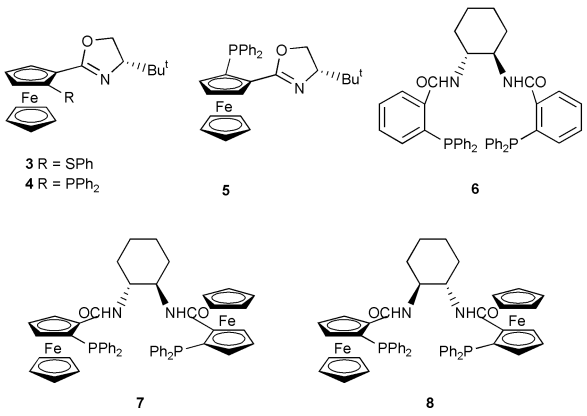
a, R^1 = Me, R^2 = Bn; **b**, R^1 = Me, R^2 = Me; **c**, R^1 = Bu^t, R^2 = Me; **d**, R^1 = Bu^t, R^2 = H; **e**, R^1 = Et, R^2 = H; **f**, R^1 = Me, R^2 = H.

From Table 1, we found that planar chirality showed great influence on the enantioselectivity of the product. By using (*S*, *R*$_p$)-ligand **5** the product with 34.5% ee was given but only 2% ee for (*S*, *S*$_p$)-ligand **4** (entries 3 and 4), apparently central and planar chirality in ligand **5** is matched in this reaction. With BINAP as the ligand, the product was isolated in high yield but low ee. Ligand **6**, developed by Trost's group, showed high enantioselectivity in many kinds of asymmetric alkylation reactions due to its 'chiral pocket effect'.[10] Only 40% ee was given when it was used in this reaction. This value is the same as in the reaction of allyl acetate and azalactone reported by Trost.[8] Above all, we deduced that both planar chirality and the chiral pocket could improve the enantioselectivity of the product. Therefore, ligands **7** or **8**, the ferrocene modification of the chiral pocket, were synthesized in high yields from **4** [eqn.

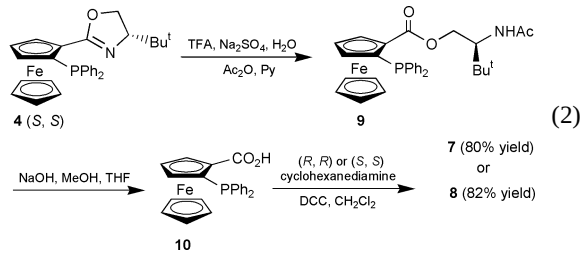
Table 1 Palladium-catalysed asymmetric allylation of **1a** with different ligands†

Entry	Ligand	Base	Yield (%)[a]	Ee (%)[b]	Optical rotation[c]
1	**(S)-BINAP**	LDA	95	18.2	–
2	**3**	LDA	—	—	–
3	**4**	LDA	91	2.0	–
4	**5**	LDA	89	34.5	–
5	**5**	KHMDS	77	9.3	–
6	**6**	LDA	93	40.0	+
7	**7**	LDA	87	57.4	+
8	**8**	LDA	93	3.8	+
9[d]	**7**	LDA	91	22.2	+
10[e]	**7**	LDA	81	50.0	+

[a] Isolated yield based on imino esters. [b] Determined by HPLC (chiralcel OJ column). [c] Detected in trichloromethane. [d] 2 mmol% $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ and 4 mmol% ligand were used as catalyst. [e] After completion of addition, the reaction mixture was allowed to stir at 0 °C.



(2)].[12] As expected, when ligand **7** was injected into the above



reaction, the enantioselectivity of the product was raised to 57.4% ee. On the other hand, the product with 3.8% ee was produced when ligand **8**, derived from (*S*,*S*)-cyclohexanediamine, was used. Obviously, ligand **7** possesses the matched chiralities. In addition, changing reaction temperature or the ratio between ligand and palladium did not improve the enantioselectivity (entries 9 and 10). The enantioselectivity of the product decreased greatly when the base was changed to KHMDS with ligand **5** (entry 5).

Several imino esters were examined with ligand **7** under the optimized conditions. The results are summarized in Table 2. It can be seen that different R^1 of the esters has a great influence on the enantioselectivities of the products. It was improved by increased steric demand of R^1 substitution. The ee values of the products were 56.9% (entry 5, R^1 = Bu^t), 52.6% (entry 6, R^1 = Et), 24.6% (entry 7, R^1 = Me), respectively, This effect was also operated in the α-methyl substituted imino esters which are important in the synthesis of quaternary carbon centers. When **1b** and **1c** were injected into this reaction, ee values of products were 53.6% (entry 2, R^1 = Me) and 75.3% (entry 4, R^1 = Bu^t), respectively. It was very strange that the product from **1b** achieved 71.6% ee when equimolar amounts of palladium and ligand were used as catalyst. The changing of the ratio of palladium to ligand has no effect in the case of **1c**.

Ligand **7** was viewed more clearly by its crystal structure (Fig. 1).‡ It was easy to deduce that the two Cp rings could become a part of a better pocket if the two phosphorus atoms were coordinated with palladium, which might be responsible for the better enantiocontrol.

Table 2 Palladium-catalysed asymmetric allylation of different amino esters with ligand **7**†

Entry	Substrate	Yield (%)[a]	Ee (%)[b]
1	**1a**	87	57.4
2	**1b**	93	53.6
3[c]	**1b**	92	71.6
4	**1c**	95	75.3
5[d]	**1d**	94	56.9
6[d]	**1e**	93	52.6
7[d]	**1f**	92	24.6

[a] Isolated yield based on imino esters. [b] Determined by HPLC. [c] 2 mmol% $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ and 4 mmol% ligand were used as catalyst. [d] 110 mmol% LDA and 110 mmol% allyl ethyl carbonate were used.

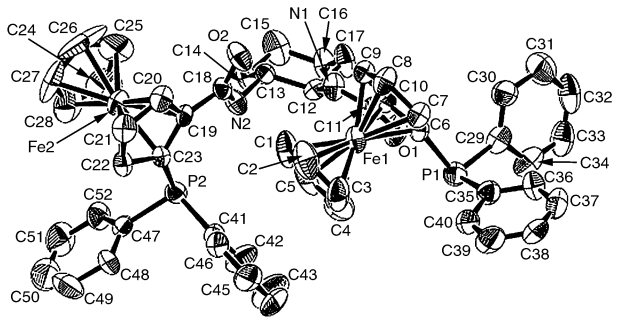


Fig. 1 ORTEP view of **7**·$2H_2O$ (hydrogen atom and water molecule omitted for clarity).

In conclusion, the catalytic asymmetric allylic alkylation between imino esters and chiral palladium allylic intermediates can be used to construct a chiral quaternary carbon center. Combination of planar chirality and a chiral pocket effect in the same ligand may provide product with a higher enantioselectivity. Up to 75% ee was realized by using ligand **7**. To the best of our knowledge, this is the highest ee value for a simple allyl system in this type of reaction. This concept for designing new ligands is worth further study. We are now exploring the application of ligand **7** and its analogues in other asymmetric reactions.

Notes and references

† To a solution of 1 mL of THF and 103 mg (0.3 mmol) of ester **1a** was added 0.23 mL (0.45 mmol, 2 M heptane–THF–ethylbenzene) of LDA at −78 °C. The solution was stirred for 1 h, then charged with a solution containing 2.2 mg (0.006 mmol) of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$, 16.3 mg (0.018 mmol) of chiral ligand **7** in 0.5 mL of THF, and a solution of 59 mg (0.45 mmol) allyl ethyl carbonate in 0.25 mL THF. The reaction was allowed to proceed at rt to completion. Work up as usual and purification by column chromatography [EtOAc–petroleum ether (1/20), the silica gel was eluted with Et_3N in advance] afforded 100 mg of **2a** in 87% yield, 57.4% ee, determined by HPLC [Chiralcel OJ Column, hexane–isopropyl alcohol (96/4)].

A photochromic system based on photochemical or thermal chelate exchange on $Ru(phen)_2L^{2+}$ (L = diimine or dinitrile ligand)

Received (in Cambridge, UK) 21st June 2000, Accepted 25th August 2000
First published as an Advance Article on the web

In the presence of a bidentate chelate containing two convergent nitrile groups, $Ru(phen)_2L^{2+}$ (L = sterically hindering aromatic diimine ligand; phen = 1,10-phenanthroline) undergoes a photochemical reaction leading to quantitative replacement of the diimine by the bis-nitrile ligand; the reverse reaction takes place upon heating, also quantitatively.

Multicomponent molecular systems for which certain parts can be set into motion while others can be considered as motionless are promising models of biological molecular machines and motors as well as potential switches.[1,2] The signals sent to the molecules in order to trigger the movement can be of an electrochemical[3] or chemical[4] nature, photoinduced redox processes being also used in a few cases.[5] In the search for non-sacrificial photochemical reactions usable for moving molecular fragments,[6] it occurred to us that ligand-field (LF) excited states of d^6 transition metal complexes are strongly antibonding and can lead, in some cases, to effective ligand exclusion and substitution by solvent molecules.[7] In the present work, we would like to describe a system in which two different chelates, an aromatic diimine and a dinitrile, can be efficiently and cleanly interchanged under the action of light or heat. In addition, significant photochromism is observed. The ligands used are represented in Fig. 1.

The aromatic diimines 6,6′-dmbp and biq are sterically hindering so that their removal from a ruthenium(II) trischelate complex will be favoured over that of phen, also considering that rotation about the C–C bond between both halves of the chelate facilitates stepwise decoordination. The bis-nitrile dCN has been previously described and used by Angelici *et al*. to make a few complexes (Mn(I), Fe(II) and Pt(II)).[8] Although no structural data are available, dCN is expected to behave as a bidentate chelate.

The following photochemical reactions have been shown to take places quantitatively under light irradiation (300 nm $\leqslant \lambda \leqslant$ 800 nm):[9]

$$Ru(phen)_2L^{2+} + dCN \xrightarrow[L = 6,6'\text{-dmbp or biq}]{h\nu} Ru(phen)_2(dCN)^{2+} + L \quad (1)$$

The efficiency of reaction (1) is solvent dependent, the best solvents being acetone or 1,2-dichloroethane (1,2-DCE). The photoproduct, $Ru(phen)_2(dCN)^{2+}$, was isolated quantitatively and authenticated by comparison with a separately prepared sample.[10] To our knowledge, it is the first example of a photochemical chelate-to-chelate exchange reaction. Crystals were grown from MeOH–*p*-xylene and an X-ray structure of the compound was obtained.[11] The ORTEP diagram is shown in Fig. 2. The ruthenium–nitrogen bond lengths range from 2.04(1) to 2.085(8) Å and are similar to those observed in the $Ru(phen)_3^{2+}$ and $Ru(phen)_2(dpq)^{2+}$ complexes[12] (dpq = dipyrido[3,2-*d*:2′,3′-*f*]quinoxaline). As also indicated by the N–Ru–N angles the geometry about ruthenium atom is distorted from octahedral. The most noticeable feature is the constraint imposed on the dCN ligand as reflected by the Ru–N(6)–C(40) and Ru–N(5)–C(2) angles (167 and 168° respectively) as well as the large dihedral angle between the two phenyl groups.

In order to demonstrate that dCN and 6,6′-dmbp or biq can be interchanged, it was essential to show that the starting complex can be regenerated. This is indeed the case: reaction (2) takes place quantitatively.

$$Ru(phen)_2(dCN)^{2+} + L \xrightarrow[L = 6,6'\text{-dmbp or biq}]{\Delta} Ru(phen)_2L^{2+} + dCN \quad (2)$$

For example, a yellow solution of $Ru(phen)_2(dCN)^{2+}$ and biq in ethyleneglycol was heated at 190 °C for 4 h in the dark. The colour of the solution changed to deep red. After removal of the solvent followed by chromatography, $Ru(phen)_2(biq)^{2+}$ was obtained in 91% yield. Moreover, the photochemical reaction (6,6′-dmbp or biq release) and the thermal back reaction (dCN

Hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°): Ru–N(1) 2.059(9), Ru–N(2) 2.054(9), Ru–N(3) 2.061(9), Ru–N(4) 2.085(8), Ru–N(5) 2.05(1), Ru–N(6) 2.04(1), N(5)–Ru–N(6) 85.1(3), Ru–N(5)–C(25) 168(1), Ru–N(6)–C(40) 167(1), C(26)–C(25)–N(5) 177(1), C(39)–C(40)–N(6) 172(1).

DOI: 10.1039/b004982o

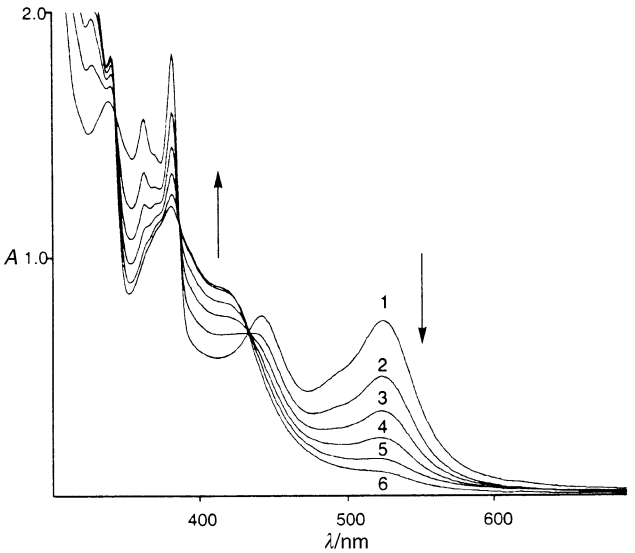

Fig. 3 Electronic spectra of a 1,2-DCE solution of $Ru(phen)_2(biq)^{2+}$ in the presence of dCN (10 eq) after visible light irradiation: **1** (0 s); **2** (20 s); **3** (40 s); **4** (60 s); **5** (90 s); **6** (120 s).

release with recoordination of 6,6′-dmbp or biq) could be carried out on the same reaction mixture containing an excess of both ligands, dCN and the aromatic diimine, in addition to the starting ruthenium(II) complex. The solvent, $EtOCH_2CH_2OCH_2CH_2OH$, in which all the components (ligands and complexes) are soluble, turned out to be compatible with both photochemical and thermal processes.

Interestingly, the absorption spectra of $Ru(phen)_2(dCN)^{2+}$ and $Ru(phen)_2(biq)^{2+}$, for instance, are significantly different. dCN is a poor σ-donor and good π-acceptor, stabilizing the d_π orbitals of $Ru(t_{2g})$ and thus leading to a relatively high MLCT (Ru → phen) excited state. In $Ru(phen)_2(biq)^{2+}$, the nature of the MLCT bond is different: biq is a better π-acceptor than phen so that the charge transfer is directed from the metal centre to biq and no more to the phen ligands. The photochromism of the system is illustrated in Fig. 3.

Without displaying colour changes as large as those obtained with organic photochromic compounds,[13,14] $Ru(phen)_2(biq)^{2+}$ (deep red; λ_{max} = 525 nm in 1,2-DCE) changes colour under irradiation to afford an orange solution of $Ru(phen)_2(dCN)^{2+}$ (λ_{max} = 382 nm in 1,2-DCE) within a few tens of seconds.

In conclusion, the present system is particularly promising for the construction of molecular photomechanical devices, combining motion and photochromism.

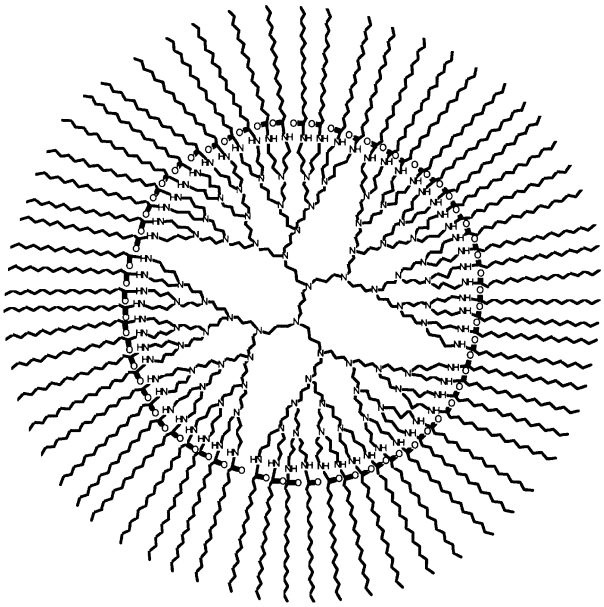
In the presence of octadecylamine, poly(propylene imine) dendrimers modified with long alkyl chains self-assemble to form well-defined aggregates that stabilise for periods exceeding 14 days the normally unstable amorphous calcium carbonate (ACC) which persists in competition with the thermodynamic product, calcite.

Templates that consist of organised biomacromolecules are known to direct the formation of most biominerals, in many cases leading to materials with unique shapes and properties.[1] In synthetic assays, the use of ordered supramolecular assemblies, such as micelles,[2] monolayers,[3] vesicles,[4] inverted micelles[5] and lyotropic liquid crystalline systems,[6] allows for the controlled nucleation of inorganic materials on molecular templates with well-defined structure and surface chemistry. One of the most abundant biological minerals is calcium carbonate, the main constituent of mollusc shells, for example.[7] In nature, all three crystalline calcium carbonate polymorphs, calcite, aragonite and the metastable vaterite, are observed. In addition, amorphous calcium carbonate, which is normally unstable at room temperature and pressure, has been reported.[8] In synthetic milieu this amorphous phase is unstable and transforms readily into one of the crystalline polymorphs. Here we report on a synthetic system in which aggregates consisting of assemblies of poly(propylene imine) dendrimers modified with long hydrocarbon chains and single chain surfactants stabilise spheroids of amorphous calcium carbonate (ACC) for extended periods of time.

Poly(propylene imine) dendrimers modified with long aliphatic chains are a new class of amphiphiles which display a variety of aggregation states due to their conformational flexibility.[9] Globular aggregates are formed when C_{16}-modified 5th generation dendrimer **1** is dispersed in aqueous media.[10] In the present work we have modified the outer surface of this dendrimer assembly by addition of **1** to aqueous solutions containing single chain surfactants (octadecylamine, OA, and cetyltrimethylammonium bromide, CTAB) at concentrations below their CMC (Scheme 1). In this way we were able to generate solid self-reinforced aggregates with different shape, size and surface chemistry depending on the choice of surfactant.† It was found that aggregates arising from the interaction of **1** and octadecylamine (OA) expressed a persistent polyhedral shape,[11] as well as a narrow size distribution (Fig. 1a,b). The extremely high fluorescence depolarization anisotropy values found for the aggregates at room temperature (r = 0.32) indicate that they have a very rigid structure.‡ When the dendrimer was mixed with CTAB, spherical aggregates with a narrow distribution and an average size of 20 nm (determined by DLS) were formed (not shown). Fluorescence depolarisation measurements showed that these aggregates are less rigid (r = 0.24) with respect to the dendrimer/octadecylamine aggregates.

The remarkable rigidity and the well-defined size and shape of the aggregates consisting of **1** and OA prompted us to exploit them as 3D templates in calcium carbonate crystallisation



1

assays.§ The addition of these novel templates to such an assay catalysed the formation of amorphous calcium carbonate. Indeed, calcified aggregates, which had retained their polyhedral shape, were recovered after only 15 min (Fig. 1c). FTIR showed strong peaks characteristic for hydrated ACC at 3433 and 1070 cm^{-1},[12] whereas only minor peaks characteristic of calcite were observed (1420, 875 and 712 cm^{-1}). Selected area electron diffraction analyses confirmed that the vast majority of these particles consisted of amorphous material.

Over the course of 4 days a discrete population of {10.4} rhombohedral calcite crystals was also identified in the bulk solution of **1**/OA doped assays, alongside large isolated ACC particles (diameter $\geqslant$ 10 μm; Fig. 1d) a small portion of which still possessed a polyhedral shape (Fig. 1c, inset). It is notable that 80% of the rhombohedra enveloped an ACC sphere (Fig. 1e). The spatial juxtaposition of the two $CaCO_3$ phases argues

strongly for a critical role of the spheres in fostering the nucleation and growth of the crystalline form.

Another notable feature of the **1**/OA doped crystallisation assays was the persistent formation of ACC spheres at the air/solution interface. It is our contention that the continuous formation of spheres at this location is linked to the active adsorption of the **1**/OA aggregates at the air/solution interface. It is significant that particle size analysis of spheres harvested from this location over a fourteen day period revealed a population of ACC spheres with diameters consistently in the range of 1–10 μm. In contrast, the particle size profile of ACC spheres recovered from bulk solution over the same time period showed a gradual shift in size to larger dimensions (> 10 μm). This was accompanied by a diminution in the total number of isolated spheres and an increase in the proportion of spheres which were associated with calcite. The ACC spheres allied with calcite were very uniform in size having diameters of 8 μm, but comprised only 10% of the population. From the integration of FTIR spectra it was concluded that at this stage 20% of the calcium carbonate was still present in the form of spherical ACC.

Aggregates prepared of **1** alone also templated the formation of ACC spheres. However, in this case the amount of ACC was reduced and the transformation to calcite was more rapid than observed previously with the OA modified aggregates: after 24 h 80% of the sample had been converted to calcite compared to 16% in the case of the **1**/OA aggregates. The use of aggregates prepared from **1** and CTAB did not lead to the generation of ACC. Instead, the formation of calcite crystals covered with disc-shaped vaterite crystals was observed (Fig. 1f). Over a period of 5 days these vaterite discs disappeared and only calcite crystals remained.

The gradual dissolution of the small ACC particles and maturation of larger ones can be attributed to the process of Ostwald ripening wherein particles with a high surface to volume ratio provide a continuous source of materials for those with lower surface activity.[13] In the present case this process also effects the gradual release of the **1**/OA aggregates originally occluded within the calcium carbonate spheres. Thus, the depletion of polymeric complex, which accompanies ACC formation at the air/solution interface, will be offset by the dynamic adsorption of surfactant/dendrimer aggregates released into bulk solution from the proportion of small ACC spheres which dissolves. One outcome of this activity will be the iterative formation of an active organic template, capable of inducing the kinetic precipitation of calcium carbonate at the air/solution interface leading to a high local nucleation density of ACC.

Although ACC has been observed as a short-lived intermediate in the presence of various scale prevention agents, to our knowledge only biological systems allow the coexistence of amorphous and crystalline calcium carbonate for extended periods of time.[12] The nucleation of the kinetic product at the expense of the thermodynamically stable form, calcite, and the stabilisation of the amorphous phase against transformation results in the formation of a unique inorganic–organic hybrid material.

Notes and references

† A solution of 18.5 mg of **1** and 15.5 mg surfactant in 100 μl THF/EtOH (2 : 1 v:v) was injected into 6 ml Ultrapure water at 60 °C and sonicated for 1 hour. Subsequently, 1.0 ml aggregate suspension was injected into 25 ml Ultrapure water at room temperature. A detailed investigation of the structures of these aggregates will be published elsewhere.

‡ Fluorescence depolarization was carried out using DPH which in a frozen system has an intrinsic anisotropy value of $r_0 = 0.362$.[14]

§ The aggregate dispersion (1.0 ml) was injected into 25 ml of a supersaturated solution of calcium carbonate ([Ca^{2+}] = 9 mM; [**1**] = 5.3 μM; [surfactant] = 0.37 mM).[15]

[2]Rotaxane molecular shuttles employing 1,2-bis(pyridinium)ethane binding sites and dibenzo-24-crown-8 ethers†

Stephen J. Loeb* and James A. Wisner

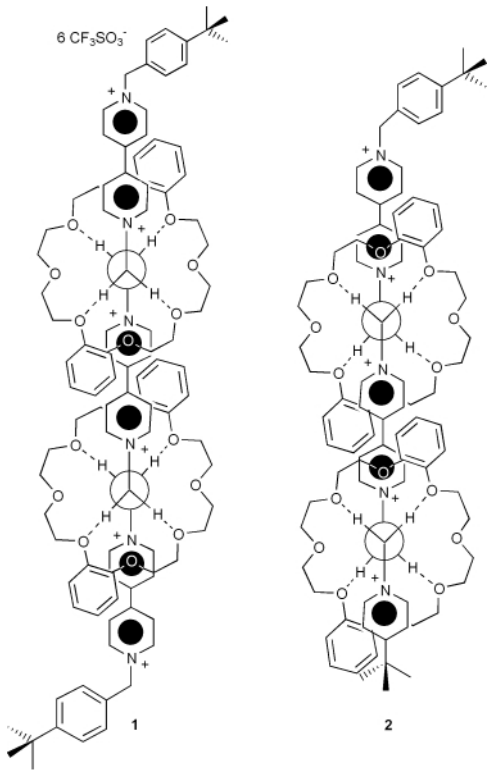
Received (in Columbia, MO, USA) 5th June 2000, Accepted 15th August 2000
First published as an Advance Article on the web

Symmetrical and unsymmetrical axles containing two binding sites of the 1,2-bis(pyridinium)ethane type are threaded with a single molecule of dibenzo-24-crown-8 ether (DB24C8) resulting in [2]rotaxane *molecular shuttles* that display translational isomerism.

One of the most intriguing developments in supramolecular chemistry is the ability to construct mechanically linked molecular systems that display switching properties resulting from the relative positioning of the internal components of the supermolecule.[1] An elegant example of this is the [2]rotaxane *molecular shuttle* pioneered by Stoddart *et al.* in which a single 'wheel' component can occupy either of two binding sites on a dumbbell shaped 'axle'.[2]

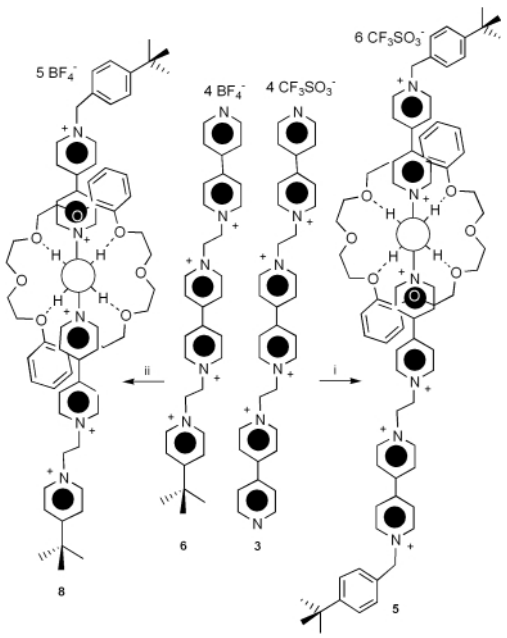
We have recently reported the synthesis of symmetrical and unsymmetrical [3]rotaxanes, **1** and **2**, employing extended axles



containing two binding sites of the 1,2-bis(pyridinium)ethane type each occupied by a dibenzo-24-crown-8 ether (DB24C8) molecule.[3] Although these [3]rotaxanes are saturated and therefore display no translational isomerism, it is possible to prepare [2]rotaxane molecular shuttles with this template and this work is reported herein.

The [2]rotaxanes **5** and **8**‡ were prepared by mixing **3** and **6** respectively with two equivalents of DB24C8 in MeCN solution followed by a 2-fold excess of the required equivalents of *tert*-butylbenzyl bromide (Scheme 1).[4] The mixtures were stirred at room temperature for 2 days, the salts precipitated by the addition of Et_2O and the products isolated as the chloride salts by column chromatography on silica gel ($MeOH/MeNO_2$/2.0 M NH_4Cl(aq), 3:1:1). Anion exchange with $NaCF_3SO_3$ and $NaBF_4$ respectively in aqueous solution produced **5** and **8** in overall yields of 13 and 19% as orange crystalline solids, which were soluble in organic solvents such as MeCN, $MeNO_2$ and CH_2Cl_2.

Noncovalent interactions between axle and wheel can be inferred by significant chemical shift differences ($\Delta\delta$) in the solution (MeCN-d_3) ^{1}H NMR spectra of **5** and **8** when compared to the respective axles **4** and **7** and free DB24C8.[5] C–H···O hydrogen bonds from axle protons to crown ether O-atoms are evident from the significant *downfield* shifts for all α^+-pyridinium and $^+NCH_2$ protons, while π-stacking between the electron-rich catechol and electron-poor pyridinium rings is indicated by *upfield* shifts observed for the β-pyridinium protons and crown aromatic protons. There exists the possibility of two translational isomers; *i.e.* the crown ether can *shuttle* from one binding site to the other. That this dynamic phenomenon occurs is supported by the fact that only one set of resonances is observed at room temperature and there is a slight exchange broadening of the axle protons interacting with the crown oxygen atoms. It was concluded that the crown ether is undergoing fast exchange between the two binding sites and the observed room temperature chemical shifts for **5** and **8** are

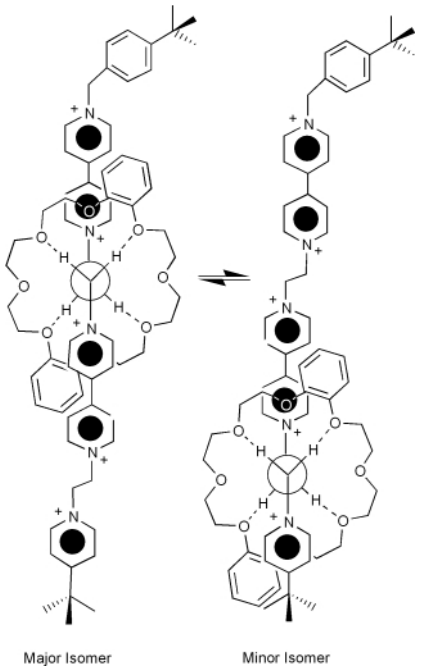


Scheme 1 *Reagents and conditions:* i, 4 equiv. of 4-*tert*-butylbenzyl bromide, 2 equiv. of DB24C8, MeCN, RT, 2 days, SiO_2 ($MeOH/MeNO_2$/2.0 M NH_4Cl(aq), 3:1:1), R_f = 0.35, $NaCF_3SO_3$(aq), 13%; ii, 2 equiv. of 4-*tert*-butylbenzyl bromide, 2 equiv. of DB24C8, MeCN, RT, 2 days, SiO_2 ($MeOH/MeNO_2$/2.0 M NH_4Cl(aq), 3:1:1), R_f = 0.31, $NaBF_4$(aq), 19%.

† Electronic supplementary information (ESI) available: ^{1}H NMR chemical shifts. See http://www.rsc.org/suppdata/cc/b0/b004784h/

DOI: 10.1039/b004784h

weighted averages of the resonances attributable to the individual occupied and vacant sites.



The ^{1}H NMR spectrum of **5** coalesced at 293 K yielding a rate of exchange between the equally populated binding sites of 320 Hz with $\Delta G^{\ddagger}$ = 57.5 kJ mol^{-1}. Similarly, **8** reached coalescence at 273 K with an exchange rate of 222 Hz and $\Delta G^{\ddagger}$ = 54.3 kJ mol^{-1}. For this unsymmetrical [2]rotaxane, the aryl crown ether resonances were used to determine the occupancy of each site. Integration of these signals at 243 K yielded a 2 : 1 ratio of isomers with the bis(4,4′-bipyridinium)ethane site being favoured. This preference is likely due to two factors: (i) the 4,4′-bipyridinium rings are the most electron-poor resulting in more favourable π-stacking and (ii) there are steric problems caused by the *t*Bu-pyridinium group which disfavour π-stacking.

An X-ray crystal structure determination§ of **8** verified the nature of the interactions observed in solution; a ball-and-stick representation is shown in Fig. 1. The DB24C8 ring is threaded on the unsymmetrical axle such that the S-shaped crown ether ring occupies the more favoured bis(4,4′-pyridinium) moiety. The unoccupied bis(pyridinium)ethane group adopts a *gauche* conformation in the solid state.

It has been demonstrated that the 1,2-bis(pyridinium)ethane/24-crown-8 ether templating motif can be used for the synthesis of symmetrical and unsymmetrical molecular shuttles. Future work will focus on controlling this switching process by external perturbations.

We thank the Natural Sciences and Engineering Council of Canada for financial support of this research and J. A. W. thanks the Ontario Graduate Scholarship program for funding.

Notes and references

‡ All new compounds were successfully characterized by ^{1}H NMR spectroscopy (500 MHz, 298 K) and LSI-MS or ESI-MS. NOESY experiments were used make individual ^{1}H NMR assignments. Synthetic note: > 3 equivalents of DB24C8 produces exclusively [3]rotaxane;[4] < 3 equivalents of DB24C8 produces a mixture of [3]rotaxane, [2]rotaxane and thread with the optimum yield of [2]rotaxane produced with 2 equivalents.

Replacement of selenium by antimony in $MoSe_2$: interconnection of the MoSbSe layers by Sb–Sb bonding

Holger Kleinke*

Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1. E-mail: kleinke@uwaterloo.ca

Received (in Oxford, UK) 21st June 2000, Accepted 22nd August 2000
First published as an Advance Article on the web

The replacement of every other Se atom in layered $MoSe_2$ by two Sb atoms led to the formation of $MoSb_2Se$; within its lattice, Sb atoms interconnect the MoSbSe sheets to form a truly three-dimensional structure, thereby enlarging the octahedral cavities.

The layered dichalcogenides of the valence-electron-poor transition metal atoms have attracted the interest of various different interdisciplinary research groups owing to potential applications such as solid lubricants, and intercalation reactions and electronic instabilities leading to energy storage applications[1] and charge density waves.[2] Consequently, extensive theoretical work (based on the Extended Hückel calculations) was performed to investigate the different physical properties[3] as well as the different metal clustering which are both dependent upon the electron count.[4]

For packing considerations, metal atoms, M, fill the octahedral voids of every other layer in the hexagonal close-packing of chalcogen atoms, Q, (realized in the CdI_2 lattice type, as observed for $ZrSe_2$[5]); different electron configurations of the M atoms bring about different distortions in the structures. For example, in going from $ZrSe_2$ through the polymorph $NbSe_2$[6] to $MoSe_2$,[7] the d electron configuration of the M^{4+} atom changes from $4d^0$ to $4d^1$ to $4d^2$: this leads to significant shifts of the atomic positions in the layers of $NbSe_2$ and $MoSe_2$, which produce in part bonding M–M contacts that do not occur in the undistorted CdI_2 type structure. $MoSe_2$ and α-$MoTe_2$[8] crystallize as the MoS_2 type, with Mo atoms surrounded in a trigonal prismatic arrangement. This is—for d^2 ions—one of the two energetically favorable deviations from ideal hexagonal close-packing of the chalcogen atoms. Here, the electronic stabilization results from lowering of the one filled d orbital in the trigonal prismatic ligand field. The other favorable configuration, realized in β-$MoTe_2$ and WTe_2,[9] is the formation of M–M zigzag chains, stabilized by the occurrence of two single bonds per M atom, *i.e.* by lowering the one filled d orbital of the t_{2g} set. Linearly linked rhomboidal clusters would be favorable for a d^3 count as in $ReSe_2$.[10] The latter two distortions can be deduced to arise from a Peierls distortion associated with the partially filled t_{2g} band.

The intercalation chemistry of the layered chalcogenides, MQ_2, known to date is substantive.[11] Usually, intercalation of cations increases the number of M-centered d electrons and thus enhances M–M bonding within the MQ_2 layers. Examples include $M'_{0.5}NbSe_2$ (M′ = Ti, V, Cr)[12] and Cu_xNbTe_2,[13] while $Zr_{1+x}Te_2$ represents a notable exception.[14]

Intercalation of anions is less favorable due to anion–anion repulsions. The problem can be avoided by connecting the anions to the MQ_2 layers *via* covalent bonds. To achieve this, one must either oxidize the Q^{2-} anions or exchange Q for less electronegative atoms, such as the heavier pnictogen atoms like antimony. Since the Sb atoms tend to form Sb–Sb bonds even in metal-rich antimonides of the valence-electron-poor transition metals, *e.g.* in $(Hf,Ti)_7Sb_4$,[15] $(Zr,V)_{11}Sb_8$,[16] $(Zr,V)_{13}Sb_{10}$[17] and (Zr,Ti)Sb,[18] and the only known molybdenum antimonide, Mo_3Sb_7, comprises Sb–Sb bonds as well,[19] it seemed most promising to use the latter method with Sb atoms as replacements for the chalcogen atoms, Q.

Subsequently, reactions aimed at hypothetical $Sb_xMo(Sb,Se)_2$ were carried out by heating the elements in the stoichiometric ratios in sealed silica tubes at 800 °C with addition of traces of iodine to promote crystal growth. Thereby, the new antimonide selenide $MoSb_2Se$ formed and was characterized by EDX and crystal structure analysis.[20] $MoSb_2Se$ crystallizes in its own structure type, which can be described based on MoSbSe layers being interconnected by additional Sb atoms (Sb3 and Sb4), as depicted in Fig. 1.

The MoSbSe layers closely resemble the $MoTe_2$ layers of β-$MoTe_2$, with the Sb atoms capping the longer Mo–Mo distances > 450 pm and the smaller Se atoms capping the Mo–Mo bonds of 281 pm (Mo–Mo in β-$MoTe_2$: 289–290 pm). This suggests a d^2 configuration of the Mo atoms, *i.e.* Mo^{4+}, as in $Mo^{4+}(Se^{2-})_2$. Correspondingly, the Mo–Se distances are very similar in both compounds, ranging from 250–252 pm in $MoSb_2Se$, compared to 253 pm in $MoSe_2$. Also, the Mo–Sb distances in $MoSb_2Se$ (282–284 pm) compare well to the longer one in Mo_3Sb_7 (285 pm), to which the Sb atoms with Sb–Sb bonding contribute.

Every Sb atom of the MoSbSe layers forms one homonuclear bond to one interlayer Sb atom, the length of which (285 pm) suggests a typical single bond, as also found in KSb (283 and 285 pm),[21] *cyclo*-Sb_5^{5-} (between 281–291 pm),[22] and Sb_{11}^{3-} (276–285 pm).[23] Furthermore, each of these intralayer Sb atoms takes part in four longer bonds (325–330 pm, dashed lines in Figs. 1 and 2). These distances are indicative of weak but clearly present interactions.[24] Ignoring them in a first approximation and applying the $(8 - N)$ rule, we assign the oxidation state of 2− to the intralayer Sb atoms, which leads to neutral interlayer Sb atoms, *i.e.* $Sb^0Mo^{4+}Sb^{2-}Se^{2-}$. The latter readily explains the presence of three Sb–Sb single bonds per interlayer Sb atom

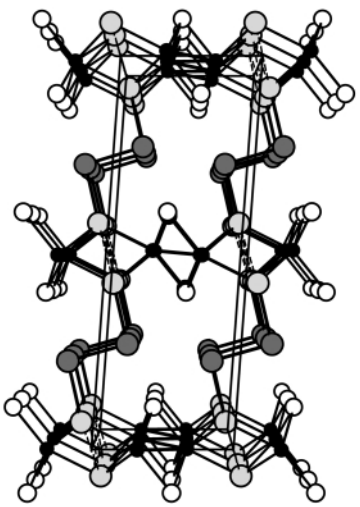

Fig. 1 Projection of the structure of $MoSb_2Se$ along [010]. Horizontal, *a* axis; Mo (●), Se (○), Sb1, Sb2 (◍), Sb3, Sb4 (◍); dashed lines, $325 < d_{Sb-Sb} < 330$ pm.

DOI: 10.1039/b005062h

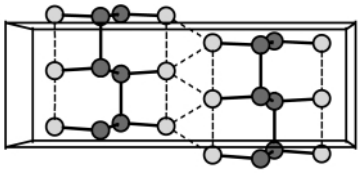

Fig. 2 Projection of the Sb atom substructure along [100]. Horizontal, *c* axis; solid lines, 285 < *d* < 292 pm; dashed lines, 325 < *d* < 330 pm.

(bond lengths 285–292 pm), which requires doubling of the monoclinic axis (Fig. 2). The doubling of the *b* axis led to only weak superstructure reflections because only the Sb3 and Sb4 atoms were shifted to form alternating short and long distances of 292 and 357 pm. These shifts are reflected in the differences in the *y* parameters of Sb3 and Sb4, while all other atoms are pairwise related, *e.g.* Mo1 *x*, *y*, *z*, Mo2 *x*, *y* + ½, *z*.

The situation is somewhat more complicated as discussed above, since the Sb–Sb bonds classified as single bonds are up to 10 pm longer than regular single bonds, and because of the presence of the four weaker bonds per intralayer Sb atom. These details suggest the oxidation states of the different Sb atoms being more similar, leading to a formulation of $Sb^{x-}Mo^{4+}Sb^{(2-x)-}Se^{2-}$ with $0 < x < 1$.

Although interlayer atoms are already present in $MoSb_2Se$, the structure is still susceptible for intercalation of cations. The distances between the layers increase by going from $MoSe_2$ through $MoTe_2$ to $MoSb_2Se$, *i.e.* from 366, to 386, to 561 pm, measured between the Se and Te atoms, respectively. As a consequence, an octahedral void remains, which is even larger in $MoSb_2Se$ than in $MoSe_2$.

Therefore, we are currently investigating possible intercalation reactions for $MoSb_2Se$. Reducing $MoSb_2Se$ might lead to reduced interlayer Sb atoms thus breaking the Sb–Sb bonds parallel to the *b* axis, which would eliminate the superstructure. Also of interest are attempts to place more Sb atoms between the MoSbSe layers by forming (hypothetical) compounds like $MoSb_3Se$ or $MoSb_4Se$.

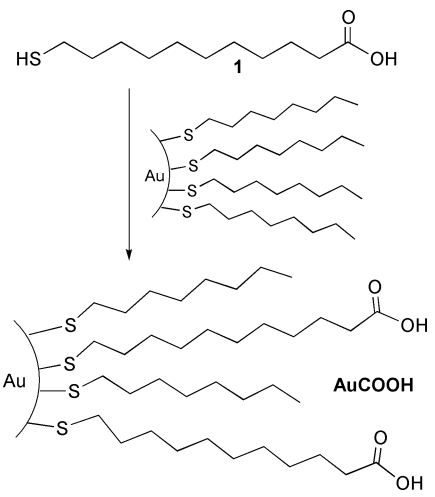
Alkanethiolate-protected gold nanoclusters are solublized through place exchange reaction with ω-thiocarboxylic acids.

Thiolate monolayer-protected gold clusters (MPCs) provide versatile precursors for the fabrication of nanoscale systems.[1] These colloidal MPCs can be readily modified through place exchange reactions,[2] providing a direct route to mixed monolayer-protected clusters (MMPCs) featuring a broad array of functionality. This functional diversity, coupled with the combinatorial nature of the place exchange process, has made MMPCs central in the creation of numerous nanoparticle-based materials and devices.

One potentially powerful application of MMPCs is biomolecular recognition.[3] In recent investigations, we have demonstrated that the mobility of thiolate ligands on nanoparticles can be exploited to create templated multivalent receptors.[4] The extension of this methodology to the recognition of protein surfaces[5] has been limited by the inaccessibility of water-soluble amphiphilic MMPCs. Recently, Murray and co-workers have demonstrated the formation of water-soluble MPCs and place exchange reactions to produce the corresponding MMPCs.[6] In both the colloid formation and place exchange steps, however, purification of the resulting colloids required lengthy dialysis to remove unreacted thiols. More significantly, attempts to exchange hydrophobic groups into water-soluble MPCs resulted in the formation of insoluble aggregates.[6c] To provide an alternative route to the formation of amphiphilic colloids we have explored the exchange of polar functionality with gold nanoparticles featuring non-polar monolayer coverage. We report here the direct formation of water-soluble amphiphilic colloids through place exchange of alkanethiolate MPCs with an ω-thiol carboxylic acid.

To obtain a system that would provide water solubility with non-polar groups present, we prepared the carboxylic acid-functionalized colloid AuCOOH through place exchange of 2 nm octanethiol colloids[7] with 11-thioundecanoic acid **1** (Scheme 1).[8] After washing with dichloromethane, the AuCOOH nanoparticles were dissolved in D_2O/NaOD, and characterized by NMR. The end-group analysis of the ^{1}H NMR spectrum of the resulting $AuCOO^-$ colloids indicated that the ratio of ω-thiol carboxylic acid to octanethiol was *ca.* 1 : 1.



Scheme 1

The functionalized colloids were also characterized by pH titration. Acid/base titrations of nanoparticles with ionizable monolayer moieties have been carried out previously.[6c,9] Fig. 1A shows the titration of $AuCOO^-$, which exhibited a pK_a of about 4.0. This corresponds closely to previous work done on carboxylate-terminated MPCs featuring a C_{12} monolayer, where a pK_a of 4.5 was reported,[8] and is considerably lower than the pK_a of 5.56 observed with tipronin (C_4)-functionalized MPCs. This disparity in pH provides further evidence of the distance dependence of sidechain–sidechain interactions arising from the radial nature of MPC systems.[10]

During titrations, aggregation of particles was observed at pH < 5. This is attributed to interparticle interactions: at low pH the carboxylic acid groups facilitate interparticle interactions through both hydrogen bonding and an increase in hydrophobicity, resulting in the formation of particle aggregates. At high pH, however, particle aggregation is disfavored due to repulsive interactions between negatively charged carboxylate particles.[11] Transmission electron microscopy (TEM) was used to better understand the aggregation process.[8,9] Samples were prepared by initially dissolving AuCOOH nanoparticles in pH 10 buffer. A portion of this solution was neutralized to pH ~ 7 with 0.1 M HCl which was then diluted with pH 7 or pH 4 buffer, producing three solutions with pH 10, 7, and 4. All the solutions were diluted with sufficient buffer to yield a final colloid concentration of 1 mg mL^{-1}. A single drop of the desired solution was deposited on a TEM grid.[12] At pH 10, there was very little aggregation, as would be expected for a highly charged colloid (Fig. 2a). When this system was deposited from a neutral pH 7 solution (Fig. 2b) both small loosely packed aggregates and individual particles were observed. At pH 4, (Fig. 2c), aggregation was increased, with very few free particles observed. Additionally, these aggregates are much larger and denser than those observed at pH 7.

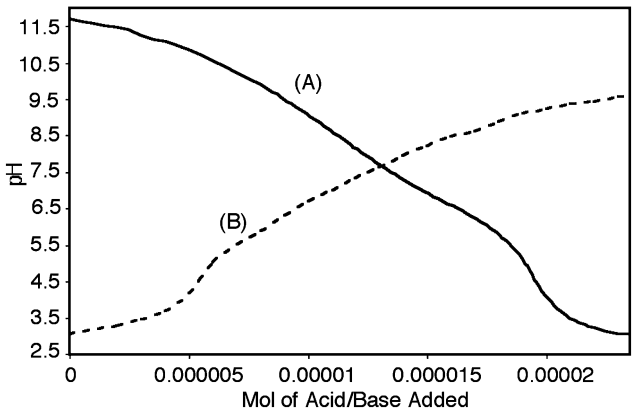


Fig. 1 Titration curves of AuCOOH. The colloid was first dissolved in a small amount of 0.1 M NaOH and brought up to a volume of 3.3 ml with distilled water. (A) Original solution titrated with aliquots of 10–50 μL 0.01 M HCl. (B) Back titration of solution. Titrated with aliquots of 10 μL 0.1 M NaOH. The pH was recorded initially and after each addition of either the acid or base.

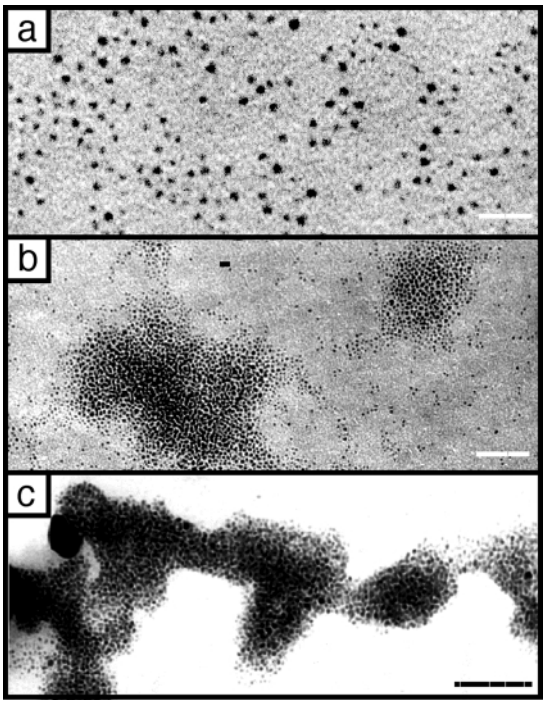

Fig. 2 TEM micrographs of ω-thiol carboxylic acid functionalized colloid at (a) pH 10, (b) pH 7, and (c) pH 4. Scale bars represent 10 nm, 25 nm, and 50 nm, respectively.

In summary, we have demonstrated the effective fabrication of a water-soluble amphiphilic MMPC through place-exchange processes. We have also shown that aggregation of these particles can be directly controlled through modulation of pH. The application of these water-soluble MMPCs to molecular and biomolecular recognition is currently underway, and will be reported in due course.

8 In a typical procedure, 11-thioundecanoic acid (740 mg, 3.4 mmol) in 4 mL of THF was added to 140 mg of C_8-functionalized nanoparticles.[4] The resulting solution was stirred under argon for two days at room temperature, forming a black precipitate of AuCOOH. Solvent was removed *in vacuo*, and the resulting solid purified by repeated suspension, centrifugation, and decanting with dichloromethane. The resulting AuCOOH colloid was soluble in polar organic solvents such as methanol, and ethanol, and slightly soluble in THF. Solublization of AuCOOH colloid aqueous solution was achieved using aqueous solution at pH 10. This solution of AuCOOH could be acidified to pH ~5 before precipitation occurred.

First published as an Advance Article on the web

The reaction of AuCl(THT) (1) with long chain primary amines ($C_nH_{2n+1}NH_2$; n = 8, 12, 16) leads to the formation of the complexes $AuCl(NH_2R)$ (R = C_8H_{17}, 2; $C_{12}H_{25}$, 3; $C_{16}H_{33}$, 4) which are characterized by classical methods and shown to self-organize in the solid state into a fibrous material; decomposition of the complexes inside the supramolecular framework yields a monolayer of ordered gold nanoparticles.

There is presently a considerable interest for the physical properties of nanomaterials (electronics, magnetism, catalysis, mechanical properties, …). If one excepts near field experiments, the study of these properties implies an ordering of the materials in 1, 2 or 3 dimensions.[1–4] It has been proposed recently that the formation of self-assembled gold nanowires could be an alternative to photolithography.[4] In many cases, gold appears as a metal of choice for applications regarding, *e.g.* microelectronics but, while the synthesis of gold nanoparticles has been known for 150 years,[5] a study of the recent literature reveals the need for new preparative methods leading to monodisperse particles of adjustable size and shape.[6–12]

Gold particles are commonly prepared by chemical reduction of a chloride precursor. For example, the well-known Turkevich method involves reduction of $HAuCl_4$ by sodium citrate in water[13] while Schmid has demonstrated that the reduction of $AuCl(PR_3)$ by B_2H_6 leads to Au_{55} nanoclusters.[14] Several new methods have been developed in the last few years which involve the reduction of gold chlorides by sodium borohydride or super-hydride.[11,12] The stabilization of the particles is generally performed by thiolate ligands or by a polymer (PVA, PVP) but, recently, amines have also been used as stabilizers.[15] It has for example been possible, using a two phase method in the presence of a long chain quaternary ammonium salt as phase transfer agent, to produce particles of regular size which could be assembled into a mono- or a bi-layer.[16–20] Alternative syntheses involve vacuum deposition onto graphite[6] or silica[7] or UV irradiation of aqueous $HAuCl_4$ solution in the presence of a polymer.[8]

In our group, we have been interested for some time in the synthesis of metal nanoparticles from organometallic precursors.[21–23] The reasons for this interest were (i) the possibility to control the kinetic of the decomposition of the precursor and therefore the size of the particles, (ii) the possibility to prepare novel structures because of the mild conditions involved and (iii) the control of the surface contamination.[22,23] Concerning gold, no readily available and purely organometallic precursor was known but some gold(I) complexes have been reported to be unstable.[24,25] We have previously shown that the chloride gold(I) complex AuCl(THT)[26] (**1**; THT = tetrahydrothiophene) could be decomposed by CO or H_2 in the presence of a polymer (PVP or nitrocellulose).[24] This prompted us to investigate the decomposition of AuCl(THT) in the presence of amine which could act as HCl acceptor. We use in this study primary amines containing long alkyl chains since these compounds are known to self-assemble and have been used as templating agents for the synthesis of mesoporous materials.[27]

We describe here the synthesis of three new gold(I) amine complexes, their supramolecular arrangement and their decomposition into gold nanoparticles.

The reaction of AuCl(THT) (**1**) in toluene at room temperature leads within a few minutes to the precipitation of gold as a polycrystalline powder. GLC-MS analysis of the solution demonstrates the formation of chlorotoluene as a mixture of its three isomers and the decoordination of THT. This indicates that, unexpectedly and probably through a mechanism analogous to that of the Friedel–Crafts reaction, toluene is a good reductant of Au(I). However, the same reaction, when carried out in the presence of one equivalent of a primary long chain amine ($C_nH_{2n+1}NH_2$; n = 8, 12, 16), leads to the formation of a white powder, insoluble in toluene, soluble in THF and acetone for n = 8, and only slightly soluble in THF and DMSO for n = 12 and 16. The solutions are however not very stable and change colour to purple after a few minutes in DMSO and a few hours in THF and acetone. These powders correspond to the complexes $AuCl(NH_2R)$ (R = C_8H_{17}, **2**; $C_{12}H_{25}$, **3**; $C_{16}H_{33}$, **4**); they were characterized by microanalysis, infrared and ^1H and ^{13}C NMR spectroscopy, and TGA.† Mass spectra obtained using the DCI or the FAB techniques only evidenced the presence of the free amine ligand because of the decomposition of the compounds. It was however possible to follow the decomposition of **2**–**4** in the solid state by TGA experiments which demonstrate the successive elimination of the chloride and amine ligands. GLC-MS analysis of the solution shows the presence of free THT but chlorotoluene is not detected. All these data are in agreement with a simple substitution of THT by amine.

A powder of complex **2** was investigated by TEM (Transmission Electron Microscopy; see Fig. S1, ESI†). At the microscopic level, the powder is formed from nanocrystals the size of which is found near 2 nm see Fig. S1(*b*), ESI.† It is possible to determine by WAXS analysis (WAXS: Wide Angle X-ray Scattering) that these nanocrystals are ordered and that the first Au–Au distance is *ca.* 3.25 Å. This result rules out the presence of metal–metal bonds (Au–Au distance in bulk gold: 2.88427 Å) but is in agreement with the presence of aurophilic contacts such as the ones recently found in the crystal structure of AuCl(piperidine) (Au···Au: 3.301(5) Å).[25]

In the solid state, complexes **2**–**4** are stable under argon but, when slightly heated or left in air, their decomposition into metallic gold is visible through the colour change of the materials from white to purple and eventually to gold. The reaction can be monitored by infrared spectroscopy. For example, in the case of **2**, a change in the N–H stretching bands, from sharp peaks at 3251 and 3211 cm^{-1} to a broad signal in the same region, indicates the decoordination of the amine ligand. The powder XRD spectra (XRD: X-ray Diffraction) of complex **2** illustrates this transformation: at room temperature several features are visible which were not attributed but, when heated at 70 °C, new peaks are visible which correspond to metallic

† Electronic supplementary information (ESI) available: experimental details and full characterization of complexes **2**–**4**, powder XRD spectra of **2** and TEM micrographs of **2** and gold nanoparticles. See http://www.rsc.org/suppdata/cc/b0/b005327i/

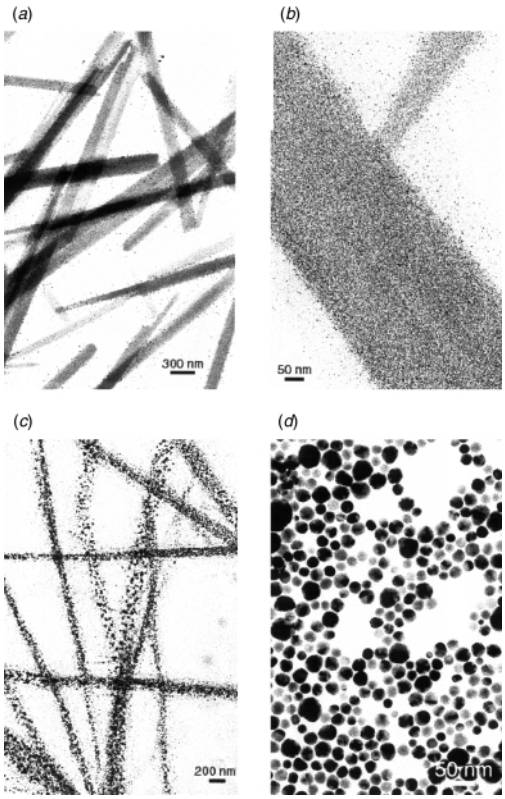

Fig. 1 TEM micrographs of $AuCl(NH_2C_8H_{17})$ (**2**) after deposition using a microinjector for ordering (*a*, *b*) and decomposition in the solid state into gold nanoparticles (*c*, *d*).

gold. At 80 °C, the transformation is complete and sharp peaks corresponding to well-crystallised fcc gold are observed (see Fig. S2, ESI).†

At the mesoscopic level, the nanoparticles of these complexes display a supramolecular organization into a fibrous material as shown in Figs. S1(*a*), 1(*a*) and 1(*b*).† These fibers are composed of interconnected self-assembled cylinders which organize spontaneously at the surface of the microscopy grid and are presumably present in solution. This probably accounts for the unexpected low solubility of these materials. Attempts at orienting the fibers were made by depositing a drop of a solution of **2** onto a microscopy grid using a microinjector; it is visible on Figs. 1(*a*), 1(*b*) that fibers can adopt privileged directions but further developments are necessary in order to achieve regular arrays.† In agreement with the XRD experiments, the transformation of the gold(I) complexes into gold nanoparticles can also be observed on a microscopy grid prepared by deposition and evaporation of a droplet of a solution (suspension) of **2**–**4** in THF. When a grid supporting complex **2** is left in air for a few days, the initial complex nanocrystals transform into regular gold nanocrystals within the frame of the supramolecular arrangements described here-above (see Figs. 1(*c*), 1(*d*)). The size distribution of the nanoparticles is at the end of the growth process relatively broad and centred at 23 nm [±6 nm; Fig. 1(*d*)]. This order of magnitude of size is frequently obtained for gold nanoparticles and suggests a poor, if any, control of the particle growth by the amine ligands. This is not unexpected since the poor stabilization of the soft gold centres by the hard amine ligands has already been discussed in the literature.

The decomposition of **2** can also be carried out in a THF solution under 3 bars H_2 at room temperature, in the presence or not of an excess of amine. After 15 hours, the resulting purple solution does not contain any precursor any more but well-crystallised gold nanoparticles of *ca.* 10 nm (±3 nm) which self-assemble on the microscopy grid used for TEM characterizations as shown in Fig. S3.† After several days, no gold is present in solution any more and a gold mirror is observed on the walls of the Fisher-Porter bottle.

In conclusion, we have described a new method for the preparation of gold nanoparticles using a gold(I) amine precursor. If this method does not appear to allow a good control of the particles size, it leads surprisingly to a good control of the size dispersity and, which is unexpected and more important, it allows a self-organization of the particles. There is presently a growing need for the controlled deposition of nanoparticles on physical or microelectronic devices. Several routes are possible and employed: sputtering, OMCVD, sol–gel, deposition of organized solutions of nanoparticles, … The growth of nanoparticles, in the solid state, as monolayers within the frame of a supramolecular arrangement is an alternative process of interest, for example for gold deposition onto microstructures. These studies are presently in progress.

We thank the CNRS, EC through the TMR network ‘CLUPOS’ for support of this research and TEMSCAN service of the ‘Université Paul Sabatier’ for electron microscopy facilities.

An intramolecular π–π interaction has no effect on the lifetime of an aryl radical cation

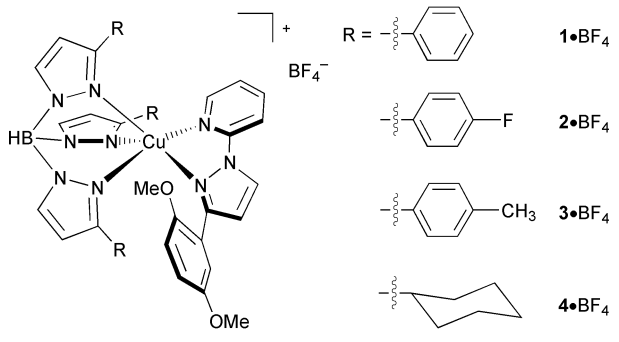
Received (in Cambridge, UK) 25th July 2000, Accepted 23rd August 2000
First published as an Advance Article on the web

The lifetimes of electrochemically generated $[Cu(L^{1\cdot+})(Tp^{Ph})]^{2+}$ and $[Cu(L^{1\cdot+})(Tp^{Cy})]^{2+}$ are identical to within experimental error.

We have recently reported that the complexes $[Cu(L^1)(Tp^R)]BF_4$ (L^1 = 1-{pyrid-2-yl}-3-{2′,5′-dimethoxyphenyl}pyrazole; $[Tp^R]^-$ = tris-[3-arylpyrazolyl]borate: **1**·BF_4–**3**·BF_4, Scheme 1) exhibit an unusual, fully reversible L^1-based 1-electron oxidation by cyclic voltammetry in CH_2Cl_2/0.5 M $NBu^n_4PF_6$ at 298 K.[1] This led us to suggest that an intramolecular π–π stacking interaction observed in **1**·BF_4–**3**·BF_4 might be kinetically stabilising the $[L^{1\cdot}]^+$-containing oxidation products. This would not be without precedent, in that others have detected unusual reversible voltammetric oxidations of intramolecularly π–π-stacked monocyclic aryl moieties in sesterbenzobicyclo[2.2.2]octane[2] and *ortho*-cyclophane[3] derivatives. In addition, a related $n \rightarrow \pi^*$ charge-transfer interaction leads to a 1000-fold increase in the lifetime of sulfanyl radical cations in aromatic, compound to chlorinated, solvents.[4] If true, such a result would be of relevance to the properties of proteins such as galactose oxidase (GOase), which contains a tyrosyl radical that is involved in a π–π interaction with a tryptophan indole ring.[5] This π–π interaction is vital to the function of the enzyme,[6] although its detailed role in catalysis is unknown. We now report the synthesis of a complex closely related to **1**·BF_4–**3**·BF_4 but lacking the π–π interaction, which has allowed us to quantify the effects of π–π stacking on the properties of $[L^{1\cdot}]^+$. We also describe the spectroelectrochemical characterisation of the aryl radical complex products $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$.



Scheme 1

Treatment of hydrated $Cu(BF_4)_2$ with one molar equivalent of L^1 and $K[Tp^{Cy}]$[7] in CH_2Cl_2 affords, following concentration and layering with hexanes, a dark green compound analysing as $[Cu(L^1)(Tp^{Cy})]BF_4$ (**4**·BF_4) in 55% yield.† This complex exhibits a d–d absorption in CH_2Cl_2 at $\nu_{max} = 15.6 \times 10^3$ cm^{-1} (ε_{max} = 104 M^{-1} cm^{-1}), which bears a low-energy shoulder. X-band EPR spectroscopy of **4**·BF_4 in 10:1 CH_2Cl_2:toluene shows $\langle g \rangle$ = 2.13, $\langle A\{^{63,65}Cu\} \rangle$ = 65 G, $\langle A\{^{14}N\} \rangle$ = 14 G at 298 K and $g_\parallel$ = 2.25, $g_\perp$ = 2.04, $A_\parallel\{^{63,65}Cu\}$ = 167 G at 77 K. The close correspondence of these parameters to those shown by **1**·BF_4–**3**·BF_4, which exhibit square pyramidal geometries in the solid state and in solution,[1] strongly suggests that the molecular structure of **4**·BF_4 is essentially identical to those of our earlier compounds. A single crystal X-ray analysis‡ confirmed the proposed molecular connectivity (Fig. 1). Apart from the short apical distance Cu(1)–N(2) (Fig. 1), which we have found to be a very plastic parameter in square-pyramidal Cu(II)/trispyrazolylborate complexes,[8] the co-ordination geometry at Cu differs insignificantly from that of **1**·BF_4.[1]

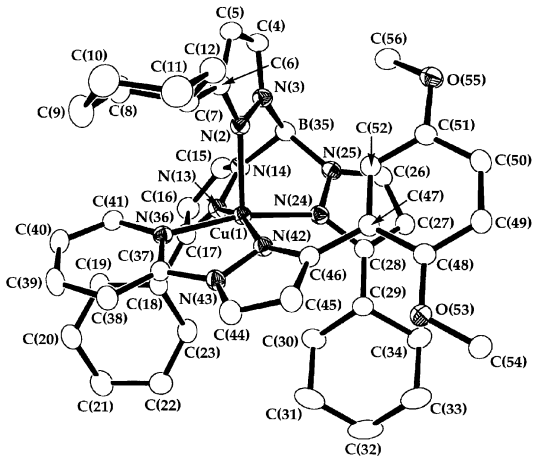


Fig. 1 View of the complex cation in the crystal of **4**·BF_4·$2CHCl_3$ with 35% probability ellipsoids, showing the atom numbering scheme employed. For clarity, all H atoms have been omitted. Selected distances (Å) and angles (°): Cu(1)–N(2) 2.153(2), Cu(1)–N(13) 2.024(2), Cu(1)–N(24) 1.984(2), Cu(1)–N(36) 2.029(2), Cu(1)–N(42) 2.0596(19), N(2)–Cu(1)–N(13) 92.41(8), N(2)–Cu(1)–N(24) 93.80(8), N(2)–Cu(1)–N(36) 98.86(8), N(2)–Cu(1)–N(42) 102.66(8), N(13)–Cu(1)–N(24) 85.70(8), N(13)–Cu(1)–N(36) 94.34(8), N(13)–Cu(1)–N(42) 164.25(8), N(24)–Cu(1)–N(36) 167.32(8), N(24)–Cu(1)–N(42) 97.69(8), N(36)–Cu(1)–N(42) 78.99(8).

The cyclic voltammogram of **4**·BF_4 in CH_2Cl_2/0.5 M $NBu^n_4BF_4$ at 298 K exhibits all the processes shown by **1**·BF_4–**3**·BF_4 in this solvent.[1] Hence, a chemically reversible L^1-based 1-electron oxidation is obseved at $E_{\frac{1}{2}}$ = +1.06 V *vs.* ferrocene/ferrocenium (ΔE_p = 96 mV),§ which is 60–90 mV more positive than the values we have recorded for **1**·BF_4–**3**·BF_4. In order to quantify any kinetic stabilisation of $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ afforded by intramolecular π–π stacking, we have measured the half-lives of $\mathbf{1}^{2+}$, $\mathbf{2}^{2+}$ and $\mathbf{4}^{2+}$ at 298 K in the electrochemical cell using convolution methods.[9] The values obtained are almost identical within experimental error: $\mathbf{1}^{2+}$, $t_{\frac{1}{2}}$ = 1.7(2) s; $\mathbf{2}^{2+}$, $t_{\frac{1}{2}}$ = 1.39(17) s; and $\mathbf{4}^{2+}$, $t_{\frac{1}{2}}$ = 0.98(11) s. Although it is unclear whether the assumption of first-order decomposition kinetics employed by the convolution procedure is valid in our system, it is clear that

DOI: 10.1039/b006005o

the kinetic stabilities of $\mathbf{1}^{2+}$, $\mathbf{2}^{2+}$ and $\mathbf{4}^{2+}$ are essentially identical.

Attempts to electrogenerate bulk samples of $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$ for EPR measurements were unsuccessful, resulting in appreciable decomposition of the sample over the timescale of the experiment. *In situ* spectroelectrochemical characterisation of the oxidised species $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$ was therefore undertaken. Electrooxidation of $\mathbf{1}\cdot BF_4$ in CH_2Cl_2/0.5 M $NBu^n_4BF_4$ at 243 K at a potential corresponding to the $\mathbf{1}^{+}/\mathbf{1}^{2+}$ couple using an optically transparent electrode proceeds isosbestically and results in substantial changes in the UV, vis and NIR regions of the spectrum (Fig. 2). The oxidised solution for $\mathbf{1}^{2+}$ shows ν_{max} = 12.4 (ε_{max} = 1000), 19 (sh), 22.2 (3 400), 26 (sh) and 32.5 $\times$ 10^3 cm^{-1} (15 500 M^{-1} cm^{-1}) at 243 K (Fig. 2). The absorption spectrum of $\mathbf{2}^{2+}$ generated under identical conditions is barely distinguishable from those of $\mathbf{1}^{2+}$. Re-reduction of both samples at 0 V also proceeds isosbestically and quantitatively regenerates $\mathbf{1}^{+}$ or $\mathbf{2}^{+}$, demonstrating the chemical reversibility of this process under these conditions.

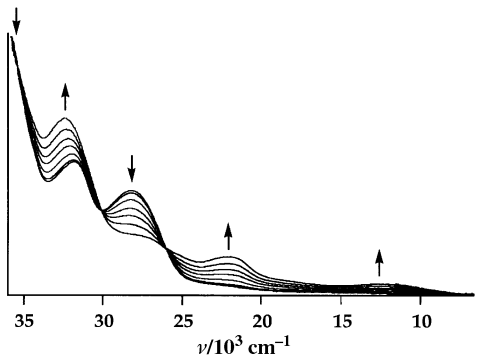

Fig. 2 Oxidation of $\mathbf{1}^{+}$ to $\mathbf{1}^{2+}$ by controlled potential electrolysis in CH_2Cl_2/0.5 M $NBu^n_4PF_6$ at 243 K.

The $[C_6H_4(OMe)_2$-1,4·$]^+$ radical cation exhibits ν_{max} = 21.7 (ε_{max} = 9 540 M^{-1} cm^{-1}), 23.3 (9 040) and 33.3 $\times$ 10^3 cm^{-1} (13 000) in aqueous solution,[10] but is optically transparent in the range 11–21 $\times$ 10^3 cm^{-1}.[11] The 22.2, 26 and 32.5 $\times$ 10^3 cm^{-1} bands from $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$ quite closely match those shown by $[C_6H_4(OMe)_2$-1,4·$]^+$; we therefore assign these bands to local excitation transitions within the $[L^{1\cdot}]^+$ moiety. The 12.4 $\times$ 10^3 cm^{-1} absorption can be attributed to a $[Tp^{Ph}]\rightarrow[L^{1\cdot}]^+$ LLCT transition. By comparison, the $[(C_6H_6)(C_{10}H_8)]^{\cdot+}$ complex exhibits a gas-phase intra-dimer CT band at 10.9 $\times$ 10^3 cm^{-1},[12] while $[(C_6H_6)(C_7H_8)]^{\cdot+}$ exhibits three such bands, at 8.5, 10.8 and 14.9 $\times$ 10^3 cm^{-1}.[13] The observation of such a transition for $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$ is clear evidence that the intramolecular π–π-stacking interaction in these complexes is retained following oxidation. The assignment of the shoulder near 19 $\times$ 10^3 cm^{-1} is uncertain; we tentatively suggest that this may correspond to a second LLCT transition, or to a $Cu\rightarrow[L^{1\cdot}]^+$ MLCT band.

To conclude, we have demonstrated that the intramolecular π–π interaction exhibited by $\mathbf{1}^{+}$ and $\mathbf{2}^{+}$ is retained following their 1-electron oxidation, but that this interaction has no measurable effect on the kinetic stability of the resultant aryl radical. The unusual longevity of the dimethoxyphenyl radical cation species $\mathbf{1}^{+}$ and $\mathbf{2}^{+}$, and those formed from sesterbenzobicyclo[2.2.2]octane[2] and *ortho*-cyclophane[3] derivatives, presumably originates rather in steric protection of the radical center afforded by the overlying aryl ring. These results demonstrate that the tyrosyl/tryptophan π–π interaction in GOase probably has little or no effect on the chemical reactivity of the tyrosyl radical in this enzyme, except to shield it from external solvent. We are continuing to investigate the effects of π–π stacking on the spectroscopic and luminescent properties of aryl radicals and their complexes, and will report these results in due course.

The authors would like to thank Sanja Radojevic and Professor Mary McPartlin (University of North London) for a preliminary X-ray study of $\mathbf{4}\cdot BF_4$. Funding by The Royal Society (M. A. H.), the government of Singapore (L. M. L. C.), the Committee of Vice-Chancellors and Principles and EPSRC (X. L.) is gratefully acknowledged.

Received (in Cambridge, UK) 10th July 2000, Accepted 18th August 2000
First published as an Advance Article on the web

Dihydroimidazole *N*-oxides 1 undergo 1,3-dipolar cycloaddition with alkyne dipolarophiles and the cycloadducts suffer isoxazoline N–O bond cleavage to afford ene-1,1-diamines, with subsequent cyclisation to pyrrolo[1,2-*a*]imidazole-5,6-diones if possible.

We have recently described the synthesis of 4,5-dihydroimidazolium 3-oxide **1**, and its diastereoselective 1,3-dipolar cycloaddition reactions with alkenes to produce the rarely reported imidazo[1,2-*b*]isoxazoles (Scheme 1).[1] These latter, on N–O reduction and recyclisation, are potential sources for chiral pyrroloimidazoles and thence for pyrrolidines. Whilst exploring the reactions of this dipole with alkynes we isolated unexpected ene-1,1-diamine products which correspond to a C–C bond formation at C-2 of the dihydroimidazole ring with transfer of the nitrone oxygen atom to the new side-chain. Where possible, a second cyclisation to give pyrroloimidazole-5,6-diones is observed. We report these results herein and account for them in terms of the predicted 1,3-dipolar cycloadditions followed by isoxazoline ring opening. Ene-1,1-diamines are useful reagents in heterocyclic synthesis and in some cases possess biological activities.[2] Our results represent a new approach to such systems, that is very different from 'traditional' enediamine synthesis, *e.g.* from diamines with ketene acetals, or cyclic ureas with active methylene compounds,[2] or from acylation of 2-methyl cyclic amidines.[3] Biological activity has also been recorded for some pyrrolo[1,2-*a*]imidazoles.[4]

The nitrone **1** as its hydrochloride salt was prepared *in situ* from the aminohydroxylamine **2** dihydrochloride as previously described,[1] by treatment with triethyl orthoformate (toluene, 60 °C), and used directly. Reaction of the nitrone hydrochloride solution with methyl propynoate (1.25 eq., Et_3N, 2.1 eq., 60 °C, 18 h) led to isolation of the formyl alkoxycarbonyl enediamine **3a** (Scheme 2, Table 1). Similar reactions were observed with ethyl, 2-propyl and *tert*-butyl propynoates to afford further enediamines **3b**–**d** (Scheme 2, Table 1). With other 2-alkynoates (namely ethyl but-2-ynoate, methyl oct-2-ynoate, methyl and ethyl non-2-ynoate, and ethyl 3-phenylpropynoate) as reaction partner for the nitrone **1**, the corresponding alkanoyl alkoxycarbonyl enediamines **3e**–**i** were observed as the products.[5,6]

The products **3** are represented as the enaminoketone tautomer A (Fig. 1), although they may in principle also exist as the imino–enol tautomer B. Solution spectroscopy suggests the enaminoketone representation. All of **3a**–**i** display a peak in the

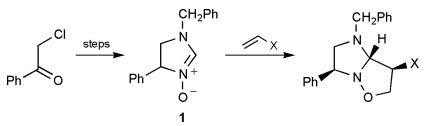
^{13}C NMR spectrum for a conjugated aldehyde (δ 186–187 for **3a**–**d**) or ketone (δ 193–197 for **3e**–**i**), respectively. The resonances for the enamine double bond are observed in the ranges δ 85–90 (NC=*C*CO) and δ 165–170 (N*C*=CCO). In the ^1H NMR spectra of **3a**–**d**, the signal observed at δ 9.7–9.75 (1H, s) is consistent with the aldehydic proton, whilst a broad singlet, δ 9.5–10.4 represents the NH. The geometry of the enediamine is shown with the formyl/alkanoyl substituent *syn* (and potentially hydrogen-bonding) to the NH of the heterocyclic ring (N-3), as supported by the ^{13}C NMR chemical shifts of the C=O carbons, see above, and our experience with related structures.[7]

We have further probed the questions of tautomerism and geometry in the solid state by X-ray crystal structure analysis of enediamines **3f** and **3g**. We have previously shown that related enediamine **4** exists in the solid state as the *syn*-enaminoketone form.[7] In the current work, it was found that compound **3f** displays an NH proton and a dihedral angle N-1/C-2/C(α)/



Scheme 1

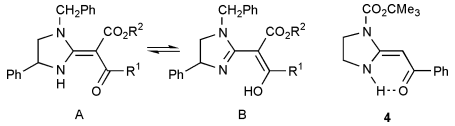


Fig. 1 Tautomerism of enediamines **3**.

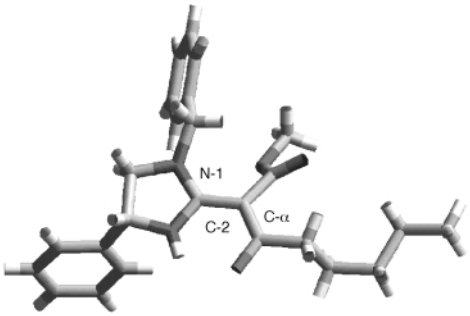

Fig. 2 X-Ray crystal structure of enediamine **3f**.

CO_2Me of 21° (Fig. 2).† This near-planarity suggests that hydrogen bonding is operating from N-3(H) to the keto-carbonyl group, consistent with the enaminoketone tautomer in the solid state. On the other hand, compound **3g** reveals two independent molecules in the unit cell, dihedral angles N-1/C-2/C(α)/CO_2Me of 100° (Fig. 3) and 113°, with some alkyl chain conformational differences.† These large deviations from planarity, precluding a C-2,C(α) double bond, and the location of a proton on oxygen rather than N-3 (Fig. 3), imply that the hydrogen bonding is absent and that the imino–enol tautomer B is present in this instance.

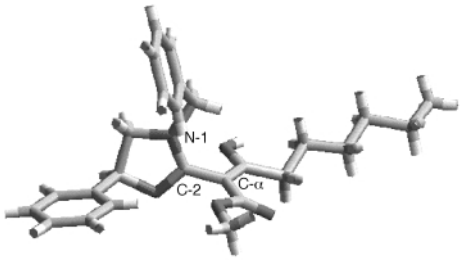

Fig. 3 X-Ray crystal structure of enediamine **3g**; two independent molecules per unit cell.

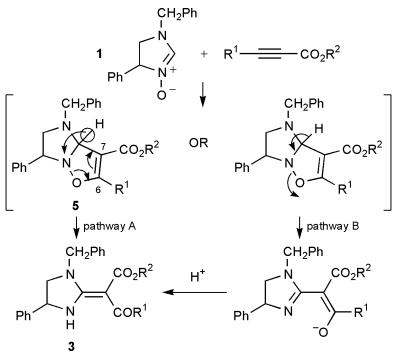
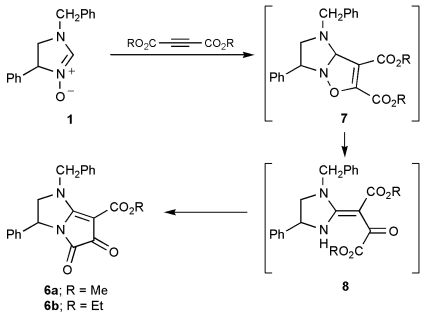
The formation of the enediamine **3** can be best rationalised through N–O cleavage of the expected imidazoisoxazole products **5** of an initial 1,3-dipolar cycloaddition of nitrone **1** (Scheme 3). Two possibilities can then be envisaged, pathways A and B of Scheme 3. Pathway A postulates a sigmatropic 1,5-H shift of the bridgehead hydrogen atom and bond reorganisation that would not be possible for the cycloadducts of alkene dipolarophiles (Scheme 1). Alternatively, pathway B suggests loss of the bridgehead proton and N–O bond cleavage, followed by reprotonation.[5] This elimination has a triply stabilised enolate as a leaving group, which would not be the case in the cycloadducts formed from alkenes.

A further unexpected reaction was observed when alkyne-1,2-dicarboxylates were reacted with nitrone **1**. Using dimethyl



Scheme 3



Scheme 4

or diethyl butyn-1,4-dioates, the 2,3,5,6-tetrahydro-1*H*-pyrrolo[1,2-*a*]imidazole-5,6-diones **6a** and **6b**, respectively, were isolated (58 and 20%), Scheme 4. Again, formation of these bicyclic products can be rationalised by initial dipolar cycloaddition to afford imidazoisoxazoles **7**. N–O cleavage *via* either of the pathways proposed in Scheme 3 would lead to an enediamine intermediate that now carries an electrophilic ester group suitably disposed to permit the secondary recyclisation.[8]

We have thus shown that dihydroimidazolium nitrones **1** undergo 1,3-dipolar cycloaddition with alkyne dipolarophiles, and that the cycloadducts suffer N–O bond cleavage to afford enediamines, and subsequent cyclisation where possible.

We thank EPSRC & SB Pharmaceuticals for a CASE studentship and the Open University for financial support (J. N. M.), Dr J. N. Iley for useful discussion, the EPSRC for its support of the National X-Ray Crystallography Service Centre, and the EPSRC National Mass Spectrometry Service Centre (Swansea) for some MS data.

Received (in Cambridge, UK) 21st July 2000, Accepted 1st September 2000
First published as an Advance Article on the web

The new phase, $LiSb_3O_8$, synthesised by solid state reaction at 900 °C, has an ordered rutile structure with 1:3 cation order and monoclinic symmetry: a = 10.2578(9), b = 4.7063(3), c = 5.6017(5) Å, β = 96.467(7)°, space group $P2_1/a$.

The rutile structure is found in a variety of oxides (*e.g.* TiO_2, SnO_2) and halides (*e.g.* MgF_2). More complex, ordered rutile structures with 1:1 cation order occur in dirutiles (*e.g.* $CoReO_4$), although with different cation arrangements, and with 1:2 order in trirutiles (*e.g.* $ZnSb_2O_6$).[1] We present here, the first example of 1:3 cation order in the new phase $LiSb_3O_8$, the structure of which can therefore be described as a tetrarutile.

$LiSb_3O_8$ is a thermodynamically stable phase, synthesised by solid state reaction of Li_2CO_3 and Sb_2O_3 powder mixtures in Pt foil boats in air, initially at 700 °C for 2 h to expel CO_2 and finally at 900 °C for 2–3 days, with intermittent regrinding. The powder X-ray diffraction (XRD) pattern (Stoe Stadi diffractometer, Cu-Kα_1 radiation) was indexed by trial-and-error, using the TREOR program in the Stoe software package, on a monoclinic unit cell, a = 10.2578(9), b = 4.7063(3), c = 5.6017(5) Å, β = 96.467(7)°. The first 20 indexed lines are given in Table 1. A search through both the International Centre for Diffraction Data file and the Inorganic Crystal Structure Database did not reveal any similar powder pattern or unit cell and therefore, $LiSb_3O_8$ probably had a previously unreported structure type.

† Electronic supplementary information (ESI) available: Fig. 2: experimental, calculated and difference XRD profiles. Table 3: bond lengths and selected bond angles for $LiSb_3O_8$. Table 4: oxygen–oxygen distances in $LiSb_3O_8$. See http://www.rsc.org/suppdata/cc/b0/b005915n/

The structure was determined *ab initio* using the EXPO software package. First, the Sb positions were located by direct methods. Refinement of the partial structure (Sb only) was then carried out using the program GSAS followed by difference Fourier analysis to locate the oxygen atoms. At this stage, a drawing of the crystal structure was made which showed the existence of octahedral sites for Sb within an oxygen array that approximated to hexagonal close packed. Additional octahedrally coordinated sites, which corresponded to positions with some residual electron density in a difference map, were located and assigned to Li. The structure converged fully upon Rietveld refinement of the XRD data with the final coordinates given in Table 2. The refinement was entirely satisfactory apart from the U_{iso} value for Li, which refined to a slightly negative value and was therefore fixed at 0.025 in the final stages of refinement. This could indicate difficulties in the refinement of the light atom Li in the presence of Sb or a small amount of cross-substitution ($\leqslant$ 1%) between Li and Sb sites so as to increase the effective electron concentration on the Li sites. Neutron diffraction studies are planned to resolve this question.

Bond lengths and a selection of bond angles are given in Table 3 (ESI†); projections of the structure are given in Fig. 1 and a profile fit is shown in Fig. 2 (ESI†). The structure has a rutile-like subcell, with a supercell caused by 1:3 ordering of Li:Sb on octahedral sites in the columns of edge-sharing octahedra parallel to c in the rutile subcell; $V_{supercell} = 4V_{subcell}$; Z = 2; $a_{supercell}//[102]_{subcell}$; $c_{supercell}//[10\bar{1}]_{subcell}$. *ac* Projections of the subcell and supercell are shown in Fig. 1(a) as dotted and continuous lines, respectively. The columns of edge-sharing octahedra run vertically in the plane in Fig. 1(a) and therefore, run obliquely through the supercell. These columns are seen edge-on in Fig. 1(b), as a $[10\bar{1}]$ projection of the

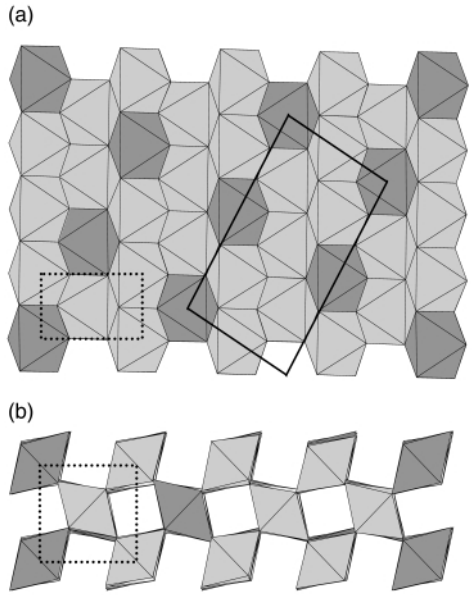

Fig. 1 Projections of the $LiSb_3O_8$ structure. Dark octahedra: LiO_6; light octahedra: SbO_6. (a) Projection in the *ac* plane showing subcell (dotted) and supercell (continuous); (b) projection down [10$\bar{1}$] showing columns of edge-sharing octahedra with corrugated *tp* oxide layers running horizontally and vertically.

supercell. As with rutile, edge-sharing of octahedra leads to structural distortion associated with cation repulsion effects and this reduces the O–Sb–O and O–Li–O angles facing the shared edges to *ca*. 80° (Table 3). Li–O and Sb–O distances are in the ranges 1.99–2.11 and 1.95–2.10 Å, respectively, giving very similar sized LiO_6 and SbO_6 octahedra.

The structure may be described in two rather different ways: either as filling of half the octahedral sites in a distorted hexagonal close packed (*hcp*) oxide array; or, as filling of all the (undistorted) octahedral sites in a tetragonal packed (*tp*) array.[2,3] The latter viewpoint is a more accurate description; although the structure does not possess fourfold symmetry (unlike the parent rutile structure), the corrugated *tp* layers are seen running horizontally and vertically in Fig. 1(b), together with the diamond-shaped (in projection) columns of edge-sharing octahedra and the square-shaped columns containing empty distorted tetrahedral and distorted octahedral interstitial sites. The *tp* nature of the oxide ion array is further demonstrated by consideration of the oxygen–oxygen closest distances. In *hcp*, 12 equidistant oxygens are expected; in *tp*, ideally there are 11 equidistant oxygens, plus 2 somewhat further away. The distribution of distances in $LiSb_3O_8$ clearly falls into the second category (Table 4, ESI†): for the four crystallographically distinct oxygens, there are 11 O–O distances in the range 2.60–3.13 Å and 2 O–O distances at 3.34–3.49 Å; the next shortest O–O distances are at 3.92 Å.

Antimonates are often isostructural with compositionally similar niobates and tantalates. The rutile-related structure of $LiSb_3O_8$ is, however, distinct from that of both $LiNb_3O_8$ and $LiTa_3O_8$. $LiNb_3O_8$ has a cation-ordered α-PbO_2 structure in which cations occupy half the octahedral sites in an *hcp* oxide array.[4,5] The distribution of occupied octahedral sites gives rise to zigzag chains of edge-sharing octahedra, rather than the linear chains in $LiSb_3O_8$ and other rutile derivatives; also the oxide array is *hcp* instead of *tp*. $LiTa_3O_8$ exists in three polymorphic forms. The L polymorph is isostructural with $LiNb_3O_8$.[5] The M polymorph also has an α-PbO_2 superstructure but with a different cation arrangement to that of the L polymorph[6,7] and is isostructural with the mineral wodginite. The structure of the H polymorph is quite different and contains a mixture of TaO_7 pentagonal bipyramids and TaO_6 octahedra.[8–12]

$LiSb_3O_8$ is the first rutile derivative structure with 1:3 cation order and may therefore be described as a tetrarutile. It is possible that other $M(I)M(V)_3O_8$ phases may have the same structure (although not with $LiNb_3O_8$ and $LiTa_3O_8$, apparently). It is also possible that other tetrarutile structures may form with different cation arrangements, in the same way that different dirutile cation arrangements exist.[1]

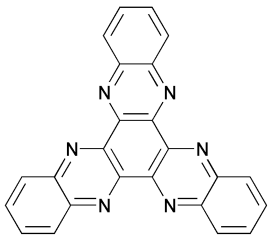
First published as an Advance Article on the web

One-pot reaction of $AgNO_3$ and a large aromatic bridging ligand, diquinoxalino[2,3-a:2′,3′-c]phenazine, which has three bidentate coordination sites, afforded a Ag^I complex consisting of two independent three-dimensional (3D) networks which are enantiometric and interpenetrating.

A major goal of the polymer-based approach to crystal engineering is to develop new robust materials with useful electronic, magnetic, electrochemical, optical or catalytic properties. Among various types of molecular-based frameworks, interpenetrating networks are of particular interest with regard to the topological types of 3D nets postulated by Wells.[1] Since the groups of Robson[2] and Ciani[3] reported their first pioneering works on '3D racemates' using suitable metal ions and polydentate ligands, in which two enantiomeric interpenetrating networks are included, compounds bearing two or more metal chelating sites have often been used as connecting units for the generation of interpenetrating 3D networks.[4–6]

In our effort to construct novel 3D coordination polymer networks, diquinoxalino[2,3-a:2′,3′-c]phenazine (L) has attracted our attention. This ligand is a nitrogeneous aromatic compound with three bidentate sites, which was expected to provide a coordination network characterized by a delocalized π-electron system. We report here, the synthesis and X-ray crystal structure of a novel Ag^I complex[7] **1** with L, consisting of an interpenetrating enantiomorphic pair of nets.



L

Complex **1** was prepared in the dark by carefully layering a solution of $AgNO_3$ in MeCN on top of a solution of L in CH_2Cl_2. After *ca.* two weeks, yellow–orange crystals of **1** $\{(Ag_3L_2)(NO_3)_3\cdot solvent\}$ were isolated in *ca.* 90% yield. The structure of **1** was established by single-crystal X-ray diffraction.‡

Each Ag^I center in **1** acts as a two-connecting node by connecting two ligands of L. Interestingly, **1** exhibits twofold interpenetrating networks with the two-connected (Ag^I) and three-connected (L) nodes. A single cationic network of the doubly interpenetrating networks is shown Fig. 1(a). The basic building block of the network contains distorted tetrahedral Ag^I atoms and two types of ligand L with B ligands parallel to the *xy*-plane [Fig. 1(a)]. The coordination geometry around each Ag^I center is not perfectly tetrahedral. A ligands in the building block make an interplanar angle of 100° with B ligands and arranged in a propeller fashion around them. These basic building blocks are linked by Ag^I atoms to form a 3D network. A ligands along the *z*-axis are connected by Ag^I atoms to form a one-dimensional threefold helical network [see the bold lines in Fig. 1(b)]. A crystallographic C_3 axis exists perpendicular to ligand B. Interestingly, these helices are interlinked with ligands

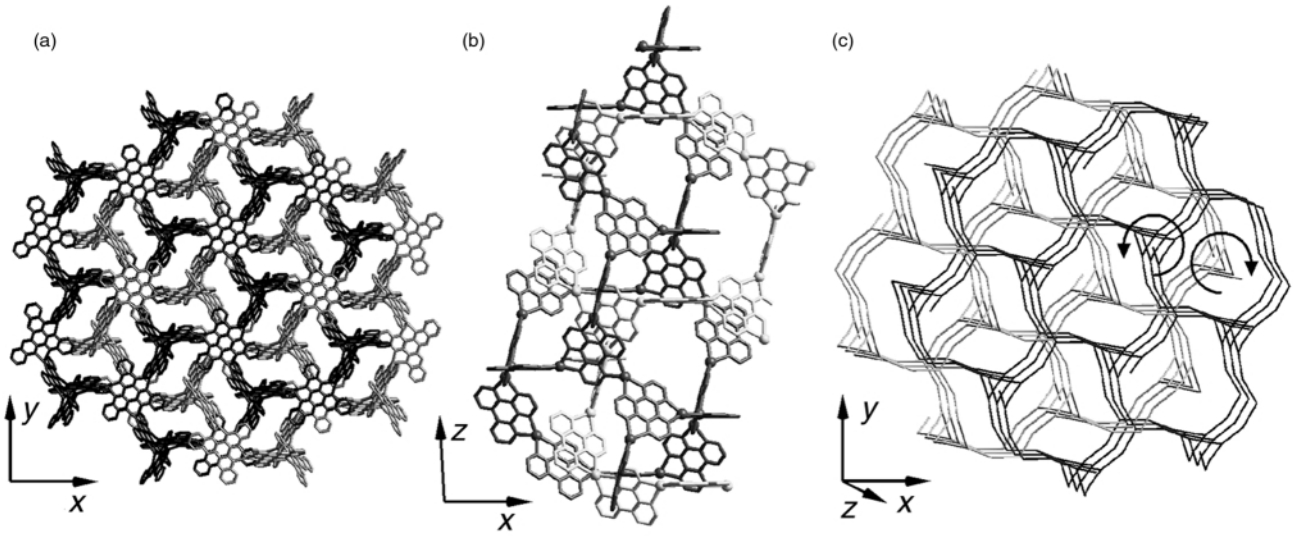

Fig. 2 Representations of (a) a top view of the doubly interpenetrating networks of **1**, where the two networks are colored black and gray, (b) a side view of the two interpenetrating networks of **1**, where the outer phenyl rings of the ligands are omitted for clarity and (c) a schematic view of the 3D nets in which the ligands are replaced by trigonal nodes. Note the difference in the handedness of the helical networks in each 3D net.

B *via* Ag^{I} atoms to form a 3D network with large channels. The shortest loop in the network is a 20-gon that is constituted of 10 Ag^{I}-atoms and 10 ligands [see the bold lines in Fig. 1(b)]. The structure can be regarded as a 3D network in which half of the nodes are replaced by three-fold helices, and is quite different from that of the Ag^{I} complex with Hat (1,4,5,8,9,12-hexaazatriphenylene) which similarly has three bidentate sites but differs in the size of the π-plane. In the Hat complex, all the Ag^{I} centers are chelated by three Hat ligands to form an octahedral coordination environment.[5a]

The extended structure of **1** reveals interesting twofold interpenetrating networks as shown in Fig. 2(a) and (b). These two interpenetrating networks are topologically equivalent but differ in the handedness of the threefold helices [see Fig. 2(c)], where the two arrows show the handedness of helices. Thus complex **1** contains an interpenetrating enantiomorphic pair of nets with a (10,3)-a type topology[1a] consisting of Ag^{I} ions coordinated by nitrogeneous aromatic ligands in a tetrahedral fashion. This type of interpenetration of 3D nets was referred to by Wells as 'a 3D racemate'.[1a] The interactions observed between the two interpenetrating networks are aromatic edge-to-face interactions between A ligands in one network and adjacent B′ ligands in the other, with no face-to-face interactions between B and B′ ligands observed in the structure. Although the channels in one network are occupied by another network, there are still large vacant spaces between the two, corresponding to the 53% of crystal volume, which is filled by solvent molecules and the counter anions. However, some of the solvent molecules and counter ions were found to be disordered owing to the high symmetry of the network.

This study has revealed a one-pot, high-yield synthesis of a Ag^{I} complex consisting of doubly interpenetrating 3D networks with nitrogeneous heterocyclic bridging ligands L. Furthermore, L has a large delocalized π-electron system which may allow facile d–π interactions between ligands and remote metal centers throughout extended 3D networks.

High yield synthesis and crystal structures of the Ru_6–Sn cluster compounds $[Ru_6C(CO)_{16}SnCl_2]$ and $[Ru_6C(CO)_{16}SnCl_3]^-$

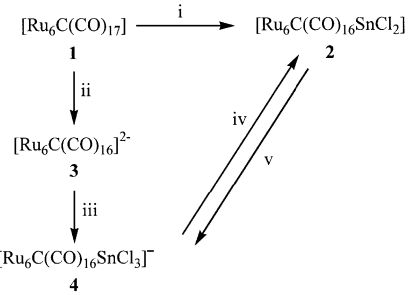
First published as an Advance Article on the web

Addition of two molar equivalents of $SnCl_4$ to $[Ru_6C(CO)_{16}]^{2-}$ yields first the new $[Ru_6C(CO)_{16}SnCl_3]^-$ cluster anion and then $[Ru_6C(CO)_{16}SnCl_2]$, the latter being also the single product of the direct addition of $SnCl_2$ to $[Ru_6C(CO)_{17}]$.

We are currently investigating the preparation and catalytic activity of bimetallic nanoparticles derived from fully characterised bimetallic cluster compounds.[1–3] Recent results have indicated that, once formed within the cavities of the mesoporous solid MCM-41, such nanoparticles exhibit a surprising stability and resist sintering even under moderately vigorous conditions. To this end, we have established a need for nanoparticles containing Ru–Sn cores. This association of metals is known to be highly versatile, and is used in both selective oxidation and hydrogenation catalysis.[4] However, few Ru–Sn mixed-metal clusters have been reported.[5–9] In this paper we report the synthesis of the new bimetallic clusters $[Ru_6C(CO)_{16}SnCl_2]$ **2** and $[Ru_6C(CO)_{16}SnCl_3]^-$ **4**. We regard these new cluster species as derivatives of Sn(IV) containing *formally* the bidentate ligand $[Ru_6C(CO)_{16}]^{2-}$.

The reaction sequence for the preparation of the compound $[Ru_6C(CO)_{16}SnCl_2]$ **2** and the anion $[Ru_6C(CO)_{16}SnCl_3]^-$ **4** is outlined in Scheme 1. Direct reaction of $[Ru_6C(CO)_{17}]$ **1** with stannous chloride in dichloromethane is slow but over a period of several days under reflux, product **2** may be obtained in good yield (91%). The mechanism by which this reaction occurs is uncertain but would appear to take place first by simple carbon monoxide extrusion followed then by the addition of $SnCl_2$. However, the *formal* oxidation state of the Sn in **2** is (IV)† indicating that a redox process of the type $[Ru_6C(CO)_{16}]$ to $[Ru_6C(CO)_{16}]^{2-}$ occurs at some stage during the reaction sequence. In this sense, the reaction might be described as a oxidative-addition to Sn(II), leading to reduction of the cluster fragment.

In agreement, reactions of the dianionic cluster $[Ru_6C(CO)_{16}]^{2-}$ with stannic chloride in dichloromethane produce the same Sn(IV) cluster **2** and in addition the anion $[Ru_6C(CO)_{16}SnCl_3]^-$ **4** (as its PPN^+ salt). Anion **4** is obtained in 67% yield when equimolar amounts of $[Ru_6C(CO)_{16}]^{2-}$ **3** and $SnCl_4$ are reacted. Treatment of **4** with further stannic chloride (1 mole) results in Cl^- ion abstraction and the formation of **2**. The other product of this reaction is the Sn(IV) anion $[SnCl_5]^-$. This reaction is easily reversed, and addition of Cl^- {as [PPN]Cl} to **2** results in the formation of **4**. The ease with which cluster **2** accepts the additional Cl^- to generate a coordinated $SnCl_3^-$ group is of interest and in line with the established chemistry of $SnCl_4$. This emphasises the view of compound **2** as an adduct of the type $XSnCl_2$, where X = the bidentate dianionic ligand $[Ru_6C(CO)_{16}]^{2-}$.



Scheme 1 Synthesis of the cluster species $[Ru_6C(CO)_{16}SnCl_2]$ and $[Ru_6C(CO)_{16}SnCl_3]^-$ **3**. *Reagents and conditions*: i, reaction with $SnCl_2$ in dichloromethane, reflux, 4 days; ii, reaction with KOH–MeOH; iii, reaction with $SnCl_4$ in dichloromethane at room temperature; iv, reaction with $SnCl_4$ in dichloromethane under reflux; v, reaction with [PPN]Cl in dichloromethane at room temperature.

Clusters **2** and **4** have been fully characterised by the usual spectroscopic and analytical techniques, and their molecular structure established by single crystal X-ray diffraction.[10]

The mass spectrum of **4**, obtained by ESI-MS run in negative mode, consists of a peak at *m/z* 1289, corresponding to the formulation $[Ru_6C(CO)_{16}SnCl_3]$. The IR spectra of **4** in the ν_{CO} stretching region consists of peaks at 2086, 2056, 2035, 2026, 1987 and 1973 cm^{-1} corresponding to terminal carbonyls, and a broad peak at 1825 cm^{-1} corresponding to bridging CO.

The molecular structure of the anion $[Ru_6C(CO)_{16}SnCl_3]^-$ **4** is shown in Fig. 1, together with selected bond lengths and angles. It consists of the intact core of the $Ru_6C(CO)_{16}$ cluster, with one Ru–Ru edge bridged by a $SnCl_3$ fragment. It is

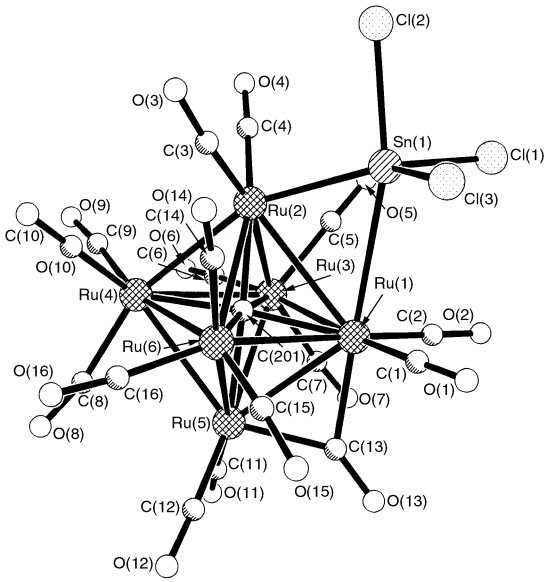


Fig. 1 Molecular structure of $[Ru_6C(CO)_{16}SnCl_3]^-$ **4** with atom numbering scheme. Selected bond lengths (Å) and angles (°): Molecule 1: Ru(1)–Sn(1) 3.140(2), Ru(2)–Sn(1) 2.581(3), Sn(1)–Cl(1) 2.391(6), Sn(1)–Cl(2) 2.459(5), Sn(1)–Cl(3) 2.406(5), Ru(1)–Ru(2) 3.039(3), Ru–Ru (mean) 2.89(2), C–O (mean) 1.177(8), Ru(1)–Sn(1)–Ru(2) 63.28(6), Cl(1)–Sn(1)–Cl(2) 164.13(13), Cl(2)–Sn(1)–Cl(3) 93.70(19), Cl(1)–Sn(1)–Cl(3) 101.1(2). Molecule 2: Ru(7)–Sn(2) 2.583(3), Ru(8)–Sn(2) 3.102(2), Sn(2)–Cl(5) 2.478(6), Sn(2)–Cl(6) 2.371(6), Sn(2)–Cl(4) 2.386(5), Ru(7)–Ru(8) 3.043(3), Ru–Ru (mean) 2.90(3), C–O (mean) 1.17(1), Ru(7)–Sn(2)–Ru(8) 63.97(6), Cl(4)–Sn(2)–Cl(6) 101.6(2), Cl(6)–Sn(2)–Cl(5) 93.1(3), Cl(5)–Sn(2)–Cl(4) 93.8(2).

DOI: 10.1039/b004585n

monoanionic and the asymmetric unit of the structure contains two independent anions and two PPN^+ cations. Fifteen carbonyl ligands are terminally bound to the ruthenium atoms, and one is bridging a Ru–Ru bond.

The geometry of the Ru_6C octahedron has remained almost unchanged, with the mean Ru–Ru bond distance of 2.89(2) Å in molecule 1 and 2.90(3) Å in molecule 2 identical to that of 2.90(2) Å found in $[Ru_6C(CO)_{17}]$.[11] The Ru–Ru bond spanned by the tin atom is the longest (Ru(1)–Ru(2) 3.039(3) Å in molecule 1 and Ru(7)–Ru(8) 3.043(3) Å in molecule 2), as has been previously observed in other Ru–Sn mixed-metal clusters.[5–9] The Ru(2)–Sn(1) (2.581(3) Å) in molecule 1 and the Ru(7)–Sn(2) (2.583(3) Å) in molecule 2 bond lengths are within the range observed previously, as in $[(\mu\text{-}H)_2(\mu_3\text{-}S)(\mu\text{-}Cl)Ru_3(CO)_8(SnCl_3)]$ (Ru–Sn 2.571(1) Å),[5] $[Ru_3(\mu\text{-}H)(\mu_3,\eta^2\text{-amphy})\{\mu,\eta^1:\eta^2\text{-}PhC{=}C(H)Ph\}(SnPh_3)(CO)_7]$ (Ru–Sn 2.662(1) Å),[6] $[Ru_3(\mu\text{-}H)(\mu_3,\eta^2\text{-amphy})\{\mu,\eta^1{:}\eta^2PhC{=}C(H)Ph\}(SnPh_3)(CO)_7]$ (different isomer, Ru–Sn 2.623(1) Å),[6] in which a SnR_3 fragment is terminally bound to a ruthenium atom; and $[Me_3Sn(CO)_3Ru(SnMe_2)]_2$ (Ru–Sn 2.638(2)–2.694(2) Å),[7] $[Ru_3(CO)_{10}(SnR_2)_2]$ (Ru–Sn 2.733(2)–2.739(2) Å),[8] $[Ru_3(CO)_9(\mu\text{-}SnR'_2)_3]$ (Ru–Sn 2.715(2)–2.734(2) Å),[9] $[Ru_3(CO)_9(\mu\text{-}SnR_2)(\mu\text{-}SnR'_2)_2]$ (Ru–Sn 2.705(2)–2.750(2) Å),[9] $[Ru_3(CO)_9(\mu\text{-}SnR_2)_2(\mu\text{-}SnR'_2)]$ (Ru–Sn 2.641(2)–2.729(2) Å),[9] and $[Ru_2(CO)_6(\mu\text{-}SnR_2)(dppm)]$ (Ru–Sn 2.699(1)–2.715(1) Å),[9] in which SnR_2 fragments are bridging Ru–Ru edges. The Ru(1)–Sn(1) and the Ru(8)–Sn(2) bonds (3.140(2) and 3.102(2) Å, respectively) in **4** are much longer but still within bonding distance, implying that the $SnCl_3$ fragment forms an asymmetrical bridge, intermediate between the symmetrically bridging and terminal bonding modes observed in other Ru–Sn clusters.[5–9] This confers to the tin atom a nearly perfect trigonal bipyramidal coordination geometry, with Ru(1) or Ru(8) equatorial, and Ru(2) or Ru(7) in axial position.

The IR spectrum of compound $[Ru_6C(CO)_{16}SnCl_2]$ **2** contains CO stretching bands attributable to terminal carbonyl ligands only. Compound **2** has been characterised by positive electron impact mass spectrometry, and its spectrum consists of the parent ion at *m/z* 1256 followed by peaks corresponding to loss of CO ligands.

The molecular structure of $[Ru_6C(CO)_{16}SnCl_2]$ **2** is shown in Fig. 2, together with selected bond lengths and angles. As with anion **4**, it consists of a $Ru_6C(CO)_{16}$ octahedron edge-bridged by a $SnCl_2$ fragment. Each ruthenium atom bears three terminally bound carbonyl ligands, except for the two ruthenium atoms supporting the Sn(IV) bridge, which bear two carbonyl ligands only. The Ru_6C core remains unchanged. Again the Ru–Ru edge bearing the $SnCl_2$ fragment is the longest (Ru(1)–Ru(2) 3.0559(11) Å [3.039(3) Å in **4**]), with the other Ru–Ru bonds ranging from 2.8280(10) to 2.9429(10) Å [2.89(2) Å (mean) in **4**]. The Ru–Sn bonds (2.5907(11) and 2.5733(12) Å) are very similar to the shortest Ru–Sn bond in **4** (2.581(3) Å), and within the range observed in previously reported Ru–Sn clusters (2.571(1)–2.750(2) Å).[5–9]

In this work we have demonstrated that simple derivatives of Sn(IV) containing the 'ligand' $[Ru_6C(CO)_{16}]^{2-}$ may be readily obtained. The coordination chemistry about the central Sn(IV) ion would appear to be normal (tetrahedral or tbp). This fundamental idea has been extended to other metal systems and, for example, related derivatives of square planar Pt(II) have been obtained similarly. These new Ru–Sn clusters have been shown to be ideal precursors to catalytically active Ru–Sn nanoparticles.

We gratefully acknowledge Dr Neil Feeder and Dr John E. Davies for data collection and structure refinement and the European Commission for a TMR grant to B. F. G. J. and for a Marie Curie Fellowship to S. H.

The X-ray structure, magnetic susceptibility, and high-field (high-frequency) EPR spectrum of manganese 5,10,15-tris-(pentafluorophenyl) corrole unambiguously establish that the complex contains an isolated, slightly rhombic, manganese(III) center.

Manganese(III) porphyrins are very efficient catalysts for functionalization of hydrocarbons in processes that involve high valent intermediates.[1,2] Spectroscopic identification of odd-spin manganese(IV) and spin-coupled manganese(V) porphyrins by magnetic resonance measurements is relatively straightforward, *via* utilization of EPR and NMR, respectively.[3–6] However, even-spin manganese(III) porphyrins are EPR-silent (X-band) and their NMR spectra are not easily interpretable. For example, an early assignment of the origin of the paramagnetic shifts in manganese(III) porphyrins was recently revised,[7] and there is some evidence indicating that the complexes might better be described as manganese(II) porphyrin radical cations.[8] A recent development relevant to this question is the utilization of high-field (high-frequency) EPR (HF-EPR) spectroscopy for elucidation of the electronic structures of high-spin manganese(III) complexes.[9]

The close relationship of porphyrins and corroles suggests that metallocorroles could also be very interesting catalysts. This proposal was only recently explored, taking advantage of the novel electron-poor 5,10,15-tris(pentafluorophenyl)corrole, H_3tpfc,[10] whose substitution pattern matches that of the most active porphyrin-based catalysts. First, it was demonstrated that the iron and rhodium complexes of H_3tpfc are potent catalysts for oxygen and carbene transfer to olefins and alkanes,[11] followed by full characterization of H_3tpfc[12] and its $Cr^{V}O$, $Fe^{IV}Cl$ and $Rh^{III}(PPh_3)$ complexes.[13,14] The manganese corrole [(tpfc)Mn] was also found to be an epoxidation catalyst, as well as an excellent precursor to a relatively stable oxomanganese(V) corrole.[1b,15] The apparent importance of this result together with the rather limited information on the electronic structures of manganese corroles[16,17] were the driving forces for the current investigations. A combination of HF-EPR spectroscopy, X-ray crystallography, and magnetic susceptibility measurements, led to the conclusion that [(tpfc)Mn($OPPh_3$)] is an authentic manganese(III) complex that does not experience significant intermolecular interactions.

Obtaining X-ray quality crystals of [(tpfc)Mn] was a difficult task; NMR examination of material from different crystallization batches revealed significant variations in chemical shifts. Since we suspected that these differences were due to solvent coordination, we added external ligands to the recrystallization mixtures. These attempts finally met with success: with triphenylphosphine oxide as additive, X-ray quality crystals of [(tpfc)Mn($OPPh_3$)] were isolated.[18] The structure of [(tpfc)Mn($OPPh_3$)] (Fig. 1) is quite different from that of the previously reported square planar manganese(III) corrole, [(e-7,13-mc)Mn].[1b,16] In the latter complex the metal is located almost perfectly within the N_4 plane and the macrocycle is planar, whereas in [(tpfc)Mn($OPPh_3$)] the manganese is 0.29 Å out of both the N_4 and the corrole core planes. This causes some

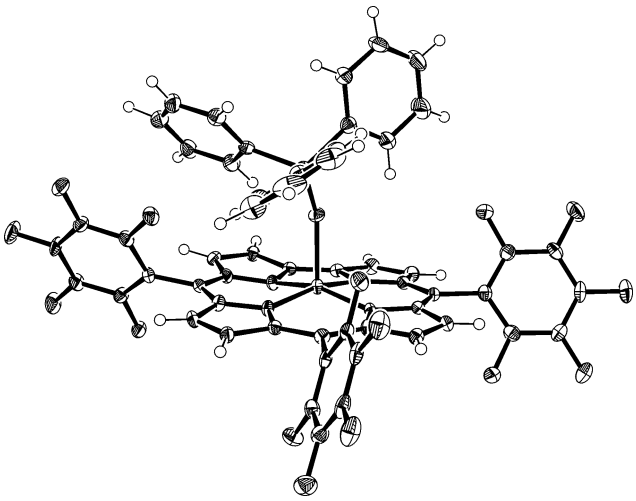

Fig. 1 ORTEP view of [(tpfc)Mn($OPPh_3$)].

elongation of the average Mn–$N_{pyrrole}$ bonds {from 1.894 in [(e-7,13-mc)Mn] to 1.916 Å in [(tpfc)Mn($OPPh_3$)]} with slight deviations of the tpfc atoms from the mean plane. Another significant difference is the absence of interactions between the corroles in [(tpfc)Mn($OPPh_3$)], which is a dominant factor in the structure of [(e-7,13-mc)Mn]. Rather, the potential empty space is occupied by the triphenylphosphine oxide ligand (Fig. 2).

The absence of intermolecular interactions is also reflected in the magnetic susceptibility measurements on [(tpfc)Mn($OPPh_3$)], performed in the temperature range 2–300 K.[19] The magnetic moment of 4.88 μ_B confirms that the complex possesses a simple high-spin (S = 2) ground state; and the very flat plateau in the μ_{eff} *vs*. temperature plot down to 10 K (Fig. 3) is perfectly in line with the molecular packing deduced from the X-ray structure (Fig. 2).

Since the consequences of lowered symmetry on the electronic structures of corrole *vs*. porphyrin complexes have

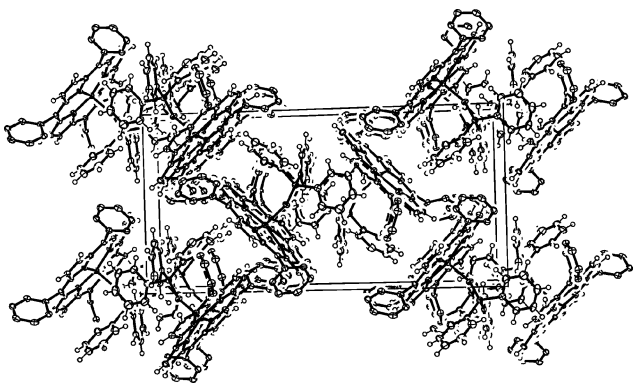

Fig. 2 Unit cell of [(tpfc)Mn($OPPh_3$)], approximately along the *a*-axis. Fluorine atoms have been omitted for clarity.

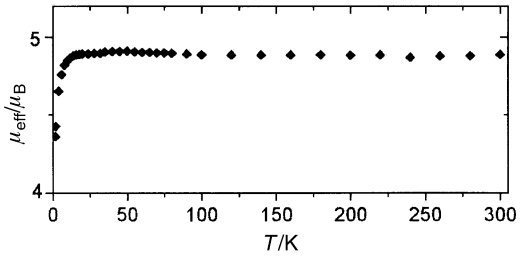

Fig. 3 Variation of the magnetic moment of [(tpfc)Mn(OPPh$_3$)] with temperature.

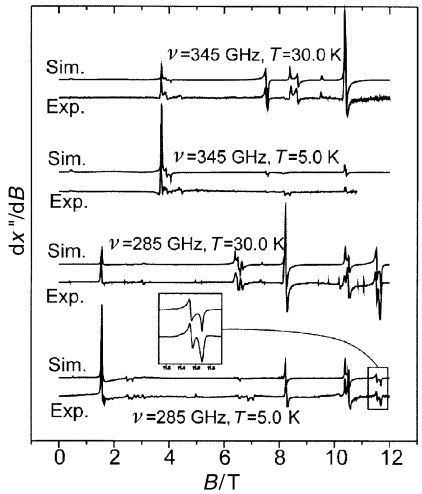

Fig. 4 Experimental and simulated HF-EPR spectra of [(tpfc)Mn(OPPh$_3$)].

not yet been quantified experimentally, we measured HF-EPR spectra of [(tpfc)Mn(OPPh$_3$)] at two different frequencies (285 and 345 GHz) and at two different temperatures (5 and 30 K). The spectra shown in Fig. 4 are very well reproduced by simulations of randomly oriented powder samples employing the following parameters: $g_{||}$ = 1.980(4), $g_{\perp}$ = 1.994(4), D = 2.69(2) cm^{-1}, E = 0.030(3) cm^{-1}, $W_{1/2}$ = 150 G (T = 5 K), $W_{1/2}$ = 180 G (T = 30 K).[20] One of the most sensitive lines to g-value rhombicity is that centered at 8 T (285 GHz), which consists of the transitions ($|-1> \rightarrow |0>$) and ($|0> \rightarrow |+1>$). The fact that this line is not split puts an upper limit of 0.005 on the difference between g_x and g_y. An expansion of one of the easily observed line splittings attributable to the rhombic zero-field splitting is shown in the insert of Fig. 4. The rhombic zero-field splitting is small compared to that found in tris(β-diketonate) complexes of manganese(III) (E = 0.26 cm^{-1}, E/D = −0.06),[9b] but we emphasize that the corresponding line is not split in the spectra of manganese(III) porphyrins and phthalocyanines. Although the lower molecular symmetry of metallocorroles compared to metalloporphyrins is also pronounced for systems with no preferred coordination geometry,[21] the *electronic* deviation from axiality is quite small. We thus conclude that treating a corrolate as a trianionic porphyrinate is not unreasonable.

We have fully characterized a manganese complex of H$_3$tpfc. Employing three different methods, we have shown that [(tpfc)Mn(OPPh$_3$)] contains an authentic, isolated S = 2 manganese(III) center.

We thank Dr M. W. Day (Beckman Institute) for assistance with the crystal structure determination and Ms S. Mossin (University of Copenhagen) and Dr A.-L. Barra (CNRS, Grenoble) for recording the HF-EPR spectra. This research was supported by the Fund for the Promotion of Research at the Technion (Z. G.), the National Science Foundation (H. B. G.), and grant # 9800549 from the Danish Natural Science Research Council (J. B.).

$RbCuPO_4$ – a maximum copper tetrahedral framework adopting the zeotype ABW structure

Paul F. Henry, Robert W. Hughes, Suzanna C. Ward and Mark T. Weller*

First published as an Advance Article on the web

The sky blue $RbCuPO_4$-ABW is the first reported maximum copper (framework ratio 1 : 1) zeotype framework, consisting of alternating PO_4 and flattened CuO_4 (Cu–O 1.89–1.95 Å) tetrahedra; a second metastable very pale green–blue phase can also be produced by quenching, with conversion to the purely four-coordinate copper material accomplished by application of slight mechanical pressure.

The incorporation of transition metals into frameworks, including zeolites, is of great interest due to the properties potentially imparted by the presence of d-metal centres including catalytic activity, colour and magnetic ordering phenomena. Zeolite structures containing first row transition metals have received most attention, although in general the levels of substitution have been low, presumably due to the reduced stability of tetrahedral coordination over higher coordination environments (5- and 6-fold) in the aqueous media used to synthesise the majority of framework materials. Work to date has centred on the first row transition metals that do show appreciable tetrahedral coordination chemistry to oxygen, namely Co^{2+} and Zn^{2+}. Frameworks containing high levels of Co^{2+} were first described by Chippindale *et al.*[1] and were extended by Stucky and coworkers, using hydrothermal methods, to include the ABW and related semi-condensed frameworks such as $NaCoPO_4$, $KCoPO_4$, NH_4CoPO_4 and $RbCoPO_4$.[2] We completed this series by synthesising $CsCoPO_4$ ABW using a solid state route.[3] Until recently, the levels of other transition metals that could be doped into most zeolite structure types remained low, at around 5% of the tetrahedral sites. However, synthesis of other maximum transition-metal ABW related frameworks has now been achieved by our group to include $CsFeSiO_4$[4] and $RbNiPO_4$.[5]

We have found that the zeotype structures that permit high levels of transition metal substitution are generally denser, in terms of tetrahedral units per unit volume, and exist with low levels of hydration, for example the ABW, CAS, ANA and BIK zeolite families.[6] In terms of transition metal substitutions, the ANA structure type is the most versatile with transition metal substituted leucite[7] and pollucite[8,9] phases described in the literature. However the levels of substitution in this system are limited through compound stoichiometry at 16.6% of the framework sites, *i.e.* to the one trivalent tetrahedral site.

Here we describe the synthesis and structural characterisation of the ABW-type structure material $RbCuPO_4$, where half of the tetrahedral framework sites are occupied by copper.

A polycrystalline sample of $RbCuPO_4$-ABW was produced as follows. Stoichiometric amounts of $Cu(MeCO_2)_2$ (Aldrich, 99.9%), $(NH_4)_2HPO_4$ (Aldrich, 99%) and RbOH (Aldrich, 50% solution by weight in water) were dissolved in dilute nitric acid. 100 ml ethanol was then added to the solution and the pH slowly raised by the addition of ammonia solution until precipitation occurred. The resulting mixture was slowly evaporated to give a thick gel paste, which was decomposed over 12 h in a furnace at 250 °C. The powder was thoroughly ground in an agate pestle and mortar before being fired at 650 °C and then 750 °C, each for 12 h. Soluble impurities were removed by washing with deionised water followed by firing for 12 h at 750 °C. Powder X-ray diffraction patterns were collected for preliminary phase identification and subsequent Rietveld analysis using a Siemens D5000 diffractometer (Cu-Kα_1 radiation; λ = 1.54056 Å). GSAS was used for Rietveld refinement of the powder X-ray data.[10]

Differential thermal analysis (DTA) and thermogravimetric analysis (TGA) were performed using a Polymer Laboratories STA1500 DTA/TGA balance. The sample was heated in air at a rate of 5 °C min^{-1} from room temperature to 600 °C, held for 30 min at this temperature and then cooled back to room temperature at 10 °C min^{-1}. Diffuse reflectance UV–VIS spectra were obtained from a Lambda19 spectrophotometer with solid state attachment. The Kubelka–Munk function was applied to the data to compensate for the effects of particle size. Elemental analysis was carried out using a JEOL JSM-6400 SEM equipped with a TRACOR series II energy dispersive X-ray analysis system.

Inspection of the powder X-ray diffraction (PXD) pattern of the as-synthesised material showed that the majority phase present could be indexed on an orthorhombic unit cell with a = 8.5262(4) Å, b = 5.3562(3) Å and c = 8.9064(4) Å. There were also several weaker peaks that were indexed on a monoclinic unit cell with a = 5.0424(8) Å, b = 8.5880(2) Å, c = 9.6434(2) Å and α = 91.51(1)°. Both unit cells were consistent with structure types that have been previously reported for the ABW-type framework.[11]

Grinding the product followed by further PXD pattern collection showed that the proportion of the two phases present was altered, with the orthorhombic phase growing in intensity. Quenching the reaction from above 600 °C to RT without any grinding gave the monoclinic phase as the major phase (*ca.* 9 : 1 ratio). Pelletisation of the product under 6 tonnes cm^{-2} for 10 min followed by regrinding gave essentially *only* the orthorhombic product and increased the intensity of the blue colouration of the product. We have also recently found that nickel doping into $RbCuPO_4$ stabilises the monoclinic ABW subtype and details of the new sub-structure will be published elsewhere.[12]

Data for Rietveld profile analysis on the orthorhombic phase were collected over a period of 16 h between 10 and 110° using a step size of 0.02°. The initial model used for the refinement was that of Henry and Weller for $CsFeSiO_4$.[4] Weak constraints (standard deviation 0.01 Å) were placed upon bond lengths in the refinement due to the poor definition of the oxygen positions from powder X-ray diffraction data. A few weak impurity peaks (< 5% of the maximum peak intensity) were also excluded from the refinement. The final refinement profile is illustrated in Fig. 1 and the structural model is given in Table 1. Derived bond lengths and relevant framework bond angles are given in Table 2. It can be seen from Table 2 that the phosphate tetrahedra are much more regular than the cuprate polyhedra, which are flattened in accordance with the expected Jahn–Teller distortion found in other four-coordinate Cu^{II} compounds.[13]

TGA showed the orthorhombic phase to be a non-hydrated framework, as no weight losses were observed between RT and 800 °C. Fig. 2 illustrates the DTA trace obtained for the orthorhombic phase between RT and 600 °C. It can be seen that

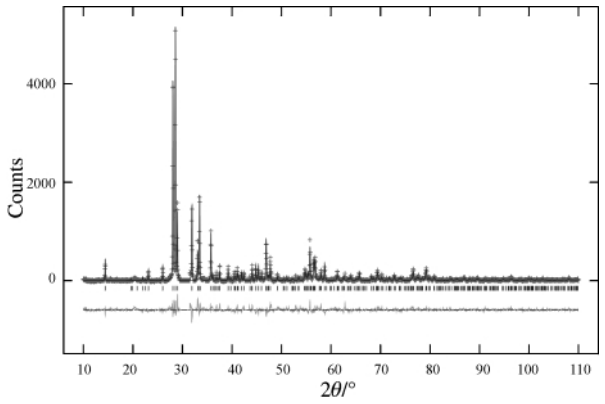

Fig. 1 Final profile fit obtained from the powder X-ray diffraction data for $RbCuPO_4$. The observed data are crosses, the calculated profile pattern the solid line and the lower continuous line the difference plot. Tick marks show the allowed reflection positions.

Cu–O4	1.896(12)	O1–Cu–O3	132.1(11)
		O1–Cu–O4	107.3(12)
		O2–Cu–O3	127.5(12)
		O2–Cu–O4	113.3(12)
		O3–Cu–O4	95.8(12)

there are two phase transitions on heating, at 410 and 550 °C, only one of which is reversible on cooling. It is thought that the first transition is the orthorhombic–monoclinic phase transition but the second transition is yet to be characterised. The first transition can be assigned as the orthorhombic–monoclinic phase interconversion because it is absent on cycling and rapid cooling is known to give the monoclinic phase. Further investigation is planned using variable temperature powder neutron diffraction in order to study the copper coordination sphere, the orthorhombic–monoclinic phase transition and the high temperature polymorph.

Elemental analysis using EDAX confirmed the ratio of Rb:Cu:P to be 1:1:1 within experimental error and the UV–VIS spectrum showed an absorption centred at approximately 610 nm in the visible region, which is consistent with that expected for copper coordinated to four oxygen atoms, *e.g.* $CaCu(MeCO_2)_4.6H_2O$,[13] and the observed sky blue colour.

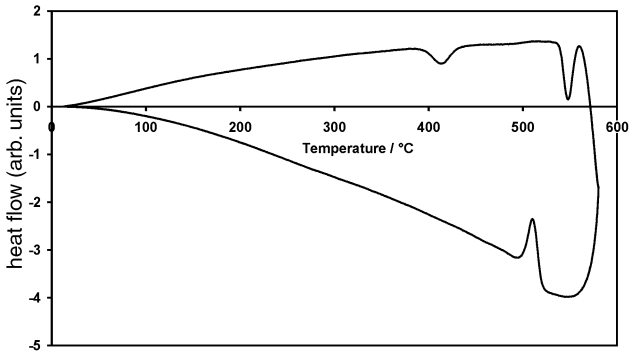

Fig. 2 DTA trace of $RbCuPO_4$ between RT and 600 °C showing two transitions, the first at 410 °C is irreversible under the experimental conditions and the second at 550 °C in the heating cycle and 510 °C in the cooling cycle is reversible.

In this case, the small pore size, illustrated by the fact that the extra-framework counter cation cannot be ion exchanged, either in solution or by melt methods, means that the material is very unlikely to be a selective catalyst, with any activity being restricted to the surfaces of the particles. However, we have shown that high levels of transition metals can be doped into zeotype frameworks using this experimental route, which may lead to new catalytic materials in the future.

We have successfully synthesised the first maximum copper framework (1:1 framework species ratio) with a zeolite topology, $RbCuPO_4$-ABW. Two structurally similar phases exist at room temperature with the proportions being determined by the final heating regime, cooling conditions and subsequent grinding. Slow cooling followed by grinding gives a framework containing purely four-coordinate copper whereas quenching without grinding gives a metastable monoclinic phase as the major phase (*ca.* 9:1 ratio). This second phase, which is very pale green-blue, can be converted back to the purely four-coordinate Cu containing framework by the application of moderate pressure (*e.g.* mechanical grinding or pelletisation). This transition is readily observed by the marked colour change.

We would like to thank the EPSRC for financial support for R. W. H. and the Southampton oceanographic centre for access to SEM facilities.

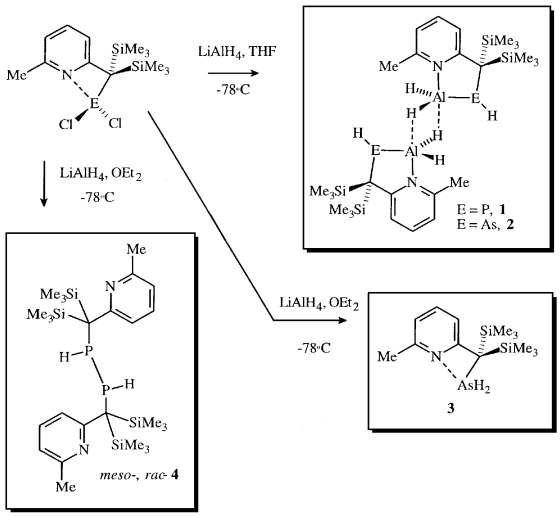
Received (in Columbia, MO, USA) 12th May 2000, Accepted 15th August 2000
First published as an Advance Article on the web

Reaction of $RECl_2$ ($R^- = C(SiMe_3)_2$(6-Me-2-pyridyl)$^-$, E = P or As) with $LiAlH_4$ in THF affords directly bonded aluminium hydride–pnictide hydride complexes as weakly associated hydride bridged dimers, $[RE(H)–Al(H)_2]_2$; a strong solvent dependency of these reactions, which had previously been observed with the formation of the disecondary diphosphane in Et_2O (E = P), is further confirmed by the formation of $RAsH_2$ from $RAsCl_2$ and $LiAlH_4$ in Et_2O.

Compounds containing group 13–15 bonds are of interest as potential precursors to group 13–15 ceramic and semiconductor materials.[1,2] Access to the class of compounds possessing aluminium(III) to phosphorus(III) or arsenic(III) bonds has mainly involved dehydrosilylation reactions of $E(SiMe_3)_3$ with lithium aluminium hydride, $LiAlH_4$,[3] or the trimethylamine adduct of alane, H_3AlNMe_3,[1] affording $(Et_2O)_2Li\{\mu\text{-}E(SiMe_3)_2\}_2AlH_2$, $[H_2Al\{\mu\text{-}P(SiMe_3)_2\}_3]$ and $[H_2AlAs(SiMe_3)_2(NMe_3)]$. Analogous compounds with gallium to phosphorus or arsenic bonds have similarly been prepared.[4,5] Another approach to making compounds with group 13–15 bonds where the metal has exclusively hydrido anionic ligands, other than the simple Lewis base adducts MH_3,[6–9] is transmetallation involving $H_2(X)MPCy_3$ and $LiPCy_2(THF)_n$, Cy = cyclohexyl, M = Ga, X = Cl,[10] M = In, X = H.[9] All the aforementioned phosphide and arsenide compounds are based on secondary phosphines or arsines, the pnictide bearing two substituents, either a trimethylsilyl group or a C-centred ligand. The prospect of forming dihydrido metal complexes based on primary phosphines and arsines is a synthetic challenge because of the likely propensity of spontaneous elimination of hydrogen and formation of polymeric material, although we have noted in earlier studies that secondary amine adducts of alane can be stabilised by the bulk of the amine ligand itself; 2,2,6,6-tetramethylpiperidine forms a stable Lewis base adduct with alane,[6] as does $H\{N(SiMe_3)_2\}$ for which the adduct is a distillable liquid.[7]

Our approach in gaining access to dihydridoaluminium(III) compounds based on primary phosphide and arsenide species, $(H_2)Al–P/As(H)R$, is to incorporate a bulky alkyl group bearing an N-donor centre on the pnictide, notably (6-Me-2-pyridyl)$(SiMe_3)_2C^-$ (= R^-), which has been shown to stabilise unusual bonding configurations, as has the related ligand, C(2-$(SiMe_3)_2$(2-pyridyl)$^-$, allowing access to a range of new compounds.[11–17] The combined steric hindrance of R^- coupled with the N-donor group has the tendency to reduce the degree of aggregation of the target species. In this context its noteworthy that $[H_2Al\{\mu\text{-}P(SiMe_3)_2\}_3]$ is trimeric whereas the NMe_3 adduct of the arsenic analogue is monomeric, $[H_2Al-As(SiMe_3)_2(NMe_3)]$.[1] Herein we report the synthesis of the first alane compounds based on primary phosphine and arsenine moieties, and also the synthesis of a primary arsine, $RAsH_2$, and its structure determination, a first for this class of compound.

The new phosphide and arsenide compounds, $(H_2)Al–P/As(H)R$, **1** (P) and **2** (As), were prepared by the reaction of $RECl_2$ with $LiAlH_4$ in THF, Scheme 1.† The choice of solvent in their synthesis is crucial. We have previously reported that



Scheme 1

the reaction of $RPCl_2$ with $LiAlH_4$ in Et_2O affords reproducibly the disecondary diphosphane, **4**, as a mixture of the *rac* and *meso* isomers, and not the expected dihydride species,[12] Scheme 1. In contrast we have now established that the analogous reaction of $RAsCl_2$ with $LiAlH_4$ in Et_2O does in fact result in the target dihydride species, $RAsH_2$, **3**.†

Single crystals of **1**, **2** (Fig. 1) and **3** suitable for single crystal X-ray diffraction were obtained from hexane solutions at −30 °C.‡ Compound **1** decomposes at temperatures above

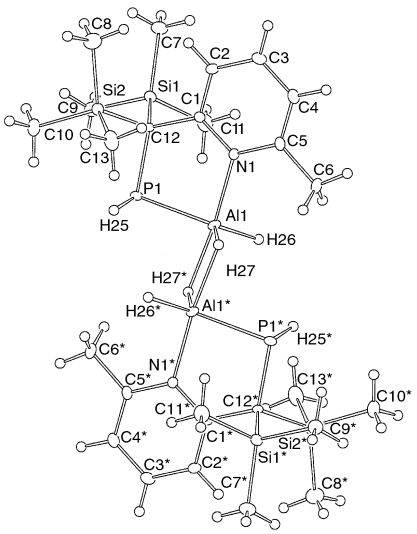


Fig. 1 Projection of $[H_2Al\{P(H)R\}]_2$, **1**. Important bond distances (Å) and angles (°) (values for the arsenic analogue, **2**, in square brackets: Al–N 2.040(2) [2.043(1)], Al–E 2.330(1) [2.4184(5)], Al–H, 1.668, 1.633 [1.60, 1.52(20)], E–H 1.303 [1.54], E–C, 1.913(2) [2.041(2)]; N–Al–P 88.85(6) [89.96(4)], Al–E–C 96.29(8) [92.76(5)], Al–N–C 119.2(2), 120.9(2) [119.5(1), 120.5(1)], Al–E–H 94.6 [93.8].

DOI: 10.1039/b003990j

116 °C to a dark red oil, whereas **2** melts at 206–208 °C. **3** decomposes above 50 °C, darkening in colour from yellow to orange at around 120 °C and at 160 °C it becomes dark red and gradually melts.

Complexes **1** and **2** are isostructural in the solid state (monoclinic, $P2_1/n$) and are dimeric, being weakly associated *via* metal–hydride bridging. The central feature of the two structures is the novel five membered heteroatomic rings containing Al–E bonds, with bond distances of 2.330(1) and 2.418(5) for Al–P and Al–As respectively. The P–Al bond distance is short in comparison to other alkylaluminium–phosphorus complexes, in particular 2.681(4) Å in $[(Me_3C\text{-}CH_2)_3Al{\cdot}P(SiMe_3)_3]$, 2.498(7) Å in $[(Me_3SiCH_2)_2(Br)\text{-}Al{\cdot}P(SiMe_3)_3]$, 2.436(2) Å in $[(Me_3SiCH_2)_3AlP(SiMe_3)_2]_2$,[2] 2.3916(16) Å and 2.4041(14) Å in $[H_2AlP(SiMe_3)_2]_3$[1] and 2.4001(13) Å in $[(Et_2O)_2Li[\mu\text{-}P(SiMe_3)_2]_2AlH_2$,[3] a factor most likely attributable to the steric crowding around the metal centre. The Al–As bond distance is comparable to that found in $[H_2AlAs(SiMe_3)_2]{\cdot}NMe_3$,[1] 2.438(2) Å, and in $[(Et_2O)_2Li[\mu\text{-}P(SiMe_3)_2]_2AlH_2$,[3] 2.4934(7) Å, while it is shorter than in $[(Me_3SiCH_2)(Br)AlAs(SiMe_3)_2]_2$, $[(Me_3CCH_2)_3AlAs\text{-}(SiMe_3)_3]$ and $[(Me_3SiCH_2)_2AlAs(SiMe_3)_2]_2$[2] which have Al–As bond distances of 2.505(3) Å, 2.72(2) Å and 2.567(2) Å respectively. For **1** and **2**, the H atom on E and the bridging H on Al are coplanar; however, in geometrical terms they point away from each other, and at 3.185 Å, **1**, and 3.263 Å, **2**, there is no significant interaction. The non-bridging H on Al and the H on E point away from each other in **1** and **2**.

Despite many attempts we have been unable to obtain a satisfactory refinement for the crystals of $RAsH_2$, **3**, as we have for **1** and **2**. This is due to an inherent twinning disorder and as such the *R*-factor converged at 18%. Although this prejudices discussion on bond distances and angles within the crystal lattice, it is evident that the As centre is involved in a planar four membered chelate with the pyridine ring, through a N···As interaction, similar to that observed in $RECl_2$. Complex **3** is the only arsenic dihydride complex to exhibit N–As connectivity. Given the thermal instability of arsenic hydride it is not surprising that only four other AsH_2 complexes have been structurally characterised[18–20] in the solid state, and these have been stabilised through attachment either to a transition metal, *e.g.* $[Ir(CO)ClH(Pet_3)_2(AsH_2)]$,[18] or to silicon in $[(2,4,6\text{-}i\text{Pr}_3C_6H_2)(^t\text{Bu})Si(AsH_2)_2]$.[20]

In order to assess the potential of complexes **1** and **2** as possible single source precursors for CVD the solids were slowly heated *in vacuo* to 200 °C which resulted in decomposition to an orange solid for **1** and a black solid for **2**. Microprobe analysis on the decomposed solids showed an approximate 1 : 1 ratio for Al : P for **1**, but not so for the As : Al ratio for **2**, which was 1 : 26. There was also evidence of a high percentage of Si present in the samples, indicating that decomposition *via* β-hydrogen transfer to form an intermediate HAl=ER, followed by β-hydrogen elimination of HR, is not evident. While it appears that compounds **1** and **2** are not a direct route to aluminium phosphide and arsenide, a new class of compounds has been established, and the ability of N-functionalised donor alkyl ligands to stabilise an unusual bonding configuration is noteworthy; extending the work to other donor alkyl ligand systems (group 15 and 16), and to the heavier group 13 elements is a synthetic challenge.

We are grateful to the Australian Research Council for support of this work.

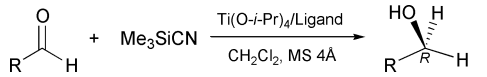
First published as an Advance Article on the web

The asymmetric addition of Me_3SiCN to aldehydes catalyzed by titanium(IV) complexes of *N*-sulfonylated derivatives of β-amino alcohols gave excellent ee's up to 96% ee.

Optically pure cyanohydrins are important chiral building blocks for a wide variety of chiral products such as α-hydroxy acids, α-hydroxy aldehydes, α-hydroxy ketones, β-hydroxy amines, β-amino alcohols and α-amino acid derivatives.[1] Therefore, in recent years, a number of synthetic methods have been reported employing enzymes, synthetic peptides, and chiral metal complexes.[1,2] Of chiral metal complexes reported so far, titanium-based Lewis acids have attracted the most interest, and the chiral ligands used include TADDOLs,[3] BINOLs,[4] sulfoximines,[5] peptides,[6] Schiff bases[7] and others.[8–10] For examples, the TADDOL–Ti(O-*i*-Pr)$_2$Cl$_2$ catalytic system reported by Narasaka *et al*. gave a 96% ee for benzaldehyde as a substrate at −65 °C.[3] However, for aliphatic aldehydes, the catalytic system gave low ee values of 68–77% ee. With the use of 20 mol% of the sulfoximine–Ti(O-*i*-Pr)$_4$ catalyst reported by Bolm and Müller, the ee values could be up to 91% ee.[5] Recently, Belokon *et al.* reported a very efficient [(salen)Ti(μ-O)]$_2$ catalyst to give the best ee value of 92% ee with the use of only 0.1 mol% of the catalyst.[7] In these studies, the best enantioselectivities were reported by Uang *et al*. with the use of the diamide–Ti(O-*i*-Pr)$_4$ catalytic system giving ee values higher than 96% ee.[9] Despite extensive studies, limitations such as poor enantioselectivities, the lack of wide-range substrate generality, high catalyst loading, or even a stoichiometric use of chiral ligand, were usually encountered. This makes the development of practical and highly effective catalytic systems for the preparation of chiral cyanohydrins much more challenging. Herein we report the synthesis of a new family of *N*-sulfonylated β-amino alcohols with one or two stereocenters as chiral ligands, and the asymmetric addition of Me_3SiCN to aldehydes was conducted‡ (eqn. 1).



(1)

In this study, we first synthesized the *N*-sulfonylated β-amino alcohols (*S*)-**3** and (*S*)-**4** with only one stereocenter. Unfortunately, the catalytic reaction using (*S*)-**3** or (*S*)-**4** with an equimolar amount of Ti(O-*i*-Pr)$_4$ as a catalyst gave no conversion or low enantioselectivity of 7% ee at 0 °C (entries 1 and 2, Table 1). These results prompted us to develop a novel family of β-amino alcohols with two stereocenters, and based on the route described by Reetz *et al.*,[11] the β-amino alcohols **5** and their *N*-sulfonylated derivatives **6** and **7** with two stereocenters were prepared. The synthetic strategy provides a tremendous pool of various β-amino alcohols *via* variation of both R and R′ groups. While creating the second stereogenic carbon center, it was found that the second stereocenter is controlled by the original amino chiral carbon center, and the major (*R*,*S*)-stereomer and the minor (*S*,*S*)-stereomer can be easily separated by chromatography.

In using the (*R*,*S*)-**6**–Ti(O-*i*-Pr)$_4$ system, the asymmetric addition of Me_3SiCN to benzaldehyde afforded the cyanohydrin in only 14% yield at 0 °C (entry 3). In contrast, employing (*R*,*S*)-**7a** resulted in significant improvement of ee values to 68% ee

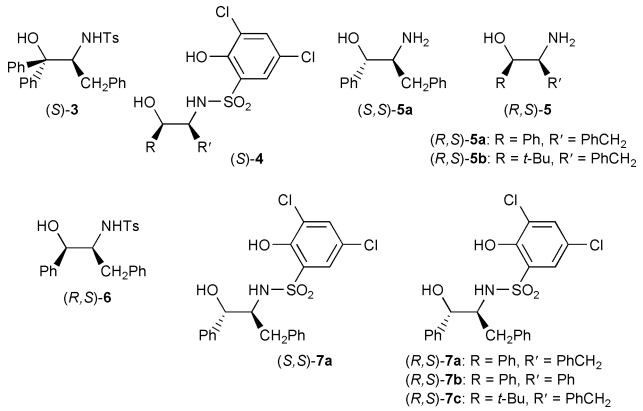
[a] Without addition of powdered molecular sieves. [b] Yields were based on ^{1}H NMR analyses of the mixture of cyanohydrin and unreacted aldehyde. In parentheses, isolated yield. [c] Determined by HPLC with Chiralcel OD column for **1a**–**1f**, Chiralcel AS for **1g** and Chiralpak OJ for **1h** after protected as acetyl esters except **1h** as a benzoyl ester. Absolute configurations were determined by comparison of optical rotations with literature values.

DOI: 10.1039/b006128j



(entry 4). From entries 5 and 6, a significant temperature effect was observed with enantioselectivities of 79% ee at −40 °C (entry 5) and 96% ee at −65 °C (entry 6). Another key factor for the successful practice of highly efficient enantioselective trimethylsilylcyanation of aldehydes is the use of powdered 4 Å molecular sieves. In the absence of molecular sieves, the ee value significantly decreased from 96 to 77% ee with the yield decreased to 52% (entry 7). When as little as 5 mol% of (*R*,*S*)-**7a** was used, an excellent enantioselectivity was still obtained with 94% ee (entry 8). Replacing (*R*,*S*)-**7a** with (*R*,*S*)-**7b** gave a lower enantioselectivity of 62% ee (entry 9). When (*R*,*S*)-**7c** with a benzyl substituent at the amino carbon and a *tert*-butyl substituent at the hydroxy carbon was used, a much lower ee value of 38% ee was obtained (entry 10). For (*S*,*S*)-**7a**, which is a diastereomer of (*R*,*S*)-**7a**, the reaction gave only 8% ee of *S* configuration (entry 11). In addition, other metallic reagents such as $AlMe_3$, $AlEt_3$, Et_2AlCl, $Ti(O\text{-}i\text{-}Pr)_2Cl_2$, $Ti(O\text{-}i\text{-}Pr)Cl_3$ and $TiCl_4$ were also examined. However, the reactions gave low enantioselectivities with the best ee value of only 37% ee. Solvent effect was also studied, and CH_2Cl_2 was the best choice.

The enhanced unique reactivity of the *N*-sulfonylated amino alcohol (*R*,*S*)-**7a** has been suggested to arise from the following factors: (a) phenoxides are known to form strong bonds to group 4 transition metals, and with electron withdrawing halogen groups, the phenoxide moiety may lead to enhanced Lewis acidity at the metal center to improve the reactivity; (b) the phenolic ring further enhances conformational rigidity of these tridendate ligands, which may be an important factor in the transfer of asymmetry.

From entries 12–18, the generality of the asymmetric catalytic reactions employing the (*R*,*S*)-**7a**–$Ti(O\text{-}i\text{-}Pr)_4$ catalytic system was conducted. For aromatic aldehydes (entries 12–16), the asymmetric cyanosilylations gave (*R*)-cyanohydrins with excellent ee values except in the cases of 2-methoxybenzaldehyde (86% ee) and 1-naphthaldehyde (77% ee). The best ee value of 96% ee was obtained for benzaldehyde (entry 6) or 2-naphthaldehyde (entry 15). It is worth noting that, in this study, ee values of 95 and 93% ee were obtained for aliphatic isobutyraldehyde and α,β-unsaturated (*E*)-cinnamaldehyde (entries 17 and 18), respectively.

In conclusion, the first example of highly effective asymmetric addition of a cyano group to aldehydes using *N*-sulfonylated β-amino alcohols as ligands has been reported with excellent enenatioselectivities and with broad substrate generality. Besides, the similar sulfoxamide ligands were also applied to asymmetric diethylzinc addition to aldehydes.[12] This study clearly demonstrates that differences in ligand structures strongly influence the enantioselectivity, and several trends were noted. First, the generation of the second stereocenter greatly improved enantioselectivities. Second, substitution of a flexible benzyl group at the amino carbon ((*R*,*S*)-**7a**) for a rigid phenyl group ((*R*,*S*)-**7b**) resulted in a significant drop in the ee value. Third, aryl substituents on the stereogenic center at the alcoholic carbon proved to be superior to alkyl substituents. The mechanistic study of the catalytic systems and their further applications are currently underway.

‡ *General procedures for asymmetric cyanosilylation of aldehydes*: Under dry dinitrogen atmosphere, 0.05 mmol of the chiral ligand, 0.05 mmol of $Ti(O\text{-}i\text{-}Pr)_4$, and 100 mg of powdered 4 Å molecular sieves were mixed in 2.0 mL of dry DCM at rt. The mixture was stirred for 1 h and cooled to −65 °C. To the resulting yellow solution were added 1.5 mmol of Me_3SiCN and 0.5 mmol of aldehyde. After the solution was stirred at this temperature for 48 h, the reaction was quenched with 1 M HCl, and the mixture was then vigorously stirred for 4 h. The aqueous phase was extracted with ethyl acetate (3 × 10 mL), and the combined organic layers were dried over $MgSO_4$, and concentrated *in vacuo*. Flash chromatography of the residue on silica gel (elution with 5:1 hexane–ethyl acetate) gave a cyanohydrin. ee was determined by HPLC after protection as acetyl esters (except **1h**, which was protected as a benzoyl ester).

Chemo- and regioselective crossed alkyne cyclotrimerisation of 1,6-diynes with terminal monoalkynes mediated by Grubbs' catalyst or Wilkinson's catalyst†

A novel protocol for crossed alkyne cyclotrimerisations mediated by Grubbs' catalyst [$RuCl_2$(=CHPh)(PCy_3)$_2$] allows the efficient synthesis of 4,6-substituted indolines with high regioselectivity, and it is complementary to alkyne cyclotrimerisations mediated by Wilkinson's catalyst [RhCl(PPh_3)$_3$] allowing the regioselective synthesis of the corresponding 4,5-substituted isomers in many cases.

The transition metal catalysed cyclotrimerisation of alkynes has been recognised as a versatile synthetic approach for highly substituted benzenes.[1] While the intramolecular version has been established as an efficient synthetic method, the efficiency of the conceptually more flexible crossed cyclotrimerisation of tethered diynes with monoalkynes has to be evaluated by the ability to gain control over the chemo- and regioselectivity of this process.[2] Only a few reports appear using differently substituted diynes and monoalkynes in crossed cyclotrimerisation reactions,[2d,h,m,3] and in most cases the observed regioselectivity was either dependent on a reactivity preference of a given substrate or limited by the use of sterically encumbered substituents.

Recently, we reported a novel synthesis of indolines based on a rhodium-catalysed crossed cyclotrimerisation with *N*-functionalised alk-1-ynylamides, a process which provides flexible access to 4-, or 7-, as well as to 4- and 7-substituted indolines.[3] While servicing a number of objectives in indole synthesis, this method has not yet been applicable for the regioselective synthesis of indolines bearing substituents in the 4,6-, or 4,5-position—a feature of numerous compounds of synthetic and medicinal interest.[4] We propose below a solution to this challenging issue by using either Grubbs' catalyst [$RuCl_2$(=CHPh)(PCy_3)$_2$] **A** or Wilkinson's catalyst [RhCl(PPh_3)$_3$] **B** in crossed alkyne cyclotrimerisations.

At the outset of our studies we anticipated that a crossed alkyne cyclotrimerisation based on a cascade of metathesis steps could contribute to the above problem set, because metathesis catalytic cycles usually begin with a regioselective addition of the ylidene-transition metal complex to the less hindered site of an olefinic or acetylenic substrate.[5] Based on the findings of Blechert and Roy, that the complex **A** caused a fully intra- or intermolecular alkyne cyclotrimerisation,[6] we projected a catalytic cycle as outlined in Scheme 1. The preferred addition of complex **A** to the least substituted alkyne moiety of the 1,6-diyne should be supported by a coordination of the remaining triple bond to the ruthenium complex, thus causing the chemo- and regioselectivity of this process. A cascade of intra- and intermolecular, as well as ring closing metathesis steps, which are related to the well established enyne and olefin metathesis,[7] would finally result in the liberation of the ruthenium benzylidene catalyst and in the preferred formation of the corresponding *meta*-isomer.

A first set of examples was obtained by the reaction of the 1,6-diyne **1** (0.02 M in CH_2Cl_2) with the monoalkynes **2a–d** (5 eq.) in the presence of 5 mol% **A** at 40 °C (Scheme 2, Table 1). During a period of 10–20 h the starting material was consumed giving the isoindolines **3a–d** in 81–89% yield after chromatography on silica gel (entries 1–4). Although in some cases the amount of **2** could be reduced to 2 eq., best results were obtained using 5 eq., which effectively suppressed a competitive cotrimerisation of **1**. In agreement with our mechanistic hypoth-

esis, well pronounced selectivities were observed with ratios of *meta*:*ortho* = 5:1 and 6:1 for **3a** and **3b**–**d**, respectively.‡

Most strikingly, when the same set of compounds was treated with 5 mol% Wilkinson's catalyst **B** in toluene at 20 °C, the regioselectivities of the above reactions could be reversed giving the *ortho*-isomers of **3a**–**d** as major products with ratios of *meta*:*ortho* = 1:8, 1:4, 1:10, and 1:1.5, respectively (Table 1, entries 5–8).§ However, in the case of complex **B**—a catalyst that is assumed to operate through rhodacyclooligoolefins as intermediates in alkyne cyclotrimerisations—the outcome of regioselectivity was markedly dependent on the substituent of the monoalkyne **2**.

Finally, we applied our findings to the regioselective synthesis of 4,6- and 4,5-substituted indolines using either complex **A** or **B** as catalyst and the 1,6-diynes **4a** (R^2 = Me) or **4b** (R^2 = Ph) together with the monoalkynes **2b**–**e** (Scheme 3, Table 2).[8] When complex **A** was applied in CH_2Cl_2 at 40 °C the indolines **5a**–**d** were obtained in 51–70% yield, and once again with excellent *meta*-selectivities of *meta*:*ortho* = 9:1 and 9.5:1 for **5a**–**c** and **5d**, respectively (entries 1–4). However, a higher catalyst load of 10 mol% **A** was in some cases necessary for the completion of the reaction. Notably, nearly uniform isomer ratios were observed being independent of the substitution pattern of the alkynes used. These uniform ratios and comparably higher selectivities for the formation of the 4,6-substituted indolines *meta*-**5a**–**d** should be attributed to the electron richness of the alk-1-ynylamide moiety in **4a** and **4b** causing a clear and distinct preference for the addition of the electrophilic ruthenium benzylidene complex **A** to this electron rich triple bond and thus underlying our mechanistic hypothesis.

Gratifyingly, when the 1,6-diyne **4a** and the monoalkynes **2b**,**c** were treated with 5 mol% Wilkinson's catalyst **B** in toluene at 20 °C, again a switch in regioselectivity was observed, allowing the regioselective synthesis of 4,5-substituted indolines.§ Under these conditions the products **5e** and **5b** were obtained in 54 and 67% yield with excellent selectivities of *meta*:*ortho* = 1:10, and 1:20, respectively (entries 5 and 6). However, only a moderate preference for the *ortho*-isomer of **5b** (*meta*:*ortho* = 1:3) was found in the reaction of **4a** (R^2 = CH_3) with but-3-yn-1-ol **2d**, and the reaction of **4b** (R^2 = Ph) with **2c** occurred without a significant selectivity. Obviously crossed alkyne cyclotrimerisation catalysed by complex **B** are more sensitive to steric hindrance and the substitution pattern of the alkynes, than those catalysed by **A**.

In conclusion, we have achieved a new protocol for chemo- and regioselective crossed alkyne cyclotrimerisations mediated by Grubbs' complex **A**, which is most likely based on a cascade of metathesis steps. This novel catalytic protocol offers an efficient, flexible and highly regioselective access to 4,6-substituted indolines. Moreover, in many cases the regioselectivity of the alkyne cyclotrimerisation could be switched affording the corresponding 4,5-substituted indolines, when Wilkinson's catalyst **B** was used. Notably, both catalysts are commercially available and tolerate a wide range of functionalities.

Financial support of this work by the Deutsche Forschungsgemeinschaft (Wi-1696) is gratefully acknowledged.

Notes and references

‡ All new compounds exhibited satisfactory spectra and elemental analyses. The regioisomers could be separated by simple flash chromatography on silica gel.

§ Regioselectivities of crossed alkyne cyclotrimerisations using catalyst **B** were solvent dependent. Best selectivities were obtained with non-polar solvents like toluene. A detailed discussion on the solvent-dependency of this process will be presented in the full account of this study.

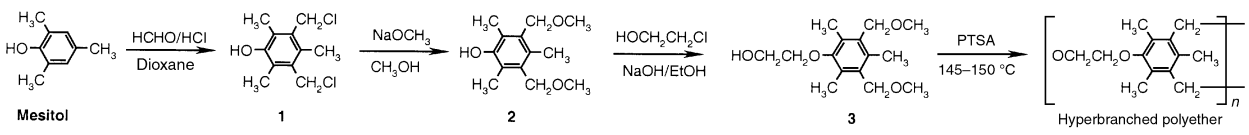
Melt self-condensation of 1-(2-hydroxyethoxy)-3,5-bis-(methoxymethyl)-2,4,6-trimethylbenzene in the presence of an acid catalyst *via* a transetherification process yielded a soluble high molecular weight hyperbranched polyether, whose structure was established by NMR spectroscopy.

Highly branched macromolecules, such as dendrimers and hyperbranched polymers, adopt compact conformations and possess a large number of terminal functional groups. This drastically alters both their solution and bulk properties. Several reviews have appeared in the recent literature, that describe the synthesis, structural properties and applications of dendrimers and hyperbranched polymers.[1–4] Despite the presence of significant levels of structural imperfections, hyperbranched polymers present one major advantage over their structurally perfect cousins and that is the ease of synthesis, which is most often a one-pot self-condensation of an AB_2-type monomer. More importantly, several of the interesting *dendrimeric* properties, such as low melt-viscosity and high functionality, are also exhibited by hyperbranched polymers, thereby making them excellent alternatives to the synthetically cumbersome dendrimers for certain kinds of applications. A large variety of hyperbranched polymers, namely polyesters, polyurethanes, polyamides, polyphenylenes, polysiloxanes, polycarbonates and polyethers have been reported.[3,4] One important feature of the polyether class is their high solubility in common organic solvents, which make them more readily amenable for the study and exploitation of their properties in solution. Hyperbranched polyethers of several types have also been reported in the literature.[5–8] Most of these procedures yielded moderate to high molecular weight polymers, however, they lack adaptability toward structural variation, in that they always require a phenolic group and an aryl/benzyl halide.

Recently, we reported a melt transetherification methodology for the synthesis of linear polyethers.[9] Fully substituted bisbenzyl methyl ethers readily underwent *melt-condensation* with diols in the presence of an acid catalyst to give polyethers of moderate molecular weights. In this report the transetherification methodology is extended for the preparation of a hyperbranched polyether under *melt* condition. For this purpose an AB_2 monomer having a hydroxy group (A) and two benzyl methyl ether groups (B) was targeted. An additional requirement for the transetherification approach to function effectively without crosslinking is the preclusion electrophilic aromatic substitution, which is fulfilled by complete substitution of all the aromatic sites in the monomer.[9] The simplest monomer that meets all these criteria is 1-(2-hydroxyethoxy)-3,5-bis(methoxymethyl)-2,4,6-trimethylbenzene (**3**), which is readily prepared from commercially available mesitol, as shown in Scheme 1. Mesitol was bis-chloromethylated and reacted with $NaOCH_3$–methanol to give the intermediate **2** in good yield. It was then treated with 2-chloroethanol to give the monomer **3**. This monomer was readily polymerized at 145–150 °C in the presence of toulene-*p*-sulfonic acid (PTSA) as catalyst. Typically, the polymerization is carried out under N_2 purge for 30 min and then under reduced pressure (0.01 mm of Hg) for an additional 15 min to attain high molecular weight. To start with, the contents of the reaction vessel formed a clear melt but as the condensation proceeded it transformed into a solid mass. The solid polymer was dissolved in THF, filtered to remove any unwanted insoluble material, and then precipitated into methanol. The precipitate was isolated and dried to give the polymer in 82% yield. The expected structure of the resulting hyperbranched polyether is shown in Scheme 1.

The ^{1}H-NMR spectra of the monomer **3** and the polymer are shown in Fig. 1, along with the assignments of the various peaks. Comparison of the spectrum of the monomer with that of the polymer reveals several interesting features. Firstly, as expected for high conversions, there is a 50% decrease in the relative intensity of the peak **d**, corresponding to Ar-CH_2OCH_3 protons, and a complete disappearance of the peak **b**, corresponding to the –CH_2OH protons, in the spectrum of the polymer (Fig. 1-B). Furthermore, two types of benzylic protons (**a**$_1$ and **a**$_2$) of equal intensity—one corresponding to the unreacted benzyl methyl ether (Ar-CH_2OCH_3) and the other to the reacted one (Ar-CH_2OR–), are seen in the polymer spectrum. These observations confirm that the transetherification process has indeed occurred to very high conversions to yield a polymer with the expected structure. One other interesting feature is the transformation of the peaks corresponding to the aromatic methyl groups from two singlets (**e** and **f**) in the monomer to a cluster of at least five well-resolved peaks (six inclusive of a shoulder), suggesting the presence of several distinct chemical environments in which they are present.

In general, hyperbranched polymers are expected to have different types of subunits, such as dendritic (D), linear (L) and terminal (T) units. Most often, the presence of these various units is established and quantified based on the ^{1}H-NMR signals corresponding to the aromatic protons belonging to them. Interestingly, in the present polyether a significantly more intense Ar-CH_3 signal appears to reveal the presence of these subunits. A total of six aromatic methyl signals (in the region between 2.3–2.5 ppm) are seen, as opposed to a total of seven that might be expected if no coincidental overlaps are present—two each corresponding to dendritic and terminal units and three to the linear unit. As expected, the sum total of the intensities of these Ar-CH_3 peaks is in the expected ratio with respect to the other peaks, **c** and **d**. In order to calculate the degree of branching (DB), it is essential to identify and quantify the mole fraction of the various subunits D, L and T, in such hyperbranched structures. Based on topological considerations



Scheme 1

DOI: 10.1039/b005552m

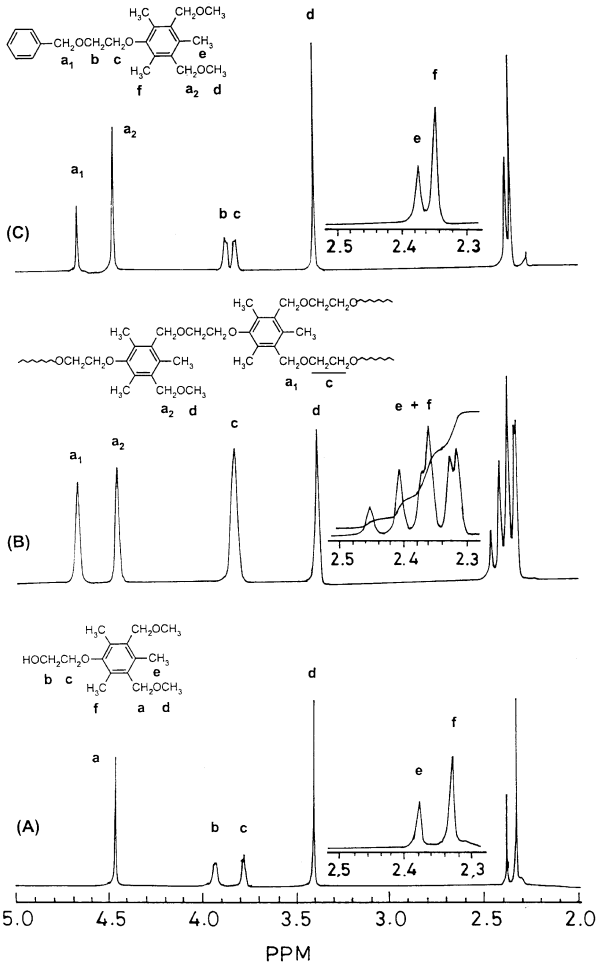


Fig. 1 500 MHz ^{1}H-NMR spectra of the monomer (A), polymer (b) and model compound (C), in $CDCl_3$.

it has been shown that hyperbranched structures will always possess equal number of D and T units (at high conversions), and the DB has been calculated for several polymers using a simplified expression (eqn. 1), from the mole fraction of the terminal units alone.[8,10–13]

$$\mathrm{DB} = \frac{[\mathrm{D}]+[\mathrm{T}]}{[\mathrm{D}]+[\mathrm{L}]+[\mathrm{T}]} = \frac{2[\mathrm{T}]}{[\mathrm{D}]+[\mathrm{L}]+[\mathrm{T}]} \quad (1)$$

In order to identify the methyl peaks belonging to the terminal units, a model compound **4** (see Fig. 1-C) was prepared by reacting **2** with 2-benzyloxy-1-chloroethane in presence of a base, and its ^{1}H-NMR spectrum is shown in Fig. 1. Upon comparison of the spectrum of the model compound with that of the polymer, it is clear that the peaks between 2.34–2.39 ppm in the polymer corresponds to the Ar-CH_3 protons of the terminal unit. The sensitivity of the chemical shifts of these methyl protons to its chemical environment is apparent when one compares the spectrum of model compound **4** with that of the monomer; the transformation of a remote hydroxy group to a benzyl ether causes a significant downfield shift of the two *ortho*-methyl protons peak, **f**. Thus, a non-exact match between the chemical shifts of model compound **4** and the polymer is not surprising; the *ortho*-methyl signal **f** appears slightly further downfield in the polymer. Thus, the DB was calculated from the relative intensities of the two peaks assigned to the terminal unit (between 2.34–2.39 ppm) with respect to the total intensity of all the methyl signals (between 2.3–2.49 ppm), as per the above formula. This number works out to be 0.78 suggesting that a fairly high degree of branching has been achieved. In the absence of the dendritic model compound,[13] we rely on the *ca.* 1 : 2 intensity ratio of the shoulder to peak (**e** : **f**) in the polymer spectrum to confirm the absence of peaks due to other subunits within this one. Typical values for DB quoted in the literature range from 0.4–0.8.[14] Special efforts using a gradual addition of the AB_2 monomer to a polyfunctional B-type core monomer (B_f), are often needed to further increase the degree of branching.[15]

The molecular weight of the polymer was determined by GPC using polystyrene standards and it showed a broad distribution with M_W of 103 000 and a polydispersity of 5.8. The high polydispersity is typical of such hyperbranched structures. The DSC thermogram of the polymer was recorded under a dry N_2 purge, and the sample was first heated to 150 °C and then quenched to −100 °C at 30 °C min^{-1}. It was then reheated from −100 to 150 °C at 10 °C min^{-1} and cooled at the same rate to record the thermograms. No crystallization and melting transitions were observed either during the heating or cooling runs, which suggests that the samples were completely amorphous. A glass transition temperature (T_g) was, however, clearly visible at 28 °C.

In conclusion, we have shown that the *melt transetherification* approach can be readily adapted for the preparation of hyperbranched polyethers. More importantly, the intermediate **2** is readily amenable to a variety of structural variation by incorporation of various types of alkyl and oligoethyleneoxy spacers, to generate a wide range of AB_2 monomers. Such an inclusion of spacer segments into hyperbranched polyethers is not readily possible using most other previous methods, which makes this approach especially useful for preparing a range of hyperbranched structures starting from a single intermediate. A particularly interesting series of hyperbranched polyethers would be the one that incorporates oligoethyleneoxy segments. This would lead essentially to branched polyethylene oxides, which could serve as potential candidates for solid polymer electrolyte applications.[16,17] Work along these lines is currently in progress and will be reported shortly.

We would like to thank Department of Science and Technology, New Delhi, for financial support, and Dr Shiv Venkataramani, 3M-Center, St. Paul, for GPC analysis.

Quadruple hydrogen bonded oligo(*p*-phenylene vinylene) dimers

Abdelkrim El-ghayoury, Emiel Peeters, Albertus P. H. J. Schenning and E. W. Meijer*

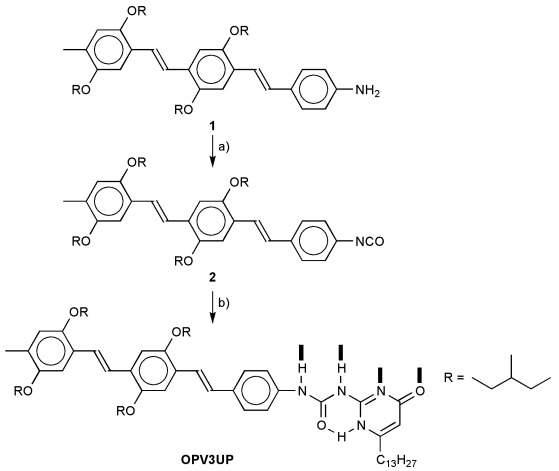
Laboratory of Macromolecular and Organic Chemistry, Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, The Netherlands

Received (in Cambridge, UK) 21st July 2000, Accepted 23rd August 2000
First published as an Advance Article on the web

Direct self-assembly of π-conjugated oligomers *via* self-complementary quadruple hydrogen bonding is achieved and the first steps towards supramolecular polymers with functional side chains are described.

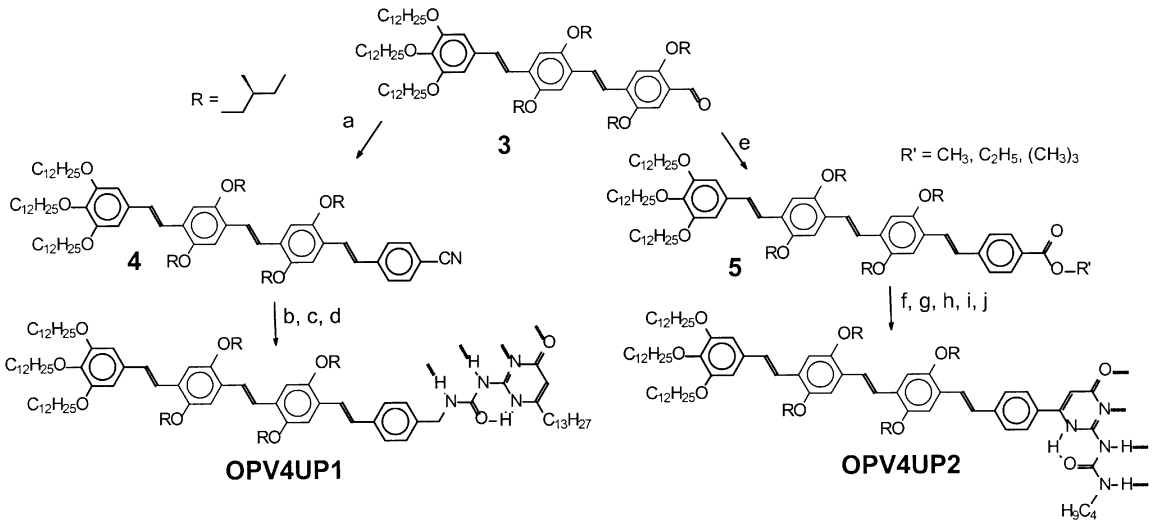
Conjugated polymers are investigated for a manifold of electronic semiconductor applications.[1] It is also widely accepted that well-defined oligomers will play a crucial role in the future advancement of π-conjugated materials, since their precise chemical structure and conjugation length stand for defined functional properties and facilitate enhanced control over their supramolecular architecture.[2,3] Synthetic efforts have been mainly directed towards the synthesis of extended linear conjugated oligomers of length of 5–10 nm, but cyclic,[4] bicyclic,[5] spiro[6] and dendritic[7] structures have also been reported. Further, different π-conjugated functionalities have been combined in a large number of well-defined donor–acceptor molecules. The major challenge is now to obtain control of the supramolecular ordering over length scales extending into the macroscopic regime.[8] Only a few examples have been reported on spatial organization of functional π-conjugated entities by making use of hydrogen bonding motifs. Self-assembled fibers of mono and bisthiophene bisurea compounds have been reported and showed efficient charge transport within these fibers.[9] Superstructure formation of π-conjugated materials has also been obtained by hydrogen bonding complexation of perylene bisimide derivatives with a ditopic melamine compound[10] and with chlorine singlet excited-state electron donor and a naphthalene bisimide acceptor.[11]

Recently, we have reported supramolecular polymers which exhibit real macroscopic polymeric properties.[12] These polymeric systems are based on the strong dimerization of quadruple hydrogen-bonding self-complementary 2-ureido-4[1*H*]-ureido-pyrimidinone units. These recent developments pave the way to combine the specific electronic and optical properties of conjugated oligomers with the material properties of polymers, by incorporating well-defined π-conjugated moieties in these supramolecular polymeric assemblies. Here we report on the synthesis of the ureidopyrimidinone derivatives **OPV3UP**, **OPV4UP1** and **OPV4UP2** (depicted in Schemes 1 and 2) and on their supramolecular ordering.



Scheme 1 Synthesis of **OPV3UP**. (a) di-*tert*-butyl tricarbonate, CH_2Cl_2, 100%; (b) 6-tridecylisocytosine, pyridine, 90 °C, 26%.

Compound **OPV3UP** was prepared starting from the amino functionalized oligomer. Using di-*tert*-butyl tricarbonate the amine functionality was quantitatively converted to the isocyanate **2**.[13] Reaction of **2** with 1.5 eq. of 6-tridecylisocytosine



Scheme 2 Synthesis of **OPV4UP1** and **OPV4UP2**. (a) diethyl 4-cyanobenzylphosphonate, *t*-BuOK, DMF, 91%; (b) $LiAlH_4$, Et_2O, 93%; (c) $COCl_2$, toluene, 100 °C, 100%; (d) 6-tridecylisocytosine, pyridine, 90 °C, 52%; (e) diethyl 4-(methylbenzoate)phosphonate, *t*-BuOK, DMF, THF; (f) KOH, EtOH, 80 °C, 100%; (g) $(COCl)_2$, CH_2Cl_2, DMF, 100%; (h) $MgCl_2$, Et_3N, EtOAc, HCl aq., 30%; (i) $(NH_2)_2C{=}NH{\cdot}HCO_3$, EtOH, 90%; (j) n-$C_4H_9NCO$, pyridine, 90 °C.

DOI: 10.1039/b005903j

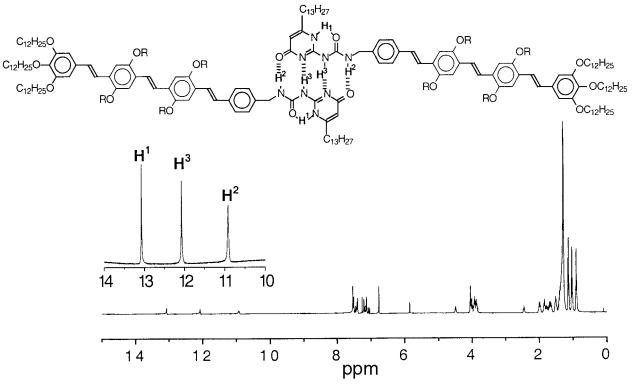


Fig. 1 ^{1}H-NMR spectra of **OPV4UP1** recorded in $CDCl_3$.

in anhydrous pyridine at 90 °C afforded **OPV3UP** in 26% yield after column chromatography. The low yield of **OPV3UP** is probably due to the relatively low reactivity of aromatic isocyanates. Therefore, benzylic isocyanates were used for the preparation of **OPV4UP1**. To obtain the benzylic isocyanate, aldehyde **3** was allowed to react with diethyl 4-cyanobenzylphosphonate in a Wittig–Horner reaction to give the nitrile compound in 91% yield. The nitrile functionality was subsequently reduced using LAH to afford the benzylic amine. The pure compound was isolated after work-up and precipitation in 93% yield. The amine derivative was reacted with phosgene in refluxing toluene to give the isocyanate. Reaction of the latter with 6-tridecylisocytosine in anhydrous pyridine at 90 °C gave **OPV4UP1** in 52% yield. In order to obtain full conjugation between the OPV and hydrogen bonding unit, **OPV4UP2** was synthesized. Reaction of aldehyde **3** with diethyl 4-(methylbenzoate)phosphonate in a Wittig–Horner reaction afforded a mixture of esters **5**. Saponification of these esters gave quantitatively the acid, which was quantitatively converted to the acid chloride using oxalylchloride in DCM and DMF. The β-ketoester was obtained in 30% yield by reaction of the acid chloride with potassium ethylmalonate in presence of triethylamine and magnesium chloride. Reaction of the β-ketoester with guanidinium carbonate yielded quantitatively the isocytosine. The desired compound **OPV4UP2** was finally obtained in 90% yield by reaction of the isocytosine and *n*-butylisocyanate in anhydrous pyridine at 90 °C.

All the compounds **OPV3UP**, **OPV4UP1** and **OPV4UP2** were fully characterized.† These π-conjugated oligomers form quadruple hydrogen bonded **DDAA**-dimers in solution as is evident from the ^{1}H-NMR spectra (Fig. 1). The large downfield shift for the N–H protons gives direct evidence for the involvement of these protons in strong hydrogen bonding.[14] The electronic absorption spectra recorded in $CHCl_3$ solution display a weak band in the visible spectral region (λ_{max} = 409 nm) for the less extended π-conjugated **OPV3UP**. In the case of tetrameric oligophenylene vinylene, **OPV4UP1** and **OPV4UP2**, the absorption maxima are located at λ_{max} = 431 and 446 nm, respectively. The red shift of the absorption maxima of **OPV4UP2** indicates conjugation between the OPV segment and the hydrogen bonding unit. In addition, in dilute $CHCl_3$ solution (*ca.* 10^{-5} M) these hydrogen bonded species are present in dimeric form since the association constant of the ureidopyrimidinone units is extremely high ($K_{dim} = 6 \times 10^7$ M^{-1} in $CHCl_3$ solutions).[15] In dodecane solution, both the dimers of **OPV4UP1** and **OPV4UP2** aggregate into larger architectures and circular dichroism (CD) spectroscopy shows an exciton coupling of the π–π* transition in this solvent. In other words, the side-chain chirality is expressed at the supramolecular level.[16] In the bulk, the two trialkoxybenzene capped dimers are liquid crystalline, but investigation concerning their detailed structure is in progress.

In conclusion, directed self-assembly of π-conjugated oligomers *via* self-complementary quadruple hydrogen bonding has been achieved. It opens new possibilities for the design of electronically active supramolecular materials in which the specific properties of well-defined oligomers can be combined with the material properties of polymers.

We thank Michel Fransen for the synthesis of the starting materials, Joost van Dongen for MALDI-TOF MS measurements, and Dr Rint Sijbesma for fruitful and helpful discussions. This work has been supported by Netherlands Organization for Scientific Research (NWO) and the Royal Netherlands Academy of Arts and Sciences.

The bioinorganic chemistry of zinc: synthetic analogues of zinc enzymes that feature tripodal ligands

Gerard Parkin

Department of Chemistry, Columbia University, New York, New York 10027, USA.
E-mail: parkin@chem.columbia.edu

Received (in Cambridge, UK) 15th June 2000, Accepted 18th August 2000
First published as an Advance Article on the web 29th September 2000

Zinc, as a constituent of more than 300 enzymes, plays essential roles in biological systems. The active sites of these enzymes feature a zinc center attached to the protein backbone by three or four amino acid residues, the nature of which influences the specific function of the enzyme. In order to understand why different zinc enzymes utilize different amino acid residues at the active site, it is necessary to understand how, and why, the chemistry of zinc is modulated by its coordination environment. Answers to these questions are being provided by a study of synthetic analogues of zinc enzymes, *i.e.* small molecules that resemble the enzyme active sites. This article provides an account of those studies that have specifically used tripodal ligands to mimic the active site protein residues in an effort to ascertain the bioinorganic chemistry of zinc.

1. Introduction

Once dubbed a 'boring element',[1] zinc is now experiencing a dramatic renaissance in its chemistry due to the important roles that it plays in biological systems.[2] For example, an average adult human contains *ca*. 3 grams of zinc,[3] and its bioavailability has been shown to have an effect on the occurrence of malaria, pneumonia, and also the common cold.[2,3] To a large degree, the primary influence of zinc in biological systems resides with its presence in *ca*. 300 enzymes. The active sites of many of these enzymes feature a tetrahedrally coordinated zinc center that is attached to the protein backbone by three amino acid residues, with the fourth site being occupied by a water molecule (Fig. 1).[2,4] The specific function performed by each of these enzymes is dictated by both *(i)* the nature of the residues which bind zinc to the protein, typically His (N), Glu (O), Asp (O), and Cys (S), and *(ii)* the amino acid spacer lengths between the active site residues. For example, a selection of zinc enzymes and their functions, which differ according to the composition of the active site, are illustrated in Table 1 and Fig. 2. While it is recognized that the prevalent use of zinc in biological systems is a manifestation of the unique characteristics associated with the Zn^{2+} ion (Table 2),[5] the factors that are responsible for modifying the detailed properties of the active sites of zinc enzymes are not known with certainty. For this

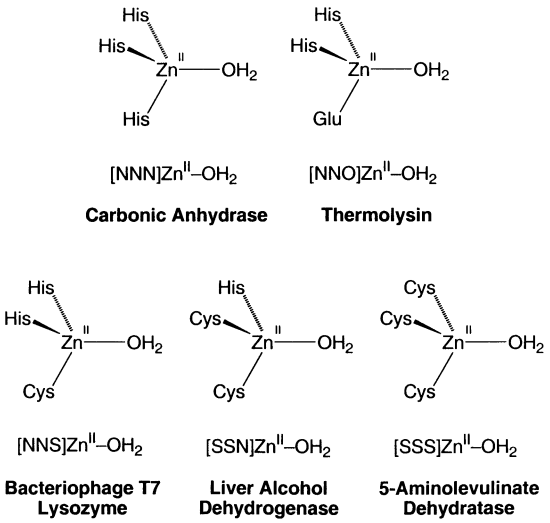

Fig. 2 Active site coordination motifs in representative zinc enzymes.

Table 2 Properties of Zn^{II} that are pertinent to its role in enzymes (information taken from refs. 2 and 3)

Redox properties	The divalent zinc ion is exceptionally stable with respect to oxidation and reduction and so it does not participate in redox reactions, in contrast to Mn, Fe, and Cu.
Coordination geometries	The d^{10} configuration of Zn^{2+} indicates that zinc complexes are not subject to ligand field stabilization effects and so coordination number and geometry is only dictated by ligand size and charge. In enzymes, zinc shows a strong preference for tetrahedral coordination which enhances both the Lewis acidity of a zinc center and the Brønsted acidity of a coordinated water molecule. Only Cu^{II} is a better Lewis acid.
Ligand binding properties	Zinc is an element of borderline hardness, so that nitrogen, oxygen and sulfur ligands can all be accommodated, in contrast to magnesium and calcium which favor binding to oxygen. Therefore, zinc binds strongly to many proteins.
Ligand exchange	The flexibility in coordination geometry makes ligand exchange more facile than for Ni or Mg and enhances the ability of zinc to effect a catalytic cycle.
Ligand nucleophilicity	Anions such as OH^-, OR^- and SR^- retain nucleophilic character when coordinated to zinc. Only Mn^{II}, Fe^{III}, and Cu^{II} are better in this regard.

reason, a number of research groups are actively studying the chemistry of synthetic analogues of zinc enzymes (*i.e.* small molecules that resemble the enzyme active sites) as part of a concerted effort to establish how, and why, the chemistry of zinc is modulated by its coordination environment.[6] The purpose of this article is to provide an account of those studies that have specifically used tripodal ligands to mimic the active site protein residues in an effort to ascertain the bioinorganic chemistry of zinc.

2. Tripodal ligands as mimics for protein binding

The importance of studying synthetic analogues of zinc enzymes resides with the fact that such species are more amenable to structural, spectroscopic, and mechanistic studies than the enzymes themselves. As such, these studies enable the bioinorganic chemistry of zinc to be established for well defined systems. Accurate synthetic analogues of zinc enzymes are not, however, trivial to obtain. A simple illustration of this statement is provided by the fact that whereas *pseudo*-tetrahedral coordination geometry is prevalent in zinc enzymes, higher coordination numbers are common for simple zinc complexes in both the solid state and solution.[4e,7,8] Furthermore, binuclear degradatory pathways are inhibited for the enzyme by virtue of the fact that the active sites are located in its interior. To circumvent such problems involving departures from tetrahedral coordination and oligomerization, considerable attention must be given to ligand design in order to procure synthetic analogues that mimic well the enzyme active sites. Since the active sites of most zinc enzymes are of the composition [{XYZ}Zn^{II}–OH_2], where X, Y, and Z are three protein residues (Table 1 and Fig. 2), a rational approach towards obtaining synthetic analogues is to use tridentate ligands which incorporate the requisite X, Y and Z donor groups to mimic the protein ligation. A further refinement of this approach is to use a *tripodal* ligand in which the X, Y, and Z groups are attached to a common tetrahedral (or trigonal pyramidal) center.

There are at least three advantages of using tripodal ligands, rather than acyclic or cyclic ligands, to support tetrahedral zinc centers. Specifically:

(i) As a result of its trigonal nature, a tripodal ligand enforces the 'facial' (as opposed to 'T-shaped') binding that is required to create a tetrahedral metal center (Fig. 3). In contrast, acyclic

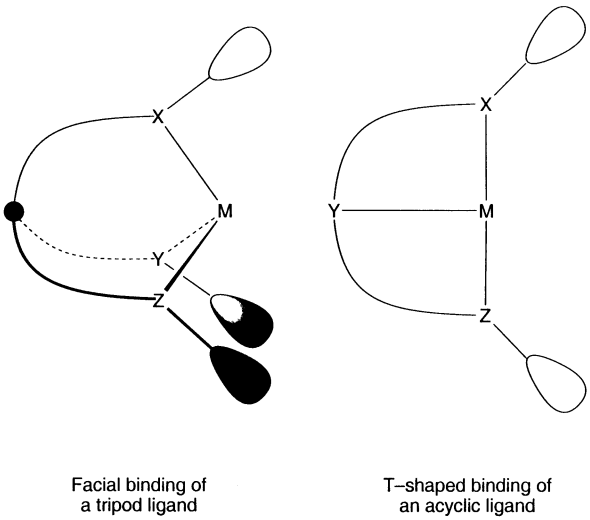

Fig. 3 Comparison of the facial coordination of a tripodal ligand with the T-shaped binding of an acyclic ligand.

tridentate ligands often bind in a 'T-shaped' manner that has no significant biological relevance.

(ii) Tripodal ligands typically possess only a single relevant binding conformation, whereas macrocyclic ligands are more conformationally flexible.

(iii) The directional nature of tripodal ligands is such that it is possible to incorporate substituents that directly influence the steric environment about the metal center. In contrast, substituents in macrocyclic ligands are not, in general, suitably placed to have a profound impact on the sterics of the coordination pocket.

Trofimenko's tris(pyrazolyl)borate ligand system, [$Tp^{RR'}$] (Fig. 4),[9] which features prominently in this article, provides an

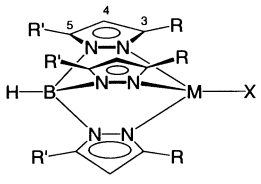

Fig. 4 The tris(pyrazolyl)hydroborato ligand system, [$Tp^{RR'}$]MX.

exemplary illustration of the above virtues of a tripodal ligand. Indeed, with bulky *tert*-butyl substituents on the 3-position of

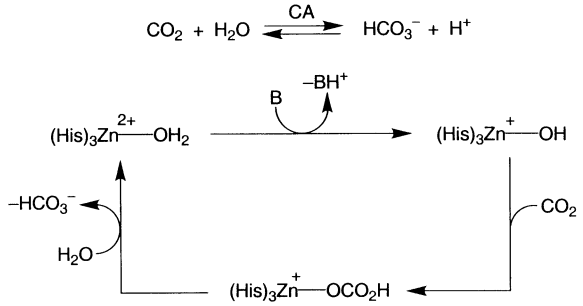
the pyrazolyl groups, the ligand has been referred to as a 'tetrahedral enforcer' due to its tendency to favor tetrahedral coordination.[10] Not only can the substituents at the 3-position be used to modify the size of the coordination pocket, they may also be used to influence the electronic properties of the metal center. For example, in addition to simple alkyl and aryl substituents, electron withdrawing perfluoroalkyl groups, *e.g.* CF_3, may be incorporated.[9] Finally, it should be noted that substituents such as Bu^t provide a valuable ^{1}H NMR spectroscopic probe that facilitates reactivity and mechanistic studies.

3. Synthetic analogues of zinc enzymes incorporating tripodal ligands

In view of the very large number of zinc enzymes known, a systematic and comprehensive investigation of synthetic analogues for all of these enzymes is yet to be conducted. For this reason, the selection of enzymes discussed in this article is eclectic, with the specific intention being to illustrate aspects of the chemistry of those enzymes which feature mononuclear tetrahedral active sites of the type [{XYZ}Zn^{II}–OH$_2$]. The chemistry will be discussed according to the nature of the {XYZ} ligand complement at the active site, ranging from nitrogen rich carbonic anhydrase, [(His)$_3$Zn^{II}–OH$_2$], to sulfur rich 5-aminolevulinate dehydratase [(Cys)$_3$Zn^{II}–OH$_2$].

(a) The [(His)$_3$Zn^{II}–OH$_2$] motif: carbonic anhydrase

Carbonic anhydrase, the first enzyme recognized to contain zinc, has played a pivotal role in the development of zinc enzymology.[11] It is recognized to be an 'ancient' enzyme since it has widespread occurrence in prokaryotes, it is ubiquitous in nature, and is one of the most efficient enzymes known. As implied by its name, its physiological function is to catalyse the reversible hydration of carbon dioxide (Scheme 1), and thus



Scheme 1

carbonic anhydrase plays an important role in respiration and intracellular CO_2/HCO_3^- equilibration. X-Ray diffraction studies demonstrate that the zinc center of the active site is coordinated to the protein by the imidazole groups of three histidine residues and a water molecule (or hydroxide ion, depending upon pH) (Fig. 5), and the overall features of the mechanism of action are illustrated in Scheme 1.[11]

Numerous studies have been performed using tridentate nitrogen donor ligands to model the structure and function of the active site carbonic anhydrase.[6] However, very few of these studies have successfully enabled the isolation of structurally-characterized mononuclear four-coordinate zinc–hydroxide or zinc–aqua complexes that mimic the active site of carbonic anhydrase. It is, therefore, significant that the first such complexes were obtained using sterically demanding tris(pyrazolyl)borato ligands, namely [Tp$^{RR'}$]ZnOH.[12] For example, [Tp$^{Bu^t,Me}$]ZnOH, the first monomeric terminal zinc hydroxide complex to be isolated, has been synthesized by (*i*) the direct reaction between equimolar amounts of $Zn(ClO_4)_2 \cdot 6H_2O$, K[Tp$^{Bu^t,Me}$] and KOH in methanol, and (*ii*) by metathesis of [Tp$^{Bu^t,Me}$]ZnI with Bu$^n_4$NOH (Scheme 2).

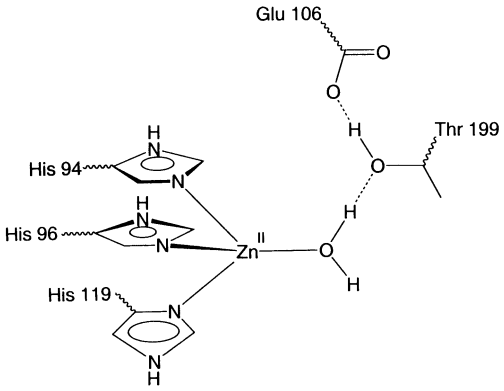


Fig. 5 Active site of carbonic anhydrase.

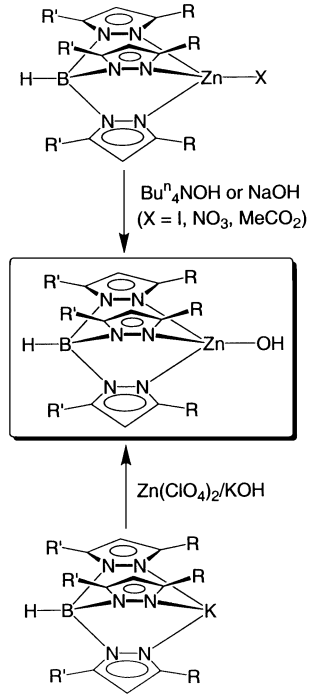

Scheme 2

The molecular structures of [Tp$^{Bu^t,Me}$]ZnOH and [Tp^{Cum,Me}]-ZnOH have been determined by X-ray diffraction, thereby confirming the monomeric and tetrahedral nature of the complexes, as illustrated for [Tp$^{Bu^t,Me}$]ZnOH in Fig. 6. It is important to emphasize that the presence of bulky substituents (*e.g.* Bu^t and $C_6H_4Pr^i$) is essential for the successful isolation of the four-coordinate [Tp$^{RR'}$]ZnOH terminal hydroxide complexes. For example, a simple phenyl substituent in the 3-position of [Tp^{Ph}]ZnOH does not afford a stable derivative.[13] Furthermore, the absence of bulky susbtituents on simple macrocyclic ligands results in oligomerization *via* either hydroxy-bridges, *e.g.* $\{[\{Me_3[9]aneN_3\}Zn(\mu\text{-}OH)]\}_2^{2+}$,[14] or hydrogen bonding interactions, *e.g.* $[\{[12]aneN_3\}Zn(OH)]_3(ClO_4)_3 \cdot (HClO_4)$.[15] More recently, a monomeric five-coordinate anionic zinc hydroxide with a trigonal-bipyramidal geometry, $\{[\eta^4\text{-}N\{CH_2CH_2NC(O)NHBu^t\}_3]ZnOH\}^{2-}$,[16] has been synthesized; notably, this complex also features bulky amide substituents that provide a hydrogen bonding cavity in which the hydroxide ligand resides.[17]

In addition to being structurally determined by X-ray diffraction, the hydroxide ligand in [Tp$^{RR'}$]ZnOH is well characterized spectroscopically, as illustrated by the IR and NMR spectroscopic data listed in Table 3. For example, the ^{1}H NMR spectrum of [Tp$^{Bu^t,Me}$]ZnOH in C_6D_6 illustrates that the hydroxide proton is observed as a sharp signal at δ −0.07 ppm.

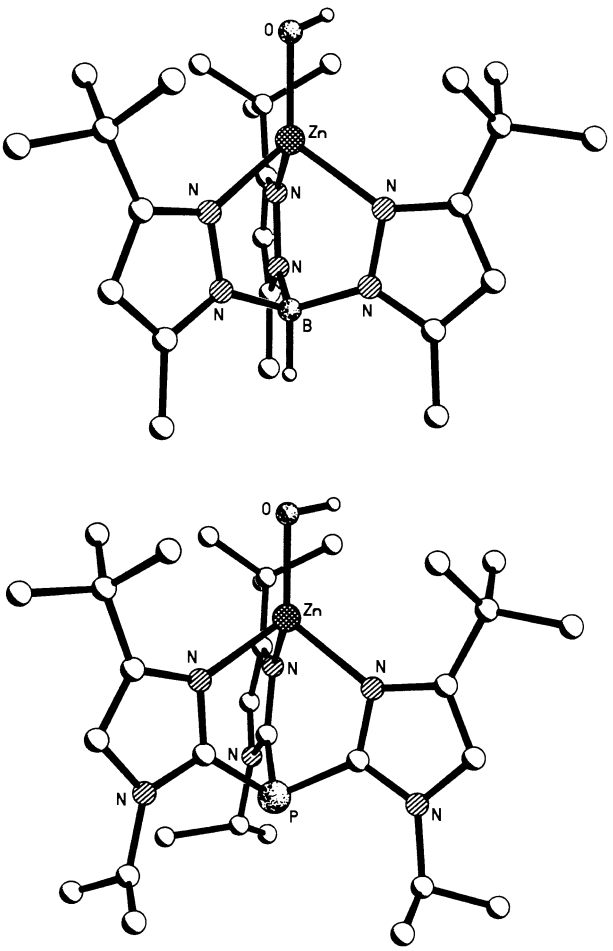

Fig. 6 Molecular structures of $[Tp^{Bu^t,Me}]ZnOH$ and $\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$.

Table 3 Spectroscopic data for $[Tp^{RR'}]ZnOH$ complexes (data taken from ref. 9*b*)

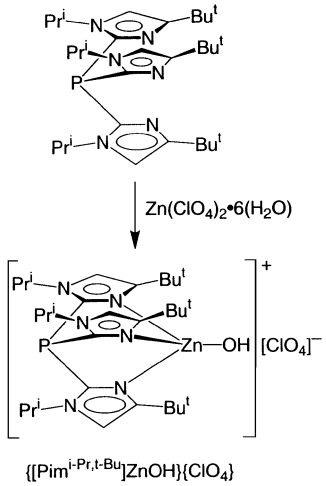
$[Tp^{Bu^t,Me}]ZnOH$	3676	−0.07	−8
$[Tp^{Pr^i_2}]ZnOH$	3668	−0.29	−36
$[Tp^{Ar_2}]ZnOH$[a]	3558		
$[Tp^{Cum,Me}]ZnOH$	3647		

[a] Ar = *p*-$C_6H_4Bu^t$

While the $[Tp^{RR'}]ZnOH$ complexes represent a major advance in bioinorganic zinc chemistry by providing the first well characterized tetrahedral zinc hydroxide complexes, their structural similarity to the enzyme is limited by the fact that the nitrogen donors are not of the imidazolyl type, but are rather pyrazolyl-based. Nevertheless, a tetrahedral terminal zinc hydroxide complex has been obtained by the use of the sterically demanding neutral tris[2-(1-isopropyl-4-*tert*-butylimidazolyl)]phosphine ligand, $[Pim^{Pr^i,Bu^t}]$. Specifically, the hydroxide complex $\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$ was isolated as the perchlorate derivative upon reaction of $[Pim^{Pr^i,Bu^t}]$ with $Zn(ClO_4)_2{\cdot}6H_2O$ (Scheme 3).[18] The molecular structure of $\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$ has been determined by X-ray diffraction, as illustrated in Fig. 6, which emphasizes the strong relationship with that of $[Tp^{Bu^t,Me}]ZnOH$. The Zn–O and Zn–N bond length data listed in Table 4 reinforce this similarity, and also the relationship with carbonic anhydrase. Since $\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$ is the only structurally characterized monomeric tetrahedral zinc hydroxide derivative with three imidazole moieties attached to zinc, the complex represents the best structural model for carbonic anhydrase to date.

As with the tris(pyrazolyl)borate derivatives, $[Tp^{RR'}]ZnOH$, the importance of bulky substituents in enabling the isolation of



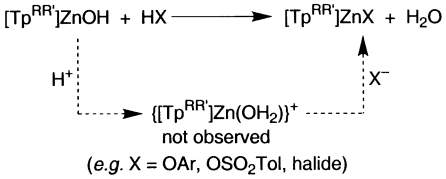
Scheme 3

Table 4 Comparison of Zn–O and Zn–N bond lengths in carbonic anhydrase with those of synthetic analogues

	d(Zn–O)/Å	*d*(Zn–N)/Å
$\{[Pim^{Bu^t,Pr^i}]ZnOH\}^+$	1.86	2.08
$[Tp^{Bu^t,Me}]ZnOH$	1.85	2.05
$[Tp^{Cum,Me}]ZnOH$	1.85	2.05
$\{[Tp^{Bu^t,Me}]Zn(OH_2)\}^+$	1.94	2.02
CAI	1.9	1.9
CAII	2.05	2.11

$\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$ is underscored by the fact that analogous zinc hydroxide complex species have not been isolated using other tris(imidazolyl)phosphine ligands with less sterically demanding substituents.[6*f*] Furthermore, tris(imidazolyl)carbinol and tris(imidazolyl)alkane ligands have likewise failed to yield structurally characterized terminal zinc hydroxide complexes.[6*f*]

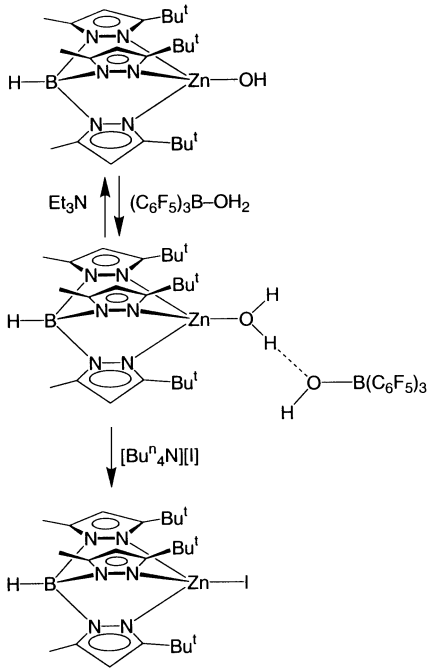
The first essential step in the proposed mechanism of action of carbonic anhydrase (Scheme 1) involves reversible proton transfer which interconverts the aqua and hydroxide forms of the active site, $[(His)_3Zn–OH_2]^{2+}$ and $[(His)_3Zn–OH]^+$. However, while several studies have addressed the factors that influence the pK_a of zinc-bound water molecules in a general sense,[8,15,19] there is to date only a single report demonstrating reversible deprotonation/protonation of a four-coordinate $[Zn–OH_2]^{2+}/[Zn–OH]^+$ pair of complexes. The paucity of such examples is due to the fact that protonation of a zinc hydroxide moiety is typically accompanied by displacement of the aqua ligand by the counter anion (Scheme 4),[20] as illustrated by the



Scheme 4

reaction of $[Tp^{Bu^t,Me}]ZnOH$ with *p*-$TolS(O)_2OH$ to give $[Tp^{Bu^t,Me}]ZnOS(O)_2Tol$.[20*d*] It is, therefore, significant that $[Tp^{Bu^t,Me}]ZnOH$ may be protonated by $(C_6F_5)_3B(OH_2)$ to give a zinc aqua derivative $\{[Tp^{Bu^t,Me}]Zn(OH_2)\}[HOB(C_6F_5)_3]$ in which the water molecule is *not* displaced by the counter ion (Scheme 5).[21] Furthermore, the reaction is reversible and subsequent treatment of $\{[Tp^{Bu^t,Me}]Zn(OH_2)\}^+$ with Et_3N regenerates $[Tp^{Bu^t,Me}]ZnOH$.

The molecular structure of $\{[Tp^{Bu^t,Me}]Zn(OH_2)\}$-$[HOB(C_6F_5)_3]$ has been determined by X-ray diffraction, as



Scheme 5

illustrated in Fig. 7. A notable feature of the structure of {[Tp$^{Bu^t,Me}$]Zn(OH$_2$)}[HOB(C$_6$F$_5$)$_3$] is that the Zn–O bond [1.937(2) Å] is significantly longer than that in [Tp$^{Bu^t,Me}$]ZnOH

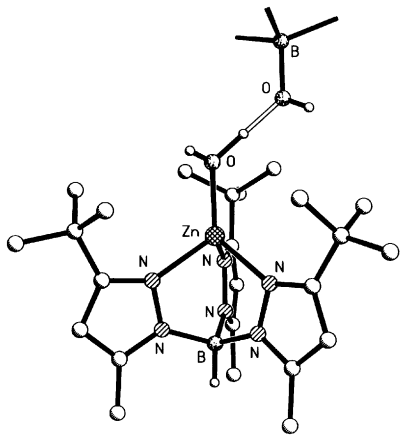


Fig. 7 Molecular structure of {[Tp$^{Bu^t,Me}$]Zn(OH$_2$)}[HOB(C$_6$F$_5$)$_3$].

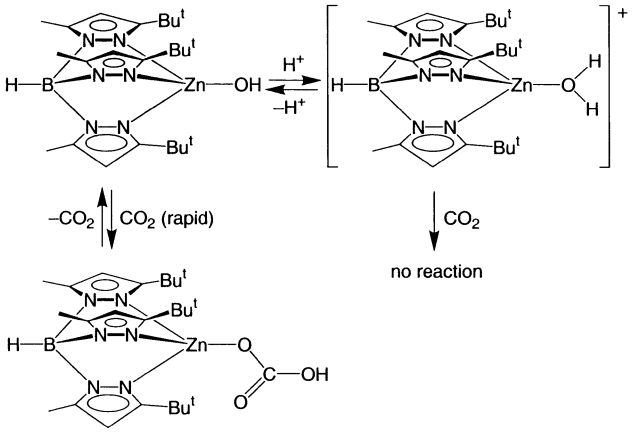
[1.850(8) Å]. Such lengthening is in accord with the fact that the hydroxide ligand has been protonated. Another interesting aspect of the structure of {[Tp$^{Bu^t,Me}$]Zn(OH$_2$)}[HOB(C$_6$F$_5$)$_3$] is the existence of a hydrogen bond interaction between the coordinated water molecule and the [(C$_6$F$_5$)$_3$BOH]$^-$ counter anion, which bears an analogy to that between the zinc-bound water molecule in carbonic anhydrase and the Thr-199 residue (Fig. 5). The existence of these hydrogen bonding interactions is consistent with the water molecule attached to a tetrahedral Zn^{II} center being acidic. Although the pK_a of {[Tp$^{Bu^t,Me}$]Zn(OH$_2$)}$^+$ has not been accurately determined due to the complications mentioned above, an estimate of *ca*. 6.5 has been cited,[6b] which is comparable to the value of *ca*. 7 for carbonic anhydrase.

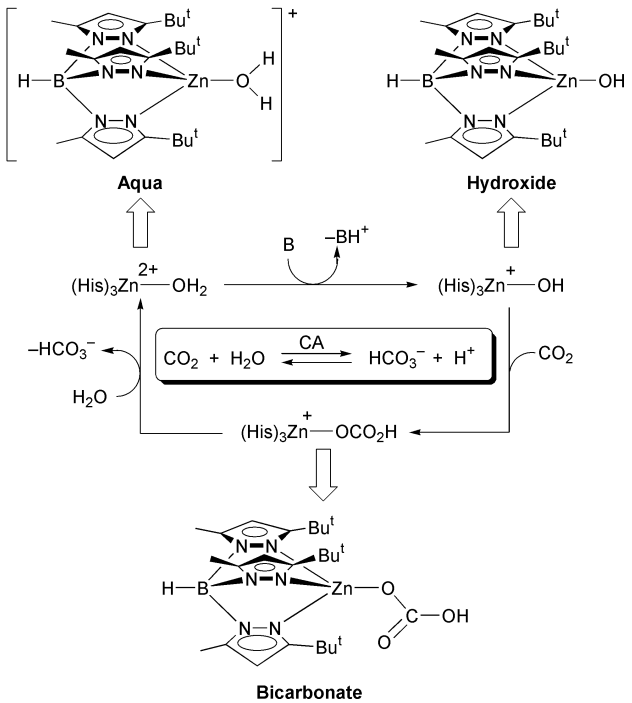
Following deprotonation of the zinc-bound water molecule, the second key step of the mechanism of action of carbonic anhydrase involves the reaction of the nucleophilic zinc–hydroxide group with carbon dioxide to give a bicarbonate intermediate. An excellent precedent for this transformation is provided by the reaction of [Tp$^{Bu^t,Me}$]ZnOH with CO_2 to generate the bicarbonate complex [Tp$^{Bu^t,Me}$]Zn(OCO$_2$H), as illustrated in Scheme 6.[12c] IR spectroscopic studies demonstrate that the bicarbonate ligand is characterized by absorptions at



Scheme 6

1302 and 1675 cm^{-1}, which are indicative of unidentate coordination.

Also of relevance to a catalytic cycle, the formation of the bicarbonate complex [Tp$^{Bu^t,Me}$]Zn(OCO$_2$H) is reversible, and removal of the CO_2 atmosphere results in regeneration of the hydroxide derivative [Tp$^{Bu^t,Me}$]ZnOH (Scheme 6).[12c] Furthermore, ^{1}H NMR spectroscopic studies demonstrate that the equilibration is rapid on the NMR time-scale. Thus, upon addition of CO_2 to [Tp$^{Bu^t,Me}$]ZnOH, the sharp signal attributed to the hydroxide ligand broadens substantially and merges into the base line. The spectroscopic transformation is reversible, and the signal of the hydroxide complex gradually reappears upon progressive removal of the CO_2 atmosphere. The tris(pyrazolyl)hydroborato system has, therefore, allowed direct observation of all three zinc species that correspond to the proposed zinc intermediates of the mechanism of action of carbonic anhydrase, namely aqua, hydroxide, and bicarbonate complexes (Scheme 7). Moreover, their interconversion has



Scheme 7

been shown to be facile. As such, {[Tp$^{Bu^t,Me}$]ZnOH$_2$}$^+$, [Tp$^{Bu^t,Me}$]ZnOH and [Tp$^{Bu^t,Me}$]Zn(OCO$_2$H) represent to date the most thoroughly characterized synthetic analogue system corresponding to carbonic anhydrase.

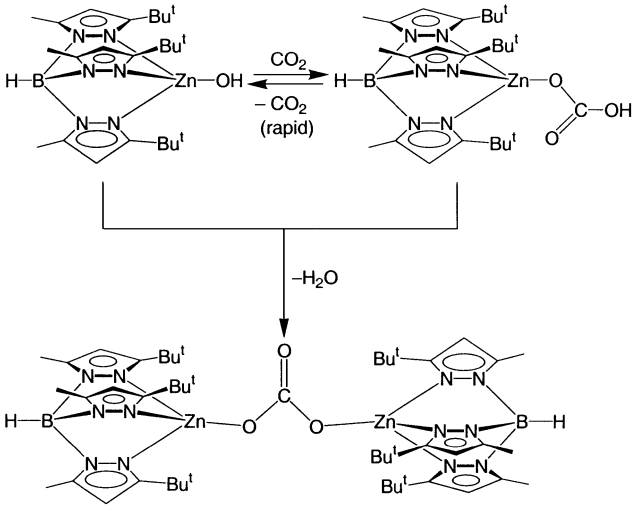
The functional equivalence of [Tp$^{Bu^t,Me}$]ZnOH as a synthetic analogue of carbonic anhydrase has been established by using

^{17}O NMR spectroscopy which demonstrates that [Tp$^{Bu^t,Me}$]Zn-OH is capable of catalyzing the exchange of oxygen atoms between CO_2 and $H_2{}^{17}O$ [eqn. (1)],[12c] a reaction that is also catalyzed by carbonic anhydrase.

$$CO_2 + H_2{}^{17}O \rightleftharpoons CO^{17}O + H_2O \quad (1)$$

Specifically, ^{17}O NMR spectroscopy indicates that, in the presence of a [Tp$^{Bu^t,Me}$]ZnOH catalyst and CO_2, the ^{17}O NMR spectroscopic signal for $H_2{}^{17}O$ in benzene solution is rapidly replaced by the signal for $CO^{17}O$. Under comparable conditions, but in the absence of a [Tp$^{Bu^t,Me}$]ZnOH catalyst, a mixture of $H_2{}^{17}O$ and CO_2 takes several days to reach isotopic equilibrium in benzene solution, thereby clearly demonstrating the efficiency of [Tp$^{Bu^t,Me}$]ZnOH as a functional carbonic anhydrase mimic. Related to the exchange of oxygen atoms between [Tp$^{Bu^t,Me}$]ZnOH and CO_2, the hydroxide complex [Tp^{Ph,Me}]ZnOH reacts with CS_2 to give [Tp^{Ph,Me}]ZnSH and COS.[22]

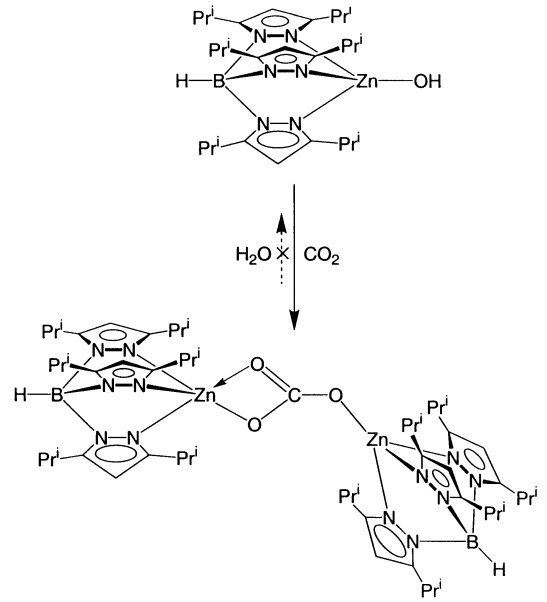
Another aspect of the reaction between [Tp$^{Bu^t,Me}$]ZnOH and CO_2 which deserves mention is that of the condensation reaction between [Tp$^{Bu^t,Me}$]Zn(OCO_2H) and [Tp$^{Bu^t,Me}$]Zn-OH.[12c] Thus, as a result of the facile interconversion between [Tp$^{Bu^t,Me}$]Zn(OCO_2H) and [Tp$^{Bu^t,Me}$]ZnOH, condensation of the latter two molecules may occur to generate a bridging carbonate complex {[Tp$^{Bu^t,Me}$]Zn}$_2$(μ-η^1,η^1-CO_3) which may be isolated over a period of days by virtue of its lower solubility (Scheme 8). The bridging carbonate complex {[Tp$^{Bu^t,Me}$]-



Scheme 8

Zn}$_2$(μ-η^1,η^1-CO_3) is, however, extremely sensitive towards water, thereby regenerating the hydroxide derivative [Tp$^{Bu^t,Me}$]ZnOH.[12c]

The course of the reaction between [Tp$^{RR'}$]ZnOH and CO_2 is strongly influenced by the nature of the pyrazolyl substituents, as illustrated by the reactivity of [Tp$^{Pr^i_2}$]ZnOH towards CO_2 (Scheme 9). Thus, in contrast to the {[Tp$^{Bu^t,Me}$]Zn} system, the bicarbonate complex [Tp$^{Pr^i_2}$]Zn(OCO_2H) is insufficiently stable to be spectroscopically detected and [Tp$^{Pr^i_2}$]ZnOH reacts rapidly with CO_2 to yield the bridging carbonate complex {[Tp$^{Pr^i_2}$]Zn}$_2$(μ-η^1,η^2-CO_3) (Scheme 9), which also differs from that of the {[Tp$^{Bu^t,Me}$]Zn}$_2$(μ-η^1,η^1-CO_3) counterpart by virtue of the nature of the carbonate bridge. In particular, whereas the carbonate ligand in {[Tp$^{Bu^t,Me}$]Zn}$_2$(μ-η^1,η^1-CO_3) binds in a symmetric manner, with unidentate coordination to each zinc center, that in {[Tp$^{Pr^i_2}$]Zn}$_2$(μ-η^1,η^2-CO_3) binds asymmetrically, with unidentate coordination to one zinc center and bidentate coordination to the other zinc center (Scheme 9); the bidentate coordination mode is presumably a consequence of the lower steric demands of the [Tp$^{Pr^i_2}$] ligand. It is also noteworthy that the reactivity of the carbonate ligand towards water is strongly influenced by the nature of the bridge. Thus,



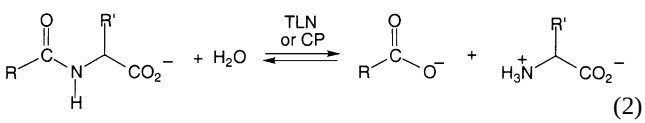
Scheme 9

{[Tp$^{Pr^i_2}$]Zn}$_2$(μ-η^1,η^2-CO_3) is stable towards water (Scheme 9), whereas {[Tp$^{Bu^t,Me}$]Zn}$_2$(μ-η^1,η^1-CO_3) reacts instantaneously to give [Tp$^{Bu^t,Me}$]ZnOH. The significant difference in reactivity emphasizes the extent to which the coordination mode of a carbonate ligand and, by inference, that of a bicarbonate ligand, dictates its stability towards water. Since the final step of the proposed mechanism of action of carbonic anhydrase involves displacement of bicarbonate by water, the above difference in reactivity of {[Tp$^{Pr^i_2}$]Zn}$_2$(μ-η^1,η^2-CO_3) and {[Tp$^{Bu^t,Me}$]-Zn}$_2$(μ-η^1,η^1-CO_3) towards H_2O suggests that factors which promote bidentate coordination of a bicarbonate ligand could inhibit the catalytic cycle. In support of this notion, the increased catalytic activity of [{[12]aneN_4}ZnOH]$^+$ over that of [{[12]aneN_3}ZnOH]$^+$ towards hydration of CO_2 has also been attributed to the greater tendency of the former to form a unidentate, rather than bidentate, bicarbonate intermediate.[23,24]

A final issue concerned with the formation of the bicarbonate intermediate of the catalytic cycle (Scheme 1) is that it requires that the coordinated water be deprotonated prior to reaction with CO_2. Comparative studies on both the hydroxide [Tp$^{Bu^t,Me}$]Zn-OH and aqua {[Tp$^{Bu^t,Me}$]Zn(OH_2)}[HOB(C_6F_5)$_3$] complexes allows this proposal to be confirmed. Thus, whereas [Tp$^{Bu^t,Me}$]-ZnOH reacts rapidly with CO_2 to yield the bicarbonate derivative [Tp$^{Bu^t,Me}$]Zn(OCO_2H), the aqua complex {[Tp$^{Bu^t,Me}$]Zn(OH_2)}$^+$ is inert under comparable conditions (Scheme 6).

(b) The [(His)$_2$(Glu)Zn^{II}–OH_2] motif: thermolysin, carboxypeptidase and neutral protease

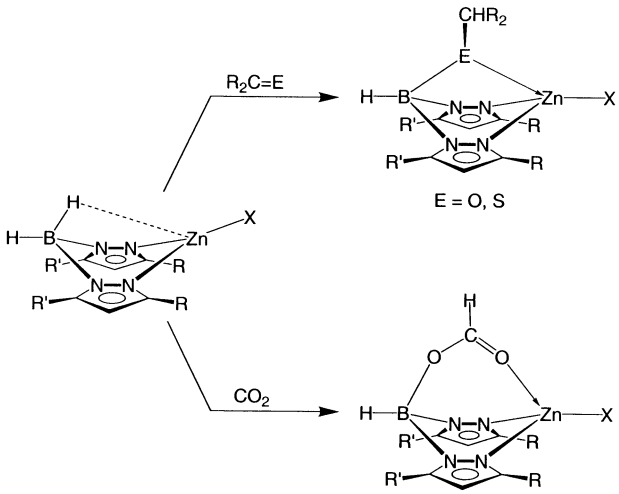
Thermolysin (TLN), carboxypeptidase (CP) and neutral protease are a class of related zinc proteases that are responsible for catalyzing the hydrolysis of peptide bonds [eqn. (2)].



(2)

The active sites of carboxypeptidase, thermolysin, and neutral protease bear a close resemblance, with the zinc centers of each being bound to the protein by a combination of one glutamate and two histidine residues. The similarity between thermolysin

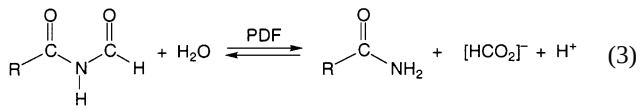
and carboxypeptidase is further emphasized by the fact that the glutamate residue of each enzyme is capable of binding in both a unidentate and bidentate manner. Efforts to obtain synthetic analogues of these enzymes have focused on the use of a variety of tridentate ligands with $[N_2O]$ donor arrays,[25–29] but many of these ligands do not enforce tetrahedral coordination geometries akin to those in the enzymes. For example, ligands such as bis[(3,5-diisopropylpyrazolyl)ethyl] ether, $O(CH_2CH_2pz^{Pr^i_2})_2$, bind with a 'T-shaped' configuration, rather than with the facial configuration required to mimic the tetrahedral coordination in enzymes.[26] The use of a $[N_2O]$ tripod ligand, however, ensures facial binding. Interestingly, such ligands may be constructed directly on the zinc center by insertion of R_2CO (R = H, Ph) or CO_2 into the B–H bond of a bis(pyrazolyl)hydroborato derivative (Scheme 10).[30] The formate derivative $[\eta^3$-$(HCO_2)Bp^{Bu^t,Pr^i}]ZnCl$ that is obtained by reaction of CO_2 with $[Bp^{Bu^t,Pr^i}]ZnCl$ is particularly significant because it is the first structurally characterized tetrahedral zinc complex of a tridentate $[N_2O]$ ligand in which the O-donor is a carboxylate group. Since only one oxygen coordinates to zinc, the complex is better regarded as a synthetic analogue of thermolysin or carboxypeptidase B rather than of carboxypeptidase A. In addition to using boron as a tripod linker, carbon has also been used as a linker atom to prepare the $[N_2O]$ donor ligand $[HC(pz^{Me_2})(C_6H_2MeBu^tO)]^-$, from which the zinc complexes $[HC(pz^{Me_2})(C_6H_2MeBu^tO)]ZnX$ (X = Cl, Me) have been synthesized (Fig. 8).[28]



Scheme 10

(c) The $[(His)_2(Cys)Zn^{II}–OH_2]$ motif: bacteriophage T7 lysozyme and peptide deformylase

The active site of bacteriophage T7 lysozyme, a zinc enzyme which destroys bacteria by cleaving the amide bond between L-alanine and *N*-acetylmuramate moieties of polysaccharide components within their cell walls, consists of a tetrahedral zinc center which is bound to the protein backbone *via* one sulfur and two nitrogen donors of cysteine and histidine residues, with the fourth site being occupied by a water molecule (Fig. 2).[31] The active site of peptide deformylase is similar to that of T7 lysozyme, but recent studies suggest that the zinc form has low activity and that the active form of the enzyme which is responsible for the hydrolytic cleavage of a formyl group [eqn. (3)] is actually an *iron* enzyme.[32]



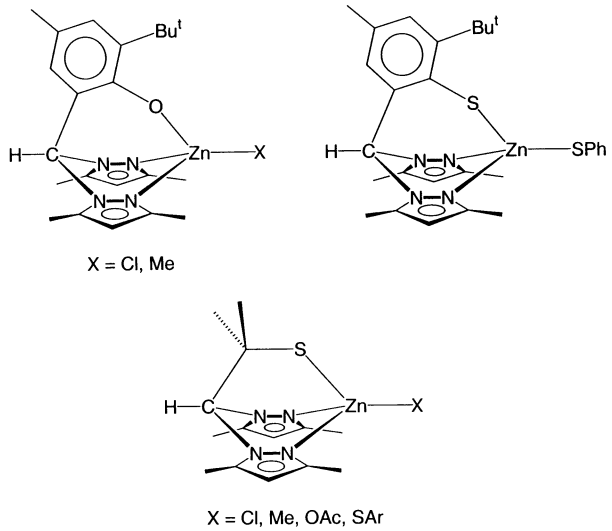


Fig. 8 [NNO] and [NNS] ligands based on the bis(pyrazolyl)methane fragment.

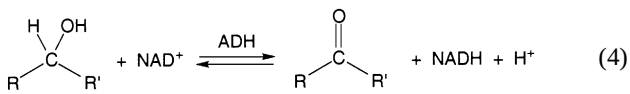
In part due to the propensity of sulfur to act as a bridge between metal centers, tridentate $[N_2S]$ ligands that support monomeric tetrahedral zinc centers analogous to the active sites of peptide deformylase and T7 lysozyme are not common. A second problem is that a variety of studies indicate that the ability of sulfur to coordinate to zinc is very sensitive to the nature of the ligand. For example, the sulfur atom of the thioether derivative $[S(CH_2CH_2pz^{Me_2})_2]ZnCl_2$ does *not* coordinate to zinc.[33] Nevertheless, the use of a tripod construction enforces 'facial' binding of a $[N_2S]$ donor ligand and, by analogy with the $[N_2O]$ ligands $[\{R_2C(H)O\}Bp^{Bu^t,Pr^i}]$ described above, the tetrahedral zinc complex, $[\eta^3$-$\{Ph_2C(H)S\}Bp^{Bu^t,Pr^i}]ZnI$ may be obtained by insertion of Ph_2CS into a B–H bond of $[Bp^{Bu^t,Pr^i}]ZnI$ (Scheme 10).[34] Related complexes, $[HC(pz^{Me_2})_2(C_6H_2MeBu^tS)]ZnSPh$ and $[HC(pz^{Me_2})_2(CMe_2S)]ZnX$ (Fig. 8), derived from $[N_2S]$ ligands that use a carbon, rather than boron, atom linker have also been synthesized.[28,35] Although mononuclear zinc hydroxide complexes of the type $\{[N_2S]ZnOH\}$ have yet to be structurally characterized, it is worth noting that a related dinuclear species has recently been isolated. Thus, only one of the two thioether linkages of the $[N_2S_2]$ bmnpa ligands in the bridging hydroxide complex $\{[(bmnpa)Zn(\mu\text{-}OH)]_2\}^{2+}$ coordinates to each zinc center, such that each zinc adopts a $\{[N_2S]Zn(\mu\text{-}OH)_2\}$ coordination environment [bmnpa = *N*-bis-2-(methylthio)ethyl-*N*-(6-neopentylamino-2-pyridylmethyl)amine].[36a] A dinuclear hydroxide complex with a similar motif, but in which thiosulfate $[S_2O_3]^{2-}$ provides the sulfur ligand, has also been reported.[36b]

(d) The $[(His)(Cys)_2Zn^{II}–OH_2]$ motif: liver alcohol dehydrogenase

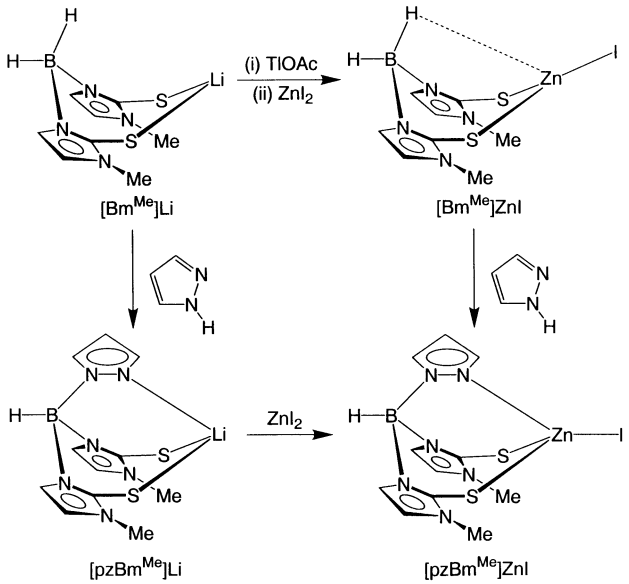
Alcohol dehydrogenases (ADH) belong to an important class of enzymes that catalyze the biological oxidation of primary and secondary alcohols. The oxidations proceed *via* the formal transfer of a hydride anion to the oxidized form of nicotinamide adenine dinucleotide (NAD^+), coupled with the release of a proton [eqn. (4)].



Liver alcohol dehydrogenase (LADH) is the most widely studied of this class of enzymes. X-Ray diffraction studies demonstrate that the active site consists of a zinc center which is coordinated in a distorted tetrahedral manner to a histidine and two cysteine residues of a single polypeptide chain, with a

water molecule occupying the fourth coordination site (Fig. 2). In addition to the catalytic site, there is also a zinc center that is coordinated tetrahedrally to four cysteine residues, which plays a structural role. Although the sulfur-rich composition of the active site of LADH is relatively uncommon for zinc enzymes, two other examples that have similar active sites are spinach carbonic anhydrase[37] and cytidine deaminase.[38] The coordination environment of the catalytic site in LADH is also not well precedented in zinc chemistry. For example, even though a variety of tridentate [NS_2] donor ligands have been synthesized with a view to modeling LADH,[39–41] none of these previous studies has yielded structurally characterized mononuclear tetrahedral complexes that mimic the active site of LADH. The principal problems of these ligands are associated with (*i*) the proclivity of thiolate groups to act as bridging ligands and thus form oligonuclear structures, and (*ii*) the preference of certain tridentate [NS_2] ligands to bind with a meridional (*i.e.* 'T'-shaped) geometry, rather than the facial binding required to mimic the active site of LADH.

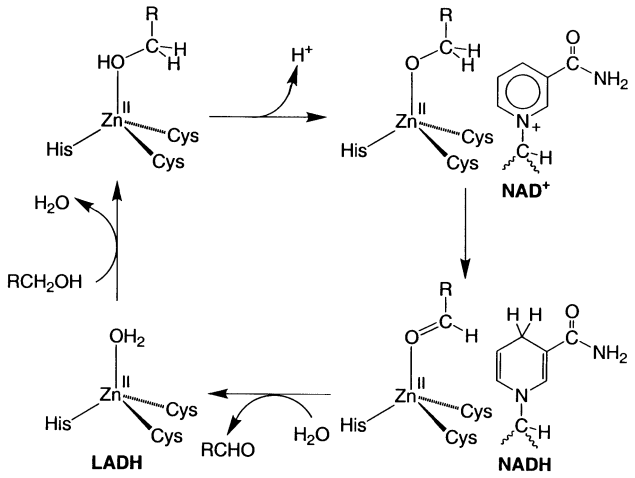
A suitable tridentate [NS_2] donor ligand has, nevertheless, been obtained by reaction of pyrazole with a bis(mercaptomethylimidazolyl)borate derivative.[42] Specifically, the reaction of $LiBH_4$ with methimazole (2 equivalents) yields [Bm^{Me}]Li, from which the [NS_2] donor [$pzBm^{Me}$]Li may be obtained by reaction with pyrazole (Scheme 11). Subsequent transfer of the [NS_2] ligand to zinc is readily achieved by treatment of [$pzBm^{Me}$]Li with ZnI_2, thereby resulting in the formation of [$pzBm^{Me}$]ZnI. Alternatively, [$pzBm^{Me}$]ZnI may be obtained *via* reaction of the [Bm^{Me}]ZnI with pyrazole (Scheme 11).



Scheme 11

The molecular structure of the zinc iodide complex, [$pzBm^{Me}$]ZnI, has been determined by X-ray diffraction which demonstrates that it is indeed mononuclear with a distorted tetrahedral coordination geometry about zinc, and Zn–N and Zn–S bond lengths that are comparable to those within the enzyme. As noted above, the ability of [$pzBm^{Me}$] to provide a facial set of donors is associated with the use of a tetrahedral center as a point of attachment for the donor groups. In this regard, Riordan and coworkers have also recently used tripodal phenylborato ligands to provide [NS_2] donation that is capable of stabilizing monomeric structures, as illustrated by [$Ph(pz)(CH_2SBu^t)_2$]ZnBr and [$Ph(pz^{Bu^t})(CH_2SBu^t)_2$]ZnSPh.[43]

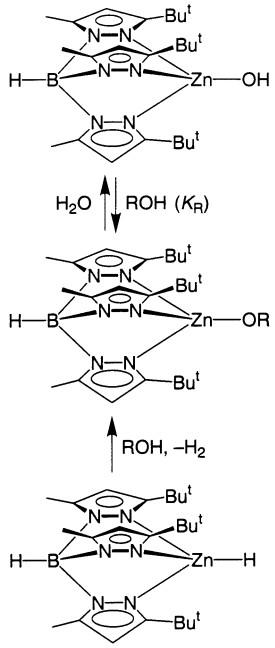
A simplified version of the postulated mechanism of action of LADH is illustrated in Scheme 12, with the essential features involving (*i*) binding NAD^+ (nicotinamide adenine dinucleotide), (*ii*) displacement of the water molecule by alcohol, (*iii*) deprotonation of the coordinated alcohol affording a zinc alkoxide intermediate,[44] *(iv)* hydride transfer from the alkoxide to NAD^+ giving a zinc-bound aldehyde, (*v*) displacement of the aldehyde by water, and (*vi*) release of NADH. The role of the zinc center is, therefore, to facilitate the formation of an alkoxide and thereby enhance hydride transfer to NAD^+. Conversely, in the reverse direction, coordination of the ketone or aldehyde to the zinc center serves to enhance the electrophilicity of the carbonyl carbon atom and thereby promote reduction.



Scheme 12

Interestingly, although the generation of a four-coordinate zinc alkoxide intermediate is an essential step in the catalytic cycle of LADH (Scheme 12), until recently, there was little precedent for the formation of simple aliphatic alkoxide complexes from either zinc aqua or hydroxide derivatives. In view of the non-existence of well defined mononuclear zinc hydroxide complexes with a pseudo-tetrahedral {[NS_2]$Zn^{II}X$} structure, such studies have necessarily focused on complexes with a different structural motif, and specifically those supported by tris(pyrazolyl)hydroborato ligation for which a series of [$Tp^{RR'}$]ZnOH complexes are known. Significantly, ^{1}H NMR spectroscopy demonstrates that the zinc hydroxide [$Tp^{Bu^t,Me}$]-ZnOH complex reacts with ROH (R = Me, Et, Pr^i) to generate the alkoxides [$Tp^{Bu^t,Me}$]ZnOR (Scheme 13);[45] however, in contrast to the reactions of [$Tp^{RR'}$]ZnOH with acidic alcohols (*e.g.* phenols and trifluoroethanol),[46] the simple alkoxides [$Tp^{Bu^t,Me}$]ZnOR (R = Me, Et, Pr^i, Bu^t) are only formed as minor components in an equilibrium mixture (Fig. 9).[45] As such, the alkoxides [$Tp^{Bu^t,Me}$]ZnOR are not readily isolated from the reaction of [$Tp^{Bu^t,Me}$]ZnOH with ROH. It is, therefore, significant that the alkoxides [$Tp^{Bu^t,Me}$]ZnOR may be isolated from the reaction of the hydride complex [$Tp^{Bu^t,Me}$]ZnH with the respective alcohol (Scheme 13). The molecular structure of [$Tp^{Bu^t,Me}$]ZnOEt has been determined by X-ray diffraction, thereby demonstrating its mononuclear tetrahedral nature and confirming its relationship to the proposed intermediate in the mechanism of action of LADH.

An understanding of the factors which influence the stability of tetrahedral zinc alkoxide complexes with respect to hydrolysis is critical to understanding the mechanism of action of LADH. The data presented in Fig. 9 indicate that the equilibrium constant for formation of [$Tp^{Bu^t,Me}$]ZnOR from [$Tp^{Bu^t,Me}$]ZnOH and ROH (R = Me, Et, Pr^i, Bu^t) is highly dependent upon the nature of R, decreasing markedly in the sequence: Me > Et > Pr^i > Bu^t, a trend that is a result of steric and electronic influences (Table 5). Therefore, in an effort to identify the relative importance of these components, the equilibria involving the reactions of [$Tp^{Bu^t,Me}$]ZnOH with a series of *para*-substituted phenols, *p*-XC_6H_4OH, for which electronic substituent parameters (*e.g.* Hammett σ constants) are available, have been studied.[47] Significantly, the data



Scheme 13

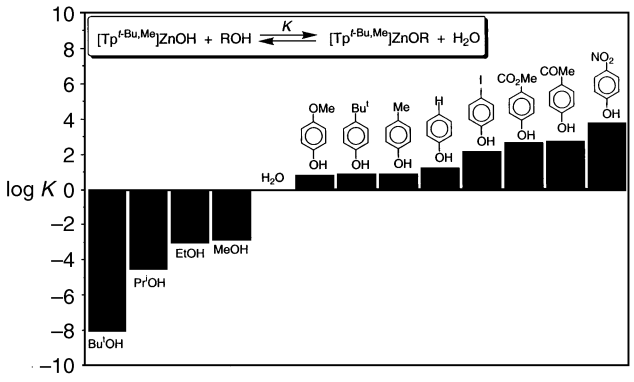


Fig. 9 Variation in alcoholysis equilibrium constant as a function of R.

Table 5 Equilibrium constant and thermodynamic data for alcoholysis reactions of [Tp$^{Bu^t,Me}$]ZnOH with ROH (data taken from ref. 45)

R	K_R(300 K)
Me	$1.4(2) \times 10^{-3}$
Et	$9(2) \times 10^{-4}$
Pr^i	$3(1) \times 10^{-5}$
Bu^t	$\approx 10^{-8}$

presented in Fig. 9 demonstrate that the alcoholysis reactions are very sensitive to electronic influences, being strongly favored for electron withdrawing substituents. Thus, a Hammett plot of log *K vs.* σ gives a good linear correlation with a ρ value of 2.8. The alcoholysis reactions have also been studied computationally using DFT calculations (B3LYP) and the results are in excellent agreement with the experimental results.[47]

The computational study demonstrates that the trend illustrated by the Hammett plot is a consequence of electron withdrawing substituents increasing Zn–OAr BDEs to a greater extent than the corresponding H–OAr BDEs.[47] Thus, rather than exhibit the 1:1 correlation between M–X and H–X bond energies that has been reported for certain other systems,[48] the Zn–OAr BDE is substantially more sensitive to the *para* substituent than is the H–OAr BDE (Fig. 10), *i.e.* D(Zn–OAr) = 1.48 D(H–OAr) − 61 kcal mol^{-1}.[47]

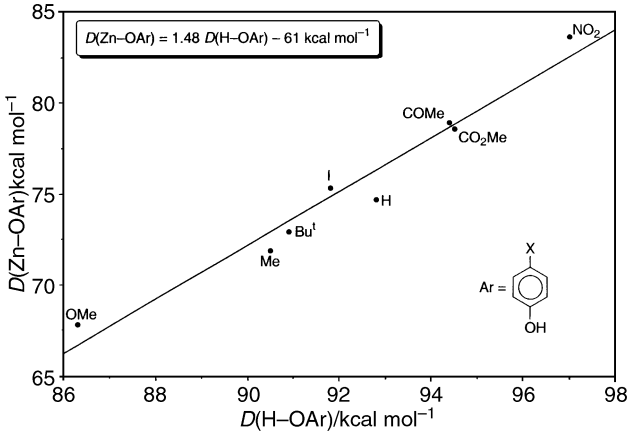

Fig. 10 Correlation of calculated [Zn]–OAr and H–OAr BDEs.

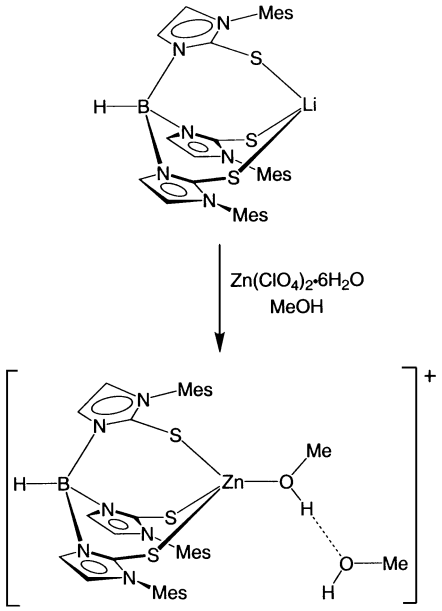
Theoretical studies on phenols have rationalized that the ability of an electron withdrawing *para* substituent to increase the H–OAr BDE is a result of preferential stabilization of the ground state by increasing the delocalization of the electron density from the oxygen atom.[49] On the other hand, electron-donating *para* substituents decrease the H–OAr BDE, but the effect is principally due to stabilization of the ArO• radical, with destabilization of ArOH contributing only to a small degree. The greater influence of an electron withdrawing substituent on the Zn–OAr *vs.* H–OAr BDE is proposed to be a consequence of the $Zn^{\delta+}$–$OAr^{\delta-}$ bond being more polar than the $H^{\delta+}$–$OAr^{\delta-}$ bond, *i.e.* an electron withdrawing substituent would exert a greater influence in stabilizing the partial negative charge on the oxygen atom in [Tp$^{Bu^t,Me}$]ZnOAr than in ArOH.

Calculations on the alkoxides [Tp$^{Bu^t,Me}$]ZnOR (R = Me, Et, Pr^i, Bu^t) indicate that the observed trend is a result of the homolytic Zn–OR BDE decreasing rapidly upon increasing the bulk of R as compared to that for the corresponding H–OR BDE. The greater sensitivity of the Zn–OR BDEs to the bulk of R has been attributed to steric interactions between R and the *tert*-butyl substituents of the [Tp$^{Bu^t,Me}$] ligand in [Tp$^{Bu^t,Me}$]Zn-OR playing a more important role that the interactions between R and H in ROH.[47]

In view of the unfavorable thermodynamics for the formation of the alkoxide derivatives [Tp$^{Bu^t,Me}$]ZnOR from [Tp$^{Bu^t,Me}$]-ZnOH, it is noteworthy that the use of the related tris(mercapto-mesitylimidazolyl)borate ligand [Tm^{Mes}], which features [S_3] rather than [N_3] coordination, favors the formation of an *alcohol* adduct. Thus, the alcohol complex {[Tm^{Mes}]Zn(HOMe)}$^+$ is obtained by reaction of Li[Tm^{Mes}] with $Zn(ClO_4)_2$ in methanol (Scheme 14).[50] This observation indicates that the sulfur rich coordination environment provided by [Tm^{Mes}] stabilizes alcohol binding to zinc and thereby suggests that one of the reasons why LADH utilizes a sulfur rich coordination environment is to increase the stability of the required alcohol intermediate with respect to that of an aqua species.

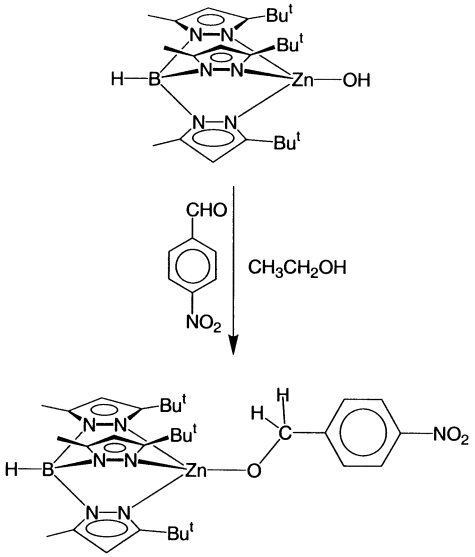
The alcohol coordination mode in {[Tm^{Mes}]Zn(HOMe)}$^+$ resembles aspects of that in LADH. For example, the Zn–O bond length in {[Tm^{Mes}]Zn(HOMe)}$^+$ (1.99 Å) is effectively identical to that in the $C_6F_5CH_2OH$ adduct of LADH (2.0 Å) and the hydroxy group of the coordinated methanol participates in a hydrogen bonding interaction with an additional molecule of methanol, which resembles the hydrogen bond network at the active site of LADH. For example, the hydrogen bonded O···O separation of 2.58 Å in {[Tm^{Mes}]Zn(HOMe)(HOMe)}$^+$ is effectively identical to that between the zinc-bound alcohol at the active site of LADH and Ser-48 (2.6 Å).

A final issue concerned with the proposed role of zinc alkoxide intermediates is their potential for 'hydride' transfer to NAD$^+$. Studies employing *p*-nitrobenzaldehyde as a NAD$^+$ hydride acceptor mimic[51] provide evidence that the alkoxide complexes [Tp$^{Bu^t,Me}$]ZnOR (R = Et, Pr^i) are indeed capable of



Scheme 14

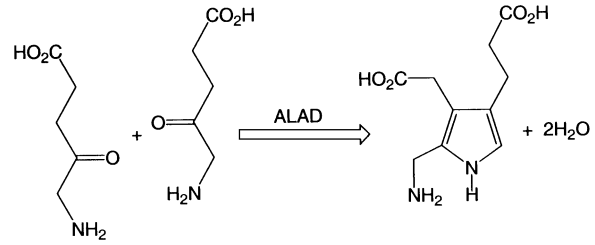
such a transformation. For example, [Tp$^{Bu^t,Me}$]ZnOEt reacts with ArCHO (Ar = *p*-$C_6H_4NO_2$) in benzene to yield [Tp$^{Bu^t,Me}$]ZnOCH_2Ar and MeCHO (Scheme 15). Furthermore, solutions of ArCHO in ROH (R = Me, Et, Pr^i) yield ArCH_2OH at *ca*. 90 °C in the presence of [Tp$^{Bu^t,Me}$]ZnOH.



Scheme 15

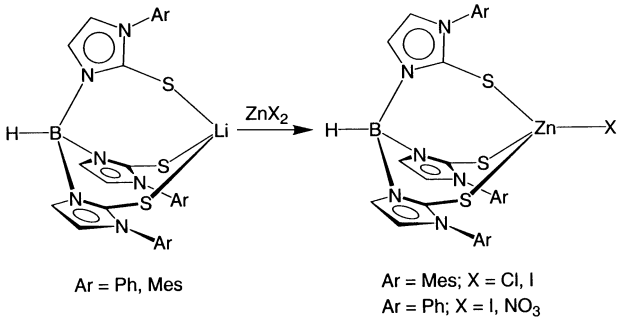
(e) The [(Cys)$_3$Zn^{II}–OH$_2$] motif: 5-aminolevulinate dehydratase

5-Aminolevulinate dehydratase (ALAD), also known as porphobilinogen synthase (PBGS), catalyzes the dimerization of 5-aminolevulinic acid (ALA) to porphobilinogen, a monopyrrole (Scheme 16).[52] This transformation is of considerable importance since it is the first step in the biological synthesis of tetrapyrroles (including heme, chlorophyll and cobalamins). ALAD is a zinc dependent enzyme, containing both catalytic and structural zinc sites, of which the catalytic site possesses the unusual composition of [(Cys)$_3$Zn^{II}(OH$_2$)] (Fig. 2).[53] As discussed above for liver alcohol dehydrogenase, due to the proclivity of sulfur containing ligands to bridge more than one zinc center, mononuclear tetrahedral zinc complexes with sulfur rich coordination environments that mimic the active site of ALAD are not common. Nevertheless, the sterically demanding



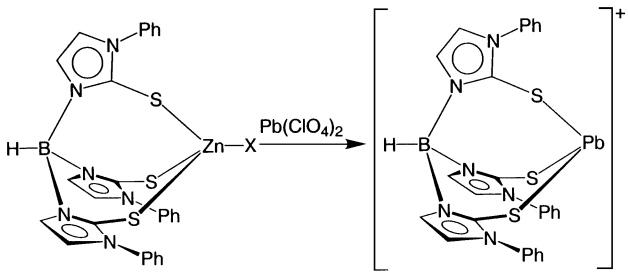
Scheme 16

tris(mercaptoarylimidazolyl)borate ligands, [Tm^{Ar}] (Ar = Ph, Mes), described above may be considered to provide the requisite motif which mimics the three cysteine residues at the active site of ALAD. Thus, a series of [Tm^{Ar}]ZnX complexes have been prepared, *e.g.* [Tm^{Ph}]ZnX (X = I, NO_3) and [Tm^{Mes}]ZnX (X = Cl, I),[50] as illustrated in Scheme 17.



Scheme 17

An important aspect of the chemistry of ALAD is concerned with lead poisoning. Specifically, lead is the most commonly encountered toxic metal pollutant in the environment,[54] and its toxicological properties are associated with its interactions with proteins and, in particular, ALAD.[55] The existence of a series of [Tm^{Ar}]ZnX derivatives has enabled the replacement of zinc by lead in complexes which mimic aspects of the coordination environment in the active site of ALAD to be studied. Significantly, both [Tm^{Ph}]ZnI and {[Tm^{Ph}]Zn(NCMe)}(ClO_4) react rapidly with Pb(ClO_4)$_2$•*x*H_2O to give the lead complex {[Tm^{Ph}]Pb}(ClO_4) (Scheme 18).[56]



Scheme 18

The molecular structure of {[Tm^{Ph}]Pb}$^+$ has been determined by X-ray diffraction (Fig. 11), thereby demonstrating that the trigonal-pyramidal geometry bears a close correspondence to the active site of Pb^{II}–ALAD.[57] For example, {[Tm^{Ph}]Pb}$^+$ and Pb^{II}–ALAD have very similar average Pb–S bond lengths of 2.7 and 2.8 Å, respectively. It is also important to emphasize that the lead coordination environment in {[Tm^{Ph}]Pb}$^+$ is in marked contrast to that of zinc in {[Tm^{Ph}]Zn(NCMe)}$^+$, an observation which clearly indicates that trigonal-pyramidal lead centers have a reduced tendency to bind an additional ligand compared to that of zinc. The reduced Lewis acidity of a three coordinate Pb^{II} center is of significance to the inactivity of Pb^{II}–ALAD since the mechanism of action has been proposed to involve activation of ALA by interaction of the ketone group with the

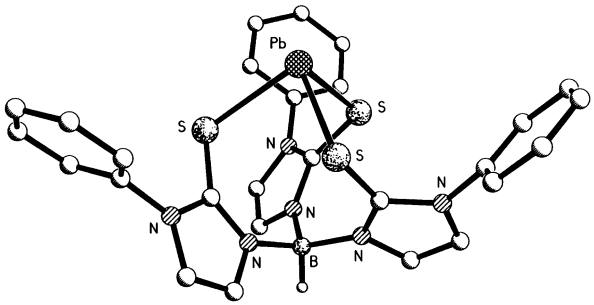


Fig. 11 Molecular structure of {[Tm^{Ph}]Pb}$^{+}$.

Zn^{II} center.[52] The reduced Lewis acidity of a three coordinate Pb^{II} center indicates that the formation of the required tetrahedral intermediate [(Cys)$_3$Pb^{II}–ALA] would be inhibited.

The binding preferences of lead and zinc to ligands which mimic the coordination motif in ALAD is of relevance to obtaining a thorough understanding of the factors responsible for the debilitating effects of lead poisoning. It is, therefore, significant that a study of the equilibrium involving ligand exchange between {[Tm^{Ph}]Pb}(ClO$_4$) and Zn(ClO$_4$)$_2$ in MeCN [eqn. (5)] indicates that the preference of [Tm^{Ph}] to coordinate Pb^{II} over Zn^{II} in this system is *ca.* 500 : 1. This value is substantially greater than the *ca.* 25 : 1 relative affinity of these metals to reside at the active site of human erythrocyte ALAD.[58]

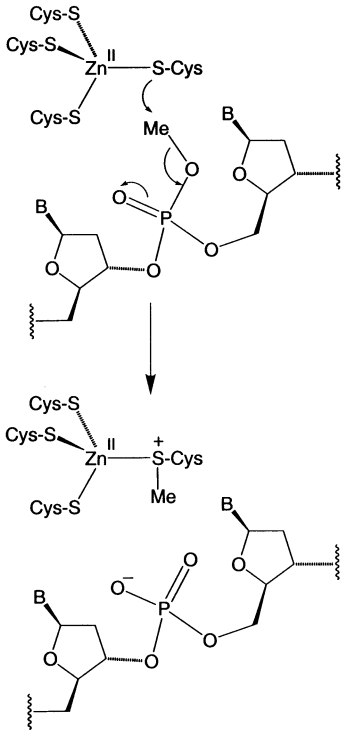
$$\{[Tm^{Ph}]Pb\}^{+} + Zn^{2+} + MeCN \overset{K}{\rightleftharpoons} \{[Tm^{Ph}]Zn(NCMe)\}^{+} + Pb^{2+} \qquad (5)$$

More interestingly, despite the fact that [Tm^{Ph}] prefers to bind to Pb^{II} rather than Zn^{II}, the lead in {[Tm^{Ph}]Pb}$^{+}$ may be replaced by zinc in the presence of NaI. Thus, addition of NaI to a mixture of {[Tm^{Ph}]Pb}(ClO$_4$) and Zn(ClO$_4$)$_2$ in acetonitrile results in the formation of {[Tm^{Ph}]Zn(NCMe)}$^{+}$ due to the equilibrium being shifted to the right by precipitation of Pb^{II} as PbI$_2$. This observation is of relevance since a completely effective means to reverse the toxic effects of lead in the human body are not yet known, despite efforts to develop lead complexing agents.[59]

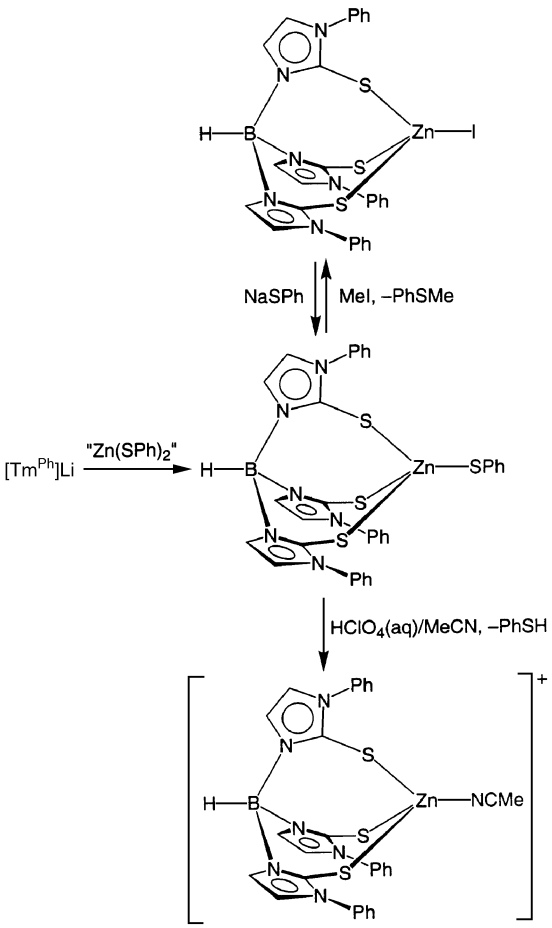
(f) The [(Cys)$_4$Zn^{II}] motif: The Ada DNA repair protein

In addition to the ubiquitous [{XYZ}Zn^{II}–OH$_2$] motif in which the coordinated water molecule plays a critical role, recent studies indicate that zinc may also play an important role by activating thiols towards nucleophilic attack. For example, alkylation of zinc thiolates has been proposed to be a step in the mechanism of action of the Ada DNA repair protein which is responsible for demethylating DNA in a stoichiometric manner (Scheme 19);[60] related zinc thiolate reactivity has also been proposed for other enzymes.[61] The active site of the Ada repair protein possesses a [(Cys)$_4$Zn] motif and has been modeled by the anion [Zn(SPh)$_4$]$^{2-}$.[62] Thus, Wilker and Lippard have reported that [Me$_4$N]$_2$[Zn(SPh)$_4$] reacts with (MeO)$_3$PO to form PhSMe, (MeO)$_2$PO$_2^-$, and [Zn(SPh)$_3$]$^-$ *via* initial heterolytic dissociation generating an incipient thiolate anion. More recently, the thiolate complex [Tm^{Ph}]ZnSPh (Scheme 20) has been introduced as a model for the Ada repair protein, in which the [Tm^{Ph}] ligand mimics the three cysteine residues that remain bound to zinc during the course of the alkylation reaction.[63] The phenylthiolate ligand in [Tm^{Ph}]ZnSPh also possesses nucleophilic character and is alkylated by MeI to give PhSMe and [Tm^{Ph}]ZnI, a transformation that is analogous to the reactivity exhibited by tris(pyrazolyl)borate complexes [Tp$^{RR'}$]ZnSR[64] and other scorpionate thiolates.[65]

Methionine synthases are a class of enzymes related to the Ada protein in that thiolate alkylation is a common feature.[61*a*] The active sites of the various methionine synthases also feature cysteine coordination, and Riordan and coworkers have recently



Scheme 19



Scheme 20

introduced the use of the phenylborato ligands [PhB(CH$_2$SBu^t)$_3$] and [Ph(pz$^{Bu^t}$)(CH$_2$SBu^t)$_2$] as [S$_3$] and [NS$_2$] donors to mimic the active sites in these enzymes (Fig. 12).[43]

In addition to alkylation of zinc–cysteine thiolates, proteolytic cleavage of such groups is of relevance to the mechanism

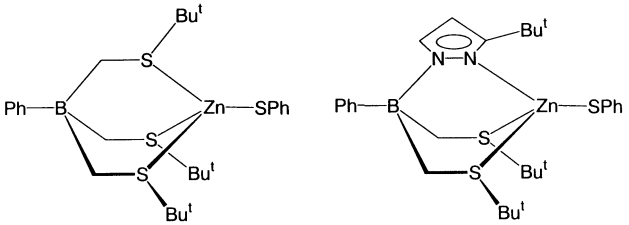


Fig. 12 Methionine synthase mimics.

of action of matrix metalloproteinases (matrixins) which are an important group of zinc enzymes responsible for degradation of the extracellular matrix components.[66] One of the mechanisms for activating the proenzyme involves proteolytic cleavage of the cysteine thiolate residue and a chemical model for this process is provided by the reactivity of $[Tm^{Ph}]ZnSPh$ towards H^+. Specifically, treatment of $[Tm^{Ph}]ZnSPh$ with $HClO_4$ in acetonitrile results in elimination of PhSH and formation of $\{[Tm^{Ph}]Zn(NCMe)\}(ClO_4)$, as illustrated in Scheme 20.

4. Metal ion substitution for probing zinc enzymes

As a result of the poor spectroscopic properties of Zn^{II}, it is difficult to obtain information concerning the structure of the active site of the enzyme and the nature of the intermediates involved in the catalytic cycle. For this reason, considerable effort has been directed towards investigating enzymes in which the zinc has been replaced by various other metals in an effort to incorporate a spectroscopic probe, *e.g.* Co^{II} (UV–vis) and Cd^{II} (NMR).[67] However, the various metal substituted enzymes often exhibit markedly different activities, and so the use of metal ion substitution to provide insight into the mechanism of action depends critically on a knowledge of the chemistry of various metal ions in coordination environments that are closely related to the enzyme active site. Therefore, in an effort to provide such information, the chemistry of other metals in coordination environments related to those of zinc enzymes has also been investigated.

(a) Influence of the metal on active site coordination geometry

Cobalt is the metal that is most commonly substituted into zinc enzymes because it has distinct electronic spectroscopic properties and also has a strong tendency to form tetrahedral complexes. However, structural studies on a series of closely related metal complexes indicate that substitution of zinc in enzymes by other metals is actually likely to have a significant impact on the structure of the active site,[68] as illustrated by the carbonic anhydrase synthetic analogues $\{[Tp^{Pr^i_2}]M(\mu\text{-}OH)\}_n$. Thus, of these derivatives, only the zinc complex $[Tp^{Pr^i_2}]ZnOH$ exists as a tetrahedral terminal hydroxide derivative, whereas the manganese, iron, cobalt, nickel and copper derivatives exist as five-coordinate dinuclear complexes with bridging hydroxide ligands, $\{[Tp^{Pr^i_2}]M(\mu\text{-}OH)\}_2$ (M = Mn, Fe, Co, Ni, Cu)[12d] (Fig. 13).

Interesting differences as a function of metal are also observed for complexes obtained using tris(imidazolyl)phosphine ligands. For example, the reactions of $[Pim^{Pr^i,Bu^t}]$ with $M(ClO_4)_2{\cdot}6H_2O$ (M = Zn, Cd) yield $\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$ and $\{[Pim^{Pr^i,Bu^t}]Cd(OH_2)(OClO_3)\}^+$ which, as illustrated in Fig. 14, possess significantly different structures.[69] Thus, the zinc complex $\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$ exists as a simple tetrahedral hydroxide derivative, whereas the cadmium counterpart is a *five*-coordinate *aqua* complex, $\{[Pim^{Pr^i,Bu^t}]Cd(OH_2)(OClO_3)\}^+$. In addition to the different structures, the fact that

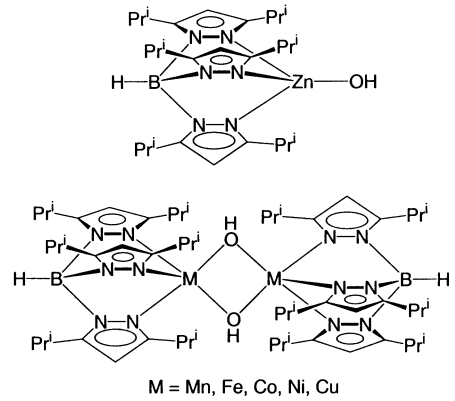

Fig. 13 Mononuclear and dinuclear metal hydroxides.

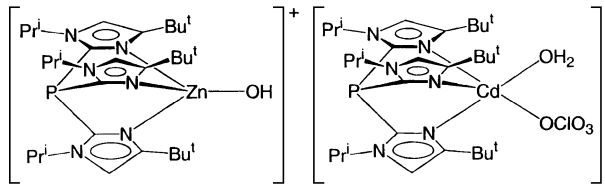

Fig. 14 Comparison of the structures of $\{[Pim^{Pr^i,Bu^t}]ZnOH\}^+$ and $\{[Pim^{Pr^i,Bu^t}]Cd(OH_2)(OClO_3)\}^+$.

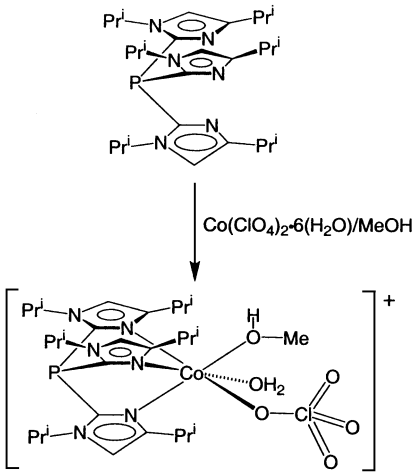
the cadmium center binds a ligand as weakly coordinating as perchlorate is particularly interesting because it indicates that biologically more pertinent anions should also coordinate to a tetrahedral $[\{N_3\}Cd^{II}(OH_2)]$ center and thereby suggests that Cd^{II}–carbonic anhydrase may not be tetrahedral.

The observation that the cadmium complex $\{[Pim^{Pr^i,Bu^t}]Cd(OH_2)(OClO_3)\}^+$ also exists as an aqua species provides a rationalization for the reduced activity of Cd^{II}–carbonic anhydrase since access to a hydroxide species is required for efficient carbonic anhydrase activity. The reluctance of the aqua complex $\{[Pim^{Pr^i,Bu^t}]Cd(OH_2)(OClO_3)\}^+$ to convert to a hydroxide species is a consequence of the coordinated perchlorate ligand since the acidity of a coordinated water molecule is reduced considerably upon the binding of an anionic ligand, *i.e.* the pK_a of the monocation $\{[Pim^{Pr^i,Bu^t}]Cd(OH_2)(OClO_3)\}^+$ would be expected to be greater than that of dicationic $\{[Pim^{Pr^i,Bu^t}]Zn(OH_2)\}^{2+}$. The fact that Cd^{II}–carbonic anhydrase only exhibits significant activity at higher pH (corresponding to the ionization of a cadmium-bound water molecule with a pK_a of *ca.* 9) is in accord with the isolation of the aqua species $\{[Pim^{Pr^i,Bu^t}]Cd(OH_2)(OClO_3)\}^+$, with a higher pH being necessary to generate the requisite hydroxide species.

An investigation of the reaction of $Co(ClO_4)_2{\cdot}6H_2O$ with $[Pim^{Pr^i_2}]$ in methanol also indicates the reluctance of cobalt to form simple tetrahedral cobalt hydroxide complexes by forming the six-coordinate aqua–methanol–perchlorate complex $\{[Pim^{Pr^i_2}]Co(OH_2)(HOMe)(OClO_3)\}^+$ (Scheme 21).[70]

Structural studies on a series of complexes of the bis(2-mercapto-1-methylimidazolyl)(pyrazolyl)hydroborato $[NS_2]$ donor ligand also indicate interesting differences in coordination mode as a function of the metal. Thus, of the $[pzBm^{Me}]_2Zn$, $[pzBm^{Me}]_2Co$ and $[pzBm^{Me}]_2Cd$ derivatives (Fig. 15), only the zinc complex has a tetrahedral $M[S_4]$ structure which resembles the $[(Cys)_4Zn]$ structural sites in enzymes such as LADH. In contrast, the cobalt and cadmium derivatives, $[pzBm^{Me}]_2Co$ and $[pzBm^{Me}]_2Cd$, exhibit structures in which the B–H groups also interact with the metal center. The non-tetrahedral nature of the latter complexes indicates that zinc has a greater preference for tetrahedral $M[S_4]$ coordination, which is in accord with its prevalent role in the structural sites of enzymes.



Scheme 21

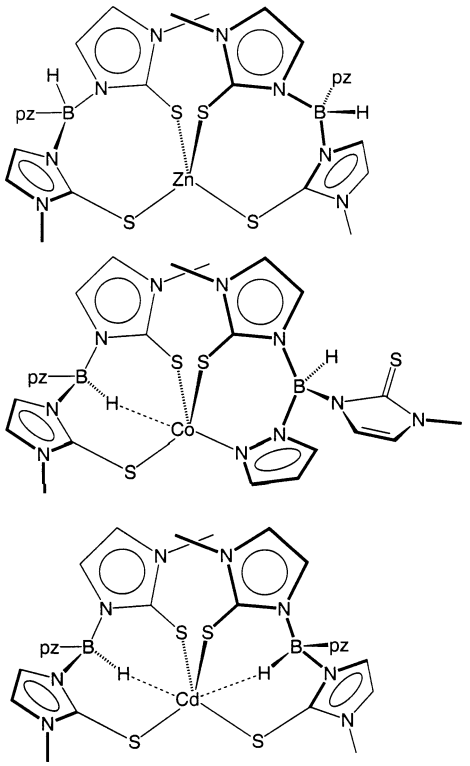


Fig. 15 Structures of $[pzBm^{Me}]_2M$ (M = Zn, Co, Cd) indicating the greater preference of zinc to adopt tetrahedral $M[S_4]$ coordination.

(b) Nitrate ligands as a probe for trends in bicarbonate coordination modes in metal-substituted carbonic anhydrases

The final step of the carbonic anhydrase catalytic cycle, *i.e.* displacement of a bicarbonate ligand by water, is undoubtedly dependent on the coordination mode of the bicarbonate ligand. For example, Co^{II}–carbonic anhydrase is less active than the zinc enzyme and X-ray diffraction studies indicate that the bicarbonate ligand binds in a bidentate manner. An appreciation of the factors that influence the coordination mode of a bicarbonate ligand is, therefore, critical to understanding the relative activities of metal-substituted carbonic anhydrases. However, such a study is presently not possible due to the general instability of bicarbonate complexes, with no zinc bicarbonate complex having been structurally characterized. For this reason, the nitrate ligand has been employed as a probe to provide an indication of the structural variations that would be expected for a series of bicarbonate complexes.[12c,68] Specifically, since bicarbonate and nitrate ligands are isoelectronic and sterically similar, the *variation* in nitrate coordination mode (Fig. 16) for a series of analogous metal complexes is anticipated to correlate with the *trend* observed for analogous bicarbonate complexes.

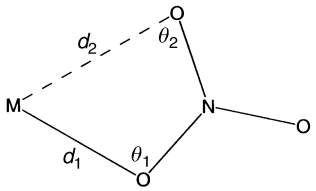

Fig. 16 Parameters used in classifying nitrate coordination mode.

The variation in nitrate ligand coordination mode has been examined for the tris(pyrazolyl)hydroborato and tris(imidazolyl)phosphine complexes, $[Tp^{Bu^t,R}]M(NO_3)$ and $\{[Pim^{Pr^i,Bu^t}]M(NO_3)\}^+$,[68] as summarized in Table 6. Nitrate ligand coordination modes may be classified as either bidentate ($\Delta d < 0.3$ Å; $\Delta\theta < 14°$), anisobidentate ($0.3 < \Delta d < 0.6$ Å; $28 < \Delta\theta < 14°$), or unidentate ($\Delta d > 0.6$ Å; $\Delta\theta > 28°$), depending upon the degree of asymmetry. The data listed in Table 6 indicate that the bidenticity increases in the sequence Zn < Hg < Co < Cu ≈ Ni ≈ Cd, reflecting the different electronic properties of the metals. Steric effects are also important in influencing the coordination mode, as illustrated by the observation that the asymmetry of the nitrate coordination mode decreases across the series $[Tp^{Bu^t}]Zn(NO_3)$,[68a] $[Tp^{Ph}]Zn(NO_3)$,[71] and $[Tp]Zn(NO_3)$[72]

Table 6 Comparison of nitrate coordination mode of $LM(NO_3)^{Q+a}$ with activity of M^{II}–CA (data taken from ref. 68*d*)

M	M^{II}–CA activity (%)	Δd/Å		$\Delta\theta$/°	
		$[Pim^{Pr^i,Bu^t}]$	$[Tp^{Bu^t,R}]^b$	$[Pim^{Pr^i,Bu^t}]$	$[Tp^{Bu^t,R}]^b$
Zn	100	0.53	0.60	24.4	29.6
Co	50	0.27	0.34	10.8	15.8
Ni	2	—	0	—	0
Cu	0	0.13	0	5.9	0
Cd	2	0.13	0.23	7.4	1.8
Hg	0	0.39	—	19.3	—

[a] $Q = 1$ for L = $[Pim^{Pr^i,Bu^t}]$; $Q = 0$ for L = $[Tp^{Bu^t,R}]$. [b] R = H for M = Zn, Co, Cu, Ni; R = Me for M = Cd.

Interestingly, with the exception of mercury, the nitrate coordination mode in these complexes correlates with the activity of metal substituted carbonic anhydrases: Zn > Co >> Cu ≈ Ni ≈ Cd ≈ Hg (Table 6). Specifically, those metals with almost symmetric bidentate coordination are inactive, whereas those with significant asymmetry (Zn and Co) are active. In this regard, it is also noteworthy that the carbonate ligand in the complexes $\{[Tp^{Pr^i_2}]M\}_2(\mu\text{-}CO_3)$ (M = Mn, Fe, Co, Ni, Cu)[12d] exhibits varying degrees of asymmetry that closely parallel the series of nitrate complexes described above, and thereby provides further support for the notion that nitrate is a good model for bicarbonate.

(c) Spectroscopic models

Finally, another use for synthetic analogues is to provide spectroscopic signatures that enable the assignment of the coordination environments of the active sites of metalloenzymes. For example, (*i*) the similarity of the electronic spectrum of blue $[Tp^{Bu^t}]CoCl$[68b] with that of the high pH form of Co^{II}–carbonic anhydrase is consistent with the notion that the active site exhibits a pseudo-tetrahedral coordination geometry,[67] (*ii*) comparison of the electronic spectra of purple $[Tp^{Bu^t}]NiCl$, yellow $[Tp^{Bu^t}]Ni(\eta^2\text{-}O_2NO)$ and green $[Tp^{Me_2}]Ni(\eta^2\text{-}O_2NO)(THF)$,[68b] with the electronic spectrum of Ni^{II}–carbonic anhydrase supports the notion that nickel is six-coordinate in the enzyme at neutral pH, and (*iii*) comparison of the electronic spectrum of Cu^{II}–carbonic anhydrase with those

of [Tp$^{Bu^t}$]CuCl and [Tp$^{Bu^t}$]Cu(η^2-O_2NO) indicates a greater similarity to the five-coordinate structure.[68b]

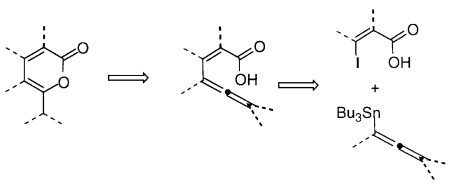
Palladium-catalysed regio- and stereoselective annulation of allenyl stannanes by β-iodo vinylic acids gives the corresponding α-pyrones in high yields. This annulation most probably proceeds through a Stille reaction/cyclisation sequence.

Five- and six-membered ring unsaturated lactones (butenolides or pyrones) constitute an important class of biologically active compounds and their synthesis has been the focus of considerable attention in synthetic organic chemistry[1] as well as in medicinal chemistry.[2] Numerous methods reported in the last decade for the synthesis of these structures involve transition metal (Ag, Hg, Rh, Pd) promoted intramolecular additions of carboxylic acids to alkynes.[3] In general, the lactonisation reaction of alk-4-ynoic acids proceeds through a stereoselective *trans* addition reaction *via* a *5-exo* process. In addition to the formation of γ-alkylidenebutenolides, in some cases six-membered lactones resulting from the *6-endo* mode have been obtained as minor products. This problem of regioselectivity was recently solved by Larock *et al.* who demonstrated that substituted isocoumarins or α-pyrones could be prepared by treating β-halogeno α,β-unsaturated esters with internal alkynes in the presence of a palladium catalyst.[4] Nevertheless, two α-pyrone regioisomers were obtained in the case of non-symmetric alkynes. On the other hand, we have previously described the synthesis of dienoic acids or enynes bearing a carboxylic acid function from β-iodovinylic acids and vinyltin or alkynylzinc reagents.[5] This methodology was then applied to the synthesis of γ-tributyltin methylidenebutenolides.[6] To broaden our synthesis strategy and to design a system suitable for *6-endo* lactonization, we planned the preparation of allenyl substituted alkenoic acids which we thought would exclusively undergo *6-endo* mode cyclisation mediated by a palladium complex (Scheme 1).[7]

We report here the selective one pot synthesis of α-pyrones under palladium complex catalysis. Our investigation began with the coupling of tributylstannylallene[8] with (*Z*)-3-iodoprop-2-enoic acid[5] under conditions previously defined by our group.[6] Unfortunately, neither allenyl substituted propenoic acid nor cyclised products (5- or 6-membered ring lactones) were detected. Only a large amount of tin by-products were recovered, among them the tributylstannyl ester of the starting iodovinylic acid. In order to avoid the proteolysis of allenylstannane and to promote the cross coupling reaction, we examined the reaction under various conditions (solvent, catalyst, presence of additives,...). First the influence of the nature of the carboxylic acid derivative on conversion rates was examined. In DMF and in the presence of 1% of tetrakis(triphenylphosphine)palladium,† the ethyl ester of **1a** yielded exclusively ethyl hex-2-en-4-ynoate. The use of tributyltin carboxylate (Table 1 entry 4) under identical conditions to those used for the synthesis of tributyltin methylidenebutenolides, led to 52% yield of 6-methylpyran-2-one **3a**, without any trace of hexa-2,4,5-trienoic acid. Finally, we found that an 83% yield of **3a** could also be obtained from **1a** at rt in DMF using 5% palladium acetate, triphenylphosphine, sodium carbonate and tetrabutylammonium bromide.



Scheme 1

Next the nature of the solvent and of the palladium complexes were examined. THF was found to be ineffective whereas acetonitrile afforded a very poor yield (< 25%) of cyclised product. We also observed that phosphine-liganded palladium appeared to be more efficient than other palladium salts such as

Table 1 Synthesis of αpyrones

Entry	R (**1**)	Allenylstannane	α-Pyranone	Yield (%)

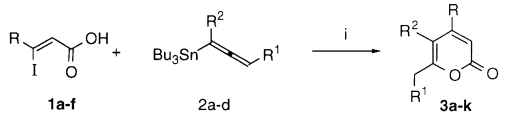
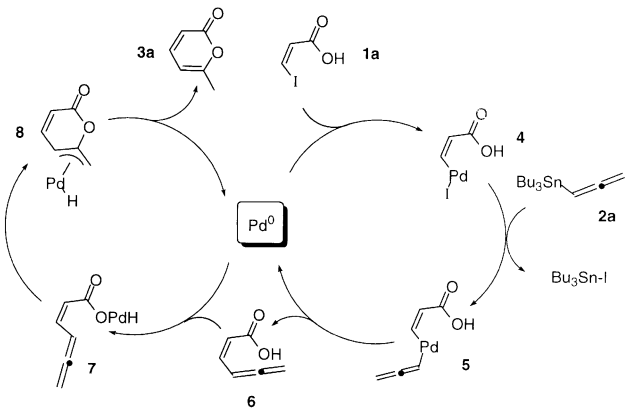


Scheme 2 $Pd(OAc)_2$ (5%), PPh_3 (10%), Na_2CO_3 (4 eq.), *n*-Bu_4NBr (1 eq.), DMF, rt.

palladium acetate (without additional triphenylphosphine) or bis(acetonitrile)palladium chloride. Tetrakis(triphenylphosphine)palladium gave approximately identical yields to the $Pd(OAc)_2/PPh_3$ couple.

The reaction of tributylstannylallene with a range of (*Z*)-3-substituted 3-iodoprop-2-enoic acids under regio- and stereocontrol gave good yields of 4-substituted-6-methylpyranones **3a**–**f** as the sole products (Table 1 entries 1–6) (Scheme 2). Other allenylstannanes were used under similar conditions in order to determine the scope of the reaction. High regioselectivity was observed in each case. The use of 3-alkylallenylstannanes (entries 7–10) showed that the regioselective heteroannulation reaction occurred only on carbons 1 and 2 of the allenyltin. On the other hand, γ-alkylidenepyranones previously obtained by Larock *et al*. from a reaction of allenes with (*Z*)-3-iodopropenoic acids were not observed. This almost certainly indicates a different mechanism to those proposed by Larock and Yamamoto respectively.[9,10]

A plausible mechanism for the heteroannulation reaction is shown in Scheme 3. First, a Stille mechanism[11] would yield 3-allenylpropenoic acid **6** by oxidative addition, transmetallation (formation of **5**) and reductive elimination. Cyclisation would then occur *via* an attack on the carboxylate function at the β-position of the allenyl moiety, which would give the π-allylpalladium intermediate. The latter would subsequently provide α-pyrone and regenerate the palladium(0) catalyst.[12]



Scheme 3 Postulated mechanism for heteroannulation.

An alternative pathway involving the attack of **4** on the central carbon atom of the stannylallene **2a** could be excluded on the basis of the experiments conducted with 1 or 3-substituted allenylstannanes since other regioisomers should have been obtained rather than **3h**–**g**‡.[9]

In conclusion, under palladium complex catalysis, β-iodovinylic α,β-unsaturated acids react with allenyl stannanes *via* heteroannulation selectively to provide diverse α-pyrones. Studies to extend this reaction to other γ-halogeno pronucleophiles are currently under way and will be reported in due course.

Notes and references

† General procedure for the heteroannulation summarised in Table 1: palladium acetate (112 mg, 0.5 mmol), triphenylphosphine (131 mg, 0.5 mmol), tetrabutylammonium bromide (3.2 g, 10 mmol) and sodium carbonate (5.3 g, 50 mmol) were progressively added to a degassed solution of 3-substituted-3-iodopropenoic acid **1** (10 mmol) in anhydrous DMF (40 mL). The mixture was stirred at rt for 10 min and allenylstannane **2** (10 mmol) was then added. The reaction mixture was stirred for 4 h. After conversion was complete (checked by TLC; reaction time < 10 h), the reaction was quenched with aqueous NH_4Cl solution. After ether extraction (3 × 20 mL) and usual treatments, the crude products were chromatographed on silica gel to obtain compounds **3a**–**k**. All new compounds were fully characterised spectroscopically.

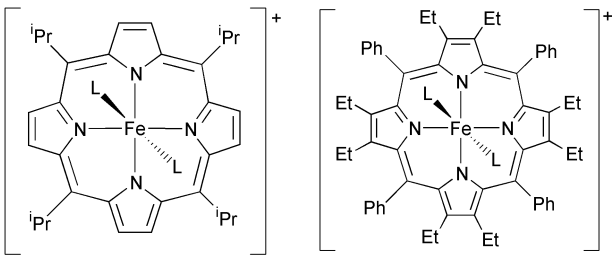
Received (in Cambridge, UK) 25th July 2000, Accepted 29th August 2000
First published as an Advance Article on the web 27th September 2000

Bis(thf)(porphyrinato)iron(III) complexes with highly S_4-ruffled and S_4-saddled porphyrin cores are determined to be very pure intermediate spin complexes on the basis of NMR, EPR, Mössbauer, and magnetic data.

Iron(III) porphyrins with an intermediate spin state (S = 3/2) have attracted much attention since Maltempo pointed out the important contribution of this spin state in certain bacterial heme proteins known as cytochromes c′.[1] Among various attempts to prepare complexes with the intermediate spin state, the use of anionic ligands with a very weak ligand field, such as ClO_4^-, has brought about successful results.[2–5] In general, iron(III) ions of these complexes are in the admixed intermediate spin state represented as S = 5/2,3/2.[6] Thus, Reed and Guiset ranked the relative field strengths of weak axial ligands on the basis of the characteristics of the admixed spin state and called the hierarchy a magnetochemical series.[7] Cheng and coworkers reported that highly saddle shaped [Fe(OETPP)Cl] is in the admixed S = 5/2,3/2 spin state in spite of the presence of the much stronger chloride ligand at the axial position.[8,9] Weiss and coworkers quite recently reported, however, that the S = 3/2 character in these complexes is much smaller than originally reported.[10] We have been interested in the effects of nonplanar porphyrin rings on the physicochemical properties of iron(III) porphyrin complexes.[11–13] We have anticipated that the iron(III) complexes of highly nonplanar porphyrins such as [Fe(T^{i}PrP)(THF)$_2$]ClO_4 (**1**) and [Fe(OETPP)(THF)$_2$]ClO_4 (**2**)



[Fe(T^{i}PrP)(L)$_2$]ClO_4
1: L = THF

[Fe(OETPP)(L)$_2$]ClO_4
2: L = THF

could show a very pure intermediate spin state as compared with well characterized [Fe(TPP)(THF)$_2$]ClO_4, since the $d_{x^2-y^2}$ orbitals in the deformed porphyrin complexes are destabilized by the short Fe–N bond lengths.[8,13] In this paper, we report that strongly S_4-ruffled **1** and S_4-saddled **2** actually show very pure intermediate spin states.

1 was prepared from $AgClO_4$ and [Fe(T^{i}PrP)Cl] in THF solution. The purple crystals were recrystallized from THF/heptane. The ^{1}H NMR spectrum taken at 233 K showed the pyrrole signal at −52.1 ppm and the CH and CH_3 signals at 9.8 and 4.8 ppm, respectively. Two signals at 14.4 and 20.5 ppm,

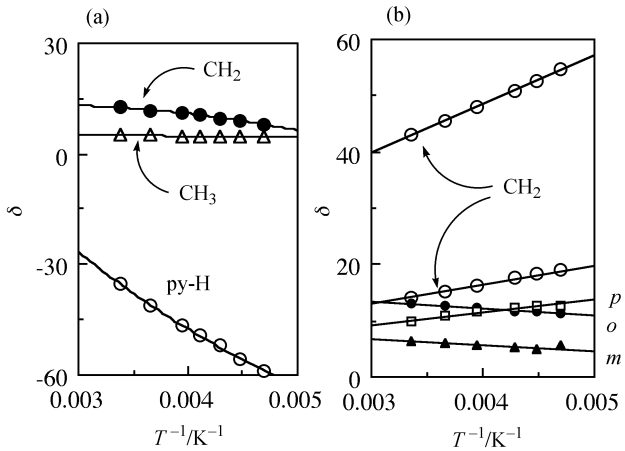


Fig. 1 Temperature dependence of the ^{1}H NMR chemical shifts of some protons in (a) **1** and (b) **2** taken in CD_2Cl_2 solution.

each corresponding to 8H, were assigned to the methylene protons of the coordinated THF ligands; these signals disappeared when the sample recrystallized from THF-d_8/heptane was used. Fig. 1a shows the temperature dependence of the chemical shifts of some protons. The existence of the extremely upfield shifted pyrrole signal indicates that **1** is in the admixed intermediate (S = 3/2,5/2) spin state where the S = 3/2 state is the main contributor.[7] The downfield shift of the THF signals can be explained in terms of the occupancy of an unpaired electron in the d_{z^2} orbital; the unpaired electron in this orbital is transferred to the axial ligand *via* σ bonding to induce downfield shifts of the ligand signals. Fig. 2a shows the EPR spectrum taken in frozen CH_2Cl_2 solution at 4.2 K. The g values were

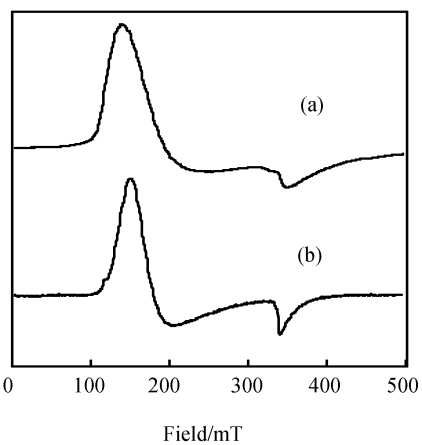

Fig. 2 EPR spectra of (a) **1** and (b) **2** taken in frozen CH_2Cl_2 solution at 4.2 K.

DOI: 10.1039/b006006m

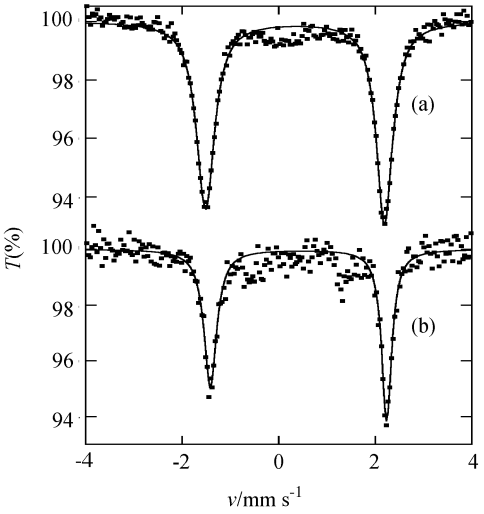

Fig. 3 Mössbauer spectra of (a) **1** taken at 76 K and (b) **2** taken at 290 K.

estimated to be 3.99 and 1.97, suggesting that the spin state of **1** should be regarded as $S = 3/2$ at 4.2 K. Magnetic moments taken for the solid sample by SQUID showed almost constant values, 3.90 ± 0.10 μ_B at 50–300 K, which are quite close to the spin only value $\mu = 3.87$ μ_B expected for $S = 3/2$ complexes. Fig. 3a shows the Mössbauer spectrum measured on a microcrystalline sample at 76 K. The isomer shift (δ; relative to α-iron foil) and quadrupole splitting (ΔE_q) were determined to be 0.34 and 3.71 mm s^{-1}, respectively. Large ΔE_q values are usually observed for complexes with $S = 3/2$ or $S = 3/2,5/2$.[14] Taken together, it is concluded that **1** is a highly pure intermediate spin complex.

2 was similarly prepared from [Fe(OETPP)Cl] and $AgClO_4$ in THF solution. The coordination of the THF ligands was confirmed by ^{1}H NMR analysis. Fig. 1b shows the temperature dependence of the chemical shifts of some protons. Fairly large downfield shifts of the methylene signals, 51.0 and 17.5 ppm at 233 K, clearly indicate that the β-pyrrole carbons have a considerable amount of π-spin density. Fig. 2b shows the EPR spectrum taken in frozen CH_2Cl_2 solution at 4.2 K. The *g* values were 4.01 and 2.00, suggesting that the spin state of **2** should also be represented as $S = 3/2$ at 4.2 K. The spin state was further confirmed by the magnetic moments determined by the Evans method in CH_2Cl_2 solution as well as by SQUID magnetometry in the solid; the former showed the magnetic moment to be 4.0 ± 0.1 μ_B at 193–303 K, and the latter gave values 3.85 ± 0.05 μ_B at 20–300 K. Fig. 3b shows the Mössbauer spectrum measured on a microcrystalline sample at 290 K. The δ and ΔE_q values were determined to be 0.50 and 3.50 mm s^{-1}, respectively. Taken together, it is concluded that **2** is also a very pure intermediate spin complex.

Formation of the very pure intermediate spin complexes, **1** and **2**, indicates that the $S = 3/2$ state is stabilized in both ruffled and saddled porphyrin complexes. The major reason must be the short Fe–N(porphyrin) bond lengths commonly observed in highly deformed porphyrin complexes.[8,15] We have recently determined the crystal structure of **1**.[16] As expected, **1** has a strongly S_4-ruffled porphyrin core with the *meso*-carbons deviating above and below the average porphyrin plane by *ca*. 0.68 Å. The Fe–N(porphyrin) bond distances of **1**, av. 1.967(12) Å, are significantly shorter than those of other bis(THF) complexes such as $[Fe(OEP)(THF)_2]ClO_4$ (av. 1.994 Å),[4] $[Fe(TEtP)(THF)_2]ClO_4$ (av. 2.006 Å)[17] and $[Fe(TPP)(THF)_2]ClO_4$ (av. 2.016 Å).[18]

In conclusion, we have shown that highly S_4-ruffled **1** and S_4-saddled **2** are highly pure intermediate spin complexes on the basis of the NMR, EPR, Mössbauer, and magnetic data.

This work was supported by a Grant-in-Aid for Scientific Research (No. 10640551) from the Ministry of Education, Science, Culture and Sports of Japan. Thanks are due to the Research Center for Molecular Materials, the Institute for Molecular Science, for assistance in obtaining the low-temperature spectra. The authors are grateful to Dr Hiroshi Fujii, Dr Yasuhiro Funahashi, and Mr Masahiro Sakai of the Institute for Molecular Science for assistance with the SQUID measurements.

Synthesis and characterization of the monomer Ga{(NDippCMe)$_2$CH} (Dipp = C$_6$H$_3$Pr$^i_2$-2,6): a low valent gallium(I) carbene analogue

Ned J. Hardman, Barrett E. Eichler and Philip P. Power*

First published as an Advance Article on the web 27th September 2000

The reaction between solvent free Li{(NDippCMe)$_2$CH} (Dipp = C$_6$H$_3$Pr$^i_2$-2,6), 'GaI' and potassium in toluene afforded Ga{(NDippCMe)$_2$CH} 1 which features a V-shaped, two-coordinate, six-electron gallium(I) center electronically analogous to a singlet carbene carbon.

Neutral, molecular derivatives of low-valent gallium usually exist as Ga–Ga bonded tetramers[1] or hexamers[2] of formula $(GaR)_4$ or $(GaR)_6$ which may dissociate to monomers in either the vapor or the solution phase.[3] Lower degrees of aggregation than four are extremely rare in the solid state, and the monomeric compound Ga(Tp$^{Bu^t_2}$) [Tp$^{Bu^t_2}$ = tris(3,5-di-*tert*-butylpyrazolyl)hydroborato] is the only such example to have been well characterized. In this species, the bulky tridentate Tp$^{Bu^t_2}$ ligand prevents association by coordinatively saturating the gallium center to afford a complex with four electron pairs in the metal valence shell.[4] In related work it has been demonstrated that the anion of the salt [K(18-crown-6)(thf)$_2$][Ga{N(Bu^t)CH}$_2$] contains a two-coordinate gallium center that has just three valence electron pairs and is electronically analogous to a carbene carbon.[5] In addition, the use of extremely bulky terphenyl ligands in the compounds MC$_6$H$_3$Trip$_2$-2,6 (M = In or Tl; Trip = C$_6$H$_2$Pr$^i_3$-2,4,6) has shown that unassociated, low valent, one-coordinate, monomers with only two electron pairs in the metal valence shell can be stabilized.[6]† In attempting to extend this work to lower valent gallium we were struck by the close steric resemblance (Fig. 1) between the terphenyl ligand C$_6$H$_3$Trip$_2$-2,6[7] and the Dipp substituted β-diketiminate ligand (NDippCMe)$_2$CH (Dipp = C$_6$H$_3$Pr$^i_2$-2,6).[8] This led to the hypothesis that the use of a crowded β-diketiminate ligand should stabilize a Ga(I) derivative with a low degree of aggregation. The synthesis and characterization of such a compound are now described.

Yellow crystals of Ga{(NDippCMe)$_2$CH} **1** were obtained‡ by the reaction of Li{(NDippCMe)$_2$CH} with "GaI"[9] and subsequent treatment with potassium to reduce any I$_2$Ga{(NDippCMe)$_2$CH} formed in the reaction. Compound **1** was characterized by ^{1}H and ^{13}C NMR spectroscopy, UV-VIS and IR spectroscopy and C, H elemental analyses. These data were consistent with the structure (Fig. 2) obtained by X-ray crystallography§ which showed that the molecule is monomeric and has a V-shaped two-coordinate geometry at gallium. The central GaN$_2$C$_3$ ring atoms, the C(4) and C(5) methyl carbons, and the *ipso*-carbons C(6) and C(18) are essentially coplanar. The substituent aryl (Dipp) ring planes are oriented at angles of 88.2 and 89.2° with respect to the plane of the GaN$_2$C$_3$ ring. The C–C and N–C distances within this ring are similar to those previously reported for this ligand.[10]

The most interesting structural features in **1** concern; (a), the two-coordinate environment at gallium, (b), the Ga–N distances which average 2.054(2) Å, and (c) the NGaN angle of 87.56(6)°. The Ga–N distances in **1** are relatively long in view of the low coordination number of the gallium atom, and do not support the presence of significant multiple Ga–N bond character which might have arisen from delocalization of the π-electrons of the C$_3$N$_2$ ring moiety. Instead, the bonding in **1** is probably best viewed as involving a Ga$^+$ ion complexed by the bidentate, monoanionic ligand [(NDippCMe)$_2$CH]$^-$. The increased ionic and less directional character of the Ga–N bonds are also consistent with the narrow N–Ga–N angle. The Ga–N distances in **1** are shorter than the 2.230(5) Å observed in Ga(Tp$^{Bu^t_2}$)[4] as a result of the lower metal coordination number. On the other hand, the Ga–N distances in [Ga{N(Bu^t)CH}$_2$]$^-$ [Ga–N 1.985(6) Å][5] are shorter than those observed in **1**, probably as a result of the lower steric effects of the {N(Bu^t)CH}$_2$ ligand.¶ The relatively long Ga–N distances in these monovalent complexes are underlined by the fact that the trivalent digallium species {HC(Bu^t)N}$_2$Ga–Ga{N(Bu^t)CH}$_2$[11] {which has the same ligand as that in [Ga{N(Bu^t)CH}$_2$]$^-$} has Ga–N distances of 1.836(4) and 1.839(6) Å. These values are typical of those found for three-coordinate Ga–N bond lengths in trivalent complexes with similarly sized ligands.[12]

A significant feature of interest in **1** is the presence of a lone pair of electrons at gallium which suggests that this ligand will display significant Lewis base chemistry. Experiments on this aspect of **1** are in progress.

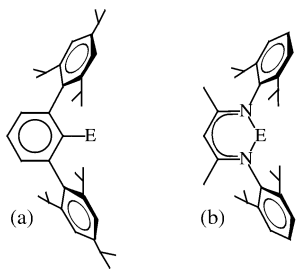

Fig. 1 Schematic drawing of the C$_6$H$_3$Trip$_2$-2,6 (Trip = C$_6$H$_2$Pr$^i_3$-2,4,6) and (NDippCMe)$_2$CH (Dipp = C$_6$H$_3$Pr$^i_2$-2,6) ligands illustrating their steric resemblance and the protection they afford the bound site E.

† $GaC_6H_3Trip_2$-2,6 has been stabilized as an iron carbonyl complex in which the gallium is two coordinate.[6c]

‡ All manipulations were carried out under anaerobic and anhydrous conditions. Crystals of Li{$(NDippCMe)_2CH$} were synthesized by the reaction of H{$(NDippCMe)_2CH$}[8] with Bu^nLi and grown from toluene. The structure of this lithium salt consists of weakly associated monomers in the crystal phase. Crystals of Li{$(NDippCMe)_2CH$} (2.2 g, 5.2 mmol) in toluene (30 mL) were added dropwise to a well stirred slurry of 'GaI'[9] (1.5 g, 7.6 mmol) in toluene with cooling in a dry ice/acetone bath. The mixture was allowed to come to room temperature overnight and cooled again with a dry ice/acetone bath, whereupon excess potassium (0.5 g, 12.8 mmol) was added by a solids-addition tube. After stirring for 1 h the solution was allowed to warm to room temperature overnight. The resultant red solution was filtered and the volume was reduced to incipient crystallization (10 mL). Storage at *ca*. −20 °C for 48 h afforded yellow crystals of **1** (0.97 g, yield 39%); Anal. Calc. (found) for $C_{29}H_{41}GaN_2$: C, 71.46 (71.90), H, 8.48 (8.86)%. Remarkable cumulative stereoselectivity in cyclopropanation with supramolecular Cu(I) catalytic complexes

Tomislav Portada, Marin Roje, Zlata Raza, Vesna Čaplar, Mladen Žinić* and Vitomir Šunjić*

Department of Organic Chemistry and Biochemistry, Rudjer Bošković Institute, 10001 Zagreb, Croatia. E-mail: zinic@rudjer.irb.hr

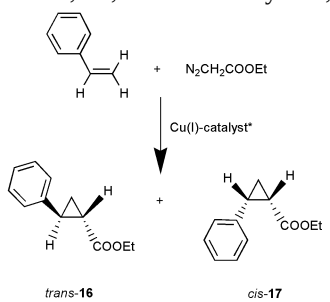
Received (in Liverpool, UK) 24th July 2000, Accepted 30th August 2000
First published as an Advance Article on the web 27th September 2000

Supramolecular Cu(I) catalyst 1 exhibited 77% cumulative (dia- and enantio-) stereoselectivity and one of the highest diastereoselectivities (86% de) obtained to date in the cyclopropanation of styrene with ethyl diazoacetate.

Enantioselective transformations based on the use of chiral organometallic catalysts present one of the most important strategies for production of enantiomerically pure compounds.[1,2] On the other hand, extensive development of supramolecular chemistry enabled syntheses of the cavity-containing receptor molecules capable of binding and recognition of selected substrate molecules.[3,4] Design of cavity-containing supramolecular catalysts with a built in organometallic catalytic center presents an attractive but until now lesser explored possibility.[5]

Here we describe the first approach to a chiral supramolecular catalyst for enantioselective cyclopropanation. In the classical cyclopropanation of styrene with ethyl diazoacetate (Scheme 1), chiral bidentate bisoxazoline–Cu(I) catalytic complexes possessing C_2-symmetry are most frequently used.[2a–d] The cumulative stereochemical outcome of the reaction is evaluated by ee and de of the formed cyclopropanes. While with some catalysts very high enantioselectivity (more than 90% ee) is achieved, diastereoselectivity is usually low to medium, in the range 40–50% de. Our new strategy toward supramolecular catalysts for cyclopropanation is based on the design of cavity-containing ligands with a built-in bisoxazoline unit (Fig. 1). Since the bridge connects two centers of C_2-symmetric bisoxazoline unit, a certain degree of helicity is induced to the bridge. According to the proposed reaction mechanism of bisoxazoline–Cu(I) catalyzed cyclopropanations, a cyclopropane ring forms by the electrophilic attack of Cu(I) bound carbene to prochiral alkene.[6] Consequently, with a macrocyclic supramolecular catalyst of sufficient size, the reaction should occur inside the helical cavity. In this way, the local C_2 chirality at the metallic center is to a certain degree extended to the reaction space defined by the size of the cavity. Compared to classical acyclic bisoxazoline–Cu(I) catalysts, this strategy offers the advantage of stereochemically more defined catalyst topology beyond the catalytic site that could result in the improved diastereo- and enantioselectivity of the cyclopropanation reaction.

To test this hypothesis, the macrocyclic ligands **1**–**4** (Scheme 2, **1**–**4** obtained in 29, 27, 49 and 25% yields, respectively),



trans-**16** *cis*-**17**

Scheme 1 Cyclopropanation of styrene with ethyl diazoacetate catalysed by chiral bisoxazoline–Cu(I) complexes.

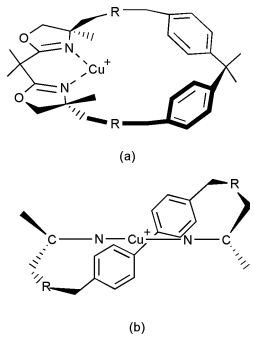


Fig. 1 General structure of C_2-symmetric supramolecular Cu(I) catalyst (*a*); helicity of the macrocycle connecting stereogenic centers of the bisoxazoline unit (*b*).

possessing different sizes of the macrocyclic ring, have been prepared and their Cu(I) complexes used in cyclopropanation of styrene with diazoacetate.[7]

The enantio- and diastereoselectivities obtained in the cyclopropanations with Cu(I) complexes of the macrocyclic ligands **1**–**4** at two standard ligand/Cu(I) ratios,[2b] are collected in Table 1 and compared to those obtained with the Cu(I) complexes of the acyclic bisoxazoline ligands **14** and **15**.[2b] It turns out that the complexes of the two smallest macrocyclic ligands, **1** and **2**, exibit the highest diastereoselectivity (86% de for **1**) and enantioselectivity (81% ee for **2**) affording nearly the same cumulative stereoselectivity (75–77%). For the two larger macrocycles **3** and **4** both de and ee dropped; for the former de is somewhat higher (50–54% de) than for the latter (42% de), whereas ee in both cases remains quite similar (66–68%). As compared to acyclic precursor **14**, however, the cumulative stereoselectivity for the *trans*-**16** isomer obtained with **1** and **2** is 20% higher than that for **14** (57–58%) and also higher than that obtained with the best bisoxazoline in the acyclic series, ligand **15**[2b] (69–70%). The cumulative stereoselectivity increase for **1**–**4** shows clear dependence on the size of the macrocycle cavity being the lowest for the most flexible, **4**, and the highest for the most rigid, **1**. In the series acyclic **14**–macrocyclic **4** to **1** the remarkable increase of de from 38 to 86% is observed. Interestingly the ee's in the series are rather similar (65–68%) except for the peak value for **2** (81%). These results reveal the importance of the catalyst topology for the diastereoselectivity outcome of the reaction and show the advantage of macrocyclic over acyclic catalysts. The exceptional diastereoselectivity observed for the **1**–Cu(I) catalyst can be explained by high degree of stereoselection induced by the helicity of the bridge which strongly favors formation of *trans*-**16** over *cis*-**17** (Fig. 2).

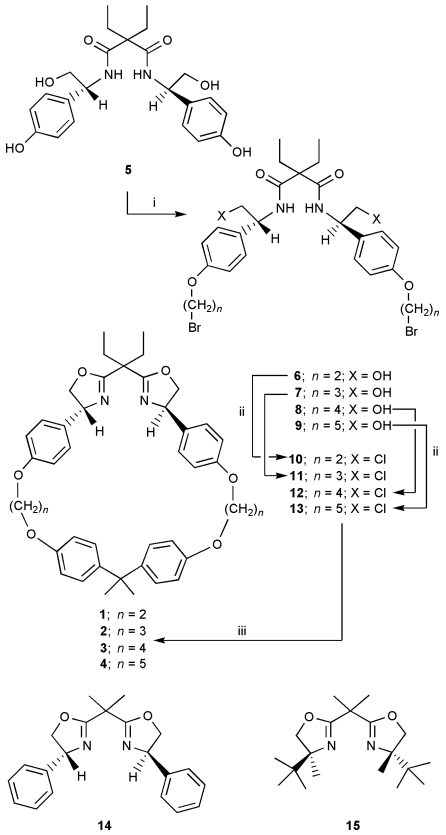
[a] Isolated, not optimised yields. [b] Determined by chiral GC analysis, using Chirasil Dex-CB column. [c] Cumulative (diastereo- and enantio-) selectivity calculated in % of (1*S*,2*S*)-*trans*-**16** and (1*R*,2*R*)-*trans*-**16** formed in catalytic reactions by using ligands **1**–**4**, **14** and the ligand **15**, respectively.



Scheme 2 (i) $Br(CH_2)_nBr$ (*n* = 2-5); K_2CO_3,MeCN; (ii) $(Cl_3CO)_2CO$; PPh_3, CH_2Cl_2 or $SOCl_2$; (iii) Cs_2CO_3, MeCN. Structures of the reference ligands **14** and **15**. All prepared compounds have correct spectroscopic and elemental analysis data.

In conclusion, we report on the synthesis of the first supramolecular Cu(I) catalysts comprising macrocyclic ligands **1**–**4** and their application in stereoselective cyclopropanations of styrene with ethyl diazoacetate. The macrocyclisation principle used with such catalysts which produced the highest cumulative stereoselectivity in cyclopropanations reported to date could be of general value considering variety of catalytic transformations based on C_2-symmetric organometallic ligands.[1,2] Our work on the cavity-tuning of the supramolecular Cu(I) catalysts, and their applications in other catalytic enantioselective reactions is in progress.

First published as an Advance Article on the web 27th September 2000

A new lipophilic guanosine carrying a porphyrin chromophore on the ribose moiety has been prepared: evidence is reported for the formation of a supramolecular complex based on G-quartets and containing an array of eight porphyrins.

Understanding and mimicking natural photosynthesis with the goal of producing molecular electronic devices and eventually clean energy is currently one of the areas of major investigation in chemistry.[1]

A particular impetus to the field has been the solution of crystal structures for the reaction centres of photosynthetic bacteria *Rhodopseudomonas viridis* and *Rhodobacter sphaeroides* R-26,[2] as well as the structure elucidation of the antenna complex of *Rhodopseudomonas acidophila*.[3] In particular, the so-called light harvesting system LH2 is an elegant supramolecular assembly in which two distinct sets of 18 and 9 bacteriochlorophylls-a, respectively, are arranged in a circular disposition.

Several synthetic models for such a system have been proposed in the literature, wherein porphyrin arrays were obtained by covalent synthesis.[4] An alternative, and more attractive approach, has been based on the supramolecular strategy of having porphyrin-carrying subunits spontaneously self-assemble to give organised chromophore arrays.[5]

For several years, we have been studying the self-assembly of lipophilic guanosine derivatives in chlorinated organic solvents.[6] These compounds, in the presence of alkali metal ions, form octameric[6b] [Fig. 1(a)] or polymeric[6c] [Fig. 1(b)] species based on the hydrogen-bonded G-quartet.[7] In particular, while 3′,5′-diacyl-2′-deoxyguanosines form octamers or polymers depending on the amount of alkali metal ion added, 5′-acyl-2′,3′-isopropylidene guanosine derivatives form only discrete octamers.[8] The basic structure of the G8 octamer appeared to us to be an ideal non-covalent scaffold for the formation of porphyrin arrays.

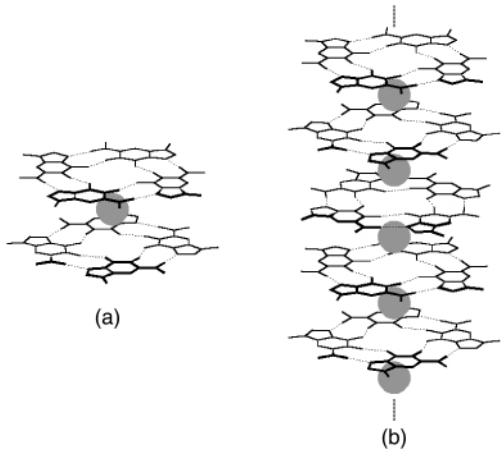

Fig. 1

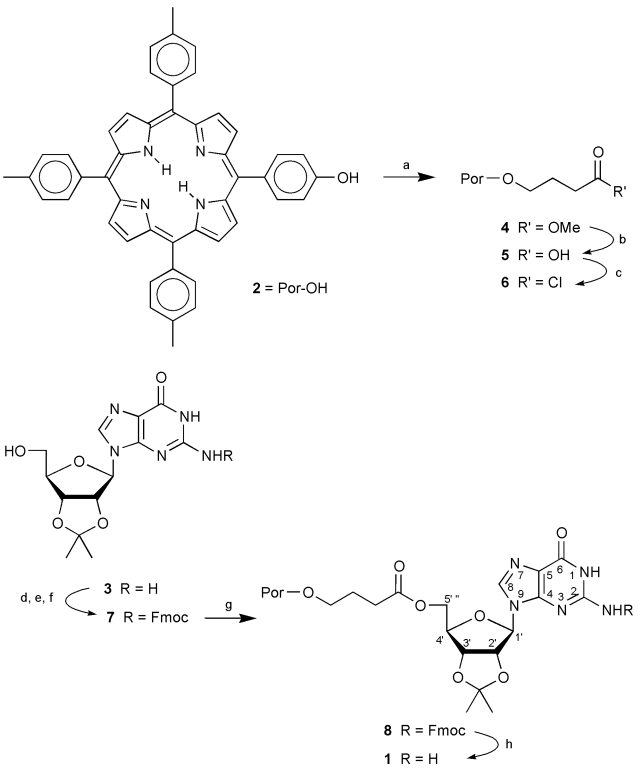
We report here the preparation of a self-assembled porphyrin array consisting of eight chromophores arranged in a circular disposition.

Porphyrin-carrying lipophilic guanosine **1** was synthesized starting from 5-(4′-hydroxyphenyl)-10,15,20-tritolylporphyrin **2**[9] and commercially available 2′,3′-isopropylidene guanosine **3** according to Scheme 1.

Hydroxyporphyrin **2** was alkylated with 4-bromobutyric acid methyl ester, and the resulting ester **4** (93%) was then hydrolysed to give carboxylic acid **5** (95%), which was converted into the corresponding acyl chloride **6**.

Isopropylidene guanosine **3** was converted into the *N*(2)-Fmoc derivative **7**[10] (56%) and condensed with porphyrin acid chloride **5** to give ester **8** (31%). Deprotection of ester **8** gave the porphyrin-functionalised guanosine **1** (76%). All of the compounds were characterized by NMR, ESI mass spectrometry and elemental analysis (ESI†).

Derivative **1** self-assembles in chloroform in the presence of potassium picrate giving rise to octamers consisting of two G-quartets, as inferred from UV–VIS, CD, 1D and 2D ^{1}H NMR studies.



Scheme 1 *Reagents and conditions*: (a) $BrCH_2CH_2CH_2CO_2Me$, K_2CO_3, DMF; (b) KOH, dioxane, MeOH, H_2O, 80 °C then dil. AcOH; (c) $SOCl_2$, THF, reflux; (*d*) Me_3SiCl, pyridine; then (e) FmocCl then (f) H_2O; (g) **6**, CH_2Cl_2, pyridine; (h) piperidine, CH_2Cl_2.

DOI: 10.1039/b006160n

Proton NMR spectra (ESI†) show the characteristic features of G-quartet formation upon K^+ complexation. Thus, the broad singlet at 6.37 ppm for the N(2)H2 splits into two signals centred at 9.69 ppm [H-bonded N(2)H] and 6.43 ppm [free N(2)H], respectively, at −10°C. These separate signals for the exocyclic amine, already visible although broader at room temperature, are diagnostic of G-quartet formation.[13] The NOESY spectrum shows cross peaks among both these N(2)H2 protons and the N(1)H imino proton at 12.52 ppm.[6b,13] Conversely, there is no significant shift of any other signal in the ^{1}H NMR spectrum upon complexation.[14]

In the present case, the nucleoside protons for porphyrin-functionalised guanosine **1** are not split upon K^+ coordination, as was previously observed for the 3′,5′-diacyl deoxyG-derivatives,[6a,b] and NMR data indicate an exclusive *syn* conformation of the nucleobases around the glycosidic bond (*e.g.* a strong NOE cross peak between H8 at 7.31 ppm and H1′ at 6.04 ppm). So far, all the 5′-alkanoyl-2′,3′-isopropylidene G derivatives that we have investigated have behaved in this way.[8]

The visible spectra of ester **4** and derivative **1** in $CHCl_3$ before K^+ extraction are nearly superimposable, as would be expected if no electronic interaction between the guanine and porphyrin chromophores takes place.[5a] In addition, the spectrum of **1** after K^+ extraction does not change, ruling out a self-assembling process in which porphyrin stacking is involved. This stacking in fact would lead to strong electronic interactions with consequent modification of the absorption. The stoichiometric ratio of 8 molecules of derivative **1** per picrate ion can be deduced from quantitative absorption measurements.

The CD spectra of **1** before and after complexation with K^+ picrate are shown in Fig. 2. Before K^+ extraction, the signal is very weak and no exciton couplets can be observed. Complexation of the cation produces a dramatic effect in the CD spectrum, as exciton couplets appear both in the guanine absorption region (*ca.* 270 nm) and in the Soret region (*ca.* 417 nm). While the couplet centered at 270 nm is diagnostic of the assembly of guanine bases into an octamer,[11] that corresponding to the Soret band indicates a weak, intermolecular, electronic interaction between porphyrin chromophores:[12] this demonstrates that porphyrins are disymmetrically arrayed around the $[G]_8K^+$ complex. The relatively low intensity of this signal is likely to be due to the conformational freedom of the porphyrin chromophores, which are attached by flexible linkers to the G-quartet platforms.

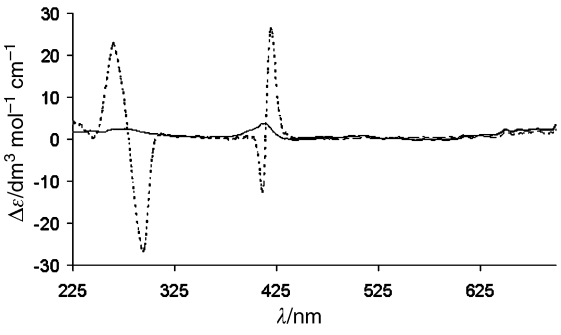

Fig. 2 CD spectra of **1** (0.3 mM in $CHCl_3$) before (——) and after (·····) K^+ extraction.

In conclusion, we have synthesized a new porphyrin derivative which responds to K^+ ions by forming a supramolecular array of eight porphyrins with a circular disposition (see ESI for a tentative structure†). The detailed stereochemistry of the aggregate is now under investigation, as well as the photochemical energy transfer processes possible in this octameric system. Preparation of new derivatives capable of forming aggregates with a larger number of porphyrins arranged circularly around the G-quartets is also being pursued.

We are indebted to Professor J. T. Davis (Maryland) for helpful discussions and suggestions, and to Dr E. Cortini for technical assistance. Financial support by MURST (cofin. 99, ex 40%), CNR (Rome) and University of Bologna (ex 60%) is gratefully acknowledged.

Influence of ion exchange conditions on the defect chemistry and performance of cobalt doped layered lithium manganese oxide based intercalation compounds†

Alastair D. Robertson, A. Robert Armstrong and Peter G. Bruce*

School of Chemistry, University of St. Andrews, North Haugh, St. Andrews, Fife, UK KY16 9ST. E-mail: p.g.bruce@st-andrews.sc.uk

Received (in Oxford, UK) 3rd May 2000, Accepted 8th August 2000
First published as an Advance Article on the web 28th September 2000

It is shown that by varying the conditions used to exchange Na by Li in layered sodium manganese oxide based compounds, not only are the guest ions exchanged but the defect chemistry of the host is modified and this has an important effect on the reversibility of lithium intercalation; in particular, defect 2.5% Co doped layered lithium manganese oxide exhibits a capacity to store lithium equivalent to 200 mA h g^{-1} which fades by only 0.08% per cycle on cycling at 25 mA g^{-1}.

One of the greatest challenges in the field of rechargeable lithium batteries is to replace the $LiCoO_2$ positive electrode with an alternative lithium intercalation compound that is safer, cheaper and less toxic, such as a lithium manganese oxide. The spinel, $LiMn_2O_4$, has been widely studied in this regard.[1–4] Recently, we reported the first synthesis of the layered intercalation compound, $LiMnO_2$, which involved the low temperature ion exchange of Na by Li in $NaMnO_2$.[5,6] The present interest in layered $LiMnO_2$ based materials is significant.[5–12] When doped with Co, high capacities to store Li are obtained but reversibility on cycling is insufficient. Here, we report that varying the ion exchange conditions has an important effect on the defect chemistry in these layered materials, and this has a critical influence on the all-important reversibility of the lithium intercalation reaction.

The layered sodium manganese cobalt oxide phases, $Na_xMn_{1-y}Co_yO_2$, were prepared as described previously.[11] The initial reaction mixture contained 1 mol of Na per transition metal ion, *i.e.* $x = 1$. Ion exchange was carried out using an 8-fold excess of LiBr in either ethanol at 80 °C for 48 h or hexanol at 160 °C for 8 h. Following ion exchange the materials were washed with ethanol and water. Powder X-ray diffraction was carried out on a Stoe STADI/P diffractometer in transmission mode and using an Fe-Kα_1 source ($\lambda = 1.936$ Å). Neutron diffraction data were collected on the GEM diffractometer at RAL. Chemical analysis was carried out using well established methods; for Li and Na this was conducted by flame emission whereas atomic absorption spectroscopy was employed for Mn and Co. Oxidation states were obtained by $KMnO_4$/iron(II) ammonium sulfate titration.[13] BET measurements indicated that the surface areas were between 5 and 10 m^2 g^{-1}.

Powder X-ray diffraction patterns of the as-prepared Na materials revealed that they contain two phases, one may be indexed based on the layered phase whereas the other exhibits the characteristic peaks of Na_2CO_3. Evidently the Na_2CO_3 has not reacted completely and by implication the layered sodium phase is Na deficient, *i.e.* $x < 1$. The Na_2CO_3 is removed during the ion exchange and subsequent washing in ethanol–water. Focussing on the layered lithium phases, powder neutron diffraction patterns for these phases prepared in either hexanol or ethanol exhibit a single phase that may be indexed based on the layered O3 structure of $LiCoO_2$ (space group $R\bar{3}m$, structure type α-$NaFeO_2$). For the Co doped materials prepared in hexanol, full structure refinements have been reported previously.[11] Before discussing further Rietveld refinement of the ethanol samples it is instructive to consider the results of chemical analysis (Table 1). Several conclusions may be drawn from these results. First the sodium phase is alkali metal deficient ($x < 1$), consistent with the XRD data, and this is carried through to the Li phases after ion exchange. There is evidence of a somewhat greater alkali metal content after ion exchange than before indicating that some lithium intercalation accompanies the ion exchange process. Table 1 also reveals that the Na phase contains vacancies on the transition metal sites, these vacancies are retained in ethanol samples prepared at 80 °C whereas ion exchange in hexanol at 160 °C eliminates almost all the vacancies. The transition metal vacancies in the Na phase will be associated with negative effective charges which are likely to trap some of the Na^+ ions; this can explain the retention of a small amount of Na during the ethanol exchange. The ion exchange conditions used here are somewhat reducing, and this is sufficient to result in some lithium intercalation in ethanol and hexanol. The more aggressive conditions of reflux in hexanol at 160 °C cause, in addition, reduction of the host with the associated elimination of the transition metal vacancies, without the transition metal vacancies to trap Na^+, the ion exchange process is more complete. Overall it is evident that the ion exchange process is not

† Electronic supplementary information (ESI) available: powder neutron diffraction profile for $Li_x(Mn_{0.975}Co_{0.025})O_2$ prepared in ethanol. See http://www.rsc.org/suppdata/cc/b0/b002552f/

Table 1 Compositional analysis of as-prepared 2.5% Co Na phase[a] and ion exchanged Li phases for layered $A_xMn_{1-y}Co_yO_2$ materials

Nominal Co content	A = Na or Li; Ion exchange conditions	Composition	Average TM oxidation state	No. of TM vacancies	Mn^{3+} occupancy of TM sites
0.025	Na	$Na_{0.53}Mn_{0.92}Co_{0.025}O_2$[a]	3.672+	5.5%	28.5%
0.025	Li; Ethanol, 80 °C	$Na_{0.048}Li_{0.58}Mn_{0.91}Co_{0.025}O_2$	3.610+	6.5%	33.8%
0.025	Li; Hexanol, 160 °C	$Na_{0.009}Li_{0.62}Mn_{0.96}Co_{0.028}O_2$	3.412+	1.2%	55.3%
0.1	Li; Ethanol, 80 °C	$Na_{0.035}Li_{0.54}Mn_{0.87}Co_{0.087}O_2$	3.579+	4.3%	31.5%
0.1	Li; Hexanol, 160 °C	$Na_{0.012}Li_{0.64}Mn_{0.90}Co_{0.094}O_2$	3.368+	0.6%	53.4%

[a] Content of Na determined by CHN analysis, thereby allowing the amount of Na_2CO_3 and Na in the main phase to be calculated.

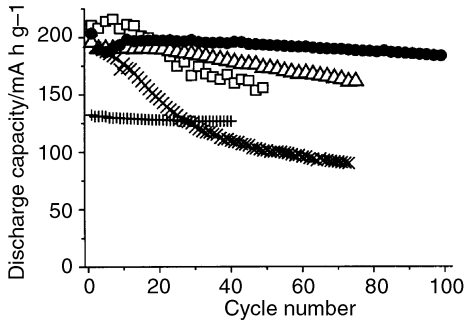

Fig. 1 Discharge capacities as a function of the number of charge–discharge cycles carried out at 25 mA g^{-1} (C/7) and 30 °C between potential limits of 2.4 and 4.6 V for; (●) 2.5% Co prepared in ethanol: (△) 2.5% Co prepared in hexanol: (□) 10% Co prepared in hexanol: (X) $Li_{1.07}(Mn_{1.78}Co_{0.05})O_4$ spinel and (+) $LiCoO_2$ cycled between 3.3 and 4.2 V.

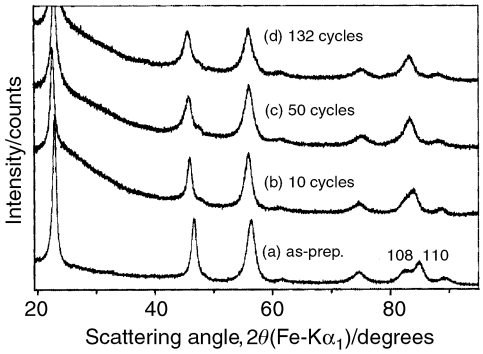

Fig. 2 Powder X-ray diffraction patterns collected on $Li_x(Mn_{0.975}Co_{0.025})O_2$, prepared in ethanol at 80 °C, (a) before cycling, (b) after 10 cycles, (c) after 50 cycles and (d) after 132 cycles. Cycling was carried out at 25 mA g^{-1} and over the range 2.4–4.6 V.

restricted to the anticipated simple exchange of Na by Li, instead it plays a critical role in controlling the defect chemistry/non-stoichiometry of the transition metal host.

Returning to the neutron data for the 2.5% Co doped ethanol sample (ESI†), Rietveld refinement was carried out based on the O3-$LiCoO_2$ structure, which possesses cubic close packed oxide ions. Li and Na were placed in the octahedral sites (3b) of the alkali metal layers and Mn and Co in the octahedral sites (3a) of the transition metal layers. The Na and Co occupancies were fixed at values obtained from the chemical analysis ($Na_{0.048}Li_{0.58}Mn_{0.91}Co_{0.025}O_2$). The Li and Mn occupancies were allowed to vary freely. The refined occupancies are in good agreement with the chemical analysis. A good fit to the observed data was obtained and the crystallographic data are presented in ref. 14. $LiMnO_2$ is monoclinic owing to a cooperative Jahn–Teller distortion promoted by the high spin Mn^{3+} ions. For the Co doped materials it has been shown that cobalt is in the trivalent state.[11] The presence of Co^{3+} along with the alkali metal deficiency and, in the case of the ethanol samples, vacancies on the transition metal sites conspire to reduce the occupancy of the octahedral sites by Mn^{3+} to a level where they can no longer promote a cooperative distortion which typically occurs at *ca.* 50% occupancy of the transition metal octahedral sites by Mn^{3+}. As a result none of the samples exhibit a monoclinic distortion.

What effect does the presence of transition metal vacancies have on the behaviour of these materials as intercalation electrodes? The variation of discharge capacity with cycle number is shown in Fig. 1. Considering first the hexanol samples, reducing the Co content from 10 to 2.5% improves the capacity retention on cycling. However the highest degree of reversibility is obtained from the 2.5% Co doped sample prepared in ethanol; this corresponds to a capacity fade of only 0.08% per cycle. High capacities to store Li are of no value for application in rechargeable lithium batteries unless accompanied by a high degree of reversibility of the intercalation reaction. This is now becoming recognised as a key feature that must be built into the chemistry of intercalation compounds for rechargeable lithium battery electrodes. The capacity of $LiCoO_2$, used as the positive electrode in the current generation of rechargeable lithium batteries, is also shown for comparison. The layered manganese based materials may be particularly relevant to the market in sub 3 V electronics for which high capacity cathodes delivering their charge above 2.4 V could be combined with graphite anodes to yield high capacity low voltage cells for such electronic applications. This is one of the most rapidly growing markets for rechargeable lithium batteries.

We have shown previously that Co doped materials prepared in hexanol convert to spinel on cycling.[11] This is also the case for the samples prepared in ethanol. The merging of the 108 and 110 peaks is indicative of the transformation (Fig. 2). It is interesting to compare the capacity fade of the layered compounds prepared in hexanol and ethanol which convert to spinel *in situ*, with a directly prepared cobalt doped lithium manganese spinel cycled over the same voltage range. The chosen spinel, which was prepared by conventional solid state reaction, has a very similar composition to the 2.5% Co doped material prepared in ethanol containing, as it does, a similar concentration of vacancies on the transition metal sites. Whereas spinels are known to cycle well when confined to a potential range around 4 V, the irreversibility of the intercalation process on cycling over the wider voltage range is clearly severe even for Co doped samples (Fig. 1), yet this is not the case for the *in situ* spinels.

The results presented here show that by changing the mild ion exchange conditions, it is possible to modify the defect chemistry/stoichiometry of the host. In particular, by forming a layered lithium manganese oxide based spinel with Co and vacancies on the transition metal sites it is possible to improve significantly the reversibility of the intercalation process which is a critical property for applications as an electrode material.

P. G. B. is indebted to the EPSRC for financial support and RAL for the provision of neutron facilities.

The rate of protonation of the nitrile carbon in *trans*-[Mo(N$_2$)(NCC$_6$H$_4$R-4)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)$_2$] (R = MeO, Me, H, Cl, MeCO or NO$_2$) shows an unusual non-linear dependence on the identity of R, revealing how both kinetic and thermodynamic factors control the site of protonation in complexes containing a variety of protonatable ligands.

Understanding the factors which define where protons bind to metal complexes is important in gaining insight into the reactivity of certain metalloenzymes,[1] and in controlling the regio-, stereo- and product-specificities of metal-mediated reactions.[2,3] However, we are still some way from being able to predict where protons will bind to complexes containing a variety of potential sites, as is evident when we consider the reactions shown in Fig. 1.
