5	D-Glucose	Cyclohexanone	**4** (61%)[d]

[a] See Scheme 1 for the reaction conditions. [b] Isolated yields from the free sugar after chromatography on silica gel. [c] Diastereomer ratio at the exocyclic asymmetric center. [d] The only other byproduct is the protonation product, 1,5-anhydro-2,3,4,6-tetra-*O*-acetyl-D-glucohexitol.

step, pyridine which suffered a samarium(III)-induced ring opening was replaced by 2,6-lutidine. This one-pot four-step procedure from the persilylated sugars (steps ii–v, Scheme 1) provided only the α-products **3a**–**d** as determined by ^{1}H-NMR analysis of the crude acetylated reaction mixtures, in yields of 58–85% from the commercial free sugar after silica gel column chromatography. The only identified byproduct was the 1,5-anhydromannohexitol (reprotonation product) in about 10%, presumably arising from traces of HI present in the starting glycosyl iodides. With the two aldehydes tested (entries 3 and 4, Table 1), a mixture of diastereomers were produced with selectivities (10:1 and 4:1, respectively) in line with the results previously obtained with anomeric 2-pyridyl sulfones.[2] D-Glucose provided *C*-glycosyl compound **4** by the same sequence of reactions (entry 5). Noteworthy is the absence of elimination products, particularly striking in the gluco series.

While this procedure is well suited for the rapid conversion of commercial sugars to simple 1,2-*trans*-*C*-glycopyranosyl compounds, more elaborated synthetic schemes would require protecting groups more stable than trimethylsilyl groups. We therefore tested the benzylated mannopyranosyl iodide available by TMSI treatment in DCM at rt of either the glycosyl acetate **5**[5] or the trimethylsilyl glycoside **6** (entries 1 and 2, Table 2). Reductive samariation as reported above in the presence of cyclohexanone provided comparable results. The same one-pot transformation (i, TMSI; ii, SmI_2, cyclohexanone) on the trimethylsilyl glycosides derived from glucose **7**, galactose **8** and fucose **9** also provided an unprecedented level of *C*-glycosylation for these series (72–75% yield), obviously to the detriment of the competing elimination reaction. For these three substrates, it was necessary to conduct the samariation step in the presence of one equiv. of 2,6-lutidine which greatly reduces the amount of the competing protonation leading to the 1,5-anhydro sugars. As usual, the 1,2-*trans* compounds were the only detectable *C*-glycosylation products, as indicated by the values of the H1–H2 coupling constants in the ^{1}H-NMR spectra (9.2 Hz for **11** and 9.3 Hz for **12** and **13** in a chair conformation of the pyranose ring). These results significantly differ from those obtained from anomeric 2-pyridyl sulfones.[2] Substitution of the 2-pyridyl sulfone group by an iodine atom in an otherwise identical structure resulted, under identical conditions, in an improvement of the *C*-glycosylation reaction at a synthetically

useful level (72 *vs*. 39% yield in the gluco series) with a concomitant decrease in the elimination reaction. We also noticed a further improvement by incorporating catalytic amounts of NiI_2 with SmI_2,[9] and conducting the coupling reaction at −10 °C (80% of **11**, entry 4).

The utility of this new procedure has been demonstrated in a fast synthesis of the carbon-linked mimic of the D-glucopyranosyl(β1→6)-D-mannopyranoside dimer **17** (Scheme 2). Reductive samariation of iodide **14** in the presence of aldehyde **15**[10]† provided the β-*C*-dimer **16** in 66% yield. Only one isomer was detected at the exocyclic asymmetric center. Methyl xanthate formation and radical reduction furnished the methylene-linked dimer which was debenzylated and characterized as its per-*O*-acetyl derivative **17**.‡

In summary, we have shown that the silylated or benzylated glycopyranosyl iodides are useful *C*-glycosyl donors for the synthesis of 1,2-*trans* *C*-glycosyl compounds. Work is in progress to delineate a precise mechanism for the transformation.§

Notes and references

† Aldehyde **15** was prepared from methyl 2,3,4,6 tetra-*O*-benzyl-α-D-mannopyranoside in an overall yield of 54% by the following five-step sequence of reactions: i, Ac_2O, CF_3COOH, (4:1), 25 °C, 1 h; ii, MeONa, MeOH, 25 °C, 12 h; iii, 1.4 equiv. PPh_3, 4 equiv. I_2, imidazole, toluene, 70 °C, 1 h; iv, 1.4 equiv. Bu_4NCN, DMF, 0 to 25 °C, 3 h; v, 3 equiv. DIBAL-H, CH_2Cl_2,, −78 °C, 0.5 h.

§ We do not yet have a reasonable explanation for the significant differences between the behavior of anomeric iodides and anomeric 2-pyridyl sulfones. It is possible that there is a change in the electron transfer mechanism (inner *vs*. outer sphere ET) on going from anomeric 2-pyridyl sulfones to anomeric iodides inducing a change in the product distribution (C–C bond formation *vs*. elimination).

Molecular recognition involving Kemp's triacid: selectivity towards the 8-substituted quinoline system as seen in the cocrystalline adducts with 8-aminoquinoline and 8-hydroxyquinoline

Graham Smith,*[a] Urs D. Wermuth[a] and Jonathan M. White[b]

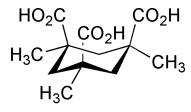
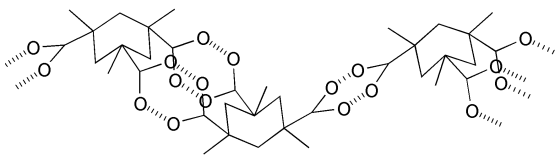
Received (in Cambridge, UK) 20th June 2000, Accepted 25th October 2000
First published as an Advance Article on the web

The crystal structure determinations of two molecular adducts of Kemp's triacid (*r*-1,*c*-3,*c*-5-trimethylcyclohexane-1,3,5-tricarboxylic acid = KTA), [$(KTA)_2$(8-aminoquinoline)] (1) and [$(KTA^-)_2$ (8-hydroxyquinoline$^+$)$_2$] (2) have revealed an interactive selectivity towards the 8-substituted quinoline system.

Kemp's triacid (*r*-1,*c*-3,*c*-5-trimethylcyclohexane-1,3,5-tricarboxylic acid) was synthesized in 1981[1] and its unique all-equatorial carboxylic acid configuration demonstrated, and later confirmed in crystal structure analyses.[2,3] Most significantly, the molecules showed no intramolecular hydrogen bonding associations involving the carboxylic acid groups as might have been expected but instead formed an unusual chain structure made up of head-to-tail cyclic hydrogen bonded units, with two at the head and one at the tail. This association is not only unique to Kemp's triacid but the polymeric or 'catemer' mode[4] is itself rare among carboxylic acids where the discrete cyclic hydrogen-bonded dimeric association [graph set $R^2_2(8)$[5]] predominates. The structure also indicates the possible reason for both the high melting point (241–243 °C) and the amomalously small p$K_{a2,3}$ value for the acid (1.5)[1] where the unusually high value for pK_{a3} (for an aliphatic tricarboxylic acid) makes the trianion one of the most basic carboxylate anions known.



Kemp's triacid (KTA)



KTA Framework structure

Previous work has indicated that Kemp's triacid and its derivatives, such as the 2 : 1 condensation products with various aromatic diamines (*e.g. m*-xylidenediamine and acridine yellow), possess potential for molecular recognition.[2] These diacid products have discrete encapsulating environments with dimensions which vary with the nature of the parent aromatic diamine used. However, no actual structures of adducts of this type are known. The trianionic form of Kemp's acid has exhibited enhanced affinity compared to the trianions of the *cis-trans*-isomer and other tricarboxylic acids, for the tetraprotonated [21]ane N_7 macromolecule.[6,7] It is proposed that interaction proceeds *via* hydrogen bonding between the favourably oriented carboxylate groups and all or most of the four protonated sites of the macromolecule. These studies in fact involve recognition of Kemp's triacid rather than using it to recognize other simple molecular species. Work in our laboratories has primarily been directed towards both the homogeneous and heterogeneous self-assembly of carboxylic acids as well as co-crystallization of carboxylic acids with Lewis bases, particularly in those cases where proton transfer does not occur.[8] Kemp's triacid was therefore interacted with a series of bifunctional carboxylic acids and Lewis bases with a view to examining the structures of the adducts formed, using single crystal X-ray diffraction. These included compounds having particular associative utility in structure making, including the isomeric monoaminobenzoic acids, 2-aminopyrimidine, 2,6-diaminopyridine, adenine, melamine, xanthine, hypoxanthine, and urea. The very limited success we achieved is reflected in the paucity of structural data on KTA and its compounds in the CSD. However, with 8-aminoquinoline (8-AQ),† large crystals of an adduct were obtained which was confirmed by elemental analysis as having the unexpected stoichiometry [$(KTA)_2$(8-AQ)] (**1**). The crystal structure of **1**‡ indicated that Kemp's triacid has particular affinity for the 8-amino-substituted quinoline system. This structure retains the basic hydrogen-bonded backbone polymer, based upon the KTA repeating unit, as found in the parent acid,[2,3] with the 8-aminoquinoline molecules linking the chains laterally by hydrogen bonds between the 8-amino substituent group [N(2)] and the CO_2H groups in the polymer chains (Fig. 1). Another feature of the structure is the 50% disorder of the 8-AQ molecules across inversion centres in the cell, meaning that half of the molecules lie with the amino group directed towards one carboxylic acid in the first chain [N(2)···O(1), 2.97 Å (x, 1 + y, z)] while the other half are directed towards another acid group in the second chain [N(2)···O(5), 3.14 Å (−1 + x, 1 + y, z)]. The hetero-nitrogen is not involved in intermolecular hydrogen bonding but does form an intramolecular hydrogen bond with the amino group (2.62 Å). Furthermore, this nitrogen is not protonated as might be

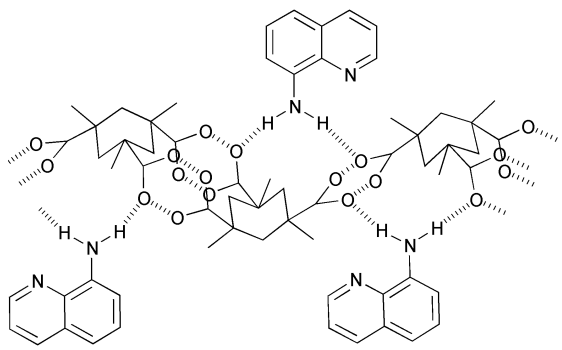


Fig. 1 Molecular associations in the KTA chain polymer structure and the laterally linking 8-aminoquinoline molecules in **1**, shown in the schematic. The 8-AQ molecules are 50% disordered across inversion centres in the unit cell. Hydrogen-bonding distances (Å) in the structure (shown as broken lines) are: intra-chain: O(1)···O(2), 2.68; O(4)···O(6), 2.60; O(3)···O(5), 2.68. Inter-chain: N(2)···O(1), 2.97; N(2)···O(5), 3.14.

DOI: 10.1039/b004945j

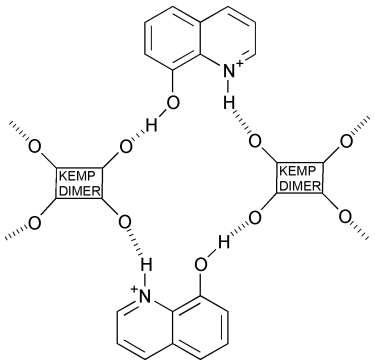

Fig. 2 The centrosymmetric dimeric KTA anion units and the cross-linking 8-hydroxyquinolinium cations in **2**. Schematic shows the hydrogen-bonding associations in the ribbon polymer. Hydrogen-bonding distances (Å) in the structure are: intra-dimer: O(1)···O(6),[a] 2.53; O(3)···O(5), 2.57; inter-dimer: N(1)···O(2), 2.68; O(7)···O(5),[b] 2.66. Unless otherwise indicated, atoms are carbon. [a] $-x$, $1-y$, $1+z$. [b] $-1+x$, y, z.

expected {comparative pK_a values of the acid (pK_{a1} = 3.3) and base [pK_{a2} (hetero-N) = 4.0}.

The apparent size specificity for KTA towards 8-AQ prompted a trial involving another available 8-substituted quinoline, quinolin-8-ol (8-HQ) with Kemp's acid using similar preparative conditions.† This also resulted in the production of good crystals but these had an analysis consistent with a 1:1 complex rather than 2:1 as found in **1**. The crystal structure of [(KTA)(8-HQ)] (**2**)‡ (Fig. 2) unexpectedly showed the presence of a chain polymer based on unusual centrosymmetric hydrogen-bonded KTA dimer repeating units, in contrast to the KTA backbone structure as found in **1** and in the parent acid. These dimer interactions differ from conventional hydrogen-bonded cyclic dimers in that they involve the *cis*-related acid groups [O(1)···O(6), 2.53 Å]. The oxygen of one of these acid groups [O(6)] is devoid of a proton which is located on the hetero-N of the 8-HQ molecule. This protonated group subsequently forms a strong hydrogen bond with the other oxygen of the second CO_2H group [N(1)···O(2), 2.68 Å]. The HO groups of the two bridging 8-HQ molecules provide the links between the dimer units *via* O(5) [O(7)···O(5), 2.66 Å] in a three-centre relationship which involves the third CO_2H group in an intramolecular hydrogen bond [O(3)···O(5), 2.57 Å]. There is a labile partial molecule of 8-HQ in the lattice which appears to be lost during collection of X-ray diffraction data while maintaining crystal stability and further work on this phenomenon is proceeding. The formula for the adduct **2** after removing the effect of the disordered partial molecule of lattice 8-HQ is therefore $[(KTA^-)_2(HQ^+)_2]$.

The presence or absence of proton transfer with examples of this type may be predictable on the basis of pK_a differences between the interacting species. For the pyridine system, this ΔpK_a minimum is found to be 3.5.[10] However, with Kemp's triacid and the 8-substituted quinoline system, the difference would appear to be considerably less than this [for 8-HQ: pK_a = 5.0 (hetero-N); ΔpK_a = 1.7 (proton transfer) while for 8-AQ: pK_a = 4.0; ΔpK_a = 0.7 (no proton transfer)]. The hetero-N in both 8-AQ and 8-HQ is readily protonated by relatively strong nitro-substituted aromatic carboxylic acids [*e.g.* 3,5-dinitrobenzoic acid (pK_a = 2.8), 5-nitrosalicylic acid (pK_a = 2.2) and 3,5-dinitrosalicylic acid (pK_a = 2.1)] giving 1:1 adducts,[10] based on cyclic hydrogen-bonded A–B heterodimers.[11] These form in preference to the B–B homodimer found in the parent structure of 8-HQ[12] and in its adducts with the neutral compounds chloranil[13] and 1,3,5-trinitrobenzene.[14] Adducts **1** and **2** therefore differ significantly in many respects: adduct **1** has 2:1 stoichiometry, involves no proton transfer, is based on a hydrogen bonded polymeric backbone structure and interacts with 8-AQ in a parallel cross-linking mode. Adduct **2** has effectively a 1:1 interactive stoichiometry but involves proton transfer and is based on hydrogen-bonded dimers which interact with two cross-linking 8-HQ molecules in a perpendicular mode. However, these two examples provide chemical evidence of the particular molecular specificity of Kemp's triacid for at least the 8-(interactive group)-substituted quinoline system. This basic proposal is currently being pursued using other similar Lewis bases.

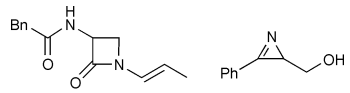
Eyring plots of ln *E vs.* 1/*T* show inversion temperature in kinetic resolution by lipases, demonstrating that clustering effects in the substrate solvation manage the enzymatic selectivity.

Over the past few years, the use of enzymes in organic synthesis has become increasingly important owing to the basic discovery that enzymatic reactions can occur in organic solvents as well as in water.[1] Indeed, enzymatic selectivity is remarkably dependent on the organic solvent[2] and many attempts have been made to explain this influence.[3] However, less attention has been paid to the effect of temperature on selectivity.[4]

We report here the results of our studies on the effect of temperature on the kinetic resolution of racemic β-lactam **1** by



(*R*,*S*)-**1** (*R*,*S*)-**2**

PGA (Penicillin G-Acylase). Furthermore, we also reanalyzed another enzymatic process that has been reported previously, involving the kinetic resolution of azirinol **2** by lipase PS.[5]

Over the past decade, the dependence of stereoselectivity on temperature has been evaluated in several non-enzymatic reactions; *e.g. cis*-dihydroxylation of olefins,[6] reduction of ketones[7] and nucleophilic addition to imines[8] and carbonyl compounds.[9] By plotting the logarithm of selectivity *vs.* the reciprocal of *T*, according to the modified Eyring equation [eqn. (1)], a peculiar behavior is sometimes observed: the existence of two linear regions intersecting at a point defining a temperature denoted the inversion temperature (T_{inv}), whose significance is still a matter of debate.[10]

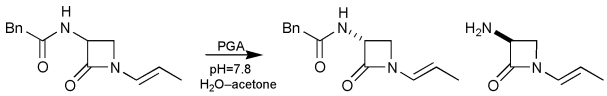
$$\ln S = -\Delta\Delta H^{\ddagger}/RT + \Delta\Delta S^{\ddagger}/R \qquad (1)$$

This break point leads to two sets of activation parameters: one for $T < T_{inv}$ and the other for $T > T_{inv}$. Our preceding studies demonstrated that the presence of an inversion temperature accounts for a particular effect of the reaction solvent on the stereoselectivity. We have proposed that T_{inv} constitutes a transition temperature between two different solute–solvent clusters, which act as two distinct supramolecules with different thermodynamic properties, reactivity and, therefore, different trends of stereoselectivity with temperature.[11]

We have recently shown[12] that in nucleophilic addition to aldehydes, T_{inv} depends mainly on the aldehyde–solvent couple and its value may be determined by ^{13}C NMR analysis using variable temperature (VT) experiments. NMR techniques provide a powerful method for investigating the local electronic environment of the molecular structure, and nuclear shielding is a sensitive probe of intermolecular interactions and solvent effects.[13] We found that the variation of the C=O chemical shift of the studied aldehydes with temperature presents two linear trends, whose intersection (referred to here as T_{NMR}) lies near the T_{inv} of the same substrate–solvent system, within the experimental error. Therefore, we considered that T_{NMR} and T_{inv} might have a common origin, and could in fact represent two independent experimental observations concerning the same solvation-clustering phenomenon.

We report here the first experimental example of inversion temperature in the field of stereoselective enzymatic reactions[14] and also confirm the presence of interconversion of solute–solvent supramolecules by means of VT ^{13}C NMR analysis.

As part of an ongoing project on the total synthesis of new β-lactam antibiotics,[15] we became interested in the kinetic resolution of racemic 1-*N*-(propen-1-yl)-3-*N*-(phenylacetoxy)-aminoazetidin-2-one **1** by PGA (supported on Eupergit) (Scheme 1). The experiments were carried out by incubating the substrate in phosphate buffer (pH = 7.8) and acetone (2:1 ratio) at different temperatures. Conversion of the reaction was monitored by titration of the phenylacetic acid formed with NaOH solution and the enantiomeric excesses of **3** and unreacted **1** were determined by HPLC analysis on a chiral column.[16] With an increase in temperature, we observed an initial linear lowering of the selectivity ratio *E*[17] until it reached a minimum value of 24 corresponding to $T = 301$ K (Fig. 1). Upon further warming, *E* increased, to reach a maximum value of 130 at $T = 328$ K. Least-squares analysis of these results enabled us to determine that $T_{inv} = 301$ K. Notably, the highest enantioselectivity is reached at the highest temperature.[18] Usually, $E = 100$ is considered the minimum satisfactory value for the industrial application of an enzymatic process. Thus, in our case, a slight variation in temperature made an inadequate enzymatic method very efficient.



(*R*,*S*)-**1** (*R*)-**1** (*S*)-**3**

Scheme 1

Next, we performed a series of VT ^{13}C NMR analyses of **1** in deuterated water and d_6-acetone (2:1 ratio). The δ value of the phenylacetoxy C=O chemical shift decreases with an increase in temperature between 278 and 323 K, and two linear regions may be clearly recognized by least-squares analysis (Fig. 2). T_{NMR} occurs at $T = 306$ K and corresponds to T_{inv}, within the experimental error. We looked for other studies on temperature dependent selectivity in enzymatic processes in the literature. In 1997 Sakai *et al.*[5] described the kinetic resolution of racemic phenyl-2*H*-azirine-2-methanol **2** in diethyl ether. The selective

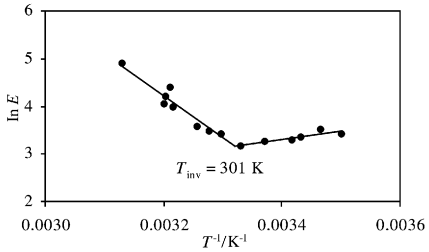


Fig. 1 Eyring plot for the selectivity ratio *E* in the kinetic resolution of **1** by PGA at different temperatures in H_2O–acetone (2:1).

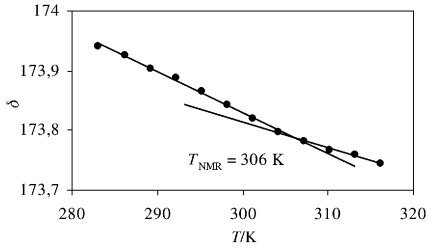

Fig. 2 Plot of the ^{13}C chemical shift of the phenylacetoxy C=O *vs. T* for **1** in D_2O–d_6-acetone (2:1).

acetylation reaction promoted by lipase Amano PS in the presence of vinyl acetate as an acylating agent, proceeded smoothly until 233 K, with progressively higher selectivity (Fig. 3). At T = 233 K, the enantioselection reached a maximum (E = 99) and then decreased. A least-squares analysis of the tabulated data allowed us to determine a T_{inv} at T = 229 K. To test for the presence of a T_{NMR}, we prepared **2** by the reported method[19] and studied the evolution of δ *vs.* T in d_{10}-diethyl ether. The results for the quaternary aromatic carbon[20] are reported in Fig. 4. Again, two linear regions exist and T_{NMR} occurs at T = 222 K, quite near to the corresponding T_{inv}. The different rates of variation of the chemical shift δ *vs.* T indicate an abrupt change in solute–solvent interactions, which reflects a change in substrate solvation.[21] The same solvation change causes the presence of the T_{inv} in an Eyring plot which regards the same substrate in the same solvent of the NMR analysis.

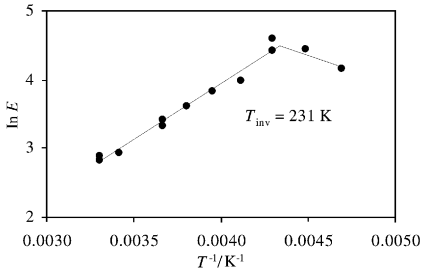

Fig. 3 Eyring plot for the selectivity ratio E in the kinetic resolution of **2** by lipase Amano PS at different temperatures in diethyl ether.

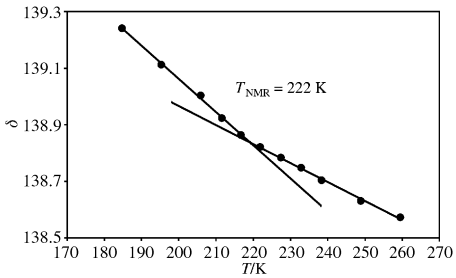

Fig. 4 Plot of the ^{13}C chemical shift of the quaternary aromatic carbon atom *vs. T* for **2** in d_{10}-diethyl ether.

Thus, once again the T_{inv} and the T_{NMR} appear as two independent experimental results due to the same phenomenon. Actually, we think that a reorganization between two differently ordered solvation clusters generates both the T_{inv} and the T_{NMR}. The T_{NMR} reveals the presence of dynamic phenomena on the ground state of solute–solvent clusters which thus appear to be much more structured than generally believed. The T_{inv} reveals the same dynamic phenomena, which now act on diastereomeric transition states leading to a different stereoselectivity below and above the T_{inv}.[22]

From the experimental data reported here, it results that even enzymatic reactions show temperature dependent phenomena of substrate solvation because of the presence of a T_{inv} and a corresponding T_{NMR}, so that even enzymatic reactions experience reorganization of different solute–solvent clusters depending on temperature. Because of the difference in selectivity above and below the T_{inv}, it follows that those solute–solvent clusters contribute to differentiate the Gibbs free energies of the two diastereomeric substrate–enzyme complex transition states. Thus our data provide evidence that solvent molecules are still present in substrate–enzyme transition states.

Our experimental data clearly suggest that enzymatic reactions are only a particular case of a more general phenomenon. Solvation always plays a fundamental role in stereoselectivity and the substrate cannot be considered a mere isolated species in solution, but rather a part of a more complex and well defined solute–solvent cluster.

This work was supported by MURST and by the University of Bologna (funds for selected topics). Penicillin G Acylase was kindly supplied by Recordati (Italy).

20 The same conclusion is achieved even in the case of the other carbon atoms.
21 Partial ordering of molecules is possible in solution, and a temperature-dependent change in this order is already manifested in the nonlinearity of some spectroscopic properties. See *e.g.*: J. B. Robert, *Mol. Phys.*, 1997, **90**, 399; M. A. Wendt, J. Meiler, F. Weinhold and T. C. Farrar, *Mol. Phys.*, 1998, **93**, 145.
22 An alternative explanation of T_{inv} could be a change of the enzyme conformation induced by temperature. However, the presence of T_{inv} in many non-enzymatic reactions[6–12] renders our interpretation more plausible (see for instance ref. 3).

Synthesizing silver halide nanoparticles in supercritical carbon dioxide utilizing a water-in-CO_2 microemulsion

Ionic species can be stabilized in the water core of a water-in-CO_2 microemulsion in supercritical fluid CO_2; by mixing two microemulsions containing Ag^+ and X^- ions separately, silver halide (AgX) nanoparticles were synthesized in supercritical CO_2; the water-in-CO_2 microemulsion may provide a reaction system for a wide range of nanoparticle syntheses involving ionic species in supercritical CO_2.

Reverse micelles and microemulsions formed in liquid and supercritical carbon dioxide (CO_2) allow high polar compounds to be dispersed in this nonpolar fluid.[1] A recent report demonstrated that silver ions in the water core of a water-in-supercritical CO_2 microemulsion could be reduced to nanosized metallic silver particles by a reducing agent dissolved in the fluid phase.[2] The rate of formation of silver nanoparticles in the water-in-supercritical CO_2 microemulsion is fast, suggesting the microemulsion is dynamic in nature.[3] By collision, exchange of contents between two water-in-supercritical CO_2 microemulsions probably would take place effectively. This suggests the possibility of performing nanomaterials synthesis in supercritical CO_2 by mixing water-in-CO_2 microemulsions containing different ions in the water cores. The water-in-CO_2 microemulsion system thus may function like a 'nanoreactor' for a wide range of chemical syntheses involving ionic species as starting materials in supercritical CO_2.

Recently, Ida *et al.* found that the ionic conductivity of silver iodide increased significantly as the particle size decreased to the nanometer-size range.[4] Silver chloride and silver bromide are indirect gap semiconductors and silver iodide is a direct gap semiconductor. Much attention has been paid to the changes in band gap energies for small semiconductor particles as the particle radius decreases.[5] Rosseti *et al.* explained the particle size dependence of the excited state electronic properties of silver iodide and silver bromide as a consequence of electron and hole localization in the small crystallites.[6] Water-in-oil microemulsion technology has been used to synthesize a variety of nanoparticles. Usually, nanometer-sized particles with a high degree of monodispersity can be obtained using this technology.[7] Formation of nanoparticles in supercritical fluids offers significant advantages over conventional liquid-phase systems including rapid separation of solvent and the possibility of depositing the particles *in situ* in porous materials utilizing the unique properties of the supercritical fluid phase.[2]

Sodium bis(2-ethylhexyl) sulfosuccinate (AOT) obtained from Sigma, was purified using a method described by Williams *et al.*[8] The perfluoropolyether–phosphate (PFPE-PO_4) received from Ausimont has a general structure of $CF_3O[OCF(CF_3)CF_2]_n(OCF_2)_mOCF_2CH_2OCH_2CH_2OPO(OH)_2$ with an average molecular weight of 870. The carbon dioxide, SFE grade, was obtained from Oxarc.

Two homemade high-pressure vessels were utilized for the synthesis. One vessel (9.5 ml volume) was equipped with a fiber-optic system (5 mm pathlength) connected to a CCD array UV–VIS spectrometer. The high-pressure fiber-optic spectroscopy cell is described elsewhere.[3] The other vessel was a 15 ml high-pressure view cell with sapphire windows.[2] Each system could be isolated from the other by Valco high-pressure valves.

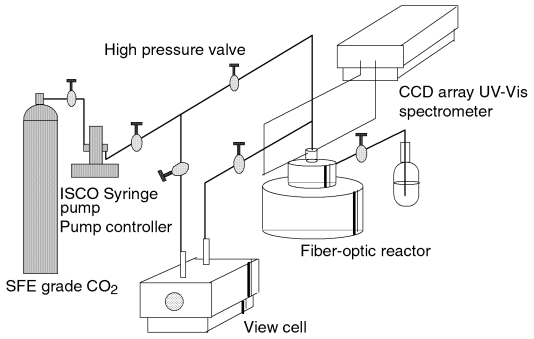

Fig. 1 Schematic diagram of the supercritical CO_2 microemulsion reaction system.

A schematic diagram of the entire supercritical fluid system used for this study is shown in Fig. 1.

The reverse micellar solutions were prepared by using sodium bis(2-ethylhexyl) sulfosuccinate [AOT] (12.8 mM) and the cosurfactant perfluoropolyether phosphate [PFPE-PO_4] (25.3 mM) at the water-to-surfactant ratio, $W = [H_2O]/[AOT] = 12$. The $AgNO_3$ was made to 3.3 mM and NaI, NaBr and NaCl were made to 6.6 mM. The silver nitrate solution was always placed in the 9.5 ml fiber-optic cell and the sodium halide solutions were placed in the 15 ml view-cell. Each solution was stirred for 1 h in the pressurized vessel to ensure the formation of a homogeneous optically transparent microemulsion. For the supercritical fluid carbon dioxide experiments, the vessels were first both pressurized to 80 atm. At the end of 1 h, the 15 ml vessel was pressurized to 200 atm and the microemulsion containing the halide solution was pushed into the fiber-optic cell by opening an interconnecting valve and the spectra were recorded.

Fig. 2 shows the UV–VIS absorption spectra of silver halide nanoparticles observed in the supercritical fluid CO_2 experiments. The spectra for silver iodide show a broad band in the approximate range 410–450 nm. The peak wavelength of the absorption band increased with time after the mixing, varying from *ca.* 422 to 429 nm. About 30 s after the mixing, the peak wavelength reached approximately a constant value at 429 nm and the peak absorption intensity also became constant for the remainder of the experiment. These spectra are consistent with the UV–VIS spectra previously reported by Sato *et al.* for nanosized silver iodide particles formed in an AOT/isooctane reverse micelle system.[9] For silver bromide, we observed shoulder peaks in the range 300–350 nm. Again the observed spectra are consistent with the previously reported observations for silver bromide nanoparticles.[9] The spectra of silver chloride showed an absorption threshold shorter than silver bromide, also in agreement with the literature report.[9]

The size of the silver halide nanoparticles can be estimated by first calculating the band gap energies for the semiconductors. For direct allowed transitions, such as silver iodide, the following equation has been derived by Ravich *et al.*[10]

$$\sigma h\nu = K(h\nu - E_g)^{1/2} \quad (1)$$

DOI: 10.1039/b005924m

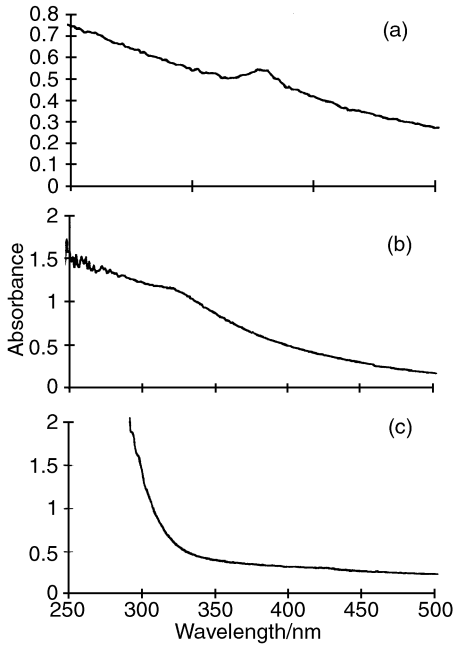

Fig. 2 Absorption spectra of AgX nanoparticles synthesized in the water-in-supercritical CO_2 microemulsion: (a) AgI, (b) AgBr and (c) AgCl.

and for indirect gap semiconductors, like silver bromide and silver chloride,

$$\sigma h\nu = K'(h\nu - E_g')^2 \quad (2)$$

In these equations, σ and $h\nu$ are the absorption coefficient and the photon energy, respectively, K and K' are proportionality constants, and E_g and E_g' are the band gap energy and the indirect energy transition threshold, respectively.

The average diameter of the nanoparticle, d_p, can be estimated from the band gap energy, E_g,[9,11]

$$E_g = E_{g,bulk} + (h^2/2d_p^2)[(1/m_e) + (1m_h)] - [(3.6e^2)/(4\pi\varepsilon d_p)] \quad (3)$$

where m_e and m_h are the effective mass of an electron and a hole in a semiconductor, respectively. In eqn. (3), $E_{g,bulk}$ is the energy of the band gap of the bulk semiconductor, ε is the dielectric constant of the semiconductor and e is the charge of an electron. The following parameters[8] were used for the calculations: for AgI, $E_{g,bulk}$ = 2.83 eV, $\varepsilon/\varepsilon_0$ = 4.91, and m^*/m_0 = 0.2; for AgBr, $E_{g,bulk}$ = 2.5 eV, $\varepsilon/\varepsilon_0$ = 4.62, m_h/m_0 = 0.645, and m_e/m_0 = 0.215. For the other symbols, ε_0 is the dielectric constant of vacuum, m_0 is the rest mass of an electron and m^* is represented by the following equation, $m^* = [(1/m_e) + (1/m_h)]^{-1}$.

The variation of AgI nanoparticle diameters with time during synthesis in supercritical CO_2 can be calculated using eqn. (3) and the UV–VIS spectroscopic data. The results for silver iodide showed a sharp increase in particle size in the first few seconds until a stable size of *ca.* 3.4 nm in supercritical CO_2 was reached. For silver bromide, we obtained a particle size *ca.* 3.0 nm. The size of the silver chloride particles could not be calculated since the effective mass of a hole is not available.

A rapid expansion of supercritical solution (RESS) method[12] was used to collect the synthesized silver halide particles. The size distribution of AgI particles collected on a copper grid by the RESS method is shown in Fig. 3. The particle sizes shown in Fig. 3 (*ca.* 3–15 nm) are larger than the calculated AgI size based on the spectroscopic method. Rapid expansion of the water-in-CO_2 microemulsion apparently can cause agglomeration of the AgI nanoparticles. Other methods of collecting the synthesized nanoparticles in supercritical CO_2 with minimum agglomeration are currently under investigation.

To obtain more information on the mechanism of silver halide nanoparticle formation in supercritical CO_2, the absorbance *vs.* time for the products AgI, AgBr and AgCl were

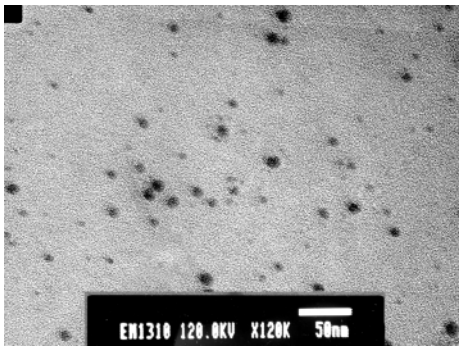

Fig. 3 TEM micrograph of the AgI particles collected on a copper grid using the RESS method.

investigated at 426, 325 and 300 nm, respectively. The time that required for the absorbance–time curve to reach a plateau was used as a measure of the completion of the reaction. The reaction time followed the order AgI (16 s) > AgBr (28 s) > AgCl (40 s). Similar experiments by mixing water/AOT/hexane microemulsions (containing Ag^+ and I^- separately) would require *ca.* 3 min to reach the plateau for the formation of the AgI nanoparticles. The formation of silver halide nanoparticles in the water-in-CO_2 microemulsion system involves several processes including collision, intermicellar exchange and reaction between silver ion and halide ion as shown in the graphical abstract. The intermicellar exchange process involves the distribution of silver nitrate and sodium halide from water droplets to the surfactant phase. This process should depend on the hydrophobicity of sodium halide, *i.e.* NaI > NaBr > NaCl. The observed reaction speed follows the order of hydrophobicity of sodium halide, suggesting that the most hydrophobic species probably reside close to the interface and exchange faster. The reaction between Ag^+ and I^- is expected to be very fast because of the large K_{sp} values for all AgX. The rate-determining step for the formation of silver halide nanoparticles in the water-in-supercritical CO_2 probably is the intermicellar exchange process.

Ruthenium(II) complex with a notably long excited state lifetime†

Daniel S. Tyson, Jason Bialecki and Felix N. Castellano*

Department of Chemistry and Center for Photochemical Sciences, Bowling Green State University, Bowling Green, Ohio 43403, USA. E-mail: castell@bgnet.bgsu.edu

Received (in Columbia, MO, USA) 25th July 2000, Accepted 10th October 2000
First published as an Advance Article on the web

A new Ru(II) diimine complex, [Ru(5-pyrenyl-1,10-phenanthroline)]$_3$(PF$_6$)$_2$ ([Ru(py-phen)$_3$]$^{2+}$), possesses a room temperature excited state lifetime of 148 ± 8 μs.

Visible-absorbing luminescence probes that display long decay times are becoming increasingly important in biophysics, high-throughput screening, clinical chemistry, and lifetime-based chemical sensing.[1–4] One particular class of luminophores based on transition metal complexes displaying metal-to-ligand charge transfer (MLCT) excited states[5] have shown promise in such luminescence-based technologies.[1–4] In the interest of expanding these initial efforts, new MLCT compounds with prolonged emission decay times deserve special attention.

The photophysical properties of transition metal complexes displaying MLCT excited states are dominated by non-radiative decay processes and can be largely predicted by the energy gap law.[6] Excited state lifetimes in such complexes are modulated through simple modifications of the ligands and/or the central metal atom. Although this approach has proven quite successful, complexes with very long lifetimes consequently possess large energy gaps, generally with MLCT absorption bands in the UV. Alternatively, MLCT complexes containing ligands with large π-systems extend excited state lifetimes by imparting significant electronic delocalization into the charge transfer excited state.[7] Even though such complexes absorb in the visible, useful for analytical luminescence applications, their lifetimes are only slightly larger than that observed in the parent diimine complexes.

The room temperature lifetimes of the charge transfer-based emission in Ru(II) diimine complexes can be dramatically extended (approaching 50 μs) by tethering a pyrene molecule to one of the ligands within the complex.[8–12] The observed MLCT-based emission in such complexes is substantially longer-lived relative to the parent compounds as a result of energy transfer processes between the MLCT fragment and the pyrene unit.[8–12] In previous work, we have suggested that the energy transfer process can be controlled by adding additional pyrene molecules to the ligand periphery, which has the effect of increasing the formation of 'pyrene-like' triplets, further extending the lifetime of the complex. The present work takes advantage of this concept and has successfully generated a new Ru(II) diimine complex, [Ru(py-phen)$_3$](PF$_6$)$_2$ (Fig. 1), where py-phen is 5-pyrenyl-1,10-phenanthroline, with a room temperature lifetime of 148 ± 8 μs.

Full details regarding the synthesis of py-phen and [Ru(py-phen)$_3$](PF$_6$)$_2$ are presented in the ESI†. Briefly, py-phen was prepared from 5-bromo-1,10-phenanthroline and 3-pyreneboronic acid using standard Suzuki coupling conditions. [Ru(py-phen)$_3$](PF$_6$)$_2$ was synthesized by refluxing Ru(DMSO)$_4$Cl$_2$ and py-phen in 95% ethanol, followed by precipitation of the PF$_6$-salt, and final purification accomplished through gel filtration chromatography. The absorption and emission spectra of [Ru(py-phen)$_3$]$^{2+}$ in MeCN are displayed in Fig. 2. The tethered pyrene chromophores are largely responsible for the structured π–π* absorption bands between 300 and 350 nm.

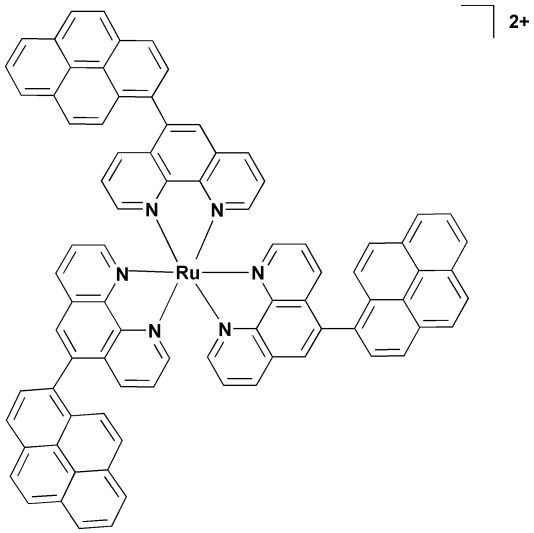

Fig. 1 Molecular structure of [Ru(py-phen)$_3$]$^{2+}$.

The absorption bands in the visible are due to the d$_\pi$(Ru) → π*(py-phen) MLCT transitions in the molecule. Regardless of excitation wavelength (300–532 nm), this complex displays only one visible emission band centered near 600 nm in MeCN at room temperature with a quantum yield of 0.071 ± 0.010. This emission band is characteristic of MLCT-based luminescence typically observed in Ru(II)–diimine complexes.[5] Using single photon counting techniques (342 nm excitation), no singlet emission could be observed from the pyrenyl units when grafted onto the metal complex. The corrected excitation spectrum of [Ru(py-phen)$_3$]$^{2+}$ (600 nm emission) is almost completely superimposible at all wavelengths with its absorption spectrum, suggesting a singlet energy transfer efficiency near unity. Similar behavior has been observed in related Ru(II)–pyrene chromophores.[9,11,12]

The excited state lifetime of [Ru(py-phen)$_3$]$^{2+}$ in thoroughly deaerated MeCN at infinite dilution is 148 ± 8 μs as measured with 458 nm laser pulses from an N$_2$-pumped dye laser (500 ps

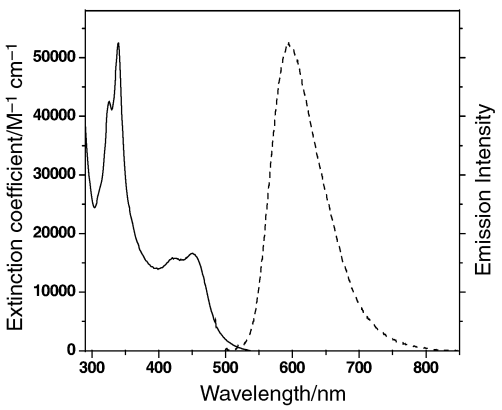

Fig. 2 Absorption (solid line) and emission (dashed line) spectra of [Ru(py-phen)$_3$]$^{2+}$ in MeCN at room temperature. The emission spectrum was recorded with 458 ± 2 nm excitation.

DOI: 10.1039/b007336i

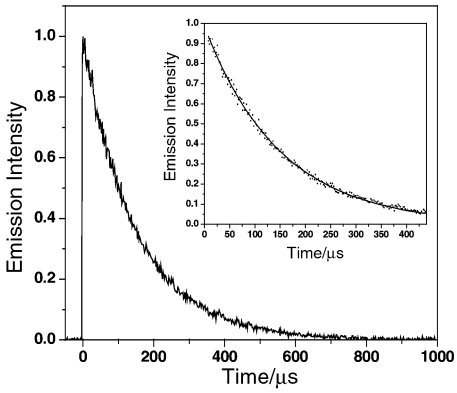

Fig. 3 Time-resolved emission decay of $[Ru(py\text{-}phen)_3]^{2+}$ in deaerated MeCN obtained with 458 ± 2 nm pulsed excitation (500 ps fwhm) detected at 600 nm. The decay represents an average of 128 laser pulses. Inset: data fit to a single exponential decay model.

fwhm), Fig. 3. A fast luminescence decay component (< 16 ns) was also observed, consistent with data obtained on related compounds.[8,10,11] This exceptionally long lifetime agrees well with the decay kinetics observed in the transients from the nanosecond laser flash photolysis experiments. However, the transient absorption profiles observed in $[Ru(py\text{-}phen)_3]^{2+}$ at all times following a 460 or 532 nm laser pulse are similar to that obtained with the uncoordinated py-phen ligand following 355 nm excitation. Therefore, the absorption transients provide evidence for the existence of a 'pyrene-like' triplet state at all delay times while there is no direct observation of a MLCT-based triplet state. The only observed radiative decay pathway for the $[Ru(py\text{-}phen)_3]^{2+}$ complex at room temperature is MLCT-based photoluminescence. In the model complex $[Ru(Ph\text{-}phen)_3]^{2+}$, where Ph-phen is 5-phenyl-1,10-phenanthroline, the lifetime under similar conditions is 1.15 μs.[13] In $[Ru(py\text{-}phen)_3]^{2+}$, the lifetime is extended *ca.* 129-fold relative to $[Ru(Ph\text{-}phen)_3]^{2+}$ as a consequence to the stabilization imparted by the energy transfer processes.

The observed excited state lifetime in $[Ru(py\text{-}phen)_3]^{2+}$ is very sensitive to subtle changes in oxygen concentration. Under our experimental conditions, high purity argon gas was continuously flowed through the cuvette during the measurement cycle, while maintained at a constant temperature of 20 ± 1 °C. Significant changes in lifetime could be correlated to the argon flow rate and temperature.

The long lifetime associated with the $[Ru(py\text{-}phen)_3]^{2+}$ complex permits a dynamic excited state self-quenching reaction at relatively dilute concentrations. Under our experimental conditions we did not observe any deviation in Beer's law behavior in the ground state absorption spectrum nor were we able to identify any new bands in the steady-state emission spectrum at concentrations between 2×10^{-6} and 2×10^{-5} M. Over this concentration range, the rates of emission decay are well modeled by a Stern–Volmer expression, recently used to describe self-quenching processes in Pt(II) diimine compounds.[14] The derived self-quenching rate constant of 1.3×10^8 M^{-1} s^{-1} is valid under optically dilute conditions and is clearly not a result of ground state aggregation.

The uncoordinated py-phen ligand displays structured phosphorescence at 77 K in 4:1 EtOH:MeOH in the presence of ethyl iodide when excited in the UV (342 nm). Visible excitation (458 nm) of $[Ru(py\text{-}phen)_3]^{2+}$ in the same frozen matrix yields a similarly structured emission, reflecting the dominance of pyrene-like triplets in the excited states. The decay kinetics of $[Ru(py\text{-}phen)_3]^{2+}$ at 77 K are complex, containing a long component of 46 ± 2 ms.

Energy transfer processes between the excited MLCT and pyrene states at room temperature facilitates the extension of the excited state lifetime in $[Ru(py\text{-}phen)_3]^{2+}$. The observed 148 μs lifetime is substantially beyond the range of any previously measured lifetime in this class of chromophores. Importantly, this lifetime was obtained without relying on energy gap law predictions. The complex is susceptible to dynamic self-quenching processes under optically dilute conditions. To our knowledge, this is the first example of such behavior in a Ru(II)–diimine complex. The room temperature emission in $[Ru(py\text{-}phen)_3]^{2+}$ is MLCT-based, however at 77 K, the emission emerges as a π–π*-based phosphorescence.

This communication describes a novel solid, crystals of which are grown by a diffusion technique, consisting of alternating fullerene and radical cation salt layers.

Fullerenes are known to form only neutral molecular complexes with the tetrathiafulvalene derivatives (TTFs†): (BEDT-TTF)$_2C_{60}$;[1] OMTTF•C_{60}·C_6H_6;[2] DBTTF·C_{60}·C_6H_6[3] and some others.[2,3] The lack of charge transfer defines the dielectric properties of these complexes.[2,3] On the other hand, TTF radical cation salts with different inorganic and organic anions demonstrate metallic and superconducting properties.[4] An example is a series of the BEDT-TTF salts with linear and polymeric anions which possess superconducting properties: (BEDT-TTF)$_2$X, X = I_3^-, IBr_2^-, AuI_2^-, ReO_4^-, $Cu(NCS)_2^-$ and (BEDT-TTF)$_4Hg_{2.89}Hal_8$, Hal = Cl, Br.[4] Since the properties of radical cation salts are affected by the polarizability of the molecules, we prepared compounds in which the TTF radical cation salts are surrounded by highly polarizable fullerene molecules (α_M = 85 Å^3 for C_{60}).[5]

In previous work we prepared a number of C_{60} neutral complexes and intercalated them by exposure to iodine vapor. The iodine replaces a solvent molecule and oxidizes a donor to a radical cation to form ($D^{\cdot+}I_n^-$)C_{60}, where $n \leqslant 5$ and D = DBTTF, TPDP or TMDTDM-TTF.[6] The intercalation process results in an increase of the conductivity of the complexes by 1–3 orders of magnitude. However, the diffusion process of intercalation does not allow synthesis of crystals with homogeneously distributed iodine. Therefore, we tried to synthesize such three-component compounds in solution. We reported earlier that cocrystallization of BEDT-TTF·$I_{3.5}$ in a saturated fullerene solution in a chlorobenzene–benzonitrile (1:5) mixture yielded (small) single crystals of (BEDT-TTF·I_3)C_{60}.[7] However, the crystals were not of adequate size to allow crystal structure determination.

Here we report the first crystal structure of (BEDT-TTF·I_3)C_{60} and a new general synthetic procedure for C_{60} complexes comprising radical cation salts of donors. The procedure allows the complexes to be prepared as single crystals suitable for diffraction studies.

(BEDT-TTF·I_3)C_{60} **1** was prepared by slow diffusion of iodine dissolved in acetonitrile which was layered on a solution of C_{60} and BEDT-TTF (1:1) in a 9:1 toluene–1,2-dichlorobenzene mixture. Crystals of **1** were formed as black hexahedrons on the walls of a flask. Simultaneously, planar rhomb-shaped crystals of β-(BEDT-TTF)$_2I_3$ free of C_{60} crystallize as an admixture.

The technique is based on the insolubility of both the fullerene and the donor radical cation salt $D^{\cdot+}I_n^-$ in acetonitrile. In this case the diffusion of the acetonitrile solution of iodine into the toluene–1,2-dichlorobenzene layer results in the formation of the ($D^{\cdot+}I_n^-$)C_{60} compound.

Single crystal X-ray diffraction data of **1**‡ shows that C_{60}, $(BEDT\text{-}TTF)^{\cdot+}$, and I_3^- are fully ordered, with the fullerene, $(BEDT\text{-}TTF)^{\cdot+}$ and I_3^- moieties residing in special positions on two-fold axes. The densely packed C_{60} layers parallel to the *bc* plane alternate with $(BEDT\text{-}TTF)^{\cdot+}$, and I_3^- layers. Fig. 1 shows the view of the crystal structure of **1** along the *b* axis.

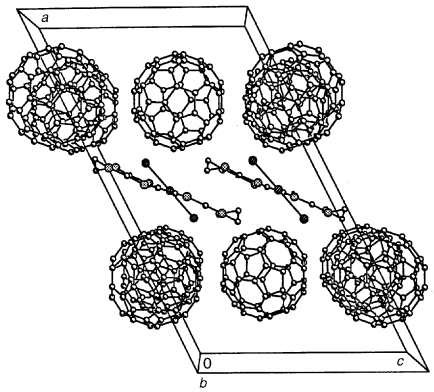

Fig. 1 The projection of the crystal structure of **1** along the *b* axis.

The shortest distance between the centers of the C_{60} molecules in parallel layers is 15.61 Å. Within the layers each C_{60} molecule is surrounded by six adjacent C_{60} molecules with center-to-center distances equal to 9.93–9.97 Å, close to similar distances in neat C_{60} crystals (9.94 Å at 153 K).[8] Adjacent C_{60} molecules within the layers are oriented with the five-membered rings facing each other or with the 6–5 bond of one molecule facing the center of the pentagonal ring of the adjacent molecule, with C···C distances in the range 3.22–3.37 Å.

The ion radical layer (Fig. 2) consists of chains in which the $(BEDT\text{-}TTF)^{\cdot+}$ ion alternates with I_3^-. One of the ethylene hydrogen atoms forms short contacts of 3.10(1) and 3.20(1) Å with two iodine atoms (Fig. 2). Adjacent chains are shifted with respect to each other to form a chequer-like arrangement of $(BEDT\text{-}TTF)^{\cdot+}$ and I_3^- within the layer. Short van der Waals S···I contacts (3.80–3.96 Å) link two $(BEDT\text{-}TTF)^{\cdot+}$ molecules in adjacent chains. The shortest S···S distance between $(BEDT\text{-}TTF)^{\cdot+}$ molecules in neighboring chains is 3.75–3.85 Å, which is larger than the sum of the van der Waals radii of two sulfur atoms (3.6 Å).

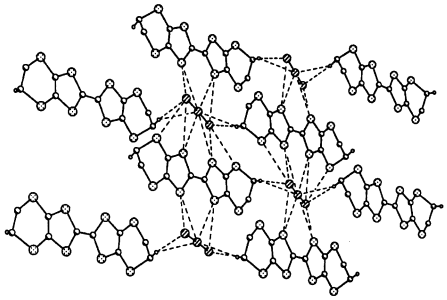

Fig. 2 The projection of the layer comprising $(BEDT\text{-}TTF)^{\cdot+}$ and I_3^- on the *bc* plane. Only H-atoms involved into short van der Waals contacts with I_3^- are shown.

DOI: 10.1039/b005541g

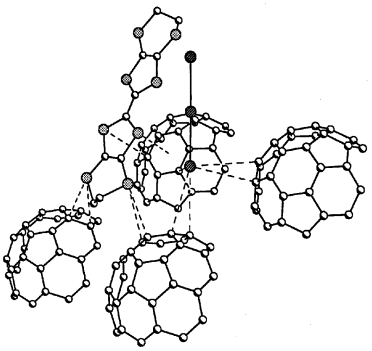

Fig. 3 Short van der Waals contacts between $(BEDT\text{-}TTF)^{\cdot+}$, I_3^- and C_{60}. Only the van der Waals contacts with one layer of C_{60} molecules are shown. Similar contacts are formed in the second adjacent layer.

Short van der Waals contacts exist between the C_{60} and the $(BEDT\text{-}TTF)^{\cdot+}/I_3^-$ layers (Fig. 3). Each $(BEDT\text{-}TTF)^{\cdot+}$ and I_3^- form short contacts with three C_{60} molecules in each of the adjacent layers. The S(BEDT-TTF)···C(C_{60}) distances (3.25–3.40 Å) in **1** are significantly shorter than those in the C_{60} complexes with neutral tetrathiafulvalenes: 3.446–3.556 Å in $(BEDT\text{-}TTF)_2C_{60}$;[1] 3.47–3.72 Å in DBTTF•C_{60}•C_6H_6;[3] 3.412–3.793 Å in $(TMDTDM\text{-}TTF)_2C_{60}(CS_2)_3$.[3] Such shortened contacts of $(BEDT\text{-}TTF)^{\cdot+}$ and C_{60} in **1** are a result of the penetration of the $(BEDT\text{-}TTF)^{\cdot+}$ molecules into the cavities in the fullerene layers (Fig. 3), while in the C_{60} complexes with neutral TTFs, the TTF molecules envelope the spherical surface of C_{60}. The linear I_3^- anions also extend into the cavities in the C_{60} layers to form five shortened van der Waals I···C(C_{60}) contacts [3.77–3.83(3) Å] (Fig. 3).

In contrast to $(BEDT\text{-}TTF)_2C_{60}$, in which the neutral BEDT-TTF molecule has a 'boat' conformation, $(BEDT\text{-}TTF)^{\cdot+}$ has an almost planar shape in **1** (Fig. 4). However, the short contacts with the C_{60} molecules affect the geometry of $(BEDT\text{-}TTF)^{\cdot+}$. In contrast to the η-$BEDT\text{-}TTF\cdot I_3$ salt,[9] $(BEDT\text{-}TTF)^{\cdot+}$ in **1** has a 'chair' conformation with the fold along the S1–S2 and S1a–S2a vectors, and dihedral angles between the planes ≈ 7.4°. The central S_4C_2 fragment of the molecule is not fully planar, but twisted around the double bond. The torsion angle between the plane formed by C1, S1, S2, and C1a, S1a, S2a is 174.1°. The six-membered ring has a sofa conformation, the deviation of the C4 atom from the plane of the other ring atoms being 0.806(4) Å. The central C=C bond length in $(BEDT\text{-}TTF)^{\cdot+}$ is 1.402(8) Å, close to that in η-$BEDT\text{-}TTF\cdot I_3$ [1.40(1) Å][9] and corresponding to a +1 charge on $(BEDT\text{-}TTF)^{\cdot+}$.

The ordering of the C_{60} molecules in **1** allows their bond lengths to be analyzed. The averaged lengths of the 6–6 and 6–5 bonds of C_{60} are 1.395(5) and 1.449(5) Å, respectively, the values being close to those of the 6–6 and 6–5 bonds in neutral $(BEDT\text{-}TTF)_2C_{60}$ [1.389(7) and 1.452(1) Å, respectively].[1] The diameters of the C_{60} molecule in three orthogonal directions running through the centers of the oppositely located 6–6 bonds

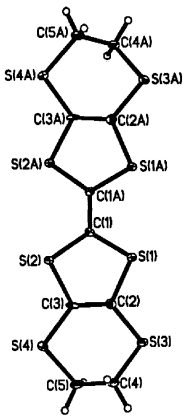

Fig. 4 Geometry of the $(BEDT\text{-}TTF)^{\cdot+}$ radical cation in **1**.

are equal to 6.941, 6.943 and 6.974 Å, thus the deviation from sphericity is only *ca.* 0.03 Å.

Thus, the structure of **1** retains to a great extent the features of the C_{60} structure, with radical cation layers separating the C_{60} layers. The $(BEDT\text{-}TTF)^{\cdot+}$ and I_3^- ions interact mostly electrostatically within the layer, while they form van der Waals contacts with fullerene layers.

1 is a semiconductor with $\sigma = 10^{-4}$ S cm^{-1}. Such behavior is characteristic of simple $BEDT\text{-}TTF\cdot I_3$ salts[9] with an integer charge (+1) on the BEDT-TTF molecule. In the current structure it can be associated also with the nature of the radical cation layer, in which there is no overlap of the π-orbitals of the $(BEDT\text{-}TTF)^{\cdot+}$ radical cations. It is known that BEDT-TTF salts with a formal charge of +0.5 show higher conductivity. However, the compound of composition $((BEDT\text{-}TTF)_2I_3)C_{60}$ cannot be prepared by the diffusion method. Recrystallization of the $(BEDT\text{-}TTF)_2I_3$ salt in fullerene solution yields only the neutral $(BEDT\text{-}TTF)_2C_{60}$ complex and the BEDT-TTF salts free of fullerene.

‡ *Crystal data* for **1:** $C_{70}H_8S_8I_3$, M = 1485.94; black hexagons, 0.4 × 0.2 × 0.2 mm, monoclinic, *C*2/*c*,*a* = 29.590(2), *b* = 9.9271(7), *c* = 17.2881(12) Å, β = 116.7350(10)°, V = 4535.4(5) Å^3, Z = 4, D_c = 2.176 g cm^{-3}. X-ray data were collected at 90 K using a Bruker SMART1000 CCD diffractometer installed at a rotating anode source (Mo−Kα radiation, λ = 0.71073 Å) and equipped with an Oxford Cryosystems nitrogen gas-flow apparatus. The data were collected by the rotation method with 0.3° frame−width (ω scan) and 20 s exposure time per frame. The data were integrated, scaled, sorted and averaged using the SMART software package of programs.[10] Empirical absorption corrections were applied (μ = 2.49 mm^{-1}) for the data collected using the SADABS program from the SMART software package.

The structure was solved by direct methods using SHELXTL NT version 5.10.[11] Positions of hydrogen atoms were found from the difference electronic density Fourier synthesis and refined using a 'riding model' with variable U_{iso}; 20392 reflections were collected, 4206 unique (R_{int} = 0.0639). Least-squares refinement on F^2 with anisotropic thermal parameters for all non-hydrogen atoms gave R_1 = 0.032 [for 3246 observed reflections with $F > 4\sigma(F)$], wR_2 = 0.085, final GOF = 1.03.

Received (in Cambridge, UK) 18th September 2000, Accepted 18th October 2000
First published as an Advance Article on the web

A series of new unsymmetrical 1, 1′-disubstituted ferrocenediyl ligands featuring thioether or thiolate substituents have been conveniently synthesised and, as an example of their coordinating ability, a bridged palladium dimer has been formed and structurally characterised.

Although ferrocene was discovered nearly fifty years ago, the search for new ferrocene derivatives and chemistry continues apace. In particular, versatile, stable and synthetically undemanding ferrocenyl and ferrocenediyl ligands are sought after due to their extensive coordination chemistry and applications within catalysis.[1,2] Ferrocene species with donor heteroatoms (*e.g.* P, N, S, O) substituted onto the cyclopentadienyl rings are well known, especially those featuring homo-substitution (*i.e.* the same donor atom along with the same alkyl or aryl substituents). Much less well-known are unsymmetrical 1,1′-disubstituted ferrocenes featuring hetero-combinations of N, P or S atoms, formed *via* bromo,[3,4] lithio[5,6] or stannyl[7,8] intermediates. These ligands are neutral in character and their preparations are often non-trivial. So far as we are aware, examples of unsymmetrical purely S-substituted neutral and neutral–anionic ferrocenediyl ligands (*i.e.* analogous to the hemilabile P/S$^-$,[9] P/O$^-$,[10,11] and N/O$^-$[12] ('SHOP') based-catalysts) are hitherto unknown. Here, we report the new and convenient syntheses of the first examples of these types of ligands and a preliminary study of their coordination chemistry which has led to the isolation and structural characterisation of a novel palladium dimer complex.

The new ligands **1**–**4** can be synthesised from the well known 1, 2, 3-trithia[3]ferrocenophane[13] (Scheme 1). By utilising an elegant method first described by Herberhold *et al*,[14] the trisulfur bridge can be cleaved by organolithium reagents to form (after air oxidation) bis(1′-organylthiolatoferrocenyl)disulfanes. Herberhold *et al.* have prepared the species RS–Fc–SS–Fc–SR (R = *n*-butyl, phenyl; Fc = 1,1′-ferrocenediyl), but during our research into the formation of redox-active and sterically hindered ligands for homogeneous catalysis, we reacted the ferrocenophane (1 equiv.) with mesityllithium (2 equiv.) and formed RS–Fc–SS–Fc–SR **1** (where R = mesityl). This species may be an interesting, sterically hindered ligand in its own right, but at present, we have concentrated on the formation of the monoferrocenediyl species **2**–**4**.† On reaction of **1** (1 equiv.) with lithium triethylborohydride (2.2 equiv.) in THF and after acid/base work-up, the air-sensitive orange solid **2** was isolated in 88% yield. ^{1}H NMR spectroscopy showed the unsymmetrical substitution of the cyclopentadienyl rings with the presence of signals due to S-mesityl, S–H and *four* pseudo triplets for the C_5H_4 ring protons.

A solution of **1** was also treated with methyllithium (2.2 equiv.) and the reaction mixture stirred for 16 h. Cleavage of the disulfide linkage was effected and the crude orange mixture obtained was washed, extracted and purified *via* column chromatography [neutral grade II alumina, CH_2Cl_2–hexane (1:4)] and **3** was isolated as an air- and moisture-stable orange oil (50%) (*N.B.* 25% of **1** was also isolated). The use at this stage of various organolithium reagents can of course, lead to derivatisation and a possible 'fine-tuning' of the steric and redox properties of the ligands. Finally, a solution of **1** (1 equiv.) in THF was treated with lithium triethylborohydride (2.2 equiv.) and stirred for 1.5 h. On evaporation to dryness, a dark red oily product **4** was formed in quantitative yield but was not isolated due to its unstable nature. As confirmation of its formation and as a preliminary investigation into its coordination chemistry, **4** was treated with *trans*-[Pd(PhCN)$_2$Cl$_2$] (2 equiv.) in toluene and heated to 60 °C for 16 h. Following work-up and crystallisation in CH_2Cl_2–hexane (1:1), the purple–black product **5** was isolated in 81% yield as a crystalline solid. The X-ray analysis of **5**‡ shows that the desired bidentate coordination of the ferrocenediyl species has been achieved. Surprisingly, however, a bridged dimer has been formed where, for each ligand, one of the sulfur atoms is binucleating and carries a formal negative charge whereas the other links to a single palladium ion and is formally neutral (Fig. 1). The complex has non-crystallographic C_2 symmetry about an axis passing through the centre of, and normal to the plane of, the Pd_2S_2 ring, *i.e.* both ferrocenediyl units lie on the same side of the two linked coordination planes. Each ferrocenediyl unit adopts a staggered conformation, their S–C_5H_4 bonds 'subtending' angles of 45 and 46° for Fe(1) and Fe(2), respectively. The two palladium coordination planes are folded by *ca.* 30° out of plane with respect to each other about the S(3)···S(4) vector. The transannular Pd···Pd and S···S distances in the central four-membered ring are 3.394 and 2.998 Å, respectively. The geometry at each palladium centre is distorted square planar with *cis* angles in the ranges 81.1(2)–101.9(2) and 81.0(2)–102.5(2)° at Pd(1) and Pd(2), respectively. The Pd–S distances fall into two distinct groups with those to the negatively charged bridging sulfurs sig-

nificantly shorter than those to the others. Surprisingly, the Pd–S bridge distances are symmetric, *i.e*. there is no *trans* influence of the chloride ligands. The complexes are linked by a combination of C–H···π and π–π interactions to form sheets that extend in the *ab* plane (Fig. 2). The space between adjacent parallel sheets is occupied by disordered dichloromethane molecules. This type of bridged system featuring a thioether/thiolate ligand appears to be unique, the only other similar species being a palladium dimer featuring bridging *di*thiolate ligands.[15]

† *Syntheses*: **2**: compound **1** (0.50 g, 0.65 mmol) was dissolved in dry, deoxygenated THF (30 cm^3) and to this lithium triethylborohydride (1 M solution in THF, 1.40 cm^3, 1.40 mmol) was added and the reaction mixture stirred for 1.5 h. The solvent was removed *in vacuo* and the residue then redissolved in diethyl ether. The dark red solution was poured onto dilute base (1% KOH) (20 cm^3), followed by dropwise addition of conc. HCl. The layers were separated and the aqueous layer extracted with diethyl ether (3 × 20 cm^3). The combined organic layers were dried ($MgSO_4$) and evaporated to dryness to leave an air-sensitive orange solid **2** (0.42 g, 88%); $\delta_H(CDCl_3)$ 2.21 (3H, s, CH_3), 2.47 (6H, s, CH_3), 2.98 (1H, s, SH), 4.10 (2H, t, C_5H_4), 4.21 (4H, t, C_5H_4), 4.33 (2H, t, C_5H_4), 6.86 (2H, s, C_6H_2); *m/z* 367 ($M - H^+$), 334 ($M - SH^+$).

3: a solution of **1** (0.58 g, 0.79 mmol) in THF (40 cm^3) was treated with methyllithium (1.6 M solution in diethyl ether, 1.1 cm^3, 1.74 mmol) and the reaction mixture stirred for 16 h. The solvent was evaporated *in vacuo*, the residue was dissolved in diethyl ether (50 cm^3) and water (10 cm^3) was added. The layers were separated and the aqueous layer extracted with diethyl ether (3 × 20 cm^3). The combined organic layers were dried ($MgSO_4$), then evaporated to dryness. The product was purified by column chromatography [neutral grade II alumina, CH_2Cl_2–hexane (20:80)] and after removal of the solvent, isolated as an orange oil (0.15 g, 50%); $\delta_H(CDCl_3)$ 2.24 (3H, s, CH_3), 2.34 (3H, s, SCH_3), 2.51 (6H, s, CH_3), 4.13 (2H, t, C_5H_4), 4.26 (4H, m, C_5H_4), 4.34 (2H, t, C_5H_4), 6.88 (2H, s, C_6H_2); *m/z* 382 (M^+), 367 ($M - CH_3^+$), 271 ($M - C_5H_4SCH_3^+$).

4 and **5**: a solution of **1** (0.10 g, 0.135 mmol) in THF (30 cm^3) was treated with lithium triethylborohydride (1 M solution in THF, 0.3 cm^3, 0.30 mmol) and the reaction stirred for 1.5 h. The air-sensitive dark red solution of **4** was formed in quantitative yield and due to its instability was reacted *in situ* without work-up. Thus, a toluene (30 cm^3) solution of **4** was treated with bis(benzonitrile)palladium(II) dichloride (0.103 g, 0.27 mmol) also in toluene (30 cm^3). There was an immediate darkening of the solution to deep purple and stirring at 60 °C was continued for 16 h. A black ppt. was filtered off and the filtrate washed with water (2 × 10 cm^3), dried ($MgSO_4$) and evaporated to dryness. The crude residue was washed with hot hexane (2 × 40 cm^3) and recrystallised from CH_2Cl_2–hexane (1:1) to leave a purple crystalline powder **5** (0.11 g, 81%); $\delta_H(CDCl_3)$ 2.16 (6H, s, CH_3), 2.41 (6H, s, CH_3), 3.29 (6H, s, CH_3), 4.07 (2H, m, C_5H_4), 4.28 (2H, m, C_5H_4), 4.44 (2H, m, C_5H_4), 4.57 (2H, m, C_5H_4), 4.60 (2H, m, C_5H_4), 4.66 (2H, m, C_5H_4), 5.07 (2H, m, C_5H_4), 6.80 (2H, m, C_6H_2), 6.93 (2H, s, C_6H_2); *m/z* 982 ($M - Cl^+$), 897 ($M - mes^+$).

_S_-Nitrosoglutathione (GSNO) undergoes decomposition induced by hydroxyl radicals (·OH) in aqueous medium at neutral pH forming nitrite (NO_2^-) and glutathione disulfide (GSSG) and therefore it is proposed that ·OH could interfere in the GSNO metabolism.

S-Nitrosothiols (RSNO) are important class of compounds which are now believed to play a major role *in vivo* in connection with the storage and transport of nitric oxide (·NO) within the body.[1,2] The mechanism of the formation of RSNO from the reaction of ·NO with protein thiols in the presence and in the absence of oxygen is reasonably well understood.[3–6] The involvement of RSNOs in the storage and transport of ·NO within the body makes them potential candidates for medical applications. For example *S*-nitrosoglutathione (GSNO) is currently used to inhibit platelet aggregation during some operations.[7,8] Therefore, the kinetics and mechanism of the release of ·NO by RSNO is very important. Excellent reports on the kinetics and mechanism of the degradation of RSNO leading to the release of ·NO by metal ions and some nucleophiles are now available.[9,10] Reaction of *S*-nitrosocysteine (SNCys) with hydrogen peroxide yields peroxynitrite anion.[11] It is also reported that GSNO reacts with superoxide radicals ($O_2^{\cdot -}$) generating glutathione disulfide (GSSG) and equimolar quantities of nitrite and nitrate.[12]

Glutathione (GSH) is the most abundant sulfur-containing intracellular entity (cellular concentration *ca.* 5 mM) and therefore the endothelial nitric oxide has to diffuse through the cells in presence of GSH. This leads to the assumption that *in vivo* conditions, the most likely *S*-nitrosation product could be the GSNO.[13] Hydroxyl radicals (·OH) are the main DNA damaging agent which can be produced *in vivo* during oxidative stress and on exposure to ionizing radiations.[14] Understanding of the reaction between ·OH and GSNO is, therefore, a matter of utmost importance in a biological perspective. The present communication describes a novel reaction pathway for the decomposition of GSNO in presence of ·OH at neutral pH. To our knowledge, this is the first report on the reaction of ·OH with a possible reservoir for ·NO in biological systems.

One of the major difficulties involved in the ·OH reaction with RSNOs is that the components of most of the ·OH generating systems such as H_2O_2 photolysis, Fenton reaction, *etc*., themselves can induce degradation of RSNOs. In this context, radiation chemical method is an ideal choice where ionizing radiations such as γ-rays can radiolyze water and produce both oxidising and reducing radicals. Therefore, in the present work we have used radiation chemical technique to produce ·OH as shown in reactions (1) and (2).

$$H_2O \rightsquigarrow e_{aq}^-, H^{\cdot}, {}^{\cdot}OH, H_2, H_2O_2, H_3O^+ \quad (1)$$

$$N_2O + e_{aq}^- + H_2O \rightarrow {}^{\cdot}OH + OH^- + N_2 \quad (2)$$

The yields of various radicals and molecular products are normally expressed as *G*-values which are defined as the number of molecules formed or destroyed per 100 eV absorption of radiation energy, in SI units, the yields are, $G(^{\cdot}OH) \approx G(e_{aq}^-) \approx G(H_3O^+) = 0.28$, $G(^{\cdot}H) = 0.062$, $G(H_2O_2) = 0.072$ and $G(H_2) = 0.047$ μmol J^{-1}.[15] In the presence of N_2O the $G(^{\cdot}OH) = 0.56$ and $G(OH^-) = 0.28$ μmol J^{-1} as per reaction (2).

GSNO was synthesised from $NaNO_2$ in presence of HCl.[16] N_2O saturated solutions containing GSNO (10^{-3} M) and EDTA (10^{-4} M) at pH 7.3 were irradiated at different doses in a ^{60}Co-γ-source and the decay of GSNO was monitored by both UV–VIS spectrophotometry and HPLC. The unirradiated solution of GSNO was found to be stable for many hours when protected from light. The $G(-GSNO)$ values obtained in both cases were 0.53 and 0.54 μmol J^{-1} respectively. GSSG and nitrite were found to be the major products of radiolysis from the HPLC analysis. The decay of GSNO and the corresponding products build up are shown in Fig. 1. The calculated G(GSSG) and $G(NO_2^-)$ are 0.13 and 0.41 μmol J^{-1}, respectively. The pH of the solutions were determined before and after irradiation and a dose dependent reduction in pH was observed which is tabulated in Table 1. A blank solution without GSNO under similar conditions was also irradiated and obtained no major pH changes.

A good material balance can be observed from the G(GSSG) and $G(NO_2^-)$ values as $G(-GSNO) \approx G(GSSG) + G(NO_2^-)$. A minor contribution of NO_2^- is anticipated from the decay of peroxynitrite which could be formed as a result of the reaction of GSNO with H_2O_2 formed during radiolysis, as reported earlier.[11] However, this contribution is expected to be ⩽ 0.072 μmol J^{-1} [this value corresponds to $G(H_2O_2) = 0.072$ μmol J^{-1}]. Therefore, the major reaction is definitely between ·OH and GSNO. ·OH generally reacts with thiols including GSH by

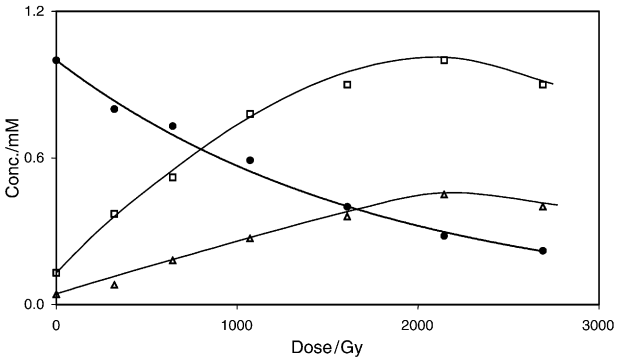

Fig. 1 Dose dependent decay of GSNO (●) at pH 7.3 and the corresponding formation of NO_2^- (□) and GSSG (Δ) determined by using HPLC (Column: 25 cm, Nucleosil, 5C-18; eluent: mixture of sodium phosphate (10^{-3} M) and sodium sulfate (10^{-2} M) in water; flow rate: 1 ml min^{-1}; λ = 210 nm).

H-abstraction (from –SH) forming thiyl radicals ($RS^{\cdot}$) as the main intermediate as reported earlier.[17,18] Although the sulfur is bonded to NO in GSNO, the most potential site for $^{\cdot}OH$ attack is expected at the sulfur centre. On the other hand, the H-abstraction reaction which is reported in the case of GSH will not be possible in the present case. Therefore, based on the above observations we propose a reaction mechanism involving the attack of $^{\cdot}OH$ at the electron rich sulfur centre of GSNO [reactions (3)–(6)]. The initial attack of $^{\cdot}OH$ in GSNO (electron transfer) would produce a highly unstable cationic species as shown in reaction (3), which may lead to the breakage of the S–N bond and result in the formation of $GS^{\cdot}$ and NO^{+}. However, such a cationic intermediate ($GS^{+}NO$) is expected to be very short lived and no experimental evidence for its exact identity as well as its transnitrosation reaction [reaction (4)] is available at this moment. The subsequent reactions of NO^{+} with OH^{-} which is formed as shown in reaction (3), can lead to nitrite and H^{+} formation. The combination of two sulfur centered radicals ($RS^{\cdot}$) and the corresponding formation of disulfide (RSSR) is a well known reaction reported in the case of low molecular weight thiols.[19] Therefore, a similar radical–radical reaction of $GS^{\cdot}$ is proposed for the formation of GSSG.

$$GSNO + {}^{\cdot}OH \rightarrow [GS^{+}NO] + OH^{-} \quad (3)$$

$$[GS^{+}NO] \rightarrow GS^{\cdot} + NO^{+} \quad (4)$$

$$OH^{-} + NO^{+} \rightarrow H^{+} + NO_2^{-} \quad (5)$$

$$GS^{\cdot} \rightarrow \tfrac{1}{2}\,GSSG \quad (6)$$

Therefore, the overall reaction mechanism can be written as

$$GSNO + {}^{\cdot}OH \rightarrow \tfrac{1}{2}\,GSSG + NO_2^{-} + H^{+} \quad (7)$$

The dose dependent reduction in the pH values (Table 1) provides clear support to the above mechanism. Further, we exclude the possibility of the formation of nitrate as the reaction is carried out in N_2O saturated solutions where the presence of oxygen is insignificant.

In conclusion, the mechanistic aspects of the reaction of $^{\cdot}OH$ with GSNO, one among the biologically important *S*-nitrosothiols, have been proposed for the first time. The fast decay of GSNO in the presence of $^{\cdot}OH$ and the corresponding formation of nitrite and glutathione disulfide provide evidence for the possible interference of $^{\cdot}OH$ in the GSNO metabolism. One more question to be asked from these findings is, does GSNO have any sacrificial role like glutathione in terms of its protective role against oxidative stress? However, such a role can be established only after a clear understanding of the concentration of GSNO *in vivo* and of the exact rate constant of $^{\cdot}OH$ with GSNO, which are yet to be investigated. Our work is currently being concentrated in these directions.

We thank the Rubber Research Institute of India, Kottayam, for the γ-irradiation experiments. V. M. M. thanks the Nuclear Science Centre, New Delhi, for a fellowship. Part of the financial support for this work is from the Board of Research in Nuclear Sciences (BRNS), Govt. of India.

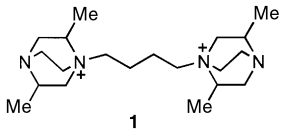
Received (in Irvine, CA, USA) 26th June 2000, Accepted 12th September 2000
First published as an Advance Article on the web

The framework topology of the novel molecular sieve GUS-1 is reported; the crystalline architecture is characterized by a one-dimensional 12-membered ring channel system that is closely related to the channels of mordenite and ZSM-12.

The search for new microporous solids has shown some successes in recent years as the number of new topologies has doubled within a decade.[1] A key factor is the use of the structure-directing effects of organic species for generating new frameworks. We report here the structure of a novel molecular sieve GUS-1 using 1,1′-butylenedi(4-aza-1-azonia-2,5-dimethylbicyclo[2.2.2]octane) dihydroxide (**1**-hydroxide) as organic structure-directing agent (SDA).

The GUS-1-containing sample was synthesized under hydrothermal conditions. A synthesis mixture of composition $1SiO_2:0.1R^{2+}(OH^-)_2:0.1NaOH:50H_2O$, where the silica source was fumed silica (Cab-O-Sil M-5, Cabot), was heated at 150–175 °C statically under autogeneous pressure for 10–20 d. In order to remove the occluded organics, the sample was calcined at 700 °C for 6 h in air. R^{2+} stands for structure **1** and



1

its hydroxide form, **1**-hydroxide, was prepared by refluxing 1,4-dibromobutane and excess 2,5-dimethyl-1,4-diazabicyclo[2.2.2]octane in acetone–methanol, followed by ion-exchange.§

The GUS-1 phase tends to come along with ZSM-12, and the synthesis of the new phase in pure form has not been successful so far. Synthesis under all-silica conditions gave a sample with relatively higher GUS-1 content, making structure elucidation of the new phase possible. Further synthetic details are forthcoming.

Structure determination of GUS-1 was carried out from synchrotron powder diffraction data. The powder pattern was collected at the X7A beamline at the National Synchrotron Light Source at Brookhaven Laboratory. The calcined sample was packed in a 1 mm capillary. Acquisition was carried out at room temperature at the wavelength λ = 1.196417 Å.

The reflections of GUS-1 were indexed using the program TREOR.[2] A solution was obtained in the orthorhombic system with lattice constants a = 16.411(2), b = 20.044(2), c = 5.0427(3) Å and figures of merit[3,4] $M(16)$ = 53 and $F(16)$ = 60(0.003,85), after refinement of the unit-cell. Systematic absences indicate C-centering and are consistent with the space groups *Cmmm* and subgroups, and possibly $C222_1$.

A weak, unindexed line is found at position d = 14.4 Å. The interplanar distance is characteristic of the (100) reflection of zeolite SSZ-31.[5] The other peaks of SSZ-31 are not visible in the powder pattern due to the high density of peaks and the structural relations between SSZ-31 and ZSM-12. The SEM pictures show a large number of particles with the typical needle shape of ZSM-12 crystals. Overgrowth of thin needles is observed on the crystallites of ZSM-12, which is assigned to GUS-1. A small number of particles with the fan-like morphology characteristic of SSZ-31 crystallites are also present in the sample.[5]

GUS-1 possesses a small *c*-axis, c = 5.0 Å, reducing the structure determination to a search of the two-dimensional projection of the zeolite into the *ab* plane of the cell. In addition, the N_2 adsorption measurements reveal that the adsorption isotherm of the sample containing the two phases, GUS-1 and ZSM-12, is very similar to the isotherm of pure ZSM-12, suggesting that the unknown phase is a molecular sieve with 12-ring channels too. Models have been built with *Cmmm* symmetry and 12-ring channels running along the *c*-axis. A good candidate was found showing the same projection as mordenite along the pore. The model contains four independent tetrahedral sites of equal multiplicity, in agreement with the ^{29}Si MAS NMR spectrum of the sample where three lines in the ratio 1:2:1 are observed in addition to the seven peaks of ZSM-12.[6]

An optimization of the geometry of the framework has been performed using a distance least squares (DLS)[7] refinement of the atomic positions in space group *Cmmm* and subgroups, assuming a distance $d_{Si–O}$ = 1.61 Å. The model refined in space group *Cmmm* shows a high residual R value, R_{DLS} 0.0150. However, typical R_{DLS} values are obtained for the subgroups *Cmm*2 and *C*222 where R_{DLS} = 0.0024 and 0.0029, respectively. A high R_{DLS} value indicates strong distortions of the framework in the presence of a reflection plane in the *ab* plane. The framework with *Cmmm* symmetry exhibits Si–O–Si bond angles of 180° due to the presence of a bridging oxygen atom on an inversion center. Straight Si–O–Si bond angles are recurrent in the mordenite group, as an oxygen atom is found on an identical symmetry element in mordenite[8] and dachiardite.[9] The 180° bond angle constraint is released by reducing the symmetry of the framework to *Cmm*2 or *C*222.

Further framework searches were performed using the program FOCUS.[10,11] The structure factors of the phase GUS-1 were extracted using the Lebail method[12] in the GSAS software[13] and normalized after estimation of the scale factor by a Wilson plot.

The mordenite-like structure found by model building was generated with the highest frequency. A variety of frameworks with 12-ring channels was also obtained. Most of them are derived from the same mordenite sheet but distorted with the bonds directed up or down at different nodes. All these solutions were discarded based on the poor match of their simulated powder pattern to the experimental data and the high R_{DLS} values.

The Rietveld refinement was performed with the two phases in approximate composition 40% GUS-1 and 60% ZSM-12. The impurity SSZ-31 was ignored during the refinement. The space group *C*222 was selected for the framework of GUS-1 and

the initial atomic coordinates were the positions obtained from the DLS refinement. For ZSM-12 the powder pattern shows the superstructure reflections indicating the doubling of the *c* dimension. The space group is assumed *C*2/*c* and the atomic positions obtained by Fyfe *et al.* were used as starting model.[6] Peak broadening corrections due to particle size effects were applied for both phases. Soft geometric constraints on the Si–O distances were maintained for the two structures until the final stage of the refinement.

Fig. 1 shows a close fit between the calculated and the experimental powder pattern confirming the framework topology of GUS-1. The final residuals are R_{wp} = 7.4%, R_p = 5.5%, and the R_F factors for the individual phases are R_F = 9.8 and R_F = 7.9% for GUS-1 and ZSM-12 respectively.¶

The Si–O distances were maintained for both structures in the range 1.58–1.62 Å. For GUS-1 the averaged Si–O distance $d_{Si–O}$, is 1.60 Å and the Si–O–Si bond angles range from 136 to 169° with an average of 151°.

The Rietveld refinement performed for the space group *Cmm*2 for GUS-1 gave slightly higher *R* factors. The coexistence in the sample of two other phases (including the SSZ-31 impurity) probably introduces a bias in the structure refinement of GUS-1 as the line intensities cannot be properly estimated. It should be noted in particular that the Si–O distances reported by Fyfe *et al.* for the refinement from synchrotron data of all-silica ZSM-12 vary from 1.53–1.70 Å, suggesting that the structure model adopted for ZSM-12 is not completely satisfactory.[6] Therefore, the main result of the Rietveld refinement with the available data is the confirmation of the framework topology of GUS-1.

The structure of GUS-1 is shown in Fig. 2. GUS-1 is a molecular sieve with one-dimensional, 12-ring channels running along the *c*-axis. The projection of the structure in the *ab* plane is similar to the projection of mordenite along the pores [Fig. 2(a)]. GUS-1 shows also common features with ZSM-12. Both structures have the same framework density, *TD* = 19.3 Si atoms per nm^3, have a short axis with a repeat unit of *ca.* 5 Å and possess the same secondary building unit $4^2 5^4 6^2$ [Fig. 2(b)]. But the most striking similarity is the channel structure: both zeolites have an identical channel net composed of six-rings only [Fig. 2(c)]. The channel aperture of GUS-1 is elliptical in shape with deformation from circular shape intermediate between mordenite and ZSM-12. The minor and major free diameters are 5.6 and 7.0 Å, respectively, calculated in the topological symmetry *Cmmm*, with an oxygen radius 1.35 Å.[1]

It is worth mentioning that linear faults along the pore direction have been found in mordenite.[14–16] Different strain-free structures related to mordenite can be obtained by half unit-cell shifts of the four-ring columns along the *c*-axis.[17,18] A simple model describes the faulting as a one-half shift of the *c*-axis,[14,16] which leads to the formation of units $4^2 5^4 6^2$ [Fig. 2(b)]. The framework of mordenite can adopt locally the GUS-1 topology in a highly defective sample by gathering of faults.

In summary, the crystal structure of a new high-silica microporous solid has been elucidated from the synchrotron powder X-ray diffraction data of a mixture of phases. The new framework GUS-1 has symmetrical topology *Cmmm* and shows structural relationships with both mordenite and ZSM-12 frameworks. The formation of ZSM-12 in the presence of GUS-1 may be partly due to the instability of the present SDA.‖ The search for a new SDA that is more stable and suitable for GUS-1 formation is now in progress.

An ordered microporous carbon that preserves the structural regularity of Y zeolite has been prepared by a template carbonization technique using Y zeolite.

The synthesis of porous carbon materials is of great importance for both practical and fundamental reasons. The recent development of industrial technology requires porous carbons to have a tailored pore structure. The importance of pore structure control has been pointed out for applications such as electrode materials for electric double-layer capacitors and adsorbents for methane storage. To meet the requirements, many novel approaches to control pore structure have been proposed. The detailed features of these techniques have been recently reviewed by Kyotani.[1] One of the most important and elegant techniques is a template carbonization method,[2–7] which utilizes the inorganic templates whose opening or pores are controlled at the nanometer level. We demonstrated that porous carbons with a surface area as high as 2200 $m^2\ g^{-1}$ could be prepared using Y zeolite as a template.[8] There were also a few other reports on such carbon formation in zeolite channels.[9,10] Recently, two Korean research groups have independently obtained mesoporous carbon with ordered structure using mesoporous silica (MCM-48) as a template.[11,12] Their works are the first example of synthesizing an ordered mesoporous carbon. However, none of these porous carbons has a regular microporous structure. Here, by filling as much carbon as possible into the channels of Y zeolite template, we attempted to prepare an ordered microporous carbon that retains the structural regularity of Y zeolite. The obtained microporous carbon has a periodical ordering of 1.4 nm, which is the same as the spacing of (111) plane of Y zeolite.

A two-step method was used in the preparation of carbon material. In the first step, dry Y zeolite powder (Na-form, $SiO_2/Al_2O_3 = 5.6$, Tosoh Inc., HSZ-320NAA) was impregnated with furfuryl alcohol (FA) under reduced pressure at room temperature. The mixture of FA and zeolite powder was stirred for 5 days and then filtered, followed by washing the product with mesitylene. The FA/zeolite composite was placed in a vertical quartz reactor and FA was polymerized in zeolite by heating the composite at 150 °C under N_2 flow. The resultant PFA (polyfurfuryl alcohol)/zeolite composite was heat-treated at 700 °C for 4 h to carbonize the polymer in the zeolite channels. After this first carbon filling, the reactor temperature was raised to 800 °C and then propylene gas (2.0% in N_2) was passed through the reactor for 4 h. This second step resulted in pyrolytic carbon deposition into the remaining opening of the composite. After the propylene CVD, the zeolite framework in the carbon/zeolite composite was dissolved by successive washing with HF and HCl solution. Carbon was obtained as an insoluble fraction. The elemental analysis of the carbon was as follows: C, 94 wt%; H, 2 wt%; O, 4 wt% (difference). The ash content was nearly zero with an experimental error of ±0.1 wt%, indicating almost perfect removal of zeolite template.

The crystallinity and the microscopic features of the carbon were examined using an X-ray diffractometer (XRD, Shimadzu, XD-D1, Cu-Kα radiation) and transmission electron microscopy (TEM, JEOL, JEM-2010). The pore structure was investigated with an automatic volumetric sorption analyzer (Quantachrome, Autosorb-1) using N_2 as the adsorbate at −196 °C. The micropore and mesopore volumes were determined from methods describe elsewhere.[8]

Fig. 1 shows the XRD patterns of the original Y zeolite and the carbon liberated from the carbon/zeolite composite. The former pattern [Fig. 1(a)] is characterized by the appearance of many sharp peaks due to the framework topology of Y zeolite. Among these peaks, the strongest appearing at $2\theta = 6.19°$ can be indexed as the diffraction from the (111) plane. In the XRD pattern of the carbon [Fig. 1(b)], a sharp peak appeared at $2\theta = 6.26°$, together with a very broad and weak peak in the range $2\theta = 23–27°$. This type of broad peak is often observed as the (002) diffraction from carbonaceous materials with poor crystallinity. However, a sharp peak at 2θ *ca.* 6° as observed in Fig. 1(b) has not, to our knowledge, been reported. The presence of the sharp peak indicates that this carbon has a long-range ordering with a periodicity of 1.41 nm, almost the same as the spacing of the (111) plane in Y zeolite (1.43 nm). The presence of such periodical ordering was further confirmed by the lattice fringe image discussed below.

From TEM observation, it was found that each carbon particle consists of a thin and dense envelope with straight lattice fringes present inside each envelope. Fig. 2(a) shows a typical image of lattice fringes, which run along the envelope located on the upper part of this picture. The regular spacing of the observed lattice planes is about 1.3 nm and the diffraction from these planes was clearly observed as a pair of sharp spots in the corresponding electron diffraction pattern [Fig. 2(b)].

Taking the results of our previous work[8] into consideration, we can ascribe the envelopes observed in the particles to the carbon deposited on the external surface of the zeolite particles. When we prepared porous carbon with a shorter CVD period (2 h), many of the resultant carbon particles had no envelope

DOI: 10.1039/b006295m

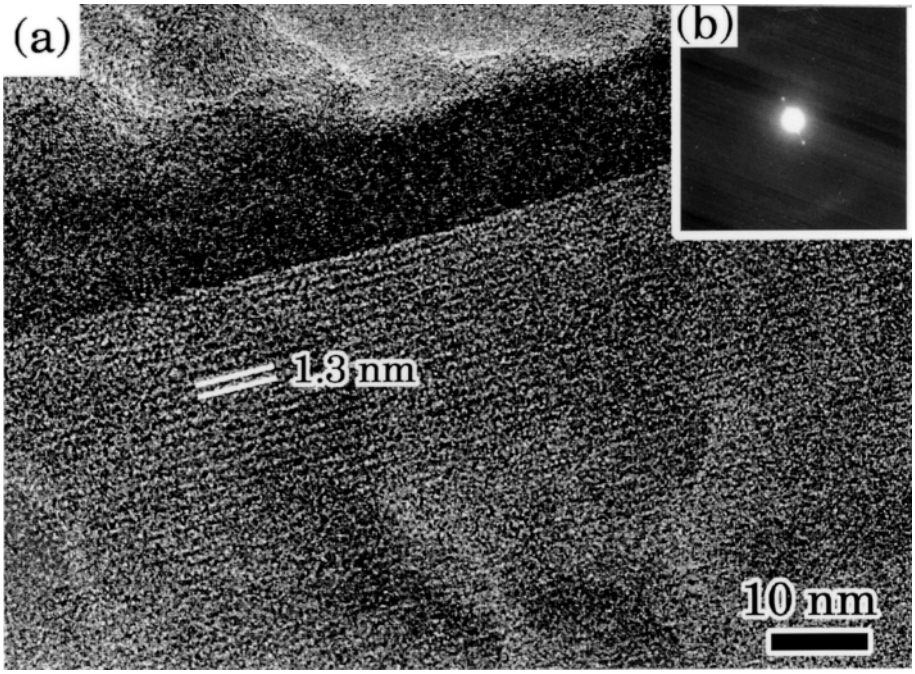

Fig. 2 (a) High-resolution TEM image of part of a carbon particle. (b) Electron diffraction pattern taken from the image of (a).

and the XRD pattern of this carbon did not show such a broad (002) XRD peak as in Fig. 1(b). This finding indicates that the broad XRD peak arises from the envelopes and there is no stacking structure of (002) layers in the ordered carbon.

Fig. 3 shows a N_2 adsorption–desorption isotherm of the carbon. In the relative pressure range of >0.2, the isotherm shows an almost flat sorption characteristic. Furthermore, there is almost no hysteresis loop in the isotherm. These findings clearly indicate the absence of mesoporosity in the carbon. The BET surface area, the micropore and mesopore volumes were calculated from this isotherm to be 1910 $m^2\ g^{-1}$, 1.1 $cm^3\ g^{-1}$ and 0 $cm^3\ g^{-1}$, respectively. In our previous study,[8] we prepared high surface area carbons by a one-step carbon filling method, *via* propylene CVD over Y zeolite. The resultant carbons had both micro- and meso-porosity. The porosity of the carbon obtained here, however, shows highly developed microporous structure without any mesopores.

In conclusion, a microporous carbon with a long-range periodic ordering (d = 1.4 nm) has been synthesized for the first time. Such structural periodicity in the carbon would originate from the structural ordering in Y zeolite. It is well known that Y zeolite consists of a tetrahedral network structure of sodalite units, which results in a supercage, *i.e.* a large cavity with a diameter of 1.3 nm. Each supercage is connected to four other supercages by an opening with a diameter of 0.74 nm. Due to this framework topology, many sharp XRD peaks appeared as in Fig. 1(a). However, the carbon gave only one sharp XRD peak at the angle corresponding to the (111) diffraction [Fig. 2(b)]. No other peak was observed at the angles where sharp peaks from the zeolite appeared. This implies that the carbon retains only the structural ordering of (111) plane stacking of Y zeolite.

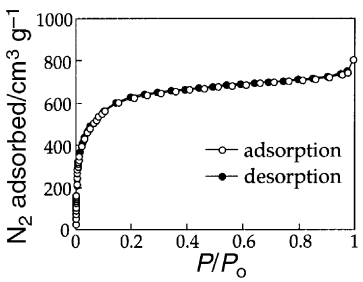

Fig. 3 N_2 adsorption–desorption isotherm at −196 °C for the carbon. The adsorption and desorption curves are plotted using open and filled circles, respectively.

The formation of the ordered microporous carbon suggests that the amount of carbon filled into the zeolite channels by the present method was sufficient to preserve the network structure reflecting the zeolite template. Also, if one can fill zeolite channels with a sufficient amount of carbon for other types of zeolites with three-dimensional structures such as ZSM-5, ZMS-11 and A zeolite, this opens up a possibility for the preparation of a series of microporous carbons having the structural regularity of template zeolites.

We thank the High Voltage Electron Microscope Laboratory of Tohoku University for microscopical analysis. This work was partly supported by the Grant-in-Aid for Scientific Research on the Priority Area 'Fullerene and Nanotubes' by the Ministry of Education, Science, and Culture of Japan.

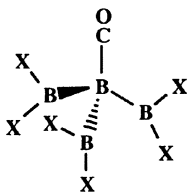
Received (in Cambridge, UK) 14th September 2000, Accepted 18th October 2000
First published as an Advance Article on the web

The borane carbonyl adduct $(Cl_2B)_3BCO$ has been prepared and characterised by spectroscopic methods and X-ray crystallography and is compared with the fluorine analogue $(F_2B)_3BCO$ which has also been structurally characterised by X-ray crystallography.

In recent years the study of carbon monoxide as a ligand has attracted renewed attention largely as a result of the discovery and characterisation of many so-called 'non-classical metal carbonyls' for which metal to CO π-backbonding is thought to be absent or at least much reduced in comparison with more classical species.[1] These compounds merit comparison with the few known boron carbonyl complexes such as the borane carbonyls H_3BCO,[2]† B_4H_8CO,[4] and $(F_2B)_3BCO$ **1** prepared by



1, X = F; **2**, X = Cl

Timms,[5,6] the related silicon containing species $(Cl_3Si)_2(Cl_2B)BCO$,[7] and the osmium cluster complex $[Os_3(CO)_9(\mu\text{-}H)_3(\mu_3\text{-}BCO)]$ prepared by Shore *et al.*[8] Herein we report the X-ray structure of **1** and the preparation and X-ray structure of the chloro analogue $(Cl_2B)_3BCO$ **2**.

Compound **2** was prepared by two methods. In the first instance, BCl_3 was passed through a column of boron granules contained in a graphite tube inductively heated to *ca.* 2000 °C under high vacuum, using an apparatus slightly modified from that described for the preparation of BF.[5,6] The hot vapour emerging from the graphite tube, believed to be a mixture of BCl and BCl_3 in a mole ratio of about 1 : 3, was then condensed on the liquid nitrogen cooled walls of the surrounding vacuum vessel. When the condensate was allowed to warm to room temperature with continuous pumping through a cold trap, a mixture of BCl_3 and B_2Cl_4 was collected; no B_4Cl_4 was detected in contrast to earlier studies involving BCl.[9] However, when a similar experiment was carried out in which the condensate was allowed to warm to room temperature in the presence of a 3×10^4 Pa pressure of CO, the resulting volatiles comprised not only BCl_3 and B_2Cl_4 but also the white crystalline solid **2**.

Spectroscopic data for **2** were consistent with the formula $(Cl_2B)_3BCO$‡ which was confirmed by X-ray crystallography (*vide infra*). The formation of **2** in the above experiment may involve the intermediacy of $(Cl_2B)_2BCl$, just as the condensation of BF is known to yield $(F_2B)_2BF$ which, in the presence of CO, gives **1** and B_2F_4.[5] Compound **2** was also prepared in a more direct manner and in essentially quantitative yield by treating **1** (prepared as described in ref. 5) with an excess of BCl_3 vapour for a few minutes at room temperature.

The structures of both **1** and **2** were determined by X-ray crystallography.§ Compound **1** crystallises with two molecules in the asymmetric unit one of which is shown in Fig. 1. Compound **2** resides on a crystallographic C_3 axis and part of the crystal structure is shown in Fig. 2. On a molecular level, the structures are very similar and also similar to that reported for the PF_3 analogue of **1**, $(F_2B)_3BPF_3$.[11] The central boron atoms in each structure are all within a degree of being tetrahedral and the B–B bond lengths [1.677(5)–1.690(5) Å for **1** and 1.694(7)

DOI: 10.1039/b007484p

Å for **2**] are of the same order as those observed in $(F_2B)_3BPF_3$ [1.677(15) Å][11] and B_2F_4 [1.67(4) Å].[12] The B–F bonds in **1** range from 1.302(4) to 1.317(4) Å [*cf.* 1.30, 1.32(3) and 1.305(15) for BF_3,[13] B_2F_4[12] and $(F_2B)_3BPF_3$[11] respectively] whilst the two B–Cl bond lengths in **2** [1.748(7) Å] are similar to other B–Cl bond distances for trigonal planar boron.[14] Both **1** and **2** have C_{3v} symmetry, crystallographically constrained in the latter case, such that the three BX_2 planes lie parallel to the BCO axis. Despite the similarity in the molecular structures, however, **1** and **2** pack differently in the solid state. Thus, although there are no close intermolecular contacts in either structure, **1** [and $(F_2B)_3BPF_3$] crystallises in a centrosymmetric space group $P2_1/n$ [*Pnma* for $(F_2B)_3BPF_3$] whereas **2** crystallises in the polar space group *R*3*m* with all BCO vectors aligned along the crystallographic *c* axis.

The CO stretching frequencies for **1** (2162 cm^{-1})[5] and **2** (2176 cm^{-1}) are both higher than that of free CO (2143 cm^{-1}) but are close to those observed in many non-classical metal carbonyls[1] and in $(Cl_3Si)_2(Cl_2B)BCO$.[7] Such values are often characteristic of non-classical carbonyls and are associated with increased σ-donation and little if any π-donation into the CO π*-orbitals[1,3] (electrostatic effects are also thought to be important[3]). As expected, both **1** and **2** have C–O bond lengths which appear to be shorter than CO itself [**1**, 1.117(3), 1.116(3) Å; **2**, 1.091(14) Å; CO, 1.1281 Å]. However, given the relatively large esds involved, such comparisons must be made with due caution.

In conclusion, we note that the synthesis of **2** and the structures of **1** and **2** provide a significant contribution to what is known about CO adducts of boron and to the study of non-classical CO complexes in general. Both **1** and **2** are stable to CO loss and future studies, both theoretical and experimental, will address the magnitude of the B–C bond dissociation energy.

We thank the EPSRC for support and for a studentship (J. A. J. P.).

Notes and references

† A recent and comprehensively referenced theoretical analysis of the bonding and stability of the compounds H_3BCO, F_3BCO and $(C_6F_5)_3BCO$ has been carried out by Berke and Erker *et al*.[3] where the analogy between borane carbonyls and non-classical metal carbonyls is also addressed.

‡ *Spectroscopic data* for **2**: ^{11}B NMR (CD_2Cl_2) δ 68.2 [br s, 3B, $(Cl_2B)_3BCO$], −20.7 [br s, 1B, $(Cl_2B)_3BCO$] (referenced to $BF_3{\cdot}Et_2O$). IR (thin film on AgCl window) ν(CO) 2176 cm^{-1}. Mass spectrum (EI), *m/z* 166 (B_3Cl_3CO), 221 (B_4Cl_5), 249 (B_4Cl_5CO) all with correct isotope patterns.

§ A suitable single crystal of **1** was prepared inside a Lindemann tube by condensing its vapour into the tube, sealing it under vacuum and cycling the temperature between 20 and 35 °C. A colourless needle crystal of **2** was grown under vacuum at 4 °C and transferred and sealed under nitrogen in a Lindemann tube prior to mounting on the diffractometer. Both compounds are pyrophoric.

Crystal data: for **1**: CB_4F_6O, M = 185.25, monoclinic, space group $P2_1/n$ (no. 14), a = 10.909(3), b = 11.518(3), c = 11.098(3) Å, β = 90.548(18)°, U = 1394.4(6) $Å^3$, Z = 8, D_c = 1.765 Mg m^{-3}, λ = 0.71073 Å, μ(Mo-Kα) = 0.218 mm^{-1}, F(000) = 704, T = 292(2) K.

For **2**: CB_4Cl_6O, M = 283.95, rhombohedral on hexagonal axes, space group *R*3*m* (no. 160), a = 11.150(5), c = 7.586(4) Å, U = 816.8(7) $Å^3$, Z = 8, D_c = 1.732 Mg m^{-3}, λ = 0.71073 Å, μ(Mo-Kα) = 1.520 mm^{-1}, F(000) = 1700, T = 292(2) K.

Data for both structures were collected on a Siemens SMART diffractometer over the range $2.55 < \theta < 27.51°$ for **1** and $3.42 < \theta < 27.51°$ for **2**. The structures were solved by direct methods using SHELXL97[10] and refined by least squares methods against all 2363 F^2 values with $F^2 > -3\sigma(F^2)$ to $wR2$ = 0.1102 [$R1$ = 0.0419 for 1117 data with $F^2 > 2\sigma(F^2)$] for **1** and all 316 F^2 values with $F^2 > -3\sigma(F^2)$ to $wR2$ = 0.0939 [$R1$ = 0.0391 for 280 data with $F^2 > 2\sigma(F^2)$].

Both crystals suffered significant degradation during the later stages of data collection owing to the propensity of the two compounds to sublime at room temperature and for this reason only the first set of frames in each data set were used in solving the structures. Because of the extreme sensitivity of both compounds they were mounted in Lindemann tubes rather than in frozen oil drops which, owing to the nature of the diffractometer cooling apparatus, precluded data collection at low temperature.

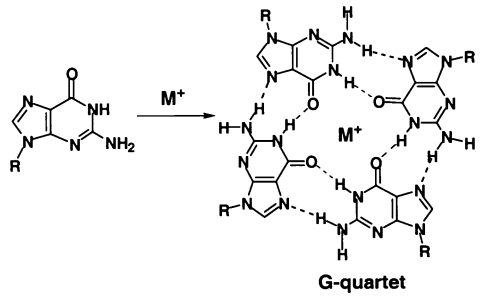
In the presence of Na^+, a 1,3-*alternate*-calix[4]arene bearing four guanosine units forms a self-assembled nanotube.

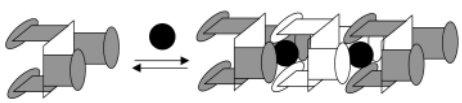
With the current interest in fabricating nanoscale structures for potential biomedical and materials applications much attention has focused on supramolecular tubes. Nanotubes have been made from cyclic peptides,[1] lipids,[2] oligocyclodextrins,[3] hydrogen-bonded rosettes[4] and coordination complexes.[5,6]

Predicting and controlling structure is essential for optimizing function. Herein, we report our initial efforts on building functional nanotubes, with an eye towards using them as artificial ion channels. Our design hinges on the metal cation-templated self-assembly of guanosine, a nucleobase that readily forms a hydrogen-bonded quartet in the presence of cations (Scheme 1).[7,8] The cyclic G-quartet, stabilized by Na^+ or K^+, can further organize by stacking. Telomeric DNA forms a G-quadruplex with a cation-filled channel;[9] and G-wires, over 1000 nm in length, have been imaged by atomic force microscopy.[10] We have also recently shown by X-ray crystallography that lipophilic G nucleosides self-associate to give extended, tube-like structures upon cation coordination.[11]



Scheme 1

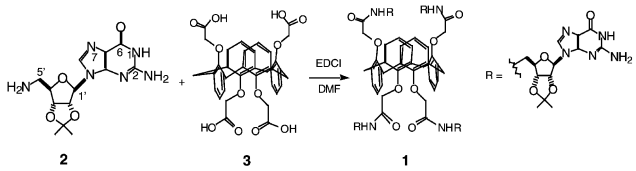
Our modular approach towards constructing nanotubes involves using sodium cations to trigger the one-dimensional polymerization of G_4-calix **1**, a compound with four G moieties attached to a calix[4]arene-1,3-*alternate* scaffold. The 1,3-*alt* core in monomer **1** orients two orthogonal pairs of self-complementary G nucleosides so that they are well positioned for intermolecular hydrogen bonding with neighboring monomers (Scheme 2). Hosseini and coworkers introduced the calix[4]arene-1,3-*alt* scaffold to organize groups in this alternating 'up-down-up-down' fashion[12] and demonstrated this scaffold's utility by using Ag^+–cyano coordination bonds to form a self-assembled 'metallatubulane.'[6]



Scheme 2 Representation of nanotube formation by G_4-calixarene **1** upon cation-templated self-assembly. Squares represent the 1,3-*alt*-calix[4]arene core, ovals represent the guanosine moieties, and solid spheres represent the Na^+ cations.

† Electronic supplementary information (ESI) available: experimental and synthetic details. See http://www.rsc.org/suppdata/cc/b0/b007332f/

Compound **1** was readily prepared in six steps from guanosine and the parent *tert*-butylcalix[4]arene.[13] The final step in the synthesis of G_4-calix **1** involved the EDCI-promoted coupling of 5′-amino-2′,3′-isopropylidene G **2**[14] with the calix[4]arene-1,3-*alt* tetraacid **3**[15] (Scheme 3). The G_4-calix **1** was isolated by precipitation from MeOH, purified on microcrystalline cellulose TLC plates, and characterized by FAB-MS and ^1H NMR spectroscopy. The FAB-MS indicated complete substitution of a G residue at each of the calixarene's four sidechains. The symmetrical ^1H NMR spectrum of G_4-calix **1** in DMSO-d_6 confirmed its 1,3-*alt* conformation, and also verified that nucleoside coupling to the calixarene had occurred at the more nucleophilic 5′-amine of G **2**, and not at the less reactive exocyclic N2 amino group.



Scheme 3

The G_4-calix **1** was soluble in a MeCN–H_2O (1:1) binary mixture. Addition of $NaBPh_4$ to a solution of G_4-calix **1** in this mixture resulted in the instantaneous and quantitative precipitation of a white solid. The ^1H NMR spectrum of this material in d_6-DMSO confirmed that it was a mixture of G_4-calix **1** and the BPh_4^- anion. Transmission electron microscopy (TEM) images (Fig. 1) show the precipitate to consist of micrometer-long

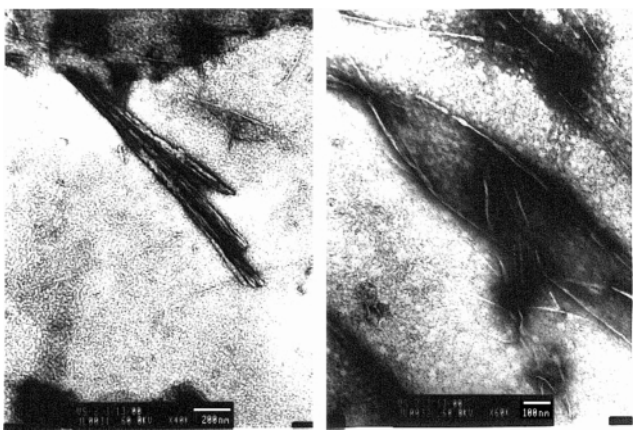


Fig. 1 Representative TEM images of the precipitate formed by G_4-calixarene **1** and $NaBPh_4$ in MeCN–H_2O (1:1) solution. Objects have thicknesses between *ca.* 3 nm (many of the objects in the right image) and *ca.* 50 nm (most objects in the left image), and lengths between 80 nm and 1.5 μm. The thinnest rods, with the approximate thickness of a G-quartet, may correspond to single self-assembled nanotubes. The thicker objects are likely bundles of nanotubes. The unit scale is 200 nm for the left image and 100 nm for the right image.

DOI: 10.1039/b007332f

(b) Data for titration of $NaBPh_4$ into a MeCN–H_2O (1 : 1) solution containing 2′,3′-isopropylidene guanosine. Note that there is essentially no difference between the results of experiments (a) and (b). (c) Data for titration of $NaBPh_4$ into a MeCN–H_2O (1 : 1) solution containing G_4-calix **1**. Note the difference in the scale of the *y*-axis (heat evolved) for experiment (c), as compared to experiments (a) and (b). (d) Integration curve for raw data from titration (c). The inflection point is consistent with formation of a complex having a 1 : 1 ratio for G_4-calix **1** : $NaBPh_4$. The total enthalpy of the interaction is −9 kcal mol^{-1}.

strands, visible as either single tubes or as bundles of tubes (ranging from *ca.* 3 nm to 50 nm in thickness). The strands are relatively straight, without much bending. The thickness of the individual tubes was near the microscope's limit of resolution, namely *ca.* 3 nm. Since our recent X-ray structure of a lipophilic G-quadruplex showed a tubular structure with a 2.65 nm diameter,[11] the individual rods formed from Na^+ templated aggregation of G_4-calix **1** have dimensions expected for a G-quartet. These electron micrographs of insoluble aggregates, showing such defined structure, are entirely consistent with nanotube formation by G_4-calix **1** upon Na^+ coordination.[16]

The stoichiometry of the insoluble aggregate formed between G_4-calix **1** and $NaBPh_4$ was quantitatively determined using isothermal titration calorimetry (ITC). Titration of a solution of G_4-calix **1** in MeCN–H_2O (1 : 1) with $NaBPh_4$ resulted in the rapid and significant generation of heat, until a 1 : 1 ratio of G_4-calix **1** and $NaBPh_4$ had been reached [Fig. 2(c) and 2(d)]. The total enthalpy of Na^+ binding by G_4-calix **1** was −9 kcal mol^{-1}; and this exothermic reaction coincided with precipitation of the $(\mathbf{1}\cdot Na^+)_n$ aggregate from solution as its BPh_4 salt. The absence of other inflection points in the ITC experiment, besides that for the prominent 1 : 1 G_4-calix **1**–$NaBPh_4$ stoichiometry, suggests that nanotube formation by G_4-calix **1** does not pass through shorter, intermediate structures. In other words, cation-templated nanotube formation of $(\mathbf{1}\cdot Na^+)_n$ is highly cooperative. Control ITC experiments showed that 2′,3′-isopropylidene guanosine, a compound lacking the calixarene framework, does not bind $NaBPh_4$ in this polar MeCN–H_2O (1 : 1) solvent mixture [Fig. 2(a) and (b)]. Thus, the heat evolved upon addition of $NaBPh_4$ to MeCN–H_2O (1 : 1) is the same whether or not 2′,3′-isopropylidene guanosine is present in solution. These ITC experiments clearly illustrate the entropic advantage of attaching the G moieties to the 1,3-*alt*-calixarene scaffold. Moreover, cation-templated aggregation of G_4-calix **1** is kinetically fast, and self-assembly of G_4 tetramers occurs even in this highly competitive hydrogen-bonding solvent mixture.

The assembly process that gives the $(G_4\text{-calix } \mathbf{1}\cdot Na^+)_n$ is completely reversible. Both temperature and pH can be used to control the cation-templated aggregation of G_4-calix **1**. For example, the precipitate formed from G_4-calix **1** and $NaBPh_4$ at 25 °C can be solubilized in MeCN–H_2O (1 : 1) simply by heating. DSC of a suspension of $(\mathbf{1}\cdot Na^+)_n$ in MeCN–H_2O (1 : 1) revealed a sharp transition temperature of 44.5 °C for dissolution. Cooling the sample back to 25 °C resulted, again, in precipitation of $(\mathbf{1}\cdot Na^+)_n(BPh_4^-)_n$. In addition to temperature, pH also had a dramatic effect on the solubility, and presumably the aggregation state, of $(\mathbf{1}\cdot Na^+)_n$. Protonation of the G nucleobase's exocyclic N2 amine and N7 should disrupt the structure of the hydrogen-bonded G-quartet. Indeed, this is consistent with the observation that the insoluble $(\mathbf{1}\cdot Na^+)_n(BPh_4^-)_n$ was completely redissolved in MeCN–H_2O upon changing from pH 7 to 2. This pH-dependent cycle was reversible, as addition of triethylamine base so as to change the solution's pH from 2 to 9 caused reprecipitation of $(\mathbf{1}\cdot Na^+)_n(BPh_4^-)_n$. The thermal lability and acid sensitivity of these hydrogen-bonded nanotubes formed from G_4-calix **1** is consistent with the reversible nature of self-assembly.

Three features of our nanotube design are worth emphasizing: (1) long-range structure can be controlled by cation templation, which triggers formation of an extensive hydrogen-bonded assembly based on the G-quartet; (2) aggregation is enabled by covalent attachment of guanosine units to the *alt*-1,3 calixarene scaffold, and (3) self-association of G_4-calix **1** occurs even in highly polar solvents. Future studies will focus on using temperature, pH, and other variables, to control the polymerization and depolymerization of G_4-calix **1**. The reversible formation of these structures in water at temperatures near 40 °C makes G_4-calix **1** and its analogs interesting as materials for biomedical applications. Finally, we are preparing lipophilic analogs of G_4-calix **1** in an effort to make artificial ion channels that self-assemble within a bilayer membrane.

15 The calix[4]arene-1,3-*alt* tetraacid **3** was prepared by hydrolysis of the known tetraester: K. Iwamoto and S. Shinkai, *J. Org. Chem.*, 1992, **57**, 7066.
16 Control experiments confirmed that the appended guanosine units in G_4-calix **1** are essential for cation-templated aggregation. Thus, addition of $NaBPh_4$ to a solution of a calix[4]arene-1,3-*alt*-tetramethylamide dissolved in MeCN–H_2O (1 : 1) showed no evidence for precipitation. Moreover, ^1H NMR experiments in the same solvent showed no evidence for formation of soluble aggregates from Na^+ and calix[4]arene-1,3-*alt*-tetramethylamide (see ESI† for details regarding these control experiments).

The central 'relay' unit in hydraphile channels as a model for the water-and-ion 'capsule' of channel proteins

Clare L. Murray, Hossein Shabany and George W. Gokel*

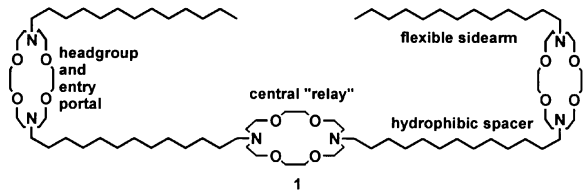
Bioorganic Chemistry Program and Dept. of Molecular Biology & Pharmacology, Washington University School of Medicine, 660 South Euclid Ave., Campus Box 8103, St. Louis, MO 63110, USA. E-mail: ggokel@molecool.wustl.edu

Received (in Columbia, MO, USA) 28th June 2000, Accepted 16th October 2000
First published as an Advance Article on the web

The central relay of hydraphile channels is a model for the central ion-capsule of the KcsA K1 K^+-conducting channel of *Streptomyces lividans*; organization of water and concomitant electrostatic stabilization of a transient K^+ appear to be the functions in both cases.

The synthetic ion channels that we call 'hydraphiles' transport Na^+ in phospholipid bilayers.[1] These compounds use crown ethers, typically 4,13-diaza-18-crown-6, as headgroups[2] to maintain their position at the boundary between the bilayer and the aqueous phase on either side of the membrane. Fluorescence studies[3] have shown that the distal macrocycles of **1** are each 14 Å from the bilayer's midplane and in an environment intermediate in polarity between methanol and ethanol. These data are consistent with the macrocycles being proximal to the glyceryl fragment (midpolar regime) of the phospholipid—at opposite ends of the membrane's insulator slab. The headgroups are connected to a 'central relay unit' by means of hydrophobic dodecyl chains that measure *ca.* 14 Å in the extended conformation. The central relay is a polar residue incorported to provide the transient cation a means of sabilization at the bilayer's midplane—the least polar regime in the membrane. In many of the compounds we have studied, this unit is a third crown ether (*e.g.* **1**)

Recently, the solid state structure of a K^+-selective channel from *Streptomyces lividans* (KcsA K1 channel)[4] was reported and has begun to revolutionize our understanding of channel-forming proteins.[5] In this report, the structure of the natural channel is characterized thus: 'From inside the cell…the pore begins as a tunnel 18 Å in length (the internal pore) and then opens into a wide cavity (~ 10 Å across) near the middle of the membrane.' This description applies almost as well to our hydraphile channels. In the same paper, the following question is posed. 'Why is there a 10 Å diameter cavity in the center of the channel with an ion in it?' In a subsequent theoretical report,[6] it was concluded that the central capsule provides a means for electrostatic stabilization of cations in the non-polar midplane of the phospholipid bilayer. We believe that the cavity is equivalent to our 'central relay unit' and we present evidence to that effect in this report.



1

Hydraphiles **1**–**8** were prepared by a three-step sequence. First, monobenzyldiaza-18-crown-6 ($PhCH_2 < N18N > H$) was prepared either by benzylation of diaza-18-crown-6 or by partial hydrogenolysis of dibenzyldiaza-18-crown-6.[7] Alkylation of $PhCH_2 < N18N > H$ with an excess of $Br(CH_2)_nBr$ afforded $PhCH_2 < N18N > (CH_2)_nBr$ which was then allowed to react with $H < N18N > H$. Compound **9** was prepared in an analogous fashion except that $H < N18N > H$ was monoalkylated with dansyl chloride rather than benzyl bromide. Based on studies to determine the optimal length,[8] the hydraphiles were designed to be *ca.* 38–42 Å between the proximal nitrogen atoms of the terminal macrocycles. For small central units, proportionally longer hydrophobic chains were incorporated.

8

Sodium cation flux was measured by using the ^{23}Na NMR-based method of Riddell *et al.*[9] This technique permits quantitative detection of the Na^+ transport rate in vesicles prepared[10] from phosphatidylcholine and phosphatidylglycerol (4:1 w/w, pH = 7.3). The NMR experiment is somewhat complex and we have therefore normalized the data relative to a simultaneously determined standard (**9**).[11] Transport rates for **9** have been determined independently more than 10 times and each of the values shown in Table 1 for **1**–**8** represents at least three independent experiments.

The efficacy of a diaza-15-crown-5 central unit (**3**) is half that of the corresponding 18-membered ring (**1**, **2**). A further reduction in transport efficacy is observed when the central macroring is reduced in size to 12 atoms (**4**): transport efficacy falls again (k_{rel} = 69). Transport is about the same (within *ca.* 10% experimental error) when the 4,4′-bipiperidyl central unit (**6**) replaces diaza-12-crown-4 (**4**). The transport rate falls (to k_{rel} = 50) when the central ring of **4** (2N and 2O donors) is 'lysed' (**5**, 4O donors). All transport efficacy is lost when either pyrazine (**7**) or 4,4′-dioxybiphenyl (**8**) is incorporated as the central unit.

When the hydraphiles were designed, the central unit was intended to be a 'relay' for transient cations. It was presumed that the cations would be partially solvated as is thought to be the case in protein channels. Crown ethers often bind cations that, in turn, are bound to water. In the present case, we postulate that the central unit helps to organize water and that the cation 'passes over' it rather than necessarily being exchanged for water bound in the cavity. 18-Membered crown ethers are well known to bind water. Indeed, we reported the

Table 1 Sodium cation transport by hydraphile ionophores[a]

Compound	Structure	d^a/Å	$k_{rel}{}^b$ (%)
1	$PhCH_2 < N18N > C_{14} < N18N > C_{14} < N18N > CH_2Ph$	43	211
2	$PhCH_2 < N18N > C_{12} < N18N > C_{12} < N18N > CH_2Ph$	38	200
3	$PhCH_2 < N18N > C_{14} < N15N > C_{14} < N18N > CH_2Ph$	42	100
4	$PhCH_2 < N18N > C_{14} < N12N > C_{14} < N18N > CH_2Ph$	41	69
5	$PhCH_2 < N18N > C_{12}O(CH_2CH_2O)_3C_{12} < N18N > CH_2Ph$	42	50
6	$PhCH_2 < N18N > C_{14} < NC_5 > — < C_5N > C_{14} < N18N > CH_2Ph$	42	80
7	$PhCH_2 < N18N > C_{16} < NC_4N > C_{16} < N_{18}N > CH_2Ph$	42	< 2
8	$PhCH_2 < N18N > COC_{11} < OC_6H_4–C_6H_4O > C_{11}CO < N18N > CH_2Ph$	38	< 2
9	$Dn < N18N > C_{12} < N18N > C_{12} < N18N > Dn$	38	100

[a] Distance measured on CPK molecular models between the two proximal nitrogen atoms on the distal macrocycles. [b] Rate relative to dansyl channel, arbitrarily set at 100. Comparative rates are recorded for 10 μM ionophore concentration.

first case of a protonated azacrown complexing a water molecule in 1977.[12] Other examples abound.[13] The solid state structures show a water molecule bridging alternate heteroatoms in the 18-membered ring macrocycles. Such bridging is also possible for the 15- and 12-membered ring compounds but the number of symmetry equivalent bridges is reduced. Thus, on a single surface of 18-crown-6, there are five possible 1,3-heteroatom arrangements that could be bridged by water. In 15-crown-5, there are only three and in 12-crown-4, only two are possible. The Na^+ transport rates observed for **2** (18-crown), **3** (15-crown) and **4** (12-crown) are 211, 100 and 69. This is a ratio (for **2**:**3**:**4**) of 2.1:1:0.7. The ratio of symmetry equivalent water bridges is 1.7:1:0.7. Opened-chained compound **5** can also form water bridges but it is not even as well organized as is **4**. The data presented here for the change from 18- to 15-membered rings and open chains differ some from an earlier,[14] related study.[15] The trend is similar, however.

The 4,4′-bipiperidyl unit of **6** was included because it is a fairly rigid molecule[16] and the N↔N separation is almost identical to the transannular N,N-distance in 4,13-diaza-18-crown-6. When the 4,4′-ring junction is *anti*, the cyclohexane-like units are coplanar. Molecular models show that the overall aspect is concave when the ring junction is *syn*, the nitrogen atoms are focused to a point above the ring junction, and the N↔N separation is barely 6 Å. We speculate that the bipiperidyl unit adds rigidity to the overall structure while providing H-bonding donor or acceptor sites either in the form of neutral nitrogen, protonated nitrogen, or the carbonyl groups. The argument is bolstered by the ESI-MS study that shows **6** to be incapable of binding three cations whereas **1** can easily do so (see following communication).[17]

When a macrocycle comprises the central unit, water may be organized by complexation and appropriately situated either to solvate a transient cation or to exchange with the water present in the partially hydrated cation. Such an arrangement is tantamount to the now well known second-sphere coordination of metal–ammonia complexes.[18] Such a coordinative arrangement is also possible, although probably less effective for the *syn*-oriented bipiperidyl units. In the latter case, however, a partially solvated cation of the form $M(OH_2)_2{}^+$ could bridge the N↔N space as illustrated in Fig. 1. The hydraphiles containing either piperidine in which the nitrogens are clearly very close together (*ca.* 3 Å) or biphenylene, which lacks significant donor groups, fail to transport cations despite the presence of all of the other essential elements.

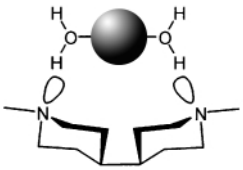

Fig. 1 Presumed coordination of a dihydrated alkali metal cation by 4,4′-dipiperidine.

We believe that simple, structural models such as the hydraphiles offer an effective means to probe complex biological phenomena. Clearly, these central units lack the focused, α-helices that afford electrostatic stabilization in the KcsA K1 channel.[1,4] Still, variations in the structure of the central relay are possible in this model system which permits functional subunits to be transformed—clearly an advantage over single site mutagenesis. Additional structural alterations are in progress and the results will be reported in due course.

We thank the NIH (GM 36262) and NSF (CHE-9805840) for grants that supported this work.

11 Gramicidin is so effective at forming channels, it gives positive results even when experimental conditions are less than optimal. Thus, a negative observation for a hydraphile when gramicidin is positive could be misleading. Dansyl channel **9** is effective but frail enough to indicate experimental difficuly.

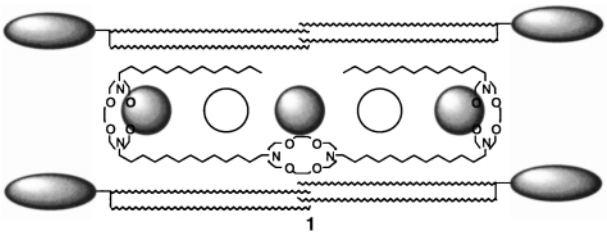
First published as an Advance Article on the web

A novel, pentamacrocyclic host molecule has been prepared in which four symmetry-equivalent diazacrown ethers lead to a dramatic enhancement in Na^+ transport, across a phospholipid bilayer, relative to open-chained analogs lacking the fourth crown.

Our strategy[1] to design functional, non-peptide cation-conducting channels[2] has two key elements. First, the system was designed to be flexible so that the structural features could adapt if their exact physical organization had not been correctly evaluated. Second, the planned design was modular so that a compound exhibiting ionophoretic activity in a phospholipid bilayer membrane could be selectively and readily altered. The incorporation of flexibility into the framework could permit minor structural adjustments to compensate for design flaws but could also lead to a non-optimal structural arrangement. This, in turn, could result in poorer function than that of which the system was actually capable.

The first hydraphile structure **1**,[3] a tris(macrocycle), was



1

covalently-linked to define the overall transmembrane distance but the corresponding opposite side pendant chains were attached only at the distal macrocycles. The conformation shown for structure **1** has been inferred by changing the macroring sizes,[4] by incorporating fluorescent residues,[5] and by other methods.[6] The filled and open circles in the figure are meant to represent Na^+ and H_2O, respectively, but details of the structure within the membrane are not in hand nor are they implied. Note that we use shorthand developed for the purpose[7] to represent **1** as follows: C_{12} < N18N > C_{12} < N18N > C_{12} < N18N > C_{12}.

Studies to determine optimal overall length,[8] coupled with the efforts described above, have led to the conviction that we could connect the two flexible sidechains to form a more rigid and more efficacious structure. Compound **7** (Scheme 1) was a target of this approach. The synthetic plan required a strategy different from that that we had used previously. Compound **1**, which is not cyclic, can be constructed without the requirement for a cyclization reaction.[9] Tetramacrocycle **7**, the key compound in this report, was prepared by a sequence that is detailed in Scheme 1. Monobenzyl-4,13-diaza-18-crown-6[10] ($PhCH_2$ < N18N > H) was alkylated with methyl 12-bromododecanoate. The ester was hydrolyzed, treated with oxalyl chloride to give $PhCH_2$ < N18N > $(CH_2)_{11}COCl$, and then treated with diaza-18-crown-6 to give $PhCH_2$ < N18N > $(CH_2)_{11}CO$ < N18N > - $CO(CH_2)_{11}$ < N18N > CH_2Ph. Debenzylation was accomplished by hydrogenolysis to afford the tris(macrocycle). The diacid, $HO_2C(CH_2)_{11}$ < N18N > $(CH_2)_{11}CO_2H$, a compound that was in hand from previous studies[11] was converted into the corresponding dichloride. The cyclization reaction between H < N18N > $(CH_2)_{11}CO$ < N18N > $CO(CH_2)_{11}$ < N18N > H and $ClCO(CH_2)_{11}$ < N18N > $(CH_2)_{11}COCl$ formed tetramide **6**. Reduction of **6** (BH_3/THF) gave tetraamine **7** as a yellow oil (76% overall from tris(macrocycle). Treatment of Ph_2CH_2 < N18N > H with $ClCOC_{11}O–C_6H_4–C_6H_4–O–C_{11}COCl$ gave $PhCH_2$ < N18N > $CO(CH_2)_{11}O–C_6H_4–C_6H_4–O–(CH_2)_{11}CO$ < N18N > CH_2Ph (65%, yellow oil). Hydrogenolytic debenzylation afforded the biphenyl-bridged bis(macrocycle). The latter underwent cyclization with $ClCO-C_{11}OC_6H_4C_6H_4OC_{11}COCl$ to give tetraamide **2**. Reduction of **2** (BH_3/THF) afforded tetraamine **3** (72%, yellow oil). Compounds **4** (40%), **5** (60%) and **8** (62%) were prepared in a fashion similar to that shown in Scheme 1 and were characterized by standard chemical methods (^1H, ^{13}C NMR and FAB-MS). Dansyl channel **9** has been previously described.[5]

The Na^+ transport efficacies of the compounds prepared as part of this study were assessed in phospholipid bilayers by using the dynamic ^{23}Na NMR method of Riddell *et al.*[12] This method involves the formation of liposomes from phosphatidyl glycerol and phosphatidyl choline in the presence of 100 mM NaCl. The salt is present within the liposomes and in the

6	$C_{11}CO$<N18N>COC_{11}	COC_{11}<N18N>$C_{11}CO$	250
7	C_{12}<N18N>C_{12}	C_{12}<N18N>C_{12}	340
8	C_{12}<N18N>C_{12}	$(CH_2)_{12}S(CH_2)_8S(CH_2)_{12}$	190
9	C_{12}<N18N>C_{12}	Dansyl	100[c]

[a] We estimate the experimental error to be ±10%. [b] The rate relative to gramicidin is 27%. [c] The rate relative to gramicidin is 24%.

surrounding bulk aqueous phase. The ^{23}Na NMR spectrum observed under these conditions is a singlet. Addition of a Dy^{3+} shift reagent to the aqueous phase renders the two Na^+ ions magnetically non-equivalent and two signals are observed. Addition of an ionophore to the bilayer permits exchange of Na^+ ions with a concomitant change in linewidth. The exchange rate constant (k) can be evaluated from the linewidth change according to the relation $k = 1/\tau = \pi[(\Delta\nu - \Delta\nu_0)]$. In this relationship, τ is the half-life and ν represents the linewidth. The experimentally determined values of K are then compared with the value determined for the dansyl channel (Dn<N18N>C_{12}<N18N>C_{12}<N18N>Dn **9**).[13] The compounds that were studied for the present report are recorded in Table 1. Sodium cation transport by ionophores **1**–**9** was investigated at very low concentration (0–20 μM). The rate is reported as the relative rate $k_{rel} = 100\ k_{obs}/k_9$. A value of <2 means that the compound does not transport Na^+ at a rate sufficient to be observed under the experimental conditions. Dansyl channel **9** is used as the standard rather than gramicidin because the latter is 'too robust'. When experiments are not properly executed, gramicidin will still show transport behavior but **9** requires a proper experimental environment and is therefore a better control and standard.

Channel **1** transports Na^+ with a rate 27% that of gramicidin while its rate is 105% relative to **9**, the standard used throughout this study. The most important finding of the study is that when an additional crown ether is present as a central unit to organize water (see preceding communication), joining the flexible sidechains with a fourth crown produces an ionophore significantly (3.5-fold) more active than **1**. The very high efficacy of this structure supports previous conclusions concerning distance and polarity requirements. The family of structures also permits us to probe the effects of certain of the modular subunits.

First, we note that both compounds **2** and **3** are inactive in the ^{23}Na NMR experiment. We attribute this to the lack of a water-organizing central unit (see preceding communication).[14] When the center of the channel possesses one biaryl unit and an amide-substituted diazacrown **4**, activity is restored but it is modest (30% of **9**). Reduction of the amide residues in **4** affords **5** which has substantially increased Na^+ transport activity (150% of **9**). An increase in transport is expected because the amide residues conformationally restrict the macrocycle to which they are attached. The tetraamide precursor to **7**, *i.e.* **6**, is considerably less flexible than **7** but is also 2.5-fold more active than **1**. There may also be a deleterious effect of an arene on cation transport. In the low polarity environment of the phospholipid bilayer, a cation–π interaction between Na^+ and benzene[15] could substantially diminish the transport rate. Thus, the rate for **8**, which lacks an arene, exceeds that of **5** by a small but significant amount.

An important question is whether the increase in Na^+ transport may be attributed to the presence of the crown, to the higher level of organization present where the two flexible sidechains were, or to both. We know from the results reported in the preceding communication that 4,4′-dihydroxybiphenyl is inactive as a 'central ion capsule.' Thus, the fact that ionophoretic activity of **7** is twice that of **5** confirms that both variables are important. When only arenes are present as the central units, no Na^+ transport is measured in the NMR experiment.

The present effort demonstrates that a tetramacrocyclic hydraphile is more efficacious than its flexible counterpart. This confirms that distance relationships, headgroup functions, and ion–capsule interactions occur as previously surmised.

We thank the NIH (GM-36262) and the NSF (CHE-9805840) for grants that supported this work.

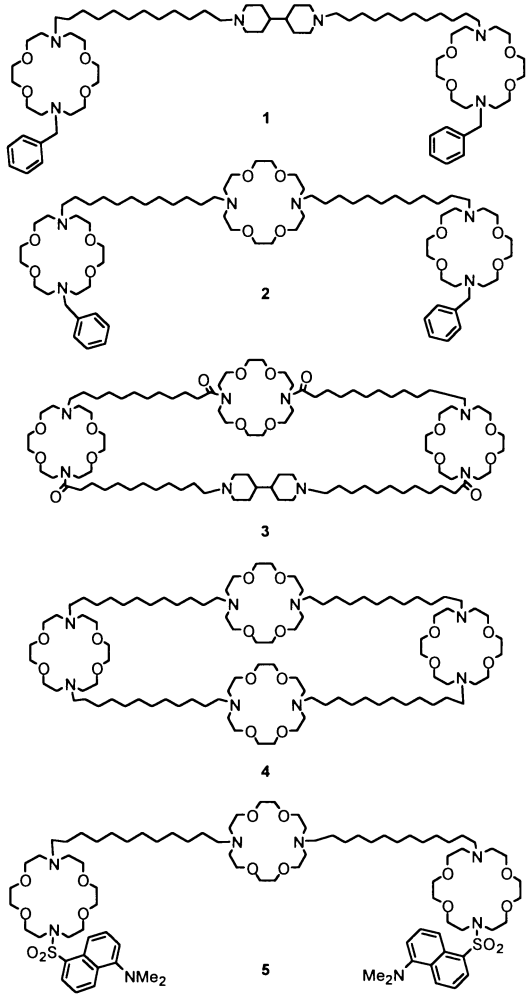
First published as an Advance Article on the web

The polynitrogen-containing cation transporters 1–4 are shown by electrospray mass spectrometry to form multicationic species. In the absence of Na^+, protonated species dominate but increasing the sodium concentration leads to all binding sites being occupied.

The study of cation-conducting channels currently presents an enormous challenge to both chemists and biologists.[1] An important goal for the former is to prepare compounds that are inherently simpler than protein, or even peptide, channels[2] that transport cations at substantial rates across phospholipid bilayer membranes. With functionality achieved, experimental study of the systems should offer insight into the details of such phenomena as ion transport, selectivity, and gating kinetics. A major question concerns the chemical details of cation transport within the pore. A postulate that K^+ transport and selectivity were influenced by cation–π interactions within the pore[3] was disproved by site-directed mutagenesis.[4] The chemical roles of polyarenes in synthetic channels[5] and of the central ion capsule[6] in the KcsA K1 channel of *Streptomyces lividans*[7] beg further exploration of alkali metal cation interactions in low polarity media. In a previous study, electrospray mass spectrometric results demonstrated that all three macrocyclic rings of a hydraphile channel-former could simultaneously bind cations.[8] We now report that the novel tetramacrocyclic[9] and nitrogen-heterocycle-containing[10] channel-formers reported in the preceding two communications can bind a full complement of alkali metal ions by using crown ethers but not piperazine or bipiperidyl donors.

Cation transport through a phospholipid bilayer for the hydraphile family has been demonstrated by using fluorescence (H^+),[11] ^{23}Na NMR (Na^+),[12] and planar bilayer conductance methods (Na^+).[13] The ability of hydraphile channels to span the bilayer[14] has been confirmed and the optimum length for this family of channels has been established.[15] The compounds reported here are elaborations of the previously known systems and all exhibit effective Na^+ transport in a phospholipid bilayer (NMR method). Thus, under comparable conditions, the transport rates in mixed phosphatidyl choline–phosphatidyl glycerol bilayer liposomes, the following Na^+ transport rates were observed at room temperature: **1**, 80%; **2**, 210%; **3**, 50%; and **4**, 340%. In all cases, the values are expressed as a percent of the rate observed for the dansyl-sidearmed channel, **5** (100%).

Compounds **2**[11] and **5**[14] were prepared as previously reported and the synthesis of **4** is described in the preceding communication.[9] Compound **1** was prepared by treatment of $PhCH_2{<}N18N{>}H$ with $Br(CH_2)_{12}Br$ (Na_2CO_3, KI, 2 h) in boiling PrCN to give $PhCH_2{<}N18N{>}(CH_2)_{12}Br$ as a yellow oil (39%). Further reaction of the above with 4,4′-bipiperidine (procedure as above, 16 h) gave **1** as a colorless solid (8%, mp 55–56 °C). The preparation of **3** required a more elaborate approach. Benzyldiaza-18-crown-6 was alkylated with $Br(CH_2)_{11}CO_2Me$ (Na_2CO_3, cat. KI, BuCN, 20 mL, 24 h, 50%)



to give $PhCH_2{<}N18N{>}(CH_2)_{11}CO_2Me$. Hydrolysis (2 M NaOH, 93%) followed by treatment with $(COCl)_2$ (2 M solution in CH_2Cl_2, 2 h) gave $PhCH_2{<}N18N{>}(CH_2)_{11}COCl$, which was allowed to react directly in CH_2Cl_2 with $H{<}N18N{>}H$ (Et_3N, 6 equiv., cat. DMAP, to give the tris(crown) diamide as a yellow oil (65%). The tris(crown) diamide was debenzylated (H_2–Pd/C, 60 psi, abs. EtOH) to give $[H{<}N18N{>}(CH_2)_{11}CO]_2{<}N18N{>}$ (yellow oil, 95%). A similar strategy was used to prepare $ClCO(CH_2)_{11}NC_5H_9C_5H_9N(CH_2)_{11}COCl$, beginning with the alkylation of 4,4′-bipiperidine by $Br(CH_2)_{11}CO_2Me/Na_2CO_3$ (cat. KI, BuCN, 20 mL, 24 h) to give $MeO_2C(CH_2)_{11}NC_5H_9C_5H_9N(CH_2)_{11}CO_2Me$ (71%). This, in turn, was hydrolyzed (2 M NaOH, 94%, colorless solid, mp 260 °C, decomposed) and treated with ClCOCOCl (excess, 2 M

solution in CH_2Cl_2). The latter was treated with [H < N18N > $(CH_2)_{11}CO]_2$ < N18N > (Et_3N, 6 equiv., cat. DMAP, CH_2Cl_2, 48 h) to afford tetraamide **3** as a yellow oil (30%).

Compounds **1**–**4** present an opportunity to directly assess the interactions of the hydraphile's modular elements and Na^+. Assuming that a crown macroring will bind a single Na^+ ion, we anticipate that we will observe ions corresponding to [**1**·2Na]$^{2+}$, [**2**·3Na]$^{3+}$, [**3**·3Na]$^{3+}$, and [**4**·4Na]$^{4+}$. The projected maximum complexation by **1** or **3** is based on the expectation that 4,4′-bipiperidyl will not complex Na^+. This is particularly important considering the conclusions of the preceding communication that the bipiperidyl unit can organize water but its nitrogen donor groups are too far apart to effectively coordinate with Na^+.[10]

The mass spectrometric analyses were conducted using an electrospray ion source (ESI-MS).[16] The inlet temperature was *ca.* 55 °C. Typically, 1.5 mg of channel was dissolved in 1 mL of $CHCl_3$ and the spray solution was prepared by adding 1 mL of MeOH–$CHCl_3$ 1 : 1 (v/v) and 40 μL of 100 μM NaOH to 60 μL of the sample solution. After mixing, 20 μL of the sample solution was loop injected by continuous infusion [10 μL min^{-1} MeOH–$CHCl_3$ (1 : 1, v/v)]. The instrument continuously scanned (magnetic) at 20 s decade^{-1} of mass over the range from 2000 to 400 Da. The data thus obtained are shown in Table 1.

For each structure, we have calculated the anticipated molecular weights for adducts of **1**–**4** with 1, 2, 3 and 4 Na^+ ions. In each case, the most abundant ion (base peak) observed was the disodium adduct. In all cases, the maximum number of Na^+ ions complexed was equal to the number of macro-rings and no higher order ions were detected. It is also interesting to observe that the ion currents for the complexes containing either three or four Na^+ ions (**2**, **3** or **4**) were significantly larger than observed for either cation complex of **1**.

The most significant finding of the present study is that in all cases, the number of Na^+ ions bound by each host molecule corresponded to the number of macrocycles. In no case did the number of Na^+ ions exceed the number of macro-rings indicating a generalized affinity of the cation for any of these structures. In principle, if 4,4′-bipiperidyl could support cation complexation directly, the complexes [**1**·3Na]$^{3+}$ and [**3**·4Na]$^{4+}$ would have been observed at *m/z* values of 424.7 and 442.1, respectively. Peaks corresponding to such complexes were sought but not observed.

An interesting observation is that the higher organization of **3** relative to **2** appears to result in a more stable tris(Na^+) complex. Thus, the [host·2Na]$^{2+}$: [host·3Na]$^{3+}$ ion abundance ratios for **2** and **3** are 100 : 20 and 100 : 45. The 'central' macrocycle is bis(amidated) in **3** and is expected to be a weaker donor for Na^+. It appears that the diamine opposite can help to stabilize this complex relative to the situation in which the additional structural element is absent.

The critical inference we draw from these data is that direct interaction between the bipiperidyl unit of **1** and a cation is not detectable, even in the low dielectric medium of electrospray mass spectrometry. Extending this to the low polarity, insulating regime of a bilayer, we infer that bipiperidyl cannot directly support cation complexation in that situation either. This does not prove, but strongly supports, the notion that the function of **1** as a channel is due, in part, to the interaction of bipiperidyl with intrapore water or waters of hydration rather than directly with Na^+.[10]

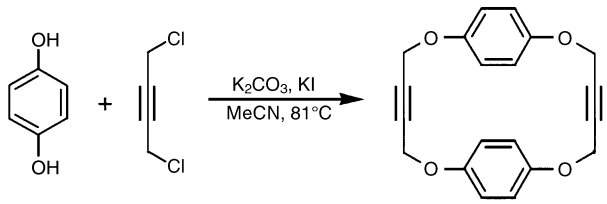
Compound 1, synthesized from hydroquinone and 1,4-dichlorobut-2-yne, was characterized by X-ray crystallography and shown by electrospray ionization mass spectrometry to form 1 : 1 complexes with sodium and 2 : 1 complexes with potassium cation.

The interaction of arenes with alkali metal and ammonium ion cations is of considerable theoretical interest but of even greater potential import in biology. Three of the essential amino acids contain aromatic sidechains capable of serving as π-donors. Together, phenylalanine (Phe, F), tryptophan (Trp, W), and tyrosine (Tyr, Y) comprise 8.4% of the amino acids in all known protein sequences. The ability of arenes to complex K^+ was demonstrated experimentally by Kebarle and coworkers in 1981.[1] Additional experiments by the groups of Castleman[2] and Lisy[3] confirmed their observations and extended them to Na^+. Burley and Petsko surveyed data available in the Protein Data Bank and demonstrated the plausibility of ammonium ion–arene interactions in proteins.[4]

Important as this work was, cation–π interactions received little additional attention until it was postulated that the selectivity of protein channels could be understood in terms of K^+–arene interactions.[5] By using site directed mutagenesis, Heginbotham, MacKinnon and coworkers[6] showed that the selectivity filter of the shaker K^+ channel of *Drosophila melanogaster* did not require a cation–π interaction. The crystal structure of the K^+-selective KcsA K1 channel of *Streptomyces lividans* recently reported by MacKinnon and coworkers shows no evidence for K^+–arene interactions.[7] Still, the potential importance of such interactions is great. In recent work of our own, we reported the first crystal structure data confirming K^+–arene, cation–π interactions for the sidechains of phenylalanine,[8] tryptophan,[9] and tyrosine.[10]

We now propose that the ideal 'π-receptor' molecule would possess two arenes held rigidly face-to-face at a distance appropriate to bind an alkali metal cation. For Na^+, this distance should be *ca.* 2 Å, depending on the exact coordination number. To maintain rigidity, electron richness, and symmetry, we chose acetylene units to serve as spacers. Aryl ether links were selected for covalent attachment. Because the oxygen atoms were adjacent to an arene, their π-donicity was expected to be minimal and synthetic access should be facilitated. The target compound **1** was dubbed a 'pyxophane' after the word 'pyx', meaning chest.[11]

Pyxophane **1** was synthesized by alkylation of hydroquinone with 1,4-dichlorobut-2-yne, followed by oligomerization (or dimerization) and cyclization (Scheme 1). Hydroquinone, butyne, potassium carbonate and potassium iodide were heated at reflux for 24 h in acetonitrile. The solvent was removed and the residue was extracted with dichloromethane. The extract was purified by chromatographing over silica using dichloromethane. The purified product was recrystallized from toluene to afford **1** as fine white needles (5% yield, mp 265–266 °C).



Scheme 1

The solid state structure of **1** (Fig. 1) was obtained by X-ray methods.[12] In the solid state, the molecule lies in a chair conformation with an arene–arene distance of 5.5 Å and an alkyne–alkyne distance of 7.0 Å. By subtracting the arene and alkyne thicknesses (3.4 Å), we deduce a cavity size of 2.1 × 3.6 Å. This distance suggests that a sodium cation, with a diameter of 1.98 Å, should be able to easily fit into the host molecule but a larger cation such as K^+ (2.7 Å diameter) should not.

Cyclophane **1** is related to the cyclophanes synthesized by Jarvi and Whitlock,[13] the primary difference being in the rigid spacer length. In their studies, they used longer diyne spacers which afforded a larger cavity, a necessity for the incorporation of organic guest molecules.

Electrospray ionization mass spectrometry (ESI-MS) is the ideal tool to assess alkali metal cation complexation in the low polarity environments of non-polar solvent and vacuum. Such an environment is clearly relevant to the *ca.* 30 Å non-polar span of a phospholipid bilayer commonly referred to as the insulator regime or the 'hydrocarbon slab'. The study involved three steps. First, an attempt was made to detect intramolecular complexation of Na^+ by **1**. This should lead to an ion of the type $[\mathbf{1}\cdot Na]^+$ having a weight of (320 + 23 =) 343 Da. The corresponding experiments with K^+, Rb^+, and Cs^+ are not expected to produce ions of the type $[\mathbf{1}\cdot M]^+$ because these metal ions are too large to bind intrapyxially. If 2 : 1 complexation is required, the dominant ion will be $[\mathbf{1}_2\cdot M]^+$. The absence of a

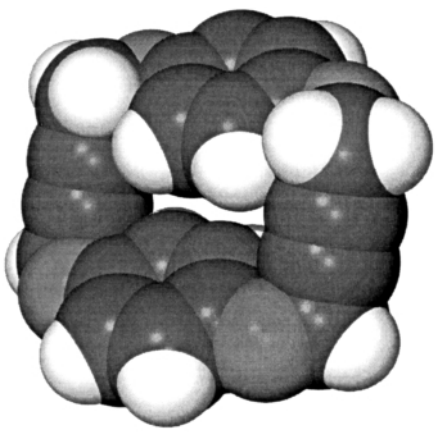


Fig. 1 Solid state structure of pyxophane **1** shown in the CPK metaphor.

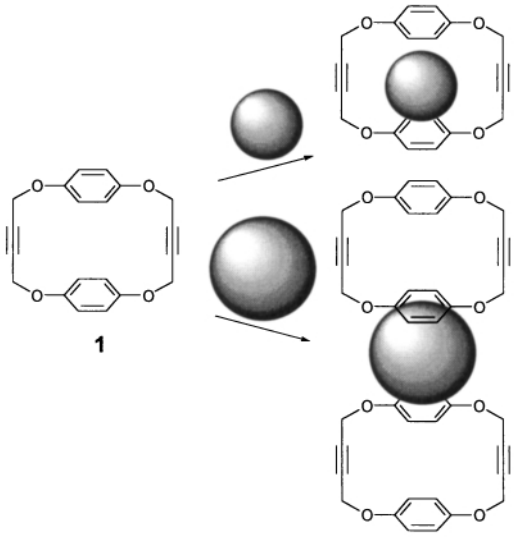
DOI: 10.1039/b005443g



Scheme 2

1·M^+ ion and the presence of one corresponding to $\mathbf{1}_2$·M^+ would be good evidence for 'external' dimer complex formation. Finally, an experiment identical in other respects to those described above but involving Na^+ and 1,4-dimethoxybenzene **2** should not exhibit any significant complexation (neither **2**·M^+ nor $\mathbf{2}_2$·M^+).

The mass spectrometric analyses were conducted using an electrospray ion source (ESI/MS).[14] Pyxophane **1** (typically 1.5 mg) and dry NaCl were dissolved in 1 mL of $CHCl_3$ and the spray solution was prepared by adding 1 mL of MeOH–$CHCl_3$ (1 : 1, v/v) and 40 μL of 100 μM NaOH to 60 μL of the sample solution. After mixing, 20 μL of the sample solution was loop injected by continuous infusion (10 μL min^{-1} MeOH–$CHCl_3$ (1 : 1, v/v)). The instrument continuously scanned (magnetic) at 20 s $decade^{-1}$ of mass over the range from 2000 to 400 Da. The inlet temperature was *ca.* 55 °C. The base peak (100% relative abundance) in the ESI-MS spectrum was observed at *m/z* 343.1 which corresponds to an ion having the composition [**1**·Na]$^+$. A small peak at *m/z* 663.2 (*ca.* 7%) corresponds to [$\mathbf{1}_2$·Na]$^+$.

The binding selectivity was evaluated by comparing the intensity of the electrospray ion signal for the [M·Na]$^+$ complex, with the intensity of the signals for [M·K]$^+$, [M·Cs]$^+$, and [M·Rb]$^+$. These complexes were produced and analyzed separately. By far, the strongest binding was observed for Na^+ as evidenced by an intense *m/z* 343 ion [**1**·Na]$^+$. Although Cs^+ (ionic diameter = 3.32 Å) showed a moderately intense *m/z* 453 ion indicating some affinity for **1**, neither K^+ (2.66 Å) nor Rb^+ (2.94 Å) showed any significant binding. Further, the [M·Na]$^+$ ion was associated with higher mass ions consistent with solvent complexation, offering additional evidence that the Na^+ ion is occupying the central cavity of **1**. As controls, methoxybenzene (anisole) and 1,4-dimethoxybenzene **2** were run under conditions identical to those under which [**1**·Na]$^+$ was found to be the base peak in the spectrum. Sodium complexation was not observed for either compound. The complexation results are suggested by Scheme 2 in which the spheres represent Na^+ (smaller) and K^+ or Rb^+.

The preliminary data presented here support size-selective π-complexation of alkali metal cations. Additional complexation studies in both the gas and solution phases are underway with these and closely related host molecules.

Iminium intermediates, formed from the condensation of glyoxylic acid and resins functionalized with a secondary amine, are coupled to boronic acids transferred to solution from the corresponding [*N*,*N*-diethanolaminomethyl polystyryl boronates by *in situ* transesterification with the ethanol co-solvent to provide arylglycine derivatives.

In comparison with the traditional approach to solid-phase synthesis where a single resin-bound substrate is employed, the simultaneous use of two or more heterogeneous substrates, reagents or catalysts has seldom found real synthetic utility. Resin-to-resin transfer reactions (RRTR) constitute one type of multiresin system whose particular advantage is to allow the practice of solid-phase synthesis in a convergent fashion.[1] In RRTR, one resin-bound substrate is transferred to solution-phase by action of a phase-transfer agent, or chaperone, and coupled *in situ* to another resin-bound substrate. The concept of RRTR could find applications in combinatorial chemistry where each resin-bound substrate can be a member of a respective library assembled using the practical techniques of solid-phase synthesis. Recently, we have reported a successful RRTR system to effect Suzuki cross-coupling reactions between resin-bound aryl iodides and arylboronic acids supported onto [*N*,*N*-diethanolaminomethyl polystyrene (DEAM-PS).[2] The DEAM-PS resin facilitates the synthesis of functionalized arylboronic acids which can otherwise be difficult to isolate and handle in solution.[3] Their subsequent use in RRTR processes eliminates time-consuming cleavage and transfer operations, thereby considerably simplifying the outlook of library synthesis by manual or automated means. Herein, we describe the preliminary optimization of a resin-to-resin borono-Mannich reaction that produces arylglycine derivatives. Compounds of this nature are of particular interest for their biological activity.[4]

The boronic acid Mannich reaction first reported by Petasis[5] is compatible with a wide range of solvents including hydroxylic ones.[5–8] We envisioned that an alcohol, employed as co-solvent, could act as a neutral phase transfer agent required to cleave the DEAM-PS supported boronic acids under mild conditions appropriate toward a RRTR system. The boronic acid liberated *in situ* as an ester could then add to the imine formed between an amino functionalized resin and an activated aldehyde such as glyoxylic acid (Scheme 1).[6] We have first optimized conditions using DEAM-PS supported *p*-tolylboronic acid (**2**, R = 4-Me-C_6H_4- in Scheme 1), piperazinyltrityl resin, and glyoxylic acid in a semi-automated synthesizer.† The reaction was found to be rather slow and strongly dependent on the nature of the solvent system, THF–EtOH (7:1) and DMF–*n*-BuOH (7:1) being first and second best respectively. The current set of optimal experimental conditions first involve incubating the dialkylamino resin with glyoxylic acid monohydrate (1.1 eq.) for 2 h in dry THF at rt.‡ Then, four eq. of DEAM-PS bound boronic acid are added along with the appropriate volume of 8:3 THF–EtOH. The suspension is shaken at 65 °C for up to 48 h. This way, conversion levels superior to 75% were observed in the case of *p*-tolylboronic acid as seen after cleavage of the final resin mixture **1** and **4** with 5% trifluoroacetic acid/DCM to give the corresponding amino acid product **5a** as a bis(trifluoroacetate) salt (Table 1, entry 1).§ The rest of unreacted starting resin **3** is cleaved into the bis(trifluoroacetate) salt of piperazine (**6**) which can be eventually removed by precipitation. There are no other by-products observed, as the left over DEAM-PS resin (**1**) does not give any artifacts upon treatment with trifluoroacetic acid in the product release step. Interestingly, the transesterification of resin **2** with EtOH, a process required for phase transfer of the DEAM-PS-boronate, appears to be a dynamic equilibrium. The latter is driven forward by the large excess of EtOH, and through consumption of the boronic acid which adds to the putative iminium intermediate to form supported product **4** (Scheme 1). We have devised control experiments aimed at measuring the extent of transesterification of DEAM-PS supported *p*-tolylboronic acid in 7:1 THF–EtOH. Equilibrium is reached within 15 min of exposure of **2** to the 7:1 THF–EtOH solvent. Successive incubations of the resin under constant resin–solvent proportions, followed by rinses with dry THF, revealed that approximately 40% *p*-tolylboronic acid is released from the resin under these conditions.¶ In fact, since there is some left over DEAM-PS-boronate (**2**) at the end because of the transesterification equilibrium, we have found it necessary to include water–THF washes in order to wash off all excess boronic acid from the resin mixture prior to the acidolytic release of product **5**.‖ It is noteworthy to mention that although this RRTR was found to proceed in the absence of ethanol (the water introduced from the aldehyde hydrate may be sufficient to promote phase transfer of the boronic acid) conversion levels were generally higher in THF–EtOH.

Next we have studied substrate generality for this new RRTR system (Scheme 2). As shown in Table 1, conversion values and product yields were generally good except for the RRTR of electron-poor arylboronic acids.§ Thus, conversion values were highest for DEAM-PS supported *p*-methoxybenzeneboronic acid (entries 3, 7, 8), and lowest for *p*-bromophenylboronic acid (entry 4). According to entry 6, DEAM-PS-supported alkenylboronic acids are also appropriate substrates. In this case the use

[a] Preparation of resin substrates, RRTR trials, and subsequent cleavage of the resin mixture were carried out as indicated in the Notes and references section.†,‡ [b] Based on the relative amounts of product and respective bis(trifluoroacetate) salt **6**, **10**, or **13** calculated by integration of relevant peaks by ^{1}H NMR after 24–48 h reaction time. [c] Yields of crude product based on ^{1}H NMR analysis with an internal standard.

of a RRTR strategy using DEAM-PS resin is even more advantageous for handling and storage purposes since the otherwise air-sensitive alkenylboronic acids can be stabilized through immobilization as diethanolamine** adducts. An example using an acyclic amine (**11**) was equally successful (entry 8), showing that in principle a variety of secondary amines such as terminal *N*-alkylamino acids could be employed. Although only electron-rich arylboronic acids currently provide satisfactory conversions to crude material of high purity, analytically pure samples of most reported compounds can be obtained following precipitation with MeOH–ether, and filtration of the unreacted dialkylamine as a bis(trifluoroacetate) diammonium salt. We have also confirmed that the examples performed in a RRTR format provide yields comparable to reactions using non-supported boronic acids.

By minimizing cleavage, solvent concentration, and transfer operations this new borono-Mannich RRTR is thus potentially useful in the convergent solid-phase synthesis of libraries of arylglycine derivatives. In principle, this could be achieved by combining libraries of dialkylamino resins with libraries of DEAM-PS-supported arylboronic acids made by solid-phase derivatization of functionalized ones.[2,3] Studies such as this one looking at the structural and electronic preferences of substrates are crucial in order to select the most appropriate types of building blocks.

Notes and references

† *Materials and methods*: *N*,*N*-diethanolaminomethyl polystyrene (DEAM-PS) was made according to ref. 3. All boronic acids were purchased from commercial sources (Aldrich, Lancaster, or CombiBlocks) and were loaded onto DEAM-PS as described in ref. 3. The dialkylaminotrityl resins were made by the condensation of excess diamine (20 equiv.) onto commercial chlorotrityl polystyrene (Rapp Polymere) swelled in NMP. Loading measurements were carried out by analysis of nitrogen content. For RRTR's, runs were done in 10 mL Teflon fritted vessels on a Quest 210 instrument with solvent wash unit (Argonaut Technologies). Cleavage was effected on-line and crude products were obtained after evaporation of solvents. Yields and purity were estimated by comparison with an internal NMR standard (EtOAc, 15 s relaxation delay).

‡ *Typical procedure for the borono-Mannich RRTR. Preparation of* **5c**. To piperazinyltrityl resin **3** (32 mg, 0.030 mmol, theor. loading: 0.95 mmol g^{-1}) weighed out in a reaction vessel was added a solution of glyoxylic acid monohydrate (0.032 mmol) in dry THF (2 mL). The suspension was allowed to mix at rt under a nitrogen atmosphere for 2 h. An excess of DEAM-PS boronic ester **2c** (127 mg, 0.120 mmol, theor. loading: 0.95 mmol g^{-1}) was then added followed by 1.5 ml of 8:3 THF–EtOH. The suspension was mixed at 65 °C for 48 h under a nitrogen atmosphere and then cooled to rt. The resin mixture was filtered and rinsed with 8 : 3 THF–EtOH (3×), 2 : 1 THF–H_2O (3×) and CH_2Cl_2 (5×), mixed with 3 ml of 5% TFA/CH_2Cl_2 in the same vessel at rt for 1 h, then filtered and rinsed with CH_2Cl_2 (3×) and MeOH (2×). The combined filtrates were concentrated and dried under high vacuum for 12 h to afford crude **5c** as a clear oil (14 mg, 90% conversion). An analytically pure sample was obtained by dissolving the oil in a small amount of MeOH followed by addition of ether, filtration of the precipitate, and concentration of the resulting solution.

¶ The reverse reaction (**1** + *p*-tolylboronic acid) gives a similar outcome under the same conditions, showing that the transesterification process is under equilibrium.

‖ The DEAM-PS boronate linkage is very sensitive to water even in trace amounts. In contrast with alcoholysis, hydrolysis appears to be irreversible and quantitative.

** The IUPAC name for diethanolamine is 2,2′-iminodiethanol, and for DEAM-PS is [*N*,*N*-bis(2-hydroxyethyl)amino]methyl polystyrene.

Synthesis of substituted α-methylene-γ-butyrolactones from chloroformates *via* palladium catalysed cyclisation–anion capture

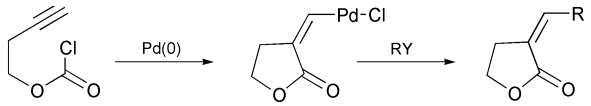
Ronald Grigg* and Vladimir Savic

Molecular Innovation, Diversity and Automated Synthesis (MIDAS) Centre, School of Chemistry, Leeds University, Leeds, UK LS2 9JT

Received (in Cambridge, UK) 17th August 2000, Accepted 5th October 2000
First published as an Advance Article on the web

Cyclisation of chloroformates onto proximate alkyne functionality in the presence of a Pd(0) catalyst followed by anion capture affords α-methylene-γ-butyrolactone derivatives in moderate to good yields.

α-Methylene-γ-butyrolactones constitute an important group of natural products possessing a range of biological activities.[1] Their biological profiles are based on the specific reactivity of the α,β-unsaturated functionality acting, in most cases, as a Michael acceptor in reactions with biological nucleophiles.[2] The importance of this class of compounds has led to a number of synthetic procedures for the preparation of α-methylene-γ-butyrolactone derivatives.[2,3] Our approach is based on our palladium catalysed cascade cyclisation–anion capture methodology, (Scheme 1).[4] In the current context cyclisation of appropriate chloroformates onto the alkyne functionality in the presence of a Pd-catalyst would produce a vinylpalladium moiety suitable for further functionalisation by an anion-capture reagent.



Scheme 1

Compared to the existing Pd-based methodology[5] for the preparation of α-methylene-γ-butyrolactones this approach allows direct access to β-substituted derivatives of this important class of compounds. In a recent communication we report similar methodology for the preparation of oxindole derivatives.[6]

The required chloroformates **(1)** were readily prepared from homopropargylic alcohols **2** by stirring the alcohol with excess of $COCl_2$ in toluene at rt for 16 h, (Scheme 2). These alcohols, if not commercially available, were easily prepared using a standard propargylation procedure of aldehydes in the presence of activated zinc (Scheme 2).

The cyclisation reactions (Scheme 3, Table 1) of chloroformates in the presence of an equimolar amount of $NaBPh_4$ as the anion capture reagent were performed in THF at 65–70 °C (oil bath temperature) in the presence of $Pd(OAc)_2$ (10 mol%)–PPh_3 (20 mol%). In cases of terminally unsubstituted alkyne functionality the expected γ-butyrolactones were isolated in moderate to good yields (Table 1, entries a–e) as the only product. The stereochemistry of all the γ-butyrolactones described in this communication was established from NOE data. The presence of a terminal substituent on the alkyne moiety of the chloroformates (Table 1, entries f and g) resulted in formation of the expected product together with the direct capture product **4**. It is likely that sterically induced slower cyclisation due to the presence of a terminal substituent caused the formation of the direct capture products **4**.

The (*Z*-)-lactone isomer formed in the above reactions can be easily isomerised *via* Michael addition–retro Michael to produce the (*E*)-isomer in almost quantitative yield by heating in the presence of excess of a secondary amine (Scheme 4). The opening of the lactone ring was not observed in this reaction.

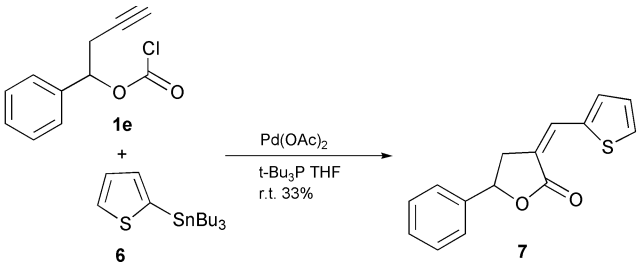
Scheme 4



1e + **6** → **7**

Scheme 5

We briefly investigated the application of organostannanes as anion-capture reagents, (Scheme 5). Stirring the chloroformate **1e** and **6** in the presence of $Pd(OAc)_2$ and *t*-Bu_3P at rt afforded the lactone **7** in 33% yield. This reaction remains to be optimised but indicates possible further applications of organostannanes in these processes.

In summary, we have developed a simple procedure for the preparation of (*Z*)-isomers of α-methylene-γ-butyrolactone derivatives from homopropargyl chloroformates. The reaction affords the lactones in good yield but the presence of a terminal substituent on the alkyne induces formation of the direct capture product as well. Isomerisation of the α,β-double bond is possible in the presence of a secondary amine providing access to the (*E*)-stereoisomer. Chloroformates and carbamoyl chlorides constitute new starter species for our wide ranging catalytic cascade cyclisation–anion capture methodology.[4] Further studies involving the application of other anion-capture reagents and the application of this methodology to the synthesis of some naturally occurring lactones are in progress.

We thank Leeds University and the EPSRC for support.

Phosphine–phosphite, a new class of auxiliaries in highly active and enantioselective hydrogenation

Oscar Pàmies, Montserrat Diéguez, Gemma Net, Aurora Ruiz* and Carmen Claver

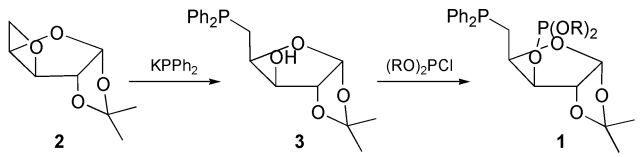
Departament de Química Física i Inorgànica, Universitat Rovira i Virgili, Pl. Imperial Tarraco 1, 43005 Tarragona, Spain. E-mail: aruiz@quimica.urv.es

Received (in Cambridge, UK) 27th September 2000, Accepted 24th October 2000
First published as an Advance Article on the web

Excellent enantioselectivities (ee > 99%) and good activities (TOF > 1200 h^{-1}) are achieved under mild reaction conditions in the Rh-catalyzed hydrogenation of α,β-unsaturated carboxylic acid derivatives with the first family of phosphine–phosphite ligands containing a sugar backbone; these ligands are better than their diphosphine, diphosphite and phosphinite analogues.

The scope of asymmetric hydrogenation of alkenes has been gradually extended both in reactant structure and catalyst efficiency over many years.[1] Chiral bidentate phosphorus ligands have played a dominant role in the success of asymmetric hydrogenation.[1,2] The early excellent enantioselectivities obtained with Binap[3] and Dipamp[4] promoted the synthesis and application of a wide variety of new diphosphanes.[2] Recent reports on the use of chiral diphosphite[5] and diphosphinite[6] ligands in asymmetric hydrogenation have demonstrated their potential utility. Nevertheless, the search for new highly efficient ligand systems derived from readily available simple starting materials is still of great importance. Chiral auxiliaries from the chiral pool have attracted much attention, making tedious optical resolution procedures unnecessary. Carbohydrates are particularly advantageous because they are inexpensive compounds. Nevertheless, despite the accessibility and the excellent enantioselectivities obtained with sugar-derived ligands,[5–7] their full potential in providing chiral ligands has scarcely been exploited.[2a] In a previous paper, different types of phosphorus ligands with a xylofuranoside backbone have been applied to asymmetric hydrogenation with varying degrees of success. Moderate enantioselectivities (up to 35%) with phosphine–phosphinite and diphosphinite ligands have been reported by Brunner and Pieronczyk.[8] More recently, we reported moderate (up to 35%) and good (up to 91%) enantiomeric excesses at room temperature with diphosphites[9] and diphosphines,[10] but in both cases the activities were low.

Continuing our interest in carbohydrates as an available chiral source for preparing ligands and encouraged by the success of diphosphine[2] and diphosphite[5] ligands, we have designed a new family of chiral bidentate phosphine–phosphite ligands **1** with a xylofuranoside backbone which combines the advantages of both ligand types (Scheme 1). A feature of these ligands is that they have two different phosphorus donor sites than can *a priori* match the intermediates better, thus influencing their reactivity and achieving good enantioselectivity.[11] We also report their highly active and enantioselective rhodium catalyzed asymmetric hydrogenation of α,β-unsaturated carboxylic acid derivatives. To the best of our knowledge this is the first example of phosphine–phosphite ligands applied to hydrogenation.[12]



Scheme 1

The new ligands **1a–d** were synthesized very efficiently in two steps from oxetane **2**, as shown in Scheme 1. Compound **2** is easily prepared on a large scale from D-(+)-xylose.[13] The key step is the oxetane ring opening using a slight excess of potassium diphenylphosphide in DMF to afford phosphine **3** in 80% yield after column chromatography.[14] This step is a novel strategy for easily synthesizing related ligands. Reacting **3** with 1 equivalent of the corresponding phosphorochloridite formed *in situ*[15] in the presence of base provided easy access to the desired ligands **1a–d**. These were isolated in good yields as air-stable solids that are fairly robust towards hydrolysis. Selected spectroscopic data are shown in Table 1.

Table 1 ^{31}P NMR spectroscopic data for ligands **1a–d**[a]

Ligand	$(RO)_2PCl$	$\delta(P_1)$[b]	$\delta(P_2)$[c]	$J(P_1–P_2)$/Hz

1c		−22.5	150.0	33.1
1d		−22.5	148.4	15.5

[a] In $CDCl_3$. [b] P_1 = phosphine. [c] P_2 = phosphite.

In a first set of experiments, we used the rhodium-catalyzed hydrogenation of methyl *N*-acetamidoacrylate **4** to investigate the potential of ligands **1a–d** for asymmetric catalysis (Table 2).[16] The reaction proceeded smoothly at 1 bar of H_2 at room temperature in CH_2Cl_2. Ligand **1a**, with the achiral biphenyl moiety at the phosphite, not only showed high asymmetric induction (88.2%) but also very high catalytic activity (Table 2, entry 1). The presence of bulky *tert*-butyl groups in the *ortho*-positions of the biphenyl moiety (ligand **1b**) have an extremely positive effect on enantioselectivity (ee > 99%, Table 2, entry 2).[17] Interestingly, the sense of the enantioselectivity is reversed; the (*S*) enantiomer was obtained with ligand **1a** and the (*R*)-enantiomer was obtained with ligand **1b**. Ligands **1c** and

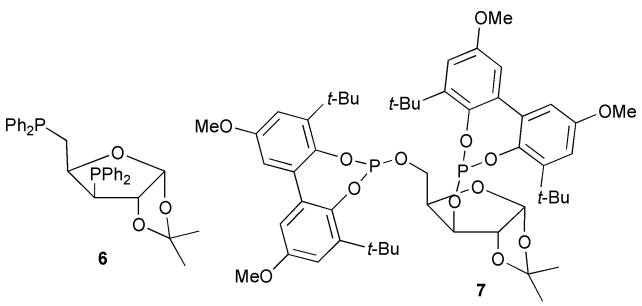
1d containing a stereogenic binaphthyl moiety result in a high reaction rate and a high enantioselectivity (Table 2, entries 3 and 4). Ligand **1c**, which has an (*S*)-binaphthyl moiety, produces an ee of 98.3% (*S*), while diastereomer **1d**, which has an (*R*)-binaphthyl moiety, produces an ee of 97.6% (*R*). Therefore, if we compare the results with ligands **1a**–**d**, we can assume that the fast interchanging atropoisomers of ligand **1a** predominantly adopt the same configuration as that of **1c**, while the biphenyl moiety in ligand **1b** predominantly adopts an (*R*) configuration, probably due to the presence of the *tert*-butyl group in the *ortho*-position. We can conclude that the sense of the enantiodiscrimination is predominantly controlled by the configuration of the biphenyl or the binaphthyl at the phosphite moiety.

In general, the hydrogenation of **5** (Table 2, entries 5–8) follows the same trend as for **4**. However, the enantiomeric excesses are somewhat lower and the reaction rate was slightly slower. The configuration of the hydrogenated product is not affected by the presence of the phenyl group in **5**. The catalyst precursor containing ligand **1b** produced the highest enantiomeric excess (98.8%; Table 2, entry 6).

It is remarkable that these phosphine–phosphite ligands showed higher degrees of enantioselectivity and higher reaction rates than their corresponding diphosphine **6**[10] (Table 2, entry 9) and diphosphite **7**[9] (Table 2, entry 10) analogues under the same reaction conditions.



In summary, we have described the first application of phosphine–phosphite ligands in asymmetric hydrogenation. The combination of high enantioselectivities and high performances in simple unoptimized reactions and the low cost of the ligands makes these catalyst systems very attractive for further investigation. Moreover, these ligands were better than their diphosphine and diphosphite counterparts. These results open up a new class of ligands for asymmetric hydrogenation. Research into other substrates and the use of these ligands in other metal-catalyzed reactions is the subject of further investigations.

We thank the Spanish Ministerio de Educación y Cultura and the Generalitat de Catalunya (CIRIT) for their financial support (PB97-0407-CO5-01) and for awarding a research grant (to O. P.).

13 Oxetane **2** was prepared by slightly modifying the procedure described: P. Y. Goueth, M. A. Fauvin, M. Mashoudi, A. Ramiz, G. L. Ronco and P. J. Villa, *J. Nat.*, 1994, **6**, 3.
14 Brunner *et al.* previously synthesized this phosphine in low yield (10%) from the related monotosylated compound: H. Brunner and W. Pieronczyk, *J. Chem. Res. (S)*, 1980, 74; H. Brunner and W. Pieronczyk, *J. Chem. Res. (M)*, 1980, 1251.
15 Phosphorochloridites are easily prepared in one step from the corresponding biphenol or binapthol as described: G. J. H. Buisman, P. C. J. Kamer and P. W. N. M. van Leeuwen, *Tetrahedron: Asymmetry*, 1993, **4**, 1625.
16 In a typical run, a Schlenk tube was filled with a dichloromethane solution (6 mL) of substrate (1 mmol), $[Rh(cod)_2]BF_4$ (4.95 mg, 0.01 mmol) and ligand (0.011 mmol). This was then purged three times with H_2 and vacuum. The reaction mixture was then shaken under H_2 (1 atm) at 293 K. To remove the catalyst, the solution was placed on a short silica gel column and eluted with CH_2Cl_2. Conversion and enantiomeric excesses were determined by gas chromatography.
17 Detailed kinetic studies are under way.

Ethylenediamine zinc hydrogen phosphite, $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$, containing two independent, interpenetrating, mixed inorganic/organic networks

$[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ combines the structural features of templated networks and coordination polymers.

A vast number of inorganic networks templated by organic species have been reported over the last 10 years.[1] The possibilities of incorporating the phosphorus(III) containing, pseudo-pyramidal $[HPO_3]^{2-}$ hydrogen phosphite group into extended structures templated by *inorganic*, alkaline earth cations was explored a few years ago.[2] We have recently described two polymorphs of $ZnHPO_3\cdot N_4C_2H_4$, the first network hydrogen phosphite templated by an organic species (2-cyanoguanidine).[3] Here, we report the synthesis,† crystal structure,‡ and some properties of ethylenediamine (en) zinc hydrogen phosphite, $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$, which shows a new type of structure combining the features of templated networks and coordination polymers.

A simulation based on the $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ single crystal structure was in excellent agreement with X-ray powder data, indicating phase purity and high crystallinity. TGA (ramp at 10 °C min^{-1} to 900 °C) for $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ revealed the onset of a 17% weight loss at *ca*. 200 °C, which was complete by *ca*. 700 °C. This is in good agreement (calc. weight loss = 17.1%) with a process involving the loss of all the organic species to result in a residue of nominal stoichiometry '$ZnHPO_3$.' ^{31}P MAS NMR for $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ showed a sharp resonance at δ −1.18 (relative to 85% H_3PO_4). There were strong spinning side bands, consistent with the inherently asymmetric environment of the P atom in the $[H_3PO_3]^{2-}$ grouping. The ^{13}C spectrum consisted of a single line at δ = 42.30 relative to $SiMe_4$.

$[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$, which is built up from seven framework atoms (Fig. 1), contains ZnO_3N tetrahedra and HPO_3 pseudo-pyramids as the polyhedral building units. The Zn–N bond corresponds to a direct link between zinc and the en template. The Zn species makes three Zn–O–P links to nearby P atoms [d_{av}(Zn–O) = 1.934(1) Å]. P1 makes three bonds to Zn neighbors [d_{av}(P–O) = 1.516(1) Å], with the expected[4] terminal P–H bond as its fourth vertex. The average Zn–O–P bond angle of the three bridging O atoms is 142.08°. The geometrical parameters of the organic component of $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ are typical. Fourier difference maps clearly located two H atoms attached to the N atom, thus the en "template" (if the term is still appropriate for this structure) is neutral, in accordance with the charge balancing requirement. Crystallographic symmetry generates the complete en template, which is therefore bonding to Zn from both its terminal N atoms, as Zn–N–C–C–N–Zn, or Zn–en–Zn (H atoms omitted). This linkage forms the connection between *next*-nearest neighbor sheets (*vide infra*).

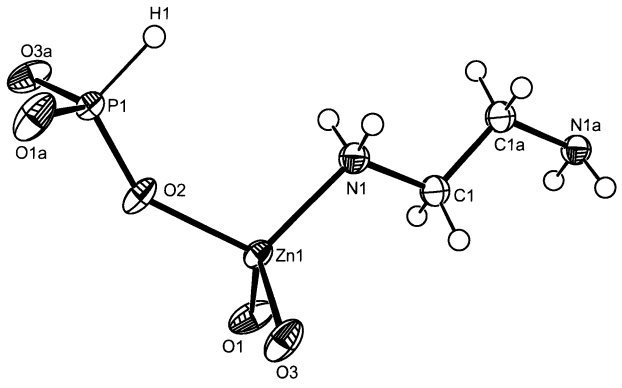

Fig. 1 Detail of the $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ structure (50% thermal ellipsoids) showing the atom labeling scheme. Symmetry generated atoms are indicated by, *e.g.*, O1a.

The connectivity of the strictly alternating ZnO_3N and HPO_3 units in $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ results in infinite layers (Fig. 2) propagating normal to [101]. Polyhedral 4-rings and 8-rings are apparent in these formally neutral sheets, and this topology can be described in terms of a 4.8^2 network (*i.e.*, each nodal Zn or P atom participates in one 4-ring and two 8-rings), which forms a characteristic part of feldspar (*e.g.*, $KAlSi_3O_8$) like phases[5] and various aluminosilicate zeolite structures,[6] although the 8-rings maybe subject to various degrees of distortion. The atom-to-atom dimensions of the $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ 8-ring are approximately 6.51 × 7.14 Å. Each 4-ring has two 'up' (approximately along [101]) and two 'down' vertices, thus both the Zn–N and P–H bonds point into the inter-sheet region.

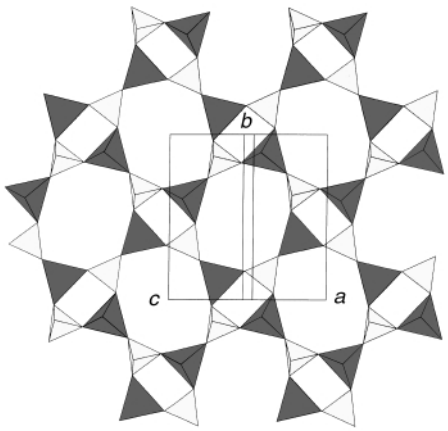

Fig. 2 Polyhedral view approximately down [101] of the 4.8^2 sheet topology of $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$ (dark shading for the ZnO_3N groups, light shading for the HPO_3 groups).

An unusual templating effect occurs in $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$, with the sheet-to-sheet Zn–en–Zn chain sticking *through* an 8-ring in an intermediate zincophosphite layer (Fig. 3). A somewhat similar effect through-the-ring effect involving a protonated template not bound to the inorganic network (and a totally different overall structure) has been seen in the gallofluorophospahte ULM-18.[7] In $[H_2N(CH_2)_2NH_2]_{0.5}\cdot ZnHPO_3$, every 8-ring is templated in the same way, thus, two completely independent but interpenetrating sets of inorganic sheets (Fig. 4) are 'knitted

DOI: 10.1039/b007268k

together' by a covalent bonding network *via* zinc and the template rather than by H bonds or van der Waals's forces. This configuration has clear parallels with the structures of interpenetrating coordination polymers.[8,9] However, N–H···O hydrogen bonds, as commonly seen in organically-templated zinc phosphates,[10] are also important in $[H_2N(CH_2)_2NH_2]_{0.5}{\cdot}ZnHPO_3$, with N1–H2···O1 [$d$(N1–H2) = 0.85(3) Å, d(H···O) = 2.22(3) Å, d(N···O) = 2.998 (2) Å, θ(N–H···O) = 152(2)°] and N1–H3···O3 bonds [0.90(2), 2.04(2), 2.931(2) Å. 169(3)°] occurring, the latter of these evidently somewhat stronger. Each 8-ring is stabilized by four N–H···O links (two from below, two from above), with all four associated with the same ethylenediamine grouping.

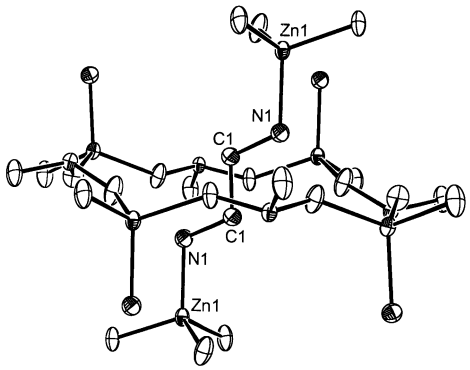

Fig. 3 Side-on view of an 8-ring window in one layer of $[H_2N(CH_2)_2NH_2]_{0.5}{\cdot}ZnHPO_3$ showing the Zn–en–Zn grouping passing through it. For the central 8-ring shown, Zn–en links are terminated at N, and all H atoms are omitted for clarity.

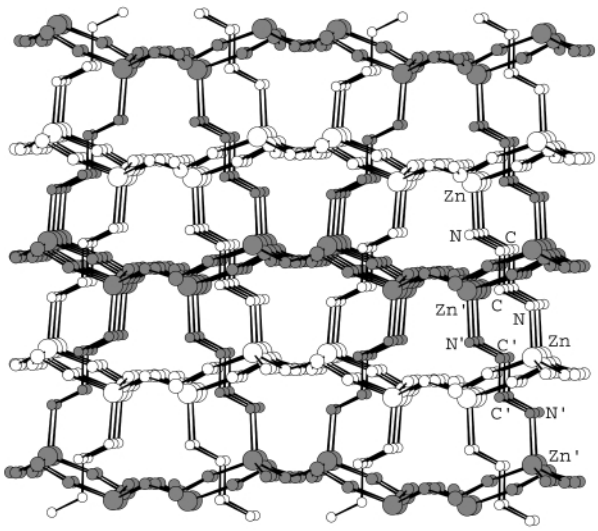

Fig. 4 Side on view approximately down [10$\bar{1}$] of a set of layers in $[H_2N(CH_2)_2NH_2]_{0.5}{\cdot}ZnHPO_3$. The unshaded atoms (unprimed labels) and shaded atoms (primed labels) form separate interpenetrating networks. For clarity, all H atoms are omitted.

We thank David Apperley (University of Durham EPSRC National Solid State NMR Service) for collecting the NMR data.

Notes and references

† *Synthesis*: 0.814 g ZnO, 0.824 g H_3PO_3, 0.602 g ethylenediamine (molar ratio of $Zn:HPO_3^{2-}$:en = 1:1:1) and 18 g of H_2O were added to a PTFE bottle and shaken well. The mixture was transferred to a Teflon-lined, 23 ml hydrothermal bomb, sealed, and heated to 150 °C for two days. The bomb was left to cool for 24 h, and the solid product, consisting of large (up to 2 mm) transparent lumps of the title compound was recovered by vacuum filtration and rinsing with water and methanol.

‡ *Crystal data*: $[H_2N(CH_2)_2NH_2]_{0.5}{\cdot}ZnHPO_3$, M_r = 175.42, monoclinic, space group $P2_1/n$ (no. 14), a = 5.9335(3), b = 10.8863(5), c = 7.7611(4) Å, β = 102.066(1)°, V = 490.25(7) Å^3, Z = 4, μ = 52.2 cm^{-1}, D_c = 2.377 g cm^{-3}, F(000) = 348, $R(F)$ = 0.022, $R_w(F)$ = 0.026. Data collection using a Bruker SMART 1000 CCD diffractometer (graphite-monochromated Mo-Kα radiation, λ = 0.71073 Å, T = 300 K): monoclinic cell parameters from 3479 reflections (6.5 < 2θ < 65.0°), 4999 reflections scanned (2 < 2θ < 65°). After merging (R_{Int} = 0.018), 1649 of the 1752 unique reflections were considered observed [$I > \sigma(I)$]. An absorption correction was applied with SADABS (min., max. equivalent transmission factors = 0.543, 0.928). Hydrogen atoms were located from difference maps and their positions and isotropic thermal factors were refined without constraints.

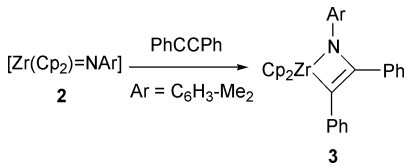
Treatment of a dichloromethane solution of Bu^tCP, containing a catalytic amount of $TiCl_4$, with an excess of the primary amines RNH_2 (R = Pr^i, Bu^t) quantitatively affords the corresponding bis-dialkylaminophosphine $P(Bu^tNH)_2CH_2Bu^t$. $P(Pr^iNH)_2CH_2Bu^t$ is structurally characterised by a single crystal X-ray diffraction study of its bis-*trans*-$PdCl_2$ complex.

The direct addition of nucleophiles HNR_2 to alkenes and alkynes has been shown to be kinetically unfavourable due to high activation barriers caused by unfavourable approach of the substrates.[1] Catalysis is therefore of fundamental importance for the amination of alkynes, by providing alternative lower energy kinetic pathways. A survey of the literature in this area reveals a stronger precedence for catalytic *intra*-molecular hydroamination of alkynes employing complexes of titanium,[2] nickel,[3] palladium,[4] gold[5] and lanthanides.[6] In contrast, catalytic *inter*-molecular hydroamination of alkynes appears much more difficult and these reactions are often hampered by low turnover numbers. The use of Hg^{II} reagents appears to be the most general route for the hydroamination of alkenes and alkynes[7,8] and examples of thallium,[9] lanthanides,[10] uranium and thorium[11] containing catalysts exist.

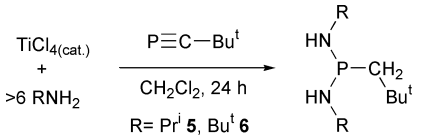
Recently, Bergman *et al.*[12] have demonstrated the utility of the zirconocene diamide [$Zr(\eta^5$-$C_5H_5)_2(NHC_6H_3$-$Me_2)_2$] **1** for the stoichiometric and catalytic addition of amines to internal alkynes and allenes, yielding enamines and imines respectively. The thermolysis (α-elimination) of **1** yields the transient imide '[$Zr(\eta^5$-$C_5H_5)_2(NC_6H_3$-$Me_2)$]' **2** which catalyses the addition of alkynes (RCCR, R = Me, Ph) to 2,6-dimethylaniline. Although intermediates have not been observed during the catalytic cycle, the proposed intermediate metallacyclobutene complex [$Zr(\eta^5$-$C_5H_5)${$N(C_6H_3$-$Me_2)(Ph)CC(Ph)$}] **3**, formed from a stoichiometric [2 + 2] addition of diphenyl acetylene to the metal nitrogen unsaturated bond of **2**, has been prepared and structurally characterised (see Scheme 1).



Scheme 1

Although phosphaalkynes, RCP, contain a slightly polarised bond[13] their similarity in reactivity to alkynes is now very well established.[14] However, although nucleophilic, *trans*-metallations and 1,2-additions have been described,[13] there are no examples to date of hydroaminations of this class of unsaturated molecule. Recently we have been interested in the cycloaddition chemistry of the phosphaalkyne Bu^tCP with Ti and Zr imides.[15] The reaction of Bu^tCP with the transient imide '[$Cp_2ZrN(C_6H_3$-$Me_2)$]' **2** affords the azaphosphacyclobutadiene complex [$Cp_2ZrN(C_6H_5$-$Me_2)PC(Bu^t)$] **4** which is isostructural with **3**. The MNPC fragment in **4** is in agreement with the expected bond polarity of the unsaturated reactive sites.

During the course of this work we have discovered that the reaction of catalytic amounts of $TiCl_4$ with the primary amines RNH_2 (R = Bu^t, Pr^i) followed by the addition of $PCBu^t$ yields the dialkyldiaminophosphines $P(NHR)_2CH_2Bu^t$ (R = Pr^i **5**,† Bu^t **6**†) in near quantitative yields (90–95%) (Scheme 2). No reaction occurs in the absence of $TiCl_4$.



Scheme 2

Compounds **5** and **6** are colourless oils which can be easily purified from the crude reaction mixtures by sublimation *in vacuo* on to a cold finger (liquid nitrogen, 60–70 °C, 10^{-2} mbar, yield 95%). The ^{1}H NMR spectrum of **5** displays the expected five signals. The septet at δ 3.16 and two doublets at δ 1.40, 1.31 are assigned to the methine, methylene and NH protons respectively, the NH resonance being broadened by ^{14}N quadrupolar coupling. The singlet at δ 1.1 is attributed to the *tert*-butyl protons, and the doublet of doublets at δ 1.03 is assigned to the diastereotopic methyl groups of the isopropyl units which are further coupled to the methine protons. The ^{31}P-{^{1}H} NMR spectrum displays a singlet at δ 57.2. In order to unambiguosly assign the connectivity of **5**, the bis-diaminophosphine complex *trans*-[$PdCl_2${$P(Pr^iNH)_2CH_2(Bu^t)$}$_2$] **7**† was prepared from the reaction of [$PdCl_2(NCPh)_2$] **8** and 2 equiv. **5** in acetone. Crystals suitable for X-ray analysis were grown from a concentrated toluene solution cooled to −50 °C and the molecular structure is depicted below together with relevant bond lengths and angles (Fig. 1).‡ The structure is unremarkable, but serves to confirm the dihydroamination of the phosphaalkyne. The bis-aminophosphine units adopt a

Scheme 3

trans-orientation in **7** and the phosphorus atoms display a tetrahedral coordination geometry.

Surprisingly, a survey of the literature shows a relative paucity of structural information on diaminophosphines and only $P(Ar^*NH)_2Ar$ (Ar^* = $C_6H_2Bu^t_3$-2,4,6)[16] and $P(Ar_fNH)_2Ar^*$ (Ar_f = $C_6H_2(CF_3)_3$-2,4,6)[17] have been crystallographically characterised. A few complexes of the group 6 metals have also been reported.[18]

The mechanism of formation of the diaminophosphine has not been fully determined, however Winter *et al.*[19] reported that treatment of $TiCl_4$ with an excess of primary amines affords imido complexes of type $[TiCl_2(NR)(NH_2R)_x)]$ **9** which clearly are likely candidates for the active catalytic species. Furthermore, in unpublished results Regitz and Asmus[20] have recently shown that the reaction of $[Ti(\eta^5\text{-}C_5H_5)Cl_3]$ with Bu^tNH_2 and $PCBu^t$ in toluene yields $[Ti(\eta^5\text{-}C_5H_5)Cl\{PNBu^t(NHBu^t)CHBu^t\}]$ **10**, (probably *via* a [2 + 2] addition of $PCBu^t$ to the intermediate titanium imide $[Ti(C_5H_5)Cl(NBu^t)]$, followed by a 1,2 addition of NH_2Bu^t across the activated P=C bond) (Scheme 3).

The mechanism of formation of the diaminophosphines **5** and **6** by di-hydroamination of $PCBu^t$ probably proceeds *via* the intermediacy of $[TiCl_2(NR)(NH_2R)_x)]$ **9** and $[TiCl_2(NR)P(NHR)CHBu^t]$ which is analogous to **10**, the excess $[NH_3Bu^tCl]$ formed subsequently removing the resulting substrate '{PNR(NHR)CHBu^t}' *via* a double protonation step.

We thank the EPSRC for financial support (D. J. W.) and Professor Manfred Regitz for unpublished results cited in ref. 20.

Ordered, hydrothermally stable mesoporous molecular sieve SBA-15 with hexagonal channel porosity has been synthesized for the first time under microwave–hydrothermal conditions from aged precursor gel within 15 min at 373 K; the crystallized product has been characterized using X-ray diffraction, nitrogen adsorption–desorption and transmission electron microscopy techniques.

Widespread applications of molecular sieves in the fields of separation and catalytic science have emphasised on the search for new structures with new framework compositions.[1] Thus, the last two decades have witnessed a rapid growth of molecular sieve science which has resulted in the discovery of an ordered, mesoporous molecular sieve family (designated as M41S)[2] for the first time. These materials, which can be synthesized with pore sizes from 15 to over 100 Å, are the potential candidates for a wide range of applications such as shape-selective catalysis and sorption of large organic molecules, guest–host chemistry and chromatographic separation. However, poor hydrothermal stability of these materials restricts their application potential. Thus, attempts are being made to improve their hydrothermal stability using various synthesis and post-synthesis routes. These attempts have resulted in the synthesis of the ordered, hydrothermally stable mesoporous molecular sieve SBA-15, which has been synthesized using a triblock organic copolymer as a template under hydrothermal conditions.[3] Here, we report, for the first time, a successful rapid synthesis of SBA-15 molecular sieve under microwave–hydrothermal (M–H) conditions within *ca.* 120 min. The term microwave–hydrothermal process was coined by Komarneni *et al*. in 1992 and this process has been used for the rapid synthesis of numerous ceramic oxides, hydroxylated phases, porous materials and metal powders.[4]

The microwave-assisted synthesis of molecular sieves is a relatively new area of research.[5] This method has been successfully applied for the synthesis of several types of zeolites namely zeolite A, Y, ZSM-5, MCM-41, metal substituted aluminophosphate and gallophosphate.[6–11] Microwave-assisted synthesis of molecular sieves offers many distinct advantages over conventional synthesis. They include rapid heating to crystallization temperature due to volumetric heating resulting in homogeneous nucleation, fast supersaturation by the rapid dissolution of precipitated gels and eventually a shorter crystallization time compared to conventional autoclave heating. Furthermore, it is energy efficient and economical.[4–11]

Microwave–hydrothermal synthesis of SBA-15 molecular sieve was performed using a MARS5 (CEM Corp., Matthews, NC, USA) microwave digestion system. This system operates at a maximum power of 1200 W and the power can be varied from 0 to 100% and is controlled by both pressure and temperature to a maximum of 350 psi and 513 K, respectively. A 2.45 GHz microwave frequency was used which is the same as that in domestic microwave ovens. The syntheses were carried out in double-walled digestion vessels which have an inner liner and cover made up of Teflon PFA and an outer strength vessel shell of Ultem polyetherimide. In a typical synthesis, 4 g of triblock poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) ($EO_{20}PO_{70}EO_{20;}$ M.W. 5800, Aldrich) was dispersed in 30 g of double distilled water. The resultant solution was mixed with 120 g of 2 M HCl (J. T. Baker) solution under stirring to obtain a homogeneous solution. Finally, 9.50 g tetraethylorthosilicate (TEOS, Aldrich) was added to the homogeneous solution with stirring to form a reactive gel. Thus obtained gel was allowed to crystallize under microwave–hydrothermal conditions at 373 K for the desired time. The crystallized product was filtered off, washed with warm distilled water, dried at 383 K and finally calcined at 813 K in air for 6 h. The calcined product was characterized by X-ray diffraction (X'pert system, Phillips, USA), nitrogen adsorption–desorption isotherm measurements at 77 K (Autosorb, AS-1, Quantachrome, USA) and transmission electron microscopy (JEM-2010, JEOL, Japan). To study the progress of crystallization under microwave–hydrothermal conditions, samples were prepared for 15, 30, 60, 90 and 120 min at 373 K and were characterized using X-ray diffraction and nitrogen adsorption–desorption methods. The standard SBA-15 sample was also prepared by following the reported synthesis preocedure[3b] and was used as a reference to estimate the purity of the samples obtained under microwave–hydrothermal conditions.

The specific surface area, S_{BET}, for crystallized samples was calculated by the standard BET method[12] for nitrogen adsorp-

[a] $a_o = 2d_{100}/\sqrt{3}$. [b] Reference sample was prepared by following the reported conventional synthesis route.[3b]

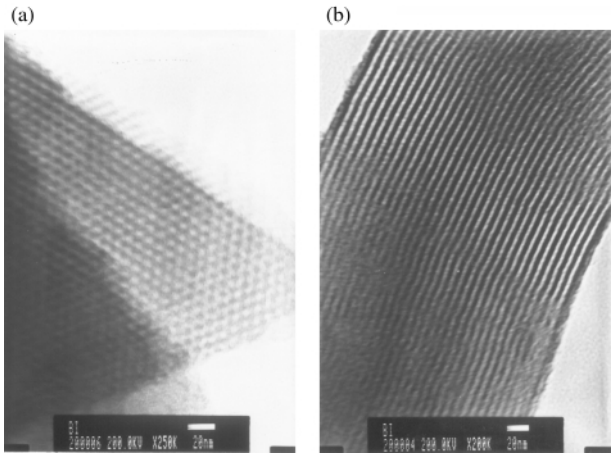

Fig. 2 Transmission electron micrographs with different orientations of a calcined hexagonal SBA-15 sample obtained at 120 min under M–H conditions.

tion data in a relative pressure range from 0.05 to 0.2. The calculation of pore size distribution (PSD) was performed by analyzing the adsorption data of the N_2 adsorption–desorption isotherm using the recently developed KJS (Kurk, Jaroniec, Sayari) approach.[13] The pore diameter corresponding to the maximum of PSD is denoted as W_{KJS}. The total pore volume was estimated from the amount adsorbed at a relative pressure of 0.95. The external surface area S_{ex}, and primary mesopore volume V_p, were estimated using the α_s-plot method, as described elsewhere.[14]

The X-ray diffraction patterns for SBA-15 samples obtained at various time intervals showed a well resolved pattern with a prominent peak at 2θ *ca.* 0.9° and two peaks at 2θ *ca.* 1.6 and 1.7° for all the crystallized samples which match well with the pattern reported for SBA-15.[3b]

Typical nitrogen adsorption–desorption isotherms for various samples are shown in Fig. 1. All the nitrogen adsorption–desorption isotherms are found to be of type IV in nature as per the IUPAC classification. The pore structure parameters for various SBA-15 samples calculated from the X-ray diffraction data and nitrogen adsorption–desorption isotherms are given in Table 1. Interestingly, the relative condensation pressure, which is a function of pore diameter, was found to increase with an increase in crystallization time which in turn reflected an increase in pore dimension and decrease in silica wall thickness for SBA-15 samples. These results are in good agreement with those reported under the conventional hydrothermal route[3b] and may be due to the rapid dehydration of EO blocks of the copolymer[15] at 373 K as a function of time under microwave–hydrothermal conditions. The condensation point for the 120 min sample was found to match with that of the reference sample (Fig. 1). Furthermore, a good agreement of pore structure parameters for the 120 min sample was observed with that of the reference sample. This indicates that the optimum reaction time for this synthesis is *ca.* 120 min at 373 K under microwave–hydrothermal conditions which is extremely short compared to the crystallization time required for conventional synthesis (*i.e.* 1–3 days). This observation is further reinforced by transmission electron microscopy (Fig. 2) which showed the ordered hexagonal pore structure with a one-dimensional channel structure of *ca.* 75 Å size, which is in close agreement with the value obtained from the KJS approach (Table 1), for a 120 min sample crystallized under M–H conditions.

In summary, the present study has established an extremely rapid synthesis method for SBA-15, which should also be applicable to other surfactants.

The support (in part) of this work by the NSF MRSEC program under grant number DMR-0080019 is gratefully acknowledged.

The action of heat and pressure on a co-crystallate of C_{60} and a calixarene, where the fullerenes are pre-organized in separated linear columns, gives a linear [2 + 2] addition polymer of $(C_{60})_n$ without crosslinking.

Co-crystallizations and supramolecular assemblies are giving rise to an explosion of new crystal structures. Aesthetics, apparent ease of synthesis (self assembly), and the challenge of understanding and manipulating the weak forces that dictate crystal structures are driving this very active field.[1]

Fullerenes have three-dimensional arrays of reactive double bonds that present an unusually difficult problem for controlling the topology of multiple addition reactivity. Solid state pre-organization offers a potential solution. Scattered reports support this hypothesis. An unusual addend transfer reaction, not favored in solution, has been observed in the solid state with a Diels–Alder anthracene/C_{60} adduct.[2] A derivatized fullerene has been shown to assemble spontaneously into macroscopic rods and vesicles.[3] Pressure-induced dimerization of C_{60} to produce C_{120} is more efficient in a co-crystallate than in the bulk.[4] Pressure-induced dimerization of bulk C_{70} is interesting because it leads to selection of a single [2 + 2] addition isomer of C_{140}, even though five equi-energy combinations are possible.[5] Bulk C_{60} can be polymerized under pressure to give, depending on conditions, a variety of [2 + 2] addition polymers, some approaching distinct phases.[6]

Fullerenes are particularly prone to co-crystallization with other molecules[7–10] and under fortunate circumstances, the crystallizing components can become organized in useful ways. One such opportunity is provided by the report that C_{60} co-crystallizes with a calixarene in strictly linear, separated columns.[11] As shown in Fig. 1, the C_{60} molecules are in close van der Waals contact within a column (9.92 Å center-to-center distance) but parallel columnar stacks of calixarenes separate the fullerene columns from each other (12.81 Å center-to-center

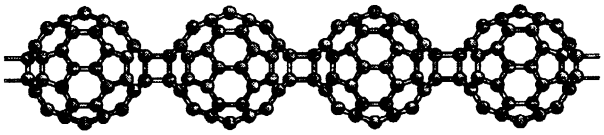

Fig. 2 Schematic depiction of the strictly linear [2 + 2] addition polymer of C_{60}.

distance). We reasoned that the action of heat and pressure should lead to strictly linear nanorods of a [2 + 2] addition polymer $(C_{60})_n$ (Fig. 2) and that the calixarenes would prevent crosslinking. The C_{60} molecules in the co-crystallate are known to be freely rotating at room temperature[12] so the pre-positioned fullerenes can readily adopt the required orientation of bonds[13,14] for mutual [2 + 2] addition.

The co-crystallate of *p*-bromocalix(4)arene propyl ether and C_{60} **1**, was prepared by the published method.[11] The identity of the product was checked by single-crystal X-ray determination. Sample homogeneity was checked by consistency of size, shape and color (dark red) under a microscope. Samples (*ca.* 20 mg) were packed in octahedrally shaped MgO containers, wrapped with Re foil for heating, fitted with a thermocouple, and pressed hydrostatically in a cube anvil. The pressure was increased gradually to the desired value (5 GPa) over a 30 min period followed by 1 h of heating at 200 °C. Samples were allowed to cool prior to the release of pressure since heat without pressure causes depolymerization. The polymerized product **2** had a black obsidian-like appearance. Bulk C_{60} was polymerized in a similar manner at 5 GPa and 200 °C to produce a 'crosslinked' material **3**, and at 1.5 GPa and 400 °C to produce an 'orthorhombic phase' **4**.[6]

Energy dispersive X-ray spectroscopy showed that the atomic composition of co-crystallate **1** and its polymerized product **2** were identical. The IR spectrum of **1** is a simple composite of its constituents: C_{60} and calixarene [Fig. 3(a) and (b)]. After pressure/heat treatment to produce **2**, bands due to the calixarene (1600–800 cm^{-1}) are unchanged, indicating that the calixarene component has not undergone chemical reaction [Fig. 3(c)]. On the other hand, several new bands appear in the 'fingerprint' region for fullerene derivatization (800–500 cm^{-1}) indicative of symmetry-lowering reactivity of C_{60}. Comparison of **2** with pressure/heat-treated pristine C_{60} samples **3** and **4** [Fig. 3(d) and (e)]† reveals a very close similarity to the orthorhombic phase **4** of polymerized C_{60}, but not to the crosslinked phase **3**. The Raman spectra of **2** and **4** are also very similar, in both the high and low energy regions (Fig. 4).† This indicates that the detailed mode of polymerization in **2** and in the orthorhombic phase of C_{60} is the same. Since there is growing consensus that the structure of **4** is a linear [2 + 2] addition polymer,[6] and since it is difficult to understand how **2** could be anything but a linear [2 + 2] addition polymer, the spectral consistency of **2** and **4** supports a correct structural assignment in both (Fig. 2).

Partial polymerization of **1** at 1.5 GPa and 150 °C gives a product from which C_{60}, C_{120}[15] and a presumably linear isomer of C_{180} can be separated by HPLC from the sonicated 1-chloronapthalene extract. The evidence for the linear isomer

of C_{180} includes (i) an HPLC retention time [Buckyprep(toluene–1,2-dichlorobenzene (1 : 1)] of 5.3 min compared to C_{60} (4.0 min) and C_{120} (4.6 min), (ii) a *single* HPLC peak rather than *four* that are observed in the low pressure trimerization of bulk C_{60},[16] (iii) an IR spectrum quite different from that of the proposed *triangular* isomer of C_{180},[16] (iv) a fullerene-like UV–VIS spectrum (λ_{max} = 327, 710 nm), and (v) photodegradation to C_{60} and C_{120}. The extremely low solubility and light sensitivity of this material has thwarted attempts to isolate it in significant amounts.

There has been significant effort put into the characterization of photo-[17] and pressure/heat-polymerized[18] C_{60}, partly justified on the basis of potential applications as conductors or nanowires.[6] In order to test the nanowire hypothesis we have subjected the linear polymer to a number of physical and chemical stability tests.

Of potential utility is the observation that it is insoluble in all common solvents and thermally stable at reasonable temperatures. Differential scanning calorimetry at 4 °C min^{-1} heating rate shows an irreversible endothermic process in the range 185–295 °C, consistent with thermal depolymerization at higher temperatures to give C_{60}. This is confirmed by subsequent solubility in organic solvents and UV-VIS identification of C_{60}. HPLC analysis showed traces of C_{120} were also present.

To model charge carrying, the polymer was exposed to reducing agents such as Na/THF or Hg/$R_4N^+Br^-$/THF. In both cases, complete dissolution of the polymer occurred and discrete C_{60}^- ions were detected (λ_{max} = 1075 nm). When smeared onto a platinum electrode and subjected to cyclic voltammetry, cathodic sweep peaks led to the production of C_{60}^- and C_{60}^{2-} in solution. Presumably reduction of the polymer causes monomers to dissociate from the surface like pearls dropping off a necklace. Dimeric C_{120} is known to dissociate immediately upon reduction.[15] In a comparable test for positive hole carrying, the polymer was exposed to oxidizing agents and anodic current. It is stable to aqueous $KMnO_4$ and HNO_3 but a moderate excess of bromine gradually produces $C_{60}Br_8$ (identified by isolation and IR spectroscopy).[19] On a platinum electrode, an irreversible anodic wave was observed at the same potential as C_{60} (*ca.* 1.4 V *vs.* Fc/Fc$^+$) suggesting irreversible decomposition. Although C_{60}^+ is now known as a stable entity,[20] it reacts instantly with errant nucleophiles in the solvent and supporting electrolyte.

In summary, this work shows how crystal engineering can be used fruitfully in fullerene polymer chemistry.[21] With its symmetrical [2 + 2] addition linkages, linear $(C_{60})_n$ is a chemically elegant polymer. One would like it to have a useful application. However, the present work suggests this will not be found as a nanowire. Rather, an analogy can be made to a nano*fuse*. Isolated single chains are unlikely to carry any current at all and bundles of chains are likely to be fragile. We note, however, that the proposed linear-chain isomer of KC_{60} is a metal[22] so stoichiometric intercalation of small cations can stabilize a lattice.

We thank Prof. Harry Green and Dr Larissa Dobrzhinetskaya for assistance with the cube anvil experiments, Prof. David Bocian for assistance in obtaining Raman spectra, Prof. Koichi Komatsu for a preprint of ref. 16 and the US National Institutes of Health NIH (GM 23851) for financial support.

Electrochemical detection of catechol and dopamine as their phenylboronate ester derivatives

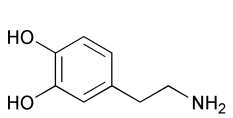
Sharon M. Strawbridge, Stephen J. Green* and James H. R. Tucker*

School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD. E-mail: j.h.r.tucker@exeter.ac.uk; stephen.j.green@exeter.ac.uk

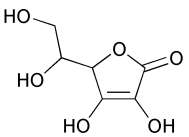
Received (in Cambridge, UK) 5th September 2000, Accepted 5th October 2000
First published as an Advance Article on the web

By virtue of its reaction with phenylboronic acid to form a boronate ester, dopamine can be detected electrochemically in aqueous solutions, at physiological pH, in the presence of excess ascorbic acid.

It is well known that, in aqueous media, certain diols and boronic acids react together to form boronate esters, to an extent dependent upon the pH of the solution.[1] Such reactions have previously been used in the detection of sugars both by fluorescence spectroscopy[2] and, as part of recent progress in the electrochemical sensing of organic molecules,[3] by electrochemical measurements.[4] Here, we show that boronate esters, formed by the reaction of the aromatic diol 1,2-dihydroxybenzene (catechol) with phenylboronic acids, are electrochemically oxidised at potentials considerably more positive (by *ca*. 0.5 V) than that necessary to oxidise catechol itself, at a given value of pH. This positive shift indicates that, while formation of the neutral ester is thermodynamically favourable, the oxidised ester tends to revert back to (oxidised) catechol and the phenylboronic acid; cyclic voltammograms of these systems are consistent with such a mechanism. These properties extend to the boronate ester formed by reacting phenylboronic acid (PBA) with the catecholamine neurotransmitter dopamine **1**.



1



2

This has allowed us to electrochemically detect dopamine in the presence, as would be the case in any human sample, of excess ascorbic acid **2**. Detection is achieved *via* oxidation of the ester, which occurs at a potential positive enough of the values for dopamine and ascorbic acid oxidation to allow resolution by voltammetry (the values for dopamine and ascorbic acid are too close to allow their resolution). Other electrochemical approaches to the problem of dopamine detection, including the use of electrodes modified with ion-exchange membranes,[5] polypyrrole films,[6] templated silicate films,[7] and self-assembled monolayers[8] have met with varying degrees of success but there is presently no direct method, electrochemical or other, of measuring the level of dopamine in human samples; abnormal levels of dopamine have been linked to brain disorders such as Parkinson's disease[9] and schizophrenia.[10]

As aliquots of phenylboronic acid were added to a 1 mM solution of catechol in phosphate buffer at pH = 8, the form of cyclic voltammograms, recorded in this solution using a glassy carbon working electrode, was found to change from the typical form for the quasi-reversible electrode reaction of the catechol itself.[11] With each addition of PBA, a diminution of the catechol oxidation peak was accompanied by the growth of a more positive oxidation peak. Fig. 1 shows voltammograms recorded for catechol alone and for catechol in the presence of 20 equivalents of PBA; the latter clearly shows a new oxidation peak (b) at E_{pa} ('anodic peak potential') = 619 mV *vs*. Ag/AgCl. Since PBA is not electroactive in the potential window

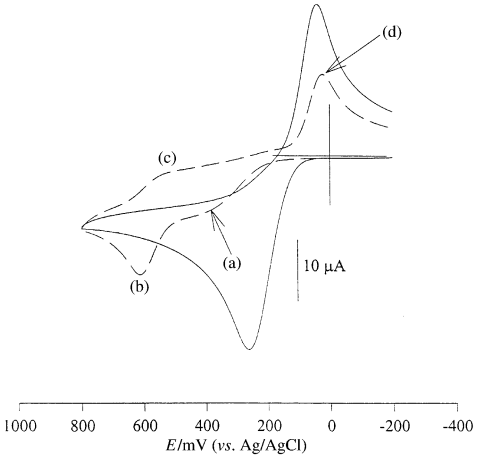


Fig. 1 Cyclic voltammograms, recorded using a glassy carbon working electrode in aqueous buffer at pH = 8 and 298 K, of 1 mM catechol (——) and 1 mM catechol plus 20 molar equiv. of PBA (- - -). Sweep rate 100 mV s^{-1}.

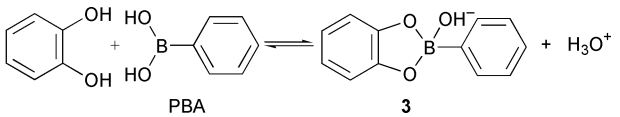
examined, the new oxidation peak is attributed to the oxidation of the boronate ester **3**, the presence of which in equilibrium with PBA and catechol accounts for the positive shift of the remaining catechol oxidation to peak (a). The formation of **3** (Scheme 1) was evidenced by ^{1}H NMR studies conducted over the pH range 6–8 (phosphate buffer, 10% d_4-methanol in H_2O), where the spectra of an equimolar mixture of PBA and catechol (each at 0.05 M) contained signals in the aromatic region consistent with the formation of a 1 : 1 adduct between the two reactants.



PBA **3**

Scheme 1

The peak (b) associated with the oxidation of **3** appears as for an electrochemically quasi-reversible, two-electron reaction ($E_{pa} - E_{pa/2} \approx 50$ mV; $E_{pa/2}$ is the half-peak potential). The somewhat smaller return peak (c) for reduction of the oxidised ester ($i_{pa}/i_{pc} \approx 0.34$; i_{pa} and i_{pc} are the anodic and cathodic peak currents, respectively), suggests that it is removed by a homogeneous reaction. Given that the second reduction peak (d) is at the potential observed previously for the reduction of oxidised catechol (benzoquinone) and was largely removed by reversal of the voltammogram at 400 mV (*i.e.* just short of oxidising **3**), we conclude that the oxidation of **3** leads to its cleavage to yield benzoquinone and (presumably) PBA.

With a view to obtaining fine control over the oxidation peak potential for the boronate ester, additional voltammetric studies were performed replacing PBA with the *meta*-substituted phenylboronic acids **4** and **5**. Only a slight effect was observed. The oxidation peaks for the esters formed from catechol with **4** and **5** were, respectively, coincident with and only 16 mV

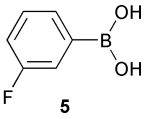
4



5

positive of that for the oxidation of **3** (results independent of pH over the range 6–8). ^{1}H NMR studies (pH = 7.5, phosphate buffer, 10% d_4-methanol in H_2O, reactants each at 0.05 M) revealed a similar trend in the ratio of boronate ester to boronic acid, following the order **5** > PBA ≈ **4**. The same trend was also observed using ^{11}B NMR (128 MHz, using BF_3:OEt_2 as an external standard), where each spectrum contained a boron signal corresponding to the boronate ester at *ca*. 18 ppm upfield from the signal corresponding to the boronic acid. The trend observed broadly reflects that for esters formed by reacting boronic acid with aliphatic diols,[1c] and is consistent with boronate ester formation being more favourable as the pK_a of the boronic acid decreases.[12] This is expected since electron withdrawing groups on the phenyl ring would tend to stabilise the product.

To demonstrate the possible use of these phenylboronic acid–catechol systems for the detection of biologically important catecholamines, differential pulse voltammetry was performed, using a glassy carbon electrode in pH = 7.5 phosphate buffer solution, to show how the neurotransmitter dopamine **1** could be detected in the presence of excess ascorbic acid **2**. Fig. 2 shows how the oxidation peak for 0.5 mM dopamine [voltammogram (a)] was obscured by that for oxidation of an added 5 mM of ascorbic acid [voltammogram (b)]. Then, after addition of 10 mM of PBA [voltammogram (c)], a new peak emerged at around 600 mV *vs*. Ag/AgCl, which (by analogy to the catechol/PBA case†) is for oxidation of an ester formed between dopamine and PBA, thus allowing the otherwise hidden dopamine to be detected. The figure inset confirms that the new peak recorded in voltammogram (c) does not indicate ester formation between PBA and ascorbic acid. Voltammogram (d) is that for 0.5 mM ascorbic acid in the presence of 10 mM of PBA and shows no peak for oxidation of an ester (the ascorbic acid voltammogram was unchanged by the addition of PBA and we conclude that no significant ester formation occurs). In voltammogram (e), where ascorbic acid was replaced by dopamine, a peak for oxidation of the boronate ester appeared at around 600 mV just as in voltammogram (c) in the main figure.

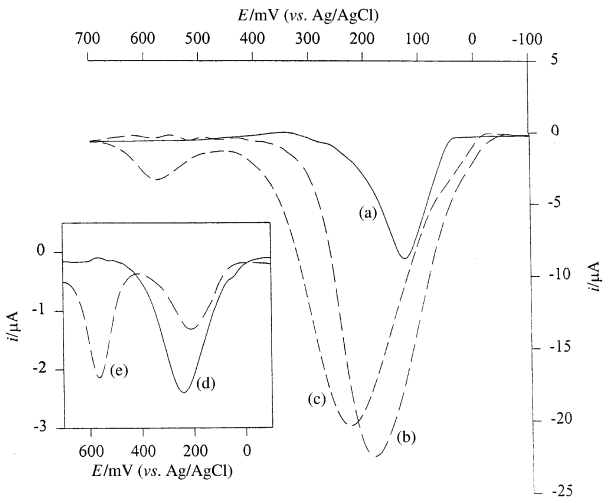


Fig. 2 Differential pulse voltammograms, recorded using a glassy carbon working electrode in aqueous buffer at pH = 7.5 and 298 K, of (a) dopamine **1** (0.5 mM), (b) **1** (0.5 mM) plus ascorbic acid **2** (5 mM), (c) **1** (0.5 mM) plus **2** (5 mM) plus PBA (10 mM), (d) **2** (0.5 mM) plus PBA (10 mM), and (e) **1** (0.5 mM) plus PBA (10 mM). Sweep rate 20 mV s^{-1}; pulse amplitude 50 mV.

Dopamine can thus be detected electrochemically in solutions, at physiological pH, containing an excess of ascorbic acid (we found the limit to be an excess of around 20-fold). We believe that this approach can readily be applied to the development of electrochemical sensors for dopamine and related catecholamines, especially since, once oxidised, the esters formed tend to revert back to the initial reactants, making the sensor re-useable.

We thank the EPSRC for the award of a quota studentship (to S. M. S.).

Notes and references

† The cyclic voltammetry of dopamine/PBA resembles that of catechol/PBA.

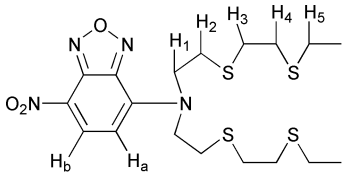
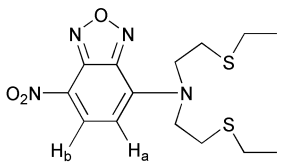
Selective and drastic fluorescence enhancement for mercury ion was observed in 1,4-dioxane–water (60/40) using a fluoroionophore bearing a nitrobenzoxadiazolyl group linked to a 3,6,12,15-tetrathia-9-azaheptadecane moiety.

It is very important to develop a easy mercury determination system for monitoring its concentration in polluted areas. Chromo- and/or fluoro-ionophores are very effective for determination for metal ion concentration in terms of handling and equipment. Although several analytical reagents have been made for the determination of Hg^{2+}, most lack selectivity and sensitivity.[1,2] It is well known that Hg^{2+} might quench the fluorescence of fluorescent reagents because of its open-shell, paramagnetic properties.[3,4] A fluoroinophore, constitituted of a thiaaza crown unit and a boron dipyrromethene dye moiety, for Hg^{2+} was reported recently.[5] The emission spectra of the fluoroinophore, however, changed with polarity of the solvent, and so the complexation experiments were mainly carried out in acetonitrile. To the best of our knowledge, we now report the first fluoroionophore which increases the fluorescence intensity according to the concentration of Hg^{2+} selectively in a polar solution containing water.

The novel fluoroionophores **1** and **2**,† prepared by the



1



2

reaction of 4-chloro-7-nitrobenzoxadiazole with 3,6,12,15-tetrathia-9-azaheptadecane and 3,9-dithia-6-azaundecane, respectively, are constructed of ionophore and fluorophore moieties. The ionophore moiety contains sulfur atoms which have an affinity for soft metal ions such as Ag^+, Tl^+ and Hg^{2+}, because of its soft donor properties.[6,7] A nitrobenzoxadiazolyl moiety might function both as a fluorophore and as a chromophore.[8] It is expected that the electron density of the fluorophore moiety is reduced by the electron-withdrawing effect of coordinated metal ions and that remarkable changes in the fluorescence intensity and the absorption spectra should be caused when the ionophore moiety is complexed to a metal ion.[9]

On addition of various metal ions, changes in spectral properties of fluoroionophores **1** and **2** were measured by spectrophotometry and spectrofluorometry. 1,4-Dioxane–water (60/40 v/v) solution was used as solvent since the fluoroionophores are insoluble in pure water. The maximum wavelength of absorption (λ_{max}) for **1** is 492 nm, and that (λ_{em}) of the emission spectrum at an excitation wavelength of 492 nm is 536 nm. The spectral properties for **1** are independent of pH between pH 1 (0.1 mol dm^{-3} HNO_3) and neutrality. Fig. 1 shows the absorption and the emission spectra of 1,4-dioxane–water (40/60 v/v) solutions containing 1×10^{-5} mol dm^{-3} **1**, an equimolar quantity of a metal ion, *i.e.*, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Tl^+, Ag^+ or Hg^{2+}, and 0.1 mol dm^{-3} HNO_3. On addition of Hg^{2+} and Ag^+ to a solution of **1**, blue shifts were observed for the absorption spectra and the absorbances were decreased similarly. On the other hand, the emission spectrum of **1** in the presence of Hg^{2+} ion was enhanced much more than that for Ag^+ ion, while the fluorescence intensity of **1** for Ag^+ was slightly higher than that for free **1**. A hypsochromic shift of *ca.* 18 nm of λ_{max} was observed on addition of Hg^{2+} ion, caused by the interaction between the metal ion and the nitrogen atom, associated with the chromophore moiety on the ionophore unit. Similar hypsochromic shifts have been reported for donor–acceptor type chromoionophores.[10,11] In the presence of other metal ions, *i.e.*, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} or Tl^+, no spectral change for **1** was observed. Compound **2** exhibited no spectral change even in the presence of Hg^{2+} and Ag^+ ions under the same conditions as **1**. Such a difference in the spectral changes between **1** and **2** for Hg^{2+} and Ag^+ ions is attributable to a difference of stabilities of their complexes.[12,13]

Fig. 2 shows fluorescence intensity changes for **1** as a function of the concentration of the added metal ions. It is obvious that the fluorescence intensity increases with the concentration of Hg^{2+} and Ag^+. Compound **1** forms a 1:1 complex with Ag^+ quantitatively leading to small change in the

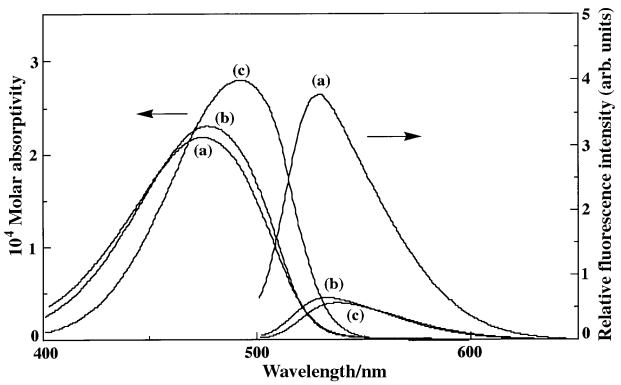


Fig. 1 Absorption and emission spectra of 1,4-dioxane–water (40/60 v/v) solution containing 1.0×10^{-5} mol dm^{-3} **1** 0.1 mol dm^{-3} HNO_3, and 1.0×10^{-5} mol dm^{-3} of metal ion. (a) Hg^{2+} added; (b) Ag^+ added; (c) Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Tl^+ added or absence of metal ion.

DOI: 10.1039/b007577i

(a) Plots of chemical shifts for protons of fluorophore moiety *vs.* [Metal ion]/[**1**]. (□, ■): H_a, (○, ●): H_b. (b) Plots of chemical shifts for protons of the ionophore moiety *vs.* [Metal ion]/[**1**]. (□, ■) H^1, (○, ●) H^2, (△, ▲) H^3, (◇, ◆) H^4, (▽, ▼) H^5.

fluorescence intensity. On the other hand, the complex of **1** with Hg^{2+} was gradually formed even above an $[Hg^{2+}]/[\mathbf{1}]$ ratio of 1 ($[Hg^{2+}] = 1.0 \times 10^{-5}$ mol dm^{-3}) and drastic enhancement in the fluorescence intensity compared with that for the complex with Ag^{+} was observed. These results demonstrate that the fluorescence intensity of the Hg(II) complex of **1** is much higher than that of the Ag(I) complex, although the former complex is less stable. The spectroscopic properties of the complex should preferentially depend on the strength of the interaction between a metal ion and the nitrogen atom connected to the nitrobenzoxadiazolyl moiety while the stability of the complex is governed by the degree of the affinity of the ionophore moiety to the metal ion.

^{1}H NMR titration of **1** with metal ions was carried out using acetonitrile-d_3 as solvent. Fig. 3 shows Hg^{2+} and Ag^{+} induced changes in the ^{1}H NMR chemical shifts for the protons of **1**. Addition of Hg^{2+} and Ag^{+} caused downfield shifts for the methylene protons of the sulfur containing moiety, indicating the coordination of sulfur atoms to the metal ion in which metal ion is probably wrapped by the tetrathiazaalkane moiety. A drastic downfield shift of H_a was observed on the addition of Hg^{2+}. This phenomenon suggests a decrease in the π-electron density of the nitrobenzoxadiazolyl moiety. The much larger change in the chemical shifts for the protons of the nitrobenzoxadiazolyl moiety upon the addition of Hg^{2+} relative to that of Ag^{+} suggests that the interaction of the nitrogen atom of the tetrathiazaalkane moiety with Hg^{2+} is stronger than with Ag^{+}.

In conclusion, the present study demonstrates that 3,6,12,15-tetrathia-9-azaheptadecane **1** bearing a nitrobenzoxadiazolyl moiety is a viable candidate as a fluoroionophore for a new Hg^{2+} ion sensor. This fluoroionophore **1** can discriminate Hg^{2+} ion well among heavy metal ions by an enhancement of the fluorescence intensity. In this case, the calibration curve for the relative fluorescence intensity *vs.* concentration of added Hg^{2+} shows linearity up to $[Hg^{2+}]$ 1.5×10^{-5} mol dm^{-3} 1,4-dioxane–water (60/40 v/v) (Fig. 2). This fluoroionophore can thus determine trace amounts of Hg^{2+} selectively even in acidic polar media containing water.

Notes and references

† The fluoroionohores **1** and **2** were synthesized as follows: 7-chloro-4-nitrobenzoxadiazole (2.2 mmol), the corresponding thiazaalkane (2 mmol)[13] and potassium carbonate (2 mmol) were dissolved in EtOH (50 mL) and stirred over night. After the reaction was complete, the solvent was evaporated *in vacuo* and 100 mL of water was added to the residue. The aqueous solution was extracted with $CHCl_3$ (3×100 mL) and the extract dried over $MgSO_4$. After removal of the solvent, the product was purified by column chromatography.

[2]Rotaxane with a cation-binding wheel

Rameshwer Shukla, Martin J. Deetz and Bradley D. Smith*

Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556-5670, USA. E-mail: smith.115@nd.edu

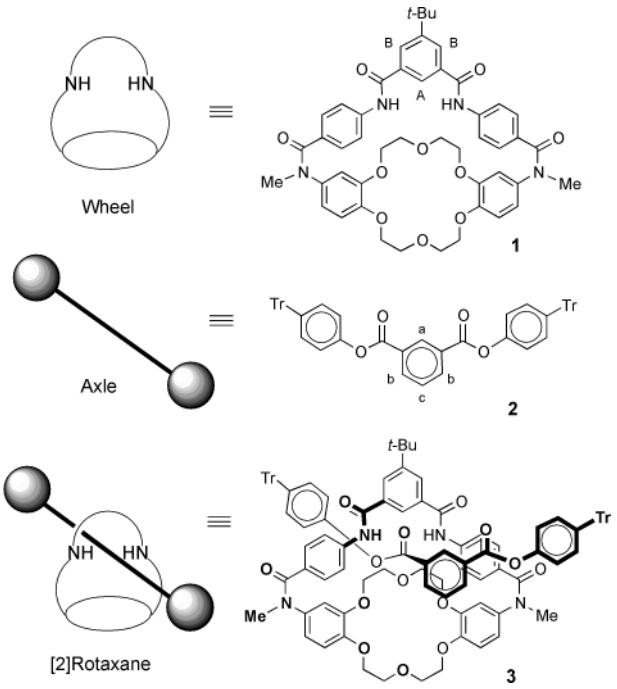
Received (in Columbia, MO, USA) 7th July 2000, Accepted 4th October 2000
First published as an Advance Article on the web

A [2]rotaxane with a crown ether-containing wheel component is synthesized and shown to bind K^+ which alters the rotaxane's dynamic properties.

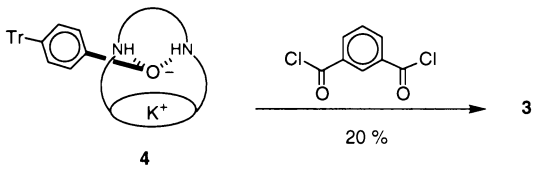
There is a growing interest in the chemistry of mechanically interlocked molecules.[1–6] This report concerns rotaxanes, interlocked molecules that are comprised of two molecular components, a wheel and a penetrating axle. Rotaxanes can exhibit a number of dynamic features such as shuttling (the wheel sliding along the axle),[1] pirouetting (the wheel rotating around the axle),[7] and unthreading (loss of the axle from the wheel).[8] There is hope that these dynamic features can be controlled and eventually utilized in molecular machines.[9,10] At present, a major research goal is to develop switching strategies to regulate these dynamic features.

Most of the rotaxanes reported to date have used macrocyclic wheels.[1] We are interested in macrobicyclic wheels with the generalized structure shown in Scheme 1. The structure is composed of a cation-binding macrocycle (*e.g.*, crown ether, porphyrin, *etc.*) and an anion-binding bridge [*e.g.*, diamine, bis(amide), *etc.*]. The anion-binding bridge should allow a range of rotaxanes to be prepared using the versatile anion-templated methodology recently introduced by Vögtle and coworkers.[11,12] The wheel component in these rotaxanes can bind metal cations which in turn should influence the rotaxane's dynamic processes.

In this initial study, we use the bridged crown ether **1** as the rotaxane's wheel component. Recently, we reported a six-step, gram-scale synthesis of **1** and demonstrated that a close structural analogue can simultaneously bind an alkali metal cation and a halide anion.[13] Based on this knowledge, we reasoned that host **1** should be able to bind the potassium salt of 4-tritylphenolate, and that the resulting 'wheeled potassium phenolate' **4** would react with isophthaloyl dichloride to form [2]rotaxane **3**. Indeed, we can consistently produce **3** in 20% isolated yield.† The compound is thermally stable, for example, heating a DMSO solution at 413 K for 3 h produces no evidence of rotaxane unthreading.



Scheme 1



The structure of **3** was proved by NMR and mass spectrometry. A positive ion FAB mass spectrum shows a weak molecular ion signal at *m*/*z* 1646 (M+H), and intense signals at 1668 (M+Na) and 1684 (M+K). A sample treated with KCl shows only the signal at 1684 (M+K). The ^{1}H NMR spectrum is particularly revealing. The signal for the two isophthalate protons, H_b, in axle **2** is a doublet at 8.43 ppm when the axle is free in $CDCl_3$ solution [Fig. 1(a)], but when the axle is part of rotaxane **3** the two protons are no longer chemically equivalent and two doublets at 8.64 and 8.55 ppm are observed (Fig. 1(b)]. The room-temperature ^{1}H NMR spectrum of **3** in $CDCl_3$ was assigned by a combination of COSY and ROESY methods. Formation of the rotaxane shifts the signals for the wheel's internal bridgehead proton H_A and its two NH residues strongly upfield. Conversely, the axle's central phthalate protons, H_b and H_c, are shifted downfield. The ROESY spectrum indicates that the rotaxane adopts a predominant supramolecular co-conformation in $CDCl_3$ with the wheel and axle oriented as shown in structure **3**. For example, the axle proton H_a interacts

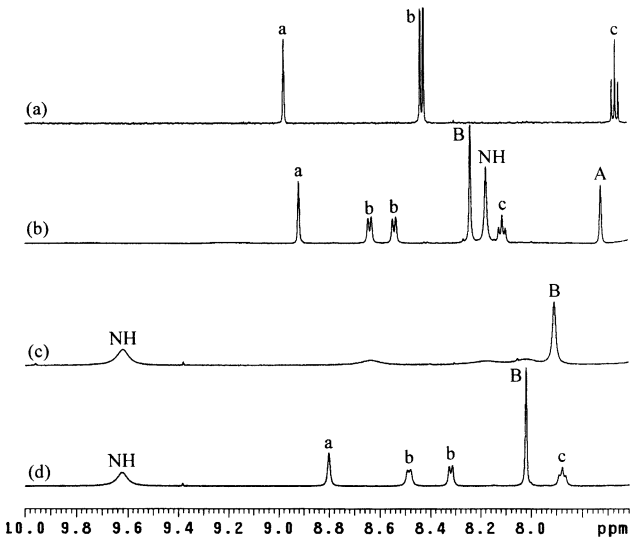


Fig. 1 Partial ^{1}H NMR spectra (600 MHz, 295 K) of (a) axle **2** in $CDCl_3$, (b) rotaxane **3** in $CDCl_3$, (c) rotaxane **3** in DMSO-d_6 and (d) rotaxane **3** and KPF_6 (5 equiv.) in DMSO-d_6.

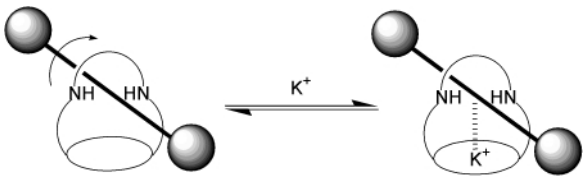
DOI: 10.1039/b007329f

through-space with the wheel NH residues and proton H_A, there are also cross-peaks between axle protons H_b and H_c and the wheel's benzocrown signals.

The ^{1}H NMR spectrum of **3** in DMSO-d_6 shows broad signals for the axle protons at room temperature [Fig. 1(c)], but they become resolved upon warming. Thus, in DMSO the rotaxane populates multiple axle/wheel orientations.‡ The NMR signals also sharpen upon addition of five mol equivalents of KPF_6 at room temperature [Fig. 1(d)]. There are two possible explanations for this observation: either the added K^+ increases the rate of exchange between different rotaxane co-conformations, or the K^+ freezes out a single co-conformation (Scheme 2).[14] Evidence for the latter explanation is gained from a ROESY spectrum which is consistent with a predominant co-conformation that is different to the one in $CDCl_3$. For example, the axle proton H_a now interacts with the wheel's benzocrown signals whereas the axle proton H_c does not.

Our results suggest that cation-binding macrobicyclic wheels such as **1** can be incorporated into a range of mechanically interlocked structures, and that these compounds are likely to display cation-dependent dynamic behaviour. This is a step towards the eventual development of cation-switchable molecular machines.[9] We gratefully acknowledge financial support from the US National Science Foundation and the University of Notre Dame.



Scheme 2 Binding of K^+ freezes out a single rotaxane co-conformation.

Notes and references

† The anion-templated esterification reactions reported by Vögtle and coworkers require non-polar solvents and a small amount of crown ether to act as a phase-transfer catalyst.[12] In our case, rotaxane formation with salt-binding bicycle **1** is achieved using preformed phenolate salt in a range of organic solvents such as chloroform, THF or even THF–DMF. The reaction fails to yield **3** if the caesium or tetrabutylammonium salt of 4-tritylphenolate is used instead of the potassium salt, which is tentative evidence in favor of **4** as a reactive intermediate.

‡ We have not yet fully characterized the rotaxane's dynamic behaviour. The two most likely motions are pirouetting and shuttling.

This short review focuses on recent advances in controlled polymerization and macromolecular architectonics by means of a variety of organized media with constrained geometries.

Introduction

In nature, macromolecules are essential materials for the diversity of life. Plants synthesize cellulose from sugars to support their body, and of course, proteins, polymers of amino acids, exist universally as primary materials for structuring, molecular recognition, electron and energy transfers, catalysis, and so forth. In biological systems, short- and long-range interactions are operative to allow multi-level ordering of macromolecules, which is essential for biological events. Formation of macromolecules in biological systems occurs also in such constrained, organized media, resulting in rigorous control of primary and even higher-ordered structures. On the other hand, chemical synthesis of macromolecules, which is usually conducted in homogeneous, non-constrained media, simply follows statistics of numerous elementary reaction steps, leading to the formation of macromolecules with poorly controlled architectures. In this respect, utilization of constrained media for artificial macromolecular synthesis is an interesting subject, which possibly allows spatial control of the primary structures of polymers and even their two- and three-dimensional multi-level structuring.

This short review focuses on recent advances in controlled polymerization and macromolecular architectonics by means of a variety of organized media with constrained geometries.

Overview

The present article describes some historical background and recent studies on controlled polymerizations in constrained media such as (1) micelles, (2) lipid bilayers, (3) liquid crystals, (4) organic crystals, (5) inclusion complexes, (6) microporous zeolites, and (7) mesoporous materials (Fig. 1), which are arranged in the order of increasing the rigidity of the media (Fig. 2).[1]

For the polymerization with constrained media, there are principally two approaches. One is to conduct polymerization of ordinary monomers in confined spaces of the media, while the other is to polymerize monomers which themselves are organized or co-organized to form constrained media. Studies on the polymerization in inclusion complexes, microporous zeolites, and mesoporous materials include examples only from the former approach. On the other hand, although both approaches are possible in the polymerization with micelles, lipid bilayers, liquid crystals, and organic crystals, this article focuses mostly on recent examples from the latter approach. The review article also focuses on several attempts to stabilize such organized media by polymerization, in order to fabricate well defined two- and three-dimensional macromolecular objects and hybridized materials.

Polymerization in micelles

Amphiphilic molecules having both hydrophobic long alkyl chains and hydrophilic groups are known to form micelles in aqueous media, where the alkyl chains are aggregated to form the core, while the hydrophilic head groups are exposed to water on the exterior surface to minimize the interfacial energy. In general, micelles are spherically shaped with a diameter of 3–4 nm, while under certain conditions rod-like micelles are formed, which have a cylindrical shape with a diameter of the cross section similar to the above. As for the polymerization of surfactant monomers, free radical polymerization has mostly been studied, since it is tolerant to water. In the polymerization in micelles, the chain growth is often affected by the structure and properties of the micelle. Furthermore, micelles are not static but dynamic. Therefore, a rapid exchange of the surfactant monomers between the micellar phase and the aqueous phase takes place during the polymerization (Fig. 3). The average time taken for surfactant molecules to leave a micelle is in the range 10^{-5}–10^{-9} s, which is much shorter than that for the growing radical to propagate (10^{-2}–10^{-6} s).[2–4] Hence, micelles are considered to be more or less soft media for polymerization.

† Former name: Keisuke Kageyama.

Takuzo Aida, born 3rd May 1956 in Japan, received his BSc degree in Physical Chemistry from Yokohama National University in 1979, and his MSc and Ph.D degrees in Macromolecular Chemistry from the University of Tokyo in 1981 and 1984, respectively, on Precision Macromolecular Synthesis with Metalloporphyrins. In 1984, he began an academic career at the University of Tokyo, where he has been Professor of Chemistry since 1996. He received the CSJ Award for Young Chemists in 1988, the SPSJ Award in 1993, and more recently the Wiley Polymer Science Award and IBM Science Award in 1999, and Nagoya Medal Seminar Silver Medal in 2000. His research interests include (1) synthesis of controlled macromolecular and supramolecular architectures, (2) photo- and supra-molecular chemistries of dendritic macromolecules, (3) mesoscopic materials sciences, and (4) bio-related molecular recognition and catalyses. In 1996, he was selected as a researcher of JST PRESTO Project 'Fields and Reactions'. In 2000, he held an appointment as the leader of JST ERATO Project on 'Nanospace'

Keisuke Tajima, born 23rd July 1974 in Japan, received his BSc and MSc degrees in 1996 and 1998, respectively, from the University of Tokyo, where he is currently a Ph.D student, focusing on utilization of mesoporous materials for controlled macromolecular synthesis. In 1999, he was selected for a JSPS Young Scientist Fellowship, and received the Best Presentation Award from CSJ in 1999.

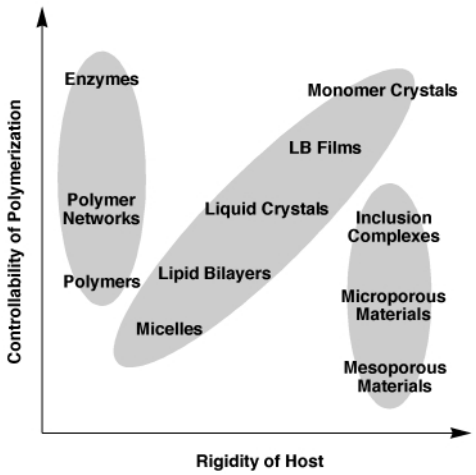

Fig. 2 Rough relationships between host rigidity and controllability of polymerization.

A typical phenomenon in free radical polymerization of surfactant monomers is that the propagation reaction above critical micelle concentration (c.m.c.) can be accelerated by 'condensation effect of monomer'. Examples include polymerization of anionic,[5] cationic,[6] and nonionic[7] surfactant monomers. In some cases, surfactant monomers in micelles spontaneously undergo radical polymerization without externally added initiators.[8,9] For example, the polymerization of sodium dodecyl 2-hydroxy-3-methacryloyloxypropyl phosphate **1** in

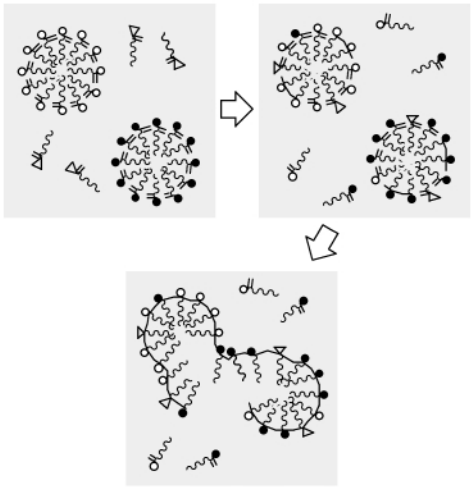

Fig. 3 Dynamical features of polymerization in micelles.

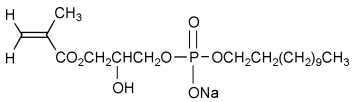
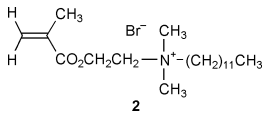
water at a concentration above the c.m.c (*ca.* 10^{-3} mol L^{-1}) takes place even at room temperature (35 °C) without initiator, to attain 100% monomer conversion.[8] In contrast, in methanol where **1** does not aggregate to form micelles, no polymerization



1

occurs unless radical initiators are added. The spontaneous polymerization may also be accounted for by 'condensation effect of monomer'. That is, the methacryloyl group of **1** is condensed at the core of the micelle, where the local monomer concentration must be as high as that in bulk.

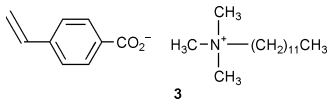
Control of molecular weight of polymer by the size of micelle is a challenging subject. However, owing to the dynamic characteristics of micelles, monomer reactivity, rather than micelle size, is the predominant factor for determining the molecular weight. On the other hand, the synthesis of stereoregular polymers in micelles is also an interesting subject, considering possible orientations of polymerizable groups in micelles. However, successful examples are only very limited.[10,11] For example, Dais and coworkers have reported that the polymerization of dodecyl-2-methacryloyloxyethyldimethylammonium bromide **2** initiated by γ-rays at a monomer



2

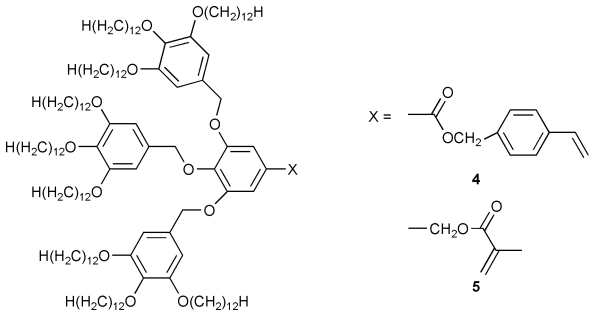
concentration above the c.m.c. leads to a polymer consisting exclusively of syndiotactic sequences at 25 °C.[11] In contrast, when a radical initiator such as 2,2′-azobisisobutyronitrile (AIBN) is used in place of γ-rays for initiating the polymerization, the tacticity of the resulting polymer at 50 °C is not directed but almost comparable to that of a polymer formed under homogeneous conditions.[10]

Polymerized micelles with an enhanced physical stability can be formed by free radical polymerization of surfactant monomers but only under very restrictive conditions owing to dynamic characteristics of micelles. For example, a rod-like micelle consisting of cetyltrimethylammonium 4-vinylbenzoate **3** is stabilized by radical polymerization of the vinylic group of the counter anion.[12] The resulting polymer micelle, as observed by small-angle neutron scattering, is likely to retain its original rod-like architecture, which shows an enhanced thermal stability and no longer dissociates upon dilution.



3

Dendrimers can also provide constrained media for polymerization. Percec *et al.* have recently reported an interesting phenomenon in free radical polymerization of self-assembled dendritic monomers. Dendritic monomers **4** and **5** are self-



organized at a concentration above 0.20 mol L^{-1} to form spherical micellar aggregates in benzene.[13] In the interior of the aggregate, the polymerizable groups are condensed, so that the polymerization by a free radical initiator is considerably accelerated. As the polymerization proceeds, the interior of the aggregate becomes more constrained and thus protected from invasion of further initiator molecules. Consequently, the polymerization takes place in a 'living' fashion, to give a polymer with a narrow molecular weight distribution (MWD). Of further interest, the shape of the resulting macromolecule depends on the degree of polymerization (D_p) (Fig. 4). When D_p

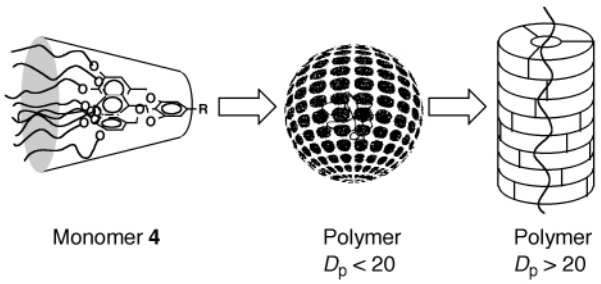


Fig. 4 Illustration for shape transition in free radical polymerization of self-organized dendritic monomers **4** and **5**.

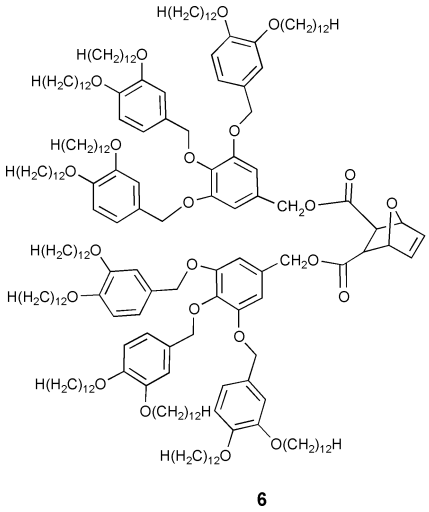
is lower than 20, the polymer remains spherical. On the other hand, when D_p exceeds 20, the polymer becomes cylindrical, as directly observed by atomic force microscopy (AFM). As an extension of the present study, the living ring-opening metathesis polymerization of dendritic monomers having at the focal point a 7-oxanorbornene unit **6** has been reported.[14] Interestingly, the rate constant of propagation is increased discontinuously at a certain monomer conversion where D_p exceeds a critical value for the shape transition from a densely packed, spherical architecture to a more accessible, cylindrical one (Fig. 5).

Polymerization in lipid bilayers

Certain amphiphilic molecules such as lipids are known to form vesicles, *i.e.* liposome-like bilayer assemblies, which have been actively studied as synthetic analogues of biological membranes. In vesicles, the hydrophobic alkyl chains of lipids form two-dimensional (2-D) aggregates, while the hydrophilic head groups form ionic surfaces to contact water. Vesicles are larger



6

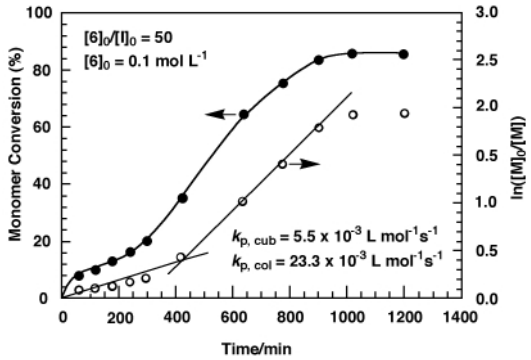


Fig. 5 Self-acceleration characteristics in ring-opening metathesis polymerization of a dendritic monomer **6**; $k_{p,\,cub}$, $k_{p,\,col}$: rate constants of propagation in cubic and columnar phases, respectively.

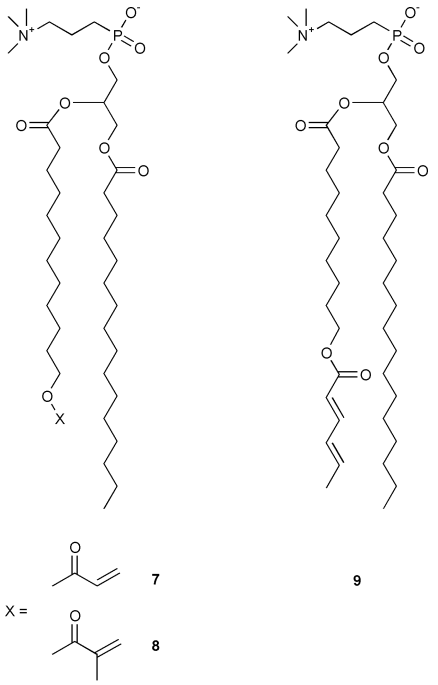
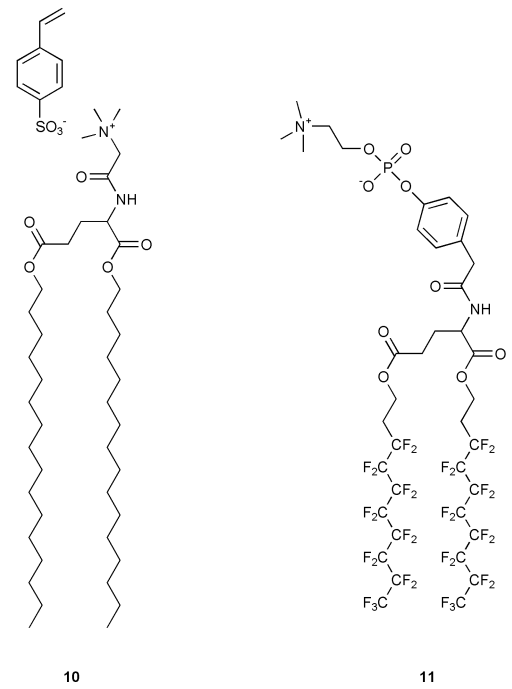
than micelles and have a much smaller surface curvature. Although a lateral diffusion of lipid molecules within a layer can occur, exchange of the lipid molecules among vesicles is slow. At a given temperature (T_m), vesicles show a main phase transition, which is attributed to a conformational change of the alkyl chains. At temperatures below T_m, the lipid molecules are in a solid-like state with a low mobility, where the alkyl chains adopt a *trans* conformation. On the other hand, at temperatures above T_m, they are in a liquid crystalline state with greater diffusibility, where the alkyl chains adopt a *gauche* conformation.[15] Since the pioneering works by Ringsdorf *et al.* on the formation of polymerized vesicles,[16] extensive studies have been made on free radical and photo-initiated polymerizations of synthetic bilayers.[17] In contrast to micelles, vesicles are stabilized easily through polymerization to give macromolecular containers which can be used for a variety of applications such as drug delivery.

Free radical polymerization of lipid monomers in bilayer membranes shows significantly different kinetics from those in the bulk phase.[18–20] For example, in the polymerization of a vesicle consisting of a phosphatidylcholine derivative having an acryloyl (**7**), methacryloyl (**8**), or sorbyl group (**9**) at the hydrophobic chain end, the degree of polymerization (D_p) is proportional to $[M]^2$ and $[I]^{-1}$ at a high monomer conversion ([M] and [I] are concentrations of monomer and initiator, respectively). In contrast, in bulk under otherwise identical conditions to the above, D_p is proportional to [M] and $[I]^{-0.5}$. These contrasting trends indicate that the polymerization of the lipid monomers in the bilayer state is terminated mostly by recombination of the growing polymer radical with a fragment radical of the initiator, rather than self-recombination of the





growing polymer radicals.[21] This is likely due to a reduced mobility of long polymer chains in bilayer media.

Phase transitions of bilayer membranes also affect polymerization kinetics. For example, in free radical polymerization of lipid monomer **9**, the activation free energy E_a and frequency factor A, obtained in a temperature range below the phase transition temperature T_m, are 10 kcal mol^{-1} and 10^7, respectively (Fig. 6).[22] On the other hand, at temperatures

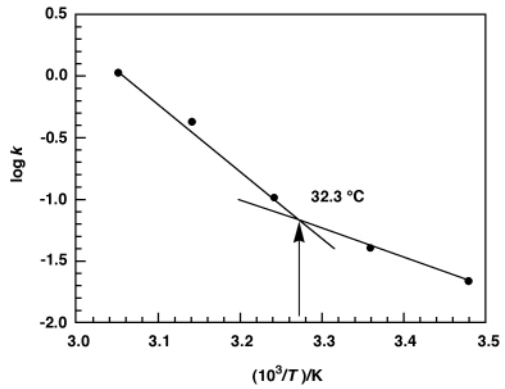


Fig. 6 Effect of phase transition on propagation rate constant in free radical polymerization in a bilayer membrane of a lipid monomer **9**.

higher than T_m, they are 24 kcal mol^{-1} and 10^{16}, respectively. Such discontinuous changes in kinetic parameters upon phase transition indicate a large effect of the lateral diffusibility of **9** on the polymerization kinetics.

Control of molecular weight of the polymer in bilayer membranes is also an interesting subject, and numerous attempts have been made by, *e.g.* changing monomer/initiator mole ratio, phase separation, and addition of chain transfer agents.[19,23] For example, a mixture of a hydrocarbon lipid monomer **10** and a non-polymerizable fluorocarbon lipid **11** forms a phase-separated bilayer membrane (Fig. 7), since fluorocarbons are poorly miscible with hydrocarbons.[23] In this phase-separated system, the molecular weight of the resulting polymer becomes lower as the content of **10** in the membrane (≈ size of the monomer domain) is decreased.

As bilayer membranes are not stiff enough to fix the orientation of polymerizable groups for steric control, only

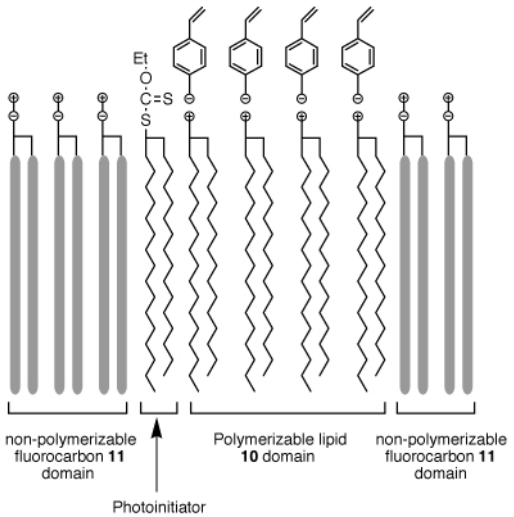

Fig. 7 Illustration for photoinduced polymerization in a phase-separated bilayer membrane of a mixture of a lipid monomer **10** and a non-polymerizable fluorocarbon lipid **11**.

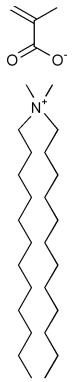
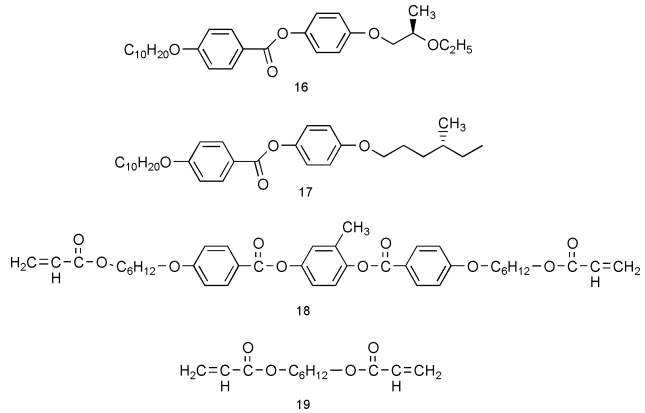
limited examples of stereospecific polymerization in bilayer media have been reported. An old but interesting example is the polymerization of a vesicle consisting of dioctadecyldimethylammonium methacrylate **12**.[24] Upon irradiation of the vesicle, the methacrylate anion on the surface of the vesicle is polymerized to give a highly syndiotactic poly(methacrylate) anion. In contrast, under homogeneous conditions in ethanol, no polymerization occurs under otherwise identical conditions.

Vesicles can be used as templates for the synthesis of topologically unique polymers.[16] Recent examples include selective polymerization of a heterobifunctional lipid monomer **13** containing diene and dienoyl groups at the hydrophobic and hydrophilic termini of its alkyl chain, respectively.[25] O'Brien and coworkers have reported that photoirradiation of vesicles of **13** results in the polymerization of the dienoyl group exclusively, while radical initiation with AIBN gives rise to the selective polymerization of the diene group. Of interest, a simultaneous or a sequential polymerization of both the dienoyl and diene groups of **13** in the vesicular state results in the formation of a novel ladder polymer **14** and not a 2-D cross-



12



16 17 18 19

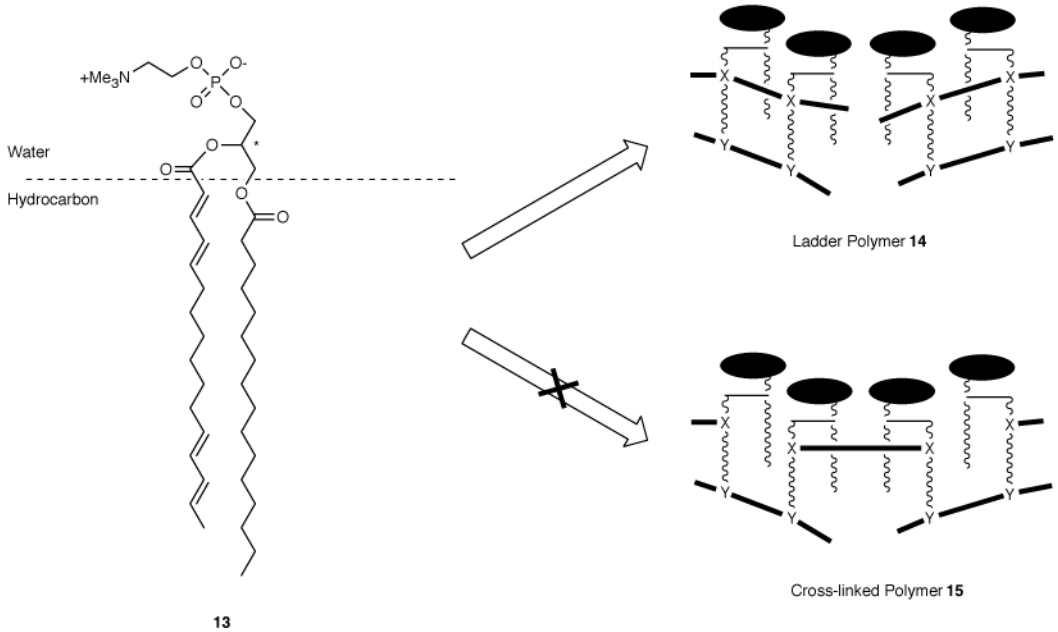
linked network **15** (Fig. 8). Addition of a surfactant molecule to polymer **14** in water results in destruction of its vesicular assembly, as observed by light scattering, whereas polymer **15** with a cross-linked architecture is robust under similar conditions. These contrasting trends suggest that polymer **14** is not cross-linked but a ladder.

Polymerization in liquid crystals

Liquid crystals have been utilized for optical materials such as LCDs. Depending on the manner of molecular orientation, several different LC phases such as nematic, smectic, and cholesteric phases are formed. LC media are more constrained than micellar and even bilayer media, and therefore attractive for control of polymerization.

Molecular orientation of monomers considerably affects the polymerization kinetics in LC media. A mixture of **16** and **17** forms a smectic C* (SC*) LC phase at room temperature, which becomes isotropic when heated to 70 °C. Bowman and coworkers have found that free radical polymerization of mesogenic monomer **18** in the SC* LC phase at 25 °C, as observed by differential scanning calorimetry (DSC), proceeds with much higher propagation and termination rates than in the isotropic phase at 70 °C.[26] In contrast, when non-mesogenic monomer **19** is polymerized in the SC* phase (35 °C), the propagation rate is not much different from that under isotropic conditions, but the termination is considerably slower. According to polarized IR spectroscopy, mesogenic and non-mesogenic monomers **18** and **19** are oriented normal and parallel to the smectic layer of the LC phase, respectively. Since addition of **18** to the LC phase does not affect the *d* value, mesogenic **18** most likely exists in the smectic layer (Fig. 9a). In contrast, non-mesogenic monomer **19** is possibly intercalated between the smectic layers, as the *d*-value of the LC phase becomes larger upon addition of **19** (Fig. 9b). This work provides a clear demonstration that the polymerization kinetics depend considerably upon spatial segregation and orientation of monomers in LC media.

In the polymerization in LC media, structural characteristics of the LC phase may give rise to unique organized structures of produced polymers. Recently, Akagi and Shirakawa *et al.* have reported an interesting observation that the polymerization of acetylene in a chiral LC phase leads to helical fibers of polyacetylene.[27] An optically active binaphthol derivative **20** having mesogenic units combined with a 1 : 1 mixture of **21** and **22** forms a chiral nematic LC phase, where the polymerization of acetylene with a homogeneous Ziegler–Natta catalyst ($Ti(OBu^n)_4/Et_3Al$) proceeds to give single-handed helical fibers of polyacetylene, as observed by scanning electron microscopy (SEM). The helical sense of the fibers can be controlled by the absolute configuration of the LC solvent. For example, in the nematic phase of the (*R*)-binaphthol derivative **20**, helical fibers with an anticlockwise sense result (Fig. 10). Circular dichroism spectroscopy of the fibers also shows a clear Cotton effect in the region of a π–π* transition of the conjugated backbone. In this case, the twisted molecular packing of **20** in the chiral nematic



13

Fig. 8 Illustration for different modes of polymerization in a bilayer membrane of a lipid monomer **13**.

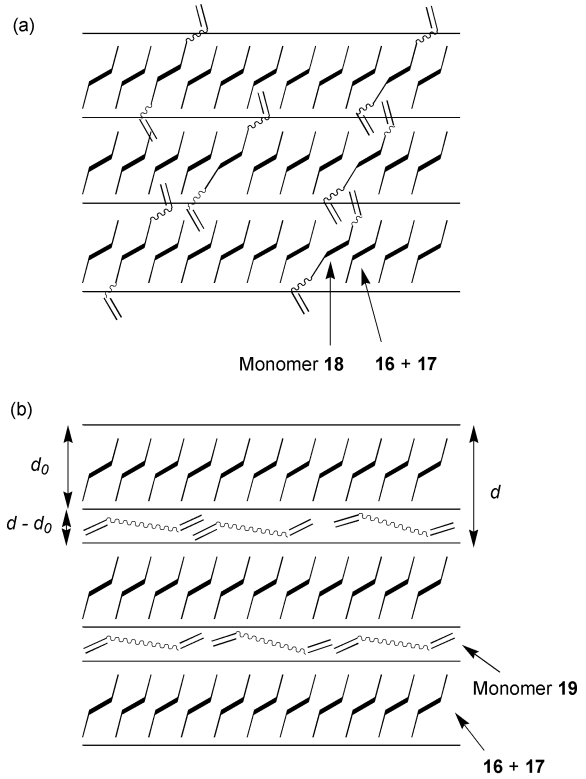


Fig. 9 Proposed models for photoinduced polymerizations of mesogenic and non-mesogenic monomers (**18**, **19**) in a smectic C* liquid crystal.

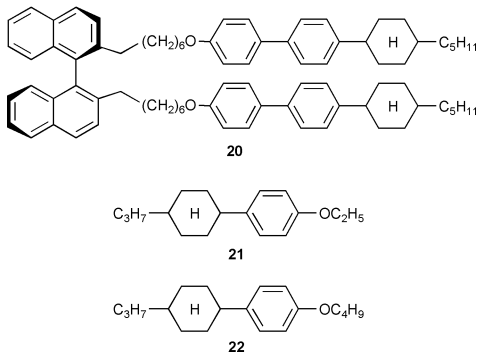

phase is likely to serve as a template for the formation of helical polyacetylene fibers.

Much attention has also been paid to the polymerization of LC monomers for obtaining polymeric materials with predictable structures from their LC phases. Stupp *et al.* have reported the synthesis of a conceptually new two-dimensional (2-D) polymer by the polymerization of a mesogenic monomer in a smectic LC phase (Fig. 11).[28] Monomer **23** has an acrylic group at a terminus, a nitrile group in the middle, and a mesogenic group at the other terminus. **23** is organized to form a smectic LC phase **24** (non-polymerized form of **25**) by a π–π interaction among the mesogenic groups and a homochiral interaction among the chiral nitrile groups. The acrylic and nitrile groups in the LC state are polymerized by heating, to give a cross-linked 2-D network structure **25**, which still shows certain characteristics of the original LC phase. Although the polymer is soluble in chloroform, it most likely retains a sheet-like structure originating from the smectic phase even in solution. Analysis by

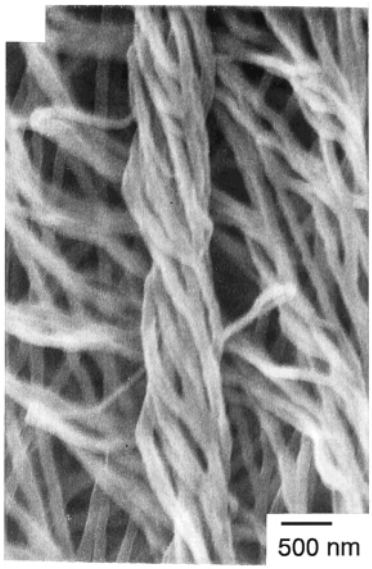

Fig. 10 A SEM micrograph of helical polyacetylene fibers formed with a homogeneous Ziegler–Natta catalyst in a chiral nematic phase of a mesogenic (*R*)-binaphthol derivative **20**. Fig. 11 Illustration for thermal-induced polymerization in a smectic liquid crystalline phase of a mesogenic monomer **23**.

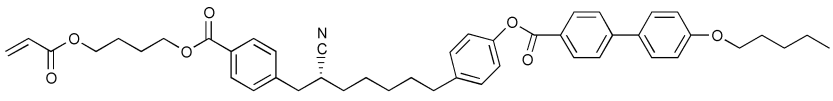
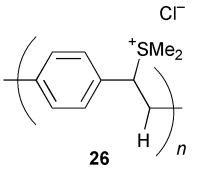
gel permeation chromatography (GPC) indicates that the polymer has an ultrahigh molecular weight (17 000 000) with a broad molecular weight distribution, suggesting that the polymer is a nanometer-sized 2-D object. According to transmission electron microscopy (TEM), this polymer can be spread over a glycerin surface upon casting from its dilute



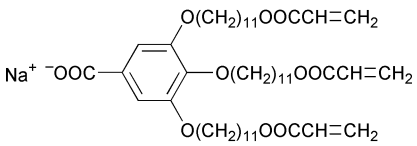
23

chloroform solution, to give a single-layered polymeric film with a thickness of < 100 Å. Along the line of this study, a triblock molecule having a relatively large coiled head group with crosslinkable oligobutadiene units anchored by a rigid mesogenic tail has been synthesized. Owing to the relatively large head group, this rod-coil molecule self-assembles to form a 'mushroom-shaped' cluster of limited size rather than an infinite 2-D sheet as in the case of **23**. Annealing of this molecule in a LC phase at 250 °C resulted in crosslinking of the oligobutadiene domains to form a soluble polymeric nanoscale object with a molecular weight of *ca.* 70 000 (M_w/M_n = 1.11). Although extended annealing promotes the crosslinking and enhances the yield, no substantial increase in molecular weight results. Therefore, the crosslinking occurs within individual clusters to fix the mushroom shape.[29] This is an interesting 2-D approach to the template synthesis of nanoscale polymeric objects.

Not only thermotropic LCs but also lyotropic LCs can be stabilized by polymerization. Gin and co-workers have reported an interesting example of the stabilization of a lyotropic LC phase by polymerization.[30] When a water-soluble polymeric precursor of poly(*p*-phenylenevinylene) (PPV) **26** is mixed with



26



27

amphiphilic acrylate monomer **27** in aqueous media, an inverse hexagonal lyotropic LC phase is formed, in which **26** is likely to be threaded into the hexagonal column and oriented parallel to its *c*-axis (Fig. 12). Subsequently, the acrylate group of **27** is

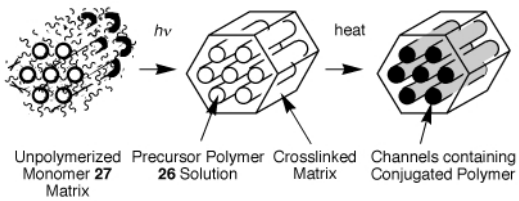


Fig. 12 Illustration for photoinduced polymerization of an amphiphilic acrylate monomer **27** in a lyotropic liquid crystalline phase and subsequent thermal transformation of the precursor polymer **26** into poly(phenylenevinylene).

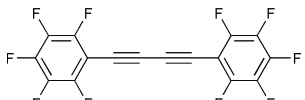
polymerized by photo-irradiation, and the resulting mixture is heated to promote the removal of dimethyl sulfide and HCl to convert **26** to fluorescing PPV. Interestingly, the fluorescence of PPV from the resulting hybrid material is much stronger than that of bulk PPV, suggesting that the hybridized PPV chains are spatially isolated from one another and protected from self-quenching of the excited state. The present self-assembling/polymerization approach is unique, and can be applied not only to the design of anisotropic optical materials but also to the fabrication of new silica/polymer hybrids[31] and polymer-supported transition metal catalysts.[32]

Polymerization in organic crystals

In the crystalline state, the arrangement and orientation of molecules are strictly determined by crystal packing. Topochemical polymerization, in which the polymerization of a crystallized monomer occurs without changing the symmetry of the crystal lattice, has been well known since the 1960s. Representative examples include topochemical polymerization of diacetylenic monomers in the crystalline state, which occurs upon exposure to UV light or γ-rays.[33] [2 + 2] Photopolymerization of diolefinic monomers in the crystalline state has also been studied extensively.[34] In general, topochemical polymerization is highly sensitive to the crystal structure of monomers. If the crystal packing of monomers is not suited for the active growing end to propagate, no polymerization occurs. For example, for diacetylenic monomers to polymerize topochemically, monomer molecules in the crystalline state are required to adopt a tilted molecular stacking with a distance between the diacetylene centers of *ca.* 4.7–5.2 Å and an angle between the molecular stacking axes of *ca.* 45°. On the other hand, for topochemical polymerization of diolefinic monomers, a center-to-center distance of 3.5–4.2 Å between the polymerizable units is required.

Although crystal engineering of organic molecules has been greatly advanced in recent years, 'crystal design' for topochemical polymerization has not been established yet. A general approach to the 'design' of monomer crystals for topochemical polymerization makes use of some directional forces such as hydrogen-bonding and π–π interactions for suitable alignment of monomer molecules in the crystalline state. For example, Grubbs and coworkers have attempted to prepare polymerizable crystals of diacetylene[35] and diolefin[36] derivatives by using π-stacking interactions. To achieve a suitable orientation of the polymerizable groups, monomers having phenyl and perfluorophenyl groups in proximity to the polymerizable units are co-crystallized. X-Ray crystallography of the co-crystal of **28** and **29** shows a face-to-face stacking of the monomers, where

28



29

the distance between the polymerizable units is short enough for the topochemical polymerization to occur (Fig. 13). In fact, the

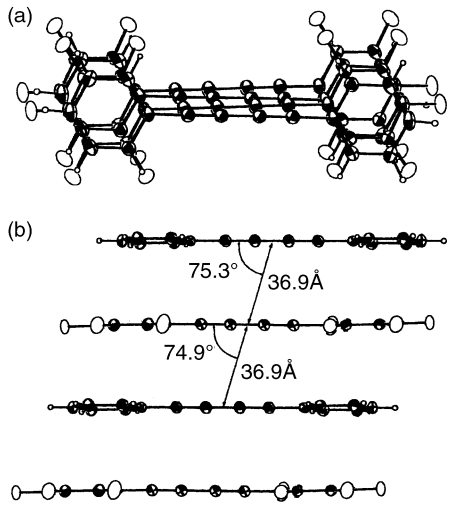


Fig. 13 Crystal packing views of a co-crystal of phenyl- and perfluorophenyl-substituted diacetylenic monomers (**28**, **29**). Reprinted in part with permission from: *Angew. Chem., Int. Ed. Engl.*, 1997, **36**, 248 (© 1997, WILEY-VCH Verlag GmbH).

co-crystals undergo topochemical polymerization upon irradiation with UV light, whereas no polymerization occurs when

unimolecular crystals of **28** and **29** are irradiated under the same conditions.

Stereochemical aspects of topochemical polymerization are also interesting. Single crystals of diethyl (*Z*,*Z*)-hexa-2,4-diene-1,6-dioate **30** have been reported to undergo photoinduced polymerization without change of crystal shape.[37–40] In contrast, methyl, butyl and isopropyl esters of (*Z*,*Z*)-hexa-2,4-diene-1,6-dioic acid in the crystalline state are not polymerized under the same conditions. Interestingly, the topochemical polymerization of **30** is highly stereospecific. When **30** is polymerized by a radical initiator in bulk or solution, a polymer consisting of a mixture of *trans*-1,4- (four possible stereo sequences), *cis*-1,4-, and 1,2-sequences is formed (Fig. 14). On

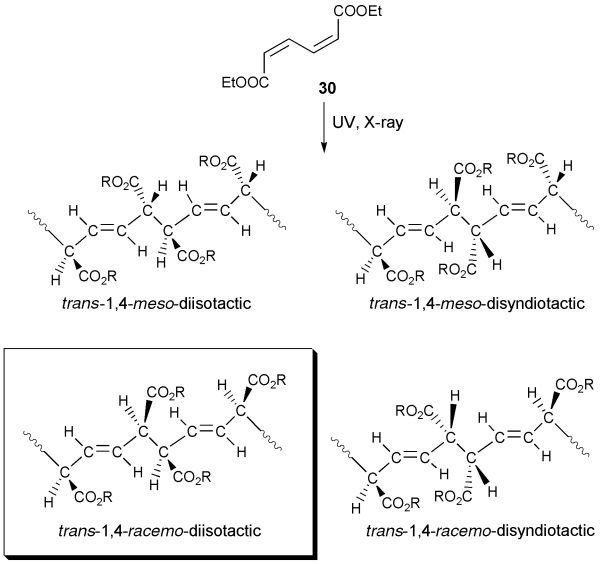

Fig. 14 Schematic representation for stereospecific polymerization in a crystal of diethyl (*Z*,*Z*)-hexa-2,4-dienedioate **30** by UV light.

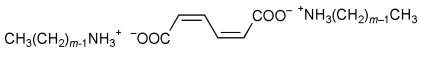
the other hand, in the crystalline state, an ultrahigh molecular weight polymer consisting exclusively of a *trans*-1,4-*meso*-diisotactic sequence is formed. This perfect steric regulation demonstrates a large effect of crystal packing on the stereochemical course of the polymerization. As observed by X-ray crystallography, the polymer chains are completely oriented along the longer axis of the monomer crystal. Thus, if no structural defect exists in the monomer crystal, the molecular weight of the polymer may be controlled by the length of the longer crystal axis.[41] In relation to this study, Nakanishi and coworkers have reported a novel crystallization method for controlling the size of diacetylene crystals for topochemical polymerization for application to non-linear optics.[42,43]

More recently, topochemical polymerization of long-chain alkylammonium (*Z*,*Z*)-hexa-2,4-diene-1,6-dioates **31** has been



31

reported to produce layered polymer crystals.[44,45] During the polymerization, the alkylammonium group of **31** is intercalated between the crystalline layers of poly(muconic acid) (Fig. 15). The interlayer spacing *d* is increased linearly with the carbon number of the alkylamino group. The intercalated alkylammonium group can be removed from the polymer crystal by stirring in acidified methanol at room temperature, to leave a layered crystal of poly(muconic acid). Interestingly, when crystals thus obtained are exposed to alkylamine, re-intercalation of the amine into the crystalline layers occurs. Thus, this material can be considered as an organic clay, and may be useful for molecular recognition, separation and catalysis.

Although successful examples include only a narrow range of monomers, topochemical polymerization in the crystalline state has a high potential for controlling the locus of polymerization and polymer architectures.

Polymerization in inclusion complexes

It is well known that host molecules such as urea, thiourea, and perhydrotriphenylene are crystallized, in the presence of guest molecules, to form inclusion complexes. In many cases, inclusion complexes consist of one-dimensional columnar channels of crystalline host molecules, which are filled with guest molecules. If the included guest molecules are loosely packed, they can eventually be exchanged with other molecules of similar structures. When the guest molecules have polymer-

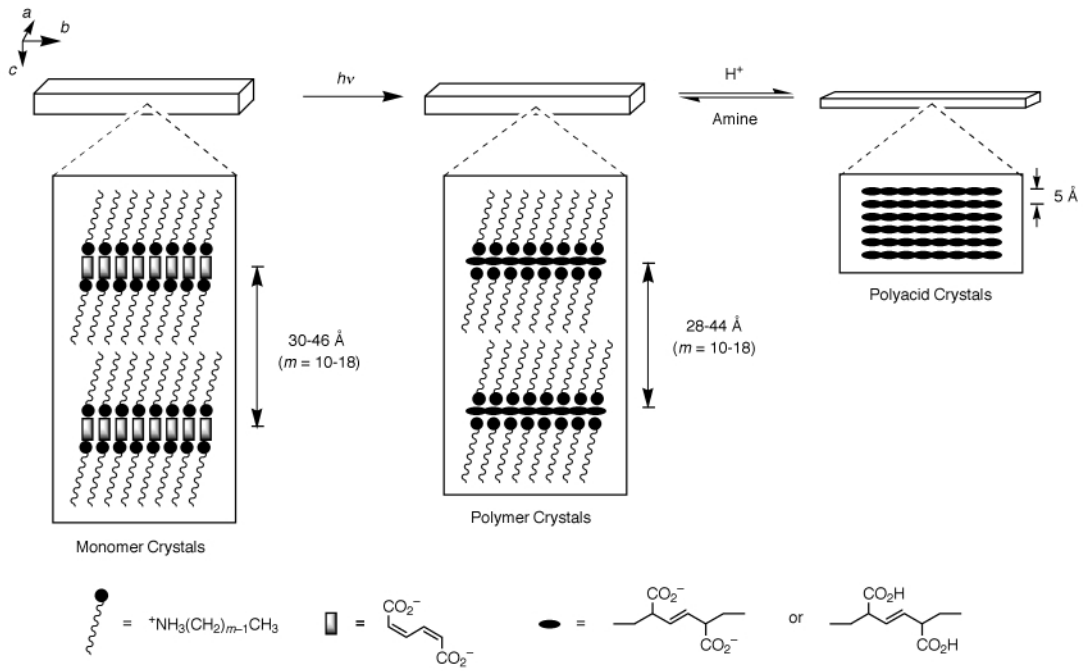


Fig. 15 Proposed models for topochemical polymerization in a crystal of a long-chain alkylammonium (*Z*,*Z*)-hexa-2,4-dienedioate **31** and subsequent transformation into a layered crystal of poly(muconic acid).

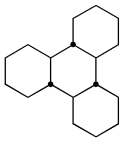
izable groups, one can polymerize these monomers in confined spaces of the crystalline channels. This is denoted 'inclusion polymerization'.

Historically, extensive studies on inclusion polymerization have been made in the 1960s–1980s. Farina and coworkers have reported the inclusion polymerization of various diene and triene monomers in the crystalline channels of perhydrotriphenylene **32** with an average diameter of *ca.* 5.5 Å.[46] For



32

example, when an inclusion compound of **32** with *trans*-penta-1,3-diene as the guest is irradiated with γ-rays, a highly isotactic polymer consisting exclusively of 1,4-*trans* sequences is formed, indicating a strong spatial demand of the crystalline channel for the chain growth. Asymmetric synthesis of poly(*trans*-penta-1,3-diene) is also possible by the polymerization of the same monomer in the crystalline channels of optically resolved perhydrotriphenylene. Takemoto and Miyata *et al.* have made systematic studies on inclusion polymerization with crystalline channels of cholic acid derivatives by taking advantage of their high ability to include a variety of monomers (Table 1).[47] As the result, the size of the channel has been found

Table 1 Space size effects on the radical polymerization in inclusion complexes

Cavity size of host	Motion of propagating radicals	Polymerization rate	Selectivity of reaction
Large	Unrestricted	Fast	Low

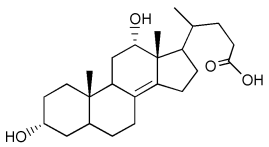
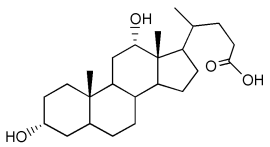
Small	Restricted	Slow	High

to affect kinetics and specificity of the polymerization. For example, *trans*-2,4-dimethylpenta-1,3-diene can be polymerized in the crystalline channels of apocholic acid **33** at ambient



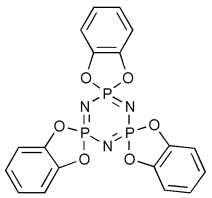
33



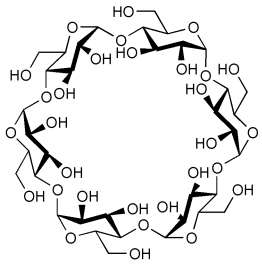
34

temperatures, but no polymerization occurs even at 100 °C in slightly smaller crystalline channels (4 × 6 Å) of deoxycholic acid **34**. According to electron paramagnetic resonance (EPR) spectroscopy, the propagating radicals are included tightly in the channel of **34**, while loosely held by the channel of **33**. Furthermore, when *trans*-penta-1,3-diene is polymerized within the channels of **34**, a polymer with a 99% 1,4-*trans* structure is formed, whereas the selectivity is lower by 10% when the slightly larger channel of **33** is utilized. Cyclophosphazene **35** also forms inclusion compounds with a channel diameter of 5 Å, which have been extensively studied by Allcock *et al.* for the polymerization of various vinyl monomers[48] and dienes.[49] For example, a γ-ray induced polymerization of methacrylonitrile included in the channel of **35** gives a highly isotactic polymer soluble in THF. This is in contrast with a γ-ray induced bulk polymerization of methacrylonitrile, which affords an insoluble, cross-linked polymeric mass.[48]

Recently, α,ω-amino acids and α-cyclodextrin **36** have been found to form inclusion complexes, where the cyclodextrin acts



35



36

as the host for the amino acids to form crystalline channels.[50] Upon heating, polycondensation of the included amino acids takes place to give polyamides in the solid state (Fig. 16).

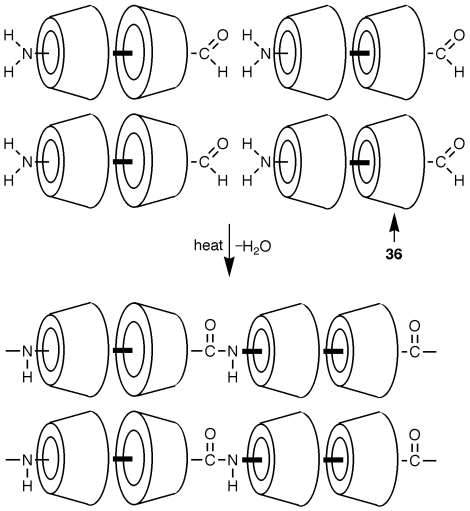


Fig. 16 A proposed scheme for solid state polycondensation of α,ω-amino acid in the presence of α-cyclodextrin **36** to form a polyrotaxane.

Interestingly, the polymerization mixtures are water-soluble, although the polyamides alone are insoluble in water owing to strong intermolecular hydrogen bonding interactions. This observation indicates a high coverage of the polyamide chains by α-cyclodextrin, *i.e.* formation of a polyrotaxane.

Polymerization in microporous zeolites

Microporous zeolites are porous inorganic crystalline materials with a pore diameter of 3–10 Å and possess ion exchangeable sites on the internal surface. Similarly to inclusion complexes, microporous materials can provide confined spaces for controlled polymerization. Historically, radical polymerization of polar vinyl monomers has most extensively been studied with microporous zeolites, by focusing attention on (1) possible elongation effects on the lifetime of growing radicals[51] and (2) possible steric effects on the chain growth step.[52]

Recently, microporous zeolites have been used as catalyst supports for the polymerization of olefins, in which, however, spatial effects of the microporous cavities are not very clear. For example, in the polymerization of ethylene with supported zirconocenes by microporous zeolites, coupled with methylalumoxane (MAO) as cocatalyst, the activity is not related to the internal surface area of the zeolite, but the external surface area and the content of aluminium in the silicate framework appear to be more important.[53]

In view of fabrication of organized hybrid materials, polymerization in microporous zeolites is attractive but somewhat limited, as their pores are too narrow to allow guest molecules to be packed continuously. However, synthesis of nanowires of conducting polymers such as poly(methylacetylenes),[54] polypyrroles[55] and polyanilines[56] has been reported. For example, when a pyrrole vapor is diffused into Cu^{II}-doped

zeolite channels, the polymerization occurs with a color change, to give a polypyrrole/zeolite hybridized material (Fig. 17), which however does not show any significant electronic conductivity.

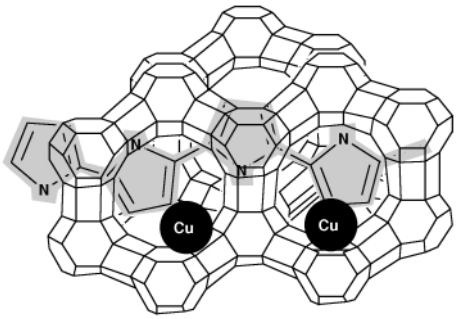

Fig. 17 A proposed model for Cu^{II}-catalyzed oxidative polymerization of pyrrole in zeolite-Y to form a conducting hybrid material.

In relation to microporous zeolites, inorganic materials with layered architectures have been synthesized, which are able to change the interlayer distance upon intercalation of guest molecules. Polymerization with such layered inorganic materials as the reaction media has also been investigated,[57] mainly for the synthesis of functional polymer/inorganic hybridized materials. For example, oxidation polymerization of aniline[58] and pyrrole derivatives[59] within the interlayer spaces gives electroactive composite materials (Fig. 18a). From a more

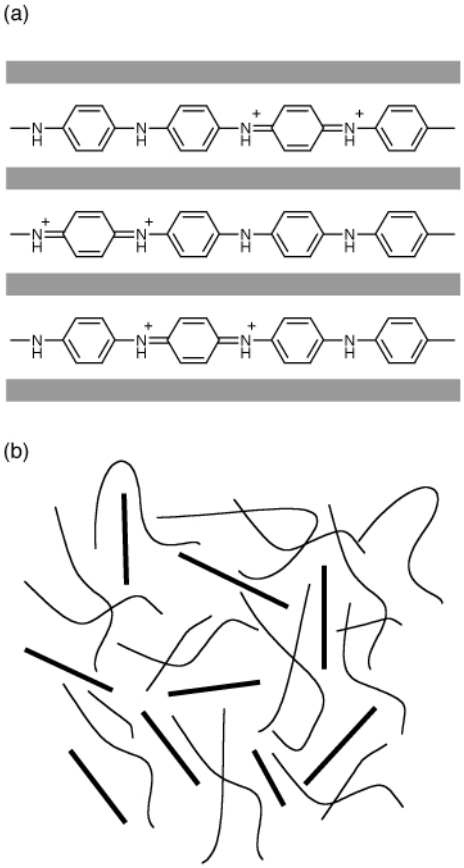

Fig. 18 Proposed structures of (a) an electroactive composite material of polyaniline with a layered inorganic material and (b) a composite material containing uniformly dispersed clay 2-D sheets in a polymer matrix.

practical point of view, certain clays with layered architectures have also been utilized for the ring-opening polymerization of heterocyclic monomers such as lactams,[60] lactones[61] and cyclic carbonates,[62] and coordination polymerization of olefins,[63] where the monomers intercalated between the 2-D inorganic sheets are polymerized to give nanocomposite materials. Because of a uniform dispersion of the clay 2-D sheets at the molecular level in polymer matrices, the hybrid materials exhibit excellent mechanical properties and unique gas barrier characteristics (Fig. 18b).

Polymerization in mesoporous materials

Since the first report on mesoporous silicate MCM-41 in 1992, a variety of mesoporous silicate materials have been developed.[64] These inorganic materials are prepared by using rod-like micelles as templates, and have an ordered hexagonal or cubic array of uniformly sized mesoscopic channels with a pore diameter variable from 15 to 100 Å. Mesoporous materials have an advantage over microporous zeolites for the inclusion of large molecules. A comprehensive review of the inclusion chemistry with mesoporous materials has been reported.[65] Although mesoscopic pores are large enough for the inclusion of ordinary polymers, the included polymer chains may retain their freedom of conformational change. Thus, mesoporous materials are more attractive than microporous materials not only in view of the control of polymerization locus but also for fabrication of polymeric materials.

Recently, several studies on macromolecular synthesis with mesoporous materials have been reported. For example, Aida and coworkers have utilized MCM-41 for the radical polymerization of methyl methacrylate (MMA) with benzoyl peroxide as initiator, and obtained a polymer (PMMA) with a much higher molecular weight than that formed in solution under otherwise identical conditions.[66] Electron paramagnetic resonance study (EPR) has shown the formation of long-lived propagating polymer radicals within the mesoscopic channels, where *ca.* 25% of the initial intensity of the EPR signal remains even after a month (Fig. 19). Furthermore, molecular weight of the

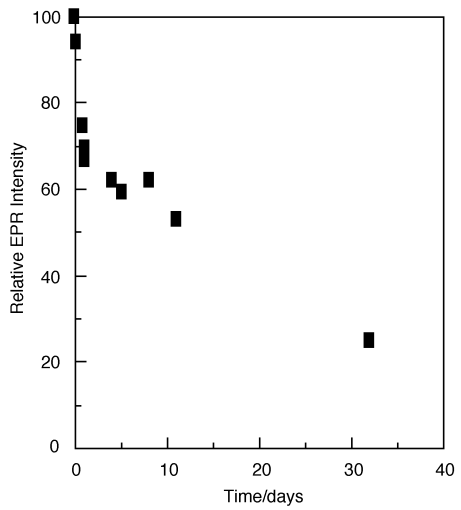

Fig. 19 An electron paramagnetic resonance (EPR) trace of free radical polymerization of methyl methacrylate (MMA) by 2,2′-azobisisobutyronitrile (AIBN) in mesoscopic channels of MCM-41.

polymer can be controlled over a wide range M_n = (1.3–3.0) × 10^5 (M_w/M_n = 2.5) by changing initial molar ratio of MMA to BPO (Fig. 20). On the other hand, the tacticity of the polymer is not particular but almost identical with that of PMMAs obtained by a free radical polymerization in solution.[67] Thus, the mesoscopic pores of MCM-41 are not small enough to affect the stereochemical course of the chain growth. Bein and coworkers have also investigated free radical polymerization of MMA with MCM-41, and reported that PMMA formed within the mesoscopic channels shows no glass transition probably because of a strong interaction between the polymer chain and the internal surface of the mesopore.[68]

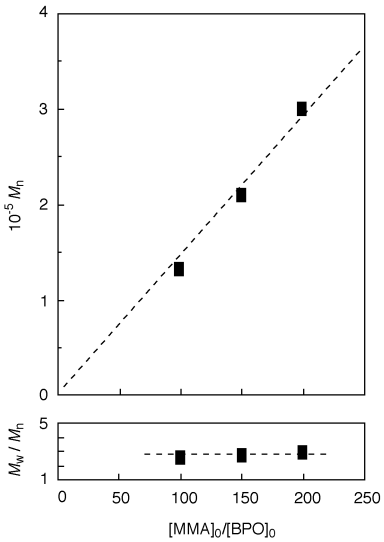

Fig. 20 Molecular weight control in free radical polymerization of methyl methacrylate (MMA) by benzoyl peroxide (BPO) in mesoscopic channels of MCM-41.

Chemical properties of the mesopore surface can be tuned by the introduction of aluminium, titanium, and some other transition metal ions to the silicate framework. For example, a highly Lewis acidic mesoporous silica (Al-MCM-41) can be prepared by doping aluminium in the silicate framework. Aida and coworkers have found that lactones are polymerized in a living manner in the presence of Al-MCM-41 and an alcohol at 50 °C, to give polyesters with narrow molecular weight distribution (MWD).[69] By changing the mole ratio monomer/alcohol, the molecular weight of the polymer can be controlled over a rather wide range. A sequential polymerization of two different lactone monomers with an Al-MCM-41/alcohol system gives the corresponding block copolymer with narrow MWD. Furthermore, Al-MCM-41 is easily separated from the polymerization mixture by filtration, and can be used again for the polymerization. NMR studies have indicated that the alcohol is incorporated into the polymer terminus at the initiation step of the polymerization. In contrast with the case using Al-MCM-41, no polymerization occurs in the presence of a pure silicate MCM-41 or modified MCM-41 with methylated silanol functionalities under otherwise identical conditions to the above. Furthermore, use of a microporous aluminosilicate zeolite-Y (pore diameter = 8 Å), in place of Al-MCM-41, results in no polymerization. These observations suggest that the large pore size as well as the Lewis acidic character of the surface is essential for the polymerization. The postulated mechanism of polymerization is shown in Fig. 21, in which the monomer is activated by a possible cooperation of Lewis acidic aluminium sites and Brønsted acidic silanol functionalities.

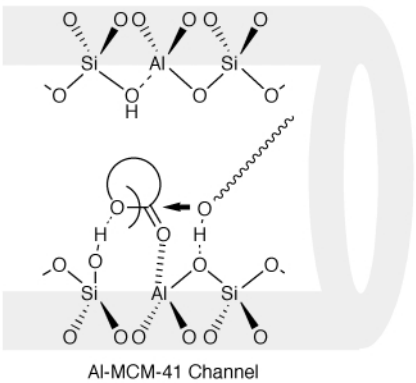

Fig. 21 A proposed mechanism for activation of lactone on the interior wall of Al-MCM-41 for ring-opening polymerization with alcohol.

Mesoporous silicates have been used as inorganic supports for metallocene catalysts for the polymerization of olefins.[70] However, only limited examples have been reported that indicate some spatial effects of mesoscopic pores on the polymerization. For example, co-oligomerization of ethylene and propylene with an MCM-41-supported zirconocene compound, in conjunction with methylalumoxane (MAO) as cocatalyst, has been investigated,[71] where the pore size has been claimed to affect the molecular weight of the resulting co-oligomer. When MCM-41 prepared with a C_{16} surfactant is used as the support, a co-oligomer with M_n of 1280 is formed. On the other hand, when the support is MCM-41 prepared with a shorter-chain C_{14} surfactant, a co-oligomer with M_n of 1730 is formed.

Recently, Aida and Kageyama *et al.* have found that a titanocene complex supported by a particular type of mesoporous silicate denoted mesoporous silica fiber (MSF, pore diameter = 27 Å),[72] in conjunction with MAO, produces crystalline nanofibers of ultrahigh molecular weight (M_n = 6 200 000) linear polyethylene.[73] The polyethylene is obtained as a cocoon-like white mass with a low bulk density. Scanning electron microscopy (SEM) shows that the fibers are 30–50 nm in diameter (Fig. 22), and the crystalline density is close to a

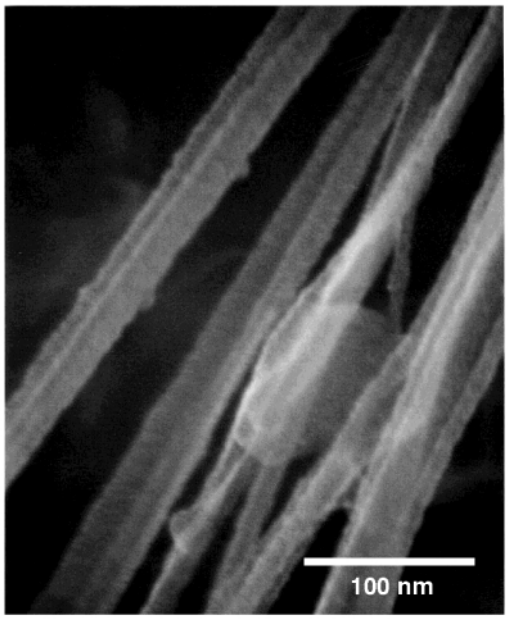

Fig. 22 A SEM micrograph of crystalline polyethylene fibers formed by polymerization with a supported titanocene by mesoporous silica fiber (MSF) in conjunction with methylalumoxane (MAO). Reprinted in part with permission from: *Science*, 1999, **285**, 2113 (Copyright © 1999, the American Association for the Advancement of Science).

theoretical upper limit for polyethylene. Unlike ordinary high-density polyethylenes consisting of folded-chain crystals, the polyethylene fibers thus obtained consist exclusively of extended chain crystals, according to small angle X-ray scattering (SAXS) and differential scanning calorimetry (DSC). For the formation of crystalline nanofibers of polyethylene, the 'extrusion polymerization' mechanism, which mimics biological formation of natural fibers such as crystalline cellulose fibers, has been postulated, where the polymer chains, formed at the activated titanocene sites within the individual mesopores, are extruded into the solvent phase and assembled to form extended-chain crystals (Fig. 23). Thus, the mesoscopic pore in this particular case serves as a template, which can suppress the kinetically favored chain folding process, since the pore diameter (27 Å) is almost one-order of magnitude smaller than the lamellar thickness (270 Å) of the folded-chain crystals of ordinary polyethylenes. Since most studies on precision polymerization have focused on the control of primary structures of polymers, the present finding, which enables control of a

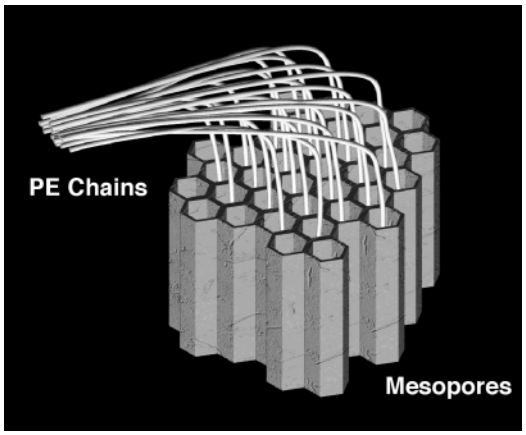

Fig. 23 A proposed mechanism for the formation of fibrous polyethylene with titanocene-mounted mesoporous silica fiber (MSF).

ternary structure, is unique and may have a high potential for the fabrication of novel polymer materials from specialty as well as commodity monomers. Along the line of this study, a novel hybridized thin film of polyethylene and silica (Fig. 24) has

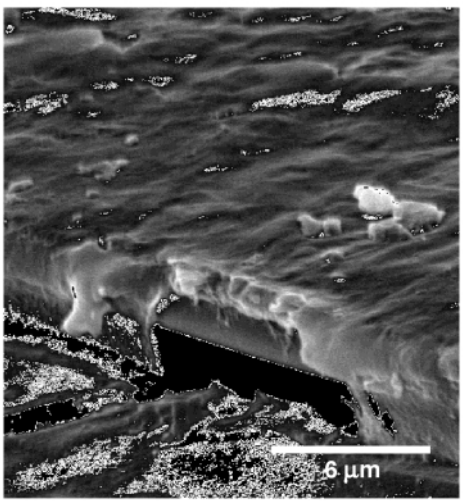

Fig. 24 A SEM micrograph of a polyethylene/silica/mica hybridized thin film formed by polymerization of ethylene on a titanocene-mounted mesoporous silica film in conjunction with methylalumoxane (MAO). been synthesized[74] by the polymerization of ethylene on a mesoporous silica film[75] doped with titanocene.

In relation to the above study, Mallouk and Ozin and coworkers have utilized MCM-41 as a mold for the fabrication of a fibrous poly(phenolformaldehyde) resin.[76] When an acid-catalyzed polyaddition/condensation of phenol and formaldehyde is carried out within the mesoscopic channels of MCM-41, and then the silicate framework is destroyed by HF, mesofibers of poly(phenolformaldehyde) with a diameter of *ca.* 20 Å and an aspect ratio of more than 10^3 is obtained (Fig. 25). In contrast, when the polymerization is conducted in the presence of non-porous silica Cab-O-Sil, only a non-fibrous, agglomerated polymeric mass results.

Since polymer chains included in individual mesoscopic pores are isolated from one another and oriented parallel to the pore axis, fabrication of photo-conducting materials with mesoporous silica has attracted attention. For example, Wu and Bein have reported the synthesis of a graphite-type conducting carbon wire by the polymerization of acrylonitrile within the mesoscopic channels of MCM-41 and its subsequent pyrolysis (Fig. 26).[77] The graphite/MCM-41 adduct, obtained by pyrolysis at 1000 °C, shows a notable microwave conductivity of

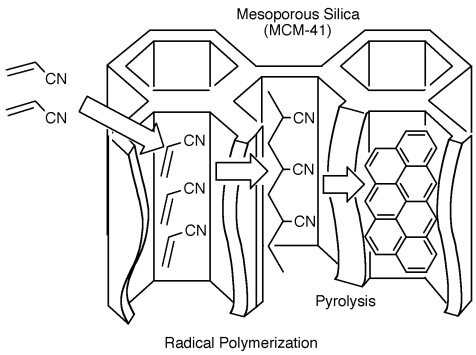

Fig. 26 Illustration for free radical polymerization of acrylonitrile within the mesoscopic channels of MCM-41 and subsequent pyrolysis to form a conducting carbon nanowire.

0.1 S cm^{-1}. A polyaniline wire encapsulated within the mesoscopic silicate channel has also been synthesized, which however shows only a low microwave conductivity (0.0014 S cm^{-1}).[78] Variation of the pore diameter of the mesoscopic channel would make it possible to tune the conducting properties of the hybridized material. Similarly, Ozin and coworkers have reported ring-opening polymerization of [1]silaferrocenophane **37**.[79] Compound **37** is incorporated into the hexagonal channels of MCM-41 by sublimation under vacuum, and then the adduct is heated at 140 °C, whereupon the polymerization occurs to give a poly(ferrocenylsilane)/MCM-41 hybrid (Fig. 27). When the hybrid is pyrolyzed at 900 °C under nitrogen, the included polymer is decomposed to leave iron nanoparticles with an average particle size of 20 ± 5 Å. The magnetic properties of the pyrolyzed product indicate that the iron nanoclusters in the interior are supermagnetic.

Concluding remarks

Template-assisted polymerization, *i.e.* polymerization of pre-organized monomers or in constrained media, has a long history, but is still growing even more rapidly. This is not only from a continuous interest in short- and long-range information transfers in the molecular world but also for a strong demand

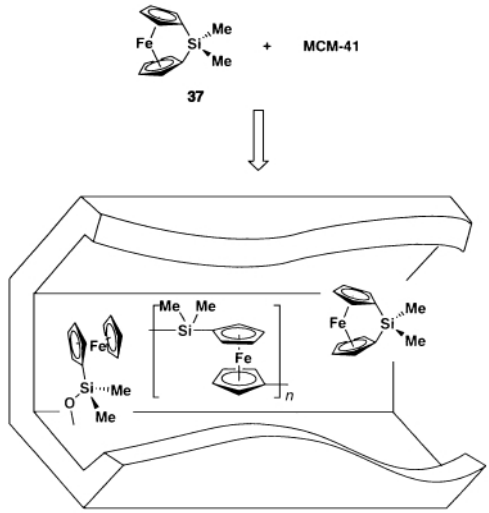

Fig. 27 Illustration for ring-opening polymerization of [1]silaferrocenophane **37** within the mesoscopic channels of MCM-41.

from the next-generation material design for fabrication of well defined nanostructures. Bringing together knowledge about biology and physics as well as organic, inorganic, supramolecular, and macromolecular chemisty into this area will lead to further breakthroughs in science and technology.

First published as an Advance Article on the web 21st November 2000

A series of polyammonium halide salts have been converted to the phosphate ion form. The resultant salts constitute a new category of non-aqueous ionic liquid (NAIL); these new ionic liquids (Liquid Ionic Phosphates) have been characterized by standard methods and have been investigated for their electrical conducting characteristics.

Previously we have reported the preparation of several series of polycationic organic salts.[1] Subsequently, we considered the possibility of converting these new (solid) polyammonium salts into a unique category of ionic liquids through conversion of the gegenion. Numerous reports have been made of the conversion of monoammonium (solid) salts to non-aqueous ionic liquids by such anion conversion. The most extensively investigated series of NAILs include those in which the organic cation is either an *N*-alkylpyridinium or an *N*-alkyl-*N*′-alkylimidazolium species.[2–5] These species have involved *only* organic *mono*cations, with the single exception of a dicationic species involving two imidazolium sites at opposite ends of a long alkyl chain.[6] Of particular interest to us was the use of hexafluorophosphoric acid[7] to generate the corresponding hexafluorophosphate liquid salts from the polycationic species previously synthesized in this laboratory.

Using the established procedure for preparing such salts, with our polycationic organic salts it was observed that only a relatively low yield of such hexafluorophosphate salts could be isolated. Attempts to improve the yield through vacuum evaporation of the aqueous medium resulted in the isolation of a totally new and intriguing category of ionic liquids, liquid ionic phosphates (LIPs). It is with these new materials that the present report is concerned.

Using two separate anion exchange methods we have prepared a series of rt LIPs. The first of these involves vacuum evaporation of the aqueous supernatant solution from the preparation of the hexafluorophosphate species. Moderate yields of clear viscous liquids that exhibit NMR spectra (^{1}H, ^{13}C and ^{31}P) in accord with the assigned structures are isolated (*vide infra*). The second approach involves the more traditional anion exchange using an insoluble resin. Passage of the parent halide salts through a bed of DOWEX™ 21K in the phosphate ion form followed by vacuum evaporation of the eluent also yields the clear, highly viscous liquids providing the same analyses as noted above. A series of LIPs prepared by these methods and so analyzed is illustrated in Fig. 1. LIPs **1**–**8** are derived from the polycationic halide salts prepared in this laboratory. Species **9** has been prepared from the corresponding chloride prepared by a reported procedure,[4] and was included as a general reference to previously available NAILs derived from imidazolium salts.

The ^{1}H and ^{13}C spectra (measured in D_2O) are in total accord with those previously reported[1] in the preparation of the parent halide salts. The ^{31}P NMR spectra (also in D_2O) exhibit sharp singlet signals between δ = 0.91 and 1.20 (relative to 85% phosphoric acid). A representative example of these salts and

Table 1 Densities and specific conductivities of LIPs

LIP	Density/ g mL^{-1}	Specific Conductivity, σ/Ω^{-1} cm^{-1} 25 °C	40 °C	60 °C	$\sigma/\sigma_{KCl\ Ref.}$[a]
1	1.78	0.057	0.063	0.061	19
2	1.86	0.063	0.052	0.082	21
3	1.96	0.026	0.027	0.042	9
4	1.82	0.063	0.06	0.071	21
5	1.58	0.064	0.081	0.087	21
6	1.82	0.038	0.052	0.05	13
7	1.58	0.053	0.056	0.071	18
8	1.9	0.042	0.053	0.067	14
9	1.98	0.022	0.03	0.037	7

[a] 0.02 M KCl(aq) reference, specific conductivity = 0.03 Ω^{-1} cm^{-1} at 25 °C.

their spectra is provided by **7**: δ_H: 1.86, br s, 4H; 3.16, s, 12H; 3.49, br s, 4H; 4.35, s, 4H. δ_C: 20.87, 51.98, 56.28, 65.41, 81.35. δ_P: 1.20.

The hexafluorophosphate salts also isolated in these reactions exhibit corresponding ^{1}H and ^{13}C NMR spectra, but the ^{31}P signals appear as symmetrical septets centered at $\delta \sim -144$. Further, the isolated hexafluorophosphate salts appear to be universally contaminated with phosphate. Through quantitative measurement of the ^{1}H NMR spectra for these LIPs their anhydrous nature can be established, although they are fully soluble in water and adsorb water from room air. Specifically, from ^{1}H NMR measurements it is determined that the water content of the new LIPs is below the limit of reliable measurement, that is less than 0.5%. Unlike the hexafluorophosphate salts which are insoluble in water to the point that NMR measurements can not be made, the new LIPs are fully soluble in water. Both types of salts are soluble in DMSO allowing measurement of the ^{1}H and ^{13}C NMR spectra of the crude reaction products.

In addition to the measurement of their densities, specific conductivity measurements were performed on the LIPs **1**–**9**. A YSI Model 31 conductivity bridge was used for these measurements, with a constant temperature bath to maintain temperature of the sample during measurement at several temperatures (25, 40 and 60 °C). A 0.02 M solution of KCl in water was used as reference material (specific conductivity of 0.03 Ω^{-1} cm^{-1} at 25 °C). The results for these determinations are shown in Table 1.

In comparison with previously prepared rt NAILs, the presently described LIPs exhibit particular advantages. These include: (a) ease of preparation, requiring only ordinary ion-exchange in aqueous medium rather than the use of the quite reactive (and under certain circumstances hazardous) hexafluorophosphoric acid, tetrafluoroboric acid or aluminum chloride, which require controlled atmospheric conditions; (b) the resultant salts are unreactive with water; (c) although viscous, the LIPs are liquids at rt, while the hexafluorophosphate salts of monocations melt above rt and the hexafluorophosphate salts of polycations we have synthesized remain solid up to 75 °C; (d) particularly high specific conductivities; and (e) the potential for use as media for electrochemical processes requiring a large electrochemical window.

We are in the process of exploiting this new category of NAILs for utility in a variety of processes, including electrochemical conversions, media for "green" chemical reactions, catalysts for chemical conversions, syntheses of related species exhibiting water-insolubility, and the performance of separations without the use of volatile solvents. Further, determinations of the diffusion coefficients, mobilities of ions within the viscous media, and potential applications for electrochemical storage cells are being made.

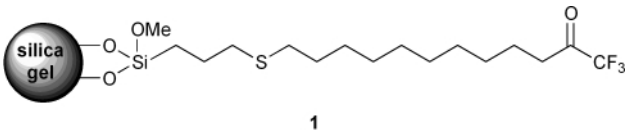
Covalent attachment of trifluoromethyl ketone catalyst to a solid support such as silica gel increased the stability of catalyst dramatically, so solving an intrinsic problem of dioxirane-mediated epoxidation of alkenes catalysed by ketones.

Dioxiranes have been shown to be powerful and environmentally safe oxidants, which can be generated *in situ* from ketones and Oxone® ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$).[1] In principle, only a catalytic amount of ketone is required and, moreover, with a chiral ketone there exists the opportunity for catalytic asymmetric epoxidation.[2] However, an intrinsic problem of this catalytic epoxidation procedure is that the turnover number (TON) of ketone catalysts is generally very low owing to their instability under the epoxidation conditions. It has been generally known that ketone catalysts can be destroyed *via* Baeyer–Villiger oxidation and/or formation of 1,2,4,5-tetroxane *etc*.[1]

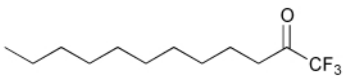
We proposed that the decomposition of ketone catalysts in the dioxirane-mediated epoxidation of alkenes could be prevented by covalent attachment of ketone catalysts to a suitable solid support,[3] since, as shown in Fig. 1, site isolation of catalytic centres can minimise the possibility of 1,2,4,5-tetroxane formation, and, moreover, the migration of a solid-bound alkyl chain in the Baeyer–Villiger oxidation step may need larger movement energy than that of the homogeneous analogue. Of course, this approach can provide an additional advantage of easy recycling of catalyst.

To test our rationale, we prepared a new silica-bound trifluoromethyl ketone **1** and compared its stability in the dioxirane-mediated epoxidation of alkenes with its homogeneous analogue, 1,1,1-trifluorododecan-2-one **2**. Here we report our preliminary results.

The silica-bound trifluoromethyl ketone **1** was simply prepared by the reaction of 1,1,1-trifluorodode-11-cen-2-one **3**[4] with 3-mercaptopropylsilanised silica gel **4**[5] in the presence of α,α′-azoisobutyronitrile (AIBN) as a radical initiator in acetonitrile (Scheme 1).[6] The fluorine and sulfur analyses of **1** (F, 2.61%; S, 2.90%) indicated that 0.45 mmol g^{-1} of trifluoromethyl ketone moiety was incorporated and the coupling yield of **3** with **4** was 50%. Thus, 0.45 mmol g^{-1} of unreacted thiol groups exist in the silica-bound trifluoromethyl ketone **1**. The attachment of trifluoromethyl ketone moieties to silica gel in the silica-bound ketone **1** was also confirmed *via* IR spectroscopy (1766 cm^{-1} for $\nu_{C=O}$).



1



2

In order to compare the catalytic efficiency and stability of silica-bound ketone **1** with its homogeneous analogue **2**, the epoxidation of alkenes were carried out with Oxone® in a MeCN–H_2O solvent system under the modified condition employed by Shi and co-workers.[7] The results are summarised in Table 1.

As shown in Table 1, the silica-bound ketone **1** exhibited comparable catalytic activity with that of its homogeneous analogue **2**. In a ratio of ketone : olefin of 0.5 : 1 at room temperature, epoxidation of alkenes using 2.07 equiv. of Oxone® and 8.7 equiv. of K_2CO_3 was complete within 5 min after addition of Oxone® and K_2CO_3, and afforded the corresponding epoxides in very high yield.[8] Most of the oxidised products were obtained in nearly pure form by simple filtration of the ketone **1**, followed by extraction of organic product and evaporation of the solvent. The observed results suggest that trifluoromethyl ketone moiety on silica gel remains highly exposed to the reactants and thus substrates can access to the catalytic sites easily.

The silica gel supported trifluoromethyl ketone **1** could be easily recovered after reaction by simple filtration and the recovered ketone **1** was reused several times without any significant loss of activity. All epoxidations of *trans*-β-methylstyrene using the recycled ketone **1** afforded *trans*-β-methylstyrene oxide in nearly quantitative yield, even after tenth use.[9] As we proposed, the retainment of the catalytic activity during several cycles can be explained by that the decomposition of the supported ketone catalyst **1** *via* Baeyer–Villiger oxidation and/or 1,2,4,5-tetroxane formation[10] proceeds much more slowly than that of its homogeneous analogue **2**. We could not find any carbonyl peak of the Baeyer–Villiger oxidation product (ester) in the IR spectrum of **1** recovered after

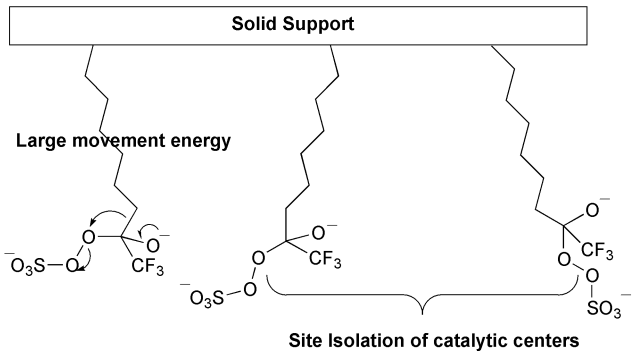


Fig. 1

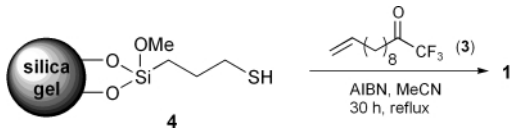

Scheme 1

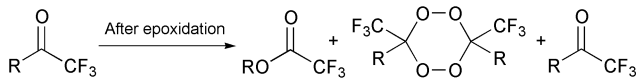
Table 1 Epoxidations of alkenes with Oxone® catalysed by silica-bound ketone **1** or its homogeneous analogue **2**[a]

Entry	Alkene	Yield (%)[b] Using catalyst **1**	Using catalyst **2**
1		94	93
2		>98	>98
3		>98	>98
4		>98	>98
5		>98	>98
6		>98	>98
7		>98	>98
8		71	67
9		>98[c]	>98[d]

[a] The reaction conditions were not optimised: substrate (1 equiv.), ketone catalyst (0.5 equiv.) Oxone® (2.07 equiv.) and K_2CO_3 (8.7 equiv.) in MeCN–aqueous EDTA (4×10^{-4} M) (1.5/1, v/v) at room temperature. Under such conditions, the blank reaction (the epoxidation of *trans*-β-methylstyrene only with Oxone®) gave the epoxide only up to 16% yield. [b] Yields were determined by GC and ^{1}H NMR analysis of crude products. [c] 93% of α-pinene oxide and *ca*. 5% of α-campholenic aldehyde. [d] 84% of α-pinene oxide and *ca*. 15% of α-campholenic aldehyde.



2 (R = $C_{10}H_{21}$) **5** (8%) **6** (77%) **2**

Scheme 2

10 runs. In contrast to the silica-bound catalyst **1**, *ca*. 85% of its homogeneous analogue **2** was decomposed after a first run of the epoxidation of *trans*-β-methylstyrene. The main decomposed products were ester **5** (*ca*. 8%) and 1,2,4,5-tetroxane **6** (*ca*. 77%) (Scheme 2). The structure of **6** was assigned by NMR and HRMS analyses.[11]

In conclusion, we have achieved excellent results for the heterogeneous dioxirane-mediated epoxidation of alkenes using silica gel supported trifluoromethyl ketone **1**. This silica-bound ketone was reused ten times without loss of activity. This retainment of the catalytic activity during several cycles was explained by that the decomposition of the supported ketone catalyst **1** *via* Baeyer–Villiger oxidation and/or 1,2,4,5-tetroxane formation[10] proceeds much more slowly than that of its homogeneous analogue **2**. Thus, this type of immobilisation of ketone catalysts will provide a possibility to increase their stability, which is an intrinsic problem of dioxirane-mediated epoxidation catalysed by ketones. The current study will also provide some insight for the development of new chiral ketone catalysts. In the search for efficient ketone catalysts for asymmetric epoxidation, both turnover number and enantioselectivity are crucial issues to be considered.

This research was supported by a grant from Korea Institute of Science and Technology.

3 Recently, simply for the easy separation of catalyst from the reaction mixture, some polymer-bound ketones have been employed: T. R. Boehlow, P. C. Buxton, E. L. Grocock, B. A. Marples and V. L. Waddington, *Tetrahedron Lett.*, 1998, **39**, 1839; A. Shiney, P. K. Rajan and K. Sreekumar, *Polym. Int.*, 1996, **41**, 377.

4 1,1,1-Trifluorododec-11-en-2-one **3** was synthesised by the published procedure: J. Biovin, L. E. Kaim and S. Z. Zard, *Tetrahedron*, 1995, **51**, 2573.

5 3-Mercaptopropylsilanised silica gel **4** (1.14 mmol of S g^{-1}) was prepared by the reaction of Silica gel 60 (70–230 mesh, Merck) and (3-mercaptopropyl)trimethoxysilane according to the published procedure: C. Rosini, C. Bertucci, D. Pini, P. Altemura and P. Salvadori, *Tetrahedron Lett.*, 1985, **26**, 3361; C. Rosini, P. Altemura, D. Pini, C. Bertucci, G. Zullino and P. Salvadori, *J. Chromatogr.*, 1985, **348**, 79; P. Savadori, C. Rosini, D. Pini, C. Bertucci, P. Altemura, G. Uccello-Barretta and A. Raffaelli, *Tetrahedron*, 1987, **43**, 4969.

6 Some of chiral catalysts have been anchored on silica by same methodology: C. E. Song, J. W. Yang and H.-J. Ha, *Tetrahedron: Asymmetry*, 1997, **8**, 841; D. Pini, A. Mandoli, S. Orlandi and P. Salvadori, *Tetrahedron: Asymmetry*, 1999, **10**, 3883.

7 Z.-X. Wang, Y. Tu, M. Frohn and Y. Shi, *J. Org. Chem.*, 1997, **62**, 2328.

8 The epoxidation of *trans*-stilbene in a MeCN–H_2O solvent system under the same reaction conditions[7] reported by Shi (1.38 equiv. of Oxone®, 5.8 equiv. of K_2CO_3 and 0.5 equiv. of ketone) afforded the corresponding epoxide in *ca*. 76% yield. However, the yield was dramatically increased only by increasing the amount used of Oxone® and K_2CO_3. In a 0.5 : 1 ketone : olefin ratio at room temperature, epoxidation of *trans*-stilbene proceeded completely within 5 min after addition of 2.07 equiv. of Oxone® and 8.7 equiv. of K_2CO_3 and afforded the corresponding epoxide in nearly quantitative yield (Table 1).

9 There was some loss of ketone **1** owing to its slight solubility in the reaction medium and thus, in a each run, the amounts of substrate were used based on the amounts of the recovered ketone **1**.

10 However, our site isolation hypothesis is not very convincing yet since the loading of the ketone catalyst on the silica gel is so high that the interaction between immobilised molecules can not be excluded.

Received (in Irvine, CA, USA) 27th July 2000, Accepted 13th October 2000
First published as an Advance Article on the web 22nd November 2000

Dianionic members of the Mn_{12} family of single-molecule magnets have been prepared by two-electron reduction of the neutral cluster; the $[PPh_4]_2[Mn_{12}O_{12}(O_2CCHCl_2)_{16}(H_2O)_4]$ representative has been shown to possess an $S = 10$ ground state and to exhibit out-of-phase ac susceptibility signals diagnostic of single-molecule magnetism behavior.

An exciting development in nanoscale magnetic materials occurred in 1993 when $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]$ **1** was identified as a nanoscale magnet,[1] the first to comprise discrete, (magnetically) non-interacting molecular units rather than a 3D extended lattice (metals, metal oxides, *etc.*). This initiated the field of molecular nanomagnetism and such a molecule has been termed a single-molecule magnet (SMM).[2] Other $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_x]$ (R = Et, Ph, *etc.*; x = 3 or 4) derivatives have since been studied,[1,3] and they display similar properties. SMM behaviour is due to a combination of a large ground state spin (S) of S = 10 and negative (easy axis) magnetoanisotropy as gauged by a negative zero-field splitting parameter D. As a result, there is a significant barrier for the relaxation of the cluster's magnetization vector, and these Mn_{12} molecules are thus magnetizable magnets.

More recently, the one-electron reduced complex $[NPr_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ and related species with S = 19/2 ground states have also been found to be SMMs.[3] In addition, new examples of SMMs have been found in the family of $[Mn_4O_3X(O_2CMe)_3(dbm)_3]$ (X = Cl^-, Br^-, F^-, N_3^-, $MeCO_2^-$, *etc.*) complexes containing a $[Mn_4(\mu_3\text{-}O)_3(\mu_3\text{-}X)]^{6+}$ core and an S = 9/2 ground state,[2,4] as well as a few other species.[5–7] Here, we report that the two-electron reduced form of the $[Mn_{12}]$ complexes has been successfully isolated and that this retains both a high ground state S value and the SMM properties of the $[Mn_{12}]^{0,-}$ species. This extends the Mn_{12} of SMMs to a third oxidation level and provides an invaluable new datum point for our future understanding of how changing spin state and magnetic anisotropy can affect the properties of these important molecules. We herein report the synthesis and characterization of the new $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]^{2-}$ species.

$[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ complexes with electron-withdrawing groups [R = $CHCl_2$ (**2**), C_6F_5 (**3**), $C_6H_3(NO_2)_2$-2,4 (**4**), *etc.*] to facilitate multi-electron reduction were prepared from **1** using the procedure reported elsewhere.[1,3] The representative CV in MeCN of **2** (Fig. 1) shows three quasi-reversible one-electron reduction processes at 0.91, 0.61 and 0.29 V *vs.* ferrocene, and a fourth irreversible reduction at lower potential. These values are significantly more positive than for the R = Me and Ph derivative (Table 1).[1,3] In addition, the second and third reductions appear more reversible by electrochemical criteria (peak currents and separations) than those for previous $[Mn_{12}]$ derivatives. The dianionic species were therefore targeted and successfully prepared on a large scale using I^- as reducing agent, as employed for one-electron reductions.[3] Thus, addition of 2 equivalents of NPr^n_4I or PPh_4I in MeCN, removal of solvent and recrystallization from MeCN–Et_2O–hexanes or CH_2Cl_2–hexanes gave dark red–brown $[PPh_4]_2[Mn_{12}O_{12}(O_2CCHCl_2)_{16}(H_2O)_4]$ **5**, $[NPr^n_4]_2[Mn_{12}O_{12}(O_2CC_6F_5)_{16}(H_2O)_4]$ **6** and $[NPr^n_4]_2[Mn_{12}O_{12}(O_2CC_6H_3(NO_2)_2\text{-}2,4)_{16}(H_2O)_4]$ **7**,† as well as others [eqn. (1)].

$$[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4] + 2NPr^n_4I \rightarrow [NPr^n_4]_2[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4] + I_2 \quad (1)$$

The structure‡ of the dianion of **5** (Fig. 2) confirms the same structure as in the neutral and monoanionic species, but now with a $2Mn^{II}$, $6Mn^{III}$, $4Mn^{IV}$ description indicating that the two added electrons are on outer Mn^{II} (formerly Mn^{III}) ions (Mn9 and Mn11 of Fig. 2) rather than Mn^{IV} ions in the cubane, as found in the one-electron reduced complexes,[3] which are Mn^{II}, $7Mn^{III}$, $4Mn^{IV}$. The assignment of $Mn^{II}/Mn^{III}/Mn^{IV}$ is based on relative Mn–O distances, bond valence sum calculations, and Jahn–Teller (JT) axial elongations only on six Mn sites. ^1H NMR studies in solution are consistent with electron-detrapping amongst the outer eight Mn ions on the NMR timescale, as also found for the mono-anionic species.[3]

The ground state of **5** was determined from reduced magnetization ($M/N\mu_B$) *vs.* H/T measurements in the 10–70 kG

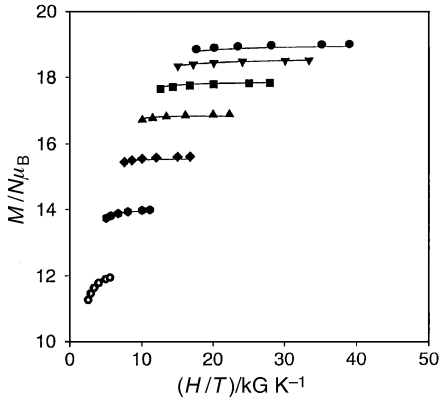

Fig. 3 Plot of (M/N μ_B) *vs.* H/T for complex **5** at 10 (⊕), 20 (●), 30 (◆), 40 (▲), 50 (■), 60 (▼) and 70 (●) kG. The solid lines are fits using the appropriate method;[9] see text for the fit parameters.

and 1.80–4.00 K ranges (Fig. 3). Fitting of the data gave $S = 10$, $D = -0.27$ cm^{-1} (-0.39 K) and $g = 2.00$. The ground state spin is thus similar to the $S = 10$ and 19/2 values for the neutral and monoanionic complexes, respectively. This suggested that the dianionic complexes might also be SMMs, *i.e.* show slow magnetization relaxation (reorientation) rates, and this was confirmed in ac susceptibility studies by an out-of-phase signal (χ_m'') in the 2–3 K range (Fig. 4, bottom). ac Susceptibility studies monitor the response of a material's magnetization (magnetic moment) to an applied, oscillating field, and a non-zero χ_m'' signal shows that the magnetization cannot relax fast enough to keep in-phase with the oscillating field. The positions of the χ_m'' peaks, at which temperature the relaxation rate equals the ac frequency, are in the 2–3 K range, lower than the 4–6 and 6–8 K ranges for the χ_m'' peaks in the monoanionic and neutral complexes, respectively (Fig. 4). This is consistent with the changing S and D values on progressive reduction since the barrier to thermally-activated reversal of the magnetization direction is related to $S^2|D|$ and $(S^2 - \frac{1}{4})|D|$ for integer and half-integer spins, respectively. The $S(D)$ values for the three oxidation levels are: $[Mn_{12}]$, 10 (≈ -0.5 cm^{-1}); $[Mn_{12}]^-$, 19/2 (≈ -0.4 cm^{-1}); $[Mn_{12}]^{2-}$, 10 (≈ -0.3 cm^{-1}).

In conclusion, the $[Mn_{12}]$ family of SMMs now provides three oxidation levels for the study of this important new phenomenon. In particular, the $[Mn_{12}]^{2-}$ *vs.* $[Mn_{12}]$ comparison

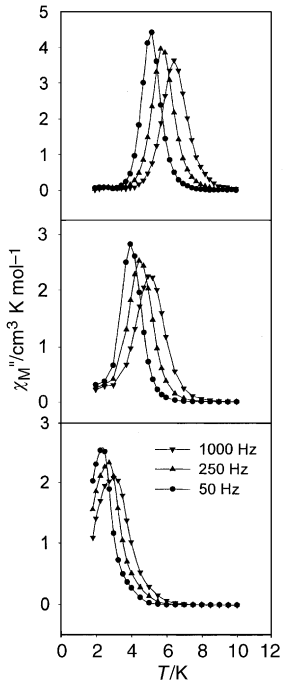

Fig. 4 Plot of the out-of-phase ac susceptibility (χ_m'') for complex **2** (top), $[NPr^n_4][Mn_{12}O_{12}(O_2CCHCl_2)_{16}(H_2O)_4]$ (middle) and complex **5** (bottom) at the indicated oscillation frequencies of the applied field.

provides an invaluable opportunity to study how the magnetic properties and quantum tunneling behaviour of equivalent spin ($S = 10$) systems vary with changing magnetoanisotropy.

This work was supported by the National Science Foundation.

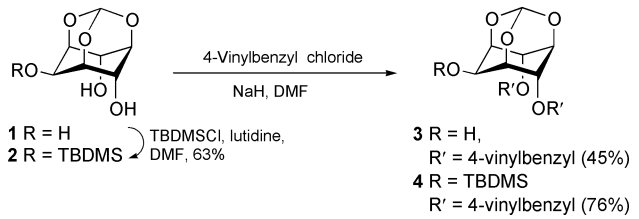
Received (in Cambridge, UK) 30th August 2000, Accepted 19th October 2000
First published as an Advance Article on the web 22nd November 2000

Free radical-promoted cyclopolymerisation of a 4,6-bis(4-vinylbenzyl)-*myo*-inositol orthoformate 4, whose X-ray structure has been determined, was studied and the first formed intermediate was trapped using (tetramethylpiperidine *N*-oxyl) (TEMPO) 7.

Cyclopolymerisation[1,2] is a useful method for controlling the regio- and stereochemistry of monomer additions, leading to polymers with well-defined microstructures.[3] We were interested in the use of a scaffold with oriented hydroxy functionality based on a rigid monomer which would undergo cyclopolymerisation to afford a polymer with an organised backbone and oriented functional groups. We selected the 4,6-bis(4-vinyl)-benzyl)-*myo*-inositol orthoformates **3** and **4** as suitable monomers to deliver these features.

The monomers **3** and **4** were prepared from *myo*-inositol orthoformate **1**[4] either by selective derivatisation[5] at positions 4 and 6 with 4-vinylbenzyl chloride (to give **3**) or selective silylation[6] at the 2-position followed by benzylation at positions 4 and 6 (Scheme 1). The key structural feature offered by these monomers includes the orthoformate group which, after the polymerisation reaction, may be easily deprotected to yield (ideally) an all-axial triol repeat unit.



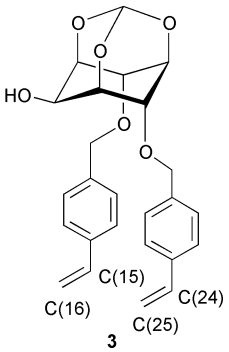
Scheme 1 Preparation of monomers **3** and **4**.

Both monomers gave suitable crystals for X-ray analysis, but disorder in the silyl side chain of **4** yielded data with an unacceptably high *R* factor. The X-ray structure† of monomer **3** revealed two conformations (ratio 3:1) in the unit cell with a characteristic edge-to-face interaction of the aromatic rings.[7] The monomer structures differed only in the relative orientation of the vinyl groups. The important interatomic bond distances of the major conformer of **3** measured from the X-ray data, are presented in Fig. 1.

Heating a toluene solution of the monomer **4** at 65 °C in the presence of 2–3 wt% AIBN afforded an organic soluble polymer of M_n 10 000–20 000 which is formulated as a linear cyclopolymer **5** (Scheme 2).‡ The evidence for the cyclopolymer **5** comes from the X-ray structure of the monomer and the trapping of the first formed cyclic radical intermediate.

Thermal decomposition of the AIBN initiator would give the cyanoisopropyl radical which would add selectively to the less substituted end of the vinyl group.[8] Intramolecular cyclisation by 'head' to 'tail' addition, from C(15) to C(25), is likely to be the more favourable reaction pathway as the distance from C(15) to C(25) shown in Fig. 1, is significantly shorter than the other measured distances. Supporting evidence for this pathway is provided by the trapping experiment discussed below. Similar interatomic bond distances were found in **4**.

Interatomic distances (Å)	
C(15)-C(24)	4.907
C(15)-C(25)	3.935
C(16)-C(24)	5.167
C(16)-C(25)	4.151



3

Fig. 1 Selected interatomic bond distances in a crystal of the monomer **3**.

The TEMPO radical trapping technique, developed by Rizzardo, Solomon and Moad,[9–11] and also exploited by Busfield and Jenkins,[8] was used to isolate the reactive radical intermediate generated during cyclopolymerisation. The optimum trapping experiment involved heating a 29 mM benzene

solution of the monomer **4** in the presence of AIBN **6** (28 mM) and TEMPO **7** (10 mM) to give the alkoxyamine **8** in 5% yield (the mass balance was mainly starting material) (Scheme 3). The low yield of product arises from competing reaction of the cyanoisopropyl radical with the aminoxyl agent.[8] To our knowledge this is the first example of trapping of the cyclic intermediate in a styrenic radical cyclopolymerisation, and may offer important opportunities to study the kinetics of the early propagation steps of such processes.

The structure determination of the cyclic product **8** was performed by ^{1}H NMR TOCSY and NOE experiments. Selective 1-D TOCSY experiments assisted in determining the connectivity sequence of atoms. Mutual NOE effects were observed between H_a and H_c in compound **8**, indicating that the methine protons are part of the same cyclic structure. The observed ^{1}H NMR coupling constant (13.3 Hz) between H_c and $H_{b'}$ is more consistent with the *syn* diastereoisomer (predicted 12.4 Hz) than the *anti* (predicted *J* 4.0 Hz) (Fig. 2).§

In conclusion we have confirmed the existence of a cyclopolymerisation by trapping the reactive radical intermediate. Furthermore, interatomic bond distances between the vinyl groups in both **3** and **4**, as established in the solid state, favour the formation of a cyclic structure. Hence, the monomers based on *myo*-inositol orthoformate show interesting opportunities to prepare a rigid scaffold with oriented functionality.

We thank EPSRC for financial support and provision of the Swansea MS service, the Cambridge Overseas Trust, Robinson College, and the CVCP for scholarships (to T.-H. K.) and Dr P. Grice for the ^{1}H TOCSY NMR experiments. We thank Professor I. Jenkins, Dr J. H. G. Steinke and Dr W. McDonald (ICI/DuPont) for their interest in this work.

Notes and references

† *Crystal data* for **3**: Colourless needle-shaped crystals, mp 136 °C, of $C_{25}H_{26}O_6$ were monoclinic, space group $P2_1/c$, with a = 6.072(6), b = 24.506(6), c = 14.217(3) Å, α = 90, β = 99.35(4), γ = 90°, V = 2087(2) Å^3, Z = 4, T = 180 (2) K, μ = 0.96 mm^{-1}, ρ_{calc} = 1.344 Mg m^{-3}, M = 422.46. One of the vinyl groups, C(24) and C(25), appears to be disordered about two orientations. The final $R_w(F^2)$ = 0.1037 with a goodness of fit = 1.014, while the conventional $R(F)$ = 0.0559 for 7948 reflections with $F_o > 4[\sigma(F_o)]$. CCDC 182/1833. See http://www.rsc.org/suppdata/cc/b0/b007057m/ for crystallographic files in .cif format.

‡ Further details of the cyclopolymerisation (see following Communication, DOI: 10.1039/b007058k) will be described in a full paper.

§ Molecular modelling[12] of **8** using the MM2 force field in MacroModel v5.5® indicated that the distance between the methine hydrogens H_a and H_c in either the *syn* or *anti* isomers was 2.43–3.74 Å, within the NOE experimental range. It is impossible to distinguish the two alternative *syn*-diastereoisomers (relative to the 2-TBDMSO substituent).

Ring closing metathesis of a 4,6-diallyl-*myo*-inositol orthoformate as a model for an inositol cyclopolymer

Tae-Hyun Kim,[a,b] Mark Giles[b] and Andrew B. Holmes*[a,b]

[a] *Department of Chemistry, University Chemical Laboratory, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: abh1@cam.ac.uk*

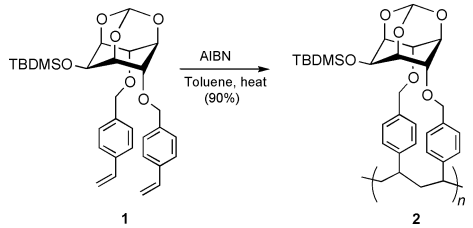
Received (in Cambridge, UK) 30th August 2000, Accepted 19th October 2000
First published as an Advance Article on the web 21st November 2000

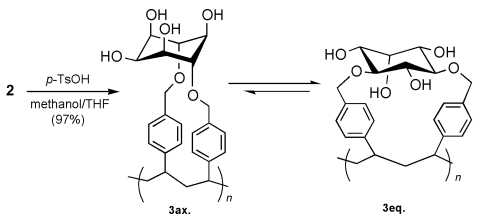
Ring closing metathesis (RCM) of the diallyl inositol derivative 5 gave the product 6 which after cleavage of the orthoester served as a model for assignment of the preferred conformation of the analogous deprotected inositol cyclopolymer 3.

In the preceding Communication the cyclopolymerisation of the conformationally locked 4,6-bis(4-vinylbenzyl)-*myo*-inositol **1** to the novel cyclopolymer **2** was reported (Scheme 1).[1]



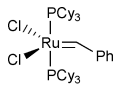
Scheme 1 Polymerisation of the monomer **1** to cyclopolymer **2**.

The rigid inositol unit of the monomer **1** acts as a template to bring both polymerisable styryl groups into close proximity for cyclopolymerisation. The monomer **1** was polymerised at high dilution (0.1 mmol ml^{-1}) in toluene with 2–3 wt% of AIBN as a radical initiator to give a soluble linear cyclic polymer **2** in high yield (80–90%) with molecular weight M_n of 10 000–20 000 as determined by GPC.† It was hoped that removal of the orthoester and silyl groups would release a hydrophilic polymer with oriented fiunctionality. Thus the polymer **2** was heated in a mixture of THF and methanol in the presence of toluene-*p*-sulfonic acid to give the hydroxylated polymer **3** (Scheme 2). The polymer **3** would be expected to exhibit interesting hydrophilic and metal binding properties if all five hydroxy groups remained axial **3ax**.[2,3] However, the alternative conformation **3eq**. would also be feasible. Unfortunately the polymer **3** shows very broad ^{1}H and ^{13}C NMR spectra, making the full conformational interpretation difficult, and hence conformational studies using model small molecules were carried out to gain insight into this feature.



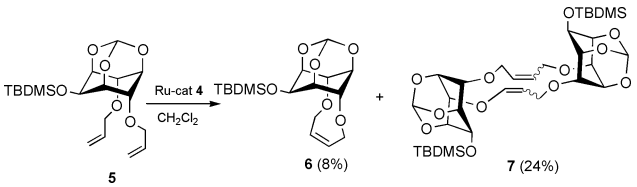
Scheme 2 Deprotection of polymer **2** to give two alternative conformations of **3**.

The model compounds were thought to be accessible by ring closing metathesis (RCM)[4,5] of the monomer **1** using the ruthenium based alkylidene catalyst **4**.[6] However, attempted ring closure of the monomer **1**, under high dilution (11.2 mM),



4

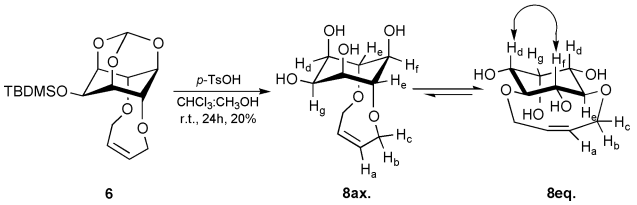
failed and gave only oligomeric products. This was ascribed to the rigid steric arrangement of the two styryl groups in a single unit of **1**, making the formation of another ring difficult. RCM of an alternative monomer with flexible alkyl linking groups was therefore carried out. The diallyl inositol **5** was formed in 78% yield by treating **1** with allyl bromide and sodium hydride in DMF. On treatment of the monomer **5** with the ruthenium initiator **4**, the ring closed product **6** and 'dimer' **7** were obtained, together with starting material (35%) and oligomeric products (Scheme 3). The double bond stereochemistry of these symmetrical products has not been assigned, but it is reasonable to assume that compound **6** has the *Z*-double bond configuration.



Scheme 3 RCM of the diallyl inositol **5**.

The RCM product **6** was deprotected to give the model compound **8** (Scheme 4).‡

Analysis of the ^{1}H NMR spectrum of the deprotected product **8** indicated that the preferred ring conformation was **8eq**. The protons H_d (δ 3.20, dd, *J* 9 and 3), H_e (δ 3.31, br t, *J* 9, 9) and H_f (δ 2.92, dt, *J* 6 and 9) were all axial and the measured coupling constants were in good agreement with those predicted by computer modelling.[7] A strong ^{1}H NMR NOE effect was also observed between the signals due to H_d and H_f (see Scheme 4) and between H_a (δ 5.75, br s) and H_e.



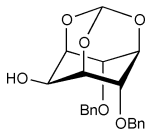
Scheme 4 Deprotection of the ring closed product **6** showing the observed NOE for **8eq**.

Variable temperature (VT) ^{1}H NMR experiments were carried out for both the deprotected RCM product **8** and the analogous 'dimer' in DMSO over the temperature range 300–330 K. However, although the signals due to the OH peaks altered as a result of the breaking of hydrogen bonds, there were

DOI: 10.1039/b007058k

no dramatic changes in the other signals. This demonstrates the rigidity of the structure in inhibiting inositol ring-flipping.

The ^{1}H NMR signals of the inositol ring protons of the 4,6-dibenzyl-*myo*-inositol orthoformate **9**[5] occurred at δ 4.45



9

(1H, m), 4.30 (2H, m) and 4.23 (3H, m) and resembled closely the analogous signals in the polymer **2** (δ 4.5–4.2, br multiplet), indicating that the ring conformation was maintained, as expected, in the polymer. The ^{1}H NMR chemical shifts (δ 3.60–2.92) of the ring protons of the deprotected metathesis product **8eq.** are shifted upfield compared with those in the model **9**. Similarly the inositol ring protons of the deprotected polymer **3** (δ 3.7–3.0) are shifted upfield from which it is concluded that the inositol ring in **3** has the conformation **3eq.** The ^{13}C NMR spectra peaks of **3** were too broad to be assigned.

In conclusion, we have established the conformation of the novel inositol polymer **3** using the model compound **8** prepared by ring closing metathesis. The ^{1}H NMR analysis strongly suggests that the polymer **3ax**. is converted into **3eq**. when deprotected.

We thank EPSRC for supporting this work and provision of the Swansea MS service, and the Cambridge Overseas Trust, Robinson College, and the CVCP (award of scholarships to T.-H. Kim).

Notes and references

† Full details of the synthesis and properties of polymers based on the monomer **1** will be described in a full paper.

‡ A similar sequence of reactions was carried out using 'dimer' **7**, and the spectroscopic properties of the inositol ring atoms were very similar to those discussed for the small ring analogue **6**.

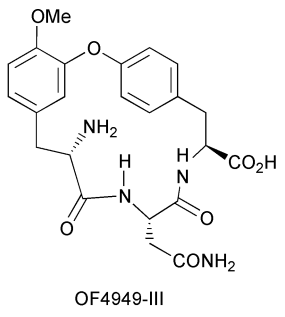
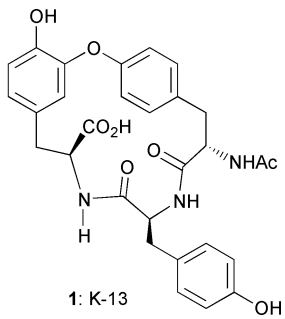
The cyclic tripeptide K-13 has been prepared in 11 steps from commercially available starting materials (11% overall yield); the key step is the Pd-catalysed macrocyclisation of the zinc reagent prepared by selective insertion of zinc into the aliphatic C–I bond of the linear tripeptide 3, followed by Pd-catalysed macrocyclisation.

The conformation of peptides is a key parameter in determining their biological activity. Cyclic peptides, in which the degrees of conformational freedom are reduced, are therefore potentially important targets. Some examples of natural products falling into this class include the aminopeptidase inhibitor OF4949-III[1a] and the ACE inhibitor K-13 (**1**).[1b] There is



OF4949-III



1: K-13

substantial interest in the preparation of these targets,[2] and analogues of these compounds have been proposed as potential therapeutic agents.[3] Previous routes to these and related compounds have relied on macrocyclisation involving classical amide bond formation, or on formation of the biaryl ether. This latter approach has employed oxidative phenol coupling using thallium trinitrate, Ullmann cyclisations and the S_NAr reaction.[4] These approaches have the advantage that the precursors for cyclisation are generally easy to prepare, with minimal reliance on protecting groups.

We have already described the palladium-catalysed reaction between aromatic iodides and the organozinc reagent derived from a protected iodolalanine derivative.[5] The reaction has proved to be versatile and has been extended to dipeptide-derived organozinc reagents.[6] We have therefore explored whether this reaction might be applied to the synthesis of K-13,[7] in which the key macrocyclisation step is a Negishi cross-coupling reaction of the corresponding open chain peptide **3** (Scheme 1).[8] This approach has the benefit of requiring the synthesis of relatively simple macrocyclisation precursors, and the potential for broader application since there is no absolute requirement for a biaryl ether in the target.

It was expected that the crucial C–C bond formation could be achieved after chemoselective Zn insertion into the aliphatic C–I bond, followed by a palladium-catalyzed cross-coupling reaction of the resulting organometallic reagent. The viability of this type of coupling in an intermolecular sense had already been demonstrated.[9] Compound **3** could be obtained by amide bond formation between the peptide **4** and the N-protected biaryl ether amino acid **5**, in which the hydroxy group of the serine residue could then be transformed into an iodide.

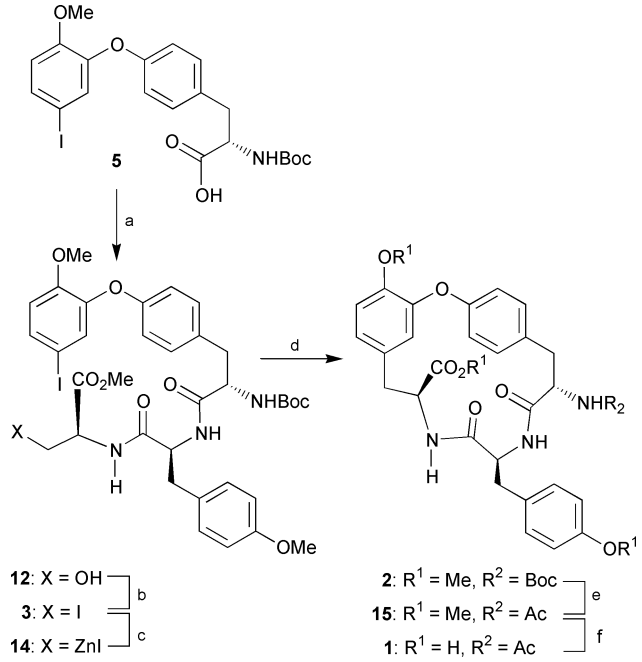

Scheme 3 *Reagents and conditions*: (a) **4**, EDCI, BtOH, iPr_2NEt, DMF, rt, 16 h, 94%; (b) $(PhO)_3PMeI$, DMF, rt, 20 min, 76%; (c) Zn, I_2 (cat), DMF, rt, 30 min; (d) $Pd_2(dba)_3$, (0.03 equiv.), P(*o*-Tol)$_3$, (0.12 equiv.), 3×10^{-3} M THF, 60 °C, 16 h, 35%; (e) i, TFA, thioanisole, CH_2Cl_2; ii, Ac_2O, pyridine 87%; (f) $AlBr_3$, EtSH, CH_2Cl_2, 85%.

The synthesis of fragment **5** started from commercially available *N*-Boc protected tyrosine **6**. Thus, nucleophilic aromatic substitution reaction between *N*-Boc protected tyrosine **6** and 2-fluorobenzaldehyde afforded the diaryl ether **7**, which was directly transformed into the corresponding methyl ester **8** in 85% overall yield (Scheme 2). Perkin reaction on the aromatic aldehyde **8**, using MCPBA in $CHCl_3$, followed by treatment of the formate intermediate with a catalytic amount of K_2CO_3 in MeOH, provided the phenol **9** in quantitative yield, which was used in the next step without further purification. This compound had already been synthesised by Jung using a different route in 30% yield over three steps.[9] At this stage, the enantiomeric purity of compound **9** was checked by removal of the Boc protecting group and Mosher's amide formation using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride. The enantiomeric purity of **9** was found to be > 95% by ^{1}H-NMR spectroscopy. The use of the free carboxylic acid derivative of tyrosine **6** in the reaction with 2-fluorobenzaldehyde is crucial to ensure high enantiomeric purity; use of the corresponding methyl ester derivative afforded racemic mixtures under a wide variety of conditions. Compound **9** was treated without further purification, following Jung's conditions,[9] with one equivalent of Chloramine-T hydrate (sodium salt of *N*-chlorotoluene-*p*-sulfonamide)–NaI to produce a mixture of 5-iodo **10** and 3,5-diiodo derivatives in a 90 : 10 ratio. This mixture was submitted to methylation (MeI, K_2CO_3, DMF) to give **11** (71% from **8** over three steps).This procedure allowed the synthesis of compound **11** on a multigram scale in 60% overall yield from commercially available *N*-Boc-tyrosine and 2-fluorobenzaldehyde. Finally, acid **5** was obtained in quantitative yield by saponification.

With the key intermediate **5** in hand, the synthesis of the crucial precursor **3** proved straightforward (Scheme 3). Thus, condensation of compound **5** and HCl·**4**[10] gave the dipeptide **12** (94%), which was transformed into the iodide **3** (76%) using $(PhO)_3PMeI$ in DMF.[11] Treatment of iodide **3** with zinc dust in DMF gave a solution of the organometallic intermediate **13**, which was added dropwise to a dilute solution of a catalyst prepared from $Pd_2(dba)_3$ and P(*o*-Tol)$_3$ in THF (maximum conc. of **13**, 3×10^{-3} M at 60 °C, and the solution was then stirred overnight. After extractive work up, cyclic dipeptide **2** was isolated by flash chromatography (35%). Compound **2** was transformed into K-13 following the experimental procedure published by Evans and Ellman[7] in good overall yield (74%). Synthetic K-13 exhibited physical and spectroscopic properties in close agreement with those reported.[12]

We thank the Spanish Ministerio de Educación y Cultura for a fellowship (M. P.-G.), the EU for a Marie Curie fellowship, HPMF-CT-1999-00050 (M. P.-G.), and Professor J. Zhu for providing spectra of synthetic K-13 for comparison.

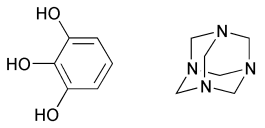
The crystal structure of an organic cocrystal, 1,2,3-trihydroxybenzene–hexamethylenetetramine (1/1), has been solved from conventional laboratory X-ray powder diffraction data that are significantly affected by preferred orientation, using a direct space structure solution approach based on the Monte Carlo method.

A sound knowledge and understanding of the role that intermolecular forces play in supramolecular assembly is generally obtained from systematic crystallographic studies. Where crystals are available of suitable quality for single-crystal diffraction, these techniques remain the method of choice. However, when no such material is available, this valuable structural information can often be obtained from powder diffraction data.

The use of X-ray powder diffraction for *ab initio* structure determination of purely organic molecular solids is a rapidly expanding field, mainly due to the considerable advances in the development of direct space methods of structure solution.[1–6] Here we report the first application of such a method to the structure determination of an organic cocrystal containing two different molecular building blocks, the 1 : 1 adduct of 1,2,3-trihydroxybenzene [$C_6H_3(OH)_3$; pyrogallol **1**] and hexamethylenetetramine [$(CH_2)_6N_4$; HMTA **2**] from conventional laboratory powder diffraction data. Despite the presence of two different molecular components in the structure and evidence of significant preferred orientation in the data, the Monte Carlo method employed here smoothly generated a starting structure for Rietveld refinement. This structure determination demonstrates both the power of this technique as a tool in the systematic study of intermolecular interactions and as an emerging force in the field of crystal engineering, and the feasibility of using lower resolution powder data collected using laboratory-based powder diffractometers rather than relying on the availability of synchrotron radiation for solving structures with this degree of complexity.



1 **2**

Previous studies have used single-crystal X-ray diffraction to explore the use of bis- and tris-phenols in crystal engineering and the interaction of this type of phenol, acting as a hydrogen bond donor, with HMTA as a hydrogen bond acceptor.[7] However in the case of pyrogallol–HMTA (1/1), investigation of the crystal structure was carried out using powder diffraction data. This type of material is an ideal target for the direct space structure solution technique as it is the organization of these well-defined building blocks within the crystal structure that is of greatest importance.

The direct-space methods approach structure solution by postulation of trial crystal structures constructed from known molecular connectivity, independently of the powder diffraction data. The trial structures are generated by movement of a structural model around the unit cell including variation of molecular conformation when required, and each structure assessed by comparison between the corresponding calculated diffraction pattern and the experimental diffraction data. The structure solution, or global minimum, is then located using a global optimization strategy such as Monte Carlo[2,6] (the method used here), simulated annealing[3,5] or genetic algorithm techniques.[4]

In the application of direct space structure solution methods, the presence of more than one molecule in the asymmetric unit makes the problem more complex in terms of the number of degrees of freedom (*i.e.* the number of structural parameters varied to generate new trial crystal structures), and to an extent, the effect on *R*-factor discrimination. There are few examples of such materials solved from powder diffraction data using the direct space structure solution approach,[8] a situation made more complicated here due to the presence of two entirely different molecules in the cocrystal with the location of each molecule in the unit cell being unique and non-superimposable. The exact hydrogen-bonded relationship between the molecules in this system was not predictable in advance.

The powder diffraction pattern was indexed on a monoclinic unit cell (space group $P2_1/n$) consistent with the presence of one molecule of each component in the asymmetric unit. Hence the structural model used in the Monte Carlo structure solution comprised a complete HMTA molecule and a pyrogallol molecule excluding the hydrogen atoms on the three hydroxyl groups. Both molecules were constructed using standard bond lengths and angles, and treated as rigid units during structure solution, although not in the subsequent refinement. Trial crystal structures were then generated by completely independent translation and rotation of the two molecular components within the unit cell. With more than one independent molecule required to define the structure, the number of degrees of freedom required for random movement is increased (from 6 to 12 in this case) without conformational flexibility being introduced. The calculation was run for 500000 Monte Carlo moves and R_{wp} was found to be typically 52–68% for most random structures whereas the best structure solution corresponded to an R_{wp} value of 18.9%. This solution was used as the starting model for a successful Rietveld refinement (Fig. 1).

Diffraction data had been collected in both disc and capillary geometries and it was clear from the difference in relative intensities of related peaks in these data that there was a significant degree of preferred orientation present. Although these effects were minimized by the use of the capillary data for both solution and refinement, variation of a preferred orientation parameter was still required in refinement.‡ In such cases, this distortion of the data often has a disastrous effect on traditional structure solution, whereas in our experience, direct-

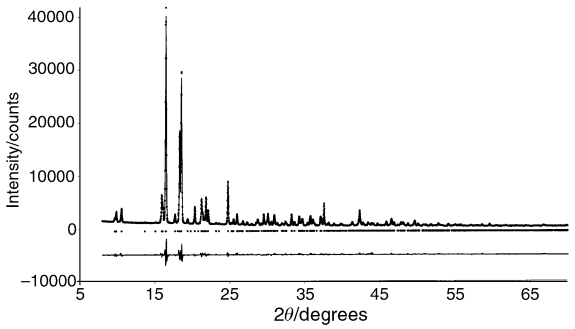

Fig. 1 Final observed (circles), calculated (solid line) and difference (below) X-ray powder diffraction profile for the final Rietveld refinement of pyrogallol–HMTA (1/1). Reflection positions are also marked.

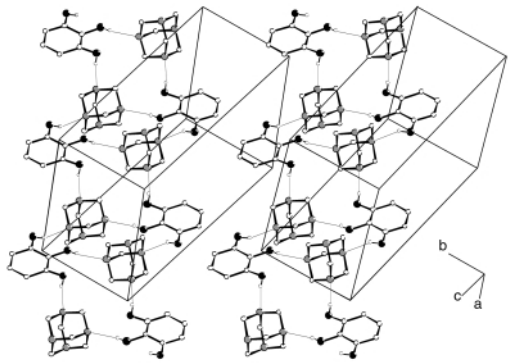

Fig. 2 Stereoview of the crystal structure of pyrogallol–HMTA (1/1) showing the alternating O–H···N rings generating a puckered molecular ribbon. Only hydrogen atoms involved in hydrogen bonding are shown and hydrogen bonds are indicated by thin lines. Intermolecular O···N distances are 2.90(1), 2.79(1) and 2.69(1) Å.

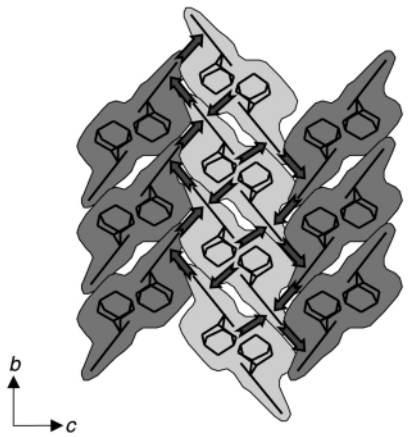

Fig. 3 A schematic diagram of the crystal structure of pyrogallol–HMTA (1/1) with each ribbon shown end-on and represented by a shaded area with the molecular units indicated by black lines. C–H···π(arene) interactions within each stack (light areas) and between neighbouring stacks (dark areas) are indicated by block arrows. C···π(arene) distances, *i.e.*: to the centroid of the ring, are 3.64(1) Å and 3.69(1) Å, respectively.

space methods appear to be more robust, presumably because a substantial amount of structural knowledge is included in the calculation through the use of a structural model.

In the structure, all three hydroxyl groups in the pyrogallol molecule act as hydrogen bond donors, and hence three N atoms in each HMTA molecule act as acceptors. This differs from the majority of systems, in which HMTA acts as a double acceptor of hydrogen bonds:[7] rather less frequently HMTA behaves as an acceptor of just one hydrogen bond, a full complement of four hydrogen bonds, or as in this case, of three hydrogen bonds.[7–9]

O–H···N hydrogen bonds are formed from the hydroxyl groups in the 1 and 3 positions linking alternating pyrogallol and HMTA molecules in a chain running parallel to the [100] direction. Pairs of these chains are linked by further O-H···N hydrogen bonds from the hydroxyl groups in the 2 positions to another N atom in each HMTA unit forming two distinct cyclic $R^4_4(18)$ motifs. The result is a lightly-puckered molecular ribbon running parallel to the [100] direction in which the HMTA cages lie alternately above and below the plane (Fig. 2). These ribbons are then linked into a continuous three-dimensional framework by C–H···π(arene) interactions. There are edge-to-face interactions between pyrogallol units in neighbouring ribbons, occupying one face of each ring: the other face of each ring is involved in a C–H···π(arene) interaction with a C–H bond from an HMTA unit in a neighbouring ribbon. The latter C–H···π(arene) interactions link sets of neighbouring parallel ribbons into columns stacked in the [010] direction, while those between the pyrogallol units link neighbouring stacks together to form a herringbone pattern (Fig. 3). Propagation of these two types of C–H···π(arene) interactions based on aromatic and aliphatic C–H bonds links all the parallel ribbons into a single bundle, so that the overall supramolecular structure is three-dimensional.

In this study we have shown that it is possible to determine the crystal structures of relatively complex materials such as cocrystals with multiple fragments in the structure solution process, from conventional laboratory X-ray powder diffraction data that is significantly affected by the presence of preferred orientation. The successful application of direct space techniques to the structure solution of materials containing a greater number of independent structural fragments or molecules with a considerable degree of conformational flexibility from powder data of this quality is clearly a possibility. Subsequent rationalization of the intermolecular forces in this system show an unpredicted network of both weak and strong hydrogen bonds, demonstrating the invaluable contribution that powder diffraction will have in improving our understanding of non-covalent forces and their role in crystal packing.

This research was supported by the Royal Society through the award of a fellowship to M. T.

‡ *Crystal data* for pyrogallol–HMTA (1/1), $C_{12}H_{18}N_4O_3$: M_r = 266.30, monoclinic, a = 10.7691(2), b = 7.0107(2), c = 16.7519(4) Å, β = 91.402(2)°, V = 1264.38(3) Å^3, space group $P2_1/n$ (no. 14), Z = 4, D_c = 1.39 g cm^{-3}, T = 273 K.

Sample preparation: a microcrystalline sample produced by crystallisation of a methanol solution containing equimolar quantities of **1** and **2**.

Data collection and Rietveld refinement: the powder diffraction data were collected on a Stoe STADI/P diffractometer using Cu-Kα_1 radiation, and a linear PSD. Data were measured over $5 < 2\theta < 75°$ in 0.02° steps for 15 h. In refinement, all atom postions (except the hydroxyl H atoms which were given calculated positions) were refined subject to soft constraints, and isotropic atomic displacement parameters (refined for non-H only) constrained according to atom type. Final refinement gave R_{wp} = 7.40%, R_p = 5.40% for 654 reflections and 117 parameters; preferred orientation fraction = 0.807.

1D crystals of lanthanide halides of the form $LnCl_3$ (Ln = La, Nd, Sm, Eu, Gd, Tb or Yb) have been inserted into single-walled carbon nanotubes (SWNTs) using the molten salt capillary filling method; *ca*. 20–40% of all the observed SWNTs were filled with melts in the range 650–910 °C with no observable damage to the carbon tubules; high resolution transmission electron microscopy (HRTEM) studies showed that the nanostructures of the encapsulated crystals varied with tubule diameter.

The unique physical properties of carbon nanotubes[1] have generated considerable interest and the expectation of new types of materials with useful practical applications. Theoretical studies[2–5] suggest that the introduction of foreign materials into their hollow cavities will have interesting effects both on the properties of the filling material and the filled nanotubes. Recently, the filling of SWNTs with Ru, silver metal and other species has been demonstrated.[6–10] Related work has shown that the doping of the interstices of SWNTs with vapour or liquid phase species, including alkali metals, bromine, or charged iodine chains, leads to a 10–100 fold decrease in their measured resistivities and to charge transfer behaviour detectable by Raman spectroscopy.[11,12] Lanthanide (or rare earth) ions have optical and magnetic properties that are particularly interesting when they are situated in a confined geometry. Additionally, as their spectral and dynamic properties alter when the reduced dimensions also affect the chemical and physical properties of the host, these species can act as a local probe for the chemistry and structure of the host material.[13] We present here preliminary results with respect to the incorporation and low-dimensional crystallisation properties of lanthanide halides within SWNTs.

Single-walled carbon nanotubes can be filled both by solution–deposition[6] or by capillarity[7–10] providing, in the latter case, that the filling medium has a surface tension in the range 100–200 mN m^{-1} and a melting temperature ideally below 900 °C.[7,14] The lanthanide halides $LnCl_3$ (Ln = Y, La, Pr, Nd, Gd or Dy) have surface tensions that fall below this threshold in the temperature range 820–950 °C.[15] In this study, we describe the filling properties of three of these halides (Ln = La, Nd and Gd) and four additional halides (Ln = Sm, Eu, Tb and Yb) for which surface tension data were unavailable (Table 1) but for which similar melting behaviour is assumed.

Samples of SWNTs were prepared by a high yield arc synthesis method.[16] The as-prepared SWNTs (*ca.* 30 mg) were intimately mixed with the anhydrous halides (*ca.* 70 mg) by grinding in an agate mortar and pestle under dry-box conditions. The samples were sealed under vacuum in a silica quartz ampoule that was then attached to the tip of a thermocouple and placed in a tube furnace. The temperature was slowly raised (3–5 °C min^{-1}) to a target temperature of *ca.* 10–50 °C above the melting point of the respective lanthanide chloride (Table 1), held at this temperature for 1 h and then furnace cooled to room temp. The specimens were characterised in a JEOL JEM-3000F FEGTEM operated at 300 kV (coefficient of spherical aberration (C_s) = 0.57; point resolution = 0.16 nm). Images were acquired digitally on a Gatan model 794 (1 k × 1 k) CCD camera, and the magnification was calibrated accurately using Si <110> lattice fringes. Energy dispersive X-ray microanalysis (EDX) was performed with a LINK 'ISIS' system using a 0.5 nm diameter electron probe.

All the lanthanide halides in Table 1 filled 20–40% of the observed SWNTs with continuous lanthanide halide single crystals. The HRTEM micrograph in Fig. 1(a) shows an example of $TbCl_3$ filling observed within a SWNT bundle. An enlargement of the tubule on the periphery of the bundle

Table 1 Surface tension data and synthesis conditions for lanthanide halides incorporated into SWNTs

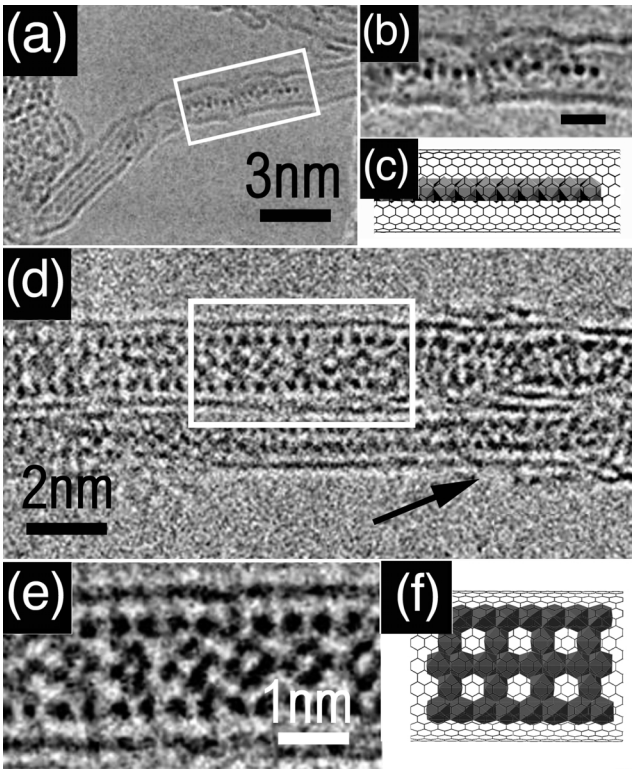

Fig. 2 (a) HRTEM micrograph showing a twisted 1D chain of $GdCl_3$ formed within a (10,10) SWNT. (b) Enlargement of boxed region from (a) showing a linear array of dark spots which terminates towards the right of the micrograph (scale bar = 1 nm). (c) Structural representation showing a 'top-down' view of (b) [*i.e*. similar to Fig. 1(c) but rotated 90°] about the SWNT axis). (d) Bundle consisting of one wide (*ca.* 2.5 nm) and one narrow (arrow = *ca.* 1.6 nm) SWNT both filled with $NdCl_3$. (e) Enlargement of the boxed region in (d) showing the unusual microstructure of the $NdCl_3$ filling. (f) Suggested structural model for (e).

[Fig. 1(b)] reveals that the crystal images as a 'zigzag' array of dark spots which we take to be a chain of $TbCl_x$ polyhedra. Most of the dark contrast in the 1D arrays must originate from the strongly scattering Tb^{3+} centres with the coordinating Cl^- ions being effectively invisible. Groups of three adjacent spots are arranged into nearly equilateral triangles of side *ca*. 0.47 nm. The bulk structure of $TbCl_3$ consists of $TbCl_9$ polyhedra arranged into a 3D hexagonal network (*i.e*. UCl_3-type[17,18]). Within the confines of the 1.6 nm diameter SWNT in Fig. 1(b), it is possible only to accommodate 1D polyhedral chains from the 3D structure, as shown in Fig. 1(c). The individual polyhedra within the chains are likely to be of reduced coordination owing to lattice terminations enforced by capillary confinement and the likeliest candidate structure is therefore a 1D network of edge-sharing $TbCl_6$ octahedra as depicted on the right of Fig. 1(c) (*cf.* $CdCl_2$[18]) and in detail in Fig. 1(d). We have recently reported a related reduction in coordination of 6:6 to 4:4 coordination for bilayer KI crystals incorporated into SWNTs.[19]

Fig. 2(a) shows a 1D chain of $GdCl_3$ incorporated into a 1.4 nm SWNT. The SWNT is bent into an 'elbow' and, on either side of the bend, the crystal images with different contrast suggesting a different orientation formed as a result of a twist induced by the bend. On the right of the bend, the crystal images as an apparently linear array of dark spots, as can be seen in the enlargement in Fig. 2(b). In this case we assume that the crystal has a similar structure to that depicted in Fig. 1(c) but that it is rotated 90° about the SWNT axis [*i.e*. relative to Fig. 1(c)] so that the polyhedral chain is viewed in 'top down' projection as depicted in Fig. 2(c). This crystal can also be seem to terminate within the SWNT capillary.

Fig. 2(d) shows a bundle of two SWNTs, one wide (*ca*. 2.5 nm) and the other narrow (*ca*. 1.6 nm), corresponding approximately to (12,12) and (20,20) SWNTs, respectively, both of which are continuously filled with crystalline $NdCl_3$. This crystal has an unusual microstructure as can be seen by the enlargement in Fig. 2(e). The encapsulated crystal consists of two linear 1D arrays of dark spots separated, in the middle, by a continuous series of groups of four dark spots arranged into diamonds. This microstructure cannot readily be reconciled with the bulk structure of $NdCl_3$,[18] but may instead correspond to the suggested arrangement in Fig. 2(f) in which 'diamond' arrays of $NdCl_x$ polyhedra formed along the centre of the SWNT are bounded by 1D arrays of $NdCl_x$ polyhedra formed along their walls. This arrangement is based using a similar interpretation as for Figs. 1(b) and 2(b), *i.e*. that each dark spot corresponds to a heavy Ln^{3+} centre within one or more $LnCl_x$ polyhedra viewed in projection.

In conclusion, we have demonstrated the first example of lanthanide halide insertion into SWNTs in high yield by a simple and reproducible method, and have also found that the diameter of the host SWNT profoundly influences the obtained structure of the filling material. The nature of these related crystallisation phenomena within SWNTs will be discussed more fully in a forthcoming publication. Experiments are also under way in our laboratory to understand the filling mechanism and to investigate the physical properties of these novel composites.

Polycyclitols. Novel conduritol and carbasugar hybrids as a new class of potent glycosidase inhibitors

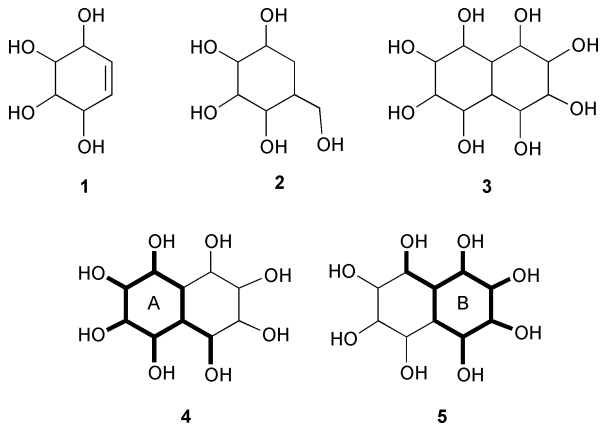
Goverdhan Mehta* and Senaiar S. Ramesh

Department of Organic Chemistry, Indian Institute of Science, Bangalore, 560 012, India

Received (in Cambridge, UK) 6th September 2000, Accepted 31st October 2000
First published as an Advance Article on the web 22nd November 2000

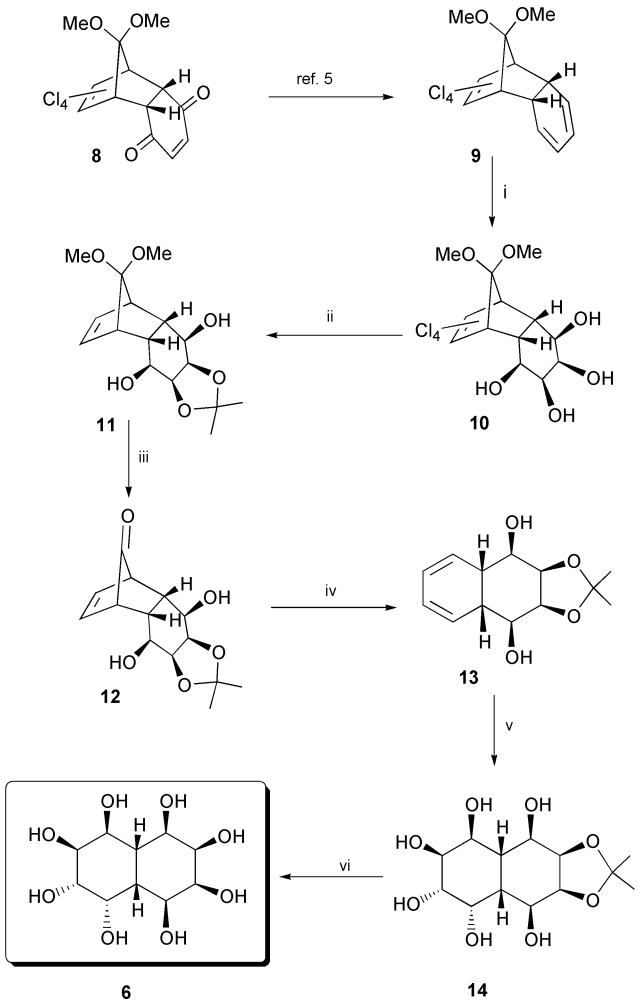
We have conceptualized new molecular entities (bicyclitols) in which two conduritol and two carbasugar moieties are embedded in a polyhydroxylated decahydronaphthalene framework and achieved their syntheses in a stereo- and regioselective manner. One of the bicyclitols was found to be a potent and selective α-glucosidase inhibitor.

Conduritols **1** (six diastereomers designated A–F are known)[1] and carbasugars **2** are a class of polyhydroxylated cyclohexanoids that have evoked a great deal of synthetic interest in recent years.[1,2] In view of their promising therapeutic potential in the management of wide ranging disorders like diabetes, viral infections, HIV and cancer among others, many analogues and structural variants of **1** and **2** have been synthesized and their biological activities, particularly glycosidase inhibition has been evaluated.[3] Considering the fundamental importance of competitive and specific glycosidase inhibition in new drug development, we have conceived of a new family of polyhydroxylated polycyclic systems (polycyclitols) represented by **3** as potential glycomimics.[4] Bicyclitol **3** is an interesting entity which can be considered as a hybrid of two conduritols with shared, common ring junction carbon atoms. Alternately, **3** can be regarded as a hybrid of two carbasugars A and B (see, bold portions in **4** and **5**), both of which are ring annulated. Herein,



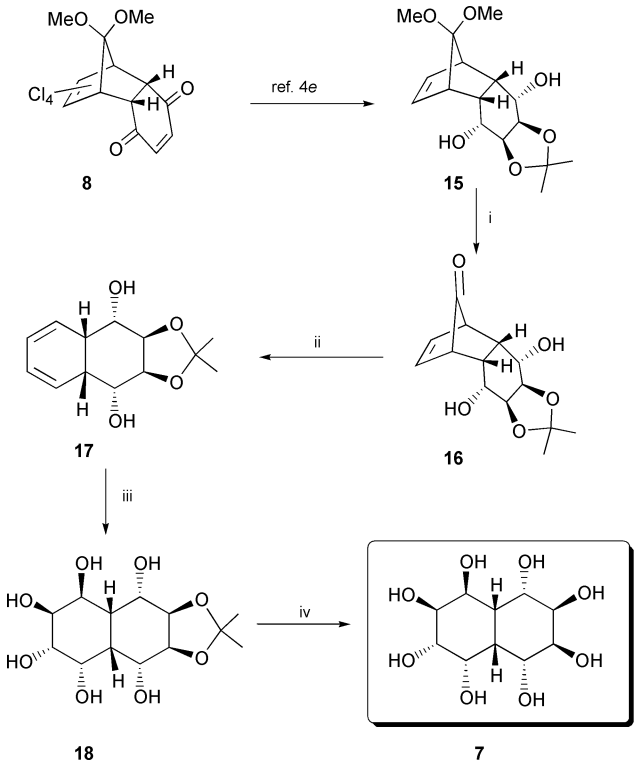
we report the stereo- and regioselective syntheses of two polycyclitols **6** and **7** based on the general structure **3**, and show that one of them **6** is a potent and selective inhibitor of α-glucosidase.

Our synthesis of **6** emanated from the readily available Diels–Alder adduct **8** of 5,5-dimethoxy-1,2,3,4-tetrachlorocyclopentadiene and *p*-benzoquinone, which was elaborated to the tricyclic diene **9** following the tactically modified literature procedure.[5] Exhaustive OsO_4 mediated dihydroxylation of **9** occurred exclusively from the *exo*-face to furnish the all *cis*-tetrol **10**.[6] Selective monoprotection and reductive dechlorination in **10** led to the symmetrical **11**.[6] Careful deketalisation in **11**, while retaining the acetonide protective group led to the desired norbornen-7-one† **12**, Scheme 1. Thermally induced decarbonylation in **12** to the cyclohexadiene derivative **13**[6] was smooth and further catalytic, OsO_4 mediated double dihydroxylation proceeded stereoselectively to furnish **14** as a single diastereomer. Acetonide deprotection in **14** provided the octahydroxydecahydronaphthalene **6**,[6] a hybrid of conduritols D (right ring) and E (left ring), Scheme 1. The absence of symmetry in **6** and **14**, revealed through the presence of 10 and 13 lines, respectively, in the ^{13}C NMR spectra, uniquely settled the stereochemical pattern present in these bicyclitols. Bicyclitol **6** was screened against α- and β-glucosidases (from Bakers' yeast and almonds, respectively) that accept corresponding *p*-nitrophenylglycosides as substrates and it was very satisfying to find impressive inhibition of α-glucosidase with a K_i value[7] of 12 μM (*cf.* K_i = 25.4 μM for deoxynojirimycin, DNJ). Interestingly, **6** exhibited no significant inhibitory activity



Scheme 1 *Reagents and conditions*: i, OsO_4 (cat.), NMMO, Me_2CO:tBuOH (5:2), 2 d, 66%; ii, (*a*) Amberlyst-15, acetone, mol. sieves 4 A, 75%; (*b*) Na, liq. NH_3, THF, EtOH, 49%; iii, Amberlyst-15, acetone, 98%; iv, $C_6H_5NO_2$, 160 °C, 62%; v, OsO_4 (cat.), NMMO, $Me_2CO:H_2O$:tBuOH (5:5:2), 85%; vi, 30% CF_3COOH, 95%.

DOI: 10.1039/b007224i



Scheme 2 *Reagents and conditions*: i, Amberlyst-15, acetone, 95%; ii, $C_6H_5NO_2$, 160 °C, 34%; iii, OsO_4 (cat.), NMMO, Me_2CO:H_2O:tBuOH (5:5:2), 73%; iv, 30% CF_3COOH, 90%.

against β-glucosidase at mM concentration, thus highlighting its selectivity towards α-glucosidase.

The promising inhibitory profile of **6**, spurred us to prepare a diastereomer **7** of **6**. Diels–Alder adduct **8** was readily transformed to the *endo*,*endo*-diol-**15**.[6] Deketalisation to **16** and decarbonylation led to the cyclohexadiene derivative **17**,[6] Scheme 2. Catalytic OsO_4 mediated double dihydroxylation was once again highly diastereoselective and the hexahydroxyacetal **18** was obtained. Acetonide deprotection in **18** delivered the projected bicyclitol **7**,[6] a hybrid of conduritols A (right ring) and E (left ring). Once again the lack of symmetry (^{13}C NMR) in **7** and **18**, uniquely delineated the stereochemical pattern generated during the double dihydroxylation of **17**. When **7** was evaluated for its inhibitory activity against α- and β-glucosidases, no significant inhibition was observed for either of the enzymes at mM concentrations, indicating that stereochemical alterations in the hydroxy substituents has a major impact on the enzyme inhibitory activity (*cf.* **6**). This result provides further impetus to prepare many more diastereomers of **6** and **7** for further evaluation and efforts towards that end are underway.

In short, we have devised a new family of glycosidase inhibitors, composed of conduritol and carbasugar hybrid structures and describe the synthesis of an octahydroxydecahydronaphthalene, which exhibits significant and selective α-glucosidase activity.

We thank JNCASR for financial support and the SIF facility at I.I.Sc for the high field NMR spectra. One of us (SSR) thanks CSIR for a research fellowship. We thank Dr Utpal Tatu, Department of Biochemistry for help in enzymatic assays.

A simple regiospecific strategy for labelling hydrogen atoms in α-amino acids

Received (in Cambridge, UK) 21st September 2000, Accepted 31st October 2000
First published as an Advance Article on the web 22nd November 2000

Simple methods for the regioselective introduction of deuterium labels at the α- and β-carbon atoms of leucine using a Co(III) imino acid complex are described which have a general applicability to the synthesis of a range of labelled amino acids.

Deuterium labelled amino acids are useful probes of protein structure[1] and biosynthetic pathways for interesting, potentially useful, metabolites.[2] As such they are significant synthetic targets and a substantial catalogue of synthetic[3] and biosynthetic[4] strategies for the preparation of labelled α-amino acids now exists in the literature. Many of these strategies involve complex, multi-step syntheses and their application as universal methods for the preparation of families of deuterium labelled amino acids is limited by relatively low yields or relatively high substrate specificity. Given these restrictions, a simple and general synthetic strategy has been developed by which the metal ion activation and protection of sites in α-imino acids coordinated to Co(III) may be harnessed to incorporate, regioselectively, deuterium or tritium labels on the α- and β-carbon atoms of various α-amino acids.

Syntheses of α-amino acid complexes of Co(III) are readily achieved by intramolecular condensation of coordinated amido ion (NH_2^-) with an α-keto acid coordinated *cis* to the amido ion,[5] Scheme 1. These ammine complexes have three useful properties: the complexes are substitutionally inert, the imine is protected from hydrolysis in aqueous solution, and sites, including the imine-N, imine-C and β-carbon atoms are activated for further reaction. For example, the protons on the β-carbon of $[Co(NH_3)_4(2\text{-iminopropanoate})]^{2+}$ readily exchange with deuterium ions in dilute NaOD solution. Then, it is possible to reduce, rapidly, the imino acid ligand to the corresponding amino acid (alanine) with BH_4^- ion in dilute, basic solution without significant reduction of the metal centre.[5] These reactions can be employed to prepare a range of amino acids containing a specific deuterium label at the α-carbon using BD_4^- ion and/or at the β-carbon using basic D_2O and BD_4^- or BH_4^-. To illustrate this strategy, the synthesis and isolation of three deuterium-labelled analogues of leucine are described.

The leucine–iminato complex, **3**†, was prepared by a method analogous to that for the alanine–iminato complex.[5] The 4-methyl-2-oxopentanoate complex, **2**, was treated with aqueous base to induce intramolecular condensation between the coordinated α-keto acid and amido ion, Scheme 1. Treatment of **3** with sodium borodeuteride (at pH 10) for 60 s gave **4**,‡ in which the α-carbon of the coordinated leucine was completely labelled with deuterium. A sample of **3** was dissolved in a carbonate–deuterium carbonate buffer (pD 10) and exchange of the protons on the β-carbon for deuterium was monitored by ^1H NMR spectrometry to completion. The isolated complex, **5**, was then treated with either sodium borohydride or sodium borodeuteride to prepare the corresponding complexes **6** and **7**,‡ in which coordinated leucine was labelled with deuterium at the β-carbon and at the α- and β-carbon atoms, respectively. Direct introduction of the D label from BD_4^- ion at the α-C atom occurs even in H_2O and base catalyzed proton exchange at the β-C atom leads to capture of D^+ from D_2O. Complexes **3**–**7** were purified by cation-exchange chromatography to remove traces of cobalt(II) generated during their preparation.

The deuterium labelled amino acids **8**–**10**§ were isolated following treatment of the corresponding Co(III) complexes (**4**, **6**, **7**) with excess ammonium sulfide and filtration to remove precipitated CoS. They were purified by ion exchange chromatography (dilute aqueous ammonia as eluent)[6] and characterized by ^1H and ^{13}C NMR spectrometry, microanalysis and electrospray mass spectrometry. Examples of ^{13}C NMR spectra of the deuterium labelled leucine are reproduced in Fig. 1. Coupling between the deuterium labels and the α- and β-carbon atoms generates characteristic splitting patterns in the peaks assigned to these atoms.

Analogous chemistry has been used to introduce deuterium labels into other amino acids, including glycine, alanine and valine, details of which will be published elsewhere. A wide range of (α-imino acidato)cobalt(III) complexes is also readily accessible by oxidation of the corresponding (α-amino acidato)cobalt(III) complexes with $SOCl_2$[7] and the chemistry described here whould provide the means to prepare selectively labelled analogues of many amino acids. The methods are

simple, rt processes and the pure amino acids can be recovered readily.

The stereoselectivity of the chemistry used to prepare the labelled amino acids needs to be addressed. The products isolated from tetraammine complexes are racemic but they can be resolved readily with chiral ion exchange eluents. However, similar chiral cobalt(III) reagents also influence the imino acid[8] reductions stereoselectively and a report on this issue is currently being prepared.

Electrospray mass spectrometric analysis of labelled amino acids by Dr Margaret Shiel and associates of the Department of Chemistry, University of Wollongong, NSW is gratefully acknowledged.

Notes and references

† When necessary, compounds were purified by cation-exchange chromatography (Dowex 50W-X2, 200–400 mesh, BioRad) using HCl solutions as eluents.

For **2**: $[(NH_3)_5Co(OH_2)](ClO_4)_3$[9] (5.00 g, 10 mmol) was added to sodium 4-methyl-2-oxopentanoate (6.1 g, 40 mmol) in $HClO_4$ solution (0.4 M, 4 mmol). The mixture was heated at 45 °C for 3.5 h and the resulting precipitate recrystallized from hot water, producing scarlet crystals of **2** (3.9 g, 76%). δ_H(0.1 M DCl) 4.1 (12 H, br, *cis* 4 × NH_3) 3.5 (3 H, br, *trans* NH_3), 2.73 (2 H, d, β-CH_2), 2.19 (1 H, m, γ-CH), 0.99, 0.98 (6 H, d, 2 × CH_3); δ_C(0.1 M DCl) 188.2 (α-C=O) 174.0 (β-C=O), 44.7 (γ-CH_2), 26.5 (δ-CH), 22.7 (2C, s, 2 × CH_3) (Found: C, 15.3; H, 5.3; N, 15.3; Cl, 14.9; Co, 12.6%. $C_6H_{24}N_5O_{11}Cl_2Co$ requires C, 15.26; H, 5.12; N, 14.83; Cl, 15.02, Co, 12.48%).

For **3**: **2** (3.6 g, 7.6 mmol) was dissolved in NaOH (0.08 M, 7.6 mmol) and stirred at 25 °C (30 s) before addition of acetic acid to pH 4.0. The orange product, **3**, was eluted from ion exchange resin (H^+ form), evaporated to dryness and recrystallized from water by the addition of $HClO_4$ (70%, CAUTION) (2.1 g, 59%). δ_H(0.1 M DCl) 4.1 (3 H, br, NH_3) 3.6 (6 H, br, 2 × NH_3), 3.3 (3 H, br, NH_3), 2.95 (2 H, d, β-CH_2), 2.13 (1 H, m, γ-CH), 0.99, 0.98 (6 H, d, 2 × CH_3); δ_C(0.1 M DCl) 187.6 (O–C=O), 173.0 (α-C=N), 42.3 (β-CH_2), 26.2 (γ-CH), 21.5 (2C, s, 2 × CH_3) (Found: C, 15.6; H, 4.9; N, 15.2; Cl, 14.5; Co, 12.7%. $C_6H_{22}N_5O_{10}Cl_2Co$ requires C, 15.87; H, 4.88; N, 15.42; Cl, 15.61; Co, 12.98%).

‡ For **4**: **3** (0.25 g, 0.8 mmol) was dissolved in a carbonate–bicarbonate buffer solution ($[CO_3^{2-}]$ = $[HCO_3^-]$ = 0.5 M) and $NaBD_4$ (0.08 g, 4 mmol) added. Following vigorous mixing (60 s) the product was rapidly trapped on ion exchange resin (Na^+ form) by suction and washed with water and 0.5 M HCl and the orange product eluted with 2 M HCl. Evaporation gave an orange solid, **4**. The labelled amino acid was removed from this complex without further purification.

Complexes **6** and **7** were prepared by analogous treatment of **5** with $NaBH_4$ and $NaBD_4$, respectively. For **5**: **3** (1.5 mmol, 0.50 g), was dissolved in a carbonate–deuteriobicarbonate buffer ($[CO_3^{2-}]$ = $[DCO_3^-]$ = 0.25 M, pD = 10.0). The resulting deep orange solution was stirred at 25 °C for 10 h and the orange product, **5**, was isolated as above.

§ For **8**–**10**: Complexes **4**, **6** and **7** were individually dissolved in water (10 cm^3) and an 8% solution of $(NH_4)_2S$ added dropwise to reduce and precipitate the cobalt. The resulting CoS suspensions were removed by filtration and the solutions desalted on ion exchange resin (H^+ form); the sorbed material was washed with water before eluting with 0.5 M ammonia solution. Fractions containing the amino acids were evaporated and recrystallized twice from H_2O–propan-2-ol to give white powders (yields from **2** to isolation ~50%). **8**: $\delta_H(D_2O)$ 1.70 (1 H, m, γ-CH), 1.75 (2 H, ABXq, β-CH_2), 0.97, 0.98 (6 H, d, 2 × CH_3); δ_C (D_2O) 187.9 (COOH), 56.8 [1C, t, *J*(CD) 24 Hz, α-CD], 42.4 (β-CH_2), 24.9 (γ-CH), 20.9, 21.0 (2 × CH_3); *m/z* (ES-MS) 133.0 (M^+) (Found: C, 54.4; H, 9.13; N, 10.5%. $C_6H_{12}DNO_2$ requires C, 54.52; H, 9.15; N, 10.6%). **9**: $\delta_H(D_2O)$ 3.73 (1 H, s, α-CH) 1.69 (1 H, m, γ-CH), 0.97, 0.98 (6 H, d, 2 × CH_3); $\delta_C(D_2O)$ 187.8 (COOH) 56.5 (α-CH), 42.3 (1C, m, CD_2), 24.5 (γ-CH), 19.9, 20.9 (2 × CH_3); *m/z* (ES-MS) 134.0 (M^+) (Found: C, 53.2; H, 8.5; N, 10.4%. $C_6H_{11}D_2NO_2$ requires C, 54.1; H, 8.32; N, 10.5%). **10**: δ_H (D_2O) 1.70 (1 H, m, γ-CH), 0.97, 0.98 (6 H, d, 2 × CH_3); $\delta_C(D_2O)$ 187.9 (COOH), 56.6 [1C, t, *J* (CD) 24.45 Hz, α-CD], 42.4 (1C, m, β-CD_2), 24.5 (γ-CH), 19.8, 20.9 (2 × CH_3). *m/z* (ES-MS) 135.0 (M^+) (Found: C, 53.9; H, 7.50; N, 10.3%. $C_6H_{10}D_3NO_2$ requires C, 53.7; H, 7.51; N, 10.4%).

The copper-catalysed S_N2' addition of ZnR_2 to allylic (*Z*)-ArCH=C(CH_2X)(CO_2Et) (X = Br, Cl, OSO_2Me) fashions only ArCH(R)C(=CH_2)(CO_2Et); use of a chiral ligand gives up to 64% ee for this demanding reaction.

The reactions of organometallic nucleophiles, MR, with allylic halide (or pseudohalide) substrates $R^1CH{=}CR^2CH_2X$ often lead to a mixture of S_N2 (attack α to the leaving group X) and S_N2' (attack γ to X) products.[1] This feature causes problems in metal-catalysed asymmetric γ-additions to unsymmetrical allylic electrophiles where the catalyst must control both the regio- and enantioselectivity. Catalysts showing superlative selectivity for both these aspects are rare.[2–6] Pointers in the stoichiometric literature suggested to us that the regiochemical problem might be overcome with substrates where R^2 is an ester function[7] and if an organozinc reagent[8] is used as the terminal organometallic in the catalytic cycle. In particular, we were keen to apply these ideas to enantioselective copper-catalysed S_N2' additions of MR to allylic halides as very few successes have been reported for this otherwise intrinsically useful transformation.[9,10] Aside from controlling the regiochemistry the ester could play two additional roles. Firstly, a more rigorously bound asymmetric transition state might be attained, *via* carbonyl co-ordination. Secondly, the products from such carbonyl containing substrates are present in many compounds of biological interest.

The allylic bromides **2** (Scheme 1) were selected for initial trials with commercial $ZnEt_2$ to demonstrate the viability of this approach. Compounds **2** are attractive as they are available in just two, chromatography-free, steps *via* known Baylis–Hillman chemistry (Scheme 1).[11] Additionally, bromination of **1** proceeds with very high (*Z*)-selectivity[12] to afford solid products which may be crystallised to high chemical and stereochemical purity. Simple mixture of THF solutions of **2** and $ZnEt_2$ in the presence of $[Cu(MeCN)_4]BF_4$[13] (3 mol%) at −20 °C leads to rapid formation of **4** (R = Et) as apparently the

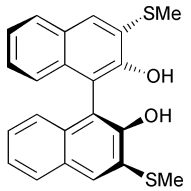
sole product (Scheme 1). Extremely high chemo- and regioselectivity, technical simplicity, and high rate ($\sim$50 TON h^{-1}) characterise these reactions (Table 1).† The reactions can be run at even lower copper loadings, for example, **2a** gives a near quantitative yield of **4a** (R = Et) at 0.5 mol% Cu^{I} (>290 TON h^{-1}). In the absence of Cu^{I} polar co-solvents are necessary to provide high chemical yields[7] (in the absence of any copper, yields of <12% were attained in our control reactions). The new catalytic protocol is superior to use of classical Gilman cuprates. For example, reaction of **2a** with $LiCuMe_2$·LiI in THF affords only a 8:1 $S_N2':S_N2$ mixture. Compounds **4** (R = Et) are the intimate precursors of a number of biologically active molecules showing, for example, inhibition of *angiotensin-converting* and *epithelial neutral endopetidase* enzymes[14] or those showing molluscicidal activity against endoparasite carrying *Biomphalaria glabrata*.[15]

Preliminary approaches to rendering these reactions viable as catalytic asymmetric syntheses are also reported in Table 1.† Relatively high copper and ligand loadings were used to maximise the asymmetric induction obtained as this is noted to be a problematic area.[9,10] Ligand **7** was selected as an initial



(S_a)-**7**

candidate based on its efficacy in asymmetric conjugate addition.[16] Varying the leaving group indicated chloride to be the best leaving group with respect to enantioselectivity, although the chemical yield suffered somewhat in this case. Very high chemical yields were realised with the mesylate **6**, but the product **4a** is essentially racemic, while the formate **5** does not participate in the reaction. Ligand **7** was confirmed as the optimal structure by screening a small library of compounds against a test reaction of **3a** with $ZnEt_2$; none of the other structures lead to very active catalysts. Similarly, changing to a terminal $AlEt_3$ organometallic source is not tolerated.

In conclusion, a new type of efficient catalytic S_N2' chemistry has been developed. The degree of stereocontrol realised in these reactions appears to be due more to electronic than steric factors, however, more experiments are required before the details of the asymmetric transition state become clear. These studies together with applications of the compounds **4** to the synthesis of biologically active compounds are underway in our laboratories.

We thank the EPSRC for support of this project through grants GR/M75341, GR/M84909, GR/N37339 and for access to their Mass Spectrometry Service (University of Swansea). S. G. and S. W. are grateful to the EU for support through COST (working groups D12/0009/98 and D12/0022/99) and SOCRATES. J. G. acknowledges the support of the Generalitat de Catalunya.

Notes and references

† *Representative procedures and compound data.* An argon-protected solution of $[Cu(MeCN)_4]BF_4$ (6.3 mg, 0.02 mmol, 3 mol%) in THF (0.7 cm^3) at −20 °C was treated sequentially with solid **2b** (211 mg, 0.67 mmol) and $ZnEt_2$ (1.0 cm^3 of 1.0 M hexane solution, 1.0 mmol). After 40 min the pale yellow solution was quenched with aqueous HCl (2 M, 3 cm^3), the product was extracted with diethyl ether, and the organic fraction dried ($MgSO_4$). The solvent was removed and the product assayed directly by ^1H NMR spectroscopy. In all cases the spectra were consistent with a >20:1 $S_N2':S_N2$ selectivity.

For asymmetric runs, ligand **7** (38 mg, 0.10 mmol, 20 mol%) and $[Cu(MeCN)_4]BF_4$ (15.7 mg, 0.05 mmol, 10 mol%) in dry THF (1 ml) were stirred at −20 °C in the presence of $ZnEt_2$ (0.10 mmol). Solutions of the allylic chloride **3b** (140.2 mg, 0.52 mmol) in THF (0.55 cm^3) and $ZnEt_2$ (0.77 ml of a 1.0 M hexane solution, 0.77 mmol) were added by syringe pump over 20 min and the reaction stirred for a further 20 min at −20 °C. The reaction was worked up as above. In cases (Table 1) where the reaction was not complete unreacted allylic chloride was removed by flash chromatography or treatment with DABCO.

Received (in Cambridge, UK) 30th August 2000, Accepted 26th October 2000
First published as an Advance Article on the web 23rd November 2000

The X-ray crystal structure and electrochemical data of a manganese complex $[L_2Mn_2^{III}(\mu\text{-}O)(\mu\text{-}AcO)_2][PF_6]_2$ with L being an enantiopure C_3-symmetric 1,4,7-triazacyclononane derived from L-proline are compared to those of $[Me_3TACN_2Mn_2^{III}(\mu\text{-}O)(\mu\text{-}AcO)_2][PF_6]_2$; catalytic studies reveal the applicability of the complex in enantioselective epoxidations.

The tridentate macrocycle 1,4,7-triazacyclononane (TACN, **1**) and derivatives thereof, in particular 1,4,7-trimethyl-1,4,7-triazacyclononane (Me_3TACN, **2**), have extensively been used as ligands in the coordination chemistry of transition metals (Scheme 1).[1]

Triazacyclononanes imitate the coordination sphere of the three histidines which are often encountered in metalloproteins and therefore such (TACN) metal complexes are of interest as structural and functional enzyme models as well as catalysts. For example, dinuclear TACN–manganese complexes mimic enzymes like manganese superoxide dismutase and manganase catalase,[2] and in 1994 Unilever reported their use in low-temperature bleaching with hydrogen peroxide.[3] Bein and de Vos described stereospecific epoxidations of unfunctionalised olefins,[4] and with manganese complexes bearing chiral TACN derivatives we[5] and others[6] achieved enantioselective epoxidations. Other applications include oxidations of benzylic alcohols[7] and sulfides[8] to benzaldehydes and sulfones, respectively, and the use of perfluorinated TACN–Mn complexes.[9] Moreover, hydroxylation and hydroperoxidation of poorly reactive hydrocarbons was achieved by the activation with such complexes with acetic acid.[10] Here, we present the synthesis of the enantiopure C_3-symmetric trispyrrolidine-1,4,7-triazacyclononane (TP-TACN, **3**) and describe the preparation and characterisation of its dinuclear manganese complex **5** which is capable of catalysing enantioselective epoxidations.

TP-TACN **3** was obtained as an air-sensitive colourless oil by reduction of L-proline-derived cyclotripeptide **4**[11] with a large excess of borane–tetrahydrofuran (Scheme 2).[12] Isolation of the product was achieved by addition of MeOH to destroy the excess of borane followed by refluxing in 4 M HCl–dioxane. Treatment of this acidic mixture with solid NaOH followed by extraction with DCM liberated the triamine. Distillation of the crude product under reduced pressure (120–125 °C; 2.6 10^{-1} mbar) afforded **3** in 83% yield.† The dinuclear manganese(III) complex **6** (74% yield)‡ crystallised from a solvent mixture of MeOH and water containing triamine **3**, manganese(III) acetate, sodium acetate and ammonium hexafluorophosphate providing single crystals suitable for X-ray diffraction analysis.§ The comparison of selected bond distances and angles of **6** with the corresponding values of Wieghardt's Me_3TACN manganese complex **5**[2a] reveals the structural similarity between both compounds. For example, the Mn–Mn distances in **6** [average value 3.155(2) Å] and the one in **5** [3.149(3) Å] overlap within their threefold standard deviation. Similarly, the Mn–O–Mn angle in **6** is 122.2(3)°, while the one reported for **5** is 120.9(1)°.

From temperature-dependent (4–300 K) magnetic susceptibility measurements (SQUID magnetometer) of solid **6** a ferromagnetic coupling (J = +4.6 cm^{-1}; $H = -2JS_1 \times S_2$; $S_1 = S_2 = 2$; $D1 = D2 = 2.3$ cm^{-1}; $g1 = g2 = 1.992$) yielding an $S = 4$ ground state was established in agreement with **5**.

Fig. 1 shows the X-band EPR spectra of the electrochemically generated one electron reduced and oxidised states of the PF_6-salt of **6** in acetonitrile at 30 K. A detailed analysis of the multiline spectra is currently under investigation and will be published elsewhere.

The electrochemical properties of **5** and **6** have been studied by cyclic voltammetry (CV) under identical conditions in acetonitrile solution containing 0.1 M tetra-*n*-butylammonium hexafluorophosphate ($TBAPF_6$) as supporting electrolyte in the potential range +1.6 to −1.0 V. All redox potentials are referenced *vs.* the ferrocenium/ferrocene couple (Fc^+/Fc). Scheme 3 summarises the data.

The CV of **6** exhibits one reversible one-electron reduction at $E_{1/2}$ = −0.62 V corresponding to a $Mn^{III/III}$/ $Mn^{III/II}$ transition and, in addition, two successive quasi reversible [ΔE^p = 109 and 87 mV (scan rate: 50 mVs^{-1})] one-electron oxidations at $E_{1/2}$ = 0.51 and 1.12 V corresponding to $Mn^{III/III}$/$Mn^{III/IV}$ and $Mn^{III/IV}$/$Mn^{IV/IV}$ transitions, respectively. Thus, the redox behaviour of **6** is similar to that of **5**, however, all transitons are shifted towards more negative potentials (by 0.1, 0.08 and 0.09 V, respectively). These results show that TP–TACN and its manganese complex are chiral analogues of Me_3TACN and its corresponding metal complex. Furthermore, the CV data reveal that TP–TACN can better stabilise higher oxidation states than Me_3TACN, which could be particularly useful in oxidation

catalysis. In order to probe this hypothesis and to investigate the potential of **3** to serve as an asymmetric catalyst we briefly investigated enantioselective epoxidations of styrenes.

Catalytic activity of **5** was observed in the epoxidation of vinylarenes. With H_2O_2 as oxidant and 2 mol% of catalyst in acetone at −25 °C, approximately 28% conversion of styrene was observed after 2 h giving the corresponding epoxide with 24% ee (*S*-enantiomer; all ee-values were determined by GC using a chiral column). Extending the reaction time to 4 h increased the conversion (*ca*. 88%) of the olefin but reduced the enantioselectivity (15% ee). The significantly greater conversion coupled with the lower enantioselectivity after the longer reaction time suggests that the catalytic species is changing during the course of the reaction. Substituted arenes, such as 3-nitrostyrene and 4-chlorostyrene were epoxidised as well giving products with 26 and 21% ee, respectively.

We are grateful to the DFG (SPP Sauerstofftransfer/ Peroxidchemie) and the Fonds der Chemischen Industrie for support of this research. We thank Professor Dr Wieghardt, Dr Bill (MPI für Strahlenchemie, Mülheim) and Professor Dr Kölle (RWTH Aachen) for helpful discussions. We also acknowledge Dr Lehmann (MPI für Kohlenforschung, Mülheim) for the X-ray diffraction data collection.

One-step synthesis of ordered mesocomposites with non-ionic amphiphilic block copolymers: implications of isoelectric point, hydrolysis rate and fluoride†

Received (in Columbia, MO, USA) 7th July 2000, Accepted 18th October 2000
First published as an Advance Article on the web 24th November 2000

Highly ordered hexagonal silica/block copolymer mesostructured composites have been prepared using syntheses with fluoride over a wide range of pH conditions (pH 0–9), by controlling the rates of hydrolysis and condensation of the tetramethoxysilane silica source.

Highly ordered mesoporous silica structures have now been well demonstrated through the use of cationic surfactant (S^+) and anionic silica moieties (I^-) under basic pH conditions[1,2] or by using cationic silica (I^+) assembly through hydrogen bonding mediation with either cationic surfactants (S^+)[2] or hydronium ion solvated neutral block copolymers [$N^0(H_3O^+)$].[3,4] Pinnavaia and coworkers[5,6] have shown that worm-like mesostructures with monodispersed pore sizes can be obtained using non-ionic surfactants (N^0) and partially ionized silica [$N^0(H_3O^+)I^-$] at neutral pH. Prouzet and coworkers[7] have obtained similar results by starting with a clear [$N^0(H_3O^+)X^-I^0$] solution at pH *ca.* 2 and increasing condensation by adding fluoride.

In both the ordered and disordered worm-like structures that have been obtained, a common feature is the independent control of hydrolysis and silica polymerization. For example, highly ordered mesostructures can be created by varying the pH and charge on the silica species at high pH[8] or alternatively near the isoelectric point[9] where the rate of silica polymerization can be readily controlled. Hydrogen-bonding interactions, such as occur among polyethylene oxide–polypropylene oxide–polyethylene oxide (PEO–PPO–PEO) triblock copolymers and silica species in acid media, facilitate simultaneous synthesis and processing of ordered mesostructured materials into thin films,[10] fibers[11] and monoliths.[12] Features of the inorganic species, such as the isoelectric point, associated cations[13,14] and the cosolvent generated on hydrolysis of alkoxide,[15] are important factors in these synthesis approaches.

Fluoride is a well known catalyst for hydrolysis and polymerization of silica species[16] and has been used in the synthesis of mesoporous silica materials under various conditions in order to improve structural order.[5,6,9,17,18] Silva and Pastore[17] first reported the effect of fluoride on synthesis of mesoporous materials with cationic surfactants. Guth and coworkers[18] synthesized mesoporous materials with cationic and non-ionic surfactant species, in the presence of fluoride at a pH between 6.5 and 11. However, use of the non-ionic surfactant species yielded poorly ordered mesostructures compared with those obtained using cationic surfactants. Pinnavaia, Prouzet and their coworkers[6,7] reported the fluoride-mediated synthesis of MSU-*X* materials with worm-like disordered channel structures with poorly defined crystallographic symmetry, using non-ionic surfactant species under neutral conditions. Stucky and coworkers[9] reported synthesis of highly ordered SBA−15 materials using amphiphilic PEO–PPO–PEO triblock copolymer P123 and tetraethoxysilane (TEOS) under acidic conditions (pH ⩽ 3) in the presence of a small amount of fluoride. Here, we report one−step syntheses of well ordered PEO–PPO–PEO/silica mesostructures over a large pH range (0–9), including mild neutral conditions.

The preparation of such materials relies on the control of tetramethoxysilane (TMOS) hydrolysis and silica polymerization in the presence of fluoride and amphiphilic block copolymer, the structure-directing agent. In a typical synthesis batch, 2.0 g of Pluronic P123 ($EO_{20}PO_{70}EO_{20}$, M_{av} = 5800, BASF) was dissolved in 62 g of HCl or NaOH aqueous solution (pH = 0–12) and then 0.3 g of 0.5 M NH_4F solution was added at 313 K with magnetic stirring. To this mixture, 3.2 g of TMOS (98%, Aldrich) was quickly added with vigorous magnetic stirring. The resulting gel mixture was stirred for 1 day at 313 K and aged under static conditions for 1 day at 373 K in an oven. Another set of samples was prepared using P123 and the same procedures, except that NH_4F was not added to the reaction mixtures. The solid products were filtered off and dried at 373 K and subsequently calcined in air at 823 K.

Using these synthesis conditions, clear and homogeneous solutions form first, after which precipitates start to form as the reactions proceed. The times at which precipitates appear are highly dependent on the pH of the reaction mixtures and the presence of fluoride, as shown in Fig. 1. As noted above, the total aqueous solution (TAS) used for the reaction typically consisted of 62 g of HCl or NaOH solution (pH = 0–12). At pH 2 without fluoride, it takes *ca.* 8 h before precipitation begins to occur. This is because pH 2 is near the isoelectric point of silica and the silica polymerization rate is slow under these conditions.[15] Fluoride promotes precipitation, increasing dramatically the rate of silica condensation, for example, more than an order of magnitude at pH 2, due to its catalytic effect on the hydrolysis.[16]

Fig. 2 shows powder X-ray diffraction (XRD) patterns for mesoporous silica produced using structure-directing P123 block copolymer surfactant species and TMOS, with and without fluoride. The patterns in Fig. 2(a) all show an intense

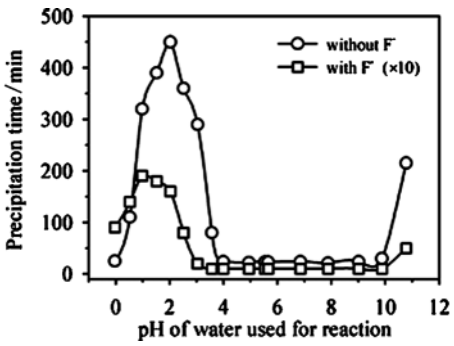

Fig. 1 Silica precipitation time plotted *vs.* pH of the synthesis solutions in the preparation of PEO–PPO–PEO/silica mesophases. The precipitation time is defined to be the cloud point at which the clear reaction mixture forms colloidal silica particles.

† Electronic supplementary information (ESI) available: TEM images and properties for calcined mesoporous silica. See http//www.rsc.org/suppdata/cc/b0/b005608l/

DOI: 10.1039/b005608l

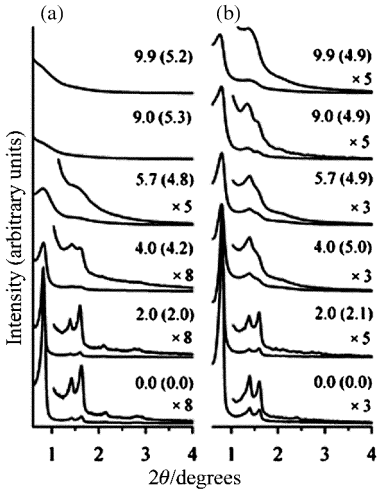

Fig. 2 XRD patterns for calcined mesoporous silica prepared using P123 surfactant species and TMOS: (a) without fluoride and (b) with fluoride. Numbers before parenthesis denote the pH of the precursor HCl or NaOH solution used for the reactions, while the numbers within parenthesis indicate the pH values of the reaction mixture after silica precipitation was complete. The pH of doubly distilled water was 5.7. XRD patterns were collected with a Cu-Kα X-ray source using a Scintag X_2 instrument.

XRD diffraction peak and two or more weaker peaks up to pH 4 (TAS), which are characteristics of a 2-d hexagonally ordered (*P*6*mm*) structure.[1,3,4] This indicates that hexagonal mesoporous silica materials with high mesoscopic ordering are obtained up to pH 4 (TAS) without fluoride. For materials prepared at pH > 4 without F^-, disordered products are obtained. XRD patterns in Fig. 2(b) obtained from the mesoporous silica materials synthesized in the presence of fluoride are very similar to those of the materials obtained without fluoride up to pH 4 (TAS) and indicate the persistence of 2-d hexagonal mesostructural ordering up to pH 9 (TAS). Transmission electron microscopic images for calcined materials confirm that the materials obtained up to pH 9 (TAS) have highly ordered 2-d hexagonal structures.† Lattice parameters, surface areas, pore volumes, and pore sizes are listed in Table 1 (ESI†). It is noteworthy that ordered materials can be obtained from the reaction mixture of P123, doubly distilled water, NH_4F and TMOS without any acid or base catalyst, whereas the absence of fluoride under otherwise identical conditions yields the disordered products [Fig. 2(a)]. A disordered material is obtained at pH 10 (TAS) and there is no precipitation above pH 11 (TAS) with F^-. Morphologies and XRD peak shapes of the hexagonal mesoporous materials are dependent on the reaction pH. Rod-like morphologies, with bundles of silica fibers aligned coaxially with the rods' long axes,[9] are obtained in the SBA-synthesis region below the silica isoelectric point, while above the isoelectric point, where anionic silica species are present, particles with more irregular morphologies are observed.

The results above suggest that suitable oligomeric silica species, formed from fully hydrolyzed monomeric silica species, are needed for interaction with the structure-directing block copolymer to obtain ordered mesostructures. This is due to competition between the condensation of partially hydrolyzed silica species and the hydrolysis of alkoxysilane moieties associated with the silica precursors.[16] Above pH 4 (TAS), silica oligomers may contain the organic moieties from incomplete hydrolysis due to relatively rapid condensation compared to the rate of hydrolysis.[16] The presence of such residual organic moieties leads to weaker interactions between hydrophilic block polymer and silica oligomers, resulting in poorly organized mesocomposites. Indeed, the reaction mixtures above pH 4 without fluoride yield gel-like precipitation and disordered or amorphous silica structures.

On the other hand, addition of fluoride results in the formation of white precipitates and well ordered mesostructures up to pH 9 (TAS). This indicates that hydrolysis of TMOS can be completed before significant condensation of the silica species occurs, which is consistent with the catalytic activity of fluoride for hydrolysis.[16] However, such catalytic activity of fluoride is dependent on the nature of the silica precursors. When TEOS is used as silica source instead of TMOS under the present conditions, ordered mesostructures are obtained up to pH 2.7 with fluoride and disordered mesostructures above pH 2.7[9] because the hydrolysis rate can compete with the rate of condensation. Hydrolysis of TEOS is slower than that of TMOS, because of steric hindrance at ethoxide moieties and reduced solvation of resulting ethanol.[16] The more rapid hydrolysis of TMOS thus makes it a preferable silica precursor to TEOS for producing ordered mesostructures. Nevertheless, such ordered mesostructures can be produced using TEOS or other precursor species, provided the silica sol is pre-hydrolyzed near pH 2[12,19,20] where the hydrolysis rate is fast and the condensation rate is slowest.[15]

In conclusion, highly ordered PEO-PPO-PEO/silica mesostructures can be prepared over a diverse range of pH (0–9) by controlling the relative rates of hydrolysis and condensation of silica species through the use of fluoride and TMOS. Cubic (*Im*3*m*) and 3-d hexagonal ($P6_3/mmc$) block copolymer/silica mesostructures can be synthesized using Pluronic F127 ($EO_{100}PO_{70}EO_{100}$) and Brij 76 [$C_{18}H_{37}(OCH_2CH_2)_{10}OH$] structure-directing surfactant species with TMOS and fluoride near the isoelectric point (pH 2) of silica.

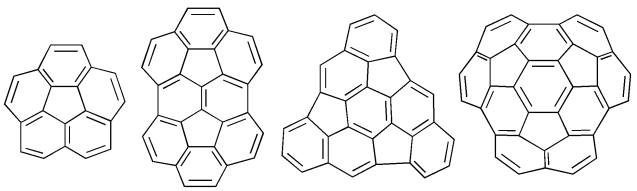
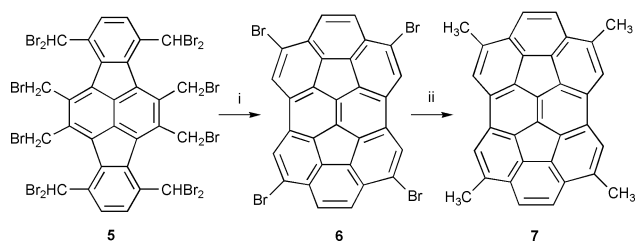
Tetrabromosemibuckminsterfullerene 6, obtained by a novel synthetic route, is converted to the tetramethyl derivative 7; X-ray crystal structure determination of the latter reveals a highly nonplanar, bowl-shaped molecule with solvating CCl_4 molecules separating the hydrocarbon moieties.

The considerable attention given to C_{60} and the family of fullerenes has led to renewed interest in curved-surface polynuclear aromatic hydrocarbons known as fullerene fragments or 'buckybowls.'[1] Corannulene (**1**), first synthesized in the 'pre-fullerene' era, is the smallest member of this family.[2] Several other buckybowls are now known,[1] including two semibuckminsterfullerenes $C_{30}H_{12}$ (**2**[3] and **3**[4]) and the largest to date, circumtriindene $C_{36}H_{12}$ (**4**).[5] Most of the buckybowls



were obtained by flash vacuum pyrolysis (FVP) which involves high temperatures and separation of the precursor molecules in the gas phase; *i.e.* factors believed to be important for the formation of these strained systems.[1] Only recently have more practical, condensed phase alternative synthetic protocols developed.[3b,c,6–8] In this communication we report a novel, convenient route to tetrasubstituted semibuckminsterfullerene **2**, as well as an X-ray crystal structure determination of the tetramethyl derivative. The latter represents the first X-ray crystallographic results for a semibuckminsterfullerene.

Recently we discovered that carbenoid coupling of the dibromomethyl groups of tetrakis(dibromomethyl)fluoranthene leads to the formation of 1,2,5,6-tetrabromocorannulene in high yields.[8] Application of this protocol to dodecabromide **5** is also successful in producing the corresponding tetrabromosemibuckminsterfullerene **6**, although in more modest yield (Scheme 1). Thus, 30 min reflux of **5** in a 3:1 mixture of dioxane and water with sodium hydroxide provides *ca.* 25% yield of **6**.[9] Although the yield of this transformation is similar to that of McMurry coupling,[3b,c] it nonetheless represents a major improvement due to convenience, low cost, and greater reproducibility. The previous method requires long periods of slow addition of the substrate to the reaction mixture (high dilution conditions), as well as strict anhydrous conditions and a deoxygenated environment.[3b,c] None of those requirements are necessary for the present method, since it only involves a short period of reflux in aqueous solvent. Hence this method has much greater potential for the large scale production of **2** and its derivatives.



Scheme 1 *Reagents and conditions*: i, NaOH, dioxane–water (3:1), reflux 30 min, 26%; ii, $AlMe_3$, $NiCl_3$(dppp), DME, reflux 12 h, 80%.

Since the carbenoid coupling of **5** leads cleanly to symmetrically substituted **6**, it provides an opportunity for further elaboration of this novel molecule. For example, the four bromine atoms in **6** can easily be replaced by methyl groups leading to **7**.[10] We have been attempting X-ray diffraction studies of semibuckminsterfullerene **2** for some time. Several crystals of **2** were grown from various solvent systems, but they failed to produce useful X-ray diffraction data as a result of poor scattering or multiple twinning. Thus we sought to finally solve this problem with **7** since it produced attractive crystals from a variety of solvents. But again we encountered difficulties—what appeared to be crystals of high quality under the microscope did not produce good diffraction data. Finally we succeeded with a crystal grown by slow evaporation of a carbon tetrachloride solution.[11]

Crystal structure determination shows that **7** crystallizes with two symmetrically independent solvating carbon tetrachloride molecules (Fig. 1). The ideal molecular point symmetry of **7**(C_{2v}) is reduced in the crystal to C_s. The crystallographic mirror plane passes through the carbon atoms and four chlorine atoms of the solvating CCl_4 molecules and bisects the three central carbon–carbon bonds of **7**. The hydrocarbon part exhibits very significant curvature, forming a well developed bowl as predicted for **2** earlier by theory.[3a] The pyramidalization angles defined by the π-orbital axis vector method (POAV)[12] are highest at the central carbon atoms, then

DOI: 10.1039/b007771m

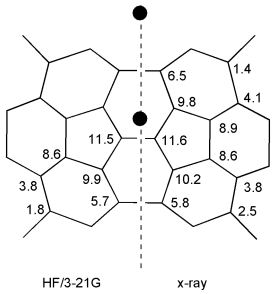

Fig. 2 POAV pyramidalization angles calculated for the crystal structure (right) and for the *ab initio* HF/3-21G optimized geometry (left) of **7**. The dotted line describes the crystallographic mirror plane and the dots represent the solvating CCl_4 molecules.

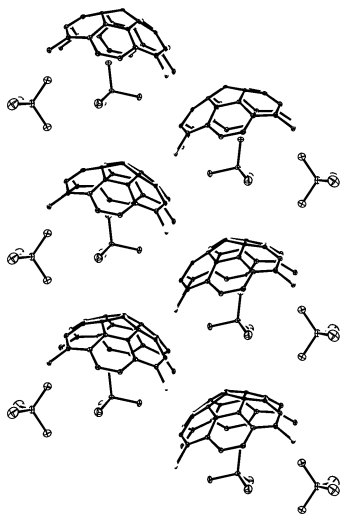

Fig. 3 Crystal packing pattern in **7***2CCl_4. Hydrogen atoms omitted for clarity.

gradually decrease when going toward the rim (Fig. 2). In the region of maximum curvature the pyramidalization of the carbon atoms is quite comparable with that of buckminsterfullerene which has a pyramidalization angle of 11.6°.[12] Comparison of the POAV angles calculated for **7** in the crystal with those based on the *ab initio* optimized geometry of the isolated molecule[13] not only demonstrates the adequacy of the theoretical model, but also suggests that crystal packing forces have very little effect on the curvature of this strained molecule.

Buckybowls have the potential to stack in a concave to convex fashion. Of the very few X-ray crystal structure determinations reported to date, stacking was found in cyclopentacorannulene $C_{22}H_{10}$[14] as well as in $C_{36}H_{10}$,[15] while it is absent in the crystals of corannulene.[16] The present case represents a novel situation, since **7** co-crystallizes with carbon tetrachloride molecules (Fig. 3). One of the solvating CCl_4 molecules separates two molecules of **7** with one of the chlorine atoms in the concave orientation and three chlorine atoms on the convex side. The 'concave' chlorine atom forms twelve nonbonding C···Cl distances in the range of 3.262(7) to 3.501(7) Å, roughly equal or shorter than the sum of the respective van der Waals radii, and in addition, it has six slightly longer C···Cl distances in the range 3.582(7) to 3.747(7) Å. As a consequence of the 'stuffing' of **7** with the solvent molecule, close contacts between the hydrocarbon moieties are minimized. The closest of these, 3.528(9) Å, is between the methyl group carbons, and the nearest intermolecular distance between bowl carbon atoms is 3.654(10) Å. Thus, this solid state arrangement is not, strictly speaking, 'bowl-to-bowl stacking' even though some piling of the solvated molecules is evident.[17]

In conclusion, tetrabromo- and tetramethylsemibuckmisterfullerenes **6** and **7** can be prepared by a convenient, non-pyrolytic route that allows for scale-up. Moreover, the crystal structure of **7** shows that the curvature of this system, at least in the interior region of maximum curvature, is comparable to buckminsterfullerene.

Received (in Cambridge, UK) 25th September 2000, Accepted 31st October 2000
First published as an Advance Article on the web 24th November 2000

The adsorption of a cationic azobenzene derivative into both siliceous and aluminium containing mesoporous silica films has been investigated; photoisomerization was found to occur in the temperature range 80–300 K and the mesoporous aluminium containing silica films were proved to be useful reaction media to immobilize organic photochromic species.

Mesoporous materials prepared by supramolecular templating approaches can accommodate guest species in their pores to form host–guest complexes and the resulting nanocomposites may exhibit useful functions in the areas of catalysis, adsorption and sensing.[1] Here we report the synthesis of the aluminium containing mesoporous silica films for the first time and applied these as nano-reactors for organic photochemical reactions. Photochemistry in constrained media is a growing new field which yields a wide variety of useful applications including sensitive optical media, reaction pathways for controlled photochemical reactions, and molecular devices for optics.[3] For such applications, mesoporous silica films possess attractive features such as large surface areas and porosity, controllable pore sizes, reactive pore surfaces, and stability over a wide temperature range.

In the present study, the introduction of a cationic azobenzene into the mesoporous silica films was conducted using *p*-(ω-dimethylhydroxyethylammonioethoxy)azobenzene bromide (AZ) as the guest species. Photochemical reactions of azobenzenes are sensitive to the microenvironment and so can be employed as photoreactive probes to estimate microenvironments (free volume and rigidity), to which conventional characterization techniques do not have an access.[4] Moreover, geometrical changes of azobenzenes have been utilized as a trigger to design photoresponsive supramolecular systems.[5,6] Accordingly, the photochemistry of azobenzenes in mesopores is worth investigating from the viewpoints of probing mesopores as well as constructing photofunctional materials.

Aluminium-containing mesoporous silica films were synthesized by the rapid solvent evaporation method which we have developed.[7] This method is promising for the preparation of silica-surfactant mesostructured materials in a controlled morphology,[8,9] since the reaction is very simple and the resulting films are highly transparent and homogeneous. Aluminium tris(*sec*-butoxide) (ATSB) was used as the aluminium source and co-solidification with silica was conducted by the reported synthesis method for aluminosilica xerogels[10] with slight modification. A typical synthetic procedure for the transparent thin films of aluminium-containing silica-surfactant mesostructured materials is as follows: silicon tetraethoxide (TEOS), ethanol, water and HCl (molar ratio of 1:4:1.2:0.006) were mixed at 60 °C for 10 min with magnetic stirring. ASTB was then added and the mixture allowed to react for a further 10 min at 60 °C. Then, an aqueous solution of octadecyltrimethylammonium chloride was added and the mixture allowed to react for a further 2 h at room temperature. The resulting solution was spin coated on a substrate and calcined in air at 300 °C for 18 h to prepare mesoporous silica films; ASTB/TEOS ratios were set at 0.05, 0.031, 0.025, 0.022 and 0.014.

SEM images of the film surfaces (data not shown) indicate that the films are continuous and crack free when the ASTB/TEOS ratios were 0.031, 0.025, 0.022 and 0.014. When the ASTB/TEOS ratio was increased to 0.05, a homogeneous solution cannot be obtained under the experimental conditions and the resulting film is slightly turbid. The X-ray diffraction patterns of the calcined films with different Al contents are shown in Fig. 1(a)–(c). Although the diffraction peaks broadened with an increase in the loaded Al amount, a single diffraction peak indicative of the surfactant templated mesostructures was observed for all the samples. Nitrogen adsorption isotherms of the calcined films on a glass substrate are of type IV indicating that the films are mesoporous. The average pore sizes as derived from the isotherms by the Horvath–Kawazoe method[11] were 3.2, 2.9 and 2.8 nm for the films with Al/Si = 0, 0.014 and 0.031, respectively.

For the introduction of AZ, the mesoporous silica films were immersed in an ethanol solution of AZ. The amount of AZ adsorbed onto the Al free film was very low even for extended reaction times or if a concentrated AZ solution was used. On the other hand, AZ was adsorbed effectively into the Al containing mesoporous silica films. It is thought that the partial substitution of Si by Al leads to successful introduction of AZ into the mesopores through electrostatic interactions between the dye and the negative charge at the substituted Al site. The UV–VIS absorption spectrum (Fig. 2) of the film (Al/Si = 0.0031) after the reaction with AZ showed an absorption band centered at 338

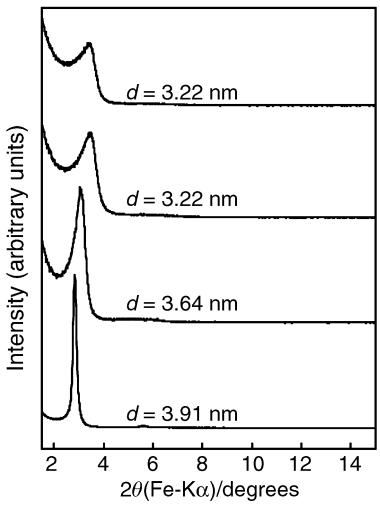

Fig. 1 X-Ray diffraction patterns of mesoporous silica films with Al/Si = 0 (a), 0.0014 (b) and 0.0031 (c); trace (d) is (c) after adsorption of AZ.

(b) The variation of the absorbance due to *trans*-AZ at 340 nm as a function of the Al/Si ratio. Open and filled circles represent samples before and after washing with ethanol.

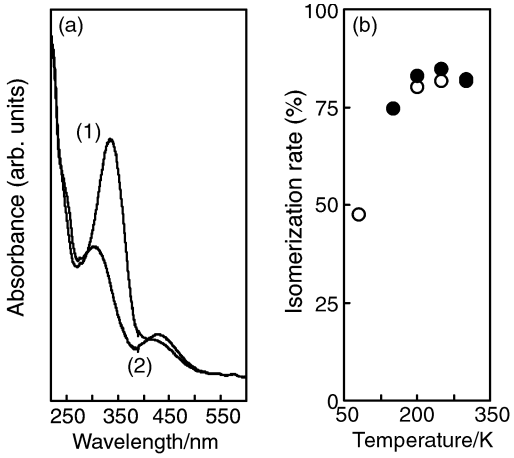

Fig. 3 (a) The change in the absorption spectrum of the AZ adsorbed mesoporous silica film (Al/Si = 0.0031) before (1) and after (2) UV irradiation. (b) The temperature dependence of the fraction of the photochemically formed *cis*-isomer at the photostationary states for the AZ adsorbed mesoporous silica film (Al/Si = 0.0031). Open and filled circles represent the values obtained on cooling and heating, respectively.

nm, which is ascribable to the π–π* transition of *trans*-AZ. With an increase in the Al content, the absorbance due to *trans*-AZ increased as shown in the inset of Fig. 2. The absorbance of the films after washing with ethanol is also shown in Fig. 2(b). The absorbance due to *trans*-AZ was decreased by washing, indicating that weakly bound AZ was removed from the films. As seen in Fig. 2(b), the decrease in the absorbance is almost same irrespective of the amount of loaded Al, suggesting that there are two different adsorption sites for AZ; strongly acidic sites at the substituted Al and weakly acidic sites probably at the silanol groups. Intermolecular interactions between adsorbed AZ may also be a factor leading to differences in behavior of the adsorbed species.

The absorption maximum observed for the film (Al/Si = 0.0031) essentially matched that of a dilute (3×10^{-5} M) ethanol solution of the dye. Considering the fact that the absorption spectra of aggregated AZ molecules such as found in crystals or AZ adsorbed on a layered silicate[12] are quite different from that of the present system, it is clear that the AZ cations are adsorbed and dispersed as monomers on the surface of the mesoporous silica irrespective of the amount of loading. Assuming that the molar absorption coefficient of AZ adsorbed in the mesoporous silica is the same as that of AZ in a dilute ethanol solution and that the film thickness is 0.5 μm, the concentrations of the AZ in the films are determined to be 0.42, 0.37, 0.29 and 0.23 mol L^{-1} for the films with Al/Si ratios of 0.031, 0.025, 0.022 and 0.014, respectively. Such high concentrations of AZ cannot be achieved in any solvents due to solubility limitations. The AZ cations are thought to be distributed in the one-dimensional channels with a mean separation between adjacent AZ molecules of 1.7 nm at the maximum loading level (Al/Si = 0.031).

When the as-coated films were calcined at higher temperature (*i.e.* 450 °C), the capacity for the adsorption of AZ was dramatically decreased. This observation can be rationalized by the condensation of hydroxy groups on the mesopore surfaces as well as diffusion of the loaded Al into the silica walls from the pore surface. Since the films are thin (0.5 μm), oxidative decomposition of the template is facile when compared with surfactant occluded in the bulk samples. Thus, the mesoporous silica films with cation exchangeable sites on the pore surfaces are readily available by surfactant removal at relatively low temperature (300 °C).

The adsorbed AZ in the mesopores exhibits photochemical isomerization upon UV and visible light irradiation.[13] The reactions were monitored by the change in the absorbance of the *trans*-isomer of the AZ at 340 nm and a typical change in the absorption spectrum is shown in Fig. 3(a). The ratio of the *cis*-isomer formed by the UV irradiation at the photostationary state at room temperature was roughly estimated to be no less than *ca.* 90% from the absorbance change. It is known that the photoisomerization is affected by the free volume and the rigidity of the surroundings.[14–16] The van der Waals volume of azobenzene is 144 $Å^3$ and photoisomerization requires an extra 127 $Å^3$.[15] The pore size of the mesoporous silica films used in the present study is large enough for AZ to isomerize. The photochemical isomerization was measured in the temperature range 80–400 K and the temperature dependence of the yield of the photochemical reactions is shown in Fig. 3(b). Photochemical isomerization occurs even at 80 K, showing that the mesoporous silica films can be utilized as a nano-reaction vessel in a wide temperature range for organic photochemical reactions.

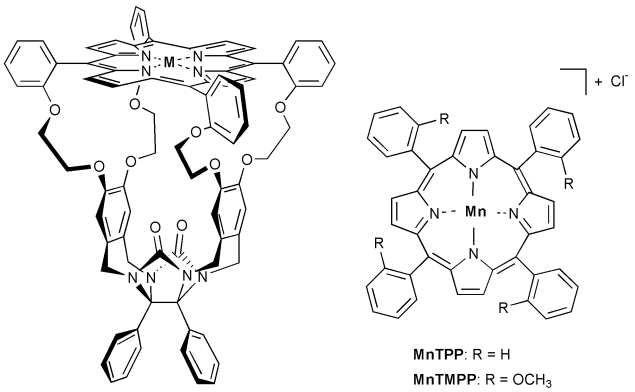
A porphyrin-capped molecular clip epoxidises olefins, depending on the axial ligand used, with enhanced activity or stability

The mono-oxygenase cytochrome P450 selectively binds substrates in the direct proximity of an Fe(III) protoporphyrin IX, which catalyses the activation of molecular oxygen and the subsequent incorporation of one of the oxygen atoms into the bound substrate and reduction of the other one to water.[1] Much research has been devoted to the elucidation of the complex working mechanisms of the enzyme, and several simplified synthetic models have been constructed which make use of molecular oxygen or a single oxygen donor (*e.g.* sodium hypochlorite) as the oxidant. Many of these model systems utilize Mn(III) porphyrins functionalised with straps or caps to establish an environment in which the oxygen transfer from the metal to the substrate is under steric control.[2] Regio- and stereoselective oxidation has been achieved,[3] in which for example *cis*-stilbene has been oxidised with a major preference for the production of the *cis*-epoxide.[4] Other approaches involve the coupling of a metalloporphyrin to known cavity molecules, such as cyclodextrins[5] and cyclophanes,[6] which can bind substrates and oxidise them with enhanced rates or selectivities. Here we describe initial catalytic studies using the new cavity-containing manganese porphyrin **Mn1** as a catalyst. The molecule consists of a molecular clip[7] equipped with a porphyrin roof situated symmetrically above the receptor, thus creating a rigid and relatively closed cavity with a diameter of approximately 9 Å.[8] Whilst the free base host **$H_2$1** has been applied in the construction of rotaxanes, it was also our intention to utilize its Mn(III) derivative as an olefin epoxidation catalyst. In this paper, the catalytic properties of **Mn1** in the



epoxidation of α-pinene and *cis*- and *trans*-stilbene, applying the biphasic dichloromethane–aqueous NaOCl system previously used by us[9] and by other groups,[10] are compared to those of the reference porphyrins **MnTPP** and **MnTMPP**. Particular emphasis is directed toward the relative activity and stability of these catalysts. It will be shown that by a strong host–guest binding of the axial ligand in the cavity of **Mn1** the rate of epoxidation is enhanced, while by shielding the outside of the cavity of **Mn1** the catalyst's stability is increased. Although the Fe(III) porphyrin in cytochrome P450 features axial coordination by a cysteine thiolate, most of its synthetic mimics utilize more stable pyridine, imidazole or phenolate derivatives to enhance the activity and stereoselectivity of the catalytic center. In previous studies in which **MnTPP** was used as the catalyst, it was found that the strength of axial ligand binding was related to the enhancement of the activity of the catalyst, since the electron donating properties of the ligand facilitate the formation of the proposed Mn(V)–oxo species.[9] For optimal results 500 equivalents of pyridine (Py) were, however, required in the reaction, because of its relatively weak binding to the porphyrin metal ($K_a \approx 1000\ M^{-1}$). Since NMR studies had revealed that in host **Zn1** Py is bound within the cavity with a very high association constant ($K_a = 1.1 \times 10^5\ M^{-1}$) due to stabilising cavity effects,[8] it was calculated that under the applied epoxidation reaction conditions† **Mn1** would require only *one* equiv. of Py to achieve a >99% binding to the porphyrin metal (Fig. 1, approach A). Indeed, the effect of this supramolecular activation of **Mn1** by Py, compared to **MnTPP** under the same reaction conditions (*one* equiv. of Py), resulted in a 5–10 fold initial rate enhancement in the epoxidation of olefins (Table 1, Fig. 2). As a result of this, it requires more than 10 h for the reaction to be completed in the case when **MnTPP** is used as the catalyst, while when using **Mn1** it is complete within 2 h. The rate enhancement exhibited by the **Mn1**–Py system is not caused by electronic or steric effects of the alkoxy groups, as control experiments using **MnTMPP** showed that this catalyst exhibited even lower epoxidation rates than **MnTPP** (Table 1). The rate enhancing effect is further illustrated when one equiv. of the even stronger binding axial ligand imidazole (K_a with **Zn1** $= 3.2 \times 10^5\ M^{-1}$) is used as the axial ligand in **Mn1**: α-pinene is epoxidised by **Mn1** within approximately 1 h with an initial rate $k_0 = 17 \times 10^5$/mol dm^{-3} s^{-1}. In addition to rate enhancement, Py-activated epoxidation of *cis*-stilbene by **Mn1** preferentially produced *cis*-stilbene oxide over the *trans*-isomer (Table 1), which is a commonly observed phenomenon for Py–Mn(III) porphyrin catalyst systems.[9,10]

A drawback of the **MnTPP** and **MnTMPP** catalysts is their instability. During the course of the epoxidation reaction the brown organic layer gradually decolourises, especially when the

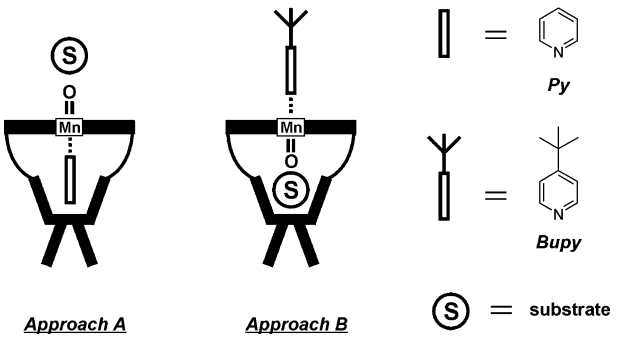


Fig. 1 Two approaches in which **Mn1** is used as an epoxidation catalyst in combination with Py or Bupy as the axial ligand.

amount of unreacted olefin decreases. This phenomenon has been attributed to the formation of μ-oxo-bridged Mn(IV) porphyrin dimeric structures, which are unreactive in further catalysis and rapidly decompose.[9] This rapid decomposition was also found to occur in the case of the **Mn1**–Py system used in approach A. To prevent this, the bulky axial ligand 4-*tert*-butylpyridine (Bupy) was used to coordinate to **Mn1** on the outside of the cavity (Fig. 1, approach B). It was expected that coordination of this ligand, which does not fit within the cavity,‡ would efficiently prevent μ-oxo dimer formation since the other face of the porphyrin is protected by the receptor cavity. When the epoxidation reactions using **Mn1** were carried out in the presence of 500 equiv. of Bupy, catalyst destruction was indeed prevented, as was concluded from the fact that the organic layer retained its brown colour, and, more importantly, that newly added amounts of substrate were epoxidised. The epoxidation experiment was repeated sequentially several times. The observed initial rate was found in all cases to be almost identical, indicating that no decomposition of the catalyst occurred. This gave turnover numbers of > 1000 per catalyst.§ When **MnTPP** or **MnTMPP** were used as the catalyst in combination with Bupy, this stabilization did not occur and the catalysts decomposed.

Assuming complete shielding of the outside of **Mn1** by Bupy implies that the oxygen transfer to the substrate has to occur within the cavity. From molecular modelling studies it became clear that the substrates cannot react *via* the side of the cavity, *i.e.* they need to enter the cavity completely to reach the manganese–oxo species. The epoxidation results of *cis*- and *trans*-stilbene using the **Mn1**–Bupy system are summarised in Table 1 and compared to those when **MnTPP** or **MnTMPP** are used as the catalyst. Whilst for the epoxidation of *trans*-stilbene not much difference is observed between the catalysts with regard to initial rate and epoxide yield, the epoxidation rate of *cis*-stilbene clearly decreases going from **MnTPP** to **MnTMPP** to **Mn1**. This decrease in rate coincides with a simultaneous increase in steric hindrance by the substituents of the *meso*-phenyl rings. Apparently, these groups have more steric influence on a *cis*-stilbene substrate than on a *trans*-stilbene substrate. Remarkably, the rate of epoxidation of *cis*-stilbene catalysed by the **Mn1**–Bupy system (epoxidation within the cavity) is similar to that catalysed by the **Mn1**–Py system (epoxidation outside the cavity) (Table 1). This implies that additional factors play a role in the epoxidation reaction. Further studies are currently under investigation.

In summary, we have shown that by means of a unique supramolecular activation of **Mn1** only one equiv. of the axial ligands pyridine or imidazole are required to activate the catalyst for the epoxidation of olefins. Coordination of a bulky axial ligand on the outside of the cavity of **Mn1** strongly enhances the stability of the catalyst, which in this approach is protected from further oxidative decomposition. Current research is focused on the functionalisation of Mn(III) porphyrins with molecular clip receptors on both faces, so that both approaches of supramolecular activation and catalyst protection are combined.

Notes and references

† *Reaction conditions*: to a CH_2Cl_2 solution (0.65 ml) of the substrate (0.626 M), the manganese catalyst (2.5 mM), the phase transfer catalyst tetrabutylammonium chloride (5 mM), the axial ligand pyridine (2.5 mM) or 4-*tert*-butyl pyridine (1.25 M), and an internal standard (1,3,5-tri-*tert*-butylbenzene (0.17 M) in a Schlenk tube was added an aqueous NaOCl solution (2 ml, 0.6 M). The mixture was stirred at a constant rate under nitrogen for 3 h, and during the course of the reaction samples were taken from the organic layer which were analysed by GLC and ^{1}H NMR.

‡ This was concluded from ^{1}H NMR experiments on mixtures of **Zn1** and Bupy in $CDCl_3$, which indicated no binding within the cavity of the host even when 500 equiv. of the axial ligand were added.

§ More than 4 portions of substrate could be oxidised without any decomposition of the catalyst. Due to phase separation between the solvent and the epoxidation products it then became more difficult to measure a reliable rate of conversion when the number of portions were increased beyond 4.

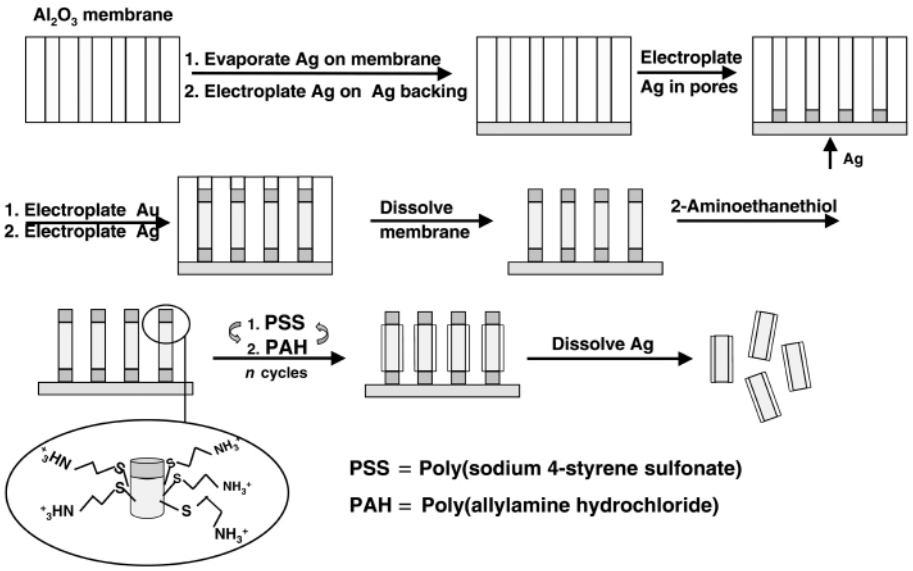
Alternate adsorption of anionic and cationic polyelectrolytes creates smooth organic films on the walls of template-grown Au nanowires, which can be made chemically reactive on their ends by removal of a sacrificial Ag layer.

Much of the current research on nanophase materials focuses on the synthesis of colloidal particles of controlled size, shape, and surface chemistry. These particles are interesting as building blocks of larger superstructures, which have possible applications in electronics, photonics, catalysis, chemical sensing, and other areas. Monodisperse collections of spherical and polyhedral nanoparticles are known to crystallize into well ordered two- and three-dimensional arrays.[1] On the other hand, it is now becoming clear that less symmetric particles and linkers can give rise to more complex and interesting superstructures, both on the nanoscale[2] and on larger length scales.[3] Recently, we have studied the synthesis and assembly of rod-shaped colloidal particles.[4] This synthesis, which involves the electrochemical replication of porous alumina and polycarbonate membranes, allows one to make cylindrical wires with a controlled sequence of 'stripes' along their length. Different metal stripes selectively adsorb self-assembled monolayers (SAMs) or DNA oligomers, which can be used to direct the assembly of these particles on surfaces. Here, we report the stepwise formation of multilayered organic films on the cylindrical walls of Au nanowires by alternate adsorption of monolayers of poly(styrene sulfonate) (PSS) and poly(allylamine hydrochroride) (PAH). By removing a sacrificial Ag layer from the tips, it is possible to prepare nanowires that are chemically insulated along their length, but reactive at their ends. This reactivity is demonstrated by covalently linking fluorescent dye molecules exclusively to the exposed ends of the nanowires.

The porous templates used for the electrosynthesis of Au nanowires were commercially available Anodisc alumina membranes (200 nm pore size, 8.9×10^8 pores cm^{-2}, 60 μm thickness). Au replicas were made by a modification of the methods of Possin,[5] Martin[6a] and Moskovits.[6b] Ag was thermally evaporated onto the branched side of the alumina membrane to make the membrane electrically conductive (*ca.* 200 nm thick Ag). Ag was then electroplated (using Technic Silver 1025 plating solution) onto the evaporated Ag film to increase its thickness around to *ca.* 2 μm. The narrow branched pores were filled with Ag at a current density of 0.55 mA cm^{-2} of the membrane. Au was then grown electrochemically inside the pores by changing the electroplating solution (to Technic Orotemp 24). After the Au wires were grown to the desired length (2–6 μm), another 500–800 nm of Ag was grown. The metal-filled membrane was then glued to a glass slide and the alumina template was dissolved using NaOH solution. This left the Au nanowire array attached to a silver base, and left each nanowire capped with Ag. Suspensions of free Au nanowires were prepared by first dissolving the alumina membrane in NaOH and then the Ag backing and capping layers in nitric acid.

The surface derivatization of Au nanowires by polyelectrolyte multilayers[7] was performed as shown in Scheme 1. The nanowire array was first reacted with 2-aminoethanethiol hydrochloride to render the Au surface positive. The derivatized surface was then dipped in a solution of poly(sodium 4-styrene sulfonate) (PSS) (average molecular weight ≅ 70,000), which

† Electronic supplementary information (ESI) available: colour versions of Scheme 1 and Figs. 1 and 2. See http://www.rsc.org/suppdata/cc/b0/b007999p/



Scheme 1 Strategy for formation of a multilayer polyelectrolyte film on a gold nanowire array.

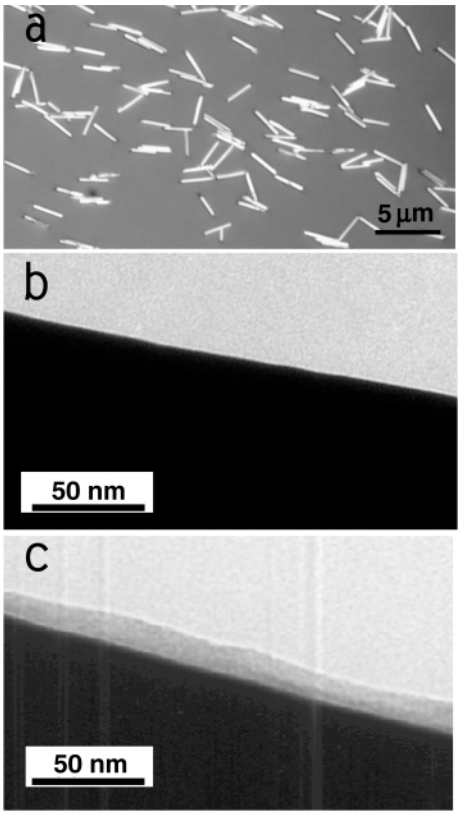


Fig. 1 (a) Optical micrograph at 1000× magnification of 2.4 μm Au nanowires, and TEM images of (b) an untreated Au nanowire and (c) an Au nanowire derivatized with a multilayer film of alternating polyanions and polycations as shown in Scheme 1.

contains negatively charged sulfonate groups in the polymer chain. In this step, anionic PSS adsorbs onto the positively charged surface and inverts the surface charge. The samples were then washed several times with water and reacted with poly(allylamine hydrochroride) (PAH) (average molecular weight ≅ 15,000), which contains positively charged $–NH_3^+$ groups. The polyanion, wash, polycation, wash cycles were repeated 10 times in order to produce multilayer films. Finally, the derivatized Au nanowires were freed from the surface by dissolving their Ag backing and caps in aqueous HNO_3.

Optical and electron microscopy was used to assess the quality of the nanowires and surface films. Fig. 1(a) and (b) show optical and transmission electron micrographs (TEM) of the nanowires. Many identical particles are produced by replication of a single membrane, and the underivatized nanowires have smooth, clean surfaces after the alumina template is dissolved away. Fig. 1(c) shows a TEM image of the surface of a gold nanowire modified by ten alternate adsorptions of PSS and PAH according to Scheme 1. Note the formation of a smooth polymer film with a thickness of *ca.* 13 nm, which is consistent with the 1 nm per bilayer typically found for adsorption of PSS/PAH on planar substrates.[7]

Because the top and bottom of the nanowires are capped with Ag during the polyelectrolyte adsorption steps, removal of Ag creates a clean surface that is chemically distinct from the 'insulated' cylindrical walls. This property was tested by reacting the free nanowires with 2-aminoethanethiol to form a self-assembled monolayer on the exposed surface. The thiol-treated nanowires were then reacted with fluorescein isothiocyanate and imaged using fluorescence microscopy. Studies on fluorescently-tagged monolayers have addressed the issue of fluorescence quenching near a metal surface. Although fluorescence is attenuated by non-radiative energy transfer to the metal, it is still strong enough for detection.[4,8,9] Fig. 2 compares a fluorescence optical micrograph of the derivatized nanowires with brightfield reflectance images from the same regions. Only the tips are fluorescent as a result of the thiourea link between isothiocyanate-functionalized probe molecule and 2-aminoethanethiol bound to the Au surface, confirming that both ends are accessible to the probe molecules. In contrast, the length of the nanowires are non-fluorescent, confirming that they are covered by a multilayer films that is not affected by the thiol–isothiocyanate derivatization steps.

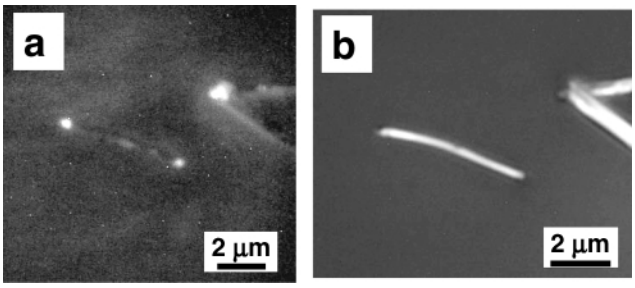

Fig. 2 Optical micrographs of Au rods derivatized with polymer multilayers according to Scheme 1, then etched to remove Ag from the tips and reacted with 2-aminoethanethiol and fluorescein isothiocyanate. (a) Fluorescence micrograph image and (b) a bright-field micrograph image of the derivatized rods on a quartz substrate.

In conclusion, we have successfully derivatized gold nanowires by alternate adsorption of the anionic and cationic polyelectrolytes poly(styrene sulfonate) and poly(allylamine hydrochroride). This process leads to smooth multilayer films around the Au surface, but not on surfaces that are first capped with Ag. It is now possible to selectively derivatize these nanowires, thus opening a door to possible applications in nanoscale electronics and other areas.

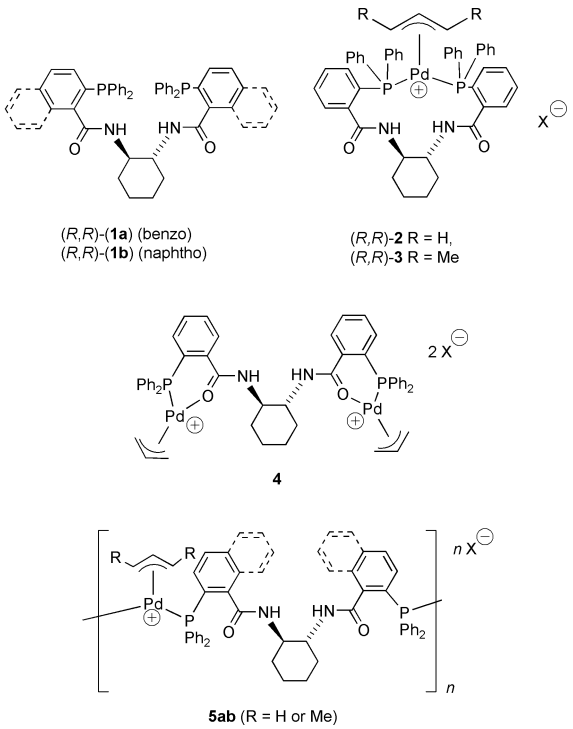
A mononuclear Pd–allyl complex of the Trost modular ligand displays non-C_2-symmetric ligand coordination and is in equilibrium with a hierarchical series of non-chelate oligomers.

We have an ongoing interest in 'memory effects'[1] in Pd-catalysed allylation, particularly in relation to reactions involving the Trost modular ligand **1a**.[2] During such processes, the coordination mode of **1a** to Pd in Pd–allyl intermediates is generally assumed to be exclusively *P*,*P* chelating and C_2-symmetric[3] (*e.g.*, **2**/**3**). However, the crystalline binuclear complex $[Pd_2(\mathbf{1a})(allyl)_2]^{2+}$, an active catalyst for allylation, is readily prepared.[1b] In the solid state and in solution this exists as a single species **4** (X = OTf) in which Pd is *P*,*O*− coordinated. In stark contrast, the mononuclear species '[Pd(**1a**)(allyl)]$^+$' is an amorphous solid which dissolves to give a number of *P*−coordinated species (^{1}H, ^{13}C and ^{31}P NMR).



A 23 mM solution of '[Pd(**1a**)(allyl)]$^+$' in CD_2Cl_2 at 25 °C displays two distinct sets of ^{31}P NMR signals of approximately equal abundance [Fig. 1(a)]. The first is a cluster of signals in the range δ 24.5–27. These have no discernible coupling and comprise two outer sets of signals and a broader major central set [Fig. 1(a), open square].

The second set is a pair of AB spin systems in a ratio of 62.5 : 37.5 [Fig. 1(a), open/closed circles] the ratio of which varies with temperature [Fig. 1(b)]‡ but not concentration (1–180 mM). The identical $^2J_{PP}$ coupling (32.9 Hz), similar chemical shifts and low entropic difference (ΔS^0 = 2.4 ± 0.1 J K^{-1} mol^{-1}) suggests these to be diastereoisomers. Note that π-allyl rotamers of **2** can only be non-degenerate through non-C_2-symmetric conformation of coordinated ligand **1a**.[3] Above −15 °C, concentration *independent* line-broadening§ indicates unimolecular diastereoisomer interconversion just below the NMR time-scale [*cf.* Fig. 1(a) and (b)].

When the concentration of '[Pd(**1a**)(allyl)]$^+$' is increased, the proportion of **2** decreases [Fig. 1(c)]. Dilution confirms a reversible equilibrium governed by a term or terms of type $[Pd]^n$, where $n > 1$, and thus a monomer-oligomer equilibrium. As predicted, lower temperatures favour oligomer [see Fg. 1(b)], presumably due to substantial ΔS; however, a reliable van't Hoff relationship (−75 → 25 °C) could not be established owing to precipitation at lower temperatures. ^{31}P NMR analysis of the mol fraction **1a** in monomeric *vs*. oligomeric species at varying concentration (1–180 mM, CD_2Cl_2, 25 °C) yields a curve [Fig. 2(a)]. Using sequential equilibria between hierarchical oligomers [*i.e.* $(X)_n$ + **2** ↔ $(X)_{n+1}$, where '*X*' is an unspecified Pd complex] as a model[4] we could successfully predict equilibrium concentrations (solid line). In DMSO-d_6, near-identical diastereomer ratios (63 : 37) and monomer–oligomer concentration dependences were observed.

The monomer–oligomer equilibria does not cause observable ^{31}P NMR line-broadening in **2**, and thus monomer–oligomer

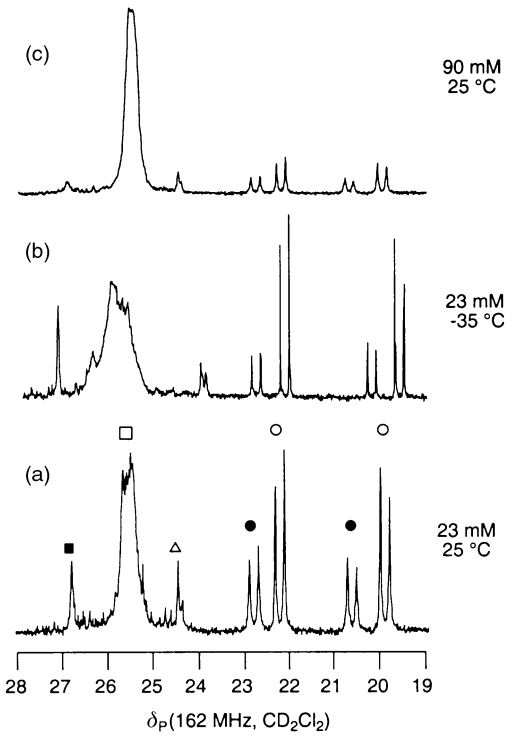


Fig. 1 ^{31}P NMR spectra of [Pd(**1a**)(allyl)][OTf] in CD_2Cl_2 at two temperatures and concentrations. Circles: monomer **2** (R≡H, two diastereomers), open square: oligomer **5a** (R = H), filled square: tentatively assigned as '$[Pd_2(\mathbf{1a})_3(allyl)_2]^{2+}$' (reversibly generated by addition of 0.5 equivalent **1a**), triangle: *P*,*O*-coordinated species analogous to **4** or mono- and *bis*-*P*-allylated **1a** {isochronous with an independently prepared sample of [*P*,*P*′-$allyl_2$-**1a**][$(OTf)_2$]}.

DOI: 10.1039/b007785m

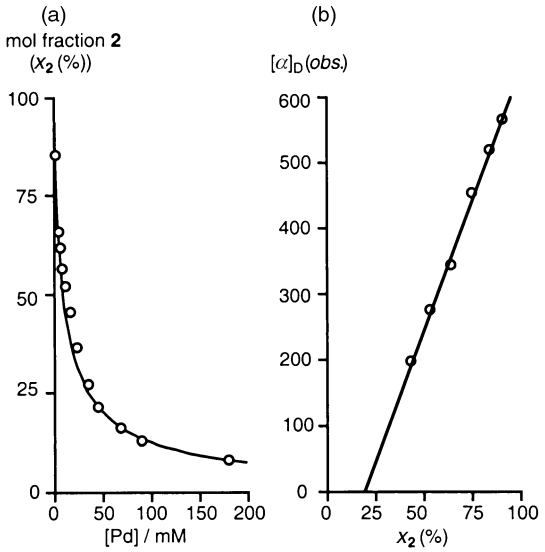

Fig. 2 (a) Concentration of '[Pd(**1a**)(allyl)][OTf]' in CD_2Cl_2 ('[Pd]', *x*-axis) *vs*. mol fraction **2** (x_2, *y*-axis) data: circles (^{31}P NMR) line: best fit. (b) Mol fraction **2** [x_2 (%), *x*-axis] at concentrations of [Pd(**1a**)(allyl)][OTf] in the range 3 → 20 mM *vs*. ($[\alpha]_D$, *y*-axis) circles: data, line: linear regression of $[\alpha]_D$ (obs.) = $[x_2\{\alpha_2\}_D + (100 - x_2)\{\alpha_5\}_D]$.

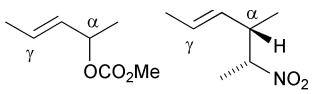
interconversion is slower than the NMR timescale. However, the specific rotation of [Pd(**1a**)(allyl)][OTf] in CH_2Cl_2 at 22 °C varies dramatically with concentration, *vide infra*, and fast equilibrium ($t_{1/2} \leq 2$ s)[5] at the real time-scale was confirmed by polarimetry after rapid dilution (100 → 10 mM). Analysis of mol fraction monomer (x_2, ^{31}P NMR) and $[\alpha]_D$ over a range of concentrations [Fig. 2(b)] reveals a simple relationship. This demonstrates that the variation of the net specific rotation, $[\alpha]_D$ (obs.), does not arise from large concentration dependent rotations of individual species, but rather from the monomer–oligomer distribution. Linear regression¶ yields an intrinsic specific rotation,[6] $\{\alpha\}_D$ for **2** (R = H) of +644 (±8). The linearity of x_2 *vs*. $[\alpha]_D$ (obs.) also suggests congruence in the $[\alpha]_D$ of the (lower) oligomers and extrapolation to $x_2 = 0$ yields $\{\alpha\}_D = -151$ (±17). This value is significantly different in sign and magnitude from that of **2** and hints that the oligomers are not of the form $(\mathbf{2})_n$. Given the propensity for **1a** to exist in an elongated conformation[1] and the size of the chelate ring in **2** (13-membered) we suggest oligomeric structures of type **5a** (R = H)[7] where the central chirality of the diamide backbone is not within a chelate ring {*cf*. monomer **4** ($[\alpha]_D = 38$, $c = 0.1$, CH_2Cl_2) and ligand **1a** ($[\alpha]_D = 61$, $c = 2.3$, CH_2Cl_2)}.



(±)-**6** (2*R*, 3*S*)-**7**

In recent reports on the asymmetric allylation of $EtNO_2$ by (±)-**6** (→**7**) which is suggested to proceed *via* intermediate π-allyl complex **3**, moderate ee values at high catalyst loadings were suggested to be the result of a memory effect arising through slow interconversion of isomers of **3** of differing symmetry. For example with 4 mol% 'Pd(**1a**)', **7** was obtained in 53% ee whilst with 0.5 mol% the ee increased to 97% ee. It was suggested that 'by lowering the catalyst loading which, in effect, reduces the concentration of the π-allylpalladium intermediate, the unimolecular equilibration event now *outcompetes* the bimolecular nucleophilic addition'.[2a] However, if equilibration is unimolecular and capture by nucleophile is bimolecular, as suggested, then the relative rates of these processes is given by $\{k_{eq}[\mathbf{3}]/k_{Nu}[\mathbf{3}][Nu]\}$. Since this reduces to $\{k'[Nu]^{-1}\}$, in which catalyst loading does not feature, this interpretation of memory effect attenuation‖ is unsatisfactory. However, in view of the results described herein, the possibility of analogous equilibrium between **3** and oligomers** such as **5a** (R=Me) must be considered. In contrast to oligomeric intermediates, *P*,*P*-chelation in **3** will allow efficient central chirality transmission through the helical Ar_3P-donor arrays,[8] albeit in a non-C_2-symmetric fashion.[3] Lower catalyst loadings, favouring monomer, would thus lead to higher selectivity. Furthermore, oligomerisation may also account for decreased selectivities at lower temperatures[3b] or the superiority of **1b** over **1a** (see **5b**)[9] in certain processes.

We thank the EPSRC (GR/N05208) and Lancaster Synthesis for generous support.

Notes and references

‡ A van't Hoff analysis of ^{31}P NMR integrals from spectra obtained between +25 and −75 °C yielded: $\ln K_{eq} = (221 \pm 2.9/T) - 0.283 \pm 0.01$; $r^2 = 0.999$.

§ Line width, $\omega_{1/2}$: 6 ± 1.5 Hz (25 °C, 1–180 mM) → 2 ± 0.5 Hz (constant −15 to −75 °C). Strong correlations between A/B′ and A′/B and weak correlations between A/A′ and B/B′ in the 2D ^{31}P{^{1}H} EXSY (500 MHz) spectrum [δ_P, 22.2/19.9 (A,B) and 22.8/20.6 (A′,B′)] suggest that equilibrium proceeds *via* interconversion of ligand conformation rather than ligand dissociation, or π–σ–π allyl fluxionality.

¶ The principle of optical superposition (van't Hoff) is assumed to apply.

‖ The lower selectivity at higher catalyst loading (4 mol%) does not arise exclusively from a regiochemical memory effect (see Fig. 3 in ESI†).

** Ionisation of **6** may generate **3** directly, or indirectly *via* oligomeric Pd(0) species.

3 As far as we are aware, there is no published experimental data on the symmetry of *P*,*P*-chelate coordination of **1a** to Pd. However, the working model, based on molecular modelling, always employs fully C_2-symmetric coordination: (*a*) B. M. Trost and F. D. Toste, *J. Am. Chem. Soc.*, 1999, **121**, 4545; however, also see footnote 36 in (*b*) B. M. Trost and X. Ariza, *J. Am. Chem. Soc*, 1999, **121**, 10 727.

4 Quantitative analysis of monomer-oligomer equilibrium will be described elsewhere.

5 Slow equilibration is observed in $PdCl_2$ complexes of simple (achiral) diphosphines with alkyl or polyether backbones: D. C. Smith and G. M. Gray, *J. Chem. Soc., Dalton Trans.*, 2000, 677; however, the ability of **1a** to act as a *P*,*O*-donor to cationic Pd(II) (as in **4**) may catalyse interconversion.

6 There are no observable chromophores in the region of the sodium D-line in the UV spectrum of the mixture of complexes: E. L. Eliel and S. H. Wilen, *Stereochemistry of Organic Compounds*, John Wiley and Sons, New York, 1994.

7 Such oligomers could be linear or cyclic, see *e.g.* B. L. Shaw, *J. Organometal. Chem.*, 1980, **200**, 307.

8 The major contributor to the magnitude and sign of the optical rotation is likely to be the degree of order and sense of the aryl phosphine rotors. The sextuple phenyl array is the mainstay of the 'cartoon' representation of the 'chiral pocket'. Since ligand **1a** is particularly effective with slim cyclic allyl substrates and less so with bulky linear ones (see *e.g.* B. M. Trost, A. C. Krueger, R. C. Bunt and J. Zambrano, *J. Am. Chem. Soc.*, 1996, **118**, 6520) the tightness of the 'chiral pocket' may exacerbate oligomerisation with the latter class.

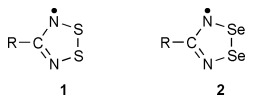
First published as an Advance Article on the web 27th November 2000

The two title compounds are isostructural with pairs of diselenadiazolyl radicals associating in an unprecedented manner *via* an orthogonal interaction between singly occupied molecular orbitals which renders them essentially diamagnetic in the solid state.

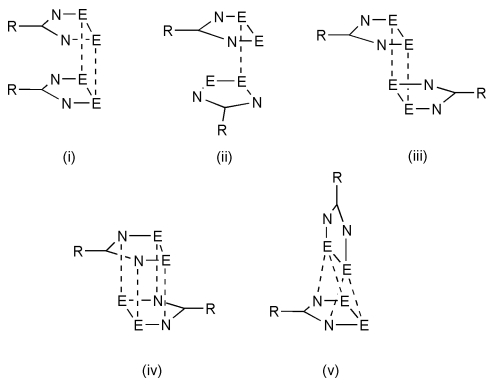
The 1,2,3,5-dithiadiazolyl radical **1** is an extremely persistent stable free radical.[1] Solution EPR studies on several derivatives



1 **2**

have established[2] that the dimerisation energy is substantial ($\Delta H_{dim} \approx 35$ kJ mol^{-1}). In 1985, Mews and coworkers described[3] the crystal structure of $[CF_3CNSSN]_2$ and predicted that association of dithiadiazolyl radicals could occur through a favourable π-bonding interaction between singly occupied molecular orbitals (SOMOs). The energy differences between *cisoid*, *transoid* and twisted conformations [Fig. 1(i)–(iii)] was estimated[3] at < 10 kJ mol^{-1} and examples of all of these three modes of association have since been established by X-ray crystallography.[1] More recently a fourth, *trans*-cofacial motif has been observed [Fig. 1(iv)].[4]

The isoelectronic diselenadiazolyl radicals **2** have also been prepared[5] and exhibit a greater tendency to dimerise in solution.[6] Theoretical studies have estimated[7] that ΔH_{dim} is higher [*cf.* **1** and **2** (R = H) with $\Delta H_{dim} = 33$ and 46 kJ mol^{-1}, respectively, using the same basis sets]. In the solid state, derivatives of **2** have invariably crystallised in the *cisoid* configuration observed for **1** [Fig. 1(i)]. Here we report the syntheses and characterisation of two diselenadiazolyl radicals **2a** and **2b** (R = *p*-ClC_6F_4 and *p*-BrC_6F_4, respectively), which associate in an unprecedented manner [Fig.1(v)].



(i) (ii) (iii) (iv) (v)

Fig. 1 Modes of association of dithiadiazolyl (E = S) and diselenadiazolyl (E = Se) radicals: (i) *cis*-cofacial, (ii) twisted, (iii) *trans*-antarafacial, (iv) *trans*-cofacial (v) orthogonal.

† Electronic supplementary information (ESI) available: analytical data for **2a** and **b**. See http//www.rsc.org/suppdata/cc/b0/b004705h/

Radicals **2a** and **2b** were prepared† from *p*-ClC_6F_4CN and *p*-BrC_6F_4CN using standard synthetic procedures,[5] and purified by sublimations under static vacuum (100 °C, 10^{-2} Torr). The crystal structures of **2a** and **2b** are isostructural, although not isomorphous.‡ The structure of **2b** contains two molecules of conventional geometry[8] in the asymmetric unit (Fig. 2). However, their mode of association is exceptional; The two heterocyclic rings in **2b** are inclined at 85° with respect to each other, with each of the selenium atoms of one ring situated approximately equidistant between an N and an Se atom of the second ring. This leads to a set of intermolecular Se···N and Se···Se contacts in the range 3.09–3.21 Å. The Se···Se contact is similar to that observed in conventional *cisoid* diselenadiazolyls. Because of the anisotropy in the van der Waals radius of selenium (*ca*. 2.15 Å perpendicular to the ring plane and *ca*. 1.7 Å in the ring plane),[9] the Se···Se interaction in this orthogonal arrangement (sum of van der Waals radii is 3.85 Å)[9] is likely to be weaker than that observed in the *cisoid* dimers (sum of the van der Waals radii perpendicular to the ring plane is *ca*. 4.3 Å).[9] A packing diagram of **2b** viewed in the *ac* plane (Fig. 3) shows how the dimer pairs pack in an antiparallel fashion along the crystallographic *c*-axis. The inter-dimer separation along the *c*-direction is longer, with the closest inter-dimer Se contacts in the range 3.6–3.7 Å.

Previous magnetic studies on other derivatives of **2** have indicated that the π*–π* interaction between cofacial radicals renders them diamagnetic. In order to establish the strength of the orthogonal interaction between radicals, variable temperature magnetic measurements were carried out on samples of both **2a** and **2b**.

Susceptibility measurements were made on a SQUID magnetometer with an applied field of 1 T in the range 1.8–300 K and isothermal magnetisation curves were recorded at 1.8 and

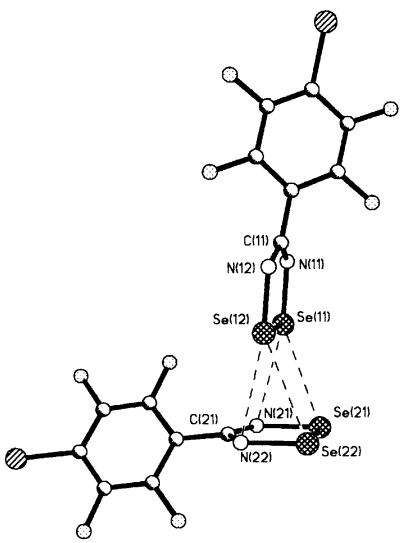


Fig. 2 Asymmetric unit of **2b**, with atom labelling scheme; the structural parameters of **2a** are the same as those for **2b**, within error.

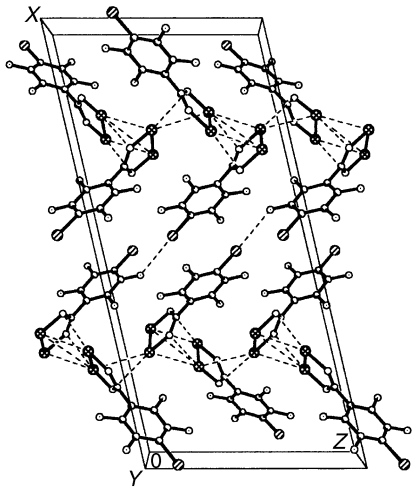

Fig. 3 Crystal structure of **2b** viewed in the *ac* plane. The closest inter-dimer contacts (illustrated) are Se···Se at 3.60 Å and Se···N at 3.46 Å.

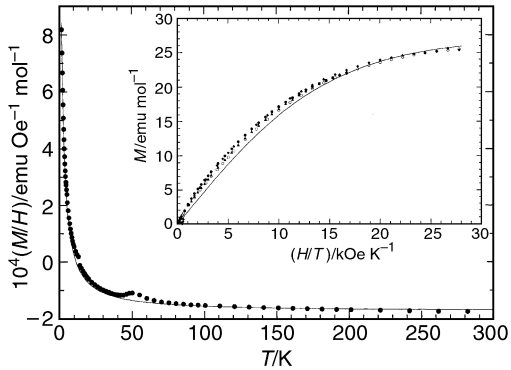

Fig. 4 Magnetic susceptibility as a function of temperature for **2b**. The solid line is the fit to the Curie–Weiss law and a diamagnetic contribution. Inset: Magnetisation behaviour of the unpaired spin moments of **2a** and **2b** as a function of the applied field. The solid line is the Brillouin function corresponding to S = 1/2 and a mol fraction of 0.0049 paramagnetic molecules. The data for **2a** has been scaled to the number of paramagnetic molecules found in **2b**.

3.0 K. A plot of susceptibility *vs.* temperature for both **2a** and **2b** are similar (that for **2b** is shown in Fig. 4) and shows that both **2a** and **2b** are essentially diamagnetic. A rapid increase in susceptibility at low temperatures is due to the presence of a small number of paramagnetic centres in the sample (a small spike can be observed at 50 K due to the antiferromagnetic transition of a minute amount of oxygen in the sample). A good fit to the Curie–Weiss law, including a diamagnetic contribution indicates that, for **2a**, the mol fraction of paramagnetic centres was 0.0045 and for **2b** 0.0054.

After a diamagnetic correction, the behaviour of the magnetisation as a function of the applied field in **2a** and **2b** closely follows a Brillouin function for S = ½ (Fig. 4, inset). A fit to the Brillouin function yielded mol fractions of paramagnetic centres as 0.0031 and 0.0049 for **2a** and **2b** respectively, in good agreement with the susceptibility results.

A preliminary examination of the interaction between SOMOs for this orthogonal mode of association indicates a symmetry-allowed bonding interaction (Fig. 5) which could give rise to a closed-shell singlet and thereby rationalise the observed diamagnetism. However, the poor orbital overlap anticipated from the perpendicular orientation of π* orbitals could also be anticipated to favour an open shell ground state. The magnetic measurements clearly indicate a singlet ground state, although both closed-shell singlet (spin-paired dimer) and open-shell singlet (antiferromagnetically coupled radicals) are possible. In the latter case, the singlet–triplet separation would need to be extremely large to suppress the paramagnetism arising from the triplet state. However, very large exchange

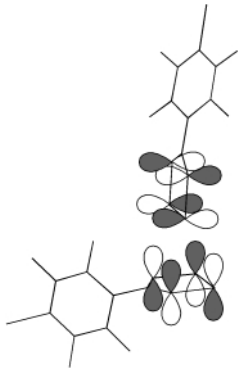

Fig. 5 The π*–π* bonding interaction between orthogonal π-systems on neighbouring diselenadiazolyl radicals.

interactions in group 15/16 radicals are not without precedent; Fujita and Awaga recently reported[10] a dithiazolyl radical with an exchange interaction of −1300 K. Further theoretical and experimental studies are required to confirm the electronic ground state of **2**, *viz-a-viz* an open shell or closed shell singlet. These studies, and additional structural studies on closely related diselenadiazolyl radicals, will be the subject of a future report.

We thank the Royal Society for an equipment grant (J. M. R.) and the EPSRC for a studentship (R. J. L.). This work was also supported by the Materials Program of the Comision Interministerial de Ciencia y Technologia under grant MAT97-951.

An unusual oxidative rearrangement of azabicyclo[2.2.1]heptenes, providing a stereoselective route to 2′- and 3′-hydroxycyclopentylglycines

Patrick D. Bailey,*[a] I. M. McDonald,*[b] Georgina M. Rosair[a] and David Taylor[a]

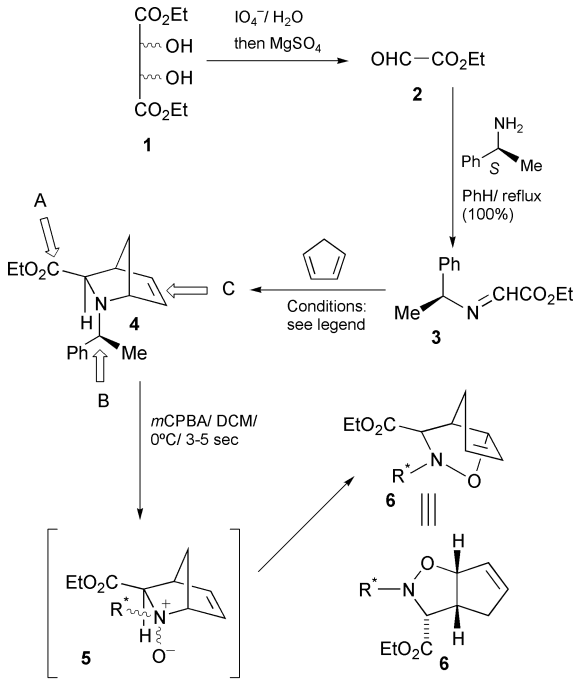
Received (in Liverpool, UK) 11th August 2000, Accepted 30th October 2000
First published as an Advance Article on the web

Treatment of the azabicyclo[2.2.1]heptene derivative 4 with *m*CPBA for 3–5 seconds generates the oxazabicyclo-[3.2.1]octene derivative 7 (X-ray structure) *via* rapid Meisenheimer rearrangement of the *N*-oxide 5, whilst heating 7 in MeCN for 4–6 h leads to further rearrangement to the more thermodynamically stable oxazabicyclo[3.3.0]octene isomer 6; 6 and 7 can be readily reduced to enantio-pure hydroxylated cyclopentylglycine derivatives.

Pharmacologically active peptoids can be generated by attaching the side-chains of a parent peptide to carrier moieties such as sugars, steroids, or porphyrins.[1] We have been exploring the use of azabicyclo[2.2.1]heptanes as rigid templates for such systems which, if they can be derivatised appropriately, offer potential as 3D structures on which to construct peptoid libraries. We were also attracted to such systems because we had developed an extremely short, efficient, and highly stereoselective route to these systems some years ago;[2] the aza-Diels–Alder reaction of the imine **3** with cyclopentadiene gives the azabicyclo[2.2.1]heptene **4** as a single stereoisomer, and we wished to explore the derivatisation of this adduct.[3] This communication, however, reports some unexpected results that have instead provided a short, efficient, stereo- and regio-specific route to hydroxylated cyclopentylglycines.

As outlined in Scheme 1, the adduct **4** could be efficiently prepared using ethyl glyoxylate generated using the procedure developed by Roberts' group.[4] After formation of the imine, the cycloaddition reaction was found to be most reliable when conducted in trifluoroethanol in the presence of TFA (1 equiv.). As reported by ourselves[4] and others,[5] this reaction proceeds both with excellent *exo* diastereo-control (in contrast to the *endo* selectivity observed for acyclic dienes[2]), and with extremely high asymmetric induction resulting from the presence of the α-methylbenzyl auxiliary (72% isolated yield, 95:5 *exo*:*endo*, 90% asymmetric induction). After chromatography, **4** was obtained as a single stereoisomer, from which we hoped an epoxidation/nucleophilic ring-opening sequence would allow derivatisation at site **C**, whilst further pharmacophores could be introduced at sites **A** and **B**. However, treatment with *m*CPBA failed to give the desired epoxide (even under acidic conditions whereby the nitrogen would be expected to be protonated), but instead yielded an isomeric oxygenated product which we initially assigned as the *N*-oxide **5**. Small amounts of a by-product were also generated, which was identified as the oxazabicyclo[3.3.0]octene **6** from NMR data.†

We had expected that an X-ray crystal structure of the '*N*-oxide' would confirm its identity and allow us to assign its stereochemistry at the chiral nitrogen, but this surprisingly revealed that the isomeric oxazabicyclo[3.2.1]octene **7** had been formed instead (Fig. 1‡). Optimisation of the reaction conditions established that the highest yield of **7** was obtained when the cyclo-adduct **4** was reacted at room temperature with *m*CPBA for only *3–5 seconds* and, that clean conversion to **6** could be achieved by refluxing **7** in acetonitrile for 24 h. Presumably **7** is formed *via* a Meisenheimer rearrangement,[6–9] but the rapidity and selectivity of the initial reaction, in which



Scheme 1 Formation of the oxazabicyclo[3.3.0]octane system **6**. The aza-Diels–Alder reaction (**3** → **4**) was in TFE, TFA (1 eq.), 0 °C, 3.5 h (72% yield, 95% *exo*, 90% asymmetric induction). See text and Scheme 2 for yields and identification of the products **5** and **6** from *m*CPBA oxidation of **4**. [R* = (*S*)-1-phenylethyl].

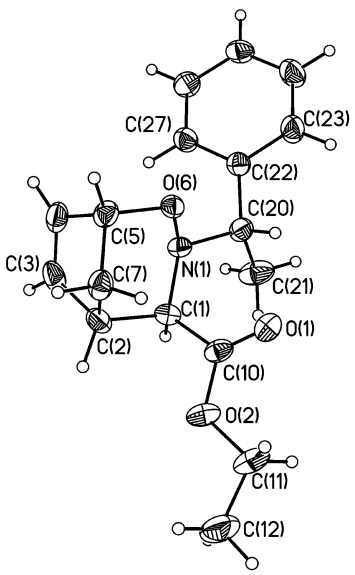


Fig. 1 X-Ray crystal structure of **7** with crystallographic numbering.‡

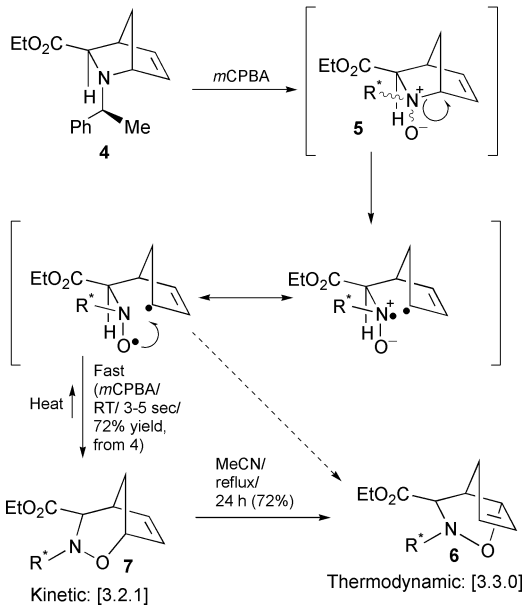
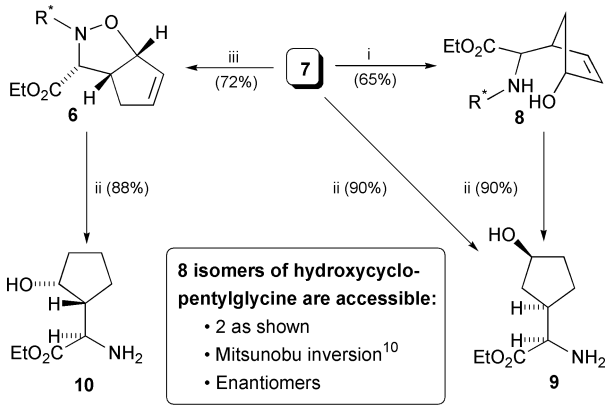


Scheme 2 Possible mechanism for the formation of **6** and **7**; heterolytic bond cleavage of **7** would also be consistent with its thermolysis to **6**. [R* = (*S*)-1-phenylethyl].



Scheme 3 Conversion of the oxazabicyclooctanes **6** and **7** into hydroxylated cyclopentylglycines such as **9** and **10**. Conditions: (i) Zn–AcOH; (ii) H_2 (50 psi)– $Pd(OH)_2$/C; (iii) MeCN, reflux, 24 h. [R* = (*S*)-1-phenylethyl].

the di-radical must be retained within a solvent cage, is extraordinary. Unprecedented, as far as we are aware, is the establishment of an equilibrium with the Meisenheimer intermediate (or possibly *via* heterolytic bond cleavage of **7**), providing a route by which the thermodynamically more stable adduct **6** can be generated (see Scheme 2).

With an efficient route to two isomeric oxazabicyclooctanes achieved, we wished to explore whether they could be converted into hydroxy-substituted cyclopentylglycines. The key transformations are shown in Scheme 3. In particular, Zn–AcOH treatment of the [3.2.1] isomer **7** allowed selective cleavage of the N–O bond, yielding the 4′-hydroxycyclopent-2′-enyl glycine derivative **8**. Hydrogenation of the double bond (Pearlman's catalyst, 50 psi) resulted in concomitant removal of the α-methylbenzyl auxiliary to afford the 3′-hydroxycyclopentyl glycine **9** as a single (2*R*,1′*R*,3′*S*) stereoisomer; the same hydrogenation conditions also allowed direct conversion of **7** to **9** (90% yield). On the other hand, these hydrogenation conditions enabled us to reduce the [3.3.0] isomer **6** directly to the 2′-hydroxycyclopentyl glycine **10**, also as a single (2*R*,1′*R*,2′*R*) stereoisomer. Closely related analogues of **8** have been used in the synthesis of cyclopentenylglycine,[11] and of carbocyclic analogues of nikkomycin[12] and polyoxin C.[13]

In summary, the asymmetric aza-Diels–Alder adduct **4** reacts with *m*CPBA to generate the Meisenheimer rearranged product **6**, which can be converted into the [3.3.0] system **7** by simple heating. These two isomers can be separately reduced, to provide access to a wide range of cyclopentylglycine derivatives, with complete regio-, diastereo- and enantio-control.

We thank Dr A. S. F. Boyd and Dr R. Fergusson for NMR and mass spectra, the EPSRC for financial support, and we acknowledge the use of the EPSRC's Chemical Database Service at Daresbury.

Unexpected dimerisation of a 2*H*-azaphosphirene complex

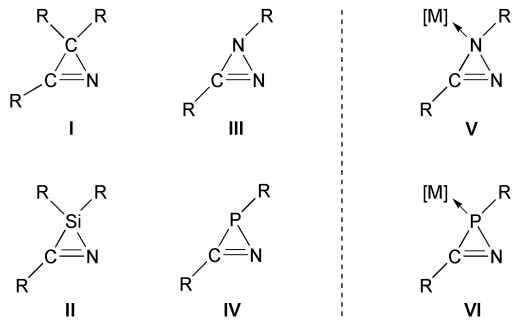
First published as an Advance Article on the web

Heating a 2*H*-azaphosphirene complex in the solid state afforded the first head-to-tail dimer, a 2,5-dihydro-2,5-diphosphapyrimidine complex, a η¹-diphosphene complex and another complex having low-coordinated phosphorus centers; whereas the latter was detected only by ^{31}P NMR spectroscopy, the dimer was isolated and structurally characterized.

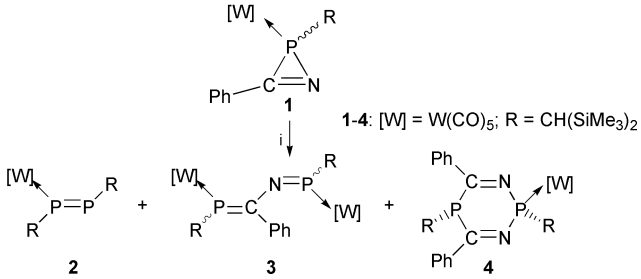
In comparison to 2*H*-azirenes[1] **I** (Scheme 1), which are versatile building blocks in heterocycle syntheses, the chemistry of heteroatom-substituted ring systems of type **II**–**IV** is much less explored. For example, transiently[2] formed 2*H*-azasilirenes **II** readily dimerise in solution in a head-to-head or head-to-tail manner, the orientation depending mainly on the carbon substituents.[3] Interestingly, even at low temperatures, 1*H*-diazirenes **III**[4] preferentially undergo ring enlargement[4] or rearrangement reactions,[5] but do not form dimers. Although 2*H*-azaphosphirenes **IV** have been claimed as intermediates, no dimerisation was reported; instead, ring cleavage occurred at room temperature to yield a short-lived phosphinidene and a nitrile derivative.[6] 1*H*-diazirene complexes **V** are, to the best of our knowledge, unknown. Recently, we reported syntheses[7] and reactions of 2*H*-azaphosphirene complexes **VI**, which gave access, *e.g.* to differently sized unsaturated phosphorus heterocycles either *via* ring cleavage[8] or *via* selective P–C[9] and P–N bond[10] cleavage ring expansion reactions.



Scheme 1 2*H*-azirenes (**I**), heteroazirenes (**II**–**IV**), 1*H*-diazirene (**V**) and 2*H*-azaphosphirene complexes (**VI**) (**I**–**VI**: R, R′ = alkyl, aryl; [M] = metal complex fragment).

Here we report the first dimerisation of a 2*H*-azaphosphirene complex leading to a head-to-tail dimer, a 2,5-dihydro-2,5-diphosphapyrimidine complex; a η¹-diphosphene complex and another complex having low-coordinated phosphorus centers were detected as by-products.

Heating the neat 2*H*-azaphosphirene tungsten complex **1**[11] for a short period afforded three phosphorus-containing products **2**, **3** and **4** in a ratio of *ca.* 1:3:10 (Scheme 2); heating complex **1** for longer periods, *i.e.* 1 h, did not significantly affect the ratio. Whereas the η¹-diphosphene tungsten complex **2**[12] ([d_8]-toluene): δ 391.3 ppm (^1J(P,P) 513.4 Hz, ^1J(P,W) 230.8 Hz, P=*P*W(CO)$_5$), 443.1 ppm (^1J(P,P) 513.4 Hz) was isolated in 8% yield by column chromatography, the dinuclear complex **3** decomposed during chromatography, but the chemical shifts, phosphorus–phosphorus and phosphorus–tungsten coupling constant magnitudes of **3** (AM-type; δ (P_A) 360.9 ppm, ^3J(P,P) 162.1, ^1J(W,P) 264.3 Hz) (δ (P_M) 160.9 ppm, ^3J(P,P) 162.1, ^1J(W,P) 272.4 Hz) revealed the existence of low-coordinated phosphorus centers,[13] thus allowing a tentative structural assignment with an atom connectivity as shown in Scheme 2 (P_A = P=NR,P_M = P=CR_2). The unusually great ^3J(P,P) value might result from the two-fold η¹-coordination mode of the two phosphorus centers.[14] The main product, the 2,5-dihydro-2,5-diphosphapyrimidine tungsten complex **4**, was confirmed by elemental analyses and NMR spectroscopy.† Further investigations using the analogous 2*H*-azaphosphirene chromium and molybdenum complexes[15] showed that the reaction course strictly depended on the nature of the metal; in contrast to the chromium (and tungsten) complex, heating the 2*H*-azaphosphirene molybdenum complex afforded the corresponding η¹-diphosphene molybdenum complex[12] as main product.



Scheme 2 *Reagents and conditions:* (i) 615 mg of complex **1**, 130 °C, 15 min; column chromatography (Al_2O_3, −50 °C, light petroleum–diethyl ether 90:10); **4**: bright yellow solid, yield: 43%, mp 156 °C (decomp.).

The ^{31}P NMR data of complex **4** are similar to those found for non-coordinated 2,5-dihydro-2,5-diphosphapyrimidine derivatives, which have been recently synthesized for the first time using a completely different approach.[16] The line broadenings in the ^{1}H and ^{13}C{^{1}H} NMR spectra of complex **4** at ambient temperature, which disappear upon cooling to −55 °C are remarkable; *e.g.* in the ^{13}C{^{1}H,^{31}P} NMR spectra two distinct resonances appear for the imino and also for the *ipso* carbon atoms of the phenyl rings. So far, we have no explanation for this phenomenon. Furthermore, the methine carbon atom (δ 9.9 ppm) and also the protons of one trimethylsilyl group (δ −0.73 ppm) of the three-coordinated phosphorus center resonate at remarkably high field, which probably indicates a shielding caused by the ring current of a nearby phenyl group. The molecular structure of complex **4** (Fig. 1), as established for the solid state by X-ray crystallography,‡ shows a slightly distorted boat conformation of the six-membered ring with the P1 and P2 atoms in the bow and stern positions (Fig. 2). The steric situation of the P2-bonded bis(trimethylsilyl)methyl group is noteworthy; as shown by the two different distances P2–C20 1.882(9) Å and P2–C13 1.829(10) Å, this group is asymmetrically flanked by the two phenyl rings, which act like a pincer, but only for one of the two trimethylsilyl groups. If this steric situation is retained in solution, this would convincingly explain the observed shielding of the proton and carbon atoms of the respective methine and trimethylsilyl groups.

Currently we are investigating the reaction of 2*H*-azaphosphirene complexes with various nickel(II) and palladium(0) complexes; such complexes have been shown to catalyze the

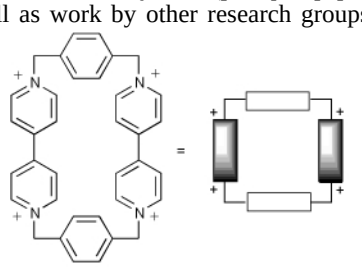
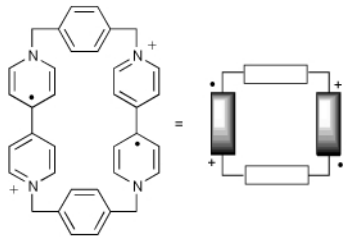
First published as an Advance Article on the web

A redox-active macrocyclic ionene oligomer, cyclobis(paraquat-*p*-phenylene), exhibited an enhanced activity as an electron phase-transfer catalyst for the reduction of quinones compared with acyclic benzyl viologen, due to the inclusion of the substrate into the catalyst cavity.

Compounds having one or more viologen units have attracted much attention because of their versatile applications.[1,2] Of particular interest among recent developments are a series of elaborate works on supramolecular chemistry by Stoddart *et al.*[2] which have led to successful construction of a variety of supramolecular architectures such as pseudorotaxanes, rotaxanes and catenanes mainly using a redox-active macrocyclic ionene oligomer,[3] *i.e.* cyclobis(paraquat-*p*-phenylene)[4] **1**. Theirs as well as work by other research groups[5] unambiguously show that **1** and related compounds form inclusion complexes with a variety of guests. However, little is known to date of their applicability in other fields including catalysis.



1



2

On the other hand, electron transfer catalysis by viologen compounds, which function as mediators of electron transfer, has continuously been attracting considerable interest.[1,6] Such compounds have been applied to the reduction of various substrates such as aldehydes and ketones,[6a,b] quinones,[6c] azobenzene,[6d] acrylonitrile,[6e] nitroalkenes,[6f] and nitroarenes,[6g] to the reductive desulfonation of α-nitro sulfones,[6h] and to the dehalogenation of diphenylbromomethane,[6i,j] *gem*- and *vic*-dibromides[6k,l] and α-halogeno ketones[6m] with either zinc or sodium dithionite in either a monophase or a two-phase solvent system. The viologen compounds thus far used include alkyl viologens,[6b,f–h,l,m] ionene polymers[7] having viologen units in the main chains,[6d,i–k] vinyl polymers having viologen units in the pendant groups,[6a,c,e] and so forth. However, no cyclic viologen compounds have ever been examined for catalysis.

The present research combining the above two fields of chemistry was motivated by the premise that, if the substrate is included in the cavity of **2**, a reduced species of **1**, the viologen units might be able to mediate the electron transfer more efficiently than acyclic viologens such as benzyl viologen **3** because of the close vicinity of the substrate to the units, and hence **1** would exhibit a higher activity of electron transfer catalysis than **3**. This communication reports that the experimental results using quinones as substrates validated this conjecture. In addition, to the best of our knowledge, this work presents the first example that the fundamental constituent of a cyclophane, *i.e.* the viologen moiety in the case of **1**, directly plays a pivotal catalytic role for the substrate included in the cavity of the host.

Fig. 1 shows the results of reduction of 1,4-benzoquinone with zinc in the presence of **1** in an alkyl acetate–H_2O (1:1) two-phase system at 25 °C.[8] Conversion of the substrate increased in the order: AcOMe < AcOEt < AcOBu. Thus, in general, the extent of reduction in the two-phase solvent systems became increasingly higher with increase in the hydrophobicity of the organic phase.[9] 1,4-Naphthoquinone could also be reduced similarly to 1,4-dihydroxynaphthalene. It should also be noted that, under the present reaction conditions, the reduction of quinones occurred to a considerable extent even in the absence of catalyst, and that **3** exhibits almost no ability to mediate electron transfer. However, it is obvious that **1** is, as expected, a much better mediator of electrons than **3**.

Fig. 2 depicts the results of the inhibition experiments using compounds having a phenyl or *p*-phenylene group, which can be included in the cavity of **1**, for the reduction of benzoquinone with zinc in different two-phase solvent systems, using either **1** or **3** as a catalyst.[8] The reduction of benzoquinone in AcOBu–H_2O (1:1) with use of **1** was retarded by the addition of 1,4-bis[2(2-hydroxyethoxy)ethoxy]benzene **4**.[10] Similarly, the same reduction in methyl benzoate[11] (BzOMe)–H_2O (1:1) or phenyl acetate[11] (AcOPh)–H_2O (1:1) two-phase systems was also retarded in comparison with the reduction in AcOBu–H_2O (1:1), in spite of the hydrophobic nature of these organic solvents (see above). On the other hand, almost no distinct inhibition effect was observed when **3** was used as a catalyst.

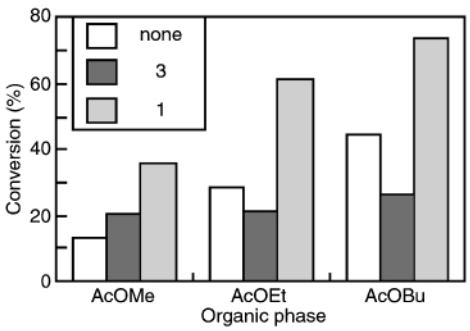


Fig. 1 Reduction of benzoquinone with zinc in alkyl acetate–H_2O (1:1) two-phase systems in the presence of **1** or **3** and in the absence of catalyst. *Conditions*: benzoquinone, 40 mM, 1.0 ml; viologen compound, 20 mM (as viologen unit), 1.0 ml; Zn, 0.20 mmol; 25 °C, 1.0 h.

† Present address: Department of Applied Chemistry, Faculty of Engineering, Toyo University, Kujirai, Kawagoe, Saitama 350-8585, Japan.

DOI: 10.1039/b007404g

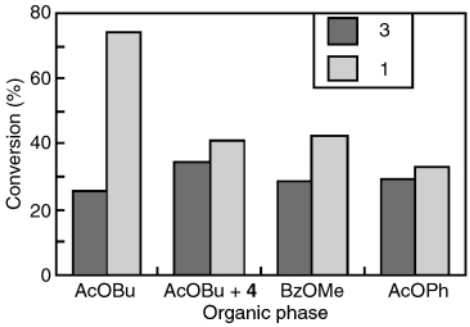

Fig. 2 Reduction of benzoquinone with zinc in the presence of **1** or **3** in different two-phase systems to prove that inclusion of the substrate into the cavity of **1** occurs; AcOBu–H_2O (1:1), AcOBu–H_2O containing 1,4-bis[2(2-hydroxyethoxy)ethoxy]benzene **4**, BzOMe–H_2O (1:1), and AcOPh–H_2O (1:1) (from left to right). *Conditions:* benzoquinone, 40 mM, 1.0 ml; viologen compound, 20 mM (as viologen unit), 1.0 ml; template compound **4**, 0.10 mmol; Zn, 0.20 mmol; 25 °C, 1.0 h.

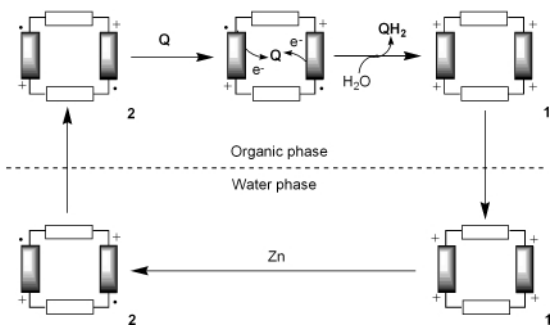
Thus, it is concluded that inclusion of the substrate in the cavity of **1** does occur, and hence the enhancement of the catalytic activity of **1** compared with that of **3** (*cf.* Figs. 1 and 2) in the two-phase solvent systems can be attributed to the easier electron mediation due to the close proximity of the included substrate to the redox-active viologen units.

Cyclic voltammetry of **1** in acetonitrile exhibits only two reversible reduction processes,[12] suggesting that the two viologen units in **1** are independent of each other in the reduction process. Thus, the species produced by the initial two-electron reduction of **1** with zinc is most likely to be radical cation **2**. From this the fundamental mechanism of the catalysis in a two-phase solvent system can be derived as illustrated in Scheme 1. First, **1** is reduced with zinc in the aqueous phase to **2**, which is then transferred into the organic phase[13] where the substrate (**Q**) is included in the cavity of **2**. The substrate is then reduced to hydroquinone (**QH_2**) with concomitant reoxidation of **2** to **1**. The regenerated **1** is transferred back into the aqueous phase to participate in the next catalytic cycle. The slow reactions in the two-phase solvent systems as compared with that in homogeneous DMSO–H_2O (1:1)[14] could possibly be attributed, at least in part, to the slow extraction rate of **2** from the aqueous phase into the organic phase. The mechanism for the reduction in a homogeneous mixed solvent would be essentially the same as above, apart from the absence of the phase transfer processes. However, since chemical shift values of the protons of **1** were changed on mixing it with quinones in DMSO-d_6–D_2O (4:1), the possibility cannot be ruled out, irrespective of the reaction modes, that the substrate first included in the cavity of **1** is then reduced after reduction of the host in the inclusion complex.

In summary, when a viologen-containing macrocyclic ionene oligomer was used as catalyst, electron transfer catalysis on quinone reduction could be enhanced due to facilitated electron mediation between the substrate and the viologen units in the inclusion complex. Further investigation of catalysis using **1** and related compounds is in progress to reveal the scope and limitations as well as to gain a deeper insight into the reaction mechanism.



Scheme 1 Fundamental mechanism for the reduction of a quinone compound (**Q**) with zinc in an organic solvent–H_2O (1:1) two-phase system in the presence of **1**.

Noguchi, *Polymeric Materials Encyclopedia*, J. C. Salamone (Ed.-in-Chief), CRC Press, Boca Raton, FL, 1996, vol. 5 (H–L), p. 3392.

8 A typical reaction procedure was as follows. In an atmosphere of oxygen-free nitrogen 1.0 ml of a 40 mM quinone solution in an organic solvent and 1.0 ml of a 10 mM solution of **1**·4Cl^- in 50 mM phosphate buffer (pH 7.0), were placed in a Schlenk tube, and the mixture was deaerated three times by the freeze–thaw technique. Then, 0.20 mmol of activated zinc powder, was added in an atmosphere of nitrogen. The mixture was vigorously stirred (>1200 rpm) with a Teflon-coated magnetic bar for l h at 25 °C. The product was solely hydroquinone and quantified by HPLC. In all the experiments, the concentration of the viologen unit was the same (20 mM) with chloride as counter ion. To ensure the accuracy of the concentration of **1**·4Cl^-, special care was taken of the water content in its synthesized sample, which was determiend by elemental analysis.

9 It should be noted that this statement is only superficial, because the solubility of the alkyl acetates in water greatly depends on the alkyl groups, indicating that the reaction conditions can be considerably different from one another.

10 This compound has been used as a template in the template-directed synthesis of **1**,[4] and therefore can be included in the cavity of **1**.

11 Note that the phenyl groups of these organic solvents can be included in the cavity of **1**. See for example: T. T. Goodnow, M. V. Reddington, J. F. Stoddart and A. E. Kaifer, *J. Am. Chem. Soc.*, 1991, **113**, 4335.

12 P. R. Ashton, C. L. Brown, E. J. T. Chrystal, T. T. Goodnow, A. E. Kaifer, K. P. Parry, D. Philp, A. M. Z. Slawin, N. Spencer, J. F. Stoddart and D. J. Williams, *J. Chem. Soc., Chem. Commun.*, 1991, 634.

13 Note that **2** is more hydrophobic than **1**, and hence will be transferred into the organic phase more easily than **1**.

14 The reduction of quinones with zinc in a homogeneous mixed solvent such as DMSO–H_2O (1:1) was, on the whole, faster than the same reaction in a two-phase solvent system. However, clear comparison of the catalytic activities of viologen compounds **1** and **3** was hampered by the precipitation of radical cation **2**.

N-Hydroxyphthalimide-catalyzed radical addition of 1,3-dioxolanes and molecular oxygen to alkenes under ambient conditions: a new route to β-oxycarbonyl compounds

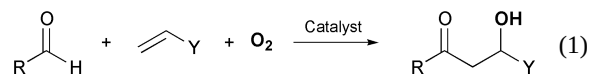
First published as an Advance Article on the web

A novel catalytic hydroxyacylation of alkenes using 1,3-dioxolanes and molecular oxygen has been developed, and the reaction of 2-methyl-1,3-dioxolane with methyl acrylate under dioxygen atmosphere in the presence of catalytic amounts of NHPI and $Co(OAc)_2$ produced the corresponding adduct in 81% yield.

Addition of aldehydes to terminal alkenes has received attention as a method for the synthesis of ketones from aldehydes.[1] The frequently used methodologies are the direct hydroacylation of alkenes with aldehydes by transition-metal catalysts[1] and the addition of acyl radicals to alkenes bearing electron-withdrawing substituents such as fumarate by radical initiators.[2] If the concomitant introduction of acyl and hydroxy moieties to alkenes can be carried out by a cascade reaction, this type of reaction is referred to as *hydroxyacylation* and would provide a novel route to β-oxycarbonyl compounds which constitute important structural subunits in key intermediates leading to pharmaceuticals [eqn. (1)].[3] Although there is one report on the hydroxyacylation of alkenes like acrylates with acyl radicals from aldehydes using dioxygen as a hydroxy source assisted by a cobalt(II) Schiff-base complex,[4] the attempt was not fully successful due to the decarbonylation from acyl radicals as well as the reaction of acyl radicals with O_2 leading to carboxylic acids which cause undesired side reactions.

***Hydroxy**acylation*

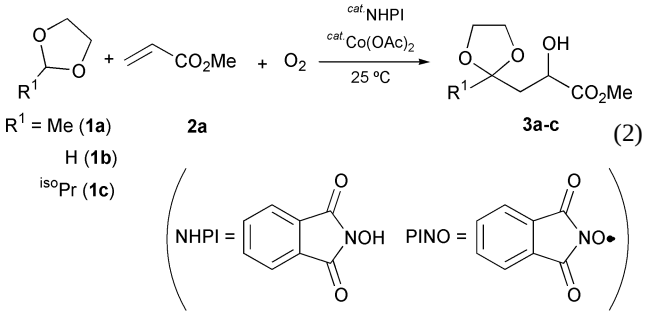


(1)

To overcome these drawbacks arising from acyl radicals, we employed 1,3-dioxolanes, masked aldehydes, as an acyl source in place of an aldehyde.[5] This paper describes the development of a novel catalytic method leading to β-hydroxy carbonyl compounds after deprotection under acidic conditions.

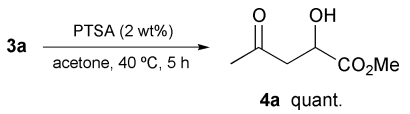
Recently, we have shown that *N*-hydroxyphthalimide (NHPI) combined with a Co(II) species serves as a catalyst for the generation of alkyl radicals from alkanes even under ambient conditions, and that the resulting alkyl radicals are readily captured by O_2 to give oxygenated products.[6] In this catalytic system, phthalimide *N*-oxyl (PINO) is the active species abstracting hydrogen atoms from the alkanes.[6a] This finding prompted us to study the generation of α,α-dioxaalkyl radicals from 1,3-dioxolanes and their addition to alkenes using the NHPI/Co(II)–O_2 catalytic system [eqn. (2)].

At the beginning, a mixture of 2-methyl-1,3-dioxolane (**1a**) (15 mmol) and methyl acrylate (**2a**) (3 mmol) was allowed to react under O_2 (1 atm) in the presence of NHPI (5 mol%) and a small amount of $Co(OAc)_2$ (0.05 mol%) at rt for 3 h (Table 1, Run 1).† The apparent hydroxyacylation based on the concomitant introduction of a dioxaalkyl radical and a hydroxy group to **2a** was achieved to form β-hydroxy ketal (**3a**) in 81% yield. In a previous paper, we showed that a Co(III)–dioxygen complex derived from the Co(II) species and O_2 assists the formation of a PINO radical from the NHPI.[6a] Accordingly, the Co(III) which fails to react with O_2 could not promote the reaction under O_2 at rt (Run 2).[6a,7]

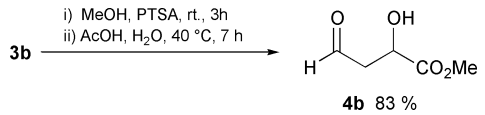


(2)

From 1,3-dioxolane (**1b**), the corresponding adduct **3b** was obtained in high yield (82%) (Run 4). The introduction of the masked formyl group to **2a** is promising, since the direct use of formaldehyde is restricted due to its intractability. These dioxolane moieties could be easily deprotected upon treatment under acidic conditions to form the corresponding carbonyl compounds [eqns. (3) and (4)].



(3)



(4)

The reaction of **1a** or **1b** with various alkenes was run under selected reaction conditions (Table 2). Acrylonitrile (**2e**) was found to serve as a good acceptor of **1a** and **1b** in a similar manner as **2a**, giving cyanohydrin derivatives in good yields. However, methyl crotonate (**2c**) bearing a β-methyl group retarded the hydroxyacylation, probably owing to the steric hindrance towards attack by an α,α-dioxaalkyl radical on **2c**.[8] To our surprise, methyl vinyl ketone (**5a**) reacted with **1a** to afford a cleaved product, 3-(1,3-dioxolan-2-yl)butanoic acid (**6**) in 83% yield along with 3-(1,3-dioxolan-2-yl)butylaldehyde (**7**)

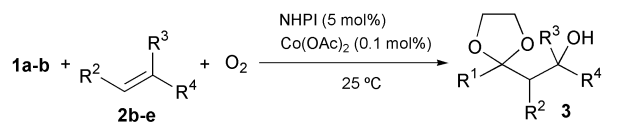
Table 1 Reaction of **1a–c** with methyl acrylate (**2a**)[a]

Run	**1a–c**	NHPI/ mol%	Co(II)/ mol%	*t*/h	Yield (%)[b]
1	**1a**	5	0.05	3	81
2[c]	**1a**	5	0.05	3	n.d.
3	**1a**	—	0.05	3	1
4[d]	**1b**	10	0.1	2	82
5	**1c**	5	0.1	14	76

[a] **2a** (3 mmol) was allowed to react with **1a–c** (15 mmol) in the presence of NHPI and $Co(OAc)_2$ under atmospheric oxygen at rt. [b] GC yield. [c] $Co(acac)_3$ was used. [d] **1b** (30 mmol) was used.

DOI: 10.1039/b008418m

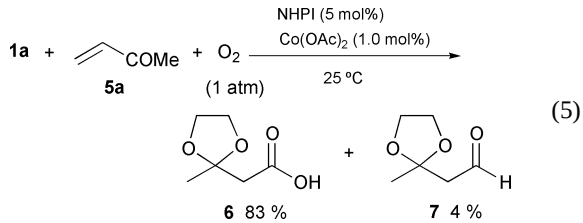
Table 2 Reaction of **1a–b** with various alkenes under ambient conditions[a]



Run	1a–b	2b–e R²	R³	R⁴		t/h	3 (%)[b]
1	**1a**	H	Me	CO_2Me	**2b**	15	84
2[c]	**1a**	Me	H	CO_2Me	**2c**	15	16
3[d]	**1a**	CO_2Et	H	CO_2Et	**2d**	2	77
4	**1a**	H	H	CN	**2e**	16	77[e]
5	**1b**	H	Me	CO_2Me	**2d**	15	60
6	**1b**	H	H	CN	**2e**	16	60[e]

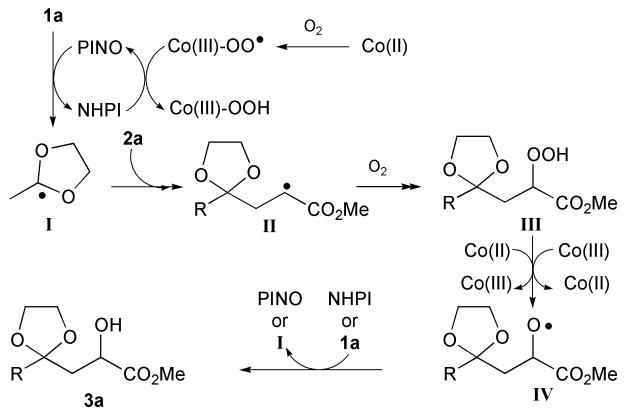
[a] **2b–e** (3 mmol) were allowed to react with **1a–b** (15 mmol) in the presence of NHPI (5 mol%) and $Co(OAc)_2$ (0.1 mol%) under atmospheric oxygen at rt. [b] GC yield. [c] NHPI (10 mol%) was used. [d] $Co(OAc)_2$ (0.05 mol%) was used. [e] Isolated yield.

(4%) [eqn. (5)]. The carboxylic acid **6** is considered to be formed *via* the further oxidation of aldehyde **7**.[9]

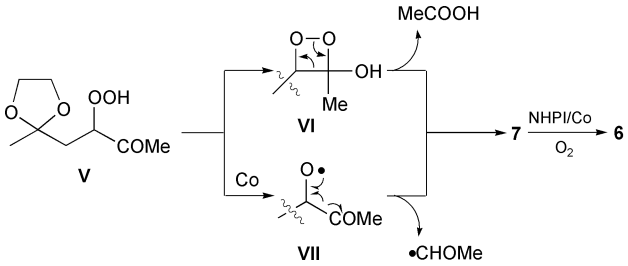


(5)

A plausible reaction path for the apparent hydroxyacylation of **2a** with **1a** under dioxygen is shown in Scheme 1. The reaction may be initiated by the hydrogen atom abstraction from NHPI by the action of the Co(III)–dioxygen complex, giving PINO which then abstracts the dioxolane hydrogen of the **1a** to form an dioxolane radical **I**. The **I** radical having a highly nucleophilic character seems to readily add to **2a**, yielding a radical species **II**. Under the conditions in which O_2 is present in the reaction system, the resulting radical **II** is rapidly trapped by O_2 to give a hydroperoxide **III**. It is well-known that hydroperoxides like **III** are subjected to redox decomposition by Co ions to form an alkoxyl radical **IV** which is eventually



Scheme 1 Proposed reaction path for the radical addition of **1a** to **2a** under dioxygen in the presence of NHPI and $Co(OAc)_2$.



Scheme 2

converted into **3a** through the hydrogen abstraction from either NHPI or **1a**.[10]

Although it seems rather hazardous to make an accurate assessment about the reaction path for the formation of **6** from **1a** and methyl vinyl ketone **5a**, we can make two proposals which seem to agree with the experimental results. It is probable that an α-hydroperoxyketone **V** derived from **1a** and **5a** might decompose into aldehyde **7** *via* formation of a hydroxydioxetane **VI** (Scheme 2). This type of reaction through the hydroxydioxetane is shown in the autoxidation of ketones like diisopropyl ketone.[11] However, an alternative proposal is also possible, *viz.* the hydroperoxide **V** is subject to the redox decomposition to generate an alkoxy radical intermediate **VII** which then is converted into **7** *via* β-scission.

In conclusion, we have developed a novel method for the introduction of both a masked acyl or formyl group and a hydroxy or keto function to a double bond of alkenes. Further work on the extension of this method is actively underway.

This work was partly supported by the Japan Society for the Promotion of Science under the Research for the Future program JSPS.

Notes and references

† *A typical procedure for reaction of 2-methyl-1,3-dioxolane **1a** with methyl acrylate **2a***: To a solution of **1a** (15 mmol), NHPI (0.15 mmol) and $Co(OAc)_2$ (0.0015 mmol) in a two-necked flask, equipped with a balloon filled with O_2 (1 atm), was added **2a** (3 mmol). The mixture was vigorously stirred at rt for 3 h. The recovery of unreacted **1a** under a reduced pressure followed by flash chromatography on silica gel (*n*-hexane–AcOEt = 1 : 2) afforded methyl 2-hydroxy-4-(1,3-dioxolan-2-yl)valerate (**3a**) (462 mg, 81% yield) as a colorless liquid.

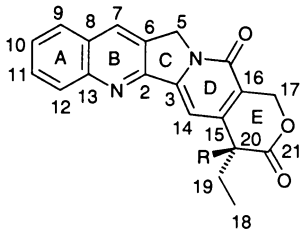
First published as an Advance Article on the web

Addition of the enolate derived from isopropyl α-(methylsulfanyl)butyrate to *N*-(quinolylmethyl)-2-fluoropyridinium triflate 7, followed by oxidation–hydrolysis of the resultant 2-fluoro-1,4-dihydropyridine 8b afforded pyridone 9b, from which 20-deoxycamptothecin (11), a known precursor of camptothecin, was synthesized by a radical cyclization–desulfurization, with subsequent elaboration of the lactone E ring by chemoselective reduction.

Camptothecin and 20-deoxycamptothecin[1] are pentacyclic alkaloids with a pyrrolo[3,4-*b*]quinoline nucleus fused to a 2-pyridone ring. First isolated by Wall *et al.* in 1966 from *Camptotheca acuminata*,[2] camptothecin has recently re-emerged as one of the most promising agents for cancer treatment, topoisomerasa I being identified as the intracellular target for the drug.[3] Due to this interesting cytotoxic activity, camptothecin and its structural derivatives have been the objective of many total syntheses using a variety of approaches.[4,5]



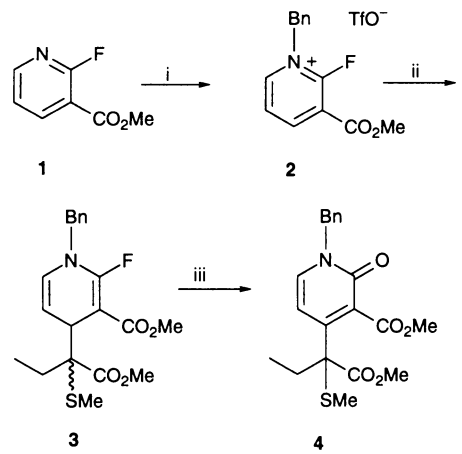
We present here a new, concise synthesis of (±)-20-deoxycamptothecin, a known synthetic precursor of camptothecin. Our approach involves the convergent construction of a suitably substituted and functionalized tetracyclic ABCD derivative **10** and the closure of the lactone E ring at the final synthetic step. For this purpose, we planned to take advantage of the synthetic potential of 1,4-dihydropyridines generated by nucleophilic addition of enolates to *N*-alkyl-3-acylpyridinium salts. In our previous work[6] these dihydropyridines have been further elaborated to complex polycyclic indole alkaloids either after acylation of the unsubstituted enamine moiety or *via* a dihydropyridinium cation generated by protonation or interaction with an electrophile.

For the synthesis of camptothecin we envisaged that, after the regioselective addition of a butyric ester enolate (the C_{18}–C_{21} fragment) to an appropriate *N*-(quinolylmethyl)-2-fluoropyridinium salt, the intermediate 2-fluoro-1,4-dihydropyridine could undergo a different transformation, namely an oxidation with concomitant hydrolysis of the C–F bond, leading to a 4-substituted-2-pyridone. Then, the quinoline and pyridone rings would be connected following the Comins procedure,[5*d–f*] by radical cyclization taking advantage of a bromine atom present at the 2-position of the quinoline nucleus. A methoxycarbonyl substituent at the β-position of the starting pyridinium would not only increase the electrophilicity of the pyridine ring in the nucleophilic attack but would also be subsequently converted to the C-17 oxymethylene group of the alkaloid.

To test the viability of our proposal for the construction of the pyridone moiety we first applied the nucleophilic addition–oxidation sequence to the model *N*-benzyl-2-fluoropyridinium salt **2** (Scheme 1). Knowing the reluctance of 2-halopyridines to undergo alkylation with alkyl halides and tosylates,[7] 2-fluoropyridinium salt **2** was prepared by alkylation of the corresponding 2-fluoropyridine **1**[8] with benzyl triflate. Without isolation, pyridinium triflate **2** was allowed to react with the enolate derived from methyl α-(methylsulfanyl)butyrate, which in related additions had exhibited better C-4 regioselectivity than the corresponding unsubstituted butyrate enolate.[9] Following our synthetic plan, the resulting 1,4-dihydropyridine adduct **3** was converted into the desired pyridone **4**[10] by oxidation with DDQ with hydrolysis of the C–F bond. The overall yield of the three-step sequence from 2-fluoropyridine **1** was 65%.

The application of the above strategy to the synthesis of camptothecin required starting from the pyridinium salt **7**, which incorporates the 2-bromoquinolyl-3-methyl fragment needed for the closure of the five-membered C ring. This salt was obtained by alkylation of 2-fluoropyridine **1** with triflate **6**, prepared from 2-bromo-3-(iodomethyl)quinoline (**5**).[11] Pyridinium triflate **7** was allowed to react as in the above *N*-benzyl series with the enolate derived from methyl α-(methylsulfanyl)butyrate and then with DDQ to provide pyridone **9a** in 50% overall yield from 2-fluoropyridine **1**. This pyridone already incorporates all the carbon atoms of the natural product. As expected, treatment of **9a** with tris(trimethylsilyl)silane–AIBN brought about both a radical arylation[12] and desulfurization to give the key tetracycle **10a** in 65% yield (Scheme 2).

The construction of the lactone E ring of camptothecin required the chemoselective reduction of the conjugate ester rather than the aliphatic one of **10a**. This transformation had already been reported from the diethyl ester analog **10c** by treatment with DIBAL (no details given).[5*k*] However, in our hands, the sequential treatment of **10a** with DIBAL–CH_2Cl_2 at −70 °C or DIBAL–THF at −40 °C and $NaBH_4$ gave the diol **12** as the only isolable product in 80% yield. Neither were we able to induce this transformation from diethyl ester **10c**, prepared in



Scheme 1 Model studies. *Reagents and conditions*: i, BnOTf, Et_2O, rt, 10 min; ii, methyl α-(methylsufanyl)butyrate, LDA, THF, −70 °C, then −40 to −10 °C, 1.5 h; iii, DDQ, 3:1 THF–MeOH, rt, 12 h.

DOI: 10.1039/b007814j

90% yield by transesterification of **10a** (EtOH, KF, reflux, 3 days). Diol **12** was also formed as the major product in 75% yield.

The above results prompted us to differentiate the two ester groups as in the pioneering Winterfeldt synthesis of camptothecin from a closely related tetracyclic substrate.[13] Thus, we focused our attention on tetracycle **10b**, which was prepared by reaction of pyridinium triflate **7** with the enolate derived from isopropyl α-(methylsulfanyl)butyrate, followed by DDQ oxidation (50% overall yield from **1**) and subsequent radical cyclization (65% yield). Gratifyingly, treatment of **10b** with DIBAL–hexanes in DME at −70 °C and then with $NaBH_4$ in isopropanol afforded a 1:1 mixture of the target lactone **11** (20-deoxycamptothecin)[5a] and lactol **13** (65% yield), which were easily separated by column chromatography. The conversion of lactol **13** into **11** (65% yield) has recently been reported.[5n] Taking into account that 20-deoxycamptothecin (**11**) has previously been converted by hydroxylation at C-20 either to racemic (Me_2NH, $CuCl_2$, O_2, DMF)[5a] or natural [(+)-(20*S*)]-camptothecin [LHDMS, THF, (+)-(2*R*,8a*S*)-(camphorylsulfonyl)oxaziridine],[5m] the above synthesis constitutes a formal total synthesis of this natural product.

The above results significantly expand the methodology for the synthesis of nitrogen compounds based on the addition of carbon nucleophiles to *N*-alkyl-3-acylpyridinium salts as they open new synthetic possibilities for the subsequent elaboration of the initially formed 1,4-dihydropyridine adducts.

Thermally induced gelation of an oil-in-water emulsion stabilised by a graft copolymer

First published as an Advance Article on the web

Oil-in-water (O/W) emulsions exhibiting reversible thermally induced gelation have been prepared using a graft (comb) copolymer containing poly(*N*-isopropylacrylamide) [poly(NIPAM)] as the backbone and poly(ethylene glycol) methacrylate as the side chains.

Emulsions are dispersions of one immiscible liquid in another. They occupy a significant position in colloid science and occur as products (or during processing stages) in a number of areas including the paint, food and agrochemical industries.[1] The majority of emulsions studied or produced commercially are prepared using short-chain surfactants. The properties of these systems are reasonably well understood.[1,2] In recent years copolymers have been employed as macrosurfactants to prepare emulsions.[3,4] One of the advantages of using macrosurfactants for emulsion preparation is the large degree of architectural control that can be exerted in order to explore and optimise copolymer structure—emulsion property relationships. Water-soluble copolymers can be prepared which exhibit solvent–polymer interactions that are thermally responsive. This compositional control thus allows fine control over the lower critical solution temperature of the copolymer.[5] The preparation of emulsions using thermally responsive copolymers is a new area of research and is the subject of this communication.

The objective of the present study was to prepare emulsions with stabilities which are responsive to environmental conditions (*e.g.* temperature). We reasoned that the use of copolymers based on poly(*N*-isopropylacrylamide) [poly(NIPAM)] would provide gross conformational changes at the oil-in-water (O/W) interface at temperatures lower than the cloud point of short-chain ethylene-oxide based surfactants. Perrin *et al.*[3,6] have used hydrophobically modified poly(sodium acrylate) copolymers in order to prepare emulsions the stability of which are sensitive to pH and ionic strength. Mathur *et al.*[7] employed pH sensitive poly(acrylic acid)-g-poly(ethyleneoxide) copolymers in order to break emulsions. Our interest in the use of poly(NIPAM) copolymers to prepare emulsions follows from our earlier work involving swellable poly(NIPAM) microgel particles,[8] linear poly(NIPAM) chains adsorbed at latex particle interfaces[9] and depletion flocculation of emulsions.[10,11] The use of copolymers based on poly(NIPAM) to prepare emulsions was expected to provide large and reversible changes in emulsion properties (*e.g.* viscosity) as the temperature approaches the lower critical solution temperature (LCST). The results presented below show that this is indeed the case.

The copolymer comprised of poly(NIPAM) and poly(ethylene glycol methacrylate) (PEGMa); the latter having a number average molecular weight of 360. AIBN and *tert*-butyl alcohol were used, as the initiator and solvent, respectively, during the free radical copolymerisation stage.[12] Proton NMR data revealed that there was on average one PEGMa group per six NIPAM units in the copolymer. Fig. 1 shows how the turbidity and viscosity vary with temperature for poly(NIPAM–PEGMa) in water. The LCST of the copolymer is taken as *ca.* 34 °C from the turbidity data. This is *ca.* 2 °C higher than that of poly(NIPAM) homopolymer, which is attributed to the hydrophilic nature of the PEGMa in the copolymer.[13] The O/W

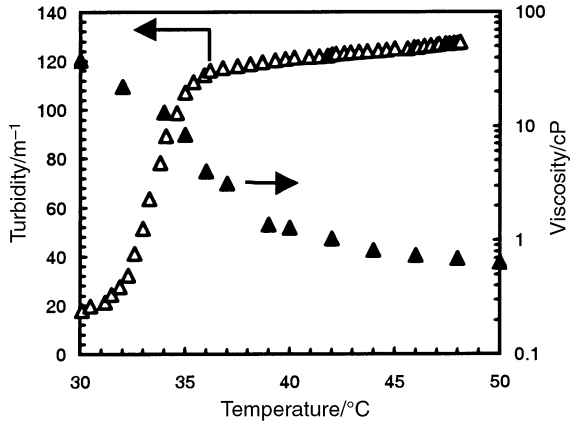

Fig. 1 Variation of the turbidity (Δ) and viscosity (▲) of poly(NIPAM–MPEGMa) solution as a function of temperature. The concentration of copolymer used was 2.5 wt%.

emulsions were prepared by first dissolving the copolymer in water (5 wt%). 1-bromohexadecane was then added to the copolymer solution, before the mixture was sheared using a Silverson SL2T laboratory mixer operating at *ca.* 7500 rpm. A control emulsion was prepared using the short-chain surfactant $Me(CH_2)_8(OCH_2CH_2)_6OH$, ($C_9E_6$) for comparison.

Fig. 2 shows the variation of viscosity with temperature for the emulsions prepared using poly(NIPAM–PEGMa) and C_9E_6. The viscosity data were measured using an Ostwald capillary viscometer. The viscosity for the emulsion prepared using poly(NIPAM–PEGMa) decreases with increasing temperature and reaches a minimum at 44 °C. A dramatic increase in viscosity occurs above 48 °C. The viscosity increased to such an extent that gelation of the emulsion occurred (see Fig. 3). As

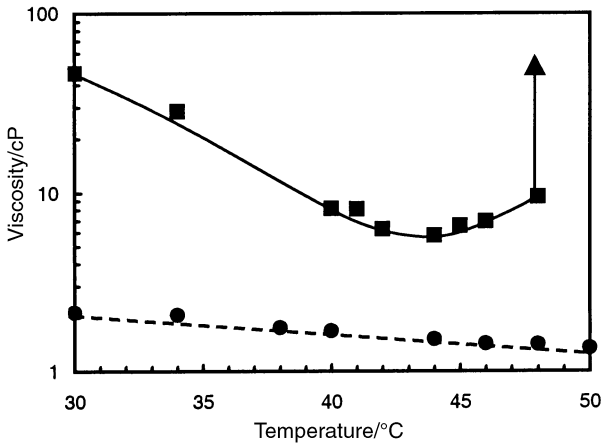

Fig. 2. Effect of temperature on the viscosity of emulsions prepared using poly(NIPAM–MPEGMa) (■) and C_9E_6 (●). The volume average diameters were 9.6 and 4.9 μm, respectively. The volume fraction of the dispersed phase was 0.30. The concentration of copolymer or C_9E_6 present was 2.5 wt% with respect to the total emulsion.

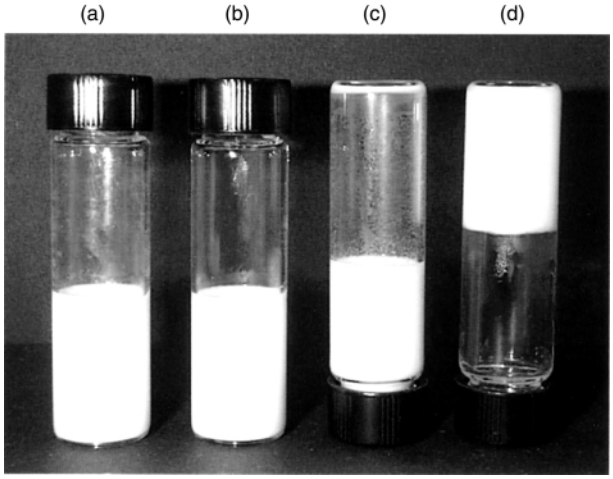

Fig. 3 Emulsions prepared using C_9E_6 (a) at RT and (c) at 50 °C and poly(NIPAM–MPEGMa) (b) at RT and (d) at 50 °C. Note that tubes (c) and (d) have been inverted.

expected, the emulsion prepared using C_9E_6 exhibited a slight decrease in viscosity over the whole experimental temperature range. It should be noted that the rheological behaviour observed for the emulsion prepared using the copolymer is opposite to what is observed for concentrated poly(NIPAM) microgel dispersions, which form gels at room temperature and flow when the temperature exceeds the LCST. It was found that emulsion gelation could be reversed by agitation at 50 °C or cooling to room temperature in the absence of agitation. The emulsions did not break as a result of gelation reversal, although there was evidence of a slight increase in droplet size. Optical microscopy revealed residual flocs were present in the emulsions after one heating/cooling cycle. The emulsion viscosity measured at 30 °C increased by *ca.* 5% as a result of one heating/cooling cycle.

The data shown here demonstrate that it is possible to reversibly gel our O/W emulsion using temperature variation alone. The mechanism by which this occurs is of interest to both the polymer and emulsion science communities. The fact that the gelation temperature is significantly greater than the LCST of the copolymer in solution suggests that the onset of gelation is not solely due to the collapse of the copolymer in the aqueous phase. The viscosity data for the copolymer (Fig. 1) show a decrease in viscosity with increasing temperature and rules out any contribution from temperature-induced continuous phase thickening (*e.g.* associated with the copolymer chains in solution) to emulsion gelation. The zeta potential for the droplets was measured at *ca.* 5 mV, which indicates that electrostatic stabilisation of the emulsions is not significant. The LCST of poly(NIPAM) chains adsorbed at highly charged surfaces is known to increase to values above that for the solution polymer.[14] However, this effect is not likely to occur in the present system due to the low charge of the droplets.

The stability of the emulsions arises primarily from steric stabilisation afforded by the adsorbed copolymer. The mechanism tentatively suggested for emulsion gelation involves thermally induced flocculation due to collapse of the adsorbed poly(NIPAM–PEGMa) layer at temperatures greater than the solution LCST. The depth of the secondary minimum would increase with increasing temperature (decreasing copolymer layer thickness) leading to stronger flocculation at higher temperatures. At 45 °C the minimum is sufficiently greater than *kT* to provide strong gelation *via* adhesive droplets. The collapse of the adsorbed layer presumably results in a rigid interface which opposes coalescence of flocculated droplets. It is likely that interpenetration and entanglement of interfacial copolymer chains contributes to the limits of residual flocculation observed upon cooling. Note that this good degree of reversibility for the copolymer stabilised emulsions is distinctly different to the behaviour of emulsions stabilised by short-chain ethylene oxide surfactants (*e.g.* C_9E_6) when heated to above the phase inversion temperature. For the latter emulsion breaking results from heating to the phase inversion temperature in absence of shear.

The work described above has shown that the use of poly(NIPAM–MPEGMa) graft copolymers allows the reversible gelation of O/W emulsions. This could have significant technological importance in the field of emulsion stability as the thermally induced gelation results in reversible transformation of a liquid emulsion into a highly viscous gel within a short period of time upon application of modest heating. Copolymers based on NIPAM can be prepared that have a range of LCST values. These ratios can be carefully controlled *via* copolymer architecture modification during synthesis. This versatility should allow the gelation temperature to be finely tuned to suit specific applications. The mechanism by which gelation occurs will be further investigated using light scattering, rheological and small-angle neutron scattering measurements and the results of these stuides will be published in due course.

We acknowledge the Department of Chemical Engineering for access to the PCS instrument.

Formation of allylsilanes from $Cl_2[P(C_6H_{11})_3]_2Ru=C(R)H$ and vinylsilanes—β-SiR'_3 elimination from ruthenacyclobutanes as a terminating step in olefin cross-metathesis

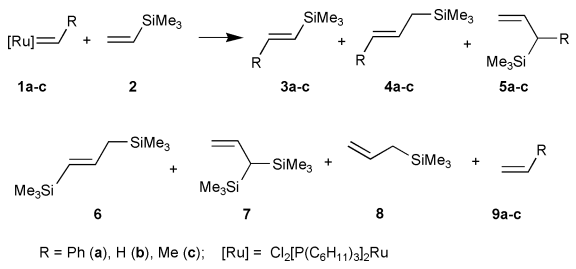
Stoichiometric reactions of the Grubbs carbene complex $[Cl_2\{P(C_6H_{11})_3\}_2Ru=C(Ph)H]$ with vinylsilanes, $H_2C=C(SiMe_nR_{3-n})H$ (R = Ph, OEt; *n* = 1, 2, 3), afford metathesis products and allylsilanes formed by β-SiR_3 elimination followed by reductive elimination; the formation of allylsilanes constitutes a terminating step in the Ru-catalysed cross-metathesis of olefins with methylsubstituted vinylsilanes.

Metallacyclobutanes[1] play an important role in a number of stoichiometric and catalytic transformations. Two of the catalytically most important reaction modes of metallacyclobutanes are (a) reductive elimination to give cyclopropanes and a metal–ligand fragment[2] and (b) reductive decoupling to form an olefin–carbene complex (olefin metathesis).[3] In these reactions the metallacyclobutanes are formed as intermediates by addition of the C=C bond of an olefin to the M=C bond of an $L_nM=C(R)R'$ complex. Several types of olefin metathesis are known, such as ring-opening metathesis polymerisation, self- and cross-metathesis of linear olefins, acyclic diene metathesis (ADMET), and ring-closing metathesis (RCM).[3]

We recently reported[4] on the highly selective cross metathesis of styrene $H_2C=C(Ph)H$, with several vinylsilanes $H_2C=C(SiR_3)H$, to give (*E*)-H(Ph)C=C(SiR_3)H and ethylene catalysed by the Grubbs catalyst $[Cl_2\{P(C_6H_{11})_3\}_2Ru=C(Ph)H]$ (**1a**).[5] Very high conversions even at rt were observed when R = OR′ (R′ = Et, $SiMe_3$); however, the conversion significantly decreased with increasing substitution of Me for OR′.[4] To determine the reason for the decreasing selectivity we studied the stoichiometric reaction of **1a** with various vinylsilanes and now report on (a) the first evidence for β-silyl migration in metallacyclobutanes, (b) the very high selectivity of β-SiR_3 *versus* β-H migration and (c) hints for β-migration as the terminating step thus limiting the efficiency of the catalyst.

When an equivalent of trimethylvinylsilane (**2**) was added to a solution of **1a** in C_6D_6 a smooth reaction was observed.† After 6 h at rt 98% of **2** and 99% of **1a** had been consumed. A detailed analysis of the organic reaction products revealed the formation of 15% of **3a**, 57% of **4a**, 6% of **5a**, in addition to small amounts of **6** (5%), **7** (2%), **8** (5%), **9a** (2–5%) (Scheme 1) and unidentified Ru complexes. Cyclopropanes were not detected.



Scheme 1

Only compounds **3a** and **9a** are those expected from olefin metathesis. All other products (**4a**–**8**) are allyl derivatives containing the C_3 fragment of the metallacycle. Obviously, the metallacycle formed by addition of **2** to the Ru=C bond of **1a** breaks down by two different pathways: (a) reductive decoupling to give the metathesis products **3a**, **9a** and a [Ru]=C(R)H species and (b) elimination of an allylsilane derivative and formation of a [Ru] fragment.

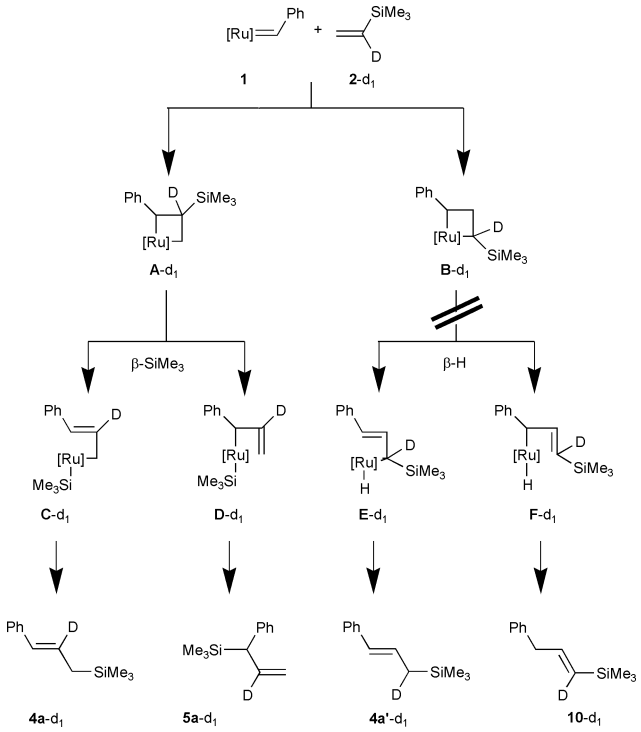
Pathway (b) causes a decrease of the catalytically active [Ru]=C(R)H species and presumably is the most important factor in reducing the efficiency of the catalytic system. The conclusion is supported by the following observation: When Me in **2** is replaced stepwise by OEt, both the ratio of the metathesis product (type **3**) to the allyl derivative (type **4**) in the stoichiometric reaction [0.26 ($SiMe_3$), 0.68 ($Si(OEt)Me_2$), 13 ($Si(OEt)_2Me$)] and the cross-metathetical conversion of styrene to vinylsilane mixtures catalysed by **1** drastically increase. Analogously, a strong shift toward the metathesis product is observed when Me is stepwise displaced by Ph.

The reactions of **2** with the methylidene complex **1b** and the ethylidene complex **1c** instead of **1a** proceeded similarly, albeit more slowly. The reaction rate decreased in the series **1a** > **1b** > **1c**. Again mixtures of metathesis products and allyl derivatives were obtained. The reactions of **2** with **1b** and **1c** were accompanied by a substrate-independent decomposition of the Ru complexes[6] which gave rise to a reduction in the conversion of **2** (41% for **1b** and 35% for **1c**, each after 6 h). Within error limits, the product distribution after 6 h was the same as that after 18 h.

The formation of the major allyl derivative (**4a**) in the reaction of **1a** with trimethylvinylsilane (**2**) can be explained in two different ways: (i) by β-$SiMe_3$ elimination to give an allyl(silyl) complex (see Scheme 2: **C**/**D**) followed by reductive elimination or (ii) by β-H elimination to give a hydrido(α-silylallyl) complex (Scheme 2: **E**/**F**) again followed by reductive elimination. The labeling experiment (Scheme 2) allows exclusion of pathway (ii). The ^{2}H-NMR spectrum of the products obtained from the reaction of **1a** with $H_2C=C(D)SiMe_3$ (**2**-d_1) exhibited only signals in the *olefinic* region. From the absence of signals in the *aliphatic* region it follows that **4a′**-d_1 has not been produced. The formation of more than 1% of **4a′**-d_1 (with respect to **4a′**-d_1) would have been detected. Another product of pathway (ii), compound **10**, has not been identified among the reaction products in earlier experiments (see Scheme 1). These results indicate that there is a strong preference for β-SiR_3 elimination over β-H elimination. In fact, products derived from β-H elimination have not been detected in the stoichiometric experiments. Thus the ratio **4a**/**5a** = 57 : 6 presumably reflects the relative stabilities of different allyl(silyl) complex intermediates **C** and **D**.

The bis(silyl)allyl derivatives **6** and **7** are secondary products derived from the reaction of [Ru]=C($SiMe_3$)H with **2**. Their formation establishes that [Ru]=C($SiMe_3$)H species are also formed in the reaction of **1** with **2** as we proposed earlier.[4] Until

DOI: 10.1039/b008536g



Scheme 2

now, all our attempts to synthesise $[Cl_2\{P(C_6H_{11})_3\}_2Ru{=}C(SiMe_3)H]$ or to spectroscopically detect $Ru{=}C(SiMe_3)H$ species in the cross-metathesis of vinylsilanes with styrene catalysed by **1** have failed.[4]

Our results demonstrate that β-SiR_3 elimination in β-SiR_3-substituted ruthenacyclobutanes followed by reductive elimination strongly competes with olefin metathesis and thus presumably is the most important factor limiting the catalytic efficiency of the system. The migratory aptitude considerably decreases in the series $SiMe_3$ > $Si(OEt)Me_2$ > $Si(OEt)_2Me$ and $SiMe_3$ > $Si(Ph)Me_2$ > $Si(Ph)_2Me$. Although there is a strong preference for SiR_3 migration compared to H migration it seems likely that β-H elimination and subsequent reductive elimination in systems without a SiR_3 substituent could also drain the active species from the catalytic cycle and thus limit the turnover number in cross-metathesis.

Notes and references

† Typically, in an NMR tube 1.21×10^{-5} mol of vinylsilane was added by syringe to a solution of $[Cl_2\{P(C_6H_{11})_3\}_2Ru{=}C(Ph)H]$ (0.01 g, 1.21×10^{-5} mol) and anthracene (internal standard) dissolved in 0.65 ml of C_6D_6. The reactions were followed by ^{1}H-NMR spectroscopy for 6 h. Conversions and selectivities were calculated using the internal standard method.[7] Products were identified by GC-MS spectra and by a comparison of their ^{1}H NMR spectra and their retention times (GC) with those of authentic samples.

Received (in Cambridge, UK) 18th September 2000, Accepted 6th November 2000
First published as an Advance Article on the web

The potentially tetradentate NS_3 thiophenophane binds strongly to Cu(I) through a thiophene S, pyridine N and one thioether S, leaving the remaining thioether S donor in an exodentate arrangement forming an infinite polymeric link between Cu(I) atoms.

The thiophenic sulfur is considered to coordinate poorly to transition metals.[1] Only a few S-bound thiophene coordination complexes exist and for several of these the M–S distances exceed the sum of the covalent radii.[2] However, sterically constrained ligand systems incorporating thiophene have been used to successfully achieve S-binding.[2c,3] If incorporated into a macrocycle the rigid thiophene unit may impose limitations on the possible orientations of donor atoms and hence on the size and shape of the macrocyclic cavity and on the coordination properties.[2d,f,3] For example in macrocyclic thioethers, the thiophene may affect the donor properties of the thioethers by influencing the orientation of the sulfur lone pairs and this property may be used to control the structure of transition metal complexes. When the conformation of the ligand causes some of these lone pairs to be arranged in an exodentate fashion the possibility exists for bridging metal centres or coordination-polymer formation. This property of macrocyclic complexes, that the donor groups within the macrocycle are constrained and so provide a degree of control over the final polymeric structure, has not been widely used in coordination-polymer chemistry. Indeed, the use of macrocyclic complexes as structural elements in coordination polymers is surprisingly rare and typically involves specifically arranged exodentate donor groups[4] on the macrocyclic complexes or separate bridging ligands linking the macrocyclic complexes together.[5]

Herein we report the synthesis of 2,10-dithia[3](2,6)pyridino[3](2,5)thiophenophane (L), a small sterically constrained thiophenophane, and its use in the construction of a Cu(I) coordination polymer in which exodentate thioether donors bridge Cu(I) thiophenophane units containing a bound thiophene sulfur. Thiophenophane L was very difficult to prepare and isolate. Initially, it was prepared by high-dilution base coupling of 2,6-bis(chloromethyl)pyridine[6] and 2,5-bis(methylsulfanyl)thiophene[7] in a 1:1 molar ratio. Purification by column chromatography gave a stable white crystalline solid in 4% yield. 2,5-Bis(methylsulfanyl)thiophene could only be prepared in low yield and was difficult to purify, therefore the alternate precursors 2,6-bis(methylsulfanyl)pyridine[8] and 2,5-bis(bromomethyl)thiophene[9] were used with a slight improvement in yield (10%). CPK models show L is very strained and inflexible. Sulfur inversion is not possible but ring flipping of the pyridine and 'wobbling' of the thioether bridges can occur. These processes are consistent with the presence in the ^{1}H NMR spectrum of signals from two AB methylene proton systems.†

Given the constrained nature of the thiophenophane, it was of interest to determine the conformation in the solid state and to assess the potential for binding to a metal centre.‡ The thiophenophane exists in an *anti*, boat, boat conformation with the thiophene and pyridine rings tilted at 37.5° with respect to each other (Fig. 1). The pyridine N and thiophene S atoms point in opposite directions. Both thioether S atoms adopt a splayed endodentate conformation with respect to the thiophene S and point in the same direction as the thiophene S atom suggesting coordination to a metal ion may be possible. All bond lengths and angles are within the normal range.[10]

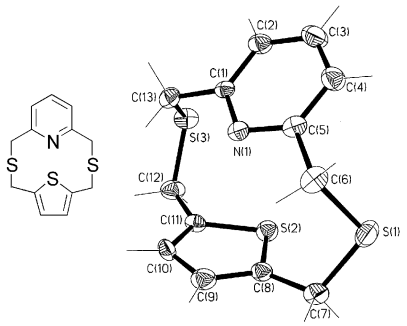

Fig. 1 Thiophenophane L: (left) schematic view; (right) ORTEP view (50% probability ellipsoids). Selected bond lengths (Å) and angles (°): C(6)–S(1) 1.837(3), S(1)–C(7) 1.833(3), C(8)–S(2) 1.735(4), C(8)–C(9) 1.357(5), C(9)–C(10) 1.429(5); C(6)–S(1)–C(7) 103.5(2), C(5)–C(6)–S(1) 113.5(3), C(8)–C(7)–S(1) 115.6(2).

Equimolar reaction of L and $[Cu(MeCN)_4]PF_6$ in MeCN gave an air-stable cream solid in 63% yield, which analysed with a 1:1 ligand to metal ratio and gave ^{1}H and ^{13}C NMR spectra consistent with a symmetrical but dynamic complex.† In order to establish the disposition of the thiophenophane an X-ray structure analysis was undertaken.‡

The crystal structure is severely disordered. The central Cu(I) and thioether S-donors lie on a mirror plane and the mirror operation causes the unsymmetrical L to be disordered equally over two sites (Fig. 2). The disordered thiophene and pyridine rings are intertwined and tilted by 52.9° with respect to each

other. The two disordered ligands are required by symmetry to occupy the same thioether and Cu(I) positions but, coincidentally, they also occupy the same C(10) position. The central Cu(I) atom adopts a distorted tetrahedral geometry and is bound to a pyridine N, a thiophene S and an endodentate thioether S from one thiophenophane, and to an exodentate thioether S from the arm of a second symmetry related thiophenophane (Fig. 2). Each $[Cu(L)]^+$ unit is bound to another adjacent $[Cu(L)]^+$ unit *via* one of the exodentate thioether sulfur atoms to form a one-dimensional zigzag chain. This is the first reported thiophenophane polymer and the first polymer containing a bound thiophene sulfur. The ligand adopts a skewed *syn*, chair, boat conformation with the pyridine and thiophene rings lying approximately parallel at 16.8° to each other. From the above-mentioned data, the ligand appeared to be rather inflexible. However, the X-ray structure shows that the ligand is flexible enough to allow flipping of the pyridine ring so that the ligand sits in a *syn* conformation to promote thiophene S-binding to the Cu(I) ion. In each $[Cu(L)]^+$ unit the bound endodentate thioether S points in the same direction as the thiophene S while the other arm adopts an exodentate conformation (Fig. 2). This configuration of the thiophenophane prevents positioning of both thioether S-donors for coordination to the Cu(I) ion and promotes an intramolecular π–π-interaction (3.59 Å) between the thiophene and pyridine rings.

The thiophenophane is responsible for a very irregular coordination geometry about the Cu(I) ion. The Cu–S(exodentate) distance of 2.191(3) Å is short when compared to the normal Cu–S(endodentate) distance. The Cu–S(thiophene) bond length of 2.550(4) Å is around the upper quartile of all reported Cu(I)–S distances (2.18–3.01 Å).[10] The shortest M–S(thiophene) bond is a Ni(II)–S distance of 2.143(6) Å in a Ni(II) thiaporphyrin complex.[3b] The only reported Cu(I)–S(thiophene) distances are 2.960(5)[11] and 3.155(5) Å[2f] which are too long to be considered formal bonds but perhaps indicate weak interactions. The coordinated thiophene sulfur in $\{[Cu(L)]PF_6\}_\infty$ is approximately pyramidal, as indicated by the 103.4° angle between the Cu–S bond and the vector from sulfur to the midpoint of the mean plane of the thiophene ring. This angle is at least 10° smaller than any other reported value[2a,c,10] and is a consequence of the very restricted binding by the rigid ligand. The thiophene ring bond lengths show alternation in both the free and bound thiophenophane consistent with a localised bonding scheme. The one-dimensional polymer lies along the two-fold screw axis parallel to the *a*-axis and has a zigzag motif (Fig. 3).

The symmetrical nature of the complex in CD_3CN, as observed by ^1H and ^{13}C NMR spectroscopy, is inconsistent with the asymmetry found in the crystal structure and suggests dissociation of each polymeric chain in solution. Variable temperature ^1H NMR spectra were measured in CD_3CN down to the solvent limit of 238 K. Results showed the methylene protons nearest the thiophene moiety remained as a singlet resonance with no evidence of broadening or coalescence. However, the signals of the methylene protons adjacent to the pyridine ring collapsed and split into an AB system. These results suggest that in solution the pyridine ring remains bound to copper while the thiophene S is not bound. In addition, the complex must undergo an exchange process involving both of the thioether donor atoms and possibly the solvent. Electrospray mass spectrometry under normal operating conditions showed peaks which could be assigned to a number of species including a parent ion $[Cu(L)]^+$ at *m/z* 342 (100%), $[Cu(L)MeCN]^+$ at *m/z* 383 (78%), $[Cu(L)_2]^+$ at *m/z* 621 (15%) and $\{[Cu_2(L)_2]PF_6\}^+$ at *m/z* 813 (37%). This further indicates that $[Cu(L)]^+$ is dynamic and labile in solution and is probably involved in a series of complex equilibria.

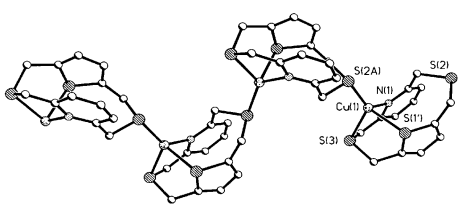

Fig. 3 View of a zigzag polymer chain formed by $[Cu(L)]^+$ units (PF_6^- anions and hydrogen atoms omitted) showing the exodentate thioether coordination linkage.

We have shown that when thiophene was placed in a small sterically constrained macrocycle it not only influenced the conformation of the bound ligand in a metal complex but was also, by its proximity, forced to bind to that metal. In addition, the conformational changes had ramifications for the structure as a whole leading to the formation of a coordination polymer. This work points to the usefulness of macrocyclic complexes as building blocks for coordination polymers.

We thank Associate Professor Bill Henderson (University of Waikato) for electrospray-MS data and the University of Otago for financial support.

The first incorporation of nano-sized zeolites in membranes is reported and polydimethylsiloxane membranes filled with colloidal silicalite-1 are applied in the pervaporation of ethanol–water mixtures.

The incorporation of zeolites and porous amorphous fillers in dense membranes improves the performance (normalized flux and selectivity) of these membranes in both gas separation and pervaporation for several types of feed mixtures.[1–4] All porous fillers reported up to now have particle sizes in the micron range. As a consequence, the minimal membrane thickness of the composite membranes was inherently higher than that of most unfilled membranes and the absolute fluxes remained low. The recent development of small 'nano-sized' colloidal zeolites leads to the possibility for the preparation of thin, defect-free, filled polymer layers. The synthesis of stable silicalite-1 particles with diameters as small as 70 nm was reported, as well as that of zeolite A (in the range 50–230 nm) and zeolite Y (80–110 nm).[5–7] We report here, the first incorporation of nano-sized zeolite particles in a polymeric membrane, that of silicalite-1 in PDMS (polydimethylsiloxane), and the performance of these membranes in the pervaporation of an aqueous ethanol solution.

Nano-sized silicalite-1 was synthesized following a procedure reported earlier:[8] tetraethylorthosilicate (98%, Acros Chimica), tetrapropylammonium hydroxide (TPAOH, 40% aqueous solution, Alfa) and water were mixed in order to obtain a mixture with a molecular composition of 9 TPAOH : 24.5 SiO_2 : 416 H_2O. The mixture was stirred for 24 h at room temperature and refluxed for 3 days at 100 °C. The silicalite-1 crystals were separated from the mother liquor by repeated centrifugation and washing. After redispersion and freeze-drying, the powder was calcined in air (1 °C min^{-1} heating rate, 2 h at 110 °C and 12 h at 550 °C). The particle size and shape observed by SEM (Fig. 1) and XRD were in good agreement with previous results.[8] The dry zeolite was dispersed in toluene by stirring and ultrasonic treatment. The suspension was then mixed with PDMS (prepolymer and crosslinker in a 10 : 1 ratio, General Electric, RTV 615 A and B) so as to give a 15 vol% solution of membrane constituents (polymer + zeolite) with the desired polymer : zeolite ratio. After a prepolymerisation step at 70 °C for 45 min, the casting solution was poured into a Petri dish and the solvent was evaporated overnight. To obtain complete crosslinking, the membrane was placed in a vacuum oven at 100 °C for 2 h. The maximum silicalite-1 load leading to a macroscopically homogeneous membrane was 30 wt%.

Dispersion of the zeolite in the polymer matrix was investigated by SEM. Fig. 2 shows the cross-section of a PDMS membrane containing 30 wt% nano-sized silicalite-1. Whereas a homogeneous dispersion of large zeolite crystals throughout a polymer matrix has not been reported to be problematic,[1–4] the distribution of the 70 nm crystals in the membrane was not homogeneous. An attempt was made to increase the zeolite loading and the dispersion by improving the contact between the polar zeolite surface and the apolar polymer. The nano-sized silicalite-1 was treated with a silane coupling agent to cover the surface with hydrophobic trimethylsilyl groups. The dry zeolite was dispersed in toluene and *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA, Acros Chimica, 97%) was added in a five-fold excess, with respect to the amount of silanols present. This number was estimated based on the external surface area of silicalite (45 m^2 g^{-1})[8] and assuming a silanol density of 6 OH nm^{-2}. After ultrasonic treatment, the mixture was stirred at room temperature and refluxed overnight. Removal of unreacted MSTFA was achieved by redispersion in toluene and centrifugation (30 min at 22 100 *g*). The silicalite-1 was finally recovered by evaporating the toluene. Silylation had a positive effect on the maximum amount of zeolite that could be incorporated in the polymer matrix from *ca.* 30 wt% for the non-silylated zeolite up to 40 wt% for the silylated sample. SEM observations of cross-sections of membranes, however, did not reveal an improved dispersion.

The synthesized membranes were evaluated in the pervaporation of a 6 wt% aqueous ethanol solution at three different temperatures. The vacuum at the permeate side was maintained at a pressure below 2 mbar and the permeate was trapped with liquid nitrogen. All reported membranes had thicknesses between 200 and 400 μm. The fluxes were normalized to a thickness of 100 μm assuming an inverse proportionality

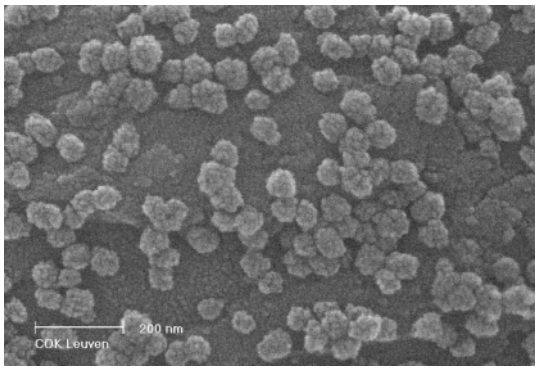

Fig. 1 SEM image of nano-sized silicalite.

Fig. 2 Cross-section of a PDMS membrane filled with 30 wt% nano-sized silicalite.

DOI: 10.1039/b007435g

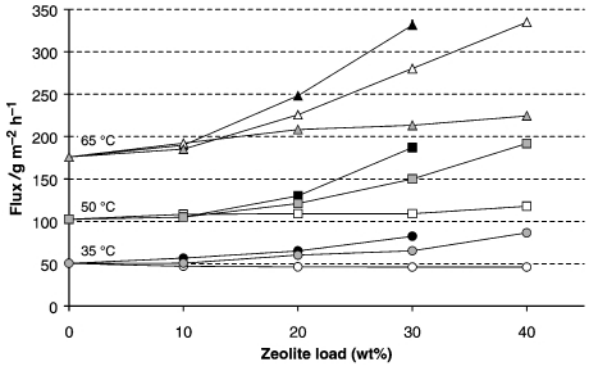

Fig. 3 Total fluxes, normalized to a membrane thickness of 100 μm, at three different temperatures for composite membranes prepared with micron-sized zeolites (open symbols) and nano-sized zeolites: silylated (grey symbols); non-silylated = black symbols).

between the flux and the membrane thickness. Selectivity is expressed as $\alpha = (y_a/y_b)/(x_a/x_b)$ in which y refers to the concentration of the components in the permeate and x to the concentration in the feed. Permeates were analysed by adding methanol as a standard and acetone as a homogenising solvent, followed by analysis with GC. Fig. 3 and Table 1 show the total normalized pervaporation flux and selectivity, respectively. At three different temperatures, a comparison was made between the performance of composite membranes filled with the self-prepared nano-sized silicalite and membranes filled with a commercial micron-sized silicalite (CBV-2802, PQ zeolites, Si : Al ratio = 550 : 1, 0.4–0.8 μm). The nano-sized zeolites show much improved pervaporation results compared with the micron-sized silicate membranes: both flux and selectivity are drastically increased at the highest loadings. Best results were obtained with the PDMS membrane containing 40 wt% of silylated nano-sized silicalite-1.

An explanation for this remarkable effect of nano-sized zeolites in PDMS for the pervaporation of ethanol–water mixtures, is probably related to the mesopores reported to be present in the silicalite-1 samples.[8] These mesopores most probably arise due to voids between the nanocrystals. The extent to which these mesopores and their silylation is responsible for the beneficial effect of the nano-sized zeolites in the pervaporation process, possibly acting as freeways for the preferentially sorbed ethanol, is currently being investigated.

Table 1 Selectivities obtained at different temperatures for composite membranes filled with micron- or nano-sized zeolties

First published as an Advance Article on the web

Charge Decomposition Analysis (CDA) applied to transition states of ethylene epoxidation is a quantum-chemical probe for the electronic character of oxygen-transfer reactions.

The insight into the electronic character of oxygen-transfer reactions, *i.e.* whether the oxidant attacks the substrate in an electrophilic or nucleophilic way, is used as a tool for an efficient development of catalysts for these reactions.[1] The most popular probe is the chemoselective oxidation of thianthrene 5-oxide introduced by Adam and co-workers.[2] Information about the electronic character of the transition states of olefin epoxidation is also provided by the effect of alkyl[3] and aryl[4] substituents at the C=C double bond on reactivity. A quantum-chemical probe has not been suggested yet, which is somewhat astonishing because the geometry optimization of transition states and the analysis of their electronic structure are key applications of modern computational chemistry. Hence, the principal aim of this work was to find a quantum-chemical probe for the electronic character of oxygen-transfer reactions.

In experimental work and recent theoretical studies by Bach *et al*., Houk *et al*. and others, it was shown that olefin epoxidation with organic peracids[5] and dioxiranes[6] follows a concerted oxygen-transfer mechanism with a *spiro* oxygen atom in the transition state (TS). The topology of the TS is coarctate.[7] Very recently, Rösch *et al.*[8,9] and we[10] supported an analogous mechanism for ethylene epoxidation by Herrmann-type complexes $[ReO(O_2)_2(CH_3)]$[8] and Mimoun-type complexes $[MoO(O_2)_2(OPR_3)]$,[9,10] as postulated by Sharpless *et al.*[11] For this work, we re-optimized TSs for ethylene epoxidation using standard density functional (DFT) methods for oxidations.[12] Calculated TS structures for dimethyldioxirane (DMDO), MCPBA, and $[ReO(O_2)_2(CH_3)]$ as oxidants are shown in the ESI†; selected geometrical parameters are given in Table 1.

† Electronic supplementary information (ESI) available. Geometries optimized at the B3LYP/II level of the transition states for ethylene epoxidation with DMDO, MCPBA, and $[ReO(O_2)_2(CH_3)]$ and predominant orbital interactions of donation *d* and backdonation *b* according to the CDA of the transition states for DMDO and MCPBA. See http://www.rsc.org/suppdata/cc/b0/b006280o/

The most simple tool for electronic-structure analysis is the calculation of atomic partial charges. The sum of NPA charges[13] at ethylene in the TSs are listed in Table 1. The values for all reactants indicate that, at the TSs, electronic charge has migrated from ethylene to the oxidant. In order to gain additional insight into the nature of the electronic interactions in the TSs, we utilized Charge Decomposition Analysis (CDA).[14,15] The Kohn-Sham MOs of a TS are expressed as a linear combination of the MOs of the fragments ethylene ('donor') and oxidant ('acceptor') in the geometry of the TS. We define (i) the interaction among the occupied orbitals of ethylene and the vacant orbitals of the oxidant as donation, *d*, (ii) the interaction among the occupied oxidant orbitals and the vacant ethylene orbitals as back-donation, *b*, (iii) the interaction of the occupied orbitals of both fragments as repulsive polarization, *r*, and (iv) the interaction of the vacant orbitals of both fragments as a rest term, Δ.[14] For the electronic character of oxygen-transfer reactions, the ratio $d:b$ in the TS is important. Oxidants with $d:b > 1$ are electrophilic, those with $d:b < 1$ are nucleophilic. Table 2 shows the CDA results. The most important fragment-orbital interactions in the TS of the ethylene epoxidation with $[ReO(O_2)_2(CH_3)]$ are visualized in Fig. 1. We draw the following conclusions:

(i) Small rest terms ($\Delta \approx 0$, Table 2) indicate that the electronic structure of the epoxidation transition states can be properly described in terms of donor–acceptor interactions between the fragments, ethylene and oxidant. This was to be expected from the Hammond postulate[16] because the strongly exothermic reactions have early TSs.

(ii) For all oxidants, donation, *d*, is an interaction between the ethylene HOMO and the σ* orbital of the O–O bond.[17] Note that the σ* orbital of the O–O bond does not neccessarily correspond to the LUMO of the free oxidant. The interaction between the lone pairs at the transferred oxygen atom and the ethylene LUMO provides the predominant contribution to backdonation, *b*, Fig. 1.

(iii) For all epoxidations investigated here, donation from ethylene to the oxidant is more important than back-donation, indicating an electrophilic attack of the oxidant on the olefin. The reason is that donation occurs earlier on the reaction coordinate. The O–O σ* orbital of the oxidant has a high coefficient from the p orbital pointing directly toward the

Table 2 CDA results of the transition states. Donation *d* (C_2H_4→oxidant), back-donation *b* (C_2H_4 ← oxidant), repulsive polarization *r* (C_2H_4↔oxidant), and rest term *Δ*

Oxidant	*d*	*b*	*d*:*b*	*r*	*Δ*
DMDO	0.231	0.175	1.32	−0.393	−0.003
DO	0.223	0.149	1.50	−0.353	−0.003
HCO_3H	0.229	0.148	1.55	−0.326	−0.004
MCPBA	0.227	0.146	1.56	−0.319	−0.004
$[Mo]O_2$	0.237	0.135	1.76	−0.312	−0.004
$[Re]O_2$	0.230	0.111	2.07	−0.276	−0.005

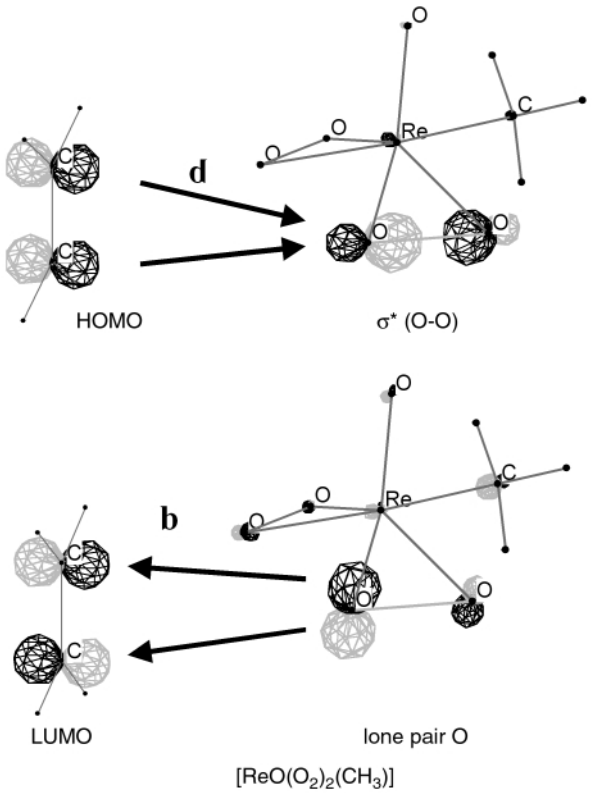

Fig. 1 Predominant orbital interactions of donation *d* and backdonation *b* according to CDA of the transition state for ethylene epoxidation with $[ReO(O_2)_2(CH_3)]$.

ethylene. Thus, at the long C(ethylene)–O distances of about 2.0 Å in the TS, the overlap integral is larger for donation than for back donation. While donation is approximately equal for all investigated epoxidations, the *b* values vary signficantly with the C–O distances (Table 2).

(iv) Due to *d*:*b* > 1, an increase of the olefin HOMO energy originated by alkyl substituents will accelerate epoxidation if steric effects are negligible. This is experimentally[3] and theoretically[5c,5g] confirmed. Negative *ρ* values from Hammett studies indicate a decrease of electron density at the C=C bond in the TS.[4]

(v) The ratio *d*:*b* is a quantum-chemical probe for the electronic character of oxygen-transfer reactions. The larger the value of *d*:*b*, the more electrophilic is the oxidant. Electrophilicity increases in the series DMDO < DO < HCO_3H = MCPBA < $[Mo]O_2$ < $[Re]O_2$. The metal peroxides are the most electrophilic oxidants.

(vi) The attempt to quantitatively correlate our electrophilicity scale with experimental parameters fails due to their dependence on reaction conditions,[2,4] such as temperature and solvent, and because of the lack of accessible data.

(vii) A relation between *electronic character* (*i.e.* *d*:*b*) and *reactivity* (*i.e.* activation energy E_a) is only found within the same class of oxidants, *e.g.* for the two dioxiranes.

D. V. Deubel thanks Professor Dr W. Adam for helpful discussions and the Fonds der Chemischen Industrie for a Kekulé scholarship. This work has also been supported by the Deutsche Forschungsgemeinschaft. Excellent service has been provided by the computer centers HRZ Marburg and HLRS Stuttgart.

Solvent-free enantioselective addition of diethylzinc to aldehydes using β-amino alcohols as chiral catalysts afford chiral *sec*-alcohols with high enantiomeric excesses, and the reaction in solvent-free system is faster than that using organic solvent.

Solvent-free organic synthesis has received much attention.[1,2] From an environmental point of view, potent toxic waste should be minimized and, obviously, bulk wastes in chemical reactions are often organic solvents. Thus, the development of solvent-free organic synthesis is important. Recent advances in this field include, for example, polymerization,[3] radical addition[4] and ionic reactions.[5]

Meanwhile, solvents often play an essential role in catalytic enantioselective synthesis. They not only make the reaction mixtures homogeneous but participate to construct the stereochemically preferable reactive transition state by coordinating with metals. Thus, the use of solvent is generally considered unavoidable in achieving high enantioselectivity in asymmetric reactions.[6] So far, only a few solvent-free enantioselective catalytic reactions are known.[7] We previously reported enantioselective addition of dialkylzincs to aldehydes in the presence of *N*,*N*-dialkylnorephedrines as chiral catalysts using organic solvents such as toluene and hexane.[8]

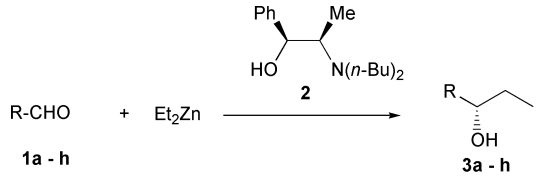
We here report a solvent-free catalytic enantioselective addition of diethylzinc (Et_2Zn) to aldehydes. In the presence of *N*,*N*-dialkylnorephedrines **2, 4** and **5** as chiral catalysts, aldehydes **1** were reacted with neat Et_2Zn without using any solvent. The reactions were homogeneous and proceeded in highly enantioselective manner to give optically active *sec*-alcohols **3** with high ees (Scheme 1).

The results of the enantioselective addition of Et_2Zn to benzaldehyde **1a** under the solvent-free conditions are summarized in Table 1. In the presence of (1*S*,2*R*)-*N*,*N*-dibutylnorephedrine (DBNE) **2**[8a] (10 mol%) as a chiral catalyst, neat Et_2Zn was added to aldehyde **1a** at 0 °C to give (*S*)-1-phenylpropanol **3a** with 87% ee in an almost quantitative yield (99%) (run 1). When the amount of DBNE **2** was 5 mol%, (*S*)-**3a** was obtained in 97% yield and 87% ee (run 2). The reaction using 3.4 mol% of DBNE **2** and 2.2 mol. equiv. of neat Et_2Zn afforded (*S*)-**3a** with 87% ee in 93% yield (run 3). It should be noted that solvent-free reactions at 0 °C were complete in 2 h (runs 1–3), whereas the same reaction in toluene takes longer time to complete.[8a] *N*,*N*-Dipropylnorephedrine **4**[8a] and 1-phenyl-2-(1-pyrrolidinyl)propan-1-ol **5**[8a,9] were also efficient chiral catalysts which afforded (*S*)-**3a** in 97–99% yields with 85% ee and 86% ee, respectively (runs 4 and 5). An acceleration of the reaction rate under solvent-free conditions is clearly seen in low-temperature reactions. Enantioselective addition of Et_2Zn using (1*S*,2*R*)-DBNE **2** as a chiral catalyst proceeded efficiently at −10 °C within 4 h to give **3a** with 89% ee in 98% yield (run 6). Moreover, the reaction even at −28 °C was complete within 6 h to afford **3a** with 87% ee in 99% yield (run 7). It should be noted that when a solvent (toluene) is used, the reaction hardly proceeds at −28 °C. The high reactivity of Et_2Zn under solvent-free conditions may be attributed to the higher concentration of neat Et_2Zn (*ca.* 9.5–10 M) than that in solvents. Thus, a strong acceleration of the reaction rate was observed in the present solvent-free enantioselective reaction without a decrease in enantioselectivity.[10] The catalytic species is, presumably, zinc monoalkoxide of **2**.[8a,11]

To clarify the generality of substrates, various aldehydes were subjected to the solvent-free enantioselective addition of diethylzinc using (1*S*,2*R*)-**2** (5 mol%) as a chiral catalyst (Table 2). *p*-Tolualdehyde **1b** and 1-naphthaldehyde **1c** were ethylated in a highly enantioselective manner to give the corresponding *sec*-alcohols **3b** and **3c** with *S* configuration in 90% ee and 91% ee, respectively (runs 1 and 2).[12] The reaction with 2-naphthaldehyde **1d** gave (*S*)-**3d** in 98% yield and 86% ee (run 3).

Cyclohexanecarbaldehyde **1g**, an aliphatic aldehyde, was ethylated enantioselectively to afford (*S*)-**3g** with 88% ee in 96% yield (run 6). Enantioselective addition of Et_2Zn to aldehyde **1h**, possessing hydrogen atoms on the α-carbon atom, gave **3h** with 84% ee in 92% yield (run 7).

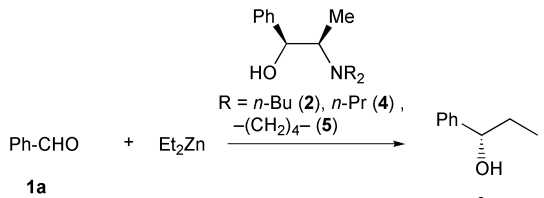
In conclusion, we have described a highly enantioselective ethylation of aldehydes under solvent-free conditions which is



a; R = Ph **e**; R = *p*-ClC_6H_4
b; R = Tolyl **f**; R = *p*-$MeOC_6H_4$
c; R = 1-Naphthyl **g**; R = *c*-C_6H_{11}
d; R = 2-Naphthyl **h**; R = $PhCH_2CH_2$

Scheme 1

Table 1 Solvent-free catalytic enantioselective addition of diethylzinc to benzaldehyde



Run[a]	Chiral catalyst (mol%)	*T*/°C	*t*/h	(*S*)-1-phenylpropanol **5a**[b] Yield (%)	Ee (%)
1	(1*S*,2*R*)-**2** (10)	0	2	99	87
2	(1*S*,2*R*)-**2** (5)	0	2	97	87
3[c]	(1*S*,2*R*)-**2** (3.4)	0	2	93	87

10 In addition, enantioselective addition of diisopropylzinc to aldehyde **1a** in the presence of 5 mol% of (1*S*,2*R*)-**2** gave (*S*)-2-methyl-1-phenylpropan-1-ol with 74% ee in 82% yield.
11 It is known that reaction between diethylzinc and *sec*-alcohol easily forms zinc monoalkoxide at 30 °C. Formation of zinc dialkoxide requires heating (80 °C). M. Ishimori and T. Tsuruta, *Mackromol. Chem.*, 1963, **64**, 190.
12 A typical experimental procedure is as follows (Table 2, run 1): To an ice-cooled 2-necked flask containing (1*S*,2*R*)-DBNE **2** (13.7 mg, 0.05 mmol), neat Et_2Zn (370 mg, 3 mmol) was transferred into the flask through a cannula under an argon atmosphere. After the mixture was stirred for 10 min at 0 °C, aldehyde **1b** (120 mg, 1.0 mmol) was added slowly to the mixture, and the mixture was stirred for 2 h. After excess Et_2Zn was removed under a reduced pressure, the reaction was quenched by satd. aq. ammonium chloride. The mixture was extracted with ether and the organic layer was dried over magnesium sulfate. Concentration and purification on silica gel TLC gave (*S*)-**3b** (149 mg, 99%). Ee was determined to be 90% by HPLC analysis using a chiral stationary phase (Chiralcel OB-H).

Are anthocyanidins the immediate products of anthocyanidin synthase?

First published as an Advance Article on the web

Anthocyanidin synthase catalyses the *in vitro* conversion of its natural substrate, leucocyanidin, to *cis*- and *trans*-dihydroquercetin, quercetin and a small amount of cyanidin; incubation of *trans*-dihydroquercetin gave quercetin.

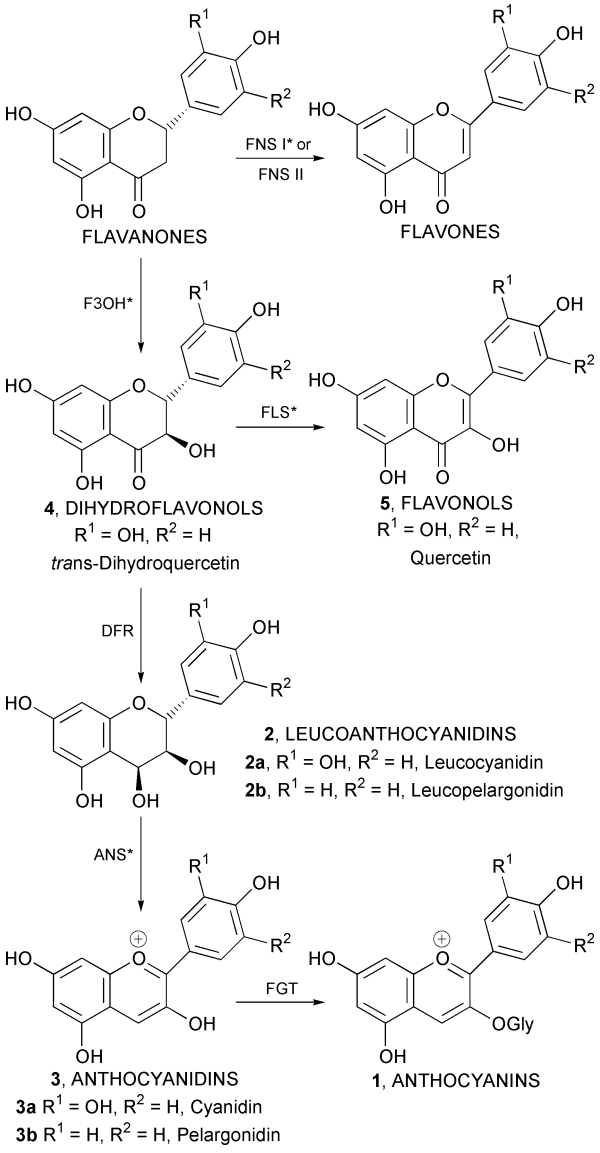
Flavonoids are an important class of plant metabolites whose roles include attracting pollinators, signalling in plant-microbe interactions, protecting plants against radiation and aiding seed dispersal.[1] There is biomedical interest in flavonoids since they inhibit cell proliferation, are antioxidants and display anti-mutagenic, antinflammatory, antithrombic and antihypertensive effects.[2,3] The anthocyanin sub-family of flavonoids cause pigmentation and are used as food colourants.

The penultimate step in the biosynthesis of the anthocyanin family **1** of flavonoids is catalysed by anthocyanidin synthase (ANS) (Scheme 1).[4] Although there are reports on other enzymes involved in anthocyanin biosynthesis, until recently the only reported work on the ANS concerned the identification of its genetic locus and putative gene sequence.[5] The presence of conserved sequence motifs (*e.g.* HXD and RXS motifs, which are involved in iron and co-substrate binding respectively[6,7]) imply ANS belongs to the family of 2-oxogluatarate (2-OG) dependent dioxygenases.[8] Saito *et al.* reported that ANS from *Perrila fructescens* was indeed a 2-OG dependent oxygenase requiring an unusually high level of ascorbate for activity.[9] It was demonstrated that oxidation of leucocyanidin **2a** (R^1 = OH, R^2 = H) and leucopelargonidin **2b** (R^1 = H, R^2 = H) was coupled with conversion of 2-OG to succinate. However, it was noted that the anticipated anthocyanidin products cyanidin **3a** and pelargonidin **3b**, respectively, were only observed in the crude assay incubations subsequent to acidification. The acidified incubations were analysed by HPLC (monitoring at 520 nm) and peaks corresponding to the appropriate anthocyanidin references identified.[9] Here, we report studies on the selectivity of ANS that lead us to question whether anthocyanidins are the immediate products of the ANS reaction.

The ANS gene from *Arabidopsis thaliana* was over-expressed in *Escherichia coli* BL21 (DE3) using the Novagen pET-24a vector and ANS was purified to *ca.* ~90% purity (by SDS-PAGE analysis) *via* anion-exchange Q-Sepharose and gel filtration chromatography.†

The natural substrates for ANS are relatively difficult to synthesise in enantiomerically pure form and are unstable in solution. Therefore, we investigated the use of a dihydroflavonol, *trans*-dihydroquercetin **4**, as an alternative substrate. Photodiode array (PDA) HPLC analysis identified the product of *trans*-dihydroquercetin incubation as the flavonol quercetin **5**. This result was confirmed by NMR and mass spectrometric analyses. Selected data for the incubation product: (^{1}H NMR 500 MHz; CD_3OD) δ: 4.60 (C-OH, 1H, s br), 6.18 (1H, d, J = 2.0), 6.38 (1H, d, J = 2.0), 6.88 (1H, d, J = 8.5), 7.73 (1H, d, J = 2.0), 7.63 (1H, dd, J = 2.0, J = 8.5); *m/z* (negative ion ESI MS) 301.4 Da.

Using a stopped UV assay the ANS catalysed conversion of *trans*-dihydroquercetin to quercetin was shown to be dependent on both 2-OG and iron(II) and to require a high concentration of ascorbate for significant turnover (40 mM), consistent with the results for ANS from *Perilla fructescens*.[9] Analyses were complicated by precipitation of the flavonoids and their iron



Scheme 1 Later stages of anthocyanin biosynthesis. FNS I , FNS II, flavone synthase I or II; F3OH = flavanone-3β-hydroxylase; FLS = flavonol synthase; DFR = dihydroflavonol-4-reductase; ANS = anthocyanidin synthase; FGT = flavonoid 3-*O*-glucosyltransferase. Asterisked enzymes are 2-OG dependent dioxygenases.[4]

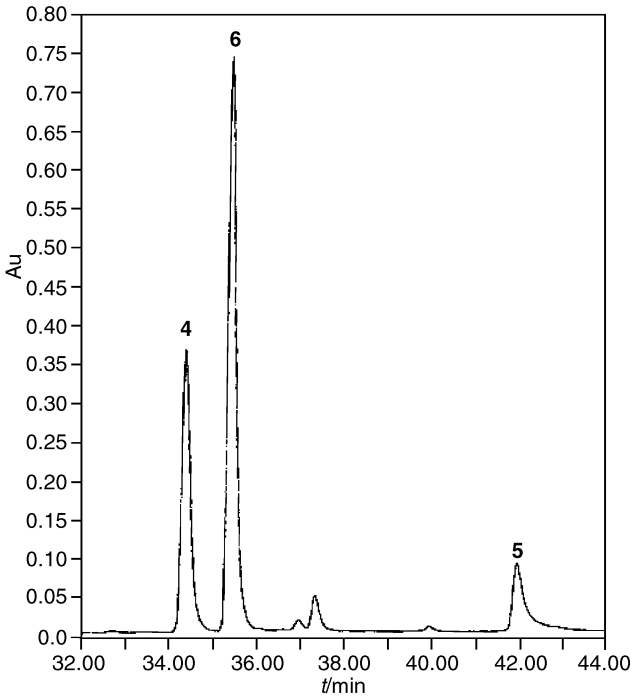

Fig. 1 HPLC trace (λ_{max} 287 nm for **4**, **6**; 372 nm for **5**) of ANS assay with leucocyanidin **2a** after incubation for 20 min. The peaks correspond to *trans*-dihydroquercetin **4**, *cis*-dihydroquercetin **6** and quercetin **5** respectively. Note the **2a** used (Apin) contained contaminating **4** but not **6**.

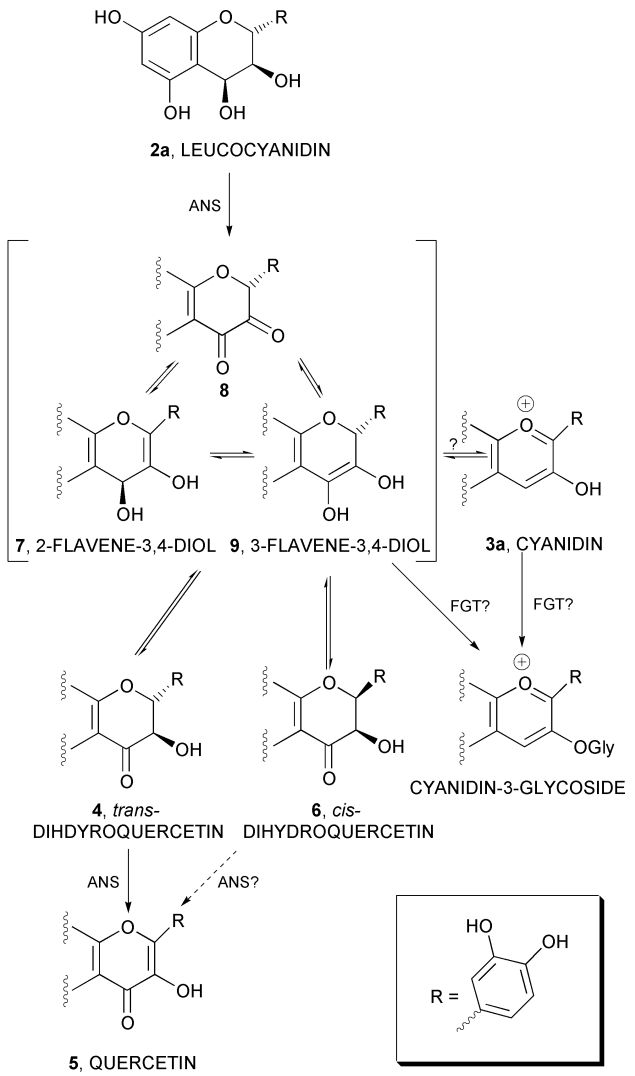

Scheme 2 Proposed intermediates for ANS and FGT turnover of leucocyanidin.[4] The absolute stereochemistry of products **4** and **6** from **2a** has not been determined.

complexes; the maximal catalytical rate was seen at *ca.* pH 6.0. Selwyn analysis[10] indicated that ANS was unstable under the assay conditions at protein concentrations < 70 μg ml^{-1}.

PDA HPLC (monitoring from 200–800 nm) was then used to study ANS catalysed oxidation of a 'natural substrate' leucocyanidin **2a** (Fig. 1). Comparison with known standards identified products as *cis*-**6**‡ and *trans*-**4** dihydroquercetin, quercetin **5** and cyanidin **3a**. The latter was clearly a minor product.

Time course analysis of the leucocyanidin incubation revealed that as the reaction progressed the relative concentration of *trans*-dihydroquercetin decreased as that of quercetin increased. Incubations using mixtures of *cis*-**6** and *trans*-**4** dihydroquercetin demonstrated that *trans*-**4** rather than *cis*-**6** dihydroquercetin was preferentially converted to quercetin **5**.

The observation that both *cis*-**6** and *trans*-**4** dihydroquercetin are produced from leucocyanidin is consistent with the major nascent product of leucocyanidin incubation being a 2-flavene-3,4-diol **7**, as suggested by Heller and Forkmann or ketone **8**, or a 3-flavene-3,4-diol **9** (Scheme 2).[4] Intermediates **7**, **8**, **9** may be non-enzymatically isomerised to give both *cis*-**6** and *trans*-**4** dihydroquercetin. Under the incubation conditions the production of cyanidin is not favoured and it is possible that *in vivo* aromatisation does not occur until the next step,[4] *i.e.* that catalysed by the flavonoid glucosyltransferase (FGT). Alternatively, it is possible that **6** is the (major) product (and substrate for FGT) with the observed **4** arising by isomerisation of **6**.

ANS catalyses conversion of *trans*-dihydroquercetin **4** to quercetin **5**, *i.e.* the same reaction catalysed by flavonol synthase (FLS) (Scheme 1)[4] may reflect incomplete evolution of substrate selectivity or that the pathway has evolved to maintain/develop redundancy in enzymes selectivities. ANS is an interesting enzyme for study due to the ease of tautomerisation/isomerisation of its products, particularly its intermediate products which have not yet been isolated.

We thank Mr A. C. Willis for N-terminal sequencing and the BBSRC, EPSRC and MRC for support of this work.

Notes and references

† The mass and N-terminal protein sequence of the first eleven residues of purified ANS were consistent with the predicted values.[5]

‡ Synthetic **6** reference was obtained by isomerisation of **4** (*trans*:*cis*, 9:1).[11] Leucocyanidin (>95% purity) was from Industrial Research Limited, New Zealand.

Molecularly defined palladium(0) monophosphine complexes as catalysts for efficient cross-coupling of aryl chlorides and phenylboronic acid[1]

Various 1,6-diene palladium(0) monophosphine complexes have been prepared from tmedaPd(CH_3)$_2$, PR_3, and the corresponding 1,6-diene. These molecularly defined Pd complexes catalyzed the Suzuki coupling of aryl chlorides with phenylboronic acid more efficiently than traditional Pd^{II}–PR_3 pre-catalysts.

The cross-coupling reaction of aryl halides and arylboronic acids (Suzuki reaction) is the most versatile and important method for the synthesis of substituted biaryls.[2] This class of compounds constitute important building blocks for the synthesis of biologically active substances, *e.g.* pharmaceuticals such as the sartan family of drugs for high blood pressure and herbicides.[3] Additionally, biaryls have found application as chiral ligands[4] for catalysis and in materials science, *e.g.* liquid crystals.[5] Suzuki cross-coupling reactions of aryl bromides and iodides have been extensively studied in organic synthesis. Apart from further expanding the scope of this reaction, current interest focuses on the use of economically more attractive aryl chlorides as substrates for this reaction. Notable advances in the cross-coupling reactions of aryl chlorides[6] with arylboronic acids have been described recently by the groups of G. Fu,[7] S. Buchwald,[8] S. A. Guram,[9] S. Nolan,[10] and W. A. Herrmann[11] as well as by our group.[12] In general, important improvements in this area have been made possible by the use of *in situ* 'Pd'–L catalysts consisting of a Pd^{II} source and sterically hindered basic ligands such as dialkylarylphosphines, tri-*tert*-butylphosphine, adamantylphosphines or N-heterocyclic carbenes. It is generally agreed that these *in situ* catalysts are reduced under reaction conditions[13] to afford coordinatively unsaturated complexes such as 16e PdL_3, 14e PdL_2, and 12e PdL, which may constitute the 'real' catalysts. The importance of coordinatively unsaturated Pd^0 species as 'true catalysts' in various cross-coupling reactions has been demonstrated.[14]

In order to avoid side-reactions which may parallel the preformation of the 'real' catalyst and which often lead to loss of catalyst activity, it is desirable to use defined Pd monophosphine complexes as catalysts. To the best of our knowledge there is no report about the use of defined Pd^0 mono- or diphosphine complexes and only one report[11] applying a defined Pd^0 dicarbene species as catalyst in the Suzuki cross-coupling reaction. Recently, we introduced triphenylphosphine palladium(0) diallyl ether as a stable and active catalyst for telomerization of butadiene and methanol.[15] In this paper we describe the use of 1,6-diene stabilized Pd^0–PR_3 complexes as efficient catalysts for the Suzuki cross-coupling of aryl chlorides.

Based on the work of Pörschke[16] *et al.*, who developed a highly effective route for the synthesis of 1,6-diene Pd^0 complexes, we synthesized various monophosphine Pd^0 species as shown in Scheme 1. As phosphine ligands triphenylphosphine, tricyclohexylphosphine, and the so-called 'Buchwald-ligand' *o*-biphenyldicyclohexylphosphine were employed. In order to investigate the influence of the 1,6-diene part on the formation of the L–Pd^0 fragment we decided also to prepare the monotricyclohexylphosphine palladium complex with diallyl ether, diallyl amine and tetramethyldivinyl disiloxane. (Ph_3P)Pd($C_6H_{10}O$) **1**, (Cy_3P)Pd(dvds) **2**, (Cy_3P)Pd($C_6H_{10}NH$) **3**, (Cy_3P)Pd($C_6H_{10}O$) **4**, and (*o*-biphenyl)PCy_2)Pd($C_6H_{10}O$) **5** were obtained by suspending (tmeda)Pd(CH_3)$_2$[17] and PR_3 at −30 °C in the corresponding 1,6-diene. After gently warming the mixtures, elimination of ethane occurred and the desired products were isolated by filtration, washed with cold pentane and dried under vacuum.

A preliminary screening of optimal reaction conditions for the Suzuki coupling of an activated aryl chloride (2-chlorobenzonitrile) with phenylboronic acid in the presence of different palladium catalysts revealed that the coupling proceeds smoothly using THF as the solvent in the presence of a mixture of potassium triphosphate and potassium fluoride as base. In order to compare appropriately the efficiency of the different defined catalysts with each other and with *in situ* catalysts, we performed catalyst tests at low palladium concentration (0.05 mol% Pd). It is important to note that there are relatively few examples of Suzuki cross-couplings of aryl chlorides known that proceed at such low catalyst loading.[8c,18] As shown in Table 1 the cross-coupling reactions of a variety of aryl chlorides with phenylboronic acid proceed in the presence of 1,6-diene stabilized monophosphine in varying yields depending on the catalyst.

Complex **1** ($PPh_3Pd(C_6H_{10}O)$) was shown to be inactive towards all the substrates, although at higher concentrations (0.5 mol% Pd) with the activated 2-chlorobenzonitrile a limited cross-coupling reaction could be observed (32%). 1,6-Diene palladium(0) complexes with the more basic ligand tricyclohexylphosphine **2**–**4** show good conversion with 2-chlorobenzonitrile, chlorobenzene and 4-chlorotoluene (67–96%). Best results were achieved with the 1,6-diene complex containing 'Buchwald's ligand' [**5** (*o*-biphenyl)PCy_2Pd($C_6H_{10}O$)]. With only 0.05 mol% of this catalyst good to excellent yields of biaryls were obtained from activated (2-chlorobenzonitrile: 97%), non-activated (4-chlorotoluene: 82%; chlorobenzene: 87%) and deactivated (4-chloroanisole: 72%) aryl chlorides. The general trend of catalyst activity is in good agreement with previously reported investigations on the corresponding *in situ* systems. However, there are some notable features of the new catalysts: 1. 1,6-Diene palladium(0) monophosphine complexes are significantly more reactive than mixtures of $Pd(OAc)_2$ or $Pd_2(dba)_3$ and phosphines (Table 2). Hence, the obtained

catalyst turnover numbers are amongst the highest yet reported for the Suzuki reaction of non-activated aryl chlorides. 2. The catalyst properties are mainly determined by the phosphine ligand as shown by an increase of product yields in the series: (*o*-biphenyl)$PCy_2Pd(C_6H_{10}O)$ **5** > $(Cy_3P)Pd(C_6H_{10}O)$ **4** ⩾ $(Ph_3P)Pd(C_6H_{10}O)$ **1**. 3. The effectiveness of the studied complexes **2**–**4** is directly related to their ability to liberate the diene part and to generate the corresponding 12e [L–Pd^0] species. Previously, it has been shown that an increasing acceptor strength of the 1,6-diene moiety results in an increasing stability of the 1,6-diene complex.[16] In agreement with these studies we observe an decrease in reactivity in the order **4** > **3** > **2**.

In summary, we have shown that 1,6-diene palladium(0) monophosphine complexes are extremely efficient catalysts for Suzuki cross-coupling reactions of various aryl chlorides. By variations of both the diene and the phosphine part of the complex the catalytic properties of the complexes can be tuned. It is clearly shown that these defined monophosphine catalysts are superior to generally applied mixtures of Pd-pre-catalysts and phosphines. Thus, this class of catalysts offers promising features for a number of other important palladium-catalyzed coupling reactions.

Received (in Cambridge, UK) 2nd October 2000, Accepted 8th November 2000
First published as an Advance Article on the web

A novel oxygen selective inorganic–organic hybrid membrane containing (*N*,*N*′-disalicylideneethylenediaminato)cobalt(II) (salcomine) as an oxygen carrier was prepared *via* the sol–gel method using poly(*N*-vinylpyrrolidone) (PVP) as the mediation agent.

Oxygen selective membranes are important in various fields such as medicine, oxygen-enriching combustion systems, and fuel cell systems. Much attention for oxygen-enriching organic polymer membranes has been focused on the synthesis of polymers where the solubility of oxygen is greater than that of nitrogen.[1] However, no permselective membrane has been successfully prepared so far using this approach. Recently, the method of oxygen carrier addition to improve the oxygen selectivity of an organic polymer gas separation membrane operating at around room temperature has attracted tremendous attention. Some efforts have been made to facilitate transport using transition-metal complexes such as cobalt porphyrin complexes[2] and cobalt Schiff base complexes.[3] In all earlier investigations it was claimed that high O_2 selectivity could only be achieved at lower operating pressures and temperatures.

A large variety of inorganic–organic hybrids prepared by the sol–gel method has been reported.[4–8] Among these, the most common method utilizes hydrogen bonding interactions between polar functional groups of organic polymers and silanol groups of silica gels. Examples include organic polymers such as poly(2-methyl-2-oxazoline) and poly(*N*-vinylpyrrolidone) incorporated homogeneously into silica gels at the molecular level.[5,6,8]

Here, we report the preparation of a SiO_2–(*N*,*N*′-disalicylideneethylenediaminato)cobalt(II) (salcomine) hybrid membrane using poly (*N*-vinylpyrrolidone) (PVP) as a mediation agent, that is capable of selective separation of oxygen. Salcomine is a well known oxygen carrier complex. Unfortunately, there is no interaction between salcomine and silica, which makes it difficult to integrate it at a molecular level. To solve this problem, we proposed to use PVP as a mediation agent which contains amide carbonyl groups in its structure. Hydrogen bonding interactions between amide carbonyl and silanol groups of silica along with coordinate bonding interactions between nitrogen atoms of amide carbonyl groups and Co(II) in the salcomine can help to disperse organic and inorganic components at a molecular level. Based on this concept, we have prepared novel inorganic–organic hybrid membranes containing oxygen carrier complexes, using the sol–gel technique.

Tetraethoxysilane (TEOS) was used as the silica source and the PVP had a molecular weight of *ca.* 630 000; the concentration of PVP in the TEOS was *ca.* 11 wt%. A selective SiO_2–PVP–salcomine hybrid membrane was prepared using the following molar sol–gel composition: TEOS : EtOH : H_2O : HNO_3 : salcomine = 1 : 20 : 2 : 0.01 : 0.01. In a typical synthesis, the homogeneous sol was prepared by stirring a mixture of TEOS, H_2O, HNO_3 and EtOH for several hours at room temperature. PVP was added to the sol with continuous stirring. Finally, after stirring for 3 h, salcomine was introduced into the sol and resulting sol was vigorously stirred for several hours to obtain a homogeneous sol.

Porous alumina tubes (NGK Insulator, Ltd.; mean pore diameter, 0.1 μm; o.d, 10 mm; i.d, 7 mm; length, *ca.*10 cm) were used as supports. Tubular supports with one end closed were dipped in the sols, withdrawn at a rate of 1 mm s^{-1}, and then dried at room temperature. The dip coating procedure was performed in a class 1000 clean room (295 K and 50% relative humidity) to avoid dust which leads to pinholes on membranes. After the dip-coating was repeated twice, the membranes were heated to 423 K at the rate of 0.5 K min^{-1}, maintained at the same temperature for 2 h, then cooled to room temperature at 0.5 K min^{-1}. These coating and heating procedures were repeated twice in a similar manner. Hybrid membranes without salcomine were also prepared by the same procedure.

The structures of the hybrid membranes were determined using FTIR (FTIR-8700, Shimadzu). FTIR spectra of both SiO_2–PVP–salcomine and SiO_2–PVP hybrids showed a typical band at *ca.* 960 cm^{-1} associated with the stretching mode of Si–OH,[9] along with the characteristic bands related to the Si–O–Si bond (*ca.* 1220, 1080, 800 and 460 cm^{-1}),[9] which confirm the presence of Si–O–Si networks in the hybrids. Other characteristic bands originating from PVP were also observed (Fig. 1). The band at *ca.* 1650 cm^{-1} is due to the stretching band of amide carbonyl groups. Compared to that of PVP, these bands were shifted to lower wavenumbers indicating the existence of hydrogen bonding between amide carbonyl and silanol groups in the hybrids.[5] This provides evidence that in hybrids the inorganic segments (silica) and organic ones (PVP) are very well dispersed at the molecular level in accord with the previous reports.[5,6,8] The spectra of SiO_2–PVP and SiO_2–PVP–salcomine hybrids were quite similar since the amount of salcomine incorporated was very low (1 mol% relative to TEOS). However, PVP aids to dissolve salcomine homogeneously in

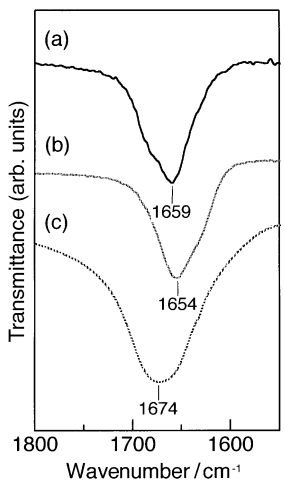

Fig. 1 IR spectra of (a) SiO_2–PVP–salcomine hybrid, (b) SiO_2–PVP hybrid and (c) PVP.

DOI: 10.1039/b007925l

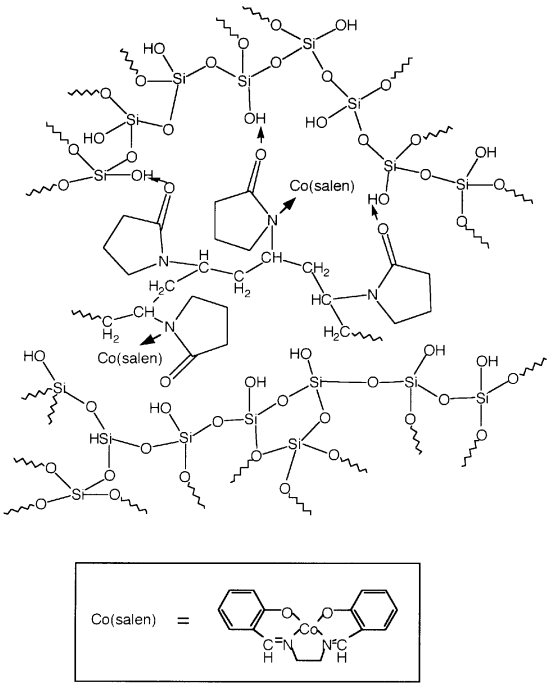

Fig. 2 Schematic representation of the structure of the SiO_2–PVP–salacomine hybrid membrane.

the sol. A possible schematic structure of the membrane is proposed in Fig. 2. As shown, silica and PVP were dispersed at a molecular level due to strong hydrogen bonding between amide carbonyl and silanol groups. Also, PVP and salcomines were well dispersed at a molecular level as nitrogen atoms of amide carbonyl groups were coordinated with Co(II) in the salcomines.[2,3] Therefore, high dispersion of salcomines in the SiO_2–PVP hybrid at the molecular level and a well dispersed inorganic–organic structure of the SiO_2–PVP–salcomine hybrid is evident.

Single gas permeation through these hybrid membranes at different temperatures was measured using O_2 and N_2 using the procedure described elsewhere[10] after drying at 373 K in a vacuum oven for 1 h. Table 1 lists the permeances of O_2 and N_2 through the SiO_2–PVP–salcomine and SiO_2–PVP hybrid membranes and shows the selectivity factor $\alpha = P_{O_2}/P_{N_2}$, where P_{O_2} and P_{N_2} are the permeances of O_2 and N_2, respectively. SiO_2–PVP–salcomine hybrid membrane showed oxygen selectivity even at high temperatures. Although the initial selectivity at 298 K was not that high ($P_{O_2}/P_{N_2} = 1.4$), the selectivity was found to increase with increasing temperature. At 423 K, the O_2/N_2 selectivity factor was 6.1, and the permeance of O_2 was 5.0 $\times$ 10^{-10} (mol m^{-2} s^{-1} Pa^{-1}). This selectivity factor is greater than the theoretical Knudsen value ($P_{O_2}/P_{N_2} = 0.94$) which can be ascribed to the strength of the Co(II)–oxygen complex bonds, which are strong at higher partial pressures of oxygen; therefore, salcomine effectively only releases oxygen at temperatures > 373 K, that is strongly trapped by salcomine at low temperature and thus lowers the mobility of oxygen. The absence of oxygen selectivity for the SiO_2–PVP hybrid membrane (without salcomine) confirms that oxygen selectivity is strongly related to the presence of salcomine.

Table 1 Permeances and selectivity factors of O_2 and N_2 through the SiO_2–PVP–salcomine and SiO_2–PVP hybrid membranes at 298, 373 and 423 K

Membrane	*T*/K	10^{-10} Permeance/ mol m^{-2} s^{-1} Pa^{-1}		Selectivity factor P_{O_2}/P_{N_2}[a]
		O_2	N_2	
SiO_2–PVP–salcomine	298	1.2	0.84	1.4
	373	4.0	0.87	4.6
	423	5.0	0.84	6.1
SiO_2–PVP	298	1.5	1.5	1.0
	373	1.2	1.1	1.0
	423	0.77	0.77	0.99

[a] Theoretical selectivity factor based on Knudsen flow is 0.94.

In conclusion, SiO_2–(*N*,*N*′-disalicylideneethylenediaminato)cobalt(II) (salcomine) hybrid membranes for oxygen separation were prepared by the sol–gel method using poly(*N*-vinylpyrrolidone) (PVP) as a mediation agent. Results indicates that the proposed structure of the membrane consisted of well dispersed inorganic (SiO_2) and organic (PVP, salcomine) segments at a molecular level. This membrane can be classified as a high O_2 selectivity membrane even at high oxygen partial pressure and relatively high temperature.

A photoinduced, multistep electron transfer in a triad containing a zinc porphyrin (electron donor) and a gold(III) porphyrin (electron acceptor) appended to an Ir(III) bis-terpyridine complex produces a charge separated state with a close to unity yield and a lifetime of 450 ns.

Photoinduced charge separation over nanometer distances in artificial arrays is a topic of high relevance both to fundamental[1] and to applied chemical sciences.[2] This function is achieved by molecular triads and higher analogues, able to undergo stepwise electron transfer under the action of light. It is essential that the multicomponent systems be rigid so as to insure good geometrical control and to favor long-lived charge separated (CS) states. In recent years, we have reported rigid triads based on ruthenium(II) bis-terpy complexes (terpy = 2,2′:6′,2″-terpyridine) and differently metallated porphyrins as electron donor and electron acceptor groups.[3,4] In this type of array, energy transfer processes from the porphyrin photosensitizer to the Ru(II) complex could efficiently compete with the desired electron transfer.[4] Ir(III) bis-terpy revealed itself to be particularly well adapted as a component unit, since it displayed a higher ligand centered excited state and remarkable redox properties.[5] Therefore Ru(II) was replaced by Ir(III) as the assembling metal ion in the synthesis of the rigid molecular triads.[6] In the previous Ir(III) bis-terpy based triad the electron donor was a free-base porphyrin (PH_2) and the terminal acceptor was a gold(III) porphyrin (PAu). Clear evidence for the formation of the fully charge-separated state (PH_2^+–Ir–PAu^-) was obtained by transient absorption spectroscopy.[6] However, charge recombination turned out to be fast (*ca.* 3.5 ns at room temperature in nitriles) due to the presence of a low-lying triplet state localized on PH_2. Substitution of the PH_2 unit with zinc porphyrin in this triad is expected to result in an increase in the triplet level; this should leave the CS state as the lowest state with the only possibility to deactivate to the ground state. Since the latter reaction is strongly exergonic (ΔG *ca.* −1.3 eV) we expect it to be placed in the Marcus inverted region[1] in a moderately polar or apolar solvent, and therefore to be slow so allowing for a long-lived CS state.

We now report the detection, upon excitation in the visible region of a toluene solution of **PZn–Ir–PAu** (Fig. 1), of a CS state with a lifetime of 450 ns. The triad **PZn–Ir–PAu**† was prepared by metallation of its free-base analogue[6] with zinc acetate in refluxing MeCN–MeOH (1:1 v/v). The absorption spectrum of this triad in toluene is very little perturbed with respect to the superposition of the spectra of the model components **PAu**, **PZn** (in toluene) and **Ir** (in acetonitrile) indicating little electronic coupling between the components. Similar indications are given by electrochemical determinations in dichloromethane where the oxidation of the PZn unit in the dyad PZn–Ir occurs at the same potential as the model **PZn**, +0.68 V (*vs.* SCE) while the PAu unit, which is reduced at −0.66 V (*vs.* SCE) in PAu–Ir *cf.* −0.70 V (*vs.* SCE) of **PAu**, is somehow affected by the presence of the substituent. Reduction of the Ir complex occurs at −0.71 V in the model dyad PZn–Ir. These data place the energy levels of the CS states PZn^+–Ir^-–PAu and PZn^+–Ir–PAu^- in dichloromethane at *ca.* 1.39 and 1.34 eV, respectively. The excited state properties determined by transient absorption and luminescence experiments‡ at 295 K both for the models and the array are reported in Table 1 with the pertinent energy levels, as derived by the maxima of emissions at 77 K. The emission of zinc porphyrin in the array is quenched with a rate exceeding our resolution time, while the only detectable excited state of the gold porphyrin, the lowest triplet, remains unchanged with respect to the model. The Ir moiety absorbs at higher energies, $\lambda < 400$ nm, therefore this unit is not excited in the present experiment. Upon laser excitation at 532 nm, after the decay of the gold porphyrin triplet (τ = 2.5 ns), a longer lived absorption is left the spectrum of which is displayed in Fig. 2. The decay is monoexponential, identical over the whole spectral region and in air-free solution the lifetime is 450 ns (inset of Fig. 2). Air equilibration of the solution results in a decrease of the exponential lifetime to 310 ns, which allows us to derive a reaction rate with oxygen of *ca.* 5×10^8 M^{-1} s^{-1}. The lifetime was unaffected by changes in the concentration of the array and in the energy of the laser pulse. The spectrum, in full agreement with the bands typical of the zinc porphyrin cation and the reduced gold porphyrin radical, is assigned to the CS state PZn^+–Ir–PAu^-. In oxygen free solutions a very weak absorption ascribable to the triplet localized on the zinc porphyrin, formed with a very low yield and a lifetime of 7 μs, is left after the decay of the CS state. An estimate of the efficiency of the charge separation process with respect to the photons absorbed by the zinc porphyrin moiety only, calculated on the basis of the molar absorption coefficient of 1×10^4 M^{-1} cm^{-1} for the cation of tetraphenyl zinc porphyrin at 680 nm,[7] yields a value very close to unity (1.2 ±

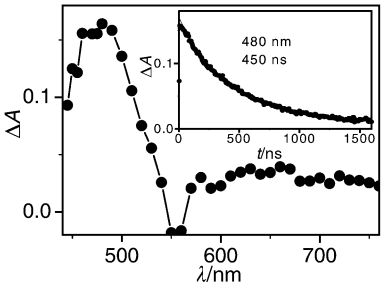

Fig. 2 Transient absorption changes detected in an air free toluene solution of **PZn–Ir–PAu** upon excitation at 532 nm. In the inset the decay at 480 nm and the fitted exponential function corresponding to a lifetime of 450 ns is shown.

0.3). Such high efficiency in the charge separation process requires a very fast primary (from the excited PZn moiety to the Ir complex) and secondary (from the reduced Ir moiety to the gold porphyrin unit) electron transfer, to prevent competition with the back reactions. The detected quenching of the luminescence is faster than 20 ps in agreement with this requirement, so is also the rise of the absorbance assigned to the CS state which cannot be resolved from the excitation profile in an experiment with 20 ps resolution. Any investigation on the model dyad PZn–Ir which could give further information on the elementary steps of the electron transfer sequence is prevented by the insolubility of the dyad in toluene. Fig. 3 shows a schematic energy level diagram for the system along with the processes and the pertinent rates. The energy levels of the CS states are derived from electrochemical data in dichloromethane and this causes some uncertainty in their location in a toluene solution.

We have shown that highly efficient formation of a long lived charge separated state occurs in this triad in toluene solution upon excitation in the visible range.

This work was supported by the French CNRS and the Italian CNR. We thank European Commission COST programme D11/0004/98 and the French Ministry of Education, Research and Technology for a fellowship to I. M. D. We are also grateful to Johnson Matthey for a generous loan of $IrCl_3$.

Silicon imido nitride with a specific surface area up to 1000 $m^2\ g^{-1}$ is obtained by ammonolysis of silicon tetrachloride in organic solvents and subsequent NH_4Cl removal at elevated temperatures in a stream of anhydrous ammonia. The material has a remarkably narrow pore size distribution and a mean pore size of 5.7 nm. TEM investigations reveal the spherical macromorphology and uniform dendritic mesostructure of the micrometer sized particles. A high number of Si-NH_2 groups on the inner surface of the material is indicated from IR measurements. ^{29}Si MAS NMR indicates the presence of SiN_4^{8-} tetrahedra.

Tailoring inorganic solids is a key feature in the search for purpose-built high-performance materials. High specific surface area and control of pore size and pore morphology are especially needed in heterogeneous catalysis.[1] For oxide materials a wide range of methods has been developed such as flame pyrolysis and sol gel techniques.[2] Due to our recent interest in the development of porous non-oxide ceramics as heterogeneous catalysts we have investigated the synthesis of silicon imido nitride as a high surface area material under various conditions. Even though this material has been widely studied as a precurser to obtain Si_3N_4 for structural applications,[3] sinterability and densification have mainly been stressed, whereas only few attempts have been made to systematically tailor its surface area and pore structure and only recently has its potential in heterogeneous catalysis become apparent.[4–6]

In order to achieve easy access to highly porous materials we have used $SiCl_4$ (Arkos, 99.8%) in various solvents (4% solution) such as pentane, toluene, tetrahydrofuran and polyethyleneglycol dimethyl ether and precipitated the diimide with anhydrous ammonia gas (UHP, Messer).† After filtration, the coprecipitated NH_4Cl was removed by sublimation in a dynamic (40 ml min^{-1}) ammonia atmosphere (1 bar) at elevated temperature [eqn. (1)]

$$SiCl_4 + 6NH_3 \xrightarrow{\text{solvent}} [Si(NH)_2\downarrow + 4NH_4Cl\downarrow] \xrightarrow{NH_3,\ \text{heat}} Si(NH)_2 + 4NH_4Cl\uparrow \quad (1)$$

1 **2**

The composition of the product **2** depends on the heat treatment. According to wet chemical analysis of the powder the N : Si ratio is 1.60 for a sample calcined at 873 K, and 1.50 at 1073 K. The formula $Si_2N_2(NH)$ instead of $Si(NH)_2$ is often assigned to intermediates during the technical process of decomposing $Si(NH)_2/xNH_4Cl$ to prepare Si_3N_4 for structural ceramics. We have therefore adopted the rather unspecific nomenclature 'high surface area silicon imido nitride' (HSA-SIN) for **2**. It is obtained with a BET surface area up to 1000 $m^2\ g^{-1}$ as a white, X-ray amorphous powder if pentane is used as the solvent and the initial precipitation is carried out at room temperature followed by heating the resulting solid to 723 K for 2 h with a rate of 5 K min^{-1}. This is the highest surface area so far reported for $Si(NH)_2$ and comparable to that for MCM-41-like materials.[7] Even though the pores do not form an ordered array according to small-angle X-ray measurements, the adsorption isotherm† (Fig. 1) indicates the presence of mesopores with a narrow pore size distribution, a sharp maximum at 5.1 nm and a mean pore diameter of 5.7 nm. No percolation effect due to ink bottle pores is observed. For applications in heterogeneous catalysis ordering of the pores is not necessary but high surface area, narrow pore size distribution and homogeneity of the inner surface are highly desirable to obtain high performance materials with good selectivity.

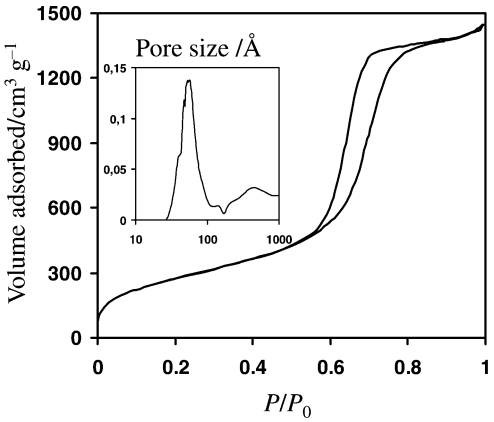

Fig. 1 Nitrogen adsorption isotherm for HSA-SIN synthesized in pentane after calcination in ammonia and its pore size distribution.

TEM investigations (Fig. 2) reveal the spherical morphology of the particles with typical size of 0.1 μm diameter. The radial dendritic channel-like mesostructure is independent of the size of the aggregates. We found that polar solvents such as tetrahydrofuran also give mesoporous silicon imido nitride but with considerably lower surface area (560 $m^2\ g^{-1}$) and two distribution maxima at 7.6 and 40.6 nm. The effect of washing the coprecipitate **1** with liquid ammonia results in an even more drastic reduction of the surface area (*ca.* 300 $m^2\ g^{-1}$) and the

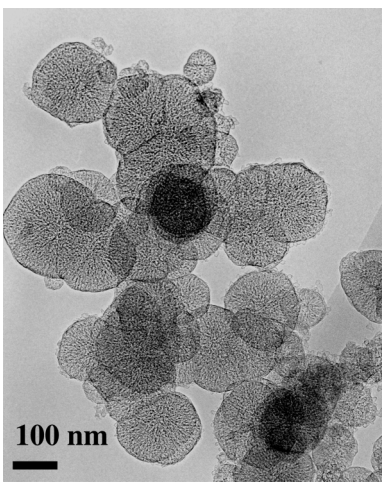

Fig. 2 Transmission electron micrograph of HSA-SIN.

DOI: 10.1039/b007884k

narrow distribution now being completely lost, with a wide range of sizes from micro- to macro-pores being observed. While washing with liquid ammonia is often applied when sinterable $Si(NH)_2$ powder is needed for structural ceramics this method to remove NH_4Cl seems highly inappropriate for specific pore structure design. So far only one group has reported a specific surface area of up to 1000 $m^2\ g^{-1}$ for silicon diimide using the precipitation method and toluene for dilution of $SiCl_4$, but the pore morphology was not discussed.[8] In our experiments, toluene reduces the total yield of the reaction by at least a factor of 10, and is therefore less appropriate.

The particle formation mechanism is still unknown. Some intergrown spheres suggest that the large spheres might have formed by merging of smaller spheres but whether this formation has occurred in solution or during heat treatment is still not clear. However, the strong impact of the solvent on the surface properties as well as the spherical morphology of the aggregates suggests that their formation occurs in solution where surface tension and solubility govern nucleation and growth. In fact we believe that NH_4Cl nanocrystals act as a template for the surrounding $Si(NH)_2$. This view is supported by the fact that polar solvents cause pore collapse due to the higher solubility and recrystallization of the NH_4Cl whereas in pentane the generated ammonium chloride nuclei remain small. This is in accord with the particle size determined from the broadening of the ammonium chloride Bragg reflections in the coprecipitate **1** (*ca*. 8 nm).

IR spectroscopy gives similar results as earlier studies[9] [ν(NH): 3374 cm^{-1}, $\delta(NH_2)$: 1548 cm^{-1}, δ(NH): 1182 cm^{-1}, $\nu_{as}(Si_2N)$: 905 cm^{-1}]. The $\delta(NH_2)$ mode indicates the presence of amino groups located on the inner surface of the material in analogy to silanol groups present on the inner surface of MCM-41. This band is stronger for samples synthesized in pentane *vs*. tetrahydrofuran, corresponding to the higher inner suface area of the former sample; exposure to air as well as lithiation with butyl lithium reduces its relative intensity. No Si–O stretching modes were observed if the material was handled properly with exclusion of moisture or air.

The ^{29}Si MAS NMR spectrum consists of one broad peak centered at −42 ppm, the signal covering the region between −35 and −55 ppm. The broadening originates from the ill defined local structure and is characteristic for amorphous preceramic silicon nitride powders[10] in which different functional groups are present. Thus in HSA-SIN, $Si(NH)_{4/2}$ groups are most abundant but $SiN_{(4-x)/3}(NH)_{x/2}$ (x = 0–3) groups in the bulk and $Si(NH)_{(4-x)/2}(NH_2)_x$ (x = 1,2) groups on the inner surface of the material are also present. A shoulder at −49 ppm indicates a high abundance of $SiN_{4/3}$ groups with a chemical shift comparable to that of β-Si_3N_4[11] at −48.7 ppm. A low level of silicon oxide impurities was also concluded from the absence of any significant peaks close to −100 ppm, though due to the high background noise, such impurities could not be completely excluded. The chlorine contamination was also low (< 2% by EDX).

The high temperature stability and low sintering tendency of the nitride is remarkable and reveals its promising potential as a support in high temperature catalysis: after 2 h of heat treatment at 1273 K in a dynamic ammonia atmosphere (1 bar, 40 ml min^{-1}) the high surface area is only slightly reduced (820 $m^2\ g^{-1}$). The pore size distribution remains narrow with only a slightly reduced mean pore size (4.9 nm).

New compounds will become available as heterogeneous catalysts and supports if morphological syntheses of non-oxide ceramics as high surface area materials are further explored. We have demonstrated that ammonolysis of silicon tetrachloride in solution is an easy route to high surface area silicon imido nitride with uniform pore morphology—a material with potential for base-catalyzed reactions suitable for further functionalization, impregnation and high temperature applications.

We thank F. Schüth for helpful discussions and financial support. A Reimar Lüst Fellowship for Stefan Kaskel was provided by the Max Planck Society. TEM images were recorded by B. Spliethoff while B. Zibrowius measured the ^{29}Si MAS NMR spectra.

First published as an Advance Article on the web

Ring opening of the cyclic $[(Bu^tP)_3As]^-$ anion results from reactions with electrophiles (RX = H_2O, MeI, CH_2=$CHCH_2I$, $PhCH_2Br$), providing a simple and general approach to triphosphine ligands of the type $[(Bu^tP)(Bu^tRP)_2]$.

We found recently that heterocyclic anions of the type $[(RP)_nE]^-$ (n = 3 or 4; E = As, Sb; R = Bu^t, 1-adamantyl, cyclohexyl) can be prepared in a single step by the reactions of alkali metal primary phosphides with $E(NMe_2)_3$ (E = As, Sb).[1] Our particular interest in these species stems from their potential to act as sources of group 15 atoms, as suggested by the isolation of Zintl compounds from the same reaction systems at higher temperatures.[1] These heterocyclic anions exhibit unusual reactivity with transition metal metallocenes, the reaction of the Lewis base complex $[\{(Bu^tP)_3As\}Li\cdot 2DABCO\cdot thf]$ **1** [DABCO = $N(CH_2CH_2)_3N$] with $[CpM(CO)_3Cl]$ (M = Mo, W) leading to addition of the $[(Bu^tP)_3As]^-$ anion to the Cp ring rather than displacement of the metal-bonded Cl ligand.[2] Here we show that $[(RP)_nAs]^-$ anions are useful synthons of the corresponding $(RP)_n^{2-}$ dianions, as illustrated by the reactions of $[(Bu^tP)_3As]^-$ with electrophiles which provides direct access to a large range of terminally substituted triphosphine ligands.

The reactions of **1** with a range of electrophiles (1:3 equiv., respectively) occur smoothly at −78 °C in thf–toluene giving insoluble precipitates of HAsO(OH) (in the case of H_2O) or organo-arsenic dihalides $[RAsX_2]$ (with organic halides as electrophiles) which are readily removed by filtration (Scheme 1). Removal of the solvent under vacuum gives 72–98% yields of the terminally substituted triphosphines $[(Bu^tP)(Bu^tRP)_2]$ (R = H **2**, Me **3**, CH_2=$CHCH_2$ **4**, $PhCH_2$ **5**).† The high purity of the materials obtained *directly* by this procedure is confirmed by their room-temperature ^1H and ^{31}P NMR spectra, which show little or no impurities. The ^{31}P NMR spectra of **2**–**5** are consistent with those of previously reported triphosphines,[3] **2** (*meso* and *racemic* isomers), **4** and **5** appearing as characteristic A_2M multiplets and **3** as a more complex eight line A_2B multiplet (*i.e.* $\Delta\delta \approx \Delta J$). A further feature of the ^1H NMR spectra of **3** and **5** is the appearance of the Me and benzyl methylene protons as deceptively simple triplets.[4] Model *ab initio* calculations reveal that the reactions producing **2**–**5** are highly thermodynamically favourable. For example, the gas-phase reaction of 3MeI with $[\{Bu^tP\}_3AsLi]$ is exothermic by 57.4 kcal mol^{-1} (at the B3LYP/6-311G** level).‡ This reaction becomes even more favourable (−66.2 kcal mol^{-1}) once solution effects are included. Calculations of the reactions involving $[\{RP\}_3AsLi]$ (R = H, Me, Bu^t) also reveal that these reactions are enthalpically driven (with negligible entropy changes being associated in solution).

Scheme 1

A limited number of terminally substituted triphosphines of the type $[(RP)(RR'P)_2]$ have been prepared previously by reactions of $[(RP)_3M_2]$ (M = alkali metal) with electrophiles.[3] These salts can be generated either by cleavage of $(RP)_n$ with an alkali metal (giving the salt as a mixture with other homologues)[5] or by reaction of $[(RP)(RHP)_2]$ (prepared by reduction of terminal halides $[(RP)(RXP)_2]$) with alkali metals.[3a] Importantly, although often efficient these procedures involve several steps starting from the simple dihalides $RPCl_2$, with extensive manipulation and purification at each stage. The electrophilic ring-opening reaction described here provides the potential means by which any primary phosphine (from which **1** and related heterocycles are prepared in a single step in crystalline form) can be converted selectively into a broad range of terminally substituted triphosphines. The closest related approach utilises $[Cp_2Zr(PPh)_3]$ as a source of $[PhP]_3^-$ in the synthesis of the cyclic compounds $[PhP]_4$ and $[(PhP)_3SnBu^t_2]$.[6]

Owing presumably to the involved and specialised synthetic methods previously required in the synthesis of tri- and tetraphosphines, to our knowledge, no studies of their coordination chemistry have been reported. The few structurally characterised examples of coordination compounds of this type are transition metal complexes in which the tri- or tetra-phosphine frameworks have been assembled at the transition metal centre.[7] However, these reactions do not appear to be selective in terms of the chain length of the phosphine incorporated, with the chain length of the phosphines being dependent on the organic substituents[7a,b] as well as the reaction conditions.[8] An illustration that these ligands can indeed be transferred *intact* to a transition metal centre is provided in this study by the synthesis† and structural characterisation§ of $[W(CO_4)\{(Bu^tP)(Bu^tHP)_2\}]$ **6** (Fig. 1). The structural features of **6** are similar to those of $[W(CO)_4\{(Bu^tP)(Me_2P)_2\}]$, the only other complex previously characterised in which a chelating triphosphine ligand is present.[7a] The presence of only one isomer of the triphosphine (the symmetric *meso* form) at the W centres of **6** is of some interest. Previous NMR studies (consistent with those presented in the current work†) have shown that this is the predominant isomer in solutions of free **2**.[3a] The fact that the isomer of **6** incorporating a *racemic* form of the triphosphine is not produced in this reaction may be due to steric factors, leading to the selection of the *meso* form in the complex.

In summary, the new, high yielding method of preparing terminally substituted non-symmetric, triphosphines should allow systematic investigation of the coordination chemistry of

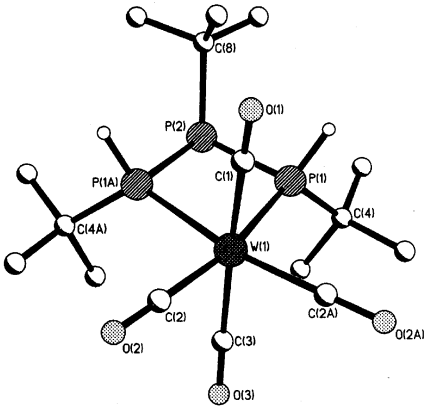

Fig. 1 Structure of **6**; H-atoms (except those attached to the P atoms) have been omitted for clarity. Key bond lengths (Å) and angles (°): W(1)–P(1) 2.512(1), W(1)–C(2) 1.990(5), W(1)–C(3) 2.017(7), P(1)–P(2) 2.215(2); P(1)–W(1)–P(1A) 72.96(5), P(2)–P(1)–W(1) 101.09(5), P(1)–P(2)–P(1A) 84.78(7).

this class of ligands. This should be of particular importance in relation to the widespread application of ligand frameworks such as $(CH_2)_n(PPh_2)_2$ (n = 1 or 2) and the growth of interest in ligand systems with well defined bite, steric and stereochemical characteristics in the field of homogeneous catalysis. Significantly, preliminary studies of the reactions of the heterocyclic anion $[\{CyP\}_4As]^-$ with electrophiles (RX) suggest that analogous tetraphosphines of the type $[(CyP)_2(CyRP)_2]$ are generated.[9]

Supramolecular self-assembly directed by carborane C–H···F interactions

Hans Lee, Carolyn B. Knobler and M. Frederick Hawthorne*

Department of Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA 90095, USA. E-mail; mfh@chem.ucla.edu

Received (in Columbia, MO, USA) 21st August 2000, Accepted 31st October 2000
First published as an Advance Article on the web

The synthesis and crystallization of 9,12-bis-(4-fluorophenyl)-1,2-carborane 1 and 9,12-bis-(3,5-difluorophenyl)-1,2-carborane 2 provide the first examples of a supramolecular assemblage directed by C–$H_{carborane}$···F interactions.

The potential utilization of the isomeric icosahedral carborane ($C_2B_{10}H_{12}$) cages as building blocks for macromolecules and supramolecular assemblies has only recently been explored.[1–3] The versatile chemistry available at the carborane C–H and B–H vertices makes carborane derivatives attractive candidates for crystal engineering.[4] Intermolecular hydrogen bonding is an important factor involved in supramolecular self-assembly motifs. Consequently, the participation of the acidic carborane C–H vertices in hydrogen bonding generates supramolecular structures. The established intermolecular interactions involving carboranes are: classical C–H···O hydrogen bonds,[5] bifurcated C–H···$(O)_2$ hydrogen bonds,[6] non-classical C–H···π hydrogen bonds[7] and B–H···H–N interactions.[1,8] Thus far, known C–H carborane interactions are limited to C–H···Y (Y= O, N, π) systems.[1,9] Fluorocarbon sites (C–F) are poor hydrogen bond components and cannot compete with O and N, although weak C–H···F interactions contribute to crystal-packing organization.[10] We report here the novel *ortho*-carborane derivatives: 9,12-bis-(4-fluorophenyl)-*o*-carborane **1**, and 9,12-bis-(3,5-difluorophenyl)-*o*-carborane **2**. Compounds **1** and **2** provide the first examples of a supramolecular assemblage directed by carborane C–H···F interactions.

Electron-rich boron vertices of *ortho*-carborane were easily functionalized by electrophilic iodination followed by palladium-catalyzed reactions of the regioselectively iodinated carborane with the appropriate fluorophenyl or difluorophenyl Grignard reagent.[11] Colorless crystals of **1** and **2** were grown from a methylene chloride–hexane solution and Et_2O, respectively,† by slow evaporation of the solvent. The structures of compounds **1** and **2** were determined by single-crystal X-ray diffraction analysis.

Crystal structures of both **1** and **2**‡ show intermolecular carborane C–H···F interactions. The unit cell of the solid-state structure of **1** contains four crystallographically unrelated, yet similar carboranes. Carborane C–H···F intermolecular distances lie in the range 2.49–3.05 Å and non-classical C–H···π hydrogen bonds with carborane C–H···aromatic centroid separations of 2.48 and 2.46 Å are observed (see caption to Fig. 1). The observed carborane C–H···F distances are consistent with phenyl C–H···F interactions reported for various fluorobenzene compounds (H···F 2.36–2.86 Å).[10] Also, close phenyl C–H···F distances (H···F 2.25–2.70 Å) are observed. All carborane C–H vertices are in close proximity to either a fluorine atom or π centroid, with the majority participating in C–H···F interactions. The solid-state IR spectrum of **1** exhibits two distinct stretching frequencies for carboranyl C–H at 3088 and 3060 cm^{-1}. These unassigned stretching frequencies represent either a carborane C–H···(F or π) interaction. The C–H stretching frequencies of the *o*-carborane C–H···π bond were reported[7] between 3066 and 3059 cm^{-1} which suggests that the lower energy stretching mode (3060 cm^{-1}) corresponds to those carborane C–H bonds involved in C–H···π interactions.

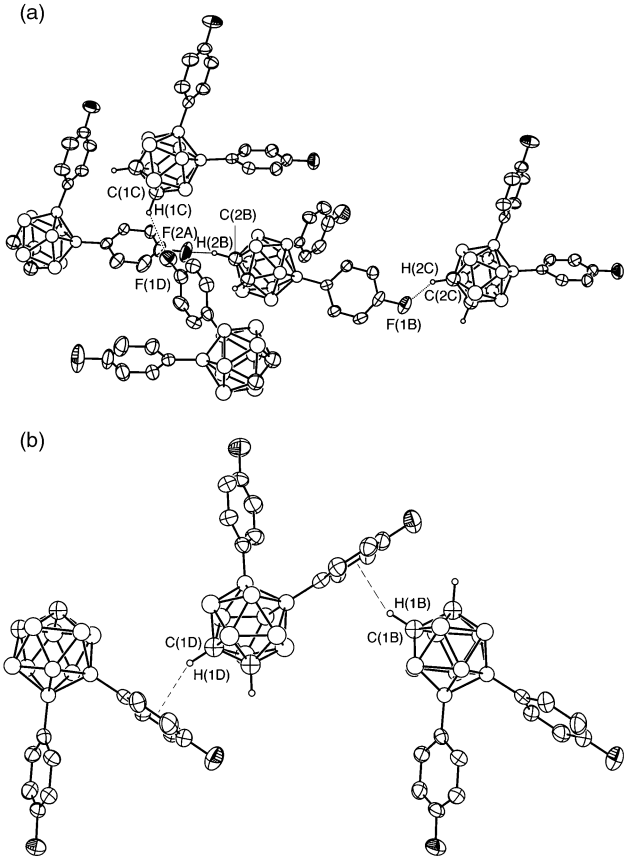

Fig. 1 Crystal packing diagram of **1**. (a) View of carborane C–H···F interactions. Selected distances (Å) and angles (°): C(1C)···F(1D) 3.593(8), H(1C)···F(1D) 2.91, C(2B)···F(2A) 3.416(7), H(2B)···F(2A) 2.49, C(2C)···F(1B) 3.557(8), H(2C)···F(1B) 2.69; C(1C)–H(1C)–F(1D) 120, C(2B)–H(2B)–F(2A) 146, C(2C)–H(2C)–F(1B) 136. (b) View of carborane C–H···π interactions. Selected distances (Å) and angles (°): H(1D)···aromatic centroid(π) 2.48, H(1B)···π 2.46; C(1D)–H(1D)–π 24.3, C(1B)–H(1B)–π 24.7. For clarity, the remaining phenyl and carborane H atoms are not shown.

In the solid state structure, molecules of **2** form a one-dimensional polymeric chain linked by two different carborane interactions having characteristic C–H···F distances. Directionality of both C–H vertices toward the fluorine atoms differ with angles of C(1)–H(1)–F(3P) 160° and C(2)–H(2)–F(11P) 124°. Intermolecular interactions of C(1)–H(1)···F(3P) 2.47 Å and C(2)–H(2)···F(11P) 2.35 Å demonstrate that the hydrogen atom bonded to C(2) interacts more strongly with fluorine than the hydrogen atom bonded to C(1) (Fig. 2). Close phenyl C–H···F interactions are not observed in **2**. The solid-state IR spectrum exhibits two different carborane C–H stretching frequencies of equal intensity (3077 and 3098 cm^{-1}). This observation is consistent with the presence of the two discrete sets of such interactions observed in the X-ray diffraction study. The position of the 3,5-difluorophenyl group in **2** allows the

DOI: 10.1039/b007353i

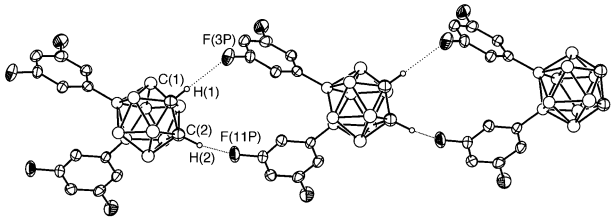

Fig. 2 Crystal packing diagram of **2**. The three molecules are related by translation. Selected distances (Å) and angles (°): C(1)···F(3P) 3.462(5), H(1)···F(3P) 2.47, C(2)···F(11P) 3.107(5), H(2)···F(11P) 2.35; C(1)–H(1)–F(3P) 160, C(2)–H(2)–F(11P) 124. For clarity, the remaining phenyl and carborane H atoms are not shown.

orientation of both carborane C–H vertices to simultaneously be in close proximity to fluorine atoms present on the neighboring molecule. This orientation leads to formation of the observed one-dimensional polymeric structure.

The crystal lattices of **1** and **2** are directed by a network of weak carborane C–H···F and/or C–H···π contacts. Although these C–H···F interactions are weak, their sum in lattice networks provides stabilization. This study demonstrates an additional motif for carboranes in supramolecular self-assembly chemistry.

We are grateful to the National Science Foundation (Grant No. CHE-9730006) for their support of this research.

Notes and references

† *Synthetic procedure* for **1**: to a dry THF (300 ml) solution of 9,12-I_2-1,2-$C_2B_{10}H_{10}$ (4.12 g, 10.4 mmol) was added 52 ml of 4-fluorophenylmagnesium bromide (1 M, in THF) at 0 °C. At 25 °C, *trans*-[$PdCl_2(PPh_3)_2$] (120 mg, 0.17 mmol) was added to the solution. The mixture was heated at the reflux temperature under nitrogen for 2 days, resulting in a black solution. Aqueous 10% HCl was added cautiously to destroy residual Grignard reagent, and all volatiles were removed *in vacuo*. The residue was dissolved in 200 ml of diethyl ether and 10% HCl (aq). The organic phase was separated and the aqueous layer was extracted with diethyl ether (2 × 100 ml). The organic phases were combined, dried over $MgSO_4$, and filtered. The solvent was removed under reduced pressure to yield a red solid. Purification by chromatography on basic aluminum oxide (toluene) gave a white solid. Crystallization from a methylene chloride–hexane solution afforded **1** (2.98 g, 8.95 mmol, 86%).

Selected data for **1**: mp 132–133 °C; ν(KBr)/cm^{-1} 3060, 3088 (carborane C–H); δ_H(400 MHz, $CDCl_3$, *J*/Hz) 1.5–3.4 (BH), 3.68 (br s, 2H), 6.80 (tt, *J* 9.0, 2.3, 4H), 7.13 (br dd, *J* 8, 6, 4H); δ_C(100 MHz, $CDCl_3$, *J*/Hz) 162.8 (d, J_{CF} 245.5, CF), 134.6 (d, J_{CF} 7.3, CH), 114.3 (d, J_{CF} 19.9, CH), 49.4; δ_B(160 MHz, BF_3·Et_2O external standard, *J*/Hz) 8.4 (s, 2B), −8.3 (d, J_{BH} 138, 2B), −13.0 (d, J_{BH} 151, 4B), −15.6 (d, J_{BH} 167, 2B); δ_F(376 MHz, $CDCl_3$, external Freon-113/C_6D_6 solution referenced at −68.0 ppm[12] relative to $CFCl_3$) −116.5; HR-EIMS: *m/z*: found 332.2376; calc. 332.2387.

Synthetic procedure for **2**: the synthesis and separation procedure was similar to that of **1**. Crystallization from Et_2O afforded **2** (79%).

Selected data for **2**: mp 189–190 °C; ν(KBr)/cm^{-1} 3077, 3098 (carborane C–H); δ_H(400 MHz, $CDCl_3$, *J*/Hz) 6.61 (br d, *J* 6.6, 4H), 6.52 (tt, *J* 9.1, 2.4, 2H), 3.74 (2H), 1.5–3.4 (BH); δ_C(100 MHz, $CDCl_3$, *J*/Hz) 50.1, 102.7 (t, J_{CF} 25.2), 115.1 (dd, J_{CF} 17.2), 162.2 (dd, J_{CF} 251.5); δ_F(376 MHz, $CDCl_3$, external Freon-113/C_6D_6 solution referenced at −68.0 ppm[12] relative to $CFCl_3$) −112.4; δ_B(160 MHz, Et_2O, BF_3·Et_2O external standard, *J*/Hz) 7.4 (s, 2B), −8.6 (d, J_{BH} 140, 2B), −13.0 (d, J_{BH} 154, 4B), −15.5 (d, J_{BH} 168, 2B); HR-EIMS: *m/z*: found 368.2196; calc. 368.2191.

The synthesis of a novel bithiophene with a pendant fullerene substituent and its electrochemical polymerisation are reported; light induced ESR measurements on the electrodeposited films reveal a photoinduced electron transfer from the donor cable (polythiophene) to the pendant acceptor cable (fullerene moieties).

The ultrafast photoinduced electron transfer from non-degenerate ground state conjugated polymers to fullerenes,[1] in association with the existing technologies for processing polymers, makes these materials potentially suitable for low-cost photovoltaic applications as large-area, flexible solar cells.[2] Within this frame, the most promising devices so far obtained are the so-called bulk heterojunction solar cells.[3–5] The active layer of such devices is a blend of conjugated polymer and fullerene: after photoinduced charge separation, the polymer matrix ensures the transport of positive carriers, while electrons travel through contacting fullerene domains. Because of the limited miscibility of the two components, clusters of fullerenes can form within the active film, so that the transport of electrons is hindered by the 'void' between such separated domains.[4] A convenient solution to overcome phase segregation and reach a homogeneous distribution of the electron transporting sites within the bulk heterojunction should be the preparation of so-called double-cable molecular systems with fullerene substituents grafted to a conjugated polymer chain. Polythiophene/C_{60} mixtures have been already employed for the preparation of prototype bulk heterojunction solar cells,[5] suggesting the investigation of double-cables consisting of a polythiophene backbone with covalently linked fullerene units. Zotti and coworkers and Ferraris *et al.* showed that such fullerene substituted polythiophenes mostly retain the favourable ground state properties of the individual polymer and fullerene moieties.[6] However, the occurrence of photoinduced electron transfer in this type of polymers has, as yet, not been observed.

Here, we report preliminary results on a novel electrosynthesised polythiophene with pendant fullerene substituents, obtained from bithiophene-fulleropyrrolidine dyad **1** (Scheme 1). Compound **1** combines solubility and the superior electropolymerisability of bithiophenes[7] and gives a double-cable polymer that is heavily loaded with fullerene electron conducting moieties.

The synthetic strategy toward bithiophene-fulleropyrrolidine **1** is outlined in Scheme 1. The route to **1** starts with commercially available 4-hydroxybenzaldehyde and 1-iodo-2-[2-(2-iodoethoxy)ethoxy]ethane. Reaction between 4-hydroxybenzaldehyde and the bis-iodo derivative in the presence of K_2CO_3 in acetone at reflux temperature afforded the product of monosubstitution **2** in 20% isolated yield. Palladium-catalysed coupling[8] of 4-bromophenol with 3-thiophene-boronic acid[9] followed by NBS-bromination gave the highly reactive derivative **3** that was coupled directly with 2-thiophene-boronic acid[9] to afford **4**. Reaction of **2** with the potassium salt of bis-thiophene phenol **4** gave functionalised bithiophene **5** in 50% yield. Condensation of **5** with sarcosine in the presence of C_{60}[10] provided **1** in 49% isolated yield. All spectroscopic and analytical data were consistent with the proposed molecular structures.†

The cyclic voltammogram (CV) of **1** shows one anodic peak at *ca.* 1.3 V, which corresponds to the generation of radical cations that *via* subsequent coupling and re-aromatisation steps afford the substituted polythiophene chain[7,11] (Fig. 1). Potential sweeping between 0 and +1.6 V leads to the rapid growth of a new redox wave centered at *ca.* 0.9 V and related to the formed double-cable poly-**1**. Similar results have been obtained in different conditions, *e.g.* by using different electrodes, solvents and substrates. Insoluble and yellow-brownish films, whose UV–VIS absorption spectra show a band ranging from *ca*. 600 nm to the glass cut-off at 300 nm, have been obtained. No photoluminescence could be observed.

The CV of poly-**1** films in monomer-free electrolyte medium (Fig. 2) shows, in positive direction, a stable redox system with

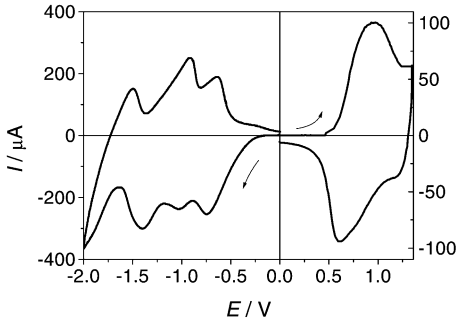

Fig. 2 Anodic (right) and cathodic (left) CV of poly-**1** (0.1 M Bu_4NPF_6 in MeCN). Conditions as in Fig. 1.

anodic and cathodic peak potentials at 0.96 and 0.61 V, respectively, corresponding to the oxidation/re-reduction ('p-doping/dedoping') of the polythiophene chain. Scanning to negative potentials up to −2.0 V shows several waves related to the multiple reduction processes of the fullerene moiety (Fig. 2).[12] The electrochemical behaviour suggests that both the polythiophene chain and the pendant fullerene moieties of the double-cable retain their individual electrochemical properties.

The photogeneration of separated charged states in poly-**1** has been observed by means of light-induced electron spin resonance (LESR) measurements. The LESR spectrum, obtained by subtracting the light-off signal from the light-on signal, is shown in Fig. 3. The spectrum reveals the photoinduced generation of two species with spin = 1/2. The signal at g = 2.0022 corresponds to delocalised radical cations (widely accepted to be polarons) on the conjugated backbone while the signal at g = 2.0004 is typical of low g-factor fullerene radical anions.[13] These results prove the occurrence of a photoinduced electron transfer from the conjugated backbone to the pendant fullerene moieties of poly-**1**, which is an essential prerequisite for photovoltaic applications. In addition, also sub-gap electronic and IR-active vibration (IRAV) bands are observed in the photoinduced UV–VIS and IR spectra of poly-**1**

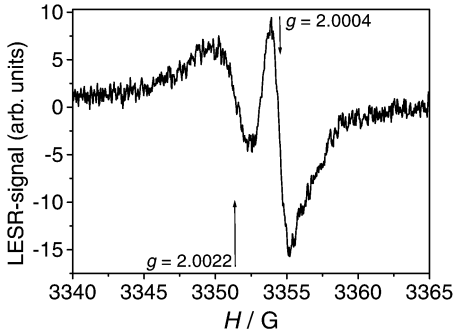

Fig. 3 LESR (light-on minus light-off) spectrum of poly-**1** on ITO coated foil. T = 77 K; excitation at λ = 488 nm (20 mW cm^{-2}).

(not shown here). These spectral features are related to the photoinduced generation of long-living charged states.[14]

In conclusion, we have shown the synthesis of a novel bithiophene-fulleropyrrolidine dyad suitable as a monomer for electrochemical polymerisation. The resulting double-cable polymer retains the peculiar characteristics of polythiophene/fullerene blends, including the ability to generate a charge-separated state after photoinduced electron transfer. Since no phase separation is expected in this type of material, donor–acceptor double-cables represent attractive candidates for photovoltaic applications.

The amine template of hexagonal mesoporous silica (HMS) can be efficiently recovered and re-used by a new extraction procedure in acidified water rendering a directly usable high quality mesoporous support.

Following the earliest reports on M41S materials,[1] Pinnavaia and coworkers[2,3] introduced an alternative route to synthesize mesoporous materials based on a hydrogen bonding interaction between a neutral amine and a non-ionic silica precursor. These materials were denoted hexagonal mesoporous silicas (HMS). An important advantage in the synthesis of these materials is the cost reduction by employing a less expensive and non-toxic surfactant and the mild reaction conditions. HMS materials are claimed to have larger pores, to be more stable and to have thicker pore walls than their MCM-41 counterparts.[4] Owing to the weak hydrogen bonding interactions, more than 90% of the neutral template can be recovered by a simple extraction procedure using ethanol as extracting solvent. A few other attempts to extract the surfactants of mesoporous templated materials have been described in the literature (MCM-41,[5,6] Al-MCM-41,[7] Al-HMS,[8] mesoporous alumino- and galloaluminophosphate[9]). In all cases, a huge amount of organic solvent is required and, mostly, the extraction needs to be followed by a calcination step to remove the remaining surfactant or the surface ethoxy groups produced during extraction.

We report on an optimized HMS synthesis including the complete extraction of the template with acidified water. This procedure yields not only a directly usable high quality support that does not require a further calcination step, but also allows re-use of the recovered template several times. Obviously, a water extraction procedure fits very well in the striving to green or sustainable chemistry.

HMS was prepared at room temperature using dodecylamine (DDA) as structure directing agent and tetraethylorthosilicate (TEOS) as silica source, according to the procedure reported elsewhere.[4] In a typical template removal, 1 g of as-synthesized material was added to 100 ml solvent and refluxed for 1 h. The residual solid was then filtered off and washed with a second 100 ml portion of solvent and dried at room temperature. Several extracted samples were prepared: HMS-E and HMS-W(HCl/DDA), where E and W indicate extraction in ethanol and water, respectively. HCl/DDA indicates the molar ratio of HCl in the solution and DDA in the as-synthesized HMS. Furthermore, portions of the as-synthesized HMS materials that were calcined in air at 550 °C for 16 h were designated as HMS-C.

The amount of template in the extracted samples (see later, Table 1) is calculated from thermogravimetric analysis. The DTG curve for as-synthesized HMS shows weight losses at 225 and 290 °C, attributed to the thermal decomposition of DDA. A notable difference in the shape of the DTG curve can be observed for the ethanol extracted HMS-E (weight loss at 270 and 400 °C). Information on the origin of these weight losses was obtained by refluxing 1 g of calcined HMS in pure ethanol for 1 h, denoted as HMS-RE. This final material shows weight losses at the same temperature as HMS-E, attributed to the esterification of the surface with ethoxy groups. This can also be inferred from IR spectroscopy (Fig. 1) where HMS-E and HMS-RE show the same bands (2905, 2936 and 2982 cm^{-1}) in the C–H vibration region. Although the extraction of surfactant molecules in ethanol is very efficient (no decomposition of DDA in the DTG curve and complete absence of DDA-bands in the IR spectrum), it yields a surface that is completely unreactive toward subsequent activation owing to the presence of chemically bonded ethoxy groups, and a subsequent calcination at 450 °C is required for further possible application of the support.

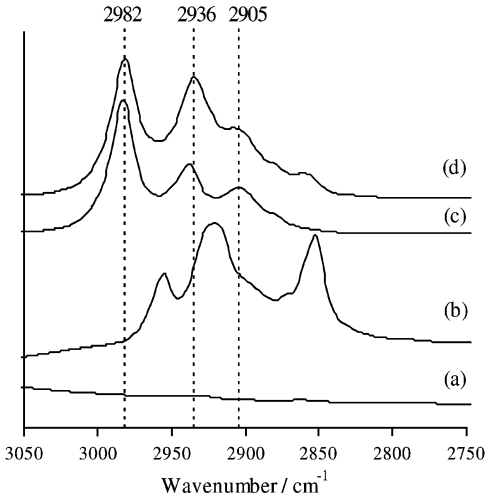

Fig. 1 Diffuse reflectance IR spectra of samples: (a) HMS-W(1), (b) dodecylamine, (c) HMS-RE and (d) HMS-E. The spectra were measured at 200 °C under an oxygen flow.

For the water-extracted HMS-W(0) 69% of the template was present, whereas for the acidified water-extracted HMS-W(1) and HMS-W(2) no weight losses were observed in the DTG curves (Table 1). The absence of template is further evidenced by the IR spectrum of HMS-W(1), where no C–H vibrations are observed. This significant difference in the degree of extraction

Table 1 Amount of template after extraction and physical properties of HMS samples

Sample	Amount of template (%)	BET surface area/ $m^2\ g^{-1}$	$V_{prim.pores}$[a]/ $cm^3\ g^{-1}$	d_{100}[b]/nm	KJS pore diameter/ nm
HMS-C	—	1015	0.71	3.70	3.55
HMS-E	0	932	0.78	3.79	3.70
HMS-W(0)	69	—	—	—	—
HMS-W(1)	0	1051	0.83	3.84	3.70
HMS-W(2)	0	791	0.54	3.63	—[c]
HMS-RC	—	908	0.67	3.78	3.30

[a] Primary pore volume measured after the capillary condensation step ($P/P_0 \approx 0.45$) in the N_2 isotherm. [b] Basal spacing. [c] The pore size distribution was too broad and irregular to determine the peak diameter.

DOI: 10.1039/b007297o

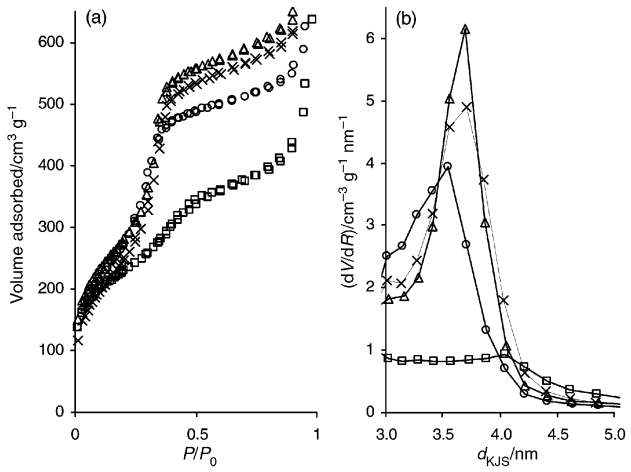

Fig. 2 N_2 sorption isotherms (a) and KJS pore size distributions (b): (□) HMS-W(2), (○) HMS-C, (×) HMS-E and (△) HMS-W(1). The textural mesopore filling of the samples (between P/P_0 = 0.9 and 1) is not shown.

can be attributed to the very low solubility of DDA in pure water, even at elevated temperature. Addition of HCl converts DDA into soluble dodecylammonium chloride (DDAHCl), which facilitates the extraction.

The effect of solvent extraction is shown in Fig. 2(a) and the physical properties of the HMS samples are also listed in Table 1. Compared to the calcined and ethanol-extracted sample, N_2-sorption results show that the template removal in acidified water [HMS-W(1)] also maintained the uniform hexagonal mesoporous structure. To calculate the pore size distribution (PSD), it is generally agreed that the BJH method underestimates the size of pores[10,11] and therefore, the KJS procedure[12] [Fig. 2(b)] is used, which is based on a corrected Kelvin equation for hexagonal materials. It is remarkable that HMS-W(1) has a more narrow PSD, a higher BET-surface area, higher primary pore volume and higher d_{100} value than the calcined and the ethanol-extracted samples. Furthermore, the amount of HCl seems to be a critical parameter in the acidified water extraction procedure. An excess of HCl [HMS-W(2)] results in a poorly ordered structure.

As to its potential use, an important step besides efficient water extraction is the re-usability of the template. To achieve this goal, the recovered DDAHCl was converted to DDA by the addition of NaOH to the extraction solvent. The precipitated DDA was dried and re-used in a fresh synthesis (HMS-RC). As can be seen in Table 1, HMS-RC has very similar characteristics as the calcined HMS-C, indicating that no degradation of the surfactant has occurred.

In summary, the results reported here clearly reveal that the amine template can be recovered easily and efficiently from hexagonal mesoporous silica in acidified water, resulting in a high quality and directly usable molecular sieve. Our synthetic approach therefore provides new opportunities in the synthesis of mesoporous supports while avoiding high-temperature treatment and organic solvents, while the template can also be re-used.

$(C_6H_5)_2N_2P_2(N_3)_6$ 1 has been prepared and characterised by multinuclear NMR, vibrational spectroscopy and single crystal X-ray analysis; the normal modes of 1 have been calculated and the antisymmetric stretching vibration of the azide group has been discussed.

In 1970 Horn reported on the reaction of 1,3-dimethyl-2,2,2,4,4,4-hexachloro-1,3-diaza-2,4-diphosphetidine with NaN_3 in MeCN yielding a highly explosive compound which was only poorly characterised.[1] To our knowledge only a few crystal structures of mono- and di-substituted phosphorus azides[2] and nitrogen-penta-coordinated phosphorus compounds[2c,3] have been published. Here we report on the synthesis and structural characterisation of the first nitrogen-penta-coordinated phosphorus species substituted with three azide groups, which can be considered as a hexazidodiphosphadiazacyclobutane.

1,3-Diphenyl-2,2,2,4,4,4-hexazido-1,3-diaza-2,4-diphosphetidine **1** was obtained in high yield as a colourless solid from the reaction of 1,3-diphenyl-2,2,2,4,4,4-hexachloro-1,3-diaza-2,4-diphosphetidine with trimethylsilyl azide in CH_2Cl_2 solution, [eqn. (1)].

Single crystals suitable for X-ray diffraction determination§ were grown from CH_2Cl_2. A view of the molecular structure of **1** is shown in Fig. 1. Compound **1** crystallises in the triclinic space group $P\bar{1}$ with two formula units in the unit cell. The two crystallographically different molecules display nearly identical bond lengths and angles.

The molecular structure of **1** reveals C_i symmetry in which each phosphorus is coordinated by five nitrogen atoms. The coordination sphere around the phosphorus atom can be regarded as a slightly distorted trigonal bipyramid.

The N_2P_2 ring is planar with a P–N–P angle of 100.6(2)° and a N–P–N angle of 79.4(2)°. The azide groups are slightly bent with N–N–N angles ranging from 171.1(4) to 175.1(4)° which

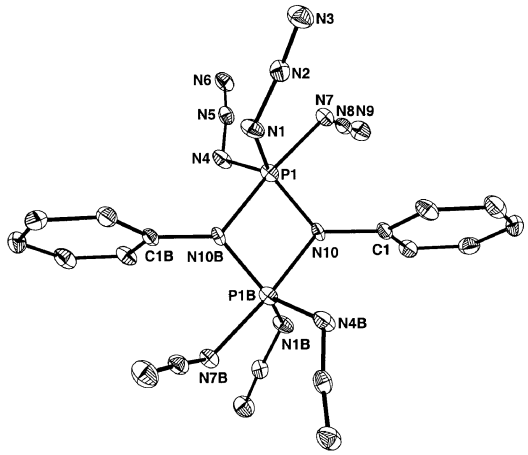

Fig. 1 An ORTEP plot of the molecular structure of compound **1** with thermal ellipsoids at 25% probability level. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): P(1)–N(1) 1.703(3), P(1)–N(4) 1.713(3), P(1)–N(7) 1.804(3), N(1)–N(2) 1.252(4), N(4)–N(5) 1.253(4), N(7)–N(8) 1.240(4), N(2)–N(3) 1.118(4), N(5)–N(6) 1.118(4), N(8)–N(9) 1.130(4), P(1)–N(10) 1.643(4), N(10)–P(1B) 1.774(3); P(1)–N(10)–P(1B) 100.6(2), N(10)–P(1)–N10(B) 79.4(2).

are in accordance with the structures of other covalent phosphorus azides.[2]

Since the two nitrogen ring atoms occupy different positions in the coordination sphere around the phosphorus atom [N(10) equatorial, N(10B) axial position, with respect to P(1) and *vice versa* for P(1B)] two considerably different $P–N_{ring}$ bond lengths [1.643(4) and 1.774(3) Å] are observed which are similar to the bond lengths found in $Me_2N_2P_2Cl_6$.[4] A similar large difference in the P–N bond length is found for the azide groups [1.703(3), 1.713(3) and 1.804(3) Å] as each phosphorus atom in **1** is surrounded by two equatorial [eq, N(1), N(4)] and one axial [ax, N(7)] azide groups. NBO analysis indicates that this structural feature can be rationalised by a 'weaker' two-electron–three-centre bond unit along the N(10B)–P(1)–N(7) [and N(10)–P(1B)–N(7B)] axis whereas the equatorial positions can be best described by two-electron–two-centre bond units.† This rather special bonding situation can best be understood in the picture of localised bond orbitals (NBOs) by strong non-covalent contributions between the two monomeric units.[5] The one lone pair (p-type atomic orbital) on each $N(Ph)P(N_3)_3$ unit interacts with the antibonding σ $P–N_3$ bond system of the second monomeric unit and *vice versa* (Fig. 2). There are three strong intramolecular donor–acceptor interactions of this type which weaken the $P–N_3$ bonds (especially $P–N_{3,ax}$) and account for the rather long $P–N_3$ bonds. However, since the lone pair (LP) on the ring nitrogen atom lies in-plane with the $P–N_{3,ax}$ bond of the second monomeric unit, the interaction with the unoccupied, antibonding $\sigma^*(P–N_{3,ax})$ is stronger than the interaction with the 'out-of-plane' $\sigma^*(P–N_{3,eq})$ bond orbitals [$LP(N_{ring}) \rightarrow \sigma^*(P–N_{3,ax})$: 85, $LP(N_{ring}) \rightarrow \sigma^*(P–N_{3,eq1})$: 38, $LP(N_{ring}) \rightarrow \sigma^*(P–N_{3,eq2})$: 34 kcal mol^{-1}].† This

[d] These displacement vectors represent approximations. Weak coupling between the axial and the equatorial azide groups is neglected for clarity.

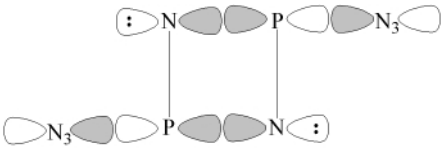

Fig. 2 Intramolecular donor–acceptor interaction in **1**: LP(N_{ring}) → σ*(P–N_3).

strong interaction of the nitrogen lone pair with the σ* P–N_3 bonds can be considered as the main driving force of the cyclisation. Moreover, this donor–acceptor bonding is strengthened by the donor properties of the phenyl ring and accounts for the stability of the dimer. Previous NMR studies on phosphine-imine/diazadiphosphetidine equilibria have shown that the formation of the dimer strongly depends on the donor properties of the nitrogen substituents.[6] Weaker donor substituents (*e.g.* $C_6H_2Cl_3$-2,4,6) result in equilibria between the monomeric and dimeric species.

As a result of this intriguing bond situation, the axial P–N_3 bond displays a higher ionic character which is manifested by a better π delocalisation along the azide unit leading to a longer terminal N(8)–N(9) bond length and a shorter N(7)–N(8) bond length than in the equatorial azide groups with a less polar P–N_3 bond (Fig. 1). In agreement with this, the hybridisation on the nitrogen attached to the P atom increases from $N_{ax}(7)$ ($sp^{1.01}$) < $N_{eq}(1)$ ($sp^{1.23}$) < $N_{eq}(4)$ ($sp^{1.31}$) resulting in a larger N(7)–N(8)–N(9) angle compared to the N(4)–N(5)–N(6) and N(1)–N(2)–N(3) angles.

Since the terminal N(8)–N(9) bond length of the axial azide group is significantly longer, the antisymmetric stretching vibrations of the axial azide group appear at lower wavenumbers than the antisymmetric stretching vibration of the equatorial azide groups (Table 1). The calculated, scaled antisymmetric stretching frequencies are in excellent agreement with the experimentally observed vibrational frequencies and confirm the results of the NBO analysis.† Owing to C_i symmetry of the molecule, there are six normal modes describing the antisymmetric stretching vibration of the N_3 moiety which are either Raman active (3 A_g) or IR active (3 A_u). In agreement with C_i symmetry, the Raman and the IR spectra of solid **1** show each three absorbtions: Raman (2158, 2135, 2111 cm^{-1}); IR (2154, 2142, 2113 cm^{-1}), which are in the typical region for the antisymmetric stretching vibration of azides.[7] The approximate displacement vectors and assignments are given in Table 1.

The difference between the axial and equatorial azide groups was also observed in the ^{14}N NMR spectrum of **1**. The ^{14}N NMR spectrum of a covalently bonded azide group (connectivity X–$N_α$–$N_β$–$N_γ$) usually shows three resonances whereas the signal of the $N_α$ and $N_γ$ are very broad owing to the large quadrupole moment of ^{14}N. The ^{14}N NMR spectrum of **1** reveals three signals for the $N_β$ atoms at −152 (br, sh) and −154 ppm which can be assigned to the two N_{eq} and N_{ax}. The resonances of the $N_γ$ atoms are found in the region of −166 (br, N_{eq}) and −169 (N_{ax}) ppm.[8] A single resonance was observed in the ^{31}P NMR spectrum at −87.6 ppm, in the region typical for penta-coordinated phosphorus.

Financial support of this work by the University of Munich and the Fonds der Chemischen Industrie is gratefully acknowledged. We also wish to thank Prof. K. Karaghiosoff for helpful advice with the NMR spectra. We thank the referees for most valuable comments.

Syntheses and thermal reactivities of symmetrically and asymmetrically substituted acyclic enediynes: steric control of Bergman cyclization temperatures

Diwan S. Rawat and Jeffrey M. Zaleski*

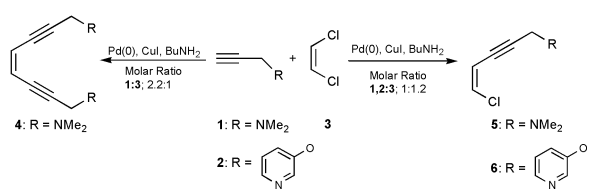
First published as an Advance Article on the web

The steric influences of the functional groups at the termini of acyclic enediynes can dramatically affect the Bergman cyclization temperatures of the resulting compounds.

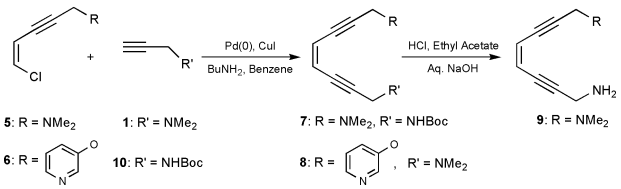
The potent antitumor activity of the enediyne natural product antibiotics[1] such as calicheamicin,[2] dynemicin,[3] esperamicin,[4] and neocarzinostatin[5] has fostered interest in the development of simple enediynes with low thermal barriers to formation of the lethal 1,4-benzenoid diradical intermediate.[6] To this end, carbocyclic enediyne frameworks,[7] and more recently, novel metalloenediyne structures,[8–13] have shown considerable promise for the development of molecules with tunable thermal reactivities. Key structural considerations within these architectures are the relative disposition of the alkyne termini, as well as the nature of the ring closing motif, both of which provide steric contributions to the thermal barrier to Bergman cyclization.[14,15] In cases of metal assisted enediyne activation, it is now established that the metal center geometry is an important influence on the cyclization thermodynamics.[11–13] However, the structural consequences derived from ligand design also contribute significantly to the initial barrier height prior to metal assisted activation.[12,13] Unfortunately, the steric influences of the metal binding functionalities have not yet been systematically evaluated for simple enediyne ligands.

As a part of our ongoing investigations of novel metalloenediyne structures and reactivities,[11–13,16] we became interested in designing simple nitrogen donor enediyne chelates with variable thermal properties. Within this theme, we report the syntheses and thermal reactivities of two symmetric and two asymmetric enediyne chelates of the form 1,8-bis(R,R′)oct-4-ene-2,6-diyne where R and R′ = dimethylamino, amino, or 3-hydroxypyridine. The asymmetric compounds are synthetically unique, and exhibit cyclization temperatures between the bis(dimethylamino) and the novel diamino compound, the latter of which is substantially more reactive. The thermal reactivities of these enediynes systematically illustrate the importance of intraligand steric hindrance in influencing Bergman cyclization temperatures.

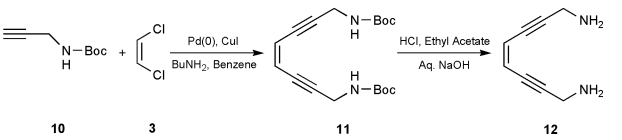
Scheme 1 illustrates the general strategy for our preparation of the symmetric dimethylamino enediyne (1,8-bis(dimethylamino)oct-4-ene-2,6-diyne,[17] **4**),† as well as the dimethylamino (**5**)‡ and 3-hydroxypyridine (**6**) substituted 5-chloropent-4-ene-2-yne synthon. Stephens–Castro coupling of 2.2 equiv. of the 3-dimethylaminoprop-1-yne (**1**) with *cis*-1,2-dichloroethylene (**3**) over a Pd(0) catalyst in the presence of CuI and $BuNH_2$ generates **4** in 79% yield. Comparable reaction conditions using 1 : 1.2 alkyne **1**,**2** : **3** stoichiometries produces the monosubstituted eneyne precursors **5**, **6** in 57–62% yield. Reaction of **5** with 1 equiv. of the *N*-Boc-prop-2-ynyl amine (**10**), or **6** with **1** under analogous conditions yields the asymmetric products **7** and **8**§ (Scheme 2). Subsequent treatment of **7** with acid removes the protecting group and generates the asymmetric primary/tertiary amine species **9**.§ The same *N*-Boc-prop-2-ynyl amine (**10**) is employed for the preparation of the *N*-Boc enediyne precursor **11** and the subsequent diamino product **12** by analogy (Scheme 3).¶



Scheme 1



Scheme 2



Scheme 3

The Bergman cyclization temperatures of enediyes **4**, **8**, **9**, and **12** (Table 1) were measured on neat materials by DSC and show a remarkable 80 °C variation across the series. The origin of the gradient derives from the steric encumbrance imposed upon the alkyne termini by the nitrogen-containing substitutents at the 1,8 positions of the enediyne framework. Beginning with R = dimethylamino, **4** is a thermally stable compound that exhibits a Bergman cyclization temperature of 186 °C. Substitution of one dimethylamino group with 3-hydroxypyridine (**8**) dramatically reduces the Bergman cyclization temperature to 149 °C. The result derives primarily from two sources. First, the ability of the pyridine ring to rotate out of the enediyne plane about the oxygen bond relieves steric clashes with the opposing substituent.[13] Secondly, the addition of the sp^3 oxygen between the pyridine ring and the alkyne termini

Table 1 Bergman cyclization temperatures of symmetric and asymmetric acyclic enediynes

DOI: 10.1039/b007360l

effectively distances the pyridine substituent from the alkyne termini by another atom, further reducing the interaction between substituents. This latter effect plays an important role as subsequent substitution to form the 1,8-bis(pyridin-3-yloxy)oct-4-ene-2,6-diyne (**13**) compound[12,16] restores the adjacent proximity of the substituents and results in only a modest decrease of the Bergman cyclization temperature of **13** (136 °C) relative to **8**. In contrast, removal of oxygen and methylene carbon atoms from **13** to form the conjugated 1,6-dipyridin-3-ylhex-3-ene-1,5-diyne (**14**) in which the pyridine rings are adjacent to the alkyne termini restores the high Bergman cyclization temperature (195 °C).[13]

A more pronounced trend is observed between the three compounds in the bis(dimethylamino) to diamino enediyne series (**4**, **9**, **12**). Monosubstitution of amino for dimethylamino (**9**) yields a dramatic 47 °C decrease in the Bergman cyclization temperature (**9** = 139 °C). Further substitution to form the diamino compound **12** produces an additional 33 °C decrease in the Bergman cyclization temperature (**12** = 106 °C, onset: 55 °C) indicating that **12** has one of the most facile thermal reactivities of an acyclic enediyne reported to date. The enhanced thermal reactivity of **12** results from a combination of the reduced steric hindrance of the primary amine functionalities, as well as an additional contribution from intramolecular hydrogen bonding.

To better correlate the thermal reactivity of **12** with that of other enediyne compounds reported in solution, we have measured the pseudo first-order rate constant (20-fold cyclohexadiene) and half-life ($t_{1/2}$) for the reactivity of **12** in DMSO by monitoring the disappearance of the –CH– ^{1}H NMR resonance at 5.7 ppm at 65 °C. A first order plot of ln([**12**]) *vs.* *t* and subsequent linear regression (R = 0.99) yielded k_{obs} = 4.16×10^{-2} h^{-1}, $t_{1/2}$ = 16.6 h. As is often observed in solution cyclization reactions of enediynes, a series of products are produced,[18] which in this case include disubstituted benzenes, and as such no dominant species could be isolated from the reaction. The low onset temperature for reactivity of this acyclic enediyne indicates that **12** may be an extremely important ligand for generating thermally reactive and therapeutically useful metalloenediyne complexes. The series also highlights the importance of ligand design in influencing Bergman cyclization temperatures and points toward the use of sterically innocent ligands in order to achieve lower metalloenediyne cyclization temperatures.

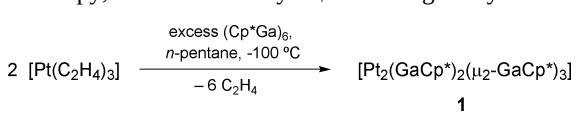
Received (in Cambridge, UK) 9th October 2000, Accepted 30th October 2000
First published as an Advance Article on the web

A new homoleptic diplatinum complex $[Pt_2(GaCp^*)_2(\mu_2\text{-}GaCp^*)_3]$ (Cp* = pentamethylcyclopentadienyl) exhibiting a central unit of two platinum atoms coordinated by five Cp*Ga groups acting as terminal as well as bridging ligands, was synthesized by the reaction of tris(ethylene)platinum(0) with an excess of $(Cp^*Ga)_6$ and was characterized by structural and quantum chemical methods.

In the past decade, the synthesis and structural chemistry of low-valent group 13 compounds and particularly their potential as ligands for the synthesis of novel group 13 element transition metal complexes and clusters, as well as the use of those latter compounds as precursors to new materials, have attracted widespread interest.[1] However, recent studies concerning this subject have almost exclusively focused on the coordination of ER species (E = Al, Ga, In) to metal carbonyl fragments.[2] When in 1998 Uhl *et al*. reported the synthesis of $[Ni\{InC(SiMe_3)_3\}_4]$, the first analogue of a mononuclear, binary carbonyl complex with exclusively terminal ER groups,[3] it was recognised as the starting point of a very fruitful new development in coordination chemistry. However, since then only three (!) other related *homoleptic* complexes have been reported by Uhl *et al*., $[M\{EC(SiMe_3)_3\}_4]$ (M = Ni, E = Ga; M = Pt; E = In),[4] and Jutzi *et al*., $[Ni(GaCp^*)_4]$.[5] We were attracted by the unique properties of ECp* compounds[1e] and have shown recently, that ECp* ligands stabilise reactive 14e L_2Pt centres produced by reductive alkane elimination to yield complexes of the type [(dcpe)Pt(ECp*)$_2$] [E = Al, Ga; dcpe = 1,2-bis(dicyclohexylphosphino)ethane].[6] Herein we describe the first example of the so far unknown series $M_a(ER)_b$ which extends the analogy between CO and ER ligands: $[Pt_2(GaCp^*)_2(\mu_2\text{-}GaCp^*)_3]$ **1**. The ER ligands are often compared to carbon monoxide or phosphine ligands, but regarding **1**, no truly analogous *neutral* homoleptic diplatinum carbonyl or phosphine complexes are known. Compounds of the type $[Pt_2(PPh_3)_2(\mu_2\text{-}dmpm)_3]$ [dmpm = bis(dimethylphosphino)-methane] bridged by a phosphine chelate ligand, may be regarded as closest congeners, at least from a topological point of view.[7]

The synthesis of **1** is outlined in Scheme 1. When tris(ethylene)platinum(0)[8] in pentane solution was treated with a 4.8-fold amount of Cp*Ga[2b] per equivalent of the platinum compound at –100 °C, a reddish brown solution was formed immediately. After warming up to room temperature and evaporation of all volatile components *in vacuo*, a dark red crude crystalline material was collected (quantitative yield based on NMR spectroscopy). After recrystallization from benzene large ruby-red octahedral shaped crystals were gathered in a yield of 70%. Compound **1** was characterised by ^{1}H NMR, ^{13}C NMR and IR spectroscopy, elemental analysis† and single crystal X-ray diffraction.‡ The ^{1}H NMR spectrum in benzene-d_6 exhibits two resonances at δ 2.15 and 2.03, respectively, with a ratio of two to three, that can be assigned to the methyl groups of the terminal and bridging Cp*Ga units, thus showing that there is no exchange between this positions on the NMR time scale. The ^{13}C NMR data show similar features.† Neither ^{71}Ga nor ^{195}Pt NMR resonances have, as yet, been identified, most likely because of extensive quadrupolar line broadening effects caused by the Ga nuclei. A single crystal X-ray diffraction study was performed, the results of which confirm the structural predictions based on analytical and spectroscopic data.



Scheme 1

Compound **1** crystallizes in the monoclinic space group $P2_1/c$ (Z = 4). The molecular structure of **1** (Fig. 1) consists of a central unit of two platinum atoms Pt(1) and Pt(2) with a quite short platinum–platinum bond length of 2.582(1) Å, compared to the common range for Pt^0–Pt^0 bonds of *ca*. 2.65–2.80 Å, *e.g.* in {[Pt(dtbpe)]$_2$} [2.765(1) Å, dtbpe = 1,2-bis(di-*tert*-butylphosphino)ethane] or neutral platinum clusters like $[Pt_3(PCy_3)_3(CO)_3]$ [2.656(2) Å, Cy = cyclohexyl].[9] For the shortest Pt–Pt distances in platinum metal values in the range 2.742–2.848 Å have been reported.[10] The Pt_2 unit of **1** is surrounded by two terminal Cp*Ga ligands [Ga(1) and Ga(2)], and three bridging Cp*Ga ligands [Ga(3)–Ga(5)]. All Cp*

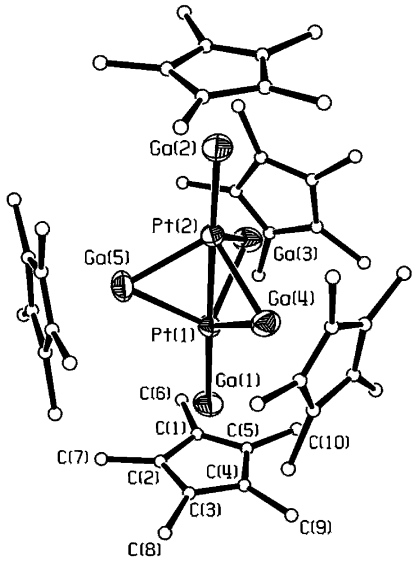


Fig. 1 Molecular structure of **1**. Selected bond lengths (Å) and angles (°): Pt(1)–Pt(2) 2.582(1), Pt(1)–Ga(1) 2.326(2), Pt(2)–Ga(2) 2.331(1), Pt(1)–Ga(3) 2.450(1), Pt(1)–Ga(4) 2.465(1), Pt(1)–Ga(5) 2.464(1), Pt(2)–Ga(3) 2.472(1), Pt(2)–Ga(4) 2.463(1), Pt(2)–Ga(5) 2.470(1), Ga(1)–Ga(3) 4.160, Ga(3)–Ga(4) 3.593, Ga(1)–C(1–5) 2.294(7)–2.310(7), Ga(4)–C(31–35) 2.313(7)–2.338(7), $Cp^*_{centroid}$–Ga(1) 1.968, $Cp^*_{centroid}$–Ga(2) 1.969, $Cp^*_{centroid}$–Ga(3) 2.013, $Cp^*_{centroid}$–Ga(4) 2.001, $Cp^*_{centroid}$–Ga(5) 2.021; Ga(1)–Pt(1)–Pt(2) 178.93(2), Ga(2)–Pt(2)–Pt(1) 178.60(2), Pt(1)–Ga(3)–Pt(2) 63.28(2), Pt(1)–Pt(2)–Ga(3) 57.95(2), Pt(2)–Pt(1)–Ga(3) 58.77(2), Ga(1)–Pt(1)–Ga(3) 121.12(3), Ga(3)–Pt(1)–Ga(4) 93.95(3).

DOI: 10.1039/b008133g

moieties are bound to the Ga centres in a nearly ideal symmetric η^5 mode with average values for the $Cp^*_{centroid}$–Ga distances of 1.969 Å for the terminal Cp*Ga units and 2.013 Å for the bridging ligands, both values being close to the free ligand of 2.081 Å (gas phase, monomer).[1a] Such distances are an indirect measure for the polarity of the Ga–Pt bond, which appears to be low compared to $[(CO)_nM–GaCp^*]$ complexes, especially for the bridging Cp*Ga ligands.[2a,6] The coordination pattern of the five Cp*Ga units at the central Pt(1)–Pt(2) core results in a diplatinum centred trigonal-bipyramidal structure (idealized D_{3h} symmetry) with an essentially linear Cp*Ga–Pt–Pt–GaCp* arrangement. The structure can also be described in terms of two face-sharing $PtGa_4$ tetrahedra. At least formally we can imagine an (unstable ?) intermediate species $[Pt(GaCp^*)_4]$ similar to the corresponding stable $[Ni(GaCp^*)_4]$ adding one reactive [PtGaCp*] fragment to yield **1**. This tendency of the heavier d-metals to form oligonuclear complexes rather than mononuclear species is well known from classical metal carbonyl chemistry. The terminal Pt–Ga distances of 2.326(2) and 2.331(1) Å are the shortest Pt–Ga bonds known and compare with average terminal Pt–Ga bond lengths of 2.369 Å in $[(dcpe)Pt(GaCp^*)_2]$.[6] The bridging Cp*Ga units exhibit an average Pt–Ga bond length of 2.464 Å, with values in the range 2.450(1)–2.472(2) Å. The shortest Pt–Ga distances of the intermetallic alloy systems PtGa and Pt_2Ga_3 amount to 2.60 and 2.45 Å, respectively.[11] A final comparison can be drawn to the complex $[(dcpe)Pt(GaR_2)(R)]$ (R = CH_2Bu^t), which exhibits the only other known Pt–Ga bond in molecular compounds [2.438(1) Å].[12] The Ga–Ga distances of compound **1** are in the range 3.593–3.691 Å for the bridging Cp*Ga units and 4.160–4.197 Å for the distances between terminal and bridging Cp*Ga ligands, which both are regarded as non-bonding. These values can be compared to the situation in $(Cp^*Ga)_6$ with Ga–Ga distances in the range 4.073–4.173 Å as a consequence of very weak bonding interactions in the solid state.[1a]

We examined the bonding situation in **1** with the aid of quantum chemical methods. To this end we first optimized the geometry of the model compound $[Pt_2(GaCp)_2(\mu_2\text{-}GaCp)_3]$ **1M** where the Cp* ligands of **1** are replaced by Cp at the gradient-corrected DFT (BP86) level of theory.[13] The calculated bond lengths of **1M** are $Pt–Ga_{terminal}$ 2.308 Å, $Pt–Ga_{bridge}$ 2.368 Å and Pt–Pt 2.829 Å. The theoretical value for the $Pt–Ga_{bridge}$ bond is significantly shorter than the experimental value of **1**, and the calculated Pt–Pt distance is much too long. Therefore we optimized the geometry of the real compound **1** at the same level of theory.[13] The calculation took three weeks cpu-time on a fast workstation and gave interatomic Pt–Pt distances which are in better agreement with experiment. The theoretical (average) values for **1** are $Pt–Ga_{terminal}$ 2.393 Å, $Pt–Ga_{bridge}$ 2.558 Å and Pt–Pt 2.676 Å. Calculated bond lengths of donor–acceptor bonds are usually longer than experimental values obtained from X-ray structure analysis, since solid state effects tend to shorten the interatomic distances.[15] Analysis of the Pt–Pt bond with the help of the NBO[16a] and AIM[16b] methods suggests weak attractive interactions only. A detailed bonding analysis will be reported in a full paper.

Though to our knowledge no intermetallic Pt_2Ga_5 bulk phase has been reported, the synthesis of heterobimetallic compounds such as **1** might provide prospects for molecular pathways to new intermetallic materials and nanophases as a valid target for further studies, following our work on single molecule sources for OMCVD of alloy thin film materials, which we have been performing for a number of years.[1d]

The support of this work by the Deutsche Forschungsgemeinschaft (Fi 502/6-1), the Degussa-Hüls AG and the W. C. Heraeus GmbH is gratefully acknowledged.

13 The calculations were carried out at BP86[14a] with the RI (resolution of identity) approximation[14b] using the following basis sets for the atoms. A quasi-relativistic small-core ECP with a valence double-zeta basis augmented by one set of f-functions was used for Pt.[14c] All-electron DZ+P basis sets have been employed for Ga and the carbon atoms of the Cp ring.[14d] Minimal basis sets have been used for the methyl groups of Cp*.[14e] Auxiliary basis sets for all atoms have been taken from the literature.[14b] The calculations have been carried out with the program package Turbomole.[14f,g] The geometry optimizations were carried out with C_s symmetry constraints.

First published as an Advance Article on the web

The reaction of D,L-5′-activated nucleotide of adenosine in the presence and absence of montmorillonite gave 60 : 40 and 96 : 4 ratios, respectively of the D,D- and L,L : D,L- and L,D-dimers.

In the RNA world paradigm for the origin of life, RNA is formed by polymerization of mononucleotides present on the primitive Earth.[1] The RNA provides both the required genetic information and the catalytic activity in the first life. RNA oligomers of A, C, I, G, and U are formed in the reaction of the corresponding activated mononucleotides on montmorillonite clay.[2–4] The information content of the heterogeneous mixture of oligomers formed in the montmorillonite-catalyzed reaction serves as a template for the formation of complementary RNAs.[3] Fifty mers of A form when the phosphoroimidazolide of adenosine (ImpA) is added daily to a decameric primer bound to montmorillonite.[5] RNAs containing about fifty monomer units are long enough to be effective templates and catalysts.[6]

There has been little or no success in the enantioselective formation of biomolecules in prebiotic experiments.[7] While chiral selection was observed in the self-directing oligomerization of activated tetranucleotides of pyranosyl-RNA[8] it has not been observed in the template-directed synthesis of RNA.[9]

It would have been a major impediment to the origins of the RNA world if RNAs composed of equal amounts of D- and L-nucleotides formed. These structures would have had less chance of forming the helices, stem loops, and pseudo knots required for the RNA to fold into the secondary and tertiary structures required for template-directed synthesis and catalysis.[6] In addition, polymers containing both D- and L-nucleotides would have increased the number of isomers formed with the resultant decrease in number of those longer RNAs required to initiate the origin of life.[6]

The potential for oligomer formation from racemic mixtures was explored in the reactions of D,L-ImpA and -ImpU on montmorillonite. The reactions of 15 mM of each of these racemic mixtures on montmorillonite resulted in the formation of oligomers comparable in length[10] to those formed from the corresponding D-enantiomers.[2,4]† This result stands in marked contrast to the RNA template-catalyzed reaction where the formation of oligo(G)s is strongly inhibited by the incorporation of a nucleotide of the opposite absolute configuration into the growing oligomer chain.[9]

The potential for homochiral selection in RNA synthesis was explored in the reaction of D,L-ImpA on montmorillonite to form pApA. Reaction mixtures were digested with alkaline phosphatase to dephosphorylate the pApA products to the corresponding ApAs. The products were separated into four peaks of increasing retention time which contained (1) D,D- and L,L-A$^{2'}$pA, (2) D,L- and L,D-A$^{2'}$pA, (3) D,D and L,L-A$^{3'}$pA and (4) D,L- and L,D-A$^{3'}$pA on two different reverse phase HPLC columns (Table 1).[11] The identity of the reaction products was established by coinjection with authentic samples. The average percentage of the homochiral products D,D- and L,L-ApA to the corresponding D,L- and L,D- diastereomers is 60 : 40 ± 3.8%, respectively.

Control reactions without montmorillonite resulted in the homochiral selection of 94 : 6 ± 3.2% for D,D- and L,L-ApA *vs.* D,L- and L,D-ApA using 0.15 and 0.60 mM D,L-ImpA (Table 2). The yields of dimeric products in the 0.15 and 0.60 mM montmorillonite-catalyzed reactions were 5.9 and 19 times greater, respectively, than those in the uncatalyzed reactions. The difference in the yields reflects the 500 times greater second order rate constant for the catalyzed *vs.* the uncatalyzed reactions of ImpA.[4,12]

The possibility that the homochiral selectivity observed in the montmorillonite-catalyzed reaction was due to an uncatalyzed solution phase process was evaluated. The percentages for the 0.15 and 0.60 mM catalyzed reactions in rows 7 and 9 of Table 1 were recalculated after subtracting the dimer yields in the control reactions. The selectivity would decrease from 65 : 35 to 59 : 41 for the 0.15 mM reaction and from 58 : 42 to 56 : 44 for the 0.6 mM reaction. These data show that the observed homochiral selection is observed in the reaction catalyzed by montmorillonite.

Low concentrations of D,L-ImpA were used to minimize trimer formation so that the product mixture would only be a measure of the chiral selection for dimer synthesis.[11] The amount of trimer formed was estimated from the relative total areas of the dimer and trimer peaks. The trimer fraction was

[a] Procedures were the same as those given for Table 1. Reactions were carried out for 2 h and the products were analyzed on the Alltima column. [b] The average of all determinations of D,D & L,L : D,L & L,D is 94:6 ± 3.2%.

isolated from the reaction of 15 mM D,L-ImpA on montmorillonite and was dephosphorylated with alkaline phosphatase and coinjected with the products from the 0.15 and 0.6 mM D,L-ImpA reactions. The areas of the peaks with the same retention times as trimers in the 0.15 and 0.6 mM reactions of D,L-ImpA were summed and compared with the corresponding amount of dimers. In the reaction of 0.15 mM ImpA for 2 and 18 h the dimer yield was 12.5 fold higher than that of the total trimer yield. With 0.6 mM ImpA the combined dimer yield was 8.3 and 4.3 times greater than that of the trimer yield for the 2 h and 18 h reactions, respectively. These data show that little dimer is converted to trimer so that the yields in Table 1 mainly reflect the homochiral selectivity for dimer synthesis.

One of the five trimer peaks had the same retention time as the D,L- and L,D-$A^{3'}$pA (peak 4 above) in the dimer fraction. None of the compounds in the trimer fraction, that were not dephosphorylated with alkaline phosphatase, had a retention time that was identical with any of the dimer HPLC peaks. These findings establish that the chiral selectivity is not due to the enhancement of the peaks due to D,D- and L,L-ApA by trimers since the only enhancement is to the D,L- and L,D-$A^{3'}$ pA peak.

The product mixture was further characterized by ribonuclease T_2 digestion where the two HPLC peaks with the longest retention times, peaks 3 and 4 above, were decreased by about 50%. This is consistent with the known cleavage of D,D-$A^{3'}$ pA and, as discovered in this study, the cleavage of D,L-$A^{3'}$ pA with ribonuclease T_2 and the resistance of L,L-$Ap^{3'}A$, L,D-$A^{3'}$ pA, and the 2′, 5′-linked ApAs to cleavage with ribonuclease T_2.

The high homochiral selectivity observed in the uncatalyzed reaction may reflect chiral selection in the stacking of the activated nucleotides[13] coupled with intrastack reactions to form dimers. The lower selectivity in the uncatalyzed reaction may reflect formation of a monolayer of activated purine nucleotides on the montmorillonite platelets.[14]

The observance of both oligomer formation and chiral selection in the montmorillonite-catalyzed reaction of activated D,L-nucleotides on montmorillonite catalysis is consistent with previous findings in montmorillonite-catalyzed reactions. For example, regioselectivity was observed in the phosphodiester bonds formed between purine nucleotides[2] and sequence selectivity was observed in the reaction of mixtures of activated purine and pyrimidine nucleotides.[11] In most of these previous studies selectivity, but not specificity, was observed. This indicates that montmorillonite exhibits partial control on the course of the condensation reactions. This limited control explains why the oligomerization of D,L-mixtures proceeds on montmorillonite. The same limited control resulted here in the preferential formation of homochiral dimers.

It is expected that the bias towards the formation of homochiral oligomers will increase as the chain length increases and the homochiral strands fold into secondary and tertiary structures. This process, together with the potential for the more rapid hydrolysis of those RNAs that contain both enantiomers because they do not form secondary and tertiary structures, could enhance the proportion of homochiral RNAs.[15,16] The scenario of chiral selection and more rapid hydrolysis of heterochiral oligomers could have resulted in an even greater preponderance of homochiral RNA. This may have led to two RNA worlds, one with D- and the other with L-RNA.[17] A chance event may have favored the survival of the D-RNA world which was the precursor to the D-RNA (and D-DNA) present in life on Earth today.

Notes and references

† The L-enantiomers of adenosine and uridine[18] were phosphorylated at the 5′-position[19] and the phosphate was converted to the L-phosphoroimidazolides of adenosine (ImpA) and uridine (ImpU).[20] Solutions of 0.15 M each of D- and L-ImpA were prepared in 0.2 M NaCl, 0.075 M $MgCl_2$ and 0.1 M HEPES at pH 8. The ImpA concentrations were determined by quantitative HPLC analysis. At the end of the reaction time the mixture was centrifuged and the supernatant was removed. The montmorillonite was washed with two 40 μL portions of ammonium acetate. The combined supernatant and extracts was adjusted to pH 4 with 1 M $HClO_4$ and incubated at 37 °C to cleave the imidazole groups from the activated nucleotides. The pH of 200 μL of the reaction mixture was then adjusted to pH 8 and 0.25 units of alkaline phosphatase (bacterial, Sigma) was added and the mixture was incubated at 37 °C for 1 h. The analysis of the ApA isomers was performed on a Waters μBondapak C-18 column[2] and on an Alltima C-18 column.[11,21] Authentic samples of the 2′,5′- and 3′,5′-isomers of L,L-ApA, D,L-ApA and L,D-ApA were prepared by appropriate reactions of the activated monomers with an excess of the corresponding adenosine derivatives. For example, L,D-ApA was prepared in the reaction of excess L-adenosine with D-ImpA. The D,D- and L,L-enantiomers and the D,L- and L,D-diastereomers had the same retention times on the two different reverse phase HPLC columns used. The D,D-enantiomers were characterized by coinjection with authentic standards.[2] Further characterization was performed on some samples by adjusting the pH of 100 μL of the reaction products to 4, adding 2 units of ribonuclease T_2 (Sigma) and incubating the mixture for 1 h at 37 °C. The ribonuclease T_2 cleaves D,D-$A^{3'}$ pA and D,L-$A^{3'}$ pA. It does not cleave any of the other reaction products. The combined peaks due to D,D-and L,L-$A^{3'}$A and D,L- and L,D-$A^{3'}$pA were diminished by about 50% by treatment with ribonuclease T_2.

First published as an Advance Article on the web

Silica-supported sulfated zirconia exhibits a comparable and even higher ether production than a reference acid resin (Amberlyst 15) giving an ether yield of 30% at 50% conversion.

Methyl *tert*-butyl ether (MTBE) has been the major gasoline additive in the past decade. However, its environmental consequences to drinking water have caused intense public attention in recent years.[1] Substantial quantities of unsaturated C_5 and C_6 compounds are present in the light gasoline produced in the fluid catalytic cracking units of refineries. Some of these compounds can be etherified with alcohols and possibly used to meet the demand for oxygenates and as a partial replacement for MTBE. Moreover, these higher ethers have lower vapor pressures and lower water solubilities compared to MTBE. Currently, ion exchange resins are the dominant catalysts for ether production. However, new catalysts could offer improvements over acid resins with respect to thermal stability, poor selectivity under certain conditions, and lack of regeneration ability. Several inorganic acid solids such as zeolites, sulfated zirconia, heteropolyoxoanions (HPA) and supported HPA catalysts have been evaluated for the production of MTBE.[2–5] Essayem *et al.* investigated etherification/esterification over two sulfated zirconia catalysts prepared by different methods and acid resins, but they found that sulfated zirconia showed faster deactivation.[6] No research has been thus far reported for the application of supported sulfated zirconia for etherification, though several researchers have reported the application of such catalysts in isomerization.[7–9] It is believed that unsupported sulfated zirconia suffers from the disadvantages of lower surface area and the very limited accessibility to the acid sites in liquid phase reactions with less polar solvents or in gas phase reactions. Therefore, development of well dispersed sulfated zirconia on supports with high surface areas is important for some acid-catalyzed reactions. This study reports preliminary results on the preparation of some inorganic acid solids, sulfated zirconia, tungstated zirconia, and supported sulfated zirconia, and their performance in the etherification of certain C_6 olefins with alcohols. These particular C_6 olefins, 2,3-dimethylbut-1-ene (23DM1B) or 2,3-dimethylbut-2-ene (23DM2B), were chosen on the basis of their potential for making oxygenated transportation fuel additives.[10]

A sulfated zirconia (SZ) was prepared by acid-treatment of $Zr(OH)_4$, obtained by precipitation of $ZrO(NO_3)_2$ solution with $NH_3{\cdot}H_2O$ at pH = 10, with 0.5 M H_2SO_4 solution, followed by evaporating and drying at 100 °C overnight and calcination at 600 °C for 2 h. A tungstated zirconia with 10 wt% WO_3 was prepared by impregnation of ammonium tungstate hydrate on $Zr(OH)_4$. Two silica-supported sulfated zirconia catalysts, referred to as SZ/SiO_2-S and SZ/SiO_2-N, were prepared by impregnation of 3 g of zirconium sulfate and 2.45 g $ZrO(NO_3)_2$ on 3 g of commercial silica gel support (S_{BET} = 650 $m^2\ g^{-1}$) in 0.5 M sulfuric acid solution, respectively, followed by calcination at 600 °C for 2 h. The third catalyst, SZ/SiO_2-NP, was prepared by precipitation of 2.45 g $ZrO(NO_3)_2$ on SiO_2 using $NH_3{\cdot}H_2O$ at pH = 10 under constant stirring, followed by sulfation in 0.5 M H_2SO_4 solution and calcination at 600 °C for 2 h. A commercial ion exchange resin, Amberlyst 15 (from Aldrich), was used as a reference catalyst. Two other commercial resins, Nafion NR50 and silica-supported Nafion SAC-13 (from Fluka and Aldrich, respectively), were also tested. Additionally, a zeolite sample H-ZSM-5, obtained from United Catalyst, was also tested.

The reactions were carried out at 80 °C for 2 h in a 25 ml stainless steel batch reactor with constant agitation under a pressure of 1.8 MPa of dried helium. The catalyst loading was 0.5 g in all the cases. Before reaction, all catalysts were dried overnight in an oven at 60 °C under vacuum. The reactants, consisting of an appropriate amount of alcohol (0.2 g methanol or 0.27 g ethanol) and 0.5 g 23DM1B with an alcohol : olefin molar ratio of *ca.* 1 : 1, were mixed with heptane (4 g) as a solvent. The products were analyzed in a Varian gas chromatograph equipped with a capillary column and FID.

Table 1 shows the results of 23DM1B etherification with methanol over the various laboratory-prepared and reference catalysts. In the reaction, 23DM2B and the ether are the major products. A small amount of 2,3-dimethylbutan-2-ol was also detected, probably due to the reaction between the olefins and a trace amount of water from the catalysts and reactant mixture. Amberlyst 15 is an active catalyst converting 23DM1B to 23DM2B and ether at an overall rate of 90%; however, this catalyst is non-selective for etherification, having instead a high (undesirable) isomerization selectivity of 80% and 19% ether yield. Nafion NR50 shows low activity and low isomerization selectivity, but an ether yield of about 16%. The silica-supported Nafion SAC-13 is less active than the unsupported Nafion NR50, a behavior which is not the same as in some other reactions, where Nafion SAC-13 exhibited higher activity than Nafion NR50 due to a high surface area and enhanced accessibility of the reactants to the acid sites.[11,12] HZSM-5 shows a similar activity to the Nafion NR50 but the highest isomerization selectivity (94%) among the all catalysts tested in this investigation and thus the lowest ether yield. For the laboratory-prepared solid acid catalysts, sulfated zirconia exhibits higher conversion, ether selectivity and yield than Nafion SAC-13, while tungstated zirconia is the least active catalyst with an isomerization selectivity similar to that of Nafion SAC-13 and SZ. SZ/SiO_2-S exhibits much higher conversion with a lower isomerization selectivity, and an ether yield of 30%, which is substantially higher than that over the reference Amberlyst 15. SZ/SiO_2-N shows 40% conversion and 64% ether selectivity, both higher than Nafion NR50, and an ether yield of 24%, which is also higher than that over

Table 1 Catalytic activity of various acid solids and commercial resins in 23DM1B etherification with methanol

Catalyst	23DM1B conv. (%)	23DM2B sel. (%)	Ether sel. (%)	Ether yield (%)
Amberlyst 15	91.0	78.7	20.6	18.8
Nafion NR50	29.0	44.0	53.9	15.6
Nafion SAC-13	3.2	21.7	58.9	1.9
HZSM-5	23.2	93.5	1.1	0.3
ZrO_2–WO_3	0.9	19.4	64.2	0.6
SZ	4.7	23.2	66.2	3.1
SZ/SiO_2-S	51.8	41.7	57.6	29.8
SZ/SiO_2-N	38.2	34.4	63.8	24.4
SZ/SiO_2-NP	21.2	28.7	67.4	14.3

DOI: 10.1039/b007475f

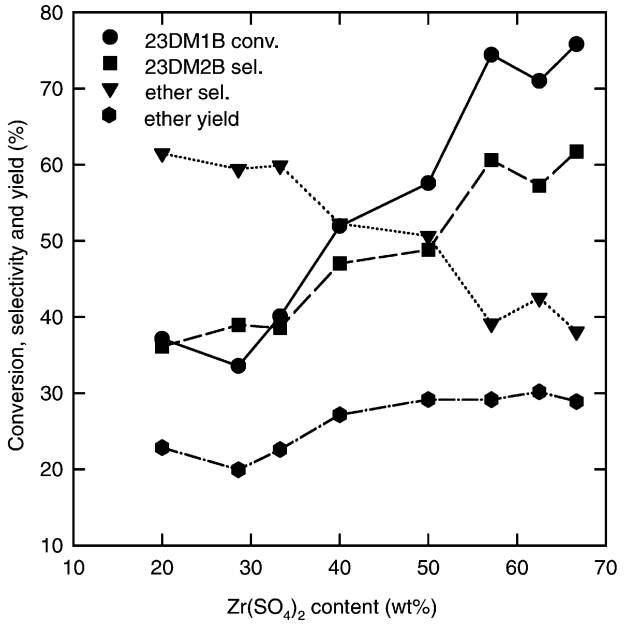

Fig. 1 Effect of $Zr(SO_4)_2$ loading of SZ/SiO_2-S catalysts on catalytic activity.

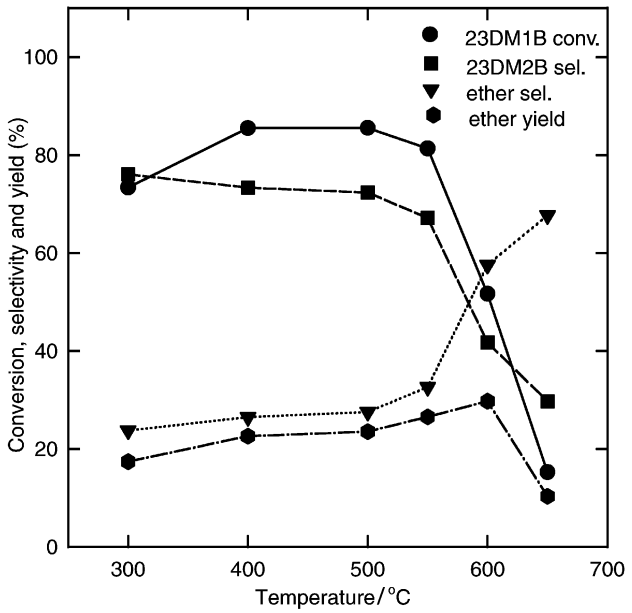

Fig. 2 Effect of calcination temperature on catalytic activity in SZ/SiO_2-S catalysts.

Amberlyst 15. SZ/SiO_2-NP exhibits a lower activity than the other two SiO_2-supported SZ catalysts, but the highest ether selectivity producing an ether yield of 14%, close to those over Amberlyst 15 and Nafion NR50. Therefore, SZ/SiO_2-S is the best catalyst in terms of ether production.

It is well known that etherification or isomerization of olefins generally occurs on acid sites. The acid content is thus an important factor influencing the catalytic activity. The surface areas of catalysts also influence the catalytic activity. Amberlyst 15 has an acid amount of 4.4 $meqH^+\ g^{-1}$ *vs.* 0.89 and 0.12 $meqH^+\ g^{-1}$ for Nafion NR50 and Nafion SAC-13, respectively, making an order: Amberlyst 15 > Nafion NR50 > Nafion SAC-13, which is in agreement with the order of activity. However, in consideration of activity per unit of acidity, the activity of the above catalysts shows a different order; Nafion NR50 > Nafion SAC-13 > Amberlyst 15, which suggests that the catalytic activity also depends on the nature of the acid site. SZ is believed to be a superacid solid, effective for acid-catalyzed reactions such as isomerization. Tungstated zirconia shows little activity probably due to a low acidity. Silica-supported sulfated zirconia could have a better dispersion of active sites for reactions and thus an improved catalytic activity. However, the catalytic behavior of these supported SZ catalysts depends on the preparation technique. Further research on the catalyst characterization is being carried out to elucidate the nature of the active sites responsible for etherification and isomerization.

The effect of varying the composition of $Zr(SO_4)_2$ in SZ/SiO_2-S was further investigated and the results are presented in Fig. 1. It is seen that the loading of $Zr(SO_4)_2$ in SZ/SiO_2-S greatly influences the catalytic activity and selectivity. Both the 23DM1B conversion and 23DM2B selectively generally increase as the $Zr(SO_4)_2$ content increases. The ether yield also increases with increasing $Zr(SO_4)_2$ loading and reaches a stable level of *ca.* 30% for $Zr(SO_4)_2$ exceeding 50 wt%.

Calcination temperature also exerts an influence on the catalytic behavior (Fig. 2). As shown, SZ/SiO_2-S catalysts calcined at 400–550 °C can give much higher conversions, over 80%, comparable to Amberlyst 15. When catalysts are calcined at higher temperatures over 600 °C, the selectivity to ether will be remarkably enhanced, although the overall conversion drops off. In terms of the ether yield, 600 °C is the optimal temperature at which the highest ether yield is achieved.

The catalytic activity of the etherification of 23DM1B with ethanol was also investigated over the resin catalysts and the inorganic acid solids. It was found that Amberlyst 15 is also an effective catalyst for this reaction, exhibiting similar conversion and selectivity to 23DM2B as for the etherification with methanol with an ether yield of 13%. Nafion NR50 and Nafion SAC-13 again are less active than Amberlyst 15, giving ether yields of 9% and 3%, respectively. Sulfated zirconia shows a lower activity than Amberlyst 15 with a conversion of 20% and 58% selectivity to ether but an ether yield of 12%, comparable to that of Amberlyst 15. The SZ/SiO_2-S exhibits 40% conversion and 48% ether selectivity, resulting in an ether yield of 18.4%, higher than that obtained over Amberlyst 15.

In summary, the commercial resin catalyst Amberlyst 15 is an effective but non-selective catalyst in the etherification of C_6 olefins with methanol and ethanol. Silica-supported SZ catalysts exhibit comparable and even higher ether yields than commercial resin catalysts such as Amberlyst 15 and are thus potential alternative catalysts, with the catalytic activity influenced by the zirconium precursor compounds and preparation technique, the ratio of SZ to silica, and calcination temperature.

First published as an Advance Article on the web

The transition-state analogues bis(*p*-nitrophenyl)phosphate and *p*-nitrophenyl phenylphosphonate for peptide hydrolysis are shown to be very effectively hydrolyzed by *Streptomyces* dinuclear aminopeptidase and its Co^{2+}, Ni^{2+}, Mn^{2+} and Cd^{2+} derivatives with high catalytic proficiencies and specific activities comparable to those of some phosphoesterases.

Enzymes are able to specifically recognize a certain type of substrates and stabilize their transition states during reactions to afford enormous rate enhancement.[1,2] Consequently, transition-state analogues can often serve as inhibitors.[2] For peptide, ester, and amide hydrolysis, the transition state is a *gem*-diolate that can be well mimicked by the tetrahedral phospho-center in phosphoesters, phosphonates and phosphoamidates, which are known to inhibit the corresponding enzymes.[3–5] Thus, it would be unusual that peptides and the transition state-like phosphoesters can both be effectively hydrolyzed by the same hydrolytic enzyme because the recognition of the substrates at the ground- and the transition-states and the hydrolytic mechanisms of these two substrate families are quite different.

Proteins from the same origin with structural and sequence similarities may have evolved to exhibit completely different functions that are not related to each other, such as α-lactalbumin and lysozyme,[6] alkaline phosphatase and arylsulfatase,[7] and among the many β-barrel proteins.[8] Some of these enzymes indeed exhibit 'alternative catalysis',[6,9] which demonstrates their evolutionary relatedness and would not by all means be completely unexpected. On the other hand, it would be quite unusual to observe an 'alternative catalysis' of an enzyme that is attributable to an evolutionarily and structurally unrelated enzyme.

Recently, we have observed that the di-Zn aminopeptidase from *Streptomyces griseus* (sAP) exhibits a remarkable hydrolytic activity towards bis(*p*-nitrophenyl)phosphate (BNPP) with a specific activity comparable to several native phosphoesterases.[10] However, it was not clear whether or not this catalysis was unique toward only that particular one phosphoester substrate. Here, we describe an extensive analysis of the hydrolyses of a few different kinds of phosphoesters, including phosphomonoester, phosphodiester, phosphotriester and phosphonate monoester, by metal-substituted derivatives of sAP. The effectiveness toward the hydrolyses of both peptide and phosphoester substrates by sAP offers a rare opportunity to investigate different hydrolytic mechanisms in a single enzymatic system.

The hydrolysis of BNPP by a few homonuclear derivatives of sAP (M_2-sAP; M = Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+} and Cd^{2+})[11,12] has been analyzed with Michaelis–Menten kinetics (Table 1; Fig. S1A in ESI†). The rate constants (k_{cat}/K_m = 0.94–100 M^{-1} s^{-1}) are much higher than the second-order constants of many synthetic chemical models, *e.g.* (1.3–43) × 10^{-5} M^{-1} s^{-1} at 35 °C and pH 7.3–10.5 for several Zn^{2+} complexes[13] (also see footnote 14). The specific activity values (1.6–158 nmol min^{-1} mg^{-1}; Table 1) are in the range for several phosphodiesterases and phosphatases (0.3–2450 and *ca.* 2–40 nmol min^{-1} mg^{-1}, respectively),[15] and comparable to ethyl(*p*-nitrophenyl)phosphate hydrolysis by metal-substituted derivatives of *Pseudomonas* phosphotriesterase (1.7–11.4 nmol min^{-1} mg^{-1} calculated from ref. 16 with k_{cat}/K_m in the range 1.1–7.2 M^{-1} s^{-1}).

In order to demonstrate that BNPP hydrolysis by M_2-sAP is not just an incidental catalysis, the hydrolyses of structurally distinct phosphoesters were investigated. The phosphonate ester *p*-nitrophenylphenylphosphonate (NPPP) contains a P–C bond and resembles the primary hydrolytic products of some chemical warfare agents.[17] Thus, the study of its hydrolysis has practical value. The second order rate constants of NPPP hydrolysis (*ca.* 1–7 M^{-1} s^{-1}; Table 1 and Fig. S1B in ESI†) by M_2-sAP are much greater than those of some metal ions,[18] and are approaching those of a few highly active tetra-valent

[a] The hydrolyses of the phosphotriesters parathione and tris(*p*-nitrophenyl)phosphate and the phosphomonoester *p*-nitrophenylphosphate by the enzyme are not detectable on the spectrophotometer after several hours at pH 8.0 and 50 °C. [b] Enzyme concentrations were in the range 0.1–0.7 μM. The di-Cu derivative did not show observable activity with a concentration of 2.0 μM under the experimental conditions, which indicates that the activity of CuCu-sAP would be at least *ca.* 10^4 × smaller than the native di-Zn sAP. [c] The substrate concentrations were in the range 1.0–20 mM. The initial rates were obtained from the change of absorbance at 405 nm (ε = 17 500 M^{-1} cm^{-1}), plotted against substrate concentration, and then fitted directly to the hyperbolic Michaelis–Menten equation, rate = $k_{cat}[E_o][S]/(K_m + [S])$ to give the kinetic parameters k_{cat} and K_m. [d] CP: catalytic proficiency.[22] [e] The specific activity (SA) is for the hydrolysis of 1 mM substrate in 1 min by 1 mg enzyme (nmol min^{-1} mg^{-1}) or extrapolated by the use of the Michaelis–Menten equation.

DOI: 10.1039/b004544f

lanthanide micelles (13.1–76.8 M^{-1} s^{-1})[19] which have Lewis acidities several orders of magnitude higher.[20] The specific activities of 1.6–9.7 nmol min^{-1} mg^{-1} against 1 mM NPPP (Table 1) are comparable to those of a few phosphatases and phosphodiesterases at 30 °C (12–355 and *ca*. 1–38 900 nmol min^{-1} mg^{-1}, respectively).[15] Conversely, the hydrolyses of the phosphomonoester *p*-nitrophenylphosphate and the phosphotriesters parathion and tris(*p*-nitrophenyl)phosphate are beyond the spectrophotometric detection limit, indicating the presence of specificity toward different phosphoesters.

Although the *p*-nitrophenol in both BNPP and NPPP is a very good leaving group, the auto-hydrolytic rates of BNPP and NPPP are still *extremely slow* with a rate constant $k_1 = 1.1 \times 10^{-11}$ s^{-1} for BNPP at pH 7.0 and 25 °C[21] and 7.65×10^{-8} s^{-1} for NPPP at pH 8.0 and 50 °C (comparable to 1.7×10^{-7} s^{-1} at 60 °C[18]). Tremendous catalytic proficiencies[22] are obtained for M_2-sAP toward BNPP and NPPP hydrolyses *i.e.* (0.94–67) $\times 10^9$ and (0.43–2.9) $\times 10^5$, respectively (Table 1). Co_2−sAP virtually decreases the half-life of BNPP hydrolysis from *ca*. 2000 years to *ca*. 1 second! These rate enhancements are remarkable when it is taken into account that the phospho-substrates are transition-state analogues of peptides during hydrolysis[1,3–5] In this case their corresponding trigonal bipyramidal transition states requires significantly more stabilization in support of their hydrolysis. For instance, an association constant of 108 M^{-1} (approximated from the average K_m of 9.3 mM for BNPP hydrolysis) would contribute 11.6 kJ mol^{-1} energy in ground-state stabilization at 298 K, which would increase the activation energy by the same amount and would reduce the reaction rate by *ca*. 100×. In the mean time, a 67×10^9 fold rate enhancement requires a decrease of 61.7 kJ mol^{-1} in activation energy at 298 K.

Finally, it is interesting that the Mn^{2+}, Ni^{2+} and Cd^{2+} derivatives of sAP also exhibit potent hydrolytic power [*i.e.* (*ca*. 1–4) $\times 10^9$ and (*ca*. 40–200) $\times 10^3$ fold rate enhancements toward BNPP and NPPP hydrolyses, respectively, Table 1] suggesting that these metal ions should be included in future design of chemical models for more extensive structural and mechanistic studies of metal-centered hydrolysis.[23]

The results have provided some mechanistic insight. The K_m values for BNPP and NPPP are similar, suggesting that they are recognized by sAP in a similar fashion. In both substrates, a hydrophobic *p*-nitrophenyl/phenyl group (as a hydrophobic anchor to bind to the active site) and a $–PO_2^-–$ group (as a *gem*-diolate transition-state analogue) are essential. On the other hand, the non-competitive property of phosphate[24] may be attributable to the lack of a hydrophobic anchor; the competitive inhibitor *p*-nitrophenylphosphate[25] contains both recognition moieties, yet is not hydrolyzed owing to the lack of an additional hydrolyzable group; and the two phosphotriesters are not hydrolyzed owing to the lack of a $–PO_2^-–$ group.

Many synthetic metal complexes have been utilized as models[26] to provide insight into the mechanistic roles of the metal ion(s) and the nucleophilic water in metallohydrolases. The specificity and tremendous effectiveness of enzymes offer a very challenging task for chemical modeling studies to achieve. We describe here that the transition-state analogues BNPP and NPPP are indeed substrates for M_2-sAP, and are hydrolyzed with remarkable rate accelerations. Although the rates of catalysis are not comparable to those of 'perfect enzymes' and much slower than those of the specific substrates of sAP,[11a,b] M_2-sAP can serve as unique '*natural* model systems' (as opposed to '*synthetic* model systems') for further studies of phosphoester hydrolysis. The results from these studies should lead us to a better understanding of dinuclear hydrolysis in chemical and biological systems.

This research was partially supported by the Petroleum Research Funds administrated by the American Chemical Society (ACS-PRF #35313-AC3).

First published as an Advance Article on the web

A resin-supported samarium enolate successfully initiated the living anionic polymerization of methacrylates to afford the corresponding homopolymer as well as block copolymer with well-controlled molecular weights, which could be quantitatively isolated from the resin, so demonstrating the applicability of the present technique for solid supported construction of macromolecular architectures.

Polymer grafting on various organic and inorganic solid supports has been attracting significant attention as an effective technique for modification of functional materials.[1] Living polymerization is one of the most powerful tools for polymer grafting, because its capability in controlling the degree of polymerization together with end-functionalization and block copolymerization allows us to construct macromolecular architectures on solid supports in a well defined manner. Our research interest is in living polymerization of functional monomers on crosslinked polystyrene beads which have been widely applied as solid supports in solid phase organic syntheses which has brought about today's expanding development of combinatorial synthesis of chemical libraries.[2] Our approach would be a promising route to combinatorial synthesis of functional polymeric materials with defined structures. Since bead-supported photo-iniferter radical polymerization has been pioneered by Otsu *et al.*, only a few examples have been reported concerning controlled polymerization on polystyrene beads.[3] Here we describe the first example of living anionic polymerization of methacrylates on polystyrene beads.

Previously we have developed samarium(III) enolate mediated living anionic polymerization of methacrylates (Scheme 1).[4] Based on this technique, we have designed a novel grafting system involving (1) an easy access to immobilized samarium enolate through reduction of the corresponding bromoisobutyrate moiety by divalent samarium iodide (SmI_2), and (2) selective cleavage of the benzyl ester linkage between the formed poly(methacrylate)s and the beads, which enables the isolation of the formed polymer so allowing examination of the polymerization behavior in detail (Scheme 2).

The resin bearing 2-bromoisobutyrate moiety **1** was prepared by the condensation of 2-bromoisobutyric acid with Wang resin (crosslinked polystyrene containing hydroxymethyl groups, 0.68 mmol g^{-1}, 100–200 mesh) using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride as a dehydrating reagent. The condensation was repeated (usually twice) until

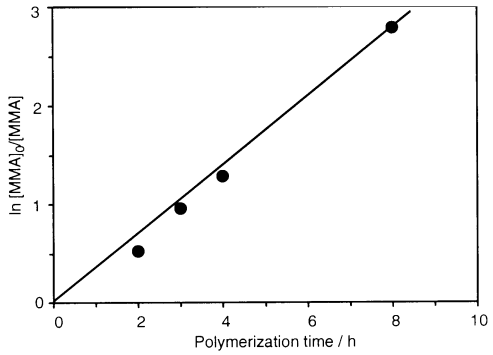

Fig. 1 $\ln[MMA]_0/[MMA]$ *vs.* polymerization time. $[MMA]_0$ = 5 mmol (50 eq. to Sm-enolate).

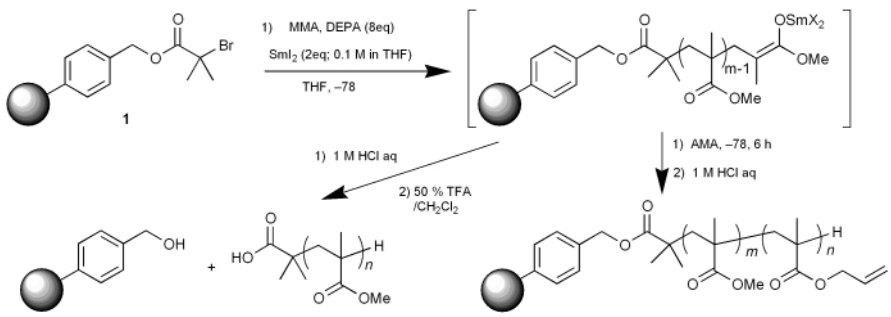

Scheme 2

complete acylation was confirmed by the disappearance of IR absorption of hydroxy groups at 3500 cm^{-1}.

The polymerization of methyl methacrylate (MMA) was performed by the addition of SmI_2 (2.0 eq. to 2-bromoisobutyrate moiety) to **1** in the presence of *N*,*N*-diethylpivaloylamide (DEPA), which is essential to accomplish well controlled polymerization in a homogeneous system, with shaking at −78 °C for 12 h.[5] The dark blue reaction mixture arising from SmI_2 gradually turned into yellow during a few hours, indicating Sm(III) enolate formation. The polymerization was terminated by the addition of 1 M aqueous hydrochloric acid, and the resulting resin was filtered off and washed with appropriate solvents. No polymer was detected in the filtrate by size exclusion chromatography (SEC), while the resin, as expected, gained weight according to the amount of MMA fed. Formation of poly(MMA) on the resin was also confirmed by IR analysis of the resin, which showed strong absorption attributable to ester carbonyl groups at 1740 cm^{-1}. Treatment of the resin with trifluoroacetic acid (TFA, 50% in CH_2Cl_2) resulted in selective cleavage of benzyl ester linkers without cleavage of the methyl ester in the side chain, and consequently poly(MMA) was quantitatively obtained.[6] The presence of carboxylic acid at the chain end of the polymer was confirmed by TLC analysis: the obtained polymer was not eluted by chloroform–THF (9 : 1, v/v) while poly(MMA) having terminal ester groups eluted easily. Isolated poly(MMA) was analyzed by SEC to estimate its number- and weight-average molecular weights (M_n and M_W). Table 1 summarizes the results of the polymerization with various feed ratios. In each case, MMA was completely consumed to give quantitatively poly(MMA) with a narrow M_W/M_n. The M_n of the polymer increased linearly with the feed ratio, demonstrating the ability of the present polymerization system to control the molecular weights of the polymer. We next examined the polymerization process on the solid state. Fixing the feed ratio to 50, separate series of polymerization was carried out with various polymerization times. The monomer conversion was determined based on the weight increase of the resin. Fig. 1 depicts a semi-logarithmic kinetic plot ($\ln[MMA]_0/[MMA]$ *vs.* polymerization time), the linear relationship of which may suggest the living character of the polymerization. The M_n of isolated poly(MMA) increased with monomer conversion (23%: M_n = 1500, 50%: M_n = 4200, > 99 %: M_n = 7700).

Finally, the living character of the present polymerization was confirmed by block copolymerization of MMA with allyl methacrylate (AMA) as shown in Scheme 2. After the polymerization of MMA (20 eq. to the initiator) was complete, AMA (20 eq.) was added and the mixture shaken at −78 °C for 12 h. The resulting resin gained weight according to the total amount of methacrylates fed, and its treatment with TFA resulted in quantitative isolation of the block copolymer. The ^1H NMR spectrum of the block copolymer showed signals assignable to methoxy groups of poly(MMA) and allyl groups of poly(AMA), where the integration ratio was in good agreement with the feed ratio (Fig. 2). SEC analysis showed that the unimodal peak of poly(MMA) shifted toward a higher molecular weight region with a narrow molecular weight distribution being maintained after AMA addition, indicating the successful formation of the block copolymer (Fig. 3).

In summary, we have demonstrated a new solid-supported living anionic polymerization of methacrylates. The initiator samarium enolate was readily and effectively generated by SmI_2-induced reduction of bromoisobutyrate moieties, supported on polystyrene beads. Further applications of the present system to multi-block copolymerization of various functional methacrylates, together with subsequent chemical modifications of the resulting polymer on polymer supports, are now in progress.

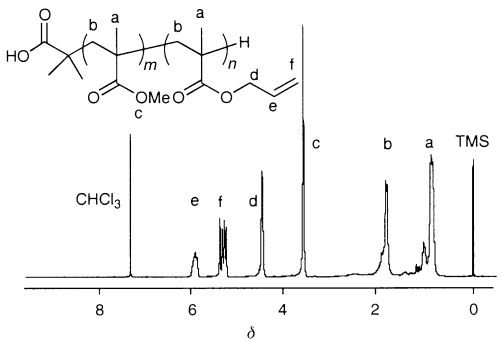

Fig. 2 ^1H NMR spectrum (300 MHz, $CDCl_3$) of poly(MMA-*b*-AMA).

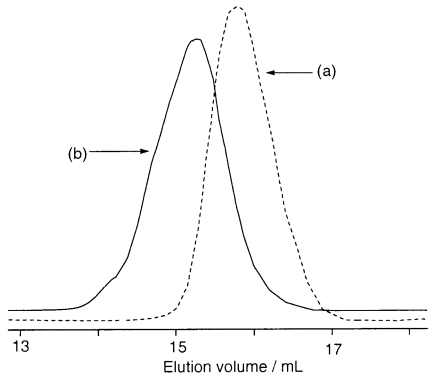

Fig. 3 SEC profiles of polymethacrylates obtained by block copolymerization: (a) poly(MMA) (M_n = 3,300, M_W/M_n = 1.24); (b) poly(MMA-*b*-AMA) (M_n = 6,800, M_W/M_n = 1.21).

5 *Typical procedure*: to resin **1** (165 mg, bromoisobutyrate unit: 0.1 mmol) swelled in THF (1 mL) were added MMA (500 mg, 5 mmol) and DEPA (126 mg, 0.8 mmol) under N_2. The resulting mixture was cooled to −78 °C, and SmI_2 (0.1 mM solution in THF; 2 mL, 0.2 mmol) was added to the mixture which was shaken at the same temperature for 12 h. Then 1 M HCl (5 mL) was added to quench the reaction. The mixture was filtered and the residual resin washed successively with water, THF and then methanol. It was dried *in vacuo* to obtain the resin bearing poly(MMA) (660 mg; quant.).

6 *Typical procedure*: the resin bearing poly(MMA) (660 mg) was swelled in TFA (50% in CH_2Cl_2, 5 mL) and shaken at room temperature for 6 h. The mixture was filtered and the residual resin was washed with CH_2Cl_2. The filtrate was concentrated by rotary evaporation to give poly(MMA) (500 mg; quant.).

First published as an Advance Article on the web

A silicon clathrate compound doped with an electronegative element, $I_8Si_{46-x}I_x$ (x = 1.5 ± 0.5), has been prepared for the first time using high pressure and high temperature conditions.

In the late 1960s, alkali-metal doped silicon clahrate compounds (M_8Si_{46} and M_xSi_{136}) were prepared by the thermal decomposition of the Zintl phase MSi (M = Na, K, Rb, Cs) under vacuum or inert atmosphere.[1] The two compounds were isostructural with the clathrate hydrates of type I (or gas hydrate) and type II (or liquid hydrate), respectively.[2] The silicon lattice of the M_8Si_{46} structure (type I) is composed of two pentagonal dodecahedra Si_{20} and six tetrakaïdecahedra Si_{24}, offering eight sites per unit cell for guest alkali atoms.[3] Fig. 1 shows the two types of polyhedra connected by a common pentagonal face.

At the period of their discovery, silicon clathrates did not raise any special interest except for their peculiar crystal structures. However, the discovery of carbon clusters, fullerene, and the superconducting properties of the intercalation compounds M_3C_{60} (M = alkali metals) suddenly raised the interest for silicon clathrates: these latter being constructed of an assembly of the smallest possible fullerene type cages.[4] This led to active research of new silicon clathrates and to the discovery of the first superconducting silicon clathrate, $(Na,Ba)_xSi_{46}$ in 1995,[5] which is also the first superconductor composed of an sp^3 Si tetrahedral network. Much attention has also been paid to the thermoelectric properties of some types of clathrate compounds, originating from their special rattling structure.[6]

Very recently, a new synthesis route for silicon clathrates has been developed, *i.e.* high pressure and high temperature (HPHT) synthesis; a silicon clathrate doped with only barium, Ba_8Si_{46}, was obtained for the first time as a bulk phase under a pressure of 3 GPa and at 800 °C.[7] This compound showed a superconductive transition (T_c) at 8.0 K (highest T_c ever found in silicon clathrates). Another type of silicon clathrate, $Ba_{24}Si_{100}$, isostructural with K_6Sn_{25} was also prepared under a pressure of 1.5 GPa at 800 °C.[8] Note that these two new compounds can only be synthesised using high pressure conditions unlike their germanium analogues, Ba_8Ge_{43} and $Ba_{24}Ge_{100}$.[9,10] The iodine doped germanium clathrate $I_8Ge_{46-x}I_x$ with x = 8/3 was synthesised more than ten years ago by thermal decomposition of germanium diiodide by Nesper's group.[11] In this context of the studies of silicon and germanium clathrate compounds, we have focused our research on the synthesis of iodine doped silicon clathrate with the aid of HPHT conditions, the first silicon clathrate structure hosting an electronegative element.

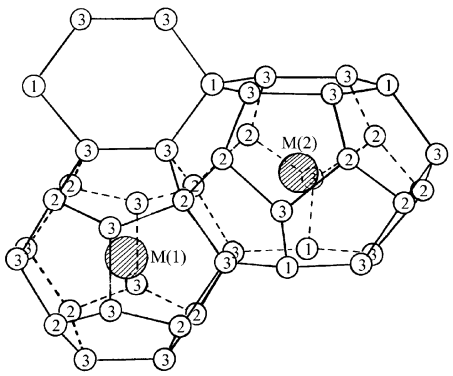

Fig. 1 Schematic illustration of the interconnected polyhedra forming the clathrate type I structure with guest atoms M(1) and M(2). Non-equivalent silicon sites are shown: Si(1), 6c; Si(2), 16i; Si(3), 24k.

Silicon powder (Katayama chemical, 99.999%, 200 mesh) and iodine (Katayama chemical, 99.8%) were mixed in various molar ratios, and finely ground. The mixture was placed in a h-BN cell (8 mm in inner diameter and 6 mm in length) which was in turn placed in a carbon tube heater and in a pyrophyllite cube as a pressure media. A cubic multi-anvil press was used (Riken model CP10). The BN cell was heated electrically by the carbon heater and the temperature was monitored by a thermocouple placed under the cell. A synthesis using a stoichiometric mixture of I/Si = 8/46, and a pressure of 5 GPa at 700 °C for 1 h gave a mixture of many phases: Si and clathrate as major phases and air-sensitive iodides SiI_2 and SiI_4 as minor phases. The iodides could be washed away by ethanol. The change in the conditions (P, T and I/Si ratio) resulted in a drastic change of the relative ratios of the various phases obtained. At a lower temperature of 500 °C under 5 GPa, the major phases were Si, SiI_2 and SiI_4 with a small portion of clathrate. At a lower pressure of < 3 GPa, only SiI_2 and Si were found. The use of higher molar ratios of iodine to silicon (I/Si = 1/2) at 5 GPa and 700 °C, gave no clathrate phase; the major phase was SiI_4. Even under the optimum conditions (P = 5 GPa, T = 700 °C, I/Si = 8/46), the yield of clathrate never exceeded 42 wt%. Surprisingly, however, an addition of only 1% of iodine doped silicon clathrate to the starting mixture (I/Si = 1/5.75) remarkably increased the yield of the clathrate formation up to 90% at P = 5 GPa, T = 700 °C, for 1 h. This suggests that the addition of seed is greatly effective for the growth of the crystals.

The new clathrate compound was found to be stable in acidic solutions like other binary clathrate compounds:[1] it was unreactive in 1 M HCl solution, although it decomposed in a concentrated HF–HNO_3 solution. In hot alkali solution (0.2 M NaOH) silicon dissolves readily but the clathrate phase is much less reactive. This finding provided us with a powerful tool to remove most of the remaining silicon from the final product. The resulting iodine doped clathrate was very fine powder, and the suspension in water had a bright orange colour. The powder sample was separated using a PTFE filter.

The clathrate sample was decomposed by a concentrated HF–HNO_3 solution in a sealed PTFE container at 70 °C. The silicon component was dissolved in the solution, and diluted with a saturated boric acid solution for analysis by inductively coupled plasma atomic emission spectroscopy (ICP, Perkin-Elmer Optima 3000). The iodine component was precipitated in the form of elemental crystals, which could be dissolved by adding potassium iodide. The precipitation of iodine crystals suggested that the iodine was included as electrically neutral atoms in the clathrate. To determine the iodine concentration by ICP, a

DOI: 10.1039/b007632p

separate solution was prepared and the iodine precipitate was dissolved with a sodium thiosulfate solution. The ICP results gave the following formulation: $I_{9.5 \pm 0.5}Si_{44.5 \pm 0.5}$ (*i.e.* an iodine wt% of 48.6 ± 1.4) with a total recovery of 97%. On heating the clathrate sample up to 800 °C for several hours under high vacuum ($< 10^{-4}$ Torr), a wt% loss of 48.1 ± 1.0 was observed. This value was in good agreement with the chemical analysis data.

X-Ray powder diffraction (XRD) data (Fig. 2) were measured using graphite monochromated Cu-Kα radiation and were collected at every 0.02° over the range 2θ = 25–120°. All reflections were indexed on the basis of a cubic unit cell with a = 10.4195(7) Å, which is the largest lattice constant so far observed for binary silicon clathrates. The crystal structure was determined by X-ray Rietveld refinement using Fullprof.[12] The space group ($Pm\bar{3}n$) of type I clathrate was assumed, and the refinements were carried out on the basis of various structural hypotheses. The only reasonable fit was obtained with a structural model, in which iodine atoms occupy all the silicon cages (2a and 6d) and 11% of the Si(2) sites of the network (see Fig. 1). The corresponding stoichiometry ($I_8Si_{44.2}I_{1.8}$) is concordant with the chemical analysis data. The replacement of the Si(1) or Si(3) sites with iodine led to very strong disagreement beween the calculated and the experimental data.

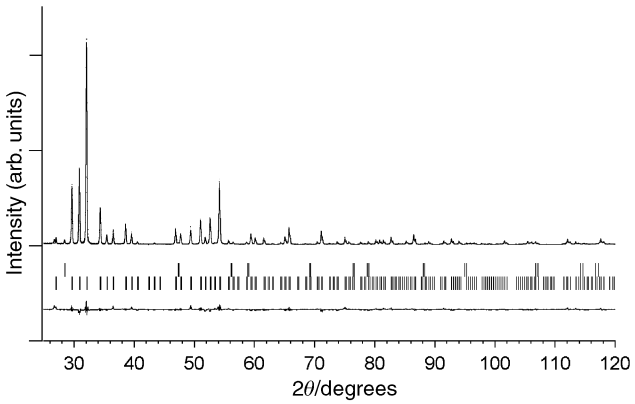

Fig. 2 Plot of the X-ray diffraction data for $I_8Si_{46-x}I_x$ with x = 1.8. Discontinuous and continuous lines represent, respectively, the experimental data points and the calculated spectra. The upper tick marks indicate the calculated reflection positions for some traces of silicon and the lower tick marks the calculated reflection positions for the clathrate phase. The lower continuous line represents the difference.

It was reported that in the germanium doped silicon clathrate ($I_8Ge_{43.3}I_{2.7}$), some iodine was present in the Si(1) sites. Therefore it should be noted that although the compositions of the two iodine doped clathrates are similar, replacement of silicon does not occur in the same sites. The coordinates of Si(2) and Si(3) sites were also refined and led to the following positions respectively: 16i (x, x, x) with x = 0.1831(5) and 24k (0, y, z) with y = 0.3099(8) and z = 0.1161(8). Although the fit is good enough to be sure about the atomic repartitions and positions (S = 2.06, R_{wp} = 0.11, see also Fig. 2), an effort is now being carried out to obtain single crystals for a more precise structural study.

Some preliminary results of the physical properties showed that the new clathrate was an electric insulator as estimated from its orange color, and showed the absence of superconductivity down to 2 K.

This study was supported by the Foreign fellowship division of the Japanese Society for the Promotion of Science (JSPS) and by the Ministry of Education, Science, Sports and Culture of Japan. This study is carried out as a France–Japan joint research project supported by the JSPS and the Centre National de la Recherche Scientifique (CNRS).

First published as an Advance Article on the web

A simple, quick, reproducible and inexpensive method is described that combines self-assembly, micro-fluidics and soft lithography, to achieve a novel example of vectorial control of thickness, area, orientation and registry of patterned single crystal silica colloidal crystals in silicon wafers, coined opal chips, for potential applications in photonic chip and lab-on-chip technologies.

Close-packed arrays of mono-disperse silica and latex micro-spheres have numerous uses, such as chromatography and photonics.[1,2] Colloidal crystals are usually prepared from mono-disperse micro-spheres through the use of dip-coating,[3] sedimentation[4] or specially designed micro-cells.[5] These micro-sphere lattices may be prepared in the form of crystals and films. In particular, sphere sizes > 800 nm in silica have proven to be notoriously difficult to make mono-disperse and coerce into well ordered lattices. Colloidal crystals and films display varying degrees of disorder that arise from sphere size polydispersity, site randomness, intrinsic point, line and planar defects, and polycrystalline domains. The defect tolerance of colloidal crystals on properties like completeness of photonic band gaps in photonic crystals and the separation efficiency of chromatographic stationary phases is a subject of intense current interest.

The patterning of mono-disperse micro-spheres on top of various substrates has been explored *via* micro-molding,[6] electrostatic assembly[7] and micro-robotic techniques.[8] These methods of organizing micro-spheres usually require long preparation times and special instrumentation and are unable to simultaneously control order, defects, thickness, area, orientation and registry of patterned colloidal crystals. Moreover, colloidal crystals obtained in these ways have a face centered cubic lattice oriented in the (111) direction. Colloidal crystals displaying a specific (100) orientation have been grown by sedimentation of micro-spheres onto a lithographically patterned substrate, a technique known as colloidal epitaxy.[9] Access to such sophisticated substrates requires use of expensive chrome masks and photolithography, both of which are unfamiliar and unavailable to most research chemists. Further, epitaxial growth of colloidal crystal film is slow and structural order is limited to layers close to the lithographically patterned substrate.

Herein we report a straightforward, fast, reproducible and cost effective way, that combines self-assembly and soft lithography for the fabrication of micron scale patterned single crystal colloidal crystals in silicon wafers and which circumvents many of the aforementioned problems. The attractiveness of this method to opal chips is that it has the capability of controlling defects in colloidal crystals as well as the number, area, orientation and registry of close-packed layer planes of micro-spheres in the colloidal crystals embedded within a single crystal silicon (100) wafer.

Soft lithography encompasses a suite of techniques that have proven to be remarkably useful for the fabrication of micron to sub-micron patterns on a range of planar and curved substrates.[10] The procedures are facile and can be readily handled in an ordinary laboratory environment. In the context of the work described in this study, a line patterned polydimethylsiloxane (PDMS) master is obtained by casting a pre-polymer gel (Sylgard 184, Corning) from the corresponding lithographically defined photo-resist pattern. When access to lithographic instrumentation is not available, PDMS masters may be easily made by non-lithographic methods, such as the use of transmission electron microscopy (TEM) grids or optical gratings as templates for making micro-molds (see below). A procedure for fabricating V-shaped groove patterns inside a Si(100) wafer begins with a PDMS master that is inked with 2 mM hexadecanethiol in ethanol and then printed onto a Au (50 nm) coated Si(100) wafer (5 nm Ti is used as an adhesion layer). The bare gold surface is then etched away by a $Fe(CN)_6^{3-}$/$Fe(CN)_6^{4-}$/$S_2O_3^{2-}$/KOH solution, and the underlying Si(100) substrate is then anisotropically etched by 3 M KOH in Pr^iOH/H_2O at 70 °C to give V-shaped grooves with 70.6° apex angles beneath the surface of the wafer, as seen in the scanning electron microscopy (SEM) image in Fig. 1(a).[11] The etching rate along the Si(100) direction is *ca.* 1 μm min^{-1}.[12]

A flat PDMS block is next put into conformal contact with the patterned wafer and a drop of a 0.1 wt% aqueous dispersion of monodisperse silica micro-spheres (diameter = 840 ± 20 nm, modified Stöber synthesis) was added at the interface between

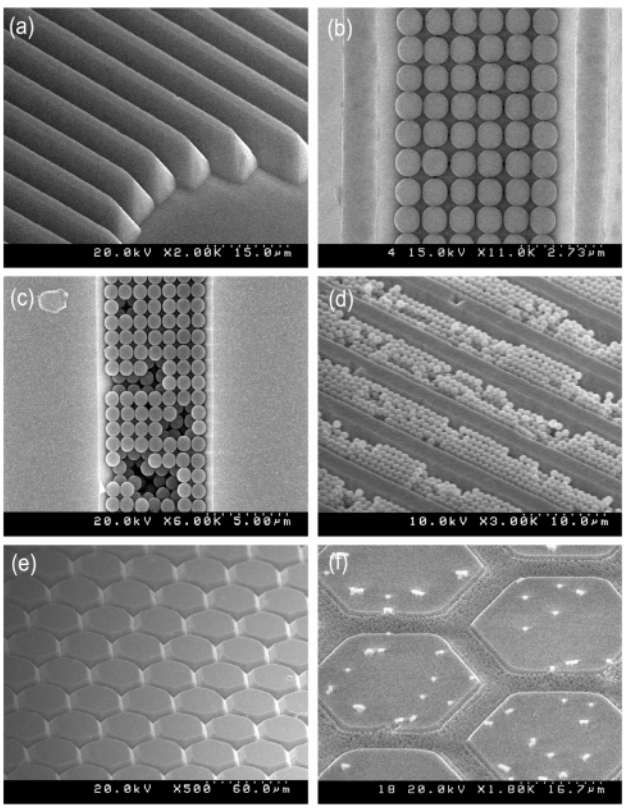

Fig. 1 SEM study illustrating vectorial control of thickness, area, orientation and registry of silica colloidal crystals grown inside silicon wafers – see text.

† Electronic supplementary information (ESI) available: pictorial representation of work described in this communication. See http://www.rsc.org/suppdata/cc/b0/b008534k/

DOI: 10.1039/b008534k

the patterned silicon wafer and the PDMS block. Micro-spheres are driven into the V-shaped grooves by capillary forces and close-pack inside the grooves upon evaporation of the water-dispersing agent. Owing to the 70.6° angular geometry of the V-shaped grooves, micro-spheres nucleate and grow in a vectorial fashion exclusively within the grooves to form a pattern of fcc colloidal crystal parallel lines. It is noteworthy that {100} layer planes are well ordered and organized parallel to the [100] face of the single crystal Si(100) wafer. This can be seen in the SEM images shown in Fig. 1(b)–(d). Over spatial areas sufficiently large for construction of photonic crystal and chromatographic micro-devices, colloidal crystals are seen to be single crystals and can be made essentially free of defects [Figs. 1(b), 2(a)]. When vacancy defects are present in the silica colloidal crystals they can easily be identified and their effect on optical and separation properties evaluated, [Fig. 2(b), (c)].

Interestingly, the first micro-spheres to nucleate in the V-shaped grooves are single-file contiguous arrangements and these linear constructions are found to be located in the apex of the V-shaped groove, [Fig. 3(a)]. These 1-D chains of micro-spheres dominate in the early stages of infiltration and when dilute aqueous dispersions of micro-spheres are used. At later stages the micro-spheres self-assemble adjacent to the 1-D chains and continue to grow up the walls of the V-shaped grooves to eventually fill them with well ordered patterns of colloidal crystals, Fig. 3(b). The edges of the grooves seem to be filled first with well defined lines of micro-spheres. Further, the observed registry of {100} layer planes of micro-spheres between adjacent grooves provides additional evidence for vectorial control of colloidal crystal nucleation and growth. These steps may provide an insight into the control mechanism that enables command of thickness, area, orientation and registry of the patterned colloidal crystal in the silicon wafer.

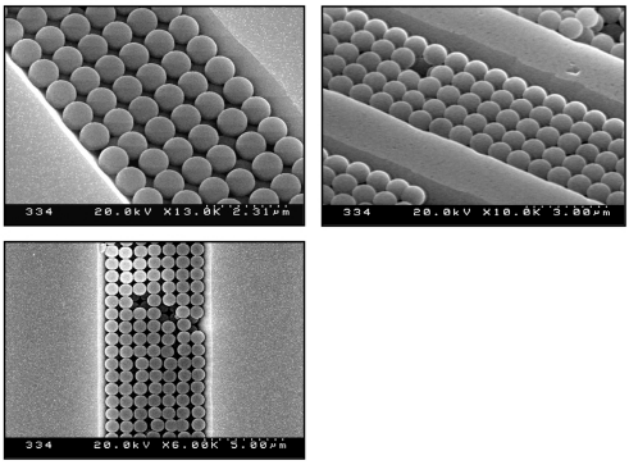

Fig. 2 SEM images depicting (a, top left) *six-layer* (100) single crystal silica colloidal crystal in a V-shaped channel of Si(100) wafer and devoid of vacancy defects. (b, top right) *Five-layer* (100) single crystal silica colloidal crystal in a V-shaped channel of Si(100) wafer depicting a single vacancy defect in top layer of micro-spheres. (c, bottom) *Seven-layer* (100) single crystal silica colloidal crystal in a V-shaped channel of Si(100) wafer depicting three vacancy-type defects in the top layer of micro-spheres.

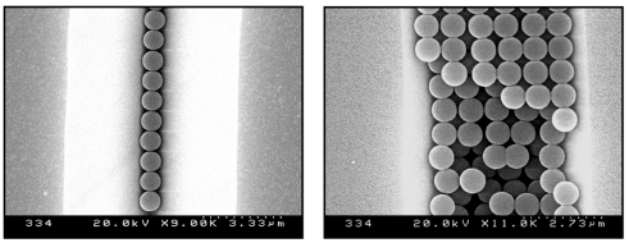

Fig. 3 SEM images depicting (a, left) the formation of a 1-D chain of silica micro-spheres grown in the apex region of a V-shaped groove that had been anisotropically etched within the surface of a single crystal (100) silicon wafer. (b, right) Vectorial growth of *six-layer* (100) oriented silica colloidal crystal within the V-shaped channel exposing the top three micro-sphere layer-planes.

The whole process outlined above is reproducible and can be finished in less than 2 h. The actual capillary infiltration and crystallization of micro-spheres in the patterned silicon wafer can be as short as seconds to minutes. As the depth of the V-shaped grooves in Si(100) is proportional to the etching time, it is easy to control groove depth to accommodate a pre-determined number of layers of silica micro-spheres. This has been achieved for one to ten layers of patterned colloidal crystals. The number of micro-spheres observed in the top (100) layer corresponds to the thickness of the colloidal crystal in the V-shaped grooves. The strategy described in this work alleviates the 'sagging' and 'pairing' problems in PDMS, which has been utilized for patterning latex micro-spheres through micro-molding in capillaries, MIMIC, on top of a silicon substrate.[6,10]

As mentioned above, PDMS masters can be made by non-lithographic approaches involving the use of TEM grids or optical gratings.[13] To exemplify this methodology, we used a hexagonal 600 mesh TEM grid to prepare the PDMS master. The bar width of the grid is *ca*. 7 μm and the pitch width is *ca*. 35 μm. A TEM grid was first laid down to a flat poly-(methylmethacrylate) (PMMA) substrate and a PDMS pre-polymer gel is then cast upon the grid. After curing at 60 °C, the PDMS master is used for the micro-contact printing followed by Au and Si(100) anisotropic etching as described above. The SEM image shown in Fig. 1(e) depicts a representative hexagonal symmetry V-shaped groove network and Fig. 1(f) displays a typical silica micro-sphere array following influx of micro-spheres into the grooves of the hexagonal pattern using the capillary infiltration method described above.

In summary, the process of growing single crystal colloidal crystal patterns of known thickness, area, orientation and registry within a substrate is experimentally straightforward, generally applicable, able to be easily integrated into chip fabrication facilities and amenable to mass production. The creation of colloidal crystal wafers, opal chips, is rapid, reproducible and cheap. They may, for example, be easily adapted for engineering lattice dimensions, refractive index contrast, structural defects, location and integration of photonic crystals coupled to optical fibers on photonic chips.[2] Additionally they may find utility for positioning and connecting lab-on-chip arrays of micro-fluidic and micro-reactor devices that perform chemical and catalytic transformations, as well as ion, molecule and macromolecule separations with simultaneous optical detection.[1] The opal chip described here is a significant advance on anything reported in the open or patent literature.

We are indebted to the Natural Sciences and Engineering Research Council of Canada and the University of Toronto for financial support of this work.

Harnessing thorium(IV) as a catalyst: RNA and phosphate diester cleavage by a thorium(IV) macrocyclic complex†

Congfang Wang, Seema Choudhary, Claire B. Vink, Elizabeth A. Secord and Janet R. Morrow*

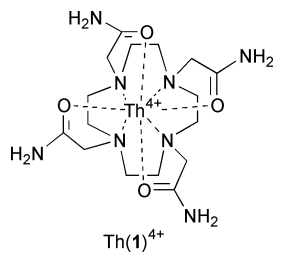
Received (in Cambridge, UK) 20th July 2000, Accepted 8th November 2000
First published as an Advance Article on the web

A robust macrocyclic tetraamide complex of Th(IV) binds phosphate diesters and promotes cleavage of RNA and phosphate diesters at 37 °C in the pH range 5.00–7.90.

Tetravalent cations such as Ce(IV), Th(IV) and Zr(IV) are among the most active catalysts for phosphate diester cleavage.[1–7] There are several reports that these metal ions promote the hydrolysis of phosphate diesters with poor leaving groups including dimethylphosphate and DNA.[1–5] Yet, the basis for this exceptional reactivity is not well understood. Studies reported to date on Ce(IV) or Th(IV) employ free metal ion or weak metal ion complexes and most studies are carried out at acidic pH to prevent precipitation of metal hydroxide complexes.[1–7] The complicated solution speciation of these systems makes mechanistic analysis difficult. Few attempts have been made to prepare well defined, catalytically active complexes of these metal ions.[4,6,7] Here, we report an unusual example of a Th(IV) complex of a neutral macrocycle which is highly resistant to dissociation in aqueous solutions. The complex efficiently promotes RNA cleavage and transesterification of a phosphate diester at neutral pH. Rate constants for RNA cleavage compare favorably to other metal ion macrocyclic complex catalysts including those containing lanthanide ions.[8–13]

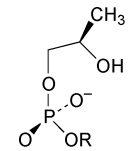


Th(**1**)$^{4+}$

The tetraamide macrocycle **1** binds to 12 members of the lanthanide(III) series with Sm(III) and Eu(III) being the most strongly bound.[12] Given that the ionic radius and coordination geometry of Th(IV) complexes are similar to those of the middle lanthanide(III) ions, **1** was studied as a ligand for Th(IV). Th(**1**)$(NO_3)_4$ was prepared in dry methanol from the free base form of **1** and $Th(NO_3)_4$.‡ NMR studies were carried out to characterize Th(**1**)$^{4+}$ in solution. The six broad ^{1}H NMR resonances observed at room temperature in D_2O sharpened but remained slightly broadened at 4 °C (ESI†).§ The ^{1}H NMR spectrum is analogous to that observed for La(**1**)$^{3+}$ which has **1** coordinated as an octadentate ligand with donor groups coordinated in a square antiprismatic arrangement.¶ The two sets of amide pendent group methylene protons appear as two doublets, the two sets of equatorial ethylene protons give rise to two doublets and the two sets of axial ethylene protons give rise to two triplets. Unfortunately, it was not possible to study the fluxional process further for Th(**1**)$^{4+}$ due to ligand decomposition at high temperatures and the insolubility of the complex in solvents other than water. However, this fluxional process likely involves ring inversion and cooperative pendent group rotation which interconverts the two carbons of the macrocyclic ring, the two sets of lower ring protons, the two sets of upper ring protons and the methylene protons in analogous lanthanide(III) complexes.[13,14] Consistent with such a fluxional process occurring, the ^{13}C NMR spectrum of Th(**1**)$^{4+}$ in D_2O at 22 °C has only three resonances‡ suggesting that, on the ^{13}C NMR timescale, the ethylene carbons are in fast exchange as has been observed for La(**1**)$^{3+}$.[13]

The Th(**1**)$^{4+}$ complex is resistant to dissociation in aqueous solution. Dissociation of Th(**1**)$^{4+}$ was studied in the presence of excess Cu(II) by monitoring formation of the Cu(**1**)$^{2+}$ complex by UV–VIS spectroscopy.[13] No dissociation of the complex (1.00 mM) was observed at pH 6.00 in a buffered solution in the presence of a 10-fold excess of Cu(II) over a period of one week at 37 °C. Remarkably, incubation of the Th(**1**)$^{4+}$ complex in the presence of an equivalent of EDTA at 37 °C and pH 6.00 did not induce dissociation of the complex over a period of a week. This inertness to metal ion release is reminiscent of the Eu(**1**)$^{3+}$ complex which did not release Eu^{3+} over a period of 6 weeks under similar conditions.[13] That this resistance to dissociation is a kinetic effect and not due to an exceptionally high formation constant for Th(**1**)$^{4+}$ relative to Cu(**1**)$^{2+}$ is suggested by competition experiments containing free **1**, $Th(NO_3)_4$ and $Cu(NO_3)_2$. When **1** (1.00 mM) was incubated simultaneously with $Th(NO_3)_4$ (1.00 mM) and $Cu(NO_3)_2$ (10.0 mM) at pH 6.00, 37 °C, all of **1** was complexed as Cu(**1**)$^{2+}$.

The ability to bind phosphate diesters is an integral part of catalysis; lanthanide(III) macrocyclic complexes that do not bind to phosphate diesters are not catalysts for cleavage.[10,13] Binding was studied in solutions containing 5.00 mM diethylphosphate and up to 40 mM Th(**1**)$^{4+}$ at pH 6.90, 21 °C with 0.10 M tetramethylammonium chloride, 5.0 mM triethylphosphate as a reference and 0.100 M Hepes buffer. Two ^{31}P NMR resonances were observed for free (0.81 ppm) and bound phosphate diester (−4.61 ppm), consistent with slow exchange kinetics on the NMR timescale. Fitting of the binding isotherm obtained by plotting the fraction of bound phosphate diester *vs.* concentration of free Th(**1**)$^{4+}$ gave a binding constant of 17 M^{-1}. Th(**1**)$^{4+}$ also bound the RNA analog **2** under similar conditions, but only a few percent was bound at pH 6.90 in the presence of 15 mM Th(**1**)$^{4+}$. In contrast, under similar conditions, diethylphosphate binding to Eu(**1**)$^{3+}$ and La(**1**)$^{3+}$ is too weak to determine binding constants and dissociation of diethylphosphate from La(**1**)$^{3+}$ is rapid on the ^{31}P NMR timescale.[13] The stronger binding and slower exchange rates of Th(**1**)$^{4+}$ are consistent with the higher charge of this actinide complex. These results are consistent with previous studies showing that ligand exchange rates for Th(IV) are slower than those of trivalent cations.[15]



2 R = Ph
3 R= 4-NO_2Ph

Although exchange of bound and free phosphate diester is slow on the NMR timescale, ligand exchange is not likely the

† Electronic supplementary information (ESI) available: ^{1}H NMR spectra for [Th(**1**)]$(NO_3)_4$ in D_2O at 21 and 4 °C. See http://www.rsc.org/suppdata/cc/b0/b005866l

rate determining step in the cleavage studies described below. Binding of Th(**1**)$^{4+}$ (15 mM) to diethyl phosphate (10 mM), pH 6.90, 0.10 M Hepes buffer at 22 °C, is complete within the 90 s it takes to record the ^{31}P NMR spectrum. In comparison, cleavage of RNA analog **3** by 15 mM Th(**1**)$^{4+}$ in 0.10 M Hepes at 22 °C has a half-life of 4.5 min.

Th(**1**)$^{4+}$ promotes transesterification of the phosphate diester **3** to form the cyclic phosphate diester and 4-nitrophenylate as determined by use of ^{31}P NMR and UV–VIS spectroscopy.‖ At pH 7.30, 37 °C with 1.00 mM complex and 0.100 mM **3**, the reaction exhibited good first-order kinetics in **3** for greater than four half-lives. Transesterification of **3** is first-order in Th(**1**)$^{4+}$ complex in the concentration range 0.60–2.00 mM with a second-order rate constant of 0.65 M^{-1} s^{-1}. Addition of 10% EDTA (based on complex concentration) to reaction solutions did not reduce the pseudo-first-order rate constant, suggesting that the reaction is not catalyzed by a small amount of free Th(IV) ion. Transesterification of **3** by Th(**1**)$^{4+}$ is essentially independent of pH in the pH range 5.0–7.9. Phosphate diester cleavage by metal ion complexes is typically pH dependent owing to the formation of metal hydroxide complexes.[6,8–11] That cleavage of **3** by Th(**1**)$^{3+}$ is not pH dependent suggests that the speciation of the Th(IV) complex does not change in this pH range. Pseudo-first-order rate constants for Th(**1**)$^{4+}$ and analogous Ln(III) complexes are listed in Table 1. Th(**1**)$^{4+}$ is 40-times more active than La(**1**)$^{3+}$, the most active lanthanide complex in the series. In addition, Th(**1**)$^{4+}$ promotes cleavage of adenylic acid oligomers more rapidly than does La(**1**)$^{3+}$ under similar conditions.

How does Th(**1**)$^{4+}$ promote RNA cleavage and why is the complex more efficient than analogous Ln(**1**)$^{3+}$ complexes? Given that the ionic radii of Th(IV) and Eu(III) are nearly identical, it is likely that Th(**1**)$^{4+}$ is nine-coordinate with a single site for the binding substrate, analogous to Eu(**1**)$^{3+}$.[13] Thus, Th(**1**)$^{4+}$ activates the phosphate diester to cleavage most probably through interaction at a single coordination site. The greater reactivity of the Th(IV) complex compared to its lanthanide(III) analogs is attributed to the greater Lewis acidity of the Th(IV) center as suggested by its strong interaction with phosphate diesters. In conclusion, we show here that it is feasible to prepare a Th(IV) complex of a neutral macrocycle which is highly resistant to dissociation in neutral aqueous solutions and is active in the cleavage of phosphate diesters and RNA. We demonstrate that the catalytic power of a tetravalent cation can be harnessed in a macrocyclic complex.

Table 1 Pseudo-first-order rate constants for cleavage of RNA and phosphate diester **3** by thorium(IV) and lanthanide(III) complexes of **1** at 37 °C

Complex	Substrate[a,b,c]	$k_{obs}/10^{-4}$ s^{-1}
Th(**1**)$^{4+}$	**3**	7.5[a]
Th(**1**)$^{4+}$	A_{10}	9.2
La(**1**)$^{3+}$	**3**	0.16
La(**1**)$^{3+}$	A_{12}–A_{18}	1.6
Eu(**1**)$^{3+}$	**3**	NR[d]
Eu(**1**)$^{3+}$	A_{12}–A_{18}	NR[d]

[a] For substrate **3** conditions were pH 7.3, 1.00 mM complex, 0.100 mM **3**, 10 mM Hepes buffer, 100 mM $NaNO_3$. [b] For A_{10} conditions were pH 7.4, 0.200 mM complex, 5 mM Hepes buffer, 0.013 mM A_{10} (adenosine concentration). [c] For A_{12}–A_{18} conditions were pH 7.6, 0.200 mM complex, 5 mM Hepes buffer, 0.08 mM A_{12}–A_{18} (adenosine concentration).[13] [d] No cleavage observed under the conditions given above.[13]

‡ Equimolar amounts of TCMC and $Th(NO_3)_4$ were heated to reflux in dry methanol for 1.5 h. The methanol was removed and the complex was isolated as a white solid in 43% yield following precipitation twice from a methanol–diethyl ether mixture. Anal. Calc. for $C_{20}H_{42}N_{12}O_{17}Th$ [Th(**1**)-(Et_2O)]$(NO_3)_4$: C, 25.16; H, 4.43; N, 17.60. Found: C, 25.02; H, 4.38; N, 17.27. FAB MS: *m*/*z* 818 [Th(**1**)$(NO_3)_3^+$]. The ^{13}C NMR spectrum of Th(**1**)$^{4+}$ in D_2O showed resonances at 52.5, 57.3, and 177.3 ppm assigned to carbons of the ethylene moiety, methylene and carbonyl carbons, respectively.

§ Only one major diastereomeric form of the complex is observed by ^{1}H or ^{13}C NMR spectroscopy. In contrast, Eu(**1**)$^{3+}$ has two diastereomers present in solution and solid state (see refs. 13 and 14).

¶ In the solid state, [La(**1**)(CF_3SO_3)(EtOH)]$(CF_3SO_3)_2$ is a ten-coordinate complex with an unusual 1,5,4 geometry while [Eu(**1**)(H_2O)]$(CF_3SO_3)_3$ is a nine-coordinate complex with a monocapped distorted square antiprism geometry.[13]

‖ The kinetics of transesterification of **3** were monitored by use of UV–VIS spectroscopy. At pH values > 6.0, the production of 4-nitrophenylate was monitored at 412 nm. At pH values < 6.0, the decrease in the absorbance of **3** at 300 nm was monitored.
