Inorganic oxides are ubiquitous materials exhibiting a vast compositional range and significant structural versatility,[1] characteristics which endow these phases with useful physical properties which can be exploited in applications ranging from heavy construction to microelectronics.[2,3] The design of new materials is driven by synthesis, and several strategies for the construction of specific oxide architectures have been described. One approach relies upon the profound influences of organic components on oxide structrures,[4] as manifested in zeolites,[5] mesoporous materials of the MCM-41 class,[6] and oxometal phosphates with entrained organic cations.[7] Another approach employs well-defined oxometalate clusters as molecular building blocks in the self-assembly of ordered oxide structures.[8–12] We recently demonstrated the confluence of these strategies in the design of the 2D network $[\{Cu_2(tpypyz)(H_2O)_2\}(Mo_5O_{15})(O_3PCH_2CH_2PO_3)]$, in which molybdate clusters are linked in one-dimension through organic tethers and crosslinked by binuclear Cu(II) complexes into a 2D network.[13] A prominent feature of the structural chemistry of this and related materials is the requirement of the secondary metal complex, such as Cu(II) organoimine, for the isolation of the product. This observation suggests that the well-known phosphomolybdate cluster $\{Mo_5O_{15}(HOPO_3)_2\}^{4-}$ could serve as one molecular building block, with an appropriate binuclear secondary metal–ligand complex acting as a linker in the construction of the extended structure. This expectation was realized in the reaction of $\{Mo_5O_{15}(HOPO_3)_2\}^{4-}$ with copper and a binucleating ligand to produce crystalline solid state oxides. However, minor variations in reaction conditions unexpectedly resulted in significant structural changes, as manifested in the 2D network material $[\{Cu_2(tpypyz)(H_2O)_2\}(Mo_5O_{15})(HOPO_3)_2]\cdot 2H_2O$ (1·2H$_2$O) and the 3D framework $[\{Cu_2(tpypyz)(H_2O)_2\}(Mo_5O_{15})(HOPO_3)_2]\cdot 3H_2O$ (2·H$_2$O).

The hydrothermal reaction of MoO_3, $Cu(C_2H_3O_2)_2\cdot H_2O$, tpypyz (tetrapyridylpyrazine), H_3PO_4 and H_2O in the mole ratio 5.80 : 2.14 : 1.00 : 4.85 : 2740 at 150 °C for 48 h yields dark green crystals of 1·2H$_2$O in 40% yield as a monophasic product.‡ In contrast, the reaction of MoO_3, Cu_2O, tpypyz, H_3PO_4, and H_2O in the mole ratio 5.89 : 1.20 : 1.00 : 7.00 : 2670 at 150 °C for 48 h yielded green crystals of 2·3H$_2$O in 35% yield. The Cu(I) starting material is required for the isolation of **2**, as is the increased ratio of MoO_3 to copper precursor since part of the molybdate is employed in the oxidation of the Cu(I) to Cu(II). The IR spectra of **1** and **2** are characterized by a series of seven median intensity bands in the 1000–1560 cm^{-1} region associated with the tpypyz ligand and two strong bands at *ca.* 921 and 897 cm^{-1} assigned to ν(Mo=O). A prominent feature at 785 cm^{-1} may be attributed to ν(Mo–O–M).

As shown in Fig. 1, the structure of 1·2H$_2$O§ consists of 2D sheets, constructed from $\{Mo_5O_{15}(HOPO_3)_2\}^{4-}$ clusters[14] linked through $\{Cu_2(tpypyz)(H_2O)_2\}^{2+}$ subunits. Each binuclear copper component links three phosphomolybdate clusters, while each cluster is in turn bonded to three binuclear copper subunits, which bridge to six neighboring clusters of the network. The periphery of a phosphomolybdate cluster is decorated by four corner-sharing copper(II) octahedra.

The phosphomolybdate cluster $\{(Mo_5O_{15})(HOPO_3)\}^{4-}$ consists of a ring of edge- and corner-sharing $\{MoO_6\}$ octahedra capped on both poles by phosphate tetrahedra sharing three vertices with the ring molybdenum centers. The pendant oxygen atom of each phosphorus tetrahedron is protonated, as indicated by charge balance considerations and confirmed by valence sum calculations. The copper coordination of the $\{Cu_2(tpypyz)(H_2O)_2\}^{4+}$ subunit is defined by two bridging oxo-groups from the phosphomolybdate clusters, three nitrogen donors from the chelating and bridging tpypyz ligands and an aqua ligand. The geometry is the common '4 + 2' variant with normal distances in the equatorial plane [Cu–O, 1.932(3) Å; 3 × N, 1.969(3) Å (ave)] and long axial distances [Cu–O(oxo), 2.409 (3)Å; Cu–O(aqua), 2.665(5) Å]. The metal-oxide substructure $\{Cu_2Mo_5O_{15}(HOPO_3)_2\}$ is 2D with intralamellar cavities occupied

† Electronic supplementary information (ESI) available: colour polyhedral representations of the structures 1·2H$_2$O and 2·3H$_2$O. See http://www.rsc.org/suppdata/cc/b1/b105563c/

 DOI: 10.1039/b105563c

by the organic component and the water molecules of crystallization.

It is now well-documented that variations in hydrothermal reaction conditions can afford quite different products. In this case, substitution of Cu_2O for $Cu(C_2H_3O_2)_2{\cdot}H_2O$ results in the isolation of $[\{Cu_2(tpypyz)(H_2O)_2\}(Mo_5O_{15})(HOPO_3)_2]{\cdot}3H_2O$§ (**2**·3$H_2O$), a material constructed from the same building blocks as **1**, in the same ratios, but with a dramatically different structure. As shown in Fig. 2(a), the structure of **2** is a 3D framework constructed from phosphomolybdate clusters and Cu(II)–tpypyz binuclear subunits. As illustrated in Fig. 2(b), the building blocks connect to form 1D $\{Cu_2Mo_5O_{15}(HOPO_3)_2\}$ chains, in contrast to the $\{Cu_2Mo_5O_{15}(HOPO_3)_2\}$ sheets formed in **1**. The Cu sites of a given chain link through the tpypyz bridges to Cu sites on four adjacent chains to provide the 3D connectivity.

The structural differences between **1** and **2** are reflected in their thermal behavior. Thus, the thermogravimetric curve for **1** exhibits a weight loss of *ca*. 2.5% between 110 and 125 °C, corresponding to the loss of two molecules of water of crystallization. In contrast, the dehydration process for **3** occurs at 170–190 °C (3.2% weight loss; 3.6% theoretical for three water molecules of crystallization). The mechanism of dehydration is dependent upon topological and energetic considerations.[15] Consequently, a lower dehydration energy is associated with accessibility of water molecules to crystal void volume such as channels or interlamellar regions. The more open layered structure of **1**, in contrast to the more dense 3D framework of **2**, is consistent with the dehydration curves. A second dehydration step, corresponding to the loss of the aqua ligands associated with the Cu(II) sites occurs at 225–240 °C for **1** and at 250–280 °C for **2**. Both **1** and **2** exhibit ligand loss in steps at 350–450 °C to give a mixture of P_2O_5 and MoO_3 as the final residues.

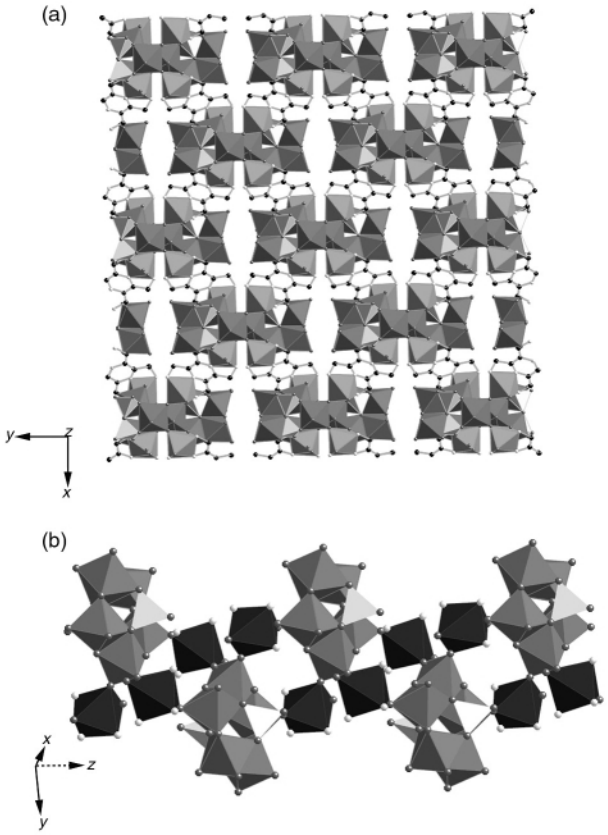

Fig. 2 (a) Polyhedral representation of the 3D structure of **2**·3H_2O viewed parallel to the *c* axis. (b) View of the 1D chain $\{Cu_2Mo_5O_{15}(HOPO_3)_2\}$ substructure of **2**. For colour versions see ESI.†

The structures of this study demonstrate that a building block approach to solid oxide materials based on molecular cluster precursors is practical.[16] However, the strategy relies on the judicious choices of a secondary metal and ligand subunits, such that the final structure reveals a synergism between the basicity of surface oxo-groups on the cluster, the coordination preferences of the secondary metal and the ligand geometry and denticity. Furthermore, the inherent versatility of metal coordination modes produces a certain unpredictability in the linkages between building blocks as manifested in this instance in the contrasting dimensionalities of the structures of **1** and **2**. While the information required for the self-assembly of the extended hybrid structures is present at the molecular level in the component building blocks, this provides only a broad blueprint for design, while further elaboration relies upon empirical observation of novel architectures derived from manipulation of reaction conditions and selection of component substructures.

Extreme (10^9) acidification of adenine-NH_2 in an open platinated nucleobase quartet. A pH switch with potential as a biological acid/base catalyst†

Marc S. Lüth, Michael Willermann and Bernhard Lippert*

First published as an Advance Article on the web 18th September 2001

The combination of electronic effects (Pt^{II} binding to N^7 and N^1) and a favourable conformation permitting efficient stabilization of the anion brings about a 10^9 fold increase in the exocyclic amino group acidity of 9-ethyladenine.

The heterocyclic nucleobases generally do not have groups with pK_a values corresponding to the physiological pH, unless present in a particular environment or chemically altered.[1] For example, the 'i motif' of hemiprotonated cytosine bases[2] is stable up to neutral pH despite the pK_a of protonated cytosine being between 4 and 5, and methylation of guanine-N^7 increases the acidity of the N1 proton by about 2.5 log units, thus bringing it down to 7.[3] Similarly, metal coordination to guanine-N^7 shifts the pK_a to *ca*. 8.[4] There is an increasing awareness that unusual pK_a shifts of nucleobase groups leading to pK_a values close to physiological pH might be the clue to an understanding of catalysis involving nucleic acids.[5–9] Scenarios include either general acid–base catalysis[5–8] or structural changes of the catalytic site due to formation of non-canonical base pairs.[9] Probably the most exciting recent example is RNA being the catalyst in the ribosomal peptidyl transferase center,[10] with a highly preserved adenine residue acting as a reversible proton acceptor and donor. The pK_a of this adenine is unusual in that it is 7.6 ± 0.2.[5]

In the course of our studies on metal-modified nucleobase quartets[11] we have now come across an example of an extreme acidification (10^9) of the 6-amino group of adenine in a complex consisting of two 9-ethyladenine (eade, A) and two 1-methyluracilate (mura, U) model nucleobases and three *trans*-a$_2$Pt^{II} entities (a = NH_3 or $MeNH_2$). *trans*,*trans*,*trans*-{$(NH_3)_2$Pt(N^7-eade-N^1)$_2$[$(MeNH_2)_2$Pt(mura-N^3)]$_2$} {**1**}$(ClO_4)_4$·4H_2O‡ crystallizes in a characteristic Z-shape with the four bases being nearly coplanar (Fig. 1).§ As in related compounds,[11] Pt–N^1 and Pt–N^7 vectors are approximately perpendicular to each other [91.8(4)°]. The ^{1}H NMR solution spectra (1D; ^{1}H–^{1}H-NOESY) in D_2O are consistent with the existence of different rotameric forms in this medium (at ambient temperature). The assignment of the resonances is realized by evaluating the ^{1}H–^{1}H-NOESY spectrum, because the A-H8 (9.31 ppm) and A-CH_2 (4.52 ppm) protons generate an intense cross-peak. Hence, the two signals at 9.35 and 9.32 ppm, which are two singlets with relative intensities of 1 : 1, can be attributed to the A-H2 protons.‡ The fact that this resonance is split suggests that the externally bonded mura ligands undergo hindered rotation about the U-N^3–Pt(1)–N^1-A bonds.[12] The corresponding A-H8 signal shows no doubling. Therefore, a rotation with a different activation energy about the central A-N^7–Pt(2)–N^7-A bonds is assumed, with the repulsive interaction of the two exocyclic A-NH_2 groups favouring the Z-form, as found in the solid state (*cf*. Fig. 1).

pD-dependent ^{1}H NMR spectra (2 < pD < 14) reveal two deprotonation steps occurring with pK_{a1} = 7.94 ± 0.31 and pK_{a2} = 11.66 ± 0.30 (3σ) (calculated for H_2O¶), which are assigned to two successive single deprotonation steps of NH_2 groups of the two adenine bases. Furthermore, the difference between the two acidity constants amounts to ΔpK_a = (11.66 ± 0.30) − (7.94 ± 0.31) = 3.72 ± 0.43. Comparison with literature data show that the amino group acidity (pK_a ≅ 16.7 in the free base[13]) increases upon Pt^{II} coordination to N^7 or N^1 by 2–3 log units and even more so if both positions are simultaneously platinated (pK_a ≅ 10.8–12.6[11,14]). The unusually low pK_{a1} of 7.94 (and the large difference between the two pK_a values) can only be rationalized if in addition to the polarizing effect of the two metal ions a fundamental conformational change is taken into account. We propose that the transition of the Z-shaped cation to a U-shaped one takes place, which stabilizes the first deprotonated species {**1**–H^+}$^{3+}$ (Fig. 2). On the basis of structural models as well as X-ray data of fragments of the title compound[15] it is obvious that (i) the four bases in the U-shape *can* adopt a perfectly planar arrangement, and (ii) the exocyclic amino groups of the *head–head* arranged adenine bases are 3 Å or less apart. In fact, any reduction of the N^7–Pt–N^7 angle from 180° further reduces this separation. This short distance permits an efficient stabilization of the NH^- group by the NH_2 group of the second adenine through intramolecular H bond formation (*cf*. Fig. 2, bottom). The situation is reminiscent of that occurring in the $N_2H_5^-$ ligand of the dinuclear Pt^{IV} complex $[(NH_3)_3Pt(NH_2)_2(N_2H_5)Pt(NH_3)_3]^{5+}$.[16] Our conclusion concerning the conformational change during the first deprotonation of the title compound is in agreement with observations for linkage isomers, *viz*. complexes containing a central N^1–Pt–N^1 bond and additional Pt^{II} entities at the N^7 positions.[11,17] There, mainly the electronic effects of the two metal ions are operative, hence pK_a values are higher and close to the normal range (10–11). As the pH is raised further, the cation is expected to adopt again the Z-shape to avoid the mutual repulsion of the two amide groups. Consequently, pK_{a2} is in the expected range

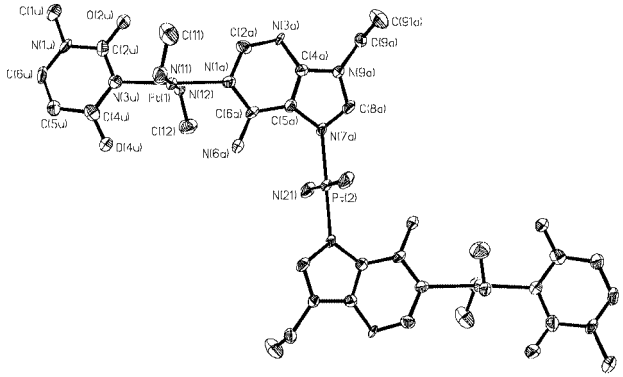

Fig. 1 X-Ray structure of the cation of {**1**}$(ClO_4)_4$·4H_2O. Selected bond distances (Å) and angles (°) are: Pt(1)–N(3u) 2.026(8), Pt(1)–N(1a) 2.055(8), Pt(2)–N(7a) 2.014(7), Pt(2)–N(21) 2.041(7); N(3u)–Pt(1)–N(1a) 175.8(3), N(3u)–Pt(1)–N(12) 87.5(3), N(7a)^a–Pt(2)–N(7a) 180.0, with the symmetry code: ^{a} $-x$, $-y$, $-z$ + 1.

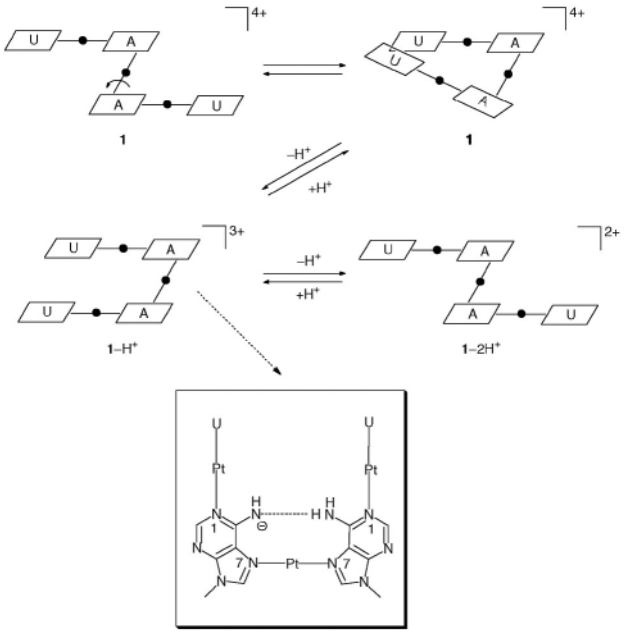

Fig. 2 Schematic presentation of the conformational pH switch.

(11.66). In the pD range corresponding to pK_{a1}, the A-H2 resonance is split into a multiplet, indicating again a hindered rotation of the terminal coordinated mura ligands in the U-form of the cation, which leads to different conformations. There is no indication of any (fast) Pt migration from either N^1 or N^7 to N^6 as observed by Arpalahti and coworkers upon heating.[18]

The compound described here behaves as a pH switch,[19] and hence changes its conformation from Z to U upon removal of a single proton and again from U to Z if a second proton is removed. *Vice versa*, the mutual orientation of the two adenine nucleobases and the close distance of the exocyclic amino groups make the compound a system with the potential of acting as an acid and a base in a reversible manner at physiological pH. The only requirement to achieve such a function would be to have the system confined in space to a situation in which the cation adopts a structure halfway between the two extremes (*cf.* Fig. 2, top). Slight mechanical oscillations of the two halves could then eject a proton or pick one up from the environment.

There is a second feature of interest to cationic {**1**–H$^+$}$^{3+}$ in its U-shape, which refers to its possible interaction with (anionic) telomere sequences of DNA. The enzyme telomerase is a key player in the development of cancer and has been found to be inhibited by conjugated π-systems capable of stabilizing guanine quartet structures of the telomeres.[20]

‡ *Experimental procedure*: *trans*-$(MeNH_2)_2Pt(mura\text{-}N^3)Cl$ (220 mg, 0.54 mmol)[21] was suspended in a weakly acidic (HNO_3, pH 4.5) aqueous solution (40 mL) of *trans*-$[(NH_3)_2Pt(eade\text{-}N^7)_2](NO_3)_2{\cdot}3H_2O$ (200 mg, 0.27 mmol).[17] A solution of $AgNO_3$ (91 mg, 0.53 mmol) in H_2O (10 mL) was added dropwise over a period of 6 h with daylight excluded and stirred for 6 d at 40 °C. After the mixture was cooled to 4 °C, AgCl was removed by filtration. The colourless filtrate was concentrated to a 20 mL volume (N_2-stream) and an excess of $NaClO_4$ was added. After 2 d, pure {**1**}$(ClO_4)_4{\cdot}1.5H_2O$ precipitated as long needles. These were filtered off and dried in air (150 mg, 32%). ^{1}H NMR (D_2O, 0.02 mol L^{-1}, 200.13 MHz, TSP, ambient temperature, pD = 5.7): δ 9.35, 9.32 (s, A-H2 with relative intensities of 1 : 1), 9.31 (s, A-H8), 7.45 (d, U-H6, ^3J 8 Hz), 5.81 (d, U-H5, ^3J 8 Hz), 4.52 (q, A-CH_2, ^3J 8 Hz), 3.46, 3.45 (s, U-CH_3 with relative intensities of 1 : 1), 1.62 (t, A-CH_3, ^3J 8 Hz); ^{195}Pt NMR (D_2O, 0.02 mol L^{-1}, 42.95 MHz, Na_2PtCl_6, ambient temperature, pD = 5.7, with relative intensities of 1:2): δ −2466 (A-N^7–Pt–N^7-A), −2594 (U-N^3–Pt–N^1-A); Anal. calc. for $C_{28}H_{57}N_{20}O_{21.5}Pt_3Cl_4$ (M = 1744.9 g mol^{-1}): C 19.3, H 3.3, N 16.1. Found: C 19.1, H 3.1, N 15.9%. Recrystallization of {**1**}$(ClO_4)_4{\cdot}1.5H_2O$ from D_2O gave suitable crystals for X-ray structure analysis and showed the presence of four water molecules per quartet in contrast to elemental analysis.

§ *Crystal data*: asymmetric unit: $C_{14}H_{31}N_{10}O_{12}Cl_2Pt_{1.5}$, M = 895.02, monoclinic, space group $P2_1/n$, a = 8.364(2), b = 26.394(5), c = 12.751(3) Å, β = 106.58(3)°, U = 2697.9(10) Å^3, T = 154(2) K, Z = 4, μ(Mo-Kα) = 8.054 mm^{-1}, Enraf-Nonius-Kappa CCD[22] with graphite monochromator, ω-scans, 5574 independent reflections, R_{int} = 0.1234; structure was solved by standard Patterson methods[22] and refined by full-matrix, least sqares on F^2 using SHELXL-93.[22] Refinement of 367 parameters converged at final R_1 = 0.0511 and wR_2 = 0.1191 for 3932 reflections with $I = 2\sigma(I)$ and R_1 = 0.0768 and wR_2 = 0.1676 for all data (5560 reflections), min. and max. features in difference Fourier map: 3.934 and −3.375 e Å^{-3}. CCDC reference number 165198. See http://www.rsc.org/suppdata/cc/b1/b105395g/ for crystallographic data in CIF or other electronic format.

¶ *Determination of the acidity constants*: the pK_a values of the nucleobase quartet {**1**}$(ClO_4)_4{\cdot}1.5H_2O$ were determined using pH-dependent ^{1}H NMR measurements in D_2O (20 °C; I = 0.1 mol L^{-1}, $NaNO_3$). Changes in chemical shifts of all non-exchangeable protons of the complex due to the change in pD were evaluated with a nonlinear least squares fit after Newton–Gauss.[23] The obtained acidity constants were then transformed to the values valid for water according to the literature.[24]

First published as an Advance Article on the web 2nd October 2001

Phosphonate esters react with γ-alumina under microwave (MW) irradiation; this reaction is a simple preparative method to graft organic pendant groups onto the surface of alumina; the efficiency of the grafting was readily checked by solid-state NMR techniques (^{31}P and ^{27}Al).

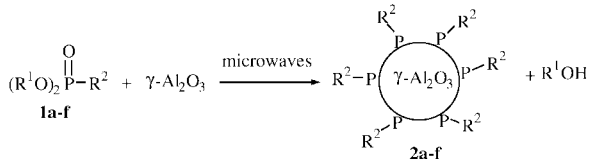
The grafting of organic moieties onto the surface of inorganic compounds is an important process widely used in numerous applications. These include, heterogenisation of homogeneous catalysts,[1] elaboration of solid phases for chromatography, organic synthesis on solid phases and the modification of the surface properties of solids. For silica, the use of siloxy groups for grafting silica is very common while for other oxides such as alumina there is no satisfactory method for grafting organic pendant groups. Alumina provides excellent properties as a support. These include ease of diffusion of reactant in the pore structure and a large available specific surface, leading to its high popularity as a support for both heterogeneous catalysis[2] and chromatography.

Phosphonyl groups are known to form very stable networks in aluminium phosphate and in ALPOs. Thus we speculated that phosphonate could be grafted onto alumina with strong bonding.[3]

Although several reactions of phosphoric or phosphonic derivatives with alumina have already been reported in the literature (studies of surface modification of oxidised aluminium[4] or surface modification of aluminosilicate[5]), the use of such reactions for grafting of functionalised organic groups has not, to our knowledge, been previously studied.

After many trials with phosphonic acid and phosphonate esters under classical heating and under microwave activation, we found that the best procedure was the reaction of a phosphonate with alumina under MW irradiation (Scheme 1 and Table 1).

The grafting of the organic chain was followed by elemental analysis (%C) of the obtained material. Although a phosphonic acid can be used to give the same type of material, phosphonate esters produced better yields in grafting than phosphonic acid (R^2 = $PhCH_2$, R^1 = OH, %C = 4.63 *cf.* entry 3 in Table 1, %C = 6.08). One reason may be that phosphonates are more easily dispersed.[6] Whatever the reason, the higher loadings were obtained by MW activation and by the use of phosphonate esters without solvent. Classical heating conditions under the same conditions (130 °C) produced inferior results when compared to MW irradiation. Although alumina is a thermal insulator it is transparent to microwaves, and therefore it is easy to activate polar molecules such as phosphonates using MWs in the presence of alumina.[7] The molecular mobility of small polar molecules (water, alcohols) is increased by MW irradiation and they desorb rapidly, hence microwave activation is well adapted for the hydrolysis–condensation reaction (Scheme 1). During the anchoring process with phosphonate, the phosphonate function was dealkylated and some monodealkylated phosphonates were recovered by washing with methanol. This dealkylation process was previously reported by Weinberg *et al.*[8] who described *via* a spectroscopic study, the adsorption of gaseous dimethylmethylphosphonate onto alumina. More recently in a spectroscopic study of the reaction of war gas on alumina, Wagner *et al.*[9] observed similar results.



Scheme 1 Reaction of phosphonate esters with γ-alumina under microwave irradiation.

A readily available commercial γ-alumina with a specific surface area of 132 $m^2\ g^{-1}$ was used. In a typical preparation, 3 g of γ-Al_2O_3 (Merck, BET = 132 $m^2\ g^{-1}$; 30 mmol) and diethylcyanoethylphosphonate **1a** (1.06 g; 6 mmol) were mixed and irradiated (15 × 4 min) by microwaves at 150 W (focused irradiation 2450 MHz; Prolabo Synthewave 402). The highest temperature observed was 198 °C. After cooling to room temperature the crude product was washed with dichloromethane (3 × 20 ml) and 150 mg of starting compound **1a** was recovered. Further washing with methanol up to a constant weight (3 × 20 ml) led to the recovery of 60 mg of monodealkylated ethylcyanomethylphosphonate in the filtrate. Further washing of compounds **2** with water at room temperature did not lead to any removal of loading groups of the grafted phosphonate. The specific surface areas of compounds **2** are

slightly decreased (104–130 $m^2\ g^{-1}$) compared to the starting γ-Al_2O_3 (132 $m^2\ g^{-1}$).

Upon drying at 200 °C for 24 h the products *e.g.* **2a** (3.50 g; %C = 4.58) were obtained and were found to be amorphous by powder X-ray diffraction. The FTIR spectrum of **2a** exhibits a sharp peak at 2254 cm^{-1} arising from the stretching mode of the nitrile group. Another important modification observed by IR (compared to the parent γ-Al_2O_3) relates to the P–O and P=O stretching bands that are located at 1042, 1114 and 1198 cm^{-1}. ^{31}P MAS NMR indicates an intense peak at 3.6 ppm (Fig. 1, ^{31}P MAS) and a wide background signal which is presumably the result of a chemical shift distribution of small peaks.

The ^{27}Al MAS NMR spectrum of **2a** (Fig. 1) shows three signals. The two main resonances are broad, with an isotropic chemical shift in the range 70–80 ppm and 10–20 ppm, arising from four- and six-fold aluminium, respectively, of γ-Al_2O_3.[10] Their asymmetric line-shape is characteristic of an amorphous material in which aluminium sites present a distribution of quadrupolar interactions.[11] Interestingly a third weaker resonance, not present in the starting γ-Al_2O_3 (not shown) is observed at −15 ppm. Its isotropic chemical shift corresponds to an octahedral aluminium site and is close to the chemical shift observed for bulk aluminophosphonate materials.[12]

DTA analysis of material **2a** shows an endothermic transition around 100 °C and a broad exothermic transition ranging from 269 to 395 °C. According to TGA a first weight loss arising from residual water is observed around 100 °C and further stepwise mass losses starting at 250 °C are observed at 280, 344 and 407 °C. The total mass loss above 250 °C represents 7.7% of the total weight.

In order to investigate the bonding mode between phosphonic acids and γ-Al_2O_3, the bonding of phosphorus with aluminium nuclei has been determined *via* a ^{27}Al–^{31}P HETCOR experiment.[13] This experiment reveals the presence of magnetization transfer and hence the spatial proximity of phosphorus and aluminium. The spectrum (Fig. 1) consists of a single cross-peak centred at −15 ppm for ^{27}Al and 3.7 ppm for ^{31}P. The ^{31}P projection corresponds closely to the one-dimensional ^{31}P MAS NMR spectra, with both a 'weak' and wide component. By contrast the ^{27}Al HETCOR projection shows only the additional resonance at −15 ppm caused by phosphorus impregnation. Unlike the two γ-Al_2O_3 signals, this resonance can be simulated with a Lorentzian line shape, indicating a more symmetric environment. This experiment suggests that the weak ^{27}Al signal at −15 ppm can be attributed to aluminium surrounded by phosphorus, and that all the phosphorus nuclei are close to aluminium nuclei. The distance between the aluminium and phosphorus atoms was estimated by a ^{27}Al–{^{31}P} REDOR experiment.[14] In this experiment, a ^{27}Al rotor synchronised Hahn-echo spectrum (S_0) was compared to the ^{27}Al REDOR spectrum (S_f), in which the heteronuclear dipolar coupling is reintroduced by application of radiofrequency pulses on ^{31}P. The difference $\Delta S = S_0 - S_f$ gives the spectrum of aluminium close to phosphorus. As expected, the difference spectrum consists of a single resonance at −15 ppm, confirming its attribution to aluminium surrounded by phosphorus nuclei.

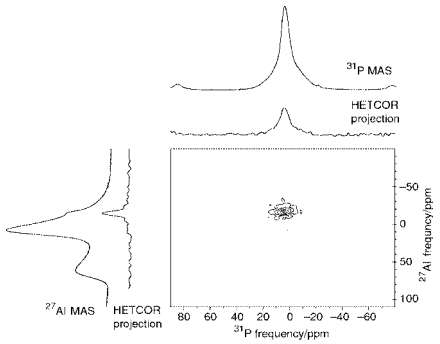

Fig. 1 ^{27}Al–^{31}P HETCOR spectrum of compound **2a** (MAS speed 14.3 kHz, CP contact time 5 ms). ^{27}Al and ^{31}P resonances are shown along the vertical and horizontal axes and are compared to the MAS spectra.

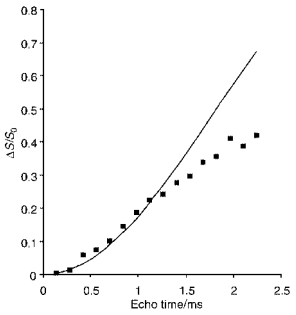

Fig. 2 REDOR fraction $\Delta S/S_0$ of the −15 ppm ^{27}Al resonance *vs.* the total echo time (MAS 14.3 kHz). The squares indicate the measured data while the solid line is the simulated curve for $D = 420$ Hz and $r = 3.12$ Å.

Fig. 2 shows the relative intensity of the REDOR fraction, $\Delta S/S_0$, as a function of echo time for the −15 ppm ^{27}Al signal. For relatively short echo times, the difference intensity increases as the dipolar coupling increases.

The dipolar coupling constant was obtained by fitting the experimental data (Fig. 2; the theoretical curve was calculated assuming that each aluminium can only be connected to one phosphorus[15]). From this fit, the dipolar coupling constant was estimated to be 420 ± 30 Hz which corresponds to a ^{31}P–^{27}Al distance of 3.12 ± 0.08 Å. This distance is consistent with an Al–O–P arrangement for which the P–Al distance is in the range of 3.10–3.22 Å as reported in the literature.[16] From the MAS NMR study, it can be stated that the global structure of aluminis not deteriorated by the grafting reaction. Indeed, the characteristic peaks around 15 and 75 ppm observed by ^{27}Al MAS NMR, corresponding to six and four-fold aluminium, respectively, are still present in the resulting materials.

In conclusion, a general preparative method for coating γ-Al_2O_3 with organic groups based on the reaction of phosphonate and γ-Al_2O_3 is proposed.

Steric acceleration of an uncatalysed ene reaction at room temperature

Nandeo Choony,[a] Peter G. Sammes,*[a] Graham Smith[a] and Robert W. Ward[b]

[a] *Department of Chemistry, School of Physics and Chemistry, UniS, Guildford, Surrey, UK GU2 7XH. E-mail: p.sammes@surrey.ac.uk*

Received (in Cambridge, UK) 24th July 2001, Accepted 7th September 2001
First published as an Advance Article on the web 27th September 2001

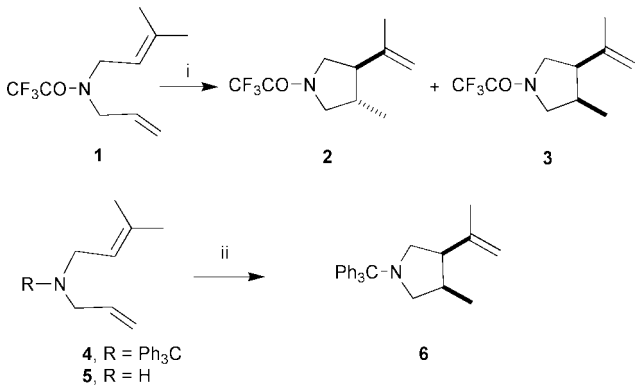
The bulky trityl steric buttress is used to effect an intramolecular, uncatalysed ene reaction that operates at room temperature, whilst smaller buttresses require heat.

The ene[1] reaction and its intramolecular counterpart[2] are synthetically useful processes that have been exploited in a wide range of chemistry. Normally the ene reaction requires the use of heat at temperatures greater than 140 °C to proceed and, for systems where the enophile is not activated by an electron withdrawing group, *much* higher temperatures are often required.[3] For systems with electron deficient enophiles, the process may be catalysed with Lewis acids, whereby the reaction has been observed to proceed at ambient temperatures[4] but such catalysis is not generally effective for non-activated enophiles.

The stereochemistry of the intramolecular ene process[2] has also been examined and, under vigorous thermal conditions, stereocontrol is often lost. Thus, heating the simple *N*-trifluoroacetyl-*N*-allyl-*N*-dimethylallylamide compound **1** at 220 °C for 30 min effects an intramolecular ene reaction and converts it into the mixture of *cis* and *trans*-pyrrolidines **2** and **3**.[5] The latter compounds are of interest as members of the kainic acid family of neuroactive agents,[6] the kainic acid series having the *cis*-stereochemistry **2** and the *allo* series the *trans*-stereochemistry **3**.[7] Thus any means of controlling the stereochemistry of the intramolecular ene process would be of synthetic value.

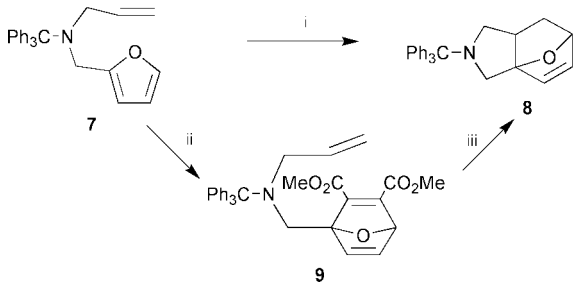
As part of our interest in the use of steric buttressing as an aid to reactions,[8] herein we describe examples of use of a steric buttress that assists ene reactions to occur under uncatalysed and low temperature conditions.

Upon heating in xylene, under argon at 140 °C, for 100 h, the trityl-protected *N*-allyl-*N*-dimethylallylamine **4**, prepared by standard methods,† smoothly produced the ene product **6** in almost quantitative yield (Scheme 1). Only one isomer could be detected by ^{1}H NMR spectroscopy (>95%), assigned from ^{1}H NOE experiments, as the *cis*-isomer. The *cis*-isomer is known to be the preferred stereoisomer in analogous carbocyclic ene reactions.[2] That a buttressing effect is operating was supported by the observation that no sign of any cyclisation product was obtained upon heating the parent amine **5** under the same conditions. The ease of the buttressed cyclisation, compared with the harsh conditions normally reported for unactivated ene reactions,[3] led us to seek other examples of the sterically assisted ene process.



Scheme 1 i, 220 °C, 30 min; ii, 140 °C, 4 days.

In earlier work we had shown that, on heating, the trityl protected *N*-allylfurfurylamine **7** undergoes an intramolecular Diels–Alder cycloaddition to the corresponding cycloadduct **8** in almost quantitative yield. At rt a competing intermolecular cycloaddition, with dimethyl butynedioate, is possible to give the cycloadduct **9** but, on heating, this loses the acetylenic ester by a retro-cycloaddition reaction and again forms the thermodynamically favoured cycloadduct **8** (Scheme 2).

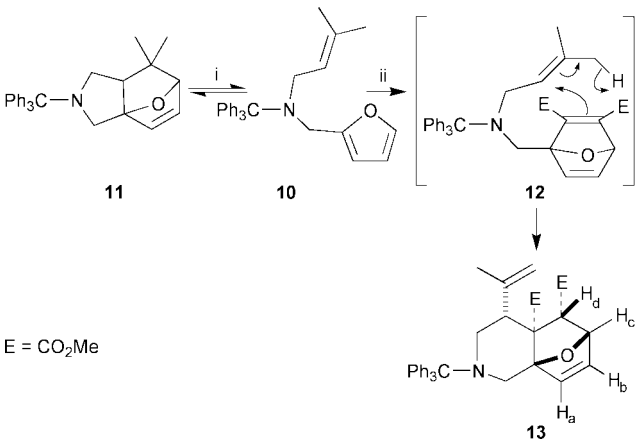


Scheme 2 i, 120 °C, 24 h; ii, $MeO_2C–C\equiv C–CO_2Me$, rt; iii, 120 °C.

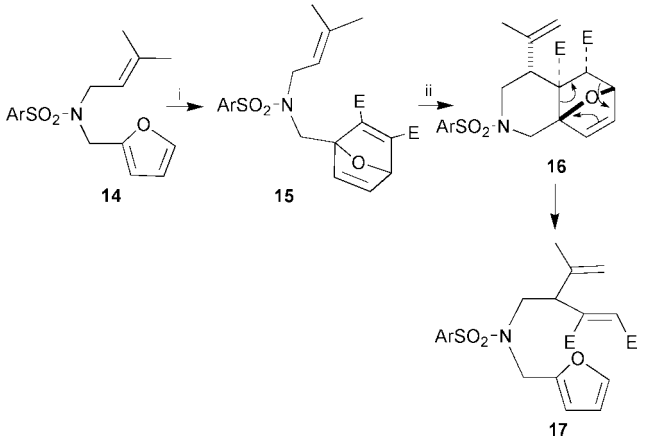
The intramolecular process, *e.g.* **7** to **8**, is sensitive to substituents on the allyl group and the dimethylallyl derivative **10**, only undergoes partial cycloaddition to **11** on heating, to form an 80:20 equilibrium ratio of the cyclised to uncyclised components at 140 °C. A similar competing, intermolecular cycloaddition was attempted with **10** as a parallel reaction to that performed on the unsubstituted allyl compound **7**.

When the tritylated amine **10** was allowed to react with dimethyl butynedioate at rt over 5 d, a new product formed in high yield. However, the compound was *not* the expected Diels–Alder product **12** but, instead, the ene product **13**, isolated as a crystalline solid, mp 164–166 °C (Scheme 3). In its ^{1}H NMR spectrum **13** showed loss of the isopropylidene group and the furan ring protons and formation of the isopropenyl group. The ring protons, H_a to H_d, showed as a tightly coupled ABXY system. NOE experiments indicated the geometry shown, resulting from an approach, *via* the transition state **12a**, from the least hindered, *exo*-face of the oxabicycloheptadiene system. It should be noted that this ene reaction involves a type 1 process

 DOI: 10.1039/b106669m



Scheme 3 i, 140 °C, xylene; ii, $MeO_2C–C\equiv C–CO_2Me$, rt.



Scheme 4 i, $MeO_2C–C\equiv C–CO_2Me$, rt, 7 days; ii, heat, 70 °C, 3 days.

of a 1,7-diene system, that normally proceed in only modest yields at very high temperatures.[2,9]

The striking buttressing effect of the trityl group was further illustrated by repeating the reaction using the 'smaller' buttress, the 4-toluenesulfonamide **14**.[10] In this case the dimethyl butynedioate adduct **15** could be isolated but showed no sign of ene products after leaving at rt for several weeks. However, on heating to 70 °C, compound **15** slowly reacted further, an ene reaction being observed, as indicated by the appearance of the compound **16** as a transient intermediate but which was unstable to the reaction conditions and underwent a subsequent retro-Diels–Alder reaction to form the furfuryl derivative **17** (Scheme 4). That this sequence of ene reaction followed by the retro-Diels–Alder process occurred, rather than an initial retro-Diels–Alder reaction, followed by an intermolecular ene process was supported by the absence of any of the starting material **14** either as a reaction product or as a transient intermediate. In contrast to the behaviour of the tosylated intermediate **16**, heating the *N*-tritylated ene product **13** at 70 °C gave no indication of the competing retro-Diels–Alder reaction, none of the open form corresponding to **17** being formed. Thus, not only does the trityl buttress assist in lowering the activation energy for the ene process but it also helps prevent the subsequent retro-Diels–Alder process from occurring. Presumably the open form (*cf.* **17**) would occupy more conformational space than is available in the presence of the sterically demanding trityl group, hence leaving the equilibrium firmly in favour of the closed form **13**.

We thank GlaxoSmithKline Pharmaceutical Research and the EPSRC for a research studentship (to G. S.)

The first Ru(II)-catalysed asymmetric hydrogen transfer reduction of aromatic ketones in aqueous media

Hae Yoon Rhyoo, Hee-Jung Park and Young Keun Chung*

School of Chemistry and Center for Molecular Catalysis, Seoul National University, Seoul 151-747, Korea. E-mail: ykchung@plaza.snu.ac.kr; Fax: 82-2-889-1568; Tel: +82-2-880-6662(Office)/880-6815(Lab.)

Received (in Cambridge, UK) 4th July 2001, Accepted 5th September 2001
First published as an Advance Article on the web 27th September 2001

The first water-soluble asymmetric hydrogen-transfer ruthenium(II) catalyst system consisting of [Ru(*p*-cymene)Cl_2]$_2$, (*S*)-proline amide, and sodium formate, which gives high conversion rates with high ee values up to 95.3% and is reusable, has been developed.

Extensive research on new and effective catalytic asymmetric reactions has been continuing to find more efficient methods for the preparation of optically active compounds.[1] While several excellent chiral catalysts have been developed, most of them have to be used in strictly anhydrous organic solvents. As a consequence of the increasing demand for efficient and environmental friendly methods, heterogenization of homogeneous catalysts by immobilizing them with the aid of liquid or solid supports is now of great interest.[2] While there have been many trials to immobilize homogeneous catalysts on solid supports, successful examples are still rare.[3] The use of homogeneous catalysts in aqueous solution and on liquid supports is more feasible and can offer a great opportunity for green chemistry.[4]

Catalytic asymmetric transfer hydrogenation of ketones has recently emerged as a viable means of synthesizing chiral alcohols.[5] Due to its operational simplicity, the easy availability of reductants, and the high enantioselectivities, the catalytic enantioselective reduction of ketones has been extensively studied during the last decade. In particular, a ruthenium catalyst bearing a chiral ligand such as mono *N*-tosylated diphenylethylenediamine (DPEN-Ts, Noyori's ligand) has been well studied.[6] In the hope of finding efficient and environmental friendly methods, we focused our efforts on finding a water-soluble catalyst system. During the course of our study on the use of amino amide as a chiral ligand,[7] we found that a combination of (*S*)-proline amide and [Ru(*p*-cymene)Cl_2]$_2$ was quite soluble in water. Recently, Williams *et al.*[8] reported the synthesis of water-soluble aminosulfonamide ligands and their applications in the Ru(II)-catalyzed enantioselective transfer hydrogenation of aromatic ketones. However, they used water as an additive to stabilize the catalyst. In this paper, we report the first water-soluble Ru(II)-catalyst system that can catalyze an asymmetric hydrogen-transfer reduction of aromatic ketones in aqueous solution. In addition to the high conversion rates and enantioselectivities, the catalytic system can be recycled at least six times withou loss of performance.

(*S*)-Proline amides **1**, **2**, and **3** (Chart 1) were synthesized according to the published methods.[9] Structure **1** was modified by the addition of a hydroxy group, as in **2**, to increase water solubility. Likewise, a fluoride group was introduced to increase polarity and to test its electronic effect. Combination of the ligand with [Ru(*p*-cymene)Cl_2]$_2$ and a hydrogen source was examined for the asymmetric hydrogen-transfer reduction of ketones. Because the organic substrates have no noticeable solubilities in aqueous solution, they form an aqueous biphasic system and the reaction occurs at the interface.

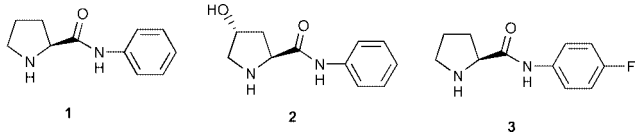

Chart 1 Proline aromatic amide derivatives.

We screened several hydrogen sources and found that HCOONa[10] was the best for the catalytic system. Ketones **4**, **5**, **6**, and **7** (Chart 2) were reduced to give *sec*-alcohols (Table 1).† The absolute configuration of the product was *R* as in the homogeneous reaction. For **4**, the conversion yields were quite high and enantioselectivities up to 95.3% were obtained. The best results were obtained for **4b**. In our previous study regarding the catalytic reaction in organic solvent such as dichloromethane using HCOOH–Et_3N (5:2) as a hydride source,[7] **1** and **3** had been used as the chiral ligands. In that case,

19	**3**	**6**	85	57.3
20	**3**	**7**	100	89.4[c]

[a] All were reacted for 4 h at 30 °C. [b] The configuration *R* was determined by the optical rotation and the retention time of chiral GC using a Chrompak Chirasil DEX CB 25 m × 0.32 μm column. [c] The conversion of **4c**, **4d** and **7** were determined by GC using a Ultra 2 50 m × 0.32 μm. E.e. was determined by HPLC using Daicel OD column.

 DOI: 10.1039/b106130p

high conversion yields (96–100%) were obtained for **4b** and **4c** and the highest enantioselectivity, up to 98.8%, was obtained for **4d**. When the substrate was **4b**, the conversion yields (>99%) and enantioselectivities (95.3%) in an aqueous solution were quite comparable to those in the homogeneous solution (96–100% and 94.6–94.8% ee, respectively). To compare the enantioselectivity dependency upon the position of the methoxy substituent, the *m*- and *p*-methoxy substituted compounds **5** and **6** were tested. For **5** and **6**, the conversion yields were quite high but the enantioselectivities were moderate. Thus, the *meta*- and *para*-substitutions were less effective than the *ortho*-substitution. Transfer hydrogenation of **7** with ligand **3** gave (*R*)-1-naphthylethanol in a quantitative yield with 89.4% ee.

Recovery and reusability of the catalytic system were tested by carrying out consecutive cycles for **4b** with ligand **3** (Table 2), with the same catalyst in aqueous solution, carefully separated from the organic phase at the end of each run. Substrate **4b** was chosen because it was used for the synthesis of medicinal intermediates.[11] After each catalytic reaction, 1 equiv. formic acid was added to regenerate sodium formate. The conversion yields and enantioselectivities were quite high even on the 6th run. The relative invariance of the conversion yields and enantioselectivities means that the catalyst system is quite stable and the environment around the reaction center is intact during the catalysis. The catalytic system can be recycled at least six times with little loss of perfomance and without producing waste water.

Table 2 Recycle test[a]

Recycle no.	Additive	Time/h	Conv. (%)	Ee (%)
0		4	99.6	95.3
1	HCOOH	5	99.3	95.3
2	HCOOH	6	99.8	95.3
3	HCOOH	6.5	99.8	95.1
4	HCOOH	7	99.7	94.6
5	HCOOH	7	99.3	94.2

[a] Reaction conditions: ligand **3**, substrate **4b**, at 30 °C.

In summary, we have demonstrated that the combination of (*S*)-proline amide and $[Ru(p\text{-cymene})Cl_2]_2$ could be used as an asymmetric hydrogen transfer catalyst for aryl ketones in an aqueous solution. To the best of our knowledge, this is the first example of the Ru(II)-catalyzed asymmetric hydrogen-transfer reduction of aromatic ketones in an aqueous solution. The catalytic system shows a catalyst performance comparable with that in homogeneous solution. The amino amide can readily be fine-tuned by changing the functional group on the amide or by incorporating different amino acids. Other asymmetric reactions with amino amides are being carried out and progress will be reported in due course.

Organocatalytic chain scission of poly(lactides): a general route to controlled molecular weight, functionality and macromolecular architecture

Frederik Nederberg, Eric F. Connor, Thierry Glausser and James L. Hedrick*

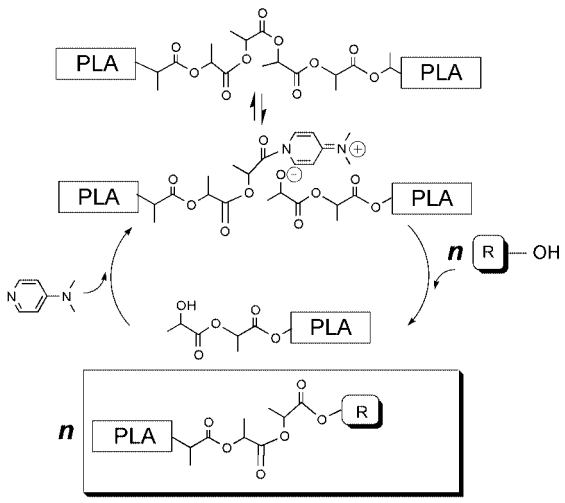
First published as an Advance Article on the web 20th September 2001

A facile, single-step transesterification approach to poly(lactides) with controlled molecular weights and end-group functionality, as well as block and star-shaped architectures is described using nucleophilic amine catalysts.

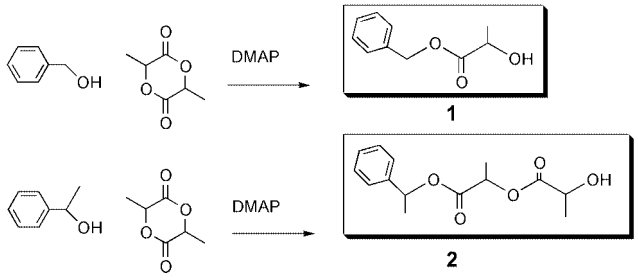
Tailor made bioresorbable polymers, particularly poly(lactide), are needed for a wide variety of biomedical applications and for controlled drug delivery media.[1] For many of these applications, molecular weight modification is accomplished by controlled chain-growth polymerization, *via* ring opening of the cyclic diester in the presence of a suitable organometallic promoter.[2–4] Another recognized procedure for the preparation of defined telechelic polymers involves the depolymerization of a high molecular weight polymer *via* metal catalysis *e.g.* the chain-end functionalization of poly(butadiene) by olefin metathesis.[5,6] Gross *et al.*[7,8] demonstated the versatility of lipase catalyzed transesterification and transacylation chain scission as a route to low molecular weight poly(ε-caprolactone) and block copolymers. In this communication, a new methodology of poly(lactide) (PLA) depolymerization is introduced as a general route to controlled molecular weight, end-group functionality and complex macromolecular architectures in a single step procedure using nucleophilic catalysts (Scheme 1). Nucleophilic catalysts (*i.e.*, tertiary amines, pyridines, imidazoles and tertiary phosphines)[9–12] have been shown to accelerate a wide variety of processes including the 'living' ROP of lactide, initiated from primary alcohols, in the presence of either 4-(dimethylamino)pyridine (DMAP) or 4-pyrrolidinopyridine (PPY).[13] The 'living' character is a manifestation of the rapid initiation and the weakly nucleophilic propagating species (secondary alcohol) that is active only to the cyclic diester monomer, precluding undesirable transesterification reactions. The new depolymerization strategy is based on a single transesterification reaction that should occur between a primary alcohol and poly(lactide), in the presence of DMAP to selectively cleave the PLA chain and produce an α-chain-end bearing the ester of the alcohol and a ω-chain-end having a secondary hydroxy, which is dormant to subsequent reactions (Scheme 1).



Scheme 1 Depolymerisation cycle.

Model reactions were performed to demonstrate the selectivity of the DMAP catalyzed transesterification of primary alcohols with poly(lactide). Excess of either benzyl alcohol or α-methylbenzyl alcohol were reacted with lactide in the presence of DMAP in CH_2Cl_2 at 38 °C (Scheme 2). The lactide was ring-opened by the benzyl alcohol with the formation of the benzyl ester. However, quantitative transesterification of the diester ring-opened product, by the excess benzyl alcohol afforded the monoester, **1**.[14] Conversely, the α-methylbenzyl alcohol ring-opened lactide produced quantitatively the diester product with no evidence of adverse side reactions, **2**.[15] This data clearly demonstrates the susceptability of lactic acid derivatives towards selective transesterification with primary alcohols and confirms that secondary alcohols are dormant towards transesterification with the ring-opened products.

The feasibility of the organocatalytic chain scission of poly(lactide) was demonstrated with several modest molecular weight polymers, to discern the end-groups and molecular weight, including; poly(D,L-lactide) having an average DP of 120 and a polydispersity of 1.14 (**3**) and a poly(L-lactide) having an average DP of 88 and a polydispersity index of 1.06, **4**. In addition, two commercially available high molecular weight poly(L-lactides) (Mn 50 000 g mol^{-1}, M_w/M_n = 1.60, **5**, and M_n 100 000, M_w/M_n = 1.61, **6**) were also used to demonstrate the generality of the procedures. Various compositions of benzyl alcohol together with 2.5 equivalents of either PPY or DMAP were allowed to react in solution (36 °C, CH_2Cl_2) with **3**.[16] The size exclusion chromatography (SEC) data (Fig. 1) clearly shows a systematic decrease in the hydrodynamic volume with benzyl alcohol content. Consistent with the SEC results, predictable molecular weights, determined from end-group analysis (^{1}H-NMR), were obtained from the alcohol to polymer ratio, further demonstrating the versatility of the transesterification approach (**7–9**, Table 1). The ^{1}H-NMR spectra clearly show the presence of the benzyl ester α-chain end and the ω-hydroxy chain-end.[13] The reactions were performed in either solution



Scheme 2 Model compounds.

 DOI: 10.1039/b106125a

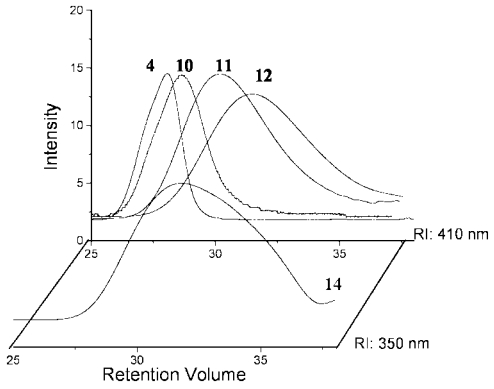


Fig. 1 SEC chromatography.

(36 °C, CH_2Cl_2) or bulk (135 or 185 °C for the D,L- or L-lactide, respectively) in the presence of either PPY or DMAP. The low temperature solution reactions took between 2 and 4 days and were particularly sluggish in the case of DMAP, whereas the bulk reactions took only 15–30 min., irrespective of the catalysts. Notably, these procedures are general and applicable towards high molecular weight commercial poly(lactides) (samples **13**–**14**, Table 1). Pyrenebutanol was used as the nucleophile and the reaction was followed by SEC using a diode array UV detector, **11**, Fig. 1. This data clearly shows that the pyrene is statistically distributed throughout the sample, confirming the utility of the procedure as a general route to functional poly(lactides). The use of α-methylbenzyl alcohol as the nucleophile in the transesterification with poly(lactide) did not result in a molecular weight or end-group change.

The organocatalytic transesterification of poly(lactide) to novel macromolecular architectures and block copolymers is demonstrated by the use of pentaerythritol and monohydroxy functional poly(ethylene oxide) (PEO) oligomers that produced either star-shaped (**15**–**17**) or block polymers (**18**–**21**), respectively. The reactions were performed in bulk and, at these temperatures, the homogeneous mixtures allowed effective transesterification for both of the high molecular weight poly(lactide) samples investigated. In each case, the ^{1}H-NMR spectra clearly show the resonances associated with the transesterification alcohol as well as the resonances associated with the hydroxy chain end, allowing molecular weight determination. In each case, the molecular weight of the polylactide was comparable to the alcohol-to-polymer ratio and the polydispersities were monomodal with no evidence of either of the homopolymers. These combined data clearly demonstrate the versitility of the organic catalyzed chain scission approach to functional poly(lactide) block copolymers and architectures in a single-step one-pot aproach.

Table 1 Depolymerization of polylactide: reactivity of assorted alcohols

Entry	PLA	Alcohol	Target DP	Exptl DP[e]	PDI[f]

Stereoselective preparation of highly functionalized (*Z*)-3-magnesiated enoates by an iodine–magnesium exchange reaction

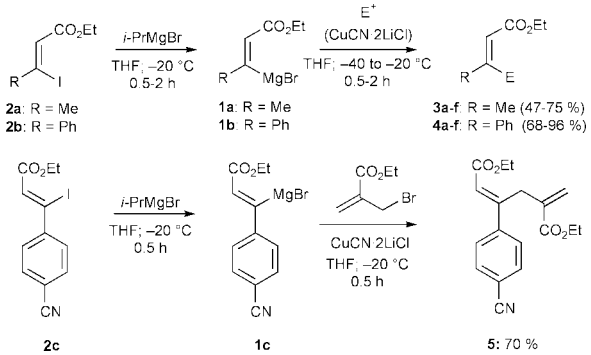
Ioannis Sapountzis, Wolfgang Dohle and Paul Knochel*

Department Chemie, Ludwig-Maximilians-Universität München, Butenandstr. 5-13, Haus F, D-81377 München, Germany. E-mail: Paul.Knochel@cup.uni-muenchen.de; Fax: +49-089-2180-7680; Tel: +49-089-2180-7681

Received (in Cambridge, UK) 12th July 2001, Accepted 5th September 2001
First published as an Advance Article on the web 27th September 2001

3-Iodoenoates are converted into the corresponding alkenylmagnesium species with complete retention of configuration of the double bond; both direct reaction and copper(I)-mediated reactions with various electrophiles provide polyfunctional enoates.

Functionalized organometallics are key intermediates for the synthesis of complex polyfunctional molecules.[1] Although organozinc reagents have been proven to tolerate many functional groups, their low reactivity precludes their reaction with some electrophiles.[1] Recently, we have shown that the iodine–magnesium exchange reaction allows the preparation of highly functionalized aryl and heteroaryl magnesium reagents[2,3] and this methodology has also been used to access alkenylmagnesium compounds.[4] Since the stereoselective preparation of stereochemically well defined *E*- or *Z*-alkenylmagnesium compounds is not possible by the direct insertion of magnesium into *E*- or *Z*-alkenyl halides, the iodine–magnesium exchange reaction may be a unique way of preparing stereochemically pure *E*- or *Z*-alkenylmagnesium derivatives.[5] Especially useful for synthetic applications are organometallic reagents bearing functional groups in close proximity to the carbon–magnesium bond in an arrangement which provides an umpolung of the standard reactivity.[6] This led us to investigate the stereoselective preparation of 3-magnesiated enoates[7] of type **1** displaying a d^3-reactivity.[6] The required 3-iodoenoates of type **2** are readily available by literature procedures.[8] Thus, the reaction of (*Z*)-ethyl 3-iodocrotonate (**2a**) with isopropylmagnesium bromide in THF at −20 °C for 2 h leads to the desired (*Z*)-ethyl 3-magnesiated crotonate (**1a**). After quenching with an electrophile, products of type **3** are obtained in good yields (Scheme 1, Table 1). (*Z*)-Ethyl 3-iodocinnamate (**2b**) behaves in a similar fashion; the I/Mg-exchange reaction is complete within 0.5 h as indicated by GC analysis of iodolized and hydrolyzed reaction aliquots. Transmetalation of **1a** or **1b** with the THF-soluble copper salt CuCN·2LiCl[9] provides a functionalized copper reagent with complete retention of the double



Scheme 1

Table 1 Stereoselective preparation of 3-substituted crotonates and cinnamates of type **3** and **4** obtained by the reaction of the 3-magnesiated crotonates **1a** and 3-magnesiated cinnamates **2b** with various electrophiles

[a] Yield of analytically pure products. [b] A transmetalation to a copper reagent with CuCN·LiCl (1 equiv.) was performed prior to the addition of the electrophile.

 DOI: 10.1039/b106195j

bond configuration. Reaction of the cuprate derived from **1a** with ethyl (2-bromomethyl)acrylate[10] provides the (*Z*)-unsaturated diester **3a** in 69% yield (>99% *Z*). Similarly, 3-magnesiated cinnamate **1b** furnishes after transmetalation with copper *E*-**4a** (92% yield; >99% *E*), thus showing in both cases complete retention of configuration of the double bond (entries 1 and 7 of Table 1).[11] Additionally we have prepared iodide **2a** as a 2:7 *E*/*Z* mixture.[12] We observed that both isomers undergo the I/Mg-exchange. However, iodolysis experiments indicate that the *E*-isomer of **1a** is less stable (30 min at −60 °C) which can be explained by the absence of chelation for this Grignard species. Due to the difficulty of preparing pure *E*-**2a** no additional experiments have been performed so far. The fact that the *E*-isomer of **2a** undergoes the I/Mg-exchange under similar conditions as the corresponding *Z*-isomer seems to indicate that chelation is not essential. The reaction of the copper derivatives of **1a**,**b** with 3-iodo-2-methylcyclopent-2-enone (−20 °C, 2 h) furnishes the dienic ketoesters **3b** and **4b** in 69% and 92% yield respectively (>99% *Z* for **3b** and >99% *E* for **4b**; entries 2 and 8). Reactive electrophiles like Me_3SnCl and tosyl cyanide react directly with the functionalized alkenylmagnesium reagents **1a**,**b** providing the *Z*-organotin derivative **3c** (72% yield; >99% *Z*) and the *Z*-1,2-cyanoester **4c** (92% yield; >99% *Z*); entries 3 and 9. After transmetalation to the copper derivative, **1b** reacts with PhCOCl to give the unsaturated 1,4-ketoester **4d** (96% yield; >99% *Z*). The unsaturated Grignard reagent **1a**,**b** adds directly to aldehydes and ketones, furnishing the corresponding lactones in 47–75% yield (entries 4–6 and 11–12). Finally, an additional cyano group is also well tolerated. Thus, ethyl 3-iodo-*p*-cyanocinnamate **2c** can be converted into the corresponding magnesium derivative (**1c**) under our standard conditions (*i*-PrMgBr (1 equiv); THF; −20 °C; 0.5 h) in high yield. After transmetalation with CuCN·2LiCl and reaction with ethyl (2-bromomethyl)-acrylate, the expected allylation product **5** is obtained (>99% *E*; 70% yield; Scheme 1).

In summary, we have demonstrated that new 3-magnesiated enoates can be prepared with high stereoselectivity (>99%) starting from isomerically pure *Z*-3-iodoenoates. These functionalized alkenylmagnesium reagents react with a range of electrophiles either directly or after transmetalation to the corresponding alkenylcopper species.[13] Extension of this method to other polyfunctional iodoalkenes and related organic halides is currently underway in our laboratories.

We thank Aventis Pharma and the Deutsche Forschungsgemeinschaft (Leibniz program) for financial support. We also thank BASF AG (Ludwigshafen), Chemetall GmbH (Frankfurt) and Degussa AG (Hanau) for generous gifts of chemicals.

5 The direct insertion of magnesium into alkenyl halides is not stereoselective. For example, the reaction of (*Z*)-1-bromooctene with magnesium in THF produces a 15:85 *E*:*Z* mixture of 1-octenylmagnesium bromide. The same behaviour is observed for the insertion of zinc dust into alkenyl iodides. In both cases, a radical mechanism operates. T. N. Majid and P. Knochel, *Tetrahedron Lett.*, 1990, **31**, 4413.

13 Typical procedure: preparation of 5-cyclohexyl-4-methylfuran-2(5*H*)-one: a dry and argon flushed 25 mL flask, equipped with a magnetic stirrer and a septum, was charged with **2a** (480 mg, 2 mmol). Dry THF was added and the mixture cooled to −20 °C. *i*-PrMgBr (3.7 mL, 0.54 M in THF, 2 mmol) was added dropwise. The exchange was complete after 2 h (checked by GC analysis of reaction aliquots) and the magnesiated crotonate **1a** was added *via* cannula to a solution of cyclohexanecarboxaldehyde (168 mg, 1.5 mmol) in THF (1.5 mL) cooled to −40 °C. After 30 min stirring at −40 °C the reaction was quenched with saturated NH_4Cl solution (2 mL) and poured into water (50 mL). The aqueous phase was extracted with diethyl ether (2 × 60 mL). The organic fractions were washed with brine (40 mL) then dried over $MgSO_4$ and concentrated *in vacuo*. The crude product was purified by flash chromatography (pentane–EtOAc 4:1) yielding the lactone **3e** as a pale colourless oil (200 mg, 73%).

First published as an Advance Article on the web 27th September 2001

The relatively hydrophobic ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate has been found to be totally miscible with aqueous ethanol between 0.5 and 0.9 mol fraction ethanol, whereas the ionic liquid is only partially miscible with either pure water or absolute ethanol; the ability to dissolve 1-butyl-3-methylimidazolium hexafluorophosphate in a 'green' aqueous solvent system has important implications for cleaning, purification, and separations using ionic liquids.

Current interest in ionic liquids[1,2] (IL) stems primarily from the heightened awareness of the potential applications for IL in Green Chemistry[3] and the associated emphasis on clean manufacturing processes. We have investigated IL as clean, environmentally benign solvents as replacements for VOCs in liquid/liquid separations and extraction processes.[4–9] From the 'green' perspective, an issue of primary importance is the separation and recovery of products from reaction systems, as well as the potential to recycle and reuse the reaction/separations media without generating secondary waste. There is concern about how to address issues such as cleaning and removal of *non-volatile* IL from surfaces or from solid products without using VOCs. For example, the commonly used 'hydrophobic' IL 1-butyl-3-methylimidazolium hexafluorophosphate, [C_4mim][PF_6],† is readily soluble in many common organic solvents but is relatively insoluble in most green solvents including water and sc-CO_2. Here, we demonstrate that [C_4mim][PF_6] can be solubilized in a green aqueous solvent system–ethanol/water.

In a traditional liquid/liquid separation processes, the principle of 'like dissolves like' forms the basis for the partitioning of solutes between the two phases; the less water-soluble the solute, the higher its affinity for the hydrophobic extracting phase. The partitioning of organic solutes in IL/water systems shows a correlation with the octan-1-ol/water partition coefficient.[6] This is consistent with solvatochromatic studies[10,11] which appear to show that IL have solvent characteristics similar to moderately polar organic molecules, but with some important and inherent differences.[12] The solvent parameters determined for IL can vary significantly depending on the experimental probe used, and depend upon the contributions from specific interactions between IL and solutes. Volume and hydrogen-bond acceptor terms appear to be most important to the overall solvating environment. In light of this, it is important to note that PF_6^- is a poor hydrogen-bond acceptor and consequently ethanol and water should not partition in significant concentrations to [C_4mim][PF_6].

Dullius *et al.*[13] have shown that tetrafluoroborate-containing IL display miscibility curves with water typical of a partially miscible two-component system with an upper thermal critical point and, at lower temperatures, the formation of a two-phase system containing IL-rich and aqueous-rich layers. Work by Friberg *et al.*[14] has highlighted the complexity of the co-miscibility/solvation profile in [C_4mim][PF_6]/water/nonionic surfactant systems and also noted that the IL exhibited only partial miscibility with hydrated ethanol.

During partitioning studies, we were intrigued by the variation in miscibility of IL with molecular solvents we had observed from simple bench tests, and in particular, the observation that [C_4mim][PF_6] was totally miscible with 80% aqueous ethanol and yet formed biphasic mixtures with both pure water *and* pure ethanol. This prompted a more detailed investigation of the phase behavior.

The ternary phase diagram for [C_4mim][PF_6] in contact with ethanol and water was determined by cloud-point titration[15] at 25 °C and is shown in Fig. 1. [C_4mim][PF_6] is partially miscible with both pure water and with pure ethanol. Regions of biphasic coexistence extend along the [C_4mim][PF_6]/H_2O and [C_4mim][PF_6]/ethanol axes, respectively. The solubility limit of absolute ethanol in the IL was determined to be 10.1 wt% and the solubility of water was 1.2 wt%. The water content of saturated [C_4mim][PF_6] has been reported in the literature ranging from 1.2 to 2.3 wt%,[7,16,17] corresponding to a mol fraction between 0.16 to 0.27. The region of complete miscibility of the three components, water, ethanol, and [C_4mim][PF_6], is shown between the two binodal curves and extends from the EtOH/H_2O axis.

To further our characterization of the ethanol/water solubility in [C_4mim][PF_6], the distribution of ethanol and water to the IL was determined (Fig. 2). Samples containing 2 mL of IL were contacted with an equal volume of aqueous ethanol solution labeled with a ^{14}C-ethanol tracer.[12] The distribution of ethanol was determined from the radiotracer partitioning, and the water content of the IL phase was measured by Karl Fischer titration.[12] In the biphasic regions, the distribution of ethanol is

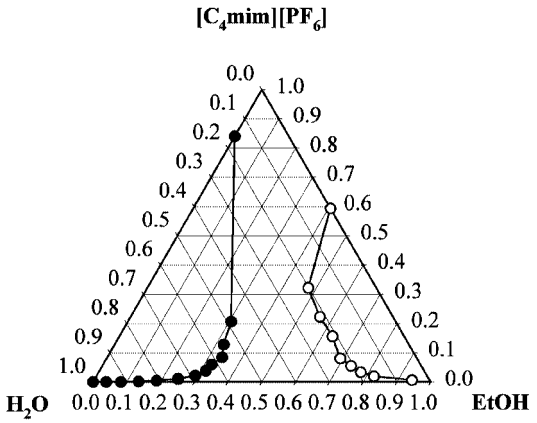

Fig. 1 Triangular phase diagram for ternary compositions of [C_4mim][PF_6], ethanol, and water determined at 25 °C and plotted as mol fraction. The region to the left of the binodal line, -●- is biphasic with water- and [C_4mim][PF_6]-rich phases; the region to the right of the line -○- is biphasic comprising ethanol- and [C_4mim][PF_6]-rich phases. In the central region, the three components are totally miscible and form a single monophasic solution.

 DOI: 10.1039/b106601n

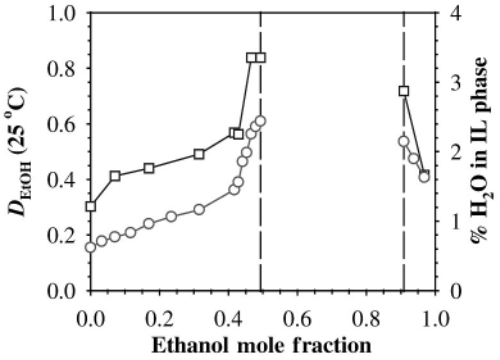

Fig. 2 The distribution ratios at 25 °C of ethanol (D_{EtOH} = ○) and water content of the IL phase (□) in 1 : 1 volume mixtures of [C_4mim][PF_6] and aqueous ethanol as a function of initial mol fraction of ethanol in the aqueous phase prior to contact with the IL phase. The monophasic region is bounded by the vertical dashed lines.

less than 1, which indicates the tendency for ethanol to remain in the aqueous phase. For the two-component [C_4mim][PF_6]/water system, the distribution ratio for the ethanol tracer between the IL and water is only 0.16. Successive increases in the mol fraction of ethanol cause an increase in ethanol distribution ratios up to a maximum of 0.61 at 0.5 mol fraction of ethanol in water. In the range 0.4–0.5 mol fraction, the distribution of ethanol to [C_4mim][PF_6] and the water content of the IL increases dramatically, and for 0.5–0.9 mol fraction the system is monophasic, shown by the vertical lines in Fig. 2. Above 0.9 mol fraction, a biphasic mixture is once again obtained.

The solubility of both ethanol and water in the IL phase increases in the presence of the other component, leading to the large homogeneous region in the phase diagram. The D_{EtOH} and water content data shown in Fig. 2 indicate that ethanol and water are dissolved together in the IL. Both the D_{EtOH} and water content increase linearly with X_{EtOH} from 0 to 0.40, where a sharp rise in both is maintained until the miscibility region. At X_{EtOH} = 0.90 a biphasic region is again observed and D_{EtOH} and water content decrease with the addition of ethanol.

The liquid structure and association in ethanol/water compositions has been the subject of extensive study;[18] when X_{EtOH} < 0.2, ethanol molecules cluster with the ethyl chains forming a hydrophobic core surrounded by water molecules. At 0.2 < X_{EtOH} < 0.8, a sandwich-type cluster containing extended chains of hydrogen-bonded ethanol and water occurs. The interactions that could occur between the water/ethanol clusters and the IL to lead to the total miscibility region is not yet clear. Free-volume cavities, or void space within the IL matrix[17] may allow ethanol and water to be dissolved together, whilst maintaining the bulk ethanol/water hydrogen-bonding structure with only weak interactions between the alkyl-groups of the IL and the hydrophobic ethyl-substituents of the water/ethanol chains.

A comparison of the vapor phase compositions above the [C_4mim][PF_6]/water/ethanol mixtures with ethanol/water mixtures only was made using SPME/GC. No discernable differences in the ethanol/water composition of the gas vapor phase was observed. This adds to our supposition that ethanol/water compositions mix with the IL whilst maintaining the bulk ethanol/water hydrogen-bonded structure.

The observation that [C_4mim][PF_6], regarded as a hydrophobic IL, can be dissolved in a 'green' aqueous solvent system has important implications for purification and separations from IL. As shown here, the addition of a solute or combination of solutes dramatically affects the solution behavior of IL, highlighting the need to fully understand these systems and instances in which their solution chemistry may vary from that of traditional organic solvents. At a practical level, these results show a method by which [C_4mim][PF_6] can be dissolved and cleaned from, for example, a reaction vessel or a solid product without using volatile chlorinated organic solvents. The IL can be recovered by distilling the water/ethanol azeotrope or by changing the solution composition to form a biphasic system.

Notes and references

† The synthesis of 1-butyl-3-methylimidazolium hexafluorophosphate from [C_4mim]Cl and HPF_6 (Ozark Fluorine Specialties) and the procedures used for the standard radiochemical assay utilized are described in ref. 12. The radiochemical assay of equal volumes of the two separated phases allows calculation of the distribution ratios directly from the activity of the two phases. ^{14}C-labeled ethanol was obtained from Sigma (St. Louis, MO). All aqueous solutions were prepared with deionized water that was purified with a Barnsted deionization system (Dubuque, IA) and polished to 18.3 MΩ cm. The water content of each ionic liquid or its mixtures was determined by Karl Fischer titration (Aquastar Karl Fischer titrator, EM Science, Gibbstown, NJ) with Composite 5 solution as the titrant in anhydrous methanol. The ternary composition diagram was determined by direct observation using the cloud-point titration method described in ref. 15.

First published as an Advance Article on the web 1st October 2001

Topological analysis of experimental and theoretical charge densities in the title complex [{2-$(Me_3Si)_2CLiC_5H_4N$}$_2$] 1 reveals the nature of the agostic deformation postulated for this complex: delocalization of the Li–C bonding electrons over the entire agostic alkyl group controls the formation of an acute Li–C–Si angle and thus a sufficient electronic saturation of the electron deficient lithium atom *via* secondary interactions.

Alkyllithium complexes are of fundamental interest in organic synthesis and as anion transfer reagents in organometallic synthesis. Their crystal structures display a remarkable range of bonding modes which have been compiled and rationalized in several surveys of this field.[1] In the title compound[2] featuring a formal lithium coordination number of only 2, 'secondary interactions', which compensate for the electron deficiency of the metal centre, should be of great importance in understanding not just the structure adopted by the complex, but also the reactivity of the species. Despite this, little is known about the details of such interactions which compensate for the electron deficiencies of the metal centres in their reduced coordination state, and include (i) close Li···Li contacts[3] and (ii) close 'agostic' type Li···H–C interactions—as evident in the title compound.[2] The importance of these Li···H–C agostic interactions was highlighted in early calculations on the trimeric lithium amide complex [{Li[μ-$N(CH_2Ph)_2$]}$_3$][4a] which concluded that Li···H–C interactions might account for 40% of the valence shell electron density for the lithium atom. Furthermore, agostic interactions[4b] are of particular interest in organotransition-metal chemistry in view of their potential relevance to important processes like C–H activation in catalytic reactions. Reliable ways of pinning down these interactions are still at a premium, notwithstanding the numerous examples reported on the basis of structural or spectroscopic measurements or of theoretical studies.

In a recent charge density study on an agostic compound we demonstrated that *topological analysis of experimental charge densities* can be used to identify β-agostic interactions in $EtTiCl_3$(dmpe) by locating the Ti···H bond critical point.[5] In this combined neutron and X-ray charge density study, however, we show that Li···H secondary interactions only play a minor role in compensating for the electron deficiency of the metal center. Fig. 1 shows the relevant molecular agostic fragment in **1** based on a precise neutron diffraction study at 20 K. This displays an acute Li–C1–Si2 angle of 88.8(2)°, leading to short Li···Si2, Li···C7 and Li···H7c contacts of 2.850(5), 2.658(5) and 2.320(6) Å, respectively. In addition, the presence of two further short intermolecular Li···H contacts [Li···H3b* = 2.329(5) and Li···H3c* = 2.245(5) Å] and a rather short Li···C3* contact of 2.496(4) Å were confirmed by the neutron diffraction study. All the Li···H contacts are remarkably short (*ca*. 0.7 Å less than the sum of the van der Waals radii; *cf*. the Li···H distance of 2.043(1) Å in crystalline lithium hydride).[6] Thus, they might be interpreted as agostic Li···H interactions. However, no significant C–H activation is evident from the neutron diffraction data [C7–H7a = 1.089(4), C7–H7b = 1.086(4), C7–H7c = 1.087(4) Å; C3–H3b = 1.085(3), C3–H3c = 1.097(4) Å]. We have therefore performed a combined X-ray and neutron charge density study[7,8] to explore for the first time the nature of Li···H–C agostic interactions on the basis of an experimental topological analysis of the electron density $\rho(\boldsymbol{r})$ of **1** using the 'Atoms in Molecules' (AIM) approach of Bader.[9,10]

DFT calculations at the B3LYP/6-311G(3d,3p) level of theory[11] on several monomeric model systems such as the donor-free species $LiCMe_2SiMe_3$ **1a** show alkyl coordination geometries (Li–C_α–Si = 85.3°, Li···H_γ = 2.11–2.29 Å) rather similar to that of the agostic alkyl backbone Li–C1–Si2–C7–H7c (Li–C_α–Si_β–C_γ–H_γ) in **1**. The agostic deformations in **1** clearly do not originate from any of the following: (i) the coordination of the σ-donor ligand, despite the short Li–N distance of 1.9508 Å; (ii) π-electron delocalization involving the aromatic pyridine ring; (iii) secondary interactions such as Li···Li contacts or intermolecular Li···H contacts; or (iv) other crystal-packing effects. Thus, **1** seems an ideal experimental benchmark system to study the nature of Li···H–C bonding, since we can focus our discussion solely on the bonding situation of the agostic backbone Li–C_α–Si_β–C_γ–H_γ of **1** (Fig. 1). Indeed, the topology of $\rho(\boldsymbol{r})$ of this fragment reveals the

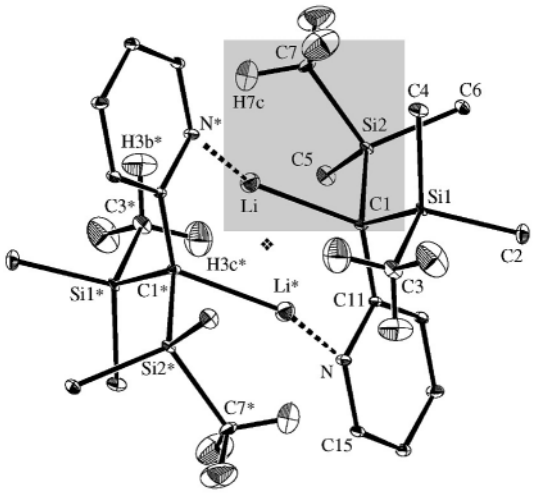

Fig. 1 Molecular structure of [{2-$(Me_3Si)_2CLiC_5H_4N$}$_2$] **1** at the 50% probability level and 20 K. Only relevant hydrogen atoms are shown. Atoms labeled with or without * are related by a crystallographic inversion centre at the midpoint of the Li–Li* vector. The location of the agostic alkyl group is indicated by a shaded area.

 DOI: 10.1039/b105452j

unusual electronic nature of the alkyl ligand. We first note the absence of a Li···H_γ bond critical point (bond CP)[9] in the experimental or theoretical $\rho(\boldsymbol{r})$ maps, indicating a lack of any significant agostic interaction. This accords with the absence of any significant C_γ–H_γ bond activation revealed by the low temperature neutron diffraction study. At this stage, the origin of the deformation of the alkyl group remains unclear.

However, analysis of the geometry of the Li–C_α–Si_β–C_γ–H_γ backbone gives some guidelines by revealing two significantly different C–Si bonds: C_α–Si_β and C_γ–Si_β [C1–Si2 = 1.8592(4) and Si2–C7 = 1.8947(7) Å, respectively]. While C_γ–Si_β seems to be slightly enlarged compared with standard single C–Si bonds such as Si2–C5(6) or Si1–C2(4) [Si–C = 1.8781(7)–1.8888(6) Å], the C_α–Si_β bond length is clearly shortened. Furthermore, the discrepancy in Si–C bond lengths is accompanied by significant differences in the nature of the C_α–Si and C_γ–Si bonding as shown by the combined charge density study: the value of $\rho(\boldsymbol{r})$ at the bond CP, $\rho(\boldsymbol{r}_c)$, for the C_α–Si_β bond [$\rho(\boldsymbol{r}_c)$ = 0.86(2) e Å^{-3}] is clearly larger than that for the corresponding C_γ–Si_β bond [0.72(2) e Å^{-3}], hinting at an increased bond order in the C_α–Si *vs.* the C_γ–Si bond. This conclusion is supported by a pronounced bond ellipticity ε of 0.13 at the C_α–Si_β bond CP (see ref. 9 and Fig. 2 for a definition of ε). Tracing the bond ellipticity between C_α and Si along the bond path[9] reveals the unusual nature of this bond in comparison with the ellipticity profiles of the theoretical benchmark systems for a C–Si single (CH_3–SiH_3) and a C=Si double bond (CH_2=SiH_2) (Fig. 2).

We further note that the Li–C_α (Li–C1) bond in **1** is significantly longer than the corresponding distance in the theoretical reference molecule LiMe:[12] Li–C_α = 2.2049 *vs.* 1.966 Å; and that the topological features of $\rho(\boldsymbol{r})$ in the two compounds indicate that the Li–C bond in the former is weaker [$\rho(\boldsymbol{r}_c)$ = 0.150(2) *vs.* 0.30 e Å^{-3}], and has a pronounced bond ellipticity (ε = 0.12 *vs.* 0.0). This suggests that the unusual double bond character of the C_α–Si_β bond might be associated with a delocalization of the Li–C bonding electrons into the C_α–Si_β bonding region, as revealed by the relief map of the negative Laplacian,[9] $-\nabla^2\rho(\boldsymbol{r})$, in the Li,$C_\alpha$,$Si_\beta$-plane (Fig. 3). This effect might be related to negative (anionic) hyperconjugation.

In conclusion, we have demonstrated by a combined neutron and X-ray charge density study on the lithium–alkyl system **1** that secondary, agostic Li···H interactions are not necessarily paralleled by significant C–H activation. Despite our findings, C–H activation probably plays an important role in lithium organic chemistry and is certainly significant in the characteristic reactivity of lithium in salient reactions such as β-H-elimination or even metallation. Furthermore, our results clearly indicate that Li···H contacts in **1** are not responsible for the unusual alkyl deformation. These deformations seem more likely to be a result of electron delocalization of the Li–C_α bonding electrons over the entire (agostic) alkyl group, leading to a reduced Li–C_α–Si_β angle, a pronounced C_α–Si_β double bond character, short Li···Si_β, Li···C_γ and Li···H_γ distances, and thus allowing a more efficient charge transfer between the electron deficient metal center and the agostic C_α–Si_β–C_γ–H_γ backbone.

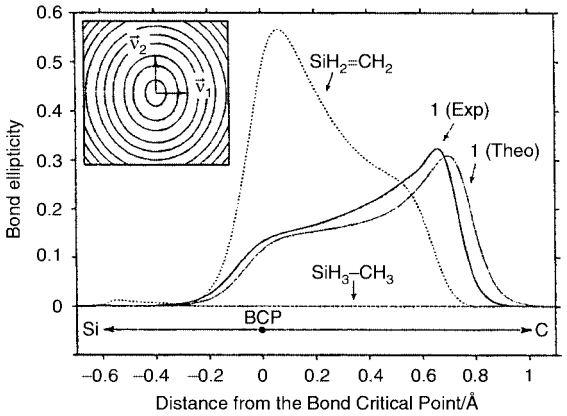

Fig. 2 Bond ellipticity[9] along the C1–Si2 bond path of **1**. The definition of the bond ellipticity is illustrated by the $\rho(\boldsymbol{r})$ contour map in the left corner showing the charge density in the plane perpendicular to the bond path at the C–Si bond CP of SiH_2=CH_2. ε is thus a measure of the non-spherical charge distribution of $\rho(\boldsymbol{r})$: $\varepsilon = \lambda_1/\lambda_2 - 1$. λ_i are eigenvalues of the corresponding eigenvectors $\vec{v}_1$ and $\vec{v}_2$ of the Hessian matrix of $\rho(\boldsymbol{r})$.

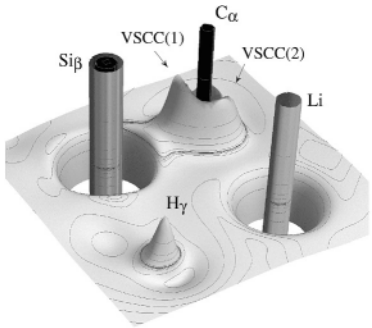

Fig. 3 Relief map of the negative Laplacian, $-\nabla^2\rho(\boldsymbol{r})$, showing the close-to-merging situation of the two valence shell charge concentrations VSCC(1) and VSCC(2) in the Li,C_α,Si_β-plane. Normally, the VSCCs on sp^3-hybridized carbon atoms are clearly separated. This effect might indicate a delocalization of the Li–C bonding electrons into the C_α–Si_β bonding region.

Received (in Cambridge, UK) 10th August 2001, Accepted 29th August 2001
First published as an Advance Article on the web 19th September 2001

A new family of discotic liquid crystals, potentially electron carriers, has been synthesised, some members of which exhibit a particularly rich thermotropic behaviour.

The discovery that 2,3,6,7,10,11-hexakis(hexylthio)triphenylene (HHTT), in a highly ordered helical (H) mesophase,[1] exhibits a charge carrier mobility (μ) on the order of $\mu = 0.1$ cm^2 V^{-1} s^{-1}, has created wide scientific and technological interests in discotic liquid crystals[2a] as potential candidates for optoelectronic applications.[2b] Since then, the charge carrier mobilities of several mesogens based on hexabenzocoronene, triphenylene, and phthalocyanine aromatic cores have been studied.[3] Values of μ as high as 0.5 cm^2 V^{-1} s^{-1} have been reported for the columnar mesophase of hexabenzocoronene derivatives.[4] Such mobility approaches the corresponding value for the intersheet mobility in graphite (3 cm^2 V^{-1} s^{-1}) and matches those of single crystals of aromatic compounds.[4] However, most of the discotic mesogens reported so far are better hole carriers than electron carriers.[3a] Only a few examples of electron carrier discotic mesogens exist to date[5,6] creating, therefore, the need for new materials.

In this communication, we report the synthesis and preliminary mesophase characterisation of a new type of discotic mesogen **4a–d**. The presence of six nitrogen atoms in the aromatic core is anticipated to significantly increase the first reduction potential facilitating electron injection and high electron mobility.[7]

The synthetic route is short and efficient (Scheme 1). The first step consists of the condensation of hexaoxocyclohexane octahydrate (**1**) with 4,5-dichlorobenzene-1,2-diamine (**2**) to afford the 2,3,8,9,14,15-hexachlorodiquinoxalino[2,3-*a*:2′,3′-*c*]phenazine **3** in 94% yield.[8] The second step is the nucleophilic aromatic substitution of **3** by alkyl thiolates.† The yield of hexakis(alkylthio)diquinoxalino[2,3-*a*:2′,3′-*c*]phenazines **4a–d** ranges between 29 and 67% depending on the ease of purification. Compounds **4b**,**c,** exhibiting a crystalline phase at room temperature, are easily purified by recrystallization whereas mesogens **4a** and **4d** having an X phase at room temperature necessitate several recrystallizations and chromatographic separations. The solubility of **4a–d** is good in common organic solvents such as $CHCl_3$ and THF. The structure and purity of **4a–d** were confirmed by ^{1}H- and ^{13}C NMR spectroscopy, mass spectrometry, and UV-visible absorption spectroscopy. In deuterated chloroform, the ^{1}H-NMR chemical shift of the aromatic protons moves to higher field on increasing the concentration, ranging from 8.26 ppm at 1.3×10^{-3} M to 8.11 ppm at 2.85×10^{-2} M.

The thermotropic behaviour of **4a–d**, as studied by differential scanning calorimetry (DSC), is strongly dependent on thioalkyl chain length (Table 1). Particularly unexpected is the number of mesophases observed upon heating for **4b** and **4c** (three and five, respectively) whereas **4a** and **4d** exhibit only two mesophases from room temperature to decomposition around 250 °C. This rich thermotropic behaviour and dependence on flexible chain length of **4a–d** is reminiscent of some LC derivatives of truxene and thiatruxene.[2b] Interestingly enough, they all have in common the same molecular shape of the aromatic core, *i.e.* a three-arm star shape rather than a disk-like shape. No clearing temperature, below decomposition, was observed for any of the four mesogens.

The types of the mesophases have been tentatively assigned based on the observations made by polarised optical microscopy and X-ray diffraction.‡ Characteristically, besides crystalline phases (Cr), LC mesophases and non-specified phases (X) were observed. Phases X are not solid, rather waxy and show birefingence. Powder diffraction patterns from these phases

[a] Based on optical microscopy and X-ray diffraction investigations. [b] Measured by DSC at heating and cooling rate of 10° min^{-1}. The data from second heating scan and first cooling scan are given and were found to be fully reproducible. [c] Decomposition occurs around 250 °C.

 DOI: 10.1039/b107135c

exhibit less order than for the solid crystalline phases but a 3-dimensional correlation of molecules is maintained, which is manifested by maxima superimposed on the halo of the isotropic alkyl side chains. We propose phases X to be mesophases of higher, three dimensional order. The presence of highly ordered mesophases for compounds **4a–d** is particular important in view of charge transport properties since well-ordered plastic crystals (PC) or helical columnar phase (H) are known to exhibit higher charge carrier mobilities than less-ordered LC mesophases.[1,6,9] LC phases show birefringence and a significant fluidity. The textures are rather unspecific for **4b–d**, whereas **4a** displays a fan-like texture with large domains, spontaneously forming above the Cr–LC transition, which can be frequently found for columnar phases. Interestingly, the X-ray investigation of the mesophases reveals rather unconventional supramolecular arrangements. Beside halos with maxima at 0.45 nm for the average distance of isotropic alkyl chains and shoulders at 0.37–0.40 nm assigned to average intracolumnar distances separating aromatic cores, several maxima are observed at small angles which can not be unambiguously indexed for all observed mesophases. Fig. 1 depicts the X-ray pattern of **4c** at 170 °C, for which we could obtain the clearest assignment of the diffraction pattern. Three dominant diffraction peaks are found which can be attributed to an oblique unit cell with the parameters a = 2.24 nm , b = 2.13 nm and β = 83.5°. The calculated data is in agreement with the observed distances. The unit cell is significantly smaller than the diameter of **4c**, which is 1.30 nm for the core including the sulfur atoms and between 3.4 and 4.2 nm depending on the orientation of the alkyl chains in the all-*trans* conformation. Thus, like in hexakis(alkylthio)triphenylenes, this implies a large degree of penetration of the alkyl chains in the aliphatic region of the neighbouring column.[11] Similar data, but with lower intensity, was obtained for **4d**, however, for **4a** and **4b** the X-ray patterns remain complex for the fluid phase at high temperature. The precise supramolecular order of these molecules is under investigation. 2D X-ray data of oriented samples and solid state NMR is in progress and will be published in detail elsewhere.

Compounds **4a–d** strongly absorb in the visible range. In toluene solution, the absorption maxima at the longest wavelength (λ_{max}) of **4a–d** are identical, located at 470 nm with an absorption coefficient (ε) of 105000 M^{-1} cm^{-1}. These compounds emit weakly in dilute solution, when excited either at 254 or 366 nm. In the solid state, absorption peaks are broadened and bathochromically shifted. This shift decreases for longer thioalkyl chains, *i.e.* λ_{max} = 503, 496, 494, and 491 nm for **4a–d**, respectively.

In conclusion, a new type of discotic mesogen, potentially electron carriers, is reported. These compounds have one or several mesophases at low temperature and one or more LC mesophases at high temperature. Future work involves: the investigation of charge carrier mobility, the synthesis of new members of the same family with lower clearing temperatures, and detailed X-ray investigations.

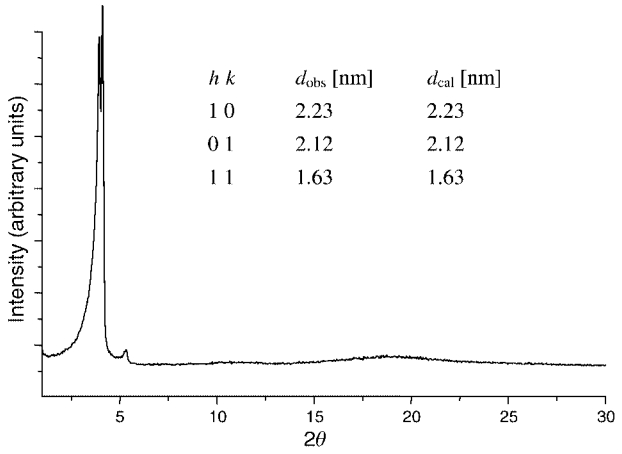

Fig. 1 X-Ray diffraction pattern of **4c** measured at 170 °C using Cu-Kα radiation. d values are calculated for an oblique unit cell with a = 2.24 nm, b = 2.13 nm, β = 83.5°.

Notes and references

† The synthesis and characterisation of 2,3,8,9,14,15-hexakis(octylthio)-diquinoxalino[2.3-*a*:2′,3′-*c*]phenazine (**4b**) is given as a representative example. An excess of octane-1-thiol (0.95 ml, 5.47 mmol) and potassium carbonate (2.53 g, 18.32 mmol) are added to a solution of 2,3,8,9,14,15-hexachlorodiquinoxalino[2,3-*a*:2′,3′-*c*]phenazine **3** (304 mg, 0.51 mmol) in 100 ml *N*,*N*-dimethylformamide. This solution is heated at 85 °C and stirred for 5 days. The reaction mixture is then poured into a large volume of water and neutralised with hydrochloric acid. The yellow precipitate is filtrated and washed with copious amounts of water. Two recrystallisations in ethanol with toluene afforded the title compound as a yellow powder in 67% yield. ^{1}H-NMR (250 MHz, $CDCl_3$, 30 °C, 2.85 10^{-2} M): δ = 8.11 (s, 6H, arom.), 3.17 (t, 12H, aliph.), 1.83 (m, 12H, aliph.), 1.54 (m, 12H, aliph.), 1.31 (m, 48H, aliph.), 0.89 (t, 18H, aliph.). ^{13}C-NMR (63 MHz, $CDCl_3$, 30 °C): δ = 144.20 (arom.), 142.39 (arom.), 141.37 (arom.), 123.19 (arom.), 31.81 (aliph.), 29.26 (aliph.), 29.17 (aliph.), 28.11 (aliph.), 22.63 (aliph.), 14.06 (aliph.). FD-MS: $C_{72}H_{108}N_6S_6$, calculated 1250.6, found 1249.8. UV-vis: λ_{max} = 470 nm, ε = 105 000 M^{-1} cm^{-1}.

‡ X-Ray diffraction investigations were carried out using a Siemens D 500 Kristalloflex with a graphite-monochromatized Cu-Kα X-ray beam. This one was emitted from a Rotating Rigaku RV-300 anode. The temperature of the sample on a copper sample holder was monitored with a bimetal sensor, previously calibrated by reference measurements.

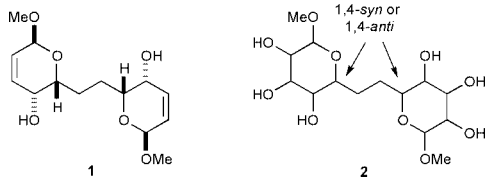
Received (in Cambridge, UK) 24th August 2001, Accepted 5th September 2001
First published as an Advance Article on the web 1st October 2001

The complex OsO_4·(*S*,*S*)-1,2-diphenyl-*N*,*N*′-bis(2,4,6-trimethylbenzyl)ethane-1,2-diamine is an effective reagent for the desymmetrisation of *meso*-1,2-bis(3,6-dihydro-2*H*-pyran-2-yl)ethanes by asymmetric dihydroxylation; this process, whose sense of diastereoselectivity depends on substitution and stereochemistry, has been exploited in the synthesis of a *C*-linked analogue of allolactose.

Previously, we have described methods for the synthesis of some stereoisomeric *C*-linked disaccharide mimetics.[1] A key feature of our approach was that diastereomeric mimetics could be prepared by minor variation of a general reaction sequence. For example, complementary undirected[2] and directed[3] dihydroxylation reactions were exploited in the two-directional elaboration of diols (such as C_2-symmetric **1**) to give products of general stucture **2** with 1,4-syn stereochemistry. In order to

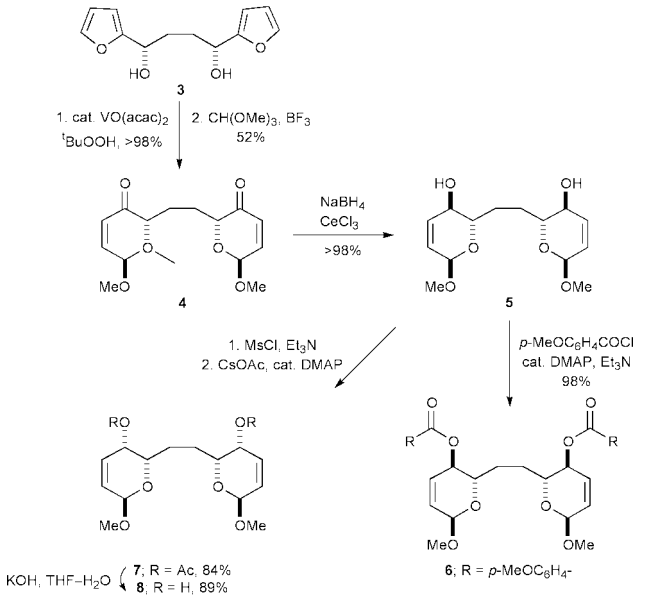


synthesise the mimetics with the opposite 1,4-stereochemical relationship, an efficient method for the desymmetrisation[4] of the *meso* difuryl diol[1] **3** or one of its derivatives would be required.

Oxidative ring expansion of the furan rings of the diol **3** using $VO(acac)_2$–^{t}BuOOH, and acetalisation, gave the dipyranone **4** as a 75 : 25 mixture of *meso* and unsymmetrical anomers, from which the required *meso* diastereoisomer was crystallised in 52% yield (Scheme 1). Reduction of **4** under Luche's conditions gave the diol **5** in > 98% yield, which was converted into the *p*-methoxybenzoyl diester **6**. The diastereoisomeric diol **8** was synthesised by hydrolysis of the diacetate **7** obtained by inversion of the dimesylate derived from **5**.

Treatment of **6** with OsO_4·**10** at −20 °C lead to complete consumption of the starting material and gave the desymmetrised diol **9**† as a single diastereoisomer in 84% yield with 60% ee (Scheme 2). Dihydroxylation occurred *anti*[2] to the pseudo-equatorial allylic *p*-methoxybenzoyloxy group. Previously, prochiral cyclic dienes have been desymmetrised using AD-mix β, with dihydroxylation occurring on the outside of their bicyclic structure.[6] This natural diastereoselectivity could be reversed by delivery of OsO_4·**10** to the double bond: dihydroxylation of **8** was highly *syn* selective, and gave, after peracetylation, the tetraacetate **11** with 93% ee (87% yield based on recovered starting material). We believe that diastereoselectivity stems from hydrogen bonding of the reagent to the pseudoaxial hydroxy group,[3] and that this reaction is the first example of a directed asymmetric dihydroxylation.

As a prelude to the diastereoselective functionalisation of the remaining double bond of **9**, we studied the functionalisation of the allylic *p*-methoxybenzoate **15** using iodine and silver benzoate in dry carbon tetrachloride (Scheme 3).[7] In view of the



Scheme 1

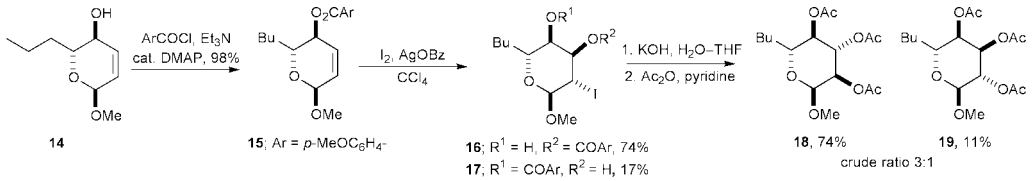
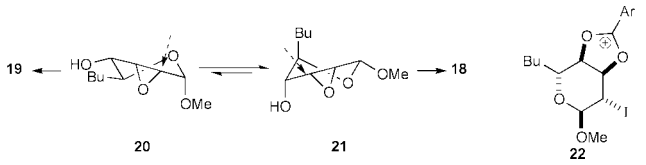


Scheme 3



Scheme 4

rigorously dry reaction conditions of these reactions, the *syn* stereospecificity of this process (**15** → **16**, **17**) and the absence of benzoate from the products are remarkable. Presumably, participation[8] of the *p*-methoxybenzoyloxy group gave the dioxonium ion **22** which was stable to the reaction conditions; subsequent hydrolysis of this intermediate, presumably on aqueous work-up, gave the observed *syn* hydroxy *p*-methoxybenzoates **16** and **17**. In general, *syn* hydroxyesters are only obtained when Prévost reactions are conducted in the presence of water because, under these conditions, the intermediate dioxonium is hydrolysed *in situ*.[9]

Treatment of the iodoesters **16**–**17** (4:1 mixture of regioisomers) with potassium hydroxide in water–THF, followed by peracetylation, gave a 3:1 diastereomeric mixture of the triacetates **18** and **19**. Presumably, **16** and **17** were converted into the same epoxide which was opened by hydroxide ion.‡ *trans*-Diaxial opening[11] of the major conformer (**20** → **19**, Scheme 4) requires opening at the site which is β to the two oxygens of the acetal;[12] consequently, reaction *via* the conformer **21** (→ **18**)—that is, away from the two β oxygens[12]—is competitive with, and in fact dominates over, this process.

In a similar vein, treatment of the desymmetrised compound **23** with iodine and silver benzoate in dry carbon tetrachloride, followed by treatment with aqueous potassium hydroxide solution, gave the *C*-linked disaccharide mimetic *ent*-**25** (Scheme 5); peracetylation gave the hexaacetate **24** in 64% yield over 3 steps. The *C*-linked allolactose mimetic **25**, in which C-6 of the galactose ring has been replaced by a methoxy group, could clearly have been prepared by the same synthetic methods using the enantiomeric diamine ligand in the key desymmetrisation step. It has been suggested that stable analogues of allolactose, the intracellular inducer of the lactose (*lac*) operon, may also exert negative control over gene expression.[13]

Our synthesis of the *C*-linked disaccharide mimetic *ent*-**25** is unusual in that neither ring derives directly from a sugar, though Vogel has reported the use of a non-carbohydrate based template to introduce one of the sugar rings to some *C*-linked disaccharides.[14] Key steps in our synthesis include the desymmetrisation of a highly functionalised *meso* di-DHP using an asymmetric dihydroxylation reaction, and the use of a *p*-methoxybenzoate ester to control the stereospecificity of a Prévost reaction.

We thank EPSRC and Aventis for providing funds under the CASE scheme for new appointees, the Royal Society for a grant and Pfizer and AstraZeneca for strategic research funding.

Notes and references

† The absolute configuration of **9** was deduced by comparing the 500 MHz ^{1}H NMR spectra of its (*R*)- and (*S*)-Mosher diesters with those of the diol **13**, which was derived from the pyranone[5] (2*R*)-**12**.

First published as an Advance Article on the web 1st October 2001

The synthesis and aminohydroxylation of a series of acyclic allylic carbamates is described: the formation of a putative O=Os=NR linkage between the transition metal and substrate is proposed to account for the high levels of regioselectivity that were observed; proof of the structure of one of the aminohydroxylation products was obtained through X-ray crystallography.

The aminohydroxylation reaction has emerged as a particularly powerful method for the oxidation of alkenes, introducing both oxygen and nitrogen in a stereospecific manner.[1] The asymmetric variant of this reaction, as pioneered by Sharpless,[2] is adept at transforming alkenes into amino alcohols with high levels of enantioselectivity. However, control of the regiochemistry of oxidation can be difficult with mixtures frequently being formed. Our interest in this reaction derives from our work on the regio- and stereoselective dihydroxylation of allylic alcohols[3] and we sought to control the aminohydroxylation of these substrates. Early work on the asymmetric aminohydroxylation (AA) reaction of allyl alcohol by Landais and coworkers[4] suggested that these substrates might show high levels of regiocontrol. However, our own work,[5] and a further study by Landais,[6] has shown that substituted allylic alcohols are not oxidised with any appreciable regioselectivity. Janda and coworkers recently modified allylic alcohol substrates and developed a range of protecting groups that bias the AA reaction (Scheme 1):[7] these allow the formation of individual regioisomers with high selectivity when the alkene is monosubstituted and with moderate selectivity when the allylic alcohol becomes more heavily substituted.

We sought to control the regioselectivity of oxidation in a different way, by formation of a carbamate derivative of allylic alcohols (Fig. 1). When subjected to the aminohydroxylation regime, the carbamate group will be chlorinated and deprotonated to form a nitrene equivalent that acts as both the oxidant and nitrogen source for the aminohydroxylation reaction. Of course, as the putative RN=Os=O fragment is contained within the allylic alcohol, we should expect high control of regioselectivity in the ensuing oxidation event.

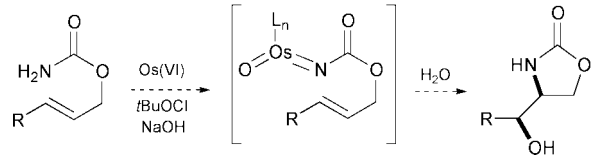

Fig. 1

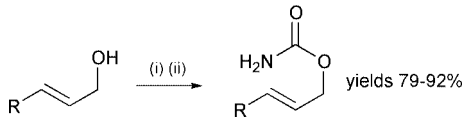
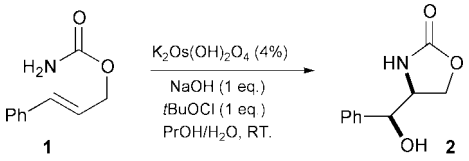
The following sequence was used to prepare allylic carbamates from the corresponding alcohol (Scheme 2) and, generally, the reaction was convenient and high yielding.



Scheme 2 *Reagents and conditions*: Cl_3CNCO; ii, K_2CO_3.

Preliminary studies concentrated on the oxidation of **1** under a range of conditions, mostly those developed by Sharpless (Scheme 3).§ Pleasingly, the reaction worked as planned, giving decent yields of hydroxyoxazolidinone **2**¶ from the allylic carbamate. Unfortunately, reaction with Sharpless' ligand $(DHQ)_2PHAL$ gave material that was racemic; this is surprising as the reactions were clearly faster in the presence of this amine ligand than without it. Other amine additives had mixed effects: quinuclidine was not shown to be efficient in promoting the reaction, whereas Hunig's base[6] gave good yields in a process that was still faster than that without any ligand at all. The reisolation of starting material was difficult to avoid and attempts to push the reaction to completion by increasing the amount of *t*BuOCl and NaOH in the mixture simply gave a more complex array of products.



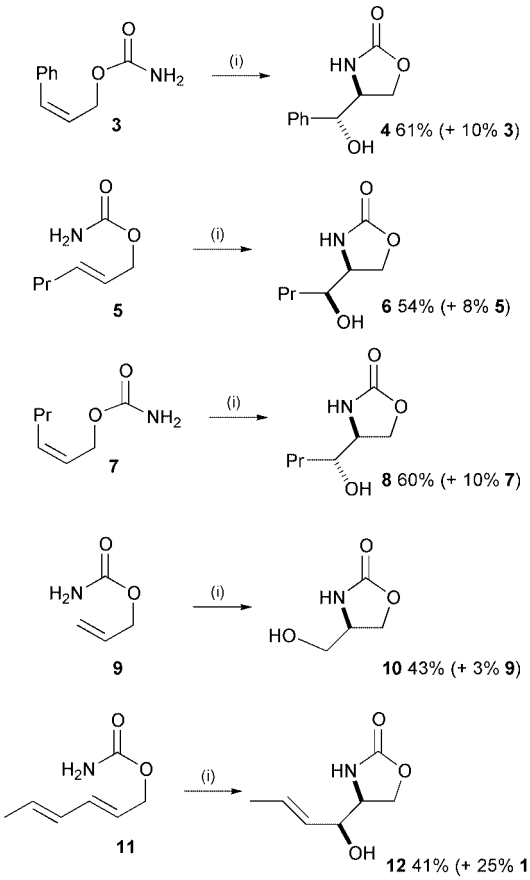
Ligand (5%)	Yield of **2** (%)	Recovered **1** (%)
$(DHQ)_2PHAL$	62	12
Quinuclidine	26	0
iPr_2NEt	59	23
None	42	23

Scheme 3

Buoyed by these encouraging results, we prepared a range of allylic carbamates and subjected them to cyclisation with catalytic potassium osmate and iPr_2NEt (Scheme 4). The reaction is clearly regioselective and stereospecific as shown by the selective formation of **2** and **4** from **1** and **3**, and of **6** and **8** from **5** and **7** respectively.

Most of the compounds shown in Scheme 4 have been reported previously in the literature[8] and we were able to

 DOI: 10.1039/b107253f



Scheme 4 *Reagents and conditions*: i, $K_2Os(OH)_2O_4$ (4%), NaOH (1 eq.), *t*BuOCl (1 eq.), *i*Pr_2NEt (5%), PrOH/H_2O, RT.

correlate the products from the aminohydroxylation reaction with that data. While compound **12** is novel, hydrogenation over palladium on carbon formed compound **6** in good yield (86%), thus allowing us to confirm the identity of **12**. In addition, we managed to obtain an X-ray crystallography analysis of **2** thus verifying its structure (Fig. 2).

The stereospecific (and suprafacial) nature of the addition leads us to postulate a mechanism based around that described in Fig. 1. A series of control experiments whereby **1**, **3**, **5**, **7**, **9** and **11** were subjected to all of the ingredients shown in Scheme 4, bar potassium osmate, gave no oxazolidinone products at all, thus ruling out a more conventional type of cyclisation reaction *via* an epi-ion.

Certainly, the success of these reactions depends on the presence of osmium which supports the *in situ* formation of a O=Os=NR fragment. The lack of enantioselectivity with Sharpless' catalysts is disappointing and could be due to a number of factors such as a lack of involvement of the ligand during the stereoselectivity determining step, disruption of the binding pocket by the carbamate tether or slow hydrolysis of the osmate ester thus promoting reaction *via* the (non-selective) second cycle.

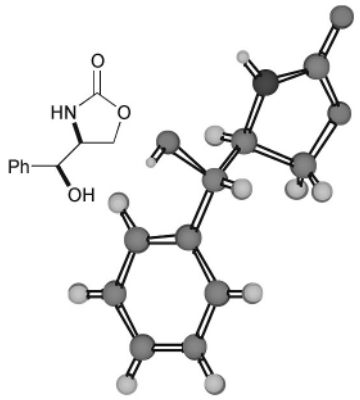


Fig. 2 X-ray structure of **2**.

To conclude, we have developed a completely regioselective regime for the hydroxyamination reaction of allylic carbamates. The reaction is stereospecific and proceeds with only catalytic amounts of transition metal. One might expect that the aminohydroxylation of chiral cyclic and acyclic allylcarbamates under these conditions should lead to diastereoselectivity as well as regioselectivity: this aspect of the work is currently under active investigation.

We are grateful to the EPSRC and Lilly for financial support of this project. AstraZeneca, GlaxoSmithKline and Pfizer are thanked for unrestricted financial support.

§ *Representative experimental procedure*: A fresh, aqueous solution (15 mL) of NaOH (45 mg, 1.1 mmol) was prepared. 14 mL of this was added in one portion to a magnetically stirred solution of *trans*-cinnamyl carbamate **1** (200 mg, 1.13 mmol) in *n*PrOH (12 mL). The solution was allowed to stir for 5 min, then *tert*-butyl hypochlorite (129 μL, 1.13 mmol) was added. The mixture was again allowed to stir for 5 min. To this was then added a solution of $(DHQ)_2PHAL$ (44 mg, 5 mol%) in *n*PrOH (13 mL) in one portion. The mixture was allowed to stir for a further 5 min before the final addition of a solution of potassium osmate (21 mg, 4 mol%) in the NaOH solution made previously (1 mL). The reaction was followed by TLC until the solution turned black, which denoted the end of turnover (12 h). The reaction was quenched by the addition of Na_2SO_3 (500 mg), and allowed to stir for 30 min. The mixture was extracted with EtOAc (1 × 25 mL), and the organic layer washed with brine (25 mL). The organic layer was then collected and concentrated under reduced pressure. Column chromatography (3 : 2 EtOAc–petroleum ether 40–60) of the crude product yielded the oxazolidinone **2** (135 mg, 62%) as a colourless crystalline solid. Received (in Cambridge, UK) 11th July 2001, Accepted 3rd September 2001
First published as an Advance Article on the web 19th September 2001

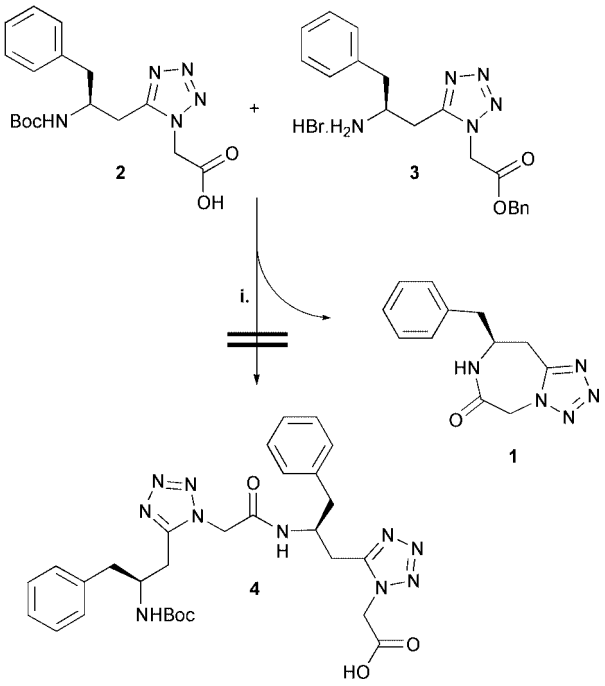
An unusual tetrazolodiazepin-6-one was prepared and shown, by X-ray crystallography, to adopt an essentially planar conformation about the tetrazole ring with geometry that closely approximates a *cis*-amide bond.

The process of transforming the topology of a bioactive molecule onto a different molecular scaffold is an important method for generating new classes of bioactive molecules. This procedure can provide important biological probes and potential therapeutics with improved potency, stability and other characteristics relative to their parent. The diazepine ring system has been used extensively in this respect; for example, benzodiazepines have found wide-spread medicinal applications and a number of diazepine-based systems have been used to construct peptidomimetic scaffolds that possess well-defined geometries, such as those found in β-turns.[1] Another important peptidomimetic scaffold is the 1,5-disubstituted tetrazole ring that has been identified as an effective *cis*-amide bond mimic.[2] The incorporation of this moiety into peptides gives *cis*-restricted peptidomimetics that have found use as protease inhibitors,[3] and biological probes.[4] In this paper we present the synthesis and X-ray structure of (8*S*)-8-benzyl-8,9-dihydro-7*H*-tetrazolo[1,5-*d*][1,4]diazepin-6-one, **1**. This compound was isolated and characterized as part of our continuing program to develop non-hydrolysable tetrazole-based *cis*-amide bond isosteres and to investigate their applications.[3,5,6] This compound is important in that it represents a combination of the two aforementioned scaffolds into one, new class of dipeptidomimetic.

Compound **1** was isolated from an attempted coupling of *N*-Boc-protected dipeptide mimic **2**,[6] with the benzyl ester hydrobromide **3**,[6] under standard EDCI mediated peptide coupling conditions (Scheme 1). The desired tetrapeptide, **4**, was not observed in the crude reaction product by ^{1}H NMR or mass spectrometry.† Purification of the crude mixture by flash column chromatography gave the cyclic tetrazole-based dipeptide mimic, **1**, in 93% yield,‡ which was recrystallised from methanol.

A few related nitrogen-containing five-membered rings fused to the diazepine scaffold are known and these have been shown to possess interesting pharmacological properties.[7,8] However, our structure is unique in that its diazepinone scaffold contains a homophenylalanine–glycine based cyclic dipeptide in which one of its *cis*-amide bonds is constrained within a tetrazole-based amide surrogate. The tetrazole moiety forces the system to adopt a '*cis*-like' geometry at the homophenylalanine–[CN_4]–glycine junction that is necessitated by the cyclic architecture of the diazepinone scaffold.

The structure of **1** was confirmed by an X-ray structure determination at 173(2) K and was satisfactorily refined (Fig. 1).§ The structural data from **1** provides information for the design of *cis*-constrained tetrazole-based peptidomimetics, and also diazepine-based dipeptidomimetic scaffolds. Very few solid state structures of tetrazole-based peptidomimetics have been reported.[9] Consequently, this class of peptidomimetic



Scheme 1 Synthesis of (8*S*)-8-benzyl-8,9-dihydro-7*H*-tetrazolo[1,5-*d*]-[1,4]diazepin-6-one. *Reagents and conditions*: i) EDCI [1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride], HOBt (1-hydroxybenzotriazole hydrate), DIPEA (*N*,*N*-diisopropylethylamine), rt, 18 h.

remains relatively uncharacterized with regards to its geometry. Such information is required if these compounds are to be fully exploited as conformationally restricted peptidomimetics.

The structural data obtained for **1** compares well with other reported 1,5-disubstituted tetrazole groups.[10] The tetrazole ring of **1** was found to be essentially planar with the torsion angles N2–C5–N5–N4, C5–N5–N4–N3, N5–N4–N3–N2, N4–N3–N2–C5, and N3–N2–C5–N5 being −0.55(15), 0.17(16)°, 0.27(16), −0.62(15) and 0.74(15)°, respectively and the ring atoms show a mean deviation from the plane of 0.003 Å. The

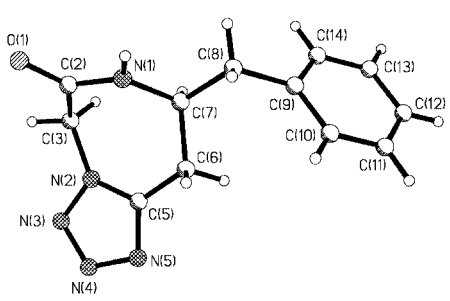


Fig. 1 Molecular structure of (8*S*)-8-benzyl-8,9-dihydro-7*H*-tetrazolo-[1,5-*d*][1,4]diazepin-6-one, **1**.

 DOI: 10.1039/b106175p

N3–N4 bond [1.2887(18) Å] possesses the most double bond character of the heterocyclic bonds. The N2–N3 and N4–N5 bonds are the longest being 1.3537(16) and 1.3650(18) Å, respectively. The N5–N4–N3 endocyclic bond angle, 111.37(11)°, is wider than the C5–N5–N4 and N4–N3–N2 bond angles, 105.79(12) and 105.56 (12)°. The dipeptide mimic is folded at the homophenylalanine–[CN_4]–glycine sequence with the torsion angles, C5–C6–C7–N1, N2–C5–C6–C7, C6–C5–N2–C3, and C2–C3–N2–C5, being 59.53(16), −9.2(2), 3.3(2), and −48.92(19)° respectively. The diazepinone ring is puckered with a mean deviation from the plane of 0.317 Å, while the phenylalanine ring adopts a flagpole orientation over the diazepin-6-one scaffold.

The tetrazole-based *cis*-amide bond mimic is known to compare well with the geometric properties of a generic *cis*-amide bond obtained from statistical analysis of published X-ray diffraction structures.[11] However, the solid state structure of **1** provides an excellent opportunity for a direct comparison of the tetrazole-based amide bond surrogate and the *cis*-amide bond, as **1** contains both these structural motifs within the constrained diazepinone ring. The geometric properties of the tetrazole-based surrogate of **1** and the *cis*-amide bond of **1** compare favourably. The N2–C5 bond [1.3455(18) Å] of the tetrazole is slightly shorter than the amide bond, N1–C2 [1.3508(19) Å]. The separation between carbon centres adjacent to the tetrazole ring [C3···C6] and the corresponding distance between α-carbons adjacent to the amide bond [C7···C3] are similar, being 3.229 and 2.911 Å, respectively. The small variation between these distances is a consequence of the increased steric bulk of the tetrazole moiety. Hence, the bond angles C6–C5–N2 [127.19(13)°] and C3–N2–C5 [131.98(12)°] of **1** are greater than the corresponding bond angles of the *cis*-amide bond, C7–N1–C2 [127.05(12)°] and N1–C2–C3 [115.81(12)°]. The $\bar{\omega}$ torsion angle at the homophenylalanine–[CN_4]–glycine junction, [C6–C5–N2–C3], is forced to adopt a planar *cis*-conformation by the fused tetrazole ring, where $\bar{\omega}$ = 3.3(2)°. Similarly, the torsion angle about the *cis*-amide bond of **1**, [C7–N1–C2–C3], is essentially planar, where $\bar{\omega}$ = 3.11(19)°.

In this paper we have presented the synthesis and solid state structure of a new class of peptidomimetic diazepinone molecular scaffold. This architecture should be amenable to attaching a wide range of amino acid R groups and thus the presentation of a diverse range of topologies.

The work was supported by a Royal Society of New Zealand Marsden grant. We are indebted to Peter Steel and Chris Fitchett for their assistance in solving the structure presented in this paper.

Notes and references

† We have recently been concerned with investigating the secondary structure of peptidomimetics that contain multiple constrained *cis*-amide bonds. To this end we targeted tetrapeptide mimic, **4**, that contains two tetrazole based *cis*-amide bond mimics.

‡ Calculated yield of **1** was based on starting benzyl ester, **3**.

§ *Crystallographic data* for **1**: $C_{12}H_{13}N_5O$, M 243.27, mp 198–200 °C, crystal dimensions 0.63 × 0.24 × 0.21 mm, orthorhombic, a = 6.374 (2), b = 8.621 (3), c = 20.890 (7) Å, γ90 (2)°, V = 1147.8 (7) Å^3, spacegroup $P2_12_12_1$, Z = 4, $F(000)$ = 512, D_{calc} = 1.408 mg m^{-3}, absorption coefficient 0.096 mm^{-1}, θ range for data collection 2.56 to 26.42, index ranges $-4 \leq h$ 7, $10 \leq k \leq 10$, $-26 \leq l \leq 25$, data/restraints/parameters 2338/0/163, goodness of fit on F^2 was 1.063, final R indices [$I > 2\sigma(I)$] R_1 = 0.0323, wR_2 = 0.0827, R indices (all data) R_1 = 0.0374, wR_2 = 0.0853, largest difference peak and hole 0.148 and −0.191 e Å^{-3}. A full sphere of data was collected at 163(2) K. Of the 14344 reflections obtained, 2338 were unique (R_{int} = 0.0271) and were used in the full-matrix least-squares refinement. CCDC 162685. Synthesis and properties of *fac*-Re(dmbpy)(CO)$_3$CHO (dmbpy = 4,4′-dimethyl-2,2′-bipyridine), a possible intermediate in reductions of CO_2 catalyzed by *fac*-Re(dmbpy)(CO)$_3$Cl

Dorothy H. Gibson* and Haiyang He

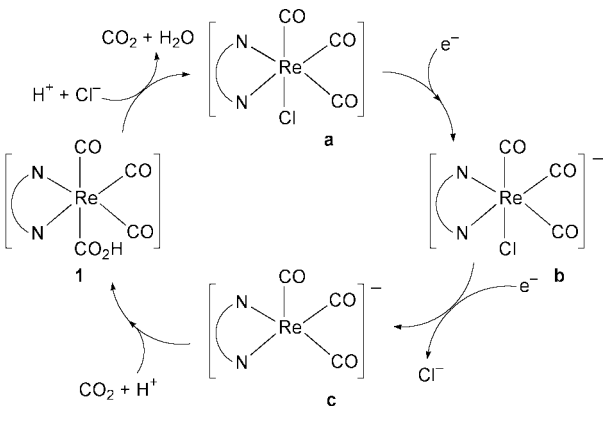
First published as an Advance Article on the web 1st October 2001

Synthesis of *fac*-Re(dmbpy)(CO)$_3$CHO 2 and its reactions with CO_2 in DMF and DMSO have been conducted; 2 transfers hydride to CO_2 to give Re(dmbpy)(CO)$_4^+$ OCHO$^-$ 5 which is rapidly transformed to *fac*-Re(dmbpy)(CO)$_3$(OCHO) 3 in DMF, thus supporting the viability of 2 in photocatalytic reactions of *fac*-Re(dmbpy)(CO)$_3$Cl with CO_2.

Photo- and electrochemical reductions of carbon dioxide catalyzed by *fac*-Re(N–N)(CO)$_3$Cl (N–N = 4,4′-dimethyl-2,2′-bipyridine) lead to carbon monoxide and *fac*-Re(N–N)(CO)$_3$(OCHO).[1] Scheme 1 shows a previously proposed photocatalytic cycle leading to CO.[1b] Proton-promoted dehydroxylation of *fac*-Re(N–N)(CO)$_3$CO$_2$H **1** would yield Re(N–N)(CO)$_4^+$ which was thought to react with chloride ion, with CO loss, to regenerate the starting rhenium complex; the photocatalytic reactions were typically conducted for *ca.* 4 h in DMF solution. The formate complex could result from intermediate metallocarboxylic acid **1** after decarboxylation to *fac*-Re(N–N)(CO)$_3$H followed by CO_2 insertion into the metal hydride bond.[2] Also, the formate could result from protonation of Re(N–N)(CO)$_3^-$ (**c** in Scheme 1) followed by rapid CO_2 insertion. Thus, competition between CO_2 and H^+ for the anion could determine the CO : formate ratio. We recently prepared the metalloacid **1**, and studied its thermolysis reactions.[3] However, reactions of **1** do not provide the formate complex even when conducted in the presence of added CO_2.

The possible intermediacy of a formyl complex as a precursor to the formate in photochemical reactions of CO_2 with *fac*-Re(bpy)(CO)$_3$H was suggested by Sullivan and Meyer.[2] Also, the possibility of formyl intermediates in photocatalytic reactions of *fac*-Re(N–N)(CO)$_3$Cl with CO_2 has been suggested by us[3,4] and others[5] because of the reaction conditions used. Triethanolamine (TEOA) was used as a sacrificial electron donor in the photocatalytic reactions.[1a,b] The decomposition of the resulting TEOA cation radical occurs through H-atom transfer from a second TEOA (yielding TEOAH$^+$ and providing a proton source in the reactions) and concurrent formation of one or more carbon-centered radicals;[6] the carbon-centered radicals are subject to further transformations.[7] Since Re(N–N)(CO)$_4^+$ is a likely reaction intermediate, as discussed above, its one-electron reduction to the acyl radical [Re(N–N)(CO)$_3$(C=O)]$^\cdot$ is possible,[8] and hydrogen atom abstraction[8,9] by this radical (from a carbon-centred TEOA radical) could yield *fac*-Re(N–N)(CO)$_3$CHO. As with other formyl complexes,[10] these could be expected to decarbonylate to *fac*-Re(N–N)(CO)$_3$H; the hydrides are known to insert CO_2 and provide formates.[2,3a] This side reaction leading to the formyl complex from Re(N–N)(CO)$_4^+$ would explain why excess Cl$^-$ is effective in suppressing formate since Cl$^-$ should speed the conversion to **a** (Scheme 1) and diminish the availability of Re(N–N)(CO)$_4^+$ for the side reaction.

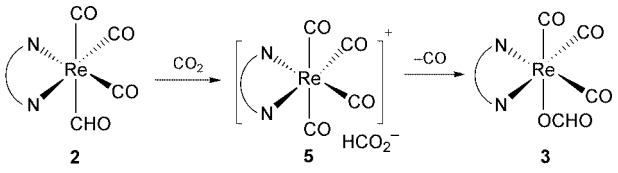


Scheme 1

We have now prepared and characterized *fac*-Re(dmbpy)(CO)$_3$CHO **2**,† and studied its reactions with CO_2 and with metalloacid **1**. Reaction of **2** with CO_2 in DMF-d$_7$ leads, primarily, to Re(dmbpy)(CO)$_3$OCHO[2,3a] (**3**; 76% yield after 1 h, 85% yield after 4.5 h at room temperature) together with the bicarbonato complex *fac*-Re(dmbpy)(CO)$_3$OCO$_2$H[3b] (**4**; 10% yield at either time). However, in monitoring the reaction solution (0.013 M in **2** and 0.17 M in CO_2[11] with ferrocene as an internal standard) at 25 °C by ^{1}H NMR spectra during the early stages of the reaction, we observed that the initial products were Re(dmbpy)(CO)$_4^+$ OCHO$^-$ **5**,‡ acid **1** and the CO_2-bridged compound *fac*,*fac*-Re(dmbpy)(CO)$_3$(CO$_2$)Re(dmbpy)(CO)$_3$ **6**.[3a] Over time, **1** and **6** are converted to **4** in the presence of CO_2 and the small amount of water in the solvent.[3b] After 20 min, **5** and **3** were present in approximately equal amounts; after 1 h, the ionic formate **5** had mostly converted (10% remaining) to the covalent formate **3**. In a second reaction, beginning at −10 °C and then warming to +10 °C and finally to 25 °C during 2 h, the yield of **5** reached *ca.* 40% (at +10 °C) before **3** began to appear. After warming to 25 °C, however, the transformation of **5** to **3** was enhanced (45% yield of **3** after 30 min). Reaction of **2** with CO_2 was also conducted in DMSO-d$_6$ (0.005 M in **2**, 0.115 M in CO_2[11]) at 25 °C for comparison. After 1.5 h, the yield of ionic formate **5** had reached 60% and **2** had been mostly consumed (< 5%); at this time no **3** had yet been formed. Also formed were **4** (10%), **6** (5%) and **1** (15%). After 24 h, the yield of **5** had dropped only to 50% as **3** was generated. Thus, the rate of conversion of **5** to **3** is highly solvent dependent.

Parts of Scheme 1 are certainly viable: we have prepared *fac*-Re(dmbpy)(CO)$_4^+$ Cl$^-$ **7**§ and observed that it slowly converts to *fac*-Re(dmbpy)(CO)$_3$Cl **8** at room temperature (38% after 5.5 h) in DMF-d$_7$. However, irradiation (450 W mercury arc lamp through a Pyrex cooling jacket) of **7** in DMF-d$_7$ showed that 84% of it was converted to **8** after 2.5 h, thus the conversion should have been complete within the time of the catalytic experiments. Ziessel[1a] found that it was necessary to increase [Cl$^-$] in order to suppress formate. While increased [Cl$^-$] could certainly increase the rate of conversion of **7** to **8**, it should have little impact on protonation of anion **c** (Scheme 1). In the manner of other metallocarboxylic acids,[12] **1**, in DMF-d$_7$, is

 DOI: 10.1039/b106270k



N–N = dmbpy = 4,4'-dimethyl-2,2'-bipyridine

Scheme 2

rapidly dehydroxylated by concentrated HCl, yielding **7** (88%) and **8** (12%) upon mixing. Efforts to prepare an authentic sample of formate **5** in the manner of **7** have failed because the excess formic acid necessary to bring the reaction to completion ensures that the formate anion is converted to the formic acid solvate.[13]

Since ruthenium formyl complexes with polypyridine ligands are reactive toward the corresponding metallocarboxylic acids[14] and **1** was expected to be a product in the photocatalytic reactions involving **8**, we have also probed the reactivity of **2** toward **1**. In DMF-d_7 (0.013 M in both **2** and **1**) after 1 h, the major product (83%) is the same intermediate species that was generated from **1** alone in this solvent; the intermediate is eventually transformed to the CO_2-bridged complex, **6**.[3b]

We found no evidence for rhenium hydrides in decompositions of **2** conducted in the presence of CO_2; the formyl complex reacts directly with CO_2 to produce **5** as shown in Scheme 2. Direct transfers of hydride from formyl complexes to carbon electrophiles are well known,[10a,c] although the electrophiles are usually stronger than CO_2. However, hydride transfer has been suggested in reactions of $Ru(bpy)_2(CO)(CHO)^+ PF_6^-$ with CO_2 although the product was not characterized.[15] The reactions of formyl complex **2** with CO_2 and the subsequent rapid conversion of **5** to **3** support the suggestion that **2** could be a viable reaction intermediate in the catalytic reactions.

A new practical ketone synthesis directly from carboxylic acids: first application of coupling reagents in palladium catalysis

Lukas J. Gooßen* and Keya Ghosh

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim an der Ruhr, Germany. E-mail: goossen@mpi-muelheim.mpg.de; Fax: +49-208-306-2985; Tel: 49-208-306-2392

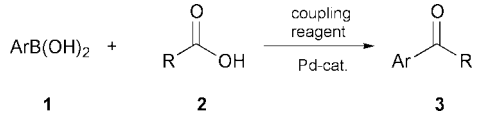
Received (in Cambridge, UK) 26th July 2001, Accepted 5th September 2001
First published as an Advance Article on the web 1st October 2001

A new palladium-catalyzed cross-coupling reaction between arylboronic acids and carboxylic acids, activated *in situ* for the oxidative addition to a tricyclohexylphosphine palladium(0) catalyst by treatment with di(*N*-succinimidyl) carbonate (DSC) is disclosed, which allows the high-yielding synthesis of various functionalized arylketones under mild conditions.

The reaction of carboxylic acid derivatives, for example nitriles, Weinreb-amides, anhydrides, or acid chlorides with carbon nucleophiles to the corresponding ketones is an important C–C bond-forming reaction that is commonly used in organic synthesis.[1] Various procedures have been developed to optimize the yield of the ketones and avoid the formation of the tertiary alcohols.[2] Highly reactive acid chlorides can be alkylated with a number of mild carbon nucleophiles, for example organotin, -zinc and -copper compounds or boronic acids.[3,4] Furthermore, ketone synthesis from thioesters[5] has been reported. However, only a few protocols have been disclosed for the highly desirable direct conversion of the plethora of carboxylic acids into ketones and all of these require aggressive lithium, magnesium, or aluminum reagents intolerant of most functional groups.[6] Recently, we reported a novel palladium catalyzed synthesis of arylketones directly from carboxylic acids and boronic acids using pivalic anhydride as an activating agent.[7] This transformation gives good yields for many substrates, however, the reactivity of the pivalic anhydride against basic groups and the inconvenience of the separation of the products from the pivalic acid are still disadvantageous. A milder and more practical ketone synthesis from carboxylic acids and readily available boronic acids,[8] which works under neutral conditions in the presence of many functional groups would be of great value especially for applications in combinatorial chemistry.

The utilization of mild coupling reagents such as DCC–HOBt, CDI (1,1′-carbonyldiimidazole) or DSC for the activation of the carboxylic acids could be the key to a much-improved process (Scheme 1). These compounds are known to cleanly convert carboxylic acids into stable intermediates, which are just reactive enough to ensure smooth conversion to the corresponding amides.[9] Due to their easy handling, their reliability and selectivity combined with an excellent tolerance of functional groups, coupling reagents have become indispensable for most applications in peptide synthesis.

In principle, a catalytic cycle for the palladium-catalyzed reaction of carboxylic acids with boronic acids consisting of the oxidative addition of an activated acid derivative producing an acyl palladium complex, followed by transmetallation of a boronic acid, and reductive elimination of the ketone appeared to be feasible.[10] However, to the best of our knowledge there is no literature precedent for the use of coupling reagents in transition-metal catalysis.[11]

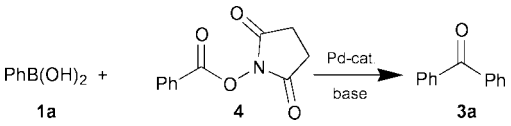


Scheme 1 Cross-coupling of boronic acids and carboxylic acids.

Due to the high stability and easy handling, we chose phenylboronic acid (**1a**) and *N*-benzoyloxysuccinimide (**4**) as our model substrates and screened various palladium catalysts for activity in the desired conversion (Scheme 2). The catalysts were prepared *in situ* from Pd(II) precursors and two equivalents of different phosphines. Some results are summarized in Table 1.

Whereas no reaction was observed for triarylphosphines, with electron-rich trialkylphosphines moderate yields were obtained (Entries 1–6). This may indicate that the oxidative addition of the *N*-benzoyloxysuccinimide is the rate-determining step which should be facilitated by increasing the electron density on the palladium. Sterically demanding tricyclohexylphosphine gave best results while tri-*tert*-butylphosphine complexes were not stable under the reaction conditions and precipitation of palladium(0) was observed.

THF proved to be the most effective solvent (Entries 6–8). The stability of the catalytic system was significantly enhanced when a mild base was added (Entries 9–13). Best results were obtained with Na_2CO_3 while the presence of soluble bases appeared to inhibit the reaction. We also investigated the



Scheme 2 Cross coupling of *N*-benzoyloxysuccinimide.

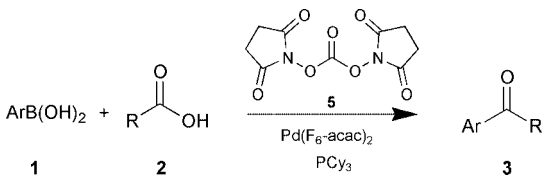
influence of the counter ion on the palladium pre-catalyst and observed faster reactions with weakly coordinating counter-ions such as NO_3^- or F_6-acac than with stronger coordinating Cl^- (Entries 16–20).[10] Under the reaction conditions, the boronic acids act as the reducing agents for the palladium so that biaryls are formed in small quantities. With dba_3Pd_2 as a pre-catalyst, lower yields were observed, which may be due to an insufficient dissociation of the dba from Pd(0). The presence of small quantities of water has little effect on the reaction outcome so that it is not necessary to dry the reagents or solvents, however, the presence of a large excess of water was found to lower the yields (Entries 13–15).

We then set out to combine the activation of the carboxylic acid with di(*N*-succinimidyl) carbonate and the transformation to the ketone into a convenient one-pot procedure (Scheme 3).† Since the activation of the acid was found to proceed smoothly within a few minutes in THF in the presence of Na_2CO_3, this was easily accomplished: in a typical procedure, all reagents except the boronic acid are dissolved in THF and the mixture is stirred until the CO_2 evolution has ceased. Then, the boronic acid is added and the reaction is heated until complete conversion. Under these conditions F_6-acac gave best results, and it is beneficial to add a slight excess of the phosphine to make up for losses during the first reaction step. The water-soluble by-products *N*-hydroxysuccinimide and boric acid are easily removed by a single water wash.

In order to test the generality of this protocol, we applied it to a variety of different substrates. Table 2 shows the broad scope of the new transformation. Both electron-rich and electron-poor alkyl, aryl and even heteroaryl carboxylic acids work equally well, many functional groups such as keto, cyano, ester, nitro, amido and even hydroxy groups are tolerated, and no side products arising from enolisation of the keto groups were observed in significant quantities.



Scheme 3 One-pot synthesis of arylketones from carboxylic acids.

[a] Conditions: 1 mmol carboxylic acid, 1.2 mmol boronic acid, 1.3 mmol DSC, 3 mol% $Pd(F_6\text{-acac})_2$, 9 mol% PCy_3, 2 mmol Na_2CO_3, 60 °C, 20 h. [b] Isolated yields.

In summary, the introduction of easy-to-handle coupling reagents as activating agents for acids in transition-metal catalysis led to the discovery of a convenient new ketone synthesis from carboxylic acids and boronic acids. Further applications of this new concept, for example, in the reduction of carboxylic acids to aldehydes or the Heck reaction of benzoic acid derivatives are under current investigation.

We thank M. Rössig and L. Winkel for technical assistance and Professor Dr M. T. Reetz for generous support and constant encouragement.

† *Synthesis of 2-(4′-methoxyphenyl) ethylphenyl ketone* (**3e**): a 100 mL flask was charged with palladium hexafluoroacetylacetonate (156 mg, 0.30 mmol), tricyclohexylphosphine (252 mg, 0.90 mmol), 3-phenylpropionic acid (**2e**) (1.50 g, 10.0 mmol), Na_2CO_3 (2.08 g, 20.0 mmol), and di(*N*-succinimidyl) carbonate (3.33 g, 13.0 mmol). The reaction vessel was purged with argon and degassed THF (30 mL) was added. The yellow mixture was stirred at 60 °C for a few minutes until the gas evolution had ceased. Then, the solution was cooled down to RT, a solution of 4-methoxyphenylboronic acid (**1a**) (1.82 g, 12.0 mmol) in THF (30 mL) was added and the purple reaction mixture was stirred at 60 °C overnight. The reaction slurry was then poured into water (300 mL) and extracted 3 times with 100 mL portions of ethyl acetate. The combined organic layers were dried over $MgSO_4$, filtered, and the volatiles were removed *in vacuo*. The residue was adsorbed on a plug of Al_2O_3. Nonpolar impurities such as the phosphine or the biaryl were removed by elution with hexane. The product (2.19 g, 91%) was then eluted with 20% ethyl acetate in hexane. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 7.93 (d, ^3J (H,H) = 9 Hz, 2H), 7.23–7.19 (m, 5H), 6.92 (d, ^3J (H,H) = 9 Hz, 2H), 3.85 (s, 3H), 3.24 (t, ^3J (H,H) = 7 Hz, 2H), 3.06 (t, ^3J (H,H) = 7 Hz, 2H) ppm; ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C, TMS): δ = 197.8, 163.5, 141.5, 130.3, 130.0, 128.5, 128.4, 126.1, 113.7, 55.5, 40.1, 30.3 ppm; MS (70 eV): *m*/*z* (%): 240 (33) [M$^+$], 135 (100), 121 (2), 107 (6), 92 (8), 77 (13); HRMS: calcd. for $C_{16}H_{16}O_2$ [M$^+$]: 240.115029; found: 240.115132; anal. calcd. for $C_{16}H_{16}O_2$ (240.30): C, 79.97; H, 6.71; N, 0.0; found: C, 80.12; H, 6.78; N, 0.0. The reactions in Table 1 and Table 2 were performed on a 1 mmol scale using 50 mg tetradecane as an internal GC standard. The products were isolated by column chromatography (Al_2O_3 hexane–ethyl acetate 10:1) and characterized by means of ^{1}H and ^{13}C NMR as well as by GC-MS and HRMS.

First published as an Advance Article on the web 21st September 2001

S_3O, a novel, linear sulfur oxide has been detected in the gas phase by means of neutralization reionization mass spectrometry; the upper limit of stability of acyclic forms of S_nO oxides has been set by theoretical calculations.

Disulfur monoxide, S_2O, and homocyclic sulfur oxides, S_nO (n = 5–10), are well known non-polymeric, sulfur-containing species formed by oxidation of cyclosulfurs S_n, and are relevant to combustion processes.[1,2] They have been detected in both the solid-state and in solution, apart from S_2O which has also been observed in the gas phase. We now report the first experimental detection of S_3O oxide, potentially significant in combustion processes but also in sulfur-rich extraterrestrial atmospheres such as that of Venus, where S_2, S_3 and higher S_n oligomers are present mainly in the sub-cloud region. Polysulfur species, that partially reach the upper region, include S_3, also denoted 'thiozone', whose role in the Venusian atmosphere can be thought of as that of ozone in the Earth's upper atmosphere.[3] As an example, the result obtained may suggest an additional way of depletion of S_3 (so far traced to photodissociation), *i.e.* the oxidation to S_3O, likely occurring from O_2 and SO_3, produced by photolysis at the cloud tops.

In this work, detection of S_3O oxide, as an isolated gaseous molecule, was accomplished by the neutralization reionization (NR) mass spectrometric technique[4] from the S_3O^+ ion, obtained by SO^+ chemical ionization (CI) of carbonyl sulfide, in the high-pressure source (0.1–0.2 Torr) of a ZABSpec-oa TOF mass spectrometer. The S_3O^+ ion and the S_3O oxide were characterized by mass spectrometric techniques and theoretical calculations.

The S_3O^+ ion was generated according to the general reaction

$$S_{n-1}O^+ + COS \longrightarrow S_nO^+ + CO$$

recently described as an oligomerization process, where each S_nO^+ ion formed further reacts with COS giving $S_{n+1}O^+$.[5]

However, in the specific case of interest, detection and structural characterization of S_3O^+ is hindered by the superimposition of the isobaric species formed in the CI of the most commonly used precursors of the SO^+ reagent. As an example, in the SO_2/CI of COS,

$$SO^+ \xrightarrow{+COS,\ -CO} S_2O^+ \xrightarrow{+COS,\ -CO} S_3O^+ \quad (1)$$

$$SO^+ \xrightarrow{+SO_2} S_2O_3^+ \quad (2)$$

the isobaric $S_2O_3^+$ ion is formed by the very efficient reaction (2).[5,6] To circumvent the problem we exploited instead the reaction occurring in the O_3/CI of COS

$$O_3^+ + COS \longrightarrow SO^+ + O_2 + CO \quad (3)$$

which proved an effective route to SO^+ in the absence of SO_2.[5] This rules out reaction (2) and allows the S_3O^+ ion from reaction (1) to be mass selected and structurally assayed by collisionally activated dissociation (CAD) mass spectrometry. The CAD spectra of the $^{32}S_3O^+$, $^{34}S^{32}S_2O^+$ and $^{32}S^{34}S_2O^+$ isotopomers were recorded, as well as the MS^3 (multi-stage mass spectrometry) spectra of several significant daughter ions, which confirmed the elemental composition of the S_3O^+ precursor ion. As an example, the CAD spectrum of $^{32}S_3O^+$ has been reported in Fig.1(a). S_3O^+ was then mass selected and neutralized by electron exchange with Xe in a first collision cell located along the flying path. After deflection of any surviving ions by a high-voltage electrode, the neutral beam was reionized in a second cell by collision with O_2. The NR spectra of $^{32}S_3O^+$ and $^{34}S^{32}S_2O^+$ ions were recorded, showing significant 'recovery' peaks of m/z 112 and 114, respectively, and pointing to the existence of neutral S_3O as an isolated species in the gas phase, with a lifetime in excess of 1 μs. As an example, the NR spectrum of $^{32}S_3O^+$ is shown in Fig.1(b). The identity of the S_3O^+ ion from the reionization process was ascertained by its CAD-TOF mass spectrum, which was compared with that of the S_3O^+ ion from the source.

The optimized geometries of the minima identified on the potential energy surfaces of S_3O^+, computed using the hybrid B3LYP function[7,8] are shown in Fig. 2. Single point energy calculations at the optimized geometries were performed using the coupled-cluster single and double excitation method, with a perturbational estimate of the triple excitations [CCSD(T)] approach,[9] using the 6-311+G(3df) basis set,[10] which includes a set of diffuse functions and three d and one f polarization functions, both on oxygen and on sulfur. All the species display a terminal oxygen atom, the most stable being the $^2A''$ planar structure **1**, as illustrated by the total and relative energies reported in Table 1.[11] All structures are probably accessible to the formation process; nevertheless, in the absence of appreciable barriers to the isomerization typical of conformer relaxation,

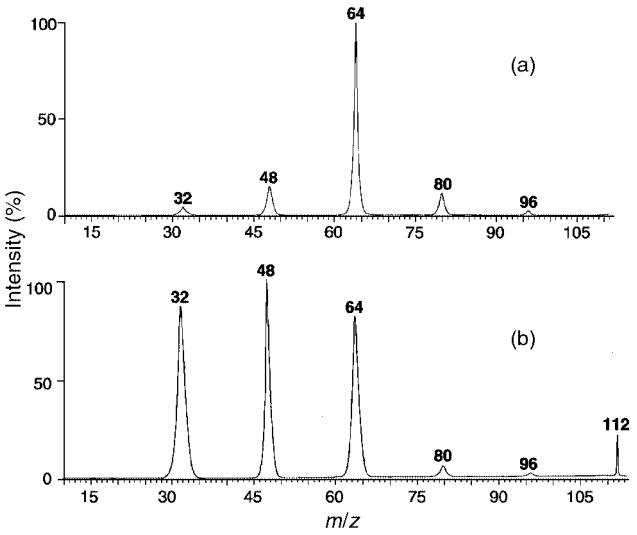

Fig. 1 (a) CAD spectrum of $^{32}S_3O^+$, He collision gas. The out-of-scale m/z 112 parent ion is not shown. (b) NR spectrum of $^{32}S_3O^+$, neutralizing gas Xe, reionizing gas O_2, 80% transmittance.

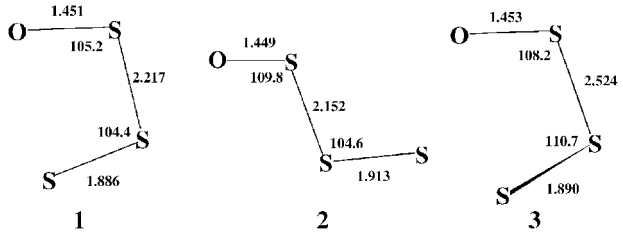

Fig. 2 Optimized geometries of the localized minima on the potential energy surface of the S_3O^+ system, computed at the B3LYP/6-311+G(3df) level. Only the main geometrical parameters are shown. Bond lengths in Å, angles in °.

Table 1 Total energies, relative enthalpies and relative free energies at 298 K of the $S_3O^{+/0}$ systems computed using the 6-311+G(3df) basis set. Total energies in Hartrees, relative energies in kcal mol^{-1}

Species	Symmetry	Relative enthalpy (B3LYP)	CCSD(T)	Relative free energy (B3LYP)	CCSD(T)
1	$^2A''$	0	0	0	0
2	$^2A''$	1.6	2.2	1.8	2.4
3	^4A	7.9	10.1	6.0	8.2
A	$^1A'$	0	0	0	0
B	^3A	7.3	12.8	5.4	11.0
C	$^3A'$	7.3	12.4	5.1	10.2
D	$^1A'$	3.8	4.3	3.6	4.1

structures **1** and **2** are expected to be the most representative of the population sampled, the quartet state being considerably less stable.

Fig. 3 shows the structures of the minima identified on the potential energy surfaces of S_3O. The most stable species are the $^1A'$ planar structures **A** and **D**, the triplet states **B** and **C** being less stable by some 10 kcal mol^{-1} (Table 1). Inspection of Figs. 2 and 3 shows that the geometrical correlation between the most stable charged and neutral species makes conceivable the formation of the latter ones by a vertical neutralization process. From a more general standpoint, the results have some bearing

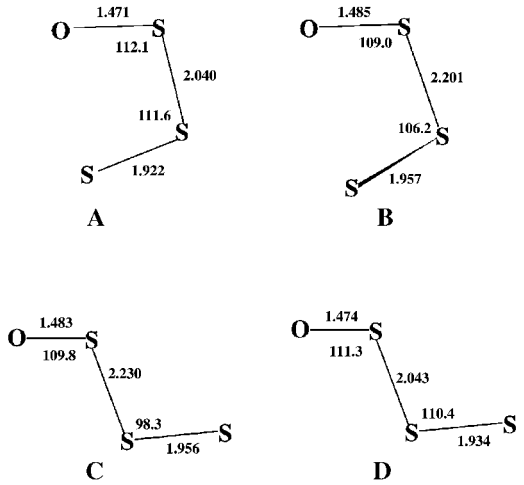

Fig. 3 Optimized geometries of the localized minima on the potential energy surface of the S_3O system, computed at the B3LYP/6-311+G(3df) level. Only the main geometrical parameters are shown. Bond lengths in Å, angles in °.

on the question concerning the relative stability of cyclic *vs.* acyclic S_nO oxides. It is well known that S_2O is an acyclic, angular molecule with a terminal O atom. As for S_3O, the only minima theoretically localized are also characterized by an acyclic structure, with a terminal O atom. Extension of the analysis to S_4O[12] shows that at the B3LYP/CCSD(T) level of theory the $\Delta H^{\ominus}$ values of the most stable acyclic isomer and the cyclic one are very close, falling within 1 kcal mol^{-1}. In summary, it appears that, among the S_nO oxides, S_3O sets the upper *n* limit of the range where acyclic species are significantly more stable.

Interaction-induced enhancement in the activity and selectivity of a titania-supported ammonium salt of a 12-molybdophosphoric acid catalyst during ammoxidation of 2-methylpyrazine†

K. Narasimha Rao, Rajesh Gopinath, M. Santhosh Kumar, I. Suryanarayana and P. S. Sai Prasad*

Catalysis & Physical Chemistry Division, Indian Institute of Chemical Technology, Hyderabad - 500 007, India. E-mail: saiprasad@iict.ap.nic.in

Received (in Cambridge, UK) 9th July 2001, Accepted 4th September 2001
First published as an Advance Article on the web 1st October 2001

A titania-supported ammonium salt of 12-molybdophosphoric acid has been synthesized, and the salt–support interaction, which enhanced the reaction rate, has been correlated with the activity of the catalyst in the ammoxidation of 2-methylpyrazine.

12-Molybdophosphoric acid (MPA) is an effective catalyst[1] for acid catalysed and redox reactions. The ammonium salt of MPA (AMPA), which exhibits better thermal stability than MPA, is also reported as a good catalyst for several reactions.[2] However, studies on the effect of impregnation of AMPA on supports are scarce. The influence of the salt–support interaction upon the activity and selectivity of the catalyst has also not yet been reported. Ammoxidation of 2-methylpyrazine (MP) to 2-cyanopyrazine (CP) is a crucial step in the production of pyrazinamide, an important anti-tubercular drug,[3] for which MPA is an effective low temperature catalyst. Recently, it has been reported[4] that higher CP selectivity may be achieved using AMPA as a catalyst rather than MPA. Hence, it is important to study the influence of support on the activity and selectivity of AMPA. It is also interesting to elucidate the effect of loading, reflected by the extent of interaction, on the performance of the catalysts.

In the present investigation we report, for the first time, the synthesis of titania supported AMPA catalysts.‡ Catalysts with varying AMPA loading have been prepared and characterized by nitrogen adsorption, X-ray diffraction (XRD), Fourier transform infrared (FTIR) spectroscopy and ^{31}P MAS NMR techniques. We have observed higher activity and selectivity on the supported catalysts than on the bulk AMPA, for the ammoxidation of MP. A good correlation is observed between the extent of interaction and the activity of the catalyst, which helps optimize the loading on the support.

A gradual decrease in the BET surface area of the catalyst with an increase in AMPA loading (Table 1) implies its uniform impregnation since titania favours interaction with the active phase.[5] The XRD patterns of 5, 10 and 15 wt% loaded catalysts show no indication of the crystallinity of the salt. This observation is in conformity with the results reported by Roy *et al*. and Pizzio *et al*.[6] The amorphous nature can be explained as follows. The hydroxy groups on the titania surface acquire a positive charge due to protonation in the acidic solution, and bind the complex Keggin ion $[PMo_{12}O_{40}]^{3-}$ by electrostatic attraction,[7] leading to interaction of AMPA with the surface. Catalysts with 20 and 25 wt% loading clearly reveal the formation of the crystalline ammonium salt, $(NH_4)_3PO_4(MoO_3)_{12}\cdot 4H_2O$ (ASTM File No. 9-412) in their diffraction patterns, indicating the completion of the interaction at 15 wt% loading.

FTIR spectra of the titania-supported AMPA catalysts with different loadings are presented in Fig. 1. The spectra show intense bands at 672 and 528 cm^{-1} due to the titania support, in addition to bands with medium intensity at 1060 and 960 cm^{-1} due to the AMPA with the characteristic Keggin structure. Literature reveals[8] that AMPA exhibits IR bands at 1410, 1065, 960, 873 and 786 cm^{-1} assigned to stretching vibrations of the NH_4^+ ion, (P–O_d), (Mo–O_t), (Mo–O_b–Mo) and (Mo–O_c–Mo)

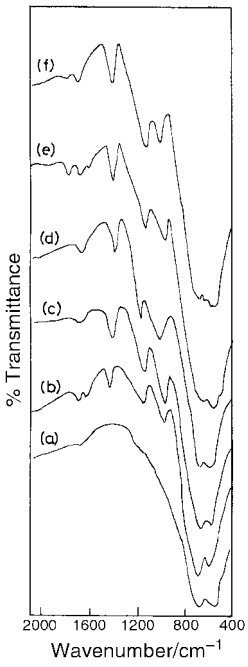

Fig. 1 FTIR spectra of the AMPA-loaded titania catalysts. Titania support (a), catalysts loaded with 5 wt% AMPA (b), 10 wt% AMPA (c), 15 wt% AMPA (d), 20 wt% AMPA (e) and 25 wt% AMPA (f).

Selectivity to CP at 360 °C (%)	40	78	83	86	91	92.5	94
Selectivity to CP at 380 °C (%)	33	75	79	81	90	90	93

[a] Numbers indicate wt% loading of AMPA on the support.

 DOI: 10.1039/b106055b

respectively. As reported by Damyanova and Fierro,[9] titania-supported MPA exhibits strong framework vibration bands of titania below 900 cm^{-1}, overshadowing the bands at 873 and 787 cm^{-1} and making interpretation of the bands based on the Mo–O bond difficult. In the present study it has been observed that the amount of AMPA loading has a marked effect on the characteristic P–O_d band at 1060 cm^{-1}. Characterization of this band by standard half-band width analysis[10] reveals some interesting observations. The half-band widths of catalysts with 5, 10 and 15 wt% loading gradually increase with values equal to 112, 160 and 176 cm^{-1}, respectively. This phenomenon indicates that the P=O bond becomes progressively weaker due to interaction of the salt with the support. As the loading increases the magnitude of the half-band width attains a constant value (180 cm^{-1}) revealing that the P=O group has attained saturation. The FTIR results are in full agreement with those of the XRD data.

^{31}P MAS NMR spectra of the 5, 10 and 15 wt% AMPA catalysts exhibit singlets at −6.300, −6.534 and −7.605 ppm, respectively. The 20 and 25 wt% samples show peaks at −10.7 ppm. Vazquez *et al*.,[7] in their studies on supported MPA, have observed a MAS NMR broad band at −7.49 ppm in the case of a carbon support and at −10.76 ppm in the case of an alumina support. This observation is in close corroboration with our results where the protonated titania is initially acidic and exhibits an NMR peak in the range −6.3 to −7.6 ppm. Once the interaction of the salt species with the acid centers is complete the NMR signal shifts to −10.7 ppm.

The variation in the activity of the catalysts (expressed as percentage conversion of MP) with the salt loading, evaluated at two reaction temperatures, is shown in Fig. 2 (MP conversion values on the bulk AMPA are 5 and 23% at 360 and 380 °C, respectively). The conversion percentage increases up to a loading of 15 wt% and remains almost constant from then on. Values of the half-width of the 1060 cm^{-1} band also display a similar trend. Hence, it appears that the extent of interaction of the salt with the support reaches a maximum at *ca*. 15 wt% loading of AMPA. Further increase in loading (where crystallization of the salt is observed) does not increase the conversion. This observation may be valuable in the characterization of supported heteropolyacids and their salts in determining the maximum extent of loading where the activity is also the maximum.

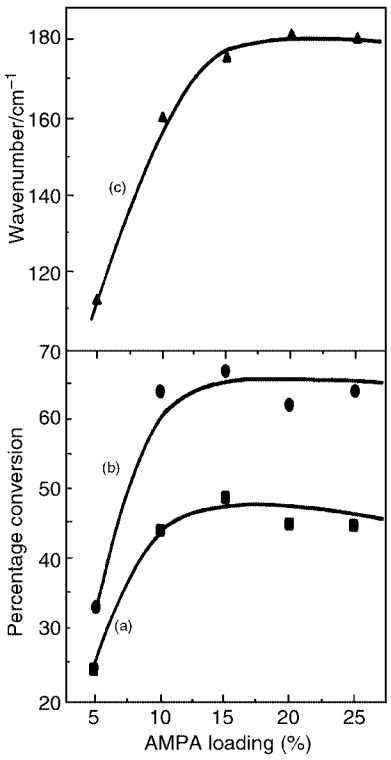

Fig. 2 Variation of conversion and the half-width of the 1060 cm^{-1} band with AMPA loading. (a) MP conversion at 360 °C; (b) MP conversion at 380 °C; and (c) half-bandwidth values.

The significance of impregnation of the salt on the support is also manifested in obtaining enhanced selectivity. Whereas high selectivity to pyrazine is observed on a titania support, impregnation of the support with 5 wt% salt completely reverses the trend by offering high selectivity to CP. This indicates that the acid centers on titania, on which pyrazine formation is more facile, are progressively covered by the salt, simultaneously exposing more active sites of AMPA. An interesting question to be answered at this juncture is how the 20 and 25 wt% catalysts, after attaining crystallinity (expected to behave like bulk AMPA), show continuous increase in selectivity. It may be expected that diffusional limitations may be responsible for lower activity and reduced selectivity in the bulk catalysts, as expressed by Forni[11] Impregnation of the active component on a suitable support, like titania, with higher loading eliminating narrow pores, appears to minimize the diffusional resistance, thus increasing the selectivity.

It may be concluded that the salt–support interaction in titania-supported AMPA offers higher activity and selectivity in the ammoxidation of MP than that of the bulk catalyst. The FTIR half-band width analysis could be a useful method in characterizing the extent of interaction and correlating it with the performance of the catalyst.

The authors are grateful to Dr K. V. Raghavan, Director, IICT, for permitting publication of the results. K. N. R. thanks CSIR, India, for the award of a Senior Research Fellowship.

Notes and references

‡ The bulk AMPA was prepared by dissolving, in a minimum amount of water, ammonium heptamolybdate (S.D. Fine Chemicals, India, AR grade) and diammonium hydrogen orthophosphate (Loba Chemie, India, AR grade) in the stoichiometric ratio, maintaining the pH at 2, followed by reflux at 100 °C for 6 h. The supported catalysts were prepared by impregnating TiO_2 (Ti Oxide, UK) with known amounts of the above salt solution, followed by drying at 120 °C. All the samples were calcined at 400 °C for 4 h in presence of air.

The BET surface area of the catalyst was determined by nitrogen adsorption, at liquid nitrogen temperature, on a conventional all-glass high vacuum apparatus. XRD patterns of the catalysts were obtained on a Siemens D-5000 diffractometer using Cu-Kα radiation. FTIR spectra were recorded on a Biorad-175 C (USA) spectrometer using the KBr disc method. ^{31}P MAS NMR spectra of solids were recorded in a 300 MHz Bruker ASX-300 spectrometer. A 4.5 μs pulse (90°) was used with repetition time of 5 s between pulses in order to avoid saturation effects. The spinning rate was 5 kHz. All measurements were carried out at room temperature using 85% H_3PO_4 as standard reference. Ammoxidation of MP was carried out at atmospheric pressure in a glass reactor taking 5 g of the catalyst (crushed to 18/25 BSS sieve) and passing a reactant mixture containing MP, ammonia, air and water at a molar ratio of 1:13:7:38, respectively, in the temperature range 360–400 °C. Steady-state product composition was analyzed by gas chromatography.

A silver-containing halogen-free inorganic photochromic glass

Sihai Chen, Tomoko Akai, Kohei Kadono and Tetsuo Yazawa*

Ecoglass Research Group, Division for Green Life Technology, National Institute of Advanced Industrial Science and Technology, AIST Kansai, Midorigaoka 1-8-31, Ikeda, Osaka 563-8577, Japan. E-mail: te-yazawa@aist.go.jp

Received (in Cambridge, UK) 11th July 2001, Accepted 3rd September 2001
First published as an Advance Article on the web 1st October 2001

A halogen-free inorganic photochromic soda-lime silicate glass containing silver ions has been developed; reversible change between colorless and yellow color in this glass is achieved through combined 193 nm excimer laser irradiation and heat treatment.

Photochromic glasses refer to the glasses that change color reversibly when exposed to actinic radiation. The word *reversibly* does not exclude examples having immeasureably slow reverse rates, but does exclude those in which the state resulting from photolysis is thermodynamically more stable than the initial states.[1] These glasses have a wide range of applications such as ophthalmic lenses, architectural or automotive glazing, information storage and display devices.[2] Until now, the most extensively studied and widely commercialized glasses are those which contain silver halide crystallites, and which were first reported in 1965 by Armistead and Stookey.[3] Although the silver ions can be sometimes replaced by other ions such as copper,[4] the halogen ions are normally irreplaceable since they act as the reducing agent during photolysis to render the electrons for silver particle formation.

In response to the increased demand for green life technology in the color glass industry, a plan to make recyclable colored glass is proposed,[5] where the color of the glass is required to be generated or erased using simple physical treatment such as photo-irradiation or heat annealing. An important point in this plan is that environment-unfriendly materials such as halogens should not be included in the glass. The normal photosensitive glasses[6] that contain silver ions and optical (such as cerium) or thermal (such as tin or antimony) sensitizers seem to comply with this requirement, but the yellow color formed cannot be erased unless melting of the glass is carried out.

In this communication, we report a successful preparation of a halogen-free photochromic glass. Different from the previously reported ones, the glass contains only silver ions, without any other sensitizers. The transparent, colorless glass gives a yellow color after treatment with 193 nm excimer laser irradiation and heat annealing at 400 °C; however this color can also be erased through heating at 500 °C.

The raw materials used are SiO_2, Na_2CO_3, $Al(OH)_3$, $CaCO_3$ and $AgNO_3$ (all analytical grade). The soda-lime silicate glass with composition of 75% SiO_2, 17% Na_2O, 3% Al_2O_3 and 5% CaO containing 0.02% Ag was prepared by melting the mixture of the above raw materials in a platinum crucible at 1450 °C for 4 h under an air atmosphere. Absorption and fluorescence measurements were conducted using a Hitachi U-4000 UV-VIS-NIR and an F-4500 fluorescence spectrophotometer, respectively. The 193 nm excimer laser applied was a Lambda Physik COMPex 102 ArF laser with pulse duration of 25 ns. The frequency of pulse irradiation was fixed at 10 Hz. The average intensity of the laser beam was measured with a Vector H 410 (Scientech) power meter.

The glass changed immediately from colorless to slightly black after exposure to the laser irradiation. As shown in Fig. 1, curve (a), several absorption bands can be clearly identified at 620, 460, 233 and 333 nm. The former three peaks are caused by the formed defects in the glass matrix. They can be assigned to non-bridging oxygen hole centers (HC_1 for 460 nm and HC_2 for 620 nm), and E′ centers (for 233 nm).[7] The 333 nm peak is caused by the formation of silver atoms.[8] Since the glass does not contain any other reducing agents, it is evident that the silver atoms are formed through electrons trapped by silver ions, resulting in the generation of large amounts of hole centers.

$$\text{Glass} \xrightarrow{\text{Laser}} h^+ + e^- \quad (1)$$

$$Ag^+ + e^- \rightarrow Ag^0 \quad (2)$$

After heating at 400 °C for 15 min [Fig. 1, curve (b)], the characteristic surface plasmon absorption band of silver particles at 406 nm appeared indicating the formation of silver particles.

$$nAg^0 \rightarrow Ag_n \quad (3)$$

More information about the fate of silver ions in the glass was traced from the fluorescence spectra, where a 335 nm fluorescence emission was assigned to the free Ag^+ ions in the soda-lime glass.[9] As shown in Fig. 2, curve (a), excimer laser irradiation resulted in *ca.* 85% decrease in the fluorescence intensity, which corresponds to a decrease in free silver ion concentration as a result of silver atom formation. Heating at 400 °C leads to *ca.* 80% recovery of silver ion concentration [Fig. 2, curve (b)], implying that large amounts of reduced silver atoms should have lost electrons to form ions again.

$$Ag^0 \rightarrow Ag^+ + e^- \quad (4)$$

It can be seen that treatment at 400 °C gives two results: one is the aggregation of silver atoms to form particles, the other is the direct dissolution of silver atoms to form silver ions.

The most interesting feature is that further heating at 500 °C for 15 min results in the disappearance of the yellow color [Fig. 1, curve (c)}, *i.e.* the silver particles, once formed, dissolved again.

$$Ag_n \rightarrow nAg^+ + ne^- \quad (5)$$

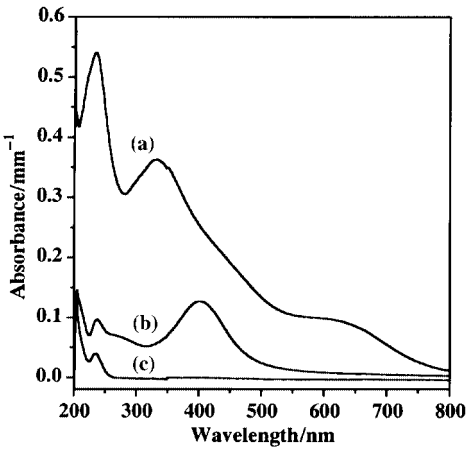

Fig. 1 Absorption spectra of the soda-lime glass containing 0.02 wt% Ag, (a) after 30 min of 193 nm excimer laser irradiation at an intensity of 100 mW cm^{-2}, and then (b) after heat annealing at 400 °C for 15 min; (c) further heat annealing at 500 °C for 15 min. The absorption spectra are referenced with an untreated sample.

 DOI: 10.1039/b106179h

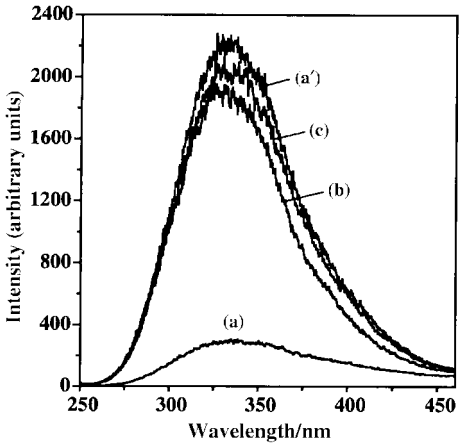

Fig. 2 The corresponding fluorescence spectra during the treatment of the glass as shown in Fig. 1. The excitation wavelength is 240 nm; (a′) represents the spectrum before treatment; (a), (b) and (c) are as detailed in Fig. 1.

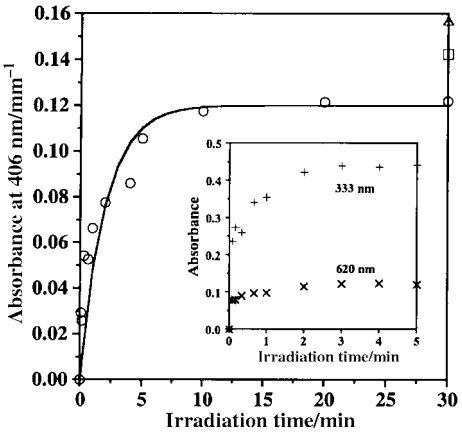

Fig. 3 The effect of laser irradiation time (*i.e.* the amount of laser irradiation pulse) on the 406 nm absorbance obtained after heat annealing at 400 °C for 15 min. The irradiation intensity is 100 mW cm^{-2}. The solid line shows a fitting of the experimental data with $y = 0.12 \times (1 - e^{-x/2})$. The inset is the change of the 333 and 620 nm absorbances after irradiation at different times. The symbols □ and △ show the 406 nm absorbance obtained at irradiation intensities of 200 and 400 mW cm^{-2} for 30 min, respectively.

This is also indicated by the further increase in silver ion concentration shown by the fluorescence spectrum [Fig. 2, curve (c)].

The reason for the silver particle dissolution may be the same as the silver atom dissolution during 400 °C treatment. Since no other oxidants are present in the glass, the hole centers produced by the excimer irradiation may be considered as the oxidant to oxidize the silver particles. As shown in Fig. 1, the band of the hole centers at 620 or 460 nm in the glass continuously decreases and finally disappears after heat treatment at 400 and 500 °C.

The silver particle formation is related to the defects formed within the glass, which is dependent upon the duration of the irradiation pulse, as well as on the laser intensity. As shown in Fig. 3, at an average intensity of 100 mW cm^{-2}, after treatment at 400 °C the formed amounts of silver particles, as indicated by the 406 nm absorbance, level off after 5–10 min of irradiation. This is explainable since the amount of HC_1 centers (at 620 nm) formed, as well as that of silver atoms (at 333 nm) reaches a maximum within 5 min of irradiation (Fig. 3 inset). Increasing the laser intensity to 200 and 400 mW cm^{-2} can stimulate the formation of silver particles, and this was shown by the increased 406 nm absorbance (□ and △ symbols in Fig. 3).

Information about the size of the silver particles formed was obtained by studying the absorption curve of the silver plasmon band, where the width of the band is related to the particle size.[10] It was found that the plasmon band can be fitted with a Lorentz function in the present experiments and that the band widths are in the range of 100–130 nm. Estimated with Mie theory corrected by the 'mean free path' effect,[10] the particle size is estimated at < 2 nm.

The experiments shown in Fig. 1 were also found to be repeatable, *i.e.* the color of the glass can be switched from colorless to yellow, and then to colorless again for many cycles. Since the defects induced by the laser irradiation finally disappeared after high temperature annealing, severe fatigue of the base glass itself was not found in the present system. This property makes this glass very attractive, not only for glass recycling, but also as an advanced material used for erasable high density information storage.

New fluorescent probes for the detection of mixed sodium and potassium metal ions

Xiaohe Xu, Hao Xu and Hai-Feng Ji*

Department of Chemistry and Institute for Micromanufacturing, Louisiana Tech University, Ruston, LA 71272, USA. E-mail: hji@chem.latech.edu; Fax: 01-318-257-3823

Received (in Cambridge, UK) 23rd July 2001, Accepted 3rd September 2001
First published as an Advance Article on the web 24th September 2001

A new fluorescent probe 2 is developed that is capable of measuring the concentration of a mixture of sodium and potassium ions in the solution. This probe contains a fluorophore that is utilized in two ways depending on the pH of the solution.

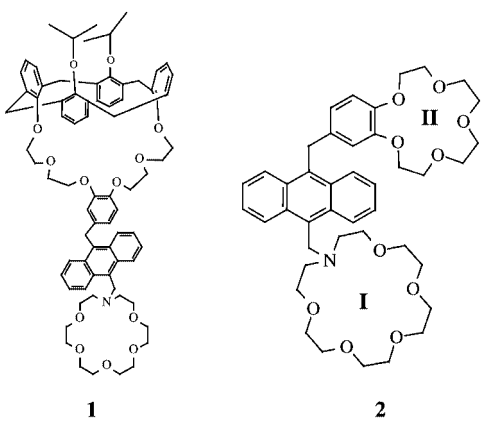
A large family of the fluorescent chemical sensors is based on photo-induced electron transfer quenching (PET) of the fluorophore by the receptor.[1–4] Most of the current PET fluorescent probes are designed for only one species. A multicolor labeling experiment entails the deliberate introduction of two or more probes to monitor simultaneously different species. This technique has major applications in flow cytometry, DNA sequencing, *in situ* hybridization, *etc*. However, only a few such two or multicolor systems have been studied because of the strict prerequisites of this technique, including absorption at a coincident excitation wavelength and well-separated emission spectra of two or more fluorophores,[5] no energy transfer between two fluorophores, no transient excited-state collisional quenching, and no excited state dimer, *etc*. These prerequisites increase the barrier in the development of multicolor sensors.

Recently,[6] we designed and synthesized one novel fluorescent probe **1**. Our results have shown that this molecule can be used to detect caesium ions in acid conditions, but potassium ions in basic solutions. Based on the same design, we synthesized another probe **2**. Logically, **2** would be a potassium sensor in basic solution and a sodium sensor in acidic solution. In this paper, we report the fluorescence-sensing behavior of probe **2**. Furthermore, the unique fluorescence behaviors of **1** and **2** suggest that another approach for a mixture of dual component sensing is feasible. We also report here that probe **2** could be a potential sensor for a mixture of sodium *and* potassium ions.

In molecule **2**, two receptors are connected with the anthracene. One receptor is benzo-15-crown-5, which is a good host for sodium ions.[7] Another is aza-18-crown-6, which is the right size for K^+ complexation.[8]

Under basic conditions, the PET fluorophore–receptor pair is anthracene and aza-crown-6 ether (ring **I**). The lone-pair electrons on nitrogen in ring **I** quench the fluorescence of anthracene. Addition of K^+ in the solution causes an enhancement in the fluorophore's emission due to the formation of the K^+–**2** complex as shown in Fig. 1. The complexations of ring **I** with other alkali metal ions are weaker than ring **I** with K^+ and only cause weak fluorescence enhancement of **2**. Meanwhile, since the crown ring **II** has no contribution to the PET process, the complexation of alkali metals by the crown ring **II** under basic conditions has no effect on the fluorophore's emission.

In an acidic environment, where the nitrogen atom of aza-crown ring **I** of **2** is protonated (hereafter referred as **2-H**$^+$), the PET fluorophore–receptor pair is switched to anthrylmethylammonium and benzo group in benzo-15-crown-5. The low fluorescence quantum yield of **2-H**$^+$ is similar to that of **2** in basic solution. The diminished emission intensity of anthrylmethylammonium is due to PET quenching of the fluorophore by the dialkoxybenzene moiety of crown ring **II**. The driving force, ΔG, is calculated to be -0.1 eV.[9] Addition of Na^+ to the solution results in an enhancement of fluorescence intensity of **2-H**$^+$ because the complexation between Na^+ and benzo-15-crown-5 (ring **II**) inhibits the PET process from benzo to anthrylmethylammonium. The complexation constants of ring



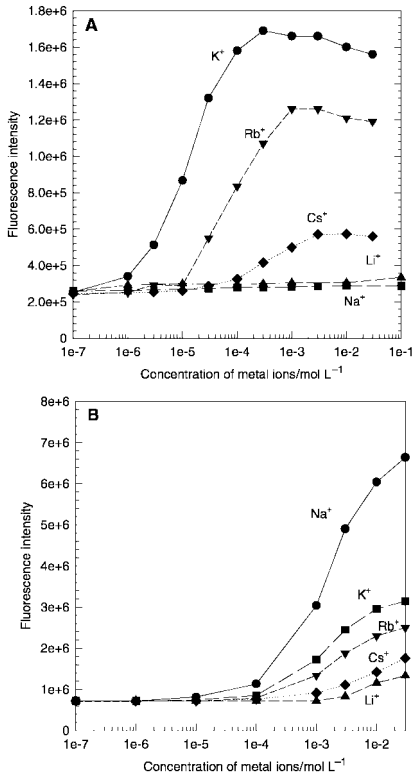


Fig. 1 (A) Changes in the fluorescence intensity (λ_{em} = 426 nm) of **2** (1×10^{-6} M) in basic methanol (morpholine, 1×10^{-2} M as proton scavenger) as a function of concentration of various alkali metal ions. (B) Change in the emission intensity (λ_{em} = 425nm) of **2-H**$^+$ (1×10^{-6} M) in acidic methanol (1×10^{-2} M HCl) as a function of concentrations of various alkali metal ions. Excitation at the isosbestic point for both **2** and **2-H**$^+$ is at 376 nm.

 DOI: 10.1039/b106632n

The quantum yields were determined relative to 9,10-diphenylanthracene in MeOH, $\Phi_f = 0.94$[6]

	Metal ion M^+ Free	Li^+	Na^+	K^+	Rb^+	Cs^+
Φ_{em} of **2**	0.048	0.060	0.053	0.39	0.31	0.12
K of aza-crown in **2** with ions	—	10	7.4×10^2	6.30×10^4	1.26×10^4	2.82×10^3
Φ_{em} of **2-H**$^+$	0.060	0.098	0.55	0.26	0.22	0.15
K of **2-H**$^+$	—	65	6.2×10^2	6.0×10^2	3.9×10^2	1.5×10^2

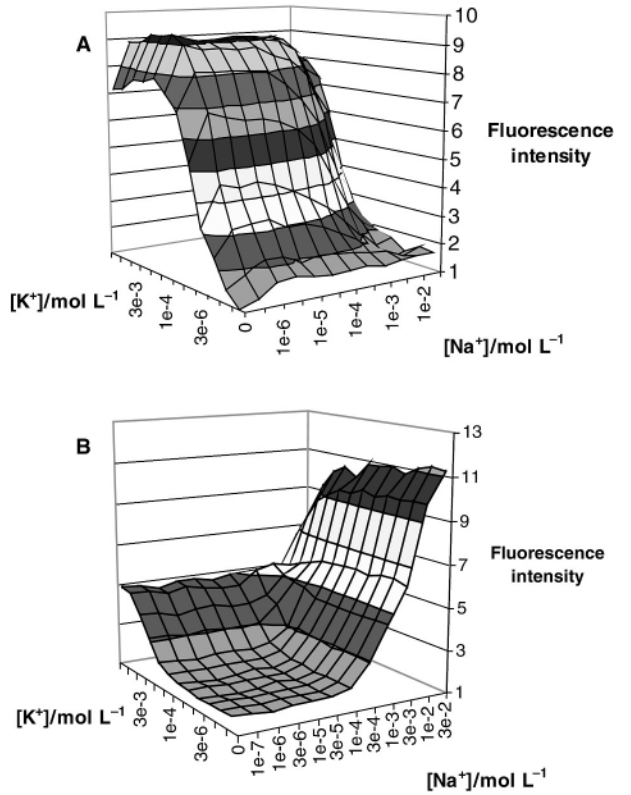

Fig. 2 (A) Changes in the fluorescence intensity (λ_{em} = 426 nm) of **2** (1×10^{-6} M) in basic methanol (morpholine, 1×10^{-2} M as proton scavenger) as a function of different concentrations of K^+ and Na^+. (B) Change in the emission intensity (λ_{em} = 425 nm) of **2-H**$^+$ (1×10^{-6} M) in acidic methanol (1×10^{-2} M HCl) as a function of different concentrations of K^+ and Na^+. Excitation at the isosbestic point for both **2** and **2-H**$^+$ is at 376 nm.

II with other alkali metal ions, except K^+, are weaker than those with Na^+, which results in weaker fluorescence enhancement of **2-H**$^+$. Though the complexation constant of ring **II** with K^+ (6.0×10^2 L mol^{-1}) is similar to the ring **II** with Na^+ (6.2×10^2 L mol^{-1}), which is consistent with those of other benzo-15-crown-5 derivatives with Na^+ and K^+ in methanol,[10–12] the fluorescence enhancement of **2** upon addition of K^+ is weaker than addition of Na^+. This is probably due to the metal ion size effect and will be explained in a full paper. Since nitrogen in ring **I** is protonated, no metal ions can be complexed into ring **I** because of electrostatic repulsion.

In probe **2**, fluorophore **I** (anthracene) and fluorophore **II** (anthrylmethylammonium) are switched by H^+, and **2** could be used to detect Na^+ at low pH, and to detect the K^+ by raising the pH of the solution. The maximum fluorescence quantum yields and the complexation constants of various metal ions with **2** under different conditions are listed in Table 1.

Further study of the fluorescence sensing behavior of **2** is conducted in a mixture of various concentrations of Na^+ and K^+ in two pH conditions (one acidic and the other basic), which is shown as a three-dimensional map in Fig. 2. In basic solution, the fluorescence enhancement region of **2** occurs when $[K^+]$ = 1×10^{-6} M to 1×10^{-4} M in the absence or presence of low concentration of Na^+ as shown in Fig. 2A. However, although the complexation constant of **2** with Na^+ is low, high concentration of Na^+ would affect the complexation of K^+ with **2**. In consequence, the fluorescence enhancement of **2** occurs at higher concentration of K^+ in the presence of high concentration of Na^+. For instance, when $[Na^+] = 3 \times 10^{-2}$ M, the fluorescence enhancement of **2** begins at $[K^+] = 1 \times 10^{-4}$ M and is completed at $[K^+] = 1 \times 10^{-2}$ M. In acidic solution as shown in Fig. 2B, the fluorescence enhancement of **2-H**$^+$ begins at $[Na^+] = 1 \times 10^{-4}$ M and is completed at $[Na^+] = 3 \times 10^{-2}$ M in the absence of K^+. In the presence of high K^+ concentrations, such as 3×10^{-3} M of K^+, the fluorescence enhancement of **2-H**$^+$ begins at $[Na^+] = 3 \times 10^{-4}$ M, which is slightly higher than that in the absence of K^+. It is also noticed that at fixed $[Na^+]$, especially at low $[Na^+]$, the fluorescence of **2-H**$^+$ increases upon addition of $[K^+]$ because K^+ could also complex with **2-H**$^+$ and cause a relatively weaker fluorescence enhancement of **2-H**$^+$ than Na^+ does.

These results suggest that probe **2** could be a potential fluorescent sensor to measure a mixture of Na^+ and K^+ in solution, the fluorescence intensity of **2** in a solution containing a Na^+–K^+ mixture is significantly different from only one metal ion species in the solution. By computer analysis of the data collected in both acidic and basic solutions, the concentrations of both K^+ and Na^+ in the solution may be determined simultaneously.

Currently, we are seeking the design of a similar system with two fluorophores switched by other factors, such as temperature, hydrogen bonds, or other supramolecular interactions.

Received (in Cambridge, UK) 26th July 2001, Accepted 5th September 2001
First published as an Advance Article on the web 1st October 2001

The tetradentate ligand, common name Salban(Bu^t)H_4 (*N*,*N*′-bis(2-hydroxy-3,5-di-*tert*-butylbenzyl)-1,4-diaminobutane) combines with appropriate amounts of $LiAlH_4$ to produce the unique monomeric, uni-ligated aluminate [Salban(Bu^t)Al]Li(thf)$_2$ (1) and the bimetallic derivative Salban(Bu^t){AlH_2Li(thf)$_2$}$_2$ (2).

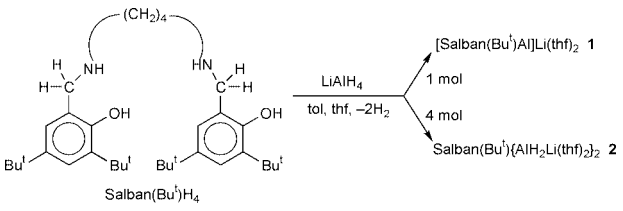
Group 13 anions have become increasingly important in recent years as reducing agents,[1] cocatalysts or counter ions for polymerization reactions[2] and in ionic liquids.[3] In their most commonly reported form, aluminates are composed of a combination of four singly-charged ligands, $[AlR_4]^-$. By comparison, there is relatively little literature focusing on chelated aluminium anions. Less frequently, they have been formed from bidentate ligands, and have the form $[L_2Al]^-$ (where L = diamine[4] or diol,[5] for example). Rarer still are those supported by a single ligand. Of this sort, only anions supported by Salan-type ligands have been reported.[6]

The Salan ligands are ideal candidates for supporting Group 13 anions since they can be deprotonated in four places to form, potentially, tetra-anions. Additionally, the hydrocarbon 'backbone' can easily be altered to allow for the synthesis of complexes with a wide variety of structures.[6,7] Two dimeric aluminates have previously been formed from Salan ligands with two- or three-carbon backbones: [SalanAl{Li(thf)$_2$}$_2$ [where Salan = Salpan (*N*,*N*′-bis(2-hydroxybenzyl)-1,4-diaminopropane)], and Salomphan (*N*,*N*′-bis(2-hydroxybenzyl)-*o*-diamino(4,5-dimethyl)phenyl).[6] In the present work we describe the first uni-ligated *monomeric* aluminate, as well as an unusual bimetallic AlH_2 derivative. These compounds have been made accessible by the use of a bulky Salan ligand with four carbons in its backbone, Salban(Bu^t)H_4 (*N*,*N*′-bis(2-hydroxy-3,5-di-*tert*-butylbenzyl)-1,4-diaminobutane).

The reaction of $LiAlH_4$ with a secondary amine was first reported in 1988.[8] Later, the intermediates in these reactions were isolated using $HN(SiMe_3)_2$.[9] More recently, several possible intermediates in the reactions of primary amines with $LiAlH_4$ have been reported.[10] We report here reactions of $LiAlH_4$ with the Salban(Bu^t)H_4 ligand. The Salban(Bu^t)H_4 ligand reacts with two moles of $LiAlH_4$ to form a mixture of two compounds, [Salban(Bu^t)Al]Li(thf)$_2$ **1** and Salban(Bu^t){AlH_2-Li(thf)$_2$}$_2$ **2**.† The ratio of reactants can be selected to favor one product exclusively over the other: **1** is isolated as a pure product from the reaction of an equimolar ratio of the two reactants, and **2** can be obtained by using four equivalents of $LiAlH_4$ (Scheme 1).

The $(CH_2)_4$ linkage in the backbone of Salban(Bu^t) is of sufficient flexibility to allow the ligand to coordinate just one metal. The structure of **1** (Fig. 1)[11] demonstrates the distorted tetrahedral geometry that results for the aluminum atom when this occurs. The angles range from 122.59(10)° (for O2–Al1–N1) to 91.48(8)° (for O2–Al1–O1). The Al–N and Al–O are suprisingly similar [Al1–N1, 1.801(2); Al1–N2, 1.785(2); Al1–O1, 1.7997(18); Al1–O2, 1.7944(17)], and short, for this type of complex. By comparison, these distances for [SalpanAl{Li(thf)$_2$}]$_2$ are 1.8–2.0 Å.[6] In fact, values of Al–O ≈ 1.7 Å are close to those ascribed to π-bonded systems such as dialkyl aluminium aryloxides[12] and Al–N distances ≈ 1.8 Å for monomeric aluminium amides with some π-bonding.[13] It is remarkable that compound **1**, which does not fulfill the usual criteria for π-bonded systems, should demonstrate such short, and uniform, bonds. However, alumoxanes such as [(Me_2AlO-Li)$_4$·7thf)] also demonstrate relatively short distances (Al–O 1.769 Å).[14] The lithium atom is coordinated to both oxygens of the Salban(Bu^t) ligand [Li1–O1, 1.963(5) Å; Li1–O2, 2.023(5) Å] and to two terminal thf molecules [Li1–O3, 1.958(5) Å; Li1–O4, 1.917(5) Å].

The crystal structure of **2** reveals the bimetallic nature of the compound (Fig. 2).[11] The aluminium atoms are five-coordinate and have a trigonal-bipyramidal geometry. The axial sites are occupied by oxygen and nitrogen atoms [O1–Al1–N1′, 167.30(11)°]. These nitrogens form longer bonds to aluminium [Al1–N1′ 2.113(3) Å] than the equatorial nitrogens [Al1–N1 1.938(3) Å]. Despite the charge on aluminium, the Al–O and Al–N distances are comparable to those demonstrated in the neutral Salan derivatives [SalanAlR(AlR$_2$)$_2$].[7] A similarity in these distances for related charged (cationic or anionic) and neutral derivatives is common. The other equatorial sites are filled by hydrogens, which were located in the structure determination. The Li–O distances for **2** are comparable to those demonstrated in **1** and do not reflect any steric interaction between the ligand Bu^t groups and the Li(thf)$_2$ unit. The Li1–H1 distance of 1.8929 Å is within the range observed for similar compounds (1.83–2.00 Å).[9,10]



Scheme 1 View of the SalbanH_4 ligand and the preparation of compounds **1** and **2**.

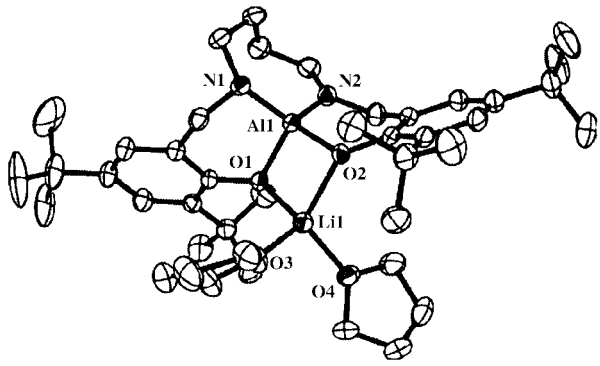


Fig. 1 Molecular structure and atom numbering scheme for **1** with selected bond distances (Å) and angles (°): Al1–N1 1.801(2), Al1–N2 1.785(2), Al1–O1 1.7997(18), Al1–O2 1.7944(17), Li1–O1 1.963(5), Li1–O2 2.023(5), Li1–O3 1.958(5), Li1–O4 1.917(5); N2–Al1–O2 101.29(9), N2–Al1–N1 118.30(11), O2–Al1–N1 122.59(10), N2–Al1–O1 120.36(10), O2–Al1–O1 91.48(8), N1–Al1–O1 101.00(9), Al1–O1–Li1 94.58(15), Al1–O2–Li1 92.73(15).

 DOI: 10.1039/b106772a

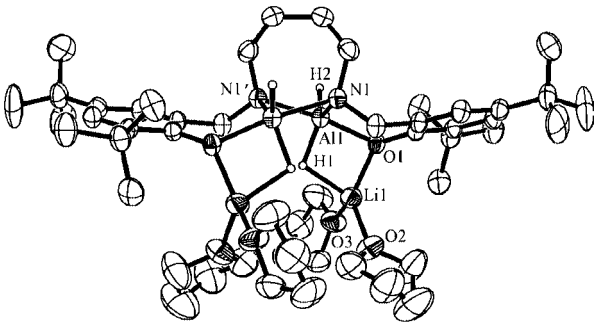

Fig. 2 Molecular structure and atom numbering scheme for **2** with selected bond distances (Å) and angles (°): Al1–H1 1.5718, Al1–H2 1.5175, Al1–O1 1.927(2), Al1–N1 1.938(3), Al1–N1′ 2.113(3), Al1–Li1 2.739(7), Li1–O1 1.887(7), Li1–O2 1.909(14), Li1–O3 1.958(18), Li1–H1 1.8929; O1–Al1–N1 93.21(11), O1–Al1–N1′ 167.30(11), N1–Al1–N1′ 79.88(13), O1–Al1–H1 85.3, N1–Al1–H1 114.4, N1′–Al1–H1 87.9, O1–Al1–H2 97.5, N1–Al–H2 123.5, N1′–Al1–H2 95.2.

In the ^{1}H NMR spectrum of **2**, one of the two Al–H resonances appears at δ 0.29 while the second is either broadened or coincident with other resonances, probably in the range 3–5 ppm, where the Al–H groups of other compounds appear ([H_2Al(pmdta)]$^+$ (pmdta = pentamethyldiethylenetriamine) = 3.09 ppm (br),[15] H_3Al–NMe_3 = 4.0 ppm[16] and [H_2AlOBu^t]$_2$ = 4.43 ppm (br)[17]. The NCH_2 groups show AB coupling consistent with diastereotopic, non-fluxional behavior in solution. In contrast, compound **1** demonstrates only one resonance for this group. Additionally, the ^{7}Li NMR spectrum of compound **2** shows two resonances in C_6D_6. However, in THF-d_8, the ^{7}Li NMR spectrum shows only one resonance which does not broaden significantly, even at −85 °C. Attempts were made to resolve ^1J(Li, H) coupling in **2** in a ^{7}Li NMR experiment similar to that reported by Heine and Stalke;[9] however, in **2** we could not observe the coupling at any temperature between 25 and −85 °C in either toluene-d_8 or THF-d_8. Our observations of the single ^{7}Li NMR resonance in THF-d_8, combined with the absence of ^1J(Li, H) coupling, suggest that the bonding of the lithium atoms in this compound are highly ionic in character.

Attempts to make boron and gallium complexes analogous to compound **1** have not been successful using the corresponding reagents $NaBH_4$ and $LiGaH_4$. In the case of $NaBH_4$ no reaction occurred after overnight reflux, and $LiGaH_4$ decomposed (depositing gallium metal) before it could react with Salban(Bu^t)H_4. We are currently exploring the utility of the chelated anion **1** as a cocatalyst in olefin polymerization and are working towards the synthesis of analogous complexes of boron and gallium using alternative routes.

The first isolable pentacoordinate 1,2λ⁵-azaphosphetine: synthesis, X-ray crystallographic analysis, and dynamic behaviour

Naokazu Kano, Azusa Kikuchi and Takayuki Kawashima*

Department of Chemistry, Graduate School of Science, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan. E-mail: takayuki@chem.s.u-tokyo.ac.jp; Fax: +81 3 5800 6899; Tel: +81 3 5841 4338

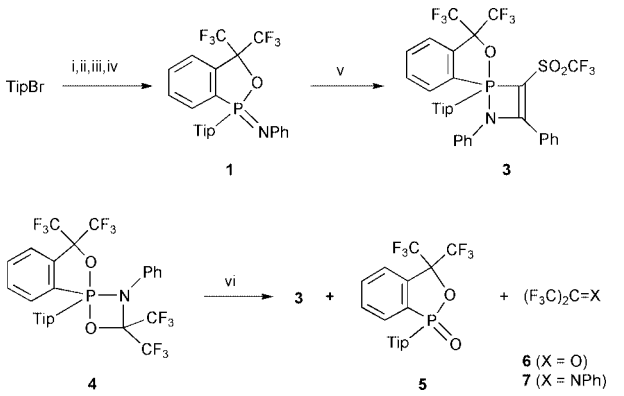
Received (in Cambridge, UK) 20th July 2001, Accepted 13th September 2001
First published as an Advance Article on the web 1st October 2001

Cycloaddition reaction of an iminophosphorane bearing the Martin ligand with an alkyne gave the first stable 1,2λ⁵-azaphosphetine, whose structure was determined by X-ray crystallographic analysis, and variable temperature NMR spectroscopy revealed the existence of equilibrium with the corresponding α-iminoalkylidenephosphorane.

There has been much interest in the chemistry of four-membered heterocyclic compounds containing a pentacoordinate phosphorus atom in view of their unique structures and reactivities.[1] For example, 1,2λ⁵-oxaphosphetanes have been intensely studied as the intermediates of Wittig reactions.[2] Such heterocycles bearing a C=C double bond in the ring would have a much more strained structure than the corresponding saturated ring compounds because of shortening of the bond length. They are expected to show interesting properties due to ring strain such as rearrangement to the corresponding conjugate phosphorus ylide accompanying bond dissociation between phosphorus and the adjacent heteroatom.[3] To the best of our knowledge, however, there have been only a few examples of such unsaturated ring compounds, *i.e.* 1σ⁴,2σ⁵-diphosphete, 1,2λ⁵-thiaphosphetene, and 1,2λ⁵-oxaphosphetene.[4–6] Furthermore, only one example of crystallographic analysis has been reported to date in spite of their potentially interesting structures.[4] On the other hand, the nitrogen analogue of a phosphonium ylide, *i.e.* an iminophosphorane, is expected to be a useful building block for nitrogen-containing four-membered heterocycles.[7] The reaction of an iminophosphorane with a reactive alkyne has been intensely studied because it is a convenient synthetic method for the corresponding α-iminoalkylidenephosphorane presumably *via* a [2 + 2]-cycloadduct of the two molecules although the intermediate has neither been observed nor been isolated yet.[8] We report here the synthesis and crystal structure of the first stable 1,2λ⁵-azaphosphetine derived from the corresponding iminophosphorane bearing the Martin ligand as well as a bulky 2,4,6-triisopropylphenyl (denoted as Tip hereafter) group.[9,10]

Reaction of iminophosphorane **1** which was prepared *in situ* from PCl_3, with alkyne **2** (1.2 eq.) in toluene-d_8 at 50 °C gave the corresponding cycloadduct **3** (27%) as colourless crystal (Scheme 1).[11]† Pentacoordinate 1,2λ⁵-azaphosphetine **3** was also obtained (5%) by thermal reaction of 1,3λ⁵,2-oxazaphosphetidine **4** with alkyne **2** (2.7 eq.) in toluene-d_8 at 140 °C, together with cyclic phosphinate **5**, ketone **6**, and imine **7**.[12] In the latter reaction, iminophosphorane **1** should be generated *in situ* together with formation of phosphinate **5** and imine **7** as indicated in the thermolysis of **4**.[11,12]

The molecular structure of **3** was determined by X-ray crystallographic analysis as shown in Fig. 1.‡ The 1,2λ⁵-azaphosphetine ring is almost planar, judging from the sum of the interior angles of the ring (359.6(8)°) and the small torsion angle of P(1)–C(1)–C(2)–N(1) (6.6(3)°). The P(1)–N(1) bond length (2.170(3) Å) is much greater than that of the trivalent 1,2-azaphosphetine, (1.824(6) Å), and that of the corresponding saturated compound, 1,2λ⁵-azaphosphetidine, (1.789(5) Å), but it is shorter than the sum of the van der Waals radii (3.40 Å),



Scheme 1 i. *n*-BuLi (1.9 eq.), Et_2O, 0 °C, 3 h; ii. PCl_3 (2.5 eq.), Et_2O, −70 °C to rt, 13 h; iii. 2-(LiOC$(CF_3)_2$)C_6H_4Li (0.5 eq.), THF–hexane, −78 °C, 30 min; iv. PhN_3 (0.9 eq.), THF, −78 °C, 12 h; v. PhC≡CSO_2CF_3 **2**, (1.2 eq.), toluene-d_8, 50 °C, 27 h, (27%); vi. PhC≡CSO_2CF_3 **2**, (2.7 eq.), toluene-d_8, 140 °C, 25 h (5%).

indicating a characteristic feature of the apical bond.[10b,13] The pentacoordinate phosphorus atom shows a distorted trigonal bipyramidal (TBP) structure with a nitrogen and an oxygen

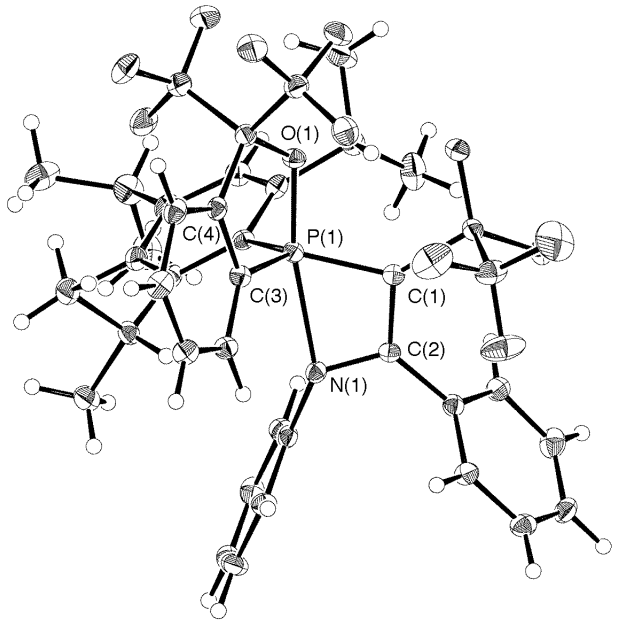


Fig. 1 ORTEP drawing of **23**·$\frac{3}{2}C_6H_6$ with thermal ellipsoid plot (30% probability for all non-hydrogen atoms). One of the enantiomers of **3** and a solvent molecule are omitted for clarity. Scheme 2

atom at the apical positions and three carbon atoms at the equatorial positions. The deviation from the ideal TBP structure is exemplified by the position of the phosphorus atom slightly above the equatorial plane by 0.204 Å and the bond angle between apical bonds (168.95(11)°). The pentacoordination characters, %TBP_a and %TBP_e were determined as 66% and 88%, respectively.[14] The deviation from ideal TBP structure seems to emerge from a steric repulsion between the N–Ph group and substituents on the phosphorus atom.

In the ^{1}H NMR spectrum of **3**, the *ortho* proton of the Martin ligand resonated at low field (δ_H 9.06 in $CDCl_3$), which is a typical feature of compounds with a TBP structure bearing a polar apical bond.[15] On the other hand, the chemical shift of **3** (δ_P 25.6 in the $CDCl_3$) in the ^{31}P NMR spectrum was at a low field for a phosphorane structure.[16] The low field shift compared to that of 1,2λ^5-azaphosphetidine indicates the contribution of the phosphorus ylide.[13] In the variable temperature ^{31}P NMR spectra of **3** in toluene-d_8, the signal shifted to the higher field almost linearly with decrease in the temperature from +90 °C (δ_P 26.9) to −90 °C (δ_P 15.6). The chemical shift of **3** in the more polar solvent, CD_3CN, also showed similar temperature dependence between +70 °C (δ_P 23.1) and −40 °C (δ_P 16.6). These results definitely show the equilibrium between **3** and **8** (Scheme 2). The higher the temperature, the more the equilibrium inclines to **8**. Compound **3** serves as a model for sequential structural change between TBP geometry of a 1,2λ^5-azaphosphetine and tetrahedral geometry of the corresponding conjugate α-iminoalkylidenephosphorane along with P–N bond formation–dissociation.

While spectroscopic studies revealed the existence of an equilibrium with the conjugate phosphorus ylide, no evidence of such an equilibrium was obtained by the following reactions. 1,2λ^5-Azaphosphetine **3** was thermally stable, and it did not decompose after heating in toluene-d_8 at 180 °C for three days. Heating of a toluene-d_8 solution of **3** with benzaldehyde at 80 °C or phenyl isocyanate at 140 °C resulted in no reaction instead of giving the corresponding Wittig-reaction products.[17]

In summary, we achieved the isolation and X-ray crystallographic analysis of the first example of a 1,2λ^5-azaphosphetine, which has been assumed to be an intermediate of the reaction of an iminophosphorane and an alkyne giving the α-iminoalkylidenephosphorane.

We thank Central Glass and Tosoh Finechem Corporation for the gifts of organofluorine compounds and alkyllithiums, respectively.

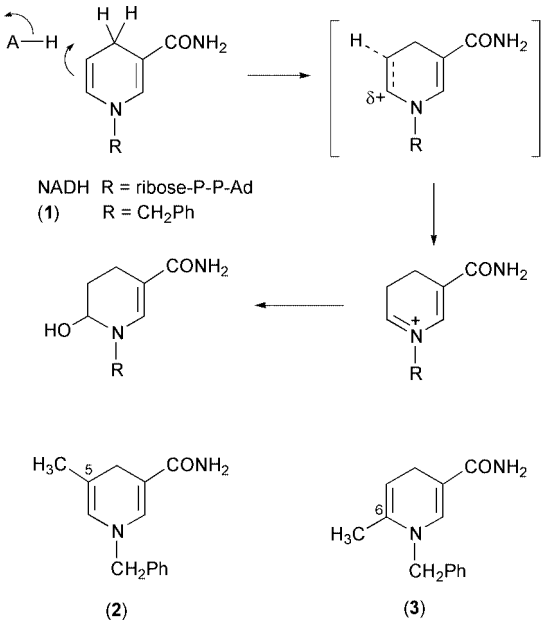
Received (in Cambridge, UK) 23rd August 2001, Accepted 12th September 2001
First published as an Advance Article on the web 3rd October 2001

A methyl substituent at C-5 of the nicotinamide ring is found to confer increased acid stability in a reduced nicotinamide model (5–20 fold) and in a reduced dinucleotide coenzyme (2–3 fold), while retaining reactivity towards hydride transfer.

Nicotinamide adenine dinucleotide is a redox coenzyme used by a large family of dehydrogenase enzymes, operating *via* a hydride transfer mechanism.[1] Dehydrogenase enzymes have found applications as catalysts for biotransformations,[2] and also as analytical biosensors.[3] Although methods for re-cycling of NADH have been developed for large scale biotransformations,[4] one major limitation of NADH and NADPH for biotechnological applications is their instability in aqueous solution. Under neutral and acidic conditions, NADH decomposes *via* general acid-catalysed protonation at C-5 ($t_{1/2}$ 2–24 h), and nucleophilic attack upon the resulting imine, as shown in Scheme 1.[5]

Model studies have shown that dihydronicotinamide analogues in which the 5,6-double bond is fused to a benzene ring,[6] or to a heterocyclic ring,[7] possess increased stability towards acid-catalysed decomposition, but the effects of such modifications in a dinucleotide coenzyme analogue have not been reported. As part of a study of bio-electrochemical applications of engineered dehydrogenase enzymes, we required a dinucleotide analogue of NADH that showed enhanced stability in aqueous solution, but which might also be accepted into dehydrogenase active sites. We describe here a simple modification to the nicotinamide skeleton, which confers increased acid stability in a nicotinamide model, and in a dinucleotide coenzyme.



Scheme 1 Mechanism for acid-catalysed decomposition of dihydronicotinamide cofactors (ref. 5).

In order to disfavour the protonation of the 5,6-double bond of reduced nicotinamide, we investigated the effect of substituting the C-5 or C-6 position with a methyl substituent. 5-Methylnicotinamide, prepared as described by Kyba *et al.*,[8] and 6-methylnicotinamide were converted to their respective *N*-benzyl derivatives, and reduced to the corresponding *N*-benzyldihydronicotinamides (**2**) and (**3**) by treatment with sodium dithionite.[9] Their stability in aqueous buffers was then compared with *N*-benzyldihydronicotinamide (BNAH, **1**). The decomposition of 0.2 mM solutions of each compound was monitored at the respective λ_{max} as described in Table 1.

In each case the rate of decomposition was found to increase with decreasing pH, indicating an acid-catalysed process. Higher rates of decomposition were found in phosphate buffer, which is known to accelerate the decomposition of NADH.[5] In each case the presence of a 5-methyl substituent led to a 5–20 fold decreased rate of decomposition, whereas the presence of a 6-methyl substituent led to a 30–70 fold increased rate of decomposition. The instability of the 6-methyl analogue (**3**) can be rationalised by the electron-donating effect of the methyl substituent upon C-6 of the nicotinamide ring, where a partial positive charge would accumulate in the transition state for protonation at C-5 (see Scheme 1). Therefore, the stabilising effect of the 5-methyl group must be due primarily to steric hindrance of attack at C-5, rather than electronic effects.

The reactivity of dihydronicotinamides (**1**)–(**3**) towards hydride transfer was assessed by reaction of 10 mM solutions in dry acetonitrile with 10 equiv. *p*-trifluorobenzaldehyde and 1 equiv. $Mg(ClO_4)_2$ at 25 °C, monitoring the disappearance of reduced nicotinamide by reverse phase HPLC *vs.* time. The half-life for reaction of BNAH (**1**) was 6 h, whereas half-lives of 1.5 h and 3.5 h were measured for (**2**) and (**3**) respectively. Therefore, no loss of chemical reactivity is observed upon addition of a methyl substituent to the 5- or 6-positions; in fact the substituted analogues are somewhat more reactive.

The same modification was then introduced into a dinucleotide analogue of NADH (see Scheme 2), using the enzyme NAD^+ glycohydrolase to catalyse the exchange of nicotinamide with an unnatural substituted nicotinamide.[10] Incubation of 0.2 g 5-methylnicotinamide with 1 unit porcine brain NAD^+ glycohydrolase and 0.2 g NAD^+ in 100 mM potassium phosphate buffer pH 7.5 for 16 h at 37 °C gave a reaction mixture containing 5:1 5-methyl-NAD^+:NAD^+. The two dinucleotides were separated by reverse phase HPLC,† and the 5-methyl NAD^+ purified preparatively. Reduction of 5-methyl NAD^+ to 5-methyl-NADH (**4**) was achieved by treatment with sodium dithionite, followed by ethanol precipitation.

The decomposition of 0.1 mM 5-methyl-NADH (**4**) was assessed in 50 mM MES buffer pH 5.5–6.5 and 50 mM potassium phosphate buffer pH 6.0–7.0, and was compared with NADH under the same conditions (see Table 1). Dinucleotides NADH and (**4**) were in general more stable than the *N*-benzylnicotinamide analogues (**1**)–(**3**), perhaps due to the folded conformation adopted by the dinucleotide in water,[11] which would offer some protection of the 5,6-double bond. Rates of

KP_i	7.0	63.0	1010	0.81	16.0	0.013	48.8	145	3.0

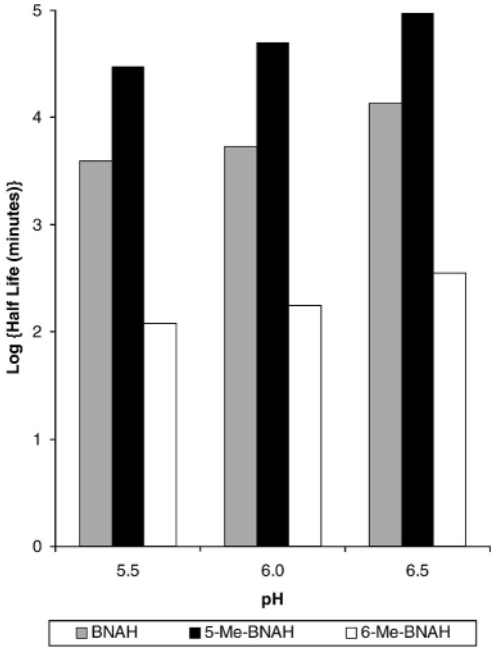

Fig. 1 Half-lives for first-order decomposition of dihydronicotinamides BNAH (**1**), 5-methyl-BNAH (**2**), and 6-methyl-BNAH (**3**) in 50 mM MES buffer pH 5.5, 6.0, and 6.0 at 25 °C.

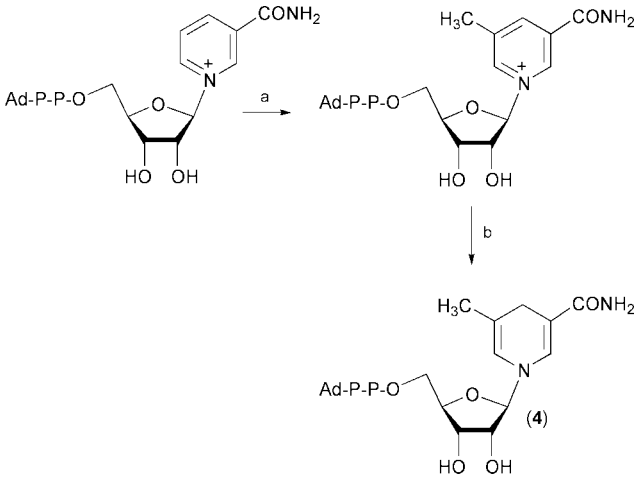

Scheme 2 Preparation of 5-methyl-NADH (**4**): a. 5-methylnicotinamide (5 equiv.), Porine brain NAD^+ glycohydrolase (1 units), 100 mM potassium phosphate pH 7.5; b. sodium dithionite (1.5 equiv.), sodium bicarbonate (1.5 equiv.), H_2O.

decomposition were again higher in more acidic buffer, consistent with an acid-catalysed decomposition mechanism. 5-Methyl-NADH (**4**) showed 2–3-fold increased stability, relative to NADH, in 50 mM MES buffer pH 5.5–6.5 and in 50 mM potassium phosphate buffer pH 6.0–7.0 (see Table 1). Thus, the stabilising effect of the 5-methyl substituent is also observed in the dinucleotide series, but is less marked than in the *N*-benzylnicotinamide series.

5-Methyl-NADH (**4**) was found to support the turnover of pyruvate by rabbit muscle L-lactate dehydrogenase, but at reduced catalytic efficiency (k_{cat} 0.0028 s^{-1}; K_M 55 μM; k_{cat}/K_M 50 M^{-1} s^{-1}) compared with NADH (k_{cat} 14 s^{-1}; K_M 7.0 μM; k_{cat}/K_M 2.0 × 10^6 M^{-1} s^{-1}), implying that the native enzyme is selective for the bound cofactor. Nevertheless, it is realistic to suggest that protein engineering could be used to design dehydrogenase enzymes capable of more efficient turnover of modified cofactors.

In summary, the introduction of a methyl group into the 5-position of the nicotinamide ring is shown to confer enhanced stability in aqueous buffers, due to the shielding of the 5,6-double bond from protonation. The same effect has been demonstrated in a dinucleotide coenzyme, which, although smaller in magnitude than in a nicotinamide model, demonstrates the feasibility of designing redox coenzymes of improved stability, which could be of considerable utility for biotechnological applications.

The authors thank the Office of Naval Research (Grant N00014-98-1-0898) for financial support, Dr H. Bright (ONR) and Dr A. Ellington (University of Texas at Austin) for helpful discussions, and Christopher Beadle (University of Southampton) for preliminary work.

Porous clay heterostructures with enhanced acidity obtained from acid-activated clays

Mark Pichowicz and Robert Mokaya*

School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: r.mokaya@nottingham.ac.uk

Received (in Cambridge, UK) 24th July 2001, Accepted 5th September 2001
First published as an Advance Article on the web 1st October 2001

Porous clay heterostructures (PCHs) with enhanced acidity may be prepared from suitably acid-activated montmorillonite clays; the higher acidity arises from Brønsted acid sites generated by acid treatment of the clay prior to its use as a host for PCH formation.

Over the past decade, extensive research has been undertaken in the synthesis of porous inorganic materials, which may be used as heterogeneous catalysts, adsorbents or as hosts for composite materials. Examples are the synthesis of pillared clays and mesoporous molecular sieves.[1–3] A recent class of clay based high surface area, porous materials are porous clay heterostructures (PCHs).[4] In the synthesis of a PCH, the clay is firstly opened up by the introduction of an ionic surfactant (*via* a cation exchange reaction) thus allowing easier access to the interlayer region.[4] Neutral amine co-surfactant molecules are then intercalated along with silica species, which leads to self-assembly of the silica into a porous network within the interlayer region. This gives an interlayer silica structure similar to that of MCM-41 molecular sieves.[4,5] The synthesis of PCHs was first reported using a fluorohectorite clay with a high cation exchange capacity (CEC).[4,6,7] A host clay with a high CEC was considered essential for the formation of PCHs.[4,6,7] However, more recently PCHs have been successfully synthesised from saponites and montmorillonites.[8,9] PCHs have been shown to act as solid acid catalysts;[6] their acidity arises from the clay and also from protons which are released during the silica polymerisation reaction to balance the layer charge of the clay. The acidity of PCHs may be improved *via* post-synthesis grafting of Al[9] or by using saponite clays with a high (tetrahedrally coordinated) Al content.[8] Here we explore the possibility of enhancing the acidity of PCHs by using acid-activated clays as hosts for the formation of porous acid-activated clay heterostructures (PAACHs). Since most of the (Brønsted) acid sites on PCHs are associated with the layers of the clay, we have attempted to enhance the acidity of the host matrix by acid treatment prior to PCH formation.

It is known that the number of matrix protons (on clay sheets), not associated with the interlayer cation, may be increased by acid treatment.[10,11] We have previously synthesised pillared acid-activated clays (PAACs) derived from an acid treated clay matrix and shown that due to the acidic nature of the host matrix, PAACs exhibit significantly different characteristics compared to conventional pillared clays and that they are superior (to conventional pillared clays) in terms of their acidity and catalytic activity for acid catalysed reactions.[12,13] We show here that high surface area PCH materials with enhanced acidity may be prepared from suitably acid-activated clays. The lower CEC of the acid-activated clay does not seem to affect the formation of a porous clay heterostructure.

The starting raw clay used was a Peruvian montmorillonite with a CEC of 91 meq (100 g)$^{-1}$, a basal (001) spacing of 15.4 Å and an anhydrous structural (layer) formula: $[Si_{7.86}Al_{0.14}]$-$[Al_{2.84}Fe_{0.30}Mg_{0.86}]O_{20}(OH)_4$. The raw clay was acid treated as previously described[11–13] to yield an acid-activated clay with a CEC of 71 meq (100 g)$^{-1}$ and a basal spacing of 15.5 Å. We were careful to ensure that the level of acid treatment was such that the acid-activated clay retained a layered structure and a substantial CEC. PCHs were prepared as follows: the clay (raw or acid-activated) was suspended in water (100 cm^3 per g clay) to which 0.5 M cetyltrimethylammonium bromide (CTAB) was added in a two fold excess of the clay CEC. The clay/CTAB suspension was stirred for 24 hours at 50 °C following which the clay was recovered by filtration and washed with deionised water to remove excess CTAB (*i.e.* until pH 7 was reached) and air dried overnight. The CTAB intercalated clay (Q^+-clay) was then stirred in neutral primary amine (octylamine or decylamine) at room temperature for 20 minutes following which tetraethylorthosilicate (TEOS) was added and the resulting suspension stirred for a further 3 hours. The final synthesis gel mixture had the molar ratio: Q^+-clay : amine : TEOS of 1 : 2 : 12. The precursor PCH was then recovered by filtration, air dried overnight and calcined at 650 °C for 5 hours. The final samples were designated PCH (from raw clay) or PAACH (from acid-activated clay) followed by C8 or C10 in parentheses to denote the use of octylamine or decylamine, *e.g.* PAACH(C8) is derived from acid activated clay using octylamine.

The CTAB solvated Q^+-clays from both the raw and acid-activated clays had basal spacings of *ca.* 22 Å; an increase in interlayer spacing of 6.5 Å. On intercalation of TEOS the basal spacings increased further to between 35–40 Å and then decreased slightly on calcination. Fig. 1 shows a representative powder XRD pattern obtained for calcined PAACH(C8). It is clear that the interlayer space is greatly expanded and that the layered structure of the clay is retained as indicated by the presence of higher order peaks. It is worth noting that, in the present case, the basal peak for PAACH samples (see Fig. 1) was much more clearly defined compared to that of PCH samples. We however also note that, during calcination, the removal of the organic matter was far quicker for PAACHs samples than for PCH samples. The PCH samples required calcination for 16 hours (at 650 °C) to totally remove the organic matter and obtain an off-white sample while a heating time of 5 hours was sufficient for PAACHs. This may suggest that PAACHs are more reactive (acidic) and therefore more readily catalyse the decomposition and removal of organic

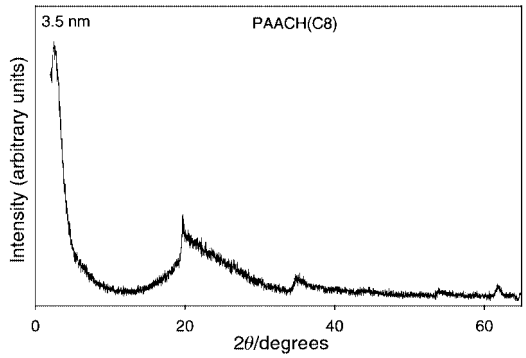

Fig. 1 A representative powder XRD pattern of a porous clay heterostructure (PAACH(C8)) derived from an acid-activated montmorillonite clay.

 DOI: 10.1039/b106660a

matter. Another possibility is that the more flexible acid-activated layers of the precursor PAACH allow easier removal (diffusion) of the organic matter; the assumption here is that acid activation disrupts the rigidity of the clay layers by removing some metal ions resulting in layers that are more structurally flexible. The manner and ease with which the organic matter is removed during calcination may therefore contribute to structural differences between PCH and PAACH that are reflected in the intensity of their basal peaks. We however note that calcining the precursor PAACH for 16 instead of 5 hours did not alter the properties of the final PAACH.

Table 1 shows the textural data obtained for PCHs and PAACHs. The PCH samples have surface area of *ca*. 800 m^2 g^{-1} while the acid-activated clay derived samples have higher surface area of 915 m^2 g^{-1} for PAACH(C8) and 951 m^2 g^{-1} for PAACH(C10). All the samples however have comparable pore volumes. The surface areas of the present materials are generally higher than that of fluorohectorite-PCH[6] but comparable to those of saponite and montmorillonite derived PCHs.[8,9] The pore volumes observed here (0.71 to 0.82 cm^3 g^{-1}) are similar to those of montmorillonite and saponite derived PCHs prepared by Ahenach *et al*.[9] but higher than that of saponite-PCH reported by Polverejan *et al*.[8] This is not unexpected since the synthesis method used here was similar to that of Ahenach *et al*.[9] The chain length of the neutral amine used has no influence on the surface area. However, using a longer chain amine (decylamine, C10) results in a slightly higher pore volume. The N_2 sorption isotherms obtained here for the PCH and PAACH materials are shown in Fig. 2. The isotherms are similar to those previously reported for PCHs.[8,9] A gradual increase in N_2 adsorption at low to medium partial pressures suggests that the materials possess supermicropores and small mesopores. The hysteresis loops are characteristic of cylindrical pores which are open at both ends, or of spaces between parallel plates, which is consistent with the structure of PCHs.[4] It is worth noting that the isotherms in Fig. 2 are significantly different from those exhibited by so-called silica bonded montmorillonite, SBM.[14]

The textural properties discussed above clearly illustrate that PCHs can be obtained using acid-activated clays as hosts. The acid contents of the present PCHs and PAACHs are given in Table 1. The acid content was determined using thermally programmed desorption of cyclohexylamine (CHA) as previously described.[15,16] Prior to thermogravimetric analysis, the base-containing samples were heated at 80 °C for 2 hours. The weight loss due to amine desorption from acid sites between 200 and 420 °C was used to quantify the acidity in mmol of CHA, assuming that each base molecule interacts with one Brønsted acid site. The total acid content (desorption between 200 and 420 °C) of PAACH is at least 30% higher than that of PCH. Furthermore the number of medium to strong acid sites (desorption between 300 and 420 °C) for PAACH is almost twice that of PCH. This suggests that the higher acidity in PAACHs is mainly due to an increase in the number of medium to strong acid sites. This is expected to have positive implications for the use of PAACHs as solid acid catalysts. We propose that the higher/stronger acid content of PAACHs is a consequence of the enhanced acidity on the clay sheets (after acid treatment) used for PAACH formation. It is also possible that some loose Al, present in the host acid-activated clay, is incorporated into the interlayer silica network. We are currently investigating the effect of using aluminosilicate rather than silica sources for PCH formation and anticipate that even higher acidity can be obtained if acid-activated saponites are used as hosts or by combining an acid activated host matrix (saponite or montmorillonite) with an aluminosilicate interlayer structure. The findings reported here open new opportunities for the preparation of acidic PCHs where the acidity can be optimised by varying the nature of the host clay and/or the type of interlayer network.

Table 1 Textural properties and acidity of porous clay heterostructures derived from raw montmorillonite (PCH) and acid-activated montmorillonite (PAACH) clays

Sample	Surface area/m^2 g^{-1}	Pore volume/cm^3 g^{-1}	Acidity[a]/mmol CHA g^{-1}
PCH(C8)	795	0.75	0.54 (0.14)
PCH(C10)	782	0.82	0.56 (0.15)
PAACH(C8)	915	0.71	0.71 (0.25)
PAACH(C10)	951	0.78	0.74 (0.27)

[a] Total acid content obtained from weight loss between 200 and 420 °C. Values in parentheses are the amounts of medium to strong acid sites obtained from weight loss between 300 and 420 °C.

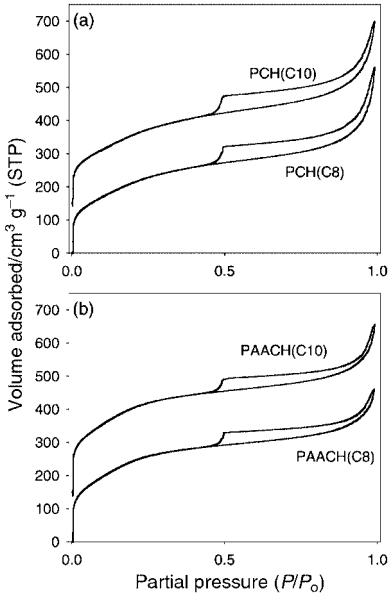

Fig. 2 Nitrogen sorption isotherms of porous clay heterostructures: (a) PCH, derived from a raw montmorillonite clay and (b) PAACH, derived from an acid-activated montmorillonite clay. C8 and C10 denote the use of octylamine or decylamine respectively as co-surfactant. For clarity, the isotherms of PCH(10) and PAACH(10) are offset (*y* axis) by 150.

R. M. is grateful to the EPSRC for an Advanced Fellowship. We are also grateful to S. Sajidu (University of Cambridge) for some of the acidity measurements.

First published as an Advance Article on the web 1st October 2001

A new manganese(III) oxamato dimer possesing an unprecedented $Mn_2(\mu\text{-}O_2CR)(\mu\text{-}OH_2\cdots O_2CR)$ core has been synthesised, structurally and magnetically characterised, and used as a catalyst for the oxidation of alkanes to alcohols and ketones by Bu^tO_2H and O_2 in CH_2Cl_2 at rt.

The past two decades have seen a considerable interest in manganese redox enzymes, particularly those containing carboxylate-bridged dinuclear active sites.[1] Among them, the less well understood but functionally important is manganese ribonucleotide reductase (MnRR), which catalyses the dioxygen-dependent reduction of ribonucleotides to deoxyribonucleotides in certain groups of bacteria.[2] This key reaction for the synthesis of DNA initiates, however, with hydrogen atom abstraction from the furanose ring of the ribonucleotide substrate by a tyrosyl protein radical generated during the process of O_2 activation by the dimanganese center.[2c] Although no crystallographic data are yet available for the native manganese enzyme, a manganese-substituted inactive form of the more extensively studied iron ribonucleotide reductase (FeRR) has been isolated and structurally characterised.[3] In this case, two Mn^{II} ions are doubly-bridged by two bidentate carboxylates of glutamato protein residues at a separation of 3.6 Å.[3b] That being so, studies concerning the reactivity of manganese model complexes bearing some structural features similar to those proposed for the different forms of the enzyme can help to understand the mechanism of conversion of ribonucleotides by MnRR.[4] Here we report on the synthesis and general physical characterisation,† crystal and molecular structure,‡ and magnetic properties of the manganese(III) dimer complex $(Ph_4P)_2[Mn_2(opba)_2(H_2O)_3]\cdot 3H_2O\cdot MeCN$ **1**, where opba is *o*-phenylenebis(oxamato). We also report a preliminary investigation of the catalytic activity of **1** towards the oxidation of hydrocarbons with alkyl hydroperoxides in the presence of dioxygen under mild conditions.

The structure of **1** consists of non-centrosymmetric dinuclear manganese(III) complex anions, $[Mn_2(opba)_2(H_2O)_3]^{2-}$ (Fig. 1), tetraphenylphosphonium cations and both water and acetonitrile solvent molecules. The coordination environment about each Jahn–Teller-elongated octahedral manganese atom is formed by two amide nitrogen and two carboxylate oxygen atoms of the tetradentate opba ligand defining the equatorial plane and with the two labile axial positions being occupied by water and/or carboxylate oxygen atoms. In fact, within the dinuclear unit, a carboxylate group from one planar [Mn(opba)] moiety is axially bound to the manganese atom from the other moiety (*syn–anti* bidentate bridging mode),[5] while a free carboxylate oxygen atom from the latter [Mn(opba)] fragment is hydrogen-bonded to an axial, manganese-bound water molecule of the former fragment [O(8)···O(14) separation of 2.702(9) Å]. This leads to an overall asymmetric doubly-bridged dimanganese(III) core which is reminiscent of the structure of the diiron(III) form of FeRR, but without the oxo bridge present therein.[3a] The Mn(1)···Mn(2) intramolecular separation through this unique nine-membered metallacyclic ring, $Mn^{III}_2(\mu\text{-}O_2CR)(\mu\text{-}OH_2\cdots O_2CR)$, in **1** is 5.693(3) Å. This is *ca.* 2.5 Å longer than the corresponding distance in the related triply-bridged $Mn^{III}_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2$ species, which have been proposed as suitable structural models of the dimanganese(III) form of MnRR.[6]

The magnetic behaviour of **1** is typical of an antiferromagnetically-coupled dimanganese(III) pair. At room temperature, the product $\chi_M T$ (χ_M being the molar magnetic susceptibility per dinuclear unit and T the temperature) is equal to 6.0 $cm^3\ mol^{-1}$ K (6.9 μ_B), a value which is consistent with two Mn^{III} ($S = 2$) ions. Upon cooling, $\chi_M T$ continuously decreases from room temperature to 0.8 $cm^3\ mol^{-1}$ K (2.5 μ_B) at 2.0 K, whereas χ_M exhibits a characteristic maximum around 6.0 K, which unambiguously indicates a diamagnetic ground singlet ($S = 0$) pair spin state. The least-squares fitting of the magnetic susceptibility data gives $g = 2.00$ and $J = -2.0\ cm^{-1}$ (where $H = -JS_1\cdot S_2$; $S_1 = S_2 = 2$). The value of the exchange coupling parameter for **1** compares well with that found for other weakly coupled di(μ-carboxylato)dimanganese(II) complexes (J values of -1.4 and $-1.9\ cm^{-1}$).[7] On the other hand, this certainly weak, although non-negligible, antiferromagnetic coupling through the carboxylate bridge found in **1** emphasises the relative importance of the exchange pathways involving the bridging carboxylate groups for the analysis of the variations in the sign and the magnitude of the exchange coupling in (μ-oxo)di(μ-carboxylato)dimanganese(III) complexes (J values ranging from +18.0 to $-8.2\ cm^{-1}$).[6b]

The oxidation catalytic activity of **1** has been examined in a non-coordinating solvent like methylene chloride and at room temperature using *tert*-butyl hydroperoxide as oxidant under aerobic conditions. The results for some representative alkanes

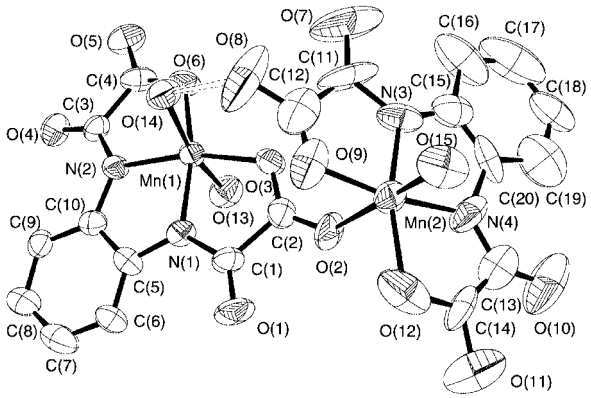

Fig. 1 Perspective view of the anionic dinuclear unit of **1** with the atom-numbering scheme (thermal ellipsoids are at the 50% probability level and hydrogen atoms have been omitted for clarity). Selected bond distances (Å) with standard deviations in parentheses: Mn(1)–N(1) 1.919(5), Mn(1)–N(2) 1.914(5), Mn(1)-O(3) 1.968(4), Mn(1)–O(6) 1.935(5), Mn(1)–O(13) 2.318(6), Mn(1)–O(14) 2.323(5), Mn(2)–N(3) 1.883(6), Mn(2)–N(4) 1.920(8), Mn(2)–O(9) 1.911(7), Mn(2)–O(12) 2.019(7), Mn(2)–O(15) 2.272(6), Mn(2)–O(2) 2.321(5).

Table 1 Results for the oxidation of alkanes and alkyl arenes catalysed by **1**[a,b]

Entry	Substrate	Product	Yield (%)[c]
1	Cyclohexane	Cyclohexanol	1.9 (3.5)[d]
		Cyclohexanone	2.2 (5.4)[d]
2	Adamantane	1-Adamantanol	8.0
		2-Adamantanol/one	1.0
3	Toluene	Benzaldehyde	3.1
		Benzoic acid	1.3
4	Ethylbenzene	1-Phenylethanol	4.2
		Acetophenone	16.9
5	Diphenylmethane	Benzhydrol	5.2
		Benzophenone	37.3

[a] Reactions were carried out at room temperature by adding a solution of the substrate (0.10 mmol) in CH_2Cl_2 (0.2 mL) to a stirred mixture of the metal catalyst (5.0×10^{-3} mmol) and Bu^tO_2H (0.30 mmol) in CH_2Cl_2 (0.2 mL) under an O_2 atmosphere for a period of 24 h. [b] In the absence of catalyst no oxidation was observed. [c] Yields refer to GLC determination based on the starting substrate. [d] With a reaction time of 72 h.

and alkyl arenes are summarised in Table 1. Complex **1** catalysed the oxidation of cyclohexane to the corresponding alcohol and ketone, cyclohexanol and cyclohexanone, respectively, with varying yields depending on the reaction time (entry 1). Interestingly, the cyclohexanol : cyclohexanone ratio dropped from 0.9 to 0.6 with longer reaction times, suggesting that secondary alcohols are further oxidised to ketones under the experimental conditions. It is also noteworthy that for our catalytic system the tertiary to secondary C–H bond relative reactivities (k_{tert}/k_{sec}; on a per bond basis) for the oxidation of adamantane was as high as 24 (entry 2). On the other hand, alkyl arenes such as toluene, ethylbenzene or diphenylmethane were oxidised selectively at the benzylic position to give the corresponding benzylic oxygenation products, and no traces of the corresponding aromatic ring hydroxylation products were detected by GLC analysis in any case. As expected, the oxidation of toluene gave some minor amounts of benzoic acid together with the main product benzaldehyde, whereas no benzyl alcohol was observed among the oxygenation products (entry 3). The oxidation of ethylbenzene and diphenylmethane afforded mixtures of the corresponding alcohol and ketone exclusively (entries 4 and 5, respectively). The total yields of benzylic oxygenation products followed the trend toluene < ethylbenzene < diphenylmethane (entries 3–5). Indeed, the oxidation efficiency along this series of alkyl arenes $PhCH_2R$ (R = H, Me, Ph) correlates directly with the C–H bond strength, thus suggesting that C–H bond cleavage is the rate-determining step of the catalytic cycle. Further kinetic studies are in progress to determine the detailed mechanism and the exact chemical nature of the active oxidant in these biomimetic oxidations.

This work was supported by the Dirección General de Enseñanza Superior e Investigación Científica (Spain) through projects PB97-1411 and PB97-1397. R. R. thanks the Ministerio de Ciencia y Tecnología (Spain) for a grant. We are specially thankful to Pedro Palanca for the assistance with the GLC measurements.

† *Synthesis and selected data*: to a solution of the diethyl ester derivative of the ligand (1.54 g, 5.0 mmol) in methanol (50 mL) was added a 25% methanol solution of Me_4NOH (8.0 mL, 20.0 mmol). Solid $Mn(MeCO_2)_3 \cdot 2H_2O$ (1.35 g, 5.0 mmol) was then added in small portions under stirring, and the resulting reaction mixture was further stirred for 15 min at room temperature. A brick-red microcrystalline solid formed abundantly which was collected by filtration and dried under vacuum. The filtered deep brown solution was reduced to a final volume of 25 mL in a rotatory evaporator. Upon standing at 4 °C in a refrigerator, a second crop of crystals separated from the concentrated solution which was also collected and dried (60%). Anal. Calc. for $C_{14}H_{16}MnN_3O_6 \cdot 2H_2O$: C 40.67, H 10.17, N 4.84. Found: C 41.05, H 9.91, N 5.12%. $(Me_4N)[Mn(opba)] \cdot 2H_2O$ (0.83 g, 2.0 mmol) was dissolved in water (50 mL) and the reaction mixture was filtered on paper to eliminate a small amount of solid particles. A solution of Ph_4PCl (0.75 g, 2.0 mmol) in acetonitrile (25 mL) was then added to the filtered deep brown aqueous solution. Well-shaped, brick-red elongated prisms of **1** suitable for X-ray diffraction were deposited after a few hours of slow evaporation at room temperature. They were filtered off and air-dried (90%). ν(KBr)/cm^{-1} 3422s (O–H) from H_2O, 2254w (C≡N) from MeCN, 1669vs and 1645vs (C=O), 1381s and 1280s (C–O) from opba. UV–Vis (MeCN) λ_{max}/nm: 210 (ε/L mol^{-1} cm^{-1} 1.4×10^5), 225 (sh), 260 (4.0×10^4), 275 (sh), 340 (9.4×10^3) and 410 (sh).

‡ *Crystal data for* $C_{70}H_{63}Mn_2N_5O_{18}P_2$: M = 1434.1, triclinic, space group $P\bar{1}$, a = 13.099(3), b = 15.446(3), c = 17.687(4) Å, α = 73.04(3), β = 79.94(3), γ = 80.84(3)°, U = 3348(1) Å^3, T = 293 K, Z = 2, μ(MoKα) = 0.50 mm^{-1}, 11 665 reflections measured, 7556 assumed as observed with $I \geq 2\sigma(I)$. Hydrogen atoms were located from a difference synthesis and refined with an overall isotropic thermal parameter. Refinement on F^2 of 875 variables with anisotropic thermal parameters for all non-hydrogen atoms gave R = 0.092 and wR = 0.251 with S = 0.94 (observed data).

2,4,6-Tris(2-fluoroanilino)-1,3,5-triazene successively undergoes one-, two- and three-fold deprotonation in the presence of Bu^{n}Li; the dilithiated triazenate exists as the dimeric complex (thf)$_6$Li$_4$[(RN)$_2$(RNH)C$_3$N$_3$]$_2$ in the solid state (R = 2-F-C$_6$H$_4$) featuring bidentate N$_{endo}$–C–N$_{exo}$ chelation sites.

The resemblance of monoanionic amidinates $[RC(NR)_2]^-$ [1] and bis-imino phosphinates $[R_2P(NR)_2]^-$ [2] in reaction and coordination behaviour corroborate the diagonal relationship between carbon and phosphorus. Both are sterically demanding, electron-rich bidentate chelates, which can be obtained from the protic precursor [RC(NR)(NHR)] and [R$_2$P(NR)(NHR)], respectively. Recently, we have shown that hexakis(organoamino)cyclotriphosphazenes $(RNH)_6P_3N_3$ act as multiprotic acids in the presence of strong bases yielding trianionic $[(RNH)_3(RN)_3P_3N_3]^{3-}$ and hexaanionic phosphazenates $[(RN)_6P_3N_3]^{6-}$.[3] Considering the diagonal C–P relationship, analogous triprotic 2,4,6-tris(organoamino)-1,3,5-triazenes **1**H$_3$ are expected to be metallated correspondingly to give anionic triazenates (Scheme 1), which promise interesting coordination modes, due to the potential three-fold symmetry of the anticipated multi-site ligands.

Here, we present initial lithiation studies of 2,4,6-tris(2-fluoroanilino)-1,3,5-triazene (**1**H$_3$), which was generated by the reaction of cyanuric chloride with an excess of 2-fluoroaniline. We monitored the reaction of **1**H$_3$ with Bu^{n}Li in THF using ^{1}H and ^{13}C NMR spectroscopy (Fig. 1). Upon addition of Bu^{n}Li the NH signal gradually shifts up-field and decreases in intensity until it vanishes once three equivalents of Bu^{n}Li have been added. The ^{13}C NMR shift of C(1) moves down-field from 127 in **1**H$_3$ to 144 ppm in Li$_3$**1**, and that of C(6) up-field from 124 (**1**H$_3$) to 115 ppm (Li$_3$**1**) (see Fig. 1 for numbering scheme). The signal of the ^{13}C nuclei of the central triazene ring shifts only slightly from 165 (**1**H$_3$) to 169 ppm (Li$_3$**1**). Throughout lithiation the ^{19}F NMR consists of a single peak, which also shifts only marginally from 130 to 132 ppm. Both ^{1}H and ^{13}C NMR of partially deprotonated species display only one set of signals for both 2-fluoroanilino and triazene moieties, indicating rapid proton transfer at room temperature. However, two sets of signals with an intensity ratio of 2:1 appear in the ^{13}C NMR spectrum of a THF solution containing the dilithiated species Li$_2$**1**H, which was recorded at −80 °C. The chemical shifts of the set of lower intensity are similar to the spectrum of **1**H$_3$ and can be attributed to the non-deprotonated anilino substituent, wheras those of the set of higher intensity, which resemble the pattern observed in the spectrum of Li$_3$**1**, are caused by the two deprotonated substituents. At −80 °C the ^{13}C nuclei of the triazene ring also give two resonances (at 164 and 169 ppm).

Single crystals were obtained from the reaction of **1**H$_3$ with two equivalents of Bu^{n}Li in THF. X-Ray structure determination revealed that two-fold deprotonation had occurred and the resulting Li$_2$**1**H exists as the centrosymmetric dimer (thf)$_6$Li$_4$(**1**H)$_2$ **2** in the solid state (Fig. 2).† Both ligands in **2** are linked by the two centrally arranged lithium ions (Li1, Li1a) forming an eight-membered [Li–N$_{exo}$–C–N$_{endo}$–]$_2$ ring core. In addition, Li1 and Li1a undergo weak cross-ring interactions to N$_{exo}$-sites and each is coordinated to an F-aryl atom and a thf molecule resulting in distorted trigonal bipyramidal coordination geometries. The other two lithium ions (Li2, Li2a) are accommodated in neighbouring N$_{exo}$–C–N$_{endo}$ chelates and are additionally coordinated to two thf molecules giving tetrahedral metal surroundings. **2** combines coordination modes of monomeric and dimeric lithium complexes of ligands featuring bidentate N–E–N chelates [E = (R)C,[4] (R$_2$)P,[5] (R)S[6]]. Li2

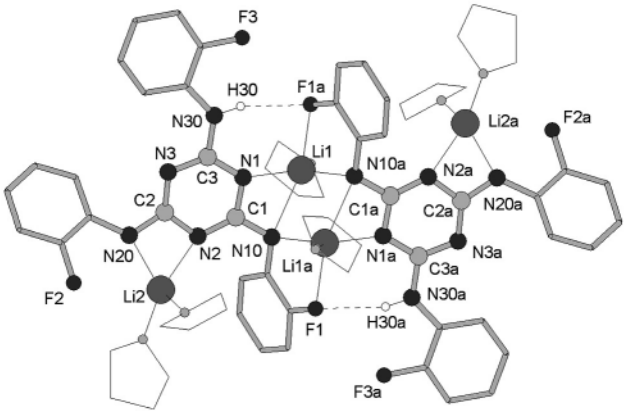

Fig. 2 X-Ray structure of **2**. Selected bond lenghts (Å) and angles (°): N1–C1 1.339(9), N1–C3 1.351(9), N2–C1 1.343(9), N2–C2 1.359(9), N3–C3 1.336(9), N3–C2 1.341(9), C1–N10 1.353(9), C2–N20 1.334(9), C3–N30 1.374(10), Li1–N1 2.03(2), Li1–N10 2.32(2), Li1–N10a 2.07(2), Li1–F1a 2.15(2), Li2–N2 2.11(2), Li2–N20 1.99(2), Li2···F2 3.072(15); C1–N1–C3 113.1(7), C1–N2–C2 115.7(7), C2–N3–C3 114.3(7), N1–C1–N2 125.5(8), N2–C2–N3 124.0(8), N3–C3–N1 127.3(7), N1–C1–N10 111.6(8), N2–C2–N20 110.5(7), N3–C3–N30 118.5(8).

corresponds to the 'monomeric' mode, where the lithium ion is chelated by a single N–E–N unit, and Li1 to the often encountered N–E–N dimer mode, where two ligands encapsulate two lithium ions in both mono- and bi-dentate fashion. A similar motif is observed in the polymeric trilithium salt of trithiocyanuric acid.[7]

In contrast to phosphazenates, where the metallation causes a marked impact on the structural parameters of the central P_3N_9 core, bonding parameters within the central C_3N_6 ligand core of **2** are not very much affected upon metallation. The C–N_{exo} bond involving the non-metallated anilino group is only marginally longer [C3–N30 1.374(10) Å] than those of the deprotonated substituents [C1–N10 1.353(9), C2–N20 1.334(9) Å], which are of similar lengths as C–N_{endo} bonds ranging from 1.336(9) to 1.359(9) Å. Accordingly, in neutral 2,4,6-tris-(amino)-1,3,5-triazenes C–N_{exo} bonds are on average only 0.02 Å longer than C–N_{endo} bonds.[8]

1H_3 is deprotonated without undergoing side reactions. The lithiation is reversible as **1**H_3 is recovered after protolysis of Li_3**1**. On the other hand, 1,3,5-triazene and 2,4,6-tris(organo)-1,3,5-triazenes are prone to nucleophilic attack by organolithium reagents at C_{endo} positions, which leads to either nucleophilic addition, substitution or ring cleavage.[9] F(aryl) functions in **2**, initially introduced to act as ^{19}F NMR spectator sites, are inert on lithiation. The absence of line broadening of ^{19}F signals indicates that there are no considerable ^{7}Li–^{19}F interactions in solution.

The electron deficiency of the central C_3N_3 ring in **1**$^{3-}$ is compensated for by the π-donating character of exocylic N centres, which allow delocalisation of negative charge across the entire C_3N_6 core. In contrast to the non-aromatic tri- and hexa-anionic triphosphazenates, triazenates H**1**$^{2-}$ and **1**$^{3-}$ feature an aromatic ligand core. This enables electronic interaction between accommodated metal centres across the aromatic ligand system. In addition, the D_{3h} symmetry of the C_3N_6 ligand core and the straightforward introduction of organo amino groups with various functionalities promise the generation of metal complexes with interesting properties.

This work was supported by the EPSRC and the Royal Society.

First published as an Advance Article on the web 24th September 2001

A [2]-catenane consisting of a bipyridinium cyclophane and a dioxybenzene macrocyclic polyether has been encapsulated within the supercages of zeolite Y by ship-in-a-bottle synthesis; laser flash photolysis reveals that the charge-separated species decays in hundreds of microseconds in contrast to the few picoseconds previously reported for the same transient in acetonitrile.

The action of many photoresponsive switches and supramolecular machines is based on the occurrence of an intramolecular electron transfer triggered by light.[1] However, one of the major problems thwarting the operation of these supramolecular devices is a fast deactivation pathway of the charge-separated transient species consisting of reverse electron transfer leading back to the ground state.[2] This energy-wasting process is generally very efficient and limits the lifetime of the photogenerated transient to the subnanosecond time scale. Generally, the 'action' of the supramolecular machine is expected to consist of the movement of a shuttle from one station to a second in the supramolecular assembly during the lifetime of the charge-separated state. This co-conformational movement requires a sufficiently long transient lifetime and is related to a retardation of the back electron transfer (BET) to the microsecond time scale.

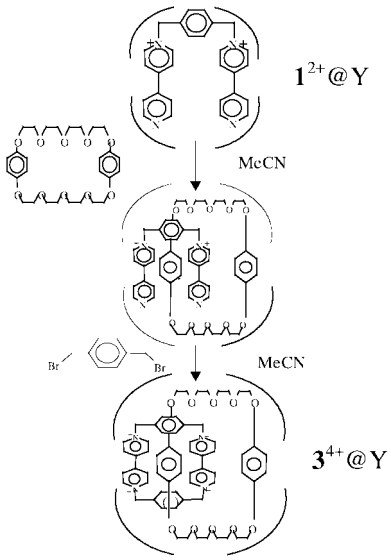
In a different context, it has been reported that incorporation of a charge-transfer (CT) complex within the internal voids of zeolites may increase the lifetime of the photoinduced radical ion pair by over six orders of magnitude.[3] As a part of our ongoing research focussed on the encapsulation of photoresponsive rotaxanes and catenanes within the rigid internal voids of zeolites, we report here the ship-in-a-bottle synthesis of [2]-catenane $\mathbf{3}^{4+}$ encapsulated within the supercages of zeolite Y ($\mathbf{3}^{4+}$@Y). We provide laser flash photolysis evidence showing that the transient of [2]-catenane $\mathbf{3}^{4+}$ within zeolite Y is much longer lived (hundreds of μs) than that observed for the same switch in MeCN (tens of ps).[4] Our report is the first to show the benefits of immobilization of a molecular switch within the rigid matrix of a zeolite.

Based on the reported single-crystal X-ray diffraction,[5] the dimensions of the [2]-catenane $\mathbf{3}^{4+}$, comprised of the viologen cyclophane as the electron-acceptor unit and the macrocyclic hydroquinone polyether as the electron-donor unit, are too large (11.7 × 10.3 × 7.0 Å) to allow its free diffusion from the exterior to the interior cages of the zeolite Y (openings 7.4 Å in diameter). It is, however, sufficiently small for accommodation within the spherical supercages (13 Å). In contrast, the smaller dimension of the macrocyclic polyether (10.6 × 4.7 Å) should allow its free diffusion through the zeolite Y micropores. A suitable strategy to prepare $\mathbf{3}^{4+}$@Y is a ship-in-a-bottle synthesis[6] consisting of constructing the big catenane within the cage by reacting smaller precursors that diffuse through the pore openings.

We have adapted the reported synthesis of catenane $\mathbf{3}^{4+}$ in solution[5] to obtain it by a ship-in-a-bottle methodology (Scheme 1).† In the first step, the open precursor $\mathbf{1}^{2+}$ is ion-exchanged inside zeolite NaY ($\mathbf{1}^{2+}$@Y), by stirring an aqueous solution of preformed $\mathbf{1}(PF_6)_2$ in the presence of the zeolite. Zeolites are microporous solids that are well suited to adsorb positively charged organic species. Subsequent formation of the [2]-catenane $\mathbf{3}^{4+}$ encapsulated within the cages of Y zeolite was accomplished by treating $\mathbf{1}^{2+}$@Y first with the macrocyclic polyether (CT complex formation), and then with 1,4-bis-(bromomethyl)benzene (closure of the cyclophane macro-ring). Formation of $\mathbf{3}^{4+}$@Y was assessed by comparing the spectra of the solid sample with those of its precursor $\mathbf{1}^{2+}$@Y and the corresponding viologen macro-ring $\mathbf{2}^{4+}$@Y.

The UV–vis absorption spectra of the cyclophane $\mathbf{2}^{4+}$ and the [2]-catenane $\mathbf{3}^{4+}$ inside zeolite Y are similar to the reported absorption spectra of these compounds in MeCN.[5] Fig. 1 shows the diffuse reflectance UV–vis absorption spectra of the samples $\mathbf{2}^{4+}$@Y and $\mathbf{3}^{4+}$@Y. A weak band with its onset at 800 nm, whose absorption increases linearly as the wavelength decreases, is observed in the spectrum of $\mathbf{3}^{4+}$@Y but is absent in the spectrum of the cyclophane $\mathbf{2}^{4+}$@Y. This absorption band is known to arise from the interaction between the electron-rich crown ether moiety and the electron-poor tetracationic cyclophane. The presence of this broad, structureless band has been taken as the simplest criterion to establish the formation of this type of complex.[5,7,8]

IR spectroscopy provides useful information since it allows differentiation between pyridine and pyridinium rings.[9] Considering the difference between $\mathbf{1}^{2+}$ and $\mathbf{2}^{4+}$ or $\mathbf{3}^{4+}$, the presence or absence of neutral pyridine rings can be used as a criterion to establish the success of the formation of catenane $\mathbf{3}^{4+}$. To follow the cyclization step shown in Scheme 1 without interference from the polyether macrocycle, FT-IR spectra of $\mathbf{1}^{2+}$@Y were



Scheme 1

 DOI: 10.1039/b104206h

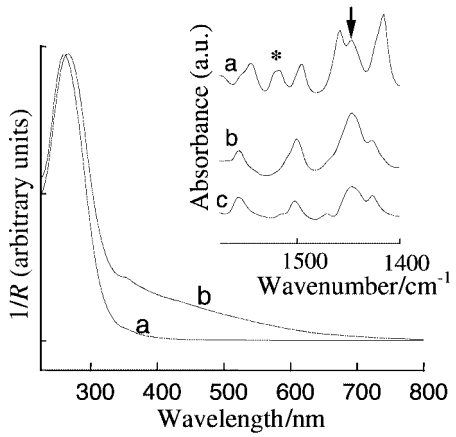


Fig. 1 Diffuse reflectance UV–vis spectra (plotted as the inverse of *R*) of $\mathbf{2}^{4+}$@Y (a) and $\mathbf{3}^{4+}$@Y (b). The inset shows part of the IR spectra of $\mathbf{1}^{2+}$@Y (a), $\mathbf{2}^{4+}$@Y (b) recorded at room temperature after outgassing at 200 °C for 1 h at 10^{-2} Pa, and that of $\mathbf{2}^{4+}(PF_6)_4$ (c) in a KBr disk. The three spectra exhibit the band corresponding to the *N*-alkylpyridinium ring (↓), but only the uncyclised $\mathbf{1}^{2+}$ has the band characteristic of the free pyridine ring (*).

compared with those for $\mathbf{2}^{4+}$@Y and for an authentic specimen of $\mathbf{2}^{4+}(PF_6)_4$ prepared as reported. Fig. 1 inset shows the corresponding FT-IR spectra.

In the context of the characterization of acidity in zeolites, it has been reported that pyridine and pyridinium ions can be safely distinguished by the presence of 1560 and 1450 cm^{-1} bands, respectively.[9] Accordingly, the IR spectrum of the viologen cyclophane shows only vibration bands corresponding to *N*-alkylpyridinium and is different from that of $\mathbf{1}^{2+}$@Y which contains bands corresponding to both *N*-alkylpyridinium and free pyridine. Similarly, the aromatic region of the IR spectrum of $\mathbf{2}^{4+}$@Y viologen macro-ring can be taken as a fingerprint, and is very similar to that recorded for the $\mathbf{2}^{4+}(PF_6)_4$ salt in the form of a KBr disk. This good match was also considered to be a good means of assessing the success of the cyclization of the bipyridinium macro-ring inside the zeolite Y supercages, providing solid evidence in support of the formation of $\mathbf{2}^{4+}$@Y and $\mathbf{3}^{4+}$@Y.

Diffuse reflectance-laser flash photolysis of $\mathbf{3}^{4+}$@Y was carried out exciting at 532, 355 or 308 nm. According to the reported work on laser flash photolysis of arene–methylviologen complexes,[3,10] it was anticipated that 532 nm would selectively excite the CT complex band. However, in our case the low extinction coefficient of $\mathbf{3}^{4+}$ at 532 nm (see Fig. 1) prevented us from obtaining any detectable transient signal upon excitation at 532 nm. Thus, we recorded the spectrum at both 355 and 308 nm. The same transient spectrum was obtained in both cases. These wavelengths, however, do not provide selective excitation of the CT complex of catenane $\mathbf{3}^{4+}$; excitation of the uncomplexed bipyridinium or hydroquinone moieties also occurs. To distinguish the contribution of the CT complex in $\mathbf{3}^{4+}$, the transient spectrum of $\mathbf{3}^{4+}$@Y was compared with that recorded for $\mathbf{2}^{4+}$@Y as a control (Fig. 2). Both spectra show similar features corresponding to bipyridinium radical cations.[11,12] However, closer inspection reveals that the absorption in the 600–750 nm region for $\mathbf{3}^{4+}$ is significantly more intense than for $\mathbf{2}^{4+}$. In addition, the decays monitored at 390 and 750 nm for $\mathbf{3}^{4+}$ are significantly different (see Fig. 2 inset), firmly proving that at least two different species are involved. This second transient would correspond to the charge-separated state of the CT complex of $\mathbf{3}^{4+}$. As expected for a single transient, the decays for $\mathbf{2}^{4+}$ monitored at 390 or 750 nm coincide.

Importantly, as Fig. 2 shows, the lifetime of the photogenerated charge-separated state of the $\mathbf{3}^{4+}$ CT complex is

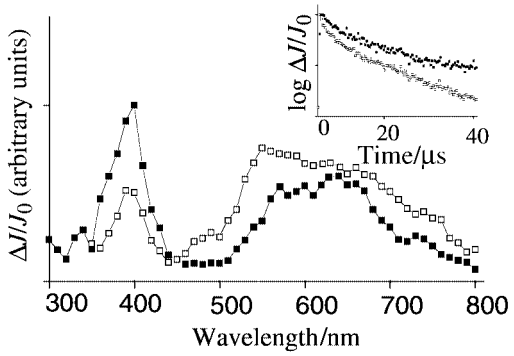

Fig. 2 Time-resolved diffuse reflectance UV–vis spectra of $\mathbf{3}^{4+}$@Y recorded 15 μs after 308 nm excitation (□), and $\mathbf{2}^{4+}$@Y recorded 2 μs after 266 nm excitation (■). The inset shows the decays of $\mathbf{3}^{4+}$@Y monitored at 705 (□) and 450 nm (■).

hundreds of μs. This contrasts sharply with previous laser flash photolysis studies of [2]-catenane $\mathbf{3}^{4+}$ in MeCN where the lifetime was tens of ps.[4] Therefore, incorporation of catenane $\mathbf{3}^{4+}$ into zeolite Y increases the lifetime of the charge-separated transient species by six orders of magnitude. This dramatic effect of incorporation of $\mathbf{3}^{4+}$ on the lifetime of the photogenerated radical ion pair can been explained by the stabilization due to the intense electrostatic fields experienced inside the zeolite pores. Since co-conformational movements are predicted to take place on the μs time scale,[2] the present finding that the charge-separated state of catenane $\mathbf{3}^{4+}$ exists for hundreds of μs when encapsulated in zeolite Y could open the possibility of observing the cyclic action of molecular-level machines.

Notes and references

† [2]-Catenane incorporated inside zeolite Y ($\mathbf{3}^{4+}$@Y) was prepared by adding a solution of the macrocyclic polyether (0.0426 g, 0.08 mmol) in dry MeCN (5 ml) to the partially-exchanged $\mathbf{1}^{2+}$@Y (0.5 g) ($\mathbf{1}^{2+}$ content 0.026 g, 0.03 mmol) previously dehydrated at 200 °C under 0.10 Torr for 2 h. The suspension was stirred at room temperature under Ar. Then, a solution of 1,4-bis(bromomethyl)benzene (0.0083 g, 0.03 mmol) in dry MeCN (5 ml) was added and the suspension was stirred at room temperature under Ar for 5 d, and then at reflux temperature for 24 h. The resulting solid was filtered off and submitted to exhaustive solid–liquid extraction using MeCN as the solvent.

Hole transfer through DNA is coupled with proton transfer processes.

The controversial long distance hole transfer through DNA was debated over the course of the last decade.[1] Today, a consensus exists that this process occurs as a multistep hopping reaction[2] with guanines (G), the DNA bases of lowest ionisation potentials, as possible carriers of the positive charge.[3,4] Since Steenken has measured a pK_a value of 3.9 for the guanine radical cation ($G^{\cdot+}$),[5] one would expect that $G^{\cdot+}$ loses the positive charge by proton transfer to the surrounding water in poorly paired (mismatched) strands. This should retard or even stop hole transfer through DNA. Recently, we have observed such a decrease of the charge transfer efficiency in experiments with double strands **1a**,**b** (Fig. 1).[6]

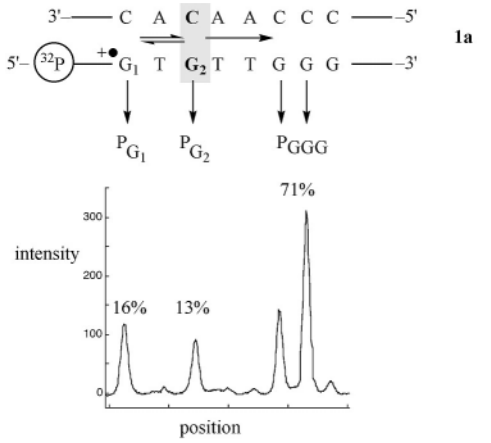

Fig. 1 Histograms of denaturing polyacrylamide gels, obtained by subtraction of control experiments (irradiation of unmodified strands) from irradiation experiments with the modified strands, which contain a 4′-pivaloylthymidine next to G_1 in the complementary strand. The histograms show the yields of products P_{G_1}, P_{G_2}, and P_{GGG} at the different positions of the radiolabelled strand. These products are formed by water trapping of the guanine radical cations and subsequent site selective strand cleavage of the radiolabelled strands.

The positive charge was injected into G_1 of strands **1a**,**b** by photolysis of a 4′-pivaloylated thymidine, situated next to G_1 in the complementary strand.[7] The hole migrates *via* G_2 through DNA until it reaches the GGG sequence, a thermodynamic sink for the positive charge.[8] The charge could be detected by nucleophilic water trapping of $G^{\cdot+}$, which led to strand cleavage products P_{G_1}, P_{G_2} and P_{GGG} after piperidine treatment (Fig. 1).[3,6] In the paired double strand **1a** the P_{GGG} yield was 71%. Thus, most of the charge migrated from G_1 to the GGG sequence in strand **1a** where the acidic proton is held within the G–C base pair by a hydrogen bridge (**2a** ⇌ **2b**). However, the P_{GGG} yield dropped from 71 to 12% in the mismatched strand **1b** having an abasic site (H) opposite G_2.[9] We explained this effect by a proton transfer from the non-paired $G_2^{\cdot+}$ in strand **1b** to the surrounding water (**3** → **4**), which slows down or even stops the charge transfer (Scheme 1).

If this interpretation is correct, methylguanosine **5** (G_{Me} in **1c**) should not stop the hole transfer through DNA because the acidic hydrogen atom is exchanged by a methyl group.[10] We therefore synthesized double strand **1c** where the abasic site is opposite to G_{Me}. Charge injection into G_1 led to the results shown in Fig. 2. Compared to the inefficient charge transfer in strand **1b**, where an abasic site opposite to G_2 reduced the P_{GGG} yield from 71 to 12%, with methyl guanosine **5** (G_{Me}) opposite the abasic site in **1c** the P_{GGG} yield increased again to 53%. This experiment strongly supports the explanation that mismatches in G–C base pairs interrupt the hole transfer through DNA by a proton shift from the mismatched $G^{\cdot+}$ to the surrounding water (**3** → **4**).

In contrast to the decrease of the hole transfer efficiency through DNA by deprotonation of $G^{\cdot+}$ (**3** → **4**), a proton shift within the oxidized hydrogen-bridged G–C base pair could increase the hole transfer rate, because the proton shift

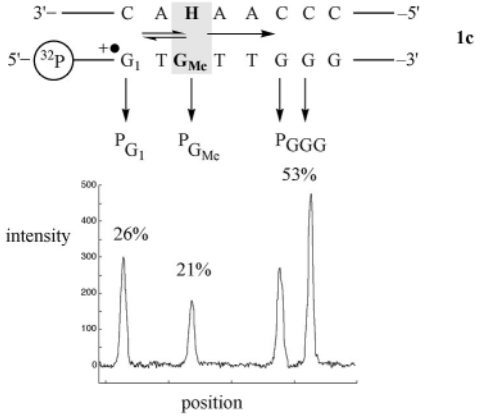

Fig. 2 Histogram of denaturing polyacrylamide gels, obtained by subtraction of control experiments (irradiation of unmodified strands) from irradiation experiments with the modified strand, which contained a 4′-pivaloylthymidine next to G_1 on the complementary strand. The histogram shows the yields of products P_{G_1}, P_{GMe}, and P_{GGG} at the different positions of the radiolabelled strand. These products are formed by water trapping of the guanine radical cations and subsequent site selective strand cleavage of the radiolabelled strands.

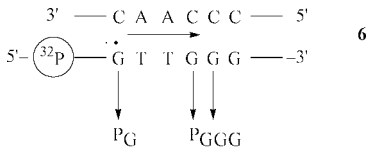
(**2a** ⇌ **2b**) stabilizes the positive charge.[5,11] The prerequisite for a rate increase is that hole and proton transfer reactions are coupled with each other. Recently, Thorp proved this process by a kinetic deuterium isotope effect of the hole injection step into G.[12] We have now demonstrated that a deuterium isotope effect also exists during hole transfer reactions between guanines. The effect was measured using double strand **6** where the hole migrates from G to the GGG sequence and its relative rate was determined by the yield ratio P_{GGG}–P_G.[13]

The results are presented in Fig. 3. As observed previously,[13] in H_2O the P_{GGG}–P_G ratio is 9.0 ± 1.0 for double strand **6**. This ratio decreases to 3.0 ± 1.0 in D_2O where all acidic protons are replaced by deuterons. A decrease of the charge transfer efficiency by a factor of 3 in D_2O can be explained by a slower deuteron shift from G·+ to C compared to the corresponding proton shift (**2a** ⇌ **2b**). But this kinetic deuterium isotope effect



H_2O: $P_{GGG}/P_G = 9.0 = 1.0$

D_2O: $P_{GGG}/P_G = 3.0 = 1.0$

Fig. 3 Product ratios P_{GGG}–P_G resulting from water trapping of the guanine radical cations and subsequent site selective strand cleavage of the radiolabelled strand. The experiments were carried out in H_2O and D_2O, respectively.

influences the rate of the hole transfer only if both processes are coupled. Thus, in charge transfer reactions through DNA the hole hopping processes between guanines are coupled with proton transfer reactions.[14,15]

Generous financial support by the Swiss National Science Foundation and the Volkswagen Foundation is gratefully acknowledged.

13 The strands and the reaction conditions are described in: B. Giese, S. Wessely, M. Spormann, U. Lindemann, E. Meggers and M. E. Michel-Beyerle, *Angew. Chem., Int. Ed.*, 1999, **38**, 996. The addition of water to G·+, which leads to P_G, competes with the hole transfer from G to GGG in double strand **6**. A kinetic isotope effect in the water addition reaction should decrease its rate in D_2O and will therefore increase the P_{GGG}–P_G ratio. The observed decrease of the P_{GGG}–P_G ratio in D_2O (Fig. 3) is therefore a lower limit for the kinetic isotope effect of the hole transfer process.
14 Proton shifts from G to C also influence the electron transfer in radical anions of G–C base pairs: A. Messer, K. Carpenter, K. Forzley, J. Buchanan, S. Yang, Y. Razskazovskii, Z. Cai and M. D. Sevilla, *J. Phys. Chem. B*, 2000, **104**, 1128.

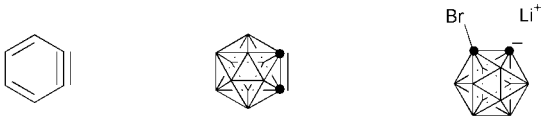
Received (in Cambridge, UK) 15th August 2001, Accepted 7th September 2001
First published as an Advance Article on the web 25th September 2001

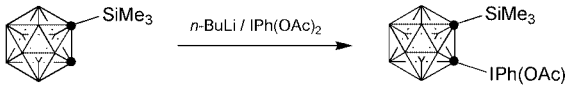
The reaction of [*o*-(trimethylsilyl)carboranyl]lithium with $IPh(OAc)_2$ in diethyl ether affords an efficient 1,2-dehydro-*o*-carborane precursor 4: the facile 2 + 4 cycloaddition of 4 with dienes in the presence of the desilylating agent is reported.

Although benzyne **1** has been widely used in organic synthesis, mechanistic studies, and synthesis of functional materials,[1–3] the chemistry of 1,2-dehydro-*o*-carborane **2**, the carborane version of benzyne, has sporadically appeared. Recently, Jones and coworkers[4–11] have described its reactions with a variety of dienes, alkynes and alkenes. In order to generate **2**, they used the bromo anion **3** as an 1,2-dehydro-*o*-carborane precursor, which is stable at 0 °C. However, the yields in their reactions are too low. To make a plausible advance into consideration in this area, methodology is desired for 1,2-dehydro-*o*-carborane precursors to generate **2** with high efficiency and under mild conditions. Recently, we found that phenyl[*o*-(trimethylsilyl)carboranyl]iodonium acetate **4** has proved to be such an example since this precursor is readily prepared from available chemicals and is stable enough to be handled without any special precaution. We now describe (i) the isolation of an excellent 1,2-dehydro-*o*-carborane precursor **4** and (ii) the efficient reactions of **4** with dienes under mild condition.



1 **2** **3**

Addition of 1 equiv. of [*o*-(trimethylsilyl)carboranyl]lithium, prepared from *o*-(trimethylsilyl)carborane and 1 equiv. of *n*-BuLi, to $IPh(OAc)_2$ in diethyl ether gave phenyl[*o*-(trimethylsilyl)carboranyl]iodonium acetate **4** as a spectroscopically pure, colorless powder relatively sensitive to air in 46% yield [eqn. (1)].†

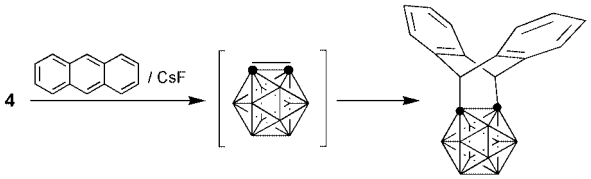


(1)

4

The ^1H and ^{13}C NMR spectra for **4** support the proposed structure.

The intermediate **4** was found to be an efficient precursor for the generation of 1,2-dehydro-*o*-carborane under mild conditions. The reaction of **4** with anthracene (1.2 equiv.) in the presence of CsF (2.4 equiv.) in diethyl ether at room temperature for 24 h afforded the carborane adduct **5** in 48% yield [eqn. (2)].‡

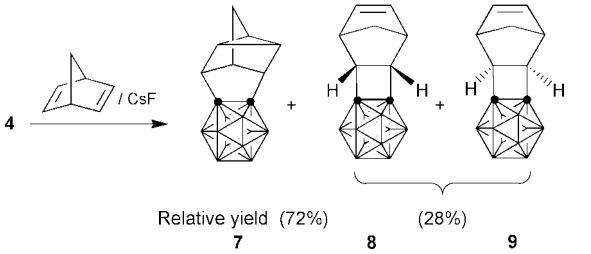


(2)

5

When KF was used as the desilylating agent with 18-crown-6, the adduct **5** was also obtained in 40% yield.[12] All the spectral data of **5** were consistent with the proposed formulation. A key feature in the ^1H NMR spectrum of **5** includes a singlet at δ 4.74 assigned to the bridgehead hydrogens. A high-field resonance at δ 51.17 in the ^{13}C NMR provides evidence for bridgehead carbon atoms. The structure of **5** was unambiguously established by a single-crystal X-ray analysis (Fig. 1).§ The central six-membered ring (C3, C4, C5, C10, C11 and C16) is puckered. The dihedral angle between C1–C2–C3–C4 and C3–C4–C11–C16 is 58.4(3)°, and that between C1–C2–C3–C4 and C3–C4–C5–C10 is 58.6(3)°.

The reaction of **4** with 3 equiv. of norborna-2,5-diene under the same reaction conditions takes place and affords three isomers (**7**, **8**, and **9**) in 62% yield [eqn. (3)].



(3)

7 **8** **9**

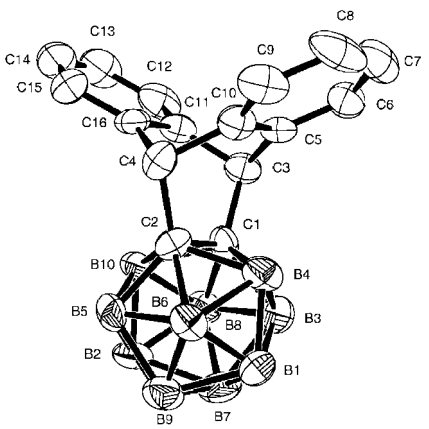


Fig. 1 Molecular structure of **5** showing the atom numbering scheme. Selected distances (Å) and angles (°): C(1)–C(2) 1.6072, C(1)–C(3) 1.5639, C(2)–C(4) 1.593(10), C(3)–C(5) 1.518(8); C(1)–C(3)–C(5) 108.6(3), C(5)–C(3)–C(11) 103.5(5), C(3)–C(1)–C(2) 109.6.

 DOI: 10.1039/b107343e

We were not able to separate **8** and **9** as also found in Jones' work.[6] Three resonances (δ 3.10, 2.80 and 1.57) and two doublets (δ 1.42 and 1.40) in the ^{1}H NMR spectrum of **7** are assigned to the methine proton and methylene proton, respectively. Five ^{13}C NMR resonances (δ 56.52, 49.83, 32.24, 25.04 and 24.58) provide evidence for the adduct **7**. The structure of **7** has been determined by X-ray crystallography (Fig. 2).§ The formation of **7–9** may involve 2 + 4 and 2 + 2 cycloaddition.

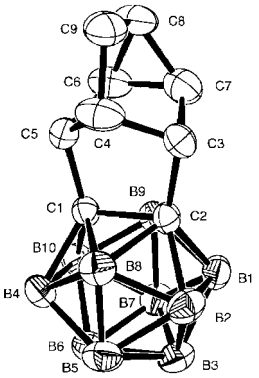

Fig. 2 Molecular structure of **7** showing the atom numbering scheme. Selected distances (Å) and angles (°): C(1)–C(2) 1.618(2), C(5)–C(6) 1.516(3), C(6)–C(7) 1.478(4), C(3)–C(7) 1.493(3); C(3)–C(4)–C(5) 92.80(15), C(4)–C(9)–C(8) 98.89(17), C(6)–C(8)–C(7) 58.40(16).

Other dienes such as naphthalene, 2,5-dimethylfuran and thiophene worked well as trapping agents for 1,2-dehydro-*o*-carborane. The results are summarized in Table 1. When the results obtained here are compared with the reported data available in the literature, much improved results are obtained by using the hypervalent iodine-1,2-dehydro-*o*-carborane precursor.

In summary, we have isolated an efficient 1,2-dehydro-*o*-carborane precursor, phenyl[*o*-(trimethylsilyl)carboranyl]iodonium acetate **4**, which readily reacts with dienes such as anthracene, naphthalene, norborna-2,5-diene, 2,5-dimethylfuran and thiophene, efficiently generating 1,2-dehydro-*o*-carborane adducts in good yield. This potential has been further exploited in a series of novel chemical transformations with this system.

We are grateful to BK21(2001) for generous financial support.

Evidence of ^{29}Si NMR paramagnetic shifts in rare-earth zeolite LSX

Received (in Cambridge, UK) 3rd July 2001, Accepted 12th September 2001
First published as an Advance Article on the web 2nd October 2001

Paramagnetic shifts have been observed for the first time in rare-earth zeolites; the ^{29}Si MAS NMR spectra of rare-earth ion-exchanged low silica X show a large range of isotropic chemical shifts that can be attributed to Fermi contact interactions with the lanthanide electronic moments.

Many zeolites of importance are solids exchanged with paramagnetic cations such as lanthanides. In the faujasite group, rare-earth zeolite Y is of high interest due to its performance as an octane-enhancing catalyst,[1] and rare-earth zeolite X is a promising material for laser applications due to the strong luminescent properties of the lanthanide complex immobilized within its cages.[2]

The effects of magnetic impurities on the ^{29}Si NMR spectra of alumino-silicates are well known. They decrease the spin–lattice relaxation, substantially broaden the resonance line as a function of the concentration of impurities,[3] and enhance the spinning-sideband patterns.[4] High concentrations of paramagnetic species in zeolites make the acquisition of NMR spectra difficult and, in general, the signal of nuclei in the neighbourhood of paramagnetic centers is not detected.[5] The use of NMR spectroscopy is relatively limited; at best, the proportion of nuclei close to paramagnetic centers can be estimated based on the intensity loss compared with diamagnetic samples.[6] In this work we show that ^{29}Si paramagnetic shifts can be observed in the NMR spectra of rare-earth zeolites, which provide information on the interaction between the paramagnetic species and the silicon atoms.

Fully exchanged rare-earth zeolites LSX are prepared by ion exchange in aqueous solution. A key parameter controlling the location of the lanthanide in the structure is the degree of hydration of the cation. The large diameter of the hydration sphere of the lanthanide cations prevents their access to the sodalite cages.† By heating the solution, the trivalent cations are partly dehydrated and are found essentially in only one site. They occupy sites on top of the six-ring windows of the sodalite cages (sites II), within the supercages of the zeolite.[7,8]

The ^{29}Si MAS NMR spectrum of LaLSX‡ exhibits a single resonance line at −83 ppm§ [Fig. 1(a)], corresponding to silicon atoms in a single environment Si(4Al). The ^{29}Si chemical shift of Si(4Al) sites does not exceed a range of 20 ppm, and varies from *ca.* −75 to −95 ppm, depending on the environment geometry.[9] The spectra of fully exchanged paramagnetic zeolites NdLSX [Fig. 1(b)] and EuLSX [Fig. 1(c)] show dramatic changes. The overall signal is very broad and exceeds 60 kHz in width, but the individual spinning sidebands are sharp. The relaxation times are very short and they are estimated to be *ca.* 0.2 s for NdLSX. The isotropic chemical shifts spread over an unusually large range, varying from *ca.* +6 to −146 ppm for our samples.

The appearance of widely spread resonance lines can be attributed to the interaction between the electronic moment of the rare-earth cations, siting on top of the six-ring windows of the sodalite cages, and the silicon nucleus. Lanthanide complexes are largely used as shift reagents in solution NMR,[10,11] where large shifts induced by the paramagnetic centers to close nuclei allow enhancement of the spectral resolution. However, only few examples in solid state NMR have been reported.[12–15]

Paramagnetic signals are difficult to detect due to the substantial broadening of the resonance lines. They can go almost unnoticed under the typical acquisition conditions for zeolites that require long recycle times, limiting the numbers of scans. Large numbers of scans are needed to get a good signal/noise ratio, but the significant decrease of the spin–lattice relaxation time enables data acquisition within reasonable times.

The overall width of the resonance line is dominated by the anisotropic part of the dipolar interaction between electronic and nuclear spins, and is proportional to the square of the magnetic moment μ of the rare-earth cations.[16,17] We observed experimentally, with a series of rare-earth LSX, that the overall width is relatively well correlated with μ^2 (Table 1).

The interaction between the unpaired electron and a given nucleus consists of two contributions: (i) the Fermi contact shift, which arises from the electron–nucleus hyperfine interaction

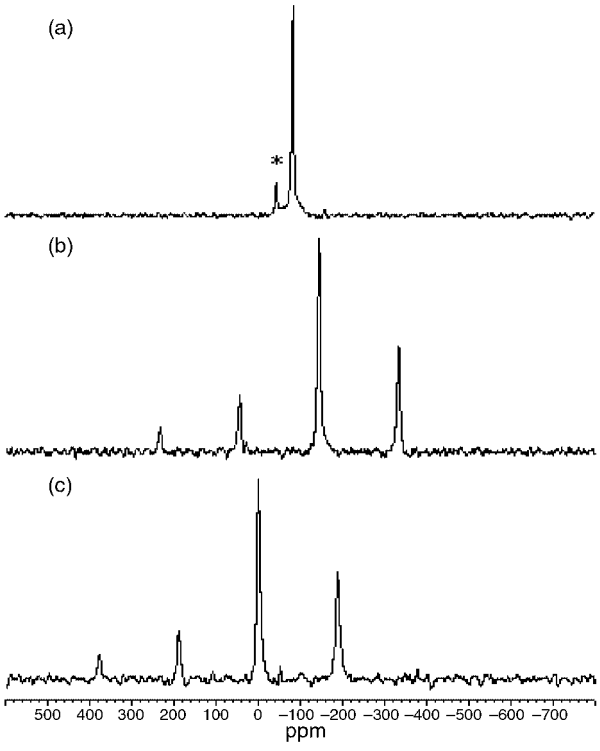

Fig. 1 ^{29}Si MAS NMR spectra of rare-earth LSX at spinning rate of 15 kHz, (a) LaLSX, (*) is the rotor contribution, (b) NdLSX and (c) EuLSX show a single line with a pattern of spinning sidebands. The pulse delay is 10 s for LaLSX and 0.1–0.8 s for the paramagnetic zeolites.

Eu^{3+}	$4f^6$	−10.7	+6	3.4

^{a} $<S_z>$ calculated according to Golding and Halton.[19]

and (ii) the pseudo-contact shift resulting from through-space dipolar interaction. The Fermi contact is proportional to $<S_z>$, the average value of the rare-earth spin over the spin levels, assuming that the hyperfine coupling constant A_{hf} does not vary across the rare-earth zeolite series, which seems reasonable as the ionic radius of the lanthanide cation remains relatively constant. The contact shift is expressed as $\Delta H = A_{hf}<S_z>\hbar\gamma_n$, where $\hbar$ is the reduced Planck's constant and γ_n the nuclear gyromagnetic factor of the observed nucleus.[18]

Fig. 2 shows a plot of $<S_z>$, calculated by Golding and Halton,[19] as a function of the experimental shift of a series of rare-earth zeolites LSX (Table 1). The variation is linear with a relatively good correlation, which suggests that the contact interaction is the predominant contribution to the paramagnetic shift. It is a through-bond mechanism despite the absence of a *direct* bond between the trivalent cation and the silicon atom. Other lanthanide systems show similar results.[13–15] The good correlation obtained in Fig. 2 confirms that the hyperfine coupling constant A_{hf} does not vary in rare-earth LSX, suggesting that the geometry of the cation site remains the same across the first half of the lanthanide series studied here.

The sign of $<S_z>$ changes once in the lanthanide series at Eu^{3+} and explains the downfield shift observed for this cation. On the other hand, a pseudo-contact shift should show an alternation of sign not observed experimentally.[20] It is interesting to note a correlation factor better than 0.997 between the ^{29}Si isotropic shifts of rare-earth LSX and the ^{119}Sn isotropic shifts in rare-earth stannates reported by Grey *et al.*[14] The deviations from the strict linear dependence of the chemical shift on $<S_z>$ due to Fermi contact, probably have the same origin in both solids.

We have demonstrated in this work that ^{29}Si NMR spectra of zeolites containing high concentrations of paramagnetic cations can be obtained. We observed paramagnetic shifts and found that the predominant contribution to the shift is the Fermi contact interaction. The shifting ability of lanthanide to close silicon atoms allows the discrimination between silicon sites in partly exchanged zeolites. Applications of rare-earth cations acting as paramagnetic shift agent in zeolites will be published later.

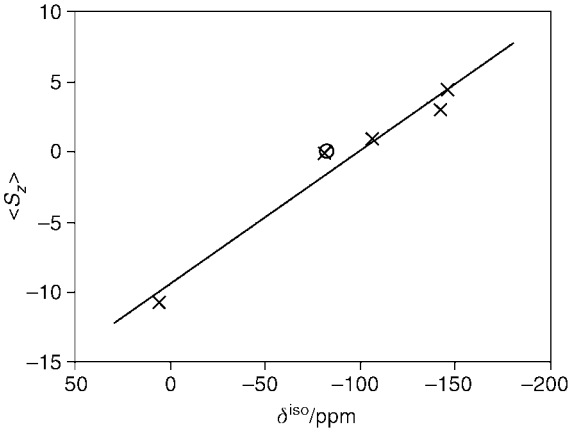

Fig. 2 Variation of $<S_z>$[19] as a function of the ^{29}Si chemical shift of paramagnetic rare-earth LSX (×) and LaLSX (○).

We thank Dr N. Mizuno and Ms S. Uchida for help in the NMR acquisitions at the University of Tokyo and Dr M. D. Williams for the NMR acquisitions performed at Arizona State University. Work at A. S. U. is supported by the U. S. National Science Foundation, Grant DMR 9804817. The NMR equipment was purchased under NSF Grant CHE 9808678.

Notes and references

† The structure of zeolite LSX (Low Silica X), the end-member of the faujasite group, with ratio Si/Al = 1, is composed of strictly alternating SiO_4 and AlO_4 tetrahedra. Faujasite consists of sodalite cages linked together through six-membered rings by oxygen atoms, forming small hexagonal prism cages. The sodalite cages are packed in a diamond-like arrangement forming large cavities with 12-ring openings, the supercages.

‡ Fully-exchanged rare-earth zeolite LSX were prepared by ion-exchanges of (Na,K)LSX (Tosoh Co. Ltd) in an aqueous solution of 0.1 M lanthanide chloride at 373 K for 24 h. Elemental analysis revealed only traces of alkali metal in the final samples.

§ ^{29}Si MAS NMR spectra were recorded at 79.5 MHz. The samples were packed in a 4-mm silicon nitride rotor and spun at 15 kHz. Acquisition parameters were π/4 pulse width, 10 s pulse delay and 2500 scans for diamagnetic samples and π/4 pulse width, 0.1–0.8 s pulse delay and a number of scans around 10000 for paramagnetic samples. Chemical shifts are reported relative to tetramethylsilane with an uncertainty of 2 ppm. Background correction was applied to remove rolling baseline when necessary.

Universal hybridization using LNA (locked nucleic acid) containing a novel pyrene LNA nucleotide monomer

B. Ravindra Babu and Jesper Wengel*

Department of Chemistry, University of Southern Denmark, DK-5230 Odense M, Denmark. E-mail: jwe@chem.sdu.dk

Received (in Cambridge, UK) 9th July 2001, Accepted 21st August 2001
First published as an Advance Article on the web 2nd October 2001

A novel pyrene LNA nucleotide monomer is shown to mediate universal hybridization when incorporated into a DNA strand or a 2′-OMe-RNA/LNA chimeric strand. For the latter, high-affinity universal hybridization without compromising the base-pairing selectivity of bases neighbouring the universal pyrene LNA nucleotide monomer is documented.

Currently, there is much focus on the development of chemically modified nucleotide monomers for universal hybridization, *i.e.* so-called universal bases able to bind isoenergically with each of the natural bases.[1] The main applications of these universal bases are as primers for degenerate PCR reactions or as hybridization probes. Promising universal bases with a 2-deoxy-β-D-ribofuranosyl moiety have been reported, *e.g.* 3-nitropyrrole,[2] 5-nitroindole,[3] pyrene,[4] isocarbostyril[5] and 8-aza-7-deazaadenine[6] derivatives. While incorporation of one of these monomers into a DNA strand induces little variation in the melting temperature (T_m value) when placed opposite the four natural DNA bases (ΔT_m ~1–3 °C), decreases in the T_m value of between 4 to 10 °C per universal nucleotide monomer incorporated compared to the corresponding fully complementary reference DNA–DNA duplex are typical.[1–7] Therefore, improved binding affinity beside applicability in PCR-based applications have been considered desirable properties of an ideal universal base.[1,5]

Stimulated by the work of Kool and collaborators on hybridization using non-polar aromatic moieties as replacements of the natural bases,[4,8] we became interested in studying LNA (locked nucleic acid)[9–12] derivatives containing non-polar aromatic moieties.† The hybridization properties of LNA are characterised by very high binding affinity and strong Watson–Crick discrimination[9–12] both as fully modified LNA and as mix-meric LNA also containing, *e.g.* DNA,[9–12] RNA[13] or 2′-OMe-RNA monomers.[14] Matray and Kool showed that the pyrene nucleoside analogue **Py** (Fig. 1) when incorporated into a DNA strand paired in a universal way with the four natural bases with moderately decreased thermal affinity (−4.5 to −6.8 °C). This behaviour was explained by intercalation of the pyrene moiety within the helix.[4] As both synthetic work[15] and NMR studies[16] have indicated the importance of the nucleobases for structural organisation and thus the remarkable binding affinity of LNA, we decided to synthesise LNA containing the derivatives **Ph^L** and **Py^L** (Fig. 1, Table 1),[17] both based on the 2′-*O*,4′-*C*-methylene-β-D-ribofuranosyl moiety known to adopt a locked C3′-*endo* RNA-like furanose conformation.[9–11]

Initially, the hybridization of the oligonucleotides **ON1**–**ON6** (Table 1) towards four 9-mer DNA targets with the central base being each of four natural bases was studied by thermal denaturation experiments.‡ Compared to the DNA reference **ON1**,[10] introduction of one abasic LNA monomer **Ab^L** (**ON2**) has earlier been reported to prevent the formation of a stable duplex above 0 °C (only evaluated with adenine as the opposite base).[15] With the phenyl monomer **Ph^L** (**ON3**), thermal denaturation with T_m values in the range of 5–12 °C was observed. Thus, compared to **Ab^L**, the phenyl moiety stabilises the duplexes, but universal hybridization is not achieved—a preference for an adenine complement being observed instead. In addition, significant destabilisation compared to the **ON1**–DNA reference was observed.

The pyrene LNA nucleotide **Py^L** (**ON4**) displays more encouraging properties. Firstly, the binding affinity towards all four complements is increased compared to **ON3** (containing **Ph^L**). Secondly, universal hybridization is induced as shown by the four T_m values all being within the range 17–19 °C. With

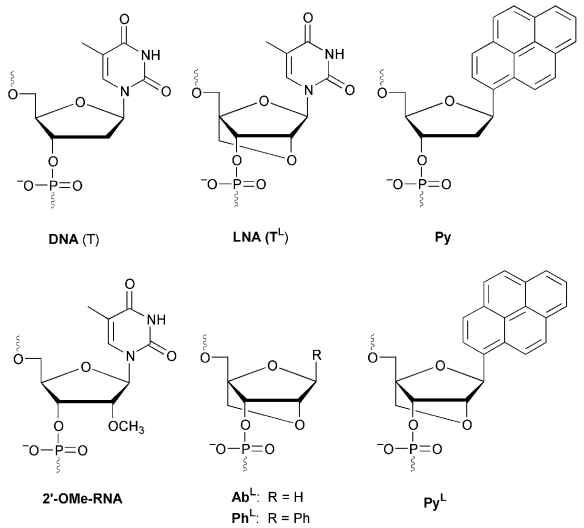

Fig. 1 Structures of selected nucleotide monomers: DNA (T), LNA (**T^L**), pyrenyl DNA (**Py**), 2′-OMe-RNA [2′-OMe(T)], abasic LNA (**Ab^L**), phenyl LNA (**Ph^L**), and pyrenyl LNA (**Py^L**). The short notations shown are used in Tables 1 and 2. For DNA, LNA and 2′-OMe-RNA, the thymine monomers are shown as examples.

[a] Melting temperatures (T_m/°C values) measured as the maximum of the first derivative of the melting curve (A_{260} *vs.* temperature) recorded in medium salt buffer (10 mM sodium phosphate, 100 mM sodium chloride, 0.1 mM EDTA, pH 7.0) using 1.5 μM concentrations of the two strands; A = adenine monomer, C = cytosine monomer, G = guanine monomer, T = thymine monomer; See Fig. 1 for structures of **T^L**, **Ab^L**, **Ph^L** and **Py^L**; DNA sequences are shown as d(sequence) and 2′-OMe-RNA sequences as 2′-OMe(sequence); 'nd' denotes 'not determined'.

 DOI: 10.1039/b106065c

respect to universal hybridization, **Py^L** thus parallels the pyrene DNA derivative **Py**,[4] but the decrease in thermal stability compared to the **ON1**–DNA reference is more pronounced for **Py^L** (~10 °C) than reported for **Py** (~5 °C in a 12-mer polypyrimidine DNA sequence[4]). It therefore appears that stacking (or intercalation) by the pyrene moiety is not favoured by the conformational restriction of the furanose ring of **Py^L**, although a comparison of the thermal stabilities of **ON2**, **ON3** and **ON4** strongly indicates interaction of the pyrene moiety within the helix.

The effect of **Py^L** could be different in an RNA-like strand, and we therefore synthesised **ON5** and **ON6**, the former being composed entirely of 2′-OMe-RNA monomers and the latter of six 2′-OMe-RNA monomers, two LNA thymine monomers **T^L**, and one central LNA pyrene monomer **Py^L**. A sequence corresponding to **ON6** but with three **T^L** monomers has earlier been shown to form a duplex with complementary DNA of very high thermal stability.[14] **ON6** is therefore suitable for evaluation of the effect of introducing high-affinity monomers around a universal base. As seen in Table 1, the 2′-OMe-RNA reference **ON5** binds to the DNA complement with slightly increased thermal stability and conserved Watson–Crick discrimination (compared to the DNA reference **ON1**). Indeed, the 2′-OMe-RNA/LNA chimera **ON6** displays universal hybridization behaviour as revealed from the four T_m values (37, 38, 39 and 40 °C). All four T_m values obtained for **ON6** are higher than the T_m values obtained for the two fully complementary reference duplexes **ON1**–DNA (T_m = 28 °C) and **ON5**–DNA (T_m = 35 °C). These data demonstrate that the pyrene LNA monomer **Py^L** displays universal hybridization behaviour both in a DNA context (**ON4**) and in an RNA-like context (**ON6**), and that the problem of decreased affinity of universal hybridization probes can be solved by the introduction of high-affinity monomers, *e.g.* 2′-OMe-RNA and/or LNA monomers.

Very recently, the effect of the universal 3-nitropyrrole DNA nucleotide on the base-pairing selectivity of neighbouring natural bases was for the first time systematically studied.[7] Reduced discriminatory ability was demonstrated in some cases suggesting caution when using this universal base in hybridization probes.[7] We therefore performed a systematic thermal denaturation study with **ON6** (Table 2). For each of the four DNA complements (monomer **Y** = A, C, G or T) used in the study shown in Table 1, **ON6**, containing a central pyrene LNA monomer **Py^L**, was hybridised with all four base combinations in the neighbouring position towards 3′-end of **ON6** (monomer **Z** = A, C, G or T, monomer **X** = T) and the same towards the 5′-end of **ON6** (monomer **X** = A, C, G or T, monomer **Z** = T). In all eight subsets of four data points, satisfactory to excellent Watson–Crick discrimination was observed between the match and the three mismatches (ΔT_m values in the range 5–25 °C).

Table 2 Thermal denaturation experiments (T_m/°C values shown) to evaluate the base-pairing selectivity of the bases neighbouring the universal pyrene LNA monomer **Py^L** in the 2′-OMe-RNA/LNA chimera **ON6**. In the target strand [3′-d(CAC**XYZ**ACG)], the central three bases **XYZ** are varied among each of the four natural bases[a]

[a] See caption below Table 1 for abbreviations and conditions used; the data for matched neighbouring bases (**X** = **Z** = T) are shown in italic.

The results reported herein have several implications for the design of probes for universal hybridization. Firstly, universal hybridization is possible with a conformationally restricted monomer as demonstrated for the pyrene LNA monomer. Secondly, universal hybridization behaviour is feasible in an RNA context. Thirdly, the binding affinity of probes for universal hybridization can be increased by the introduction of high-affinity monomers without compromising the base-pairing selectivity of bases neighbouring the universal base.§

We thank The Danish Research Agency and Exiqon A/S for financial support, Ms Britta M. Dahl for oligonucleotide synthesis, and Dr Carl E. Olsen for MALDI-MS analyses.

Notes and references

† We have defined LNA as an oligonucleotide containing one or more conformationally locked 2′-*O*,4′-*C*-methylene-β-D-ribofuranosyl nucleotide monomer(s).[9]

‡ MALDI-MS ([M − H]$^-$; found/calcd.: **ON3** 2731/2733; **ON4** 2857/2857; **ON6** 3094/3093). The purity of **ON3**, **ON4** and **ON6** was verified as >80% by capillary gel electrophoretic analysis.

§ We are currently evaluating chimeric oligonucleotides containing pyrene and other known universal bases attached to various backbones (*e.g.* LNA-type monomers, ribofuranose monomers or deoxyribose monomers in 2′-OMe-RNA–LNA oligos). One purpose of these further experiments is to evaluate the possibility of obtaining similar results as for the 2′-OMe-RNA/LNA oligo **ON6** at a lower cost, *e.g.* by substituting **Py^L** with a pyrenyl-2′-OMe-ribonucleotide monomer.

Characterization of an oxaluric acid derivative as a guanine oxidation product

Christel Seguy, Geneviève Pratviel* and Bernard Meunier*

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse cedex 4, France

Received (in Cambridge, UK) 26th July 2001, Accepted 13th September 2001
First published as an Advance Article on the web 2nd October 2001

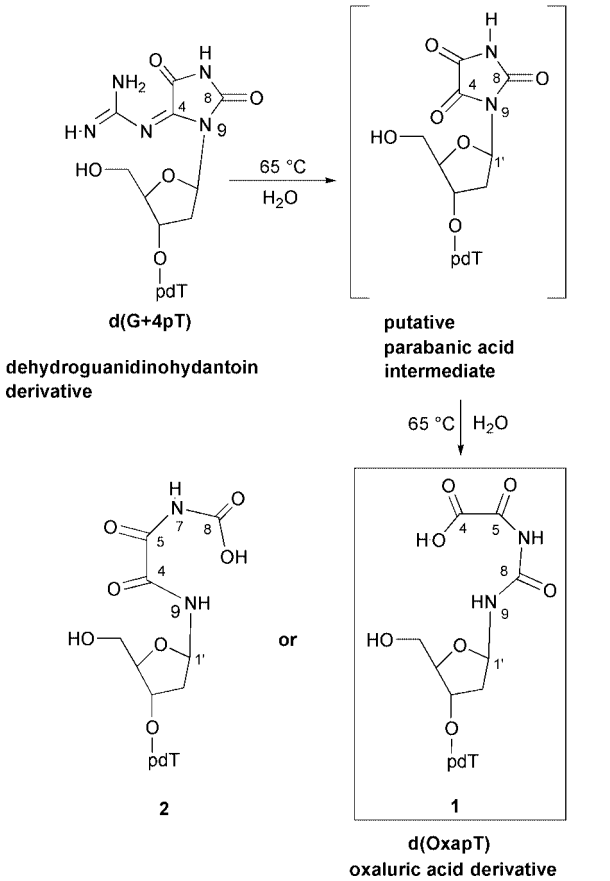
The oxidation of guanine in the dinucleoside monophosphate d(GpT) by an oxo-metalloporphyrin generates a linear oxaluric acid† derivative after heating at 65 °C for 30 min and at neutral pH.

Guanine is the most easily oxidizable nucleobase of DNA by electron abstraction since it has the lowest ionization potential.[1] The 8-oxo-7,8-dihydroguanine (8-oxo-G) derivative was reported to be one of the products of guanine oxidation by one-electron transfer.[2,3] However many other oxidation products were described including an imidazolone derivative,[4–7] a dehydroguanidinohydantoin[8,9] and a dihydroxylated derivative of guanine at C5 and C8.[8,10] These products are not highly stable under physiological conditions. Imidazolone is transformed into an oxazolone derivative[11] upon hydrolysis. The half-life of imidazolone in water at 37 °C is 2.5 h.[12] The structures of imidazolone and oxazolone derivatives are well documented.[12] The dehydroguanidinohydantoin compound was recently analyzed by NMR after stabilization by reduction into the corresponding guanidinohydantoin.[9] The half-life of dehydroguanidinohydantoin in water is 5 h at 37 °C[13] or 8 h at 0 °C.[9] The hydrolysis product of dehydroguanidinohydantoin is proposed to be an oxaluric acid derivative arising from the hydrolysis of a postulated parabanic acid intermediate (Scheme 1). Considering the short half-life of dehydroguanidinohydantoin, its hydrolysis product may be important *in vivo* as a guanine lesion. In order to determine the exact structure of this compound, we report here the ^{1}H NMR analysis of the oxaluric acid derivative, **d(OxapT)** (see Scheme 1), obtained from the two-electron oxidation of guanine in a dinucleoside monophosphate **d(GpT)**.

This oxaluric acid derivative was initially described in the literature as the oxidation product of 8-oxo-G but not in the oxidation of guanine itself. Oxidation products of 8-oxo-G were more studied than those of guanine oxidation. This is due to the easier oxidation of 8-oxo-G compared to that of guanine by available reagents.[13–17] When the guanine oxidation products arise from an intermediate oxidation at C8, they are identical to the products generated in the oxidation of 8-oxo-G. In the oxidation of 8-oxo-G by peroxynitrite, a nitration product of the dehydroguanidinohydantoin derivative was formed and its hydrolysis product, an oxaluric acid derivative, was analyzed by NMR.[17] This oxaluric acid derivative, was analyzed after incubation of the nitrodehydroguanidinohydantoin derivative for 2 days at ambient temperature. The oxidation of 8-oxo-G by singlet oxygen also gave a dehydroguanidinohydantoin derivative that was transformed into an oxaluric acid lesion.[13] The latter was analyzed by electrospray MS/MS after incubation of the reaction medium for 2 or 9 h at 37 °C. The structure of the oxaluric acid derivative obtained in this work from the oxidation of guanine was compatible with the two previously proposed structures from 8-oxo-G oxidation.[13,17]

The oxidation of guanine was performed by a cationic manganese porphyrin, Mn–TMPyP,[18] activated by $KHSO_5$, an oxygen atom donor. Oxo-Mn(v)–TMPyP is able to mediate a two-electron oxidation of guanine.[7–9] The high yield in guanine oxidation allowed us to isolate the products of guanine oxidation and to analyse them by NMR on the simplified DNA model, a dinucleoside monophosphate **d(GpT)**. The oxidation of guanine on this substrate led to two products, an imidazolone and a dehydroguanidinohydantoin derivative, referred to as **d(G+4pT)** since it corresponds to an increase of 4 amu compared to **d(GpT)**.[9]

In order to obtain the NMR data of the oxaluric acid derived from **d(G+4pT)**, the oxidation reaction of **d(GpT)** was carried out on a semi-preparative scale. The starting dinucleoside monophosphate **d(GpT)** (3 mM, 3.4 mg) was incubated with Mn–TMPyP (16 μM) and $KHSO_5$ (3.5 mM) in 80 mM TEAA, triethylammonium acetate buffer pH 6.5, at 0 °C for 10 min (final concentrations are indicated, total reaction volume = 2 mL). The reaction was stopped by the addition of HEPES buffer pH 8 (35 mM) and the products were separated by semi-preparative HPLC. This individual reaction was repeated 10 times to obtain enough material. The isolation of the oxidation



Scheme 1 Oxidation of **d(GpT)** by Mn–TMPyP–$KHSO_5$ leads to a dehydroguanidinohydantoin derivative, **d(G+4pT)**, that undergoes hydrolysis upon heating. The resulting product is an oxaluric acid derivative, **d(OxapT)**, corresponding to the highlighted structure **1** (the numbering of atoms being that of the initial guanine).

product of **d(GpT)** was done by collecting the products eluted from a reverse phase semi-preparative column (nucleosil C18, 10 μm, 250 × 6.2 mm from Interchrom, France) eluted in a gradient mode at 2 mL min^{-1}. The gradient was from 1 to 20% of CH_3CN for 1 h by combination of the two eluents, solvent A = 10 mM TEAA pH 6.5, solvent B = solvent A containing 20% CH_3CN (detection was at 260 nm). The reaction volume (2 mL) was injected directly. The collected **d(G+4pT)** fractions were pooled together and lyophilized to reduce the collected volume. The pooled fractions were then heated at 65 °C for 30 min (reaction volume = 1 mL). The hydrolysis of **d(G+4pT)** was complete under these conditions. The oxaluric acid derivative **d(OxapT)** was purified again by semi-preparative HPLC for desalting. The dried sample was dissolved in 0.5 mL of NMR solvent (DMSO-d_6). The NMR data are listed in Table 1.[19] The NH protons of the oxaluric acid moiety were at 8.59 and 9.61 ppm. The signal at 8.59 ppm was coupled to the H1' proton of the sugar moiety with a coupling constant of 9.4 Hz. The coupling between NH of the oxaluric acid moiety and H1′ from the sugar was confirmed by a 1D-TOCSY experiment (not shown).[20] These NMR data are in favor of a linear structure for the oxaluric acid derivative without having the possibility of discriminating between the two possible linear structures derived from the hydrolysis of **d(G+4pT)** to **d(OxapT)** **1** or **2** (see Scheme 1). Structures **1** and **2** correspond to the cleavage of the former C4–N9 and C8–N9 bonds of the guanine oxidation product, respectively (the numbering of atoms being that of the initial guanine). However our previous electrospray MS/MS data on **d(OxapT)**[9] are in favor of structure **1**. Structure **2** can be discarded. The fragmentation of oxaluric acid derivative (m/z = 551.0 with z = 1) during negative electrospray mass analyses gave signals at m/z = 479.1, 436.1 and 321.0 corresponding to structure **1**. The 479.1 signal corresponds to a –NH–CO–NH_2 residue attached to the sugar C1′ carbon (cleavage of the N7–C5 bond). The 436.1 signal was attributed to an amino-sugar derivative (cleavage of the N9–C8 bond) and the 321.0, to 2′-deoxythymidine 5′-monophosphate. Depending on the electrospray conditions, the loss of CO_2 due to the decarboxylation of the last carboxylic function can also be observed (cleavage of C4–C5 bond).[8] A signal at m/z = 492 was not observed. It would have corresponded to a –NH–CO–CHO residue attached to the sugar C1′ carbon (cleavage of the N7–C5 bond of structure **2**).

In conclusion the oxidative lesion of guanine, dehydroguanidinohydantoin **d(G+4pT)**, was isolated from the oxidation of **d(GpT)** by Mn–TMPyP–$KHSO_5$. It was transformed into a linear oxaluric acid derivative **d(OxapT)** upon heating at 65 °C for 30 min and at neutral pH. The linear structure of this oxaluric acid lesion is **1**, as depicted in Scheme 1, resulting from the hydrolysis of the C4–N9 bond.

The authors are indebted to Yannick Coppel for recording the NMR data, to Igor Dubey for the synthesis of **d(GpT)** and to Professor Jean Bernadou for fruitful discussions.

First published as an Advance Article on the web 2nd October 2001

A new type of mesoporous mixed transition metal oxide of Nb and Ta (NbTa-TIT-1) has been prepared through a two-step calcination, which consists of single crystal particles with wormhole mesoporous structure.

Recently, various types of mesoporous materials have been extensively synthesized. However, the walls of all the synthesized mesoporous materials are amorphous. Mesoporous materials possessing crystallized wall structure would show mechanical, thermal and hydrothermal stability, and are expected to have applications other than catalysis[1] such as for semiconductors,[2] optical devices[2] and fuel cells,[3,4] *etc*. Moreover, electronic transfer throughout the crystallized framework could enable wide application in nanotechnology.

Neutral templating routes for syntheses of inorganic mesoporous materials have introduced thick wall structures to silica with wormhole-like,[5–8] lamellar,[9,10] cubic[10] or hexagonal[10,11] mesostructures. Successful applications of these methods to other mesoporous metal oxides have shown the great utility of the synthetic procedure.[12,13] Following a typical neutral block copolymer templating route in ref. 12, we have attempted to produce various mixed metal oxides with mesoporous structure. Our efforts have been focused especially on the formation of mesopores among crystallized wall structures. Initially, we prepared niobium–tantalum mixed oxide, which has a stable oxidation state. Almost identical atomic and ionic radii might lead to full solid solubility and mixing, and are expected to promote stable crystallization.[14] In this communication, we report on the synthesis of a crystallized niobium–tantalum (1 : 1) mixed oxide with mesoporous structure.

In the synthetic route, neutral block copolymer was employed as a template for the mesoporous structure. 0.005 mol of $TaCl_5$ and $NbCl_5$ were added to 1 g of poly(alkylene oxide) block copolymer $HO(CH_2CH_2O)_{20}(CH_2CH(CH_3)O)_{70}(CH_2CH_2O)_{20}H$ (Pluronic P-123, BASF) dissolved in 10 g of ethanol. After vigorous stirring for 30 min, the resulting sol solution was aged at 40 °C in air for 7 days. Crystallized mesoporous material was obtained by a two-step calcination. First, the template was completely removed by calcination at 400 °C for 20 h to form the precursor, and in the second step the sample was calcined at 650 °C for 1 h to yield the final product. X-Ray diffraction (XRD) patterns for the two-step calcined sample confirmed crystallization of the wall structure. All the peaks can be assigned to the orthorhombic-like structure of a $(Nb,Ta)_2O_5$ mixed oxide.

To study the details of the crystallized sample, observations by transmission electron microscopy (TEM) were carried out. Fig. 1(a) presents the TEM image of a particle (*ca*. 500 nm) and its electron diffraction (ED) pattern (inset) which is typical with respect to particle size and lattice structure of the product calcined at 650 °C. The crystallinity of the sample was determined by TEM observation of diffraction patterns of 50 particles sized from 100 to 1000 nm. From the observation, we confirmed >90% of the particles were totally crystallized. Three-dimensional open pores and the wormhole-like mesoporosity are identified. The mean pore diameter is roughly estimated as 10 nm and the wall thickness is >5 nm. Fig. 1(b) shows the lattice image obtained at the edge of the particle. It demonstrates clearly the crystallized lattice of the wall around a pore. Analysis of the particle by ED and high resolution TEM observation demonstrate that this particle is a single crystal. We collected ED patterns from 10 local regions of the particle in 250-nm range and confirmed the identical patterns. (Detailed analysis will be reported elsewhere.) The regular spot patterns of the whole region and each local area indicate that the whole

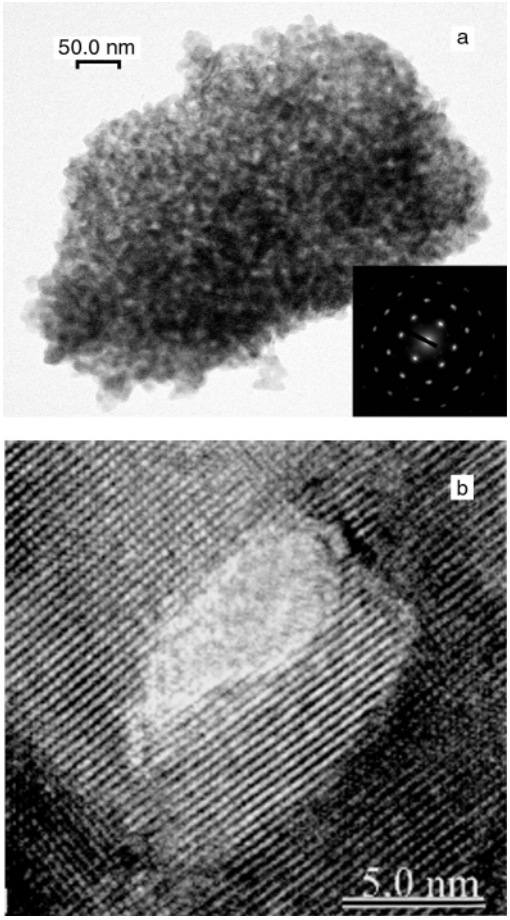

Fig. 1 TEM image and electron diffraction pattern of the sample calcined at 650 °C for 1 h (a) and the high resolution TEM image of a mesopore and wall structure (b). The images were recorded with a 200 kV JEOL JEM2010F system.

 DOI: 10.1039/b104516b

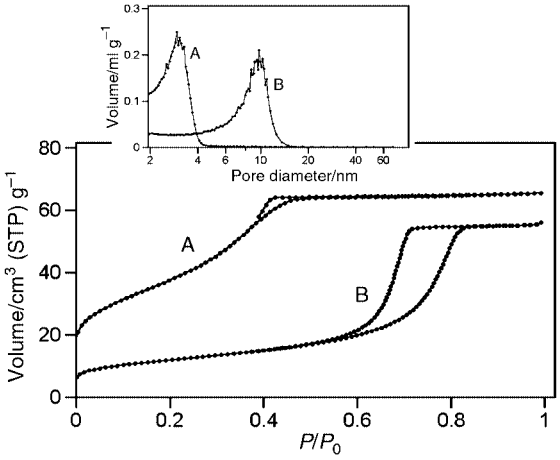

Fig. 2 Nitrogen gas adsorption–desorption isotherm and pore-size distribution (inset) of the sample calcined at 400 °C for 20 h (curve A) and that calcined at 650 °C for 1 h in the second-step (curve B). Data was collected with a Coulter Omnisorp 100CX system.

particle is crystallized in the same direction. We also carefully observed several successive lattice images of a 100 nm-region and the whole particle was confirmed to have exactly the same periodic atomic arrays. It is, therefore, concluded that this particle is a single crystal with wormhole-like mesoporous structure. From these results we conclude that the mesoporosity does not arise from the agglomeration or aggregation of smaller crystallites. Although the typical particle size of the sample after the second-step calcination was in the sub-μm range, there were particles over μm-size. They were confirmed to consist of several single crystal domains of sub-μm size. Energy dispersive X-ray (EDX) analysis on various regions (several hundreds nm in diameter for each region) in a whole particle indicated that Nb and Ta atoms were homogeneously mixed in each region, *i.e.* the particle is confirmed to be $(Nb,Ta)_2O_5$ mixed oxide.

The mesoporosity of the sample after the second-step calcination was testified by the N_2 adsorption–desorption isotherm and Barrett–Joyner–Halenda (BJH) pore size distribution analysis in the adsorption branch of the isotherm (curve B) as shown in Fig. 2. The results are also compared with the sample before the second-step calcination (curve A). Both samples indicate type IV isotherms, which are attributed to typical mesoporous structure.[15] The hysteresis loop in the isotherm curve of the crystallized sample (curve B) indicates a network pore system, *i.e.* mesopores run through the particles with a wormhole trace and form three-dimensionally complex pore media. The maximum of the pore size distribution of the sample calcined at 650 °C for 1 h of *ca.* 10 nm (Fig. 2, inset, curve B) agrees well with the TEM result. It should be noted that pore diameter expansion due to the crystallization is observed; the pore diameter of 4 nm before calcination at 650 °C (Fig. 2, inset, curve A) disappeared, while a new peak at around 10 nm appeared after the second-step calcination (Fig. 2, inset, curve B). The Brunaer–Emmett–Teller (BET) surface area decreased from 140 to 48 $m^2\ g^{-1}$ after the second-step calcination. The considerably high surface area for the crystallized oxide is a result of the mesoporous structure.

Results from TEM observation and N_2 adsorption isotherms clearly confirm the formation of single crystal particles of $(Nb,Ta)_2O_5$ with wormhole mesoporous structure. We denote this new type of single crystal particles of oxides with mesopores as M-TIT (M denotes a metal in metal oxide) type material, and we classify an M-TIT with wormhole-like mesoporous structure as M-TIT-1. The present sample is thus represented as NbTa-TIT-1. In the cases of pure Nb_2O_5 and Ta_2O_5, the wormhole-like mesoporous materials were obtained after the first-step calcination at 400 °C. However, crystallization in the second-step calcination led to the destruction of the mesoporous structure. Therefore, the mixing of two components is preferable for the preparation of M-TIT-1 materials in addition to the stepwise calcination.

The NbTa-TIT-1 showed mechanical and hydrothermal stability: no structure and surface area changes were confirmed by N_2 adsorption isotherms even after mechanical pressing at 500 kgf cm^{-2} for 17 h and after hydrothermal treatment at 200 °C and at 20 atm for 24 h.

It is reasonably expected that for other combination of metals, TIT-type materials may be formed. In preliminary results, ZrNb-TIT-1, ZnNb-TIT-1 and MgTa-TIT-1 have been prepared by the two-step calcination method. Indeed, we believe that the hexagonal-arrayed TIT series also can be prepared. Further investigation for wide variety of components is now in progress.

Received (in Cambridge, UK) 21st June 2001, Accepted 3rd September 2001
First published as an Advance Article on the web 2nd October 2001

An amine bis(phenolate) dibenzyl titanium complex having a methoxy donor on a side arm leads, upon activation with tris(pentafluorophenyl)borane, to unique living properties in α-olefin polymerization: exceptionally high molecular weight poly(1-hexene) is obtained in a living fashion at room temperature, living polymerization of 1-hexene is obtained above room temperature, and block copolymerization of 1-hexene and 1-octene at room temperature is described as well.

The quest for new α-olefin polymerization catalysts has involved many research groups for half a century. A recent addition to the arsenal of polymerization possibilities is the ability to produce polymers having narrow molecular weight distributions, and living polymerization processes. The vast majority of living processes are possible only below room temperature,[1] and the molecular weights of the polymers obtained in living processes are usually not very high. These systems are rarely utilized for block copolymerization of different monomers,[1c–e] since complete consumption of the monomer in a living fashion, followed by resumption of the polymerization process upon addition of the second monomer is difficult to achieve. Thus, all block copolymerization processes of α-olefins known to date are conducted below room temperature.

Recently, various Cp-free group IV metal complexes have been introduced as polymerization catalysts.[2] The most widely studied ligands are of the diamido type,[3] and one such system was the first to lead to living polymerization of α-olefins at room temperature.[1a] On the other hand, living polymerization involving alkoxo-type ligands[4] is quite rare.[1b,c] In this communication we introduce an amine bis(phenolate) titanium complex which, upon activation with tris(pentafluorophenyl)borane, leads to a polymerization process having unique living manifestations.

We recently introduced the amine bis(phenolate) group IV metal complexes and their application in α-olefin polymerization.[5–9] We revealed a unique effect of an extra donor arm in a titanium based catalyst on the complex reactivity and the termination/propagation rate ratio:[6] an [ONNO]-type complex was found to lead to living polymerization of 1-hexene, whereas an [ONO]-type complex led only to oligomerization of that monomer.

In our search for modified living catalysts of this family, we turned to a ligand having a side oxygen donor (Scheme 1).[9] We were interested in evaluating the effect of such a side donor, expected to bind strongly to the metal, on the living nature of a potential polymerization process. Furthermore, we wanted to explore the limits of the living process, in terms of polymerization time, molecular weight obtained, percentage of conversion and reaction temperature.

1 reacted cleanly with 1 mol equiv. of titanium tetra(isopropoxide) yielding the bis(isopropoxide) complex quantitatively. This complex was further reacted with 2 mol equiv. of chlorotrimethylsilane followed by reaction of the product with 2 mol equiv. of benzyl magnesium chloride, yielding the dibenzyl titanium complex **1a** in an overall yield of 95% (Scheme 1).

The ^{1}H NMR data are consistent with the formation of a C_s-symmetrical complex having two equivalent phenolate rings bound to the metal in a *trans* configuration, and two different benzyl groups bound in a *cis* configuration. The X-ray structure of **1a** (Fig. S1, ESI†) supported this notion, and indicated binding of the methoxy group to the titanium atom.‡

Upon activation with $B(C_6F_5)_3$, **1a** was found to be reactive in the polymerization of neat 1-hexene, exhibiting a reactivity of 20-35 g $mmol_{cat}^{-1}$ h^{-1}.§ The polymerization process induced by **1a** was found to be living for an exceptionally long time: as long as 31 hours, as expressed in the linearity of the molecular weight dependence on time (Fig. 1).[1a,e]

This system represents a rare example of living polymerization of α-olefins at room temperature.[1] Moreover, the long period at which the system remains living gives rise to a polymer having an exceptionally high molecular weight of M_w = 445 000 with a PDI of 1.12.

As this catalyst led to such a well-behaved polymerization at room temperature, it was interesting to find the temperature at which it lost its living nature. Increasing the reaction temperature to 40 °C in chlorobenzene resulted in a living process. The polymer obtained after 1 hour had a molecular weight of M_w = 16 000 with a PDI value of 1.14. Thus, this system gives rise to a rare living polymerization of α-olefins above room temperature. At 55 °C the PDI obtained was found to be 1.25 (M_w = 18 000 after one hour), and further broadening of the PDI to 1.30 (M_w = 22 000 after one hour) was obtained upon a temperature increase to 65 °C.

The most important application of living polymerization is in block copolymerization.[10] 16 μmol of **1a** were dissolved in 2.50 g of chlorobenzene, and 110 mol equiv. of 1-hexene were added. Activation with approximately 1 mol equiv. of $B(C_6F_5)_3$ dissolved in 2.50 g of chlorobenzene resulted in a living process characterized by a narrow PDI of 1.2. After 3.5 hours, complete consumption of the monomer was observed, and a polymer having a molecular weight of M_n = 9000 was obtained, supporting the polymerization of the 1-hexene employed in a living fashion (expected M_w = 9400). To further ascertain the complete consumption of the first monomer, the second monomer (1-octene) was added only after a 1.5 hours delay period (Fig. 2), resulting in resumption of the polymerization process. Stopping the polymerization after an additional 3 hours

† Electronic supplementary information (ESI) available: Fig. S1: molecular structure of **1a**. Preparation and characterization data for **1a**. Crystallographic data for **1a**. See http://www.rsc.org/suppdata/cc/b1/b105492a/

 DOI: 10.1039/b105492a

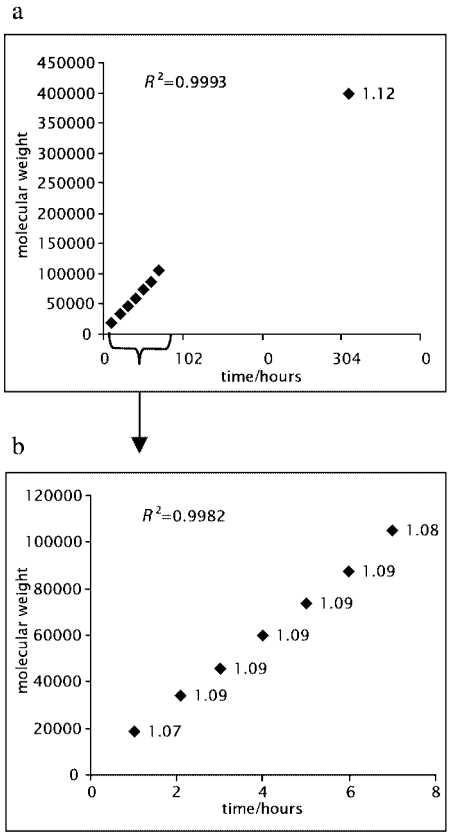

Fig. 1 Dependence of the number average molecular weight (M_n) on time (hours) using 20 mg of **1a** and 1.1 mol equiv. of $B(C_6F_5)_3$ in 30 mL of neat 1-hexene at RT and PDI values. (a) 31 hours of reaction, (b) first 7 hours of reaction.

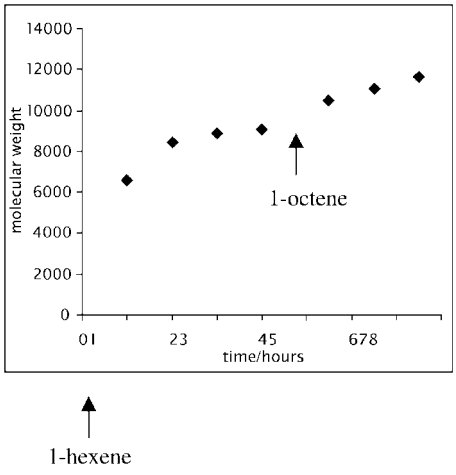

Fig. 2 Dependence of the number average molecular weight (M_n) on time (hours) in the block copolymerization of 1-hexene and 1-octene using **1a**.

yielded poly(1-hexene-block-1-octene) having M_n = 11 600 and PDI of 1.2. A ^{13}C NMR spectrum of the resulting polymer supported its assignment as an atactic copolymer of 1-hexene and 1-octene. This is a rare example of block copolymerization of α-olefins conducted at room temperature.

In summary, we present a catalytic system for polymerization of α-olefins that exhibits several unique living properties. When conducted at room temperature, the polymerization of neat 1-hexene is practically 'immortal'. Even when the reaction is allowed to stand for days, the only cause of loss of 'life' is the increased viscosity of the polymerization mixture. Thus, very high molecular weights may be obtained with extremely narrow PDI values. A solution of the monomer in chlorobenzene (diluted to enable its complete consumption) was employed for block copolymerization of α-olefins to give a di-block of homopolymers, at room temperature. We are currently studying related systems and the polymerization mechanism by which they operate.

This research was supported by the Israel Ministry of Science, Culture and Sports, and was also supported in part by the Israel Science Foundation founded by the Israel Academy of Sciences and Humanities. We thank Sima Alfi (BIU) for technical assistance.

§ In a typical polymerization of neat 1-hexene, 14 mg of **1a** (19 μmol) were added to 10.0 mL of neat 1-hexene and activated with 1 equiv. of $B(C_6F_5)_3$ at room temperature. The reaction was followed by taking 0.50 mL aliquots, weighing out the non-volatile residue, and analyzing it by GPC relative to polystyrene standards. This analysis indicated a linear consumption of the monomer and linear rise in molecular weight. A sample taken after 150 min showed a reactivity of 23.5 g $mmol_{cat}^{-1}$ h^{-1}, consistent with a TOF of 280 h^{-1}, giving an expected molecular weight of 58 800. The GPC analysis gave M_w = 55 600, M_n = 50 200, and PDI = 1.11. In a typical polymerization of dilute 1-hexene, 31 mg of **1a** (42 μmol) and 27 mg of $B(C_6F_5)_3$ were added to 502 mg of 1-hexene in 5.00 g of chlorobenzene at room temperature. A sample taken after 160 min indicated that all the monomer had been consumed. The expected molecular weight is 12 000. The GPC analysis gave M_w = 11700, M_n = 10 200 and PDI = 1.15. Occasionally, the weight of the obtained polymer was found to be lower than expected, probably due to incomplete catalyst activation, however, the TOFs were consistent with the values specified above.

Simultaneous combination of *in situ*-EPR/UV–VIS/on line GC: a novel setup for investigating transition metal oxide catalysts under working conditions

Angelika Brückner

Institut für Angewandte Chemie Berlin-Adlershof e. V. Richard-Willstätter-Str.12, D-12489 Berlin, Germany. E-mail: ab@aca-berlin.de

First published as an Advance Article on the web 2nd October 2001

***In situ*-EPR, *in situ*-UV–VIS spectroscopy and on line-GC have been for the first time simultaneously combined to follow the behaviour of lanthanum-doped CrO_x/ZrO_2 and CrO_x/Al_2O_3 catalysts during the dehydrogenation of propane to propene.**

Understanding the role of active sites in solid catalysts under working conditions is a major research goal in heterogeneous catalysis and a number of spectroscopic techniques have been adapted in recent years to study solid catalysts during reaction,[1] among them UV–VIS diffuse reflectance[2,3] and EPR spectroscopy.[4,5] These techniques provide complementary information on the structure and valence state of transition metal ions (TMI) during reaction. For example, Cr^{6+} species are not visible by EPR but do give rise to intense charge-transfer (CT) transitions in the UV–VIS spectrum while EPR is able to distinguish between Cr^{5+} and Cr^{3+} sites of different structure.[2,6] A similar situation arises, *e.g.* for different valence states in vanadia-based catalysts.[7]

In this work, both techniques have been for the first time coupled to each other and to on line-GC to widen the variety of TMI that can be simultaneously monitored under reaction conditions. Moreover, this set-up ensures identical reaction conditions for both spectroscopic techniques that are almost equal to those usually applied in catalytic tests since a fixed-bed flow reactor of similar dimensions is used. Thus, limitations in the comparability of spectroscopic results are eliminated that otherwise might arise from variations of the reaction conditions when different *in situ*-cells are used for separate EPR and UV–VIS measurements.

Combined *in situ*-EPR/UV–VIS measurements were performed using a home-made flow reactor[4,5] which was implemented in the rectangular cavity of a c.w. spectrometer ELEXSYS 500-10/12 (Bruker) operating in X-band. Details of the flow reactor are described elsewhere.[4] Simultaneous UV–VIS reflectance spectra were recorded by a fibre optics AVS-PC-2000 plug-in spectrometer (Avantes) equipped with a CCD array detector responsive from 200 to 1100 nm. The two channels of the spectrometer (master: 200–500 nm; slave: 500–1100 nm) as well as a DH-2000 deuterium-halogen light source were connected to a cylindrical quartz sensor (Optran WF, length 200 mm, diameter 1.5 mm) by fibre optic cables (length 2 m) consisting of a core of pure silica (diameter 0.4 mm) coated with polyimide. The sensor fits into the reactor through a Teflon sealing disk which is fixed by a screwing at the top end of the reaction tube. The tip of the sensor is a plane polished surface and is placed within the catalyst bed. The feed-through of the thermocouple at the bottom end of the reaction tube is realized in the same way. For on line product analysis, the reactor outlet was connected to a GC 17AAF capillary gas chromatograph (Shimadzu) equipped with a 30 m × 0.32 mm Silicaplot column (Chrompack) and a FID. The main features of the arrangement are schematically displayed in the graphic contents entry.

This setup has been used to study the dehydrogenation of propane to propene over two CrO_x catalysts: (a) $Cr/La,Al_2O_3$ prepared by thermal decomposition of ammonium dawsonite, $NH_4Al(OH)_2CO_3$, doped with 10 wt% Cr and 3.9 wt% La and (b) $Cr//La,ZrO_2$ prepared by impregnating a commercial 7 wt% La_2O_3/ZrO_2 support (MEL-CAT XZ0681/01, MEL Chemicals) with an aqueous $(NH_4)_2CrO_4$ solution to result in a Cr loading of 0.5 wt% followed by calcination at 873 K.[6] Doping by La was used since La is known to stabilize the Cr species on the surface.[8] The BET surface areas were 345 $m^2\,g^{-1}$ ($Cr/La,Al_2O_3$) and 104 $m^2\,g^{-1}$ ($Cr//La,ZrO_2$). In each run, 125 mg catalyst particles (250–355 μm) were treated in a flow of 23% C_3H_8/N_2 (W/F = 16.2 g h mol^{-1}).

The as-synthesized catalysts contain mainly hexavalent chromate species evidenced by intense CT bands around 370 nm in the UV–VIS spectra [Fig. 1(a) and 2(a)][9] besides traces of Cr^{5+} species that give rise to the very narrow singlet at $g' \approx 1.97$ in the EPR spectra [Fig. 1(b) and 2(b)]. The as-synthesized sample $Cr/La,Al_2O_3$ contains also a certain amount of Cr^{3+} reflected by a broad d–d transition band around 630 nm [Fig. 1(a)].[9] Upon heating under feed, the CT bands of chromate

 DOI: 10.1039/b107005c

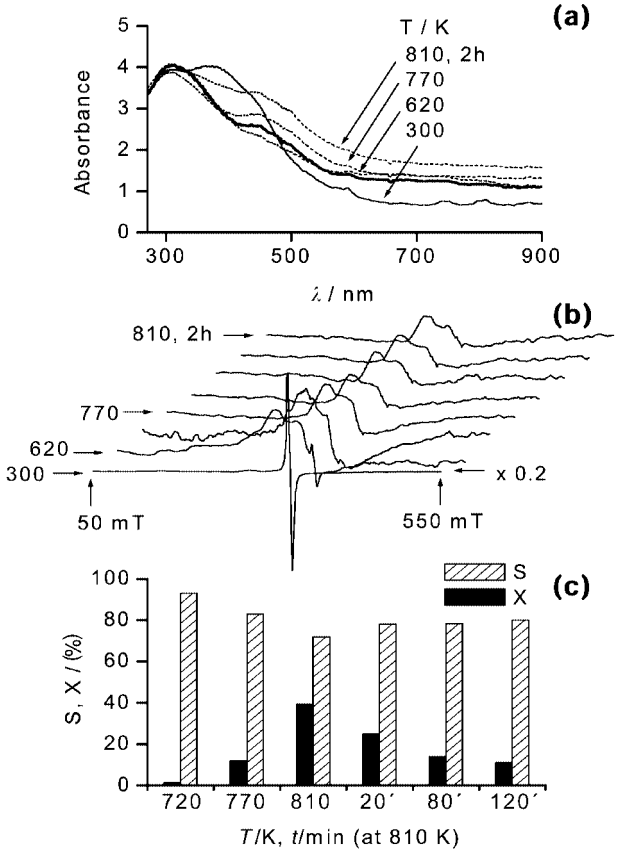

Fig. 2 UV–VIS (a) and EPR (b) spectra alongside propane conversion and propene selectivity results during heating of the $Cr/La,ZrO_2$ catalyst in a flow of 23% C_2H_8/N_2. For comparison the UV–VIS spectrum at 810 K in H_2 flow is also shown (thick line).

around 370 nm vanish and d–d bands of Cr^{3+} appear in the UV–VIS spectra [Fig. 1(a) and 2(a)]. Simultaneously, the narrow EPR singlets of Cr^{5+} disappear and a broad singlet at $g' \approx 2$ arises from weakly interacting Cr^{3+} species [Fig. 1(b) and 2(b)]. By comparing these results with the catalytic data [Fig. 1(c) and 2(c)] it is clearly evident that the reduction of Cr^{6+} and Cr^{5+} to Cr^{3+} occurs already at temperatures well below the onset of the dehydrogenation reaction. This information cannot be derived post mortem from measurements of quenched catalysts and shows that Cr sites in oxidation states higher than +3 do not exist under reaction conditions. With increasing time on stream at 810 K the propane conversion over the $Cr/La,ZrO_2$ catalyst drops markedly [Fig. 2(c)]. This is due to the partial coverage of active Cr^{3+} sites by coke deposits.[6] As a consequence, the EPR singlet of Cr^{3+} loses intensity since magnetic interaction with paramagnetic coke species may cause line broadening. In the UV–VIS spectra, deactivation leads to a gradual increase of absorbance in the visible range of the spectrum with a maximum around 470 nm arising from higher condensed carbon species such as polyaromatics and condensed rings.[10]

In comparison to sample $Cr/La,ZrO_2$, the $Cr/La,Al_2O_3$ catalyst is, despite a higher BET surface area and Cr content, less active but more stable against deactivation [Fig. 1(c)]. As for $Cr/La,ZrO_2$, carbon deposits are also formed with increasing time on stream. However, the maximum of absorbance is shifted to lower wavelength around 360 nm being characteristic of less condensed rather linear polyenylic species[10] which might be less deactivating [Fig. 1(a)]. Unfortunately, the d–d bands of Cr^{3+} ions and bands of the different carbonaceous deposites fall partially in the same wavelength range. However, the contribution of the carbon deposits to the overall absorbance is readily evident by comparing the UV–VIS spectra at 810 K in H_2 flow [thick line in Fig. 1(a) and 2(a)] reflecting only bands of reduced Cr species with those in propane/N_2 flow. The latter show higher absorbance even at 620 K when propane conversion is still below the detection limit. This suggests that carbon deposits start to form quite early but probably need to exceed a certain polymerization degree to become deactivating. Again, this is a result that cannot be obtained from *ex situ*-measurements of deactivated catalysts. The lower activity of the $Cr/La,Al_2O_3$ catalyst is most probably due to the fact that most of the Cr ions are incorporated in Al lattice positions of the catalyst bulk and, thus, not accessible by reactants. This is also supported by XPS measurements that reveal a markedly lower Cr concentration on the surface than in the bulk already for the as-synthesized catalyst which is expected to decrease even more upon reduction during time on stream. This behaviour is well known for Cr/Al_2O_3 catalysts.[9] In contrast to $Cr/La,ZrO_2$ catalysts[8] this obviously can not markedly be prevented by doping with La.

The obtained results demonstrate that the simultaneous coupling of *in situ*-EPR/UV–VIS/on-line-GC is a powerful new tool to follow the reaction-dependent interconversion of different Cr oxidation states and the deactivation behaviour of CrO_x catalysts.

Dr I. Pitsch and Dr D. L. Hoang are thanked for providing the catalyst samples as are the German Federal Ministry of Education and Research for financial support (grant no. 03C0280).

Ion-exchange as a mode of cation transfer into room-temperature ionic liquids containing crown ethers: implications for the 'greenness' of ionic liquids as diluents in liquid–liquid extraction

Mark L. Dietz* and Julie A. Dzielawa

Chemistry Division, Argonne National Laboratory, 9700 S. Cass Avenue, Argonne, IL 60439, USA. E-mail: mdietz@anl.gov; Fax: +1-630-252-7501; Tel: +1-630-252-3647

Received (in Cambridge, UK) 17th May 2001, Accepted 5th September 2001
First published as an Advance Article on the web 2nd October 2001

The transfer of strontium ion from acidic nitrate media into a series of 1-alkyl-3-methylimidazolium-based room-temperature ionic liquids containing dicyclohexano-18-crown-6 is shown to proceed *via* cation-exchange, in contrast to conventional solvents such as alkan-1-ols, in which extraction of a strontium nitrato-crown ether complex is observed.

Room-temperature ionic liquids (RTILs) have recently garnered increasing attention as environmentally benign alternatives to conventional organic solvents in a variety of synthetic,[1] catalytic,[2] and electrochemical[3] applications, a result of their unique physical and chemical properties and the relative ease with which these properties can be fine-tuned by altering the cationic or anionic moieties comprising the RTIL.[4] Very recent efforts by several investigators have focused on the application of ionic liquids in separations,[5–9] in particular, on the utility of these materials as replacements for the organic diluents employed in traditional liquid–liquid separations of organic solutes[5,6] or metal ions,[7–9] generally with encouraging results. Dai *et al*.,[7] for example, have demonstrated that highly efficient extraction of strontium ion from water ($D_{Sr} > 10^4$) can be achieved when dicyclohexano-18-crown-6 (DCH18C6) is combined with various water-immiscible 3-methylimidazolium-based RTILs, and thus, that ionic liquids offer considerable potential as diluents in metal ion separations. Full realization of this potential, however, requires a greater understanding of the metal ion partitioning process in these systems than is now available. To this end, we have examined the extraction of strontium ion from acidic nitrate media by DCH18C6 (a mixture of the A and B isomers) dissolved in a series of 1-alkyl-3-methylimidazolium (alkyl = ethyl, *n*-butyl, *n*-pentyl, *n*-hexyl, or *n*-octyl) bis[(trifluoromethyl)sulfonyl]-amides (abbreviated as C_n mim$^+$ Tf_2N^-, with n = 2, 4, 5, 6, or 8).† Comparison of the results to those obtained using a series of *n*-alkanols as diluents is shown to provide insight into the process of metal ion extraction by crown ethers in the RTILs.

Measurements of the dependency on crown ether concentration of the distribution ratio, D_{Sr} (defined as $[Sr]_{org}/[Sr]$, where the subscript 'org' and the absence of a subscript designate organic and aqueous phase species, respectively), for strontium extraction from nitric acid solution into the five RTILs yield lines of unit slope, consistent with the partitioning of a 1:1 strontium–crown ether complex ($Sr{\cdot}CE^{2+}$). The linearity of these dependencies contrasts with the non-linear dependencies observed for DCH18C6 in *n*-alkanols,[11] indicating that unlike extraction into the more conventional solvents,[11,12] the equilibrium aqueous phase concentration of the strontium–crown ether complex is not high in the RTIL systems under the experimental conditions.

As is well known, the extraction of a metal ion from an aqueous solution into an organic solvent requires that electroneutrality be maintained.[13] In conventional solvent systems involving the use of a neutral extractant, such as in the extraction of metal ions into an *n*-alkanol by a crown ether, this is achieved by aqueous phase anion coextraction. In the extraction of Sr^{2+} from nitric acid into octan-1-ol by DCH18C6,[11] for example, the 1:1 strontium–crown ether complex is accompanied by two nitrate ions:

$$Sr{\cdot}CE^{2+} + 2\ NO_3^- \rightleftharpoons Sr(NO_3)_2{\cdot}CE_{org} \quad (1)$$

For this process, the following equilibrium expression can be written:[11]

$$K'_{ex,Sr} = D_{Sr}\,[NO_3^-]^{-2}\,[CE]_{org}^{-1} \quad (2)$$

where $K'_{ex,Sr}$ is the conditional extraction constant and CE represents the crown ether. Not unexpectedly, the nitric acid dependency of D_{Sr} for DCH18C6 in such systems is characterized by increasing strontium partitioning with increasing nitrate (*i.e*. nitric acid) concentration. For example, D_{Sr} rises from 0.0025 at 0.010 M HNO_3 to 4.2 at 3.0 M acid for a 0.50 M solution of DCH18C6 in octan-1-ol. In contrast, the nitric acid dependency of D_{Sr} in the $C_n$mim$^+$ systems exhibits a significant decline in strontium partitioning as the acidity is increased. For a 0.1 M solution of DCH18C6 in C_2mim$^+Tf_2N^-$, for example, D_{Sr} falls from 468 at 0.010 M HNO_3 to 18 at 3.0 M acid. Such a result, while consistent with previously reported results in related $C_n$mim$^+PF_6^-$ systems,[9] is clearly inconsistent with the extraction of a strontium nitrato–crown complex [eqn. (1)]. (It is important to note here that repeated contact of the ionic liquids with an excess of an aqueous phase containing a high concentration of nitric acid results in the gradual disappearance of the organic phase, an apparent result of the replacement of Tf_2N^- by nitrate.)

A further indication that the observed strontium partitioning into the RTILs does not involve nitrate ion coextraction is found in the acid dependencies of D_{Sr} for DCH18C6 in C_2mim$^+Tf_2N^-$ using HCl or H_2SO_4 solutions as the aqueous phase, both of which differ little from that observed with HNO_3. Prior studies of the effect of anion on the extraction of metal ions by neutral extractants into various organic solvents have demonstrated that the need to dehydrate the anion upon phase transfer and the significant differences in the hydration energy between anions (*e.g*. $\Delta G_{hydration}$ = 293 and 318 kJ mol^{-1} for nitrate and chloride, respectively[14]) typically give rise to substantial differences in the extraction of, for example, metal nitrates and chlorides.[11] Although these differences diminish when the organic solvent is capable of dissolving high concentrations of water (thereby facilitating transfer of a hydrated anion) they remain significant. In fact, a factor of 73 difference in strontium extraction into octan-1-ol by DCH18C6 from HCl and HNO_3 has been observed, despite the presence of more than 2 M water in the solvent.[11] The absence of an appreciable anion effect in the extraction of strontium into C_2mim$^+Tf_2N^-$, particularly given the fact that the solvent, like other related RTILs[7] dissolves only a modest amount ($\leqslant$2% w/w) of water, thus strongly suggests that strontium partitioning in the $C_n$mim$^+$ systems does not involve nitrate ion coextraction.

When an ionic liquid, rather than a conventional organic solvent, is employed as a diluent for metal ion extraction by a neutral extractant, there are two other means by which

 DOI: 10.1039/b104349h

electroneutrality could conceivably be maintained. First, the anionic component of the RTIL, here the bis[(trifluoromethyl)sulfonyl]amide anion, arising in the aqueous phase from solubilization of the RTIL, could serve as the counterion:

$$Sr^{2+} + 2\ Tf_2N^- + CE_{org} \rightleftharpoons Sr(Tf_2N)_2{\cdot}CE_{org} \quad (3)$$

In the alternative, strontium partitioning could involve not extraction, but rather exchange of the strontium–crown ether complex, $Sr{\cdot}CE^{2+}$, for the cationic constituent of the ionic liquid, here $C_n mim^+$:

$$Sr{\cdot}CE^{2+} + 2\ C_n mim^+_{org} \rightleftharpoons Sr{\cdot}CE^{2+}_{org} + 2\ C_n mim^+ \quad (4)$$

for which the following equilibrium expression can be written:

$$K'_{ix,Sr} = [Sr{\cdot}CE^{2+}]_{org}\,[C_n mim^+]^2\,[Sr{\cdot}CE^{2+}]^{-1}\,[C_n mim^+]_{org}^{-2} \quad (5)$$

where $K'_{ix,Sr}$ is the conditional exchange constant. Obviously, in this case, no anion coextraction is required to maintain electroneutrality.

If extraction of a complex incorporating Tf_2N^- counterions is indeed occurring, conditions that increase the aqueous concentration of the anion would be expected to yield the highest distribution ratios. This is not the case, however. That is, although increasing nitric acid concentration is accompanied by greater aqueous solubility of the RTILs, higher acidity is also accompanied (as already noted) by decreasing D_{Sr} values. This result, together with the apparent absence of nitrate ion coextraction and the poor strontium extraction observed in the absence of the crown ether, strongly suggests that strontium partitioning in these systems involves the process depicted in [eqn. (4)].

Additional support for this conclusion is found in Fig. 1A, which depicts the relationship between the conditional partition constant for strontium and the number of carbon atoms in the alkyl group of the 1-alkyl-3-methylimidazolium cation. If we assume, as implied by eqn. (4), that differences in the extent of strontium partitioning into the various RTILs arise from differences in the free energy of transfer of the various $C_n mim^+$ cations from the organic to the aqueous phase, then previously reported values of ΔG associated with the transfer of a methylene unit from water to a water–hydrocarbon interface (-3.0 to -3.5 kJ mol^{-1})[15] or from water into a bulk hydrocarbon (-3.7 kJ mol^{-1})[16] imply that a plot of log $K'_{ix,Sr}$ *vs.* n should yield a line whose slope lies in the range -0.53 to -0.66, consistent with the observed slope of Fig. 1A (-0.64). Not unexpectedly, the analogous plot of log $K'_{ex,Sr}$ [as per eqn. (2)] *vs.* n for a series of alkan-1-ols [Fig. 1(B)] does not yield such a line, providing yet another indication that the process involved in strontium partitioning in the RTIL systems differs from that observed for conventional organic diluents.

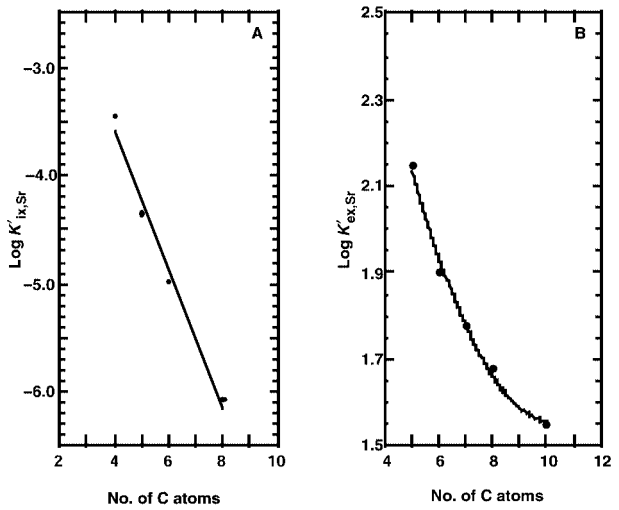

Fig. 1 Dependence of the conditional partition constants for strontium in DCH18C6–$C_n mim^+$ Tf_2pN^- (panel A; 0.1 M HNO_3) or alkan-1-ol (panel B; 1.0 M HNO_3) systems on the alkyl chain length of the solvent. (The solid line in panel A represents the line of best fit, while that in panel B is intended only as a guide to the eye.)

That ion-exchange may constitute the predominant mode by which a cation is transferred into an RTIL in the presence of a neutral extractant would seem to have significant implications for the 'greenness' of these solvents in the area of liquid–liquid extraction. That is, eqn. (4) indicates that increasing metal ion extraction will be accompanied by increasing solubilization of the RTIL in the aqueous phase, as the $M{\cdot}CE^{2+}$ complex is exchanged for $C_n mim^+$. Indeed, while the water solubility of $C_5mim^+Tf_2N^-$, for example, is only 0.03 M, this solubility is increased by 0.066, 0.082, and 0.093 M upon extraction of 0.030, 0.040 and 0.05 M $Sr(NO_3)_2$, respectively, into a 0.10 M solution of DCH18C6 in it, a result consistent with the 2:1 $C_n mim^+$:$Sr{\cdot}CE^{2+}$ stoichiometry depicted in eqn. (4). Thus, although RTILs clearly offer advantages in terms of enhanced extraction efficiency and reduced volatility *vs.* conventional organic solvents, these advantages may be diminished by aqueous phase solubility losses when they are employed as diluents in certain metal ion extraction applications. Work to further delineate the benefits and limitations of RTILs as separation media is now underway in this laboratory.

This work was performed under the auspisces of the Office of Basic Energy Sciences, Division of Chemical Sciences, United States Department of Energy, under contract No. W-31-109-ENG-38.

Notes and references

† The ionic liquids were prepared according to published methods.[10] The aqueous phase solubility of the RTILs was quantified by UV-visible spectrophotometry.[8] As anticipated, their water solubility decreased markedly (from 0.187 to 0.013 M) as the alkyl chain length increased from C_2 to C_8. The solubility of water in the RTILs was determined *via* Karl Fischer titration, and was found to decrease (from 1.84 to 0.80 M) over the range of chain lengths examined. That the RTILs are stable to contact with nitric acid was verified by examination of ^{1}H-NMR spectra acquired following 24 h contact of the ionic liquid with 3 times its volume of 8 M HNO_3. All strontium distribution ratios were determined radiometrically using a commercial Sr-85 radiotracer, assayed *via* gamma spectroscopy using standard procedures. The choice of Tf_2N^- anion was prompted by satisfactory results obtained with it in prior studies of cation extraction from water.[7]

First published as an Advance Article on the web 18th September 2001

The mixed valence cluster anion of the compound $(NH_4)_{32}[Mo^{VI}_{110}Mo^{V}_{28}O_{416}H_6(H_2O)_{58}(CH_3CO_2)_6]\cdot xH_2O$ 1 ($x \sim 250$), synthesized under one-pot conditions, contains well-defined different types of defects—missing groups compared to the complete parent $\{Mo_{154}\}$ type cluster with full D_{7d} symmetry—and acetate ligand coordination; this proves that the giant-wheel type anion can be considered as an object with a variety of nanoscale structural features ("nanostructured landscape") allowing reactions at a variety of well defined centers.

It is still a challenge to understand details of the interaction mechanisms of substrates with the surfaces of heterogeneous catalysts,[1,2] as for instance in the case of transition metal oxides which play an important role in industrial processes, *e.g.* in selective oxidations.[3] Of particular interest is MoO_3, which shows an enormous versatility of catalytical properties.[3a] A tremendous step to this end would be to consider the well defined discrete giant metal–oxide based cluster species, *i.e.*, nanoreactors (which show the same or a similar structure including defects on their large surfaces), as relevant catalytically active bulk materials, the surface of which is difficult to investigate. Remarkably, very little is known as yet about the influence of such defects present on the surface of an oxide, and their role in determining the catalytic properties.[3b] Here we report on the synthesis of $(NH_4)_{32}[Mo^{VI}_{110}Mo^{V}_{28}O_{416}H_6(H_2O)_{58}(CH_3CO_2)_6]\cdot xH_2O$ **1** ($x \sim 250$) which shows different types of well defined defects, substrate interactions/activation, and even other important structural features such as $Mo^{VI/V}$ type redox as well as acid sites, important for the catalytic action of molybdenum–oxide based catalysts. In particular the pentagonal bipyramidal MoO_7 polyhedra seem to be of interest for understanding selective oxidations.[3c]

When an aqueous solution of ammonium heptamolybdate is reduced with hydrazinium sulfate in the presence of a high acetic acid concentration, blue crystals of **1** precipitate within three weeks.‡ Compound **1** was characterized by elemental analysis, thermogravimetric analysis (to determine the crystal water content), cerimetric titrations [for the determination of the (formal) number of Mo^V centers], spectroscopic methods (IR, resonance Raman, VIS–NIR)§ and single crystal X-ray structure analysis, including bond valence sum (BVS) calculations (to determine the number and positions of H_2O and OH groups as well as the formal number of Mo^V centers).¶ The relatively low solubility of **1** in water is due to the abundance of acetate ligands and ammonium cations.

The crystal structure of **1** shows in the lattice the presence of a derivative of the "classical" tetradecameric type of molybdenum–oxide based anionic giant wheel, formulated with its characteristic building blocks as $[\{Mo_2\}_{14}\{Mo_8\}_{14}\{Mo_1\}_{14}]^{14-}$ = $[\{(O)_2{=}Mo^{VI}(H_2O)(\mu\text{-}O)(H_2O)Mo^{VI}{=}(O)_2\}^{2+}_{14}\{Mo^{VI/V}_8O_{26}(\mu_3\text{-}O)_2H(H_2O)_3Mo^{VI/V}\}^{3-}_{14}]^{14-} \equiv [Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{70}]^{14-}$ **2a**.[4] In **1a** (Fig. 1) there

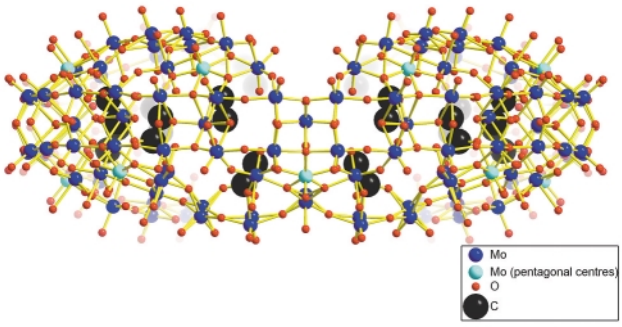

Fig. 1 Side view of the structure of **1a** in crystals of **1** in ball and stick representation with enlarged C atoms of the acetate ligands.

are six $\{Mo_2\}$ units missing while two bidentate acetate ligands are coordinated to other abundant $\{Mo_2\}$ units thereby replacing four H_2O ligands with the formation of $\{Mo_2Ac\}$* units. In addition, four $\{Mo_1\}$ units are—compared to **2a**—"released". Describing the "release" of these $\{Mo_1\}$ units is somewhat difficult (see Fig. 2): formally, 4 $\{\{MoO_2\}^{2+} + H_2O + H^+\}$ collectives of **2a** are removed and 4 $\{CH_3CO_2^- + 3H^+\}$ added, thus leading to the schematic description of **1a** as $[\{Mo_2\}_6\{Mo_2Ac\}^*_2\{Mo_8\}_{10}\{Mo_8Ac\}^*_4\{Mo_1\}_{10}]^{32-}$ or to the formula $(NH_4)_{32}[Mo^{VI}_{110}Mo^{V}_{28}O_{416}H_6(H_2O)_{58}(CH_3CO_2)_6]\cdot xH_2O$ ($x \sim 250$) for the resulting compound **1**, as stated

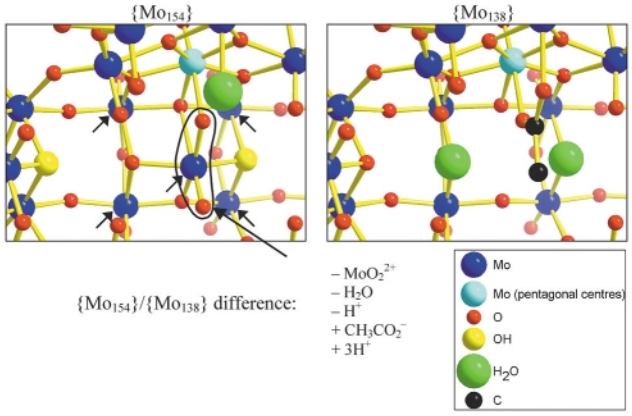

Fig. 2 Schematic representation (view from the inside of the rings) of the structural change from **2a** to **1a** at one representative $\{Mo_5O_6\}$ type compartment built up by four $\{Mo_8\}$ and one $\{Mo_1\}$ type atoms: formally, one MoO_2^{2+} group, *i.e.* the $\{Mo_1\}$ type atom with the terminal oxygen atom bonded to it and the μ-O atom bridging the Mo atom and the pentagonal Mo center of the $\{Mo_8\}$ group, is removed from **2a**. The vacant position due to the loss of μ-O at the pentagonally coordinated Mo atom is filled by an O atom of an acetate ligand while the other O atom of the carboxylate group substitutes a H_2O ligand of a neighbouring Mo center. The two μ_3-O type atoms (one of which is protonated in **2a**) of the complete $\{Mo_5O_6\}$ compartment of **2a** situated on the equator are doubly protonated in **1a**. Consequently, a protonation at the μ_3-O type atom of a neighbouring intact compartment is not possible due to space limitations.

† Dedicated to Prof. J. Strähle on the occasion of his 65th birthday.

 DOI: 10.1039/b106092a

in the abstract ({Mo_8Ac}* = {$Mo^{VI/V}{}_8O_{24}(\mu\text{-}H_2O)_2(H_2O)_2(CH_3CO_2)$}$^{3-}$; for the differing number of H atoms in {Mo_8} units see Fig. 1).

These novel {Mo_1} type defects have been generated now for the first time and could in principle be formed in the following way: **1a** is initially formed while the acetate ligands, after coordination to the {Mo_8} units (comparable to the situation of pentagonal units of the ball/basket type species[5]), subsequently expel the {Mo_1} units in order to overcome the steric strain imposed on the specific sites. Due to the loss of four {Mo_1} type centers from the cubane {Mo_5O_6} compartment, present in **1a** and for instance in $[Mo^{VI}{}_{114}Mo^{V}{}_{28}O_{432}H_{14}(H_2O)_{58}]^{26-}$ **3a**[6] as well as in all other ring type species, eight of the related 28 (μ_3-O) type atoms abundant in **2a** become doubly protonated (by reason of their *trans* positions to terminal O atoms and the removal of the {Mo_1} type atoms, corresponding to Fig. 2). This causes the absence of protonations at neighbouring {Mo_5O_6} compartments like in the parent **2a**, since the space which would be required is already occupied by the hydrogen atoms of the "new" μ-H_2O ligands (Fig. 2).

The maximum possible number of {Mo_2} type defects is six, as observed also in **3a**,[6] because more than three defects in one half of the ring would cause at least one {Mo_8} unit not to link to an {Mo_2} unit, a situation which would result in the collapse of the ring skeleton. For this type of defect generation, a relatively high pH value as in the case of lacunary Keggin ions is obligatory.[7] On the other hand, aging also favours their formation.

A significant aspect of our work is that we are able to study a variety of reactions at well defined sites of the same structurally characterized nanoobjects[4,8–10] including the deliberate generation of different types of defects.

Notes and references

‡ *Synthesis* of **1**: To a solution of $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ (2.0 g, 1.62 mmol) in 75 mL of water, acetic acid (9.0 mL, 100%) and hydrazinium sulfate (0.05 g, 0.38 mmol) were added. After stirring the mixture (pH = 3.5) in a closed flask for 75 min, the resulting blue solution was kept undisturbed at room temperature for 3 weeks. The precipitated blue crystals were filtered off, washed quickly with a small amount of cold water and sucked dry. Yield: 0.66 g (30% based on Mo).

§ *Selected data* for **1**: VIS–NIR (in H_2O) [λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1})]: 744 (1.75×10^5), 1090 (1.3×10^5). IR (KBr pellet, ν/cm^{-1}): 1616m {$\delta(H_2O)$}, 1400s {$\delta(NH_4^+)$}, 959s/906m {ν(Mo=O)}, 799m, 748m, 634s, 558vs. Resonance-Raman (H_2O, λ_e = 1064 nm, ν/cm^{-1}): 798vs, 531s, 465s, 322s, 215s. Anal. Calc. for $C_{12}H_{768}Mo_{138}N_{32}O_{736}$ (M 26382.30) C, 0.55; N, 1.70; Mo^V, 10.18 (non-coordinated) crystal water 17.07%. Found: C, 0.47; N, 1.6; Mo^V, 10.3; non-coordinated crystal water ~19% (thermogravimetry).

¶ *Crystal data* for **1**: $C_{12}H_{768}Mo_{138}N_{32}O_{736}$, M = 26382.30 g mol^{-1}, monoclinic, space group $C2/m$, a = 42.0716(14), b = 40.2653(14), c = 26.0734(9) Å, β = 112.019(1)°, V = 40947(2) Å^3, Z = 2, D_c = 2.140 g cm^{-3}, μ = 2.145 mm^{-1}, $F(000)$ = 25496, crystal size = 0.15 × 0.15 × 0.10 mm. Crystals of **1** were removed from the mother-liquor and immediately cooled to 183(2) K on a Bruker AXS SMART diffractometer (three circle goniometer with 1K CCD detector, Mo-Kα radiation, graphite monochromator; hemisphere data collection in ω at 0.3° scan at a detector distance of 5.0 cm). A total of 94 714 reflections ($0.73 < \theta < 25.01°$) were collected of which 36 348 unique reflections (R_{int} = 0.0445) were used. An empirical absorption correction using equivalent reflections was performed with the program SADABS. The structure was solved with the program SHELXS-97 and refined using SHELXL-93 to R = 0.0551 for 24 378 reflections with $I > 2\sigma(I)$, R = 0.1000 for all data; max./min. residual electron density 2.160 and −1.503 e Å^{-3}. (SHELXS/L, SADABS from G.M. Sheldrick, University of Göttingen 1997, 1993; structure graphics with DIAMOND 2.1 from K. Brandenburg, Crystal Impact GbR, 1999.) Whereas the {Mo_2} type defects show no disorder, this is the case for the {Mo_1} type units. CCDC reference number 166020. First published as an Advance Article on the web 1st October 2001

Investigation of the selectivity of a diol organic host for mixtures of DMF and DMSO, showed the formation of five inclusion compounds in which the stoichiometry varies in discrete steps and is determined by the composition of the liquid guest mixture; the structures of these compounds are described.

Molecular recognition is fundamental to supramolecular chemistry, and the formation and stability of a particular inclusion compound depends on the strengths and direction of the intermolecular forces which impinge on a particular host–guest system.[1–5] This can be exploited to carry out selective enclathration, whereby a given host molecule is exposed to a mixture of possible guests, and preferentially forms an inclusion compound with only one guest, thus enacting a perfect separation. In practice, this is seldom achieved in a single cycle, particularly when we seek to separate close isomers, where the differences between guests may be subtle.

The results of competition experiments whereby inclusion compounds are grown from solutions of pairs of guests A and B of known compositions, usually give rise to selectivity curves shown in Fig. 1.

X_B is the mole fraction of guest B in the liquid mixture and Z_B that of guest B which has been enclathrated in the host–guest crystal. Curve a results from a host displaying no selectivity,[6] curve b occurs when guest B is strongly selected over A for the whole concentration range[7] and curve c occurs when the selectivity is concentration dependent.[8] In this work, however, we present results of a host–guest system which behaves in a totally different manner.

When the host *trans*-9,10-dihydroxy-9,10-bis(*p*-*tert*-butylphenyl)-9,10-dihydroanthracene = H, is exposed to mixtures of dimethylformamide, A, and dimethyl sulfoxide, B, it forms a series of inclusion compounds of the type H·nA·(4 − *n*)B, such that *n* varies integrally from 0 to 4. The results of the competition experiments are given in Fig. 2, which shows that the stoichiometry of the inclusion compounds varies in discrete steps, and gives rise to five distinct compounds: H·4A, H·3A·B, H·2A·2B, H·A·3B and H·4B. The stoichiometry can be controlled by changing the composition of the liquid guest mixture.

Thermal gravimetry, TG, and differential scanning calorimetry, DSC were employed to analyse the stoichiometries and thermal stabilities of all five inclusion compounds.[9,10] The compound H·A·3B was difficult to isolate, because when the guest liquid mixture is in the mole fraction range X_B 0.5–1.0, the host shows a strong propensity for the formation of H·2A·2B.

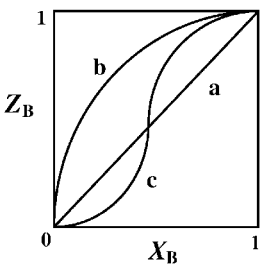

Fig. 1 Typical selectivity curves obtained from competition experiments.

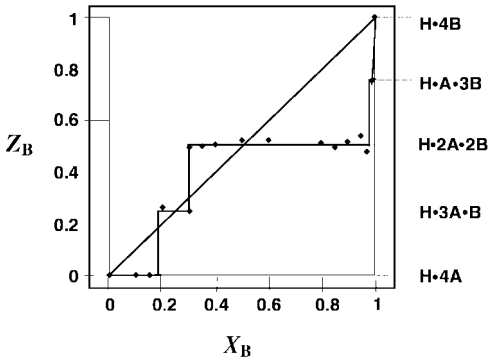

Fig. 2 Results of the competition experiments.

We therefore prepared the H·A·3B compound by using an initial guest mixture with a mole fraction X_B of 0.99.

We have elucidated the structures of all five compounds by single crystal X-ray diffraction methods at low temperatures.† The five structures are all triclinic, with similar cell dimensions and all crystallise in the space group $P\bar{1}$. A typical example, that of the H·2A·2B structure, is displayed in Fig. 3. This shows that the host molecule is located at the origin on a centre of inversion. The two DMSO molecules are hydrogen bonded to the host and the two DMF molecules are disordered and located close to a centre of inversion at Wyckoff position g.

The TG and DSC curves for H·2A·2B are given in Fig. 4. This shows that the compound desolvates in two distinct steps, the first corresponding to the loss of two DMF molecules, followed by the loss of two DMSO guest molecules. The DSC displays the concomitant A and B endotherms, while peak C is due to the melting of the host. Similar curves were obtained for the other four compounds, and allowed us to establish the stoichiometry unambiguously in each case.

The compounds are isostructural with respect to the location of the host atoms. The changes which occur in the positions of the guest molecules are summarised in Fig. 5a to 5e. In all cases

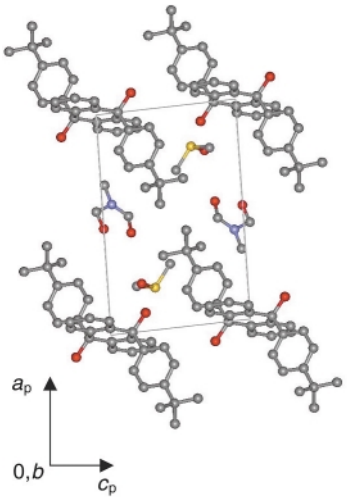

Fig. 3 Projection of the H·2A·2B structure along [010].

 DOI: 10.1039/b106080p

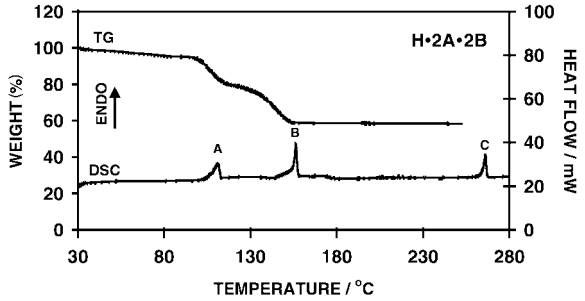

Fig. 4 TG and DSG curves for H·2A·2B.

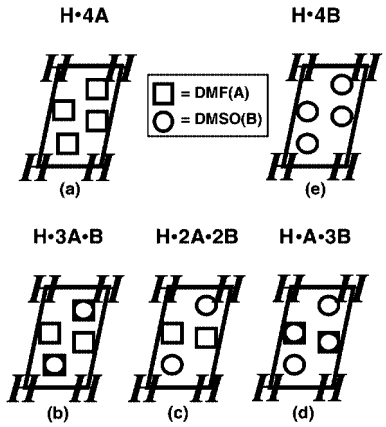

Fig. 5 Schematic diagram summarising the differences beteen the five structures.

only two guests are hydrogen bonded to the host. For the H·3A·B structure, symmetry requires the DMSO guest, B, and at least one DMF molecule to be located at two sites, each with site occupancies of 0.5. The difference electron density map showed that these guests shared the same general location. The same situation is obtained for the compound H·A·3B.

The occurrence of a host–guest system in which the ratio of mixed guests can be controlled, has implications for crystal engineering.[11,12] Thus the physical and chemical properties of such compounds can be governed, and this has significance in such fields as chemical sensors, optical and electronic properties of organic crystals as well as their thermal stabilities and kinetics of desolvation.

We are currently investigating the possibility of incorporating a variety of other guests, including chiral molecules, in clathrates formed by this host, and investigating their thermodynamic and kinetic properties.

First published as an Advance Article on the web 24th September 2001

A zeolitic material containing Ti chains activated by light allows a shape-selective transformation of organic compounds; the molecules that can enter into the zeolitic cavities are protected from the light-induced processes, while the other are degraded.

It is well known that light activated processes on TiO_2 have applications in several fields such as the removal of water pollutants[1] and organic synthesis.[2,3] When dealing with pollution problems, the complete degradation of the polluting organic molecules is of course the goal. The photoactivity of TiO_2 is generally not selective, leading to the complete decomposition of the organic compounds. However, it is intriguing to test the feasibility of selective phototransformation of organic species in an aqueous medium. For this purpose, materials that show shape selectivity properties, such as zeolites, could be used. Among them, ETS-10 (Engelhard Titanosilicate Structure 10)[4] is particularly interesting for photocatalytic applications. In fact, it has two main features: i) it is a semiconductor containing photo-excitable titanium moieties, and ii) its structure is characterized by a three-dimensional set of channels with a free entrance of about 0.8 × 0.5 nm, ref. 5 (Fig. 1). The UV-VIS spectrum of ETS-10 shows two absorption bands at 282 and 214 nm, which have been assigned to ligand-to-metal charge transfer (LMCT) transitions, involving two kinds of oxygen ligands: those which bridge Ti atoms along straight Ti–O–Ti chains (282 nm), and those in the Si–O–Ti groups (214 nm).[6] The band gap of the –Ti–O–Ti– quantum wire is 4.03 eV[7] and is slightly higher than that of TiO_2.[8] A higher energy is then necessary to obtain the production of the active carriers (electrons and holes) and for this reason, in the experiments reported below a 310 nm cut-off filter has been adopted. The irradiation of the single species were carried out on 5 ml of aqueous suspension containing 1×10^{-4} M organic compound and 1 g L^{-1} of catalyst, using a 1500 W Xenon lamp (Solarbox, CO.FO. MEGRA, Milan, Italy) simulating AM1 solar light and equipped with a 310 nm cut-off filter. The irradiance spectrum and the cells have been described elsewhere.[9] The photonic flux entering into the cell is 7.9×10^{-6} einstein min^{-1}. The content of the cell was filtered through a 0.45 μm cellulose acetate filter (Millipore HA) and analyzed by the appropriate analytical technique.

To test the selective photoactivity of ETS-10, molecules of different steric hindrance were investigated: phenol (P), 1,3,5-trihydroxybenzene (3HP) and 2,3-dihydroxynaphthalene (2HPP) have been chosen. A comparison of the relative dimensions of the molecules and of the zeolitic cavities is shown in Fig. 1, while an analysis of the degradation rate ratios is reported in Table 1. In the same Table the results obtained with TiO_2 P25 as photocatalyst are reported for comparison. The contribution of direct photolysis is negligible (see Table 1).

An interesting correlation between the size of the molecule and its photodegradability is shown. This is particularly evident comparing P and 2HPP degradation, 2HPP being degraded on ETS-10 with a rate which is 56 times higher than P, and with a degradation efficiency of the same order as TiO_2. These results provide, for the first time, evidence of the feasibility of selective photocatalytic degradation in aqueous medium. A study of the intermediates of the degradation of phenol shows that they are the same catechol and quinol on TiO_2 and ETS-10. In the case of 3HP and 2HPP, even if the intermediates have not been identified, they show the same chromatographic pattern both on

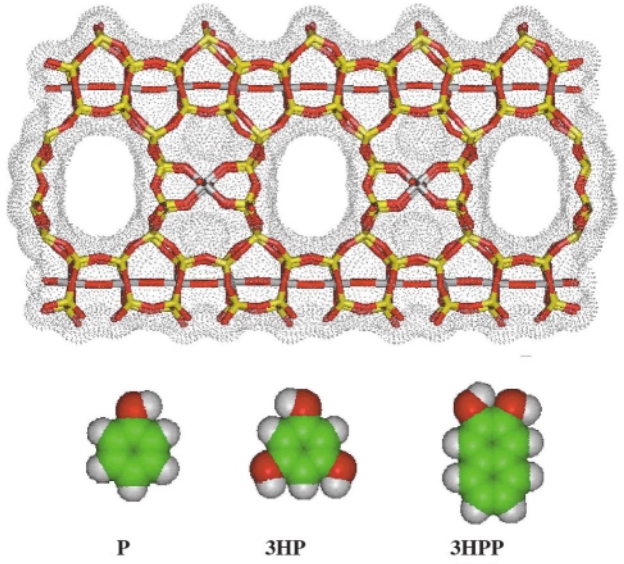

Fig. 1 Structure of zeolite ETS-10 and of the degraded molecules: phenol (P), 1,3,5-trihydroxybenzene (3HP) and 2,3-dihydroxynaphthalene (2HPP). The pointed surface in the zeolite structure evidences the accessible spaces as determined by the Connolly algorithm.[14]

Table 1 Degradation rate of hydroxyaromatic compounds on TiO_2 and on zeolite ETS-10. From these experimental data, the process efficiency (rate of degradation/photonic flux incoming into the cell) can be easily calculated;[10] in the case of dihydroxynaphthalene on ETS-10, a process efficiency of 2.8% is obtained. In parentheses are reported the degradation rate ratios (r_x/r_P) obtained comparing the values obtained in each set of experiments with that obtained for P. H-ETS-10 in the acid form was kindly supplied by the Engelhard Corporation (Iselin, NJ, USA); its external surface area is 21 m^2 g^{-1} (T-plot volumetric measurements with N_2 made with a Micromeritics apparatus). TiO_2 was a commercial Degussa P25 sample (surface area: about 50 m^2 g^{-1})

Rate/10^5 M min^{-1}	TiO_2	ETS-10	Direct photolysis
P	2.77 (1)	0.08 (1)	—
3HP	5.74 (2.07)	0.38 (4.75)	—
2HPP	7.90 (2.85)	4.46 (55.7)	0.21

 DOI: 10.1039/b106445m

TiO_2 and ETS-10. These results indicate that the degradation mechanism is similar and suggests that, like on TiO_2, the catalytic active sites of ETS-10 are titanols linked on external surfaces where the –Ti–O–Ti–O–Ti– chains are emerging and the TiO bonds are consequently broken. The bulk Ti atoms of ETS-10 cannot be considered as playing a role in the degradation for two reasons: i) imperfect structures are not directly exposed on the channels walls (see Fig. 1); ii) it has been shown[11,12] that when degradation takes place at centers located in restricted places (like titanols in defects located in zeolitic channels), the intermediate degradation products are able to back react with active species, favoring recombination. It is also to be noted that in the photocatalytic process there is no relation between the absorption on the surface and the rate of disappearance, as shown in the case of phenol (not adsorbed) and catechol (adsorbed).[13]

In view of these results and of the fact that the catalytic centers are located on the surface, it can be concluded that the zeolitic internal cavities offer a protective environment against degradation to those species which, for their small size, easily diffuse inside. This shielding effect against photodegradation is particularly marked for P, which was the smallest molecule investigated, and not present for 2HPP, which is the only studied species whose size surely does not fit the channel size and so it is the most degraded molecule. The ability to diffuse inside the cavities is then the main factor determining the shape selective degradation.

Finally, a further confirmation of the presence of catalytic sites on the external surface is given by the fact that the degradation rate of 2HPP on TiO_2 and on ETS-10, which have similar external surface area, is of the same order of magnitude.

Future developments also have to consider the influence of competitive diffusion of the molecules; this probably explains the small differences that can be observed in the rate constant values, compared to the values obtained in the degradation of the single molecules.

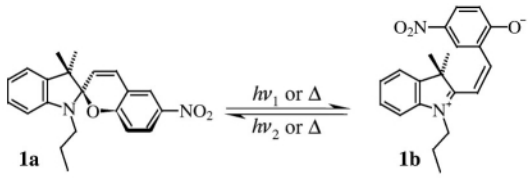
The dynamics of decay of the photoproducts of the two non equivalent molecules of *N*-(*n*-propyl) nitrospiropyrane‡ in the crystalline state is significantly different due to the effect of the specific site where each of the molecules is located in the crystal latice.

Reversible molecular transformations have been studied extensively through the years due to their fundamental importance in many chemical and biological processes and their relevance to artificial sensing.[1] Amongst the most frequently addressed optical switch systems are spiropyranes.[2] Reversible photoinduced and thermally activated ring transformations of spiropyrane systems have been studied in great detail in different solutions, including solid solutions.[3] The utilization of spiropyrane derivatives as molecular optical switches for different applications such as LC switching,[4] optical recording,[5] sensing,[6] and other optoelectronic devices[7] was also reported. Curiously, the photoactivity of spiropyranes in the crystalline state was reported only recently.[8]

The study of chemical processes in well-defined media, such as crystals, provides direct evidence for the effect of the molecular environment on the chemical reactivity. In most chemical transformations, the molecular environment in which the reaction is performed plays an important role by influencing the reaction path. Such site effects are the source of the ultimate chemical selectivity of enzymes and other biological systems. In the biological realm, a tailor-made restrictive anisotropic environment results in the selection of one specific reaction path, leading to a specific target molecule. Similar site effects are found for numerous reactions that take place in crystalline systems.[9] In many of those systems, a slight variation in the environment of the reactants results in a significant change in reactivity or in the mechanism path selection.[10] The establishment of quantitative correlations between the molecular and supramolecular structure and respective changes in properties is a long-standing goal in solid state chemistry and photochemistry. Such studies are essential for better understanding and mastering reactions in restrictive anisotropic environments.

Here we report on the photochromism of 1′-(*n*-propyl)-3′,3′-dimethyl-6-nitrospiro[2*H*-[1]benzopyran-2,2′-indoline], **1a**, in the crystalline state and on the effect of the crystal site on the chemical reactivity of the open merocyanine species.

Crystals of **1** develop a red–purple color (λ_{max} = 600 nm) upon exposure to near UV light (λ = 360 nm). The formation of the new optical band is correlated to the appearance of several new IR peaks between 1000 and 1600 cm^{-1} while the intensity of the IR bands at 1338, 1276 and 1172 cm^{-1}, decreases. These



changes in the IR and visible spectra are indicative of the formation of the merocyanine species, **1b**.[11] Based on the IR spectra we estimate that at a photostationary state the ratio between the open and the closed forms is at least 1:3.

In the dark, both the visible and IR bands decay homogeneously, an indication of a back, thermally activated, **1b** → **1a** ring closure process. The decay of the IR bands is associated with a decay of the band at λ = 600 nm. Fig. 1A depicts the absorbance of a crystalline sample at λ = 600 nm and T = 304 ± 0.1 K as a function of the time after irradiation.§ Interestingly, in contrast to most chemically active systems in crystals (but note ref. 1*a*, 9) the decay curves of the band at λ = 600 nm can be fitted only to a biexponential decay curve, indicating the presence of two independent decaying merocyanine species.¶ For example, at 304.5 K, the lifetimes of the two merocyanine species are 3095 ± 25 and 19040 ± 60 s. At 315 K the lifetimes of these two species are shortened to 875 ± 14 and 5910 ± 150 s

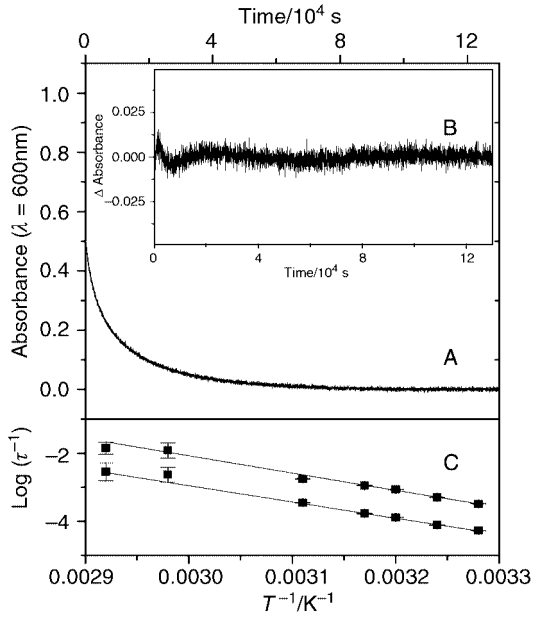


Fig. 1 (A) The absorbance of an irradiated crystalline sample of **1** as a function of the time after irradiation, λ = 600 nm; T = 304 ± 0.1 K. (B) The difference between the experimental signal depicted in A and a best-fitted biexponential curve. (C) Arrhenius plots for the two different sets of rate constants composing the biexponential decay curves.

† Electronic supplementary information (ESI) available: time decay of merocyanine absorption; overlay plot of molecules $\mathbf{1}_{(A)}$ and $\mathbf{1}_{(B)}$; plot of the ratio between the effective volume of the two sites as a function of the radius of the rigid sphere in the Monte Carlo calculation.  DOI: 10.1039/b102121b

respectively. The two sets of lifetimes extracted from the biexponential decay curves at different temperatures form two linear Arrhenius plots, Fig. 1C, attributed to the two different coexisting merocyanine species that are photogenerated simultaneously in the crystal. These two different merocyanine species are characterized by somewhat different activation energies and pre-exponential factors: $E_{a(1)} = 23.4 \pm 0.8$ kcal mol^{-1} and $E_{a(2)} = 21.9 \pm 0.9$ kcal mol^{-1}, $A_{(1)} = 13.2 \pm 0.6$ and $A_{(2)} = 11.3 \pm 0.8$ for the short-lived and long-lived species respectively. The origin of the two different photogenerated merocyanine species is revealed from the crystal structure. Crystals of **1** contain two nonequivalent spiropyrane molecules, $\mathbf{1}_{(A)}$ and $\mathbf{1}_{(B)}$, in the asymmetric unit, Fig. 2. The two nonequivalent molecules of **1** are almost identical with respect to their internal coordinates when considered as rigid bodies and the overlap between them is maximized. The minimal distance, D, between the overlapping molecules is $D = 0.137$ Å, where $D = \{[\Sigma(x_i^{(1)} - x_i^{(2)})^2]/(3N)\}^{\frac{1}{2}}$, (see supplementary material for an overlay plot of $\mathbf{1}_{(A)}$ and $\mathbf{1}_{(B)}$). The main differences between the two molecules are expressed in the nature of the sites the molecules occupy in the crystal. In the absence of a unique definition of the exact volume the molecule occupies in the crystal, we defined it using the following scheme. The molecular environment was represented by spheres having the Van der Waals radii of the atoms. A dynamical rigid sphere was placed in the void which was created by removing the reacting molecule and the diffusion equation was solved for this sphere within the rigid cage using *Monte Carlo* integration. The space that was sampled by the sphere in the infinite time-limit provides a practical definition of the volume and shape of the site hosting the molecule. The results were insensitive to the choice of the rigid sphere radius (r_s) in the range $1.6 < r_s < 2.5$ Å. The two sites are found to have roughly the same volume, Fig. 3, nevertheless, the shapes of the cavities that host each of the two molecules are remarkably different. The *n*-propyl moiety of $\mathbf{1}_{(A)}$ is interlocked between two *n*-propyl groups of neighboring molecules. In contrast, the *n*-propyl group of $\mathbf{1}_{(B)}$ is loosely bound to its environment but its nitroindoline skeleton is more tightly packed in its environment compared to $\mathbf{1}_{(A)}$. The difference in the shape of the cavities and nature of nearest neighbors seem to impose different restrictions on the degree of relaxation of the photoproduct of the reacting molecule within the reaction site. Based on this analysis we conclude that two almost equivalent molecules of **1**, that occupy two non-equivalent sites in the crystal lattice are photoactive and that they yield two structurally different merocyanine species. These two merocyanine moieties relax into two different sites in the crystal lattice and therefore exhibit different thermal reactivity for the back cyclization process.

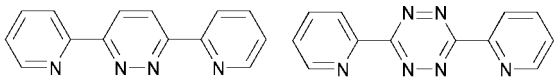
School of Chemical Sciences, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT. E-mail: e.c.constable@bham.ac.uk

Received (in Cambridge, UK) 25th July 2001, Accepted 7th September 2001
First published as an Advance Article on the web 27th September 2001

The ligand 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine forms a 1:1 complex with Na[BPh_4], which has been structurally characterised as a one-dimensional polymeric system with an unusual coordination geometry about the sodium.

Polytopic ligands incorporating multiple oligopyridine metal-binding domains are important components in the development of metallosupramolecular chemistry.[1] A key early observation was the spontaneous self-assembly of a 2 × 2 grid from the reaction of a copper(I) salt with 3,6-bis(2-pyridyl)pyridazine **I**.[2] We have recently commenced a systematic study of compounds related to **I**, including 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine **II** which has been shown to have a rich supramolecular chemistry.[3] In this paper, we report the unexpected formation of a sodium complex of **II**.



I II

In the course of our studies with **II** we noted that the purple ligand **II** gave rise to a series of variously hued pink species in addition to the expected metal complexes. These pink species, which we initially believed to be salts of **II** gave differing but repeatable ^{1}H NMR spectra. In some cases, the ^{1}H NMR spectra differed significantly from that of **II** and the compounds were characterised as protonated derivatives of **II**. In other cases, the ^{1}H NMR spectra were essentially identical to **II**. When the purple complex $[Ag_2(\mathbf{II})_2][CF_3SO_3]_2$[4] was treated with an excess of Na[BPh_4] a pink solution was obtained which eventually deposited red crystals. The same red crystalline compound was obtained directly from the reaction of **II** with Na[BPh_4] in nitromethane† No change occurred in the UV–VIS spectrum of a nitromethane solution of **II** upon the addition of three equivalents of Na[BPh_4].

In the ^{1}H NMR spectrum of the red solid, the ligand resonances are essentially identical to those of **II** in CD_3COCD_3 or CD_3SOCD_3, although the signals due to H^3 and H^6 were slightly broadened and shifted downfield by ≈ 5 Hz (300 MHz). Elemental analysis was consistent with a formulation {Na(**II**)(BPh_4)} and the FAB MS exhibited peaks at *m*/*z* 495 and 601 assigned to $\{Na(\mathbf{II})_2\}^+$ and $\{Na_2(\mathbf{II})(BPh_4)\}^+$, respectively. Somewhat surprisingly, in view of the ^{1}H NMR data, ESMS studies in MeCN exhibited the peaks at *m*/*z* 495 and 601 together with one at *m*/*z* 300 assigned to $\{Na(\mathbf{II})(MeCN)\}^+$. These data strongly suggest that the red compound is a sodium complex of **II**. Although alkali metal complexes of oligopyridines have been reported over a number of years,[5] structural data establishing the coordination mode are sparse.[6]

The solid state structure of $[\{Na(\mathbf{II})(BPh_4)\}_n]$ is presented in Fig. 1.‡ Each **II** ligand is in a transoid arrangement and presents a didentate N_2 donor set to each of two sodium ions. Although each of the aromatic rings is planar, **II** is riffled with the terminal pyridine rings making dihedral angles of 13–17° with the central tetrazine ring. As far as conventional donor atoms are concerned, each sodium is in a four-coordinate environment comprising two **II** ligands with unremarkable[6] Na–N distances in the range 2.465(2)–2.533(1) and a bite angle of 65.93(4)°. The result is a polymeric structure with chains of {Na(**II**)} units. However, before discussing the nature of the polymer, there is a feature of the coordination environment about the sodium which deserves comment.

Examination of the coordination geometry about the sodium reveals bond angles which imply that the two 'bipy' domains coordinated to each metal are best described in terms of an octahedral *cis*-$\{Na(bipy)_2X_2\}$ structure [N(3)–Na(1)–N(3B) 88.18°, N(2)–Na(1)–N(2B) 174.03°]. The sodium and boron atoms lie on two-fold axes and the tetraphenylborate ion is located in the lattice such that the ring containing C(7) is π-stacked with the tetrazine ring containing N(1) [and of course the same interaction between the symmetry related rings containing C(7B) and N(1B)]. The simplest explanation for the coordination geometry of the sodium is that the remaining two sites of the octahedron are voids filled by the two π-stacked phenyl rings. However, the stacking results in close contacts between the sodium and the two phenyl rings [Na(1)–C(12) 2.8332(18) Å, Na(1)–H(12) 2.6745 Å].

The bridging ligand **II** results in the formation of a one-dimensional polymer which is decorated by the tetraphenylborate counter ions which are locked in at each metal centre (Fig. 2). The polymeric units are then assembled in sheets with no short contacts between adjacent layers. Within each layer, the phenyl rings of the tetraphenylborates are locked into the notches between BPh_4 units of the adjacent chain, although there are no short contacts or additional stacking interactions. The ^{1}H NMR data indicate that this interaction is primarily a solid state phenomenon and no evidence for direct interaction of the tetraphenylborate with the metal centre in solution has been obtained.

We are currently investigating the coordination behaviour of **II** with other sodium salts and with other group 1 metals and

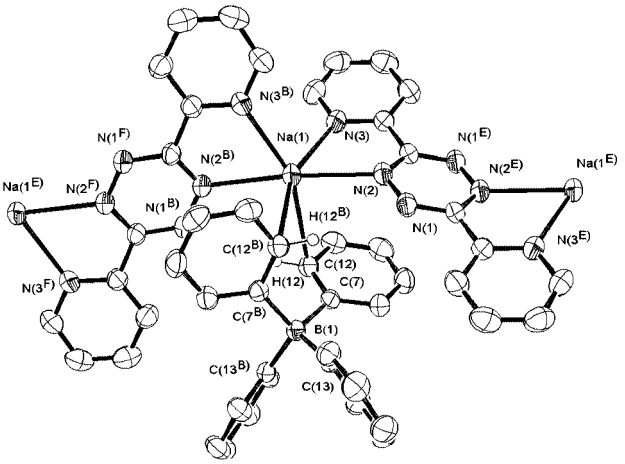


Fig. 1 The coordination geometry about sodium in the complex $[\{Na(\mathbf{II})(BPh_4)\}_n]$ as found from the solid state X-ray structure. With the exception of H(12), hydrogen atoms have been omitted and carbon atoms have only been labelled where necessary to identify phenyl rings or at sites of chemical interest.

 DOI: 10.1039/b106728c

Structural characterisation of the H-bonded $[Mn^{II}(OH_2)_2\cdots(OCH_3)_2Mn^{III}]$ motif: A model for resting state hydroxylic solvent coordination in M(II)–M(III) enzymes

A mixed-valence dimanganese complex with two water ligands bound to the Mn(II) ion and two methoxide ligands bound to the Mn(III) ion in a H-bonded arrangement has been structurally characterised and models possible resting state water/hydroxide coordination in purple acid phosphatases.

The majority of proposals for the mechanisms of metal-containing enzymes and catalysts involve reactive intermediates incorporating labile ligands which can be substituted by substrate. For metalloenzymes labile ligands are commonly water while water-derived ligands, H_2O, OH^-, $OH^{\cdot}$, O^{2-}, are also reactants in hydrolysis and oxidation reactions. Of the limiting forms of water-derived ligands, it is the *terminal* hydroxides and oxides that are rarely structurally characterised with biologically important metal ions, presumably due to their high reactivity. Despite this, terminal (hydr)oxides of iron and manganese have been designated significant biological roles.

The present report concerns the structural characterisation of a unique mixed-valence complex containing two H-bonded methoxo–water dimetal 'bridging groups', μ-($HOHOCH_3$). This moiety is homologous to the μ-(H_3O_2) group which was, in fact, our original target. Only a handful of complexes with a μ-(H_3O_2) group have been crystallographically characterised. These are exclusively homovalent. Notably the first examples were obtained using the robust metal ions, dichromium(III),[1,2] diiridium(III)[3] and dicobalt(III).[4] More recently labile diiron(III) complexes[5,6] have been characterised. In contrast to the solid state, μ-(H_3O_2) moieties are almost certainly important in the aqueous chemistry of labile dinuclear systems. The μ-(H_3O_2) group is a likely intermediate in the formation of μ-OH bridged dimers and polymers from metal aqua ions *via* 'olation' reactions,[1] and for dimetallic complexes and enzymes known to promote/catalyse hydrolysis reactions.[5,7,8]

Reaction of bpbpH† with manganese perchlorate in dry methanol leads to formation of the dark green compound $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$.[9] The X-ray crystal structure shows the two aqua and two methoxide ligands in the H-bonded $[Mn^{II}(OH_2)_2\cdots(OCH_3)_2Mn^{III}]$ motif, Fig. 1.[10] The Mn(II) and Mn(III) atoms are linked asymmetrically by the phenolate oxygen atom of $bpbp^-$. Shorter metal–ligand bond distances, and an axial Jahn–Teller distortion along the O(1)–Mn(2)–N(41) axis, identify the Mn(III) atom as that bound by the two methoxide ligands. The location of hydrogen atoms in difference maps supports assignment of two methoxide and two aqua ligands rather than two methanol and two hydroxide ligands or an intermediate symmetrically H-bonded arrangement. The terminal ligands are H-bonded with O_{aq}–H 0.97 Å, H···O_{meth} 1.80 Å, O···O 2.691(5) Å and O–H···O 152° for O(2) and O_{aq}–H 0.96 Å, H···O_{meth} 1.65 Å, O···O 2.563(4) Å and H···O 158° for O(3). To our knowledge $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ incorporates the first example of an *unsymmetrical* μ-(ROHOR) group in two senses: (i) the complex is mixed-valent, and (ii) the terminal ligands are derived from two different hydroxylic solvents. Despite considerable effort we were not successful in isolating a homologous di-μ-(H_3O_2) bridged complex from reactions without methanol, or by exchange of methoxide for hydroxide by reaction of $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ with water.

The cyclic voltammogram of $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ attests to its lability in solution: no distinct electrochemical response was observed in CVs recorded under identical conditions to those recorded for the related bis-acetate-bridged Mn^{II}–Mn^{III} complex, $[Mn_2(bpbp)(CH_3CO_2)_2](ClO_4)_2$ which we prepared for comparative purposes: $[Mn_2(bpbp)(CH_3CO_2)_2](ClO_4)_2$[12] shows a reversible wave for the Mn^{II}–Mn^{II}/Mn^{II}–Mn^{III} couple and a quasi-reversible wave for the Mn^{II}–Mn^{III}/Mn^{III}–Mn^{III} couple reflecting the structural stability of this compound in solution compared to $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$.

X-Band EPR spectra of $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ as a powder or acetone glass at 102 K (Fig. 2) display multiple, broad lines in the range 0–6000 G with the strongest resonances occurring in the 3500 G region. The spectrum of the neat powder, at 295 K, though less well resolved, is generally similar to that of the acetone glass, suggesting that either the complex retains its integrity in acetone solution or that coordinated solvent exchange has little effect on the electronic structure. Assignment of the signals has not been attempted since they result from a complicated combination of exchange, dipolar and zero-field splitting effects. The multiple hyperfine lines originating from the $S = ½$ coupled ground state are resolved at $g \sim 2$, as noted by Hendrickson and coworkers[12] for a bis-acetate-bridged Mn(II)-Mn(III) compound $[Mn_2(bcmp)(CH_3CO_2)_2](ClO_4)_2\cdot CH_2Cl_2$.†

ESI mass spectra of $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ give no indication of the structure of the cation. The $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2]^{2+}$ ion was not observed. A mixture

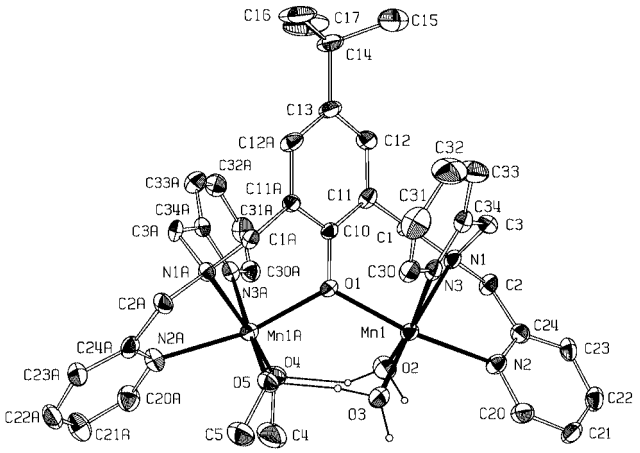

Fig. 1 Structure of the cation in $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$. Selected bond lengths (Å): Mn^{III}–OCH_3 1.849(3), 1.900(4), Mn^{II}–OH_2 2.132(3), 2.176(3), Mn^{II}–$O_{phenoxide}$ 2.143(3), Mn^{III}–$O_{phenoxide}$ 2.155(3) Å, Mn···Mn, 3.776(1) Å.

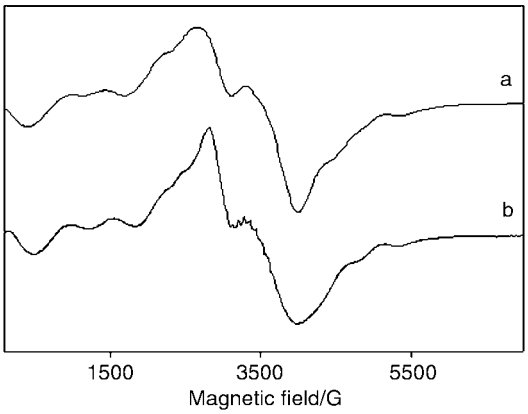

Fig. 2 The EPR spectrum of $[Mn_2(bpbp)(H_2O)_2(CH_3O)_2](ClO_4)_2$ **2**: (a) neat powder, 295 K; (b) frozen glass acetone solution, 102 K.

of solvent-dependent ions with the Mn(III)–Mn(II) $[Mn_2(bpbp)]^{4+}$ core were observed in all solvents tried (CH_3OH, CH_3CN, H_2O) reflecting the lability of the auxilary ligands. The major ion in all spectra was at *m*/*z* 348.7 which can be assigned to an oxide, $[Mn_2(bpbp)(O)]^{2+}$. The following MS/MS experiment indicates that this oxide ion is not present in solution: $[Mn_2(bpbp)(O)]^{2+}$ is produced easily by collision activated dissociation (CAD) of the $[Mn_2(bpbp)(RO)_2]^{2+}$ ions, R = H (*m*/*z* 357.8) or CH_3 (*m*/*z* 371.7), which are obtained from water or methanol solutions respectively when these are sprayed using very mild source conditions. Thus, the loss of a mass equivalent of water or dimethyl ether from the $[Mn_2(bpbp)(RO)_2]^{2+}$ (R = H, CH_3) ions to give the dominant $[Mn_2(bpbp)(O)]^{2+}$ ions is a facile fragmentation pathway. We have previously noted the facile gas phase formation of metal oxides from metal carbonates,[13] and the present case is another example which should serve as a warning to the assignment of 'novel metal–oxide' species on the basis of ESI MS alone.

The arrangement of the auxiliary solvent-derived ligands as two μ-($HOHOCH_3$) groups in, $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ can be regarded as a pertinant structural motif for coordinated solvent interactions at the active sites of dimetallic proteins, particularly those containing a mixed valence site, *e.g.* the purple acid phosphatases (PAPs). Like $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ the PAPs contain one trivalent metal ion [Fe(III)] and one divalent metal ion [Fe(II) or Zn(II)].[14] The mechanistically important nucleophilic hydroxide has been proposed to be metal coordinated; whether or not it is terminal or bridging is uncertain. $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ with its trivalent and divalent metal ion at a distance of 3.77 Å shows a way in which a M(III)-bound hydroxide (by analogy to methoxide) ion could be stabilised by H-bonding to a water molecule bound to the adjacent M(II) to give the μ-(H_3O_2) group and thus support the notion of a terminally bound hydroxide as the nucleophile and terminal water as a substitutionally labile ligand on the adjacent metal ion in PAPs. Although $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ is a plausible structural model for resting state PAP, we have no indications that it might be a useful functional model from our investigations of reactivity in promotion/catalysis of PAP-like hydrolysis reactions using phosphate ester, alkyl ester and nitrile substrates in solutions containing water. This contrasts to a structurally characterised diiron system with a μ-(H_3O_2) bridge which was shown to promote hydrolysis of acetonitrile and triphenylphosphate.[5]

Finally, the formation of $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ formally requires a one-electron oxidation of one manganese ion. The reaction occurs only in the presence of oxygen. Such spontaneous air oxidations are normal, however they are often not elucidated mechanistically. Preliminary results suggest that a background oxidation of the methanol solvent (and presumably concomitant reduction of dioxygen) has occured during the reaction. Repitition of the work using cyclohexanol to replace methanol in the reaction mixture showed a background formation of cyclohexanol. This air alcohol oxidation to aldehydes is slow but catalytic.[15]

In summary, the μ-($HOHOCH_3$) group in $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ is a plausible structural model for water/hydroxide coordination and interactions in the resting state of PAPs which, like the complex here, contain a trivalent and divalent metal ion. Preliminary work indicates that the labile $[Mn_2(bpbp)(solv)_x]^{3+}$ (solv = water and alcohols), activates oxygen to form an oxidant capable of oxidising alcohols. Future investigations will centre around the selectivity, extent and efficiency of the $[Mn_2(bpbp)(solv)_x]^{3+/4+}/O_2$ system, as an oxidation catalyst.

Support from the Danish Natural Science Council (C. J. M.) is gratefully acknowledged. Professor Keith S. Murray (Monash University) is thanked for helpful discussions. At the University of Southern Denmark we are grateful to Dr Kenneth Bendix Jensen for recording the ESI mass spectra and Jens Zacho Pedersen for recording EPR spectra.

Instituto de Ciencia de Materiales de Aragón, Facultad de Ciencias, Universidad de Zaragoza–C.S.I.C., Pza. S. Francisco s/n, E-50009 Zaragoza, Spain. E-mail: forniesj@posta.unizar.es

Received (in Cambridge, UK) 17th July 2001, Accepted 4th September 2001
First published as an Advance Article on the web 3rd October 2001

The homoleptic, tetrahedral, paramagnetic d^2 species $[NBu_4][V^{III}(C_6Cl_5)_4]$ 1 has been obtained and characterised by analytical, spectroscopic and X-ray diffraction methods.

The organometallic chemistry of vanadium is chiefly dominated by species containing carbonyl and cyclopentadienyl ligands.[1] In contrast, simple, homoleptic σ-organovanadium compounds unsupported by cyclopentadienyl or other donor ligands are still rare. The chemistry of these derivatives has, however, received renewed attention especially because some organovanadium(II) or -(III) species appear as active intermediates in chemical fixation processes of molecular nitrogen.[2] It is thus thought that the formation of $[(VR_3)_2(\mu\text{-}N_2)]$ is likely to occur *via* the homoleptic intermediates VR_3 [R = $C_6H_2Me_3$-2,4,6 (mes)[3] or CH_2Bu^t[4]]. To the best of our knowledge, the only homoleptic organovanadium(III) compounds that have been isolated to date are: anionic $[VR_4]^-$ [R = mes[5] or $C_6H_3(OMe)_2$-2,6[6]] and neutral $[VR_3]$ [R = mes,[3] $C(CN)_3$[7] or $CH(SiMe_3)_2$[8]]. However, unequivocal structural information is not available for any of them. We now report the synthesis and structural characterisation of $[NBu_4][V(C_6Cl_5)_4]$ **1**, a remarkably stable homoleptic organovanadium(III) compound.

The reaction of $[VCl_3(thf)_3]$[9] with LiC_6Cl_5[10] in a 1:8 molar ratio followed by the appropriate treatment‡ allows the isolation of $[NBu_4][V(C_6Cl_5)_4]$ **1** as a deep green solid. Once isolated, complex **1** is air- and moisture-stable in the solid state. This behaviour is in contrast with the reported observation of the ease with which the related compound $[Li(thf)_4][V(mes)_4]$ is air-oxidised to give neutral $[V(mes)_4]$.[12] Complex **1** behaves as a 1:1 electrolyte in dilute acetone solution (3.1×10^{-1} mol dm^{-3}).[13]

The solid-state structure of **1** has been established by single-crystal X-ray diffraction analysis.§ The structure of the anion $[V(C_6Cl_5)_4]^-$ is depicted in Fig. 1. It can be seen that all four σ V–C bonds are virtually identical, while the C–V–C angles take values between 98.1(2) and 117.6(2)°. Hence, the local geometry around the vanadium centre can be described as slightly distorted tetrahedral (*cf.* ideal C–V–C angle: 109.5°). The V–C distances in **1** [ranging from 214.2(5) to 215.8(5) pm] are similar to those found in other heteroleptic σ-arylvanadium(III) compounds, such as $[V\{C_6H_2(CF_3)\text{-}2,4,6\}_2Cl(thf)]$ [V–C 214.5(4) and 215.9(4) pm],[15] $[PF(NEt_2)_3][V(mes)_3F]$ [V–C 210.7(4)–213.2(4) pm][16] and $[V(mes)_3(thf)]$ [V–C 209.5(6)–211.7(7) pm].[17] The V–C_{ipso}–C_{ortho} angles within each pentachlorophenyl ring are dissimilar with values amounting to *ca.* 115 and *ca.* 130°, respectively. The swing of the aryl rings also implies the existence of two sets of *ortho*-Cl–V distances each approaching 310 and 366 pm, respectively. These structural features have been previously used as criteria which help to determine the existence of *ortho*-Cl···M interactions in other pentachlorophenyl metal derivatives.[18] Bearing in mind these criteria we suggest the non-existence of additional *ortho*-Cl···V interactions in **1** since: (i) the swing of the C_6Cl_5 rings is only moderate; (ii) the *ortho*-Cl–V distances are too long to be considered as the result of a bonding interaction; and (iii) the central core is well described as a slightly distorted tetrahedron with no evidence for the need of a higher coordination polyhedron.

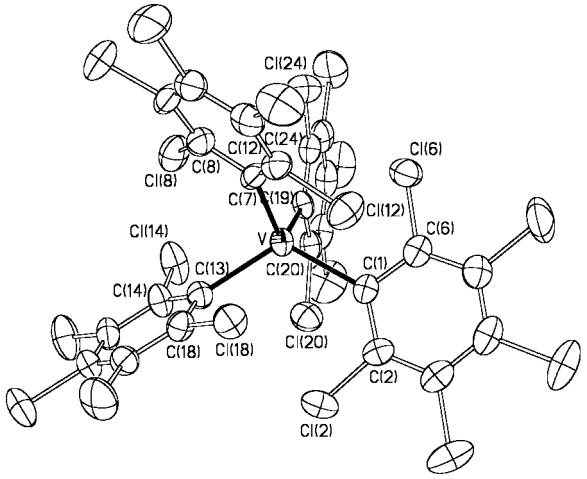

Fig. 1 Thermal ellipsoid diagram of the anion of **1**. Selected distances (pm) and angles (°): V–C(1) 214.4(5), V–C(7) 215.8(6), V–C(13) 215.2(5), V–C(19) 214.2(5), V–Cl(2) 364.6(2), V–Cl(6) 311.6(2), V–Cl(8) 311.5(2), V–Cl(12) 366.3(2), V–Cl(14) 366.3(2), V–Cl(18) 313.6(2), V–Cl(20) 304.9(2), V–Cl(24) 368.3(2); C(1)–V–C(7) 112.1(2), C(1)–V–C(13) 117.6(2), C(1)–V–C(19) 101.2(2), C(7)–V–C(13) 98.1(2), C(7)–V–C(19) 116.1(2), C(13)–V–C(19) 112.6(2).

Complex **1** has also been studied by EPR spectroscopy both in the X- and Q-bands.¶ Frozen solutions of **1** in THF/CH_2Cl_2 mixtures gave poor-quality spectra with very low signal-to-noise ratios. However, the X-band EPR spectrum of a powder sample of **1** shows four clearly defined features at room temperature, located at *ca.* 120, 280, 670 and 840 mT (Fig. 2). At lower temperatures, the two outer signals shift downfield, whereas the central ones remain almost unchanged.

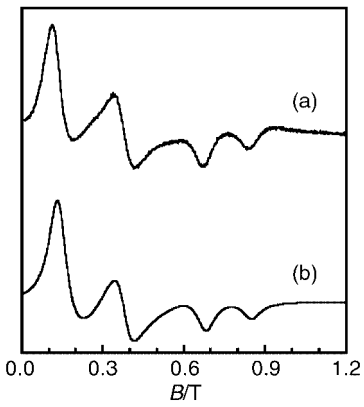

Fig. 2 X-band EPR spectrum of a powder sample of **1** at room temperature (microwave frequency 9.545 GHz): experimental (a) and calculated (b).

† Dedicated to Professor Dr Rafael Usón on the occasion of his 75th birthday.

Vanadium(III) is a non-Kramers paramagnetic system (d^2), which is usually 'EPR silent' unless located in a high-symmetry site such as cubic, octahedral or tetrahedral. When located in a tetrahedral site, the ^3F ground term in the free V(III) ion splits into two triplets ($^3T_1$ and $^3T_2$) and one singlet ($^3A_2$), the latter being the lowest energy level. Since the V(III) centre in **1** is in a nearly tetrahedral environment, the ground state orbital wave function is expected to be close to a $^3A_2$ orbital with an isotropic g-factor and the spin-Hamiltonian given in eqn. (1).‖

$$H = g\mu_B \vec{B}\cdot\vec{S} + D\left[S_Z^2 - \tfrac{1}{3}S(S+1)\right] + E(S_X^2 - S_Y^2) \qquad (1)$$

The analysis of the EPR spectrum of **1** using eqn. (1) gives a satisfactory agreement between the calculated [Fig. 2(b)] and experimental [Fig. 2(a)] spectra with the following values of the spin-Hamiltonian parameters: g = 1.98(1), D = 13.59(5) GHz and η = 0.16(1). It is interesting to note that these values also allow the reproduction of the Q-band spectrum.

In contrast to the profusion of EPR reports involving V(IV) species (d^1), there are very few EPR data available for V(III). These data have been obtained on samples of V(III) doped into ionic lattices (*e.g.* CaF_2:V, g = 1.933[19] and CdF_2:V, g = 1.937[20]) and into semiconductors (g = 1.92–1.99).[21] Recently, a detailed EPR study on samples of V(III) doped into $CsGa(SO_4)_2\cdot 12H_2O$ has been reported using high-field, multi-frequency techniques. The spectra thus obtained for the $[V(H_2O)_6]^{3+}$ cation have been analysed with an axial spin-Hamiltonian with $g_\parallel$ = 1.955, $g_\perp$ = 1.869 and D = 143 GHz.[22]

The moderate departure of the g value obtained for **1** from the free electron value can be attributed to some degree of delocalisation of the unpaired electrons over the aryl ligands in the $[V(C_6Cl_5)_4]^-$ anion. This assumption, however, cannot yet be confirmed, since the hyperfine structure expected to appear in **1** (^{51}V, I = 7/2, 100% natural abundance) is unresolved due to the broadness of the features in the EPR spectrum.

The remarkable stability of **1** has allowed the first structural characterisation of a homoleptic organovanadium(III) derivative to be obtained. Moreover, this is, to the best of our knowledge, the first V(III) compound which has a defined EPR spectrum and in which the vanadium centre is not a doping but rather a constituent element of the sample. On the other hand, the inertness of **1** could well act as a drawback for its chemical reactivity which is currently under study.

We thank Professor P. H. Rieger (Brown University, Providence) for helpful EPR discussions and suggestions. We also thank the Dirección General de Enseñanza Superior (Projects PB98-1595-C02-01 and PB98-1593) for financial support and the Gobierno de Aragón for a grant to M. A. G.-M.

Notes and references

‡ *Experimental procedure*: to a solution of LiC_6Cl_5 (*ca.* 55 mmol) in Et_2O (60 cm^3) at −78 °C was added $[VCl_3(thf)_3]$ (2.54 g, 6.80 mmol). The suspension was allowed to warm up to room temperature and, after 15 h of stirring, the by then deep green solid was filtered, washed with Et_2O (3 × 5 cm^3) and extracted in CH_2Cl_2 (50 cm^3). The extract was evaporated to dryness and the resulting residue was redissolved in Pr^iOH (80 cm^3) and filtered. The addition of NBu_4Br (4.4 g, 13.6 mmol) to the filtrate caused the precipitation of a first fraction of **1** as a deep green solid. By standing the mother liquor at −30 °C overnight, a second crop of **1** was obtained (45% overall yield). Anal. found for $C_{40}H_{36}Cl_{20}NV$: C 37.28, H 2.80, N 0.65. Calc.: C 37.22, H 2.80, N 1.08%. Biaxial smectic A liquid crystal in a pure compound

B. K. Sadashiva,* R. Amaranatha Reddy, R. Pratibha and N. V. Madhusudana

Raman Research Institute, C.V. Raman Avenue, Bangalore 560 080, India. E-mail: sadashiv@rri.res.in

Received (in Cambridge, UK) 10th July 2001, Accepted 31st August 2001
First published as an Advance Article on the web 26th September 2001

The synthesis and characterisation is reported of a low molecular weight organic compound to exhibit the biaxial smectic A (SmA_b) phase, which shows a transition from the partial bilayer uniaxial SmA_d phase to the SmA_{db} phase as the temperature is lowered.

The discovery of liquid crystalline phases in compounds with bent-core (BC) or banana-shaped molecules[1] has led to a very intense research activity in the field.[2] In the past couple of years several new compounds having this molecular architecture have been reported[3–8] in an effort to find the relationship between the molecular structure and the mesomorphic properties associated with it. At least five different B-(banana) types of liquid crystal have been clearly identified in pure compounds, though recently some new variants have been found.[8] The most fluid of the B-type of liquid crystals, which is also electrically switchable is the B_2 phase in which the bent-cores pack along a common axis to give rise to an electric polarisation of the layer. The molecular plane tilts with respect to the layer-normal to produce a *chiral* layer, though the molecules themselves are usually achiral.[9] In an earlier study, we found that binary mixtures of a compound exhibiting the B_2 phase with one made of rod-like molecules exhibiting the bilayer smectic A_2 phase showed a very interesting phase diagram.[10,11] If the concentration of the rods is between 4 and 13 mol% the mixtures exhibit a biaxial smectic A_2 (SmA_{2b}) phase in which the BC molecules undergo an orientational transition as the temperature is lowered from the uniaxial SmA_2 phase. The other known systems exhibiting the SmA_b phase were found (i) in a binary mixture of polymeric and monomeric species,[12] (ii) in an oxadiazole derivative[13] at high temperatures (above 235 °C), and (iii) in a binary mixture involving a metallomesogen.[14]

It is of obvious interest to find the biaxial SmA_b phase in a low molecular weight pure compound at a relatively low temperature. Compounds whose molecules have a strong biaxiality of shape are necessary for this purpose and the best systems appear to be those made of BC molecules. Indeed, several compounds with BC molecules are known to exhibit the smectic A (SmA) phase but NMR studies have shown that in such molecules the angle between the two arms of the bent-core is about 160°, which means that the deviation from a rod-like structure (in which this angle would be 180°) is quite small.[2] On the other hand, if the molecules have highly bent cores the compounds are known to exhibit only the B-type of liquid crystal.

Here, we report the synthesis of a compound made of BC molecules with a new architecture. The unsymmetrical molecule has an alkoxy chain attached to only one of the arms of the bent-core, while the other arm ends with the highly polar cyano group. The synthetic pathway used to obtain this compound is shown in Scheme 1.‡ Our studies show that the compound exhibits a partial bilayer smectic A_d phase in which the bent-cores of two neighbouring molecules overlap in an antiparallel orientation, as in the case of highly polar rod-like molecules.[15,16] Indeed, this is the first example of a single-component, low molecular weight compound to exhibit the biaxial smectic A to uniaxial smectic A transition.

† Electronic supplementary information (ESI) available: spectroscopic data for **1**. See http://www.rsc.org/suppdata/cc/b1/b106084h/

The liquid crystalline properties were investigated by differential scanning calorimetry (DSC, Pyris 1D, 5 °C min^{-1}) and polarised optical microscopy (Leitz Laborlux 12 POL). Observation using a polarising microscope of a sample taken from between the untreated slide and coverslip shows the following sequence of textures as the temperature is lowered. The dark field of view, corresponding to the isotropic phase, goes over at a transition point to an SmA texture in which most of the sample has a homeotropic alignment, but some parts clearly show focal-conic domains. As the temperature is lowered further, there is another phase transition in which the homeotropic regions exhibit a schlieren texture (Fig. 1), with both two-brush and four-brush defects. Strong fluctuations in intensity are seen as in the SmA_{2b} phase.[10] The presence of two-brush defects indicates that the low temperature phase has one of the following structures: (i) a biaxial smectic A phase in which the two orthogonal directors in the plane of smectic layers are also *apolar* in nature; (ii) a packing of the BC molecules of compound **1** such that each layer is polarised, but with a mutually antiferroelectric arrangement in neighbouring layers (the two-brush defects in such a case are dispirations, which are combinations of half strength disclinations which are defect patterns in the in-plane director, and screw dislocations;[17] this structure can also be described as a biaxial SmA); and (iii) another possibility would be for the molecules to tilt with an anticlinic arrangement in successive layers, in which

case again dispirations can produce two-brush defects. We rule out the last possibility in view of the X-ray results to be described later.

DSC of compound **1** shows the following sequence of transitions. The numbers above the arrows are transition temperatures in °C and the numbers in parentheses are

$$\text{Iso} \underset{(4.77)}{\overset{130}{\longleftrightarrow}} \text{SmA} \underset{(0.04)}{\overset{126.2}{\longleftrightarrow}} \text{SmA}_b \underset{(85.46)}{\overset{120.5}{\longleftrightarrow}} \text{Cr} \qquad (1)$$

enthalpies in kJ mol^{-1}. In order to confirm the biaxiality of the low temperature phase, samples contained in a cell and well aligned using a lateral electric field are employed. The thickness of the sample is 37.3 μm which is controlled using appropriate spacers and measured using an interference technique before filling the sample. As the temperature of the cell is lowered below the SmA to SmA_b transition point (T_{bu}) again the schlieren texture is seen. The application of an electric voltage of *ca.* 200 V at 10 kHz between the two ITO regions aligns the sample uniformly in the gap. Conoscopic observations between crossed polarisers, which are set at 45° to the direction of the electric field, clearly show that the uniaxial cross in the SmA phase splits to give a biaxial pattern below the relevant transition temperature (Fig. 2). As the temperature is lowered, the separation between the hyperbolic isogyres [the two dark arcs seen in Fig. 2(b)] continuously increases.

X-Ray scattering studies have been carried out by taking the sample in a Lindemann capillary tube which is slowly cooled to the desired temperature under a magnetic field of strength *ca.* 2 kG applied perpendicular to the axis of the tube. The alignment is only partial as the isotropic to SmA transition has a strong first-order character. X-Rays of $\lambda = 1.54$ Å from a rotating anode generator are used to study the scattered pattern collected using a 2D image plate. In the small angle region, a sharp reflection corresponding to the smectic layer spacing can be clearly seen (Fig. 3). As usual, the second-order reflection is very weak. The wide angle scattering corresponds to a liquid-like pattern. The measured layer spacing is equal to *ca.* 54 Å which does not vary with temperature as the sample is cooled from the SmA to the lowest temperature to which the SmA_b phase can be supercooled. This, in conjunction with the observation of two-brush defects described earlier, clearly indicates that the lower temperature phase with layer birefringence is not a tilted SmC phase. The layer spacing $d = 54$ Å is significantly larger than the calculated molecular length $l \approx 49$ Å in its most extended form with an all-*trans* configuration of the alkoxy chain. This clearly implies a partial bilayer structure of the smectic layers in both SmA and SmA_b phases, which we have to designate as SmA_d and SmA_{db} respectively.

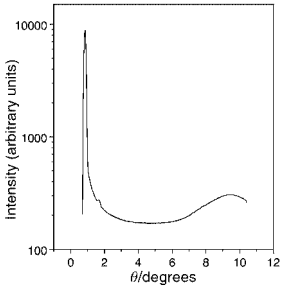

Fig. 3 Intensity profile of the X-ray diffraction pattern in the SmA_{db} phase of compound **1** at 123 °C as a function of the Bragg angle, θ. The sharp reflection corresponds to a layer spacing of 54 Å. A very weak second order reflection can also be seen. The diffuse maximum corresponds to 4.6 Å, which is a typical intermolecular separation in the liquid layers.

Thus, we believe that the occurrence of both the uniaxial and biaxial smectic A phases in compound **1** is mainly a consequence of the partial bilayer structure in which there is a dense region of biaxial aromatic cores and relatively sparsely populated aliphatic regions, which allow for considerable orientational freedom of the chains. The arrangement of the BC molecules in the SmA_{db} phase in the pure compound **1** is hence quite different from that proposed for the SmA_{2b} phase occurring in binary mixtures of rod-like and bent-core molecules. In the latter the BC molecules orient with their arrow axes along the layer-normal, whereas in the SmA_{db} phase the arrows lie in the layer-plane.

The authors wish to thank Dr V. A. Raghunathan for help in the X-ray experiments and Mr P. N. Ramachandran and Ms K. N. Vasudha for technical support.

Notes and references

‡ Compound **1** was synthesised according to a procedure which will be described in a publication under preparation. The intermediate compounds have spectral data consistent with their molecular structure.

Photosensitization of nanocrystalline TiO_2 films by pomegranate pigments with unusually high efficiency in aqueous medium

Qing Dai and Joseph Rabani*

Department of Physical Chemistry and the Farkas Center, The Hebrew University of Jerusalem, Jerusalem 91904, Israel. E-mail: rabani@vms.huji.ac.il

Received (in Cambridge, UK) 12th July 2001, Accepted 13th September 2001
First published as an Advance Article on the web 2nd October 2001

An aqueous system based on a TiO_2 layer photosensitized by natural pigment(s) from pomegranate, shows relatively high stability under illumination with a quantum yield of 0.74 and a photovoltage of 0.46 V.

Sensitization of wide band gap semiconductor electrodes by dyes absorbing visible light has been a topic of continuing interest since its introduction by Gerischer in 1972.[1] While early versions of dye-sensitized photoelectrochemical cells were inefficient, Graetzel and coworkers,[2] followed by many others (see for example refs. 3–7 and references cited therein) succeeded in achieving relatively high photon-to-current conversion efficiencies. The Graetzel cell is based on a dye adsorbed to a porous TiO_2 layer. Upon light absorption, electron injection from the excited dye to the conduction band of the semiconductor may occur on an ultrafast time scale. In a typical Graetzel cell, I^-/I_3^- ions in organic solvents serve as charge carriers. Aqueous solutions of the charge carriers have been employed only rarely,[8–11] and with one exception (showing, however, low yield)[12] were abandoned after 1990 because of low photocurrent, photovoltage or stability. However, equilibration of the TiO_2 layers with photosensitizers has often been carried out using aqueous solutions, with reasonably good results. Several natural pigments have been used as photosensitizers in organic environments,[13,14] showing ultrafast electron injection from anthocyanin dyes to TiO_2 nanocrystallite electrodes. Most of this work did not report the efficiency.

The present work shows unusual high yields in an aqueous system. The active pigment was adsorbed from seed coats of the pomegranate fruit, which is a rich source of anthocyanins.[15] The present results indicate good stability (tested for several days) besides unusually high photocurrent yields. These features were unexpected for such a simple system in an aqueous environment.

The seed coats of the pomegranate fruit were processed and separated from the solid residue by filtration. The resulting liquid was kept frozen until used. Transparent TiO_2 layers (3.3 μm thickness) were prepared on ITO surfaces using TiO_2 nanocrystallites dispersed in water at pH 1.8 by successive spin coatings followed by heating at 450 °C. The TiO_2 colloid (5 nm diameter) was prepared by hydrolysis of titanium isopropoxide. The ITO/TiO_2/dye working electrode was separated from the ITO/Pt counter electrode by a thin Teflon spacer. Iodide and iodine in water solution added at the bottom filled the space between the two plates as a consequence of capillary forces.

The ITO/TiO_2 electrode was equilibrated with the pomegranate liquid (natural pH 2.8) to which acid (HCl) or alkali (NaOH) had been added to adjust the pH in the range 1.0–5.6 by shaking for 12–24 h, inducing a violet coloration of the film. Note that low photocurrent yields were observed when the electrodes were initially equilibrated with the natural pomegranate liquid at the natural pH and subsequently washed or shaken with acidic water. This observation is apparently related to the buffer capacity of the TiO_2/H^+/dye system, which seems to have been ignored in previous works.

The natural red dye is likely to be a mixture of several pigments. The spectrum in the TiO_2 layer in the range 500–700 nm resembles that of cyanidin 3-O-β-glucoside and cyanidin 3,5-O-β-diglucoside, which are among the six pigments identified in pomegranates. Deviations below 500 nm, increasing towards the UV, indicate the presence of additional absorbing materials in the natural dye mixture. Fig. 1 shows the chemical structure of the cyanidin-3-glucoside pigment.

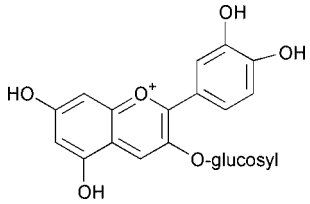

Fig. 1 Chemical formula of cyanidin-3-glucoside.

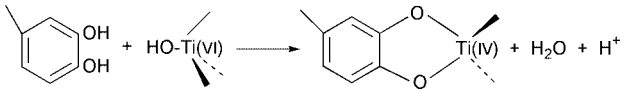
The optical absorption spectrum of the pomegranate pigments adsorbed to TiO_2 shows a peak at 560 nm, *i.e.* 40–50 nm red shifted compared to the absorption in aqueous solution. This indicates that chemical binding takes place, apparently through the hydroxy groups (Scheme 1). The formation of a very strong complex[14] takes place despite of the predominantly cationic form of TiO_2 at acid pH.



Scheme 1 Adsorption of aromatic dihydroxy compounds to TiO_2.

Typical short circuit photocurrents and open circuit photovoltages observed upon illumination with the entire visible range of a halogen lamp are presented in Table 1. The photocurrents were normalized to the light absorption and show the relative photon to current efficiencies. Table 1 shows that the aqueous Na^+ counter ion is the most effective in photocurrent generation, and the results in aqueous solutions are comparable to results in ethanol.

The spectrum of the photocurrent follows fairly closely the absorption spectrum of the dye. The effect of pH is remarkable: using 2.5 M NaI and 0.1 M I_2 in water as charge carriers, the quantum yield of the photocurrent increases from *ca.* 0.03 at pH 5.5 to 0.74 at pH 1. At the same time, the photovoltage changes only little, remaining between 0.4 and 0.46 V through the entire tested pH range. This observation is unusual, because so far it is believed that aqueous solutions much more strongly lower the

Table 1 Photocurrents and photovoltages for various iodides and solvents[a]

Counter ion	Li^+ (H_2O)	K^+ (H_2O)	Na^+ (H_2O)	Na^+ (ethanol)	$Bu^t_4N^+$ (ethanol)
Photocurrent/mA	0.45	1.2	2.2	2.1	0.78
Photovoltage/V	0.30	0.33	0.44	0.41	0.48

[a] TiO_2 layers are equilibrated with natural pomegranate liquid at the natural pH (2.8) for 24 h. Peak absorbance in the layers was 0.4. All systems contain 1 M iodide and 0.1 M iodine. Illumination carried out at 400–700 nm.

 DOI: 10.1039/b106197f

photovoltage, reduce the photocurrent and in many, if not most cases, destabilize the dye–TiO_2 binding. Stability tests of the present system showed no measurable decrease of photocurrent after 24 h illumination, corresponding to an estimated turnover number of $>10^5$. Washing the layer with water at the appropriate pH does not reduce the photocurrent magnitude or its stability. These results rule out the possibility that impurities act as a source of energy for the operation of the photoelectrochemical cell, since washing of the layers leaves only the adsorbed components in the layer, the concentration limit of which is of the order of the adsorbed pigments. Even if oxidation of photosensitizer molecules or impurities may take place in the absence of iodide, the high iodide concentrations suppress these reactions.

Another very interesting effect is the TiO_2 particle size used to prepare the layer: When nanocrystallites of diameter 18 nm are used instead of the usual 5 nm, the photocurrent decreases considerably. This is in contrast to the behavior of the popular $Ru(dcbpy)_2(SCN)_2$ (dcbipy = dicarboxybipyridine) (ethanol used as charge carrier solvent), which under similar conditions shows 50% increase of photocurrent. Apparently, the small pores in the 5 nm diameter layer serve as a filter, preventing or minimizing adsorption of undesired molecules, which reduce the photocurrent by competition for photons. Another observation of considerable interest is the decrease of photocurrent yield in the absence of bound glucose (see Fig. 1). The role of the glucose is not clear, although control experiments show that regeneration of the photosensitizer from its oxidized state is carried out predominantly, if not solely, by the iodide ions.

In conclusion, the combination of high photocurrent yield, reasonably high photovoltage and apparently good stability of the very simple dye sensitized TiO_2 system operating under aqueous conditions opens interesting perspectives in the field of solar energy conversion. Further work is in progress on the natural pigment mixture as well as on the isolated pigments, in order to better understand the chemistry, which provides the photoelectrochemical cell its unique features.

This work was supported by the Ministry of National infrastructure, and by the Belfer and Berman Foundations, Israel.

New binucleating ligands to support dizirconium organometallics

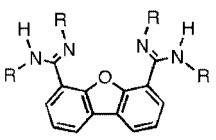
John R. Hagadorn

Department of Chemistry and Biochemistry, University of Colorado, Boulder, CO 80309-0215, USA. E-mail: hagadorn@stripe.colorado.edu

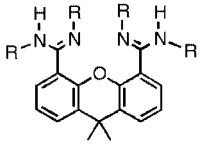
Received (in West Lafayette, IN, USA) 2nd August 2001, Accepted 1st September 2001
First published as an Advance Article on the web 2nd October 2001

A new class of bis(amidinato) ligands, which feature dibenzofuran or 9,9-dimethylxanthene spacers, are used to prepare structurally characterized dizirconium complexes.

The development of single-site catalysts for selective bond forming and cleaving processes is a major topic in organometallic chemistry. Toward this goal, much effort has gone into controlling chemical reactivity through the modification of supporting ligands.[1] This approach has been highly successful for the preparation of new mononuclear catalysts; however, equivalent advances have not been made for bimetallic complexes. The use of well-defined bimetallics as catalysts, however, is highly desirable because multiple metals acting cooperatively can activate substrates and perform reactions that fail to occur in mononuclear systems.[2,3] Thus, we have begun to develop new binucleating ligands which will allow us to explore the reactivity of binuclear organometallic complexes. Here we report two new bis(amidinato)[4] ligands and their structurally characterized Zr derivatives.



$(Pr^i_4DBF)H_2$



$(Pr^i_4Xan)H_2$

The bis(amidine) ligands $(Pr^i_4DBF)H_2$† and $(Pr^i_4Xan)H_2$ were prepared by the reaction of diisopropylcarbodiimide with doubly deprotonated dibenzofuran or 9,9-dimethylxanthene.[5] The ligands are highly soluble in hydrocarbon solvents, but they can be readily isolated as colorless crystals from warm acetonitrile solutions in moderate yield. Combustion analysis and ^1H NMR spectroscopy confirmed their formulations. IR absorption spectroscopy of $(Pr^i_4Xan)H_2$ (Nujol) revealed characteristic absorptions at ν_{NH} 3440 and ν_{CN} 1639 cm^{-1}. Related parameters for $(Pr^i_4DBF)H_2$ were observed at 3434, 3427, 3402 and 1633 cm^{-1}.

Entry into transition metal derivatives was accomplished by reaction of $(Pr^i_4DBF)H_2$ with 2 equivalents of $Zr(CH_2Ph)_4$ in toluene solution [eqn. (1)]. Removal of the volatiles under

$$(Pr^i_4DBF)H_2 + 2Zr(CH_2Ph)_4 \rightarrow (Pr^i_4DBF)Zr_2(CH_2Ph)_6 + 2PhCH_3 \quad (1)$$

reduced pressure afforded yellow $(Pr^i_4DBF)Zr_2(CH_2Ph)_6$ in quantitative yield. ^1H and ^{13}C NMR spectroscopy (C_6D_6) reveal a symmetrical ligand environment and equivalent benzyl ligands, consistent with fast fluxional behavior in solution. Crystallization of the product, however, was slow, and crystals suitable for X-ray diffraction‡ studies were obtained only after storing Et_2O solutions at −40 °C for two weeks. The solid-state structure (Fig. 1) confirmed the formulation of the dizirconium complex. Geometry at each Zr center resembles that of the guanidinate derivative $\{CyNC[N(SiMe_3)_2]NCy\}Zr(CH_2Ph)_3$, which was recently reported by Richeson and coworkers.[6] The η^2-benzyl ligands feature Zr–CH_2–C_{ipso} angles of 90.9(2) and 88.1(2)° with Zr–C_{ipso} distances of 2.721(3) and 2.682(3) Å, values which are similar to other reported Zr(η^2-benzyl) compounds.[7] The intermetal distance of 8.574(1) Å is significantly longer than the value predicted from simple MM2 calculations (7.3 Å). Interestingly, this is due to the presence of a cocrystallized Et_2O that is located between the two Zr atoms yet is not coordinated to either metal. The Zr–ether distances are short (Zr1–C69, 4.46 Å; Zr2–C69, 4.27 Å), with the H atoms bound to C69 approaching to within 3.5 Å of Zr2. This presents the intriguing possibility of using the intermetal gap as a docking site for incoming substrates that could subsequently react with metal-bound ligands.

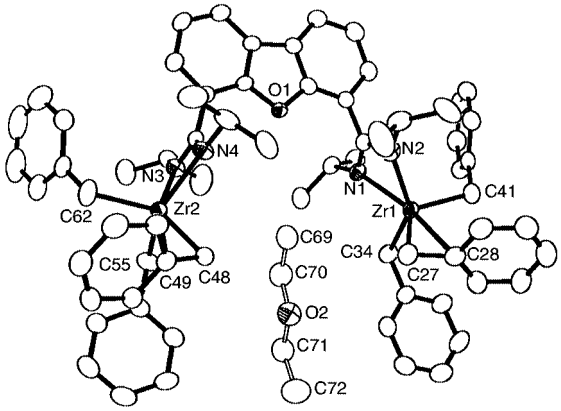


Fig. 1 Molecular structure of $(Pr^i_4DBF)Zr_2(CH_2Ph)_6 \cdot 1.5Et_2O$ drawn with 50% thermal ellipsoids. Half occupancy ether is omitted. Selected distances (Å) and angles (°): Zr1–N_{av} 2.25, Zr1–C_{av} (excl. C28) 2.27, Zr1–C28 2.721(3), Zr1–C69 4.467(4), Zr2–N_{av} 2.25, Zr2–C_{av} (excl. C49) 2.28, Zr2–C49 2.682(3), Zr2–C69 4.273(4), C48–C69, 3.756(6), Zr1–Zr2 8.574(1); Zr1–C27–C28 90.9(2), Zr2–C48–C49 88.1(2).

The related xanthene-bridged dizirconium complex $(Pr^i_4Xan)Zr_2(CH_2Ph)_6$ was prepared following the methodology similar to that used for $(Pr^i_4DBF)Zr_2(CH_2Ph)_6$ (Scheme 1). The product was isolated as yellow microcrystals from toluene–hexamethyldisiloxane mixtures in high yield. ^1H NMR spectra (C_6D_6) reveal a fluxional ligand environment. Crystals suitable for X-ray diffraction studies were grown from Et_2O at −40 °C. Metrical parameters (Fig. 2) are very similar to those of $(Pr^i_4DBF)Zr_2(CH_2Ph)_6$; however, the xanthene-bridge closes the gap between the two $Zr(CH_2Ph)_3$ moieties. Consequently, there is not a solvent molecule present between them, and the intermetal distance is reduced by over 2 Å [Zr1–Zr2 6.489(1) Å].

Reaction of a single equivalent $Zr(CH_2Ph)_4$ with $(Pr^i_4Xan)H_2$ (Scheme 1) yielded an orange solution. After stirring overnight and removal of the volatiles, the residue was extracted into warm Et_2O. Cooling to −40 °C gave orange crystals in good yield. Combustion analysis of the product indicated the

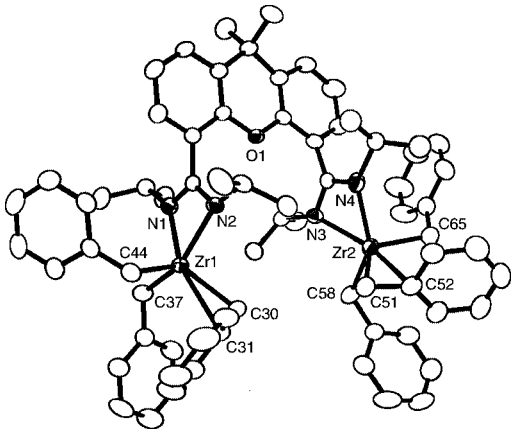

Fig. 2 Molecular structure of $(Pr^i_4Xan)Zr_2(CH_2Ph)_6{\cdot}Et_2O$ drawn with 50% thermal ellipsoids. Cocrystallized ether is omitted. Selected distances (Å) and angles (°): Zr1–N_{av} 2.24, Zr1–C_{av} (excl. C31) 2.28, Zr1–C31 2.627(3), Zr2–N_{av} 2.24, Zr2–C_{av} (excl. C52) 2.28, Zr2–C52 2.678(4), Zr1–Zr2 6.489(1); Zr1–C30–C31 86.2(2), Zr2–C51–C52 89.8(2).

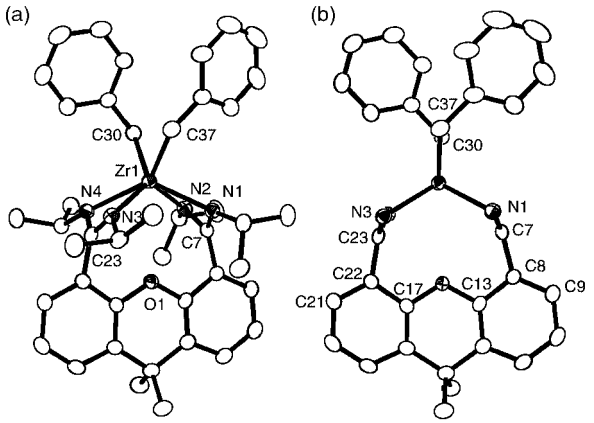

Fig. 3 Views of the molecular structure of $(Pr^i_4Xan)Zr(CH_2Ph)_2$ drawn with 50% thermal ellipsoids. Pr^i groups omitted in (b) for clarity. Selected distances (Å) and angles (°): Zr1–N1 2.269(2), Zr1–N2 2.247(2), Zr1–N3 2.288(2), Zr1–N4 2.308(2), Zr1–C30 2.280(2), Zr1–C37 2.284(2); C30–Zr1–C37 88.87(8).

empirical formula $[(Pr^i_4Xan)Zr(CH_2Ph)_2]_n$. ^{1}H NMR spectra ($C_6D_6$) were also consistent with this formulation and featured a single set of resonances for the benzyl ligands. Single crystal X-ray diffraction studies revealed the product to be mononuclear, with a single Zr atom bridging the two amidinates of the (Pr^i_4Xan) ligand (Fig. 3). Geometry at the Zr center closely resembles that observed for Group 4 dialkyl derivatives of N_4-macrocycles.[8] Interestingly, there appears to be significant ring strain as a result of this binding mode. As shown in Fig. 3(b), the amidinates are bent towards Zr giving angles of 114.1(2) and 115.2(2)° for C7–C8–C13 and C23–C21–C17, respectively. Additionally, the Zr atom is coordinated *ca.* 1.2 Å out of each NCN amidinate plane, and the Zr–N bond lengths suggest stronger coordination to one of the amidinates. Asymmetric binding, however, is not observed by ^{1}H NMR spectroscopy (in C_6D_6), and it is unclear whether this is due to fluxionality or a lack of asymmetry.

We thank Professor Clark R. Landis for helpful discussions and the University of Colorado for funding.

A new pathway in the reaction of disilene with carbonyl compounds: an 'ene' reaction instead of cycloaddition

Vladimir Ya. Lee, Masaaki Ichinohe and Akira Sekiguchi*

Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki, 308-8571, Japan. E-mail: sekiguch@staff.chem.tsukuba.ac.jp

Received (in Cambridge, UK) 26th July 2001, Accepted 7th September 2001
First published as an Advance Article on the web 2nd October 2001

The 3*H*-disilagermirene, $(^tBu_2MeSi)_4GeSi_2$, reacts with α-hydrogen containing carbonyl compounds (acetophenone, butane-2,3-dione) by an 'ene'-reaction pathway followed by isomerization or insertion reactions, representing a new mode in the reaction of disilenes with carbonyl compounds.

The stable dimetallenes containing M=M double bonds (M = heavier Group 14 elements) have now become common, easily accessible and a rather important class of organometallic compounds of Group 14 elements.[1] The reactivity of such dimetallenes has been widely studied, including a variety of addition and cycloaddition reactions. Thus, it is well established that disilenes with a Si=Si double bond react with carbonyl compounds, such as benzaldehyde, acetone, acetophenone and dibenzyl, by [2 + 2] or [4 + 2] cycloaddition reaction modes.[2] In contrast, the reaction of carbonyl compounds having α-hydrogen atoms with compounds containing polar bonds, such as Si=C or Ge=P, proceeded as an 'ene' reaction resulting in the formation of enol ether products.[1,2] Quite recently, we prepared 3*H*- and 1*H*-disilagermirenes; that is, three-membered ring compounds with endocyclic metal–metal double bonds.[3] We have found that such compounds exhibit a high reactivity of both the double bond and the strained three-membered ring skeleton.[4–6] In this paper, we report the reactions of a 3*H*-disilagermirene with carbonyl compounds containing α-hydrogen atoms. They unexpectedly produce enol ether type products, which subsequently undergo further interesting isomerization and insertion reactions.

The reaction of 3*H*-disilagermirene **1** with a slight excess of acetophenone in C_6D_6 at room temperature was complete in two hours to form quantitatively a single product. It was identified by NMR spectroscopy data as *cis*-1,2,3,3-tetrakis(di-*tert*-butyl(methyl)silyl)-1-(1-phenylvinyloxy)disilagermirane **2** (Scheme 1). The formation of this compound can be considered the result of nucleophilic attack of the carbonyl oxygen atom on the sp^2-Si atom through either a zwitterionic intermediate or six-centered transition state. This resulted in the formation of the product of a formal 1,2-addition of 1-phenylvinyl alcohol to a Si=Si double bond of **1**. The enol ether **2** was not stable at room temperature and spontaneously isomerized to the thermodynamically more stable *trans*-isomer **3**. After one day the ratio of *cis*- and *trans*-isomers of **2** and **3** was 1 : 1, whereas after two days **2** was completely isomerized to **3**. The driving force for such isomerization is most likely to be the decrease of the steric hindrance on going from the *cis*- to the *trans*-isomer.[7]

The *trans*-isomer **3** was isolated quantitatively as pale-yellow crystals by recrystallization from hexane. Its structure was determined by all spectral data† and finally confirmed by X-ray analysis.‡ From the crystal structure, the three-membered ring skeleton with a *trans*-arrangement of H- and H_2C=C(Ph)O-substituents can be clearly seen. The bond lengths lie in the normal range and the Si–Si bond length of the three-membered skeleton is 2.3383(6) Å, which is very similar to those of disilagermirane derivatives that we have previously reported (2.342(2)[5] and 2.3269(6) Å[6]). The formation in the first step of the *cis*-isomer **2** agrees with the previously established mechanism for the reaction of disilenes with alcohols, which proceeds as *syn*-addition.[8]

The reaction of 3*H*-disilagermirene **1** with an excess of the dicarbonyl compound butane-2,3-dione also occurred smoothly and cleanly in C_6D_6 at room temperature to produce quantitatively a single product in 30 minutes. Its structure was established by spectral data§ and X-ray crystallography¶ to be 1,2,3,3-tetrakis(di-*tert*-butyl(methyl)silyl)-4-methyl-5-methylene-6,7-dioxa-1,2-disila-3-germabicyclo[2.2.1]heptane **4** (Scheme 2).

X-Ray analysis of **4** showed a bicyclic structure with the norbornane-type skeleton (Fig. 1). Compound **4** has two oxygen atoms incorporated in the rings, one of which occupies the bridging 7-position. Formation of the norbornane **4** can be rationalized as the following reaction sequence. In the first step, nucleophilic attack of the carbonyl oxygen lone pair on the doubly-bonded Si atom results in the formation of the *cis*-adduct–enol ether **5**. The primarily formed **5** may isomerize to a thermodynamically more favorable **6**, due to the lower steric repulsions of the bulky silyl substituents in the *trans*-isomer. In the last step, the second carbonyl group in **6** undergoes an intramolecular insertion into the endocyclic Si–Ge bond of the three-membered ring to form the final norbornane **4**. The proposed mechanism satisfactorily explains the structure of compound **4**, in which the H atom on the Si atom is directed towards the bridge; that is, it occupies the *exo*-position. Such an arrangement of the H atom in **4** can be obtained from the *trans*-isomer **6** only by geometrical reasons, and the last compound can be imagined as the result of isomerization of the initially formed *cis*-isomer **5**.

 DOI: 10.1039/b106801f

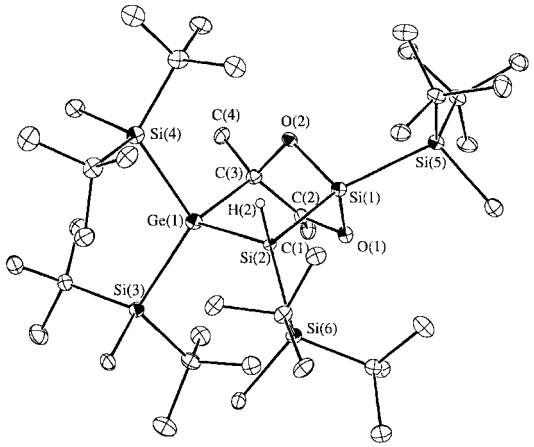

Fig. 1 Structure of **4** (hydrogen atoms are omitted for clarity). Selected bond distances [Å] are: Ge(1)–Si(2) 2.460(1), Si(1)–Si(2) 2.369(1), Ge(1)–C(3) 2.086(5), Si(1)–O(1) 1.701(4), O(1)–C(2) 1.394(6), C(2)–C(3) 1.503(7), Si(1)–O(2) 1.685(3), C(3)–O(2) 1.459(6). Selected bond angles [°] are: C(3)–Ge(1)–Si(2) 95.0(1), Ge(1)–Si(2)–Si(1) 86.1(0), C(3)–C(2)–O(1) 110.6(4), Si(1)–O(1)–C(2) 108.1(3), Si(1)–O(2)–C(3) 104.9(3).

Both reactions of 3*H*-disilagermirene **1** with acetophenone and butane-2,3-dione represent the first examples of an 'ene'-type reaction of disilenes with carbonyl compounds, which were previously commonly recognized to react only by cycloaddition pathways to form cyclic compounds.[2,9] The *cis*–*trans* isomerization of the enol ether was also previously unknown, as well as the combination of 1,2-addition and insertion pathways in one reaction.

Instituto Tecnología Química CSIC–UPV, Av. Naranjos s/n, Universidad Politécnica Valencia, 46022-Valencia, Spain. E-mail: hgarcia@qim.upv.es

Received (in Cambridge, UK) 4th April 2001, Accepted 10th August 2001
First published as an Advance Article on the web 2nd October 2001

Zeolite ITQ-7 containing germanium emits luminescence upon excitation at the wavelength of the absorption maxima; control experiments with amorphous GeO_2 and all-silica zeolites indicate that the emission is attributable to Ge atoms occupying framework positions; the emission decays on the nanosecond time scale and it fits to variable proportions of three exponential kinetics, this being compatible with the presence of three families of Ge atoms in the solid.

Zeolites in which a fraction of the framework silicon atoms are isomorphically replaced by a heteroatom, particularly by transition metals, are important heterogeneous solid catalysts. For instance, a case of special industrial relevance is titanosilicates.[1,2] Given that the heteroatom content in these crystalline metallosilicates is usually very low (< 1 wt%), there has been a considerable interest in developing experimental techniques to determine the metal atom distribution among families depending on their framework *versus* non-framework location, coordination sphere or crystallographic positions. This information is highly valuable to rationalise the activity of these solids and to find a correlation between optimum catalytic activity and the structure of the active sites.

In the context of the characterization of heteroatom distribution in crystalline silicates, pioneering reports showing that photoluminescence spectroscopy can be applied to determine the different coordination spheres of Ti atoms in titanosilicates have constituted a significant contribution.[3,4] Photoluminescence is a non-destructive routine spectroscopic technique widely available in common photochemical laboratories whose distinctive feature is high sensitivity. This contrasts with XANES and EXAFS techniques that require very sophisticated facilities.

Germanium-containing zeolites as well as microporous germanates are interesting materials. By introducing Ge into a zeolite framework one can not only change the basicity of the support[5] or influence the redox properties of the next nearest neighbour framework transition metal,[6] but the introduction of Ge can also accelerate the growth of some existing zeolites as well as the nucleation of new ones.

Unfortunately, Ge characterization in zeolites has been elusive to most of the current techniques, such as NMR and IR. Only EXAFS-XANES has been used to ascertain framework incorporation and to discuss the nature of the next nearest neighbours. There is no doubt that it would be very useful to have a more easily available technique that can give information on the following issues: is Ge incorporated in the zeolite framework? Is there a uniform (statistical) distribution of Ge in the framework? If the answer to the latter is no, the question then will be: what is the proportion of Ge among the different T positions? Herein, we present for the first time evidence that Ge-containing zeolites emit photoluminescence. The evidence that will be presented in this work shows that only the framework Ge originates photoluminescence, extra-framework GeO_2 species giving no signal under the same conditions of low-power excitation. By comparing the kinetic analysis of the emission decay with information from ^{29}Si NMR we have proposed a Ge atom distribution among different sites. The reference zeolite Ge/ITQ-7 was prepared following reported procedures.[7,8] The composition of the resulting Ge/ITQ-7 sample was 57.6 SiO_2:6.4 GeO_2[$4C_{14}H_{26}NF$], the surface area and micropore volume being equal to 660 $m^2\ g^{-1}$ and 0.24 $cm^3\ g^{-1}$, respectively.

The Ge/ITQ-7 sample exhibited room temperature emission (λ_{em} 515 nm) upon excitation at wavelengths between 220 and 300 nm. The emission and excitation spectra are shown in Fig. 1.

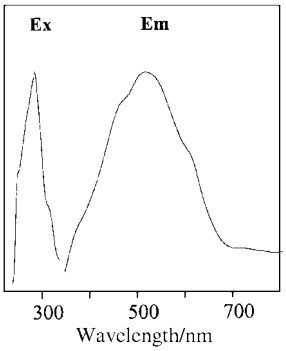

Fig. 1 Excitation (Ex, λ_{em} 515 nm) and emission (Em, λ_{ex} 290 nm) spectra of Ge/ITQ-7 after N_2 purging.

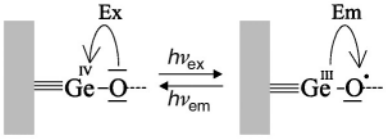
Control measurements with all-silica ITQ-7, as well as amorphous GeO_2 showed no emission, and consequently we can conclude that the emission from the Ge-containing zeolite arises from Ge atoms occupying tetrahedral framework positions. We have ascertained this by observing that other related Ge-zeolites in which Ge is known to occupy framework positions (such as ocatadecasil germanates) also exhibit photoluminescence. We propose that the emission observed arises in tetrahedral Ge atoms from the singlet ligand-to-metal charge transfer state as shown in Scheme 1. This proposal is analogous to the emission mechanism of vanadium supported on inorganic oxides and Ti emission in titanosilicates.[9]

The emission decay of Ge/ITQ-7 depends significantly on the wavelength being monitored and takes place on the nanosecond time scale (Fig. 2). The photoluminescence decay monitored at the emission maximum wavelength was clearly not mono-exponential. The variation of the temporal decay depending on the emission wavelength and the non-monoexponential kinetics can be taken as evidence for a distribution of Ge atoms among different sites. A reasonably good fit (χ^2 = 1.1) could be obtained using a three exponential function. From this theoretical fitting the lifetimes and relative contributions measured at 515 nm were 1.2 ns (24%), 5.3 ns (35%) and 12.2 ns (41%).



Scheme 1 Proposed mechanism for the observed ≡Ge–O photoluminescence.

 DOI: 10.1039/b103034p

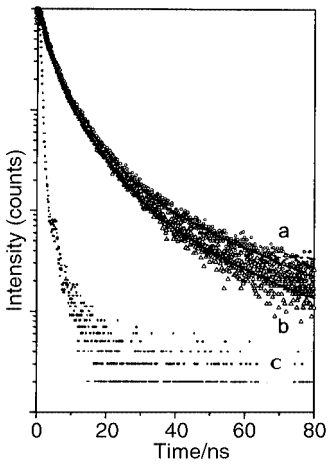


Fig. 2 Emission decays monitored at 515 (a) or 550 (b) nm upon excitation at 290 nm for Ge/ITQ-7 after N_2 purging. The lamp pulse (c) is also given to show the instrumental response. The continuous lines correspond to the fitting from which kinetic data has been obtained and they give a visual indication of the quality of the data.

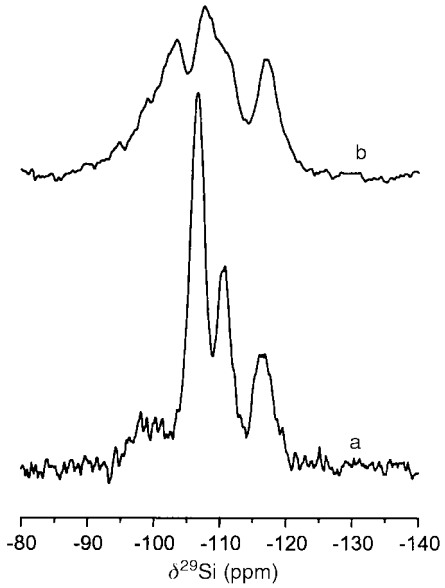

Fig. 3 MAS ^{29}Si NMR spectra of all-silica ITQ-7 (a) and Ge/ITQ-7 (b). Note that the area of the signal at −117 ppm remains unchanged, while the intensity of the peak at −107 ppm is much reduced. A new signal at −100 ppm corresponding to Ge–O–Si appears in spectrum (b).

Therefore, according to kinetic analysis and assuming identical emission efficiency for all the lumophores, the novel Ge/ITQ-7 sample should contain three different Ge sites, whose relative populations measured at 515 nm are 24:35:41. Some other non-emissive Ge atoms such as amorphous germanium oxides may also be present in the solid. Unfortunately, although photoluminescence spectroscopy is a very sensitive technique that is useful for lumophore distribution analysis, it does not give structural information on the species responsible for the emission. Herein we have addressed the structural characterization by comparing the relative intensities of the signals corresponding to the different Si nuclei in the ^{29}Si NMR spectra of the germanosilicate with that for analogous all-silica zeolites (Fig. 3). This gives indirect information on the location of the Ge atoms in the germanosilicate. As it can be seen, the intensity of the band at −117 ppm remains unchanged upon the incorporation of Ge, but there is a significant decrease in the area of the band at −107 ppm. At the same time, a new signal appears at −100 ppm corresponding to Si atoms having Ge in the coordination sphere. It is known that the signal at −117 ppm corresponds to framework atoms occupying positions in the double four member ring (4MR) units. This clearly indicates that incorporation of Ge atoms into the framework occurs preferentially in the 4MR units. In these units there is, however, the same proportion of two different crystallographic sites (T_1 and T_4). The third population observed by photoluminescence characterized by a shorter lifetime would correspond to those Ge atoms located either at T_1 or T_4 (same probability) but having a second Ge in the same 4MR unit. According to the Si/Ge ratio in a unit cell there are 6.4 Ge atoms and four 4MR units.

Alternatively, it could also be possible that the prepared material still containing its template could be somewhat distorted due to the presence of quaternary ammonium ions. Then, the third Ge atom population could arise from this lack of complete symmetry of the as-synthesized ITQ-7. Calcination was not carried out in order to minimise the presence of extra-framework Ge atoms.

In conclusion we have observed for the first time photoluminescence in Ge-containing zeolites. Controls indicate that photoluminescence originates from framework Ge atoms. Therefore, this technique is applicable for the routine determination of Ge distribution in crystalline germanosilicates. Comparison of indirect ^{29}Si NMR spectroscopy data is also in accord with framework Ge incorporation, preferentially in two equally probable crystallographic positions in the 4MR units. Although the assignment is tentative, we propose that the three different populations of Ge atoms observed by photoluminescence correspond to Ge atoms ocuppying these two crystallographic positions together with a third population corresponding to those 4MR units that contain two Ge atoms. Since it can be anticipated that germanosilicates can be applied to the synthesis of novel zeolite-containing heteroatoms, the present study is relevant to provide a routine tool to assess Ge distributions.

A bis-bidentate dioxolene ligand induces thermal hysteresis in valence tautomerism interconversion processes

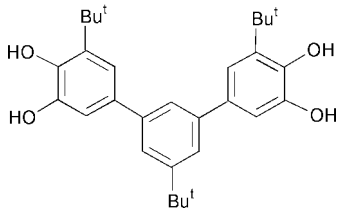
Received (in Cambridge, UK) 12th July 2001, Accepted 11th September 2001
First published as an Advance Article on the web 2nd October 2001

The use of a bis-bidentate ligand in a solid cobalt dioxolene complex affords the necessary cooperative properties that lead to thermal hysteresis in a valence tautomeric interconversion equilibrium.

Among the molecular systems that undergo valence tautomerism, cobalt–dioxolene complexes are the most attractive from a magnetic point of view. For all of the examples reported to date the tautomeric interconversion involves an intramolecular electron transfer between a six-coordinate diamagnetic cobalt(III) metal ion and a coordinated catecholate ligand yielding a cobalt(II)–semiquinone species, the metal ion being in the high-spin electronic configuration.[1–9] It is well established that the transition between the two forms can be induced by temperature and pressure changes as well as by optical irradiation. However, to date the potential application of these systems has been limited by the paucity of materials exhibiting thermal hysteresis, a necessary prerequisite for obtaining memory effects. A small hysteresis width (5 K) was found to be associated to the tautomeric interconversion showed by the Co^{III}(phen)(DBSQ)(DBCat)·$C_6H_5CH_3$ complex,[3] whereas a rather large effect was detected for Co^{III}(3,6-DBCat)(3,6-DBSQ)(py_2O) and Co^{II}(3,6-DBSQ)$_2$(py_2O) valence tautomeric pair (DBCat and DBSQ are semiquinonate and catecholate species derived from 5,5′-di-*tert*-benzylquinone).[9] In the latter system the observed behaviour has been attributed to the planar/folded change in conformation due to the steric requirements of the ancillary diazine ligand. In this sense the observed magnetic behaviour of this molecular system must be considered as a very interesting exception, but, because of its pure molecular origin, it cannot provide the basis for the development of a class of magnetic materials. The attractiveness of a class of compounds exhibiting molecular bistability is due to the fact that their properties can be tuned by means of molecular chemistry techniques. Since the fundamental origin of valence tautomerism is molecular and the cobalt(III)–catecholate and cobalt(II)–semiquinone species involved in the interconversion have different molecular volumes, a thermal hysteresis and then a memory effect must be associated with the existence of a strong cooperativity between the cobalt centers. Following this elementary paradigm, we thought that efforts of the research must be focused towards the design of molecular assemblies with mutually interacting metal centers undergoing valence tautomerism.

Bearing this in mind, we have synthesized a 1,10–phenanthroline–cobalt adduct (Scheme 1) of the dioxolene ligand 3,5-bis(3′,4′-dihydroxy-5′-*tert*-butylphenyl)-1-*tert*-butylbenzene (L)[10] which according to its geometry may act as bis-bidentate ligand towards two different metal ions. Once coordinated this ligand may give by one-electron oxidation the trinegative radical anion we indicate as Sq–Cat, which, although not physically characterized, can be expected to behave as a class II mixed valence radical ligand. A further one-electron oxidation has been shown to yield the diradical Sq–Sq species, which according to its topological properties, is characterized



Scheme 1

by a triplet electronic ground state. We have recently shown how the topology of this ligand may enforce the achievement of high multiplicity ground-states when the Sq–Sq is coordinated to two paramagnetic metal ions.[11]

The reaction of cobalt(II) chloride, 1,10 phenanthroline and L in 1:1:1 ratio in ethanol–dichloromethane (1:2 v/v) in the presence of a stoichiometric amount of triethylamine (4:1) affords a black–green powder (30% yield) of analytical formula Co(phen)L·0.5CH_2Cl_2 **1**. Compound **1** is insoluble in common organic solvents. It is reasonable to believe that this compound contains six-coordinated cobalt ions like all Co(N–N)(diox)$_2$ (N–N = diazine ligand, diox = catecholate or semiquinone) species previously described.[1,2] The main difference between this compound and previous ones is the fact that each dioxolene ligand is paramagnetic and coordinated to two different cobalt ions, thus giving rise to a polymeric structure.

The temperature dependent magnetic behavior of compound **1** is shown in Fig. 1.†

The observed magnetic behaviour is consistent with the presence of a cobalt(III)–catecholato–semiquinonato dominant species at low temperature undergoing a thermally induced valence tautomeric transition to a high spin cobalt(II)–bis(semiquinonato) species according to equilibrium (1). At 310 K, the highest temperature value we measured, it can be estimated from the χT value that each tautomer is present in equal concentration: indeed, the expected χT value for a Co^{II} center and two SQ units would be *ca.* 3.3 emu K mol^{-1}.[12] Using the

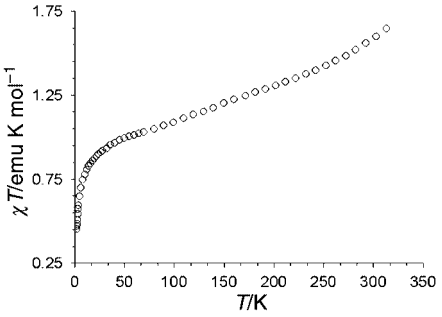


Fig. 1 χT values *vs.* T for compound **1** reported for a single Co center; it is evident that the gradual transition is due to a valence tautomeric process [eqn. (1)] occurring above 50 K.

$$[(Co^{III}/2)SQ–Cat(Co^{III}/2)]_n \rightarrow [(Co^{II}/2)SQ–SQ(Co^{II}/2)]_n \quad (1)$$

 DOI: 10.1039/b106192p

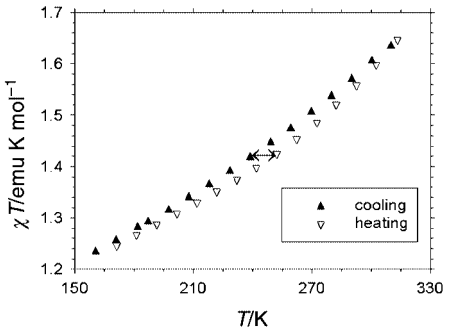

Fig. 2 Difference in the measured χT when heating (▽) and cooling (▲) the sample, respectively. The arrow evidences the maximum width of thermal hysteresis, *ca*. 12 K at 250 K.

nomenclature currently used for spin-crossover systems, the transition can be classified as gradual, but, more importantly, a thermal hysteresis width of *ca*. 12 K is observed (see Fig. 2), though the optimum conditions for observing this phenomenon, *i.e*. the full conversion to hs-cobalt(II), are not reached.

This result was obtained in three independent measurements repeated on the same sample, using 30 min for each point to ensure sample thermal equilibration. These experimental data, therefore, suggest the existence of a strong cooperativity between the magnetic centers.

A comprehensive analysis of magnetic data is not straightforward owing to the high complexity of the different magnetic interactions occurring in the present system and the orbital degeneracy of octahedral Co(II). Moreover the χT value characterizing the cobalt(II)–bis(semiquinonato) species is unknown.

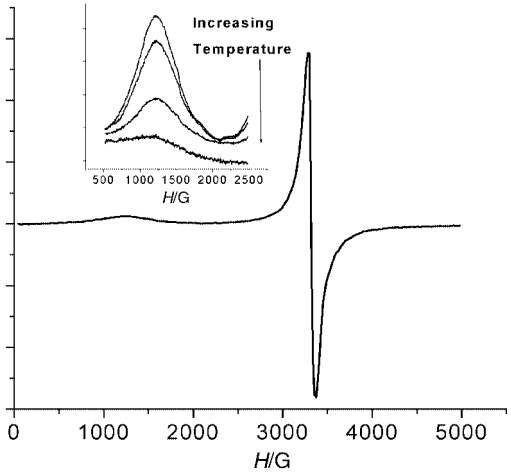

Fig. 3 EPR spectrum of **1** at 4 K. The inset shows the temperature evolution of the low-field transition at 4, 10, 20 and 40 K, respectively.

Furthermore the powder EPR spectrum (see Fig. 3) at 4 K shows a broad transition at 1530 G ($g = 4.3$) and a sharper one at 3300 G ($g = 2$). The transition at $g = 2$ can be assigned to a $Co^{III}SQ$ species and is detected also at room temperature, whereas the transition at $g = 4.3$ seems to be due to the presence of $Co^{II}SQ$ or $Co^{II}(SQ)_2$. This assignment is supported by the fact that these absorptions disappear as the temperature is increased to 40 K (Fig. 3, inset), which is a typical behavior for Co^{II} species. Detection of the $g = 2$ signal at room temperature is of significance since under fast interconversion between the cobalt(III) and cobalt(II) centers, this transition should not be detected on the EPR time scale.

The most important finding of the present experimental results is the strong cooperativity shown by compound **1**, a property that we were looking for in designing this peculiar molecular system. We feel that the observed properties can be easily manipulated by changing the dioxolene substituents, the diazine acceptors as well the crystallization solvent, in agreement with the suggestions of previous work concerning more simple molecular $Co(NN)(diox)_2$ complexes.

Notes and references

† The magnetic susceptibility of polycrystalline powder samples of **1** was measured between 2 and 310 K at an applied magnetic field of 0.1 or 1 T using a Cryogenic S600 SQUID magnetometer. Data were corrected for the magnetism of the sample holder that was determined separately in the same temperature range and field, and the underlying diamagnetism of the samples was estimated from Pascal's constants. EPR spectra were recorded at X-band frequency (9.23 GHz) on a Varian ESR9 spectrometer equipped with a continuous flow ^{4}He cryostat.

A homoleptic phosphine adduct of Tl(I)†

Ian R. Shapiro, David M. Jenkins, J. Christopher Thomas, Michael W. Day and Jonas C. Peters*

Received (in Cambridge, UK) 21st May 2001, Accepted 22nd August 2001
First published as an Advance Article on the web 27th September 2001

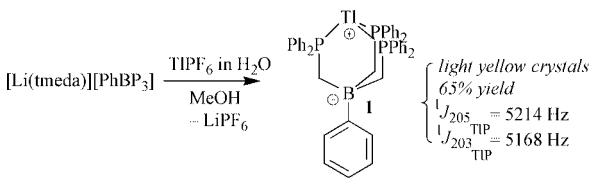
A homoleptic phosphine adduct of thallium(I) supported by a tris(phosphino)borate ligand has been isolated and structurally characterized.

Although hard donor ligands are known to stabilize simple molecular complexes of thallium-(I) and -(III),[1] well-defined examples of thallium supported by correspondingly soft donor ligands are relatively rare.[2] Regarding phosphine donors specifically, only two phosphine adducts have been structurally characterized: both of thallium(III);[3] to our knowledge, there are no well-characterized phosphine adducts for thallium(I). By comparison, there are numerous structurally characterized examples of thallium(I) supported by hard N-donor ligands including the tripodal ligands Tp (Tp = tris(pyrazolyl)borate) and Me_3-TACN (TACN = triazacyclononane).[4,5]

Our group is developing transition metal chemistry utilizing anionic tris- and bis-(phosphino)borate ligands.[6] We have set out to prepare a thallium adduct of the tris(phosphino)borate ligand, [$PhBP_3$] ($PhBP_3$ = $PhB(CH_2PPh_2)_3$),[7] for two reasons. We were surprised by the dearth of well-defined phosphine complexes of thallium and hoped that the anionic [$PhBP_3$] ligand might support and stabilize a thallium(I) species. Additionally, the previously reported lithium salt of this ligand, [Li(tmeda)][$PhBP_3$] (tmeda = tetramethylethylenediamine), is not a reagent of general synthetic utility for clean delivery of the [$PhBP_3$] ligand to transition metals. A versatile thallium reagent of this ligand therefore seems highly desirable. Herein we report the isolation and structural characterization of a homoleptic phosphine adduct of thallium(I) stabilized by the [$PhBP_3$] ligand.

It was convenient to prepare the target complex, [$PhBP_3$]Tl, **1**, by transmetallation of lithium for thallium upon addition of $TlPF_6$ to a methanolic solution of [Li(tmeda)][$PhBP_3$] (Scheme 1).‡ The reaction occurred rapidly and cleanly at ambient temperature as indicated by ^{31}P NMR spectroscopy. Following work-up, the light yellow product was isolated in reasonable yield (65%). It is worth noting that the entire reaction sequence can be executed in air without decomposition. Furthermore, the thallium salt itself is stable to moisture and oxygen for an extended period, both in solution and in the solid state.

Examination of the ^{31}P NMR spectrum of **1** (C_6D_6) showed two resonances (1 : 1 ratio) separated by more than 40 ppm, each resonance bearing a resolvable shoulder (ESI†). This spectrum represents two separate doublets from a very strong $^1J_{TlP}$ coupling interaction (5214, 5168 Hz) for each of the naturally occurring spin ½ thallium isotopes {^{205}Tl (70.5%), ^{203}Tl (29.5%), respectively}. Notably, these coupling values are significantly larger than those reported for phosphine complexes of thallium(III) (approximately 1500 Hz).[3]



Scheme 1

In order to corroborate the NMR assignment, consistent with a structure resulting from symmetric, tridentate binding of the [$PhBP_3$] ligand to the thallium cation, we sought independent structural confirmation. Slow evaporation of a benzene solution of **1** afforded crystals suitable for an X-ray diffraction study. A structural representation of complex **1** is shown in Fig. 1 (top view, 50% ellipsoids).[8] The structure confirms our assignment of **1** as a homoleptic phosphine adduct of thallium. The anionic [$PhBP_3$] ligand coordinates the thallium cation in the expected tridentate conformation (top view). The large ionic radius of the thallium(I) ion forces it to sit well above the basal plane (2.074 Å) defined by its three phosphine donor atoms. This structural feature affords a significant separation between the thallium ion and the molecule's anionic borate counter-anion (Tl1–B distance = 4.253 Å). It is interesting to compare the intramolecular Tl–B distance found in a host of structurally characterized thallium(I) adducts of variously substituted Tp ligands. The Tl–B distance is much longer in **1** than in all related Tp adducts of thallium(I) (range = 3.46–3.90 Å), and is approximately 0.6 Å longer than the mean distance (3.65 Å) for the related Tp systems.[4] The pronounced Tl–B distance in **1**, in conjunction with the absence of simple resonance contributors

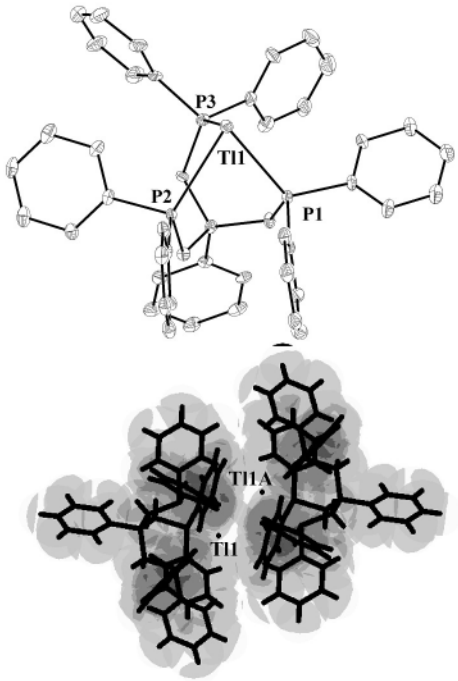


Fig. 1 Displacement ellipsoid (50%) representation of Tl[$PhBP_3$], **1**. Hydrogen atoms have been omitted for clarity. Selected interatomic distances (Å) and angles (°): Tl1–P1 2.878, Tl1–P2 2.953, Tl1–P3 2.932, Tl1–B 4.254; P1–Tl1–P2 70.82, P1–Tl1–P3 76.78, P2–Tl1–P3 77.46. The bottom view shows a transparent space-filling model of **1** depicted as a dimer [Tl1–Tl1A = 3.5652(2) Å]. The [$PhBP_3$] ligands are highlighted as bold stick figures and the positions of the Tl nuclei are labelled.

† Electronic supplementary information (ESI) available: ^{31}P and ^{205}Tl NMR spectra of [$PhBP_3$]Tl in C_6D_6. See http://www.rsc.org/suppdata/cc/b1/b104447h/

 DOI: 10.1039/b104447h

that delocalize the anionic charge from the borate counter-anion to the Tl center, suggests that **1** may be represented as a simple zwitterion (Scheme 1). Although equivalent phosphorus nuclei are observed by ^{31}P NMR spectroscopy, the three phosphine donors are not symmetrically bound in the solid state. The Tl1–P3 distance, 2.880 Å, is appreciably shorter than the Tl1–P1 and Tl1–P2 distances (2.953 and 2.934 Å, respectively).

The bottom view of Fig. 1 shows a transparent space-filling model of **1** and its neighboring thallium adduct. The asymmetric unit of **1** contains a single thallium complex that is related to the neighboring thallium atom, Tl1A, by a center of symmetry. The distance between these thallium atoms is 3.5652(2) Å, which is considerably longer than twice the covalent radius (1.64 Å) of thallium, and is consistent with a thallium–thallium dimer resulting from weak interactions. This dimeric structure does not exist in solution. Direct evidence for assigning **1** as a monomer in solution is as follows: the ^{31}P NMR spectrum of **1** shows only $^{1}J_{\mathrm{TlP}}$ coupling. We would expect to observe a weaker $^{2}J_{\mathrm{TlP}}$ coupling to the neighboring Tl nucleus if the dimeric structure exists in solution. To buttress this argument, the ^{205}Tl NMR spectrum of **1** was obtained in C_6D_6:[9] a single resonance (2809 ppm) split into a quartet by the three equivalent phosphine donors was observed (ESI†). There was no evidence for $^{1}J_{(205)\mathrm{Tl}(203)\mathrm{Tl}}$ coupling, ruling out Tl–Tl interactions in benzene solution. Finally, **1** was analyzed by electrospray mass spectroscopy (ESI/MS). The parent ion observed in positive mode (891) was consistent with the protonated monomeric form of **1**. Thus, our data imply a monomeric formulation of **1** in solution,[10] consistent with its readiness to undergo thallium loss by transmetallation chemistry (*vide infra*).

Regarding other soft, tripodal donor ligands supporting thallium(I), a good comparison to complex **1** comes from Riordan and coworkers, who recently reported a thallium(I) adduct of their second generation, anionic tris(thioether)borate ligand, [PhTt$^{t\text{-Bu}}$].[11] Notably, [PhTt$^{t\text{-Bu}}$] does not enforce a simple, 1 : 1 complex between thallium(I) and the tris(thioether) ligand in the solid state. This is despite the fact that the Tl[PhTt$^{t\text{-Bu}}$] reagent enables access to monomeric, pseudo-tetrahedral geometries for simple divalent nickel and cobalt chlorides.

To highlight the synthetic utility of the thallium reagent **1**, we examined its reactivity with CoI_2. The previously prepared Li(tmeda) adduct of [$PhBP_3$], in addition to its related ammonium salt [$^{n}Bu_4N$][$PhBP_3$], afforded ill-defined mixtures of paramagnetic products on attempted metathesis with CoI_2 in benzene and other solvents.[6] By contrast, the softer and presumably less-reducing thallium reagent **1** reacted cleanly with CoI_2 in benzene to afford the bright green, low spin cobalt iodide complex [$PhBP_3$]CoI, **2**, in good yield (91%).§ Complex **2** was structurally characterized and adopts the expected pseudo-tetrahedral geometry in the solid state (Scheme 2).[8]

In summary, we have isolated and structurally characterized a rare example of a simple phosphine adduct of thallium(I). It has been found that complex **1** displays a signature $^{1}J_{\mathrm{TlP}}$ coupling constant of 5214 Hz. In addition to exposing new possibilities for thallium coordination chemistry within a phosphine donor sphere, complex **1** promises to be an important reagent for delivering the relatively unexplored [$PhBP_3$] ligand to transition metals.

‡ *Synthesis* of [$PhBP_3$]Tl, **1**: solid [Li(tmeda)][$PhBP_3$] (7.1 g, 8.6 mmol), generated as previously described,[7] was suspended in methanol (60 mL). To this stirring suspension was added an aqueous solution (30 mL) of $TlPF_6$ (3.00 g, 8.6 mmol) over a period of 5 min. A cloudy white suspension resulted which was stirred for an additional 5 min, followed by extraction with dichloromethane (2 × 150 mL). Drying the organic extract *in vacuo* afforded a light yellow powder that was subsequently washed with hexanes and Et_2O (40 mL each). The remaining powder was extracted into benzene, stirred over $MgSO_4$, and dried thoroughly *in vacuo* to afford the thallium adduct **1** as a fine yellow powder (5.00 g, 65%). ^{1}H NMR (C_6D_6, 300 MHz, 25 °C): δ 8.13 (d, J = 6.6 Hz, 2H), 7.67 (m, J = 7.5 Hz, 2H), 7.42 (tt, J = 6.6, 1.2 Hz, 1H), 7.18–7.11 (m, 12H), 6.80–6.77 (m, 18H), 1.96 (br m, 6H). ^{31}P NMR (C_6D_6, 121.4 MHz, 25 °C): δ 21.6 [d, $^{1}J_{\mathrm{TlP}}$ = 5214 Hz for ^{205}Tl (70.5% abundance), $^{1}J_{\mathrm{TlP}}$ = 5168 Hz for ^{203}Tl (29.5% abundance)]. ^{205}Tl NMR (C_6D_6, 231.31 MHz, 25 °C): δ 2810 (q, $^{1}J_{\mathrm{TlP}}$ = 5204 ± 116 Hz). ^{13}C NMR (C_6D_6, 125.7 MHz, 25 °C): δ 139.8, 132.5, 128.8–129.1 (overlapping resonances), 124.6, 17.0 (br). ^{11}B NMR (C_6D_6, 128.3 MHz, 25 °C): δ −10.96. Anal. Calc. for $C_{47}H_{48}BP_3Tl$: C, 60.73; H, 4.64. Found: C, 61.75; H, 4.76%.

§ *Synthesis* of [$PhBP_3$]CoI, **2**: a benzene solution (50 mL) of the thallium reagent **1** (0.356 g, 0.40 mmol) was added to a stirring suspension of CoI_2 (0.250 g, 0.80 mmol) in benzene (20 mL). After stirring at ambient temperature for 24 h, the resulting green solution was filtered through Celite, concentrated *in vacuo* (50%) and filtered through Celite once again. Vapor diffusion of petroleum ether into the resulting green filtrate afforded a good yield of the desired crystalline product (0.317 g, 91.1% yield). ^{1}H NMR (C_6D_6, 300 MHz, 25 °C): δ 22.2 (br s), 15.8 (s), 10.8 (s), 7.7 (s), 7.5 (s), 4.3 (br s), 2.2 (s), −8.5 (s). IR (ν/cm^{-1}): 1433 (s), 1091 (b), 739 (s). μ_{eff} = 2.60 μ_{B} (SQUID). UV–vis (C_6H_6): 638 nm (ε = 1112), 738 nm (ε = 627). Anal. Calc. for $C_{45}H_{41}BCoIP_3$: C, 62.03; H, 4.74. Found: C, 61.76; H, 4.75%.

Received (in Cambridge, UK) 8th March 2001, Accepted 4th September 2001
First published as an Advance Article on the web 2nd October 2001

The absolute configuration of the recently identified sesquiterpene (+)-kelsoene was revised by chemical correlation with (*R*)-(+)-pulegone; the correct structure is (1*R*,2*S*,5*R*,6*R*,7*R*,8*S*)-2,8-dimethyl-6-(1-methylethenyl)tricyclo[5.3.0.0^{2,5}]decane.

Recently the sesquiterpene hydrocarbon (+)-kelsoene (**1**, also called tritomarene) was isolated from the marine sponge *Cymbastela hooperi*[1] as well as from the liverworts *Ptychanthus straitus*,[2] *Calypogeia muelleriana*,[3] and *Tritomaria quinquedentata*.[4] The relative configuration was elucidated during these studies; **1** contains a rare *cis,anti,cis* 4-5-5 carbotricyclic ring system, previously only found in the tetraterpene poduran[5] and the sesquiterpenoid sulcatine G.[6] The analysis of NMR data obtained from two dihydroisoxazoles formed after addition of (a*S*)-2′-methoxy-1,1′-binaphthalene-2-carbohydroximoyl chloride (MBCC) to the double bond of **1** according to the method of Fukui *et al*.[7] led to the conclusion that (+)-**1** possesses a (1*S*,2*R*,5*S*,6*S*,7*S*,8*R*)-2,8-dimethyl-6-(1-methylethenyl)tricyclo[5.3.0.0^{2,5}]decane structure.[8] In the present study we will show by chemical correlation with the ketone **3** and further with (*R*)-(+)-pulegone (**4**) that this assignment is incorrect. We will also present the first synthesis of enantiomerically pure **1**, which has previously only been synthesized in racemic form.[9]

Natural **1** can be isomerized by a short treatment with toluene-*p*-sulfonic acid into the more stable isomer **2**, which in turn is cleaved by ozonolysis to the tricyclic ketone **3**. Under the reaction conditions no excessive degradation of **3** or **1** or formation of byproducts occurs. The ketone **3** was the target of a short enantiospecific synthesis, because we reasoned that its racemate may be well suited to separation by GC on chiral phases due to its rigidity. It would also be formed by degradation of other terpenes exhibiting the same ring system, such as *e.g*. the tetraterpene poduran recently identified by us,[5] thus allowing its use for the determination of the absolute configuration of several natural products.

The ketone **3** was synthesized starting from (*R*)-(+)-pulegone (**4**), which was transformed by bromination and Favorskii-rearrangement into a mixture of *cis*- and *trans*-pulegonic acids (**5**),[10] separable by column chromatography. Isomerization of the double bond into the terminal position was achieved by lactonization of pure *cis*-**5** to **6**, followed by elimination with a bulky base, as has been described for *anti*-**5**.[10,11] The double bond of the resulting acid **7** was now internally acylated *via* the acid chloride to form the ketone **8**, which was photochemically transformed by a [2 + 2]-cycloaddition with ethylene into the desired ketone (1*S*,2*R*,5*R*,7*R*,8*R*)-2,8-dimethyltricyclo-[5.3.0.0^{2,5}]decan-6-one (*ent*-**3**). The ethylene attack occurs from the less hindered side. In an identical manner, *rac*-**3** was synthesized starting from *rac*-**4**. To exclude the unlikely possibility of inversion of the stereogenic centers in the course of our synthesis, *ent*-**3** was reduced with $LiAlH_4$. Preferential attack of the hydride from the less hindered side and reaction of the alcohol with tosyl chloride resulted in formation of the

tosylate **9**. An X-ray analysis of **9**† allowed the determination of its absolute configuration.[12] This tosylate could be thus identified as (1*S*,2*R*,5*R*,6*S*,7*R*,8*R*)-2,8-dimethyltricyclo-[5.3.0.0^{2,5}]dec-6-yl tosylate, exhibiting the expected absolute configuration.

Being confident on the absolute configuration of *ent*-**3**, we were now able to perform GC analyses. The absolute configuration of natural (+)-**1** can be deduced by analysis of its degradation product **3**, because its relative configuration has been elucidated during its isolation.[1] Separation of *rac*-**3** was achieved on a chiral Hydrodex-6-TBDMS stationary phase.‡ The (−)-enantiomer of **3** eluted first, as did the degradation product of synthetic (−)-kelsoene. The ketone **3** derived from natural (+)-kelsoene eluted as second peak. In addition, the synthetic (−)-**1** prepared by us showed the expected sign of optical rotation of $[\alpha]_D^{20} = -78.3$. These data unequivocally prove that natural (+)-kelsoene has the opposite configuration as previously reported and possesses a (1*R*,2*S*,5*R*,6*R*,7*R*,8*S*)-2,8-dimethyl-6-(1-methylethenyl)tricyclo[5.3.0.0^{2,5}]decane structure.

We proceeded with the synthesis of enantiomerically pure (−)-**1** to further underline the consistency of our data set. In their synthesis of *rac*-**1**, Mehta and Srinivas showed that ketone **3** is strongly hindered and not readily attacked by nucleophiles. We therefore chose their strategy to reduce steric hindrance: The bicyclic ketone **8** was transformed into the cyclobutene derivative **10** as described.[9,13] The side chain was then elaborated in a new way. Even after reduction of the steric hindrance, only small nucleophiles can be used to attack the carbonyl carbon atom. Nevertheless, epoxidation with trimethylsulfoxonium iodide was feasible with satisfactory yield. The epoxide **11** was then hydrogenated and rearranged in one step to form the aldehyde **12**. Addition of methyllithium followed by oxidation with PDC afforded the ketone **13** in a 80 : 20 dr in favor of the unwanted diastereomer. Obviously the less hindered hydrogen moves more readily in the epoxide–aldehyde rearrangement of **12**. Nevertheless, simple treatment with base epimerized this center to the thermodynamically more favored arrangement, which is also found in the natural product. Kelsoene was then formed by final methenylation with Me_2TiCp_2,[14] because Wittig olefination, despite reported by Mehta and Srinivas,[13] did not proceed with satisfactory yields. Thus enantiomerically pure (−)-**1** has been synthesized, confirming our previous assignments.§,¶

We thank Professor Nabeta and Professor G. König for kindly providing us with samples of (+)-kelsoene. We also thank the Deutsche Forschungsgemeinschaft and the Fonds der chemischen Industrie for financial support.

Note added in proof. Similar results were obtained recently by G. Mehta and K. Srinivas, *Tetrahedron Lett*., 2001, **42**, 2855, using a different synthetic strategy.

Notes and references

† *Crystal data* for **9**: orthorhombic, space group $P2_12_12_1$, $a = 9.1578(8)$, $b = 11.7038(10)$, $c = 16.1527(14)$ Å, $U = 1731.3$ Å^3, $Z = 4$, $T = -130$ °C. *Data collection*: a crystal *ca*. 0.4 × 0.16 × 0.09 mm was used to record 26944 intensities on a Bruker SMART 1000 CCD diffractometer (Mo-Kα radiation, $2\theta_{max}$ 57°). *Structure refinement*: the structure was refined anisotropically on F^2 (program *SHELXL*-97, G. M. Sheldrick, University of Göttingen) to *wR*2 0.083, *R*1 0.032 for 211 parameters and 4388 unique reflections. The hydrogens were refined using a riding model or rigid methyl groups. The Flack parameter refined to −0.07(5). CCDC 171200. See http://www.rsc.org/suppdata/cc/b1/b101579f/ for crystallographic files in .cif or other electronic format.

‡ Separations were performed on a 15 m Hydrodex-6-TBDMS capillary column (Macherey & Nagel), id 0.25 mm, programmed from 60 to 180 with 5 min after a 2 min isothermal period with H_2 as the carrier gas (45 psi).

§ The ^{1}H NMR, ^{13}C NMR, and MS data are identical to those reported in the literature.[1] $[\alpha]_D^{25} = -78.3$ ($c = 0.31$, $CHCl_3$). Literature data for (+)-**1**: $[\alpha]_D^{25} = +78.1$ ($c = 1.98$, $CHCl_3$).[1]

¶ We also tried to find out why the NMR study by Nabeta *et al*.[8] furnished the opposite result. In their work Nabeta *et al*. presented a preferred conformation for one of the two formed kelsoene-MBCC adducts. Unfortunately, they did not explain how they obtained this conformation. These adducts contain a single bond between the heterocyclic ring and the cyclic core of **1**, while in the original paper introducing this method[7] all examples contain a dihydroisoxazole ring directly linked to the parent cyclic hydrocarbon, thus reducing the inherent flexibility. Finally, only one of two formed diastereomers was investigated by NMR and no comparison with the respective (a*R*)-MBCC was performed, as should be done in Mosher-like methods. In essence, their determination of the absolute configuration relies on several NOE signals observed, while in the present study a sound chemical correlation is performed. It should be noted that recently a very informative critique of the Mosher method has been published, which also applies to related methods.[15]

Biosynthesis of the vancomycin group of antibiotics: characterisation of a type III polyketide synthase in the pathway to (*S*)-3,5-dihydroxyphenylglycine†

Tsung-Lin Li, Oliver W. Choroba, Hui Hong, Dudley H. Williams and Jonathan B. Spencer*

Received (in Cambridge, UK) 23rd July 2001, Accepted 30th August 2001
First published as an Advance Article on the web 2nd October 2001

3,5-dihydroxyphenylacetate, a precursor for the non-proteinogenic amino acid 3,5-dihydroxyphenylglycine occurring in glycopeptide antibiotics, is determined to be catalysed by a type III polyketide synthase using malonyl-CoA as a starter unit.

Vancomycin **1** (Fig. 1) is currently the antibiotic of last resort against methicillin-resistant *Staphylococcus aureus* (MRSA).[1] We are investigating the biosynthetic pathway of chloroeremomycin **2**, another important member of this family of glycopeptide antibiotics.

A number of unusual amino acids, such as (*S*)-4-hydroxyphenylglycine (4-HPG) and (*S*)-3,5-dihydroxyphenylglycine (3,5-DHPG) are found in glycopeptide antibiotics. Recently the pathway to 4-HPG from tyrosine has been elucidated[2–4] and the pivotal enzyme, 4-hydroxymandelic acid‡ synthase determined to be a novel dioxygenase.[2] In this paper we report the identification of the protein coded for by *orf*27 from the chloroeremomycin gene cluster, now named 3,5-dihydroxyphenylacetate synthase (DhpaS), as the first enzyme involved in the pathway to 3,5-DHPG. DhpaS catalyses the formation of 3,5-dihydroxyphenylacetate (3,5-DHPA) from four malonyl-CoA units and is only the second type III polyketide synthase fully characterised in bacteria.

Previous feeding studies using vancomycin-producing organisms and labeled acetate showed that the carbon skeleton of 3,5-DHPG was of polyketide origin.[5] Recently we have shown the involvement of 3,5-DHPA in the pathway to this amino acid by feeding experiments using the chloroeremomycin-producing strain *Amycolatopsis orientalis*. NMR studies showed that ^{13}C-labeled 3,5-DHPA was incorporated into the 3,5-DHPG moiety of the isolated antibiotic.[6] Homology searches of the open reading frames (*orfs*) from the biosynthetic gene cluster of chloroeremomycin[7] revealed that *orf*27 had homology (37% similarity, 28% identity) to a group of plant chalcone synthases which provide precursors for flavonoids.[8] This family of small discrete enzymes have been called type III polyketide synthases. They differ from other polyketide synthases by not possessing a phosphopantetheine prothetic group. Chalcone synthases typically use aromatic coenzyme A esters, such as coumaryl-CoA, as starter units and malonyl-CoA as the chain extender unit. Based on these findings we felt that ORF27 might catalyse the formation of 3,5-DHPA **4** from an acetyl-CoA starter unit and three malonyl-CoA extender units. Hydroxylation at the benzylic position of **4** would lead to 3,5-dihydroxymandelic acid **5**, oxidation to 3,5-dihydroxyphenylglyoxylic acid **6** and subsequent transamination should then furnish 3,5-dihydroxyphenylglycine **7** (Scheme 1).

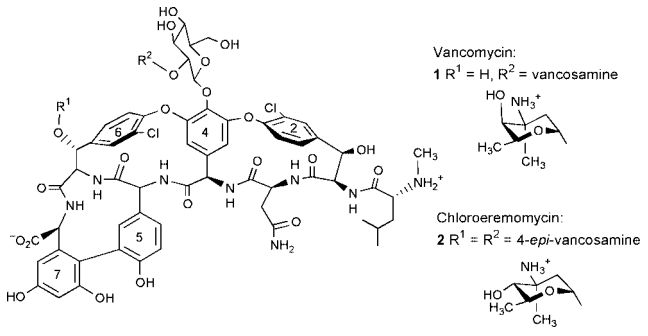

Fig. 1 Structures of vancomycin and chloroeremomycin.

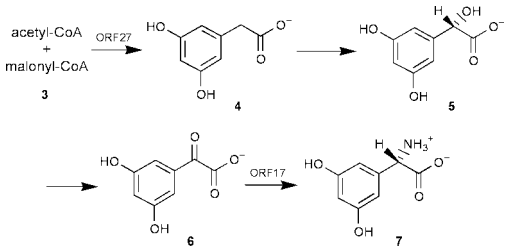
To test this hypothesis *orf*27 from the chloroeremomycin gene cluster was amplified by polymerase chain reaction using the cosmid pCZA361. Ligation into pET28 (Novagen) and transformation into *E. coli* BL21(DE3) yielded the *N*-terminal His_6-tagged protein which was purified using Ni^{2+}-NTA agarose. Electrospray mass spectrometry of the purified protein confirmed the right molecular weight for the protein without a phosphopantheine arm, therefore being consistent with a type III polyketide synthase. The enzyme was incubated in Hepes buffer (50 mM, pH 7.2) containing DTT (1,4-sulfanylbutane-2,3-diol,1.0 mM), acetyl-CoA (3.3 mM) and malonyl-CoA (10 mM) for 2 h. The enzymic mixture was acidified and extracted with ethyl acetate, silylated and analyzed by GC-CI-MS (NH_3 as reaction gas). The GC trace revealed a new peak when compared to a control reaction (Fig. 2). This compound was identified as the tris(trimethylsilyl) derivative of 3,5-dihydroxyphenylacetate by comparison with an authentic sample (identical retention time and fragmentation pattern) (Fig. 3). This proves that ORF27 is a type III polyketide synthase that catalyses the first step in the pathway to 3,5-DHPG.

The mechanism in which the polyketide chain cyclises to form 3,5-DHPA is interesting since it predicts that, if acetyl-CoA is the starter unit, an anion must be formed from a methyl ketone **8** (Scheme 2, A). In the vast majority of polyketides the folding pattern arises from an anion generated at a more acidic methylene position. It has recently been reported that malonyl-CoA serves as the starter unit for the formation of the polyketide 1,3,6,8-tetrahydroxynaphthalene.[9] If malonyl-CoA was used as the starter unit for 3,5-DHPA then the anion of the methyl ketone could be generated by decarboxylation of **9**,[10] which would be energetically more favorable than deprotonation of the



Scheme 1 Proposed pathway for 3,5-dihydroxyphenylglycine formation.

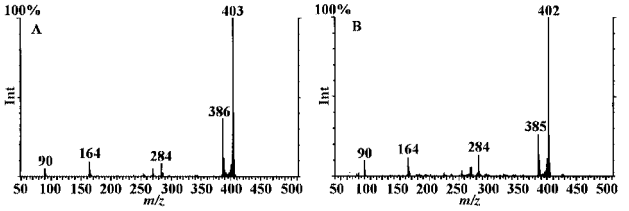

Fig. 3 (A) CI-MS spectrum of [1-^{13}C]-3,5-DHPA standard silylated (note that the standard has one ^{13}C atom and therefore gives a molecular ion one mass higher than the enzymic sample). (B) CI-MS spectrum of the peak at 19.2 minutes from the enzymic reaction (Fig. 2).

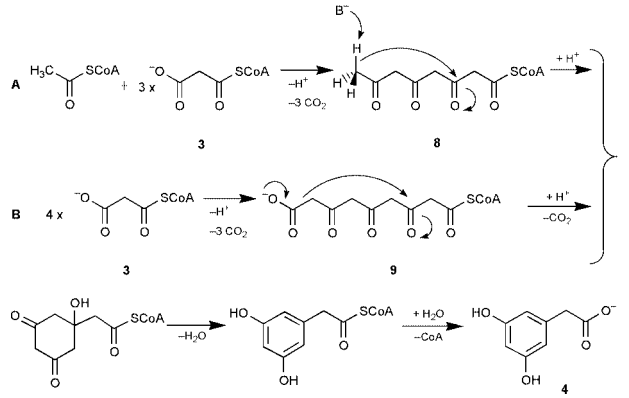
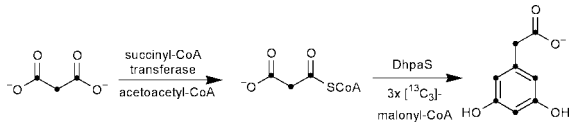


Scheme 2 Formation of 3,5-dihydroxyphenylacetic acid using either acetyl-CoA and malonyl-CoA (A) or malonyl-CoA only (B).

methyl ketone (Scheme 2, B). To determine the origin of the starter unit and investigate these two possible reaction mechanisms, labeled malonyl-CoA (formed *in situ* by transfer of CoA from acetoacetyl-CoA to [1,2,3-$^{13}C_3$]malonic acid using succinyl-CoA transferase[11]) was incubated with DhpaS in the presence of unlabeled acetyl-CoA (Scheme 3). The mass spectrum of the isolated 3,5-DHPA gives only an $[M + 8]^+$ peak, clearly showing that all the carbon atoms come from malonyl-CoA (Fig. 4).



Scheme 3 *In situ* formation of [1,2,3-$^{13}C_3$]malonyl-CoA and its utilisation by DhpaS to form labeled 3,5-DHPA (^{13}C represented as •).

The family of chalcone synthases are relatively small proteins that appear to have only one active site.[12] This is in contrast to type I polyketide synthases which are typically very large multifunctional proteins with a separate active site for each

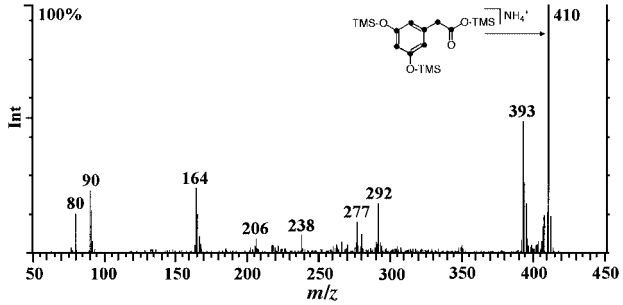


Fig. 4 Mass spectrum of labeled 3,5-DHPA formed by enzymic reaction of dihydroxyphenylacetate synthase with [1,2,3-$^{13}C_3$]malonyl-CoA in the presence of unlabeled acetyl-CoA.

reaction that they catalyse. It is therefore tempting to propose that the cyclisation to form 3,5-DHPA might be catalyzed by the same amino acids that carry out the Claisen condensation of malonyl-CoA with the growing polyketone chain since the two reactions are very similar.

In summary, we have shown that ORF27 from the chloroeremomycin gene cluster is an unusual type III polyketide synthase catalyzing the formation of 3,5-dihydroxyphenylacetic acid. Labeling experiments prove that malonyl-CoA acts not only as the chain-extender unit but also as the starter unit. This leads us to propose that cyclisation to form 3,5-dihydroxyphenylacetic acid is initiated by decarboxylation of the polyketone chain **9**.[13] This study determines that the biosynthesis of 3,5-dihydroxyphenylglycine begins with the formation of 3,5-dihydroxyphenylacetic acid or its CoA-ester, and therefore affords a new insight into how the biosynthesis of these important antibiotics occurs.

We thank the Royal Society for a Research Fellowship (J. B. S.), the Ministry of Education, Taiwan, for a Research Fellowship (T.-L. L.), the European Union for a TMR Marie-Curie Research Fellowship (O. W. C.), St. John's College, Cambridge for a Junior Research Fellowship (O. W. C.), and the BBSRC for financial support.

12 J.-L. Ferrer, J. M. Jez, M. E. Bowman, R. A. Dixon and J. P. Noel, *Nature Struct. Biol.*, 1999, **6**, 775.
13 The labeling experiments would also be consistent with the first malonyl unit loaded onto the enzyme being decarboxylated to give an acetyl starter unit. However, this reaction pathway seems unlikely since acetyl-CoA is not accepted at all by the enzyme.

Recent advances in solventless organic reactions: towards benign synthesis with remarkable versatility

Gareth W. V. Cave,[a] Colin L. Raston*[b] and Janet L. Scott[a]

[a] *Centre for Green Chemistry, School of Chemistry, Monash University, Clayton, Melbourne, Victoria 3800, Australia*
[b] *School of Chemistry, University of Leeds, Leeds, UK LS2 9JT. E-mail: c.l.raston@chem.leeds.ac.uk*

Received (in Cambridge, UK) 24th July 2001, Accepted 18th September 2001
First published as an Advance Article on the web 17th October 2001

A paradigm shift away from using solvents in organic synthesis as solventless reactions can lead to improved outcomes, and more benign synthetic procedures, in for example aldol condensation reactions, sequential aldol and Michael addition reactions *en route* to Kröhnke type pyridines, reactions leading to 3-carboxycoumarins, benzylidenes, 4-aryl-1,4-dihydropyridines and 2-aryl-1,2,3,4-tetrahydroquinazolines, and oligomerisation reactions for the synthesis of cavitands; kinetic considerations for the reaction of two solids can only be explained if a eutectic melt is formed during the reaction.

Dr Gareth Cave is a postdoctoral Research Fellow at the Centre for Green Chemistry, Monash University. Before moving to Australia he completed a PhD under the supervision of Dr Johnathan Rourke at the University of Warwick (1999), investigating the cyclometallation properties of platinum and palladium metals, whereupon he started postdoctoral studies at Monash University under the direction of Professor Colin Raston (2000). Research interests cover aspects of cyclometallation, metallomesogens, supramolecular and Green Chemistry.

Professor Colin Raston holds the Chair of Inorganic Chemistry, School of Chemistry, University of Leeds. He completed a PhD under the guidance of Professor Allan White, and after postdoctoral studies with Professor Michael Lappert at the University of Sussex, he was appointed Lecturer at the University of Western Australia (1981) then to Chairs of Chemistry at Griffith University (1988), being awarded a DSc there in 1993, and Monash University (1995), as an ARC Senior Research Fellow and ARC Special Investigator followed by the move to the University of Leeds early 2001. Research interests cover aspects of main group, supramolecular and Green Chemistry, having helped to establish the Centre for Green Chemistry at Monash University.

Dr Janet Scott is a lecturer and a Deputy Director of the Centre for Green Chemistry, Monash University. She completed a PhD under the supervision of Professors Luigi Nassimbeni and Mino Caira at the University of Cape Town where she also held the position of Lecturer until 1995. She was appointed Research and Development Manager at Fine Chemicals Corporation Pty. (Ltd) for the period 1996–1998 whereafter she moved to Australia and the Centre for Green Chemistry at Monash University, Melbourne, Australia. Her research interests centre around Green Chemistry and include the use and understanding of solvent-free reactions with the goal of attaining greater reaction control.

Introduction

Sustainability is increasingly an important issue in the wider context dealing with population, health, the environment, energy, technology, renewable resources, and, in the sciences, as an integral part of the rapidly emerging field called Green Chemistry.[1,2] This is a multidisciplinary field, requiring integrated study in the chemical, biological and physical sciences as well as many aspects of engineering. Even nanotechnology is important in Green Chemistry, providing a way of dematerialising society while providing the benefits of technology.[3] The twelve principles of Green Chemistry, as defined by Anastas and Warner,[1] and generally accepted internationally, cover complex issues including waste minimisation, reduction in energy usage, and the use of renewable resources rather than depleting natural resources such as oil, coal and gas. Biocatalysis is an important area of Green Chemistry providing a means of converting biomass, a renewable resource, into commodity chemicals.[1–3] In the chemical sciences there is a need to develop benign synthetic pathways which, in addition to being high yielding (historically the most important measure of the success of a reaction), are simple and exhibit high atom efficiency, hence a reduced number of steps and no waste, are safe, and are environmentally acceptable.[2] Another measure of the 'greenness' of a reaction is the *E* factor (= waste (kg)/1 kg product),[4] which, for pharmaceuticals, is typically >100. The emergence of Green Chemistry has resulted in a paradigm shift in the way chemists develop processes and products, and requires the development of a Green Chemistry toolbox.

Removing organic solvents in chemical synthesis is important in the drive towards benign chemical technologies. Organic solvents are high on the list of toxic or otherwise damaging compounds because of the large volumes used in industry, and difficulties in containing volatile compounds. Replacement reaction media include ionic liquids[5–7] (which have extremely low vapour pressure and can be recycled), liquid and supercritical CO_2,[8] water (often at high temperature under microwave irradiation),[1,9,10] and polyethylene and polypropylene glycol[11] (Fig. 1). Another alternative is not to use a reaction medium, the so called solventless reactions, which is the main focus of this article.[7,11–20] The choice of solventless or specific non-organic solvent reaction medium will depend on several issues, including selectivity, stereochemistry, yield, waste, viscosity, ease of recycling, energy usage, ease of isolation of product(s), competing reactions, and heat of reaction. In using a reaction medium, there are many choices within each system, for example using ionic liquids with the appropriate hydrophobic–hydrophilic balance, and varying the density of liquid and supercritical CO_2, which can affect the stereochemical outcome of addition reactions.[8]

Advantages in using solventless reactions, particularly those described herein, relative to using organic or other reaction

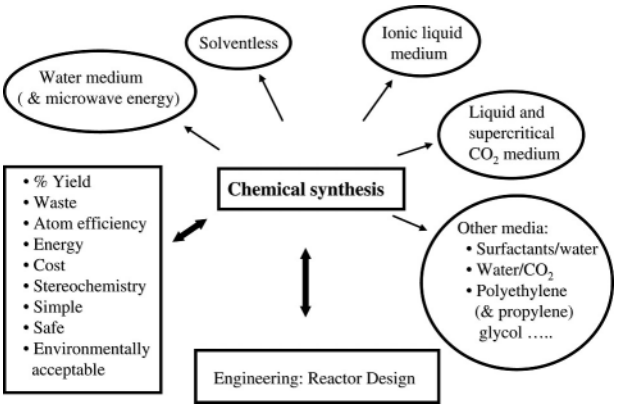

Fig. 1 Non-organic solvent reaction medium linking into reactor design.

media include: (i) there is no reaction medium to collect, purify and recycle, (ii) the compounds formed are often sufficiently pure to circumvent extensive purification using chromatography, and indeed in some cases the need for recrystallisation, (iii) sequential solventless reactions are possible in high yielding systems, (iv) the reactions can be rapid, often reaching substantial completion in several minutes compared to hours in organic solvents, (v) there is often no need for specialised equipment (see below), (vi) energy usage can be much lower, (vii) the need for pre-formed salts and metal–metalloid complexes may often be dispensed with, (viii) functional group protection–deprotection can be avoided, (ix) lower capital outlay for equipment in setting up industrial processes, and (x) considerable batch size reduction and processing cost savings are achievable such that such solvent-free protocols are not only more environmentally benign but are also more economically feasible. This is one of the original considerations in bringing Green Chemistry to the fore.[1]

There are some disadvantages in solventless reactions but these are solvable using developments in engineering reactor technology[21] (Fig. 1). Objections to the use of solventless reaction conditions include the formation of hot spots and the possibility of runaway reactions. Instead of operating in the old paradigm, notably the use of a reaction medium or solvent as a heat sink or heat transfer agent, consideration could be given to applying developments in reactor design either for continuous flow or batch systems. Our recent paper on the solventless aldol condensation reaction,[15] attracted attention in *Chem. Brit.* (June 2000, p. 18) with a subsequent letter to the editor drawing attention to the potential for run away reactions (January 2001, p. 14). Clearly measurement of heat of reaction in solventless systems is important as is effective heat dissipation. If highly exothermic reactions are identified which are otherwise suited to solventless conditions the problem could be addressed through advanced reactor design. Another objection can be difficulties in handling solid or highly viscous material. Again this can be overcome by advances in engineering and innovative reactor design. Solventless reactions may be more appropriate for small volume commodity chemicals rather than high throughput although it is possible to envisage extrusion type continuous reactors. Though the concept of grinding (including ultra high energy grinding) to promote chemical reactions has been known for some time, there have been few reports of applications of high intensity grinding in organic synthesis.[22–24]

Historically organic synthesis was carried out in organic solvents even in the absence of apparent reasons to do so (other than heat transfer considerations). In moving towards sustainable technologies the issue now becomes either carrying out solventless reactions, or using alternative reaction media, or (for a multi-step synthesis) a combination of these. In covering recent advances in solventless reactions, we will compare (where information is available) reactions in organic solvents and in other media. We initially entered Green Chemistry as a challenge to establish solventless procedures for reactions which traditionally play a pivotal role in organic synthesis. We also targeted solventless reactions, and reactions in ionic liquids, for preparing building molecules which feature extensively in supramolecular chemistry leading to advances in materials chemistry and nano-technology. This is based on the premise that any developments in supramolecular chemistry are more likely to have downstream applications if the building molecules are readily available using benign synthetic protocols. Specific reactions studied include solventless aldol reactions,[15] sequential aldol and Michael addition reactions as a route to symmetrical and unsymmetrical 1,5-diketones leading to Kröhnke type pyridines,[17–19] synthesis of 3-carboxycoumarins (and a comparison with using an aqueous slurry),[16] oligomerisation reactions affording cavitands, notably cyclotriveratrylene and related compounds (and a comparison with an ionic liquid reaction medium),[7] calix[4]resorcinarenes,[11] and 4-substituted-1,4-dihydropyridine compounds such as the commonly used cardiovascular drug Felodipine.[25] All these reactions have a common theme of dehydration, and most exhibit high atom efficiency. We note that Kröhnke type pyridines and cavitands have 'high technology' applications, for example in devices, materials chemistry, and liquid crystals, and ultimately in developing sustainable technologies, Fig. 2, but this is not

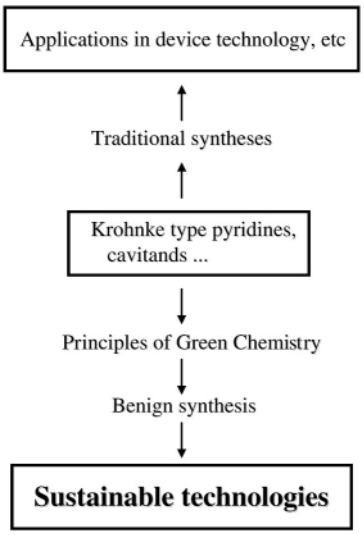

Fig. 2 Relationship between compounds with materials applications and sustainable technologies.

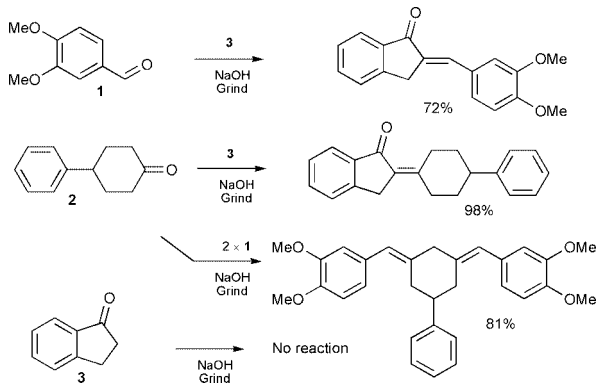
matched by their syntheses. We have also studied the kinetics of these solventless reactions, to help understand the chemistry at the molecular level which is important in developing tools for Green Chemistry.

Chemoselective, aldol condensation reactions

The aldol reaction, the formation of a β-hydroxycarbonyl compound from two carbonyl compounds with at least one being enolisable, which on dehydration becomes an α,β-unsaturated carbonyl compound, can be carried out by simply grinding together solid (or liquid) aldehydes and ketones in the presence of solid NaOH followed by washing with a dilute aqueous acid solution, Scheme 1.[15] No preformed enolates are used, no heating or cooling is required, no organic solvent is utilised in the reaction (unless product recrystallisation is required), and the only waste produced is a small amount of acidic aqueous waste. Single crossed aldol condensation products are produced in high yield even in reactions where a mixture of products is possible. Solvent free aldol condensation reactions of benzaldehyde and acetophenone derivatives have been reported by Toda *et al.*,[26] although in all cases the



Scheme 1

aldehydes are devoid of α-hydrogen atoms, thereby ensuring that only a single aldol condensation product is possible.

Interestingly, the first reports of aldol reactions utilised underivatised ketones and aldehydes with simple acid[27] or base[28] catalysis. The trend has been towards reactions using pre-formed enolates, which serve both to increase the driving force of the reaction and to ensure that the desired chemoselectivity is achieved. Numerous elegant procedures have been developed to this end[29] but they frequently require the use of reagents which are themselves somewhat noxious and result in the generation of significant quantities of waste containing metal salts such as Li^+ salts. Some routes use enol esters or silyl enol ethers but these are poor performers with regard to atom efficiency and often require the use of potentially polluting solvents and low temperatures.

In highlighting the solventless approach, the solids veratraldehyde, **1**, 4-phenylcyclohexanone, **2**, and indan-1-one, **3**, are reacted in various combinations affording aldol condensation products, with a high degree of conversion and a single major product, Scheme 1.[15] In the case of **1** and **3** a single condensation product is obtained as expected, since the aldehyde bears no α-hydrogen atoms and cannot therefore act as a carbon nucleophile. Compounds **1** and **2** may yield two products (a mono- and bis-adduct). The combination of **2** and **3** is less straightforward and a number of possible products may be envisioned including crossed aldol products with either ketone acting as a nucleophile, self condensation products of the ketones and a mixture of these two. Under solventless conditions, only one crossed aldol product is isolated. In stark contrast, for the reaction of compounds **2** and **3** in solution, without the use of a pre-formed enolate, a complex mixture of products results.[30] Attempted self-condensation of **3** under solventless conditions fails to give the condensation product.

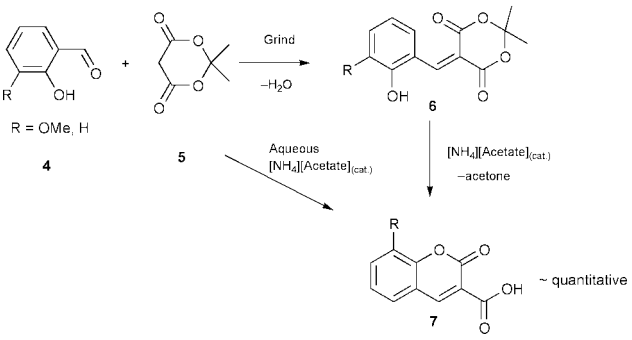
Where reaction occurs, a eutectic mixture, with melting point lower than the ambient temperature, results and the reaction mixture is in fact a *mutual solution* of the carbonyl compounds reacting together to yield a solid product which separates from this solution as the reaction proceeds.[20] This observation may provide insight into the remarkable selectivity of the ketone–ketone reaction involving **2** and **3** under these conditions, with the product arising from attack by a carbanion formed by indan-1-one on the electrophilic carbonyl carbon of 4-phenylcyclohexanone followed by spontaneous dehydration and sequestration of the product as a separate solid phase.

If dehydration occurs immediately and is *irreversible under the conditions of the reaction* the product is trapped and no equilibration occurs. The solid product appears to be insoluble in the reaction mixture and is effectively removed by this change in phase driving the reaction rapidly to completion. Stabilisation of the indanon-1-one carbanion intermediate leads to higher acidity of the α-hydrogen atoms and, as no equilibration is possible (as the product is removed from the 'reaction solution'), no products due to attack of 4-phenylcyclohexanone carbanions are noted.

Adopting the principles of Green Chemistry for the aldol condensation reaction, has resulted in establishing a new benchmark for minimising waste in these reactions while allowing for a greater degree of chemoselectivity than in solution. These are distinct advantages over the classical reactions in organic solvent. Moreover, intermediates formed by grinding together two solids and the base catalyst may be stored for months without impact on product quality, and this issue alone may be attractive in industrial applications of the solventless aldol reaction.

3-Carboxycoumarins

These compounds, **7**, can be readily prepared from 2-hydroxybenzaldehydes, **4**, and Meldrum's acid, **5**, by a room temperature reaction involving two solids or a solid and a liquid with a catalytic amount of ammonium acetate, Scheme 2.[16] The



Scheme 2

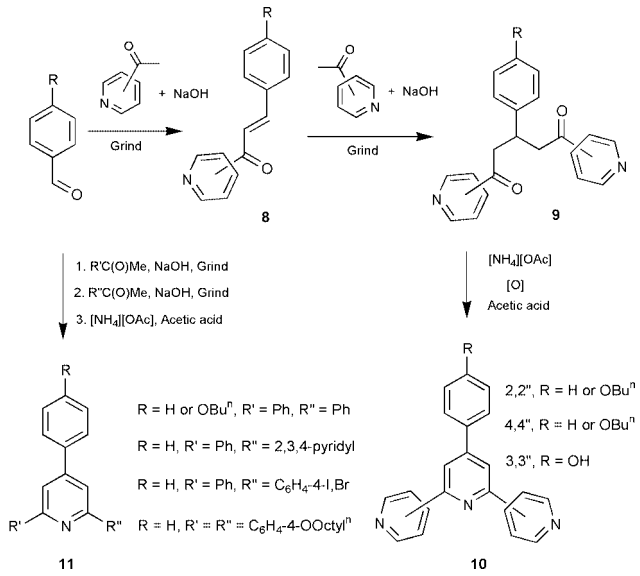
yields of **7** are quantitative, with no heating, and no use of organic solvent, with purification achieved by an aqueous wash. Alternatively the reactions can be carried out as slurries in aqueous solutions of ammonium acetate, despite the extremely low solubility of Meldrum's acid, **5**. As for the solventless reaction, the ammonium acetate solution can be reused without affecting product quality. The Knoevenagel reaction product (the benzylidene intermediate, **6**) can be isolated from a reaction mixture devoid of catalyst and further reacted, in the presence of the catalyst, either as a solid or in aqueous slurry to effect ring closure to the coumarin. Remarkably, the reaction of **4** and **5** to produce **7** proceeds *more* rapidly when carried out under aqueous slurry conditions. It is generally accepted that the 1,2-elimination in the Knoevenagel reaction is inhibited in protic solvents[31] and this provides a clue to an increase in the rate of the reactions in aqueous slurries. If the 1,2-elimination is inhibited and hydrolysis of Meldrum's acid and ring closure proceeds once the β-hydroxydiketone is formed, *i.e.* before or concomitantly with 1,2-elimination of water, then the longer lived the flexible β-hydroxydiketone, the more favourable are the conditions for coumarin formation and the more rapid the reaction.[16]

3-Carboxycoumarins represent an important class of biologically active compounds, and their synthesis is now more convenient, clean and efficient. There is no need for the use of polar aprotic solvents such as DMF or solvents in general, no heating is required, and minimal waste is generated.[16] The procedure becomes almost facile in its simplicity and equipment use is limited to vessels for stirring and suitable filtration devices. The Knoevenagel reaction of active methylene compounds with 2-hydroxybenzaldehdes has been extensively used in the first step in the synthesis of 3-carboxycoumarins. Knoevenagel himself described the solution phase condensation of 2-hydroxybenzaldehydes with malonic acid more than 100 years ago.[32] Numerous routes to 3-substituted coumarins have been published, including the use of noxious compounds such as $POCl_3$,[33] bases such as piperidine,[34] solvents such as DMF,[35] and, recently, a low-yielding 'solid phase' synthesis, utilising

ethyl malonate tethered to a Wang resin and suspended in pyridine.[36] A more benign method is a one pot microwave mediated synthesis which entails the use of a solid catalyst,[37] but this is not solvent free, unlike in our methods, Scheme 2, requiring removal of the product from the catalyst using a solvent, followed by extensive use of solvent for chromatographic purification.[37]

Synthesis of Kröhnke type pyridines

Despite the continual research and applications surrounding Kröhnke type pyridines and related compounds, the methodologies used to synthesise these compounds have changed little since a review article by Kröhnke in 1976,[38] which involves volatile organic solvents and displays only moderate to low yields with low atom efficiency. In applying the principles of Green Chemistry a new and indeed more versatile protocol has been established.[17–19] The aldol condensation of an enolisable ketone and a benzaldehyde followed by Michael addition of the enone, **8**, with a second enolisable ketone, both steps under solvent free conditions involving grinding with solid NaOH, leads to the quantitative formation of a 1,5-diketone, **9**, either symmetrical or unsymmetrical with respect to the aromatic rings, depending on the ratio of reactants and order of addition.[17–19] A Kröhnke type pyridine, either a terpyridyl **10**, or a bipyridyl or pyridine **11**, is then readily formed in high yield *via* a double condensation in the presence of ammonium acetate in acetic acid. Some of the types of compounds prepared using this new approach are shown in Scheme 3. Overall, this



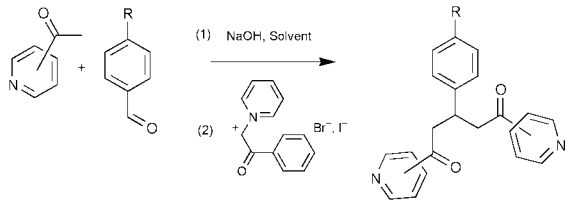
Scheme 3

solventless approach coupled with the ring closure in acetic acid allows access to a diverse range of oligopyridyls, including bipyridyls and terpyridyls (symmetrical and unsymetrical) which in many cases are not accessible using traditional methods, or are accessible only in low yields. Thus the Green Chemistry approach not only reduces the use of organic solvents and minimises other waste,[1] it allows access to new classes of compounds and associated applications. It is noteworthy that the new method is simple, occurs under mild conditions (improved energy usage), and has inherently lower costs.[18] In keeping with our 'green' approach we have also synthesised all non-commercially available starting alkoxybenzaldehydes and alkoxyacetophenones for **10** and **11** using recyclable polypropylene glycol as a low vapour pressure reaction medium.[11]

It is noteworthy that Kröhnke type pyridines and other substituted pyridines, including the related terpyridines, with their π-stacking ability, directional H-bonding and coordination properties, are prominent building blocks in both organic and inorganic supramolecular chemistry.[19,39–41] They also have luminescence properties,[42] with applications in liquid crystals,[43] photosensitisers,[44] and biochemical DNA binding reaction mechanisms.[45] Studies into the possible medical applications of substituted terpyridines have shown promising results, attributed to their ability to form complexes with metals, although the toxicity of previously synthesised materials has hampered clinical trials.[46] The significance of being able to synthesise such substituted terpyridines for use in pharmacological testing alone is reflected in the increasing number of associated international patents in recent years.[47]

The solventless reactions, Scheme 3, occur for combinations of liquids, liquids and solids, and solids. In a typical experiment, benzaldhyde and acetophenone are both colourless liquids at room temperature and upon addition of the NaOH the liquids immediately turn yellow indicating the formation of the enolate. By aggregating the reaction mixture in a mortar and pestle, the viscosity rapidly increases to form a tacky solid after *ca.* 5 min of constant mixing, which hardens after *ca.* 30 minutes as the solid aldol product, **8**. During the reaction between two solids the reaction mixture undergoes a phase transition into a eutectic melt. Grinding the solid starting materials in the absence of base, this eutectic phase can be reproduced, however, there is no observed conversion to the aldol product.

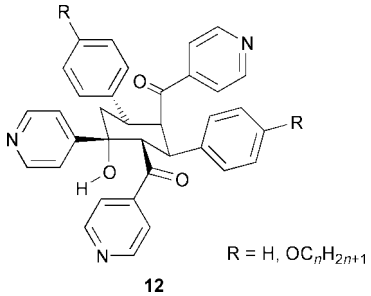
A conventional Kröhnke synthesis proceeds by treating an unsaturated ketone with the pyridinium salt formed by reacting halogenated-methyl ketone with pyridine, Scheme 4, to produce



Scheme 4

the Michael addition product **9**. Although this step is reported to be high yielding, the byproducts of the reaction generate significant waste and the reagents are expensive (see below). The direct reaction of the enone with an enolisable aryl methyl ketone in a basic solution proceeds to the 1,5-diketone,[48] thus eliminating the preliminary pyridinium salt formation. In the case of unsymmetrical compounds, there is no need to isolate the intermediate enone which is essentially formed quantitatively, thereby eliminating an intermediate purification step, and without the need to add more NaOH.

When the solvent based methods were adopted in an attempt to prepare **10**, 4,4″, R = *O*-alkyl, only the cyclohexyl product



12

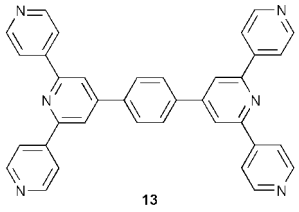
12 could be isolated from the complex reaction mixture which was devoid of target molecules. A recent paper describes the synthesis of **10**, 4,4″, R = H, under somewhat harsh conditions with a moderate 6% overall yield,[49] compared with 84% using the solventless approach.[17–19]

After the final ring closure reaction in acetic acid, addition of water results in precipitation of the product which can be collected and washed with ethanol. Although this stage of the

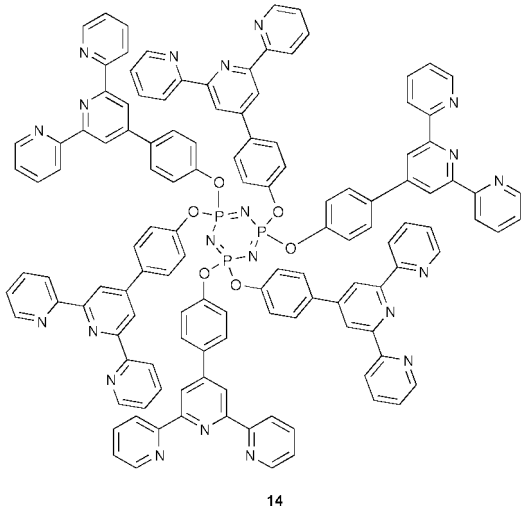
synthesis requires the use of a solvent, it should be noted that the low vapor-pressure of the acetic acid allows the use of an air condenser during the reflux, following the workup process the acetic acid can be efficiently regenerated and used as a batch process. The chosen solvent is also a naturally renewable source in alignment with the principals of Green Chemistry. Typically the traditional methods to prepare Kröhnke type pyridines generates as much as 29 times more solid waste than the 'greener' route to the same compound.[50] Moreover, even for a compound available in modest yield using traditional methods,[50] the 'greener' route is estimated to be 600% more cost effective, not taking into account the cost of energy usage and waste disposal, which is rapidly escalating. Then there is the new chemistry which is accessible, for example the synthesis of the complex molecules **13** and **14**.[50]

By utilising the above techniques, we have synthesised several novel building blocks, including **13** and **14**,[50] which have potential as supramolecular synthons, polymeric monomers, coordination ligands, mono- and di-cyclometallation ligands, and as molecules with pharmacological properties. The added halogen functionality on the terminal carbon of the alkyl chains in compounds also allows for great scope. As an example of the utility of the new pyridines now available in supramolecular chemistry, compound **10**, 4,4″, R = *O*-Octyl^n, forms hetero-multi-component molecular capsules with *C*-methylcalix[4]resorcinarene, Scheme 5.[19] The calix[4]resorcinarene is also readily prepared in high yield as the cavitand C_{4v} isomer under solvent free conditions[19] which dispenses with the need for using large volumes of acid and solvent (see below).[51] Overall, supramolecular chemistry is part of the drive towards sustainable technologies in nano-chemistry and beyond. Molecular capsules in general find applications in clean chemical synthesis,[52] drug delivery, materials and separation sciences,[53] and they are structurally related to components in biological systems such as those in viruses.[54]

The molecular capsules contain microenvironments of solvent, either four toluene molecules, or if a trace of diethyl ether is present, two diethyl ether molecules and two toluene molecules, which has implications in separation technology. Both capsules have been structurally authenticated, with the structure of the latter shown in Fig. 3, and are held together by



13

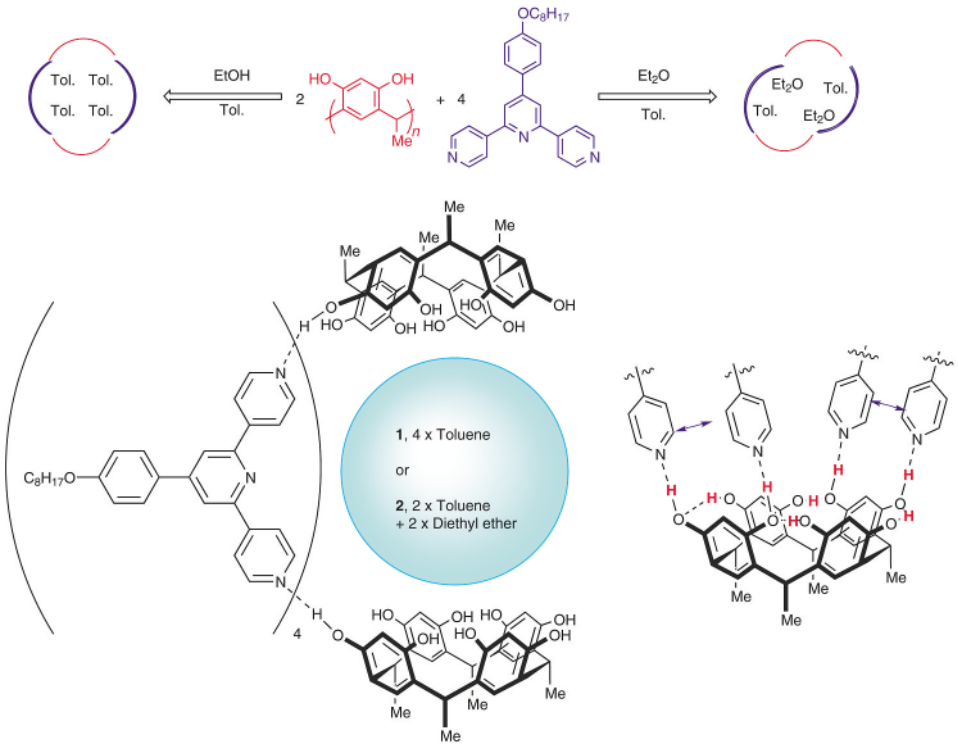


14

a total of 8 N···HO hydrogen bonds, and π-stacking associated with pairs of terpyridines.

Cavitands: calix[4]resorcinarenes, cyclotriveratrylene (CTV) and related molecules

The synthesis of *calix[4]resorcinarenes* was first reported in the late 19th century by Baeyer[55] and in spite of the increased interest in such compounds the synthetic methodology used has changed little. This typically involves heating resorcinol and the appropriate aldehyde to reflux for hours to days in a mixture of mineral acid and alcohol (usually a 2 : 2 : 1 ratio of ethanol, water



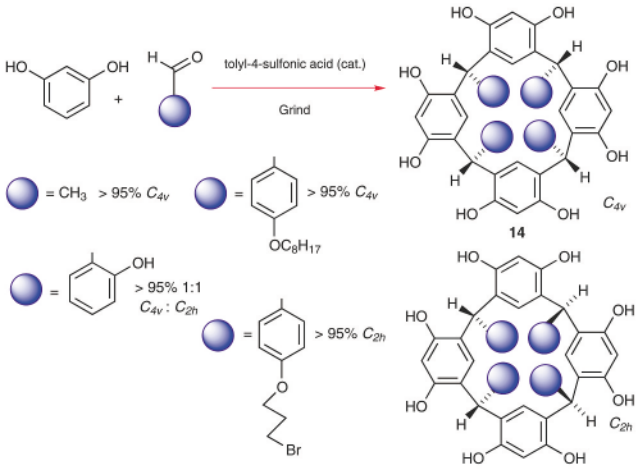
Scheme 5

and concentrated HCl).[56] In applying the principles of Green Chemistry *C*-aryl and *C*-methylcalix[4]resorcinarenes are now accessible in substantially higher yields and high purity by the direct reaction of resorcinol and aldehyde in the presence of a catalytic amount of solid acid, tolyl-*p*-sulfonic acid, at ambient temperature, under solvent-free conditions with grinding for a few minutes, Scheme 6.[11,19] This represents a significant improvement on the traditional solution phase methodology with respect to energy usage, solvent wastes and associated hazards, reaction time and yield. In addition, and again applying the principles of Green Chemistry, the relevant benzaldehyde derivatives are prepared in polypropylene glycol, which is readily recycled. Calix[4]resorcinarenes find applications as supramolecular tectons[19,57] and host molecules,[58] as components in liquid crystals,[59] photoresists,[60] selective membranes,[61] surface reforming agents,[62] HPLC stationary phases,[63] as ion channel mimics[64] and metal ion extraction agents.[65]

As noted previously,[7,20] the reaction mixtures are viscous liquids or pastes even where all reagents are solids; the melt formed on mixing the reagents stiffens within minutes to yield a sticky solid that hardens further on standing. This material is mainly the product **14** and purification involves washing with water to effect removal of the catalyst, followed by recrystallisation from hot methanol where required.

Calix[4]resorcinarenes commonly occur in two isomeric forms, namely the *rccc* or C_{4v} and the *rctt* or C_{2h} isomers.[66] For *C*-methyl- and *C*-C_6H_4-4-*O*-Octyl^n–calix[4]resorcinarenes the C_{4v} isomer results, whereas for *C*-C_6H_4-2-OH–calix[4]resorcinarene the C_{2h} isomer predominates and, for *C*-C_6H_4-4-O$(CH_2)_4$Br–calix[4]resorcinarene, a mixture of the two isomers is obtained (Scheme 6). The predominance of the C_{2h} isomer contrasts with molecular modelling calculations,[11] which indicate that the C_{4v} isomer in the crown conformer is favoured over the C_{2h} isomer in the chair conformer (in the absence of solvent effects) by 6.3 and 14.4 kcal mol^{-1} for *C*-C_6H_4-4-*O*-Octyl^n–calix[4]resorcinarenes and *C*-C_6H_4-4-O$(CH_2)_4$Br–calix[4]resorcinarene respectively. Altering the reaction time does not lead to an increase in the formation of the C_{4v} isomer.

CTV and related molecules, **16**, are versatile supramolecular host molecules, recently gaining prominence in forming complexes with large globular molecules such as fullerenes and



Scheme 6

carboranes,[67,68] yet the synthesis of these host molecules has changed little since their discovery earlier last century.[69] CTV is formed by the harsh acid catalysed condensation of veratryl alcohol **15**, or veratrole and formaldehyde. In focusing on more benign syntheses, two new methods have been developed, solventless and the use of an ionic liquid as a reaction medium, both providing reasonable yields yet being low waste generating, Scheme 7.[7] The solvent free method is particularly well suited to the analogues of CTV derived from the corresponding benzyl alcohol which are sensitive to strongly acidic conditions, while condensation in the ionic liquid N_{6444} Amide facilitates the condensation of liquid or molten benzyl alcohol monomers to the cyclic trimers. While the yields from the solventless reactions carried out at room temperature are modest, 41–59%, these are readily improved by the use of elevated temperatures.[70] The trimer is more easily isolated than in traditional syntheses, and only a catalytic amount of acid is required, the volume of solvent used is hugely reduced and is only associated with product purification. Phosphoric acid proved the best catalyst as solid tolyl-*p*-sulfonic acid results in the formation of solid product shells around the catalyst, effectively rendering the catalyst inactive.[7] Organic solvents used in product isolation are not heated above ambient temperature, thus reducing the difficulties associated with containment of vapours.

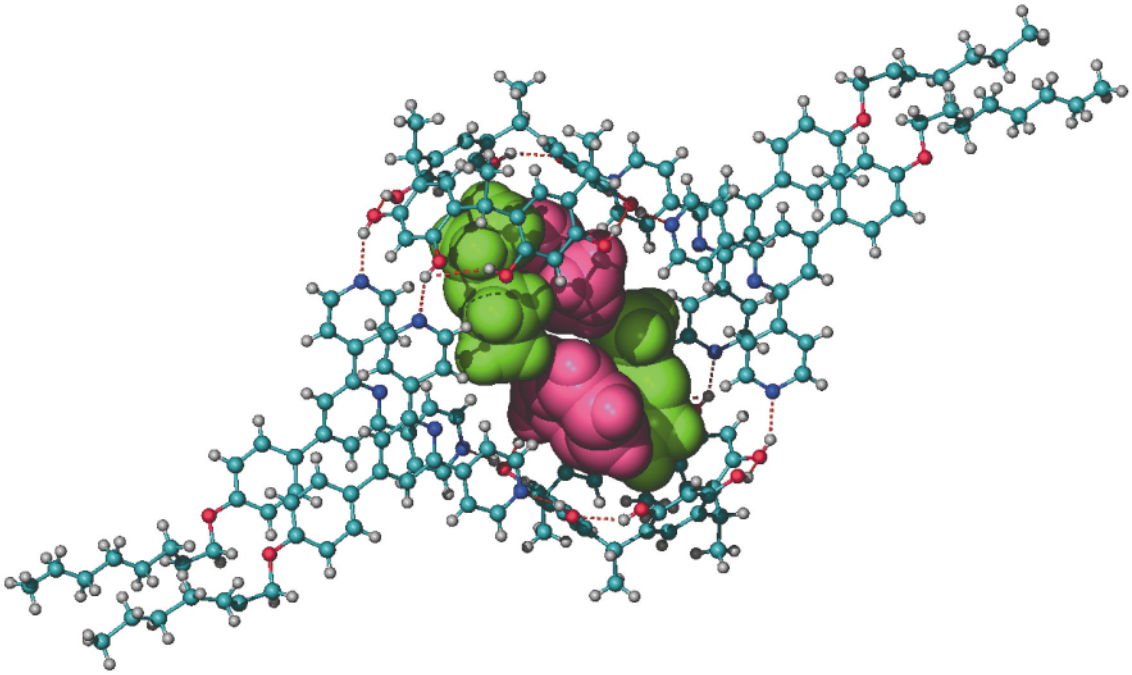


Fig. 3 Structure of [{$(OEt_2)_2$(toluene)$_2$}⊂(*C*-Methylcalix[4]resorcinarane)$_2$ (**10**, 4,4″, R = –*O*-Octyl^n)$_4$].

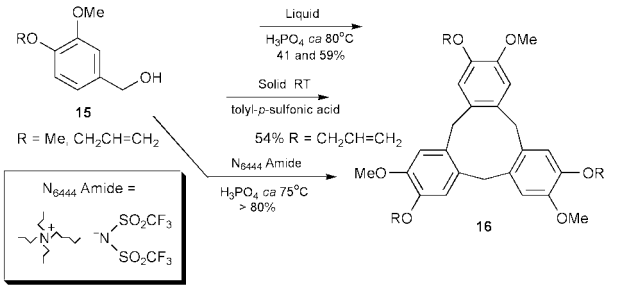

Scheme 7

In the case of the ionic liquid method, the reaction of **15** with a catalytic amount of phosphoric acid affords the trimer in very high yield, >82%, and the non-volatility of the ionic liquid provides unique recycling possibilities. Indeed it can be recycled five times before product quality is compromised and the scheme for recycling the ionic liquid is shown in Fig. 4. The

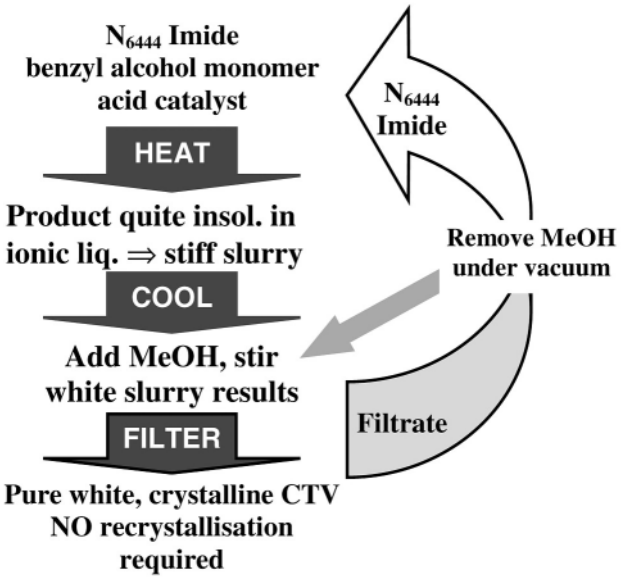

Fig. 4 Procedure for recycling of ionic liquid N_{6444} Amide in the synthesis of CTV. This anion is also commonly described in the materials and electrochemistry literature as the bis(trifluoromethylsulfonyl)*imide* ion, hence the abbreviation N_{xyyy}*Imide*.

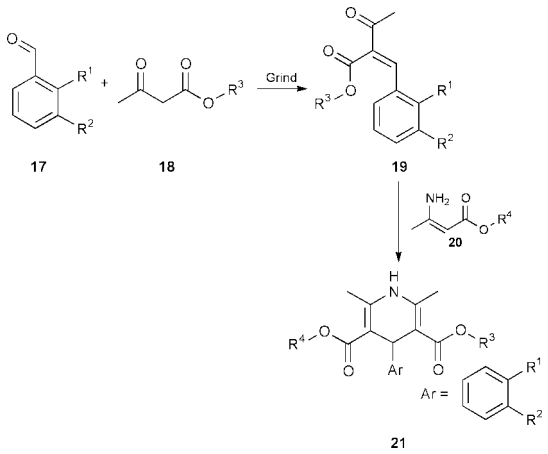
methanol used in the scheme can be removed by distillation and recycled. The high yielding reaction occurs in an ionic liquid which is strongly hydrophobic and with the negative charge on the anion diffuse and partially protected.[7] The low equilibrium concentration of water in the reaction mixture assists in driving the reaction to high yield, the excess water being continuously lost as vapour. The properties of the ionic liquid which favour the trimerisation reaction underscores the need to develop a wide range of ionic liquids of varying properties, and this is an important part of the rapidly expanding research in ionic liquids.[5–7]

Therapeutic agents

4-Aryl-1,4-dihydropyridines such as **21** are potent calcium channels agonists and antagonists and are extensively used in the treatment of cardiovascular disease (CVD),[71] which is one of the leading causes of death the world over (for example, 41.4% of deaths in the USA in 1996 were a result of CVD).[72] Following the two step regime illustrated in Scheme 8 (and similar to most industrially used synthetic routes to such unsymmetrically substituted dihydropyridine derivatives), but using solventless reaction conditions, leads to a vast improvement in extent of conversion and isolated yield while delivering significantly shortened reaction times, batch sizes that are defined only by the quantity of drug to be produced and



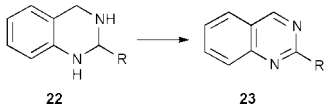
Scheme 8

concomitant improvements in energy utilisation.[73] Volatile organic compound (VOC) use is restricted to product recrystallisation, in turn facilitated by the high degree of conversion achieved which results in low quantities of residual starting materials or impurities.

The simplicity and efficacy of the solventless methodology may again be contrasted with the various strategies that have been employed to maximise conversion and minimise reaction time in traditional solvent-phase syntheses. These include azeotropic removal of water,[76–76] catalyst optimisation,[74,77] and selective deesterification of diesters using acid catalysts.[78] Reaction times are of the order of 2 to 40 hours and overall yields for the two step synthesis are significantly lower than quantitative (30 to 65%). Extractive workups[79] and the need to separate symmetrical diester byproducts from the desired product[74] serve to increase the usage of volatile organic compounds and decrease efficiency with respect to yield and number of process steps.

These reactions proceed at ambient temperature but, in common with the solution phase methods, more rapid conversion is achieved at elevated temperatures. To gain further understanding of these reactions, we have studied the rate of formation of the products **19** and **21** and find that it is possible to optimise reaction conditions with respect to maximum rate of conversion *vs*. energy use.[73]

Remarkable improvements in yield, energy use and waste minimisation are also achieved in the synthesis of 1,2,3,4-tetrahydroquinazolines **22** and the related fully aromatised quinazolines **23** (Scheme 9).[80] These compounds are biologically



Scheme 9

active[81] and derivatives are of interest as dihydrofolate reductase inhibitors,[82] antitubercular[83] and antibacterial agents.[84]

Mechanistic considerations

That many of the solventless reactions discussed above involve the reaction of macroscopic solid organic particles, yet proceed *via* a liquid or melt phase is intriguing and has formed the basis of a detailed study of several organic reactions.[20] Some of these reactions have been reported to proceed 'in the solid phase' but clearly involve the formation of a liquid phase. Catalytic transformations, including aldol condensations and oligomerisation of benzylic compounds to form cavitands, proceed *via* a liquid phase, as do many non-catalytic reactions including Baeyer–Villiger oxidations, oxidative coupling of naphthols using iron chloride, condensation of amines and aldehydes to

form azomethines, homo-etherification of benzylic alcohols using tolyl-*p*-sulfonic acid, and nuclear aromatic bromination with NBS.[20] This liquefaction implies the existence of a eutectic mixture with T_{fusion} below ambient temperature (although both reagents have higher than ambient melting points). In cases where heating is required, it is again clear that a phase change (from solid to liquid) occurs, explaining the observed reaction kinetics. We have previously examined a number of experimental examples,[20] and these along with the examples described above provide the basis for a description of such reactive systems involving intervention of a liquid phase resulting from the occurrence of a eutectic (or peritectic) melt phase. When considering reactions between solids it is important to distinguish between **solid phase synthesis** (the reaction of molecules from a fluid phase with a solid substrate as in the polymer-supported peptide syntheses); **solvent-free synthesis** (any system in which neat reagents react together, in the absence of a solvent); and **solid-state synthesis** or **solid-solid reactions**, in which two macroscopic solids interact *directly* and form a third, solid product *without intervention of a liquid or vapour phase*. A cartoon of these three processes is shown in Fig. 5. Numerous reactions such as those resulting in

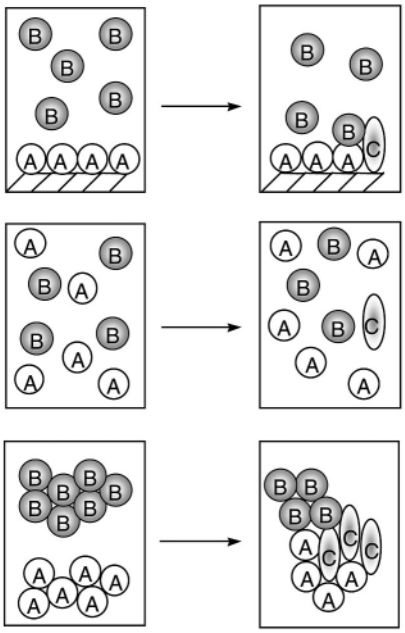


Fig. 5 Cartoon of solid phase reaction (top), solvent-free reaction (middle), and solid-state reaction (bottom).

the formation of a complex such as a charge-transfer or molecular complex,[85] reactions in a single crystalline phase such as photochemically induced solid-state transformations,[86] or the reaction of two components that crystallise together to form a discrete stoichiometric co-crystal (or inclusion compound), may be considered to occur in the solid phase.[87] However, it may be demonstrated that many reactions between discrete solid particles are actually reactions in a liquid melt phase.[20]

In the aldol condensation, observation of the phase resulting on grinding together the solid aldehydes or ketones *without* addition of the base catalyst, reveals that in some cases a liquid melt forms while in others the solid reagents occur as mechanically mixed, discrete crystalline phases (as verified by powder X-ray diffraction studies). More importantly, upon addition of the solid base catalyst, reaction is *only* observed in those systems that exhibit a phase change to a melt.[15] Thus, *the existence of a liquid phase is a prerequisite for reaction in these systems!* In systems such as these, which require addition of an acid or base catalyst, it is possible to construct the phase diagram for the two component reagent mixture. Measurement of thaw and liquidus points for the system indan-1-one **2** and 4-phenylcyclohexanone **3** yields Fig. 6. The eutectic temperature of 19 °C is below the ambient temperature of the reaction experiments. However, it is interesting to note that at a 1 : 1 mole ratio of **1** : **2** the liquidus temperature is above ambient *T*, implying that some unmelted solid **2** would be present. This is not observed in the bulk samples and may indicate the tendency of the system to supercool.[88] In addition, this implies that some heat is released on grinding of the two components which leads to complete melting of the mixture. Such heat may be generated by the occurrence of 'hot spots'[89] during initial grinding of the solids and this phenomenon should be carefully considered when high intensity grinding techniques, such as ball milling, are employed (even in cases where temperature-controlled apparatus is used).

Similar melt behaviour is noted in a number of reactions and, for example, trimerisation of benzylic alcohols, achieved by grinding 4-allyloxy-3-methoxybenzylalcohol with one equivalent of tolyl-*p*-sulfonic acid, yields a viscous melt that solidifies over a period of days yielding **16**, R = allyl (Scheme 7), which separates as a microcrystalline solid. Once again, this solvent-free reaction is not a solid–solid reaction in spite of the relatively high melting points (86 °C and 103–105 °C, respectively) of both reagents. One mole of water is produced for each mole of benzyl alcohol condensed, but this does not account for the apparent liquefaction of the reaction mixture. Although the viscosity of the monomer–acid mixture is lowest directly after the grinding of the two components, TLC analysis reveals < 5% product at this point. Thus, the water present is derived chiefly from the monohydrate catalyst and would be insufficient to achieve dissolution of the very sparingly soluble benzyl alcohol monomer.

Highly efficient solventless transformations of benzaldehyde and aniline derivatives have been reported previously,[90] and the reaction between *o*-vanillin **24** and *p*-toluidine **25** to yield the azomethine product **26** (Scheme 10), provides a striking example of a melt phase on mixing of the solid reagents.

Mixing of the finely powdered reagents (without grinding) immediately yields a bright orange fluid that has a low viscocity and may be drawn into a pasteur pipette as illustrated in Fig. 7. This liquid rapidly solidifies yielding a bright orange crystalline solid that is slightly wetted (presumably by the water produced in the condensation reaction). As with many solventless reactions, reaction is rapid and conversion virtually quantitative. Aside from drying, no further purification is required.

Clearly many of the so-called 'solid–solid' reactions are not reactions in the solid-state. Solid–solid reactions occurring between two discrete crystalline solids, without intervention of

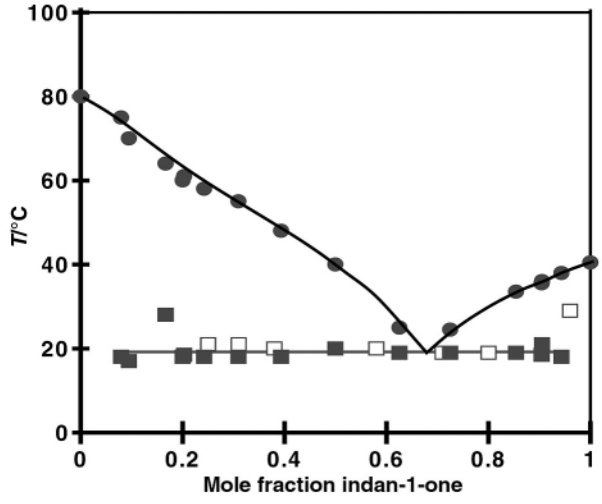

Fig. 6 Phase diagram of indan-1-one **1** and 4-phenylcyclohexanone **2** at constant (ambient) pressure. Filled circles represent liquidus temperatures, filled squares, thaw points, and open squares the onset temperature of the first endotherm measured by DSC analysis.

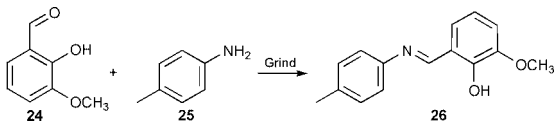

Scheme 10

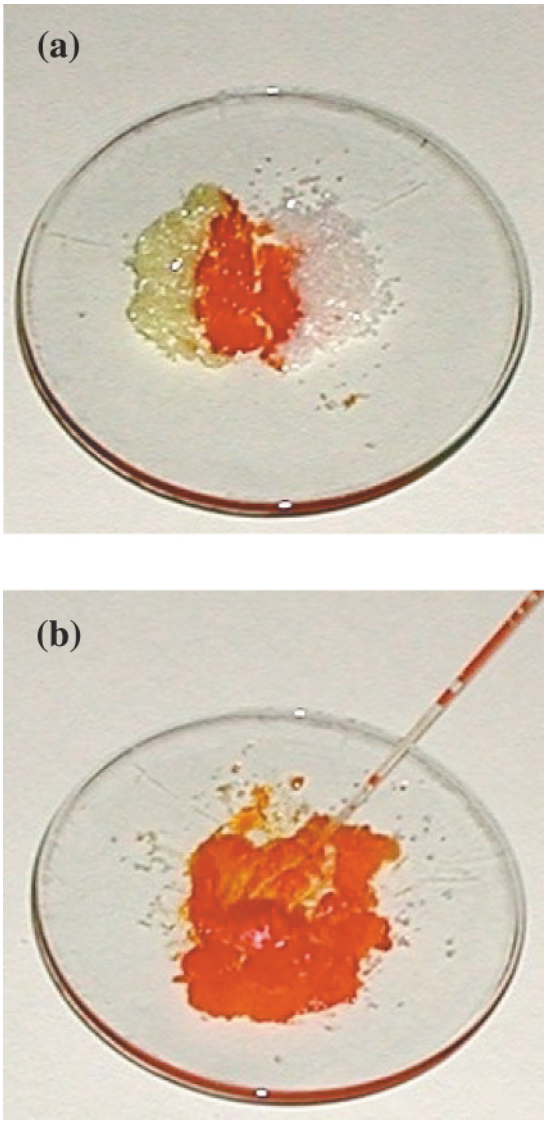

Fig. 7 Photographs of liquid phase formed upon mixing of *o*-vanillin and *p*-toluidine. (a) Pale yellow crystalline *o*-vanillin (left) and white crystalline *p*-toluidine (right) form an orange liquid phase upon contact. (b) The orange liquid phase is fluid enough to be drawn into a Pasteur pipette and solidifies rapidly to form the orange crystalline solid azomethine product.

a mobile phase (which allows a large number of productive molecular collisions) would be expected to exhibit diffusion-controlled kinetics.[91] Thus, the rapid rates noted do not support the theory of two solids reacting together without intervention of a new (liquid) phase that enables higher substrate mobility.[20]

A description of the behaviour noted is described: upon mixing of the reagents, a melt of mutually miscible A and B exists, so that these may be considered to be *mutually soluble*. In the reaction A + B ⇒ C, the overall phase equilibria may be represented by a triangular prism as shown in Fig. 8a. In this prism each rectangular face represents one binary diagram (AB, AC *etc*.).[92] Since the reactions are not thermally isolated these approximate systems at constant *T*, and the chemical and phase composition may be represented by triangular cross sections of the prism such as the central triangle in Fig. 8(b) which represent a cross-section at *T*1. This figure illustrates the situation where the temperature is above that of the binary eutectic formed by A and B (and above the binary eutectics formed by A and C, B and C and the ternary eutectic formed by A, B and C). Thus as A and B react in 1 : 1 stoichiometry to form product C the composition changes along the line qC. The liquid phase, initially composed of 1 : 1 A : B, becomes enriched in C until the liquidus line is crossed and C begins to crystallise out of the melt. At complete conversion the only phase present will be a solid, crystalline C. As the quantities of A and B, relative to each other, remain constant throughout the reaction, a vertical section of the triangular prism such as Fig. 8c can be used to depict the phase equilibria occurring. Each face of the prism is in fact a two component diagram such as that appended to the base of the triangular cross section in Fig. 8b. It may be illustrated that a number of reactive systems exhibit 2 component phase diagrams AC and BC such as those represented as dotted rectangles appended to the sides of the triangle (Fig. 8b).

Overall, these reactions should therefore be classified together with classical liquid–liquid and liquid–solid systems that react in the absence of an added solvent such as many of the solid–liquid or liquid–liquid systems presented above.

Future trends

The remarkable versatility and success of using solventless reactions to prepare several classes of compounds demonstrates that this methodology has an important place in the toolbox arsenal for Green Chemistry. In accepting the enormous challenge of Green Chemistry in the march towards sustainability, new chemistry can emerge as well as access to compounds not possible using traditional methods, and on this

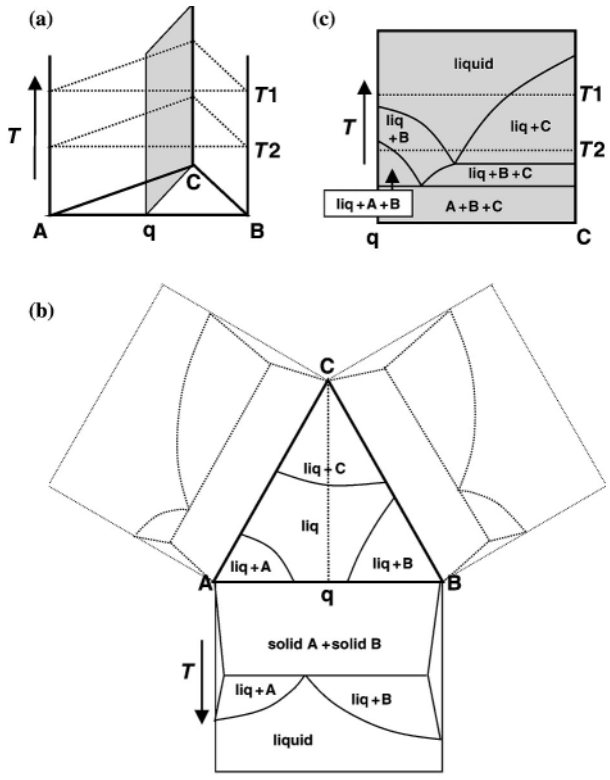

Fig. 8 (a) Triangular prism basis for a 3 component phase diagram at constant *P* (vertical axis represents increasing *T*). Consideration of cross sections such as *T*1 and *T*2 allow analysis of the phases occurring at various component concentrations at a specific, constant temperature. (b) Represents a cross section of this prism at a particular temperature (central triangle) greater than the AB, BC, AC or ABC eutectic temperature (note liquid phase at *C* = 0). (c) Diagram representing constant A and B composition of 1 : 1 mole ratio with increasing *T*. Moving along the dotted lines marked *T*1 and *T*2 indicates the phase changes occurring as *C* increases.

issue alone, the results challenge the classical approach of using volatile organic solvents in synthesis. Green Chemistry is an area of chemistry where applied and fundamental research collapses with a common thread of sustainability. It also challenges the description of certain classes of reactions between organic solids as being solid state reactions. Applying the principles of Green Chemistry has led us into developing new building blocks for supramolecular chemistry, and establishing protocol for organic synthesis. In this context then the question is: 'why wouldn't you want to embark on research in Green Chemistry?'

Sustainable silver and copper nano-contacts showing quantized conductance are prepared at a gap between two thin gold wires in solution.

Facile preparation of metal nano-structures, such as nano-wires and nano-gaps, has become an important subject in recent nano-technologies. The techniques enable us to evaluate various characteristics of nano-structures, such as quantized conductance, single-electron charging, and specific conductivity of a single organic molecule, which are useful for the fabrication of novel devices such as quantum devices.[1] Of various possibilities to fabricate nano-structures on solid surfaces, chemical techniques are of much interest because they give stable and self-ordered structures by low-cost processes.[2–4] Especially, an electrochemical method is one of the most promising techniques[4] since the control of the electrode potential leads to precise control of atomic processes on solid surfaces.[5]

Recently interesting examples have been reported[6–11] on the fabrication of nano-junctions *via* electrochemical processes and on the observation of the conductance quantization. The nano-junctions are prepared either at a gap between the tip and the substrate of a scanning tunneling microscope (STM)[6–8] or a gap between two micro-electrodes prepared by photolithography.[9,11] Another interesting method is to use the electrochemical dissolution and deposition of a thin metal wire in solution. This method is one the simplest and very useful if sustainable nano-contacts can be prepared reproducibly. At present, only one example is reported[10] for a Cu wire though the detailed preparation method is not reported.

In this paper, we report the successful observation of the quantized conductance in sustainable Cu nano-contacts, prepared by the electrochemical dissolution and deposition of Cu wires. We also report that the method is extended to the preparation of nano-contacts of various other metals such as Ag by use of the electrochemical deposition and dissolution of the metals at a stable gap such as an Au gap. This gives an interesting way to prepare nano-contacts of a variety of metals, for the fabrication of nano-contacts in solution are now only limited to Cu[7–10,12] and Au.[6,11]

The metal nano-contacts were prepared as follows. A Cu or Au wire (30 μm in diameter, 99.95% purity) was attached to a glass plate with adhesive insulating tapes, with a region of a few hundred μm in width being left as a gap, at which the metal wire could be in contact with an electrolyte solution. The electrochemical dissolution of the metal wire at the gap resulted in the formation of a thin metal wire with a diameter of a few μm (Fig. 1). Further dissolution led to the disconnection of the wire, which was easily detected by simultaneous measurement of its conductance. The nano-contact was formed just before the wire was disconnected. The formation of Ag nano-contacts was performed by the controlled deposition and dissolution of Ag at the gap of an Au wire.

A potentiostat (Toho Technical Research, 2001) and a programmed function generator (Toho Technical Research, FG-02) were used to control the potential of the thin metal wire with respect to the Ag/AgCl reference electrode. The current flowing through the thin metal wire under a constant bias (18.8 mV) was measured in the course of its electrochemical dissolution and deposition with an electrometer (Keithley 6517A), to obtain the conductance.

Fig. 1 shows an example of a thin Cu wire with a diameter of a few μm, prepared by the electrochemical dissolution of a Cu wire (d = 30 μm) for 3 min in 0.1 M H_2SO_4 + 1 mM $CuSO_4$ (M = mol dm^{-3}) at 0.3 V *vs.* Ag/AgCl, which is *ca.* 0.17 V more positive than the equilibrium potential for Cu dissolution (0.13 V). By this method, a long sustainable thin metal wire of approximately 100–300 μm in length was successfully prepared.

After the preparation of the thin Cu wire, the potential was changed from 0.3 to 0.2 V to cause further slow dissolution. The current flowing through the thin metal wire decreased with time and finally became zero, indicating that the wire was broken. Just before the wire was broken, the current showed stepwise changes, as shown in Fig. 2(a). The conductance of the Cu wire, calculated form the current and the bias voltage, is also shown on the right axis of the figure in units of quantized conductance ($G_0 = 2e^2/h$). A unit conductance of 1 G_0 is clearly observed for a long time of about 8 s. It is likely that the half unit conductance, 1/2 G_0, is also observed. Repeated experiments have shown that the conductance of 1 G_0 continues for 10 to 100 s. The observation of the unit quantized conductance indicates the formation of a Cu nano-wire consisting of a few Cu atoms. Essentially the same behavior was reported in Cu nano-contacts prepared at a gap of Cu wires[10] and a junction of electrochemical STM.[7,8]

We also succeeded in preparing sustainable Cu and Ag nano-contacts at a gap between two thin Au wires. The dissolution of an Au wire (d = 30 μm) proceeded in 0.5 M KCl when the potential was kept at 0.8 V or more positive,[13] leading to the

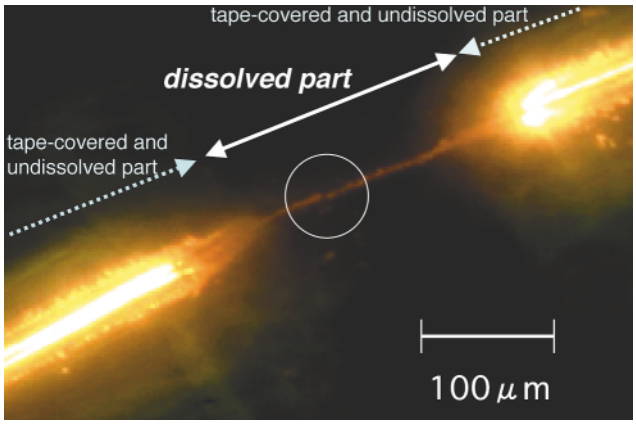

Fig. 1 Optical microscopic image of a thin Cu wire (d = 1–2 μm) prepared by electrochemical dissolution of a thick Cu wire (d = 30 μm) at 0.3 V *vs.* Ag/AgCl. The circle shows the broken part of the thin Cu wire, caused by further slow dissolution at 0.2 V.

 DOI: 10.1039/b106961f

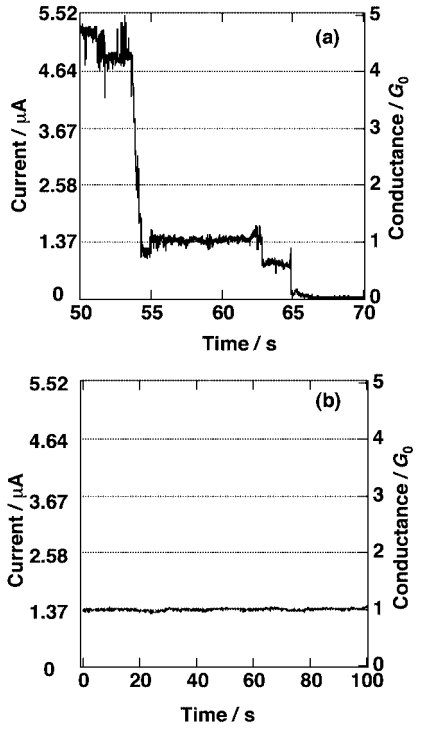

Fig. 2 Time courses of the conductance during the electrochemical dissolution of (a) a Cu wire and (b) Cu deposited at a gap of Au wires. The potential for the Cu dissolution was 0.03 V *vs.* Ag/AgCl; electrolyte: 1 mM $CuSO_4$ + 0.1 M H_2SO_4.

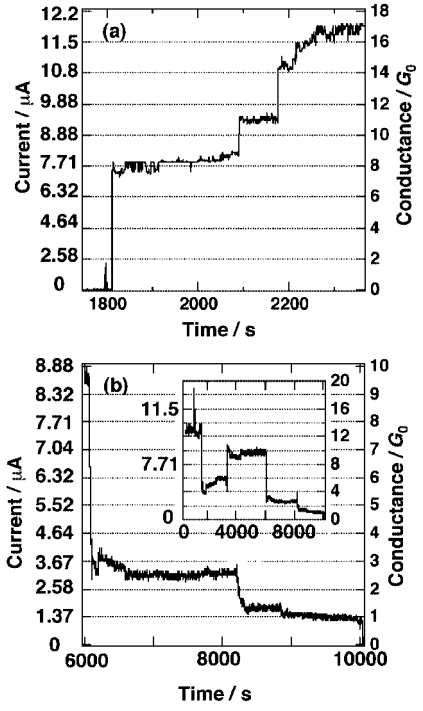

Fig. 3 Time courses of the conductance (a) during the electrochemical deposition of Ag at a gap of Au wires at −0.1 V, and (b) during the electrochemical dissolution of the deposited Ag at 0.3 V; electrolyte: 1 mM $AgNO_3$ + 0.05 M H_2SO_4

formation of a thin Au wire and finally disconnection. After the formation of a gap in a thin Au wire, Cu was deposited on it at 0.3 V in 0.1 M H_2SO_4 + 1 mM $CuSO_4$. Several repeated Cu deposition and dissolution cycles led to the formation of Cu nano-contacts showing unit quantized conductance lasting for 100 s or more [Fig. 2(b)]. The result indicates that a gap between two thin Au wires can be used effectively for the fabrication of sustainable nano-contacts of other metals.

Fig. 3 shows results of similar experiments for the deposition and dissolution of Ag at a gap of thin Au wires. Ag was deposited on Au when the potential of Au was kept at −0.3 V in 0.05 M H_2SO_4 + 1 mM $AgNO_3$, which is about 0.7 V more negative than the equilibrium potential for Ag dissolution (0.4 V). The deposited Ag was dissolved at 0.44 V. The stepwise changes of the conductance were observed both for the deposition of Ag [Fig. 3(a)] and the dissolution of it [Fig. 3(b)]. In the latter case, unit conductance, G_0, was observed for a long time of more than a 1000 s. The results again clearly show the formation of sustainable metal nano-contacts showing quantized conductance, indicating the effectiveness of the present method.

It may be noted in Fig. 3 that the conductance at several current plateaus show conductances different from integral multiples of the unit conductance (G_0). Similar behavior is also observed for Cu nano-contacts [Fig. 2(a)]. Such deviations are often observed in electrochemical systems, as reported by other workers,[6,12] The formation of certain characteristic configurations of metal atoms[14] in electrolyte solutions may be responsible for the deviations, since it is plausible that the structure of the metal nano-contacts depends on the nature of the solvent and electrolyte ions used.

In conclusion, sustainable metal nano-contacts showing conductance quantization have been successfully prepared by electrodeposition and dissolution of Cu and Ag metals at a gap of Au wires. Especially, the Ag nano-contacts, which were prepared for the first time in the present work, showed unit quantized conductance for more than 1000 s. The technique may be applied easily to various metals and other materials, whose structures can be controlled by electrochemical process, to investigate detailed properties of nano-contacts in solution.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

First published as an Advance Article on the web 5th October 2001

A new polynuclear copper(II) complex $[Cu_7(OH)_6Cl_2(pn)_6(H_2O)_2](C(CN)_3)_4Cl_2$ with hydroxo-bridging ligands has been prepared; the centrosymmetric cluster cation can be described as two Cu_4O_3Cl distorted cubane units sharing one copper cation.

Various multinuclear copper(II) complexes have been reported in the last decade with a great number of simple and sophisticated bridging ligands;[1–5] however, some nuclearities remain comparatively scarce. In the case of tetranuclear complexes with Cu_4O_4 cubane-like clusters some examples have been thoroughly described,[2] but to date little is known about clusters involving more than four metal centres.[3,4] Concerning the heptanuclear copper(II) clusters, as far as we are aware, only one example of the dicubane-like type has been described.[5] Here we report the structure and preliminary magnetic studies of a novel vertex sharing dicubane-like heptanuclear copper(II) cluster $[Cu_7(OH)_6Cl_2(pn)_6(H_2O)_2](tcm)_4Cl_2$ (**1**) [pn = 1,3-diaminopropane; $tcm^- = C(CN)_3^-$ = tricyanomethanide] with chloro- and hydroxo-bridging ligands.

1.00 mL (12 mmol) of 1,3-diaminopropane (pn) was slowly added to a warm aqueous solution of $CuCl_2{\cdot}2H_2O$ (12 mmol) and then an aqueous solution of sodium hydroxide (12 mmol) was added. To the resulting clear solution were immediately and consecutively added concentrated aqueous solutions of $CuCl_2{\cdot}2H_2O$ (2 mmol) and potassium tricyanomethanide (8 mmol). Slow evaporation gave prismatic blue crystals of $[Cu_7(OH)_6Cl_2(pn)_6(H_2O)_2](tcm)_4Cl_2$ (yield 1.28 g, 42%) suitable for crystallography.‡ The structure of **1** is unique and consists of a centrosymmetric hydroxo-bridged heptanuclear copper(II) cation (Fig. 1) which can be described as two Cu_4O_3Cl distorted cubanes which share one copper cation (Cu1) (Fig. 1 and 2). The four crystallographically independent Cu(II) centres differ markedly in their co-ordination geometry. The central atom (Cu1) presents a strongly elongated octahedral coordination which involves a CuO_4 equatorial plane with essentially equivalent Cu–O bonds [see Fig. 2(a)] and two semi-coordinated Cl anions in axial positions (Cu···Cl = 3.029(2) Å). The Cu2 and Cu3 cations have distorted square pyramidal CuO_2N_2Cl environments. In both cases, the basal planes are occupied by two hydroxo bridging ligands (O1 and O3 for Cu2; O2 and O3 for Cu3) and two nitrogen atoms of the chelating pn ligand (Cu–O range 1.977–2.016 Å and Cu–N range 1.975–2.021 Å). Both pyramids share a strongly elongated axial position filled by the bridging Cl1 atom (Cu2–Cl1 = 2.654(2) Å and Cu3–Cl1 = 2.679(2) Å) (Fig. 1). The co-ordination

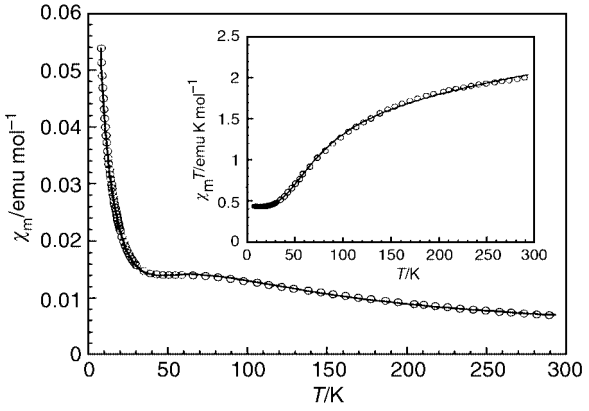

Fig. 3 Plots of molar susceptibility χ_m *vs.* T (the inset shows the $\chi_m T$ product *vs.* T) for **1** measured in a field of 1 T. The solid line was calculated using the magnetic coupling model (see text).

polyhedron of the Cu4 cation can be described as a $Cu(N_2O_2)(O_2)$ pseudo-octahedron generated by a CuN_2O_2 plane arising from two nitrogen atoms of the chelating pn ligand and the two μ_3-hydroxo ligands (O2 and O3), and two axial positions filled by the O1 hydroxo ligand and a water molecule (O4) (Cu···O4 = 2.524(4) Å). Note that the O1 hydroxo ligand may be viewed as a μ_2-bridging group since it involves two short and one long Cu–O distances as clearly shown on Fig. 2(a). Further examination of the structure shows that the tcm units, which usually act as μ_2- or μ_3-bridging ligands, are here uncoordinated; however, there are significant hydrogen bonds formed between their nitrogen atoms and the hydroxo-bridging ligands [N7(tcm)···O2 = 2.826(6) Å, O1–H···N7 = 167.3(3)° and N8(tcm)···O1 = 2.961(6) Å, O1–H···N7 = 160.6(2)°]. Such intermolecular hydrogen bonds may contribute to the stabilisation of the cluster conformation.

Magnetic susceptibility data for **1** were collected in the temperature range 2–300 K, the χ_m and $\chi_m T$ product *vs.* T plots are depicted in Fig. 3. From room temperature down to 25 K the $\chi_m T$ product decreases continuously and then reaches a plateau close to 0.43 emu K mol^{-1}, which corresponds to an $S = 1/2$ ground state. This behaviour is indicative of an overall antiferromagnetic coupling between the Cu(II) centres; this is in agreement with the strongly reduced magnetic moment at room temperature ($\chi_m T$ = 2.01 emu K mol^{-1}). Taking into account the cluster topology and connectivity (Fig. 2), it is possible to distinguish up to six different exchange pathways. However, in order to avoid an overparameterization and in view of the Cu–O–Cu angles and connectivity of the OH bridges (μ_2-OH or μ_3-OH), these six exchange pathways have been grouped into three averaged different exchange parameters. The magnetic data have been analysed with the following spin Hamiltonian:

$$\hat{H} = -2J_1(\hat{S}_1\hat{S}_2 + \hat{S}_1\hat{S}_5) - 2J_2(\hat{S}_3\hat{S}_4 + \hat{S}_6\hat{S}_7) - 2J_3(\hat{S}_1\hat{S}_3 + \hat{S}_1\hat{S}_4 + \hat{S}_2\hat{S}_3 + \hat{S}_2\hat{S}_4 + \hat{S}_1\hat{S}_6 + \hat{S}_1\hat{S}_7 + \hat{S}_5\hat{S}_6 + \hat{S}_5\hat{S}_7)$$

Calculations have been performed with the magnetism package MAGPACK.[6] The best fit obtained from a least-squares analysis of the $\chi_m T$ is $J_1 = -188.4$ cm^{-1}, $J_2 = -52.6$ cm^{-1}, $J_3 = -10.8$ cm^{-1} and $g = 2.15$ ($R = \Sigma [((\chi_m T)_{obs}^2 - (\chi_m T)_{calc}^2)/(\chi_m T)_{obs}^2] = 7.8 \times 10^{-3}$). Attempts to fit with only one or two averaged exchange parameters failed. As expected from the structural parameters depicted in Fig. 2(a) (Cu–O distances and Cu–O–Cu angles), the results show the presence of two weak antiferromagnetic interactions (J_2 and J_3) associated to the interactions by μ_3-OH as have been observed in previous cubane-type systems[2,3] and a strong one (J_1) corresponding to the exchange interaction between the two Cu connected by O1 that has a main component of μ_2-OH and a large Cu–O–Cu angle (117.6°).

This work was supported by CNRS (Centre National de la Recherche Scientifique, UMR 6521), the University of Brest (SUCRI 2E). F. T. thanks the 'Ministère de l'Education Nationale, de la Recherche et de la Technologie' for a postgraduate grant.

High regioselectivity in propylene hydroformylation using rhodium-bisphosphite catalysts is due to properties of the *SRS* diastereomer

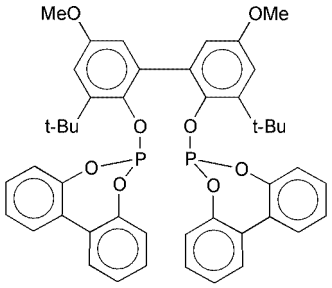
John R. Briggs and Gregory T. Whiteker*

Corporate R&D, The Dow Chemical Company, 3200 Kanawha Turnpike, South Charleston, WV 25303, USA. E-mail: whitekgt2@dow.com

Received (in Cambridge, UK) 26th June 2001, Accepted 14th September 2001
First published as an Advance Article on the web 18th October 2001

The large cone angle and bite angle of the *SRS* ligand diastereomer in biphenol-based Rh-bisphosphite catalysts lead to high linear regioselectivity in the hydroformylation of propylene.

Rhodium-catalyzed hydroformylation of α-olefins is widely used for the industrial synthesis of alcohols and carboxylic acid derivatives.[1] Biphenol-based bisphosphite ligands, such as **1**,



1

offer increased reaction rates and dramatic improvements in linear/branched regioselectivity (l/b) and chemoselectivity over conventional phosphine ligands in rhodium-catalyzed hydroformylation.[2] Unfortunately, a comprehensive mechanistic explanation of the factors that control hydroformylation regioselectivity has remained elusive. Several ligand structural features have been identified to be important in determining regiochemistry in hydroformylation, including steric bulk,[3] electrophilicity,[4] and, in bidentate ligands, bite angle.[5] In this communication we show that in this class of bisphosphite ligands, diastereomeric configuration can also have a profound effect on catalytic hydroformylation regiochemistry and activity.

Rhodium-catalyzed hydroformylation of α-olefins using **1** produces linear aldehydes with high regioselectivities while tolerating a wide variety of functional groups.[6] Structurally related optically-active bisphosphites have been developed which result in high regio- and enantioselectivities for asymmetric hydroformylation.[7] Due to the presence of three axial elements of chirality, bisphosphite **1** can potentially adopt three diastereomeric forms. The notation for these diastereomers (*RRR, SRR, SRS*) uses the middle descriptor for the central bridging biphenoxide moiety. Interconversion of these diastereomers can occur by rotations about the biaryl axes. Previous NMR studies have demonstrated facile epimerization of the cyclic dibenzo[*d*,*f*][1,3,2]dioxaphosphepin moiety in related bisphosphites.[8] This rotational process can interconvert all three possible diastereomers (*RRR, SRR, SRS*).

Rotation about the central *tert*-butyl substituted biphenyl axis could also interconvert *RRR* and *RSR* diastereomers, however, chiral HPLC studies reveal this process is slow. Analytical chiral stationary phase HPLC (Chiralcel OD, 99 : 1 hexane–propan-2-ol) separated **1** into two fractions (1 : 1 ratio) which exhibited identical UV spectra. When the column eluent was monitored using a polarimetric detector, the first peak exhibited a negative optical rotation; the second peak had a positive optical rotation. These enantiomers were physically separated by preparative chiral HPLC and then re-analyzed. Slow racemization of these enantiomers occurred ($t_{\frac{1}{2}}$ = 53 min) at 34 °C by rotation about the central bridging biaryl bond. Interconversion of diastereomers of **1**, therefore, most often occurs *via* dibenzo[*d*,*f*][1,3,2]dioxaphosphepin epimerization with a rate faster than the rate of hydroformylation.

Given the possibility that diastereomeric forms of **1** could contribute to the observed catalytic behavior, we sought to study the effect of isolated configurationally-stable bisphosphite diastereomers in propylene hydroformylation. Bisphosphite **2** was selected for study due to the presence of 6,6′-methyl substituents which prevent biaryl rotation. In addition, bisphosphite **2** contains 3,3′-*tert*-butyl substituents, which are necessary for high hydroformylation regioselectivity using ligands such as **1**. The synthesis of two of the three possible diastereomeric bisphosphites, **2**, is depicted in Scheme 1. Acid-catalyzed alkylation of enantiomerically-pure[9] (*R*)-**3** led to (*R*)-**4**. Synthesis of (*RRR*)-**2** and (*SRS*)-**2** as pure enantiomers was performed by reaction of (*R*)-**4** with the phosphorochloridite prepared by reaction of PCl_3 with the requisite enantiomer of **3**.

Rhodium-catalyzed propylene hydroformylation† was performed using (*RRR*)-**2** and (*SRS*)-**2** to investigate the effects of relative ligand stereochemistry. Hydroformylation using Rh–(*SRS*)-**2** resulted in a high regioselectivity (l/b = 46) with an

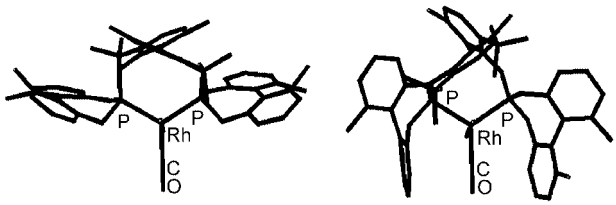

Fig. 1 Molecular mechanics structures of [(*RRR*)-**2**]Rh(CO)$_2$H (left) and [(*SRS*)-**2**]Rh(CO)$_2$H (right). Hydrogen atoms are omitted for clarity.

average rate of 513 turnovers h^{-1} over the course of 6 h. Under identical conditions, Rh–(*RRR*)-**2** gave a much lower rate (110 turnovers h^{-1}) and regioselectivity (l/b = 4) than the *SRS* diastereomer. Bisphosphite **1** exhibited a rate (434 turnovers h^{-1}) and regioselectivity (l/b = 53)[2] which was very similar to that observed with (*SRS*)-**2**. These results demonstrate that rhodium complexes of the *RRR* and *SRS* diastereomers of ligand **2** lead to inherently different regioselectivities and rates for propylene hydroformylation. The similarity between the catalytic performance of (*SRS*)-**2** and **1** suggests that during catalysis, **1** exists predominantly in the *SRS* configuration. Similar differences between bisphosphite diastereomers have been reported by van Leeuwen for asymmetric styrene hydroformylation, where the branched isomer predominates.[10] Reetz has recently reported that asymmetric alkene hydrogenation with biphenyl-based bisphosphite ligands displays an analogous difference between ligand diastereomers.[11] Our results obtained using diastereomeric structures of **2** indicate that achiral transformations mediated by bisphosphites are likewise effected by ligand structure.

Molecular mechanics calculations‡ of [(*SRS*)-**2**]Rh(CO)$_2$H and [(*RRR*)-**2**]Rh(CO)$_2$H were performed to identify the factors which could lead to their dramatically different hydroformylation behavior. The strain energies calculated for these two diastereomeric complexes were essentially identical (within 2 kcal mol^{-1}). The natural bite angle[12] for the *SRS* diastereomer was calculated to be 117°, whereas the *RRR* diastereomer was calculated to have a natural bite angle of 111°. Consistent with previous correlations[5] between hydroformylation regioselectivity and chelate natural bite angle, the more regioselective *SRS* diastereomer of **2** exhibits a larger natural bite angle than the less regioselective *RRR* diastereomer. In addition to differences in natural bite angle, these calculations also revealed a significant difference in cone angle between these two diastereomeric catalysts (Fig. 1). The cone angles at each phosphorus atom in (*RRR*)-**2** and (*SRS*)-**2** were calculated to be 104° and 157°, respectively. The *RRR* (low l/b) catalyst adopts an open geometry around the equatorial CO ligand, which should result in minimal energy differences between linear and branched alkyl or acyl intermediates. The *SRS* diastereomer, which dominates hydroformylation catalysis, is calculated to form a more crowded complex in which the two dibenzo[*d*,*f*]-[1,3,2]dioxaphosphepin moieties flank the equatorial CO ligand. This arrangement should result in large energy differences between linear and branched alkyl or acyl intermediates and could account for the high regioselectivity for linear aldehyde observed with ligands such as **1**.

Previous observations of increased hydroformylation regioselectivity with increased natural bite angle have been complicated by the relationship between cone angle and bite angle for chelating ligands.[5,12] Since large bite angle diphosphines and bisphosphites typically have larger cone angles than their smaller bite angle analogs, the inherent effect of the natural bite angle on hydroformylation regioselectivity is unclear. Recent calculations by Bo and van Leeuwen suggest that steric effects play the dominant role in determining hydroformylation regioselectivity.[13] Although the natural bite angles of (*RRR*)-**2** and (*SRS*)-**2** correlate with their hydroformylation regioselectivity, the very large difference in cone angles for these two diastereomers suggests that the high hydroformylation regioselectivity of (*SRS*)-**2** is predominantly due to an increase in steric influence of the bisphosphite ligand.

Notes and references

† Propylene hydroformylation experiments were performed in tetraglyme solution in a stirred autoclave at constant pressure (148 ppm Rh (1.4 mM), L:Rh(CO)$_2$(acac) = 2.0, 82 °C, 85 psi propylene, 45 psi 1:1 H$_2$–CO).

‡ Molecular mechanics calculations were performed using the augmented MM3 force field implemented in the CAChe software package. Natural bite angles were calculated by using a P–Rh–P bending force constant of 0 kcal mol^{-1} deg^{-2}. The authors are indebted to the reviewers for insight regarding these calculations.

An unusual hexanickel cage complex with μ- and μ_3-chloro bridges and an interstitial μ_6-chloride

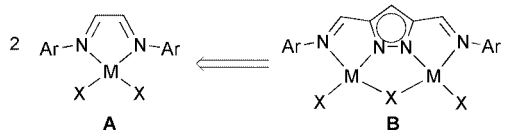
Jens C. Röder, Franc Meyer* and Hans Pritzkow

Anorganisch-Chemisches Institut, Universität Heidelberg, D-69120 Heidelberg, Germany. E-mail: franc.meyer@urz.uni-heidelberg.de

Received (in Cambridge, UK) 13th July 2001, Accepted 14th September 2001
First published as an Advance Article on the web 5th October 2001

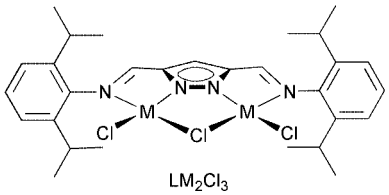
A pyrazolate-based dinucleating ligand of the bis(α-diimine) type forms an unusual hexanuclear nickel(II) cage complex incorporating an interstitial μ_6-Cl atom.

Since Brookhart and coworkers[1] introduced nickel and palladium complexes of α-diimine ligands with bulky aryl substituents as efficient pre-catalysts for olefin polymerisation,[1] these systems and various derivatives thereof have been studied extensively.[2] Most of the catalytic chemistry of such type **A** compounds is based on the presence of two active coordination sites at the single metal centre, which suggests to devise novel bimetallic type **B** complexes where two adjacent metal ions



might work in concert. The basic concept, *i.e*. the use of a pyrazolate bridge to (in a formal sense) link two N-based ligand compartments in a preorganized dinucleating scaffold, has been outlined previously and has proven to be successful for the investigation of bimetallic versions of N-donor-functionalized cyclopentadienyl compounds[3] as well as bimetallic versions of classical Werner-type coordination compounds.[4,5]

A synthetic route to a multidentate pyrazolate ligand HL that bears bulky 2,6-diisopropylphenyl substituents at the imine-N atoms and that appears suitable for the preparation of type **B**



systems has been described recently.[6] Here we report the first transition metal complexes of HL. While HL forms the sought-after LM_2Cl_3 coordination compounds for M = Pd,[7] its coordination chemistry with $NiCl_2$ was found to give rise to oligonuclear species of quite unusual topology.

Treatment of HL with 1 equivalent of KO^{t}Bu and 2 equivalents of [$NiCl_2$(dme)] afforded a green complex **1** that could be crystallised from CH_2Cl_2–light petroleum (bp 40–60 °C) solution. Its analytical data† were in accord with the anticipated composition LNi_2Cl_3, but UV–VIS spectra suggested an *OC*-6 rather than a *SP*-4 coordination of the nickel(II) ions, and FAB-MS spectra were indicative of the presence of species of higher nuclearity (Fig. 1).

The molecular structure of **1** was elucidated by X-ray crystallography‡ and is shown in Fig. 2. In **1**, three bimetallic LNi_2Cl_3 building blocks have assembled *via* Cl-bridges to form a hexanuclear array with all metal ions in distorted octahedral coordination spheres. The central Ni_6Cl_9 core consists of two roughly planar Ni_3Cl_3 ring systems that are each capped by a μ_3-Cl atom. These two Ni_3Cl_3 planes are almost parallel and are held together by the three pyrazolate clips, thus forming a cage-like structure which accommodates a single Cl atom in its

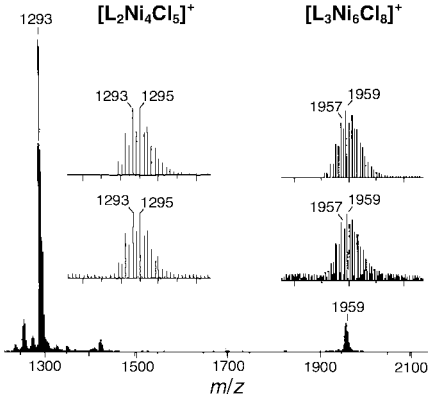


Fig. 1 FAB-MS spectrum of **1**; the inset shows the experimental (lower) and theoretical (upper) isotopic distribution for the tetranuclear $[L_2Ni_4Cl_5]^+$ and the hexanuclear $[L_3Ni_6Cl_8]^+$.

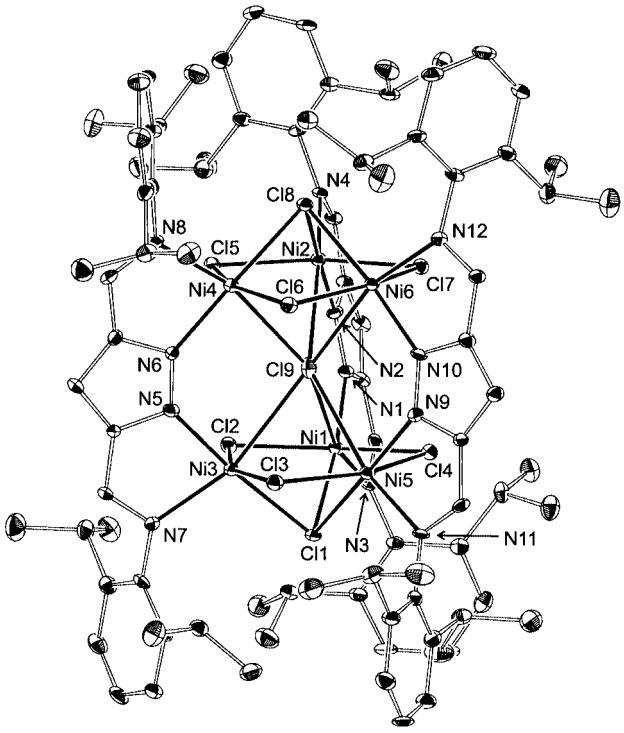

Fig. 2 Molecular structure of **1**. For clarity all hydrogen atoms have been omitted. Selected atom distances (Å): Ni–(μ-Cl) 2.360(3)–2.466(3), Ni-(μ_3-Cl) 2.402(3)–2.466(3), Ni–$N_{pyzazole}$ 1.965(7)–1.980(6), Ni-N_{imine} 2.102(7)–2.120(7), Ni1–Cl9 2.835(3), Ni3–Cl9 2.805(3), Ni5–Cl9 2.796(3), Ni2–Cl9 2.775(3), Ni4–Cl9 2.710(3), Ni6–Cl9 2.724(3), Ni···Ni within the Ni_3Cl_3 rings: 3.136(2)–3.195(3), Ni···Ni bridged by pyrazolate: 4.167(2)–4.216(2).

 DOI: 10.1039/b106258c

centre. That interstitial μ_6-Cl atom is bound to all six nickel ions in an almost trigonal prismatic fashion (trigonal twist ~ 10°). The bulky aryl substituents provide a hydrophobic shell encapsulating the central core structure.

Compared to the ubiquitous occurrence of terminal Cl and μ-Cl ligands and the frequently observed μ_3-Cl coordination, higher coordination numbers for halide ligands in discrete molecules are much less common.[8] To the best of our knowledge, μ_6-Cl atoms bound to six metal ions are very rare in molecular compounds,[9–11] and structurally characterised examples are mainly restricted to a few siloxane clusters.[11] In the latter compounds, however, the central Cl atoms are generally found in a hexagonal-planar surrounding of metal ions and feature significantly longer (and differing) metal–Cl bonds,[11] while in **1** all Ni–Cl9 distances are found in the narrow range 2.724(3)–2.835(3) Å. The structure of **1** allows for a direct comparison of these values for the μ_6-Cl with the Ni–Cl bond lengths for the μ- and μ_3-Cl bridges [*d*(Cl–Ni) = 2.360(3)–2.446(3) and 2.402(3)–2.466(3) Å, respectively], which follows the expected trend. Trigonal prismatic coordination of a Cl equidistant from six metal ions has also been reported for a hexanuclear neodymium isopropoxide complex.[9]

In the presence of donor solvents, the hexanuclear entity of **1** is degraded to complexes of lower nuclearity. From a $CHCl_3$ solution of **1** containing small amounts of EtOH, the tetranickel(II) compound $[LNi_2Cl_3(EtOH)_2]_2$ **2** was obtained in crystalline form. Its molecular structure is depicted in Fig. 3.

In **2**, two LNi_2Cl_3 building blocks are linked *via* μ- and μ_3-Cl bridges to form a stair-like dimeric aggregate (distance between the two parallel pyrazolate planes 2.034 Å), with the remaining coordination site at each metal ion now being blocked by an EtOH solvent molecules. The *OC*-6 coordination spheres of both Ni1 and Ni2 are somewhat distorted, and in particular a hydrogen bond between Cl1 and O2 causes these ligands to bend towards each other [*d*(O2···Cl1) = 3.512(2) Å]. A further H-bonding interaction is detected between the ethanol O1 atom and the π system of the opposite aryl ring [distance between O1 and the centre of the ring (C18–C23): 3.487 Å].

Formation of the unusual cage-like hexanickel array observed in **1** is not restricted to the presence of a templating μ_6-Cl atom: structures analogous to those of **1** and **2** have been obtained from the reaction of HL with $NiBr_2$(dme), where in the case of the bromo derivative of **1** the expanded Ni_3Br_3 belts give rise to an enlarged cavity suited to accommodate the larger Br atom.[6]

We thank Professor Dr G. Huttner for his generous support. Funding by the Deutsche Forschungsgemeinschaft (SFB 247, Heisenbergstipendium for F. M.) and by the Fonds der Chemischen Industrie is gratefully acknowledged.

First published as an Advance Article on the web 5th October 2001

Sulfonic acid groups anchored to the surface of mesoporous MCM-41 silica have been identified with S K-edge XANES spectra and the material is an efficient catalyst for the liquid phase condensation of phenol with acetone to form Bisphenol-A with high selectivity.

We report here that sulfonic acid functionalized mesoporous MCM-41 silica can be an efficient catalyst for the condensation of phenol and acetone at relatively low temperature to synthesize Bisphenol-A with a very high selectivity. Bisphenol-A is an important raw material for polymer and resin production, and it is produced industrially using ion-exchange resins such as Amberlyst.[1] However, thermal stability and fouling of the resins are major problems for these catalysts and the search for thermally stable and regenerable solid acid catalysts are continuing.

Zeolites have been increasingly used in the synthesis of fine chemicals due to their high surface area and confined domains.[2] However, the suitability of zeolites for the conversion of larger substrates has been severely limited by the available dimensions of their pores, which are in the micropore region with pore mouth diameter usually less than 1 nm.[3] For reactions to occur within the pores, the reaction substrates and products must be allowed to diffuse smoothly through the zeolite pores. The discovery of surfactant–templated mesoporous silica materials such as MCM-41 (hexagonal *P6m* symmetry) and MCM-48 (cubic *Ia3d* symmetry) with controlled pore diameters (2–10 nm) and topologies has extended the suitability of these materials for the conversion of larger substrates.[4] They are very promising for the application as catalysts and/or catalyst supports and are likely to offer potential improvements in reaction selectivity in the conversion of larger substrate molecules in their well-defined channels with narrow pore size distributions. However, in spite of these favorable pore dimensions, the acidity of Al-substituted mesoporous materials such as Al-MCM-41, is much weaker than that of microporous zeolites.[5] To overcome this drawback, the synthesis of inorganic–organic hybrid mesoporous materials with alkylsulfonic acid groups has been reported recently.[6–9] These hybrid materials can be synthesized either by direct one-step synthesis or *via* secondary silylation. Thus, MCM-SO_3H prepared by direct synthesis and secondary silyation is reported to be highly efficient in the synthesis of bisfurylalkanes[6] and also in the esterification of glycerol with fatty acids.[7,9] However, as the organic functional groups may be damaged or destroyed during the template removal process, the secondary silylation technique seems to offer a better alternative for preparing mesoporous acid catalysts.

Pure silica MCM-41 was synthesized according to the method described earlier.[10] Surface functionalization with sulfonic acid groups was carried out according to the method described in the literature.[7,8] Typically, 3.0 g of the freshly calcined MCM-41 sample was evacuated at 150 °C and then an excess of 3-mercaptopropyltrimethoxysilane (MPTS) in dry toluene was introduced. The mixture was refluxed for 6 h and the solid was filtered off, washed with dry toluene and air-dried. The –SH groups were converted into $–SO_3H$ groups by mild oxidation with H_2O_2 (stirring for 24 h at 60 °C with excess oxidant). The solid was filtered off, washed with water and ethanol, followed by acidification with 0.1 M H_2SO_4 followed by thorough washing with water to remove all traces of liquid acid. The solid material was finally dried at 60 °C overnight.

Sulfur loading of the solid material was determined by elemental analysis (Heraeus) and was typically in the range 0.9–1.8 meq. g^{-1} of solid. Thermogravimetric analysis (Du Pont 950) shows the material to be more hydrophobic than MCM-41. While calcined pure silica MCM-41 shows *ca.* 5% weight loss in the range 30–100 due to water removal, sulfonic acid functionalized MCM-41 (denoted MCM-SO_3H) showed only $<1\%$ weight loss in this region. Loss of sulfonic acid groups starts at *ca.* 200 °C and is completed by 325 °C. The specific surface area and pore volume of the pure silica MCM-41 material was reduced from 1035 $m^2\ g^{-1}$ and 0.85 $cm^3\ g^{-1}$, respectively, to 690 $m^2\ g^{-1}$ and 0.42 $cm^3\ g^{-1}$ after anchoring the sulfonic acid groups. Although the pore size distribution curve (Fig. 1) becomes somewhat broad after sulfonic acid group introduction and the peak maximum shifts from 27 Å (pure MCM-41) to 22 Å, the pore size distribution still remains very narrow with major fractions of pores lying within the 7 Å region. These results indicate that anchoring sulfonic groups to the channels of MCM-41 reduced the pore diameter and volume of MCM-41 but did not damage the mesoporous structure. This was also affirmed by the retention of sharp diffraction peaks in the corresponding XRD pattern.

To obtain good catalytic activity it is imperative that the thiol groups can be effectively oxidized to active sulfonic acid groups. To monitor this process, the oxidation states of sulfur were examined by studying the S K-edge XANES spectra of the sample before and after oxidation. The XANES experiments were performed at Beam line 15B at the Synchrotron Radiation Research Center facility at Hsinchu, Taiwan. Standard operating conditions were 1.5 GeV and 200 mA beam current and the

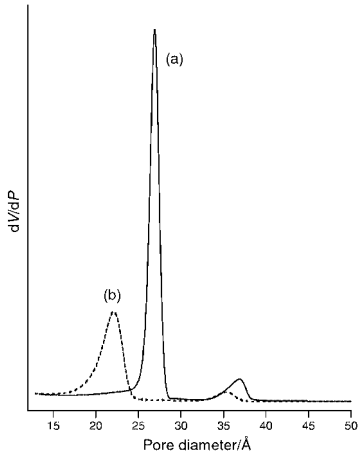

Fig. 1 Pore size distribution of (a) calcined pure silica MCM-41 and (b) MCM-41 functionalized with sulfonic acid groups.

 DOI: 10.1039/b107155f

photon energies were calibrated using the L-edge of pure Mo foil. Fig. 2 shows the S K-edge XANES spectra of the thiol functionalized samples before and after H_2O_2 oxidation. It has been reported that both the energy position (E_k) and intensity of the S s→p transition peak (white-line) are sensitively related to the oxidation state of the S atom.[11] Studies with model compounds showed an increase of E_k and amplitude of the white-line with increasing formal oxidation states of S. Thus, for unoxidized sample containing thiol groups the white-line appears at 2472 eV corresponding to sulfur in the reduced state. After H_2O_2 oxidation the white-line shifts to higher energy (2481 eV) which corresponds to sulfonic acid with S in the +5 state.[11,12] It can be seen from Fig. 2 that most of the anchored thiol groups have been oxidized to sulfonic acid groups under the above oxidation conditions.

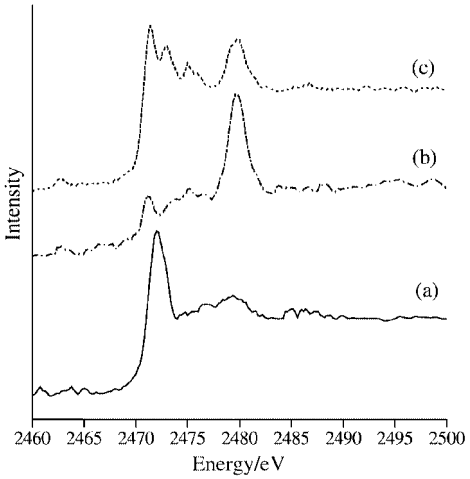

Fig. 2 S K-edge XANES spectra of thiol functionalized MCM-41 materials (a) before oxidation, (b) after oxidation and (c) sample with incomplete oxidation of thiol groups.

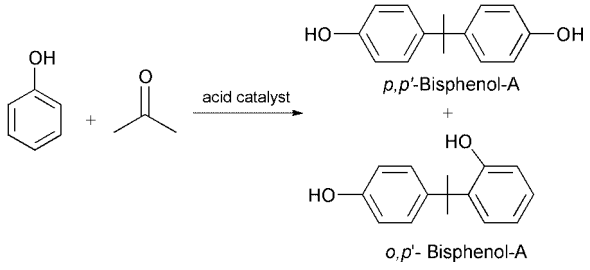
Condensation of phenol and acetone to Bisphenol-A (Scheme 1) was carried out at temperatures of 70–125 °C with the sulfonic acid functionalized MCM-41 silicas. Several other acidic zeolites such as H-ZSM-5, H-Y and H-beta have also been used for comparison. The products were analyzed and identified using a Chrompak 9000 gas chromatograph and HP 6890 GC-MS, and the results are given in Table 1. No conversion of phenol was observed in the absence of catalyst. While acidic zeolites like H-ZSM-5, H-Y and H-beta showed negligible activity at 70 °C, MCM-SO_3H showed 30% phenol conversion (*cf.* 40% maximum theoretical conversion at a phenol : acetone molar ratio of 5 : 1) with >90% selectivity towards *p,p′*-Bisphenol-A; the other product was *o,p′*-Bisphenol-A. The conversion was found to increase with the reaction temperature, but the selectivity remained almost unchanged up to 120 °C. Chroman and trisphenols were not detected at temperature below 125 °C, but small amounts (<1%) of these byproducts were detected at or above 125 °C. Recently, the synthesis of Bisphenol-A over heteropolyacid encapsulated MCM-41 has been reported.[13] However, 12-tungstophosphoric acid encapsulated MCM-41 was found to be catalytically active only at temperatures above 120 °C. Due to this high reaction temperature, several by-products such as alkylated phenols and chroman derivatives were formed, and



Scheme 1

Table 1 Synthesis of Bisphenol-A with sulfonic acid functionalized MCM-41 silicas[a]

Entry	Catalyst	Phenol conversion (%)	Selectivity[b] (%)
1	—	0	—
2	H-beta[c]	5	55
3	HY[d]	7	—
4	HZSM-5[e]	<5	10
5	MCM-SO_3H	30	92
6	MCM-SO_3H[f]	17	90

[a] *Reagents and conditions*: Phenol 4.7 g, acetone 0.58 g, (molar ratio = 5 : 1), catalyst 50 mg, 70 °C, 24 h. [b] Selectivity to *p,p′*-Bisphenol-A. [c] Si/Al = 50. [d] Si/Al = 10.6. [e] Si/Al = 80. [f] Incomplete oxidation (from XANES).

the selectivity to Bisphenol-A was much lower than that obtained with MCM-SO_3H. Furthermore, leaching of sulfur during the catalytic reaction was found to be negligible with MCM-SO_3H. Elemental analysis of the catalyst before reaction indicated *ca.* 3.4% sulfur and 5.6% carbon content. After reaction at 70 °C, these values were 3.2% S and 9.5% C. The slight decrease in sulfur content is mainly due to the increase in weight from adsorption of organic species. On the other hand, it is noted that optimization of the oxidation process in the preparation of MCM-SO_3H is essential to achieve high catalytic activity. For samples with similar sulfur loadings but with incompletely oxidized thiol groups (dotted line in Fig 2) the activity was found to be much lower (see Table 1). XANES spectra of the samples with incompletely oxidized sulfur species showed a number of peaks around 2472 eV, suggesting the presence of lower valent sulfur species such as sulfides and disulfides.[11,12] It has also been observed that at higher sulfur loadings (>1.5 meq. g^{-1} solid) part of the sulfur remains in the reduced form even after prolonged oxidation, probably due to formation of sulfides and disulfides.

In conclusion, sulfonic acid anchored MCM-41 has been found to be very effective in the synthesis of *p,p′*-Bisphenol-A with very high selectivity at relatively low reaction temperatures. S K-edge XANES studies can be used as a convenient tool for easy monitoring of the oxidation state of sulfur in the samples.

Financial support was provided by the Chinese Petroleum Corporation and the Ministry of Education, Taiwan.

First published as an Advance Article on the web 1st October 2001

Hydroboration of conjugated dienes is promoted by the hydroxy and methoxy groups, which also control the rearrangement of the initially produced allylic boranes.

The hydroboration–oxidation process has been established as a useful synthetic tool for conversion of an olefinic function to a hydroxy group with control of the regio- and stereochemistries.[1] The reaction can also be applied to conjugated diene systems but the factors governing the reaction selectivities are more complicated.[2] Synthetic use of hydroboration with conjugated diene substrates requires not only control of these factors but also a solution to overcome the poorer reactivity of the diene unit, especially those likely to give a mono-hydroboration product. Hence, only limited examples of such reactions have been reported.[3] The expected difficulties are in controlling: 1) regioselectivity of the initial addition, 2) allylic borane rearrangement of the adduct, and 3) the second addition through cyclic hydroboration and through hydroboration with an external borane.

In contrast to hydrosilylation,[4] hydroboration is known not to be directed by a hydroxy group. Borane reagents readily react with the hydroxy group before the addition to the olefinic unit, and the produced borate acts only as a steric fence for the second borane reagent. Thus, more than two equivalents of a borane reagent have been employed.[5] However, during the study of asymmetric synthesis of polypropionate units through chiral cyclic dienes, we found that the hydroxy group in **3b** promotes mono-hydroboration and the reaction completed only with one equivalent of $ThexBH_2$. Strict control of rearrangement of the initially produced allylic boranes is also caused by the oxy-functions.

Optically active cyclic dienes **3a**–**e** (Scheme 1) were prepared under strict stereocontrol by the rhodium-catalyzed reaction of stereochemically pure **1**.[6,7]

Hydroboration of an unfunctionalized substrate **3a** (X = H) with $ThexBH_2$ (2 eq.) in THF at room temperature was slow, and 48 h was required to complete the reaction. After the usual workup (30% H_2O_2 with 1 M NaOH for 5 h), two diols **4** and **5** were obtained in a 2 : 1 ratio (66.3%, Scheme 2).[8] The reaction with a smaller amount of $ThexBH_2$ (1 eq.) or a shorter reaction time (5 h) did not give any mono-hydroboration product but only the two diols **4** and **5** at the same ratio in low conversion of the reactant. Bis-substituted boranes like diisoamylborane and 9-BBN did not cause the hydroboration of **3a**, but most of **3a** was recovered after the oxidative workup.

The result with **3a** is just an additional example of a less active diene substrate for the hydroboration indicating the difficulty in interruption of the second hydroboration. In contrast, the hydroboration of a hydroxylated substrate **3b** (X = OH) occurred smoothly at room temperature with $ThexBH_2$, and was completed within 2–4 h. The product after workup was mono-hydroborated product **6** as a single isomer (>99% selectivity), and no bis-hydroboration was observed even with excess $ThexBH_2$ for a longer reaction time. Unexpectedly, the substrate **3b** was consumed even with one equivalent of $ThexBH_2$, and **6** was isolated in 86.1% yield after workup.

Since the reaction of **3b** with $ThexBH_2$ should start with quick reaction at the hydroxy group to give **A** in Scheme 3,[5] further reaction at the olefinic bond was expected to be sluggish with one equivalent of $ThexBH_2$. However, a small amount of $ThexBH_2$ can remain. Considering the low reactivity of **3a**, the oxy-function in **A** should play a role in promoting the addition of $ThexBH_2$ at the 10,11-bond from the same face of the hydroxy group. Facile allylic rearrangement in the adduct **B** results in a stable cyclic borate **D** with regeneration of $ThexBH_2$. Thus, a disproportionation of the borate species may facilitate this process.

Promotion of the hydroboration by the oxy-function in **A** was mimicked with O-protected substrates **3c**–**e** (X = OR). The

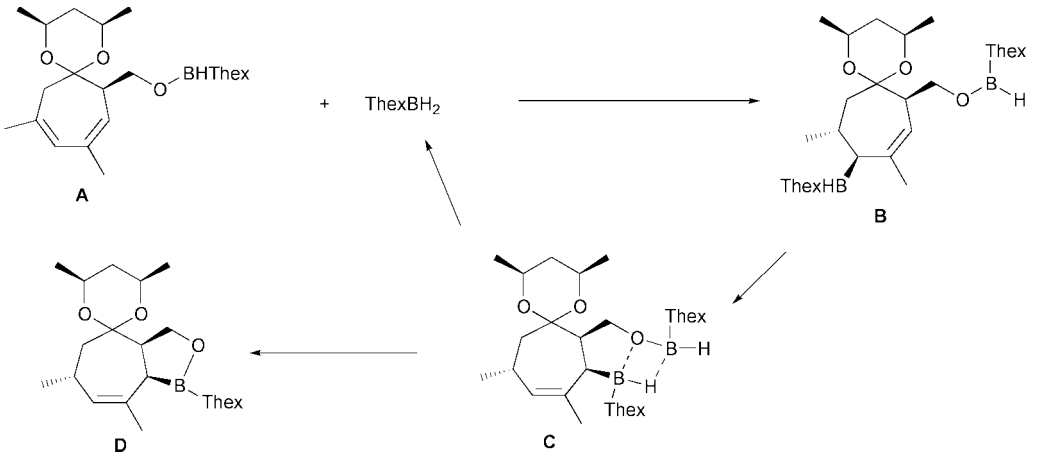

Scheme 3 Plausible mechanism of the hydroboration of **3b** with $ThexBH_2$.

reaction of **3d** or **3e** with excess $ThexBH_2$ at room temperature did not give any hydroboration product but resulted in the substrate recovery after the oxidative workup. In contrast, the reaction of **3c** (X = OMe) with one equivalent of $ThexBH_2$ proceeded even at −20 °C (7.5 h) to give **7** as a sole product in 29.0% yield together with a recovery of **3c** in 50.1%. Thus, the oxy-function having proper bulkiness and coordination ability was found to promote the hydroboration of the diene. It was also confirmed that the initial site of addition is at the 10,11-bond when the reaction is promoted by the oxy-functions. Elevation of the hydroboration temperature of this reaction increases the reaction conversion accompanied by rearrangement of **7**, which resulted in production of another regioisomer, **8**. The reaction at room temperature for 10 h afforded **8** as a single isomer in 59.9% yield after workup.

The results with **3c** indicate that the borane adduct at the 10,11-bond is fragile at room temperature. Although the observed rearrangement in **3c** is possible through cyclohydroboration (in giving a 4-membered carboborane) and retro-hydroboration, a process consisting of retro-hydroboration of the kinetic adduct and then re-hydroboration to give a thermodynamically stable adduct is more likely. When the adduct was treated with cyclohexene at −20 °C followed by warming up to room temperature, **8** was not obtained and the conversion of **3c** to **7** was reduced. Since the second olefin addition to a $ThexBH_2$ adduct is known to be slower than the first addition,[9] cyclohexene should have trapped the regenerated free $ThexBH_2$.

In this communication, we have demonstrated that the hydroxy and methoxy groups promote the hydroboration of the diene, and fully control the rearrangement of the initial adduct in a different manner. The role of the oxy-functions in the promotion of the hydroboration is suggested to be due to interruption of the retro-hydroboration. Details of the further reactions of the obtained products aiming at asymmetric synthesis of polypropionate units are in progress.

7 Stereochemically pure **1** was prepared in three steps by the reported method (see ref. 4, 64%). Treatment of **1** with $Rh_2(OAc)_4$ at room temperature resulted in predominant formation of **2** (97.1%, >99.6% diastereomeric excess). Lithium aluminium hydride reduction of **2** (94.5%) followed by isomerization with pyridinium tosylate proceeded regio- and stereo-specifically to give **3b** as the sole product (91.9%). Stereochemistry of **3b** at the acetal position was determined by NOE. The enantiomeric purity of **3b** at the 7-position was confirmed to be over 99.6%. Treatment of **3b** with methyl iodide and sodium hydride gave **3c** (93.3%), and tosylation of **3b** followed by lithium aluminium hydride reduction gave **3a** (66.5% for two steps).

8 Structures of all new compounds were fully characterized. Stereochemical assignments were based on the NOE experiments of ^1H NMR and chemical correlations.

Spontaneous polymerisation on amphibole asbestos: relevance to asbestos removal

Ivana Fenoglio, Maura Tomatis and Bice Fubini*

First published as an Advance Article on the web 1st October 2001

Taking advantage of the spontaneous polymerisation of eugenol to lignin-like species catalysed by the surface of crocidolite fibres, a procedure is proposed, possibly useful in asbestos removal and disposal, where the polymer avoids the release of airborne fibres and also scavenges ROS (reactive oxygen species).

Pioneering studies on the formation of protobiopolymers following Bernal's hypothesis[1a] on the origin of life have focused attention on the polymerisation of eugenol to lignin-like polymers,[1b] because lignin is, after cellulose, the most abundant organic material on Earth. Silica and silicates, the major constituents of the Earth's crust, have been proposed as materials exhibiting appropriate surface sites for catalysed polymerisation.[2] Various silicates have indeed been found to catalyse the polymerisation of eugenol in the presence of hydrogen peroxide. The reaction appears to be promoted by hydroxyl radicals released from the Fenton-like decomposition of hydrogen peroxide.[2a]

We have revisited this reaction from a different viewpoint and investigated whether it could take place not only on serpentine asbestos (chrysotile) but also on the amphibole asbestos crocidolite (fibrous riebeckite), considered to be the most dangerous form of asbestos.[3] The reaction was carried out by adding a solution of hydrogen peroxide to a suspension of crocidolite in an aqueous solution of eugenol. After the reaction, crocidolite fibres appear to be completely included in a polymer matrix and the resulting product is a bulk solid material. Fig. 1 compares the SEM (scanning electronic microscope) images of the product obtained with crocidolite with the original fibre. No free fibres are present at the surface of the product which appears smooth and polished. Only at higher magnification are the individual fibres trapped within the polymeric matrix detectable. No modifications in the polymer were detectable several months after the polymerisation had occurred.

It is generally accepted that free radical generation upon fibre/cell contact is one of the steps yielding the pathogenic response to inhaled fibres.[4–6] Crocidolite is highly reactive in releasing free radicals.[4,5,7,8] Two radical-generating mechanisms are usually investigated in cell-free systems[4,5,8,9] (Scheme 1): (i) the release of $OH^{\cdot}$ radicals in the presence of hydrogen peroxide, mimicking contact with lysosomal fluids, following phagocytosis by alveolar macrophages and recruited polymorphonucleated cells (PMN); (ii) the release of $CO_2^{\cdot -}$ radicals from the formate ion, used as target molecule for homolytic cleavage of a carbon–hydrogen bond, which occurs with several endogenous molecules such as peptides, proteins and lipids. The free radical release from aqueous buffered suspensions of crocidolite was measured before and after the treatment by means of the classical spin trapping technique.[5] Fig. 2 shows the EPR (electronic paramagnetic resonance) spectra of the radical adducts obtained from suspensions of, respectively, crocidolite and crocidolite treated with eugenol in a buffered solution (pH 7.4) of (a) hydrogen peroxide and (b)

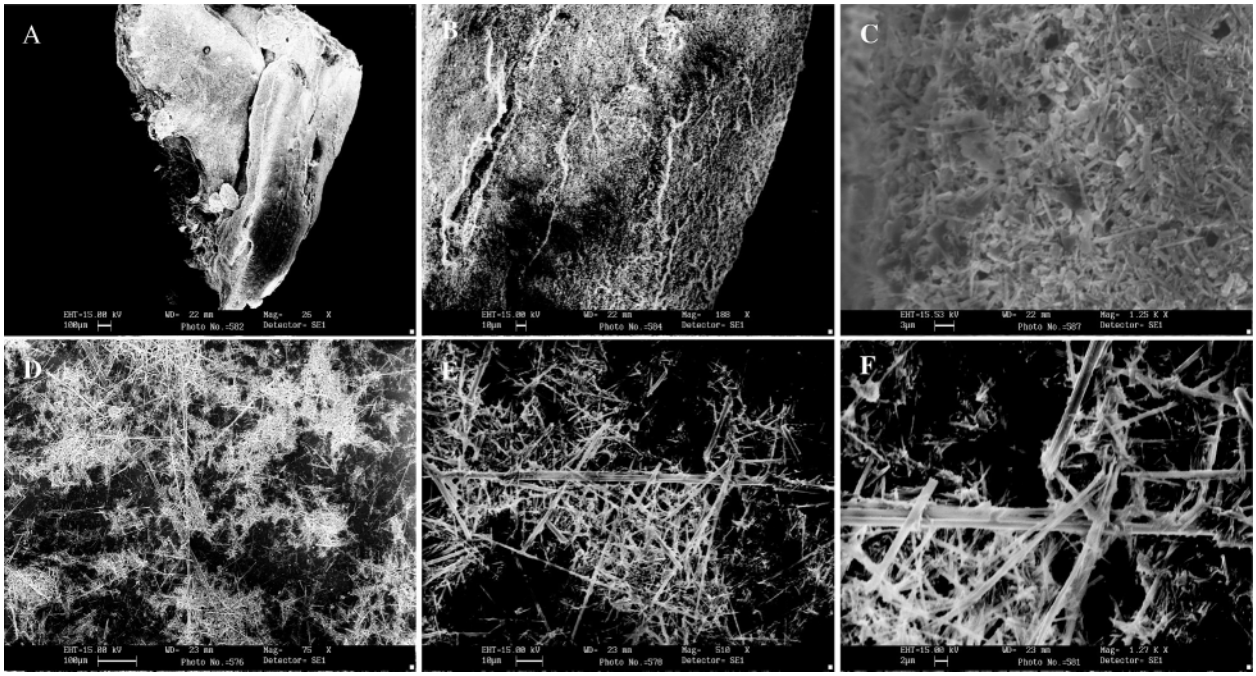

Fig. 1 SEM images at increasing magnitude of a fragment of crocidolite following surface polymerisation of eugenol (A, B, C), compared with original crocidolite fibres (D, E, F) at the same magnification. When treated with eugenol, crocidolite appears a solid, non-fibrous material. A very high magnification is required to detect the single fibres trapped into the polymeric matrix.

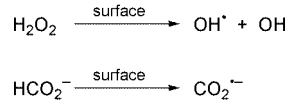

Scheme 1 Hydroxyl radical release and homolytic cleavage of carbon–hydrogen bond mediated by asbestos fibers.

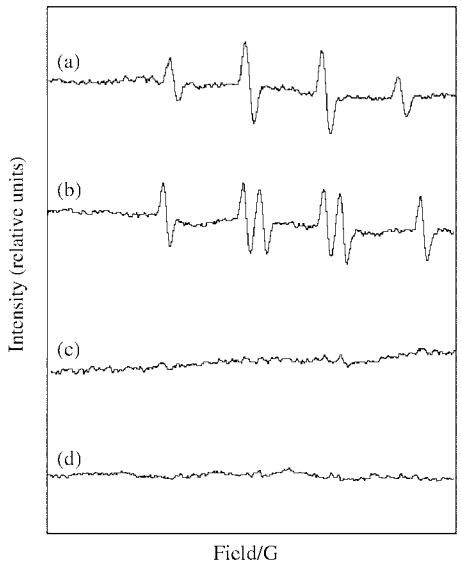

Fig. 2 Free radical release from crocidolite fibres (signals a, b) and of eugenol-treated crocidolite (signals c, d): in the presence of hydrogen peroxide (signals a, c) or sodium formate (signals b, d) the EPR spectra of the supernatant from an aqueous suspension of fibres (pH 7.4, phosphate buffer) recorded after 60 min show, with crocidolite, the typical signals of the [DMPO–OH] and [DMPO–CO_2]$^{\bullet-}$ adducts, respectively. Crocidolite fibres contacted with eugenol lose their radical release potential.

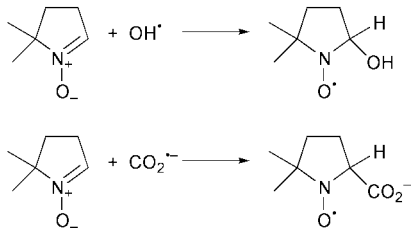

Scheme 2 Reaction of hydroxyl radical and carboxylate radical with the spin trap DMPO.

sodium formate in the presence of the spin trap 5-5′-dimethyl-1-pyrroline-*N*-oxide (DMPO) (Scheme 2). The amount of radical released is proportional to the intensity of the signals of the [DMPO–OH]$^{\bullet}$ and [DMPO–CO_2]$^{\bullet-}$ adducts, respectively. No radical release was observed from the crocidolite treated with eugenol. The activity was partially restored only after heavy grinding, which exposed fresh surfaces of fibres to the air. The inactivation may be partially ascribed to the dramatic decrement of the exposed surface but is also due to a scavenging effect of the lignin-like polymer. Lignin is, in fact, considered responsible for the antimutagenic/anticarcinogenic effect of dietary fibre. The protective effect is attributed to the scavenging property towards free radicals.[10] There is evidence that the inactivation is not due to the reaction of the surface with hydrogen peroxide: the active sites present on the surface of the crocidolite fibres are catalytic sites not consumed during the reaction with hydrogen peroxide.[8,11]

The reaction described, once set up for practical application, may be proposed as an intermediate step to be taken in the procedure of asbestos removal, which is still a controversial issue.[3,12,13] This could avoid the formation of airborne fibres, transforming a fibrous particulate material into a bulk solid for disposal. Note that if the polymerisation solution is maintained over the surface of the material during removal, any accidentally detached fibres will act as a catalyst for the reaction and will consequently be covered by the lignin-like polymer. The observed inactivation of radical release by the action of the lignin-like polymer makes this reaction advantageous with respect to other methods.[14,15] It can thus be regarded as a new approach to the problem of disposal employing a one-pot reaction under mild conditions, as a continuous surface-inactivating process takes place along with asbestos removal.

This study was supported by the Regione Piemonte, Italy.

Carbon nanotube template promoted growth of NbS_2 nanotubes/nanorods†

Yan Qiu Zhu, Wen Kuang Hsu, Harold W. Kroto and David R. M. Walton*

Fullerene Science Centre, School of CPES, University of Sussex, Brighton, UK BN1 9QJ. E-mail: d.walton@sussex.ac.uk

Received (in Cambridge, UK) 18th July 2001, Accepted 11th September 2001
First published as an Advance Article on the web 5th October 2001

NbS_2 nanotubes/rods have been generated successfully employing carbon nanotube template promoted growth; high resolution transmission electron microscopy, coupled with EDX analysis, confirm the template effect and existence of NbS_2 tube structures.

Inorganic nanotubes/nanoparticles, first reported by Tenne *et al.*,[1] have engendered intense scientific interest because of their promising electronic and mechanical properties. For example, WS_2 nanotubes have been used as scanning probe microscope tips,[2,3] and MoS_2 nanoparticle-based lubricants display excellent wear-resistance.[4] Syntheses of these materials include chemical transport,[5] gas–solid reactions[6] and *in situ* heating,[7] leading to pure MS_2 nanoparticles, short and long tubes, bundles and even microtubes. The family of inorganic nanostructures has been widened in various ways, *e.g.* by creating so-called inorganic–organic dual phase nanostructures (mixing MX_2 layers with C layers);[8,9] intercalating noble metals (Au and Ag) within the tube walls;[10,11] Ti and Nb doped MX_2 composite nanotubes.[12,13] Recently, significant developments in the generation of single-layered MX_2 tubes have been reported,[14,15] years after single-walled carbon nanotubes were first described.[16] Single layered MoS_2 nanotubes have been formed successfully using chemical transport[14] and WS_2 nanotubes have been the subject of template generation.[15,16] However, it is noteworthy that after several years of effort, NbS_2 nanotubes, a layered material possessing interesting electronic properties (*e.g.* superconducting), have only just been prepared.[17] Unfortunately, this communication contained no high resolution TEM images, so that detailed tube structures need to be determined. We now describe the successful generation of NbS_2 nanotubes/nanorods *via* a carbon nanotube template process.

A 20 mg sample of $NbCl_4$ (Aldrich Co) was added to a suspension of carbon nanotubes (20 mg, produced by the arc-discharge process), in CCl_4 (30 cm^3), and the mixture was subjected to ultrasound treatment for 30 min. It was set aside for 72 h at room temperature, then heated at 80 °C to remove the CCl_4, leaving a black powder consisting of $NbCl_4$-coated nanotubes. The nanotubes were transferred to a quartz boat placed in a quartz tube inside an electrical resistance furnace. The sample was heated at *ca.* 500 °C for 30 min in air, then at *ca.* 1100 °C in an Ar atomsphere. This temperature was maintained for a further 30 min, whilst H_2S was passed through the tube. After cooling to room temperature, the nanotube sample was examined using a CM-200 high resolution transmission microscope, with energy dispersive X-ray analysis equipment attached (EDX, element $\geq$ B).

TEM observations revealed that a proportion of the carbon nanotube surfaces were modified during the preheating process (500 °C in air). Notably, some of the tube bodies were discontinuously sheathed with crystalline structures [Fig. S1(a), ESI†]. Under these conditions, the layered structure and the hollow cores of the carbon nanotubes were difficult to recognise because of a lack of carbon contrast due to the wrapped oxide crystals. However, using focus/defocus techniques, we were able to observe the carbon layer fringes (*ca.* 0.34 nm separation) and the hollow core at the centre of the tube [Fig. S1(b) arrowed, ESI†]. The outer crystalline shell of this tube, containing Nb and O (as well as C, which presumably arises from the central carbon nanotube) according to our EDX ananlysis, was NbO_x. The lattice separation of the oxide is *ca.* 0.36–0.37 nm, *i.e.* close to that of NbO_2.

After the passage of H_2S, HRTEM analysis showed that NbS_2 nanotubes/rods (*ca.* 5–10%) were present in the specimen, together with micro-polygonal particles. The diameter of the nanotubes varies from 50 to 200 nm, and their lengths are up to a few microns. The nanotube layers are separated by *ca.* 0.60 nm [Fig. 1(a)], corresponding to layered hexagonal NbS_2 structures (a = 3.31 Å, c = 11.89 Å).[18] The inner carbon nanotube layer separation is *ca.* 0.34 nm, *i.e.* identical to the separation in the starting materials. It is apparent that the carbon template has been sheathed incompletely with NbS_2 layers, and

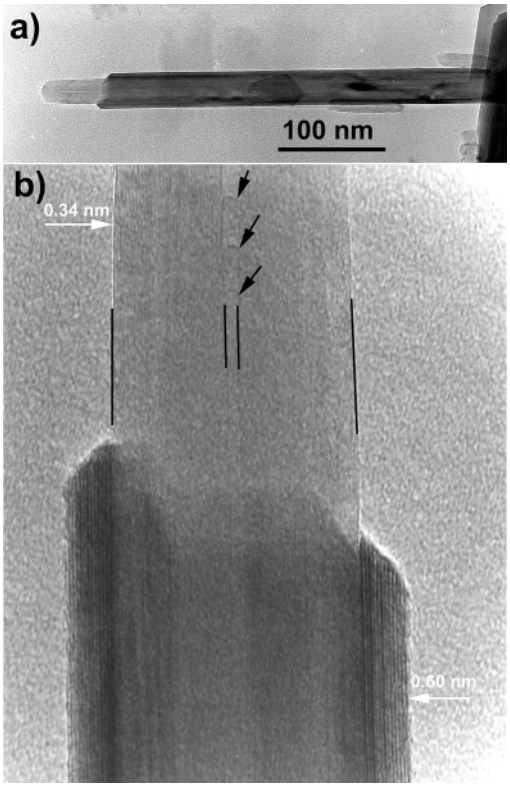

Fig. 1 HRTEM images: (a) a long open-tipped NbS_2 nanotube grown on a close-tipped carbon nanotube template; (b) the outer NbS_2 layer distance is 0.6 nm, the inner carbon layer separation 0.34 nm. The tube wall and the hollow core of the carbon template are marked by the vertical lines. Several closed inner layers of the carbon nanotube are arrowed.

† Electronic supplementary information (ESI) available: HRTEM images of a carbon nanotube wrapped in Nb oxide (a), of the inner carbon layers (b) and of an NbS_2 nanorod with NbO_x residue at the tip (c); (d) EDX profile of an isolated NbS_2 nanotube. See http://www.rsc.org/suppdata/cc/b1/b106388j/

 DOI: 10.1039/b106388j

the open-ended growth of the NbS_2 nanotube is visible [Fig. 1(b)]. In some cases, it was difficult to determine whether or not the layered nanorods had circular cross-sections [Fig. S1(c), ESI†]. The interlayer separation of this rod is *ca*. 0.60 nm, the same value as found for the tubes. At the rod tip, traces of the NbO_x lattice (indicated by the *ca*. 0.37 nm layer distance) are clearly visible [Fig. S1(c) arrowed, ESI†]. The oxide appears to be attached to the larger NbS_2 layers [Fig. S1(c) insert, ESI†] and indicates incomplete oxide-to-sulfide conversion.[19] Large polygonal particles, *ca*. 5 μm diameter, are often observed and appear to possess a layer construction at their edges, akin to the tube layers. EDX analysis revealed that most of the tubes/rods contain Nb, S and C only [Fig. S1(d), ESI†]; the Nb : S ratio is *ca*. 1 : 2. The nanoparticles in which less carbon was detected have the same Nb : S ratio, indicating that they may not be attached to any carbon nanotube templates. These experiments show that NbS_2 nanotubes and nanorods had been successfully generated. The carbon nanotubes located in the middle of the NbO_2 and NbS_2 shells [Fig. S1(b), ESI† and Fig. 1] provide direct evidence for the template effect during NbS_2 formation.

Various phases have been reported in the Nb–S system,[18] however in order to form a tube by rolling up these layers, NbS_2 needs to adopt hexagonal structures, as do WS_2 and MoS_2 nanotubes. This is shown by their 0.60 nm layer separation (Fig. 1), which is *ca*. 0.5 *c*. Prior to the report of Nath *et al*. the existing approaches to MS_2 nanotubes, *e.g*. chemical transport,[5] gas–solid reactions[6] and *in situ* heating,[7] proved to be inapplicable to NbS_2 tubes. Carbon nanotubes have often been used as templates to fabricate novel nanostructures, the most successful examples being the generation of ceramic nanorods (SiC, Si_3N_4, GaN)[20,21] and single-layered inorganic nanotubes (WS_2).[15] Taking advantage of these carbon templates, we have endeavoured to produce inorganic nanotubes by an alternative method. Furthermore, another advantage of this process is that the remaining carbon nanotube templates in the centre, together with the NbS_2 shells, form a kind of composite which may be used as a nanocable (*e.g*. metallic–metallic or a semiconducting–metallic cable).

Upon passage of H_2S at *ca*. 1100 °C over the oxidised sample, oxide-to-sulfide conversion occurs, resulting in sulfide wrapping of the template, as observed for MS_2 species formed in various processes. Further EDX analysis revealed that the Nb:S ratio is close to 1 : 2. Taking account of the 0.60 nm layer separations, we believe that our product consists of NbS_2 nanotubes/nanorods. It is noteworthy that the oxide might be unevenly and discontinuously deposited on the template surfaces [Fig. S1(a), ESI†], however after the passage of H_2S, we rarely found any uneven NbS_2 tubes (Fig. 1). This result could have arisen from the structural rearrangement occurring during lattice replacement of oxide by sulfide, *i.e*. from monoclinic NbO_2 (or other oxides) to hexagonal NbS_2. However, this conversion appears to be different from the route involved in most MoS_2 or WS_2 conversions, in which transformation proceeds from the outer shell inwards, as established by Tenne and coworkers.[19] The incompletely converted oxide residue at the tip [Fig. S1(c), particularly the insert, ESI†] provides direct evidence for this conjecture. We suggest that the oxide residue may again arise as a result of lattice rearrangement during the conversion, which may take place at one or more points (nuclei sites) and subsequent passage along the template. Meanwhile, the temperature (1100 °C) could also contribute to the smooth tube surfaces. As a result, relatively straight uniform NbS_2 nanotubes/nanorods were produced. This growth is similar to that associated with the continuous growth of WS_2 and MoS_2 nanotubes by *in situ* heating, which sometimes leaves an open growing end.[7] The main process may be represented by eqns. (1) and (2)

$$2NbCl_5 + 2O_2 \rightarrow 2NbO_2 + 5Cl_2 \quad (1)$$

$$NbO_2 + 2H_2S \rightarrow NbS_2 + 2H_2O \quad (2)$$

We thank the Leverhulme Trust, the JFCC and the Royal Society for financial support. We are grateful to J. Thorpe and D. Randall (Sussex) for assistance with TEM and SEM facilities.

Observation of a P/M interconversion of a gold–phosphine helicate *via* ^{31}P NMR

Walter Schuh, Holger Kopacka, Klaus Wurst and Paul Peringer*

Institut für Allgemeine, Anorganische und Theoretische Chemie, Universität Innsbruck, Innrain 52a, A-6020 Innsbruck, Austria. E-mail: paul.peringer@uibk.ac.at

Received (in Cambridge, UK) 9th July 2001, Accepted 5th September 2001
First published as an Advance Article on the web 5th October 2001

Ligands containing P–CH_2–CH_2–P elements have been shown to form double-stranded helicates whose axis consists of gold atoms with Au···Au contacts; the interconversion of the P and M forms of the helicate $[Au_3(\mu\text{-}pp_2)_2](OTf)_3$ (pp_2 = $PhP(CH_2CH_2PPh_2)_2$) is monitored *via* ^{31}P NMR.

The occurrence of helical motifs is of great current interest. Helical co-ordination complexes have attracted attention in view of the development and understanding of self processes.[1] We report in this paper that ligands containing P–CH_2–CH_2–P elements form double-stranded helicates whose axis consists of gold atoms with Au···Au contacts. The interconversion of the P and M helicates may be observed *via* ^{31}P NMR in solutions of the tricationic helicate $[Au_3(\mu\text{-}pp_2)_2]^{3+}$.

Whilst gold complexes of the tridentate dppm analogue Ph_2P–CH_2–PPh–CH_2–PPh_2 (dmmp) in the molar ratio of 3:2 are well known,[2] no complexes of Ph_2P–CH_2–CH_2–PPh–CH_2–CH_2–PPh_2 (pp_2) in this stoichiometry appear to be reported. Reaction of $Au(SMe_2)Cl$ with pp_2 and TlOTf in the molar ratio of 3:2:3 in MeOH results in the formation of $[Au_3(\mu\text{-}pp_2)_2](OTf)_3$, **1**, which was isolated as colourless crystals which exhibit a violet glimmer in daylight.†

The structure of **1** (Fig. 1) shows two ligand strands wrapped as a double helix around three essentially linear gold atoms. Crystals of **1** are a racemic compound: the asymmetric unit contains one helicate. The symmetry operations of the centrosymmetric space group $P2_1/c$ additionally provide one identical and two inverted helicates corresponding to a P:M ratio of 1:1 as usually observed when achiral ligands are employed. The Au–Au distances are less than 300 pm as a result of 1,6-transannular Au–Au d^{10}–d^{10} interactions in the 10-membered $(Au–P–CC–P)_2$ rings. Each gold atom is co-ordinated by two P atoms in a nearly linear geometry. It is interesting to note that the related compound $[Au_3(\mu\text{-}pp_2)I_3]$ as well as the Au(III) complex $[Au(C_6F_5)_3]_3(pp_2)$, both with the ligand:Au ratio of 1:3, do not show any helical suprastructures.[5]

The ^{31}P NMR pattern of **1** in MeOH at 333 K consists of an $[A_2X]_2$ pattern; at 213 K an $[AMX]_2$ spin system is observed in keeping with a *C*2 symmetry of the complex cation.[6] The coalescence temperature is 260 K, corresponding to a $\Delta G^{\ddagger}$ of 46 kJ.

In order to rationalise the ^{31}P NMR results with respect to the quasi-*C*2 symmetry in the crystal structure there must exist an intramolecular mechanism in solution which interconverts the terminal phosphorus atoms of the pp_2 ligand P1/P6 and P3/P4 (labelling as in Fig. 1). This is attributed to a molecular torsion pendulum motion, which converts the right-handed into the left-handed enantiomer, and *vice versa*, and thus generates an intramolecular mirror plane perpendicular to the *C*2 axis provided for rapid exchange on the ^{31}P NMR time-scale. A related dynamic process has been described for the 10-membered inorganic mesocycle $[Hg\{Fe[Si(OMe)_3](CO)_3(\mu\text{-}dppm)_2\}Cu](PF_6)$ by Braunstein and coworkers.[7]

The related dication $[Au_2(\mu\text{-}dppe)_2]^{2+}$ has been previously reported but was not structurally characterised.[8] $[Au_2(\mu\text{-}dppe)_2](OTf)_2$, **2**, was obtained analogously to **1**. The solid state structure of **2**† (Fig. 2) is related to that of **1**: the dppe ligands form a double helix whose axis passes through the two gold atoms connected by a 1,6-transannular Au–Au d^{10}–d^{10} interaction in a 10-membered $Au_2(\mu\text{-}dppe)_2$ ring [Au1–Au2, 295.94(10) pm], and the unit cell contains one left- and one right-handed isomer. Although the phosphorus atoms of the dppe ligands are inequivalent in the solid state (see Fig. 2), their

Blue emission from cysteine ester passivated cadmium sulfide nanoclusters

Sameer Sapra,[a] J. Nanda,[a] D. D. Sarma,*[a] F. Abed El-Al[b] and G. Hodes[b]

[a] *Solid State and Structural Chemistry Unit, Indian Institute of Science, Bangalore-560 012, India. E-mail: sarma@sscu.iisc.ernet.in*

Received (in Cambridge, UK) 20th July 2001, Accepted 18th September 2001
First published as an Advance Article on the web 5th October 2001

A one-pot synthesis is reported of water-soluble cadmium sulfide nanoclusters capped with cysteine ester, with an average size of 2.0 nm and fluorescing in the blue region, establishing the possibility of using these as fluorescent biological probes.

Nanoclusters of II–VI semiconductors have been extensively studied during the past two decades.[1] On reducing the size of bulk semiconducting materials below their Bohr exciton diameter,[2] the band gap can be varied continuously from the bulk value to a relatively large one, thus allowing one to tune the electronic properties.[3] These nanoclusters are typically of the order of or smaller than characteristic sizes of various features in biological molecules and therefore have potential applications as biological sensors.[4] With this application in mind, we have synthesized CdS nanoclusters passivated with cysteine ester. Our study establishes the feasibility to cap the CdS nanoclusters with biological molecules such as peptides having the cysteine amino acid, for possible use as a fluorescent probe.[5] Also, cysteine ester passivates the surface states of the nanoclusters more effectively compared to other thiols and shifts the mid-gap, surface-state dominated fluorescence closer to the band edge. For example, the PL spectra from CdS nanoclusters capped with thioglycerol always peaks at 530 ± 20 nm, although the cluster size is varied from 2.0 to 4.5 nm, thereby tuning the bandgap from 3.8 eV (≈ 325 nm) to 2.5 eV (≈ 500 nm).[6] The cysteine ester therefore acts as both a more effective capping agent, resulting in a blue emission (≈ 470 nm), as well as a biologically active end-group for targeting specific cell sites.

We have prepared cysteine ester passivated CdS nanoclusters by a one-pot solution phase technique. 1.066 g (4.0 mmol) $Cd(OAc)_2{\cdot}2H_2O$ was dissolved in 40 ml dimethylformamide (DMF) along with 0.858 g (5.0 mmol) L-cysteine methyl ester hydrochloride. 0.480 g (2.0 mmol) $Na_2S{\cdot}9H_2O$ was dissolved in 10 ml double-distilled water and added to the DMF solution dropwise under an argon atmosphere. The solution was then heated at 60 °C for 12 h. A light yellow powder of CdS nanoclusters capped with cysteine ester was precipitated with acetone after rotavaporizing the solution. The powder was dried *in vacuo* for 5 h, yielding water soluble CdS nanoclusters.

Fig. 1(a) shows a high-resolution transmission electron micrograph (HRTEM) of a CdS nanocluster. The particles are spherical in shape and the lattice fringes can be clearly observed. In order to estimate the particle size distribution, the nanoclusters were dispersed on the TEM sample holder grid and a lower resolution transmission electron micrograph, as shown in Fig. 1(b), recorded. The histogram of cluster size obtained from Fig. 1(b) is shown in Fig. 1(c), indicating an average particle diameter, d_{av}, of 2.0 nm with a standard deviation of 0.19 nm.

The powder X-ray diffraction pattern is shown in Fig. 2. The peak at $2\theta = 5.1°$ arises from the close packing of the individual clusters, defining a characteristic separation equal to the average diameter of the clusters; we estimate the d_{av} from this to be 1.7 nm, in reasonable agreement with the TEM result. The width of the diffraction peak at 27.6° is determined by the particle size *via* the Debye–Scherrer formula. We have performed a Debye–Scherrer broadening[7] on the bulk CdS XRD pattern. The bulk XRD pattern[8] and the broadened pattern are also shown in the Figure with the extent of broadening corresponding to a cluster size of 1.5 nm. The slight underestimation of particle size in this case may be due to defects present in the nanoclusters.[9,10]

The UV–VIS absorption spectra of an aqueous solution of the nanoclusters, shown by the solid curve in Fig. 3, exhibits a fairly sharp excitonic peak at 303 nm (4.1 eV), with the bandgap ≈ 3.6 eV estimated from the absorption onset. To correlate the size with the absorption threshold of the nanoclusters, we have developed a method using a realistic sp^3d^5 orbital basis[11] instead of the previously used sp^3s^* basis[12] within the tight-

 DOI: 10.1039/b106420g

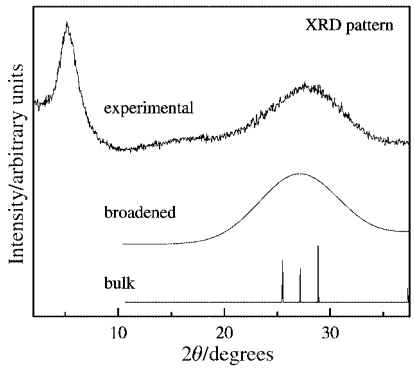

Fig. 2 XRD pattern of CdS nanoclusters. Shown below are the simulated XRD pattern for 1.5 nm clusters and the experimental bulk CdS XRD pattern.

binding model. According to our calculations, the size of CdS nanoclusters corresponding to the absorption onset shown in Fig. 3 is 1.8 nm. This is in good agreement with the size determined from TEM and XRD. The fluorescence excitation and emission spectra are also shown in Fig. 3. The particles emit strongly in the blue region of the visible spectrum (470 nm) upon illumination by UV radiation, establishing a substantial blue shift in emission compared to normally produced CdS nanoclusters with most other organic passivating agents such as

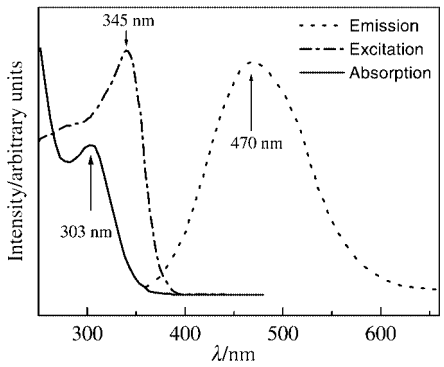

Fig. 3 UV–VIS and fluorescence spectra recorded from an aqueous solution of CdS nanoclusters.

thiols, thereby confirming cysteine as a more effective capping agent compared to thiols. FTIR results from the sample (not shown here) show that all the absorption bands of the cysteine shifted towards lower wavenumbers compared to the spectra for the pure ester, thereby indicating that the ester is bound to the heavy nanoclusters.

In conclusion, we have synthesized CdS nanoclusters passivated by cysteine-ester, suggesting the possible use as biological probes. This passivation quenches the deep trapped surface states and causes the nanoclusters to emit in the blue region, which otherwise emit yellow–orange radiation. The sizes determined from various methods are in good agreement.

We thank Mr J. Basu and Professor V. Jayaram for help with the TEM work and useful discussions. This work is supported by the Department of Science and Technology, Government of India, under the Indo–Israeli program of cooperation.

Sn-MCM-41—a heterogeneous selective catalyst for the Baeyer–Villiger oxidation with hydrogen peroxide†

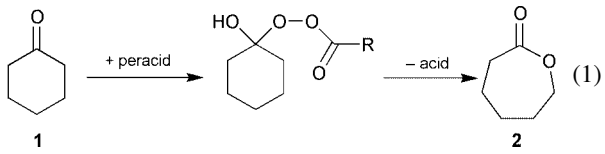
Avelino Corma,*[a] María Teresa Navarro,[a] Laszlo Nemeth[b] and Michael Renz[a]

[a] *Instituto de Tecnología Química, UPV-CSIC, Avda. de los Naranjos s/n, 46022 Valencia, Spain. E-mail: acorma@itq.upv.es*
[b] *UOP Research Center, 50 East Algonquin Road, Des Plaines, IL 60017-5016, USA*

Received (in Cambridge, UK) 4th July 2001, Accepted 13th September 2001
First published as an Advance Article on the web 5th October 2001

A new heterogeneous catalyst, Sn-MCM-41, is described for the Baeyer–Villiger reaction with hydrogen peroxide which selectively activates the carbonyl function for the nucleophilic attack by the oxidant, with high chemoselectivities when double bonds are present in the molecule.

The Baeyer–Villiger (BV) reaction is one of the most important transformations in synthetic organic chemistry. Its mechanism involves a nucleophilic attack on the carbonyl group by the oxidant followed by a concerted rearrangement with retention of the configuration at the migrating carbon atom [eqn. (1)].[1]



(1)

1 **2**

Up to the present, the only suitable oxidants for the BV reaction were the peracids which involve not only safety problems but also a bad atom economy and therefore cause waste material.[2] For economic and environmental reasons a big effort has been made to develop a catalytical method, preferentially a heterogeneous one. Recently, the catalytic action of redox molecular sieves, namely Mn-AlPO-36 and Co-AlPO-36, on the oxidation of ketones to lactones has been reported.[3] However, the reaction is carried out by peracids prepared *in-situ* from sacrificial benzaldehyde and oxygen. To overcome the waste problem, the peracid oxidant should be replaced by hydrogen peroxide activated by a suitable catalyst. Soluble Pt complexes have shown a good activity and turnover numbers (TON, catalytic cycles per metal centre) close to 50 with good selectivities towards the lactones.[4] The anchoring of these complexes onto a polymer has been attempted, but the loss of catalytic activity with respect to the homogeneous system observed introduced a serious limitation for a potential commercial application.[5] TS-1 zeolite has been used in the presence of H_2O_2 as catalyst for the BV reaction, but the selectivity to the desired product was lower than 65% due to the formation of α-hydroxy ketones and other undesired products.[6] These catalysts were designed to activate H_2O_2 by co-ordination with the metal, forming the corresponding metal peroxide that was the oxidising agent. Unfortunately, the metal peroxide formed also oxidises other functions such as alcohol or olefinic groups that may be present in the reactant molecule, and thus strongly limits the chemoselectivity of these catalysts.

We have developed a solid catalyst for the BV reaction which allows the reaction the reaction to work with H_2O_2 and is highly selective. We started from the concept that, for making a good BV solid catalyst, the catalytic sites should selectively activate the ketone instead of the H_2O_2. In this way, we could increase the positive charge on the carbon atom of the carbonyl group and facilitate the nucleophilic attack on this group by H_2O_2. Thus, Sn-MCM-41 samples with 1, 2 and 9 wt% of Sn, calculated from SnO_2, were synthesised in the following way.

An aqueous solution of hexadecyltrimethylammonium hydroxide/bromide (C_{16}TAOH/Br) was mixed with a tetramethylammonium hydroxide solution (25%, Aldrich) and an aqueous solution of $SnCl_4 \cdot 5H_2O$ (98%, Aldrich). After homogenisation, the silica (Aerosil, Degussa) was added under continuous stirring. The final composition was the following: 1 SiO_2:(0.16 − 4x) C_{16}TABr:4x C_{16}TAOH:0.26 TMAOH:x $SnCl_4$:24.3 H_2O, where x was varied between 0.04 and 0.01. C_{16}TABr was partially exchanged in order to compensate for the OH^- depletion produced by the incorporation of $SnCl_4$ into the synthesis gel. The homogeneous gel was sealed in Teflon-lined stainless steel autoclaves and heated at 135 °C under static conditions for 24 h. The resulting solid product was recovered by filtration, washed with water and dried at 60 °C for 24 h. The occluded organic was removed by heating the solid at 540 °C for 1 h in a flow of N_2, followed by 6 h in air. The solid obtained presents a typical XRD pattern of MCM-41 structure.†

For the catalytic activity tests *ca.* 1.2 mmol cyclohexanone (**1**) and *ca.* 1.5 mmol of H_2O_2 (35 wt%) were dissolved in 3.00 g of methyl *tert*-butyl ether (MTBE) and were stirred and heated to 56 °C with 50 mg of the catalyst for 6 h. The reaction was followed by GC analysis and the ε-caprolactone (**2**) product was identified by GC-MS analysis and by comparison with the authentic sample. With the Sn-MCM-41 catalyst with 1% SnO_2 a conversion of 15% was observed which corresponded to a turnover number (TON) of 55 (Table 1, entry 1), while the selectivity towards the lactone was 96%. This result was a big improvement compared to the selectivities obtained with the TS-1/H_2O_2 oxidation system (Table 1, entry 5). Conversion was increased by increasing the amount of Sn, and the high selectivity to the lactone was maintained (Table 1, entries 2 and 3). However, the TON was lower when the Sn content was increased, indicating that not all the Sn introduced was active. It must be noted that SnO_2 impregnated on silica gave no activity for the BV reaction (Table 1, entry 4). In order to discuss the nature of the active sites, a Sn-MCM-41 sample was prepared using the ^{119}Sn isotope (2% SnO_2), which can be detected by

3 4

Entry	Time/h	**3**/mg	Ratio Sn/**3** (mol/mol)	Conv. (%)	TON[a]	TOF[a]	Selectivity (%)
1	6	150	0.03	>98	32	24	>98
2	6	150	0.03	72[b]	24	48[c]	>98

[a] See Table 1. [b] The catalyst was removed by filtration after 30 min. The conversion after 30 min was already 72% and did not change during the rest of the reaction time. [c] TOF calculated on the first 0.5 h.

MAS NMR. Indeed, by this analytical method it could be confirmed that the Sn sites of Sn-MCM-41 were different to those of SnO_2.

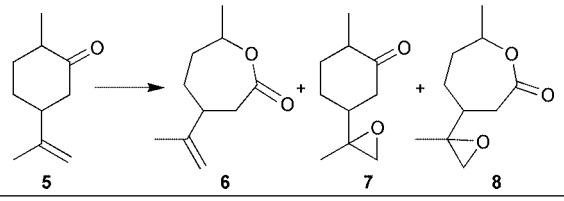
The large pore diameter of MCM-41 should allow the oxidation of sterically more demanding reactants. To study this, adamantanone (**3**) was reacted in the following way: 1 mmol of adamantanone and 1.5 mmol of H_2O_2 (35%) were dissolved in 3.00 g of dioxane, and 50 mg of Sn-MCM-41 (9% SnO_2) catalyst were added and stirred at 90 °C. After 6 h no substrate could be detected and the corresponding lactone **4** was the only product, with a selectivity to H_2O_2 of >90% (Table 2, entry 1). In order to check the possible contribution of the homogeneous reaction, another experiment was carried out in which the catalyst was separated by filtration after 30 minutes reaction time and 70% conversion. The solution was further heated for 5.5 h and the conversion did not proceed further, confirming that the active species was the metal incorporated into the framework and not any leached species in solution. Furthermore, it was shown that a homogeneous Sn species has an activity almost one order of magnitude lower than the Sn incorporated into the MCM-41 framework (*cf.* Table 1, entries 2 and 5).

With respect to catalyst life, we have observed that some deactivation occurs during the reaction when the same catalyst is recycled three times. The decrease in the catalyst activity is especially pronounced after the first recycle for which the TON decreased from 42 to 17 after 3 h. However, further recycling did not show any notable decrease in activity (16 and 16 TON for cycles 3 and 4, respectively). In order to check if the deactivation during the first recycling was due to leaching and/or to the adsorption of some product, the catalyst after the first recycling was filtered at the reaction temperature (90 °C) and then air calcined at 540 °C for 6 h. The calcined catalyst was again used in the reaction, and a TON of 35 was observed. This indicated that the decrease in activity observed in the first cycle cannot be attributed mostly to leaching of some of the less stable Sn, but it is mainly due to catalyst poisoning by organic deposits.

A very interesting result was observed when an unsaturated ketone was employed as substrate, *e.g.* dihydrocarvone (**5**). With the traditional oxidant for the BV oxidation, the peracids, the main product was the epoxyketone **7** in the case of a deficit of oxidant (Table 3, entry 1). When an excess of the oxidant was used, both types of oxidation, *i.e.* BV oxidation and epoxidation, occurred and consequently the epoxylactone **8** was obtained. When Sn-MCM-41 (9% SnO_2) was used as catalyst and H_2O_2 (35 wt%) as oxidant, the lactone **6** was the main product, although the selectivity was lower than with Sn-Beta zeolite[7] (Table 3, entry 3). This showed that with the Sn-MCM-41 catalyst unsaturated lactones can be obtained while, with the classic peracid or other reported catalysts, the unsaturated lactones cannot be synthesised because the epoxidation reaction competes very effectively (see ref. 8 and Table 3).

The reason for this extraordinary selectivity probably has its origin in the type of catalysis. If the catalyst can activate the peroxide, epoxidation will also be observed. This was the case

Table 3 Selectivities in the oxidation of dihydrocarvone (**5**) with different oxidants.



5 6 7 8

Oxidant	Equiv.	Conv. (%)	Product distribution (%) **6**	**7**	**8**	Other[a]

[a] Others products include: other oxidation products, *e.g.* the α-hydroxyketone or hydrolysis products.

for $MeReO_3$ which catalysed BV oxidation[9] as well as epoxidation.[10] So, it was more probable that the Sn-MCM-41 interacted with the ketone by activating the carbonyl group for the nucleophilic attack by hydrogen peroxide. This was tested by carrying out *in-situ* IR experiments in which cyclohexanone was adsorbed on Sn-MCM-41. The results showed that, indeed, a shift of the carbonyl band towards lower wavenumbers occurred (48 cm^{-1}), and the ketone remained co-ordinated even at 100 °C. With an all-silicon MCM-41 sample this shift in the carbonyl signal was not observed.

In summary, Sn-MCM-41 opens up a new class of catalysts for the BV reaction with hydrogen peroxide. High turnover numbers with good selectivities to lactones are observed and, furthermore, the catalysts show a reasonable chemoselectivity when olefinic groups are present in the reaction.

The authors thank the CICYT (MAT2000-1392) and UOP for financial support. M. T. N. thanks the 'Fundación Ana y José Royo' for a postdoctoral grant.

Received (in Cambridge, UK) 1st August 2001, Accepted 18th September 2001
First published as an Advance Article on the web 5th October 2001

The synthesis and structural characterisation of the diamino-bis-pyridine ligand L^2 and its diammonium-bis-pyridinium salt $[(H_4L^2Cl)_2]\cdot 6Cl\cdot H_2O$ 1, are reported; X-ray diffraction studies reveal that chloride coordination causes the latter to adopt a double-helicate structure in the solid-state.

In recent years coordination chemists have developed several strategies to predict the outcome of self-assembly processes and have used this information to exert influence over the subsequent architectures adopted during these processes.[1] Much of the current literature has concentrated on metal-assisted, self-assembly processes where ligands are tailored for the recognition of the intrinsic stereochemical properties of a particular metal ion. Fine tuning of ligand properties such as donor density, type and number as well as the spacer group separating coordination sites has led to a plethora of resultant structural motifs such as grids,[2] boxes,[3] cylinders,[4] helicates[5] and molecular polyhedra.[6] In contrast, there have been relatively few reports detailing 'metal-free' anion directed self-assembly processes, despite there being considerable current interest in the development of molecular and supramolecular systems which have the ability to bind negatively charged ions.[7,8] The motivation behind such studies is the recognition that anions enjoy an important role in biology, medicine and the environment.[8] Typically, these systems utilise hydrogen bonding and electrostatic interactions to bind anions, and many varieties exist based on chemical archetypes including amides, ureas, pyrroles, ammonium macrocycles, guanidinium and pyridinium moieties.[7,8] However, we are aware of only one such report detailing the formation of a helical structure as a result of an anion directed self-assembly process. de Mendoza and coworkers synthesised a tetraguanidinium strand that self-assembled around sulfate ions to form a double helix, as evidenced by ROESY NMR spectroscopy.[9] Herein, we report the synthesis and structural characterisation of the diamino-bis-pyridine ligand L^2 and the dinuclear double helicate of its diammonium-bis-pyridinium salt $[(H_4L^2Cl)_2]\cdot 6Cl\cdot H_2O$ **1**. To the best of our knowledge, this is the first structurally characterised example of an anion directed assembly of a helicate.

L^2 was prepared from its bis-imine progenitor,[10] L^1, by standard borohydride reduction and isolated in 65% yield as a white crystalline product of suitable quality for a diffraction study.‡§ The atomic numbering scheme and atom connectivity are shown in Fig. 1. There is a clear twist evident on traversing the molecule from N(1), through the central phenyl rings, to N(29). The two pyridyl moieties are inclined at an angle of 81° to one another and the phenyl groups are rotated by 99° with respect to each other. The nitrogen atoms N(1) and N(29) make close contacts with H(7a) and H(23a') (symmetry code: $-1+x$, $1+y$, z), respectively, forming C–H···N hydrogen bonded chains. The chains are further linked into a 3D hydrogen bonded network *via* edge-to-face N–H···π [N(22)–H(22)–centre-of-ring, 2.77] and combined N–H···π, C–H···π interactions (3.14 and 2.80 Å to centre-of-ring, respectively). Interestingly, there are no face-to-face π···π interactions between the molecules.

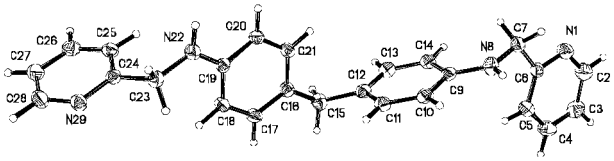

Fig. 1 Molecular structure and atomic numbering scheme of L^2.

Addition of dilute hydrochloric acid to a methanolic solution of L^2 induced the precipitation of a pale yellow solid in quantitative yield. Recrystallization afforded single crystals of **1** suitable for a diffraction study.‡§ The atomic numbering scheme and atom connectivity are shown in Fig. 2. The asymmetric unit contains two independent cations located about twofold axes. Two of the Cl^- anions are also located on two-fold axes. The structure consists of two ligand strands that wrap around two chloride anions in a double helical arrangement with a major and minor groove, both enantiomers of which are present. The chloride ions are coordinated by two pyridinium moieties, with further weaker interactions from the methylene and aromatic CH residues being evident. There is no interaction between the coordinated chloride ions and the ammonium moieties N(8). Coordination is such that the anions reside within a cleft formed by the two ligand strands giving an intramolecular $Cl^-\cdots Cl^-$ separation of 13.17 Å, (Fig. 3). Interestingly, there are no intrahelicate cross-strand π···π interactions (closest contact > 4.5 Å). There are, however, extensive inter-helicate intermolecular π···π interactions (3.4–3.9 Å) between the phenyl rings [C(9)–C(14)] and the pyridyl rings [N(1)–C(6)] of neighbouring helicates in contrast to L^2. The lattice anions are involved in extensive hydrogen bonding with the ammonium moieties [N(8)] and this results in the formation of a 3D network supported by a combination of these hydrogen

bonds and the π···π interactions. This is further enhanced by hydrogen bonding between Cl(4) and the lattice water molecule O(1w).

It is instructive here to compare and contrast the structures of L^2 and **1** with the metal helicate complexes of the bis-imine ligand L^1.[10] From the structure of L^2 it is evident that nothing inherent within it pre-organises it to form a helical motif in the absence of a suitable template. The rigid nature of the central diphenylmethane spacer does, however, predispose L^2 to coordinate to two (or more) guests. This is probably the key feature of L^2 that leads to the formation of the helicate, as it has been shown that highly flexible, sterically unencumbered polyammonium hosts do not generate this topology upon guest binding.[11] The formation of **1** is also due to the template effect of the chloride anion following protonation of L^2. Once coordinated, the anion resides within a shielded pocket at the head of the helicate. It is coordinated in pincer fashion by the two pyridinium moieties *via* charge assisted hydrogen bonds, and further stabilised by weaker interactions with methylene and aromatic hydrogen atoms from deeper within the pocket. Despite the inherent flexibility in the system, there are no intramolecular interactions between the ligand strands. Previously, it has been proposed that contacts of this type help promote and stabilise the formation of related metallo-helicates, $[M_2L^1{}_3]$, and are responsible for the resultant helicate micro-architecture.[10b–e] The lack of any cross-strand contacts here may potentially arise from the relatively larger ionic radius of the chloride anion {*cf.* M(II) cations}, but we suspect that the lack of a preferred coordination geometry for chloride more than adequately offsets this size difference. This adds weight to our contention that metal coordination, and not intra-helicate π···π interaction, is a primary driving force for helicate formation and the resultant solid-state structures in $[M_2L^1{}_3]$ compounds.[10af] The coordination of L^1 to a metal centre applies strain to the ligand, whereas the hydrogen-bonded nature of **1** allows the ligand, L^2, to adopt an unstrained conformation, notably with no intra-strand interactions. We would therefore expect protonated salts of L^1 and related ligands to coordinate anions in a similar fashion and are currently investigating these systems. ^{1}H NMR and potentiometric titration experiments are also underway to determine the stability constants of **1** and analogous systems in solution.

In conclusion, we report here the synthesis and structural characterisation of a new diamino-bis-pyridine ligand L^2 and demonstrated that it, on addition of HCl, generates a novel dinuclear double helicate. We believe this to be the first structurally characterised example of the anion directed assembly of such a motif.

Enterprise Ireland is thanked for financial support by way of a Ph.D. studentship to J. K. Mr Robert Doyle (TCD) is thanked for assistance with the ESMS.

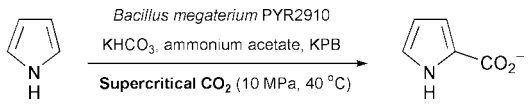
Received (in Cambridge, UK) 12th June 2001, Accepted 17th September 2001
First published as an Advance Article on the web 3rd October 2001

Pyrrole was converted to pyrrole-2-carboxylate in supercritical CO_2 using cells of *Bacillus megaterium* PYR 2910, and the yield of the carboxylation reaction in supercritical CO_2 was 12 times higher than that under atmospheric pressure.

The development of CO_2 fixation reactions on organic molecules is one of the challenges in synthetic chemistry. An increasing number of chemical CO_2 fixation reactions[1] have been reported, especially using supercritical CO_2 (CO_2 above its critical temperature (31.0 °C) and pressure (7.38 MPa, 72.8 atm)), such as the synthesis of urethane,[1b] dimethyl carbonate,[1c] styrene carbonate[1d] methyl ethanoate.[1e] On the other hand, biocatalysis is now one of the most powerful and indispensable tools for organic synthesis due to its environmentally friendliness and excellent enantio-, regio- and chemo-selectivities.[2] Some enzymatic CO_2 fixation reactions have also been reported including the central CO_2 fixation reaction in photosynthetic organisms catalyzed by ribulose-1,5-diphosphate carboxylases,[3] the reduction of CO_2 to formic acid or methanol by dehydrogenases,[4] the reductive CO_2 fixation on 2-oxoglutarate and pyruvate by isocitrate[5] or malate[6] dehydrogenases, and the CO_2 fixation on pyrrole and phenolic compounds (phenol and catechol) by decarboxylases from *B. megaterium*[7] or *Clostridium hydroxybenzoicum*,[8] respectively.

Although enzymes in nature catalyze reactions in aqueous media, their use in supercritical CO_2 has been attracting increasing attention due to its gas-like low viscosities and high diffusivities and its liquid-like solubilizing power,[9] and mostly hydrolytic enzymes, with the exception of the cholesterol oxidases[10] and the alcohol dehydrogenase,[11] have been used in supercritical fluids to improve their functions, *i.e.*, faster reaction rates.[12] Here we report that cells of *Bacillus megaterium* PYR2910 catalyzes the reverse reaction, CO_2 fixation, in supercritical CO_2 for the first time. As shown in Scheme 1, CO_2 was fixed on pyrrole to produce pyrrole-2-carboxylate at 10 MPa and 40 °C. The yield of the reaction in supercritical CO_2 was much higher than that at atmospheric pressure.

The cells of *Bacillus megaterium* PYR2910[7] were employed for the CO_2 fixation reaction. The reaction was conducted by adding CO_2 to 10 MPa to the mixture of pyrrole, the cells, $KHCO_3$, and NH_4OAc in potassium phosphate buffer. For the reaction at atmospheric pressure (0.1 MPa), the evolved CO_2 was released to keep the pressure atmospheric. The yields of the reaction at 40 °C are listed in Table 1. The yield is much higher for the reaction in supercritical CO_2 than at atmospheric pressure (Table 1, Entries 1–4). It was also confirmed by the control experiment without the cells that the non-biocatalytic carboxylation of pyrrole did not proceed (Table 1, Entry 5).[13] Therefore, the cell is surely catalyzing the CO_2 fixation reaction more effectively in supercritical CO_2 than at atmospheric pressure.



Scheme 1

The time courses of the reaction at 10 MPa and at atmospheric pressure in Fig. 1 also have a higher yield for the supercritical reaction than that of the atmospheric reaction. The reaction reached an equilibrium position within a few hours and did not proceed further. As listed in Table 1, the doubling of the quantity of cells (Entry 6) as well as the change in the initial pH value from 5.5 to 7.0 to prevent a pH decrease caused by CO_2 (Entry 7) did not have any significant effect on the equilibrium position.

The effect of pressure on the carboxylation of pyrrole was also investigated, and the result is shown in Fig. 2. The maximum yield was between 4 and 7 MPa; the yield at just above its critical pressure (7.6 MPa) is about 12 times that at atmospheric pressure (0.1 MPa). Similar pressure dependencies of the yield on pressure were also observed using an increased quantity of the cells, shorter reaction times, and different temperatures (data not shown). At present, it is not clear why the increased concentration of CO_2 in the range greater than the

Table 1 Conversion of pyrrole to pyrrole-2-carboxylate in supercritical CO_2 at 40 °C

Entry	Pressure/MPa	Cells/mL[a]	pH	Time/h	Yield (%)[b]

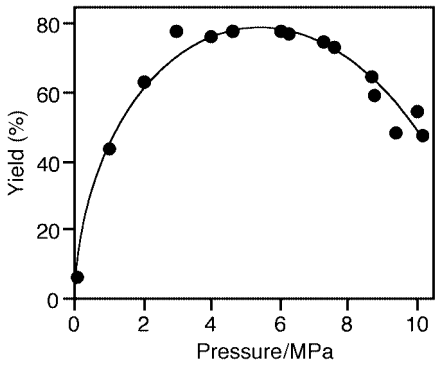

Fig. 2 Effect of pressure on conversion of pyrrole to pyrrole-2-carboxylate by the cells.

critical pressure did not favorably shift the carboxylation equilibrium.

In a typical experiment, *B. megaterium* PYR2910 was grown as previously described.[7b] To a stainless steel pressure-resistant vessel containing a magnetic stirrer bar as previously described,[11] pyrrole (0.40 M, 0.50 mL), potassium phosphate buffer (pH 5.5, 0.40 M, 0.50 mL), ammonium acetate (0.56 M, 0.50 mL), the cells (OD_{610} = 32, 0.50 mL) and $KHCO_3$ (0.60 g) were added. The vessel was then warmed to 40 °C, and CO_2 preheated to 40 °C was introduced to a final pressure of 10 MPa. The mixture was stirred at 40 °C for 3 h, and the CO_2 was liquefied at −10 °C and then the gas pressure was released. The chemical yield was measured by HPLC analysis as previously described.[7b]

In conclusion, cells of *B. megaterium* catalyzed the conversion of pyrrole to pyrrole-2-carboxylate in supercritical CO_2 at 40 °C with pressures up to 10 MPa, and a higher yield was obtained under supercritical conditions than at atmospheric pressure. This finding will play a significant role both in investigating enzyme species suitable for the biocatalysis in supercritical CO_2 and in developing synthetic methods utilizing CO_2.

Mesoporous silicon doped with 3.0×10^{19} B atoms cm^{-3} (p^+-type) is an insulating material which dramatically increases its electrical conductivity when exposed to traces of gaseous NO_2; nitrogen dioxide chemisorption at the surface generates carriers, the population of which is readily evaluated through the intensity of IR absorption.

Porous silicon (PS) is obtained through the electrochemical etching of semiconducting phosphorus- (n-type) or boron- (p-type) doped crystalline silicon.[1–3] When the etching is performed on silicon with an impurity level of around 1×10^{19} B cm^{-3} (p^+ type), a mesoporous system with a dendritic structure (see graphical abstract) is obtained, with a surface area ranging from 200 to 600 m^2 cm^{-3} (N_2 BET). Although the etching process is believed to remove selectively only silicon atoms,[4] it causes the depletion of carriers present in the pristine material: PS nearly behaves like an insulator and is consequently practically transparent to mid-IR radiation.

Curve **a** in Fig. 1 reports the spectrum, taken under vacuum, of a self-supporting membrane of PS (40 μm thick, 60% porosity). Peaks are seen around 2100 cm^{-1} and below 1000 cm^{-1}, where fall the vibrational modes of hydride-terminated silicon species,[5–7] SiH_x (or Si_yH_x) formed during the electrochemical etching, and those related to oxidised species.

The smooth increase of the background absorption below 2000 cm^{-1} (broken curve) is due to residual free carriers and is therefore described by the Drude equation,[8] according to which the absorption coefficient is proportional to both the square of the wavelength and to the concentration of carriers. Fitting the Drude equation to the background of curve **a** yields[9] *ca.* 3×10^{17} cm^{-3} free carriers, *i.e.* about 99% of the boron atoms no longer act as electron traps. Curve **a** also shows interference fringes, due to multiple reflections of the IR beam at the rather regular boundaries of the sample.

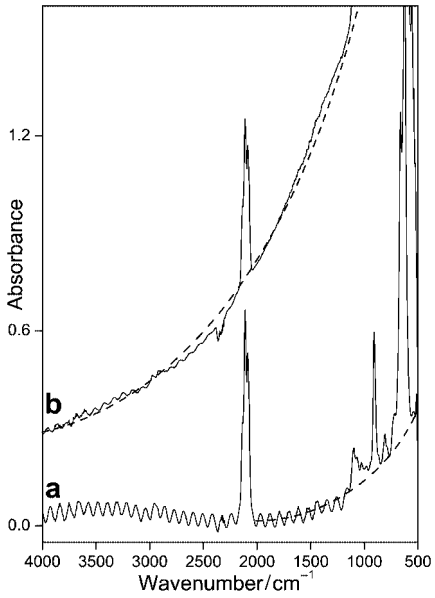

Fig. 1 IR spectra of p^+-type PS *in vacuo* (curve **a**) and under 1 mbar of pure NO_2 (curve **b**). Broken curves are simulations of the background according to the Drude law (see text).

With p^+-type PS (and only in this case), the electrical conductivity has been found[10] to increase when the voids are filled by polar liquids with high dielectric constant. On the other hand, still with p^+-type PS, it has recently been observed, through dc electrical measurements,[11] that the original semiconducting character may be partially restored through the contact of gaseous NO_2 already at very low (sub-ppm) concentrations.

We used FTIR *in situ* spectroscopy to investigate the interaction of gaseous species on the PS surface in the mid-IR region. Whereas extensive studies[5–7] have been performed on H_2 and O_2 environments in PS, no FTIR study of the interaction of other gases with the PS surface is available. A sample of p^+-PS was exposed to a few mbar of different pure gases: NO_2, CO, NH_3, NO, O_2 and acetone. While no response to the latter five species is seen, an impressive response to NO_2 develops in a few seconds. Curve **b** in Fig. 1 shows that, after the admission of gaseous NO_2, an absorption appears, monotonically increasing from about 4000 cm^{-1}. This spectral profile is again described by the Drude law: as a consequence of the interaction with NO_2, a higher concentration of carrier is observed (around 3×10^{18} holes cm^{-3}). Because of the increased absorption, interference fringes are drastically decreased.

The intensity of the IR absorption (*i.e.* the concentration of carriers) depends upon pNO_2. Fig. 2 reports the intensity measured at three arbitrarily chosen frequencies (1300, 1900 and 2500 cm^{-1}) plotted against the equilibrium pNO_2: a saturation effect is seen for comparatively low pressures, irrespective of the wavelength chosen. This suggests that the behaviour of PS in the presence of NO_2 is due to an entirely different mechanism with respect to dielectric or polarization effects invoked as explanation of the conductivity induced by polar substances condensed in the pores.[10] A chemically guided process, *i.e.* a chemisorption phenomenon, is likely to be the reason for the generation of free carriers. Attempts to evaluate volumetrically the amount of adsorbed molecules showed that this is rather small, at the most a fraction of the boron atoms present in the system. This is probably also the reason why no signal due to chemisorbed molecules is seen in curve **b** of Fig. 1.

The chemical nature of the interaction between PS and NO_2 is supported by the fact that NO_2 has the highest electron affinity[12] among the gases studied by us. This high value (2.273 eV) is probably the key factor in determining the unique selectivity shown by PS. A species roughly describable as NO_2^- may be formed by the trapping of an electron at the surface, whereas such a process is far less likely for NO and O_2, with a much smaller electron affinity[13,14] (0.45 and 0.026 eV,

 DOI: 10.1039/b106188g

respectively), and is impossible for the other molecules which do not accept electrons easily.

As it concerns the evolution of the spectra with time, two different behaviours have been observed, depending upon the NO_2 partial pressure. With pNO_2 less than 1 mbar, the intensity grows rapidly and remains constant; with higher partial pressures, the absorption reaches a maximum and than decreases slowly, the rate of decrease strongly depending upon the NO_2 pressure. Such an effect, probably due to successive reactions involving nitrogen dioxide, does not interfere, however, with the possible use of PS as an NO_2 sensor, which is of interest in the pressure region to which Fig. 2 refers.

The effect of NO_2 at low pressures is completely reversible within a few seconds, and the interaction can be repeated on the same sample several times. In contrast, with higher NO_2 pressures, the decrease of intensity of the IR absorption is accompanied by a slight oxidation of the PS sample, as shown by the increase of the absorption bands due to the stretching vibrations of oxidised species (Si–O–Si, O_3SiH and O_2SiH_2).[6] This process is irreversible and causes a decrease in the response to NO_2 in successive experiments. Uptake of oxygen by PS is mainly a surface process, at least in the initial stages, leading to the formation of a surface oxidised layer that prevents the chemisorption process. This is further evidence that the generation of free carriers in PS involves adsorption of NO_2 at the surface.

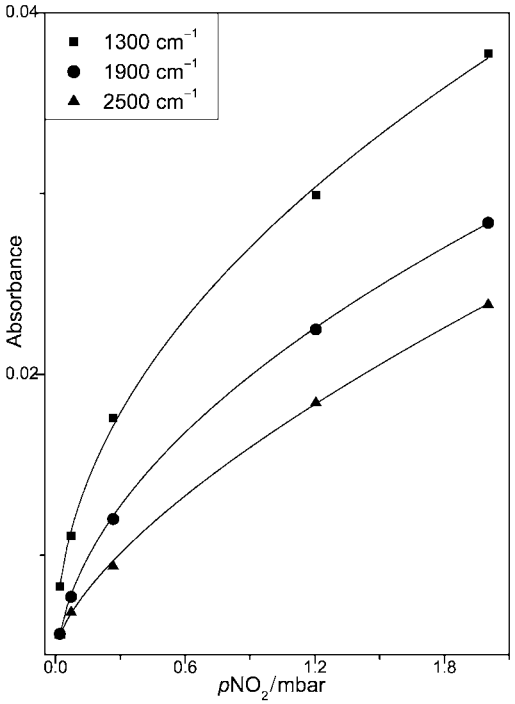

Fig. 2 Absorption normalised to unit thickness (1 μm) at three different wavenumbers against NO_2 equilibrium pressure.

For the sake of completeness, the same experiments were run on a lightly B-doped PS and on n-type PS, and no effect on the background spectrum was seen.

In conclusion, the experimental evidence reported shows that a real chemisorption process takes place at the surface of PS. Also, it suggests that PS may probably be used as a very sensitive NO_2 sensor working at room temperature. At variance with what is observed for oxide-based NO_2 sensors, PS shows a unique selectivity to NO_2 and does not sense other nitrogen compounds such as NO. We have evidence that other atmospheric components like H_2O and CO_2 do not interfere with NO_2: future work will deal with ozone, a molecule strictly similar to NO_2, and therefore a possible source of interference. The detection of the sensing effect is possible on the basis of IR measurements (Fig. 2): taking into account the availability of IR LEDs, the results reported may open a new possibility in the applications of PS as a chemical sensor towards a hazardous pollutant like NO_2, especially when present in trace amounts.

Formation and reactivity of a cobalt(II) hydroperoxide intermediate

Sunita Thyagarajan, Christopher D. Incarvito, Arnold L. Rheingold and Klaus H. Theopold*

Department of Chemistry and Biochemistry, Center for Catalytic Science and Technology, University of Delaware, Newark, DE 19716, USA. E-mail: theopold@udel.edu

Received (in Cambridge, UK) 9th August 2001, Accepted 14th September 2001
First published as an Advance Article on the web 11th October 2001

Reaction of Tp$^{t\text{-Bu,Me}}$Co–H with O_2 proceeds *via* a spectroscopically observable hydroperoxide whose reactivity in solution and in the solid state differ dramatically.

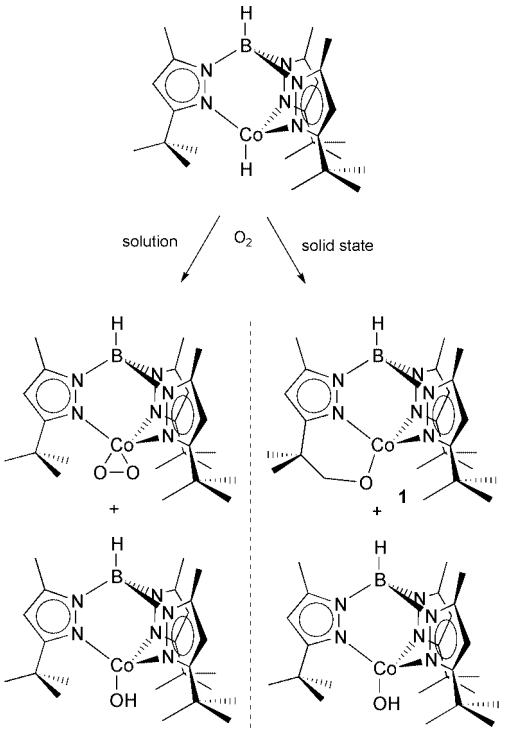
Metal hydroperoxides (M–OOH) are reactive intermediates in metal mediated reactions of hydrogen peroxide and dioxygen. Due to their lability, there are few instances in which such species can be observed spectroscopically,[1] much less characterized structurally.[2] Migratory insertion reactions of O_2 into metal–carbon bonds are rare and mechanistically diverse;[3] their extension to metal hydrides is of interest.[4]

Exposure of a C_6D_6 solution of Tp$^{t\text{-Bu,Me}}$Co-H[5] to an excess of O_2 gas at room temperature caused a rapid reaction that yielded only the known complexes Tp$^{t\text{-Bu,Me}}$Co(O_2) and Tp$^{t\text{-Bu,Me}}$Co–OH in approximately equal amounts (see Scheme 1).[6] In contrast, exposure of solid Tp$^{t\text{-Bu,Me}}$Co–H to oxygen gas (1 atm) produced a new cobalt complex (**1**), along with minor amounts of Tp$^{t\text{-Bu,Me}}$Co–OH.

1 could be separated from the hydroxide by differential solubility and recrystallization from ether yielded purple crystals of **1** in 70% yield. The ^{1}H NMR spectrum of **1** indicated a loss of the threefold symmetry of the Tp$^{t\text{-Bu,Me}}$ ligand. Structural characterization of **1** by X-ray diffraction revealed that one of the hydrogen atoms of a *tert*-butyl group had been replaced with an oxygen atom that was also bonded to cobalt, thus forming a cobalt(II) alkoxide featuring a six-membered ring. The structure determination was unfortunately marred by multiple disorder; however, it allowed the unambiguous assignment of the connectivity of **1**. Addition of one equivalent of 3-*tert*-butyl-5-methylpyrazole to **1** yielded **2**, the structure of which is shown in Fig. 1.[7] Five-coordinate **2** adopts trigonal bipyramidal geometry, with the nitrogen atoms of the free pyrazole (N31) and the functionalized pyrazole (N21) occupying axial positions and those of the remaining two pyrazoles (N1, N11) and the alkoxide oxygen (O1) taking up the equatorial positions.

Carrying out the oxygenation of Tp$^{t\text{-Bu,Me}}$Co–H in toluene at low temperature (−78 °C) revealed a color change from bright blue to purple (reminiscent of the color of Tp$^{t\text{-Bu,Me}}$Co–OH), followed by another change to a grayish green upon warming to room temperature. ^{1}H NMR monitoring of this reaction at −78 °C showed that the resonances of Tp$^{t\text{-Bu,Me}}$Co–H were slowly replaced by a new set of resonances consistent with a three-fold symmetric Co(II) species of the type Tp$^{t\text{-Bu,Me}}$Co–X.[8] Upon warming the solution to room temperature, these resonances disappeared, while those of Tp$^{t\text{-Bu,Me}}$Co(O_2) and Tp$^{t\text{-Bu,Me}}$Co–OH appeared. Further characterization of the intermediate was obtained using *in-situ* IR spectroscopy. When a toluene solution of the hydride at −61 °C was exposed to dioxygen, the Co–H stretch at 1671 cm^{-1} gradually disappeared and was replaced by a broad peak at 3347 cm^{-1}; the latter disappeared upon warming to room temperature. We note that the IR spectrum of a solution of *tert*-butyl hydroperoxide exhibits its broad O–H stretch at 3304 cm^{-1}. Repetition of the same experiment with Tp$^{t\text{-Bu,Me}}$Co–D showed a replacement of ν_{Co-D} (at 1208 cm^{-1}) with a new resonance at 2486 cm^{-1}. Unfortunately, neither experiment revealed the expected ν_{O-O} (*ca.* 800–900 cm^{-1}), which is likely obscured by the many strong bands attributable to the Tp ligand. All these observations are most consistent with the formation and subsequent decomposition of the Co(II) hydroperoxide Tp$^{t\text{-Bu,Me}}$Co–OOH.

A mechanistic proposal for the formation of Tp$^{t\text{-Bu,Me}}$Co–OOH and its different thermal decompositions is shown in



Scheme 1

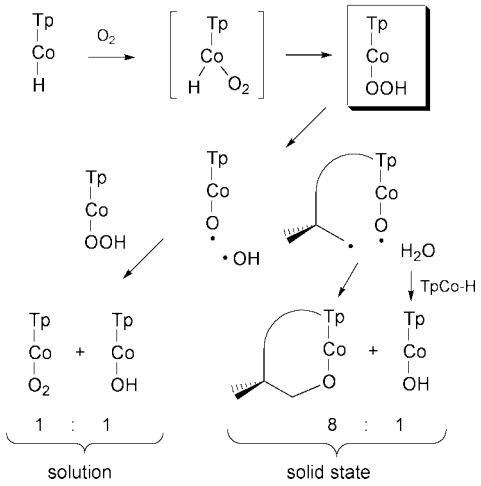

Scheme 2

Scheme 2. The commonly discussed mechanisms for reactions of metal hydrides with O_2 seem not germane here. Thus, a radical chain reaction is ruled out by the observation that Tp$^{t\text{-Bu,Me}}$Co(O_2) does not react with Tp$^{t\text{-Bu,Me}}$Co–H. An alternative deprotonation/O_2-coordination/protonation sequence is unlikely in light of the extremely low expected acidity of the hydride precursor, the conjugate base of which—*i.e.* [Tp$^{t\text{-Bu,Me}}$Co]$^-$—is highly destabilized. We favor a migratory insertion of coordinated O_2 into the Co–H bond. Such a process finds a parallel, if not exact precedent, in the reaction of Tp$^{t\text{-Bu,Me}}$Cr–Ph with O_2.[3g] Hydrogen atom abstraction by O_2, followed by binding of the resulting HO_2, is another possible pathway given the comparable strengths of the Co–H bond of Tp$^{t\text{-Bu,Me}}$Co–H ($D_{Co–H} \approx 60$ kcal mol^{-1}) and the O–H bond of the HO_2 radical ($D_{O–H} = 49$ kcal mol^{-1}).[9]

The O–O bond of peroxides is weak, and cobalt alkylperoxides have been implied to suffer homolysis of this linkage.[10] Homolytic cleavage of the O–O bond of the common intermediate Tp$^{t\text{-Bu,Me}}$Co–OOH would generate a terminal cobalt oxo species (Tp$^{t\text{-Bu,Me}}$Co=O $\leftrightarrow$ Tp$^{t\text{-Bu,Me}}$Co–O$^{\cdot}$) as well as hydroxyl radical. At this point the mechanistic pathways may diverge. In solution the fragments are free to move about and encounter other molecules; the cobalt oxo species may show selectivity and abstract weakly bonded hydrogen from Tp$^{t\text{-Bu,Me}}$Co–OOH in a bimolecular reaction yielding Tp$^{t\text{-Bu,Me}}$Co(O_2) and Tp$^{t\text{-Bu,Me}}$Co–OH in equal amounts. In contrast, in the solid the movements of both fragments are restricted. The hydroxyl radical may abstract a hydrogen atom from the nearest methyl group. The resulting primary radical then combines with the Co–O$^{\cdot}$ moiety to form **1**. The small amount of Tp$^{t\text{-Bu,Me}}$Co–OH produced probably results from diffusion of the reaction product water to unreacted Tp$^{t\text{-Bu,Me}}$Co–H.

In conclusion, our observations show that the reaction of a cobalt(II) hydride with O_2 proceeds *via* the formation of a reactive hydroperoxide intermediate; we propose that the latter is formed by a migratory insertion of bound O_2 into the metal–hydrogen bond. The subsequent transformations of Tp$^{t\text{-Bu,Me}}$Co–OOH are consistent with the formation of a terminal cobalt oxo complex. They also provide another example of different reactivity in solution *versus* the solid state. We have previously made good use of this phenomenon,[11] and it may prove of general utility in synthetic chemistry and mechanistic investigations.

The cation distribution in dehydrated NaX was predicted using appropriate interatomic potentials and (*N,V,T*) simulations, considering the cations as 'guest' particles and the framework as a 'host'; the simulations not only yield the expected different types of sites, but also highlight the cooperative placement of supercage cations which results essentially from electrostatic interactions between the cations.

The dehydrated forms of X faujasite-type zeolites have attracted much attention in the last five years, largely owing to their industrial use for gas adsorption and separation. Adsorption properties are closely related to the location of extraframework cations and to their accessibility to adsorbed molecules. The precise location of cations in channels and cages is an important prerequisite for understanding the adsorption properties of the zeolite of interest. However, the precise location of supercage cations in monovalent zeolites by conventional diffraction techniques is rendered especially difficult because of partial occupancies affecting low symmetry sites. Typically, since the initial diffraction work by Mortier,[1] there have been a significant number of studies dedicated to the reinvestigation of the location of cations in monovalent X zeolites like NaX or LiX, ranging from conventional powder or single crystal diffraction refinements[2–8] to NMR studies[5,9–12] and computational approaches.[3,13,14]

The cation distribution in NaX is usually described as follows: 32 Na^+ ions are in sites I′ within the sodalite cages facing the six-rings of hexagonal prisms (partial occupancy of site I inside the hexagonal prims may occur); 32 Na^+ ions are in sites II facing the six-rings of sodalite cages towards the supercages; the extra cations are distributed in the supercages near the 12-ring or 4-ring windows over a variety of sites referred to as III or III′ depending on their framework environment (Fig. 1). While the location of Na ions in sites I′ and II is well established, the location of the remaining Na ions in the supercages has been the subject of much controversy.

In recent years, atomistic simulations have been recognized to be an interesting alternative for yielding valuable insights into the structure and energetics of zeolites.[15] Typically, energy minimizations have been successfully applied to the siting of cations in various zeolites: Li-ABW and 4A,[16] ETS-10,[17] NaX[3,14] or Na-clinoptilolite.[18]

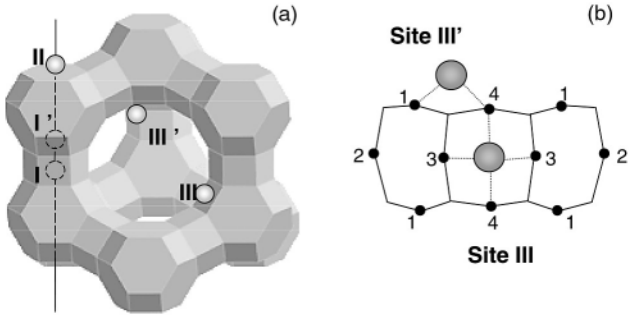

Fig. 1 (a) Schematic representation of the faujasite-type X zeolite with extra-framework cation positions. **(b)** Sites III and III′ differ in their placement relative to the four-ring windows of the supercages.

Here we predict the equilibrium distribution of Na ions in the NaX ($Na_{86}Al_{86}Si_{106}O_{384}$) zeolite using Monte Carlo simulations in the (*N,V,T*) ensemble, considering the cations as 'guest' particles and the rest of the structure as the 'host'. We believe this stochastic simulation method should be the most appropriate one to tackle this problem, especially since an important amount of Na ions are known to be statistically disordered.

The sensitivity of the equilibrium cation distribution to the framework model was explored through the use of two distinct rigid framework models. In the first one (Model 1), the host structure consisted of an incomplete and negatively charged unit-cell [$(Si/Al)_{192}O_{384}$] considering an *average* T(Si/Al) framework atom. The cation/framework interactions were modeled using a dispersion–repulsion term acting between cations and oxygen atoms only, together with a coulombic term using partial charges on all atoms (T, +1.24, Na, +1; O, −0.84396).[19] In the second model (Model 2), Si and Al were explicitly distinguished, adding explicit repulsive–dispersive interactions for Si and Al with Na ions as encapsulated in the cvff_aug forcefield.[20] In this latter case, the [$Si_{106}Al_{86}O_{384}$] host model was obtained by substituting ten randomly chosen Al atoms with Si atoms from a framework model with a strict alternation of AlO_4 and SiO_4 tetrahedra (Si : Al = 1). Following our previous computational work on NaX,[3] the following partial charges were used: Si, +2.4; Al, +1.4; Na, +1, O, −1.2. While constructed starting from the original cubic form, both incomplete zeolite models were converted into *P*1 in order to perform the simulations. Finally, (*N,V,T*) simulations were performed at 298 K using both host models over one unit-cell with periodic boundary conditions. Random translational displacements of cations (maximum of 0.3 Å) were adjusted so as to obtain an acceptance rate of 50%. A standard MC simulated annealing procedure had to be used to accelerate convergence to the most stable configuration. Equilibrium was typically reached after 10^5 moves. A further 10^6 production steps were performed to average quantities. More details are given in ref. 19.

Monte Carlo (MC) simulations using Model 1 lead to an average cation distribution in NaX where sites I′ and II are fully occupied as expected from diffraction data, with average atomic coordinates very close to the experimental ones (Fig. 2(a) and (b)). The 22 extra cations are found mainly in sites III with a small proportion in sites III′ (Fig. 2(c)), a result that contrasts with the experimental predominance of sites III′.[2,3,6,7] Neither do we obtain the secondary sites III′, recently reported as sites III′ and III″ by Seff *et al*. for example, facing AlO_4 and SiO_4 tetrahedra respectively.[6] A small 1 Å deviation is obtained between the simulated site III and its reported experimental position,[8] while the simulated sites III′ correspond quite well to the experimental ones. Both types of sites yield average simulated Na–O distances to the closest oxygens of 2.37 and

 DOI: 10.1039/b103808g

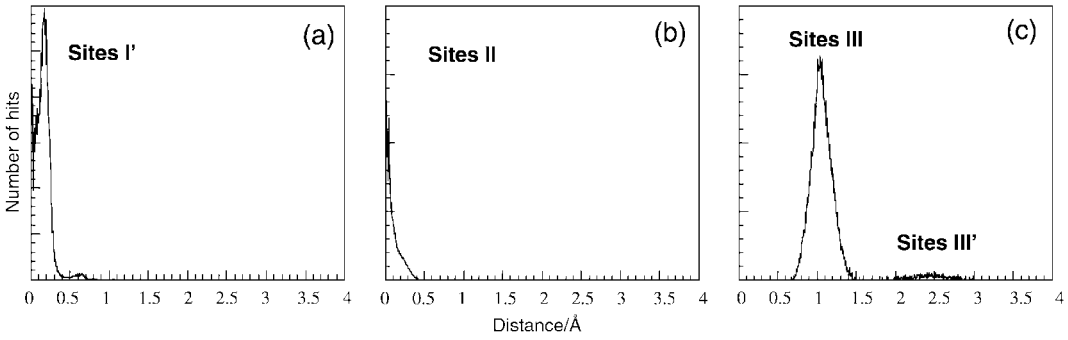

Fig. 2 Predicted cation distribution in NaX using Model 1. The computed distance distributions are indicated by reference to the observed crystallographic positions in sodium-exchanged faujasites.[8,21]

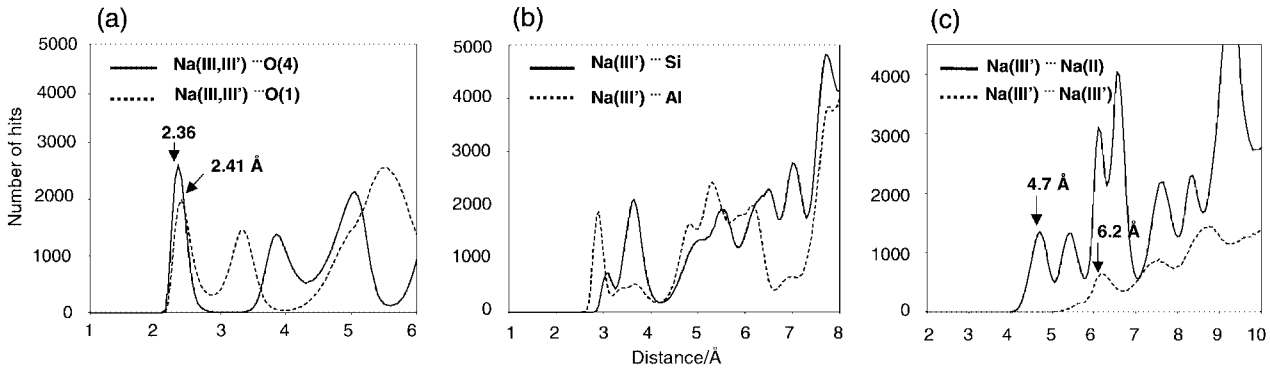

Fig. 3 Predicted cation distribution in NaX using Model 2. Selected pair distribution functions for the extra Na cations of the supercage in sites III′ (a) with framework oxygens O(1) and O(4); (b) with Si and Al framework atoms; (c) with Na ions in sites II and III′.

2.26 Å for Na ions in sites III and III′ respectively. Indeed, it turns out that the structural features of the cation distribution in the NaX zeolite are correctly predicted by the MC simulations using a crude model for the framework itself and cation/framework interactions; however, these simulations failed to predict the correct location of supercage Na ions. We concluded that such a detailed and correct description of Na ion distribution probably cannot be obtained as long as Al and Si atoms cannot be distinguished in the faujasite framework model.

Simulations were then performed with Model 2, which explicitly distinguishes Al and Si atoms in terms of coulombic and short-range interactions. Prior to the simulations, 32 Na ions were placed in sites I and 32 Na ions in sites II, so that insertions were performed on the remaining 22 Na ions exclusively. The simulated pair distribution functions reveal that all Na ions are located in sites III′, with Na···O(1) and Na···O(4) distances typical of sites III′ (Fig. 3(a)), in excellent agreement with the most recent crystal structures of NaX.[3,6] No cation was detected in sites III. Another key feature of the simulations is that they successfully predict the location of Na ions in sites III′ facing both AlO_4 tetrahedra and SiO_4 tetrahedra: Na···Si and Na···Al pair distribution functions (Fig. 3(b)) are in excellent agreement with the two types of sites III′/III″ recently evidenced in ref. 6. Also, different Al distributions were tested as starting points for our MC calculations; it shows that the location of the additional Na cations always follows the above features, assessing the influence of the specific Al distributions chosen.

Interestingly, MC simulations with both models show that the placement of supercage cations is driven by electrostatic repulsion with Na ions in sites II together with electrostatic repulsion among sites III′ themselves. Typically, Model 2 yields first II···III′ neighbours at 4.7 Å and first III′···III′ neighbours at 6.2 Å (Fig. 3(c)). Such features, difficult to pinpoint when using diffraction techniques, tend to show that the placement of cations in zeolites is to be regarded as a cooperative process rather than the occupancy of sites with specific energies, resulting from both short-range interactions with the framework and cation–cation repulsive interactions.

Synthesis and oxygenation of selenophosphate dendrimers†

Grzegorz M. Salamończyk,* Maciej Kuźnikowski and Elżbieta Poniatowska

Centre of Molecular and Macromolecular Studies, The Polish Academy of Sciences, Sienkiewicza 112, 90-363 Łódź, Poland. E-mail: gmsalamo@bilbo.cbmm.lodz.pl; Fax: +48 (42) 684-7126; Tel: +48 (42) 681-8952

Received (in Cambridge, UK) 27th July 2001, Accepted 11th September 2001
First published as an Advance Article on the web 2nd October 2001

The backbone of a selenophosphate-based dendrimer of generation 3 having three and four carbon chains is flexible enough to allow its chemical modification by means of partial or complete oxygenation with bulky peroxide.

Dendrimers constitute a relatively young, yet rapidly evolving field of chemistry. A diverse array of dendrimers have been synthesised and applied in different research areas.[1] Modification and introduction of functional groups to a dendrimer are of great present interest. However, most of these transformations rely on the formation of a bond to the surface.[2] Site directed alterations of the interior of a dendrimer appears to be a much more difficult task.[3]

We turn our attention to preparing the first dendrimers based on selenium,[4] which has been increasingly recognised as an essential element in biology and medicine.[5]

Recently, we have disclosed an expedient synthesis of thiophosphate-based dendrimers[6] involving phosphoroamidite chemistry.[7] In this paper, we report on 1) a divergent synthesis of new phosphorus- and selenium-containing dendrimers applying our developed methodology; 2) an unprecedented oxygenation of branching units of selenophosphate dendrimers to the corresponding phosphate functions, which provided another new type of dendrimer. Starting materials, the core compound, tris(3-hydroxypropyl) selenophosphate (**1**) and phosphitylating agent, bis(4-acetoxybutoxy)-*N*,*N*-diethylaminophosphine (**2**) were prepared[8] in high yield from corresponding alkanediol monoacetates[9] and cheap chemicals, in analogous manner to that described previously.[6] The key dendrimer growth step is based on acid mediated alcoholysis of phosphoroamidite.[7] For instance, Se═P[O(CH$_2$)$_3$OH]$_3$ (**1**) reacts smoothly with 3.4 equiv. of Et$_2$NP[O(CH$_2$)$_4$OAc]$_2$ (**2**) in the presence of an excess of tetrazole to furnish trisphosphite intermediate Se═P{O-(CH$_2$)$_3$OP[O(CH$_2$)$_4$ OAc]$_2$}$_3$ and the diethylammonium salt of tetrazole. Addition of pyridine[10] and black selenium to the above reaction mixture afforded first generation dendrimer **3P$_4$Se$_4$**, as shown in Scheme 1. The product, purified on the short pad of silica gel was isolated in 94% yield.

Cleavage of terminal acetates in **3P$_4$Se$_4$** using K_2CO_3 in methanol provided polyalcohol **4P$_4$Se$_4$** in quantitative yield. Reiteration of growth and deprotection reactions afforded the 2nd (**3P$_{10}$Se$_{10}$**, **4P$_{10}$Se$_{10}$**, 98% yield), 3rd (**3P$_{22}$Se$_{22}$**, **4P$_{22}$Se$_{22}$**, 70%) and 4th (**3P$_{46}$Se$_{46}$**, **4P$_{46}$Se$_{46}$**, 52%) generation dendrimers. All compounds are stable, colourless oils whose viscosity increases with increase of molecular weight.

The obtained dendrimers were characterised by ^{1}H NMR, ^{13}C NMR, ^{31}P NMR, ^{77}Se NMR, FT-IR and MALDI TOF mass spectrometry. Especially, the ^{31}P NMR proved to be useful. For example, the ^{31}P{^{1}H}NMR spectrum of the somewhat large 4th generation dendrimer **3P$_{46}$Se$_{46}$** (theoretical molecular weight 15275) showed five distinct resonance lines with accurate integration: δ = 73.99(1P, core), 73.72(3P), 73.57(6P), 73.54(12P), 73.41(24P) ppm. All signals displayed satellite side bands with the splitting of 931 Hz due to ^{31}P–^{77}Se coupling.

The chemical behaviour of selenophosphate dendrimers was found to be rather intriguing. Oxidation of thio- and selenophosphates with hydrogen peroxide[11] and its bis-silyl[12] derivative to their corresponding oxo compounds is documented and presumably proceeds *via* an addition–elimination mechanism with formation of pentacovalent phosphorus intermediates.[11]

Treatment of the 3rd generation dendrimer **3P$_{22}$Se$_{22}$** (^{31}P{^{1}H}NMR and MALDI TOF MS spectra, Fig. 1A and 1D) with *tert*-butylperoxytrimethylsilane[13] (7.7 equiv., CH_2Cl_2, rt, 2 h) resulted in regioselective oxygenation of phosphorus atoms at peripheral branching and extrusion of red selenium, which precipitated from the reaction medium.

The ^{31}P{^{1}H}NMR spectrum (Fig. 1B) shows the decline of the resonance line corresponding to P═Se (δ = 72.7 ppm) at the 3rd sphere to about half of its original height along with the appearance of new lines (P═O, δ = −0.4, −0.5 ppm). It gives the evidence that on average 6 out of 12 phosphorus atoms at third branching were oxygenated. Two resonance lines (P═O range) prompt dissymmetrisation of the macromolecule and/or existence of dendrimeric regioisomers. Addition of the next amount of peroxide (7.7 equiv., 16 h) shifts the degree of oxygenation to about 70%. At this stage more definitive information came from MALDI spectral analysis (Fig. 1E). All peaks differ in mass exactly 63 amu due to replacement of selenium (79) by oxygen (16). Major products (central peak) contain 4 P═Se and 18 P═O functions suggesting that most of the selenium left is located in the core and at first generation. Apparently no degradation of dendrimer framework has occurred. Consecutive addition of organic peroxide (7.7 equiv., 2 h) to the above mixture led to 96% of oxygenation (calculated from the integral of ^{31}P signals) with at least two compounds detected by the ^{31}P{^{1}H}NMR (spectrum not shown). The total conversion of hydrophobic dendrimer **3P$_{22}$Se$_{22}$** into water-soluble phosphate **3P$_{22}$O** took place in three days (Scheme 2).

Isolation of novel phosphate dendrimer **3P$_{22}$O** required only removal of insoluble selenium and evaporation of all the volatiles. Its ^{31}P{^{1}H}NMR spectrum (Fig. 1C) shows the coincidence of chemical shifts of the signals from all the phosphorus atoms present in the molecule.[6] The MALDI TOF

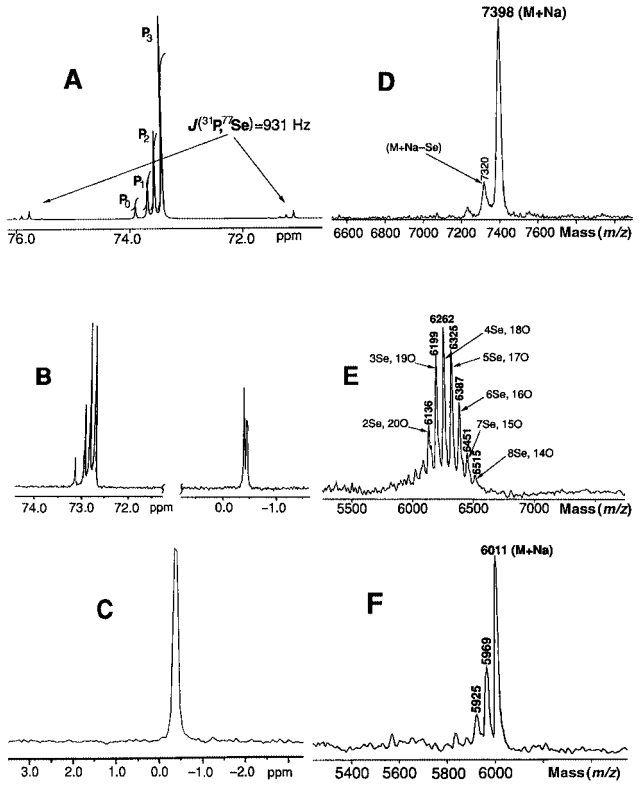

Fig. 1 $^{31}P\{^{1}H\}$NMR spectra of $\mathbf{3P_{22}Se_{22}}$ (A), at 30% conversion of $\mathbf{3P_{22}Se_{22}}$ into $\mathbf{3P_{22}O}$ (B) and $\mathbf{3P_{22}O}$ (C); MALDI TOF MS spectra of $\mathbf{3P_{22}Se_{22}}$ (D), at 70% conversion of $\mathbf{3P_{22}Se_{22}}$ into $\mathbf{3P_{22}O}$ (E) (number of oxygen atoms refers to phosphoryl oxygen) and $\mathbf{3P_{22}O}$ (F).

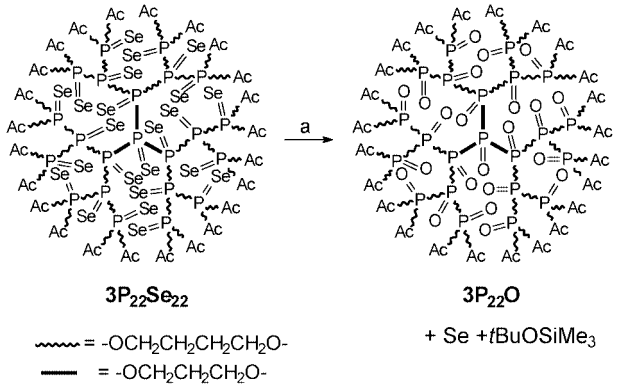

Scheme 2 The oxygenation of 3rd generation dendrimer $\mathbf{3P_{22}Se_{22}}$. (a) *t*BuOOSiMe$_3$, dichloromethane, 75 h.

MS (Fig. 1F) unambiguously confirms complete oxygenation of $\mathbf{3P_{22}Se_{22}}$ without any damage to the dendrimer backbone. Two minor peaks, which are *ca*. 43 and 86 amu in mass lower than the major one (M + Na), presumably arose due to insignificant cleavage (3% calcd. from ^{1}H NMR) of one and two peripheral acetates during the long reaction period. Interestingly, the entire dendritic structure was sufficiently flexible to allow bulky peroxide to penetrate the depth of the macromolecule. Moreover, during the reaction time, all branching units and the core must have changed their geometry from tetrahedral to trigonal bipyramidal and back to tetrahedral. It is also noteworthy to point out that the corresponding thiophosphate[6] dendrimer did not undergo oxygenation in these mild conditions.

In conclusion, we have synthesised highly pure, novel selenophosphate dendrimers *via* simple one-pot phosphitylation and selenium addition reactions. These compounds are not only the first selenium-based dendrimers, but also seem to be the largest synthetic selenium derivatives ever reported having molecular weight comparable with selenoproteins.[14] In addition, the selenophosphate dendrimer served as a macromolecular substrate for partial or complete oxygenation. The oxygenation reaction proceeded cleanly. Initially, peroxide reagent oxidised peripheral branching, then it was capable to penetrate deeper into the cascade structure. The dendrimer was even adaptable enough to make possible the modification in the core.

This study was supported by the Committee for Scientific Research, Grant No 3T09A 040 19. The authors are grateful to Professor Dr A. Skowrońska for her encouragement to work with dendrimers.

Received (in Cambridge, UK) 8th August 2001, Accepted 4th September 2001
First published as an Advance Article on the web 11th October 2001

A monoclinic centrosymmetric form of zopiclone dihydrate undergoes a sequential, two-step transformation in the solid-state upon heating which results in separation of the enantiomers into a racemic conglomerate or racemic twins.

Racemic zopiclone (a cyclopyrrolone hypnotic drug marketed as Zimovane® tablets) crystallises in two centrosymmetric forms: monoclinic dihydrate (**I**) and monoclinic anhydrous (**II**). Zopiclone is also known to form a non-centrosymmetric orthorhombic anhydrous structure[1] (**III**) (Fig. 1). This communication describes the structural basis for the reversible transformation **I**↔**II**, and provides evidence for an irreversible solid-state chiral separation in which the racemic crystal structure **II** loses its centre of symmetry during a transformation to form **III**.†

The crystal structures of all three forms were determined directly from data collected on BM16 at the ESRF (Table 1, Fig. 1), using the simulated annealing procedure described previously[4] which is now implemented in the DASH computer program.[5] In each case, repeat DASH runs converged to substantially the same crystal structure, and the ratio $\chi^2_{\text{Rietveld}}/\chi^2_{\text{Pawley}}$ (Table 1) was sufficiently small to confirm that the solution was correct.‡ As the form **II** structure was previously unknown, and is therefore the principal focus of our attention, the correctness of this solution merits careful consideration. The potential accuracy of structures solved using the global optimisation procedure implemented in DASH has already been demonstrated[4] and, reassuringly, the DASH solutions for forms **I** and **III** are essentially superimposable on the corresponding single-crystal structures.[6] This close agreement arises from the ability of the simulated annealing algorithm to 'fine-tune' both the internal and external degrees of freedom of the zopiclone molecule (and the positions of both water molecules in the case of form **I**), effectively implementing a rigid body Rietveld refinement of the structure. Although the absolute magnitudes of χ^2 for form **II** are high (*cf.* forms **I** and **III**, Table 1), it is the ratio $\chi^2_{\text{Rietveld}}/\chi^2_{\text{Pawley}}$ which is important and this is satisfactory in each case.

Our confidence in the form **II** solution is further increased by the following observations: (i) no unfavourable contacts are observed within the crystal structure; (ii) the molecular conformation and crystal packing in form **II** relate to form **I** in a way which is both obvious and physicochemically sensible in the context of the transformation. In fact, the high χ^2 values for the form **II** pattern are attributable to a degree of anisotropic line broadening, plus the presence of trace amounts of forms **I** and **III** in the form **II** sample, arising as a consequence of producing the form **II** sample *in situ*.

Examination of the crystal structures of forms **I** and **II** reveals many striking similarities. The molecular conformations of the zopiclone molecules are essentially identical (Fig. 2). Moreover, the basic packing motif is the same in forms **I** and **II** (Fig. 3). In both structures, the zopiclone molecules arrange themselves in bilayer sheets and these sheets remain essentially

[a] t_d = data collection time over specified range; resolution = maximum spatial resolution of data; $N_{\text{reflections}}$ = number of reflections in data range shown; χ^2_{Pawley} = chi-squared for Pawley-type fit[3] to data range shown; χ^2_{Rietveld} = chi-squared for DASH Rietveld-type fit to data range shown, varying only scale factor; $N_{\text{parameters}}$ = number of parameters optimised during DASH structure solution; N_{tps} = number of trial structures evaluated by DASH per second (800 MHz PIII PC); t_s = time to solution.

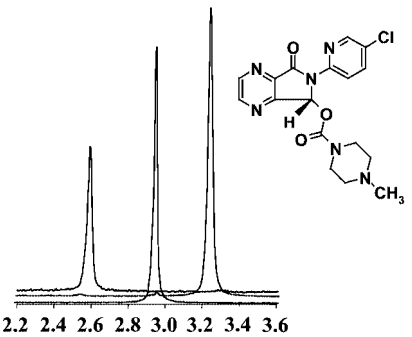

Fig. 1 Capillary X-ray powder diffraction (XRPD) patterns in the range 2.2–3.6° 2θ (λ = 0.8 Å) for the three forms of zopiclone. The data were collected on BM16 of the European Synchrotron Radiation Facility (ESRF).[2] Form **II** was produced *in situ* from the starting sample (form **I**, crystallised from toluene) by breaking the sealed end of the capillary and exposing the sample to a warm N_2 stream. The transformation was monitored *via* the growth on heating of the diagnostic (100) reflection at *ca.* 3.23°, which occurs at the expense of the dihydrate (100) reflection at *ca.* 2.96°. Further heating transformed **II** → **III**, as evidenced by the appearance of the form **III** (002) reflection at *ca.* 2.57°.

 DOI: 10.1039/b107075d

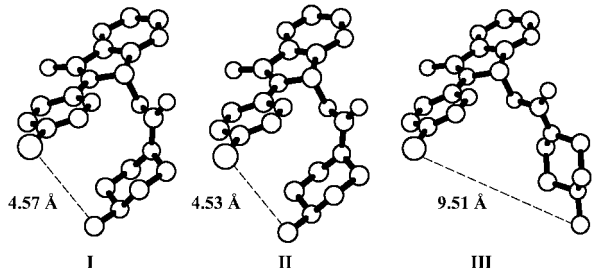

Fig. 2 The conformation of zopiclone in the crystal structures of forms **I**, **II** and **III** as determined directly from the XRPD data. The molecular conformations in forms **I** and **II** are virtually superimposable, as exemplified by the fact that the highlighted distances are approximately equal. The conformation in form **III** is significantly different.

unchanged in the dehydration process as the water molecules are cooperatively removed from the crystal structure. The process is facile and thus energetically straightforward since the principal structural change during dehydration is the slipping of each bilayer sheet by 6.61 Å along the *c* axis and 1.48 Å along the *a* axis, both relative to the form **I** unit cell.

This close structural similarity also accounts for the ease with which hygroscopic form **II** reverts to form **I** on exposure to high relative humidity at rt. The thermodynamic gain in transforming **II**→**I** is associated with the formation of $1 \times O_w$–H···N_{zop}, $1 \times O_w$–H···O_{zop} and $2 \times O_w$–H···O_w hydrogen bonds.

The exothermic transformation of form **II**→**III** at elevated temperature constitutes a spontaneous resolution of enantiomers in the solid state and is accompanied by a significant change in molecular conformation (Fig. 2). The transformation is not reversed on cooling and, unlike form **II**, form **III** is stable to high humidity. Whilst spontaneous resolution is well documented for compounds crystallising from solution or from the molten state, it is less well known (but not unknown[7]) for such a transformation to occur in the solid state. There is no doubt that the (*R*) and (*S*) enantiomers separate during the transformation, since the form **III** unit cell volume can only accommodate four zopiclone molecules and the chiral space group $P2_12_12_1$ can accommodate only one enantiomer or the other.§ What the XRPD experiment cannot tell us is whether this solid-state separation results in the formation of racemic twins or a racemic conglomerate—either possibility is consistent with the diffraction data. However, the sharpness of the powder diffraction lines indicates domain sizes in excess of 1000 Å.

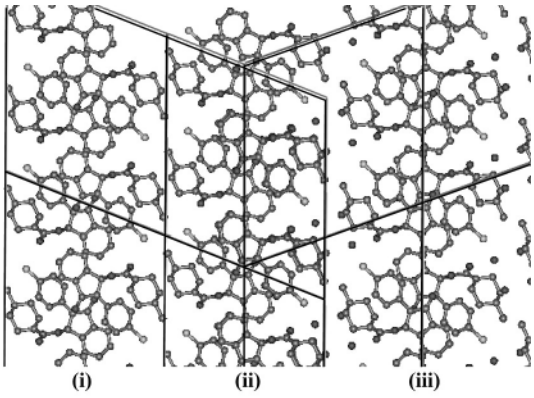

Fig. 3 Four unit cells of form **II** (left), plus four unit cells of form **I** (right), viewed down the common *b*-axis. The two structures are shown overlaid on their common packing motif to emphasise the high degree of correspondence. Viewing left-to-right: (i) the first bilayer of zopiclone molecules in form **II**; (ii) the second bilayer of form **II** overlaid by the first bilayer of form **I**. It is almost impossible to distinguish the individual bilayers in this region—the r.m.s. deviation between corresponding atoms is small (*ca*. 0.2 Å, with structures positioned on a single common atom and no least-squares fitting employed); (iii) the next bilayer of form **I**, showing the dihydrate O-atoms sandwiched between the bilayer sheets. When water is driven off, the bilayers close-pack to reduce the unoccupied volume.

Strong additional evidence to support the favourability of enantiomer separation comes from the fact that we have observed spontaneous resolution upon crystallising zopiclone from a racemic solution of the compound in ethyl acetate. The refined Flack (absolute structure) parameter[8] for a single crystal of (*R*)-zopiclone[6] (−0.04(6)) and a single crystal of (*S*)-zopiclone[6] (−0.04(6)) produced in this way was sufficient to confirm unambiguously that separation to a racemic conglomerate had indeed occurred.

We conclude that racemic zopiclone can crystallise from solution either as enantiomerically pure crystals (a racemic conglomerate formed *via* spontaneous resolution) or in the form of a centrosymmetric racemic dihydrate. Heating the latter produces a centrosymmetric racemic anhydrous structure, which undergoes chiral separation upon further heating. The analysis presented here helps to explain the significant batch-to-batch variation in physical form reported for commercial samples of zopiclone.[9] Central to detailing the transformations at molecular level was our requirement to produce a sharply diffracting sample of form **II** and then solve its crystal structure. In this regard the combination of the high instrumental resolution and count rate offered by BM16, plus the efficient global optimisation method, was ideally suited to the experiment.

We thank Paul J. Harrison for providing the stimulus to study zopiclone; Hendra for technical services; Olivier Masson for setting up BM16; the EPSRC X-ray crystallography service at the University of Southampton for absolute structure determinations and Francisco Ros for helpful comments.

Notes and references

† The solid-state transformation of form **I**→**II** was identified initially by DSC/TGA as an endothermic weight loss from rt to *ca*. 75 °C. The subsequent transformation **II**→**III** was apparent as an exotherm (*ca*. −2.4 kJ mol^{-1}) with onset *ca*. 112 °C and no corresponding weight loss. The transformations were confirmed by multi-temperature laboratory XRPD, and the reversibility **I**↔**II** was apparent in XRPD data collected at 0 and 94% relative humidities.

‡ The form **I** and form **III** solutions are redeterminations of known structures: (i) form **I** single-crystal (determined as part of this work), a = 16.374(4), b = 7.030(3) , c = 17.185(2) Å, β = 108.62(1)° at T = 123 K;[6] (ii) form **III** single-crystal, a = 5.567(3), b = 8.852(2), c = 35.677(17) Å at T = 295 K.[1] Single-crystals of form **II** could not be obtained and therefore the structure of form **II** had to be determined directly from the polycrystalline powder.

§ The possibility that form **III** is a non-centrosymmetric racemate was eliminated on the grounds that the XRPD data are entirely consistent with two single-crystal absolute configuration determinations[6] which unambiguously identify one molecule in the asymmetric unit.

Pentaporphyrin with flexible, chiral nucleosidic linkers: unexpected duality of the physico-chemical properties of its core†

Nathalie Solladié,* Maurice Gross,* Jean-Paul Gisselbrecht and Chloé Sooambar

Laboratoire d'Electrochimie et de Chimie Physique du Corps Solide, Université Louis Pasteur et CNRS, 4 rue Blaise Pascal, 67000 Strasbourg, France. E-mail: nsolladie@chimie.u-strasbg.fr, gross@chimie.u-strasbg.fr

Received (in Cambridge, UK) 17th July 2001, Accepted 29th August 2001
First published as an Advance Article on the web 11th October 2001

A new star-like pentaporphyrin, bearing nucleosidic linkers, has been synthesized, and the unexpected duality of the physico-chemical properties of its core is reported; beside the quenching of the fluorescence of the peripheral porphyrins by the central chromophore, this pentaporphyrin exhibits an unexpected shielding of the redox capabilities of its central core.

In photosynthetic systems the absorption of a photon by the light harvesting antennas is followed with minimal loss by the extremely fast migration of the excited state among the pool of chlorophylls until the reaction center is reached in the cell membrane.[1]

With the aim of mimicking these antenna complexes, multiporphyrinic dendrimers are attracting growing interest.[2] Increasing the number of chromophores around one single energy acceptor enhances the probability of capturing a photon and thus transfering energy towards the central chromophore.

We now report the synthesis of the tetranucleosidic pentaporphyrin **1**, and the interesting duality of the physico-chemical properties of its core chromophore (Fig. 1). This multichromophore device is built on a free-base porphyrin surrounded by four peripheral Zn(II) porphyrins. Beside the expected— and actually observed—antenna effect, this pentaporphyrin **1** also exhibits the characteristics which prevent electron transfers with the central porphyrin, an unexpected feature in a molecule whose arborescent shape resembles a first generation dendrimer.

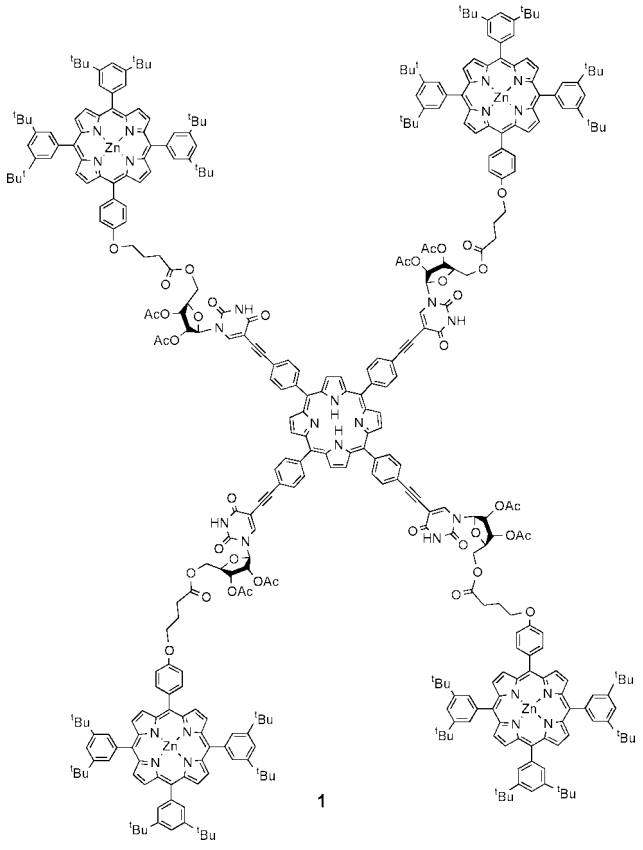

Fig. 1 Tetranucleosidic pentaporphyrin **1**.

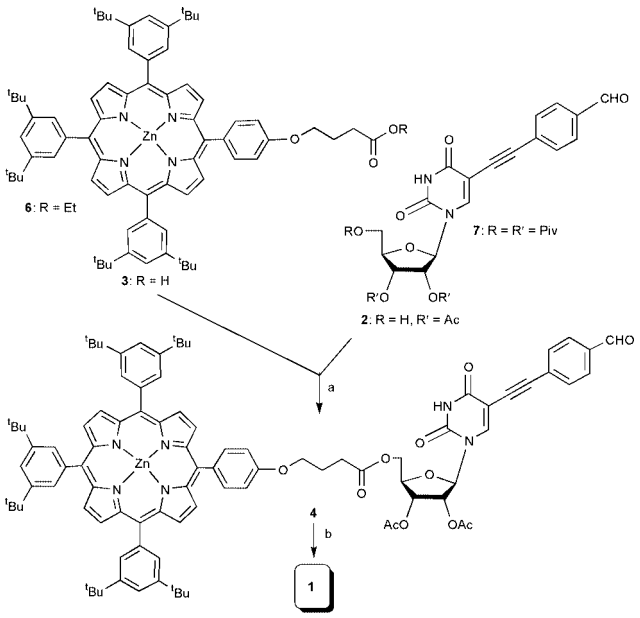
The synthetic strategy for obtaining **1** is based on the functionalization of the nucleosidic linker **2** at the O-5′ and C-5 positions. Compound **2** was prepared in five steps from the commercially available uridine.[3] The nucleoside–porphyrin conjugate **4**[4] was then obtained in 64% yield by esterification of the carboxylic acid function of the A_3B type Zn(II) porphyrin derivative **3** with the alcohol **2** (Scheme 1).[5] Preparation of pentaporphyrin **1** was achieved by construction of the central porphyrin under the conditions developed by Lindsey for the synthesis of sterically hindered porphyrins (Scheme 1).[6] Compound **1** was isolated with 35% yield after tedious purification by successive column chromatography on silica gel, followed by gel permeation chromatography (GPC) to remove some low molecular weight impurities which couldn't be removed by classical chromatography. The purity of pentaporphyrin **1** was then certified by analytical GPC. ^{1}H-NMR spectroscopy experiments were carried out at room temperature and under heating, but only ill resolved spectra were obtained. A fine structure emerged in the ^{1}H NMR spectrum recorded at 400 K, but it was not resolved enough to allow clear interpretation of the spectrum. This result suggests that compound **1** exists as a mixture of conformers. The



Scheme 1 (a) DCC (1.4 eq.), DMAP (1.2 eq.), CH_2Cl_2, rt, 4 h, 64%; (b) Pyrrole (10^{-2} M), $BF_3{\cdot}OEt_2$ cat., $CHCl_3$, rt, 48 h, then *p*-chloranil (3 eq.), reflux, 2 h, 35%.

† Electronic supplementary information (ESI) available: spectroscopic data for **4** and **1**. See http://www.rsc.org/suppdata/cc/b1/b106337p/

 DOI: 10.1039/b106337p

pentaporphyrin **1** was finally identified by FAB mass spectrometry (6411.6, $[M]^+$, calcd: 6411.3).

The UV-visible absorption spectrum of **1** is essentially the addition of the spectra characterizing the individual free-base and Zn(II) porphyrin components. The Soret band is however slightly broadened (from 13 to 15 nm) if compared with the distinct constituents.

Fluorescence measurements were carried out in CH_2Cl_2 on pentaporphyrin **1** (605, 653, 718 nm; relative intensities 3/11/12 respectively) and on the precursors **5** (653, 719 nm; relative intensities 10/2 respectively) and **6** (599, 649 nm; relative intensities 3/2 respectively). Upon excitation at 420 nm, the fluorescence spectrum of **1** is dominated by emission of the core free-base porphyrin. The emission of the four peripheral Zn(II) porphyrins is partially quenched: only a weak band is observed at 605 nm. The assumption of an energy transfer from the peripheral porphyrins to the free-base core was corroborated by the excitation spectrum of pentaporphyrin **1**, which matches the absorption of the multicomponent system fairly well.

The redox properties of **1** were ascertained by steady state and cyclic voltammetry experiments, carried out on a glassy carbon electrode in CH_2Cl_2 + 0.1 M *n*-Bu_4NPF_6. Cyclic voltammetry exhibited, for each of the precursors **5** and **6**, two reversible one-electron reductions as well as two reversible one-electron oxidations, as expected for porphyrins (Table 1).[7] Pentaporphyrin **1** gave a well resolved cyclic voltammogram, where only two oxidation and two reduction steps can be observed. The peak characteristics (ΔEp = 60 mV and peak current corresponding to a four-electron transfer) are in agreement with electron transfers on four independent redox centers. The comparison of the redox characteristics of **1** with the redox patterns of the reference compounds **5** and **6** suggests that the four distinct electron transfers occur on the Zn(II) porphyrin moieties. The potential difference between the first oxidation and the first reduction steps in **1** and in the synthons **5** and **6** indicates that the HOMO–LUMO energy gap in the Zn(II) porphyrins increases from **6** to **1**, thus indicating that the net effect of bonding **5** to **6** in the pentaporphyrin **1** is tantamount to a slightly electron-donating effect on **6**. This is consistent with the measured shifts of the potentials from **6** to **1**: 50 mV for the first oxidation and −120 mV for the first reduction (Table 1). It is worth noting that, unexpectedly, the voltammogram of pentaporphyrin **1** does not reveal any reduction or oxidation step which could correspond to the free-base core, whose potentials (Table 1) are expected to be very different to those of the zinc porphyrin. Such observations are known for bulky dendritic molecules, but is unprecedented in a molecule similar to a first generation dendrimer.[8] A tentative explanation may be found in the flexible nucleosidic linkers. Indeed, these linkers are flexible enough to allow the four arms in **1** to fold up—or collapse—on its core. Such a constriction could induce a shielding effect on the central free-base porphyrin in **1**, as it creates, both physically and in terms of spatial dielectric characteristics inside **1**, very unfavorable conditions which could slow down any electron exchange between the electrode surface and the central free-base porphyrin. The signals would thus be broadened and ultimately become undetectable on the voltammogram. Similar situations have been observed up to now with bulky dendrimers only.[8b–8d] The ^{1}H-NMR results obtained on pentaporphyrin **1**, which did not produce any well resolved spectra, also find a reasonable explanation in such a shrivelled conformation of the pentaporphyrin **1**. Recent studies consistently support this interpretation.[8f,8i] They make clear that, in a flexible molecule such as pentaporphyrin **1**, it may reasonably be expected that the important decrease in the electron transfer rate on the porphyrin core, *i.e.* the restricted accessibility to this core, is ascribable to conformational effects rather than solely to steric factors. Hence, the central free-base porphyrin behaves here as an encapsulated electroactive molecule, which is masked for electron transfer in the present experimental conditions.

Table 1 Redox potential of the studied species (**5**, **6** and **1**; **5** is the reference free-base porphyrin synthesized by condensation of **7** with pyrrole) observed in CH_2Cl_2 + 0.1 M *n*-Bu_4NPF_6 on a glassy carbon working electrode

[a] All potentials are given *versus* ferrocene used as internal standard. Reversible electron transfer: $E° = (Epc + Epa)/2$.

Since the insertion of any energy transfer relay between the core and the periphery would seriously decrease the rate of energy transfer and favour a loss of energy, the elaboration of a new family of arborescent molecules by directly attaching more than four peripheral porphyrins to the free-base core is currently under way. It is expected that such an arborescence will significantly enhance the antenna effect while retaining a shielded electroactive core. Beside the covalent approach mentioned above, the possibility of taking advantage of the nucleosidic linkers is also being explored. Indeed, it seems likely that our pentaporphyrin **1** could self-assemble with properly chosen complementary porphyrinic synthons to generate, through hydrogen bonds, more sophisticated architectures. Furthermore, the chiral nucleosidic linkers may play a key role in inducing enantioselective energy transfers.

Tetramethylammonium auride, the first compound of negatively charged gold with a non-metal cation, has been synthesised by cation exchange in liquid ammonia; it is isostructural to the corresponding bromide which further illustrates the similarities between the halogens and gold.

Gold is unique among the transition metals in its ability to form isolable non-metallic compounds that contain a monoatomic anion. The binary alkali metal aurides RbAu and CsAu have been known for about half a century,[1] but the ternary auride oxides M_3AuO (M = K, Rb, Cs) and the aurideaurates $Rb_5Au_3O_2$, and $M_7Au_5O_2$ (M = Rb, Cs)[2] have only recently been discovered.

To establish that gold in these compounds does indeed carry a negative charge numerous experiments have been undertaken. CsAu crystallises in the CsCl-structure,[1] a typical structure to be adopted by an ionic substance, and it is a semiconductor with a band gap of 2.6(2) eV.[3] CsAu liquifies at 590 °C to give a melt that exhibits ionic conductivity.[4] In addition, an ESCA study on RbAu and CsAu,[5] reveals the high value for the binding energy of the CsAu molecule,[6] and UV-photoemission experiments[7] on solid CsAu support the ionic interpretation. The anionic character of the gold in RbAu and CsAu has also been studied by ^{197}Au Mössbauer spectroscopy.[8] The ternary phases M_3AuO have been investigated by X-ray absorption spectroscopy.[9]

Furthermore, the auride ion is the only monoatomic metal anion proposed to exist in liquid ammonia.[10] Recently, it was found that the golden-brown CsAu dissolves in liquid ammonia forming colourless to pale yellow solutions, from which a characteristically blue ammoniate can be isolated.[11] The only other known reaction is the formation of the cryptated alkali metal aurides.[8] The solubility of caesium auride in liquid ammonia has prompted us to try to apply a method originally developed for the synthesis of novel ionic ozonides and superoxides to the chemistry of the auride ion.[12]

Using a macroreticular ion exchange resin with a high affinity towards caesium ions in liquid ammonia, we have managed to exchange caesium for tetramethylammonium, and have obtained tetramethylammonium auride **1** as transparent crystals.† Tetramethylammonium was chosen as the cation for this experiment, because being a derivative of the ammonium ion it behaves chemically much like an alkali metal. However, it is less reactive than the ammonium ion, since it does not contain any acidic hydrogen atoms. In addition, the positive charge is stabilised by the presence of the methyl groups.

Recently, it has been shown that **1** can also be obtained impure in a mixture with caesium chloride by a metathesis reaction of tetramethylammonium chloride and caesium auride in liquid ammonia.[13] The auride **1** has to be handled very carefully. It spontaneously ignites on contact with air and is very sensitive to pressure. It slowly decomposes at room temperature. Several powder X-ray patterns taken of the same sample sealed in a capillary show that already overnight the gold 111 reflection grows considerably in intensity, and after two weeks the sample consists solely of gold and decomposition products. Compound **1** can be stored for months without noticeable decomposition at −55 °C.

The crystal structure determination‡ shows that in **1** each gold atom is surrounded by eight tetramethylammonium ions and *vice versa* (Fig. 1). The geometrical features of the tetramethylammonium ion are as expected, with C–N bond lengths of 1.481(6) Å and C–N–C angles of 109.1(5)° and 109.6(2)°. There are four short Au···H contacts of 2.92(10) Å, eight longer ones of 3.30(4) Å and another eight of 3.35(6) Å length. The closest Au···C distances are 4 × 3.663(1) Å and 4 × 3.849(1) Å. The closest Au···Au distances are 2 × 5.433(3) Å and 4 × 5.568(1) Å. The nitrogen atoms form a lattice that is almost perfectly cubic. Thus, the structure can be derived from a caesium chloride type structure by displacing the anion from the center of the parallelepiped formed by the nitrogen atoms, as has been observed previously for other tetramethylammonium salts.[14,15] The displacement is due to four methyl groups pointing towards the auride ion from one direction, thus pushing it out of the center of the cuboid. In effect, this is the same structure as found for tetramethylammonium bromide.[15]

Taking the shortest Au···H contact in **1** and subtracting the van der Waals radius of 1 Å for the hydrogen atom, we can estimate the radius of the auride ion to be 1.9 Å, which is very similar to the bromide ion. These relatively short Au···H contacts also might be interpreted as weak hydrogen bonds between the auride ion and the tetramethylammonium ion, especially in light of the fact that hydrogen bonds have been detected in tetramethylammonium bromide,[16] in which the shortest Br···H distances are of a comparable length. The coordination of the auride and bromide ion by hydrogen in the two structures is identical and shown in Fig. 2.

Our findings correspond very well with earlier observations that the auride anion behaves crystallographically like a halide ion. Not only do RbAu and CsAu crystallise in the CsCl-structure, but CsBr and CsAu are also completely miscible in the liquid and solid state.[17] The analogy between the auride, and especially the bromide, is further supported by comparison of

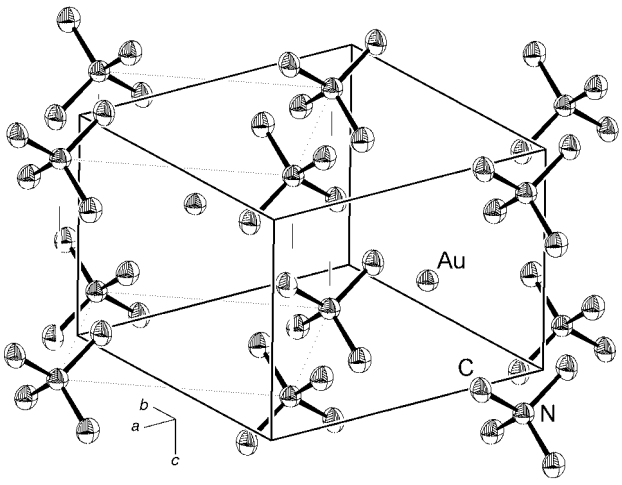

Fig. 1 Crystal structure of tetramethylammonium auride **1** (70% thermal ellipsoids, hydrogen atoms omitted). The caesium chloride type sub-cell is indicated by thin lines.

 DOI: 10.1039/b105648b

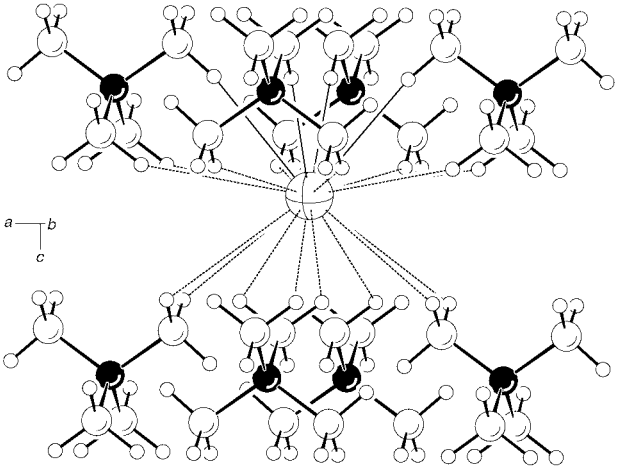

Fig. 2 Close C–H···Au contacts in **1** (thin solid lines: < 3 Å, dashed lines: 3–3.5 Å).

the crystal structures of the ternary auride oxides M_3AuO and the corresponding bromides and iodides.[18]

The presence of the auride ion in **1** is also confirmed by ^{197}Au Mössbauer spectroscopy.[19] The isomer shift of 6.33(2) mm s^{-1} relative to the source lies well within the range usually found for gold(−I) ions. The resonance signal displays no quadrupole splitting. Apparently, it is unaffected by the reduced symmetry of the auride site in comparison to the cubic environment in the CsCl-type structure.

The colourlessness of **1** seems to imply that the charge separation between the cation and the auride is very large in the sense that gold should have a filled $5d^{10}6s^2$ electron configuration. However, the isomer shift is not quite as large as that found for caesium auride [7.09(6) mm s^{-1}].[8] The C–H···Au hydrogen bonds discussed above would result in a reduction of charge at the gold atom, but it seems unlikely that such a very weak interaction would show this large an effect. The Mössbauer isomer shift is sensitive to the electronic density at the nucleus. It has been estimated that the addition of one 6s electron leads to an isomer shift of +8 mm s^{-1}. The removal of one gold 5d electron would lead to a shift of at least +1 mm s^{-1}, because a lower 5d-electron density decreases the shielding of the 5s and 6s levels, in turn increasing their density at the nucleus.[8] If back-donation of 5d electron density from the gold to empty orbitals on the alkali metal occured to some extent, then the measured isomer shift for CsAu would be expected to be larger than the isomer shift of the 'free' auride ion in compound **1**. It would also explain the observation that encapsulation of the alkali metal by a cryptand, which increases the distance between cation and anion and reduces the cation–anion interaction, leads to a decrease in isomer shift. In fact, the isomer shift values of M(2,2,2-crypt)Au (M = K, Rb, Cs) of 6.29(5), 6.08(4) and 6.08(5) mm s^{-1}, lie very close to our value.[8]

The authors wish to thank Dr Oliver Oeckler for the data collection and Sanela Kevrić for assistance with the preparative work.

Notes and references

† All operations were carried out under inert conditions either *in vacuo* or in a dry argon atmosphere.

The acidic form of the ion exchange resin (type Amberlyst 15) was charged with tetramethylammonium by reaction with a solution of tetramethylammonium hydroxide in methanol over five days. It was washed several times with methanol and thoroughly dried at 105 °C *in vacuo*.

In a typical experiment 1.5 g of ion exchange resin and 200 mg of CsAu were put into one leg of an H-shaped reaction apparatus. The connection between the legs was fitted with a glass sieve to allow filtration. Ammonia was stored over potassium at −78 °C and condensed into the reaction vessel. The colourless solution was left to stand for 4 h and then filtered to separate it from the ion exchange resin. Upon slow removal of the ammonia at −60 °C transparent crystals started to precipitate. The yield is typically < 60 mg (37%), but more of the colourless crystalline substance can be seen surrounding the ion exchange pellets.

‡ The crystals were immersed in perfluorinated polyether, selected under a microscope and picked up with a nylon loop attached to the goniometer head, transferred in liquid nitrogen to the diffractometer and mounted on the diffractometer in a cooling stream.

Crystal data for **1**: $C_4H_{12}NAu$, M_r = 271.11, tetragonal, space group $P4/nmm$, a = 7.599(3), c = 5.433(3) Å, V = 313.7(2) Å^3, Z = 2, D_c = 2.87 g cm^{-3}, T = 93 K, 7722 reflections measured belonging to two twin domains, 296 unique reflexes, μ(Ag-Kα) = 12.717 mm^{-1}, absorption correction by multi-scan, $R1$ = 0.0436 [$I > 2\sigma(I)$], $wR2$ = 0.1215 (all data), goodness-of-fit 1.102. Data were collected on a Stoe-IPDS area detector diffractometer. The SHELX-97 suite of programs for crystal structure analysis was used for solution and refinement of the structure.[20]

Multi-component assembly of the bicyclic core associated with the tRNA synthetase inhibitors SB-203207 and SB-203208. Application to the synthesis of biologically active analogues†

Martin G. Banwell,*[a] Curtis F. Crasto,[a] Christopher J. Easton,*[a] Tomislav Karoli,[a] Darren R. March,[a] Michael R. Nairn,[a] Peter J. O'Hanlon,[b] Mark D. Oldham,[a] Anthony C. Willis[a] and Weimin Yue[a]

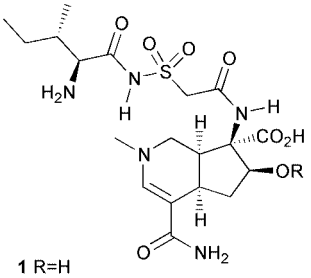
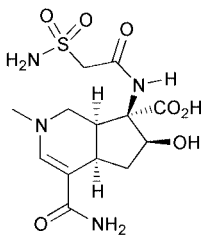
Received (in Cambridge, UK) 4th June 2001, Accepted 21st June 2001
First published as an Advance Article on the web 11th October 2001

The ketone (±)-5, which embodies the bicyclic core associated with the title tRNA synthetase inhibitors 1 and 2, has been prepared *via* a three-component coupling reaction involving 2-(hydroxymethyl)cyclopent-2-enone (15), methylamine (6) and propiolamide (10); straightforward elaboration of the readily derived acetates (−)-21 and (+)-21 has provided the biologically active analogues 23 and 24, respectively, of the title compounds.

The emergence of 'superbugs' such as vancomycin-resistant *Staphylococcus aureus* has prompted extensive efforts to identify new anti-infective agents.[1] High throughput screening regimes have led to the discovery of a number of novel leads including SB-203207 (**1**) and SB-203208 (**2**) which are potent inhibitors of both bacterial and mammalian isoleucyl tRNA synthetases.[2] The structurally related natural product altemicidin (**3**),[3] a novel acaricidal and anti-tumour agent, has been the subject of an elegant total synthesis.[4] However, the methods[4,5] currently available for construction of the hexahydroazaindene core associated with such compounds are unlikely to be practical in providing a broad range of analogues of **1** and **2** for testing as anti-infective agents. On this basis we now describe a multi-component and potentially highly flexible method for construction of the azabicyclic ketones (±)-**4** and (±)-**5** as well as conversion of the latter into biologically active analogues of the title compounds.





In our initial approach to (±)-**4** and (±)-**5** we envisaged that these might be constructed in a one-pot process from methylamine (**6**), formaldehyde (**7**), cyclopent-2-enone (**8**) and the appropriate propiolic acid derivative **9** or **10** (Fig. 1). In particular, it seemed possible that in the presence of a suitable catalyst the Schiff-base (imine) derived from condensation of **6** and **7** could participate in an 'aza-Baylis–Hillman' reaction[6] with **8** to give *N*-methyl-2-(aminomethyl)cyclopent-2-enone

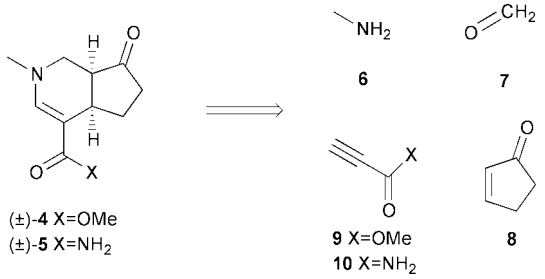


Fig. 1

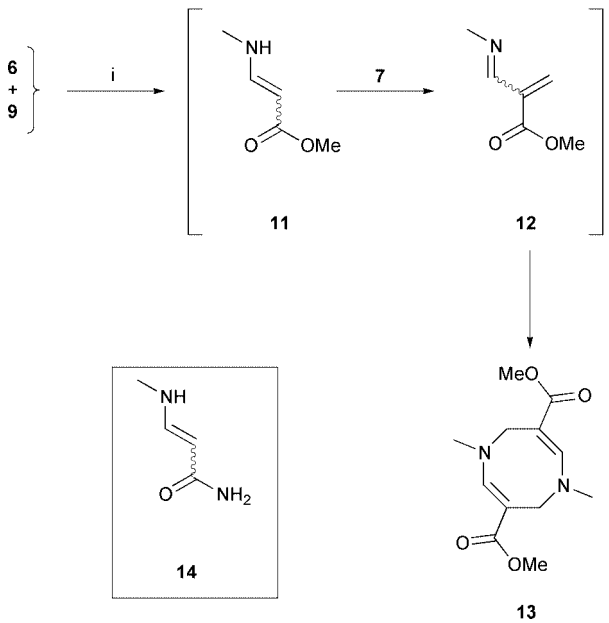
which would then react, through nitrogen in a hetero-Michael-addition reaction, with **9** or **10**. The enamine–cyclopentenone conjugate thus formed might then be expected to undergo an intra-molecular Michael-addition reaction,[7] thereby providing the target ketones (±)-**4** and (±)-**5**. In the event, mixing the four components **6**–**9** with DABCO, a proven catalyst for the Baylis–Hillman reaction, in water at room temperature (**CAUTION**—highly exothermic!) resulted in a complex mixture of products from which the 1,5-diazacycloocta-2,6-diene **13** could be isolated and the structure of which follows from spectroscopic analysis. Clearly, **6**, **7** and **9** but not **8** have been incorporated into this product and further studies revealed that simply mixing the former compounds in water (Scheme 1) provided diene **13** in 45% yield. Presumably, a key intermediate in this conversion



Scheme 1 *Conditions*: (i) H_2O, DABCO (cat.), *ca.* 18 °C, 16 h.

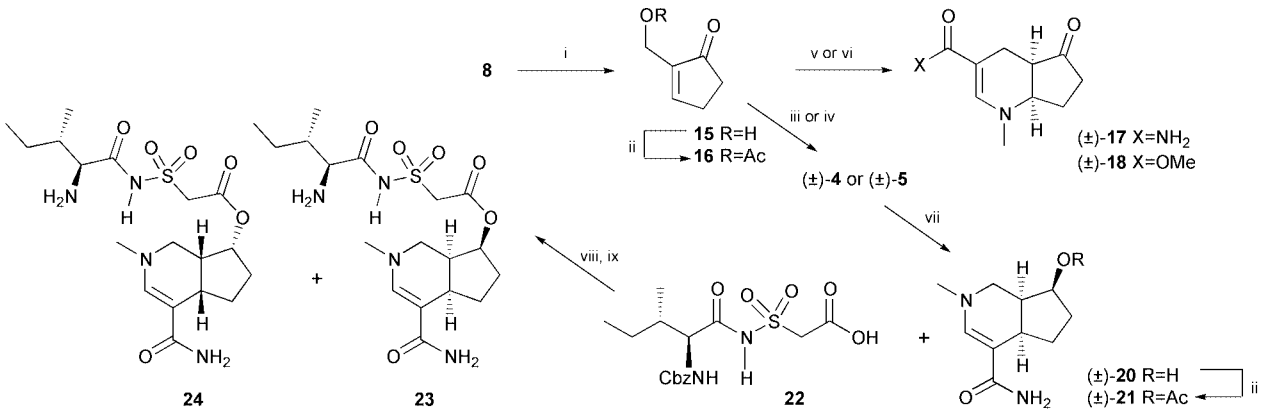
 DOI: 10.1039/b104890m



Scheme 2 *Reagents and conditions*: (i) DABCO (*ca*. 0.25 mol% wrt **8**), aq. HCHO (1.5 mole equiv.), THF, 18 °C, 23 h; (ii) Ac_2O (2 mole equiv.), Et_3N (1.65 mole equiv.), DMAP (cat.), CH_2Cl_2; (iii) **6** (1.5 mole equiv.), **9** (1.5 mole equiv.), DABCO (1.25 mole equiv.), H_2O, 18 °C, 5–7 days; (iv) **14** (1.6 mole equiv.), DABCO (1 mole equiv.), EtOH, 18 °C, 15 h; (v) **14** (1.7 mole equiv.), EtOH, 18 °C, 15 h; (vi) **11** (1 mole equiv.), $Pd(PPh_3)_4$ (10 mol%), THF, 18 °C, 10–14 days; (vii) L-Selectride® (1.0 mole equiv. of a 1 M solution in THF), THF, −17 °C, 0.5 h; (viii) **22** (2 mole equiv,), Et_3N (2 mole equiv.), ClCOCOCl (2 mole equiv.), 0 °C, 0.5 h then (+)- or (−)- **20**, Et_3N (1 mole equiv.), DMAP (cat.), DMF, 0 to 18 °C, 1.5 h; (ix) H_2 (1 atm), 10% Pd on C (cat.), MeOH, 18 °C, 4 h.

is the enamine **11**[8,9] (resulting from Michael addition of methylamine to methyl propiolate) which condenses with **7** to give the 1-aza-3-methoxycarbonylbuta-1,3-diene **12** that, in turn, undergoes cyclodimerisation to the observed product. An analogous sequence starting with amide **10**, and which would have been presumed to involve intermediate **14**,[8] failed to deliver the bis(carboxamide) analogue of compound **13**.

The above-mentioned and ready condensation of **7** with **11**, rather than its participation in an initial Baylis–Hillman reaction with **8**, clearly thwarted attempts to implement the proposed four-component coupling approach to targets (±)-**4** and (±)-**5**. To circumvent such problems, **7** and **8** were subject to a dedicated Baylis–Hillman reaction then an aqueous solution of the resulting 2-(hydroxymethyl)cyclopent-2-enone (**15**)[10] (Scheme 2) was treated with **6** and **9** in the presence of stoichiometric amounts of DABCO. In this manner the unstable ketone (±)-**4** was eventually obtained (*ca*. 20% after *ca*. 5 days). An analogous reaction using propiolamide **10** afforded the more stable congener (±)-**5** (*ca*. 20%). A superior method (40% yield after *ca*. 15 h) for producing (±)-**5** involved treating an ethanolic solution of the acetate **16**, derived from alcohol **15**, with **14**[8] (resulting from Michael addition of methylamine to propiolamide) in the presence of DABCO. Surprisingly, the same reaction when carried out in the absence of DABCO afforded the isomeric hexahydroazaindene (±)-**17** (40%) as the major product of reaction. Similarly, when a THF solution of **16** was treated with **11** in the presence of $(Ph_3P)_4Pd$ the structurally related ester (±)-**18** (*ca*. 20%) was obtained.

Diastereofacially selective reduction of ketone (±)-**5** with L-Selectride® yielded the alcohol (±)-**20** (96%), the readily available acetate derivative, (±)-**21** (63%), of which proved suitable for single-crystal X-ray analysis. Alcohol (±)-**20** was readily coupled with the acid chloride derived from **22** and the resulting diastereomeric mixture of esters was subjected to hydrogenolytic deprotection to produce an inseparable and *ca*. 1 : 1 mixture of **23** and **24**. In an effort to obtain diastereomerically pure samples of these materials several methods for preparing the monochiral forms of ketone **5** were examined but none of the several chiral catalysts that have been used to effect asymmetric Baylis–Hillman reactions[11] proved effective in promoting the enantioselective coupling of **14** and **15**. While various chiral ester derivatives of **15** participated in reaction with **14** to produce ketone **5** in acceptable chemical yield, the observed diastereomeric excesses were disappointing (< 17%). As a consequence, the racemic acetate (±)-**21** was resolved using chiral HPLC techniques (see ESI†). Coupling of each of the enantiopure alcohols with the acid chloride derivative of **22** gave, after hydrogenolytic deprotection, the target molecules **23** [from (−)-**21**] and **24** [from (+)-**21**]. Independent testing of **23** and **24** as inhibitors of *S. aureus*-derived IRS[12] revealed that the former compound shows an IC_{50} of 3.7 μM while the analogous value for the 'unnatural' diastereoisomer **24** is 12.4 μM. Interestingly, this difference in activity is even more pronounced with *S. aureus*-derived LRS (0.42 μM *vs*. no inhibition at 100 μM), *S. aureus*-derived VRS (6.35 μM *vs*. no inhibition at 100 μM) and rat liver IRS (0.57 μM *vs*. 13.5 μM).

We thank GlaxoSmithKline (Australia) Pty Ltd for financial support and Dr Brian Metcalf (formerly of SmithKline Beecham US) for his encouragement and advice. Lucy M. Mensah (GSK, Harlow) is thanked for carrying out the reported enzyme inhibition assays.

Received (in Cambridge, UK) 21st August 2001, Accepted 18th September 2001
First published as an Advance Article on the web 11th October 2001

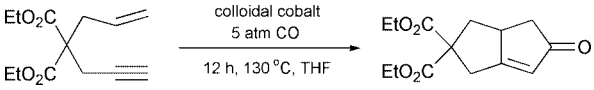
A new Pauson–Khand catalyst based on colloidal cobalt nanoparticles has been developed; the catalyst is highly effective for many intra- and inter-molecular Pauson–Khand reactions and can be recycled and reused many times without losing catalytic activity.

The development of uniform nanometer size particles has been intensively pursued because of their technological and fundamental scientific interest.[1] They have a characteristic high surface-to-volume ratio, and consequently a large fraction of the metal atoms are at the surface and hence are available for catalysis.[2] Many colloidal transition metal nanoparticles, especially noble metals, have been applied as catalysts for the hydrogenation of olefins,[3] for carbon–carbon coupling reactions and for other reactions.[4] However, colloidal nanoparticles of first-row transition metals have seldom been applied as catalysts. Here we present the application of colloidal cobalt nanoparticles for catalytic Pauson–Khand reactions.

Pauson–Khand (P–K) reactions, the cycloaddition of alkynes with alkenes and carbon monoxide to cyclopentenones, have been recognized as one of the most important methodologies in the synthesis of cyclopentenone derivatives.[5] Several research groups, including ourselves, have developed the catalytic version of P–K reactions.[6] Various catalysts applied in P–K reactions include the most popular dicobalt octacarbonyl and several other carbonyl-ligand containing organometallic compounds. Very recently, we demonstrated the first heterogeneous catalytic P–K reactions using metallic cobalt supported on either mesoporous silica or charcoal.[7] Even though these heterogeneous metallic cobalt catalysts exhibit good performance for many intramolecular and intermolecular P–K reactions, they require extreme reaction conditions of CO pressures > 20 atm and temperatures > 120 °C. For diverse applications of P–K reactions, the development of recyclable heterogeneous catalysts able to work in much milder conditions is desirable.

Several synthetic methods have been applied in the fabrication of colloidal cobalt nanoparticles, including the thermal and sonochemical decomposition of organometallic compounds,[8] and the reduction of metal salts.[9] In this report, we have applied a recently developed synthetic method to fabricate cobalt nanoparticles. This method comprises the formation of seed particles at low temperature and further aging at high temperature. For the synthesis of cobalt nanoparticles, $Co_2(CO)_8$ (2.04 g, 6 mmol), oleic acid (1.68 g, 6 mmol), trioctylphosphine (0.6 mL) and dioctyl ether (20 mL) were mixed with stirring at room temperature. The mixture was heated slowly to reflux and the refluxing was maintained for 30 min, after which the reaction mixture was allowed to cool to room temperature. A black precipitate was obtained by adding 50 mL of ethanol followed by washing with 20 ml of acetone and drying *in vacuo*. A transmission electron microscopic (TEM) image (see ESI†) confirmed that the particles are well separated and that they are nearly monodisperse, having a mean diameter of 8 nm.

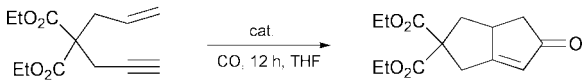
The intramolecular P–K reaction of an enyne was investigated as a test reaction [eqn. (1)]. Table 1 summarizes the results of this reaction under various reaction conditions.



(1)

Entry 1 shows that colloidal cobalt is very active with an isolated yield of product of 97% at 130 °C and a CO pressure of 5 atm. The colloidal cobalt catalyst is more active than heterogeneous catalysts based on metallic cobalt supported on mesoporous silica or charcoal.[7] Using these heterogeneous catalysts, a CO pressure of > 20 atm was required to achieve a yield of > 95% under otherwise identical reaction conditions. To check the recyclability, the catalyst was separated and reused several times (entries 2–5). The results shown in Table 1 confirm that the catalyst maintained its high activity even after five cycles of recycling and reuse. A TEM image of the catalyst after running four reaction cycles showed that the particle size of the cobalt nanoparticles was unchanged and confirmed that no particle agglomeration was observed (ESI†). However, when either the reaction temperature was decreased to 110 °C or the CO pressure was lowered to 3 atm, the catalytic activity was found to decrease significantly (entries 6–9). Thus, to preserve a high catalytic activity, the reaction temperature and CO pressure have to be maintained at a minimum of 130 °C and 5 atm of CO. Nevertheless, the colloidal cobalt catalyst still sustained a degree of activity at 3 atm of CO pressure and 130 °C, with 45% yield of product being obtained.

Table 1 Intramolecular Pauson–Khand reactions under various conditions[a]



Entry	Catalyst	*T*/°C	Pressure/atm	Yield[b] (%)
1	Colloidal cobalt	130	5	97
2	Recovered from #1	130	5	94[c]
3	Recovered from #2	130	5	94[c]
4	Recovered from #3	130	5	94[c]
5	Recovered from #4	130	5	95[c]
6	Colloidal cobalt	120	5	89
7	Colloidal cobalt	110	5	26
8	Colloidal cobalt	130	3	45
9	Colloidal cobalt	130	1	0

[a] Reaction conditions: colloidal cobalt (25 mg, 45 wt% cobalt), allylpropargyl diethylmalonate (0.42 mmol), THF, 12 h. [b] Isolated yield. [c] Yield obtained from GC.

Table 2 Pauson–Khand reactions with various substrates[a]

Entry	Substrate	Product	Yield[b](%)
1			97
2			97
3[c]			90
4[c]			85
5			94
6			97
7			93

[a] Reaction conditions: colloidal cobalt nanoparticles (25 mg, 45 wt% cobalt), substrate (0.42 mmol), CO (5 atm), THF, 130 °C, 12 h. [b] Isolated yield. [c] 10 atm CO applied.

To demonstrate the versatility of the colloidal cobalt catalyst, we applied various substrates for catalytic P–K reactions and the results are shown in Table 2. While the general intramolecular P–K reactions proceeded smoothly at 5 atm (entries 1 and 2), heteroatom-bridged enynes (entries 3 and 4), which contain either an oxa or aza functional group, required a higher CO pressure of 10 atm. The catalyst was also tested for intermolecular cycloaddition reactions (entries 5–7). Overall the colloidal cobalt catalyst is very active for these reactions. The reaction of norbornene or norbornadiene and phenylacetylene (entries 5, 6) proceeded well. The reaction between norbornadiene and alkyl-substituted acetylene also gave a good yield (entry 7).

In conclusion, we present the development of a new Pauson–Khand catalyst using colloidal cobalt nanoparticles. The catalyst is more active than heterogeneous cobalt catalysts supported on either mesoporous silica or charcoal. It can be reused several times without particle agglomeration or loss of activity. The catalyst systems are effective for many intra- and inter-molecular Pauson–Khand reactions.

Received (in Cambridge, UK) 2nd August 2001, Accepted 18th September 2001
First published as an Advance Article on the web 11th October 2001

Adsorbed *vs.* intercalated MCPA (4-chloro-2-methylphenoxyacetic acid) in highly hydrated clays taken as a soil model were clearly distinguished by ^{1}H HR MAS NMR; adsorbed herbicide gave sharp signals indicating high mobility while intercalated herbicide gave very wide unresolved spectra due to its strong interaction with the solid matrix.

Adsorption is one of the key processes affecting the ultimate fate of pesticides, or other xenobiotics, in the environment as it controls transport, mobility and degradability in soils and ground water. The adsorption–desorption mechanisms at the interface between organic and inorganic soil colloids influence movement of pesticides, and thus their availability for plant or microbial uptake, or their transformation by abiotic or biotic agents. However, the study of the biodegradation and fate of organic pollutants in soils suffers of a lack of analytical methods to follow *in situ* the biotransformation process. Direct analyses of dry parts of soils have been reported using solid-state cross-polarization magic angle spinning (CP-MAS) NMR spectroscopy. For example, ^{13}C CP-MAS NMR was used to characterize ^{13}C-atrazine (entirely labelled) residues and to follow the binding reactivity of organic matter after addition of fresh and decomposed straw.[1] These experiments, performed on dry samples, do not give the real fingerprint of an environmental material, which is usually highly hydrated with mobile pollutant at its surface. Particularly, solid-state NMR, albeit very efficient to provide structural information, cannot allow quantification of the 'bioavailability' of the pollutant. This could be elucidated by using liquid state high-resolution (HR) MAS NMR on hydrated samples. Indeed, HR MAS allows the characterization by NMR of inhomogeneous compounds with liquid-like dynamics.[2] In such systems with restricted or anisotropic motions, the effects of dipolar coupling, CSA and inhomogeneous susceptibility on resonance line widths are not averaged to zero in static experiments but are dramatically decreased by MAS. In environmental chemistry, only one example using ^{13}C MAS NMR has been described.[3] However, this approach is limited because it requires labelled xenobiotics, which are expensive and difficult to synthesize. By contrast ^{1}H NMR can be applied to any class of xenobiotic, as shown by recent studies carried out on liquid incubation media.[4] ^{1}H HR MAS NMR spectroscopy is increasingly used to study intact suspension cells or tissue metabolite composition.[5] It is also emerging as a new tool to quantitatively monitor solid phase organic reactions in combinatorial chemistry and thus to analyse resin-bound structures without any sample preparation.[6]

The purpose of the present study is to develop a method to characterize the interactions between organic pollutants and a model of soil, allowing direct analyses of contaminated soils, without any sample preparation. In this paper, we present the differentiation by ^{1}H HR MAS NMR of mobile 4-chloro-2-methylphenoxyacetate (MCPA), adsorbed at the surface of a well defined synthetic hydrotalcite used as a soil model and immobile MCPA intercalated in this bidimensional host structure [Fig. 1(a)].

Layered double hydroxides (LDH) are natural minerals, considered as the anti-type of 2:1 smectites and regarded as anionic clays. They are lamellar compounds, built by a stacking of positive $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2]^{x+}$ layers, separated by inter-

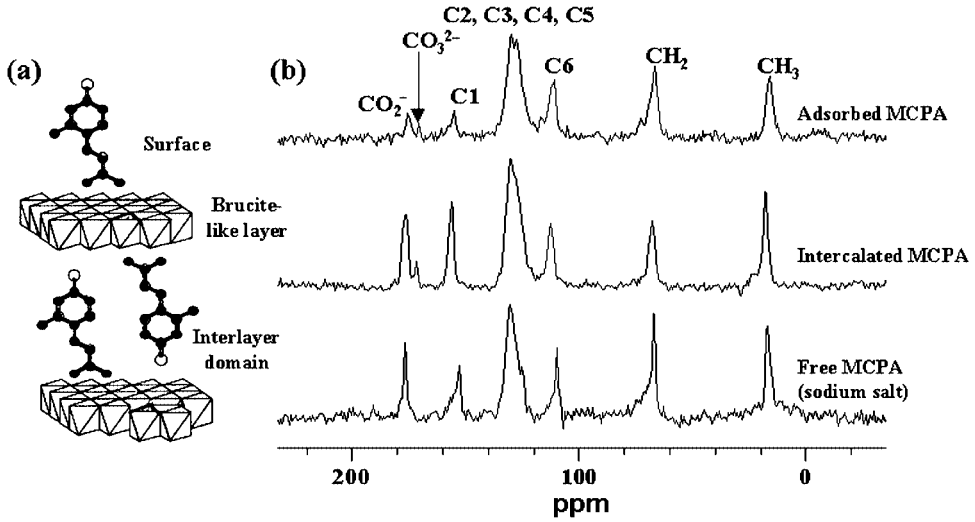

Fig. 1 (a) Structural model of the interaction of MCPA with HTLCs. (b) ^{13}C CP MAS ($\omega_r/2\pi$ = 10 kHz) spectra of adsorbed and intercalated MCPA clay, and free MCPA recorded at 75.46 MHz (recycle delay : 3 s; contact time : 1 ms; 2000 scans). The arrow indicates the presence of carbonates trapped in exchanged clays during the storage and the preparation of the samples.

 DOI: 10.1039/b106964k

layer domains containing hydrated anions $[X^{m-}_{x/m}\cdot nH_2O]$.[7] Synthetic minerals are simple to prepare with tunable M^{2+} and M^{3+} composition, layer charge density ($0.20 \leqslant x \leqslant 0.33$) and intercalated anion X^{m-}.[8] Their high anion exchange capacities make them interesting materials for the elimination of ecologically undesirable organic anions such as pesticides[9] from contaminated water or waste. Sorption studies recently demonstrated that pesticides of the chlorophenoxy carboxylate family (2.4D, MCPA, 2.4.5T) display very strong affinities to LDHs.

Adsorbed and intercalated MCPA on $Mg_{3.1}Al(OH)_{8.2}Cl\cdot nH_2O$ [Mg_3AlCl] were prepared as previously described.[10] The adsorption proceeds in two steps as shown on the adsorption isotherm (10 mg of solid, 50 ml of MCPA aqueous solution, 25 °C, 24 h equilibrium time).[10] The isotherm is clearly a mixture of S-type at low C_e equilibrium concentration (< 1.5 mmol l^{-1}) and L-type.[11] The change from S- to L-type within the same isotherm is likely to be due to changes from external to interlayer adsorption. The sorption data, at low C_e, were analysed according to the Freundlich equation: $Q = K_f C_e^{1/n}$ where $K_f = 0.666$ mmol g^{-1} and $n = 0.671$ are constants that give estimation of the adsorption capacity and intensity, respectively. The maximum of adsorption is reached for $C_e = 0.50$ mmol l^{-1}, *i.e.* 15% of the total exchange capacity at a specific surface area of the solid = 44 m^2 g^{-1}. Over this C_e value, intercalation proceeds *via* an increase of the basal spacing from 0.794 nm for [Mg_3AlCl] to 2.21 nm for [Mg_3Al(MCPA)] as shown by powder X-ray diffraction.

This high basal spacing results from the formation of intertwined double-layers of MCPA in the interlayer spaces, as reported by Prevot *et al.*,[12] with the anions hydrogen bonded to the hydroxylated surfaces in a perpendicular orientation [Fig. 1(a)].

Solid state ^{1}H MAS ($\omega_r/2\pi$ = 12 kHz) experiments carried out on both adsorbed and intercalated MCPA clays show very broad signals and do not allow the differentiation of both populations of MCPA (not shown). ^{13}C CP MAS spectra [Fig 1(b)] clearly show the presence of adsorbed and intercalated MCPA in the clay samples. The different carbons of the MCPA molecule were easily identified and their NMR signals were not shifted compared to free MCPA. A slight difference of relative CO_2^- and C1 signal intensities for the two populations (adsorbed and intercalated) was due to a lower efficiency of the CP technique at the surface. The better resolution of the intercalated MCPA spectrum can be explained by the higher structural order of this solid phase. To assess the mobility of adsorbed *vs.* intercalated MCPA in anionic clays, the samples (40 mg) were swollen with D_2O (80 μL). The sample volume was restricted to about 50 μL in the center of the rotor to increase the r.f. field homogeneity. The ^{1}H HR MAS NMR spectra were acquired at 300.13 MHz with a double bearing 4 mm MAS probehead using a single pulse experiment ($t_{90°}$ = 6.2 μs) with presaturation during relaxation for water resonance suppression. The samples were spun in a speed range of 1.33 to 1.80 kHz, sufficient for high resolution. Chemical shifts are reported in ppm relative to TSP-d_4 as external standard. The number of transients was typically 256 to achieve good signal to noise ratio.

Fig. 2(a) displays the ^{1}H spectrum of the adsorbed MCPA (0.49 mmol g^{-1}) clay hydrated with D_2O. All protons of MCPA are visible and chemical shifts are identical to those of the solution state NMR spectrum, thus indicating an efficient tumbling of the molecules at the surface. These sharp signals are

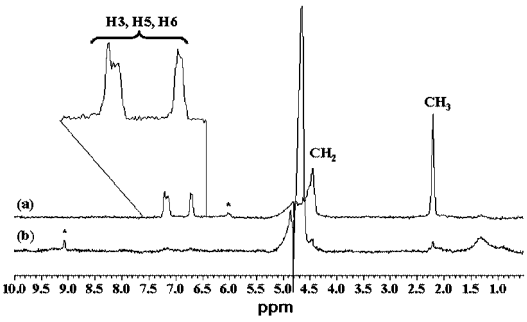

Fig. 2 ^{1}H HR MAS spectra of (a) adsorbed and (b) intercalated MCPA clay. The asterisk in spectra indicates spinning sidebands.

characteristic of weakly bounded compounds. The spectrum of the MCPA intercalated (> 4 mmol g^{-1}) compounds [Fig. 2(b)], recorded under the same conditions, displays only residual signals. In this sample the MCPA anions are tightly packed either inside the structure or at the surface because of a high packing of organic molecules which are not observed by HR MAS. These small signals could be explained by the release of a minor fraction of MCPA due to a slight hydrolysis of the matrix. This is confirmed by the presence of two broad peaks at 0.85 and 1.25 ppm, identified as protons of metallic hydroxides under colloidal form.

This communication demonstrates the potential of the ^{1}H HR MAS technique to study *in situ* interactions at the solid–aqueous interface of a solid matrix. By using a well-characterized model of soil it was possible to distinguish unambiguously the mobile and immobile pesticide. Therefore the ^{1}H HR MAS technique is a promising approach to quantitatively evaluate the bioavailable (mobile) fraction of a xenobiotic in such a solid matrix as it will be the only one giving rise to sharp ^{1}H NMR signals; any pesticide fraction strongly interacting with the soil model will not be detected. Although the detection limit of xenobiotic concentration can be evaluated to 50 μM, the environmental interactions in a whole soil will also be observable by this technique since all the powerful and sensitive solution-state experiments can be used.

We thank the CNRS (PEVS) for financial support.

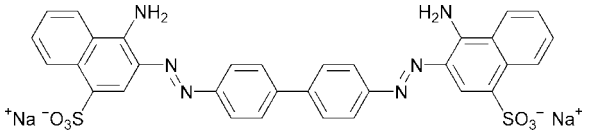
Received (in Cambridge, UK) 14th June 2001, Accepted 24th September 2001
First published as an Advance Article on the web 11th October 2001

Mesoporous (MCM-41 type) silica containing surfactant-embedded Congo Red has been prepared and tested against gas phase HCl and ammonia, as well as solutions of ionic species; it is shown that the hybrid (organic–inorganic) material is permeable to both gases and ionic species, and can act as a pH indicator and as a selective chelating agent.

Since their discovery in 1992, ordered mesoporous silicas, prepared by using surfactant molecules, have been much studied. Most work has concerned materials freed from surfactant either by calcination or extraction, those materials being suitable for catalysis, adsorption and inclusion of functional species.[1] The hybrid surfactant–silica systems have been investigated much less, and regarded usually as merely the precursors to active materials. Hybrid MCM-41 systems have been prepared with included paramagnetic molecules,[2] the motional freedom of which was measured by means of EPR spectroscopy. Some authors solubilised dyes in the surfactant solution in order to study formation of micelles and the growth of ordered mesoporous silica films by means of fluorescence.[3,4] Incorporation of dye-molecules in the micellar phase of surfactant–silica mesophases has also been achieved,[5] as dye-modified ordered mesoporous silica and zeolites may find applications in optical, optoelectronic and electrochromic devices, and in chemical sensors.[6–8]

Details on the nature of organic mesophases is lacking. Jaroniec and Antochshuck[9] have shown that the surfactant–MCM-41 hybrid material is somehow permeable to Me_3SiCl, which can diffuse and be grafted on the internal silica surface, causing some surfactant displacement. Here, we report data on the permeability of MCM-41 hybrid systems to acidic/basic gases or to solutions, obtained by means of common pH indicators embedded in the micelle. Congo Red (hereafter CR, Scheme 1) was used: nearly identical results obtained with Curcumin are not reported.

Both dye-free (MCM-41) and dye-containing (CR-MCM-41) samples were prepared following ref. 10 using tetraethylorthosilicate (TEOS, Aldrich), distilled water, hexadecyltrimethylammonium bromide (CTAB, Aldrich), Congo Red (Merck) and NaOH (Carlo Erba). 2.0 g of CTAB was added at room temperature to a basic solution (0.96 g of NaOH in 475 ml of water) under stirring. When the solution became homogenous, CR was then added. 10 ml of TEOS was added, giving rise to a coloured slurry. After 3 h the product was filtered off, washed first with distilled water and then with ethanol, and dried at 40 °C. The composition of the synthesis mixture was 1 TEOS:0.125 CTABr:0.400 NaOH:0.01 dye:525 H_2O. Samples were stored before use in a P_2O_5 desiccator. IR spectra showed the presence of negligible amounts of residual water.



Scheme 1 The Congo Red molecule.

No leaching of dye occurred when washing with either ethanol or water; the CR-containing sample was bright red. For comparison, two surfactant-free CR/SiO_2 systems were prepared, one by precipitating SiO_2 from a basic solution of TEOS in the presence of CR, and the other by impregnation of MCM-41 (after calcination in flowing air at 773 K) with a CR solution. It was found that in the surfactant-free sample washing with water brought about dye leaching. Surfactant micelles are effective in retaining the dye in the material. Indeed, ionic dyes, such as CR, can be removed from aqueous solution by ionic surfactants, which collect the dye in the froth, and have themselves a tendency to form micelles.[11]

Fig. 1 shows the XRD patterns of MCM-41 and CR-MCM-41 with high amount of dye (Si/CR = 25). In both cases, the hexagonal phase is present. A smaller d_{100} is observed for the latter: the increase in size of the hexagonal cell (from 444 to 464 pm) indicates that the dye embedded in the micelles causes some swelling. Sulfonate groups in CR probably interact with the cationic heads of surfactant molecules, which in turn interact with the negatively charged silica wall:[12] the sulfonic groups of CR are thus probably located at the surfactant–silica interface, whereas the rest of the molecule, *i.e.* aromatic rings, amino and azo groups, is embedded in the micelle.

Accessibility of the dye molecules to gases was investigated by exposing the powder to vapours of HCl and NH_3. Fig. 2 shows the diffuse-reflectance UV–VIS spectra of CR-MCM-41 before (curve 1) and after exposure to gases (curves 2–4). In curve 1, the band at 500 nm is due to the π–π* transition of the azo group,[13] which is rather sensitive to protonation. The shoulder at 530 nm could be due to some amount of ordered dye aggregates, in a head-to-tail stacking arrangement.[14]

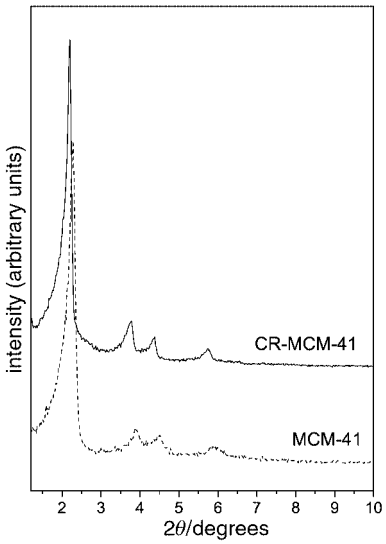


Fig. 1 XRD patterns of dye-free (MCM-41) and CR-containing (CR-MCM-41) surfactant–silica hybrid MCM-41 materials.

 DOI: 10.1039/b105261f

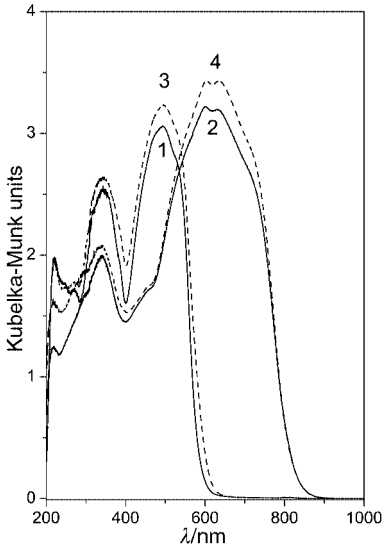

Fig. 2 Electronic diffuse reflectance spectra of CR-MCM-41 as-synthesized (curve 1), exposed to HCl (curve 2), exposed to NH_3 after HCl (curve 3) and re-exposed to HCl (curve 4).

Exposure to HCl causes a colour change from red to blue, the colour of the acidic form of CR (the same is observed with pure CR): accordingly, the π–π* transition of the azo group shifts to higher wavelength because of protonation (curve 2). Exposure to ammonia restores immediately the spectrum of the as-synthesised CR-MCM-41 (curve 3), since deprotonation of Congo Red occurs with formation of ammonium ions, the presence of which is revealed by IR spectroscopy. Subsequent exposure to HCl restores spectrum 2 (curve 4). The IR spectrum of CR-MCM-41 shows parallel changes after exposure to HCl and NH_3. More than 10 protonation–deprotonation cycles were observed, *i.e.* the probable formation of ammonium chloride within the solid does not prevent the permeation to gases.

The permeability of the hybrid material to species in solution has been investigated as follows. In a first experiment, CR-MCM-41 was contacted with an acidic solution at pH < 1, to assess whether the dye molecules were reachable by H_3O^+ species and able to display their pH-sensing properties. A change in colour from red to blue was observed immediately, indicating that protonation of CR occurs and that the azo group is accessible to H_3O^+ ions from aqueous solution. When the acidic solution was diluted, the sample colour changed back to red, indicating a reversible protonation of embedded CR. The pH at which colour change takes place is lower than with CR in aqueous solution: the same was observed for the dye in CTAB-containing aqueous solutions. This lower pH value may be accounted for considering a partition of H_3O^+ species between the hydrophilic phase (water) and the hydrophobic phase (micelles), causing a lower H_3O^+ concentration in the micelles than in aqueous solution. In order to observe the colour change of the micelle-embedded indicator, a higher H_3O^+ concentration in the aqueous phase is required with respect to the value observed for CR aqueous solution.

As CR may act as a sensitive photometric reagent toward metal ions,[15] such as Cu^{2+} (chelation involves both azo and amino groups, causing a red shift of the π–π* transition), in a second experiment CR-MCM-41 was stirred in a $CuSO_4$ solution for 12 h, then filtered off and washed. Two solvents have been considered, *i.e.* water and ethanol (95 wt%).

After contact with an aqueous Cu^{2+} solution no change occurred in the UV–VIS spectrum of the material. However, after contact with ethanol solution, a new absorption appears at *ca.* 630 nm, ascribed to π–π* transition of molecules complexing Cu^{2+} ions, in agreement with what is observed for other metal ions complexed by CR linked to a polymeric matrix.[15] Ethanol-solvated Cu^{2+} ions most probably have a higher hydrophobicity, *i.e.* a larger affinity for the micellar phase, than aquo-ions, so that the former diffuse inside the dye-containing mesophases more easily than the latter.

In conclusion, the surfactant–silica hybrid material is permeable to both gases, even strongly polar such as HCl, and ionic species. The micelle-embedded CR is readily accessible to such species and still acts as a pH sensor, in that reversible protonation–deprotonation occurs at the azo group. The embedded molecules can still act as a chelating agent through the azo and the amino groups towards Cu^{2+} ions.

We thank Professor M. Lucco Borlera (Politechnic of Turin) and Professor G. Viscardi (University of Turin) for fruitful discussions.

Efficient and selective catalytic oxidative cleavage of α-hydroxy ketones using vanadium-based HPA and dioxygen

First published as an Advance Article on the web 5th October 2001

The combination of $H_{3+n}[PMo_{12-n}V_nO_{40}]$·aq (HPA-*n*, *n* = 3) and dioxygen provides a clean and regioselective reagent for the homolytic cleavage of various representative α-hydroxy ketones (primary to tertiary) and turns out to be as efficient for the catalytic ring opening of chiral natural products.

Keggin type mixed-addenda heteropolyanions such as $[PMo_{12-n}V_nO_{40}]^{(3+n)-}$, denoted HPA-*n* (*n* = 1, 2, 3, *etc.*), have found many applications in catalysis.[1] Recently, their variable redox and acid–base properties have been used for the catalytic cleavage of different cycloalkanones by dioxygen.[2,3] Carboxylic acids, including adipic acid were obtained with high yields and selectivities. Early mechanistic studies showed clearly that the α-ketol (α-hydroxy ketone) is not a major intermediate during cyclohexanone oxidation. In fact, 2-hydroxycyclohexanone is converted to adipic acid with a better yield.

The oxidative cleavage of carbon–carbon bonds in α-ketols is widely used in organic synthesis. In many synthetic schemes, including that of Taxol®, ring opening strategies are based on prior formation of α-hydroxy ketones.[4] Most of the published procedures use stoichiometric reagents.[5] Efforts have been made to find dioxygen-based catalytic pathways running either with Bi(0)/Bi(III) salts or moisture-sensitive dichloro(ethoxy)-oxy vanadium complexes.[6] In this communication, we report on the synthetic utility of the reaction catalysed by robust oxidation-resistant compounds like vanadium-based HPA and present a general route for the selective homolytic carbon–carbon bond cleavage of α-hydroxy ketones.

Using 2-hydroxycyclohexanone (**1a**) and $H_6[PV_3Mo_9O_{40}]$·aq as the catalyst precursor, the reaction was carried out either in methanol or in an acetic acid–water mixture at 65 °C. Dioxygen consumption was monitored by a gas burette system. Colour changes of the initial solutions from orange to blue-green and finally orange-brown were observed in both cases. They are consistent with the variation of the oxidation state of vanadium [V(V)/V(IV)] and the overall reaction can be interpreted in terms of a vanadium-catalysed process assisted by dioxygen. Under dinitrogen the solution remained blue and there was no significant reaction. The results are summarized in Table 1.

Regioselective cleavage of **1a** gave adipic acid or its dimethyl ester (Scheme 1) as the major products in acetic acid or methanol, respectively (runs 1 and 2). As shown in a blank experiment, adipic acid (**2a**) conversion to dimethyl adipate (**2b**) was also catalysed by 'HPA-3'† in methanol (100% yield in 1.5 h).

The *in situ* esterification yield, as determined by comparison of the diester (**2b**) amounts before and after addition of an ethereal solution of diazomethane was about 85–90%. Very low yields (< 1%) of glutaric acid derivatives were obtained. In methanol, the major by-products identified as methyl 6-oxohexanoate (**2c**) and methyl 6,6-dimethoxyhexanoate (**2d**) also arise from the cleavage of the C(O)–CH(OH) bond.

The conversion of the 2-hydroxycyclohexanone dimer to the monomer with accessible hydroxy and carbonyl groups proved to be an important prerequesite for the exclusive scission of this bond. Otherwise, significant amounts of 2-methoxybutanedioate were formed. In fact, the availability of both groups is not necessary for the occurrence of the desired reaction in methanol, as shown in Table 1 (runs 3 and 4). Comparison of the conversion rates (not shown) of 2,2-dimethoxycyclohexanol, a potential intermediate under acidic conditions, and 2-methoxycyclohexanone showed clearly the negative effects of the OH substituent. These results are consistent with a mechanism in which there is substrate pre-coordination to $[VO_2]^+$ species.[2,7]

The use of 'HPA-3' as a catalyst for the aerobic C–C bond cleavage of α-ketols was then applied successfully to a range of representative substrates (Table 2). For all the benzoyl derivatives (**3a–d**), the reactions could be carried out at room temperature with completion of dioxygen uptake within 5 h. Methyl benzoate and/or benzoic acid were formed with 90–100% selectivity. Quantitative yields of other benzoyl derivatives or cyclohexanone are obtained with **3b** or **3d** respectively. In accordance with published results,[2,7] the outcome with 2-hydroxy-2-phenylacetophenone (**3b**, benzoin) was much more sensitive to the nature of the solvent. Significant amounts of 1,2-diphenylethanedione (benzil) were produced in AcOH–H_2O, whereas only carbon–carbon bond cleavage products (benzaldehyde and its dimethyl ketal) and methyl benzoate were formed at room temperature in methanol.

Table 1 Oxidation of 2-hydroxycyclohexanone (**1a**) or its derivatives with dioxygen catalysed by 'HPA-3'[a]

Run	Substrate	Solvent	*t*/h	Conv. (%)[b]	Yield (%)[b]
1	2-Hydroxycyclohexanone	MeOH	10	100	90 (**2a** + **2b**)
2	2-Hydroxycyclohexanone	AcOH–H_2O	3.5	100	80 (**2a**)
3	2,2-Dimethoxycyclohexanol	MeOH	7	100	83 (**2a** + **2b**)
4	2-Methoxycyclohexanone	MeOH	54	67	52 (**2b**)

[a] *Reaction conditions*: substrate (7.7 mmol), 'HPA-3' (0.078 mmol), MeOH (7 ml) or AcOH–H_2O (6.3 : 0.7 ml), dioxygen pressure (0.1 MPa), temperature (65 °C) stirred at 1000 rpm; [b] Conversions (% of substrate consumed) and yields [(mmol of product per mmol substrate) × 100] were determined by GC analysis (OV1701) after the addition of an ethereal solution of diazomethane to the crude mixture using methyl heptanoate as internal standard. Products were identified by GC-MS (RTX5-MS).

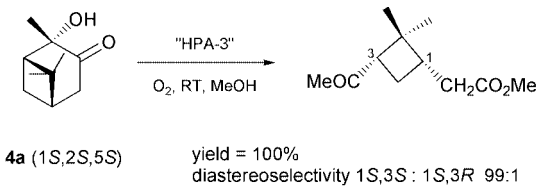
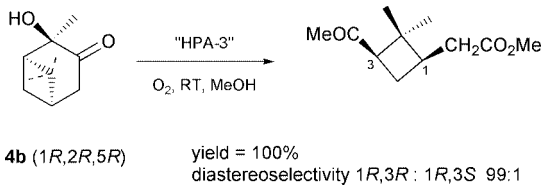
Table 2 'HPA-3'-catalysed oxidative cleavage of α-ketols[a]

Run	α-Ketol	Solvent	Conv. (%)[b]	Product(s) [Yield (%)][b]	O_2/Subst. (molar ratio)
5	2-Hydroxyacetophenone[c] (**3a**)	MeOH	100	$PhCO_2Me$ (97)	1.2
6	2-Hydroxyacetophenone[c] (**3a**)	AcOH–H_2O	100	$PhCO_2H$ (100)	1.05
7	2-Hydroxy-2-phenylacetophenone (**3b**)	MeOH	100	$PhCO_2Me$ (110); PhCHO (45); $PhCH(OMe)_2$ (45)	0.77
8	2-Hydroxy-2-phenylacetophenone (**3b**)	AcOH–H_2O	100	$PhCO_2H$ (81); PhCHO (1); PhCOCOPh (47)	0.75
9	2-Hydroxy-2-methylpropiophenone[c] (**3c**)	MeOH	100	$PhCO_2Me$ (97)	0.70
10	2-Hydroxy-2-methylpropiophenone[c] (**3c**)	AcOH–H_2O	100	$PhCO_2H$ (100)	0.50
11	1-Hydroxycyclohexyl phenyl ketone (**3d**)	MeOH	100	$PhCO_2Me$ (100); C_6H_{10}(=O) (100)	0.80
12	1-Hydroxycyclohexyl phenyl ketone (**3d**)	AcOH–H_2O	60	$PhCO_2H$ (54); C_6H_{10}(=O) (60)	0.35

[a] *Reaction conditions*: substrate (7.7 mmol), 'HPA-3' (0.078 mmol), MeOH (7 ml) or AcOH–H_2O (6.3:0.7 ml), dioxygen pressure (0.1 MPa), room temperature. [b] See Table 1. [c] Formaldehyde and acetone or their oxidized derivatives were not determined.



4a (1*S*,2*S*,5*S*) yield = 100%
diastereoselectivity 1*S*,3*S* : 1*S*,3*R* 99:1



4b (1*R*,2*R*,5*R*) yield = 100%
diastereoselectivity 1*R*,3*R* : 1*R*,3*S* 99:1

Scheme 2

Clean oxidation of **3d** to methyl benzoate or benzoic acid and cyclohexanone was only possible at room temperature; otherwise subsequent cleavage of the cycloalkanone becomes significant.[3] The oxygen consumed–substrate molar ratio was in good agreement with the stoichiometric values (Table 2). The dioxygen uptake for primary α-ketols (**3a**) was roughly twice that for tertiary ones (**3c**,**d**) as expected for pure C–C bond cleavage (runs 6, 10 and 12).

The same experimental procedure was successfully applied to natural compounds. For example, the oxidative cleavage of (1*S*,2*S*,5*S*)-2-hydroxypinan-3-one(**4a**) or its enantiomer (**4b**) led to the diastereoselective formation of methyl esters‡ of the corresponding *cis*-pinonic acids§ with 100% conversion (Scheme 2).

The epimerization of the cyclobutane carbon atom (C3) linked to the acyl group under acidic conditions is well-documented[8] but this competing reaction did not exceed 10% at 65 °C and did not occur at all at room temperature.

Cyclobutane-derived amino-acids and related peptides isolated from natural sources display interesting biological properties, and methyl pinonates are very important chiral cyclobutane synthons. However, stereoselective methodologies based usually on α-pinene oxidation are scant[9] and our approach corresponds to a convenient green alternative.

In conclusion, the present study has proved that the aerobic oxidative cleavage of α-hydroxy ketones (or α-hydroxy ketals) catalysed by 'HPA-3' could replace stoichiometric polluting reagents either for large-scale products or for fine chemicals synthesis. We are currently investigating the mechanism as well as the supported counterpart of these catalysts.

Financial support by the Comité franco-marocain (AI 217/SM/00) is gratefully acknowledged.

Notes and references

† The heteropolyacids 'HPA-3' were prepared according to described procedures.[10] Their elemental analysis gave P, 1.7, Mo, 45.5, V, 7.75% which is consistent with the formula '$H_6[PV_3Mo_9O_{40}]\cdot 11H_2O$'. Solid HPA-*n* and their aqueous solutions are multi-component systems: they contain several polyanions, positional isomers of these, $[VO_2]^+$ and often traces of V(IV).

‡ Methyl esters obtained from the oxidation of (1*S*,2*S*,5*S*) or (1*R*,2*R*,5*R*)-2-hydroxypinan-3-one were characterized by their $[MNH_4]^+$ and $[MH]^+$ signals at 216 and 199 Da, respectively, using GC-MS/CI$^+$ (NH_3). Complete retention of configuration of both asymmetric carbon atoms in the 1*S*,3*S* and 1*R*,3*R* compounds was established by NOE ^{1}H NMR studies. Specific rotations of the diastereoisomeric mixtures isolated from the oxidation of (1*S*,2*S*,5*S*)-2-hydroxypinan-3-one at 65 °C or its enantiomer (1*R*,2*R*,5*R*) at RT were +65.1 deg cm^2 g^{-1}(*c* 2.17, $CHCl_3$) and −81.4 10^{-1} deg cm^2 g^{-1}(*c* 5.03, $CHCl_3$), respectively, in accordance with data for the pure compounds.[11]

§ The IUPAC name for pinonic acid is 3-acetyl-2,2-dimethylcyclobutaneacetic acid.

Four- and two-electron rules for diatropic and paratropic ring currents in monocyclic π systems

Erich Steiner and Patrick W. Fowler

School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD. E-mail: P.W.Fowler@exeter.ac.uk; E.Steiner@exeter.ac.uk; Fax: +44 1392 263434

Received (in Cambridge, UK) 10th June 2001, Accepted 10th September 2001
First published as an Advance Article on the web 4th October 2001

The π ring current in an even-electron monocycle is dominated by the HOMO–LUMO transition, and hence corresponds to circulation of four electrons in a diatropic (4*n* + 2)-electron, but two in a paratropic (4*n*)-electron cycle.

Ring currents are, according to one widely accepted approach, the defining feature of aromatic systems.[1,2] Calculation of magnetic properties in finite basis sets is bedevilled by the problem of spurious gauge dependence. Distributed-gauge methods offer an alternative to brute-force saturation of the basis, and the particular approach known by the acronym CTOCD-DZ (continuous transformation of origin of current density - diamagnetic zero[3]) has practical and conceptual advantages. In CTOCD-DZ, when calculating the induced current density at a given point, the point itself is taken as the origin of vector potential. Current maps derived with this 'ipsocentric' choice of origin are physically realistic,[4] and can be expressed as sums of the simplest possible orbital contributions.[5] This last property is used here to deduce a simple rule for ring currents in π monocycles.

It will be shown that in Hückel theory: (i) the *diatropic* (*i.e.* diamagnetic) ring current in *aromatic* (4*n* + 2)-electron systems can be attributed to *four* electrons, those in the doubly degenerate HOMO; whereas (ii) the *paratropic* (*i.e.* paramagnetic) ring current in *anti-aromatic* 4*n*-electron systems with bond alternation can be attributed to circulation of the *two* electrons of the non-degenerate HOMO. The proof rests on a specific decomposition[3] of the current density, derived in detail in Ref. 5. Within an ipsocentric formulation, the traditional division of current density into ground-state diamagnetic and excited-state paramagnetic terms is replaced by two excited-state sums, each containing only transitions from occupied to empty orbitals.[5] In an independent-electron model, the first-order change to an occupied orbital ψ_n of an *N*-electron system in an external magnetic field $\boldsymbol{B}$ can be expressed in terms of unoccupied orbitals ψ_p and their energies ε_p as (in atomic units):where $\boldsymbol{l}$ and $\boldsymbol{p}$ are angular and linear momenta, and $\boldsymbol{d}$ is a displacement which is set equal to the position of the electron in the expression for the current density. In this partitioning, the conventional paramagnetic current arises from $\psi_n^{(\mathrm{p})}$, its size depending on accessibility of states *via* rotational transitions, and the diamagnetic current from $\psi_n^{(\mathrm{d})}$, depending on translational transitions.

$$\psi_n^{(1)} = \psi_n^{(\mathrm{p})} + \psi_n^{(\mathrm{d})} = -\frac{1}{2}\sum_{p>N/2}\psi_p \frac{<\psi_p \mid \boldsymbol{l} \mid \psi_n>}{\varepsilon_p - \varepsilon_n} \bullet \boldsymbol{B}$$

$$+\frac{1}{2}\,\boldsymbol{d} \times \sum_{p>N/2}\psi_p \frac{<\psi_p \mid \boldsymbol{p} \mid \psi_n>}{\varepsilon_p - \varepsilon_n} \bullet \boldsymbol{B}$$

For the response of planar conjugated π systems to a perpendicular magnetic field, the relevant operators are for rotation about the field direction, $R_{||}$, and the two translations within the molecular plane, $T_{\perp}$. Orbital contributions to the current density obey a symmetry-based selection rule. An occupied-to-unoccupied transition $\psi_n \rightarrow \psi_p$ gives a *paramagnetic* contribution if the product of symmetries contains a match to $R_{||}$, and a *diamagnetic* ring current contribution if it contains a match to a translation $T_{\perp}$. A transition may be translationally and or rotationally active, or neither.

Using the Hückel approximations for a ring of *N* atoms with equal coulomb parameter α connected by bonds of equal resonance parameter β, the π molecular orbitals and their energies are given by the Frost–Musulin[6] construction, where energies correspond to the vertices of an *N*-gon inscribed point-down in a circle of radius 2β, and the orbitals are sine and cosine combinations associated with an angular momentum quantum number $k = 0, 1, \ldots (N/2)$ (*N* even), $(N-1)/2$ (*N* odd). Closed-shell configurations occur at the aromatic counts of 2, 6, 10 … π-electrons, and, in the same approximation, open shells with two electrons in two degenerate orbitals at anti-aromatic counts 4, 8 … With this characterisation in terms of angular momentum, the ring-current selection rules take on an especially simple form, independent of *N* and details of the point group.

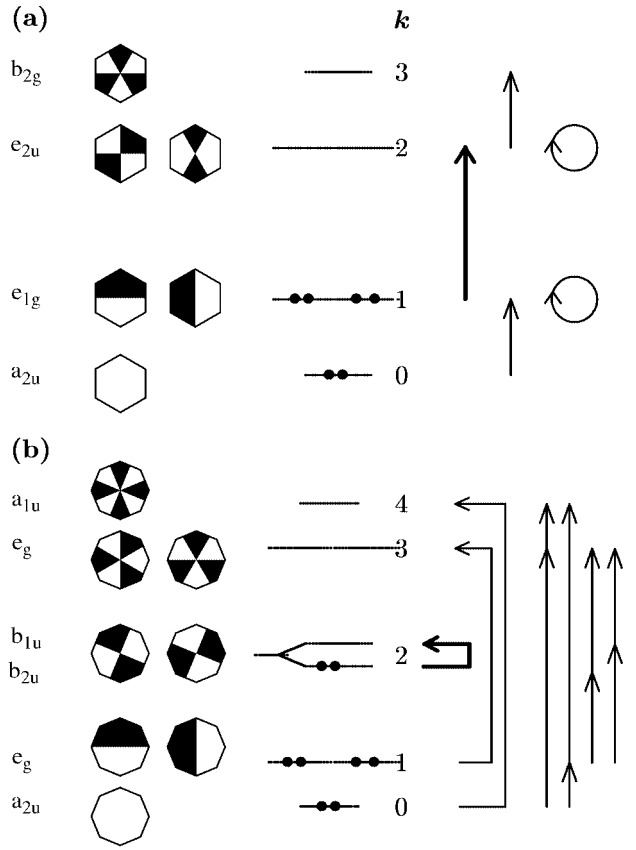

Fig. 1 Orbital energy scheme for (a) benzene (D_{6h}) and (b) planar cyclooctatetraene (D_{4h}), showing symmetries, nodal characteristics, occupancies and *k* values. Symmetry-allowed transitions are indicated by straight (translational) and bent (rotational) arrows, with the dominant HOMO–LUMO transition, responsible for the diatropic and paratropic π ring currents observed in *ab initio* calculations (*cf.* Fig. 2), highlighted.

 DOI: 10.1039/b104847n

To deduce (i), note that, in a closed-shell configuration, either all orbitals with given k are occupied, or all are empty. As $R_{||}$ mixes only orbitals of equal k, it cannot produce occupied-to-virtual transitions, and gives no paramagnetic contribution from any orbital. On the other hand, $T_{\perp}$ operators mix orbitals that differ by ±1 in k, *i.e.* on adjacent rungs of the energy ladder (Fig. 1a). The sole occupied-to-virtual translational transitions in the system are therefore those from HOMO to LUMO. Hence in a $(4n + 2)$-electron monocycle, the ring current is wholly diamagnetic and attributable to the mobility of the HOMO electrons. In all but two trivial cases, the HOMO is doubly degenerate and the system has 4-electron diamagnetism. The exceptions are $C_NH_N^{(N-2)+}$, with 2-electron diamagnetism, and $C_NH_N^{N-}$ anions which have full π systems and hence, in the Hückel model, no available transitions (in practice, their diamagnetism arises from orbitals above the Hückel manifold). In a $(4n + 2)$ system that supports bond alternation, such as $C_{10}H_{10}$ constrained to the plane, the lowering of symmetry to $D_{(2n+1)h}$ allows further mixings, as pairs of levels with mirror-image energies $\alpha \pm \lambda\beta$ become equi-symmetric. The relaxation of symmetry allows new rotational transitions between these pairs and translational transitions between levels differing by 3 in parent k value, but for modest degrees of alternation their contributions remain low because of substantial cancellation in the numerator, and any ring current remains diamagnetic and HOMO–LUMO dominated as in (i).

Statement (ii) is deduced by considering the half-filling of the π system for $N = 4n$. In full D_{Nh} symmetry, there are two non-bonding orbitals and hence an open-shell configuration. The system will distort to lift this degeneracy, as for example by adopting a structure in which alternate bonds have resonance parameters $\beta \pm \delta$. In the reduced $D_{(N/2)h}$ symmetry the HOMO/LUMO pair splits into two non-degenerate components, related by a rotational transition with a small energy denominator and large numerator in the sum over states (since $R_{||}$ transforms HOMO to LUMO (Fig. 1b), thereby producing a strong 2-electron paramagnetic π ring current. The additional transitions introduced by bond alternation are again reduced in importance by poor overlap and large energy gaps. In systems other than neutral half-filled π shells, the geometric distortion that lifts the degeneracy may be different, but it will still split a rotationally connected pair across a small energy gap, and give rise to a dominant 2-electron paramagnetic current contribution. Hence statement (ii) also holds for these other configurations.

The *ab initio* π current density maps† computed for the optimum geometries of the 6-electron systems $C_5H_5^-$, C_6H_6, $C_7H_7^+$, and the planar stationary points on the potential surfaces of $C_{10}H_{10}$ and anti-aromatic C_8H_8 (Fig. 2) all closely match the predictions made here on the basis of Huckel arguments. The isolated C_8H_8 ring is in fact non-planar at equilibrium,[8] but when restricted to the plane or clamped by electronically innocent functional groups[9] it shows exactly the paratropicity described here.[10] Likewise, $C_{10}H_{10}$ has a nonplanar equilibrium geometry but can be forced into planarity.[11] In all cases, the HOMO contribution to the map is almost indistinguishable from the total π current. The present rules, exact within the context of planar equilateral Hückel monocycles, serve in more sophisticated treatments to rationalise the magnitude and sense of computed currents and other magnetic measures of aromaticity, such as the widely used NICS criterion,[2] and give a key to interpretation of a much wider range of systems, where it can also be expected that π ring currents will be dominated by a small number of electrons close to the HOMO–LUMO frontier.[5]

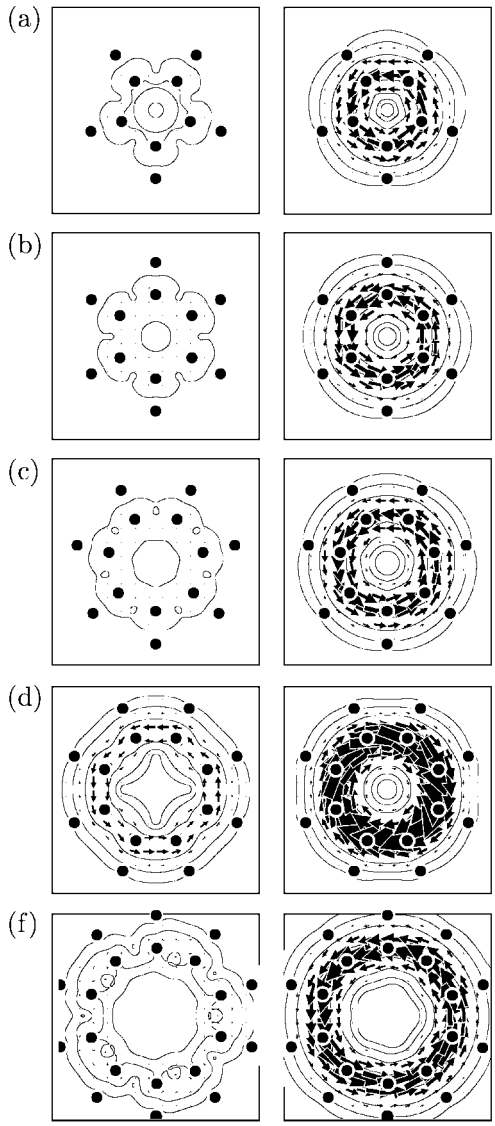

Fig. 2 Computed π ring current maps† for (a) $C_5H_5^-$, (b) C_6H_6, (c) $C_7H_7^+$, (d) planar C_8H_8, (e) planar $C_{10}H_{10}$. Left: contribution of all but the HOMO π electrons. Right: contribution of the HOMO electrons.

Catalytic asymmetric Henry reactions—a simple approach to optically active β-nitro α-hydroxy esters†

Christina Christensen, Karsten Juhl and Karl Anker Jørgensen*

Center for Metal Catalysed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark. E-mail: kaj@chem.au.dk

Received (in Cambridge, UK) 4th July 2001, Accepted 19th September 2001
First published as an Advance Article on the web 18th October 2001

The development and potential of a catalytic enantioselective Henry reaction of nitromethane with various α-keto esters catalyzed by chiral bisoxazoline–copper(II) complexes are presented.

The reaction between a carbonyl and a nitro compound, known as the Henry[1] or nitroaldol reaction, constitutes a fundamental carbon–carbon bond forming reaction in organic chemistry which has been applied for the construction of numerous natural products and other useful compounds.[2]

The catalytic asymmetric version of the Henry reaction has been successfully carried out in only a very few cases; Shibasaki *et al*. have in a series of papers shown that rare-earth–lithium–BINOL complexes can be applied as catalysts for the enantioselective reaction of aldehydes with nitroalkanes.[3,4]

This paper presents a new catalytic asymmetric Henry reaction of α-keto esters **1** with nitromethane **2** in the presence of easy-available chiral catalysts [eqn. (1)]. The present reaction is an important new development of the Henry reaction as it demonstrates (*i*) for the first time that ketones react in a catalytic highly enantioselective fashion, (*ii*) the products formed contain a chiral quaternary carbon center, the formation of which is a particularly demanding task in organic synthesis,[5] and (*iii*) highly attractive functionalized optically active β-nitro α-hydroxy esters **3** are formed.

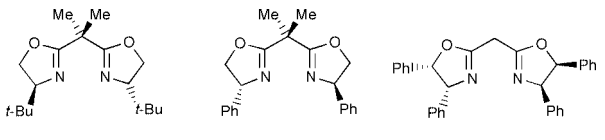
(1)

Different chiral ligands, Lewis acids and bases have been tested as catalyst for the enantioselective Henry reaction of ethyl pyruvate **1a** with nitromethane **2**. The most promising results were found when the chiral bisoxazoline ligands[6] (*S*)-*t*-Bu-BOX **4a**, (*R*)-Ph-BOX **4b** and (4*R*,5*S*)-DiPh-BOX **4c**, were used in combination with copper(II) as the Lewis acid.[7] Table 1 presents some representative results from the screening.



(*S*)-*t*-Bu-BOX **4a** (*R*)-Ph-BOX **4b** (4*R*,5*S*)-DiPh-BOX **4c**

Of the three chiral bisoxazoline–copper(II) catalysts presented for the reaction, the combination of (*S*)-*t*-Bu-BOX **4a** as ligand and $Cu(OTf)_2$ as the Lewis acid gave the most promising results with >95% conversion and 92% ee of the Henry adduct **3a** (entry 1) at rt, compared to >95% conversion and 14% ee for (*R*)-Ph-BOX–$Cu(OTf)_2$ and 11% conversion and 18% ee for (4*R*,5*S*)-DiPh-BOX–$Cu(OTf)_2$ (entries 2, 3). Reduction of the catalyst loading from 20 mol% to 10 mol% does not change the conversion and enantioselectivity of the reaction significantly when using (*S*)-*t*-Bu-BOX–$Cu(OTf)_2$ as the catalyst (entry 4). The conversion and enantioselectivity of the reaction of **1a** with **2** is also dependent on the amount of base relative to the catalyst. A reduction of the amount of Et_3N to 10 mol%, or an increase to 40 mol%, relative to the catalyst (20 mol%) gave a significant reduction in conversion and enantioselectivity for the first combination, and a high conversion and a racemic product **3a** for the latter combination (entries 5, 6). In the presence of NEt_3 and no chiral Lewis acid the reaction proceeds with full conversion (entry 7). The reaction also proceeds well in the presence of (*S*)-*t*-Bu-BOX–$Cu(SbF_6)_2$ as the catalyst: >95% conversion is found and **3a** is obtained with 81% ee (entry 8). Changing the Lewis acid from copper(II) to zinc(II) [(*S*)-*t*-Bu-BOX–$Zn(OTf)_2$] leads to a reaction with only 16% ee of the other enantiomer (entry 9).

Table 1 Some representative results from the screening of reaction conditions for the catalytic enantioselective Henry reaction of ethyl pyruvate **1a** with nitromethane **2** in the presence of Et_3N as the base at room temperature

Entry	Catalyst	Catalyst loading (%)	Base (%)	Conversion (%)[a]	Ee of **3a** (%)[b]
1	(*S*)-*t*-Bu-BOX–$Cu(OTf)_2$	20	20	>95	92
2	(*R*)-Ph-BOX–$Cu(OTf)_2$	20	20	>95	14
3	(4*R*,5*S*)-DiPh-BOX–$Cu(OTf)_2$	20	20	11	18
4	(*S*)-*t*-Bu-BOX–$Cu(OTf)_2$	10	10	84	81
5	(*S*)-*t*-Bu-BOX–$Cu(OTf)_2$	20	10	11	49
6	(*S*)-*t*-Bu-BOX–$Cu(OTf)_2$	20	40	>95	<5
7	—	—	20	>95	—
8	(*S*)-*t*-Bu-BOX–Cu(SbF6)$_2$	20	20	>95	81
9	(*S*)-*t*-Bu-BOX–$Zn(OTf)_2$	20	20	87	−16

[a] Determined by 1H-NMR spectroscopy. [b] Determined by chiral GC using a Chromopack CP-Chiracil (β-PM) column.

The reaction of **1a** with **2** catalyzed by (*S*)-*t*-Bu-BOX–$Cu(OTf)_2$ is base dependent. The results for some representative bases are: Hünigs base 31% conversion, 69% ee; dimethylaniline 14% conversion, 9% ee; *N*-methylmorpholine 65% conversion, 83% ee; Bn_3N 10% conversion, 14% ee, compared to >95% conversion and 92% ee applying Et_3N. It should also be noted that lowering the reaction temperature did not improve the enantioselectivity (at 0 °C: full conversion, 89% ee).

The potential of the reaction is demonstrated for the reaction of the α-keto esters **1a–f** with **2** catalyzed by (*S*)-*t*-Bu–BOX–$Cu(OTf)_2$ as shown in Table 2.‡

Ethyl pyruvate **1a** reacts with nitromethane **2** to give 2-hydroxy-2-methyl-3-nitropropanoic acid ethyl ester **3a** in 95% yield and with 92% ee (Table 2, entry 1). The corresponding ethyl analogue **1b** reacts in a similar way to give the Henry

6[c]	**1e**	81	86
7[c]	**1f**	99	93

[a] Isolated yield. [b] Determined by chiral GC or HPLC. [c] Reaction performed at rt. [d] Reaction performed at 50 °C.

adduct **3b** in 46% yield and 90% ee at rt (entry 2). The yield of the Henry adduct is increased to 73% without significant loss in enantioselectivity by heating the reaction mixture to 50 °C (entry 3). In the same manner, the corresponding benzyl ester **1c** gives 69% yield of **3c** with 87% ee (entry 4). The α-keto ester **1d** reacts with **2** giving a moderate yield and enantioselectivty (entry 5) compared to the other reactions presented. The aromatic α-keto esters **1e**,**f** react with **2** in the presence of (*S*)-*t*-Bu-BOX–$Cu(OTf)_2$ as the catalyst to give the optically active Henry adducts in excellent yield and enantioselectivity as 81% and 86% ee of **3e**, and 99% yield and 93% ee of **3f**, respectively, are obtained (entries 6,7).

This new catalytic enantioselective Henry reaction leads to a simple synthetic approach to attractive functionalized optically active β-nitro α-hydroxy esters,[2] while reduction of the nitro functionality gives the corresponding optically active β-amino α-hydroxy esters which are highly attractive compounds in organic chemistry,[8] *e.g.* the side chain in taxol.

In summary, the first catalytic enantioselective addition reaction of α-keto esters with nitromethane has been developed. This approach shows for the first time that ketones undergo catalytic highly enantioselective Henry reactions giving attractive optically active β-nitro α-hydroxy esters having a chiral quaternary carbon center. Further work is in progress to develop, understand and apply this new type of catalytic enantioselective Henry reaction.

Unexpected solute aggregation in water on dilution

Shashadhar Samal and Kurt E. Geckeler*

Laboratory of Applied Macromolecular Chemistry, Department of Materials Science and Engineering, Kwangju Institute of Science and Technology, 1 Oryong-dong, Buk-gu, Kwangju 500-712, South Korea. E-mail: keg@kjist.ac.kr

Received (in Cambridge, UK) 20th June 2001, Accepted 7th September 2001
First published as an Advance Article on the web 15th October 2001

Studies on cluster–cluster aggregation phenomena in aqueous solutions of fullerene–cyclodextrin conjugates, β-cyclodextrin, sodium chloride, sodium guanosine monophosphate, and a DNA oligonucleotide revealed that there are larger aggregates existent in dilute aqueous solutions than in more concentrated solutions.

There has been recent interest in cluster studies in a variety of compounds in solutions including those of functionalized fullerenes in water. C_{60} functionalized with hydrophilic groups and C_{60} inclusion complexes with γ-cyclodextrin in aqueous solution are known to form clusters and aggregates.[1,2] Molecular dynamics simulations[3] followed by experiments[4] proved the existence of submicrometer-sized clusters in electrolyte solutions. Cluster studies on polyelectrolytes,[5] amphiphilic heteropolymers,[6] and other polymers[7] have been reported. While studying the particle size of water-soluble fullerene–cyclodextrin conjugates by using laser light scattering (LLS) and scanning electron microscopic (SEM) measurements, we observed that the cluster size increased steadily with decreasing concentration of the fullerene compound, in contrast to pristine fullerenes in organic solvents.[8] Interestingly, aqueous solutions of unmodified β-cyclodextrin (CD) showed a similar behavior on dilution. Then we measured the cluster size of sodium chloride, guanosine monophosphate disodium salt (GMP), and a DNA oligonucleotide in water at different concentrations. Surprisingly, we found an inverse relationship between the aggregate size and concentration confirmed for all these solutes. This finding could be of general importance with profound implications on the universal understanding of diverse phenomena involving dilution and dilute solutions.

Recently we reported a new class of water-soluble fullerene–cyclodextrins.[9] Aqueous solutions of these fullerene derivatives have characteristic UV-Vis spectra with a broad peak in the visible region starting from ~400 nm, which was attributed to aggregation of fullerenes in water, as reported for other water-soluble fullerene derivatives.[10] While exploring further the aggregation phenomena in aqueous solutions of fullerene–cyclodextrin conjugates by LLS measurements, we observed clusters, as expected. When the particle size of these clusters was measured† in solution by LLS, after each successive dilution a steady increase in size was noticed. The results for one of the fullerene derivatives, the mono-6-aza-6-deoxy-β-cyclodextrin–[60]fullerene (C_{60} covalently bonded to β-cyclodextrin *via* a bridging nitrogen atom, CDAzF) are presented in Fig. 1. The average particle size (Z_{av} values) increased from 0.55 to 3.255 μm with decreasing concentration of the solution from 0.216 to 0.01 mM, respectively. At the highest concentration of 0.216 mM, the polydispersity was 0.086, which increased to 0.425 when the solution was diluted to 0.043 mM. For all other concentrations, the polydispersity was 1.000. The cause of this unexpected growth of the cluster size on dilution was quite intriguing, and we decided to look into it further.

The LLS studies were conducted for CD solutions of concentrations 14.27 to 0.3524 mM, prepared by dissolving appropriate quantities of the CD solid in water. Interestingly, clusters were found for each solution, their size increasing from 0.393 to 3.12 μm with decreasing solute concentration. Two of these solutions of initial concentrations 14.2 and 7.2 mM were diluted successively with water and the particle size at each dilution measured. For both the solutions the average particle size increased, from 0.393 to 0.915 μm and 0.518 to 1.285 μm, respectively. It could also be seen that the concentration *vs.* particle size curves did not merge into one line and the extent of particle size increase was higher for CD solutions of lower starting concentration than for solutions of higher initial concentration, indicating that the solution history is an important factor in the growth dynamics of the aggregates. Thus, in the aggregation process of the cyclodextrin-appended fullerene derivative, in addition to fullerenes, the macrocyclic ring also plays a vital role.

To determine if this is a phenomenon quite specific for these typical water-soluble fullerene derivatives and cyclodextrins, or a more broad-based one, the effect of dilution on the particle size of some other water-soluble compounds such as NaCl, GMP, and a DNA oligonucleotide was studied. The reason for the above choice of molecules emerged from recent experimental reports of clusters in aqueous medium of a variety of compound classes.[4]

The Z_{av} data at different concentrations for NaCl and DNA are given in Fig. 2. The concentrated aqueous solution of 5.5 M NaCl was diluted with water in successive steps to 0.785 M. The aggregate size was seen to rise from 1.491 to 4.95 μm. The dilution of a 0.2 M GMP solution in water showed a similar rise of aggregate size from 0.193 to 3.506 μm. For aqueous solutions of a DNA oligonucleotide (M_n 9.745, M_w 13.205 kg mol^{-1}; polydispersity 1.335) with an initial concentration of 2.5 g dL^{-1} the average particle size increased from 0.196 to 0.512 μm on dilution. The size did not increase significantly until a concentration of about 0.45 g dL^{-1}, beyond which further dilution led to a rapid growth of the aggregates.

Though the clusters were detected in solution, it would be more conclusive to have visual evidence. Therefore we examined the SEM scans (JEOL, JSM-5800) of Au-coated CD films cast from diluted solutions. However, no spherical particles could be identified. This was expected, as drying of the solutions would result in CD molecules settling down to their

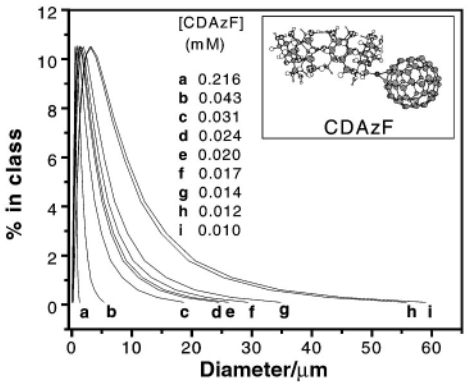

Fig. 1 Dynamic light scattering monomodal distribution plot showing increasing particle size with decreasing mono-6-aza-6-deoxy-β-cyclodextrin–[60]fullerene (CDAzF) concentration.

 DOI: 10.1039/b105399j

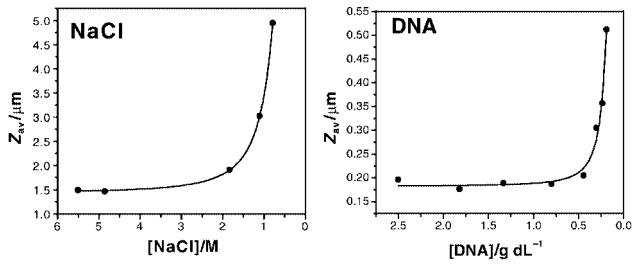

Fig. 2 Increasing Z_{av} values with decreasing concentration for different compound classes.

well identified crystal lattice. We made a comparison of the X-ray powder diffraction patterns of CD, C_{60}, and CDAzF. While both C_{60} and CD had a large number of reflections of strong intensity, the macrofullerene CDAzF was identified as highly amorphous with practically no peaks. Therefore, it was possible that its solutions cast as films might show the clusters. Solutions of the compound CDAzF at the same concentrations as for the LLS studies were cast on clean glass substrates and dried at 60 °C for 12 h under vacuum. The SEM scans clearly showed the clusters and their aggregates (Fig. 3). In the concentrated solution (0.216 mM), the shapes of the particles were irregular. However, on dilution, spherical clusters appeared, which were seen to aggregate in steps resulting in a size increase with decreasing concentration. Similarly, the SEM scans for the DNA film cast from a solution of concentration 1.9 g L^{-1} and dried at room temperature under vacuum clearly showed macroclusters (~0.5–1 μm), consisting of several spherical clusters. Above this concentration, clusters were present, but no cluster–cluster aggregation could be identified. By expecting clusters and their aggregates in the SEM scans, it was implicitly assumed that these aggregates are intrinsically stable in the drying process, *i.e*., that the SEM pictures reflect the 'original' situation. This assumption is not without ground, as very stable clusters have been reported recently,[7b] which, once formed could not be destroyed later by dissolution in water or an aqueous 0.2 M HCl solution at room temperature or by heating under vacuum at high temperature (160 °C).[11]

It appears that there is an equilibrium in the solution between clusters and aggregates of clusters, which is dynamic and dependent on various factors such as concentration, solution history, time, temperature, *etc*. That the steady increase in cluster size was primarily a concentration-related phenomenon, not time-dependent, was ascertained when we measured the cluster size of these compounds in aqueous solutions over three days. The increase in size with time was very small compared to the large and almost instantaneous increase in size on dilution.

Why are clusters formed in solution at all let alone their subsequent aggregation? There are several reports of possible mechanisms of cluster formation. To cite an example, from molecular dynamics simulations it was found that non-neutral ion pairs in a solution of NaCl are stabilized by at least one counter ion, forming large ionic clusters that include the hydration molecules.[3] In spite of several theoretical explanations, the exact nature of the interactions involved in cluster formation is not clearly known.[4] It could be attributed, depending on the nature of the species involved (both solute and solvent), to electrostatic, hydrophilic, or hydrophobic interactions. Aggregation of clusters, leading to formation of macroclusters, could be governed by similar interactions to those responsible for the formation of the clusters. The well-known Stokes–Einstein equation, $D = kT\,(6\pi\eta r_s)^{-1}$, (where k is the Boltzmann constant, D is diffusivity, and r_s, is the radius of particles in a solution of dynamic viscosity η at temperature T) provides the basic relationship that determines the diffusivity of particles. Dilutions leading to decreases in viscosity would apparently increase diffusivity of particles, facilitating the interaction among the clusters leading to cluster–cluster aggregation. On the other hand, this aggregation means an increase in the radius of the particle and consequent decrease in diffusivity. Obviously, the situation is more complex than can be visualized from a simple interpretation of the above equation, and apparently the unusual observation could have a bearing on the dynamics of the process involving clusters and aggregates of clusters. Future experimental and theoretical work would offer suitable explanations for the underlying mechanism.

The authors express their gratitude to the Korean Federation of Science and Technology and the Ministry of Education for 'brain pool' and 'BK21' projects that provided funding to carry out this work.

Notes and references

† Solutions of the compounds in high purity water (HPLC grade) were filtered using a 0.8 μm syringe filter, and the particle dimensions in solution were measured directly using quasi-elastic light scattering. Measurements (repeated three times) were done on a Malvern instrument (4700C, England), equipped with an Ar^+ laser operating at 700 mW power and 477 nm wavelength, and a computer-controlled correlator, at a 90° accumulation angle. The solutions were thermostatted to 30.0 ± 0.1 °C before each measurement in disposable polystyrene cuvettes. The data were processed using S4700 version PCS v1.26 software, which gives directly the particle size distribution, average particle size, and polydispersity.

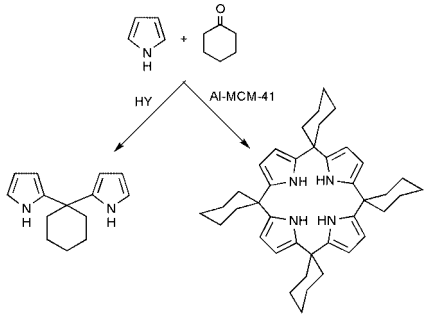
Porosity and acidity of molecular sieve Al-MCM-41 (*ca.* 30 Å pore diameter) plays a crucial role in the synthesis of novel calix(4)pyrroles; for the first time, Al-MCM-41 has been used as a solid acid catalyst to produce a number of calix(4)pyrroles with good selectivity and yields where zeolite HY (*ca.* 7.6 Å pore diameter) yields mainly the linear chain dimer and no cyclic products.

Calix(4)pyrroles, which are analogous to calix(4)arenes have gained much attention because of their properties as binders of anionic species, transition metals and neutral substrates.[1–4] Selective synthesis of these calix(4)pyrroles **1**, in high yields by an environmentally clean process is of topical interest, so as to meet the increasing demand of reducing the pollution hazards caused by the usage of homogeneous acid catalysts,[5] which require acid neutralization and tedious work-up procedures. This prompted us to study the macrocyclization reactions for the first time over zeolites,[6] as there are no reports wherein they have been used as catalysts. However, owing to their smaller pore size, they were of limited use in the synthesis of macrocycles. Nevertheless, this objective could be achieved by employing uni-dimensional molecular sieves, Al-MCM-41.[7] Here, we report for the first time the selective synthesis of various novel calix(4)pyrroles over a mesoporous Al-MCM-41 catalyst in an eco-friendly procedure.

An equimolar ratio of pyrrole and ketone was refluxed in dichloromethane over Al-MCM-41§ (Table 1). When cyclohexanone condensed with pyrrole, tetraspirocyclohexyl calix(4)pyrrole **1a**, was obtained with high yield and selectivity. Along with **1a**, the acyclic oligomers, linear dimer, trimer and tetramer (**1b**, **1c** and **1d**) were also observed. The higher reactivity and selectivity of **1a** (*ca.* 14.20 Å)[8] in Al-MCM-41 is attributed to the large pore size (*ca.* 30 Å) and high surface area (980 $m^2\ g^{-1}$). In line with this, a very low yield and selectivity were observed in HY, HZSM-5(30) and SAPO-5 zeolites as they have smaller pore sizes than the product **1a**, *viz.* 7.5, 5.6 and 7.3 Å, respectively (Scheme 1).

In the case of HY zeolite, **1b** is the major product while some amounts of **1c** and **1d** are also observed (Table 1). However, no amount of cyclic **1a** was observed. In the case of HZSM-5(30), again **1b** was the major product along with a minor component of **1a** and negligible amounts of **1c** and **1d**. It is believed that **1a** is formed due to a surface reaction. In fact, this was confirmed by surface poisoning carried out in the form of silylation with tetraethyl orthosilicate (TEOS) following the chemical vapour



Scheme 1 Shape-selective synthesis of tetraspirocyclohexyl calix(4)pyrrole over MCM-41 and HY catalysts.

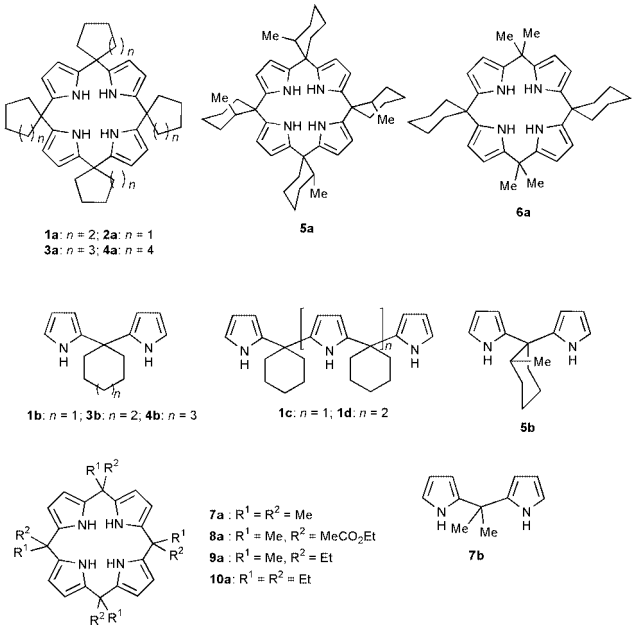
Table 1 Reaction conditions and percentage of yield of various calix(4)pyrroles over MCM-41 catalysts

Catalyst	Ketone	Time/h	Conversion of pyrrole (%)	Products yield (wt%)		
				Cyclic tetramer	Linear dimer	Others[a]
Al-MCM-41	Cyclohexanone	10	95.0	70.3 (**1a**)	12.3 (**1b**)	12.4
HY	Cyclohexanone	10	87.9	—	62.7 (**1b**)	16.2
HZSM-5(30)	Cyclohexanone	10	69.6	10.7 (**1a**)	53.0 (**1b**)	5.9
HZSM-5(30)[b]	Cyclohexanone	10	82.3	—	61.2 (**1b**)	21.1
SAPO-5	Cyclohexanone	10	16.0	—	11.6 (**1b**)	4.4
Al-MCM-41[c]	Cyclohexanone	10	93.0	64.7	7.5	20.8
Al-MCM-41	Cyclopentanone	20	74.3	62.7 (**2a**)	4.3 (**2b**)	7.3
Al-MCM-41	Cycloheptanone	72	69.8	26.7 (**3a**)	27.4 (**3b**)	15.7
Al-MCM-41	Cyclooctanone	120	78.0	8.3 (**4a**)	46.0 (**4b**)	23.7
Al-MCM-41	2-Methyl cyclohexanone	10	60.2	5.1 (**5a**)	33.8 (**5b**)	21.3
Al-MCM-41	Acetone	10	95.0	70.3 (**7a**)	12.3 (**7b**)	12.4
Al-MCM-41	Cyclohexanone + Acetone	10	92.7	8.0 (**6a**) 21.9 (**1a**) 3.1 (**7a**)	40.6 (**6b**) 12.2 (**7b**)	6.9
Al-MCM-41	Ethyl acetoacetate	72	—	Trace (**8a**)	—	—

Standard reaction conditions include pyrrole : ketone (1 : 1 mole ratio) in dichloromethane solvent (20 ml). [a] Includes linear trimer and tetramer. [b] Catalyst surface was poisoned by chemical vapour deposition with tetraethyl orthosilicate (TEOS). [c] Al-MCM-41 external surface was passivated using Ph_2SiCl_2

 DOI: 10.1039/b105690p

deposition method. However, in order to show that the macrocyclization is actually taking place inside the large pores of Al-MCM-41, the external surface of the mesoporous framework was treated with Ph_2SiCl_2 under non-diffusive conditions.[9] Yields of the cyclized product were comparable to those of the unpassivated Al-MCM-41. It is also interesting to note that SAPO-5, a mild acidic catalyst having a similar pore size as that of HY produced a lower conversion, indicating that the stronger acidic medium facilitates the condensation reaction. Other experiments involving Si/Al catalysts also resulted in low yields as well as selectivity for **1a**.



The selective syntheses of calixpyrroles over various molecular sieves were also studied by molecular simulations and the results are exactly comparable. The sorption studies[10] involving HY zeolite indicate very high loading for only **1b** (Table S1) indicating relatively free translation and rotational motion along the channels of HY. In fact, higher oligomers were not loaded during the entire length of the simulation. As expected, cyclic **1a** could not be formed even inside the supercage as its molecular size is larger than the reaction cavity size. For Al-MCM-41, when **1a**, **1b**, **1c** and **1d** are considered as sorbents along with the reactants pyrrole and cyclohexanone, the two reactants constitute a major portion of the total sorbents and decreasing concentrations of **1b**, **1c**, **1d** and **1a** were observed. This is significant given that the average energy of **1a** is much lower than the other oligomers. The stabilization energy of **1a** is consistently lower than all other products and this stabilization energy is equal to that of the single sorbent **1a** simulation run. In the presence of other oligomers and reactants, *i.e.* in the initial stages of the reaction, a maximum amount of **1b** is formed. However, subsequent reactions produce linear trimer and tetramers. These readily condense with another cyclohexanone to form highly stabilized cyclic **1a**.

The synthesis of substituted calix(4)pyrroles was also attempted by condensation of various cyclic ketones with pyrrole over Al-MCM-41 and the results are shown in Table 1. Higher and lower cylic ketones were used in the reaction with pyrrole on Al-MCM-41 in dichloromethane solvent. With cyclopentanone, tetraspirocyclopentyl calix(4)pyrrole **2a** was produced. When the ring size is increased further, the reactivity and selectivity decrease. The increased ring size could have some severe electronic and/or steric effects on the reactivity. However, when cycloheptanone and cyclooctanone were used, initially, dimers **3b** and **4b** were formed even after 10 h. When the reaction was continued for over 3 and 5 days, the respective cyclic tetramers tetraspirocycloheptyl calix(4)pyrrole **3a** and tetraspirocyclooctyl calix(4)pyrrole **4a** were formed and when 2-methyl cyclohexannone was used, tetraspiro(2-methylcyclohexyl) calix(4)pyrrole **5a** was obtained. Incidentally, this is the first report on the formation of a number of macrocyclic compounds such as **3a**, **4a**, **5a** and **7a**. All the cyclic and acyclic oligomers were fully characterized by MS, HR-MS, ^{1}H and ^{13}C NMR spectroscopy.

In the case of acetone, octamethyl calix(4)pyrrole **7a** was produced in higher yields.[11] Increasing the chain length of the ketones on either or both sides, *i.e.* by taking methyl ethyl ketone and pentan-3-one, tetramethyltetraethyl calix(4)pyrrole **9a** and octaethyl calix(4)pyrrole **10a** are observed after 3 and 5 days respectively. This could also be due to the same factors as observed in cylic ketones of higher ring size.

A type of structural mimicry was attempted when pyrrole was refluxed in dichloromethane with a 1 : 1 mixture of cyclohexanone and acetone. A minor component, cyclic tetramethyl dicyclohexyl calix(4)pyrrole **6a**, consisting of two acetone and cyclohexanone units alternately, was formed along with major **1a** and minor **7a** products. Similarly, when a β-keto ester, ethylacetoacetate was used only traces of functionalized calixpyrrole **8a**, which was confirmed by HR-MS, were formed.

The regenerability and reusability studies of the catalyst have shown that constant yields and selectivities can be obtained even after as many as 5–6 cycles. The powder X-ray diffraction patterns are very similar before and after the reaction, indicating the robustness of the catalyst. The present investigations can be extended in terms of varying the pore size and acidity in order to optimize the yield and selectivity of calix($n \geqslant 4$)pyrroles of definite size and shape. Further work along these lines is in progress.

In conclusion, a versatile, novel, shape selective, eco-friendly and simple protocol for the preparation of calix(4)pyrroles and novel calix(4)pyrroles has been achieved using mesoporous molecular sieves as catalysts.

M. R. K. is thankful to CSIR, India, for a Senior Research Fellowship.

§ *General procedure for the condensation reaction*: equimolar (1 : 1) amounts of pyrrole (7.2 mmol) and ketone were dissolved in 20 ml dichloromethane taken in a 100 ml round bottomed flask. To this, 0.5 g of the calcined and dried catalyst was added and the reaction mixture was allowed to reflux for 10 h/days depending on the reaction. After the reaction the catalyst was separated by filtration and washed thoroughly with 100 ml dichloromethane (20 × 5). The solvent was then removed under reduced pressure to give a viscous residue. Products were separated by column chromatography using silica (100-200 mesh size) with *n*-hexane as eluent. Quantification was done using the CAMAG HPTLC system and compared with isolated yields.

Received (in Cambridge, UK) 19th June 2001, Accepted 13th September 2001
First published as an Advance Article on the web 15th October 2001

Ti-containing polysiloxane epoxidation catalysts have been prepared by controlled hydrolysis of titanium- and alkylsilane precursors. These polysiloxanes exhibit very high yields to epoxides in the epoxidation reaction of primary alkenes with organic hydroperoxides.

Epoxides, particularly propylene oxide, are a class of commodity chemicals of enormous importance in the chemical industry. The oxidation of alkenes to the corresponding epoxide in liquid phase with organic hydroperoxides in the presence of a catalyst is well known. Generally, hydrocarbon-soluble organometallic compounds of transition metals can be employed as the homogeneous catalyst. Examples are vanadium or molybdenum compounds.[1] Other alternatives include the use of heterogeneous catalysts such as a chemical combination of titania–silica,[2] titanium incorporated in a zeolite framework (*i.e.* Tiβ)[3] or into the framework or grafted mesoporous silicas.[4] Although homogeneous titanium-containing epoxidation catalysts are known,[5] the selectivity to the alkene oxide obtained with such catalysts is significantly lower than those obtained with the above heterogeneous catalysts, some improvements having been found with polyorganometallosiloxane synthesized in a neutral solvent such as toluene. However, selectivity and conversion are still lower than with heterogeneous catalysts[6] and, despite more recent attempts with titano–silsesquioxanes,[7] these compounds continue to be tedious, expensive and time-consuming to prepare.

It is by now widely accepted that the active site for epoxidation in titanium-containing materials is of tetrahedral nature. This makes it very important to have a method for preparing the catalysts that will avoid the formation of titanium in octahedral coordination. In this report, we describe a new method for the synthesis of a homogeneous catalyst for the epoxidation of alkenes with a high yield of hydroperoxide to epoxide.

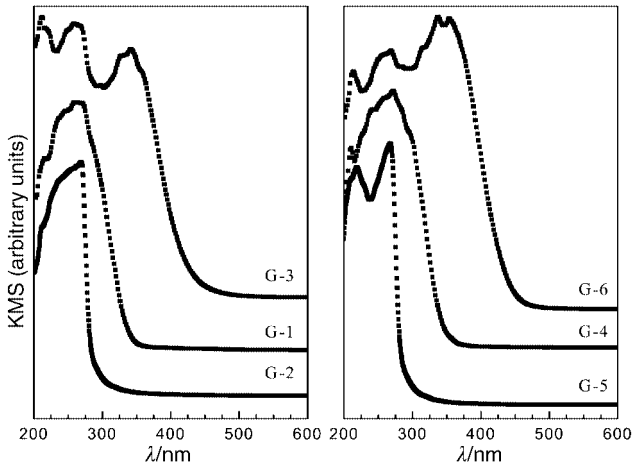

Fig. 1 Diffuse reflectance spectra (Kubelka–Munk–Schuster function) of the catalysts recorded with a Shimadzu UV-2100 spectrometer without pretreatment.

The catalysts were prepared in the following manner: 1.25 mmol of titanium(IV) precursor (titanium isopropoxide or titanium tetrachloride) was added to 100 ml of solvent (toluene or THF) under a nitrogen atmosphere and the solution was stirred for 15 min at rt. Then, 50 mmol of silicon precursor was added. Following this, 6 ml of water was added dropwise for 2 h and a clear solution was obtained, when a halogenated precursor was employed, 80 mmol of sodium carbonate was added to neutralize the HCl byproduct and excess Na_2CO_3 was removed by centrifugation at 6000 rpm for 20 min. The solvent was removed at 363 K under reduced pressure. For comparative purposes a polysiloxane was prepared without the addition of a titanium precursor in toluene (called B). Samples were also prepared in the presence of Hacac, which was added together with a titanium precursor. The Ti-loading of the catalysts was close to 1 wt % determinated by ICP-AES. The IR spectra of these titanopolysiloxanes showed bands characteristic of the aromatic ring as well as that of the Si–O bond. A clear band located at 920 cm^{-1}, associated with Ti–O–Si[8] linkages could also be discerned. A broad band was observed between 3700–3200 cm^{-1} with a shoulder at 3625 cm^{-1}, suggesting the

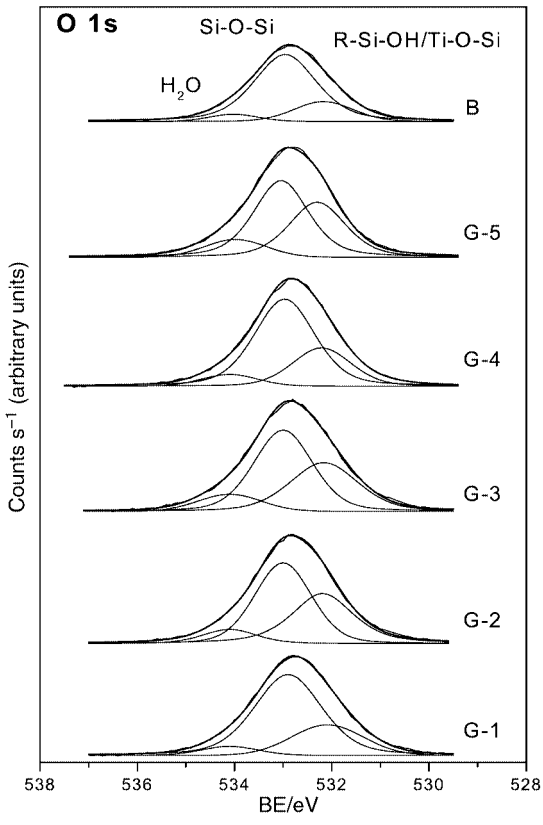

Fig. 2 O 1s core-level spectra of outgassed samples at rt acquired with a VG Escalab 200R spectrometer. The binding energies (BE) were referenced to the C 1s peak at 284.9 eV.

G-5	$Ti(iPro)_4$[b]	PhSiMet[d]	THF	0.8	90	100	95
G-6[a]	$Ti(iPro)_4$[b]	PhSiMet[d]	Toluene	1.1	60	100	91

[a] Hacac was added during the synthesis. [b] $Ti(iPro)_4$: titanium isopropoxide. [c] PhSiCl: phenyltrichlorosilane. [d] PhSiMet: phenyltrimethoxysilane. [e] Based on the EBHP consumed.

presence of phenyl-bonded silanol.[9] Catalysts G-3 and G-6 exhibited additional weak bands in the region from 1600 to 1200 cm^{-1} due to the presence of Hacac, which remains strongly adsorbed on the Ti(IV) sites[10] even after the titanopolysiloxane has been formed.

The electronic spectra (Fig. 1) of samples G-1, G-2, G-4 and G-5 showed a band centred around 250 nm, typical of Ti(IV) located in a slightly distorted tetrahedral environment,[11] although the catalysts prepared without the coordinating agent (G-1 and G-4) displayed a weak shift to higher wavelengths. This was attributed to the formation of polymeric titanium species. Despite this, the electronic spectra of samples G-3 and G-6 proved to be different, showing an additional band at about 400 nm characteristic of Ti(IV) in an octahedral environment.[11] The origin of the octahedral coordination lies in the fact that Hacac binds to Ti(IV) sites, as already confirmed by IR spectroscopy.

The photoelectron spectra of the Ti 2p core-level showed a single component for the most intense Ti $2p_{3/2}$ peak at a binding energy of 460.1 eV, corresponding—in accordance with the electronic spectra—to Ti(IV) sites in tetrahedral coordination.[12] No octahedrally coordinated Ti(IV) species (binding energy of Ti $2p_{3/2}$ peak at around 459 eV[11]) were observed in samples G-3 and G-6. A tentative explanation for this is that under the ultrahigh vacuum conditions required to pretreat the samples prior to recording the photoelectron spectra, the Hacac ligands of samples G-3 and G-6 bound to the Ti(IV) site could be lost, thus changing the original coordination $Ti(IV)_{oct} \rightarrow Ti(IV)_{tet}$. However, significant differences were observed in the O 1s line profiles (Fig. 2). This peak could be resolved into three components: the first at 534.1 eV, typical of oxygen in molecular water (H–O–H); a second at 533.0 eV, assigned to oxygen in Si–O–Si bonds, and a third at 532.3 eV, which could be ascribed to oxygen in terminal groups of the R–Si–O–H phenyl-bonded or even Si-O-Ti type.[13] The latter component (532.3 eV) increases with the increase in Ti content (sample B *vs*. sample G-1), and even more so in the catalysts prepared in the presence of THF or Hacac. The intensity of the component with a binding energy of 532.3 eV is higher than expected for the formation of Ti–O–Si bonds exclusively. This effect suggests that titanium incorporation into polysiloxane, with the corresponding Ti–O–Si bond formation, modifies the structure of polysiloxane, more OH groups being developed within the polymer.[9] This is in agreement with the electronic spectra of the titanopolysiloxane samples G-1 and G-5, in which polymeric titanium species (Ti–O–Ti–O–) were observed, with a subsequent decrease in the formation of Ti–O–Si bonds.

In a typical epoxidation run, 45 g of oct-1-ene and 33 g of a solution of 33 wt% of ethylbenzene hydroperoxide (EBHP) in ethylbenzene were heated to the reaction temperature (393 K), after which 0.30 g of catalyst was added, and was immediately completely dissolved. The organic compounds were analyzed on GC-FID equipment. Ethylbenzene hydroperoxide concentrations were measured by standard iodometric titration. All the catalysts afforded high conversions of ethylbenzene hydroperoxide (in most cases above 95%) (Table 1). However, the compounds prepared from halogenated precursors exhibited conversion levels of EBHP that were even higher than with the alkoxide precursors (G-1 *vs*. G-4). The presence of compounds that can coordinate with titanium during the preparation of titanopolysiloxanes elicited an enhancement in the selectivity to the epoxide (G-1 *vs*. G-2 and G-3, and G-4 *vs*. G-5 and G-6, respectively). In the catalysts prepared in the presence of THF or Hacac, titanium remained as isolated units in tetrahedral coordination to oxygen, as already confirmed by the UV-visible and photoelectron spectra, while those prepared in the absence of these compounds (G-1 and G-4) exhibited polymeric titanium species. The behavior of catalysts prepared with THF or Hacac was different. Thus, the values of EBHP conversion and selectivity to epoxide were found to be very high for the catalysts prepared in the presence of ether (G-2 and G-5) and somewhat lower for those prepared in the presence of Hacac (G-3 and G-6), possibly because the Hacac molecule, still present in the coordination sphere of Ti(IV)as confirmed by FTIR and DRS UV-Vis spectra, hinders the adsorption of reactants (hydroperoxide and alkene) on the active site and hence the reaction rate decreases. It is remarkable that the G-2 catalyst exhibited almost quantitative conversion of EBHP to epoxide.

First published as an Advance Article on the web 15th October 2001

Electrochemical evidence of H· produced by cavitation as the result of ultrasonic irradiation of an aqueous solution is presented.

The production of radical species[1] through the generation of high temperatures and pressure created in the interior of a collapsing cavitation bubble is one of the fundamental pieces of evidence for the phenomena classed as sonochemistry. These high temperature and pressures (estimated† to be around 5000 K and 500 atm)[2,3] are thought to break down the solvent matrix according to reaction (1).

$$H_2O \rightarrow OH\cdot + H\cdot \quad (1)$$

The radical species generated, which have been detected in a number of ways including spin trapping experiments performed by Riesz and coworkers,[1,4] have been suggested as possible pollutant destruction agents owing to their extremely high redox potential (*e.g.* OH· radicals,[5] E° = +2.8 V). However, less evidence is available for the use and detection of H· even though in principle it is generated in equivalent quantities when compared to OH· in the primary solvent degradation step [see reaction (1)]. The chemical nature of these two radical species is quite different.[6–9] As an example, the OH· radical species is known to initiate a number of different reactions within solution[10–12] while in contrast the H· atom can be rapidly consumed directly by molecular oxygen.[13] Indeed less attention has been placed on H· perhaps due to these quenching reactions.

Electrochemical evidence for the production of radical species is limited. Compton and coworkers provided evidence for OH· through a *sono*-EC' reaction involving the electrochemical generation of a radical species (from the electroreduction of fluorescein) which in turn was re-oxidised by OH· produced by ultrasound.[14] However, to the knowledge of the authors, no direct electrochemical evidence for H· appears in the literature. We present here for the first time an electrochemical method for the detection of H· produced by cavitation as the result of ultrasonic irradiation of an aqueous electrolyte solution.

Hart and Heinglein showed that it was possible to detect H· production[15] [measuring $HO_2\cdot$, see reaction (4)] using a system containing Cu^{2+}. In the electrochemical system reported here, a Cu^{2+} solution is also employed. Reaction (2) is thought to be the main process occurring as the H· diffuses into the liquid phase of the mixture employed. The rate constant for the above reaction was determined to be 9.1×10^7 dm^3 mol^{-1} s^{-1}.[16] There are several competing reactions.[3–7] Cu^+ can also be produced by reaction (4). However, the production of $HO_2\cdot$ can also be attributed to H· generation [see reaction (3)]. $HO_2\cdot$ can be generated from both products of reaction (1). However, in the absence of a scavenger for OH·, reaction (6) dominates and the geminate recombination product is preferentially formed.[16] In addition reaction (5) requires the presence of significant H_2O_2 concentrations and if this reaction was very important a non-linear response in Fig. 1 would be expected. Also $HO_2\cdot$ can be consumed by reaction (7). Under these considerations it is expected that the dominant reaction pathway leading to the formation of Cu^+ will involve the generation of H·.

$$Cu^{2+} + H\cdot \rightarrow Cu^+ + H^+ \quad (2)$$

$$H\cdot + O_2 \rightarrow HO_2\cdot \quad (3)$$

$$Cu^{2+} + HO_2\cdot \rightarrow Cu^+ + H^+ + O_2 \quad (4)$$

$$OH\cdot + H_2O_2 \rightarrow HO_2\cdot + H_2O \quad (5)$$

$$OH\cdot + OH\cdot \rightarrow H_2O_2 \quad (6)$$

$$HO_2\cdot + HO_2\cdot \rightarrow H_2O_2 + O_2 \quad (7)$$

In order to stabilise the Cu^+ species a solution containing a high Cl^- concentration was employed. The complex that forms ($CuCl_2^-$) is stable and can be electrochemically detected as shown in reaction (8) ($Cu^{2+}/CuCl_2^-$, $E_{1/2}$ = +231 mV *vs.* SCE as measured under similar conditions).

$$CuCl_2^- \rightarrow Cu^{2+} + 2Cl^- + e^- \quad (8)$$

In order to detect the generated product ($CuCl_2^-$) a pump was used to remove small quantities of liquid from the reactor and then pass this solution through a flow cell where electrochemical detection of the products could be achieved. This method has a number of advantages when compared to employing electrochemical detection of sonochemically generated products directly within the reactor. First, the mass transfer characteristics of the flow cell can be well characterised. Second, employing electrochemistry within an ultrasonic reactor, although producing efficient mass transfer close to the cavitation phenomena, leads to non-steady state mass transfer characteristics (particularly for microelectrodes) or mass transfer characteristics that require careful calibration. These two problems are avoided by employment of a flow cell.

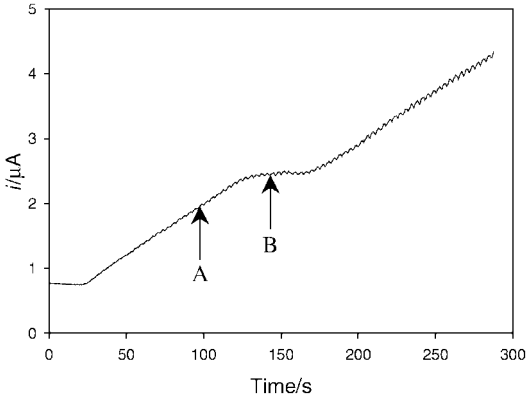

Fig. 1 Plot showing the current as a function of time for the electrochemical detection of Cu^+ produced by H· capture. The solution contained 10 mmol dm^{-3} $CuSO_4$ in 1.5 mol dm^{-3} NaCl. The experiment was performed under aerobic conditions at 25 °C. The electrode (0.071 cm^2) was held at +1 V *vs.* SCE. The solution in the reactor was exposed to 125 kHz ultrasound. The applied drive voltage amplitude was 100 V (corresponding to a measured pressure amplitude of 421 kPa).‡ Ultrasonic irradiation of the liquid was initiated at time t = 0 s, terminated at 'A' and re-started at 'B'.

 DOI: 10.1039/b107617p

A 3 mm diameter glassy carbon electrode was held at +1 V *vs.* SCE§ (a potential sufficient to oxidise any $CuCl_2^-$ produced by the reaction of $H^\cdot$ with Cu^{2+} present within the solution). Fig. 1 shows the current time response for the glassy carbon electrode employed within the flow cell. The solution contained Cu^{2+} in a high [Cl^-] media. Ultrasonic irradiation of the solution was initiated at time $t = 0$. A *ca.* 25 s lag time was observed before any $CuCl_2^-$ was detected at the electrode. This corresponds to the time taken for the solution to pass through the piping to the flow cell. The current at $t = 25$ s is seen to deviate anodically from its initial steady state condition. This is due to the electrochemical oxidation of the $CuCl_2^-$ produced by the radical trap reaction. The gradient of the current time plot at this point is constant indicating a steady production of $CuCl_2^-$ and therefore $H^\cdot$ within the ultrasonic reactor. If the ultrasonic irradiation of the solution was terminated (at time $t = 100$ s) then, after the lag time produced by the piping, the current time trace was observed to plateau out. This indicates that in the absence of ultrasonic irradiation of the solution, no significant background reactions could be observed. If the ultrasonic irradiation of the solution was repeated (time $t = 145$ s) then the current was observed to deviate anodically, indicating that it was possible to produce further quantities of $CuCl_2^-$ and hence $H^\cdot$ within the ultrasonic reactor. The gradients of the two current–time anodic deviations were the same indicating that the rate of Cu^+ production was identical in both cases. It is possible to determine the rate of $CuCl_2^-$ production from the slope of these current time transients.[17] In the example shown in Fig. 1 the rate of $CuCl_2^-$ production was 320 nmol dm^{-3} s^{-1}. This procedure can be repeated under a variety of different conditions. Fig. 2 shows how the rate of $CuCl_2^-$ production can vary as a function of $CuSO_4$ concentration. Below *ca.* 20 mmol dm^{-3} $CuSO_4$ it is apparent that the rate of production of $CuCl_2^-$ is dependent on the concentration of Cu^{2+}. Above 20 mmol dm^{-3} the rate of $CuCl_2^-$ production appears to be independent of Cu^{2+} concentration. This is consistent with other measurements (*e.g.* the Fricke reaction, known to be sensitive to $OH^\cdot$ radical production, showed Fe^{3+} productions rates up to *ca.* 250 nmol dm^{-3} s^{-1}) performed on other electrochemical trapping systems.[17]

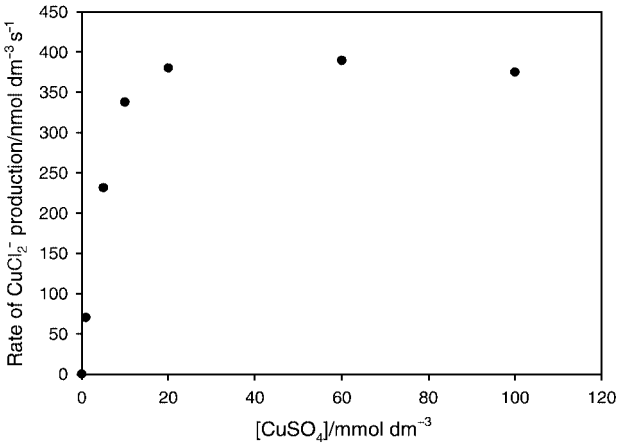

Fig. 2 Plot showing the variation in the rate of $CuCl_2^-$ production as a function of [$CuSO_4$]. The irradiated solution contained 1.5 mol dm^{-3} NaCl. The ionic strength of the solution was maintained at 1.6 mol dm^{-3} using Na_2SO_4. The frequency was fixed at 125 KHz and the drive voltage amplitude was 100 V. The aerobic solution was thermostated at 25 °C.

The results shown here demonstrate that it is possible to detect the sonochemical production of $H^\cdot$ electrochemically using a coupled chemical reaction. The criteria for this detection method are that the products of the trapping reaction are stable over the experimental timescale (as ensured by the presence of high [Cl^-]) and that a product of the trapping reaction is electrochemically active.

The sensitivity of the electrochemical flow system enables very small quantities of sonochemically generated products to be detected. This method enables electrochemically active radical trap generation rates within the nmol dm^{-3} s^{-1} range to be measured. This method can be extended to a number of different products of sonochemical reactions.[17]

Notes and references

† The estimates of the conditions within the interior of a collapsing cavitation bubble are a matter of some debate.[18] The estimation presented by Flint and Suslick relied on the measurement of sonoluminescent emission from silicone oil. The spectra obtained were fitted to a rotation vibration model for a C_2 diatomic molecule.[2] Other authors have assigned differing single value temperatures to the interior of a sonoluminescing bubble.[19,20] However, if the collapse is sufficiently rapid, the pressure and temperature within the bubble will be spatially non-uniform,[21] in which case assignment of a single value temperature is inappropriate.

‡ This pressure was measured with a Bruel & Kjaer 8103 hydrophone placed within the cell. Note that, owing to the modal nature of the sound field the pressure will vary throughout the cell depending on the particular mode excited under the physical conditions within the system.

§ This high potential was employed as it avoided unwanted electrochemical interference presumably from other sonochemical products.

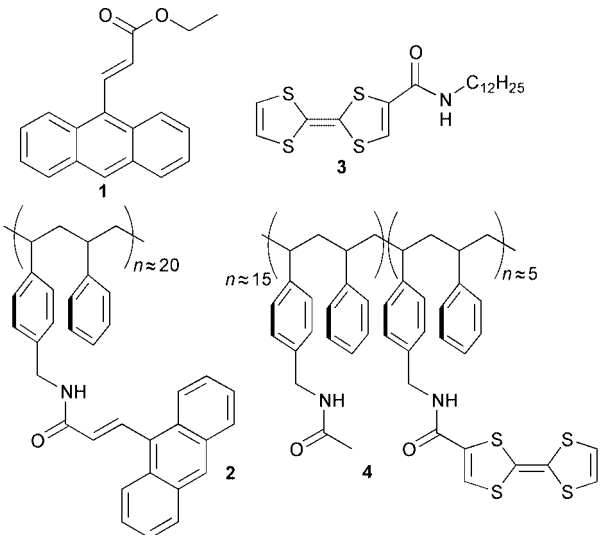
Received (in Columbia, MO, USA) 23rd July 2001, Accepted 5th September 2001
First published as an Advance Article on the web 15th October 2001

Polymer 4 and its monomeric counterpart 3 exhibit electrochemically tuneable interactions with anthracene polymer 2 and a structurally similar monomer 1 as seen by the variation of the oxidation waves of TTF groups and the fluorescence of the anthracene.

The fabrication of nanostructured materials is a promising area for the production of new molecular devices.[1] One of the more appealing approaches for the preparation of assemblies of this size scale has relied upon the use of supramolecular polymer–polymer interactions.[2] The advantages of such assemblies over their molecular brethren stems from the myriad of supramolecular architectures which can be generated through intra- and inter-polymer interactions, which can be fine-tuned by the introduction of suitable functionalities. So far, the polymer–polymer interactions approach has been limited to block copolymers capable of forming nanotubes,[3] templates for nanolithography,[4] mushrooms,[5] or micelles.[6] The development of polymer systems whereby side chain functionality plays a pivotal role is a complementary technique which allows higher aggregates to form *via* interchain interactions. This technique has been used recently for the elaboration of layer by layer surface coatings,[7] polymeric nanoparticles[8] or giant vesicles.[9]

Despite the various examples of the use of polymers for the fabrication of supramolecular assemblies, the introduction of units allowing the reversible formation of new architectures by an external physical stimuli has surprisingly received little attention.[10] Electrochemistry is rapidly emerging as an important tool for supramolecular assembly,[11] and therefore, should provide a versatile and convenient method of reversibly modulating the structure and properties of electro-active macromolecules in solution. Polymers incorporating the tetrathiafulvalene (TTF) moiety are particularly attractive materials for fabricating electrochemically controlled architectures, mainly due to this moieties ability to exist in three stable oxidation states (TTF^0, $TTF^{\cdot+}$ and TTF^{2+})[12] which will allow the formation of π-complexes with electron deficient polymers in its neutral state[13] and electron rich polymers in its electron deficient states.[14]

Here, we describe the tuneable interactions between polystyrene derivatives **2** and **4** bearing anthracene and TTF electroactive groups, respectively, in their side chains, which are capable of reversibly forming polymer aggregates in solution under electrochemical control. Polymer **2** has been shown to exist as a folded structure in chloroform, due to aromatic–aromatic interactions between the side chains.[15] The weak interactions between the electron rich anthracene side chains provide the possibility of forming stronger complexes with electrochemically generated electron-deficient moieties of suitably functionalised polymers, thereby leading to control of inter-polymer interactions in solution. Polymer **4** was targeted as a suitable candidate for the latter, and was synthesised using a similar approach to **2,** by coupling a random 1 : 1 copolymer of styrene and 4-aminomethylstyrene to 4-fluorocarbonyl-TTF.[16] Our attempt to synthesise the fully substituted polymer gave a material which proved insoluble in common organic solvents. When only 25% of the amino sites were functionalised with TTF, the polymer obtained was poorly soluble in dichloromethane (DCM), however, subsequent reaction with an excess of acetic anhydride gave the soluble polymer **4**. Monomeric analogues **1** and **3** were synthesised analogously to **2** and **4** and were used as reference compounds in our study.



The solution electrochemistry of polymer **4** in DCM displays the two expected oxidation waves for the TTF unit at 487 and 866 mV, corresponding to the formation of the radical cationic and dicationic states, respectively. These peaks are shifted to a lower potential than those of **3** (499 and 981 mV, respectively), presumably due to interactions between the TTF units and the polymer backbone.

The solution electrochemistry of **3** and **4** were then investigated in the presence of the electron rich anthracene derivatives **1** and **2** (Table 1). It can be seen that the oxidation of monomer **3** is barely affected by the presence of the anthracene derivative **1**. This result is expected for the two monomers, where strong interactions are entropically unfavourable. However with polymer **2**, the second oxidation potential of

Table 1 Variation in mV of the oxidation waves of the TTF units of **3** and **4** in the presence of anthracene **1** or **2**[a]

	1	**2**
3	−2 and +1	−2 and +10
4	−10 and +24	−26 and +24

[a] Square waves recorded in dry DCM under argon atmosphere; decamethylferocene was used as reference and $NBu^n_4ClO_4$ as electrolyte (0.1 M). The concentrations of **1**, **2**, **3** and **4** were adjusted to obtain an overall concentration of 10^{-4} M in anthracene and TTF.

 DOI: 10.1039/b106588m

3 is shifted to a higher potential. This can be explained by the fact that the electron rich character of the anthracene side-chains promotes the formation of complexes between the electron deficient radical cation of the TTF and the polymer. Further oxidation is therefore more difficult due to an encapsulation of the radical cation by the polymer.

For polymer **4**, however, the variations in solution electrochemistry are more pronounced upon the addition of **1** or **2**. Surprisingly, the first oxidation is made easier by the presence of the anthracene. On the other hand, the dication formation is less favourable. We determined, by GPC, that the TTF substituted polymer **4** exists in solution as a rather extended structure† allowing easy interactions between its side chains and the monomeric anthracene **1**. It is noteworthy that despite the high electron density of both units, there are interactions between them in the neutral state thus lowering the first oxidation potential of the TTF. It is remarkable that this effect is enhanced when both polymers are mixed. Such favourable interactions between two π-rich units on a polymer is probably due to their similar structure and electronic properties. The interactions between the anthracene and the TTF radical cations make the second oxidation harder to achieve, which is in accordance with the data observed for the monomeric TTF **3** and the polymer **2**. However, the complexes between the polymeric species are stronger, as depicted by the greater shift in the second oxidation waves.

The behaviour of the anthracene derivatives **1** and **2** in the presence of the TTF systems were then studied by fluorescence spectroscopy as it was expected that the interactions between the two moieties would quench the emission of the anthracene. The spectra of molecules **1** and **2** were recorded in the presence of an increasing amount of **3** or **4** and their corresponding radical cations which were electrochemically generated prior to their addition to **1** or **2**. A typical result is presented in Fig. 1 for the polymer **2**.

The fluorescence of **1** did not display any change when either **3** or **4** were added supporting the previous observations that very weak, if any, interactions are taking place. On the other hand, it is apparent from Fig. 1 that the fluorescence of the polymer **2** is quenched with an increasing amount of TTF. Moreover, this process is more efficient with the monomeric TTF **3** than the polymer **4**. This is due to the folded structure of **2** which can accommodate the incorporation of monomeric species within its core but must undergo a large reorganisation to interact efficiently with the polymer **4**. Furthermore, this curve could not be fitted to a simple 1:1 binding mode,

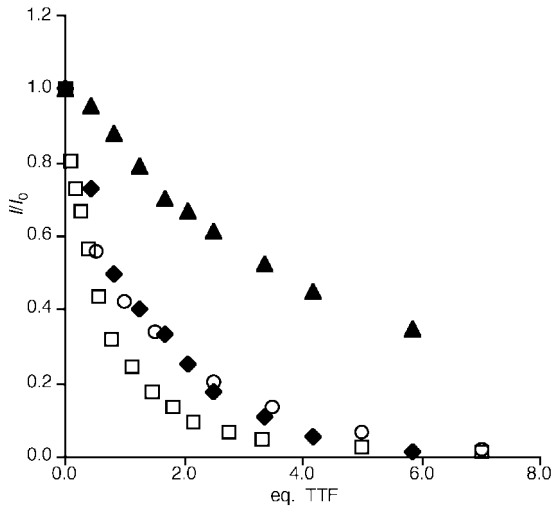


Fig. 1 Variation of the fluorescence of **2** in DCM upon addition of **3** (◆), $\mathbf{3}^{\cdot+}$ (□), **4** (▲) and $\mathbf{4}^{\cdot+}$ (○). [anthracene] = 10^{-4} M.

reflecting the multiple site aspect of polymer **2**. It is remarkable that the lower efficiency of the quenching when both polymers are present does not reflect the larger change in the oxidation waves. It can be inferred that despite the easier access of the monomers to the core of polymer **2** leading to a greater quenching, the formation of multiple interactions between two polymer chains gives an assembly which is thermodynamically more stable and probably give rise to the formation of discrete aggregates in solution. When the radical cation of the TTF moieties of **3** and **4** was generated prior to the addition to the anthracene systems, a steep initial decrease in the fluorescence intensity was observed, which is indicative of the much stronger binding as expected between π-rich anthracene units and π-deficient $TTF^{\cdot+}$ units.

In conclusion, we used two polymers with suitable side-chains as good models for the study of redox-controlled polymer–polymer interactions in solution. We have shown that a 'polymer effect' can be detected where weak interactions are established between the π-rich polymers **2** and **4** allowing a lowering of the first oxidation of the TTF. These interactions are enhanced upon oxidation of the TTF moiety of polymer **4**, thereby evoking strong donor–acceptor interactions between **2** and $\mathbf{4}^{\cdot+}$, respectively. It is anticipated that ordered aggregates are formed *via* redox controlled polymer–polymer interactions and will provide good models for the fabrication of novel devices, and their exploitation as such will be reported in due course.

Notes and references

† Polymer **4** presents a retention time which is consistent with its expected molecular weight obtained for the original copolymer of *p*-chloromethylstyrene and styrene. A folded structure would have given a longer retention time. For an example of the use of GPC for the determination of the size of a polymer in solution see ref. 15.

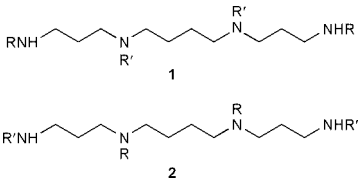
Received (in Cambridge, UK) 4th July 2001, Accepted 13th September 2001
First published as an Advance Article on the web 19th October 2001

Two types of spermine-based gemini surfactants have been synthesised; structure–activity studies have shown one type to be far superior in gene transection than the other.

Spermine-based cationic surfactants, such as dioctadecylamidoglycylspermine-4 trifluoroacetic acid (DOGS)[1] and 2,3-dioleoyloxy-*N*-[2-(sperminecarboxamido)ethyl]*N*,*N*-dimethylpropan-1-aminium trifluoroacetate (DOSPA)[2] are commercially available and are widely used for *in vitro* gene transfection studies. The preparation of these surfactants involves multi-step synthetic procedures. In both DOGS and DOSPA the spermine moiety forms the head-group of these surfactants and carries four positive charges. The presence of a multivalent head-group has been reported to favour more efficient gene transfection compared with the monovalent analogues.[2]

As part of a programme[3] aimed at the discovery and development of more efficient tools for gene transfer, we now report the synthesis and biological evaluation of novel spermine-based cationic gemini surfactants. The structure of spermine (**1**, R = R′ = H) allows the synthesis of two isomeric series of cationic gemini surfactants **1** and **2**.



We have synthesised examples of both types of gemini surfactants, varying the length of the hydrocarbon chain and the

 DOI: 10.1039/b105936j

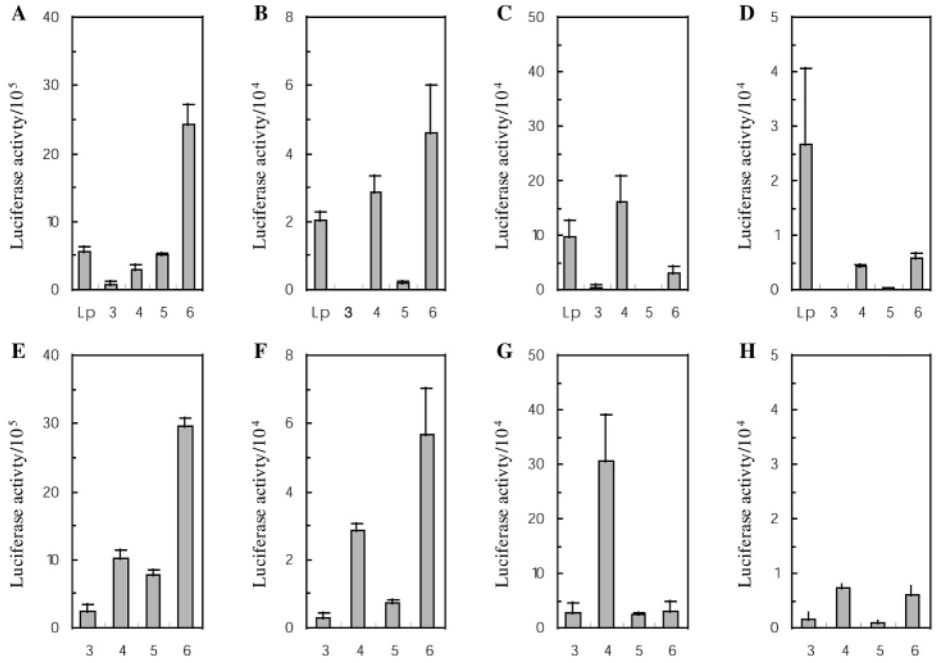

Fig. 1 Structure–activity correlations in different cell lines. Cells were incubated with DNA and gemini surfactants **3–6** at either 4 μM (CHO-DG44, A), or 8 μM (MOPC-315, B; C2C12, C; 1321N1, D). Luciferase activity (in counts per second) was averaged over 4 measurements. As control, Lipofectamine 2000™ (Lp) (Life Technologies) was incubated with DNA (100 ng well^{-1}) and used for transfection. E,F,G and H show the effect of added polylysine on the gene expression efficiency of gemini surfactants in CHO-DG44, MOPC-315, C2C12 and 1321N1 cell lines respectively. Conditions as for A–D, but the luciferase gene was complexed with poly(L-lysine) at a ratio of 1 : 4 (lysine : DNA, w/w), prior to the addition of gemini.

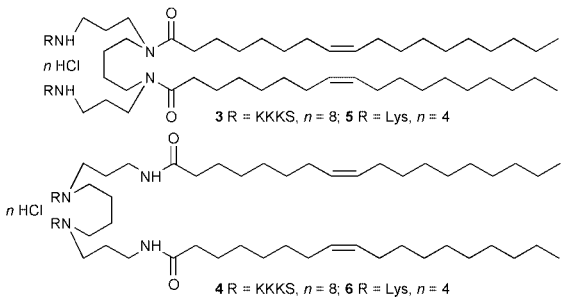
number of basic amino acid residues in the peptide head-group.[4] The general syntheses of **1** and **2** are shown in Schemes 1 and 2. The reagents used in the preparation of these molecules are all commercially available and yields of the various intermediates and final products are generally high. The solubility of these spermine-based detergents in water at neutral pH is better than 1 mg ml^{-1}, making them highly suitable for application to *in vitro* gene delivery.

Mixtures of these dimeric cationic lipids and a luciferase reporter gene were tested for their ability to transfect different types of cells in culture. For the same peptide head-group gemini surfactants of type **2** were found to be considerably better non-viral vectors than type **1**, and the oleoyl ($C_{17}^{\Delta 9}$) chain generally gave the most efficient transfection. Differences in the transfection activity of the two series of isomers are best demonstrated by comparing the isomeric pairs (**3** and **4**), and (**5** and **6**).



The transfection capabilities of these four gemini surfactants were compared to that of Lipofectamine 2000, a potent commercial cationic lipid formulation recently introduced by Life Technologies. We used four types of mammalian cell, CHO-DG44 (chinese hamster ovary), C2C12 (a mouse muscle cell line), nonadherent MOPC315 (mouse tumour cell line) and 1321N1 (a neuronal cell line). These cell lines were expected to give varying transfection efficiencies under culture conditions. Specific transfection conditions (type and amount of DNA, transfection time, presence and absence of serum) were varied in preliminary experiments for all four different cell lines to optimise transfection efficiency.

As expected, CHO cells were easiest to transfect, whereas the neuronal cells showed the maximum resistance to transfection. Results are shown in Fig. 1 A to D. Although transfection efficacy is assumed to depend on the membrane components of a cell, the lower efficacy of 1321N1 cell transfection could also be partially explained by the shortened transfection time in the absence of serum, compared to other cell lines such as CHO.

The potency of type **1** spermine-based gemini surfactants is much lower than that of corresponding type **2** isomer for all cell lines. Moreover, although surfactant **6** shows the better transfection ability for three of the four cell lines, **4** which contains more positive charges in its head-groups, is the superior gene delivery vector in the case of C2C12 muscle cells. It is also noteworthy that in all four cell lines pre-mixing DNA with either **4** or **6** gave better transfection than the same procedure using Lipofectamine 2000 (used at a concentration recommended by the supplier). These results underline the need to tailor the type of surfactant to the cell type targeted.

It is well known that the addition of polylysine to DNA can enhance the ability of cationic surfactants to deliver genes across cells.[5,6] Fig. 1 E to H show how in some cell lines the transfection activity of multi-valent gemini surfactant **4** increased by a factor of 2 to 4 in the presence of poly(L-lysine), whereas that of **6**, containing only single lysines, was not affected.

These experiments demonstrate the versatility of spermine-based gemini surfactants for the transport of DNA into cells.

$MoSe_2$ and WSe_2 nanotubes and related structures

Manashi Nath and C. N. R. Rao*

Chemistry and Physics of Materials Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Jakkur P.O., Bangalore 560 064, India

Solid State and Structural Chemistry Unit, Indian Institute of Science, Bangalore 560 012, India. E-mail: cnrrao@jncasr.ac.in

Received (in Cambridge, UK) 10th August 2001, Accepted 24th September 2001
First published as an Advance Article on the web 5th October 2001

$MoSe_2$ and WSe_2 nanotubes are obtained by the reduction of the corresponding triselenides in hydrogen or by the decomposition of the ammonium selenometallates in a hydrogen atmosphere.

Tenne and coworkers[1,2] have demonstrated that the layered metal disulfides, MoS_2 and WS_2, form fullerene-like nested polyhedra as well as nanotube structures. Nanotubes of these two sulfides have been prepared by treating the oxides, MoO_3 and WO_3, first with a mixture of 5% H_2 + 95% N_2 followed by H_2S around 900 °C.[1–3] It is likely that amorphous trisulfides are formed as intermediates in this process. Accordingly, by heating amorphous MoS_3 or WS_3 or the ammonium thiometallate precursors in hydrogen around 900 °C, we have been able to directly obtain good yields of MoS_2 and WS_2 nanotubes.[4] Fullerene-like structures of the layered Mo and W diselenides have been prepared by the reaction of the oxides with H_2Se and H_2 + N_2 at high temperatures.[2,5] In this communication, we describe our preliminary results on the synthesis of nanotubes and nanorods of $MoSe_2$ and WSe_2 by new routes. Considering that the Mo and W trisulfides are intermediates in the formation of the disulfide nanotubes, we conjectured that the corresponding amorphous triselenides could act as intermediates in the formation of the diselenide nanotubes. We have therefore, examined the hydrogen reduction of amorphous WSe_3 and $MoSe_3$, prepared by the standard procedures.[6] Equally importantly, we have carried out the decomposition of the ammonium selenometallates in a hydrogen atmosphere to obtain the diselenide nanostructures.

Reduction of $MoSe_3$ in a stream of hydrogen (100 sccm) at 850 °C yields nanotubes as evidenced by the low-resolution transmission electron microscope (TEM) images in Fig. 1(a) and (b). Fig. 1(c) shows a TEM image of a nanorod, with a layer separation of 0.64 nm. Hydrogen reduction of WSe_3 at 750 °C yields WSe_2 nanotubes. High-resolution TEM images of some of the nanotube-like structures are shown in Fig. 2(a), (b) and (c), with the lattice fringes corresponding to the expected layer spacing of 0.65 nm. The top image in Fig. 2(c) is that of a WSe_2 nanorod emanating from a precursor particle, while the bottom image in the figure appears to be due to a single-walled nanotube, but the separation between the layers is 0.65 nm. The nanorod shows lattice fringes corresponding to the (002) planes, but the nanoparticle at the tip does not show any lattice planes. Such nanoparticles can act as nucleation centres for the growth of the nanorods or nanotubes. The growth of the nanorod or nanotube starting from the inner core of a particle and proceeding towards the outer edge, is different from that of the carbon nanotubes where the layers grow from the outer edge of the catalyst particle, encapsulating the metal catalyst particle.

The formation of the diselenide nanostructures from the triselenides involves the simple reaction, $MSe_3 + H_2 \rightarrow MSe_2 + H_2Se$ (M = Mo or W). Since the triselenides are formed by the

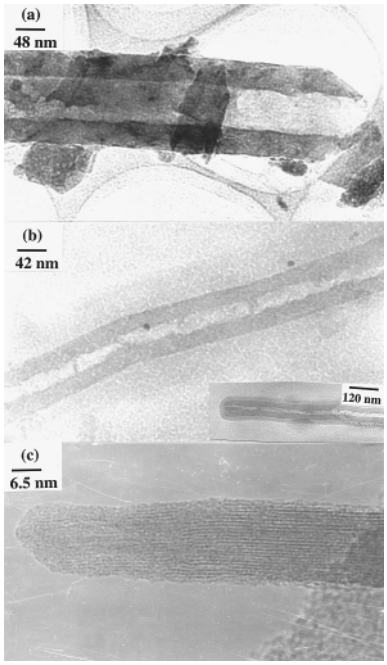

Fig. 1 (a) and (b) TEM images of a $MoSe_2$ nanotubes obtained from the decomposition of $MoSe_3$; (c) high-resolution TEM (HREM) image of a $MoSe_2$ nanorod.

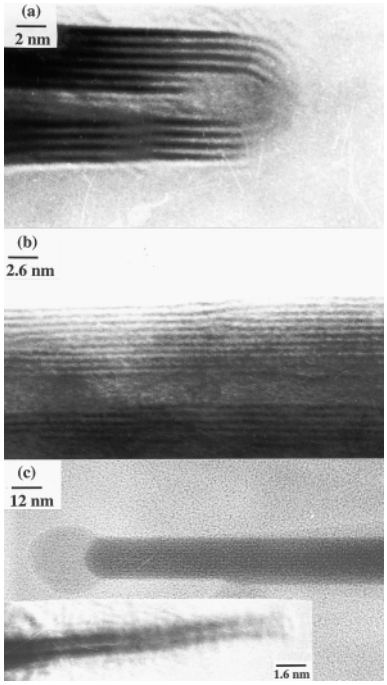

Fig. 2 (a), (b) HREM images of WSe_2 nanotubes obtained by decomposition of amorphous WSe_3 in a flow of H_2; (c) TEM images of a WSe_2 nanorod emanating from the precursor particle (top), and a single-walled WSe_2 nanotube (bottom).

 DOI: 10.1039/b107296j

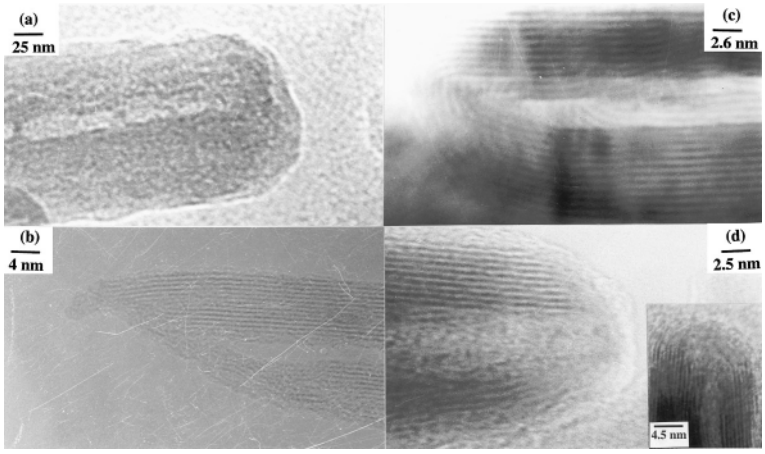

Fig. 3 (a) TEM image of a $MoSe_2$ nanotube obtained by the decomposition of $(NH_4)_2MoSe_4$; (b)–(d), HREM images of $MoSe_2$ nanotubes.

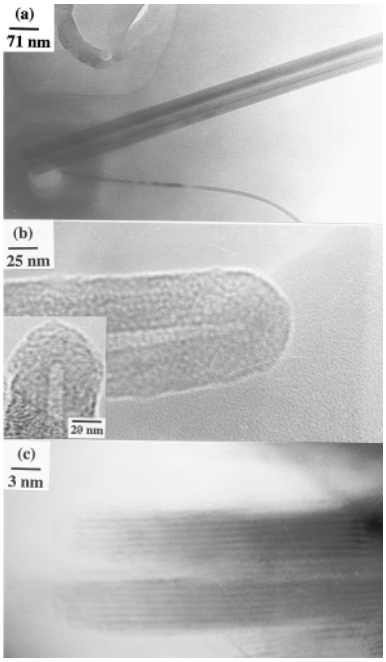

Fig. 4 (a), (b) TEM images of WSe_2 nanotubes obtained by the decomposition of $(NH_4)_2WSe_4$ in a flow of H_2. The nanotube in (a) shows a flat tip. (c) HREM image of a WSe_2 nanotube.

thermal decomposition of ammonium selenometallates, we have directly carried out the reduction of the selenometallates. Fig. 3 shows the TEM images of $MoSe_2$ nanotube structures obtained by heating $(NH_4)_2MoSe_4$ in a flow of H_2 (500 sccm) at 900 °C. The low-resolution image in Fig. 3(a) shows a nanotube closed at one end. The high-resolution images in Fig. 3(b), (c) and (d) show the $MoSe_2$ layers with a spacing of ~0.64 nm corresponding to the (002) planes. Although there is a core in the image in Fig. 3(b), the tube end has an unusual structure. The images in Fig. 3(c) and (d) appear to show closed tips, but the structure of the tip is not clearly evident. Fig. 4(a) and (b) show low-resolution images of WSe_2 nanotubes obtained by the decomposition of $(NH_4)_2WSe_4$ under a flow of H_2 (100 sccm) at 750 °C, the image in Fig. 4(b) showing closed tips. The image in Fig. 4(c) appears to be an open nanotube.

Powder X-ray diffraction (XRD) patterns of the nanotubes and nanorods of $MoSe_2$ and WSe_2 were characteristic of hexagonal structures with $a = 3.28$, $c = 12.82$ Å and $a = 3.29$ and $c = 12.99$ Å, respectively. EDAX analysis of the nanotubes showed the metal : selenium ratio to be close to 1 : 2. Selected area electron diffraction patterns commonly showed Bragg spots corresponding to the (002) and (100) planes, the (103) reflection appearing in only few of them.[7] Diffuse streaking was observed along the rows in some of the patterns.

The present study demonstrates that hydrogen reduction of the triselenides, and more significantly, of the ammonium selenometallates provides a useful route for the synthesis of the $MoSe_2$ and WSe_2 nanotubes. The reaction involved in the latter method is, $(NH_4)_2MSe_4 + H_2 \rightarrow MSe_2 + 2H_2Se + 2NH_3$ (M = Mo, W). In the decomposition of the ammonium selenometallates, the diselenide nanotubes are deposited a small distance away from the location of the starting material indicating that the amorphous triselenide may be acting as a vapor transport agent as well. In conclusion, we have been able to obtain nanotube-like structures of $MoSe_2$ and WSe_2 by the reduction of the amorphous triselenides as well as of the ammonium selenometallates. While we have been able to record a variety of nanotube and nanorod structures, with the former often exhibiting defective structures and variable wall thickness on either side of the core,[3] or loss of structure at the tip, we are presently continuing our studies in an attempt to obtain better images.

Halogen-free process for the conversion of carbon dioxide to urethanes by homogeneous catalysis

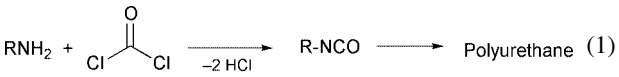
Mahmut Abla, Jun-Chul Choi and Toshiyasu Sakakura*

National Institute of Advanced Industrial Science and Technology (AIST), 1-1-1 Higashi, Tsukuba, Ibaraki 305-8565, Japan. E-mail: t-sakakura@aist.go.jp

Received (in Cambridge, UK) 12th July 2001, Accepted 18th September 2001
First published as an Advance Article on the web 5th October 2001

Carbon dioxide is converted to urethanes (carbamic acid derivatives) through reaction with amine and alcohol catalyzed by tin complexes; the addition of acetals as a dehydrating agent under high CO_2 pressure is the key to achieve high yields.

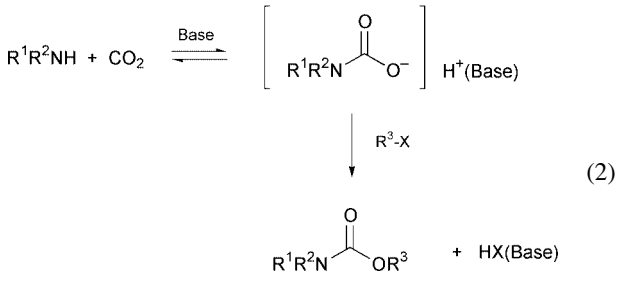
Polyurethane has many important industrial utilizations and the worldwide production still continues to grow.[1] Current commercial processes for producing polyurethane are based on isocyanate which is synthesized from a primary amine and phosgene [eqn.(1)]. This procedure has the major drawbacks of



(1)

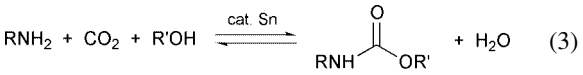
using highly toxic and corrosive phosgene, and the liberation of hydrogen chloride as a co-product.

From the standpoint of 'green chemistry', significant efforts have been made to find an alternative to the phosgene process. A very attractive substitute for phosgene is carbon dioxide because it is a typical renewable resource.[2,3] In addition, utilization of carbon dioxide is also very fascinating due to its environmentally benign nature (nontoxic, noncorrosive, and nonflammable). In particular, the application of dense carbon dioxide to organic synthesis has recently attracted much interest.[4] Most of the approaches in this context rely on the production of the carbamate anion *via* the reaction of carbon dioxide and amines, followed by the reaction with electrophiles [eqn.(2)].[5–14] However, all these methods require an equimolar



(2)

amount of electrophiles, usually alkyl halides. In this paper, we wish to report urethane synthesis by the reaction of dense carbon dioxide with amines and alcohols [eqn.(3)]. This

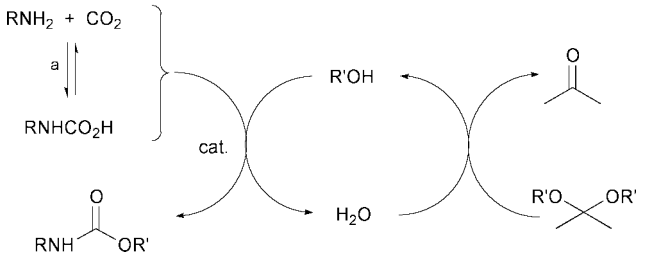


(3)

procedure is not only phosgene-free but also completely halogen-free.

Dialkyl carbonate synthesis from alcohol and CO_2 is catalyzed by metal complexes such as dialkyl(dimethoxy)tin, dialkyl(oxo)tin, and zirconium oxide.[15,16] However, the alcohol conversion is very poor. Similarly, the straightforward reaction of an amine, an alcohol, and carbon dioxide in the presence of dialkyltin compounds produced urethane only in a poor yield although the selectivity was satisfactory (Table 1, run 1).

The low conversion observed in run 1 is presumably attributable to thermodynamic limitations and catalyst deactivation by co-produced water [eqn.(3)]. In order to overcome the low conversion, we have devised a new reaction system utilizing acetals as a chemical dehydrating agent. The idea is schematically represented in Scheme 1; water is trapped by acetal to regenerate alcohol. The conversion of amine was clearly improved by this method without much decrease in the selectivity (Table 1, runs 2 to 4). The larger acetal–amine ratio further promoted the reaction. For example, the reaction of *t*-$BuNH_2$ and EtOH in the presence of two equivalents of 2,2-diethoxypropane led to a high conversion and selectivity, 100 and 84%, respectively (run 5). Since acetals are easily regenerated from acetone, the net reaction can be regarded as an urethane synthesis from CO_2, an amine, and an alcohol. As for the catalyst, dialkoxy(dialkyl)tin and its precursors such as dialkyl(oxo)tin and dialkyl(dichloro)tin exhibited high catalytic activities.[16]†



Scheme 1

Table 1 Urethane synthesis from amine, alcohol, and CO_2[a]

Run	Amine	Alcohol	Catalys	Acetal	Conversion (%)	Selectivity[b] (%)
1	*t*-$BuNH_2$	EtOH	Bu_2SnO	None	16	89
2	*t*-$BuNH_2$	EtOH	Bu_2SnO	$Me_2C(OEt)_2$	59	90
3	$CyNH_2$	EtOH	Bu_2SnO	$Me_2C(OEt)_2$	89	64
4	*t*-$BuNH_2$	MeOH	Me_2SnCl_2	$Me_2C(OMe)_2$	74	88
5[c]	*t*-$BuNH_2$	EtOH	Bu_2SnO	$Me_2C(OEt)_2$	100	84
6[d]	*t*-$BuNH_2$	MeOH	Bu_2SnO	None	66	24

[a] *Reaction conditions*: amine (10 mmol), alcohol (100 mmol), acetal (10 mmol), catalyst (0.2 mmol), CO_2 30 MPa, 200 °C, 24 h. [b] Selectivity = (yield of urethane)/conversion × 100. [c] *tert*-Butylamine (5 mmol), ethanol (50 mmol), 2,2-diethoxypropane (10 mmol). [d] *Reaction conditions*: amine (10 mmol), methanol (100 mmol), dimethyl carbonate (10 mmol), catalyst (0.2 mmol), CO_2 30 MPa, 200 °C, 24 h.

 DOI: 10.1039/b106201h

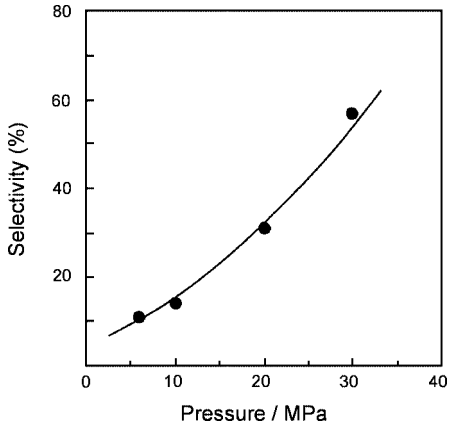


Fig. 1 Pressure effect on the Bu_2SnO-catalyzed urethane synthesis from cyclohexylamine, methanol and 2,2-dimethoxypropane (200 °C, 24 h).

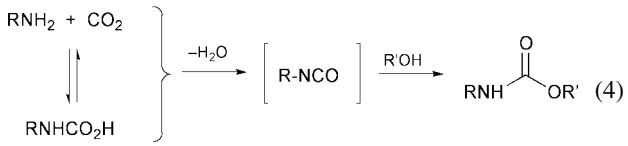
In order to obtain urethane in good yields, dense phase CO_2 under high pressure is necessary as shown in Fig. 1. The major side reactions in Scheme 1 were (i) imine formation from acetone and (ii) alkylation of amines by alcohols. The improvement of the yield under a high pressure is assigned to the depression of side reactions. Thus, high pressure promotes carbamic acid formation (step a, Scheme 1). This will prevent imine formation and amine alkylation resulting in improvement of the urethane selectivity.

A possible mechanism for urethane formation is the reaction of alcohols with isocyanates formed from CO_2 and primary amines [eqn.(4)].[17] The inactivity of secondary amines is



(4)

consistent with this mechanism.[18] In addition, a trace amount of urea was detected in the reaction mixture indicating the participation of isocyanates. On the other hand, the intermediacy of dialkyl carbonate is not very likely because the addition of dialkyl carbonate to the reaction mixture did not improve the urethane yield (Table 1, run 6).

In conclusion, we have succeeded in the catalytic synthesis of urethane directly from carbon dioxide, amines, and alcohols through a halogen-free process. This demonstrates the potential of carbon dioxide as an environmentally benign and easily available phosgene alternative.

This study was supported by Industrial Technology Research Grant Program in 2000 from the New Energy and Industrial Technology Development Organization (NEDO) of Japan.

Notes and references

† All manipulations were carried out under purified argon. In a stainless steel autoclave (20 cm^3 inner volume), carbon dioxide (liquid, 6.5 MPa) was added to a mixture of *tert*-butylamine (10 mmol), a tin complex (0.2 mmol), methanol (100 mmol), and biphenyl (50 mg, internal standard for GC analysis) at room temperature. The initial pressure was adjusted to 30 MPa at 200 °C and the autoclave was heated at that temperature for 24 h. After cooling, product yield was determined by GC and the products were further identified using GC-MS by the comparison of retention times and fragmentation patterns with authentic samples.

1 Polyurethanes had a global demand of 5.1×10^6 tons per year in 1990 with an estimated demand of 8.5×10^6 tons per year in 2000. See, *Synthetic Polymers, Technology, Properties, Applications*, ed. D. Feldman and A. Barbalata, Chapman and Hall, London, 1996, p. 273.

N-Heterocyclic carbenes can coexist with alkenes and C–H acidic sites

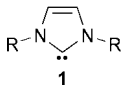
Received (in Cambridge, UK) 10th August 2001, Accepted 21st September 2001
First published as an Advance Article on the web 18th October 2001

The isolation of compounds 3 and 7a,b proves that a singlet carbene center can coexist with alkenes or C–H acidic sites in proximity without spontaneous annihilation.

Among the nucleophilic carbenes that can be isolated in pure form,[1] *N*-heterocyclic carbenes (NHC's) of the general structure **1**[2] are rapidly gaining importance as electron-donating ligands



1

for transition metal centers in different oxidation states.[3] Applications of NHC-complexes to catalysis have recently met with considerable success, olefin metathesis[4] and cross coupling chemistry[5] being the most convincing cases.[6] Usually, NHC ligands bearing simple alkyl or aryl substituents R on their N-atoms are employed, although *functionalized* ones may be of even greater preparative appeal. A pertinent example is the ruthenium complex **5** which serves as a 'designer' catalyst for olefin metathesis capable of regenerating itself once the substrate is depleted.[7] The reported synthesis of **5** involves the *in situ* generation of carbene **3** as a *transient* species which is immediately trapped by admixed $(PCy_3)_2Cl_2Ru{=}CHPh$[8] to form product **4**; though easy to carry out, this *in situ* protocol turned out to be rather low yielding (41%). Heating **4** in an inert solvent then effects the intramolecular metathesis of the tethered olefin to form the metallacyclic complex **5**.

To improve the synthesis of this promising catalyst, we were pursuing the *isolation* of compound **3** containing an alkene next to the carbene center. Although cyclopropanation of olefins is a prototype carbene reaction with low activation barrier,[9–11] the preparation of **3** is surprisingly simple. This compound is obtained in essentially quantitative yield as a crystalline solid by treatment of the imidazolium salt **2** with KOt-Bu in THF at 0 °C followed by a standard work-up.[12] The spectral data and the molecular structure in the solid state (Fig. 1) show the *presence of a carbene center in proximity to the intact alkene group*.† Difference maps clearly reveal the location of all hydrogen atoms; the volume element adjacent to the carbene C-atom has no significant electron density. To the best of our knowledge, this is the first example of an isolated carbene that coexists with an olefin in its vicinity.

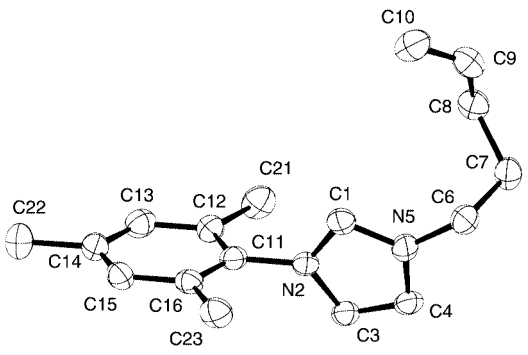


Fig. 1 Molecular structure of **3**.‡ Anisotropic displacement parameters are shown at 50% probability level. There are two independent molecules in the asymmetric unit. The major difference is found in the conformation of the alkyl chain. The torsion angle C6–C7–C8–C9 is 67.6(5)° compared to 177.1(4)° in the second molecule. The difference of the dihedral angles formed between the mesityl and the NHC is 15.8°.

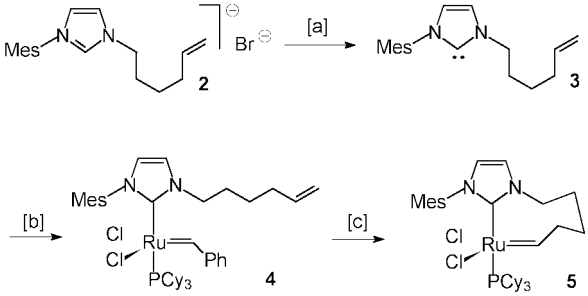
With **3** in hand, it was possible to improve the synthesis of the targeted ruthenium complex **5** (Scheme 1). Thus, reaction of $(PCy_3)_2Cl_2Ru{=}CHPh$ with isolated **3** in toluene affords complex **4** in 86% yield which cyclizes upon heating to form the desired product **5**. The use of toluene instead of *n*-pentane in the latter reaction is beneficial for solubility reasons and constitutes a noteworthy improvement over our original procedure.[7]



Scheme 1 *Reagents and conditions*: [a] KOt-Bu, THF, 0 °C, 98%; [b] $(PCy_3)_2Cl_2Ru{=}CHPh$, toluene, 0 °C, 86%; [c] *n*-pentane (reflux) or toluene (65 °C), 41–77%; Mes = 2,4,6-trimethylphenyl (= mesityl).

Next, we investigated if other functional groups that are generally believed to be incompatible with free carbenes can similarly be incorporated into NHC's. The insertion of carbenes into acidic C–H bonds is known to be a facile process;[9] therefore the preparation of compounds **7a**,**b** bearing an ester or a nitrile group seemed challenging, in particular since Arduengo[13] has previously reported that closely related dihydroimidazol-2-ylidenes rapidly insert into the acidic C–H bonds of MeCN, $MeSO_2Ph$, $HCCl_3$ or HC≡CH.[14]

Gratifyingly, however, carbenes **7a**,**b** are obtained in excellent yields by deprotonation of the corresponding imidazolium salts **6a**,**b** (Scheme 2),† although they were found to deteriorate within hours even at 0 °C. Reaction of $(PCy_3)_2Cl_2Ru{=}CHPh$[8] with these functionalized carbenes in toluene at ambient temperature provides the novel ruthenium complexes **8** (74%) and **9** (38%).§ The X-ray structure of **8** (Fig. 2) shows the characteristic π–π stacking between the benzylidene ligand and the mesityl group which was previously recognized as a highly

Direct evidence for the incorporation of univalent indium into high-silica zeolite, H-ZSM-5, by thermal auto-reductive solid-state ion exchange

Magdolna R. Mihályi* and Hermann K. Beyer

Chemical Research Center, Institute of Chemistry, Pusztaszeri út 59-67, Budapest, Hungary 1025. E-mail: rosmag@cric.chemres.hu

Received (in Cambridge, UK) 10th July 2001, Accepted 20th September 2001
First published as an Advance Article on the web 9th October 2001

In mechanical mixtures of H-ZSM-5 and In_2O_3 thermal auto-reductive solid-state ion exchange (AR-SSIE) was found to proceed upon treatment in high vacuum at 840 K resulting in the incorporation of In^+ ions into, and in an increase of the thermal stability of, the zeolitic component.

Recently, zeolites containing cationic indium species have been found to be active and selective catalysts for the reduction of nitric oxides with hydrocarbons in the presence of oxygen.[1] Among the methods for the incorporation of indium cations into zeolites, 'reductive solid-state ion exchange' (R-SSIE) proved to be especially appropriate. This process[2] was found to proceed in mechanical mixtures of crystalline In_2O_3 and H-zeolites in a hydrogen atmosphere at 620–730 K, probably in two steps *via* In_2O, according to

$$In_2O_3 + 2H_2 + 2H^+Z^- \rightarrow 2In^+Z^- + 3H_2O \quad (1)$$

where Z^- represents the fraction of the zeolite framework bearing one negative charge. Also other reductants (*e.g.* ammonia, CO and products formed by a non-oxidative thermal decomposition of templates) induce partial or complete replacement of protons of acidic OH in zeolites.[3,4] It was evidenced that In^+, once incorporated into zeolites by R-SSIE, is oxidized by O_2 to InO^+ which can again be reversibly reduced. Univalent and trivalent indium cations in zeolites can be distinguished from each other by typical IR bands of adsorbed pyridine.[5]

Ogura *et al.*[6] found that in the IR spectra of ground mixtures of In_2O_3 and H-zeolites the intensity of the bands typical of bridging hydroxyls and pyridinium ions decreased upon degassing at 850 K to a higher degree than observed in the case of mere thermal dehydroxylation. They concluded that indium cations were incorporated into the zeolite lattice by conventional solid-state ion exchange (SSIE) according to

$$In_2O_3 + 2H^+Z^- \rightarrow 2InO^+Z^- + H_2O \quad (2)$$

However, these phenomena can be consistently interpreted also in terms of an auto-reductive solid-state ion exchange, according to which In_2O_3 is first converted to In(I) oxide by thermal decomposition and then incorporated as the monovalent cation into the zeolite lattice resulting in the overall reaction:

$$In_2O_3 + 2H^+Z^- \rightarrow 2In^+Z^- + H_2O + O_2 \quad (3)$$

In the present study direct evidence is provided for the incorporation of In^+ cations according to eqn. (3) and the formation of InO^+ cations by subsequent oxidation with oxygen.

The parent H-ZSM-5 was prepared according to procedure B in ref. 7. Na and Al, determined by AAS after digestion with hydrofluoric acid, were found to amount to 0.08 and 0.82 mmol $g_{calc.}^{-1}$, respectively. The amount of acidic bridging hydroxyls (H) was assumed to equal the difference between molar Al and Na content. The parent zeolite (Si/Al = 19.5) and In_2O_3 were intensively ground in amounts corresponding to a molar Al/In ratio of 1.

IR spectra were recorded using the wafer transmission technique. Sample treatments were performed in high vacuum (HV) of about 10^{-3} Pa for 0.5 h between 670 and 840 K. *In situ* oxidation and subsequent reduction of the cationic indium species introduced by auto-reductive SSIE were carried out in oxygen and hydrogen (200 mbar), respectively, for 0.5 h at temperatures indicated in the text. The wafers were contacted *in situ* with pyridine (Py) at 470 K (5.7 mbar) for 0.5 h and then degassed in HV for 0.5 h at temperatures gradually increased between 370 K and 720 K.

Fig. 1 shows the intensity decrease of the band at 3610 cm^{-1}, typical of bridging hydroxyls, upon degassing of H-ZSM-5 with and without In_2O_3 in HV at gradually increasing temperatures. Dehydroxylation of the parent zeolite [Fig. 1, curve (A)] started at about 750 K and approached the 50% level at about 840 K. However, in the presence of In_2O_3 the intensity decrease of the IR band set in at about 720 K, and continued in a more pronounced fashion; by 840 K the degree of dehydroxylation had already reached 70% [Fig. 1, curve (B)]. The additional proton consumption in the presence of In_2O_3 must at least be attributed to the partial replacement of lattice protons by cationic indium species, but actually this process probably proceeds to an even higher degree since incorporation of metal cations into H-zeolites generally results in a greater resistance of remaining bridged hydroxyls to thermal dehydroxylation. Naturally, these results provide no information on whether the replacement of protons proceeds according to eqn. (2) or eqn. (3).

In Fig. 2 the IR spectra of Py adsorbed on H-ZSM-5/In_2O_3 and, for comparison, the parent zeolites are presented. As generally known, the band at 1547 cm^{-1} and the broad absorption zone between 1610 and 1640 cm^{-1} (with maximum absorption around 1635 cm^{-1}) are attributed to the NH stretching and ring vibration mode of pyridinium ions and, hence, are indicative of Brönsted acid sites. The spectra of Py on H-ZSM-5 pretreated, prior to Py adsorption, at only 670 K (spectrum Aa) also exhibited, besides these absorptions, less intense bands at 1446 and 1455 cm^{-1} assigned to the 19b ring vibration of Py interacting with cationic extra-framework aluminium (EF-Al) species and, superimposed on the broad

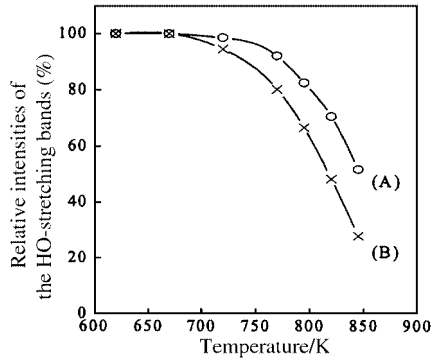

Fig. 1 Relative intensities of the hydroxyl stretching band at 3610 cm^{-1} in spectra of (A) H-ZSM-5 and (B) H-ZSM-5/In_2O_3(H/In = 1) *vs.* degassing temperature.

 DOI: 10.1039/b106081n

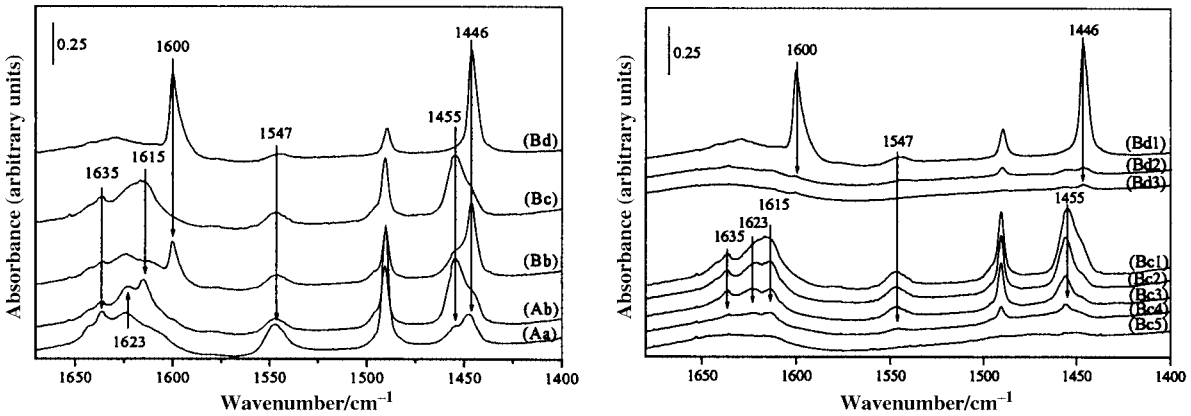

Fig. 2 IR spectra of adsorbed Py retained after degassing at 370 K on (A) H-ZSM-5 and (B) H-ZSM-5/In_2O_3 (H/In = 1) treated prior to Py adsorption in HV (a) at 670 K, (b) at 840 K, (c) at 840 K and subsequently contacted with O_2 at 720 K, and (d) reduced after pretreatment (c) with H_2 at 770 K. Two wafers, (Bc) and (Bd), were submitted to degassing procedures at 370 K (Bc1, Bd1), 470 K (Bc2, Bd2), 570 K (Bc3, Bd3), 670 K (Bc4) and 720 K (Bc5).

pyridinium absorption zone, an additional band at 1625 cm^{-1} attributed to the respective 8a ring vibration mode. According to expectation, the pyridinium bands decreased and the bands typical of Py interacting with EF-Al species increased in intensity upon thermal pretreatment at 840 K (spectrum Ab), *i.e.* at a temperature at which dehydroxylation associated with the release of aluminium from the framework already proceeds. Even a new band appeared at 1615 cm^{-1} which has not been mentioned in earlier reports. It is obviously associated with EF-Al located at a distinct crystallographic site of the ZSM-5 structure. In contrast, the drastic increase in the intensity of the band at 1455 cm^{-1} and the development of a new one at 1615 cm^{-1} upon heat treatment at 840 K was not observed in the spectrum of the H-ZSM-5/In_2O_3 mixture pretreated in the same way, *i.e.* in HV at 840 K [Fig. 2, spectrum (Bb)]. Thus, thermal dehydroxylation seems not to be significantly involved in the process which, nevertheless, results in a considerable reduction of the Brönsted acidity revealed by the intensity decrease of the band at 1547 cm^{-1} and, prior to Py adsorption, of the hydroxyl stretching band at 3610 cm^{-1} (see Fig. 1). In this context it is of great importance that concomitantly with the elimination of acidic hydroxyl groups, rather intense bands develop in the spectrum of adsorbed Py at 1466 and 1600 cm^{-1} (spectrum Bb in Fig. 2) which could earlier[5] be undoubtedly assigned to Py interacting with In^+ located on cation sites of zeolite structures. Thus, the appearance of these bands strongly evidences the incorporation of indium *via* AR-SSIE [eqn. (3)].

Thermal treatment of the H-ZSM-5/In_2O_3 mixture in the presence of O_2 after preceding AR-SSIE, *i.e.* after evacuation at 840 K (spectrum Bb in Fig. 2), resulted in Lewis acid sites of a new type revealed by bands of adsorbed Py at 1455 and around 1615 cm^{-1}, while those typical of In^+ cations disappeared (Fig. 2, spectrum Bc). In an earlier study,[5] these new bands could be assigned to Py interacting with InO^+ ions.

The bands associated with InO^+ appeared at practically the same wavenumbers as those caused by EF-AL (*e.g.* AlO^+). Nonetheless, the distinction of the two different cation species is easily possible by subsequent reduction with H_2 at higher temperature (770 K). According to expectation, such a reductive treatment (and naturally also the preceding oxidation) did not affect the spectra of pure H-ZSM-5, *e.g.* spectra Aa and Ab in Fig. 2 (not illustrated by figures). On the other hand, the same pretreatment procedure resulted in the reappearance of the two bands associated with In^+ cations at the expense of the InO^+ bands in the spectrum of the H-ZSM-5/In_2O_3 mixture (*cf.* spectra Bc and Bd in Fig. 2). Compared to the spectrum monitored after AR-SSIE (Bb in Fig. 2) the bands at 1446 and 1600 cm^{-1} even gained in intensity after the reduction with H_2 pointing to an only partial conversion of the applied In_2O_3 during the preceding heat treatment at 840 K and the completion of the incorporation process by conventional, *i.e.* hydrogen-induced, R-SSIE. After such an oxidation/reduction cycle the zeolitic phase contained only In^+ as lattice cations and even cationic EF-Al species detected in the parent zeolite seem to be displaced by In^+ from their original positions.

Monovalent cations, *e.g.* Na^+, are known to be rather weak Lewis acid sites from which coordinatively bound Py is released at relatively low temperatures. Accordingly, the bands at 1446 and 1600 cm^{-1}, indicative of In^+, practically disappeared upon degassing at temperatures as low as 470 K (*cf.* spectra Bd1–Bd3 in Fig. 2). In contrast, InO^+ proved to be a Lewis site of much higher acid strength since adsorbed Py was fully retained at degassing in HV at 470 K and gradually desorbed only in the temperature range up to 720 K (*cf.* spectra Bc1–Bc5 in Fig. 2).

Interestingly, InO^+-ZSM-5 underwent at least partial auto-reduction when heated in HV at 840 K since after such a treatment the bands typical of Py on In^+ reappeared to some degree at the expense of those attributed to Py on InO^+ (not shown in figures). Knowing this effect the idea may arise that the formation of lattice-stabilized In^+ upon heat treatment of H-ZSM-5/In_2O_3 mixtures could be due to auto-reduction of InO^+ cations previously incorporated into the zeolite structure by conventional SSIE according to eqn. (2). It is evident that the incorporation of indium into ZSM-5 should be unaffected by oxygen if it proceeds according to eqn. (2), but repressed if process (3) is correct. Experimentally it was found that in O_2 (5 mbar), even at 840 K the incorporation of any form of cationic indium ions is completely suppressed. This strongly evidences that auto-reduction of In_2O_3 in the starting mixture is the initial step in the mechanism of the ion-exchange process, and that the reaction route according to eqn. (2) can be excluded.

Room-temperature ionic liquids: a novel versatile lubricant

Chengfeng Ye, Weimin Liu,* Yunxia Chen and Laigui Yu

State Key Laboratory of Solid Lubrication, Lanzhou Institute of Chemical Physics, Chinese Academy of Sciences, Lanzhou 730000, China. E-mail: wmliu@ns.lzb.ac.cn

Received (in Cambridge, UK) 31st July 2001, Accepted 24th September 2001
First published as an Advance Article on the web 10th October 2001

Alkylimidazolium tetrafluoroborates are promising versatile lubricants for the contact of steel/steel, steel/aluminium, steel/copper, steel/SiO_2, Si_3N_4/SiO_2, steel/Si(100), steel/sialon ceramics and Si_3N_4/sialon ceramics; they show excellent friction reduction, antiwear performance and high load-carrying capacity.

Room-temperature ionic liquids were initially developed by electrochemists for use as electrolytes in batteries or for metal electrodeposition. As a non-conventional class of novel solvents, ionic liquids are becoming increasingly important and of particular interest. This is because they have a number of characteristics including negligible volatility, non-flammability, high thermal stability, low melting point, broad liquid range, and controlled miscibility with organic compounds, especially some heterocycle compounds.[1–4] Therefore they have attracted enormous attention as media for green synthesis and been successfully used to realize many important reactions.[5–8]

On the other hand, the above-mentioned properties of ionic liquids make them potent excellent lubricants. The lubricants currently used in industry are restricted in their application. For instance, lubricants for steel/steel contact may be unsuitable for aluminium/ceramics. For example, while alcohol has been successfully used as a lubricant for ceramics and aluminium it behaves poorly for steel. Clearly versatile lubricants would be of great value for the industrial community.

Bearing this in mind and taking into consideration melting point, thermal stability, hygroscopicity and viscosity, we chose 1-methyl-3-hexylimidazolium tetrafluoroborate (denoted L106) and 1-ethyl-3-hexylimidazolium tetrafluoroborate (L206) (see Fig. 1) to evaluate their tribological behavior using an Optimol SRV (SRV is the abridged name for German Schwingung, Reibung, Verschleiss) oscillating friction and wear tester with ball-on-disc configuration.[9]

The SRV test results at a medium load are listed in Table 1. It can be seen that the ionic liquid L106 exhibits excellent tribological performance for steel (SAE-52100), aluminium (Al2024), copper, single crystal SiO_2, single crystal Si(100) and sialon (Si–Al–O–N) ceramics.[10] It exhibits the lowest friction coefficients as compared with the two fluorine-containing lubricants phosphazene (X-1P)[11] and perfluoropolyether (PFPE)[12] which are widely used as lubricants for head/disk interface or space applications. Thus it can be anticipated that ionic liquids might be promising versatile lubricants.

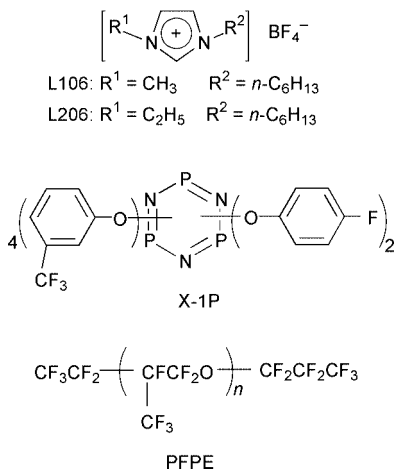

Fig. 1 Molecular structures of the ionic liquids L106 and L206 and traditional lubricants X-1P and PFPE.

Table 1 Friction coefficients for several frictional pairs lubricated with various lubricants (SRV tester, load 50 N, frequency 25 Hz, amplitude 1 mm)

	Friction coefficient		
Frictional pair (ball/disk)	L106	X-1P	PFPE
Steel/steel	0.065	0.098	0.145
Steel/Al	0.040	0.128	—
Steel/Cu	0.025	0.117	0.145
Steel/SiO_2	0.060	0.110	0.132
Si_3N_4/SiO_2	0.083	0.115	0.132
Steel/Si(100)	0.050	0.102	0.145
Steel/sialon	0.065	0.100	0.120
Si_3N_4/sialon	0.065	0.105	0.130

Table 2 shows the SRV test results for the ionic liquid L206, X-1P and PFPE under relatively high loads (≥200 N). The friction coefficient and wear volume loss of a steel disc lubricated by L206 remains at a very low level with increasing load, and the load-carrying capacity of L206 reaches up to 1000 N, much higher than that of X-1P (300 N) or PFPE (400 N).

The ionic liquids L106 and L206 are non-hygroscopic, are air- and water-stable under ambient conditions, and slightly soluble in water; the solubility of L106 in water is *ca.* 0.28 g l^{-1} at 20 °C while L206 has a similar solubility. The solubility of the ionic liquids in water has little effect on the tribological behavior. Moreover, the addition of a small amount of water (≤5 wt%) to the ionic liquids is helpful to improve the antiwear ability for various frictional pairs (steel/steel, steel/aluminium and steel/ceramic) but has little effect on the friction reduction performance.

A question then arises: why do ionic liquids exhibit superior tribological behavior? Noticing the unique dipolar structure, we propose that ionic liquids can be easily adsorbed on the sliding surface of frictional pairs. Subsequently an effective boundary film would form so as to reduce friction and wear. Furthermore, under severe friction conditions, the tetrafluoroborate anion will

Table 2 Tribological properties of ionic liquid L206, X-1P and PFPE for steel/steel contact (SRV tester, load 50 N, frequency 25 Hz, amplitude 1 mm, duration 30 min)

	Friction coefficient			Wear volume/$\times 10^{-4}$ mm^3		
Load/N	L206	X-1P	PFPE	L206	X-1P	PFPE
200	0.060	0.070	0.120	0.05	0.07	0.60
300	0.055	0.065	0.110	0.22	2.21	1.90
400	0.050	—	0.105	0.39	—	5.03
500	0.045	—	—	0.45	—	—
600	0.045	—	—	0.53	—	—

'—' lubrication failure.

 DOI: 10.1039/b106935g

decompose to form anti-scratch components such as fluoride, B_2O_3 and BN. This is confirmed by the B 1s XPS spectra of worn surfaces under different testing conditions (Fig. 2). Only BN is detected in the sliding area of steel/sialon contact lubricated with L106 under 300 N, while both B_2O_3 and BN are detected in the sliding area of Si_3N_4/sialon ceramic contact lubricated with L106 under 80 N.

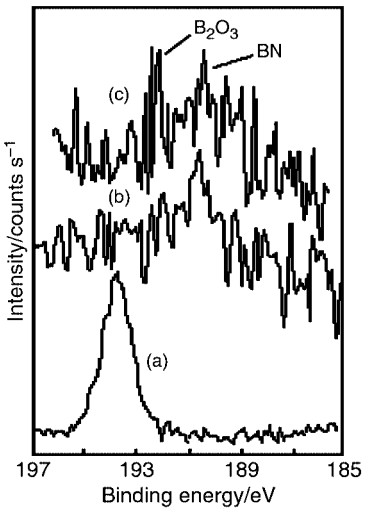

Fig. 2 B 1s spectra of neat L106 on Au (a) and in wear scar of sialon sliding against steel lubricated with L106 under 300 N (b) and of sialon sliding against Si_3N_4 under 80 N (c).

In addition, ionic liquids L106 and L206 have pour points below −55 °C and show no weight loss below 320 °C. Thus, the prominent low temperature fluidity, high temperature stability, low vapor pressure and excellent lubricity makes them an attractive alternative to conventional liquid lubricants.

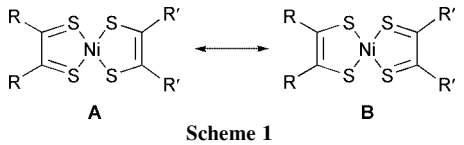
A simple method to obtain in high yields mixed-ligand nickel–dithiolene complexes, which show strong negative solvatochromism and negative first molecular hyperpolarizability, and the use of Raman spectroscopy to establish the extent of electronic delocalisation in these complexes, are reported.

Metal–dithiolenes represent a class of compounds of interest in several fields of materials chemistry.[1] Symmetrical bis-dithiolene nickel complexes exhibit an intense electronic transition at low energies assigned to a $\pi \rightarrow \pi^*$ transition between the HOMO and the LUMO, delocalised over both the ligands (R = R′, Scheme 1). This extensive electron-delocalization, while making these complexes useful as near-infrared (NIR) dyes, is irrelevant to intramolecular charge transfer, a crucial factor in generating second order non-linear optical (NLO) properties. It is known[1c] that donor substituents in the parent dithiolene $[Ni(edt)_2]$ (edt = ethylenedithiolate) raise the energy of the HOMO more than that of the LUMO, with a consequent shift of the low-energy band to lower frequencies. However, very strong donor substituents may also force the HOMO to become antibonding and the loss of one or two electrons may be observed, but examples of cations are extremely rare.[1c] On the other hand, electron-withdrawing substituents lower the energy both of the HOMO and the LUMO, and the latter MO may become bonding, leading to the formation of anions, as observed in several cases (mnt,[2a] tdas,[2b] qxd,[2c] dmit,[2d] dsit,[2e] tkr[2f] derivatives, Scheme 2). When R ≠ R′ (unsymmetrical complexes) where R is an electron donating substituent and R′ an electron withdrawing substituent, the resonance form **A** (Scheme 1) may dominate the ground state. In this case the complexes can be described as dithione–dithiolate derivatives with the R′ containing ligand contributing more to the HOMO and R containing one likewise to the LUMO. Thus the electronic transition between the HOMO and the LUMO will have intramolecular CT character, making unsymmetrical complexes potential second-order NLO chromophores.[3]

However $[Ni(R_2C_2S_2)(R'_2C_2S_2)]$ complexes are extremely rare,[4] mainly for the difficulties encountered in the synthetic procedure and in their purification. Among them $[Ni(R_2pipdt)(R'_2C_2S_2)]$ [$R_2C_2S_2$ = 1,4-dialkylpiperazine-3,2-dithione (R_2pipdt); $R'_2C_2S_2$ = maleonitriledithiolate (mnt) and trifluoromethyldithiolate (tfd)] nickel complexes have been prepared by reacting the free R_2pipdt ligand with the neutral complexes $[Ni(mnt)(NH_3)_2]$ and $[Ni(tfd)_2]$, respectively. These complexes show strong negative solvatochromism and negative first molecular hyperpolarizability (β).[5]



Scheme 1

We report here a simple method to prepare several complexes belonging to this class of potential second-order NLO chromophores, some of them not reported before, by reacting a salt of a nickel–dithiolene dication $[Ni(R_2pipdt)_2](BF_4)_2$ **1** with a salt of a nickel–dithiolene dianion $(Bu_4N)_2[Ni(S_2C_2R'_2)_2]$ **2** as shown in Scheme 2.

$[Ni(Me_2pipdt)_2](BF_4)_2$ (R = Me, **1′**) has been characterized. Structural data[6] show that the most significant bond distances and angles in the $[Ni(Me_2pipdt)_2]^{2+}$ cation fall in the typical range of square-planar nickel–dithiolene complexes (Fig. 1).

This cation has been briefly mentioned in the literature,[1c] but data on its characterisation were missing.

The cyclic voltammogram of **1′** is in agreement with a dithiolene description of this cation, showing four reversible redox steps which are ascribed to mono-electronic processes leading **1′** from the dicationic to the dianionic species.

All the obtained mixed-ligand compounds (**3a**–**f**) shown in Scheme 2 have been characterized by analytical, spectroscopic and electrochemical methods. [Ni(Me$_2$pipdt)(mnt)] (R = Me, **3a′**) has been also structurally characterised[6] (Fig. 2). Complexes **3a′**–**f′** exhibit a low-frequency peak, which shows negative solvatochromism, above 700 nm. Solvatochromic measurements and dipole analysis have been performed on [Ni(Pr$^i_2$pipdt)(dmit)] as described in ref. 5. In Table 1 a comparison of these results with those of [Ni((EH)$_2$-

pipdt)(mnt)][5] and with those obtained on [Ni(Pr$^i_2$timdt)(mnt)] is reported. [Ni(Pr$^i_2$timdt)(mnt)] belongs to a class (**4**) of apparently similar mixed-ligand derivatives, recently prepared by us,[7] where the ligand containing the electron-donating substituent is Pr$^i_2$timdt (formally the monoanion of 1,3-diisopropylimidazolidine, whatever of R_2pipdt. Both [Ni(Pr$^i_2$pipdt)(dmit)] and [Ni((EH)$_2$pipdt)(mnt)] show pronounced negative solvatochromism as indicated by their large negative values of $\mu_e - \mu_g$. The β_0-value found for [Ni(Pr$^i_2$pipdt)(dmit)] is 3× that of [Ni((EH)$_2$pipdt)(mnt)] and it is mainly due to the larger transition dipole moment and longer absorption wavelength. It is reasonable that the direction of the LLCT of these complexes is from the dithiolate-ligand to the dithione-ligand. Instead a β_0-value near to zero is found for [Ni(Pr$^i_2$timdt)(mnt)]. The different behaviour of these apparently similar complexes is related to the extent of the electronic delocalization in class **4** complexes. The low-energy band is thus assigned to a $\pi\rightarrow\pi^*$ transition in class **4** derivatives and to LLCT (dithiolate to dithione) transition in class **3** ones. Accordingly the very similar $E_{1/2}$ values related to the reduction processes of class **3** complexes (Table 2) suggest a prevailing contribution of the Me$_2$pipdt ligand to the LUMO. By contrast, class **4** complexes show corresponding $E_{1/2}$ values at intermediate values between those of the parent symmetrical complexes.[7]

Raman spectra are very diagnostic to distinguish the two classes of complex. The C=C stretch shows a shift to higher frequencies as the negative charge on the complex increases in Ni(mnt)$_2$-complexes.[8a] This peak is found at 1485 for $[Ni(mnt)_2]^{2-}$ and at 1435 cm^{-1} for $[Ni(mnt)_2]^{-}$. [Ni(Me$_2$-pipdt)(mnt)] and [Ni(Pr$^i_2$timdt)(mnt)] exhibit a peak at 1492 and 1425 cm^{-1}, respectively thus suggesting that the mnt ligand bears a −2 formal charge in [Ni(Me$_2$pipdt)(mnt)] which is significantly lowered in [Ni(Pr$^i_2$timdt)(mnt)]. Similarly, comparing the peaks assigned to the C=C stretch of the dmit ligand in [Ni(Pr$^i_2$pipdt)(dmit)] (1445 cm^{-1}) and [Ni(Pr$^i_2$timdt)(dmit)] (1388 cm^{-1}), the position of these bands is near to the frequency of the C=C peaks, respectively, in the dianionic (1435 cm^{-1}) and monoanionic (1390 cm^{-1}) $[Ni(dmit)_2]^{n-}$ complexes.[8b]

Received (in Cambridge, UK) 30th August 2001, Accepted 27th September 2001
First published as an Advance Article on the web 18th October 2001

Liquid-crystalline complexes of Pd(II) allow a new approach to the realisation of the biaxial nematic phase.

In the uniaxial nematic phase (N_u) of liquid crystals, there is no positional order and the unique axes of the molecules are oriented about a director, ***n***. In the *biaxial nematic phase* (N_b) there is, additionally, a correlation of the other molecular axes in a direction perpendicular to ***n*** and so whereas in the N_u phase the physical properties in the plane perpendicular to ***n*** are angle-independent, this is not the case in the N_b phase. Since Freiser's[1] prediction of the existence of an N_b phase, this topic has attracted much interest. Yet despite experimentalists trying to make these predictions come to life, the N_b phase in low-molecular-mass thermotropic liquid crystals remains elusive.

Two main strategies have been developed in the search for the phase. One is based on single-component systems where 'shape biaxiality' is optimised,[2] while the other is suggests that mixtures of two uniaxial nematic phases with non-coincident directors, could lead to the formation of the N_b phase.[3] The latter approach is problematic as such mixtures phase-separate into two uniaxial nematics.

In this communication, we propose a different approach which exploits total *molecular* biaxiality, *i.e.* not simply a shape biaxiality. Thus, we are seeking systems where possibilities for biaxial intermolecular interactions can be built in that lead to the realisation of long-range, orientational correlation in two orthogonal directions.

Fluoro-substitution in thermotropic liquid crystals provides a way of modifying their physical properties.[4,5] Further, the ideas of amphiphilicity and microphase separation are also well-known in liquid crystals,[6] where it is recognised that like parts of a molecule prefer to associate. Indeed, the presence of perfluorocarbon and hydrocarbon chains within the same molecule produces micro-segregation at the molecular level. We wished to use these ideas to design some organopalladium(II) complexes which would, in addition to possessing shape biaxiality, generate localised segregation, so promoting correlations perpendicular to the main nematic director.

The complexes we chose for study are based on the well-known *ortho*-palladated mesogens. We took as our starting point a system described by Espinet and Buey[7] in which dimer **1** is cleaved with the anion of a β-diketonate (Fig. 1). We used trifluoroacetylacetonate (tfac) and obtained the target complex **2** as a 1:1 mixture of isomers as shown by the ^{1}H NMR spectrum.† We were able to obtain single crystals of the dimethoxy derivative (R = R′ = MeO) and found that a single isomer crystallised.‡ However, when the solid-state packing of the molecule was considered, we found that the fluorocarbon parts of the complex remained together (Fig. 2), supporting the approach we were taking.

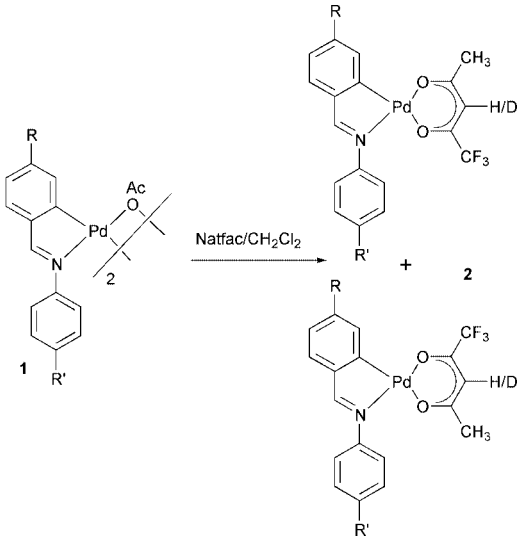

Fig. 1 Synthesis of the target complexes.

While we have made several derivatives of **2**, two are of particular note, namely with R = R′ = $-OC_6H_{13}$ (**2a**) and with R = $-OC_6H_{13}$, R′ = $-C_6H_{13}$ (**2b**). Both showed a monotropic nematic phase [**2a**: Cr • (62.6 • N) • 91.6 • I; **2b**: Cr • (11.7 • N) • 67 • I; temp. in °C]; polarised optical microscopy showed each to have an ill-defined, marbled texture. We then evaluated the thermodynamics of the N–I transition as theory predicts[8] the N_b–I transition to be second order. The enthalpy changes were small [ΔH(**2a**) = 0.20 kJ mol^{-1}; ΔH(**2b**) = 0.17 kJ mol^{-1}] as were the corresponding entropy changes [$\Delta S/R$(**2a**) = 0.075; $\Delta S/R$(**2b**) = 0.072]. It is instructive to compare this behaviour with that of the non-fluorinated analogue of **2a** (*i.e.* prepared using acac) where the N–I transition showed ΔH = 1.0 kJ mol^{-1} and $\Delta S/R$ = 0.30. This significant difference in the $\Delta S/R$ values shows that fluorination causes the transition to become much less strongly first order, providing further evidence supporting our approach.

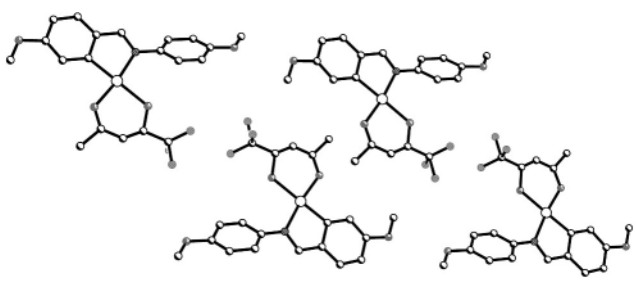

Fig. 2 The packing of **2a** in the solid state.

 DOI: 10.1039/b107775a

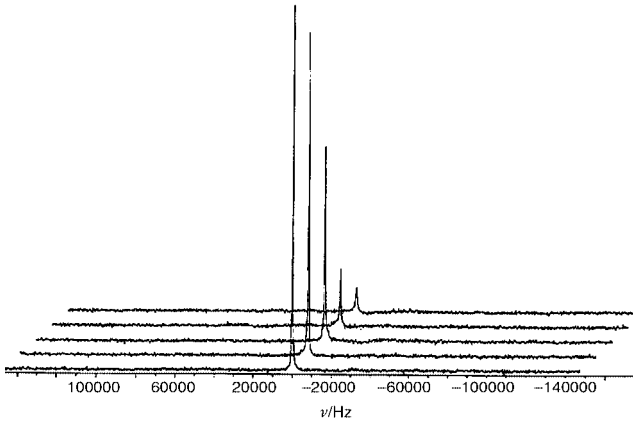

Fig. 3 ^{1}H NMR spectrum of **2a** in the isotropic phase between 365 K (most intense signal) and 335 K (least intense signal).

However, with the biaxial nematic phase, it is characterisation which is at the heart of the question[9] and the one technique which appears to offer unequivocal identification of the N_b phase is ^{2}H NMR spectroscopy.[10] It was, therefore, necessary to introduce deuterium into the complex which we did at the position shown in Fig. 1. Thus, Na^+tfac^- was deuteriated by stirring in CD_3OD–D_2O at room temperature for 4 h before the solvents were removed *in vacuo*. After reaction with **1**, deuteriated **2a** was obtained with 80% deuterium incorporation.

The spectra were measured using a quadrupolar echo sequence, and the sample was brought into the isotropic phase and then cooled slowly; a strong singlet corresponding to the isotropic phase was recorded. However the signal intensity decreased with temperature and 90% of the magnetisation was lost before the nematic phase was reached (Fig. 3). This behaviour normally suggests that the compound is either crystallising or decomposing in the probe, but after the experiment, the sample was checked visually and then by polarised optical microscopy and also by ^{1}H NMR spectroscopy, none of which suggested that either of the two processes had occurred. No definite explanation has yet been given for this experimental observation, although we cannot yet rule out vitrification.

The sample was then further cooled and at the isotropic-to-nematic transition a doublet was observed. The spectra (Fig. 4) showed a small biphasic region and allowed the measurement of the transitional quadrupolar splitting, $\Delta\nu$, even if the signal was rather weak. From the quadrupolar splitting it is possible to calculate S, the order parameter of the long molecular axis and in so doing we made the assumption that the angle between the molecular long axis and the C–D bond was 90°. On calculating values of S, it was found that at the N–I transition, it had a value of 0.105. This compares with typical transition values for a *uniaxial* nematic phase of around 0.35. Note that S is expected to start at zero for a *biaxial* nematic phase if the I → N_b transition is directly at the so-called Landau point. Our results indicate, therefore, a very low order parameter for this nematic phase consistent with the low transitional entropy ($\Delta S/R$), although we cannot say that the phase is biaxial.

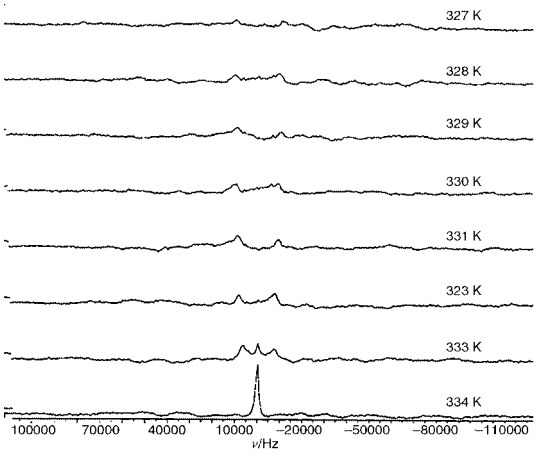

Fig. 4 ^{1}H NMR spectra in the nematic phase.

By comparison, a very similar complex named 'Azpac' (as **2a** but containing an acac ligand and with the imine link replaced by an azoxy function) was studied by ^{2}H NMR spectroscopy some years ago.[11] The deuterons were introduced *via* the aromatic rings of the ligand, here, the order parameter close to the N–I transition was found to be *ca*. 0.4. These results provide further evidence in support of our approach to the generation of biaxial materials.

Further support for this strategy comes from recent results of Monte Carlo simulations by Berardi and Zannoni[12] in which they employed a Gay–Berne potential, modified to enhance side-to-side interactions of Gay–Berne particles. Using this approach, they too were able to stabilise a biaxial nematic phase, although interestingly, when face-to-face interactions were enhanced, a biaxial smectic phase was found. The recent identification[13] of the biaxial SmA phase using such an approach experimentally lends support to their simulations and further lends support to the approach we have identified.

We thank the EU (contract ERBFMRXCT970121), NEDO and the University of Exeter for support (L. O.) and Johnson Matthey for generous loans of precious metal salts.

Notes and references

† All new complexes were satisfactorily characterised by spectroscopic methods and by CHN analysis.

‡ *Crystal data* for **2a**. $C_{20}H_{18}F_3NO_4Pd$, orange block, M_r = 499.75, monoclinic, space group $P2_1/c$, a = 12.8622(12), b = 17.3734(18), c = 8.6466(12) Å, U = 1924.4(4) Å^3, Z = 4, D_c = 1.725 g cm^{-3}, μ = 1.020 mm^{-1}, $F(000)$ = 1000, crystal size 0.07 × 0.05 × 0.05 mm. Data were collected at 150 K, on a Nonius Kappa CCD area detector diffractometer,[14] at the window of a Nonius FR591 rotating anode (λ Mo-Kα = 0.71073 Å). Combined φ and ω scans, frame increment of 2.0°, θ_{max} = 24.00° (index ranges $-14 \leqslant h \leqslant 14$, $-19 \leqslant k \leqslant 18$, $-9 \leqslant l \leqslant 9$). An absorption correction was applied by comparison of multiple and symmetry equivalent reflections, using the program SORTAV[15] (transmission factors = 0.9508/0.9321). A solution was obtained *via* direct methods and refined[16] by full-matrix least squares on F^2, with hydrogens included in idealised positions. 2857 Unique data were produced from 7543 measured reflections (R_{int} = 0.1112). 202 parameters refined to R_1 = 0.1235 and wR_2 = 0.2278 [$I > 2\sigma(I)$] (R_1 = 0.1900 and wR_2 = 0.2482 for all data), with residual electron densities of 1.617 and −0.779 e Å^{-3}. Experimental assessment of lanthanide ion donor preference: spectroscopic and theoretical dissection of static charge and dynamic polarisation contributions to axial ligation in a C_4-symmetric chiral europium complex†

James I. Bruce, David Parker* and David J. Tozer

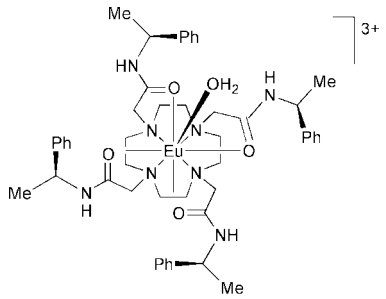
Measurements of the equilibrium constants for ligand exchange (MeCN, 295 K) involving the axial donor in a C_4-symmetric, mono-capped, square antiprismatic cationic Eu complex, supported by calculations based on an electrostatic perturbation model, have been interpreted in terms of a predominant ligand polarisation interaction defined by observation of the hypersensitive $\Delta J = 2$ normalised emission intensity, in association with measurements correlating $\Delta J = 1$ band splitting and ^{1}H NMR dipolar shifts that vindicate Bleaney's theory of magnetic anisotropy.

The correlation of optical and NMR spectral information with the structure of lanthanide complexes in solution has often been frustrated by the extreme sensitivity of the former to apparently minor variations of complex structure.[1,2] Such changes may relate to perturbations in ligand constitution or conformation—thereby defining the local site symmetry and ligand field—or be associated with complex exchange dynamics involving either inter- or intra-molecular processes. The advent of new series of well-defined lanthanide complexes for which intramolecular dynamics and solvent exchange processes are better understood, has afforded an opportunity to clarify this situation.[3] Of particular interest are the series of nine-coordinate lanthanide complexes involving the coordination of C_4-symmetric octadentate macrocyclic ligands, wherein a mono-capped, square antiprismatic coordination environment is adopted. The ninth 'capping' ligand lies along the principal C_4 axis and is susceptible to exchange by other donor ligands.[4] An example is provided by the cationic europium complex (*SSSS*)-[Eu.**1**]$^{3+}$ for



(*SSSS*)-Λ-[Eu.**1**]$^{3+}$

which dynamic NMR, X-ray analysis, CD and CPL spectroscopy have revealed that a dominant species exists in solution, as the Δ-(λλλλ) isomer.[5]† The selection of Eu for study is determined by its favourable spectroscopic characteristics: in emission not only are the $^7F_J \leftarrow {}^5D_0$ spectra the simplest of the paramagnetic lanthanides to interpret, but also the splitting of the two magnetic dipole allowed $\Delta J = 1$ transitions, in C_4 symmetry, is a direct measure of the second-order crystal field parameter, B_2^o.[6] This parameter also determines the dipolar (pseudo-contact) NMR shift in Bleaney's theory of magnetic anisotropy.[7] In axial symmetry, eqn. (1) applies,

$$\delta_{dip} = \frac{-2C_J\beta^2}{(kT)}\left[\frac{3\cos^2\theta - 1}{r^3}B_2^o\right] \quad (1)$$

where $C_J = g^2J(J+1)(2J-1)(2J+3) < J \mid a \mid J' >$. For Eu, analysis of shifted proton NMR resonances that are well-removed from the paramagnetic centre obviates problems associated with any contact shift contribution. Europium emission spectra also provide information on the dipolar polarisability of the ligand donors, by analysis of the hypersensitive $\Delta J = 2$ and $\Delta J = 4$ transitions; the oscillator strength of the $^7F_2 \leftarrow {}^5D_0$ transition is very sensitive to the Eu^{III} coordination environment.[8] However a systematic study of controlled structural variation in a common site symmetry is lacking. With these features in mind, we have measured the equilibrium constant for axial donor exchange with [Eu.**1**]$^{3+}$ in acetonitrile, interpreted changes in the Eu emission and in ^{1}H NMR spectra (CD_3CN, 295 K) and correlated these observations with a simple electrostatic perturbation model.

Addition of eight different oxygen (H_2O, MeOH, $MeNO_2$, DMF, DMSO, pyridine *N*-oxide, HMPA, Ph_3PO) and four nitrogen donors (py, 4-NMe_2py, 4-Mepy, benzylamine) to a solution of [Eu.**1**]$(CF_3SO_3)_3$ in dry acetonitrile (1 mM, 295 K) was monitored by emission spectroscopy. In each case, analysis of the resultant binding isotherms was carried out by a simple least-squares fitting procedure, monitoring changes in the intensity of the $\Delta J = 2$ transition. This allowed an estimate of the free energy change for the ligand exchange process to be determined (Table 1).‡ In addition, ^{1}H NMR spectra were measured at the same concentration of [Eu.**1**]$^{3+}$ (1 mM, 300 MHz, 295 K) adding a sufficient excess of the donor to reach the saturation limit in the corresponding emission spectral analysis. A comparison of ^{1}H NMR hyperfine shifts, in each case, suggested that the complex adopted the same overall structure: the variation with added donor of the shifted ring 'axial', equatorial and diastereotopic NCHH′CO resonances revealed a proportional change (ESI†). That this assumption was valid was corroborated by plotting the chemical shift of the most shifted ring axial proton *vs.* the splitting of the two $\Delta J = 1$ transitions, observed in the corresponding emission spectra. The linearity of this correlation confirms that the observed spectral variations are consistent with an axial donor exchange process in which the site symmetry and overall geometry is conserved. Moreover this correlation vindicates Bleaney's theory[7] demonstrably (Fig. 1).

The ratio of the integrated emission intensities for the $\Delta J = 2/\Delta J = 1$ Eu spectral bands is regarded as a useful parameter that may be used to assess changes in the Eu coordination environment.[1,2,8] The $\Delta J = 1$ transition is magnetic-dipole

† Electronic supplementary information available (ESI) space filling images of [Eu**1**·H_2O], Tables and plots of selected ^{1}H NMR data, emission spectra for [Eu.**1**]$^{3+}$ and examples of least-squares fitting analysis for selected binding isotherms. Table 1 Effect of the axial donor on the difference in free energy[ad] for displacement of MeCN compared to the ratio of emission intensities (ΔJ = 2/ΔJ = 1)[b] for Eu emission and the charges on the donor heteroatom in the absence, q, and presence, q^+, of a point charge at 2.5 Å[c]

Axial donor	ΔG^{295}/kJ mol^{-1}	ΔJ = 2/ ΔJ = 1	q	q^+
$MeNO_2$	< 5.5	0.95	0.04	0.16
MeOH	6.6	1.0	0.13	0.20
H_2O	7.8	0.6	0.20	0.26
DMF	11.7	1.9	0.20	0.31
DMSO	14.3	2.8	0.27	0.41
HMPA	18.8	3.2	0.28	0.42
Pyridine[e]	10.7	1.8	0.08	0.23
4-NMe_2py	15.7	3.5	0.11	0.26
4-Mepy	13.0	1.9	0.09	0.24
Pyridine *N*-oxide[f]	17.9	5.2	0.28	0.41
$C_7H_7NH_2$	13.0	1.8	0.19	0.28
MeCN	0	1.1	0.12	0.28

[a] Estimated by iterative least-squares fitting of the variation of emission intensity (λ_{exc} 616 nm) with the concentration of added donor for a solution of [Eu.**1**]$(CF_3SO_3)_3$ in dry MeCN (1 mM, 295 K). [b] Calculated by integrating the emission spectral intensity of [Eu.**1**] (295 K, λ_{exc} = 397 nm). [c] For $MeNO_2$, only unidentate coordination was considered. [d] It should be appreciated that different entropic contributions to the ΔG values shown are expected for each of the donors shown, as well as differential solvation effects. [e] Sterically hindered pyridines, such as 2,5- and 2,6-lutidine did not bind, nor did a representative simple imine, *N*-benzylidenemethylamine. [f] For triphenylphosphine oxide: J ratio = 3.2 and ΔG = 20.1 kJ mol^{-1}.

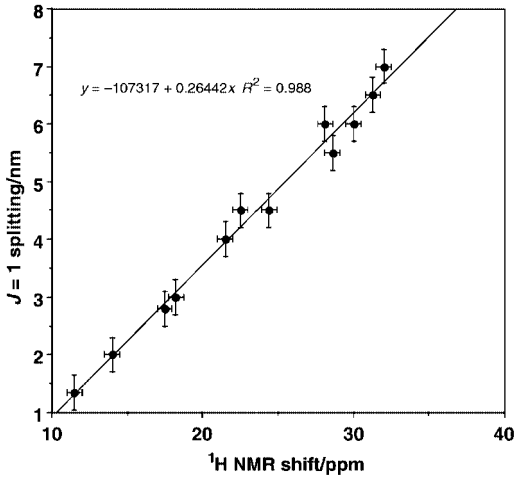

Fig. 1 Correlation of the limiting ^{1}H NMR shift of the most shifted ring axial proton resonance in [Eu**1**]$^{3+}$ (relative to Bu^{t}OH) with the separation of the $A_2 \leftarrow A_1$ and $E \leftarrow A_1$ transitions in the ΔJ = 1 emission bands for eight oxygen and five different nitrogen donors (293 K, MeCN).

allowed and its oscillator strength is generally regarded as being relatively independent of the ligand environment. Values of the ratio are collated in Table 1, and for the oxygen donors in particular, the increases in this ratio correlate quite well with the order of binding affinities (R^2 = 0.91). In the nitrogen donor series, the scope of the analysis was limited by competitive amide de-protonation in strong base, leading to a loss of C_4 symmetry. Nevertheless within the pyridine series, the ΔJ = 2/ΔJ = 1 ratio fell in the order 4-NMe_2py >> 4-Mepy > py consistent with the measured change in binding affinity. In an attempt to rationalise this behaviour, some calculations have been performed using a simple electrostatic model, involving the spatial partitioning of charges on each of the axial donor's atoms. Kohn–Sham density functional theory calculations, using the B97-1[11] exchange-correlation functional and DZP[12] basis set, were performed using the CADPAC[13] program. To reduce the basis set dependence of the calculated charges, each molecule was partitioned into atom centred Voronoi polyhedra,[14] and atomic charges were determined by integrating the charge density within each polyhedron. Calculations were performed at fixed geometries, corresponding to the theoretically optimised structures in the absence of the point charge. These values are given in Table 1 both for the charge on the ligating O or N atom for the isolated molecule in the gas phase (q) and in the presence of an arbitrary (polarising) single point charge (q^+) held 2.5 Å from the ligating donor. The donor atom was oriented towards the putative charge along its stereoelectronically preferred coordination vector. For the oxygen donors, the variation of q^+ followed the sequence of donor affinity (as measured by ΔG for exchange of MeCN) quite closely (R^2 = 0.93), whereas the correlation with q was significantly less good (R^2 = 0.8).

In conclusion, these measurements have allowed a unique assessment of donor atom preference in binding to a typical lanthanide ion. To the extent that the overall binding affinities of the donors examined do *not* correlate with Gutmann's donor number[9] (based on an $SbCl_5$ interaction) nor with Maria and Gal's alternative parameter[10] (based on donation to BF_3), such data could also be considered as the basis for an alternative measure of Lewis basicity, in which there is a dominant contribution from ligand polarisation. Indeed the experimental ΔJ = 2/ΔJ = 1 intensity ratio in complexes of [Eu.**1**]$^{3+}$ with differing axial donors may serve as a useful basis for such an analysis.

We thank EPSRC for support.

The nature of the active species in bis(imino)pyridyl cobalt ethylene polymerisation catalysts

Vernon C. Gibson,* Martin J. Humphries, Kilian P. Tellmann, Duncan F. Wass†, Andrew J. P. White and David J. Williams

Department of Chemistry, Imperial College of Science, Technology and Medicine, Exhibition Road, South Kensington, London SW7 2AY, UK

Received (in Cambridge, UK) 20th August 2001, Accepted 14th September 2001
First published as an Advance Article on the web 10th October 2001

Studies on cobalt ethylene polymerisation catalysts bearing bis(imino)pyridine ligands strongly indicate that the activated species is not the anticipated cobalt(II) alkyl cation.

In recent years there has been much interest in late transition metal olefin polymerisation catalysts. Recently, Brookhart and Bennett, and ourselves have independently reported highly active polymerisation[1] and oligomerisation[2] catalysts based on iron and cobalt bearing bis(imino)pyridyl ligands. The activity of the cobalt polymerisation catalyst family, whilst approximately an order of magnitude less than that for their iron relatives, is nevertheless highly respectable for late transition metal olefin polymerisation catalysts. However, the natures of the active sites in both the iron and cobalt systems remain little understood. Here, we report our preliminary findings on the cobalt system.

The activation of the pre-catalyst [$LCoCl_2$] **1** {L = 2,6-[CMe=N(2,6-$C_6H_3Pr^i_2$)]$_2C_5H_3N$} with methylaluminoxane (MAO) produces an initial colour change from yellow–brown to claret, with a subsequent colour change to blue. Addition of ethylene to this solution causes a colour change to aquamarine, concomitant with the onset of polymerisation.[1] An interesting observation is that if the activation with MAO is performed under an argon atmosphere as opposed to dinitrogen, the resulting solution is purple. If this solution is degassed and dinitrogen is then admitted the colour of the solution changes to blue. Degassing returns the original purple colour. Thus the activated species appears to be capable of reversibly binding dinitrogen.

The well-established mode of activation of both early and late transition metal systems [*e.g.* group 4 metallocenes and Ni(α-diimine) catalysts] involves, *via* the action of MAO, the transformation of a metal dihalide fragment L_nMCl_2 into an alkyl cation $[L_nM–R]^+$. If this activation pathway is followed by the cobalt catalyst family, a 15-electron cobalt alkyl cation of the type $[LCoMe]^+$ would be anticipated. Indeed, calculations have been reported based on cationic alkyl species of this type being the active centres.[3] We attempted to synthesise the dimethyl complex [$LCoMe_2$] in order to access a well defined analogue of this hypothesised cobalt(II) alkyl cation. However, the reaction between **1** and methyl Grignard reagents (Scheme 1) affords the reduced species [LCoMe] **2**.

This led us to investigate the reduction of **1** by other means. Clean reduction to the cobalt(I) chloride [LCoCl] **3** is achieved upon reaction of **1** with a suspension of zinc powder in toluene at 50 °C. Both **2** and **3** are claret in colour, and, as with all other cobalt(I) species reported in this study, are highly air- and moisture-sensitive. They are readily oxidised by most chlorinated solvents and other oxidising agents.

The activation of **2** or **3** with MAO affords a blue solution, which also becomes aquamarine on the addition of ethylene to the flask, colour changes that are similar to those observed upon treatment of **1** with MAO. **1–3** all yield identical polyethylene (mol. wt, PDI) when activated with MAO; the same active species thus appears to be present in each case. These observations lead us to conclude that the species produced upon activation of these procatalysts with MAO is a cobalt(I) species rather than cobalt(II).

The addition of ethylene to a sample of the cobalt(I) methyl species **2** in toluene does not lead to the formation of polymer, nor does its NMR spectrum change; **2** is, therefore, not a polymerisation-active species.‡ The addition of Al_2Me_6 does not activate **2** towards ethylene polymerisation, nor does it cause any colour change, thus a stronger Lewis acid (*e.g.* MAO) appears to be required for activation of the catalyst. As a potential model for the activation process, **2** was treated with the Lewis acid $B(C_6F_5)_3$. This afforded a royal blue solution of $[LCo(N_2)][MeB(C_6F_5)_3]$ **4**, thus providing a clue as to the nature of the second colour change in the reaction of **1** with MAO.

Molecular structures of the cobalt(I) species **3**§ and **4**§ have been determined. They are closely related, having approximate C_{2v} symmetry about an axis passing through the pyridyl nitrogen and the cobalt centre (complex **4** is depicted in Fig. 1). In both structures the metal coordination plane extends to include the ligand backbone [from C(11) through C(4) to C(23)], the maximum deviation from planarity being 0.025 Å in **3** and 0.080 Å in **4**. The 2,6-diisopropylphenyl ring systems are in both complexes oriented approximately orthogonally to the coordination plane (by between 82 and 88°). There are no significant differences between the equivalent Co–N bonds to the tridentate ligand in the two structures, or in the C=N double bond lengths. To our knowledge there are no structurally characterised square planar cobalt complexes bearing three nitrogen donors with either a chloride or a dinitrogen ligand in the fourth coordination site reported in the literature. The Co–

Selected bond lengths (Å) and angles (°) for **4**; Co–N(1) 1.812(3), Co–N(7) 1.915(3), Co–N(9) 1.908(3), Co–N(35) 1.841(3), C(7)–N(7) 1.303(5), C(9)–N(9) 1.303(5), N(35)–N(36) 1.112(6); N(1)–Co–N(7) 81.67(12), N(1)–Co–N(9) 81.68(12), N(1)–Co–N(35) 178.3(2), N(7)–Co–N(9) 163.31(12), N(7)–Co–N(35) 98.23(14), N(9)–Co–N(35) 98.44(14), Co–N(35)–N(36) 175.4(5). For **3**; Co–Cl 2.1807(10), Co–N(1) 1.797(3), Co–N(7) 1.916(3), Co–N(9) 1.912(3), C(7)–N(7) 1.317(5), C(9)–N(9) 1.322(5); Cl–Co–N(1) 179.15(10), Cl–Co–N(7) 98.89(9), Cl–Co–N(9) 98.17(9), N(1)–Co–N(7) 81.35(14), N(1)–Co–N(9) 81.58(14), N(7)–Co–N(9) 162.92(12).

N_2 bond length in **4** is comparable to those observed in tetrahedral cobalt species. In **4** the shortest anion···cation contact is an approximately orthogonal approach of 2.93 Å of one of the pentafluorophenyl fluorine atoms to the pyridyl nitrogen atom. The closest approach of a fluorine atom to the cobalt centre is 3.5 Å.

The addition of ethylene to a toluene solution of **4** causes a colour change to aquamarine, and polymer is formed, although only with low activity (11 g $mmol^{-1}bar^{-1}h^{-1}$). The addition of 10 equiv. of Al_2Me_6 as co-catalyst increases the activity by an order of magnitude (96 g $mmol^{-1}\,bar^{-1}\,h^{-1}$); the resultant polyethylene is identical in molecular weight and molecular weight distribution to that produced by the MAO activated system.

An important question then concerns how the propagating species is formed from **4**. The diamagnetic nature of the cobalt(I) bis(imino)pyridyl system makes it amenable to study by NMR spectroscopy. One useful feature of the ^{1}H NMR spectra is that the chemical shifts of the ligand resonances vary considerably depending on the nature of the substitution at the cobalt centre. The ketimine methyl resonance is particularly sensitive in this respect, with the singlet being observed at δ −1.14 in **2**, δ 0.05 in **3** and δ 1.11 in **4**, a trend which appears to correlate with the electrophilicity of the cobalt centre.

A study of the pre-catalyst **4** by ^{1}H NMR spectroscopy showed that addition of 1 equiv. of ethylene afforded a species identifiable by its ^{1}H NMR spectrum as the ethylene adduct $[LCo(\eta\text{-}C_2H_4)][MeB(C_6F_5)_3]$ **5**. The ketimine signal now occurs at δ 0.73, and a singlet resonance assignable to bound ethylene is present at δ 4.65 (*cf.* δ 5.32 for free ethylene). The ethylene is only weakly bound; if more ethylene is added to the NMR tube then rapid exchange between free and bound ethylene occurs, resulting in an averaged chemical shift for the ethylene hydrogens. The ethylene can be seen to be consumed, with polymer forming on the walls of the NMR tube. At the end of the polymerisation, **5** remains.

There are several conclusions that can be drawn from these observations. Firstly, the species that is initially formed upon activation, and thus the species from which the initation of polymerisation must occur, is a cobalt(I) cation, a species that contains *no* cobalt–C(alkyl) bond. Secondly, the aluminium co-catalyst appears to perform three functions: (i) to reduce the cobalt(II) pre-catalyst to cobalt(I), (ii) to form the cobalt(I) cation by chloride or methide group abstraction (MAO), and (iii) to enhance the stability of the catalyst, and/or the rate of polymerisation. The manner in which polymerisation is initiated from the cobalt(I) cation is currently unclear. One possibility is the reaction of a bound ethylene with a Lewis acid {*cf.* the activation of $[Cp_2Zr(butadiene)]$ by $B(C_6F_5)_3$[4]} to give a zwitterionic cobalt(III) complex. Another possibility is oxidative coupling of two molecules of ethylene to afford a cobaltacyclopentane species, analogous to the commonly postulated active site of the Phillips chromium catalyst system.[5] A third possibility is C–H σ-bond activation of the bound ethylene to afford a cobalt(III) vinyl hydride species, a reaction which has precedence in the chemistry of the group 9 metals.[6] For the first two possibilities it is less clear how **5** would be regenerated during the polymerisation. A common outcome of all of these processes, however, is the oxidation of the cobalt(I) precursor to cobalt(III). Thus, in accord with findings on other cobalt polymerisation systems,[7] and the apparent inactivity of LCo(I)R species, we err in favour of the active species being cobalt(III). Investigations into these possibilities, and other aspects of the chemistry of the cobalt system, will be reported in due course.

BP Chemicals Ltd is thanked for financial support. Dr J. Boyle and Dr G. Audley are thanked for NMR and GPC measurements, respectively.

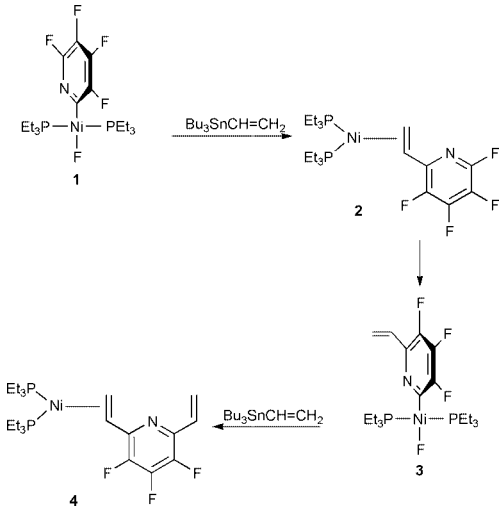
The cross-coupling reaction of pentafluoropyridine with tributyl(vinyl)tin affording 2-vinyltetrafluoropyridine by activation of a carbon–fluorine bond is catalysed by [NiF(2-C_5NF_4)(PEt_3)$_2$]; a similar reaction is observed with 2,3,5,6-tetrafluoropyridine.

A variety of methods of activating carbon–fluorine bonds by transition metal centres have been established in the last two decades.[1] However, the formation of new organofluorine compounds *via* C–F activation, followed by functionalisation within the coordination sphere of the metal is still little developed. Nevertheless, catalytic C–F activation has become a reality.[2] Catalytic cycles include the conversion of hexafluorobenzene into pentafluorobenzene and the silylation of pentafluoroacetophenone using rhodium catalysts.[3,4] In the zirconium-initiated oligomerisation of hexafluorobenzene new C–C bonds are formed in addition to the cleavage of C–F bonds.[5] The nickel-mediated cross-coupling of fluorobenzene with ^{i}PrMgCl has also been reported.[6] In this communication we present the first cross-coupling reactions that generate polyfluorinated aromatic compounds by C–F activation. We show that 2,3,5,6-tetrafluoropyridine and pentafluoropyridine can be converted catalytically into the previously unknown 2-vinylfluoropyridine derivatives by cross-coupling reactions. Fluorinated pyridines are of current interest as building blocks in pharmaceuticals, agrochemicals and dyes.[7]

Reaction of $Ni(cod)_2$ with PEt_3 in the presence of pentafluoropyridine yields *trans*-[NiF(2-C_5NF_4)(PEt_3)$_2$] **1**.[8] Treatment of a solution of **1** with $Bu_3SnCH{=}CH_2$ at room temperature results in the slow formation of three products **2**–**4** identified by NMR spectroscopy including ^{1}H–^{1}H and ^{19}F–^{19}F COSY measurements. The ^{31}P NMR spectrum of [Ni{η^2-2-C_5NF_4(CH=CH_2)}(PEt_3)$_2$] **2**, the initial product, exhibits two mutually coupled doublets (J_{PP} = 34 Hz) as found for [Ni{η^2-C_6F_5(CH=CH_2)}(PEt_3)$_2$].† [8] After 1 d of reaction, two further compounds are observed. The ^{19}F and ^{31}P NMR data of these compounds are compatible with their assignment as **3** and **4** (Scheme 1).‡ [8] The ^{19}F NMR spectrum of **3** shows a triplet at δ −367.46 (J_{PF} 47 Hz) characteristic of the metal-bound fluorine.[9] The fluorine ligand is also revealed by a doublet resonance at δ 13.6 (J_{PF} 48 Hz) in the ^{31}P NMR spectrum for the two equivalent phosphorus nuclei. The assignment as a 2-pyridyl nickel derivative is based on the presence of three additional fluorine signals in the ^{19}F NMR spectrum at δ −129.88, −159.78, −163.34. The spectrum shows no signal at *ca.* δ −80, which would be indicative of a fluorine in the *ortho* position to the nitrogen.[8] The ^{31}P NMR data of **4** resemble those for **2**. A ^{1}H–^{31}P COSY NMR spectrum measured at 233 K shows a correlation between the resonance for the olefinic proton at δ −3.58 and the signal in the ^{31}P spectrum at δ 24.4. Treatment of a reaction solution containing **2** as major product with pentafluoropyridine **5** and PEt_3 in the presence of Cs_2CO_3 affords small amounts of free 2-vinyltetrafluoropyridine **6**, which has not been described previously.§ Compound **6** was removed by distillation *in vacuo* and reacted with $Ni(cod)_2$–PEt_3 providing an alternative route to **2**.



Scheme 1 Reaction of **1** with $Bu_3SnCH{=}CH_2$.

Encouraged by these observations and other stoichiometric coupling reactions which we reported recently,[10] we turned our attention to catalytic cross-coupling methods for the synthesis of **6** (Scheme 2).¶ The coupling of pentafluoropyridine **5** with $Bu_3SnCH{=}CH_2$ in the presence of a nickel catalyst, phosphine and Cs_2CO_3 was investigated. Representative results are summarised in Table 1. The best result is obtained with **1**–PEt_3–Cs_2CO_3 as the catalytic system giving a TON (turnover number) of 4 based on the formation of **6**. All the reactions gave the coupling product **6** together with considerable amounts of 2,3,5,6-tetrafluoropyridine **7**. According to the GC-MS, there were also traces of 4-vinyltetrafluoropyridine, 2-vinyl-3,5,6-trifluoropyridine **8** and 2,6-divinyltrifluoropyridine in the product mixture. We did not observe any significant change in the activity of the catalysts by altering the solvent (NMP, DME, DMF, 1,4-dioxane, benzene) or base (Na_2CO_3, K_3PO_4). The effect of cyclooctadiene or a weakly coordinating alkene such as 3-trifluoromethylstyrene is also negligible. Base may be needed to trap small amounts of HF, formed in side reactions.[12] In a control experiment we discovered that **7** is also formed from PEt_3 and pentafluoropyridine without adding the catalyst and $Bu_3SnCH{=}CH_2$. The concomitant generation of phosphoranes

indicates that formation of **7** might proceed *via* a phosphonium salt.[11]

The formation of traces of 2-vinyl-3,5,6-trifluoropyridine **8** during the reaction suggested that a similar conversion could be obtained by employing **7** as the starting fluoropyridine in place of **5**. In addition the reaction should be cleaner as competing reactions in position 4 might be avoided. Indeed, **7** can be converted selectively into its vinyl derivative **8** in the presence of **1** as catalyst with a TON of 5.¶‖ There is no indication of the formation of trifluoropyridines or of C–H activation, which would lead to 4-vinyltetrafluoropyridine. However, there were also traces of 2,6-divinyl-3,5-difluoropyridine and 2,6-divinyl-trifluoropyridine in the product mixture. The generation of the latter compound can be explained by the use of **1** as catalyst.

The formation of **6** is of special interest since it is very difficult to prepare tetrafluoropyridines substituted in the 2-position.[10,13] We believe that precoordination of pentafluoropyridine at the nickel centre is likely to be a crucial step in the activation of the carbon–fluorine bond, controlling the regioselectivity for attack at the 2-position.[13,14]

In conclusion, we have demonstrated the first catalytic C–C coupling reactions involving C–F activation of a polyfluorinated molecule. While cross-coupling reactions of arylchlorides have been studied extensively, no examples of cross-coupling of polyfluorinated aromatics *via* C–F cleavage had been described.[15] We have shown that the scope of these reactions can be expanded to the activation of a carbon–fluorine bond using a nickel catalyst. The cross-coupling is likely to proceed *via* the formation of **2**–**4** which were observed during stoichiometric reactions. Such a mechanism is fully consistent with the intermediates observed by Espinet *et al*. in their recent study of the mechanism of Stille coupling of C_6F_5OTf.[16]

We would like to acknowledge the EPSRC and the Deutsche Forschungsgemeinschaft (grants BR-2065/1-1 and BR-2065/1-2) for financial support. T. B. also thanks Professor P. Jutzi for his generous support.

Two different one-dimensional structural motifs in the same coordination polymer: a novel interpenetration of infinite ladders by bundles of infinite chains

Md. Badruz Zaman,† Mark D. Smith and Hans-Conrad zur Loye*

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, USA. E-mail: zurloye@sc.edu

Received (in Cambridge, UK) 12th July 2001, Accepted 11th September 2001
First published as an Advance Article on the web 5th October 2001

A coordination polymer with a novel structural motif consisting of stacks of infinite ladders interpenetrated by bundles of infinite chains is described; geometrical arguments are made for the requirements that can lead to such interpenetration as a function of ligand dimensions.

To date, a large number of one-, two- and three-dimensional infinite frameworks, such as helical, brick wall, ladder, honeycomb, square grid, parquet, diamondoid and more complex 3D connectivities have been generated from tetrahedral, trigonal, and octahedral metal templates in combination with linear and nonlinear bidentate spacers.[1–3] Product topology can often be influenced by selecting the coordination geometry of the metals and the chemical nature of the organic ligands. In particular, the T-joint building block, defined by the coordination of a metal center by three *N*,*N*′-bidentate ligands, has given rise to several isomeric framework types *via* different orientation of the T-joints relative to one another.[4–6]

While different structural isomers can form from T-shaped building blocks, and while it is not unusual to find multiple structural isomers within the same batch of crystals,[4,7] it is quite rare to find two structural motifs within the same crystal structure.[8–11] The use of the long ligand 1,4-bis[(4′-pyridylethynyl)benzene] (**1**)[12] has led to the formation of a highly unusual interpenetrated network in [Cu(**1**)(solv)$(NO_3)_2$] [Cu$(\mathbf{1})_{1.5}(NO_3)_2$]·2solv (solv = solvent; EtOH for **2** and MeOH for **3**) where two dissimilar motifs co-exist in the same structure: stacks of infinite ladders of composition [Cu$(\mathbf{1})_{1.5}(NO_3)_2$] are interpenetrated by infinite chains of composition [Cu(**1**)(solv)$(NO_3)_2$].

A blue solution of $Cu(NO_3)_2{\cdot}3H_2O$ (12.2 mg, 0.05 mmol) in ethanol and/or methanol (3 mL) was carefully layered onto an ethanol and/or methanol (3 mL) solution of 1,4-bis[(4′-pyridylethynyl)benzene] (14.4 mg, 0.05 mmol). Light green precipitates formed immediately. After two weeks, green crystals of **2** and **3** grew at the interface of the two layers and also at the top of the mixture. Single crystals suitable for X-ray analysis were isolated and their structures determined.‡

The one-dimensional ladders are composed of T-shaped building blocks with the copper center in a five-coordinate trigonal bipyramidal environment (Fig. 1a) consisting of three pyridyl nitrogen donors (two axial and one equatorial), one from each of the three ligands, **1**, and two equatorial oxygen donors from two monodentate nitrate ions. The ladders stack in a terraced fashion with an offset of 1/2 the ladder width along the crystallographic *a*-axis and with a close intralayer separation of 6.1 Å.[13] The one-dimensional chains (Fig. 1b) also feature five-coordinate copper, but now in a square pyramidal coordination environment, with the basal plane consisting of two pyridyl nitrogen donors, from two *trans* ligands of **1**, and two oxygen donors from two monodentate nitrate ions. The apical site is occupied by an oxygen donor from a coordinated ethanol (**2**) or methanol (**3**) solvent molecule.

We can consider the ladder to be a 'double-chain', formed *via* the crosslinking of two chains by the ligand, **1**. The square opening is divided into two infinite rectangular channels by the ladders located above and below. These channels in turn are occupied by the single-chains, as shown schematically in Fig. 2, such that the chains fill the square openings in bundles of four. Further supramolecular interactions exist between the two structural motifs in the form of weak O–H···O hydrogen bonds between the coordinated solvent in the chains and the nitrate ions in the ladders (O–O distance = 2.72 Å for **2** and 2.75 Å for **3**). The interpenetration of stacks of ladders by bundles of chains together with the hydrogen bonding between the two distinct one-dimensional structural motifs combine to form the virtual three-dimensional frameworks of **2** and **3**.

It is interesting to note that this structural motif has not previously been observed, a fact that can be accounted for by the geometrical requirement of this double motif. The square openings between the rungs must be large enough to accommodate a bundle of four chains arranged in a 2×2 pattern. With the proviso that both the ladder and the chains that fill the ladder are constructed from the same ligand/metal pair, then the ligand (plus metal bonds) length-to-diameter ratio must fall within a fairly narrow size regime. A simple geometrical argument using space-filling models indicates that a length-to-diameter ratio of 3 : 1 would allow 4 chains to exactly occupy the opening in the ladder. Since in the structures of **2** and **3**, the chains pass through two ladders offset by 1/2, a ratio of 4 : 1 (a loose fit in the ladder

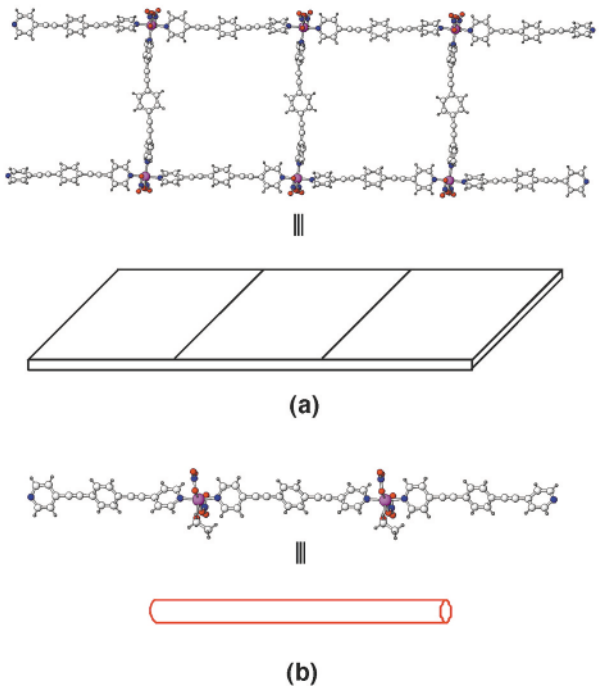

Fig. 1 Perspective view (top) and schematic representation (bottom) of a single (a) ladder motif and (b) chain motif in compounds **2** and **3**.

direction and an exact fit in the direction incident to the ladder) is required to allow for the space blocked by the second ladder. The experimentally determined ratio for both **2** and **3** is approximately 4.2 : 1. (The Cu–Cu distance is 20.4 Å while the approximate van der Waals diameter of the ligand (**1**) ranges from 3.40 Å at the most narrow to 6.43 Å at the widest point– yielding a crude 'average' vdW radius of 4.9 Å.)

Interestingly, one might have expected that shorter ligands such as 4,4′-bipyridine, which have been used extensively in the past, would have resulted in the discovery of a 1 × 1 pattern.[8] This would necessarily consist of parallel stacks of ladders without an offset. The fact that this has not been observed suggests that such a structural motif may require some hydrogen bonding between ladders for added stability. Offset systems, as described in this paper, allow for a virtual three-dimensional structure with, apparently, enhanced stability. By extension, longer ligands might form ladders and/or square grids that are interpenetrated by bundles of 9 or 16 chains in 3 × 3 or 4 × 4 patterns, respectively, with ladder offsets of 1/3 and 1/2 (or possibly 1/4). Such structures would require length-to-diameter ratios of at least 6 : 1 and 8 : 1 for 3 × 3 and 4 × 4 patterns, respectively (Fig. 3). Assuming that the 'average' vdW diameter of a typical unencumbered N,N′-bidentate ligand is ~5 Å, the lengths of the requisite ligands (assuming a 2 Å nitrogen–metal distance) would have to be ~26 and ~36 Å, respectively. (The fact that the rings in the ligand result in a 'plank-like' rather than a true 'spherical' shape should be an advantage for this type of offset structure.)

It is likely that the driving force for the formation of this type of interpenetration is the need to fill empty space in the structure. Typically, as suggested by Batten and Robson,[14] longer ligands will lead to more highly interpenetrated structures. The structural motif described in this communication fulfils that suggestion, however, not by using a self-interpenetrated structure, but rather by using two different structures, *i.e.* ladders and chains, that interpenetrate.

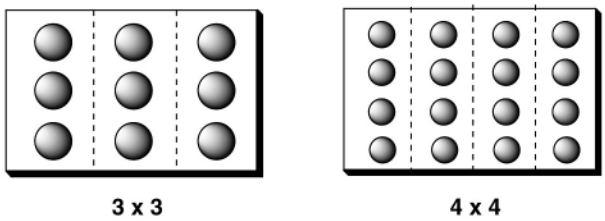

Fig. 3 Schematic representation of 3 × 3 and 4 × 4 bundles interpenetrating a stacked ladder structure. Chains (shaded circles) are running through the stacked ladders where dashed lines indicate the lateral offset of the ladders, 1/3 and 1/4, respectively.

Inorganic–organic interpenetrating frameworks: 4,4′-bipyridine *N*,*N*′-dioxide as a bridging hydrogen-bond acceptor

Alexander J. Blake,* Matthew T. Brett, Neil R. Champness,* Andrei N. Khlobystov, De-Liang Long, Claire Wilson and Martin Schröder*

School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: Neil.Champness@nottingham.ac.uk; M.Schroder@nottingham.ac.uk; A.J.Blake@nottingham.ac.uk

Received (in Cambridge, UK) 17th July 2001, Accepted 3rd September 2001
First published as an Advance Article on the web 11th October 2001

4,4′-Bipyridine *N*,*N*′-dioxide (L) acts as a hydrogen-bond acceptor in the compounds {[$M(NO_3)_2(H_2O)_4$]·L_2} (M = Co, Ni) to form doubly-interpenetrated framework materials with sixfold topological connectivity.

Developments in inorganic crystal engineering strategies comprise two major themes, coordination polymer construction[1,2] and the use of hydrogen-bonding between suitable building-blocks.[2,3] The employment of these approaches has led to the development of many unusual materials with extraordinary topological features such as interpenetration.[4] Although these themes can be viewed as quite distinct, they are highly interdependent and should not be considered as distinct approaches to crystal engineering. We have reported recently a range of highly unusual lanthanide coordination polymers using 4,4′-bipyridine *N*,*N*′-dioxide (L) as a bridging ligand,[5,6] and have also demonstrated the versatility of this ligand with d-block metal ions in which four distinct bridging modes, including H-bonding, have been observed in a single framework.[7] L can act as a hydrogen-bond acceptor *via* the N-oxide moiety and thus offers the potential to act as a H-bonding bridge between two H-bond donor building-blocks.[8] In this respect L can be thought of as an antithetic building-block compared to the 4,4′-bipyridinium cation which has been used so elegantly by Orpen and coworkers[9] to bridge halometallates by acting as a H-bond donor (Scheme 1). We now report the use of L to construct three-dimensional H-bonded arrays by linking simple aquo–metal complexes.

Mixing of L with $M(NO_3)_2$ (M = Co, Ni) in aqueous solution affords a single crystalline product following addition of EtOH to the reaction mixture as an antisolvent after *ca.* 5 days. Characterisation of this product confirms the 2 : 1 stoichiometric co-crystallisation of L and the aquated metal ions to afford species of formula {[$M(NO_3)_2(H_2O)_4$]·L_2} (M = Co **1**, Ni **2**). To fully understand the H-bonding role of L and the structural topology of the products single-crystal X-ray structural determinations were carried out for **1** and **2**.† L acts as a H-bond acceptor with eight molecules of L forming O–H···O[N(L)] H-bonds with all eight H-atoms of the four metal-coordinated water molecules (Fig. 1). However, each N-oxide unit acts as a bifurcated acceptor adopting H-bonds to two different water molecules coordinated to independent metal centres (Fig. 2). This results in each [$M(NO_3)_2(H_2O)_4$] unit being bridged by four molecules of L to a further metal-bearing fragment forming a $R^4_4(16)$ H-bonded ring. Thus, each molecule of L bridges a total of four different metal nodes[10] *via* OH···O[N(L)] H-bonds affording a structure of complex topology in which each [$M(NO_3)_2(H_2O)_4$] moiety is linked *via* bridging molecules of L to fourteen further metal-bearing units. This description does not aid structural interpretation and we prefer a view of the structure considering a virtual node positioned centrally between metal centres linked *via* the $R^4_4(16)$ H-bonded ring (Fig. 2). By using this virtual node the structure can be viewed as a network in which (4,4) nets of H_2O-linked L are pillared by [$M(NO_3)_2(H_2O)_4$] units affording a 6-connected net of ReO_3-like topology. In **1** and **2** the large separation between metal centres [13.65 **1**, 13.66 Å **2** (*cis* to bridging L), 15.24 **1**, 15.21 Å **2** (*trans* to L)] allows interpenetration to occur (Fig. 3) thus affording a doubly interpenetrated framework. Six-connected nets of ReO_3 topology based upon coordinate bonds[11] or a

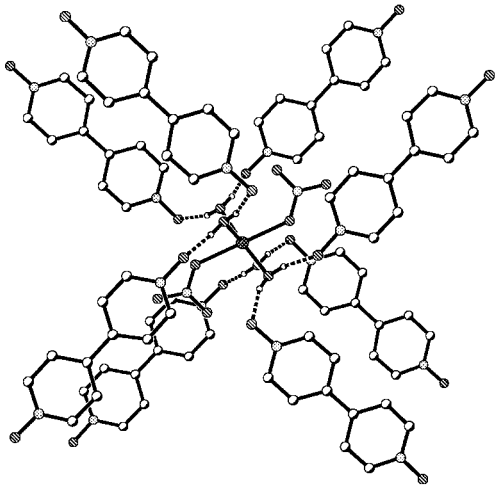

Fig. 1 O–H···O[N(L)] H-bonding observed between each [$M(NO_3)_2(H_2O)_4$] node and eight different molecules of L in **1** and **2**.

 DOI: 10.1039/b106348k

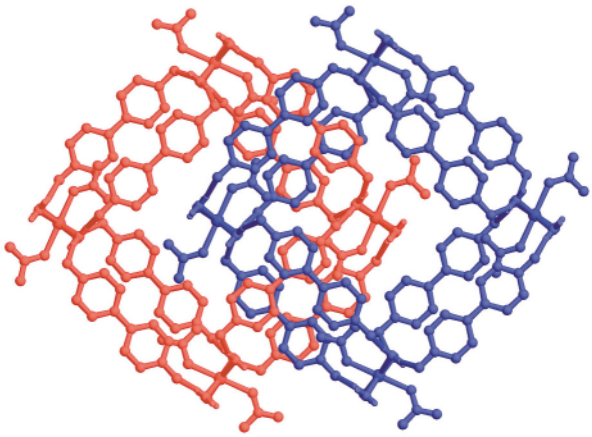

Fig. 3 Double interpenetration of six-connected hydrogen-bonded frameworks observed in **1** and **2**.

combination of H-bonds and coordinate bonds[12] have been observed to exhibit double-interpenetration previously but in only two previous examples has it been based exclusively on H-bonding.[13] The beauty of the current system is its simplicity and the potential for application to a vast range of H-bonded networks due to the large variety of metal–aquo complexes available. **1** and **2** are isotopological and both compounds crystallise in high symmetry (tetragonal) space groups.

The crystallisation conditions are crucial for the successful preparation of the H-bonded frameworks in **1** and **2**. By reacting L with $Co(NO_3)_2{\cdot}6H_2O$ in MeOH, L is sufficiently competitive as a ligand for the metal centre, in the absence of a large excess of water, such that no aquo ligands are coordinated to the metal centre, but only *N*-oxide donors. Structural characterisation by single crystal X-ray diffraction studies† reveals that the product formed exists as a discrete molecular unit, $[Co(L)_6](NO_3)_2$ **3**, in which each metal centre is coordinated by six, independent molecules of L. Each of these ligands coordinates *via* only one of its N-oxide donors leaving the other end of each ligand to engage in π–π interactions with other molecules of L in the solid-state to afford a two-dimensional (3,6) net.[7]

We have shown that L can be used to construct H-bonded frameworks by co-crystallisation with metal–aquo complexes. The large variety of metal–aquo complexes means that the H-bonding synthon reported here has potential for the construction of many new framework families such as that observed in **1** and **2**. We have also demonstrated that by using a coordinating NO_3^- anion we can control the connectivity at the metal-containing H-bonding fragment, thus determining the framework topology. We are currently exploring the variation in anion and metal centre coordination geometries for the construction of new families of H-bonded framework materials.

This work was supported by the EPSRC (UK) and the University of Nottingham.

Combined interaction of triple hydrogen bonding, dipolar π–π aggregation and micro-segregation in a melamine–barbituric acid dye assembly leads to a columnar mesophase which could be characterized by optical polarising microscopy, differential scanning calorimetry and X-ray diffraction.

The ditopic triple hydrogen bonding motif offered by *N*,*N*′-dialkylmelamines has been applied for the construction of numerous supramolecular architectures.[1–10] Recently we showed that complementary hydrogen bonding to dyes bearing imide functional groups can lead to nano- and mesoscopic assemblies which exhibit luminescence and chiroptical properties.[9,10] In these systems long alkyl chains at the melamine amino groups provide the capability to solubilise even little soluble pigment dyes by means of directional hydrogen bonds which are especially strong in low-polarity solvents. However, upon heating, such weak complexes often disassemble leading to precipitation of insoluble materials. In this communication we introduce the new and easily accessible ditopic melamine **3** bearing a much higher amount of alkyl chains which proved to be well-suited to induce stable thermotropic liquid-crystallinity upon self-assembly with a barbituric acid merocyanine dye.

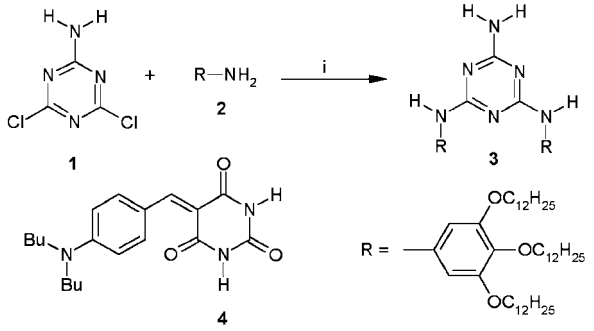
Melamine **3** is easily available according to Scheme 1 from 2-amino-4,6-dichlorotriazine **1** and tridodecyloxyaniline **2**.†

If a stoichiometric mixture of **3** and merocyanine dye **4** is dissolved in chloroform an amorphous solid is obtained after evaporation (**3·4**). This solid melts at 164 °C. Upon cooling the texture shown in Fig. 1 appears at 151 °C which remains unchanged upon further cooling to room temperature, according to optical polarising microscopy (OPM, Fig. 1).

Further heating–cooling cycles between −30 and 180 °C (DSC, 10 K min^{-1}) showed exclusively the peaks corresponding to the transition between the liquid crystalline and the isotropic phase at 161 °C (ΔH = 4.2 J g^{-1}) upon heating and at 151 °C (ΔH = −4.0 J g^{-1}) upon cooling, confirming the enantiotropic nature of the LC phase and its persistence even at low temperature. XRD studies of the LC phase revealed three Bragg reflections in the small angle region at 2θ = 2.43, 3.61 and 5.02° (CuK_α) corresponding to layer spacings of d = 36.3, 24.5 and 17.6 Å and a diffuse halo in the wide-angle region corresponding to 4–5 Å arising from disordered alkyl chains. The position of the small angle reflections exclude a smectic layer structure. As there are no references to a hexagonal or rectangular 2D lattice we evaluated the pattern under the assumption of an oblique two-dimensional lattice, assigning the observed reflections to (10), (01) and (11) and obtained the lattice parameter a = 38 Å, c = 26 Å and β = 110°.

A hydrogen-bonded circular rosette-type assembly[11] can clearly be ruled out by the small lattice parameters, which are not even sufficient to accommodate the aromatic part (diameter 44 Å) of such an extended architecture. On the other hand, the formation of a columnar mesophase from triple hydrogen-bonded tapes as suggested by Scheme 2 is fully consistent with the X-ray data.

According to Scheme 2 triple hydrogen-bonding, dipolar π–π aggregation and microphase separation ('micro-segregation')[12] of the polar aromatic units and the unpolar alkyl chains are the driving forces for the three-dimensional organisation of **3·4** in the bulk. Thus triple-hydrogen bonding between melamines and barbituric acid dyes affords polymeric tapes similar to related assemblies reported from the Whitesides group in the crystalline state.[1] The dimension of these tapes is in good accordance with the largest lattice parameter of 38 Å obtained by XRD. Typically, owing to the significant polarity contrast between the aromatic and the aliphatic part such tapes are supposed to aggregate giving extended sheets, which would lead to a smectic phase.[13] However, electrostatic and steric considerations have to be taken into account for a reasonable model for **3·4** self-assembly. Firstly, because of the parallel alignment of highly dipolar merocyanine dyes within a hydrogen-bonded tape neighbouring tapes will orient in an antiparallel fashion[14] which also provides more space to accommodate the bulky alkyl chains. Nevertheless, molecular modeling of the dimeric tape assembly shows that infinite growth perpendicular to the tape direction is impossible due to the significant sterical demand of the large number of alkyl chains. The result is a superstructure in which infinite ribbons



Scheme 1 *Reagents and conditions*: i, $NaHCO_3$, dioxane, reflux, 24 h.

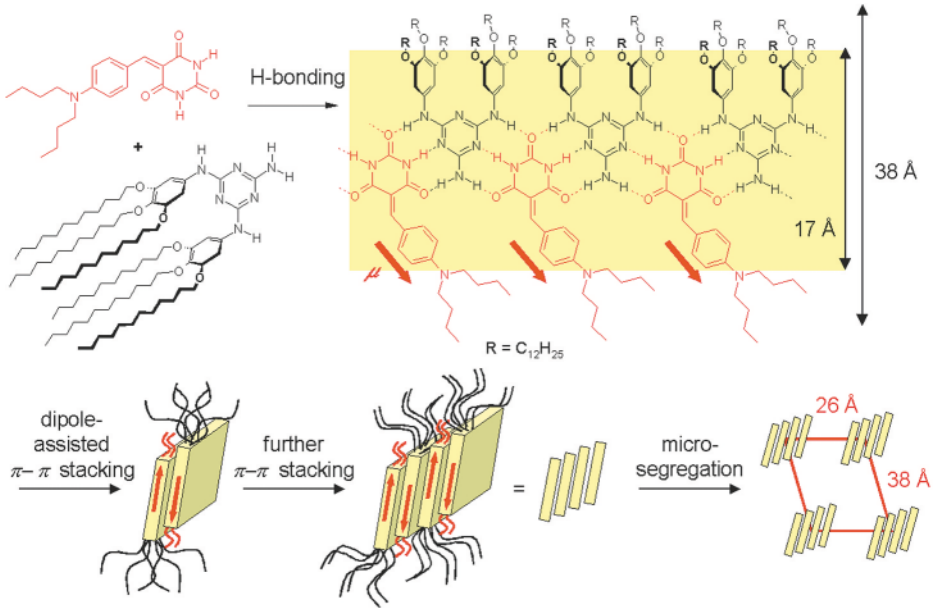
 DOI: 10.1039/b106413d



Scheme 2 Formation of a columnar assembly of **3**·**4** based on orthogonal intermolecular interactions involving hydrogen bond-directed growth of tapes (first direction) and dipole-assisted π–π stacking of these tapes to give ribbons (second direction) which finally assemble into a columnar structure by micro-segregation and steric effects. The yellow shaded area represents the π-conjugated part of the assembly.

consisting of 4–6 antiparallel tapes, arranged in a two-dimensional lattice, are separated by the fluid alkyl chains. Within the ribbons the tapes can be tilted as shown in Scheme 2, but also a non-tilted arrangement is possible. All dimensions of the given arrangement are in good agreement with the obtained lattice parameters.

To our knowledge this is the first example of a columnar mesophase formed by hydrogen-bonded rigid tape assemblies. Furthermore, in contrast to all other hydrogen-bonded columnar liquid crystals[15–17] the hydrogen bonds *and* the involved aromatic cores are organised *parallel* to the column long axes.[16] In this respect they represent counterparts to the columnar phases formed by the stacking of disc-like supermolecules in columns, where flat supermolecules are organised *perpendicular* to the column long axis.[17]

In conclusion thermotropic liquid-crystallinity has been achieved for barbituric acid dye–melamine assemblies which enlarges the set of architectures realised by organisation of these complementary building blocks, *i.e.* interfacial monolayers,[3–5] mesoscopic fibers[6] and rosette assemblies.[10] Current work in our group is directed toward further applications of the new amphiphilic melamine **3** for mesophase induction involving other dye molecules.

The 1,3,5-triarylpent-2-en-1,5-dione group selectively undergoes cyclisation and changes its colour from yellow to magenta upon coordination of Hg^{2+} on a remote site.

The development of sensing systems able to selectively trace the presence of target substrates, is an area of interest, due to its potential application in the development of new methodologies for cation and anion determination.[1] Among straightforward methods for sensing target analytes, those involving colour changes[2] are especially interesting due to their simple use and because they require less expensive equipment than closely related methods involving fluorescence[3] or electrochemical changes.[4] Colorimetric reagents would find direct application in the development of optodes based on absorption changes or disposable dip-stick rapid assays. Despite these attractive features, colorimetric selective reagents for "naked-eye" detection in water are scarce for many cations[5] and anions[6] of importance.

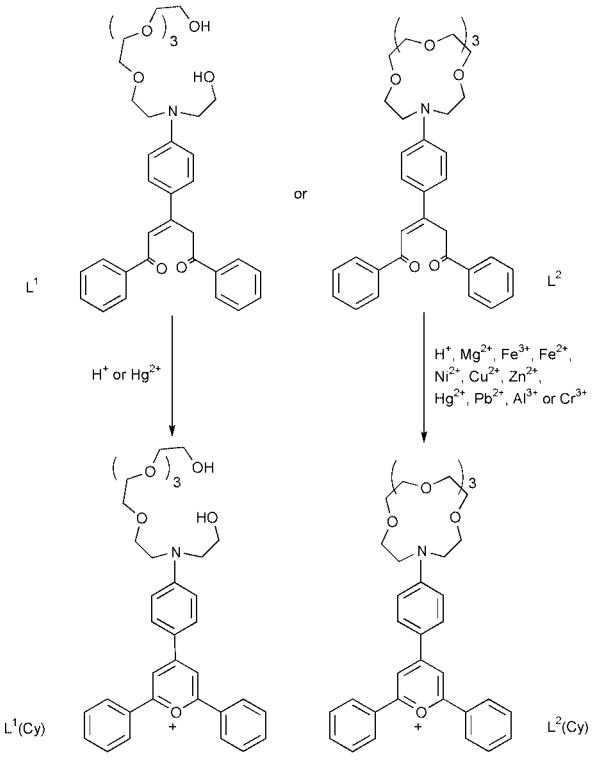
We have recently found that 1,3,5-triarylpent-2-en-1,5-dione derivatives undergo cyclisation to give the 2,4,6-triphenylpyrylium cation upon protonation of the anylinium group or by interaction with certain anions, and we have described a selective ATP colorimetric sensor based on this system.[7] To study the possibility of using similar compounds as chromogenic reagents towards metal ions we have synthesised new 1,3,5-triaryl-2-en-1,5-dione derivatives bearing aza-oxa binding sites and have studied their interaction with metal cations.

Reaction of 2,6-diphenylpyrylium perchlorate with the corresponding aryl aza-oxa derivative (see Scheme 1) gave, after column chromatography on aluminium oxide, the corresponding diketone derivatives L^1 and L^2 in a *ca.* 35% yield.[8] The ^1H NMR spectra of L^1 and L^2 present one characteristic singlet at 4.8 ppm corresponding to the methylene attached directly to one carbonyl and to the double bond. The most characteristic signals in the ^{13}C NMR spectra were two singlets at 190.5 and 196.6 ppm ascribed to the two non-equivalent carbonyl groups. The mass spectra gave molecular ions and fragmentation patterns consistent with the proposed structures. The UV–VIS spectra of L^1 and L^2 show bands in the 200–300 nm range, and a band centred at 380 nm responsible for the yellow colour of the receptors.

The transformation of the penta-1,5-diones to the corresponding pyrylium ions was studied in 1,4-dioxane–water (70 : 30 v/v) mixtures (L^1 and L^2 are not water soluble). A simple method to induce cyclisation is the addition of acid to protonate the amine. Thus, addition of HCl solutions to L^1 or L^2 caused a very significant colour change from yellow to magenta. This change was reflected in the UV–VIS spectrum of the solution that showed a new intense band centred at 550 nm, which was attributed to the highly delocalised pyrylium ring formation.[9] By fitting the plot of the absorption of the band at 550 nm as a function of the pH for compound L^1 (not shown), a logarithm of the stability constant of 4.4 ± 0.2 is obtained for the process $L^1 + H^+ = [HL^1(Cy)]^{2+} + OH^-$. This value is similar to that reported for the protonation of aniline ($\log K = 4.6$), reinforcing the idea that protonation induces diketone-to-pyrylium transformation.

It is known that the cyclisation occurs by electrophilic attack of the C1 carbon to the lone pair of the hydroxylic oxygen of the enol tautomer.[10] The basic idea in this system is that the electrophilic character of the C1 changes, depending on whether the nitrogen atom is protonated or not. Thus, the formation of the pyrylium cation, as described above, is triggered by a protonation event in a remote site (the anilinium group). The nitrogen atom, besides controlling cyclisation upon protonation, is part of a binding site in receptors L^1 and L^2. In this respect, it would also be possible that coordination of metal ions to the nitrogen would also change the electrophilicity of C1. By changing the nature of the binding sites it would be possible to tune the coordination strength between the metal ion and the nitrogen atom. Strong coordination with the amine will induce cyclisation, whereas poor coordination will not. Consequently, we have designed ligand L^1 containing an open-chain binding site and L^2 incorporating a macrocycle, and have studied the effect of metal ion addition on the colour of L^1 and L^2.

The nitrate or perchlorate salts of the cations Li^+, Na^+, K^+, Ba^{2+}, Ca^{2+}, Mg^{2+}, Fe^{3+}, Fe^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Hg^{2+}, Cd^{2+}, Pb^{2+}, Al^{3+}, Cr^{3+} and Sb^{2+} were added to solutions of L^1 or L^2 in dioxane–water (70 : 30 v/v) at pH 6 (pH was buffered with HEPES at a concentration of 0.1 M). Solutions of receptors were prepared in a 10^{-4} M concentration. Very remarkably, the colour change clearly depends on the nature of the binding sites. For instance, Fig. 1(a) shows a photograph



Scheme 1

 DOI: 10.1039/b106941c

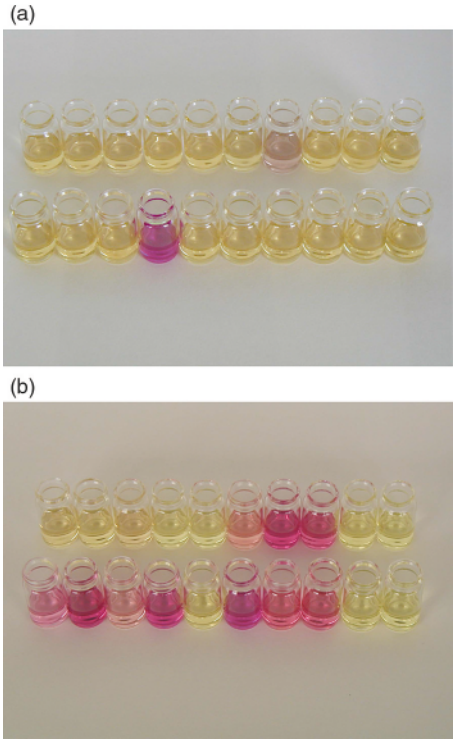


Fig. 1 Colour changes induced on (a) L^1 (1.0×10^{-4} M) and (b) L^2 (1.0×10^{-4} M) at pH 6 (HEPES 0.1 M) in the presence of certain cations in dioxane–water (70:30 v/v) solutions. From left to right and from top to bottom: Li^+, Na^+, K^+, Ba^{2+}, Ca^{2+}, Mg^{2+}, Fe^{3+}, Fe^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Hg^{2+}, Cd^{2+}, Pb^{2+}, Al^{3+}, Cr^{3+}, Sb^{2+} and no cation.

with the colour transformation observed upon addition of stoichiometric amounts of those cations to dioxane–water solutions of L^1. At this pH, a slight change in colour upon addition of Fe^{3+} was found, but the really dramatic effect is observed in the presence of Hg^{2+}. The remaining cations do not induce any significant colour change. This chromogenic behaviour in the presence of Hg^{2+} contrasts with the unspecific colour changes observed, under similar conditions, by using receptor L^2 [see Fig. 1(b)]. In this case, there is at least a partial colour change in the presence of metal cations Mg^{2+}, Fe^{3+}, Fe^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Hg^{2+}, Pb^{2+}, Al^{3+} and Cr^{3+}.

Ring closure in the presence of metal ions is most likely due to the Lewis acid character of the metals that, when coordinated to the nitrogen atom, might enhance the electrophilic character of the C1 carbon. L^2 probably forms stronger complexes (macrocyclic effect) than L^1, therefore favouring, for many metals, an effective nitrogen–metal interaction. L^1 would form weaker complexes and give poorer nitrogen–metal interactions; therefore, most of the metals do not induce cyclisation. The colour change induced by mercury is not unexpected, bearing in mind the strong complexes (compared with other metal ions) that this cation forms with oxa-aza binding sites. L^1 can be considered as a chromogenic reagent for Hg^{2+} sensing.[11]

In order to appreciate the utility of this system, quantification studies by means of extraction experiments of Hg^{2+} from water using L^1 as extractant in dichloromethane, were carried out. Thus, in a typical experiment, 10 mL of dichloromethane containing L^1 (1×10^{-3} M) were placed in a separatoty funnel with 500 mL of water containing Hg^{2+} and the mixture was shaken for 4 min. When the Hg^{2+} cation goes into the dichloromethane, a colour change in this phase proportional to the mercury concentration in water is observed. Fig. 2 shows the absorbance of dichloromethane phases used to extract Hg^{2+} from aqueous solutions at neutral pH. A good linear range is found with a remarkable detection limit for mercury determination in water of 5×10^{-8} M (10 ppb). From some preliminary fixed interference experiments with competing levels of other cations, we found that only Fe^{3+} competes significantly in the extraction experiments whereas other cations such as Cu^{2+} or Pb^{2+} does not interfere in the mercury cation determination.

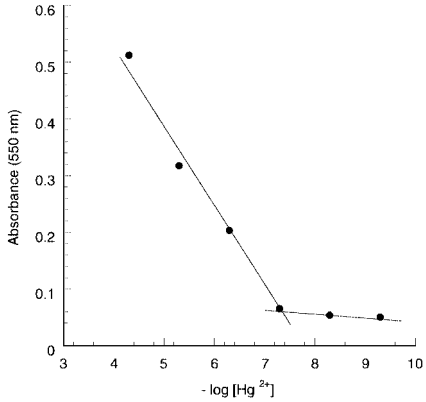

Fig. 2 Extraction experiments. Plot of the absorbance of the dichloromethane phase containing L^1 as a function of the Hg^{2+} concentration in water at neutral pH.

In conclusion, naked-eye sensing of Hg^{2+} has been achieved by using ligands based on 1,3,5-triaryl-2-en-1,5-diones containing a suitable open-chain aza-oxa binding site. Simple extraction experiments allow tracing Hg^{2+} to concentrations that are not far from the maximum contaminant level for mercury in drinking water (2 ppb) set by the United States Environmental Protection Agency (EPA).

We should like to thank the DGICYT (proyecto PB95-1121-C02-02, 1FD97-0508-C03-01 and AMB99-0504-C02-01) for support. F. S. also thanks the Ministerio de Educación y Cultura for a Doctoral Fellowship.

Synthesis and characterization of [Bu^{t}NSn(μ-NBu^t)$_2$TeNBu^t](μ$_3$-SnTe), a stannanetellurone with four-coordinate tin

Tristram Chivers* and Gabriele Schatte

Department of Chemistry, University of Calgary, Calgary, Alberta, Canada T2N 1N4

Received (in Purdue, IN, USA) 28th July 2001, Accepted 16th September 2001
First published as an Advance Article on the web 18th October 2001

Treatment of [Li$_2$Te(NBu^t)$_3$]$_2$ with Sn(O$_3$SCF$_3$)$_2$ or SnCl$_2$ in diethyl ether generates the stannanetellurone [Bu^{t}NSn(μ-NBu^t)$_2$TeNBu^t](μ$_3$-SnTe) involving four-coordinate tin with *d*(Sn=Te) = 2.589(1) Å; the two Sn and two Te atoms are in different oxidation states (+II/+IV and +IV/−II, respectively).

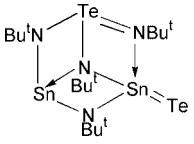
The chemistry of 'heavy ketones', a class of compound that involves a double bond between heavier group 14 and 16 elements, has undergone remarkable development recently.[1] Two methods have been exploited to stabilize these highly reactive functionalities. For example, kinetic stabilization by the use of bulky substituents on the Group 14 elements has been applied successfully to the synthesis of germanetellurones involving three-coordinate germanium.[2] In an alternative approach stabilization may be achieved by intramolecular heteroatom coordination.[3] Indeed the only known stannanetellurone involves five-coordinate tin;[4a] attempts to generate a porphyrinatotin telluride were unsuccessful.[4b] In addition to the fundamental interest in the bonding and reactions of these multiply bonded species, tin–tellurium compounds are of interest as potential precursors of the low band gap semiconductor SnTe,[5] which has a variety of applications, *e.g.* as IR detectors or in thermoelectric devices.[6] In this communication we describe the synthesis, spectroscopic characterization and X-ray structure of [Bu^{t}NSn(μ-NBu^t)$_2$TeNBu^t](μ$_3$-SnTe) **1**, the first stannanetellurone involving four-coordinate tin.

The reaction of [Li$_2$Te(NBu^t)$_3$]$_2$[7] with Sn(SO$_3$CF$_3$)$_2$ or SnCl$_2$ in diethyl ether produced **1** as orange, moisture-sensitive crystals.† Yields of pure, crystalline material were only 10–20% as a result of the thermal instability of **1** in solution. An X-ray structure analysis of **1** revealed a tricyclic structure containing a Sn=Te functionality with four-coordinate tin (Fig. 1).‡ Complex **1** contains two tin atoms in different oxidation states, +II[Sn(2)] and +IV[Sn(1)] and two tellurium atoms, also in different oxidation states, −II[Te(1)] and +IV[Te(2)]. The formation of **1** involves the redox process shown in eqn. (1) (X=Cl, O$_3$SCF$_3$).

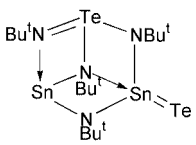
$$[Li_2Te(NBu^t)_3]_2 + 2SnX_2 \rightarrow [Bu^tNSn(\mu\text{-}NBu^t)_2TeNBu^t](\mu_3\text{-}SnTe) + Bu^tN{=}NBu^t + 4LiX \quad (1)$$
1

In effect, 1 equivalent of the [Te(NBu^t)$_3$]$^{2-}$ anion acts as a bridging, tridentate ligand to the two tin centres while the second equivalent serves as the source of tellurium for the terminal telluride and provides a bridging NBu^t group with the elimination of Bu^{t}N=NBu^t (^{1}H NMR). By contrast, no-sulfur-containing products were identified from the reaction of SnCl$_2$ with the congeneric [S(NBu^t)$_3$]$^{2-}$ dianion.[8]

As expected the Sn–Te bond distance of 2.5918(3) Å in **1** is significantly shorter than the value of 2.618(1) Å found for the previously reported five-coordinate tin complex.[4a] The calculated value for the prototypical three-coordinate tin system H$_2$Sn=Te is 2.543 Å.[1a] Typical Sn–Te single bond distances are in the range 2.73–2.79 Å.[4a,9] Thus the bond contraction in **1** is *ca.* 6%. The geometry at the four-coordinate tin atom Sn(1) is highly distorted tetrahedral with bond angles in the range 76.52(7)–127.51(6)° and the Sn(IV)–N bonds are expectedly *ca.* 0.08 Å shorter than the corresponding Sn(II)–N bonds. In addition, the Te–N bond involving the four-coordinate nitrogen atom N(1) is *ca.* 0.08 Å longer than the mean value of the Te–N bonds involving the three-coordinate nitrogen atoms N(3) and N(4). Taken together these data suggest approximately equal contributions from the resonance forms **A** and **B** to the structure of **1**.



A



B

An additional structural feature of interest is the existence of weak intermolecular interactions between the Te(−II) and Sn(+II) centres, which gives rise to parallel polymeric strands in the unit cell of **1** (Fig. 2). The Te···Sn distances of 4.5719(3)°, although somewhat longer than the sum of the van der Waals radii (*ca.* 4.2 Å),[10] can be compared with Sn(+II)···Sn(+II) contacts of 4.40–4.42 Å observed for the complex [Sn{NDipp}$_2${Sn(μ-NMe$_2$)}$_2$] (Dipp = 2,6-Pr$^i_2$C$_6$H$_3$).[11]

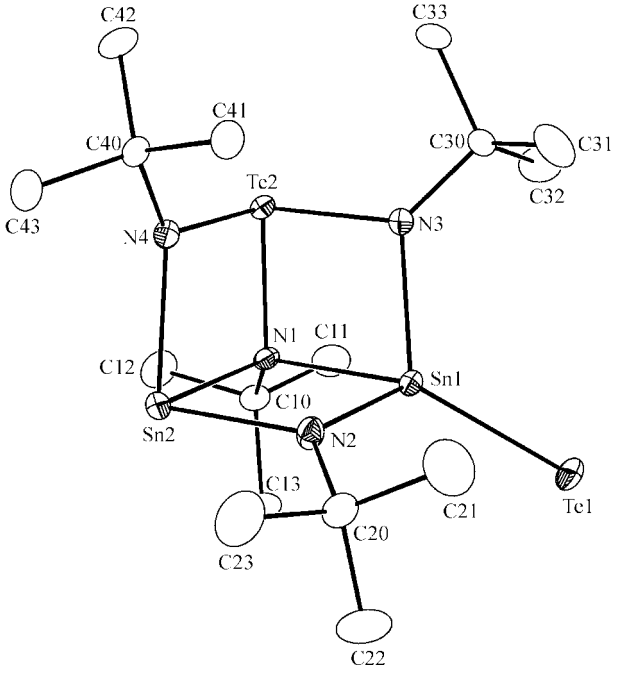


Fig. 1 Molecular structure of [Bu^{t}NSn(μ-NBu^t)$_2$TeNBu^t](μ$_3$-SnTe) **1**. Thermal ellipsoids are drawn at the 30% probability level. Selected bond distances (Å) and angles (°): Sn(1)–N(1) 2.245(2), Sn(1)–N(2) 2.019(2), Sn(1)–N(3) 2.114(2), Sn(2)–N(1) 2.326(2), Sn(2)–N(2) 2.103(2), Sn(2)–N(4) 2.181(2), Sn(1)–Te(1) 2.5918(3), Te(2)–N(1) 2.043(2), Te(2)–N(3) 1.978(3), Te(2)–N(4) 1.951(2); N(4)–Te(2)–N(3) 104.72(9), N(4)–Te(2)–N(1) 83.20(8), N(3)–Te(2)–N(1) 84.40(8), N(2)–Sn(2)–N(4) 96.87(8), N(2)–Sn(2)–N(1) 78.45(8), N(4)–Sn(2)–N(1) 72.02(7), N(2)–Sn(1)–N(1) 82.11(8), N(2)–Sn(1)–N(3) 108.70(9), N(3)–Sn(1)–N(1) 76.52(7), N(1)–Sn(1)–Te(1) 127.39(5), N(2)–Sn(1)–Te(1) 127.51(6), N(3)–Sn(1)–Te(1) 119.20(6).

 DOI: 10.1039/b106867a

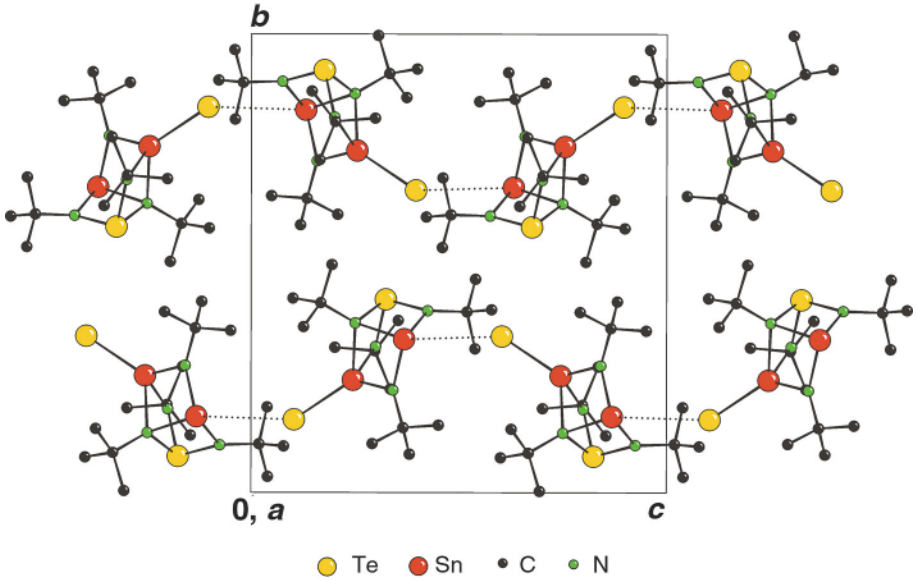

Fig. 2 View of the unit cell of **1** looking down the *a* axis.

The ^{1}H, ^{119}Sn and ^{125}Te NMR spectra in d_8-thf indicate that **1** is fluxional in solution. The ^{1}H NMR spectrum at 23 °C shows two singlets in the ratio 1:3. The broad, more intense, signal is resolved into two resonances with relative intensities 1:2 at −60 °C. In order to observe the expected resonances for inequivalent tin and tellurium environments in **1** it was necessary to record the ^{119}Sn and ^{125}Te NMR spectra at low temperatures. The ^{119}Sn NMR spectrum at −60 °C exhibits two broad resonances at δ −429.7 and +364.6 assigned to the Sn(IV) and Sn(II) centres, respectively. The ^{125}Te NMR spectrum at −60 °C also reveals two resonances at δ +1891.3 and −384.6. The former resonance falls within the range of δ 1500–1900 typical for the tris(*tert*-butylimido)tellurite ligand in metal complexes.[12] The resonance at δ *ca.* −385 is assigned to the terminal telluride ligand. The ^{125}Te NMR chemical shifts for terminal tellurido complexes of p-block elements span a very wide range: δ +1000 to +1140 for three-coordinate germanetellurones,[2] δ −2030 for a five-coordinate stannatellurone[4a] and δ −840 to −495 for R_3PTe (R = alkyl, aryl, dialkylamino).[13] The one-bond ^{119}Sn–^{125}Te NMR coupling could not be resolved in either the ^{119}Sn or ^{125}Te NMR spectra even at −80 °C. These NMR data indicate the occurrence of a fluxional process involving exchange of Te(1) between Sn(IV) and Sn(II) sites. The line-widths of the ^{119}Sn NMR resonances increase from *ca.* 300 to *ca.* 2200 Hz when the concentration of a d_8-thf solution is increased fourfold, consistent with an intermolecular process. A similar exchange process has been reported for R_3PTe (R = alkyl, aryl) in the presence of the corresponding phosphine (R_3P).[13]

A preliminary TGA experiment showed that **1** decomposes with essentially quantitative formation of $Bu^tN{=}NBu^t$ in the temperature range 180–400 °C. Investigations of related *tert*-butylimidotin tellurides as potential single-source presursors of SnTe are in progress.

We thank the NSERC (Canada) for financial support and Dr R. MacDonald (University of Alberta) for help with the X-ray structure determination of **1**.

Notes and references

† *Synthesis* of **1**: a mixture of $\{Li_2[Te(NBu^t)_3]\}_2$[7] (0.300 g, 0.423 mmol) and $Sn(O_3SCF_3)_2$ (0.353 g, 0.846 mmol) was placed in a Schlenk vessel. Addition of diethyl ether (10 mL) to this mixture produced a red solution with small amounts of a black deposit and a white precipitate. After 3 h at 23 °C the solution was filtered and the volume of the filtrate was reduced to *ca.* 3 mL. After 1 d at −19 °C colourless crystals of $Li[O_3SCF_3]{\cdot}OEt_2$ (X-ray structure) (0.181 g) were obtained. After 4 d red plate-like crystals of **1** were formed. A second recrystallization from thf at −19 °C produced X-ray quality crystals after 10 d. Complex **1** is obtained in *ca.* 10% yield from $\{Li_2[Te(NBu^t)_3]\}_2$ and $SnCl_2$ by using a similar procedure. ^{1}H NMR (d_8-thf, −60 °C) δ 1.547 (9 H, Bu^t), 1.464 (9 H, Bu^t), 1.421 (18 H, Bu^t); ^{1}H NMR (d_8-thf, 23 °C) δ 1.490 (9 H, Bu^t), 1.475 (br, 27 H, Bu^t); ^{119}Sn NMR (d_8-thf, −60 °C) δ −429.7(s), +364.6(s); ^{125}Te NMR (d_8-thf, −60 °C) δ −384.6 (s), +1891.3(s).

‡ *Crystal data* for **1**: $C_{16}H_{36}N_4Sn_2Te_2$, M = 777.07, monoclinic, space group $P2_1/n$ (no. 14), a = 10.2669(2), b = 16.4668(3), c = 14.9671(3) Å, β = 94.6721(6)°, V = 2521.97(8) Å^3, T = 173(2) K, space, Z = 4, μ(Mo-Kα) = 4.255 mm^{-1}. Crystal dimensions 0.18 × 0.18 × 0.10 mm. Data were collected on a Nonius Kappa CCD 4-circle Kappa FR540C diffractometer. Structure was solved by direct methods (SHELXS-97) and refined by full-matrix least-squares methods on F^2 with SHELXL97-2. 13494 reflections measured, 7314 unique (R_{int} = 0.0190), 6157 observed [$I \geqslant 2.00\sigma(I)$]. The final R_1 and wR_2 (all data) values were 0.0249 and 0.0528, respectively.

Efficient intramolecular general acid catalysis: a preview from a crystal structure

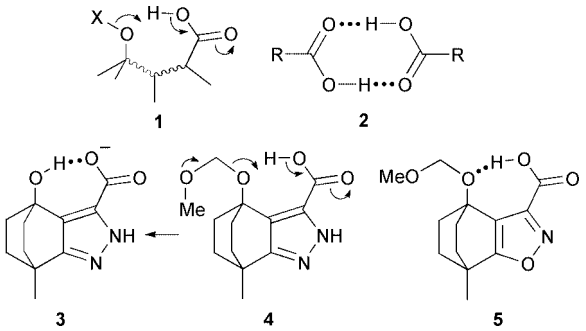
Andrew D. Bond, Anthony J. Kirby* and Encina Rodriguez

University Chemical Laboratory, Cambridge UK CB2 1EW

Received (in Cambridge, UK) 30th August 2001, Accepted 21st September 2001
First published as an Advance Article on the web 19th October 2001

The crystal stucture of acetal acid 5 reveals changes in geometry representing progress along the reaction coordinate for acetal cleavage.

We are interested in intramolecular general acid catalysis by the COOH group (**1**), and have developed systems where this is



highly efficient.[1,2] We believe that the key to high efficiency is that proton transfer takes place within a strong hydrogen bond, and have varied the geometry to try to optimise this feature. However, we could never observe the geometry of the relevant hydrogen bond in crystal structures because carboxylic acids prefer to crystallise as the dimer **2**, the double intermolecular H-bond reinforcing the intrinsic preference for the *Z*-geometry.[3] We report a first useful exception to this rule, an acetal with an intramolecular hydrogen bond strong enough to reinforce the anomeric effect, and to initiate the structural changes that will lead to acetal cleavage.

We recently obtained the structure of the product anion (**3**) of our most efficient such reaction to date, the hydrolysis of **4**. As expected it shows an almost linear intramolecular hydrogen bond from the OH to the carboxylate as acceptor.[2] We now report the structure (Fig. 1) of the reactive acetal **5**, closely related to **4**.[4] This is the first example of a carboxylic acid that makes an intramolecular hydrogen bond to an aliphatic oxygen acceptor in the solid state. [5] Low-temperature single-crystal X-ray diffraction of **5** allowed the location and free isotropic refinement of the proton in the key hydrogen bond; the isotropic displacement parameter of H(2O) refines to 0.078 Å^2, comparable to values for other hydrogen atoms in the molecule.

Acetal **5** has the same basic geometry as the methoxymethyl acetal **4**, but is expected to be a considerably stronger carboxylic acid because of the electron-deficient nature of the isoxazole ring.[1] The intramolecular hydrogen bond is not precisely linear (O(2)–O(4) = 2.625(3) Å, O(2)–H(2O) = 0.89(5) Å, O(2)–H(2O)···O(4) = 162(4)°), primarily because the proton is displaced significantly out of the mean plane of the O–C–C–C–O system. [6] This may be a remnant of the stereoelectronic preference for aliphatic oxygen to form H-bonds in the tetrahedral direction:[7] it is not obviously the result of crystal packing.

The pattern of C–O bond lengths at the acetal group centre shows that the CH_2–O bond (C(11)–O(4), Fig. 1) to the eventual leaving group, at 1.424(3) Å, is significantly longer than the MeO–CH_2 bond O(5)–C(11), (1.383(4) Å).[8] Evidently the hydrogen bond polarises the acetal group and thus enhances the anomeric effect in the direction $MeO^+{=}CH_2$ $^-$OR. Such 'desymmetrisation' of an acetal by H-bonding has not been observed previously. (Potential effects of hydrogen bonding on the anomeric effect have been discussed by Lemieux[9] in the context of the *exo*-anomeric effect of glycoside OH groups as H-bond donors, but the only published example of which we are aware in which the anomeric effect is reinforced by H-bond donors is the observation by Alder *et al.* of systematic bond length changes in two N–C–N systems.[10])

The good correlation[11] between the length of the CH_2–OX bond in methoxymethyl acetals $MeOCH_2$–OX and the pK_a of HOX, the conjugate acid of the leaving group, allows us (not without significant reservations[8]) to estimate an effective pK_a of 10 for the leaving group oxygen. (The effective pK_a of the leaving group in the transition state for the hydrolysis of **4** is about 4.[2]) The bond angle at the leaving group oxygen (C(11)–O(4)–C(5), 118.6(2)°) is close to trigonal and the acetal torsion angle around the stretched C–O bond is 88.0(3)°. (The other is typically gauche, at 68.0(4)°.) The leaving group oxygen may be thought to be behaving more like a phenol[12] than a tertiary alcohol oxygen, with the third (hydrogen) bond causing the trigonal geometry. In fact the near-trigonal bond angle at oxygen is typical for methoxymethyl acetals of tertiary alcohols (the 6 examples in the Cambridge Structural database have a mean angle of 118.6 ± 0.7°), no doubt for steric reasons.

This system (**5**) displays significant progress along the reaction coordinate of the reaction of interest, and offers the sort of detailed structural information we need for analysis, and as a basis for improving efficiency further—which means optimis-

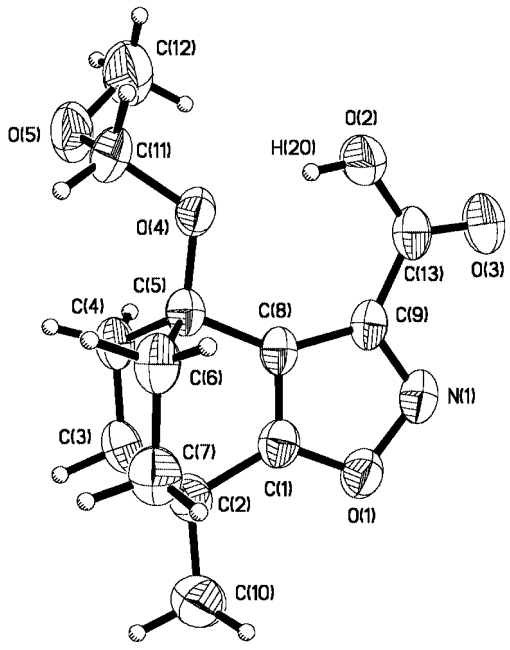


Fig. 1 Molecular conformation of the acetal acid **5** showing displacement ellipsoids at the 30% probability level.[13]

 DOI: 10.1039/b107787b

ing the hydrogen bond in the transition state. The intramolecular hydrogen bond we see in the crystal may not make a major contribution to the ground state in aqueous solution: in water, hydrogen-bonding solvation disrupts all but the strongest intramolecular hydrogen bonds. It is however, clearly the first committed species on the reaction coordinate.

3 L. Eberson, in *The Chemistry of Carboxylic Acids and Esters*, ed. S. Patai, Wiley, New York, 1969, pp. 211–340.

4 We have not measured rates of hydrolysis of **5**. From our results in the aromatic series we can expect the isoxazole system to be more reactive than weaker carboxylic acids derived from other heterocyclic systems, such as **4**, with similar geometries.

5 We could find no comparable intramolecular hydrogen bond in the Cambridge Structural Database (Version 5.21, April 2001). The closest analogue of **5** is fluorenone-1-carboxylic acid (M. L. Cote, R. A. LaLancette and H. W. Thompson, *Acta Crystallogr., Sect. C*, 1996, **52**, 1585), based on a similar 6,5-fused system geometry, where the acceptor is the ketone oxygen.

6 The deviation from planarity is significant, even considering the relatively large imprecision of the hydrogen atom position derived from the X-ray results. The O–H···O distance is longer (2.713 Å) in the anion **3** (as expected for the more electron-rich system), and almost linear (angle at H 175°), with little deviation from planarity.

7 A. J. Kirby, *The Anomeric Effect and Related Stereoelectronic Effects at Oxygen*, Springer-Verlag, Berlin and Heidelberg, 1983.

8 Mean values of of 1.3975 ± 0.0155 and 1.4077 ± 0.0065 Å for these two bond lengths, for the six acetals $MeOCH_2OR$ derived from tertiary alcohols ROH for which accurate structures are available, suggest there may also be a small steric contribution to the extension of the CH_2–OR bond. (Other things being equal the O derived from the tertiary alcohol ROH should be the better *n*-donor.)

Novel polymer-supported 2-(diphenylmethylsilyl)ethoxymethyl chloride (DSEM-Cl) linker†

Kyungjin Kim* and Bingbing Wang

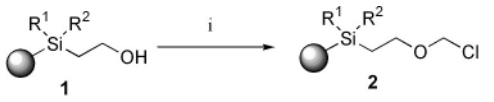
Roche Research Center, Hoffmann-La Roche, Inc., Nutley, NJ 07110, USA.
E-mail: kyungjin.kim@roche.com

Received (in Cambridge, UK) 25th July 2001, Accepted 29th August 2001
First published as an Advance Article on the web 17th October 2001

A synthetic method to prepare a novel polymer-supported 2-(diphenylmethylsilyl)ethoxymethyl chloride (DSEM-Cl) linker and its applications are described.

The selection of an appropriate linker is an important factor when considering synthetic design on solid phase. Several efforts to develop new solid supports and linkers have been reported.[1] In a previous communication, we reported synthetic strategies for the preparation of polymer-supported 2-(trialkylsilyl)ethanol linkers **1** and their functionalized silyl linkers with an application to ketopiperazine synthesis.[2] Herein we wish to report a synthetic method to prepare a novel polymer-supported 2-(diphenylmethylsilyl)ethoxymethyl chloride (DSEM-Cl) linker **2c** and its applications in our continuing efforts to explore new silyl linkers.

2-(Trimethylsilyl)ethoxymethyl chloride (SEM-Cl) has frequently been utilized in solution phase as a protection group for amines, alcohols, phenols and carboxy groups.[3] We considered that it would be worthwhile to develop a supported SEM linker based on the virtues of SEM-Cl. Our initial efforts were directed towards the preparation of polymer-supported 2-(trialkylsilyl)-ethoxymethyl chlorides **2** containing different alkyl substituents and the investigation of their stability in a broad range of chemistries (Scheme 1). After careful examination, we found that a pre-mixture of paraformaldehyde and HCl(g) could be employed as an efficient method for chloromethylation of **1**.[4] Three polymer-supported 2-(trialkylsilyl)ethoxymethyl chlorides **2** were carefully synthesized to avoid protodesilation during chloromethylation in acidic media.[5] Dimethylphenyl-substituted silyl linker **2a** proved labile under acidic conditions, yielding only a low loading (0.13 mmol g^{-1}). The diisopropylphenyl functional group of **2b** was observed to impede the attachment of starting material to the solid support, necessitating harsh reaction conditions. Finally, 2-(diphenylmethylsilyl)ethoxymethyl chloride (DSEM-Cl) **2c** showed good stability and reactivity with optimal loading capacity (0.64–0.74 mmol g^{-1}). The progress of the reaction was monitored by FT-IR spectroscopy with the disappearance of the O–H stretch at 3428 cm^{-1}. In addition, the structure of polymer-supported DSEM-Cl **2c** was confirmed using HR-MAS (high resolution magic angle spinning) ^{1}H-NMR analysis, in which methylene protons of O–CH_2–Cl were observed at 5.60 ppm.[6]



1 **2**

Entry	R^1	R^2	Yield*
2a	CH_3	CH_3	15%
2b	*i*-Propyl	*i*-Propyl	90%
2c	CH_3	C_6H_5	>70%

*The loading yield was determined by Cl analysis

Scheme 1 *Reagents and conditions*: i, HCl(g), paraformaldehyde, DME, 0 °C, 1 h.

We then examined the utility of immobilized DSEM linker **2c** for various functional groups (Table 1). Acid (entries 1 and 2), alcohol (entries 3 and 4), phenol (entry 5), amine (entry 6) and heterocyclic amide (entries 7 and 8) were successfully attached onto **2c** in good yields.[7] The unreacted chloromethyl functionality on resin was capped with methanol to avoid undesired side reactions. Acidic cleavage using a solution of TFA–CH_2Cl_2 proved efficient in providing the corresponding starting material in good yield (entries 1–7). Interestingly, the removal of the DSEM protecting group from the purine-supported linker (entry 8) showed strong stability in acetic acid, however 2-fluoro-6-chloropurine started to be released from the solid support in 50% trifluoroacetic acid–CH_2Cl_2 with 66% purity.[8] To improve purity, microwave irradiation was employed, since we anticipated that using a high temperature for a short time period would avoid other side reactions.[9] The resin suspension in 50% TFA–CH_2Cl_2 was irradiated for 3 min at 100 °C. As expected, 2-fluoro-6-chloropurine **3** was successfully recovered in quantitative yield with 93% purity. This new DSEM linker is expected to make up for the weak points of trityl and tetrahydropyranyl (THP) linkers, which show thermal and acid sensitivity when aromatic heterocycles are loaded onto the linker.

Polymeric DSEM-supported 2-fluoro-6-chloropurine **4** was then utilized to synthesize a number of 2,6-disubstituted purines

Table 1 Loading and cleavage of **2c** on various functional groups

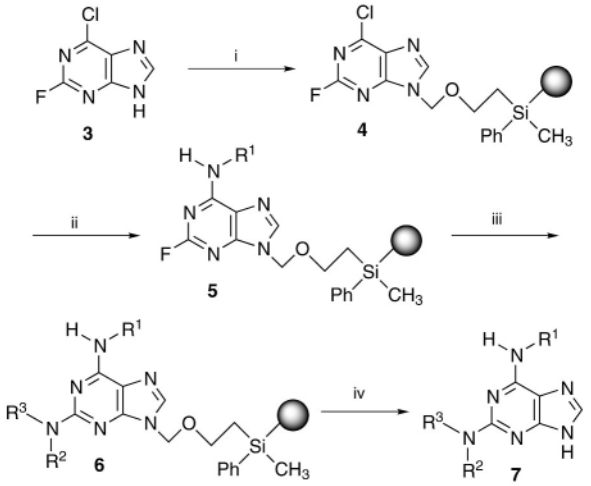

Scheme 2 *Reagents and conditions*: i, **2c**, 2-*tert*-butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine (BEMP), THF, 0 °C to rt, 3 h, 92%; ii, R^1NH_2, diisopropylethyl amine, 1 : 1 n-butanol–DMSO, 50 °C, rt, overnight; iii, R^2R^3NH, DIPEA, 1-methyl-2-pyrrolidinone, microwave irradiation; iv, 1 : 1 TFA–CH_2Cl_2, microwave irradiation, 3 min, 100 °C.

on solid phase (Scheme 2). Nucleophilic amination of **4** with benzylamine or isobutylamine proceeded successfully under the described conditions to provide **5**. Subsequent amination at C2 has been reported to require longer reaction time and higher temperature due to decreased reactivity at C2. Therefore, we applied microwave-assisted heating to enhance reaction rates. Several variations of solvents and irradiation times were examined in a parallel format *en route* to **6** using a Smith Synthesizer™. Microwave irradiation in 1-methyl-2-pyrrolidinone at 180 °C followed by a sequential microwave-assisted linker cleavage provided a good yield of **7** with high purity (Table 2).

Table 2 2,6-disubstituted purine **7** synthesis on solid phase

R^1	R^2/R^3	Microwave condition[a]	Y[b]/P[c]
Benzylamine	Morpholine	180 °C, 10 min	70/90
	N-Methylpiperazine	180 °C, 20 min	85/94
	4-Fluorophenethylamine	180 °C, 40 min	80/92
	3-Bromoaniline	200 °C, 40 min	n.a.[d]
Isobutylamine	Morpholine	180 °C, 10 min	74/95
	N-Methylpiperazine	180 °C, 20 min	89/89
	4-Fluorophenethylamine	180 °C, 40 min	82/89
	3-Bromoaniline	200 °C, 40 min	n.a.[d]

[a] Nucleophilic amination of **5** proceeded using microwave heating to provide **6** under the described conditions. [b] Isolated yield was determined after acidic cleavage of **6** based on loading capacity of **4** (0.74 mmol g^{-1}). [c] Purity score was determined by LC/MS–ELSD. [d] Starting material recovered.

In conclusion, we have successfully synthesized a new polymer-supported DSEM-Cl linker **2c**. Protection and deprotection of the DSEM linker on various functional groups was successful. Microwave-assisted linker cleavage proved to enhance the cleavage process. In particular, sequential microwave applications, utilized at the amination and linker cleavage steps, greatly accelerated the 2,6-disubstitituted purine synthesis. The DSEM-Cl linker **2c** is a promising new candidate for the protection of hydroxy and nitrogen functional groups in solid phase synthesis. In comparison with other acid-labile linkers, we envision that the new silyl linker will offer several advantages, such as stability in various reaction conditions including basic and moderately acidic media as well as elevated thermal conditions.[10] Our efforts toward the development of applications of support-bound DSEM linkers **2** are ongoing.

We are grateful to all combinatorial and NLCI group members who made this work possible. We wish to thank Dr Harald Schroeder of PRBT at Basel for providing HR-MAS NMR spectra of **1c** and **2c**.

First published as an Advance Article on the web 17th October 2001

In supercritical water the rate of methanol oxidation was controlled by ionic behavior as follows: the oxidation rate of methanol decreased with increasing proton and hydroxide ion concentration, possibly due to stabilization of the reactant, while that of CO was suppressed by added protons and enhanced by added hydroxide ions.

Supercritical water oxidation (SCWO) has been known to be a promising method for complete decomposition of organic compounds in water without emission of toxic pollutants.[1,2] One of the reasons why SCWO is suitable as an oxidation medium is that organic species and oxygen are completely miscible in water above its critical point (647 K and 22.1 MPa).[3,4] Another reason is that water reacts with O_2 to generate OH radicals at temperatures greater than 773 K,[5] which is highly active as an oxidant. On the other hand, around the critical temperature of water, the rate of complete oxidation of a hydrocarbon is suppressed with increasing water density and the yields of partial oxidation products such as CO and aldehyde increase with increasing water density.[6] This phenomenon cannot be explained solely by a free radical reaction mechanism. Ionic reaction of an organic compound, such as protonation and dehydration of some alcohols, proceeds in supercritical water near its critical point, that is, around 673 K.[7] Thus, the effect of ionic behaviour of an organic compound on oxidation in supercritical water must be taken into consideration. In this study, the effect of water density, acid, and base on methanol oxidation was examined and a possible reaction pathway of methanol oxidation in supercritical water near its critical point was proposed.

Methanol (99.7%), 1 mol L^{-1} of NaOH aqueous solution, and 1 mol L^{-1} of H_2SO_4 solution were purchased from Wako Pure Chemical and used without further purification. Pure water, which was distilled after deionization, had a conductivity 1×10^{-5} S m^{-1}. The batch type reactor (SS316) used in this study has been described previously.[8] Briefly, 1.0–3.1 g water, 0.03 g of methanol, an amount of acid (H_2SO_4) solution or base (NaOH) solution, and a given amount of O_2 (molar ratio: O_2–methanol = 3 : 1) were loaded into a batch type reactor (internal volume: 6 mL). Pressures (P_w) were calculated from the water densities (ρ_w) and steam tables.[9] The reactor was immersed in a fluidized sand bath (673 K) and the reaction was started. After a given time, the reactor was taken out from the sand bath and put into a water bath (room temperature), and then the reaction was stopped. After cooling the reactor, a stop valve on the reactor was connected with a gas sampling system and the gaseous product was collected and analyzed by gas chromatography with a thermal conductivity detector (GC-TCD) (Shimadzu GC-7A and Hitachi GC163). After gas sampling, an amount of water was added into the reactor and the liquid product was recovered and analyzed by gas chromatography with a flame ionization detector (GC-FID) (HP 6890). For all the experiments in this study, the detected products were H_2, CO, and CO_2, in agreement with the results of Anitescu *et al.*[10] The proton concentration ($[H^+]$) and ion product (K_w) of pure water was calculated by the method of Marshall and Franck.[11] The proton concentration with acid and base was calculated from the ion product of water,[11] the equilibrium constant,[12,13] and the activity coefficient.[14]

Corrections were applied for heat-up time and reactor dead space. Heat-up time (*ca.* 1 min) was subtracted from the actual run time. Corrections for dead space were estimated by using separate runs at reaction times of 540 s. The amount of CO and CO_2 obtained at 540 s was used to estimate available reactants at 120 s and 240 s.

Fig. 1 shows results at 673 K and 0.16 g cm^{-3}. In this figure, the calculated results using the model proposed by Anitescu *et al.*[10] are also shown. As shown in Fig. 1, the agreement between the experimental results and the model was good. Table 1 summarizes the experimental conditions and yields. Experiments were run for 120–540 s at a range of water densities without catalysts and also with acid and base catalysts. Methanol yield without catalyst increased with increasing water density and rapidly decreased with time at all the water densities. With acid or base catalyst, the methanol yield was higher than that without catalyst at the same water density. CO yield without catalyst decreased with reaction time but increased in the presence of acid and decreased in the presence of base. CO_2 yield was relatively low in the presence of acid and high in the presence of base. H_2 yield at all the reaction times increased with increasing water density without catalyst, while acidic conditions gave more or less the same yields as neutral conditions. H_2 yield was highest under alkaline conditions.

To consider the effect of water density, acid, and alkali on the methanol oxidation, the rate constants (k_1 and k_2) of eqn. (1) were evaluated by fitting the data in a similar manner to that of Anitescu *et al.*[10]

$$CH_3OH \xrightarrow{k_1} CO \xrightarrow{k_2} CO_2 \qquad (1)$$

Fig. 2 shows the rate constants as a function of proton concentration. While the value of k_1 exhibited a maximum with proton concentration, k_2 decreased linearly with increasing proton concentration. As suggested by Antal *et al.*,[7] alcohols tend to be protonated in supercritical water. If the stability of protonated alcohol for oxidation is higher that of a molecular alcohol, the oxidation rate (k_1) of the protonated alcohol is expected to be lower than that of unprotonated alcohol. An

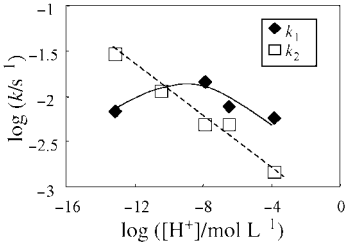

Fig. 2 Dependence of k_1 and k_2 on proton concentration.

alcohol possibly dissociates into the alkoxide ion and a proton in the presence of alkali in supercritical water because alcohols are weak acids.[15] Like the protonated alcohol, an alkoxide ion is expected to be more stable than the molecular alcohol towards oxidation. Thus the k_1 value was also low at the lowest proton concentration (in NaOH solution).

For the oxidation of CO into CO_2 (for k_2), there are two pathways: one is direct oxidation and the other is the water gas shift reaction ($CO + H_2O \rightleftharpoons CO_2 + H_2$). As shown in Fig. 2, the rate of conversion of CO to CO_2 decreased with increasing proton concentration. Analogously to methanol, CO oxidation seemed to be suppressed by increased proton concentration. Some ionic effects on the water gas shift in sub- and supercritical water have been studied. Rice *et al.*[16] and Sato *et al.*[17] examined the effect of water density (pressure) on the rate of the water gas shift reaction. While Sato *et al.*[17] reported that the rate of water gas shift reaction was independent of pressure up to 30 MPa and 673 K, Rice *et al.*[16] reported that the rate of the water gas shift reaction drastically increased with increasing pressure above 30 MPa at 683 K. Ross *et al.*[18] and Elliott *et al.*[19] suggested that the water gas shift reaction must be promoted by alkali (that is, OH^- ion) in sub- and supercritical water. The ion product of water increases drastically above 30 MPa both at 673 and 683 K.[11] Thus the rate of the water gas shift reaction is expected to depend on OH^- concentration. Fig. 3 shows the dependence of H_2 yield on OH^- concentration. The yield of H_2 (540 s) increased with increasing OH^- concentration. If the formation of H_2 were solely due to the water gas shift reaction, then the H_2 yield would be comparable with the CO_2 yield. The high H_2 yield indicates that the rate of the water gas

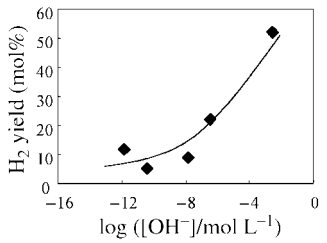

Fig. 3 Dependence of H_2 yield (540 s) on OH^- concentration.

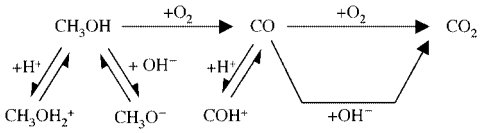

Fig. 4 Proposed mechanism of methanol oxidation in supercritical water.

shift reaction is possibly enhanced by high water density and added alkali.

Based on these results a mechanism for methanol oxidation in supercritical water can be proposed as follows (Fig. 4). Methanol is stabilized to some extent by ionic species that promote its protonation or its dissociation. Then, after methanol is oxidized to CO, the CO is stabilized by the presence of protons. The CO is oxidized to CO_2, however, hydroxide ions promote conversion of CO to CO_2 *via* the water gas shift reaction. This shows that addition of ionic species in supercritical water can have broad application in organic syntheses.

Received (in Cambridge, UK) 2nd August 2001, Accepted 20th September 2001
First published as an Advance Article on the web 18th October 2001

Exposure of the solid zwitterion $[Co^{III}(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)]$ to hydrated vapours of volatile acids (HCl, CF_3CO_2H, HBF_4) or bases (NH_3, NMe_3, NH_2Me) quantitatively produces the corresponding salts; the heterogeneous reactions are fully reversible, as the acid or base molecules can be removed by thermal treatment, regenerating the starting material.

Crystal engineering with inorganic and organometallic building blocks[1–3] allows construction of robust crystal architectures. Robustness is a prerequisite for the preparation of nanoporous materials able to withstand removal of guest molecules.[4] Zeolitic type materials are being extensively studied in the quest for solid state sensors, reservoirs, filters and sieves to be used to detect or trap small molecules.[5–7] An alternative to nanoporosity for controlled uptake and release of small molecules could be afforded by heterogeneous gas–solid reactions.[8] Solid-state reactions, however, often imply profound transformations in the chemical and physical nature of the solid material and rarely are of practical use, unless fully reversible.

Here we report that the low-cost, water soluble and robust organometallic zwitterion $[Co^{III}(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)]$, **1**, undergoes fully reversible heterogeneous reactions with the hydrated vapours of a variety of acids (*e.g.* HCl, CF_3CO_2H, HBF_4) and bases (*e.g.* NH_3, NMe_3, NH_2Me), with formation of the corresponding salts. The acid or base molecules can be removed by mild thermal treatment, regenerating **1**. Since no decomposition is observed after several uptake/release cycles, the organometallic material behaves as a *reversible* amphoteric trap towards both acid and base hydrated vapours *via* the gas–solid reaction. The reaction of solid carboxylic acids with ammonia and amines have been the subject of elegant pioneering studies.[9]

The organometallic zwitterion **1** is easy to handle and is thermally stable up to a temperature of 506 K.[10] The heterogeneous reactions of **1** with hydrated vapours of HCl or NH_3 to give the compounds **2** and **3** are depicted in Fig. 1.

Complete conversion of the neutral crystalline **1** (1–10 mg) into the crystalline salt **2** is attained after 5 min of exposure to vapours† of 36% aqueous HCl. Formation of **2** in the heterogeneous reaction is easily assessed by comparison of the observed X-ray powder diffraction pattern‡ with that calculated on the basis of the single-crystal structure determined previously.[11] The formation of **2** from **1** requires that the O–H···O bonds involving the protonated $–CO_2H$ group and the deprotonated $–CO_2^-$ of neighbouring zwitterion molecules are replaced, upon absorption of HCl, by $^+O–H\cdots Cl^-$ interactions between the $–CO_2H$ groups on the fully protonated organometallic cation $[Co^{III}(\eta^5\text{-}C_5H_4CO_2H)_2]^+$ and the Cl^- anions.

Crystalline **2** can be converted back to **1** by heating the sample for 1 h at 440 K in an oil-bath under low pressure (10^{-2} mbar). A thermogravimetric analysis (TGA) shows that **2** releases one water molecule and one HCl molecule per molecular unit at 394 and 498 K, respectively [see Fig. 2(a)]. The powder diffractogram of the final product corresponds

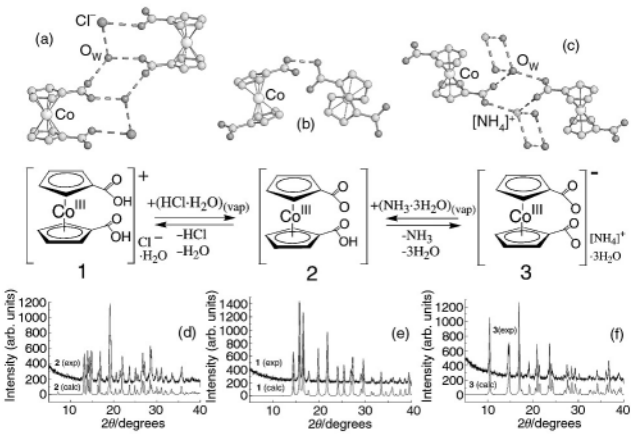

Fig. 1 Schematic representation of the uptake and release of hydrated vapours of HCl and NH_3 by crystalline $[Co^{III}(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)]$ **1**. The different relative arrangement of the organometallic moieties in the solid state is shown for **2** (a), **1** (b) and **3** (c). Hydrogen atoms not shown. Experimental X-ray powder diffraction patterns for **2** (d), **1** (e) and **3** (f), measured after each uptake–release cycle, are compared with the powder patterns calculated on the basis of the single crystal structures.

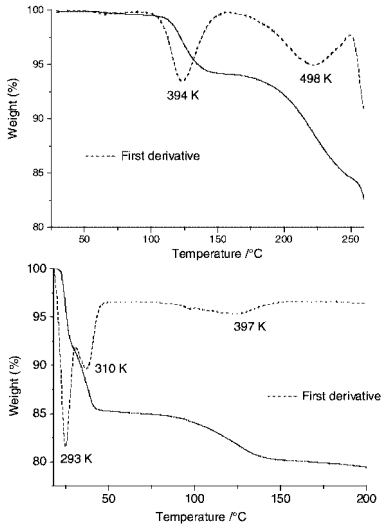

Fig. 2 Thermogravimetric analyses (TGA) corresponding to the **2** → **1** (a) and **3** → **1** (b) solid state processes. The loss in weight at 394 and 498 K in the **2** → **1** process corresponds to one water and one HCl molecules per formula unit, respectively. The loss in weight at 293, 310 and 397 K in the **3** → **1** process corresponds to a total of 3.5 water and one NH_3 molecule per molecular unit.

Table 1 Reaction of **1** with hydrated acid and base vapours

Acid[a]	Exposure time[b]	ν_{CO}[c]/cm^{-1}	Base[a]	Exposure time[b]	ν_{CO}[c]/cm^{-1}
HCl (37%)	5 min	1733s, 1707s	NH_3 (30%)	5 min	1610s
CF_3CO_2H (99%)	1 h	1723s, 1706s	NH_2Me (30%)	1 h	1610s
HBF_4 (54%)	16 h	1736s, 1708s	NMe_3 (30%)	1 h	1612s

[a] Concentration of the solution given in parenthesis. [b] Uptake time for a complete conversion of 10 mg of **1**, all processes are fully reversible. [c] Diagnostic CO stretching frequencies (KBr) for reaction products; neutral **1** is characterized by a band at 1714s cm^{-1}.

precisely to that of form **1**. Crystalline **1** can be cycled through several absorption and release processes of HCl without decomposition or detectable formation of amorphous material.

Incidentally, since compound **2** is the precursor for the synthesis of **1**,[10] the solid state conversion **2** → **1** represents an alternative an more convenient way to obtain the anhydrous zwitterion **1** directly from solid **2**.

The behaviour of **1** towards NH_3 is remarkably similar: **1** (1–10 mg) quantitatively transforms into the hydrated ammonium salt **3** upon 5 min exposure to vapours† of 30% aqueous ammonia. Single crystals of **3** for X-ray structure determination‡ can be obtained if the reaction of **1** with ammonia is carried out in aqueous solution.

As in the case of **2**, formation of **3** in the heterogeneous reaction is assessed by comparison of the observed and calculated (see caption to Fig. 1) X-ray powder patterns of **3**. The salt is characterized by the presence of charge-assisted $^+$N–H$\cdots$O$^-$ interactions between the ammonium cation and the deprotonated –CO_2^- groups on the organometallic anion.

As in the case of the reaction with HCl, absorption of ammonia is a fully reversible process: upon thermal treatment (1 h at 373 K, ambient pressure) crystalline **3** converts quantitatively into **1**. Repeated thermogravimetric analyses (TGA)§ show that **3** releases between 3 and 3.5 water molecules and 1 molecule of NH_3 per formula unit in the temperature range 293–397 K [see Fig. 2(b)]. The slight excess of water is probably due to humidity absorbed on the surface. All attempts to remove the water in excess (under low pressure) also resulted in a partial loss of the crystallization water. The powder diffractogram of the product after thermal treatment corresponds precisely to that of form **1**.

IR spectroscopy can also be utilized to quickly detect formation of the organometallic cation or anion when **1** is reacted with volatile acids or bases, as spectra in KBr show diagnostic bands for the CO stretching at 1733s and 1707s in **2**, and 1610s cm^{-1} in **3** (see Table 1). In the release process, these bands are replaced by the stretching at 1714s cm^{-1} characteristic of the zwitterionic form **1**.

Heterogeneous acid–base reactions are, obviously, well known. However, system **1** represents, to the best of our knowledge, the first example of an organometallic solid that can withstand both processes, behaving as a fully reversible 'amphoteric trap' towards a variety of hydrated vapours of acids and bases. It is worth pointing out that the process relies on the possibility of 'switching' between O–H$\cdots$O hydrogen bonds in neutral **1** and charge-assisted $^+$O–H$\cdots$X$^-$ or O$^-\cdots$[H–NR_3]$^+$ hydrogen bonds.

The experiments with ammonia or hydrogen chloride have been examined in depth. We are currently exploring the reactivity of solid **1** towards other acid and basic vapours beside those reported above. The dependence on the composition of the vapour phase on the exposure time and on the surface area is also being investigated.

The bottom-up construction of solid-state sensors, filters and sieves for small molecules is an attractive prospective of crystal engineering. While many nanoporous systems irreversibly decompose upon removal of guest molecules because of loss of stability,[12] our gas–solid reaction *exploits* the reversible interconversion between a molecular crystal and different crystalline salts where **1** can convert into either a cation or an anion, depending on the acid–base reaction. The control on solid-state reactions that can be used to trap environmentally dangerous or poisonous molecules is an attractive goal for solid-state chemistry and crystal engineering.

We thank MURST (projects Supramolecular Devices and Solid Supermolecule), the Universities of Bologna (project Innovative Materials) and Sassari for financial support.

Notes and references

† Exposure to HCl or NH_3 hydrated vapours was attained by allowing the vapours of the corresponding aqueous solutions contained in a round-bottom flask to pass into a filter funnel, in which a glass sample holder containing powder **1** was placed: in this way the powder and the solution were not in contact; the reaction took place in a closed system. Elemental analysis for **3** (single crystals): Found: C, 41.13; H, 5.34; N, 4.01. Calc.: C, 41.51; H, 5.23; N, 4.03%.

‡ Powder data were collected on a Philips PW-1100 automated diffractometer with Cu-Kα radiation, graphite monochromator. The program PowderCell 2.2 was used for calculation of X-ray powder patterns [PowderCell programmed by W. Kraus and G. Nolze (BAM Berlin) © subgroups derived by Ulrich Müller (Gh Kassel)]. The solid state structure of $[(C_5H_4CO_2)_2Co][NH_4]\cdot 3H_2O$ **3** was determined at 223 K by single crystal X-ray diffraction on a Nonius CAD4 diffractometer equipped with an Oxford Cryostream device and a graphite-monochromator (Mo-Kα radiation, λ = 0.71073 Å). *Crystal data*: triclinic, space group $P\bar{1}$, Z = 1, a = 6.442(6), b = 7.007(4), c = 9.120(4) Å, α = 68.79(4), β = 89.06(5), γ = 69.72(7)°, V = 357.2(4) Å^3, 1252 independent reflections (1338 measured), R_1 = 0.0381, wR_2 = 0.1050, GOF = 1.111. One of the O_{water} atoms in the asymmetric unit shares its position with the N atom of the $[NH_4]^+$ cation, and the two atoms were refined with an occupancy factor of 0.5. All non-H atoms refined anisotropically. The SHELX-97 package was used for structure solution and refinement based on F^2 (G. M. Sheldrick, SHELX-97, Program for Crystal Structure Determination; University of Göttingen, Göttingen, Germany, 1997).

CCDC reference number 166132. See http://www.rsc.org/suppdata/cc/b1/b106984e/ for crystallographic data in CIF or other electronic format.

§ The TGA experiments were carried out on a Perkin-Elmer TGA-7 instrument in open Al pans under N_2 atmosphere.

Abnormal binding in a carbene complex formed from an imidazolium salt and a metal hydride complex

Stephan Gründemann, Anes Kovacevic, Martin Albrecht, Jack W. Faller* and Robert H. Crabtree*

Department of Chemistry, 225 Prospect Street, Yale University, New Haven, CT 06520-8107, USA. E-mail: robert.crabtree@yale.edu

Received (in Purdue, IN, USA) 24th August 2001, Accepted 24th September 2001
First published as an Advance Article on the web 18th October 2001

2-Pyridylmethylimidazolium salts and $IrH_5(PPh_3)_2$ give an $[(N–C)IrH_2(PPh_3)_2]^+$ species with the imidazole ring bound in the 'wrong way': at C-5, not the expected C-2.

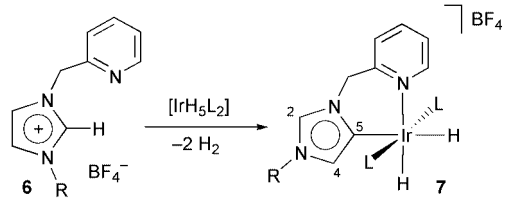
N-Heterocyclic carbenes have adopted an increasing role as ligands in homogeneous catalysis and organometallic chemistry.[1–3] Previous examples have always shown C-2 metal binding (**1**)—the same structure as in the free carbenes isolated by Arduengo *et al.*[4] C-4(5) binding as in **2** has not been considered as a likely alternative because the free carbenes always have a C-2 structure (**3**) and the adjacent nitrogens were considered to strongly stabilize both the free carbene in **3** and the M–C bond in **1** (Scheme 1).

In recent work, Sini, Eisenstein and Crabtree[5] reported DFT (B3PW91) calculations on 2- *vs.* 4(5)-binding of **1** and **2** (R = H), where a much less stable C-bound isomer was shown to result from metal binding to the 4(5) position as in **2**. The free 'carbene' at C-4(5) was calculated to lie at +20.0 kcal mol^{-1} above the C-2 carbene. With $PtCl_3^-$ bound {**1** or **2**; ML_n = $[PtCl_3]^-$}, the C-4(5) complex was calculated to lie even higher, +23.3 kcal mol^{-1} above the C-2 complex.

Previous synthetic routes from the precursor imidazolium salt most often include deprotonation to give the free carbene as intermediate;[1–3] since **3** is the stablest form of the carbene,[4,5] this route is likely always to give the C-2 bound complex, **1**. Direct metallation of imidazolium salts has also previously always occurred at the 2-position,[6] including in our own prior work.[6c]

In this communication, we report the facile reaction of the imidazolium precursor salt with a metal hydride to give a 'carbene' of type **2** with the metal attached at the 'wrong' carbon, C-5 not C-2. **2** could also be regarded as a metallated imidazolium salt.

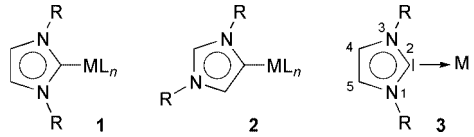
$IrH_5(PPh_3)_2$ **4** is known[7] to react with substituted pyridines (L′) in refluxing C_6H_6 *via* loss of H_2 to give the trihydrides $(L')IrH_3(PPh_3)_2$ (**5**). Since the pyridine-substituted imidazolium salts **6a**,**b** are readily available[8] from the *N*-alkylimidazole and 2-bromomethylpyridine, followed by Br/BF_4 anion exchange, we looked at their reaction with **4**. This occurred readily under similar conditions as before (refluxing THF, 2 h, recrystalization from THF–pentane) but to give the chelating carbene complex, **7** with the metal bound at C-5, not C-2 as expected [eqn. (1)].†



(1)

[**a** R = Pr^i, **b** R = Bu^n; L = PPh_3]

The identity of the product **7a** is suggested by the spectroscopic data (298 K), particularly ^1H NMR spectroscopy in $CDCl_3$ where a low field signal of unit intensity (8.72 ppm) is assigned to the imidazole 2 proton, while a signal at higher field



Scheme 1

also of unit intensity (5.17 ppm) is assigned to the 4-proton. The metal bound hydrides show very different shifts reflecting the large differences of the *trans* ligands (−10.83 ppm, tentatively[7] assigned to be *trans* to the metal-bound carbon, and −21.49 ppm, *trans* to pyridine). The $J(HH')$ of 5 Hz is typical[9] for a *cis* MH_2 arrangement, and the $J(PH)$ of 18–20 Hz is typical of a *cis* $M(PR_3)H$ arrangement. The presence of a metal bound carbene follows from the $^{13}C\{^1H\}$ spectra where the C-5 carbon is low field shifted (141.07 ppm compared to *ca.* 122 ppm in the precursor imidazolium salt). Moreover, this resonance appears as a triplet as a result of coupling to ^{31}P [$J(PC)$ 7.1 Hz]. In contrast, the C-2 carbon underwent a high field shift to 129.55 ppm, which does not suggest metallation of this carbon. As expected for equivalent phosphorus nuclei only one singlet (21.4 ppm) is observed in the $^{31}P\{^1H\}$ NMR spectra. The similarity of the NMR data of **7b** with those of **7a** leaves no doubt that they have similar structures and all data are consistent with structure **7**.

The X-ray structure‡ (Fig. 1) defines the situation unambiguously for **7a**. The Ir is attached to the imidazole 5-carbon, equivalent to C(7) in crystallographic numbering, as shown by the locations of the benzylic and Pr^i ring substituents that define the nitrogen positions; Pr^i is not adjacent to the M–C bond so the complex is of non-Arduengo type. The C–C distances in the ring are normal for an imidazolium and the Ir–C(7) bond [2.100(6) Å] is essentially single, so there is little if any Ir–C π-bonding. Other distances and angles are unremarkable.

The crystallographic data show that the molecule is chiral owing to the non-planarity of the pyridine–carbene ligand. The six- and five-membered rings of the chelate ligand are oriented at a dihedral angle of 146°. The NMR spectra, however, are consistent with a molecule with a plane of symmetry as isopropyl methyl protons and the bridge methylene protons of the ligand are equivalent; likewise there is also only a single ^{31}P resonance. This suggests a rapid interconversion on the NMR timescale (at 298 K) that corresponds to racemization *via* a boat–boat six-membered ring flip.

Complex **7** has so far shown no tendency to rearrange to the 2-isomer. Heating a DMSO solution of **7b** to 100 °C for 1 h did not show any change. At 160 °C, however, gradual decomposition of the material was observed without rearrangement of the ligand binding mode. It is still unclear if **7** is a thermodynamic or a kinetic product. The > 20 kcal mol^{-1} energy favoring 2- *vs.* 5-binding [numbering as in eqn. (1)] found[5] for the $[PtCl_3]^-$ derivative seems rather too large to be reversed by change of metal and substituents and **7a**,**b** seem most likely to be kinetic products. If so, abnormal 4(5)-binding may only be a risk for any path not involving deprotonation, such as direct metallation.

 DOI: 10.1039/b107881j

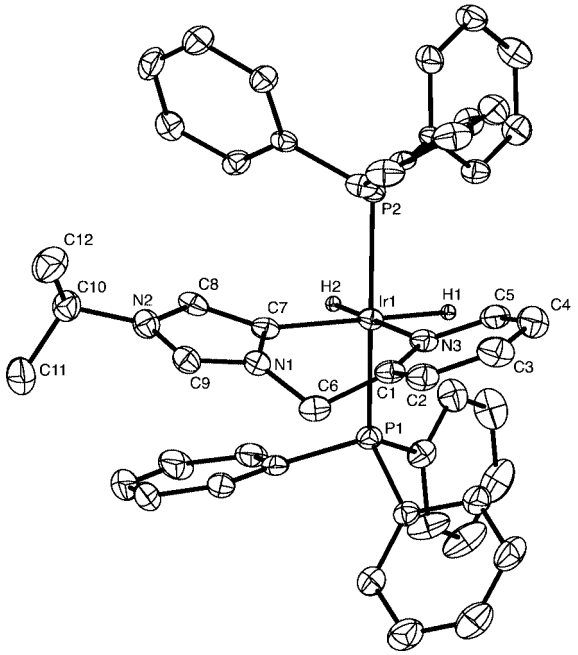


Fig. 1 Molecular structure of the cation of **7a** showing 50% probability thermal ellipsoids. Only the metal-bound hydrogens (calculated positions) are shown. Selected distances (Å) and angles (°): Ir(1)–P(1) 2.287(2), Ir(1)–P(2) 2.301(2), Ir(1)–N(3) 2.193(5), Ir(1)–C(7) 2.100(6), N(1)–C(6) 1.461(7), N(1)–C(7) 1.404(7), N(1)–C(9) 1.335(8), N(2)–C(8) 1.390(8), N(2)–C(9) 1.327(8), N(2)–C(10) 1.459(8); N(3)–Ir(1)–C(7) 89.3(2), P(1)–Ir(1)–P(2) 163.86(6).

We cannot exclude **7a**,**b** being thermodynamic products, however, in which case other carbenes currently considered Arduengo type may in fact be bound at C-4(5). Whatever the origin of the effect, care must clearly be taken in future not to assume 2-substitution always takes place in carbenes derived from imidazolium salts.

Notes and references

† *Typical synthesis*: a mixture of **6b** (BF_4 salt, 54 mg, 0.18 mmol) and $IrH_5(PPh_3)_2$ (129 mg, 0.18 mmol) in THF (8 ml) was refluxed in air for 2.3 h. After 20 min a clear solution is obtained. After the reaction mixture had cooled to room temperature it was layered with 10 ml heptane. Over a period of 12 h, crystals of **7b** formed which were filtered off and dried *in vacuo*. Yield: 124 mg (68%). The complex can be recrystallized from THF/pentane.

Spectroscopic data for **6a**: ^{1}H NMR ($CDCl_3$, 298 K): δ 9.17 (s, 1H, NCHN), 8.55 (d, $^3J_{HH}$ 4.6 Hz, 1H, py-H), 7.77 (dt, $^3J_{HH}$ 7.7, $^4J_{HH}$ 1.7 Hz, 1H, py-H), 7.66 (d, $^3J_{HH}$ 7.9 Hz, 1H, py-H), 7.59 (s, 1H, imid-H), 7.31 (dd, $^3J_{HH}$ 7.6 , $^3J_{HH}$ 5.0 Hz, 1H, py-H), 7.25 (s, 1H, imid-H), 5.51 (s, 4H, CH_2), 4.65 (septet, $^3J_{HH}$ 6.8 Hz, 1H, CH), 1.61 (t, $^3J_{HH}$ 6.8 Hz, 6H, CH_3). ^{13}C{^{1}H} NMR ($CDCl_3$, 298 K): δ 152.38 (C_{py}), 149.90 (C_{py}), 137.85 (C_{py}), 135.08 (NCN), 124.05 (C_{py}), 123.84 (C_{py}), 123.04 (C_{imid}), 119.83 (C_{imid}), 54.17 (CH_2), 53.56 (C_{Pr^i}), 22.68 (C_{Pr^i}).

For **6b**: ^{1}H NMR ($CDCl_3$, 298 K): δ 9.09 (s, 1H, NCHN), 8.51 (d, $^3J_{HH}$ 4.6 Hz, 1H, py-H), 7.73 (dt, $^3J_{HH}$ 7.7, $^4J_{HH}$ 1.8 Hz , 1H, py-H), 7.58 (d, $^3J_{HH}$ 7.8 Hz, 1H, py-H), 7.53 (s, 1H, imid-H), 7.32 (s, 1H, imid-H), 7.27 (dd, $^3J_{HH}$ 7.7, $^3J_{HH}$ 4.8 Hz, 1H, py-H), 5.49 (s, 4H, CH_2), 4.19 (t, $^3J_{HH}$ 7.5 Hz, 2H, Bu-H), 1.89–1.81 (m, 2H, Bu-H), 1.39–1.30 (m, 2H, Bu-H), 0.93 (t, $^3J_{HH}$ 7.5 Hz, 3H, Bu-H). ^{13}C{^{1}H} NMR ($CDCl_3$, 298 K): δ 152.25 (C_{py}), 149.77 (C_{py}), 137.86 (C_{py}), 136.37 (NCN), 124.06 (C_{py}), 123.80 (C_{py}), 122.93 (C_{imid}), 121.75 (C_{imid}), 54.00 (CH_2), 49.93 (C_{Bu}), 31.81 (C_{Bu}), 19.34 (C_{Bu}), 13.30 (C_{Bu}).

For **7a**: ^{1}H NMR ($CDCl_3$, 298 K): δ 8.72 (s, 1H, NCHN), 8.23 (d, 1H, $^3J_{HH}$ 5.5 Hz, py-H), 7.37–7.14 (m, 32H, py-H, Ph-H), 6.07 (t, $^3J_{HH}$ 6.3 Hz, py-H), 5.17 (s, 1H, imid-H), 4.70 (s, 2H, CH_2), 4.25 (septet, 1H, $^3J_{HH}$ 6.5 Hz, CH), 1.19 (d, 6H, $^3J_{HH}$ 6.5 Hz, CH_3), −10.83 (dt, $^2J_{PH}$ 19.6, $^3J_{HH}$ 4.9 Hz, Ir-H), −21.49 (dt, $^2J_{PH}$ 18.6, $^3J_{HH}$ 4.9 Hz, Ir–H). ^{13}C{^{1}H} NMR ($CDCl_3$, 298 K): δ 161.78 (C_{py}), 153.10 (C_{py}), 141.07 (t, J_{PC} 7.1 Hz, $C_{carbene}$), 137.04 (C_{py}), 134.93 (t, J_{PC} = 26.3 Hz, C_{Ph}), 133.55 (t, J_{PC} 6.0 Hz, C_{Ph}), 132.40 (C_{Ph}), 129.55 (NCN), 127.84 (t, J_{PC} 5.8, C_{Ph}), 125.87 (C_{imid}), 124.15 (C_{imid}), 123.56 (C_{py}), 55.03 (CH_2), 50.47 (C_{Pr^i}), 22.94 (C_{Pr^i}). ^{31}P{^{1}H} NMR ($CDCl_3$, 298 K): δ 21.36.

For **7b**: ^{1}H NMR ($CDCl_3$, 298 K): δ 8.71 (s, 1H, NCHN), 8.19 (d, $^3J_{HH}$ 5.1 Hz, 1H, py-H), 7.37–7.15 (m, 32H, py-H, Ph-H), 6.07 (t, $^3J_{HH}$ 5.9 Hz, 1H, py-H), 5.03 (s, 1H, imid-H), 4.72 (s, 2H, CH_2), 3.63 (t, $^3J_{HH}$ 6.9 Hz, 1H, CH_2), 1.47 (m, 2H, CH_2), 1.17 (m, 2H, CH_2), 0.90 (t, $^3J_{HH}$ 7.7 Hz, CH_3), −10.89 (dt, $^2J_{PH}$ 19.6, $^3J_{HH}$ 5.1 Hz, Ir-H), −19.61 (dt, $^2J_{PH}$ 18.4, $^3J_{HH}$ 5.1 Hz, Ir-H). ^{13}C{^{1}H} NMR ($CDCl_3$, 298 K): δ 161.77 (C_{py}), 153.07 (C_{py}), 141.30 (t, J_{PC} 6.9 Hz, $C_{carbene}$), 137.09 (C_{py}), 134.96 (t, J_{PC} = 26.3, C_{Ph}), 133.79 (C_{Ph}), 133.61 (t, J_{PC} 6.0, C_{Ph}), 129.59 (NCN), 127.86 (t, J_{PC} 4.7, C_{Ph}), 126.13 (C_{imid}), 125.90 (C_{py}), 124.18 (C_{py}), 55.08 (CH_2), 47.89 (C_{Bu}), 31.96 (C_{Bu}), 19.36 (C_{Bu}), 13.37 (C_{Bu}). ^{31}P{^{1}H} NMR ($CDCl_3$, 298 K): δ 21.39.

‡ *Crystal data* for **7a**: $C_{48}H_{47}BF_4IrN_3P_2$, M = 1006.89, colorless crystal, primitive monoclinic cell with dimensions: a = 9.4493(2), b = 20.6687(6), c = 22.0865(6) Å, β = 90.160(2)° and V = 4313.6(2) Å^3; Z = 4; μ(Mo–Kα) = 3.223 mm^{-1}; D_c = 1.550 g cm^{-3}. The systematic absences of: $h0l$: $l \neq \pm 2n$ and $0k0$: $k \neq \pm 2n$ uniquely determine the space group to be $P2_1/c$ (no. 14). 38573 reflections measured (KappaCCD diffractometer, T = 183 K). The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at calculated positions (including the Ir hydrides), but not refined. The final cycle of full-matrix least-squares refinement on F was based on 4789 observed reflections [$I > 3.00\sigma(I)$] and 532 variable parameters and converged with unweighted and weighted agreement factors of R = 0.033 and R_w = 0.035 (S = 0.905). CCDC reference number 171283. See http://www.rsc.org/suppdata/cc/b1/b107881j/ for crystallographic data in CIF or other electronic format.

p-Sulfonatocalix[6]arene is shown to form insoluble complexes with poly(allylamine hydrochloride) when the charge balance between the negative calixarene sulfonate groups matches the positive charge carried by the polyelectrolyte, this makes this glycosylaminoglycan analog an interesting candidate for controlled release systems in the case of proteins encapsulated in mesoscopic complexes with polyelectrolytes.

Calixarenes are one of the major classes of host molecules in supramolecular chemistry, together with cyclodextrins and crown ethers.[1] The interest in these molecules is increasing in view of the possibility of preparing water soluble derivatives.[2] Among these are the *p*-sulfonatocalix[*n*]arenes, denoted $\mathbf{1}_n$, where *n* is the number of linked aromatic rings.[3] These molecules complex organic compounds as well as inorganic ions in water[4] and are possible candidates for heparin mimics,[5] since as with heparin they display a high density of negatively charged sulfonate groups and could hence possess an antithrombotic activity.[5] Moreover the synthetic pathway to these compounds[6] is rather simple when compared to that leading to heparin and they display essentially no immune response.[7] It is well known that arginine and lysine play a key role in the sequences present in heparin recognition sites.[8] Recently, the interactions between $\mathbf{1}_4$, $\mathbf{1}_6$, and $\mathbf{1}_8$ with these single amino acids[9] as well as with their small oligomers[10] have been investigated by means not only of NMR spectroscopy to determine the stoichiometry as well as the localisation of the amino acids within the hydrophobic cavity, but also by means of isothermal microcalorimetry (ITC) to determine the standard enthalpy and entropy variations associated with complex formation. To our knowledge, the interactions between $\mathbf{1}_n$ and large cationic homopolymers in solution have never been investigated. This is of prime importance not only from a fundamental point of view, to study the influence of the correlation between the cationic groups on the complexation process, but also from a more practical point of view for the controlled release in protein–polyelectrolyte complexes.[11,12] It has been shown, that enzymes can be stabilised for long range storage when wrapped in a polyelectrolyte network,[12] but is it possible to remove the polyelectrolyte around the protein without denaturation of the enzyme? For this reason, we give here our first results describing the interactions between $\mathbf{1}_6$ and poly(allylamine hydrochloride), PAH, in a pH 7.4 Tris (10 mM)–NaCl 0.1 M buffer. Under these conditions we assume that the phenolic groups on $\mathbf{1}_6$ are not ionised. Our results were obtained by combining several physicochemical techniques aimed to describe not only the structure of the obtained mesoscopic complexes but also their formation mechanism. In order to understand the influence of the chain length upon the interactions with $\mathbf{1}_6$, two different molecular weight polymers were used, PAHS, M_w = 15 kDa and PAHL, M_w = 70 kDa.†

At a constant PAH concentration of 2.2×10^{-6} M for PAHL and 4.3×10^{-6} M for PAHS, the addition of $\mathbf{1}_6$,[6] leads to a progressive increase of the solution turbidity (Fig.1),‡ and levelling off at a given mixing ratio *r* (defined as the number of provided $\mathbf{1}_6$ to the number of initially present PAH molecules). Simultaneously with the turbidity increase, the average size of the (polydisperse) particles increases as determined by means of dynamic light scattering (DLS): the initial PAHS and PAHL have an hydrodynamic radius around 4 and 8.5 nm respectively,‡ however at r = 37.3 for PAHL, the solution contained particles of hydrodynamic radius around 10 and 99 nm which contribute to about 60% of the scattered intensity (data not shown). For PAHS at r = 12.4, the solution contains particles of the same size and also particles around 370 nm in radius (12% of the scattered intensity). For PAHL and PAHS the plateau of the turbidity isotherms are reached for r = (200 ± 30) and r = (40 ± 10) respectively (Fig. 1).

Taking into account the presence of 6 negative charges from the sulfonate groups on $\mathbf{1}_6$ and the DP of the two PAHs, these *r* values correspond to the electrical neutralisation of the polymer with a full release of the condensed chloride counter ions. This assumption was furthermore checked by means of laser Doppler electrophoresis (LDE),‡ operated under conditions of constant current, 5 mA (Fig. 2): for low *r* values the ζ potential is positive as expected in the presence of an excess of positively charged PAH whereas for high *r* the negative ζ potential reflects mainly the presence of a large excess of $\mathbf{1}_6$. The charge inversion occurs again around r = 200 for PAHL and r = 40 for PAHS (Fig. 2).

At *r* values higher than this threshold, the obtained particles sediment in about 10 to 15 min after their preparation. Hence, these particles could not be characterised by means of DLS. At lower *r* values, no sedimentation is observed even after a few hours despite the particle size increase at least in the dilute polyelectrolyte concentration regime: we are in presence of

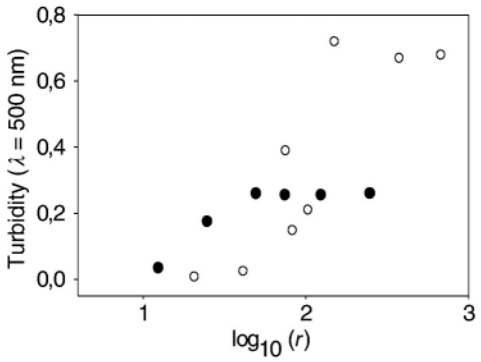

Fig. 1 Evolution of the turbidity (at λ = 500 nm) as a function of *r* for PAHL (○) and PAHS (●) at constant PAH concentration.

 DOI: 10.1039/b106361h

phase separation[13] *when neutral complexes are formed.* The used PAHL and PAHS display an average hydrodynamic radius close to 8 and 4 nm, implying that the increase in size originates from $\mathbf{1_6}$ induced intermolecular bridging. This is not unrealistic on the basis of the preferential double partial cone conformation of $\mathbf{1_6}$.[14] The obtained mesoscopic complexes are irreversible not only under dilution with Tris–NaCl buffer as displayed by a linear decrease of the turbidity with the dilution ratio (data not shown) but also by addition of either PAH or $\mathbf{1_6}$, when the plateau level of the binding isotherm is reached. The irreversibility of this process upon dilution was also checked by centrifugation of the particles (prepared at r = 44.4 for PAHL), removal of the supernatant, replacement by Millipore water and redispersion of the particles. Three centrifugation, supernatant removal, redispersion in water cycles were performed, the particles were then dried for 28 h at 110° and analysed by means of elemental analysis: they contained 33.2 C, 5.7 N, 5.0 H, 6.5 S and 13.47% Cl, whereas the initial PAH had 37.9% Cl and no sulfur content. This implies that sulfonate molecules remain bound to the PAH even after extensive rinsing and that a significant number of Cl^- counter ions have been released. Turbidity experiments performed in the absence of buffer but at 0.1 M NaCl and by varying the pH showed that the turbidity became lower than 0.01 at pH higher than 11.5 with a gradual decrease beginning after pH 9: hence the complexes are dissociated by neutralisation of the primary amine groups of PAH. These observations all point to strong interaction of electrostatic nature taking place between $\mathbf{1_6}$ and PAH. This was checked by means of ^{1}H NMR spectroscopy‡ where it appears that the signals due to $\mathbf{1_6}$ (at δ = 7.37 and 3.86 ppm) practically disappear and the peaks become broader when r is lower than 200 for PAHL and 30 for PAHS (data not shown). Hence only the unbound $\mathbf{1_6}$ molecules are seen (at high enough r) and those bound to PAH are not able to relax after radio frequency excitation. ITC‡ revealed that the dilution heat of PAHL into the Tris–NaCl buffer was slightly endothermic ($\Delta H_{\mathrm{dil,\ PAHL}}$ = 66.2 kJ mol^{-1}). The enthalpy variation associated with the reaction is equal to (−18100 ± 1500) kJ mol^{-1}, meaning that the average enthalpy per $\mathbf{1_6}$ molecule amounts to −90.5 kJ mol^{-1}. This value is 4 times larger than the binding enthalpy for lysine–$\mathbf{1_6}$ complex formation.[10] Each $\mathbf{1_6}$ molecule interacts on average with 6 monomer units (indeed the solution extracted from the calorimeter cell displays strong turbidity, we are hence in the plateau region of Fig. 1), the binding interaction per site amounts hence to about −15 kJ mol^{-1}, which is only about 1.5 times smaller than for lysine–$\mathbf{1_6}$ complexation. To conclude whether this smaller enthalpy variation per interaction site originates from intrinsic differences between the side chain of PAH and lysine or from a contribution due to the constraints imposed by the polymer chain, we will perform the same kind of ITC experiments with poly(L-lysine hydrobromide). Note that the interaction enthalpy is the same when PAHS is employed instead of PAHL. Thus if any chain effect should occur, it must take place for smaller degrees of polymerisation. Hence we have demonstrated the occurrence of strong and irreversible electrostatically driven interactions between PAH and $\mathbf{1_6}$ at pH 7.4, leading to phase separation when the polymer is neutralised by the appropriate number of $\mathbf{1_6}$ molecules. The interactions between $\mathbf{1_6}$ and PAH may be used in order to quantitatively release proteins bound inside protein–PAH complexes[11] as will be shown in a forthcoming study.

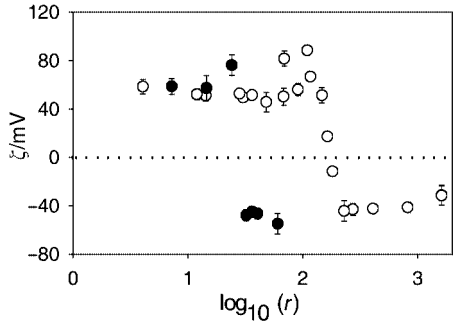

Fig. 2 ζ potential of the PAH–$\mathbf{1_6}$ complexes in Tris–NaCl buffer as a function of r: PAHL (○) and PAHS (●), the dotted line corresponds to ζ = 0. The error bars correspond to the standard deviation of the mean (n = 10).

The use of tetraalkylammonium salts or imidazolium ionic liquids in catalytic oxidations of alcohols with tetra-*N*-propylammonium perruthenate allows recovery and reuse of the oxidant; this concept may find application in the recovery of other homogenous catalysts.

The application of reagents in sub-stoichiometric quantities to perform fundamental transformations is one of the cornerstones upon which modern organic chemistry is constructed. This approach, *via* either heterogeneous or homogeneous catalysis, is environmentally and economically advantageous although there are well-documented problems associated with the removal of homogenous catalysts from reaction mixtures. Methods to circumvent this issue generally rely on covalent attachment of catalytic materials to polymeric backbones;[1] this approach has proven to be effective in certain cases but necessitates modification of the catalyst structure and this can lead to a loss of efficacy.[2] Ionic liquids have been proposed as 'green' solvents for organic synthesis due to the ease with which they can be recycled and reused whilst offering an inert, dipolar media compatible with much of conventional chemistry.[3] These properties have been reflected in their use in a range of reactions including Suzuki cross-couplings,[4] Heck reactions,[5,6] oxidation processes[7,8] and Diels–Alder reactions.[9,10] Recent reports of their utility in the immobilisation of transition metal catalysts[11] prompted us to extend these investigations to encompass reagents for the selective oxidation of alcohols. The use of tetra-*N*-propylammonium perruthenate (TPAP) as a homogenous and versatile reagent for the catalytic oxidation of alcohols has previously been reported;[12] in this communication we disclose a system that permits recycling and reuse of TPAP. A recent report describes attempts to develop a recyclable variant of TPAP through its entrapment in a complex sol–gel matrix; this method severely curtails the activity of the catalyst relative to solution-phase TPAP.[13] Our initial investigations centred on the use of imidazolium ionic liquids to permit immobilisation of the ruthenium catalyst, Table 1. TPAP oxidation (10 mol%) of benzyl alcohol in CH_2Cl_2 in the presence of 1-ethyl-3-methyl-1*H*-imidazolium hexafluorophosphate ([emim][PF_6]) and pre-dried *N*-methylmorpholine *N*-oxide (NMO) as co-oxidant proceeded smoothly; when the reaction was deemed to be complete (*via* TLC), diethyl ether was added to the solution with stirring. The insolubility of solid [emim][PF_6] in ethereal solvents results in sequestration of the catalyst, observed as the

precipitation of a black–green suspension. The clear supernatant liquid containing the oxidation products can be recovered by simply decanting and the remaining solid containing the ruthenium catalyst can be reused after drying. It was found that reuse of the catalyst was viable when applied to the oxidation of trivial substrates such as benzyl alcohol; the reaction was repeated five times without significant loss of catalytic activity. Similar results were obtained with cinnamyl alcohol but a significant slowing of the reaction was observed during the fourth recycling. Although these results were encouraging, the high cost of this particular imidazolium species[14] prompted us to search for an alternative and it was reasoned that the use of another weakly coordinating salt such as a tetraalkylammonium halide could be appropriate. Tetraalkylammonium halides have been utilized as molten salts at elevated temperatures (T > 150°C) in non-aqueous Heck reactions[15] and are cheap and readily available.[16] Oxidation of benzyl alcohol with TPAP under standard conditions (10 mol% catalyst, CH_2Cl_2, NMO, RT) in the presence of tetraethylammonium bromide (prepared by pre-drying under vacuum) afforded benzaldehyde in essentially quantitative yield. Recovery and reuse of the catalyst was found to be simple *via* the procedure described previously; the catalyst could be reused five times for simple oxidations such as this without any noticeable loss of activity. Oxidation of cinnamyl alcohol proceeded smoothly in yields comparable to those achieved with the imidazolium salt. After three recycles, however, there was a noticeable loss of activity culminating in only 85% conversion after 30 h reaction time.[17] The reasons for this loss of activity are not clear, although it has been postulated that black insoluble material produced during these oxidations could be colloidal ruthenium.[18] In an attempt to ascertain the scope and limitations of these conditions, the oxidation of a non-activated secondary alcohol was also attempted. The oxidation of menthol was rapid and high yielding for two catalyst repetitions in the presence of Et_4NBr but the reaction slowed significantly afterwards with only 66% conversion being observed after 3 days. This was still superior to the results observed with the use of the imidazolium species. The conversion of dihydrocholesterol to dihydrocholesterone was also successful in the presence of both alkylammonium and imidazolium salts. Similarly good results were obtained with the oxidation of *sec*-phenethyl alcohol; the starting material was rapidly and quantitatively oxidized to acetophenone, and the procedure could be repeated without incident. Encouraged by the outcome of these reactions, it was decided to examine the aerobic co-oxidation of TPAP in an attempt to enable isolation of the products without the need for separation from a co-oxidant. Aerobic co-oxidation of ruthenium(VII) derivatives has been reported in oxygenated toluene at 80°C.[18–20] However, these conditions were found to lead to catalyst decomposition and hence incomplete oxidation. In contrast, performing the reaction under moderate oxygen pressure (30–40 bar) in dichloromethane at room temperature resulted in rapid, clean oxidation of *sec*-phenethyl alcohol. Repetition of this process could also be achieved, and three cycles were performed with consistently good catalyst performance. The reaction was stopped after 16 h to gauge the extent of reaction in both the fourth and fifth recycles and showed that the activity of the catalyst was declining over time. If extended reaction times were employed, however, it was found that complete conversion to the ketone was still attained.

In this paper it has been demonstrated that both Et_4NBr and [emim][PF_6] may be used to enable the recovery and reuse of tetra-*N*-propylammonium perruthenate. The ease with which this procedure can be employed for oxidations with oxygen or *N*-methylmorpholine *N*-oxide as co-oxidant augurs well for its application in clean synthetic procedures.

We would like to thank Syngenta for a postdoctoral fellowship (to CR), Pembroke College, Cambridge for a fellowship (to MDS) and the Novartis Research fellowship (to SVL).

Notes and references

† As with all TPAP oxidations, care should be exercised upon addition of the oxidant to reaction mixtures as heat may be evolved. Mixing of neat ionic liquids and TPAP is not recommended; it has been observed that this reaction can be violent and exothermic.‡ Method A: representative procedure: TPAP (0.25 mmol) was added cautiously to a stirring solution of alcohol (2.5 mmol), *N*-methylmorpholine *N*-oxide (3.75 mmol) and [emim][PF_6] (0.5 g) in CH_2Cl_2 (5 mL). The solution was stirred at RT under an atmosphere of argon until TLC indicated the completion of the reaction. Et_2O (40 mL) or petroleum ether (40 mL) was added and the mixture vigorously stirred for 10 min. The mixture was allowed to stand for 5 min when the clear supernatant liquid was decanted (through a filter paper), concentrated and filtered through a plug of silica gel (10 mm × 10 mm), eluting with Et_2O to afford *the aldehyde or ketone*. The catalyst mixture was dried under vacuum before reuse.

§ Method B: representative procedure: as for method A but with tetra-*N*-ethylammonium bromide in place of [emim][PF_6].

¶ Method C: representative procedure: TPAP (0.25 mmol) was added cautiously to a stirring solution of alcohol (2.5 mmol) and Et_4NBr (0.5 g) in CH_2Cl_2 (5 mL). The solution was stirred at RT under an atmosphere of oxygen (40 Bar) until TLC indicated the completion of the reaction. Et_2O (40 mL) was added and the mixture vigorously stirred for 10 min. The mixture was allowed to stand for 5 min when the clear supernatant liquid was decanted (through a filter paper) and concentrated to afford *the aldehyde or ketone*. The catalyst mixture was dried under vacuum before reuse.

Received (in Cambridge, UK) 26th June 2001, Accepted 19th September 2001
First published as an Advance Article on the web 11th October 2001

The non-emissive platinum(II)–quaterpyridine complex shows strong photoluminescence at room temperature upon incorporation into Nafion membrane; this complex is stabilized toward photochemical decomposition in Nafion even in the presence of oxygen, and can be used as a sensitizer to generate singlet oxygen to oxidize alkenes.

Luminescent square planar d^8 platinum(II)–polypyridine complexes may oligomerize in solution leading to supramolecular architectures whose photophysical properties can be used to elucidate ligand–ligand (π–π) and metal–metal interactions.[1–4] However, in many cases they are weak emitters or even non-emissive in fluid solution at room temperature.[1–5] Thus, many researchers have diverted their attention to exploit new complexes which show strong luminescence at room temperature.[4–6] Here we report an approach to enhance the room-temperature luminescence from Pt(II)–polypyridine complexes. Our approach involves the use of Nafion membrane as the rigid matrix. Upon incorporation into the membrane, the non-emissive platinum(II)–quaterpyridine complex $[Pt(QP)](CF_3SO_3)_2$ (QP = 2,2′:6′,2″:6″,2‴-quaterpyridine) exhibits strong photoluminescence at room temperature. Furthermore, this complex in Nafion is stable and can be used as a photosensitizer to generate singlet oxygen.

Nafion represents a family of polymers which consists of a perfluorinated backbone and short pendant chains terminated by sulfonic groups. When swollen in water, the structure of Nafion is believed to resemble that of an inverse micelle.[7] The water-swollen Nafion can incorporate high concentrations of organic and inorganic compounds, thus raising the possibility of obtaining high local concentrations of substrates. The complex $[Pt(QP)](CF_3SO_3)_2$ was successfully incorporated into water-swollen Nafion (in sodium form, Nafion-Na^+) by immersing the membrane samples in an aqueous suspension of the platinum complex. The concentration of the platinum complex in the membrane was measured by its absorption spectrum, assuming that the absorption spectra obey Beer's law in the concentration range studied. Although this complex has a low solubility in water, its concentration in the water-swollen Nafion-Na^+ can be rather high (*ca.* 2×10^{-5} mol/g Nafion). It is likely that the molecules of this complex are primarily solubilized in the hydrophobic perfluorocarbon backbone region close to the fluorocarbon/water interface.

The absorption spectrum of $[Pt(QP)](CF_3SO_3)_2$ in acetonitrile has been described previously by one of the authors.[8] This complex shows intense absorption bands in the high-energy region ($\lambda < 325$ nm) which are assigned to intraligand ^{1}IL(π, π*) transitions, and moderately intense low-energy bands ranging from 320 to 370 nm which can be assigned to spin-allowed metal-to-ligand charge-transfer transitions (^{1}MLCT) involving a dπ platinum orbital as the donor orbital and π* quaterpyridine orbital as the acceptor orbital. Upon incorporation into Nafion membrane, all of the absorption bands are slightly blue-shifted (*ca.* 2 nm) compared with those in acetonitrile solution. Furthermore, weak absorption bands from 375 to 450 nm were observed at high complex loading level and attributed to the absorption of oligomerized species based on the fact that excitation with light in this wavelength region exclusively leads to excimeric emission (see below).

At room temperature, a degassed acetonitrile solution of $[Pt(QP)](CF_3SO_3)_2$ shows no emission upon excitation at 358 nm due to molecular distortion which results in nonradiative decay. This situation is quite different when the complex is incorporated into Nafion membrane. In water-swollen Nafion membrane and in a nitrogen atmosphere, this complex shows a very weak emission. However, after removal of the absorbed water by evaporation under vacuum, the dry complex–Nafion sample exhibits a strong luminescence in a nitrogen atmosphere. Possibly, the rigid matrix in dry Nafion causes the deactivation process *via* molecular distortion to be blocked. Fig. 1 shows the emission spectra of dry Nafion samples at room temperature. At low complex loading (*ca.* 1×10^{-7} mol/g Nafion) the Nafion sample shows a structured emission with λ_{max} at 476, 513 and 544 nm. and lifetime of *ca.* 3.42 μs. The long emission lifetime suggests that the transition involved is a spin-forbidden process. The vibrational progression is *ca.* 1330 cm^{-1}, which corresponds to the C=C and C=N stretching modes, the dominant high-frequency acceptor modes of LC levels involving polypyridine-type ligands.[5] Thus, this emission is assigned to be associated to the ^{3}IL (π, π*) state of the coordinated quaterpyridine ligand. At high loading a broad emission band centered at 600 nm (τ = 2.58 μs) prevails in addition to the structured ^{3}IL emission (Fig. 1). The broad

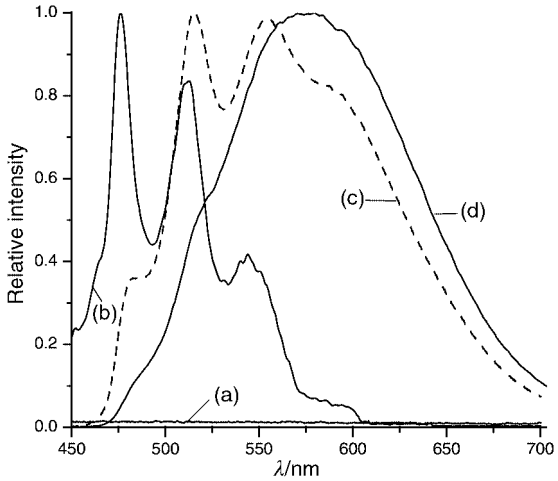

Fig. 1 The normalized emission spectra of $[Pt(QP)](CF_3SO_3)_2$ incorporated in Nafion at different concentrations and excitation wavelength: (a) in acetonitrile, 1×10^{-5} M, λ_{ex} = 358 nm; (b) in Nafion, 1×10^{-7} mol/g Nafion, λ_{ex} = 358 nm; (c) in Nafion, 1.4×10^{-5} mol/g Nafion, λ_{ex} = 358 nm; (d) in Nafion, 1.4×10^{-5} mol/g Nafion, λ_{ex} = 410 nm.

emission overlaps on the ^{3}IL emission when the complex is excited with light of wavelength < 375 nm. However, the broad emission becomes dominant at an excitation wavelength > 380 nm (Fig. 1). Since this broad emission occurs only at high loading, it is attributed to excimeric species originating from π–π interactions between the partially stacked quaterpyridine ligands in the oligomers. In other words, the broad emission originates from excitation of the oligomerized species, differently from the ^{3}IL emission which originates from excitation of the 'isolated' monomers. The oligomerization of square planar d^8 metal complexes has been well precedented.[1–6]

The rigid matrix of Nafion stabilizes the $[Pt(QP)](CF_3SO_3)_2$ complex towards photochemical decomposition. At room temperature in aerated acetonitrile solution, this complex is photochemically unstable. For example, photoirradiation of the solution within 2 h resulted in a significant decrease in absorption. However, photolysis of the complex in dry Nafion membrane immersed in acetonitrile led to no change in the absorbance of $[Pt(QP)](CF_3SO_3)_2$ over a period of 10 h. The matrix-stabilized complex was used as a photosensitizer to generate singlet oxygen and to oxidize alkenes such as *trans*-stilbene, *trans*-1,2-dimethoxystilbene and cyclohexene. The photosensitized oxidations were carried out in oxygen-saturated solution of the substrate in acetonitrile in which $[Pt(QP)](CF_3SO_3)_2$ incorporated Nafion membranes were suspended. Photoirradiation of the complex yields the photooxidation products as shown in Table 1. All the products were identified by GC–MS. Significantly, the platinum complex–Nafion sample was easily separated from the solution, and could be used for many cycles without loss of activity. We propose that this photooxidation of alkenes proceeds *via* singlet oxygen mechanism. Acetonitrile can moderately swell the complex–incorporated Nafion membrane and thus enables oxygen to diffuse into the membrane from the solvent. Interaction between oxygen and the ^{3}IL excited state of the complex results in energy transfer to generate singlet oxygen, which diffuses back to the solution to oxidize the alkenes. This proposal is supported by EPR spectroscopy. It has been established that 2,2,6,6-tetramethylpiperidine (TMP) reacts with singlet oxygen to give the stable free radical nitroxide, which can be readily detected by EPR spectroscopy.[9] Thus, we dissolved TMP in oxygen-saturated acetonitrile, and immersed the complex-incorporated Nafion membrane in the solution. Fig. 2 shows the EPR spectrum obtained after 400 s irradiation of the solution and clearly evidenced the nitroxide free radical. This obsevation shows that singlet oxygen was generated in the Nafion membrane and diffused into the solution to react with TMP to give the nitroxide radical.

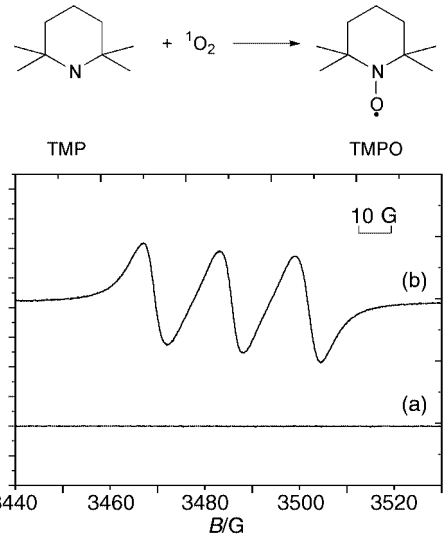

Fig. 2 EPR spectrum of nitroxide radical generated by irradiation of the Nafion-incorporated complex immersed in an oxygen-saturated acetonitrile solution of TMP: (a) in the dark; (b) after the sample was irradiated for 400 s.

First published as an Advance Article on the web 11th October 2001

Hybrid organo-silica materials possessing uniform nanoscale porosity in the super-micropore size range (1.0–2.0 nm diameter) have been prepared using neutral alkylamine and non-ionic alkyl(phenyl)polyethylene oxide surfactants as structure-directing agents.

The preparation of functionalized derivatives of surfactant-assembled nanoporous silica (including MCM-41,[1] HMS,[2] MSU-X[3,4] and SBA[5]) has been achieved by the incorporation of various moieties inside the pore channels of these mesostructures.[6] Recently, the reported syntheses of new mesostructures (designated HMM,[7] UOFMN,[8] PMO[9,10] or BSQM[11]) in which organic groups are integrated *within* the framework of mesoporous materials has opened up new prospects for the design of functional materials with uniform framework porosity.[7–13]

Reported methods to prepare organic-integrated mesostructures have thus far tended to produce materials with large mesoscale pore channels (>2.0 nm). It has been suggested that this pore size range may be too large to allow useful size- and shape-based separation/catalytic applications, and that materials possessing uniform-sized pores in the 1.0–2.0 nm size range (the *super-micropore* regime) may be better suited for such tasks.[14] Unfortunately, relatively few materials with uniform pore channels in this size domain have been described.[14]

Super-microporous hybrid organo-silica materials (hereafter designated Laurentian University Organic-Integrated Silica, or LUOIS) were synthesized using alkylamine surfactants[2] and bis(triethoxysilyl)ethane [$(EtO)_3Si–CH_2CH_2–Si(OEt)_3$, BTSE], producing organo-silica analogs of HMS silica. One such material, designated HMS-OIS-C8, was prepared by stirring BTSE (6.6 mmol) in an aqueous solution of octylamine (2.9 mmol in 25 mL water) for 24 h. Another LUOIS, denoted HMS-OIS-C12, was synthesized by stirring BTSE (7.6 mmol) in a solution of dodecylamine (3.4 mmol in 45 mL water and 5 mL ethanol) with trimethylbenzene (TMB, 3.4 mmol) for 24 h. LUOIS materials were also prepared by non-ionic surfactant assembly (*i.e.* N^0I^0),[3,4] producing organo-silica analogs of MSU-X silica. The first of these, hereafter designated MSU-2-OIS(N), was prepared by stirring BTSE (2.7 mmol) in a neutral pH solution of Triton-X100 non-ionic surfactant (0.68 mmol in 25 mL water) until a completely clear solution was obtained (12–24 h), after which NaF (0.22 mmol) was added to catalyze the silicate cross-linking and subsequent precipitation of the final product. Two other materials, MSU-2-OIS(A) and MSU-1-OIS(A), were prepared by stirring BTSE (2.7 mmol) in aqueous solutions of Triton-X100 and Brij-76 non-ionic surfactants (0.68 mmol in 25 mL water), respectively, to which was added HCl (0.2 mol L^{-1}) until the final pH reached 4.0 and 5.0, respectively. After ageing for 4 h, NaF (0.22 mmol) was added to form the solid product. For the purpose of comparison, purely siliceous samples of HMS, MSU-1 and MSU-2 were also prepared by replacing BTSE with a bimolar amount of TEOS in each of the previously outlined synthesis procedures. The LUOIS materials and their pure silica counterparts were washed free of surfactant by Soxhlet extraction over ethanol, and then characterized by powder X-ray diffraction (XRD), solid-state ^{29}Si and ^{13}C NMR spectroscopy, N_2 sorptometry and transmission electron microscopy (TEM).

The XRD patterns of all the LUOIS materials featured single diffraction peaks at low 2θ diffraction angles (in the range 1.8–2.4°), suggestive of mesostructures with uniform wormhole-motif pore channels.[2–4] ^{29}Si MAS NMR spectra of the samples in all cases showed two signals at -63 and -58 ppm which can be assigned to T^3 [*i.e.* $–CH_2–Si(OSi)_3$] and T^2 [$–CH_2–Si(OSi)_2OH$] sites, respectively. This observation, in addition to the absence of any Q^4 [*ca.* -110 ppm, $Si(OSi)_4$] and Q^3 signals [*ca.* -100 ppm, $Si(OSi)_3OH$] in these spectra, attests to the hydrolytic stability of the Si–C bonds under the synthesis conditions used to prepare these materials. TEM images of the LUOIS materials confirmed the wormhole-motif structure (Fig. 1), and showed that their pore channels were quite uniform in size.

The pore diameters of the LUOIS materials were, however, much smaller than those of purely siliceous mesostructures, in the super-micropore size range (10–20 Å, Table 1, Fig. 2). The pore structures and diameters of LUOIS materials distinguish these structures from previously reported hybrid mesostructures,[7–13] which typically possess pore channels with diameters similar to those of electrostatically-assembled mesostructures such as MCM-41 (20–30 Å).[7–13] Extensive TEM investigation of the LUOIS materials verified that the porous domains of the materials were extensive and that they contained very little or no amorphous xerogel phases. The surface areas and framework mesopore volumes of the LUOIS materials (calculated from their N_2 adsorption isotherms) were very high

[a] *d*-Spacings = d_{100} (from XRD patterns).[b] Pore sizes were calculated using the Broekhoff–DeBoer pore size distribution model (> 20 Å),[15] or the BJH model (≤20 Å). Pore diameters in parentheses were estimated from TEM micrographs of the samples.[c] Wall thickness = *d*-spacing − pore diameter.

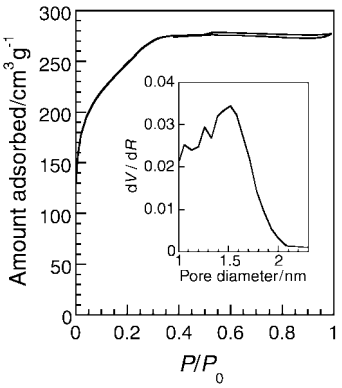

Fig. 2 Nitrogen adsorption–desorption isotherm and pore size distribution (inset) of a LUOIS material (MSU-1-OIS).

(Table 1), as is characteristic of most surfactant-assembled mesostructures.[1–14] The isotherms, however, do not usually exhibit the sharp Type IV inflexion typically observed for pure silica mesostructures. They instead exhibit Type I-like isotherms which are likely due to the microporous dimensions of the pore channels (< 20 Å) (Fig. 2). Despite having comparable framework lattice spacings to those of their pure silica counterparts (Table 1), the smaller pore diameters of the LUOIS materials suggests that these mesostructures have considerably thicker framework walls, lower surface areas and diminished pore volumes than those of pure silica mesostructures (Table 1).

That the LUOIS materials have smaller pore channel diameters than their electrostatically-assembled UOFMN/HMM/PMO counterparts can be related to the different assembly mechanisms involved in the formation of these various materials. The framework-forming precursors of UOFMN, HMM and PMO are expected to be negatively charged (owing to the high assembly pH of their synthesis) and thus strongly bound by electrostatic interaction with the cationic head groups of the alkylammonium surfactant micelles (*i.e.* S^+I^- assembly). This leads to the formation of materials which are structurally similar to pure silica mesostructures (*e.g.* MCM-41) prepared under similar conditions. In contrast, the precursors of the LUOIS materials are likely to be mostly uncharged under the synthesis conditions used, and are thus weakly interacting with the head groups of the surfactants (*viz.* by H-bonding) through S^0I^0 and N^0I^0 assembly interactions.[2,3] Moreover, these BTSE-based precursors are much more hydrophobic than the pure silica precursors involved in the formation of pristine HMS and MSU-X materials. Hence, we postulate that the combined effect of precursor hydrophobicity and the weak interaction between the precursors and micelle head groups results in the penetration of some of these precursors within the hydrophobic core of the surfactant micelles. Thus, materials with significantly reduced pore diameters are produced upon final condensation of these precursors.

The absence of any surfactant signal in the ^{13}C NMR spectra of the LUOIS materials demonstrates the ability of ethanol extraction to remove all of the assembly surfactant from the as-synthesized materials. In contrast, the acid extraction technique used for the electrostatically-assembled UOFMN materials failed to remove the surfactant entirely from the pore channels.[8] The weak surfactant–framework interaction apparent in the LUOIS materials is thus conducive for the preparation of compositionally pure organic-integrated nanoporous silica.

The integration of functional groups within the frameworks of mesostructured oxides can be useful for a wide variety of potential applications (*i.e.*, shape-selective adsorption and catalysis). Non-electrostatic assembly methodologies provide the required flexibility to prepare organic-integrated mesostructures with controlled pore sizes in both the supermicropore and mesopore size regimes, and may allow the successful incorporation of functional groups (such as highly electrophilic moieties) that may be unstable in the harsh, highly basic/acidic conditions typically used in electrostatic organosilica preparations.[7–13]

M. M., J. S. and L. M. would like to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support. P. J. K. also wishes to acknowledge the support of the NWO (The Netherlands). We also gratefully acknowledge Collin Kowalchuk (University of Western Ontario) for providing the NMR spectra of the samples. Finally, we thank Dr Stephen Bagshaw for helpful discussions.

Received (in Cambridge, UK) 30th July 2001, Accepted 24th September 2001
First published as an Advance Article on the web

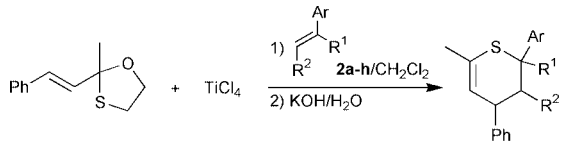
A one-step $TiCl_4$-mediated regiospecific synthesis of thiine derivatives is effected in good yields by a tandem cyclisation-fragmentation reaction.

In the last few years, thiine derivatives have received considerable attention as building blocks in organic synthesis, in particular for the construction of natural product skeletons.[1] The synthesis of six-membered ring sulfur-containing heterocycles may proceed through hetero Diels–Alder-type (HDA) reactions involving either thioaldehydes or thioketones or their α,β-unsaturated analogs, 1-thiabuta-1,3-dienes.[2–4] However, in contrast to the homologous oxygenated substrates, thioaldehydes and their derivatives (unless conveniently substituted by electron-withdrawing substituents[5–7]) present very low stability and tend to dimerise and polymerise easily.[8] In most cases, these highly reactive thio-compounds are not isolated but generated and trapped *in situ* by the diene or the dienophile.[9]

We present here the use of α,β-unsaturated oxathiolanes as precursors for unsaturated thioketone analogs (thienium cations), as heterodienes in Diels–Alder cycloadditions for the construction of α,β-unsaturated thianes, as shown in Scheme 1. To our knowledge, no report on the utilization of oxathiolanes for hetero Diels–Alder reactions has been reported. The related use of other heterocycles for HDA reaction has been recently described.[10]

The reaction of the oxathiolane **1**[11] in the presence of 1 equiv. of $TiCl_4$ in dichloromethane at −48 °C, followed by the addition of styrene, afforded, after hydrolysis by aqueous KOH and purification, 2,4-diphenyl-3,4-dihydro-2*H*-thiine, **3a**, in 65% isolated yield. The cycloaddition was completely regioselective and gave a mixture of two *cis–trans* stereoisomers in a 1 : 1 ratio. The formation of the thiine derivative **3a** occurred with loss of the C_2H_4O fragment of the starting oxathiolane.

This cycloaddition–fragmentation process was extended to several substituted styrene derivatives, and the results and yields of the corresponding thiine derivatives **3** are presented in Table 1.



1 **3a-h**

2a, 3a Ar = Ph, R^1 = H, R^2 = H
2b, 3b Ar = Ph, R^1 = H, R^2 = Me
2c, 3c Ar = Ph, R^1 = Me, R^2 = H
2d, 3d Ar = *p*-MePh, R^1 = H, R^2 = H
2e, 3e Ar = *p*-MeOPh, R^1 = H, R^2 = H
2f, 3f Ar = *p*-ClPh, R^1 = H, R^2 = H
2g, 3g Ar = *p*-FPh, R^1 = H, R^2 = H
2h, 3h Ar = Ph, R^1 = Ph, R^2 = H

Scheme 1

A regiospecific reaction occurred in all the examples examined; the aryl group of the styrene derivative always being located at the 2-position of the cyclic sulfide.

A stereoselective cycloaddition was observed with β-methylstyrene **2b** (entry 2), for which the two phenyl groups of **3b** are exclusively *trans* diequatorial. In contrast, α-methylstyrene **2c** (entry 3) afforded **3c** in 76% yield as a 45 : 55 *cis–trans* mixture. *cis–trans* ratios were calculated by ^{1}H-NMR and by GC. The diastereomeric assignments were based on the NOESY ^{1}H-NMR correlations between H-2 and H-4 protons.

Electron-donating (entries 4, 5) as well as electron-deficient substituents (entries 6, 7) on the *para* position of the aryl ring of **2** were compatible with the reaction conditions, and gave the corresponding thiine derivatives **3** with stereoselectivities generally in favor of the *trans* isomer. The *p*-methoxystyrene **2e** led to a poor yield due to its partial polymerisation. The coordination of the methoxy group to Ti(IV) could explain the change in reactivity. Indeed, the formation of **3** did not occur in a coordinating solvent such as Et_2O. It is interesting to note that the presence of a *p*-chloro substituent in **2f** (entry 6) reversed the stereochemical outcome of the reaction.

The reaction of **1** with sterically hindered 1,1-diphenylethylene gave **3h** in 69% isolated yield, after crystallisation in ethanol. Thus, the cyclisation does not seem particularly influenced by the steric hindrance of the substrates. However, no reaction occurred between **1** and oct-1-ene under the reaction conditions.

By the present procedure, 2,4-diaryl substituted dihydrothiapyrans **3** could be prepared for the first time.

The order of addition of the reactants was an important feature of this reaction. When the styrene derivative was added at the beginning of the reaction polymerisation occurred and compound **3** was formed in low yields.

The addition of $TiCl_4$ to **1** led to a poorly stable orange precipitate in dichloromethane at low temperature, which was attributed to the formation of a titanium(IV) alcoholate–thienium cation intermediate of type **A**, presumably involving the cleavage of the C–O bond of the heterocycle (Scheme 2). Upon addition of the styrene derivative, the precipitate slowly disappeared with the plausible formation of an intermediate of type **B**. When the reaction was quenched by aqueous potassium

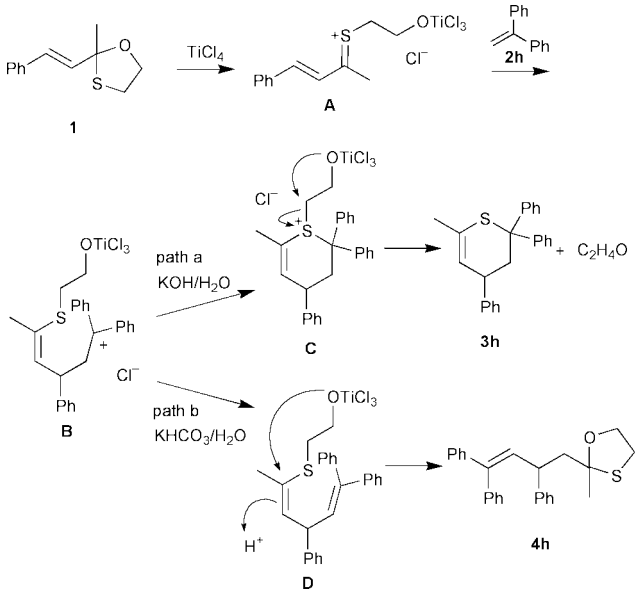

Scheme 2

hydroxide (path a), thiine **3** was formed with fragmentation of the C_2H_4O unit, presumably of ethylene oxide, *via* intermediate **C**. However, upon hydrolysis by aqueous potassium bicarbonate, the 4,5-unsaturated oxathiolane **4h** could be isolated in 25% yield in the case of 1,1-diphenylethylene as the dienophile, *via* path b. To explain the formation of **4h** the intermediate formation of **D** can be proposed.

The *in situ* generation of a thienium salt **A** from stable oxathiolanes in the presence of Lewis acids seems an interesting alternative to 1-thiabuta-1,3-diene equivalents. The formation of a thienium cation intermediate from a dimethyl-substituted six-membered ring oxathiane has also been proposed.[10]

Work is in progress to further extend the cyclisation–fragmentation process to other substrates and to get a better understanding of the mechanism of the reaction.

11 Compound **1** was prepared by a method adapted from the synthesis of G. H. Wilson, M. G. Huang and W. W. Schloman, Jr, *J. Org. Chem.*, 1968, **33**, 2133.
12 Typical procedure for the synthesis of **3**: to a vigorously stirred solution of **1** (1.0 mmol) in dichloromethane (10 ml) at −48 °C under inert atmosphere was added a CH_2Cl_2 solution of titanium tetrachloride (1.0 mmol). After formation of an orange precipitate, the styrene derivative **2** was added dropwise. After the complete disappearance of the precipitate, the solution was quenched with an aqueous solution of potassium hydroxide (1.0 M). The aqueous layer was extracted twice with diethyl ether. The organic layers were dried over $MgSO_4$, and the solvent was removed *in vacuo*. The crude product was purified by silica gel column chromatography with a mixture of hexane–diethyl ether (99 : 1) as the eluent. In the case of **3b** and **3h**, the products were purified by crystallisation in ethanol. The compounds were analysed by ^1H and ^{13}C-NMR, mass spectrometry and HRMS.

Received (in Cambridge, UK) 25th July 2001, Accepted 1st October 2001
First published as an Advance Article on the web 17th October 2001

The complex $[(PPh_3)Ag(CB_{11}H_6Br_6)]$ 1 is an effective and selective catalyst (0.1 mol% loading) for a hetero-Diels–Alder reaction, which shows a marked dependence on the presence of trace amounts of water, while addition of Ag[Y] [Y = $CB_{11}H_{12}$, $CB_{11}H_6Br_6$, O_3SCF_3] to a phosphine functionalised support gives an efficient and recyclable Lewis acid catalyst for this transformation.

Cationic silver(I)–phosphine complexes have been used as effective promoters for a wide-range of organic transformations including allylation, aldol, ene and glycosylation reactions, asymmetric aldol reactions, Mukaiyama aldol reactions, asymmetric allylations and hetero-Diels–Alder reactions.[1] It is well established that these reactions are accelerated by other Lewis acids (for example; Ti, B, Al and Sn complexes). However, many of these established catalysts are sensitive to air, water and product inhibition and consequently are used in a low substrate/catalyst ratio. The use of silver(I)–phosphine complexes can provide a practical solution to this problem, as many complexes are stable in air and retain activity in the presence of reaction product. Nevertheless, the best examples from the literature routinely employ high catalytic loadings (5–10 mol%) to achieve competitive rates and product yields. We are interested in developing silver(I) Lewis acids partnered with the carborane anion [1-*closo*-$CB_{11}H_{12}]^-$ and derivatives,[2] in the anticipation that the weakly coordinating nature of these anions will reveal enhanced activity for these systems. As the hetero-Diels–Alder reaction is one of the most useful methods for the synthesis of bioactive heterocycles we chose to test the new complexes in this challenging reaction.

We report here the synthesis of two new silver(I)–phosphine complexes containing $[CB_{11}H_{12}]^-$ and $[CB_{11}H_6Br_6]^-$ respectively and their use as efficient catalysts at low loadings for a hetero-Diels–Alder reaction. Additionally, we report that this methodology may be transferred to a solid support with good activity, low leaching and promising recycleability.

Addition of 1 equivalent of PPh_3 to a CH_2Cl_2 solution of $Ag[CB_{11}H_6Br_6]$ or $Ag[CB_{11}H_{12}]$ affords the new complexes $(PPh_3)Ag(CB_{11}H_6Br_6)$ **1** and $(PPh_3)Ag(CB_{11}H_{12})$ **2**, respectively, in good yields after recrystallisation from CH_2Cl_2–hexanes. Both complexes have been fully characterised‡ by multinuclear NMR spectroscopy, microanalysis and X-ray crystallography. In solution the complexes display C_{5v} symmetry in both the ^{11}B and $^1H\{^{11}B\}$ NMR spectra, showing that the $\{AgPPh_3\}^+$ fragment is fluxional over the cage surface, as has been observed previously for other *exo* polyhedrally bound $\{Ag(PPh_3)\}$ fragments.[3] The $^{31}P\{^1H\}$ NMR spectra show a pair of concentric doublets for both **1** and **2**: $J(AgP_{average})$ 715 Hz and $J(AgP_{average})$ 743 Hz, respectively. The solid state structure of complex **1** is shown in Fig. 1.§ In the asymmetric unit, the silver is ligated by one phosphine and the three bromine atoms

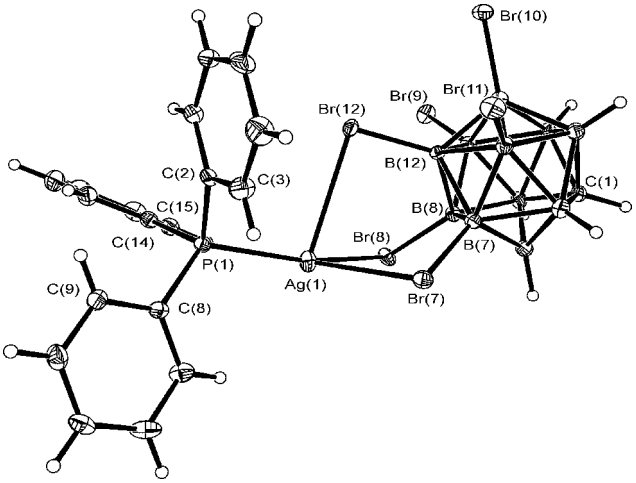

Fig. 1 Solid state structure of complex **1**. Ellipsoids are shown at the 50% probability level. Selected bond lengths (Å) and angles (°): Ag(1)–Br(7) 2.8710(5), Ag(1)–Br(8) 2.6963(5), Ag(1)–Br(12) 3.0953(5), Ag(1)–P(1) 2.4032(10); P(1)–Ag(1)–Br(7) 117.44(3), P(1)–Ag(1)–Br(8) 155.55(3), Br(8)–Ag(1)–Br(7) 87.471(14).

that radiate from the B(7)–B(8)–B(12) triangular face of the cage. Bond lengths and angles are unremarkable, aside from the fact that the silver centre appears to have a vacant site lying roughly opposite to B(12). Examination of the supramolecular structure revealed that this site is filled by a long Ag(1)–Br interaction [Ag(1)–Br(11)′ 3.4901(5) Å], affording a ribbon-like structure in the lattice (ESI†). The asymmetric unit found for **2** is grossly similar to **1**, the $\{AgPPh_3\}$ fragment interacting with the cage through three 3-centre–2-electron Ag–H–B, interactions.

We have investigated the reaction between *N*-benzylidene aniline **I** and Danishefsky's diene **II** (Scheme 1) using as catalysts the silver complexes **1**, **2** and, for comparison, $(PPh_3)Ag(OTf)$ (OTf = O_3SCF_3). In the absence of any catalyst there was only a trace (< 5%) of product after 24 h at room temperature. On the bench (2 h, room temperature, 1 mol% catalyst, CH_2Cl_2) both complexes **1** and **2** afforded essentially quantitative (> 99%) yields of **III** on workup, while $(PPh_3)Ag(OTf)$ gave **III** in 70% yield. However, it was only when catalyst loadings were reduced to 0.1 mol% and the reactions were monitored by NMR spectroscopy that the efficiency of complex **1**, in particular, for this transformation was revealed.

Fig. 2 shows a plot of time *vs*. reaction course for complexes **1**, **2** and $(PPh_3)Ag(OTf)$. $[(PPh_3)Ag(ClO_4)$ was also tested, not

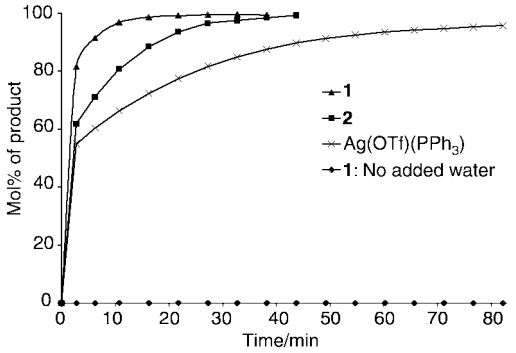

Fig. 2 Relative rates of reaction CD_2Cl_2 solutions, 0.1 mol% **1**, **2** and $(PPh_3)Ag(OTf)$, 50 mol% added H_2O. Also shown: **1** with no added water.

shown here, and showed a very similar time dependent profile to $(PPh_3)Ag(OTf)$.] It is clear that complex **1** gives the fastest rate of catalysis, the reaction being complete in ~15 min, yielding a turnover frequency (TOF) of *ca.* 4000 h^{-1}. Complex **2** is slower than **1**, with complete reaction effected after 50 min, while $(PPh_3)Ag(OTf)$ does not attain 100% conversion, even after 80 min. Although these results reflect the previously enunciated relative weakly coordinating properties of carborane anions,[2] especially the halogenated examples,[4] it is pleasing to see that these ideas can be applied to a synthetically useful transformation, using well defined catalysts.

Importantly, and somewhat surprisingly, we have found that water plays an important role in this reaction. When these NMR experiments are performed in rigorously dry solvent (CD_2Cl_2, vacuum distilled from CaH_2), no catalysis occurs (Fig. 2). Addition of a substoichiometric (1 μl, 50 mol%, unoptimised) amount of H_2O to the sample immediately initiates catalysis. While water-accelerated catalysis is becoming appreciated more widely,[5] we currently can only speculate as to its rôle in this system. These results, however, implicate a polarised, silver-bound water molecule in the catalytic process, with the resulting Lewis-assisted Brønsted-acid similar to that previously reported in lanthanide catalysed aromatic electrophilic substitutions[6] and the catalytic role of coordinated water in certain zeolites.[7] Consonant with this idea, when the reaction was repeated in the presence of the hindered base 2,6-di-*tert*-butyl-4-methylpyridine no product was formed, while a control experiment taking **I** and **II** with just 50 mol% water also resulted in no product formation. On the bench, it is probably adventitious water that is made available to the reaction.

Catalyst **1** is also selective for imines over aldehydes in this reaction. A competition experiment demonstrated preferential activation of imine **I** in the presence of an equimolar amount of benzaldehyde. Thus, after 15 min at room temperature the product arising from reaction with the imine was isolated in 70% yield whilst the aldehyde adduct was produced in only 5% yield.

Polymer supported Lewis acids have been recently attracting significant attention as they represent one method of generating clean, efficient and re-usable catalysts.[8] However, the incorporation of the Lewis acidic sites onto the polymer often requires a multistep synthesis. Given that one of the most popular supports is polymer bound triphenylphosphine,[9] we were interested to see if the high activity and efficiency shown by complexes **1** and **2** could be transferred to this support. Stirring a CH_2Cl_2 solution of Ag[Y][Y = $CB_{11}H_{12}$ **3**, $CB_{11}H_6Br_6$ **4**, OTf **5**] with commercially available resin (Fluka) afforded a material that was an efficient catalyst in all three cases for the hetero-Diels–Alder reaction under investigation.¶ Moreover, all the resins were shown to be re-usable over at least three catalyst runs (>95% isolated yield, *vide infra*). In concert with this, low leaching levels (0.3% Ag, by AAS) where also determined, while the supernatant from freshly prepared and filtered supported catalyst afforded only trace product (<5%) when used in the reaction. These supported catalysts also show a significant dependence on the presence of water. If no water is added then catalyst performance drops off rapidly on the second and third runs, however with 10 mol% water high yields of >95% are afforded over three consecutive cycles (ESI†). At the relatively high catalyst loadings (10 mol%) used in these preliminary experiments the counter ion effects observed in the homogeneous system are not observed.

In conclusion, we have demonstrated that silver(I)–phosphine complexes partnered by carborane anions based on $[CB_{11}H_{12}]$ are effective and active catalysts in a hetero-Diels–Alder transformation, and that water dramatically effects the observed rate of reaction. These catalysts may also be supported on commercially available resin to give active and recyclable Lewis acid catalysts. Full details of the synthesis, solution and solid state structures of **1** and **2** along with comparisons of the catalytic performance when other common anions are partnered with silver(I)–phosphines will be reported in due course.[10]

A. S. W. thanks the Royal Society for a University Research Fellowship. The EPSRC and JERI are thanked for providing funds for the purchase of a diffractometer. The referees are thanked for useful comments.

¶ *General procedure*: ~3 mmol g^{-1} polymer-bound PPh_3 (Fluka, 200–300 mesh) with a slight excess of Ag[Y] in CH_2Cl_2 was used to generate the polymer bound catalyst. After washing with CH_2Cl_2 and drying *in vacuo*, catalytic runs were performed using *ca.* 10 mol% catalyst and 10 mol% H_2O in CH_2Cl_2 (5 ml) (1 h, room temp.). The support was recycled by cannula filtration of the supernatent under argon and drying *in vacuo*.

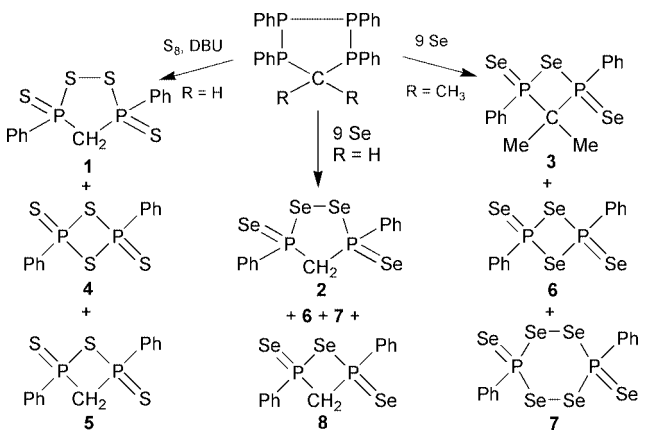
Received (in Cambridge, UK) 9th August 2001, Accepted 25th September 2001
First published as an Advance Article on the web 18th October 2001

Oxidative addition of elemental sulfur and selenium to cyclomonocarbatetraphosphines $(PhP)_4CR_2$ (R = H, Me) afforded novel five- and four-membered heterocycles $PhP(E)CH_2PhP(E)E_2$ (E = S, Se) and $PhP(Se)CMe_2$-PhP(Se)Se.

Although the chemistry of cyclophosphines $(R'P)_n$ (R′ = alkyl, aryl; n = 3–6) has been studied extensively, tetraphospholanes $(R'P)_4CR_2$ have received less attention, despite their ease of access from cyclophosphines.[1] Due to the stability of the endocyclic P–C bond they are a valuable source of $PhPCR_2PPh$ moiety as shown herein for oxidative addition reactions with elemental sulfur and selenium (Scheme 1). Four- and five-membered heterocycles described here represent only the third known heterocycle with the atomic sequence PCPSe (and the first X-ray structure determination reported), whilst the heterocyclic sequence PCPSeSe is the first example. The parallels in S chemistry are also scarce; PCPS rings were prepared using low-coordinate phosphorus starting compounds such as diphosphaallene,[2] phosphanylidene[3] and thioxophosphane with phosphonium ylide.[4] The only known heterocyclic compound with the PCPSS atomic sequence, **9**, has been isolated in low yield as a side product in the reaction of sulfur and diphosphaallene with stabilizing bulky supermesityl side groups.[2a] Partially sulfur oxidised derivatives $(PhP)_4CH_2S$ and $(PhP)_4CH_2S_2$ were obtained from the reaction of $(PhP)_4CH_2$ with lower molar amounts of sulfur.[5]

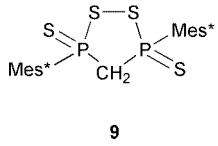
Our aim was to obtain thermodynamically stable products, thus all the reactions were performed in refluxing toluene (under N_2). Treatment of $(PhP)_4CH_2$ with 8 equivalents of sulfur and a catalytic amount of DBU, followed by fractional crystallisation afforded colourless crystals of **1** in a moderate yield (40%, Scheme 1).[6]

Crystallographic analysis of **1** (Fig. 1)[7] reveals the formation of a five–membered PCPSS heterocycle with a *trans*-geometry of exocyclic phenyl and sulfur substituents. The central heterocycle has an envelope shape, with S(2) atom lying 1.1 Å out of the plane defined by the other ring atoms (mean deviation of this plane is 0.04 Å), which is in contrast to the half-chair conformation found in the only known PCPSS heterocycle **9**.[2a]

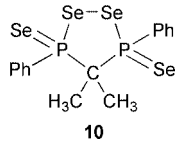


Scheme 1

The internal bond lengths in **1** are comparable to those in **9**. The envelope shape however accounts to significant changes in internal bond angles, the P–C–P angle as well as PSSP dihedral angle are substantially decreased in **1** [P–C–P angle in **1** 114.47(9)°; 119.6(4)° in **9**; PSSP dihedral angle in **1** 49.48(3)°; 54.8(1)° in **9**]. Also the S(3)–P(1)–C(2) and S(4)–P(2)–C(8) angles of 115° are decreased due to lower steric hindrance of phenyl *vs.* supermesityl substituent in **9** (corresponding angles 126°). The shortest intermolecular contacts in **1** are 3.47 Å [S(2)···S(3)], which is less than twice the van der Waals radius for sulfur (3.70 Å).



9



10

The $^{31}P\{^1H\}$ NMR spectrum of **1** (in $CDCl_3$) shows a singlet at δ 80.3. A minor singlet (*ca.* 4% intensity) with a very similar shift of δ 80.9 has been also observed in the spectrum, belonging to a less energetically favourable conformation or *cis*-isomer of **1**. The ^1H NMR spectrum of **1** contains multiplets for the phenyl ring protons and a triplet for the CH_2 group [δ 3.9, ^2J(HP) 9.9 Hz]. These spectral data are in a very good agreement with those reported for **9** [δ_P 87.6, $\delta_H(CH_2)$ 3.96, ^2J(HP) 9.6 Hz].[2a]

Treatment of $(PhP)_4CH_2$ with 9 equivalents of grey selenium in boiling toluene, hot filtration to remove insoluble **6** and unreacted selenium, concentration of the filtrate *in vacuo* and cooling afforded the orange crystalline solid **2** in 94% yield (Scheme 1). The minor impurities, heterocycles **7** and **8**, can be removed by recrystallisation from hot toluene.[8]

Crystallographic analysis[7] reveals **2** to be almost isostructural with **1** (Fig. 1). The central heterocycle has again envelope

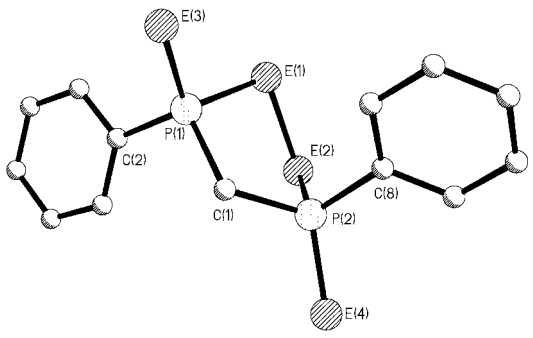


Fig. 1 Molecular structure of **1** (E = S) and **2** (E = Se). H atoms omitted for clarity. Selected bond lengths (Å) and angles (°) for **1** and **2** (values in square brackets): P(1)–C(1) 1.839(2) [1.830(7)], P(2)–C(1) 1.839(2) [1.839(6)], P(1)–E(1) 2.1160(7) [2.249(2)], P(2)–E(2) 2.1095(7) [2.247(2)], E(1)–E(2) 2.0667(7) [2.338(1)], P(1)–C(2) 1.810(2) [1.809(7)], P(2)–C(8) 1.810(2) [1.828(8)], P(1)–E(3) 1.9394(7) [2.100(2)], P(2)–E(4) 1.9419(7) [2.100(2)], P(1)–C(1)–P(2) 114.47(9) [116.7(4)], P(1)–E(1)–E(2) 97.07(3) [93.40(6)], P(2)–E(2)–E(1) 95.73(3) [91.97(6)], E(1)–P(1)–C(1) 102.71(6) [105.2(2)], E(2)–P(2)–C(1) 100.90(6) [102.7(2)], C(2)–P(1)–E(3) 114.86(6) [114.0(2)], C(8)–P(2)–E(4) 114.78(7) [114.0(2)], E(1)–P(1)–E(3) 107.16(3) [106.82(9)], E(2)–P(2)–E(4) 107.77(3) [107.91(9)].

 DOI: 10.1039/b107214e

conformation, with Se(2) lying 1.27 Å out of plane defined by other ring atoms (mean deviation of this plane is 0.04 Å). The PCP angle, P···P distance and PSeSeP torsion angle vary little from the corresponding values in **1**, as expected the ring dimensions are increased due to larger radii of Se atoms (see *e.g.* differences in Se–Se and S–S bond length for **2** and **1**), however Se(3)–P(1)–C(2) and Se(4)–P(2)–C(8) angles (114°) show no significant change when compared with corresponding angles in **1**. The shortest intermolecular contacts in **2** are 3.48 Å [Se(2)···Se(3)].

The $^{31}P\{^{1}H\}$ NMR spectrum of **2** comprises of a singlet (δ_P 43, in $CDCl_3$) with symmetric sets of selenium satellites. The satellite spectrum is generated mainly from two distinct isotopomers with one ^{77}Se atom in exo- or endo-positions of the ring, both having an AXX′ pattern (A = ^{77}Se, X = P). Simulation of the satellite spectra enabled determination of all four P–Se coupling constants[9] as well as a homonuclear P–P coupling [^2J(PP) ±34.1 Hz].

By the treatment of $(PhP)_4CMe_2$ with 9 equivalents of grey selenium in the same manner as **2** (including work-up procedures), orange crystalline **3** has been obtained in 68% yield (Scheme 1).[10] Crystallographic analysis of **3** (Fig. 2)[7] reveals that oxidation of $(PhP)_4CMe_2$ proceeds surprisingly with the formation of a four-membered PCPSe ring. The unit cell contains two independent molecules, in both the central ring is folded (17 and 28° along the Se···C diagonal) with phenyl and exocyclic selenium substituents in *trans* configuration. No X-ray structure determination of a PCPSe ring has been reported up to date, the nearest parallels found are PCPS rings, both thiadiphosphetanes with known X-ray data[2b,4] show *cis* configuration and folded geometry of the central ring (19.2 and 29.4° along C···S diagonal). Internal P–Se bond lengths in **3** [2.274(2)–2.283(2) Å] are slightly increased with respect to **2** [2.247(2) and 2.249(2) Å] however they are comparable with **6** [2.276(2) and 2.284(2) Å].[11] In contrast, the internal P–Se–P angles in **3** (77.7 and 76.0° for each molecule in the unit cell) are substantially decreased when compared with corresponding angle in the planar PSePSe heterocycle **6** (85.5°).[11] The shortest intermolecular contacts in **3** are 3.59 Å [Se(1)···Se(2)].

$^{31}P\{^{1}H\}$ NMR examination of the mixture after the reaction did not show any reasonably intense signals at lower field, assignable to related five-membered heterocycle **10**. The $^{31}P\{^{1}H\}$ NMR spectrum of **3** comprises of a singlet (δ_P 52, in $CDCl_3$) with two symmetric sets of selenium satellites of AXX′ (Se_{exo}) and AX_2 (Se_{endo}) pattern (A = ^{77}Se, X = P). The simulation of the AXX′ satellite subspectrum enabled determination of a homonuclear P–P coupling, whose magnitude is surprisingly low [^2J(PP) < ±2 Hz].[12] The ^1H NMR spectrum of **3** ($CDCl_3$, 25 °C) shows a second-order A_3B_3XX' pattern (A, B = CH_3 protons, X, X′ = P) at δ 1.3, confirming magnetic inequivalence of methyl groups protons as a consequence of the folded geometry of the central heterocycle.

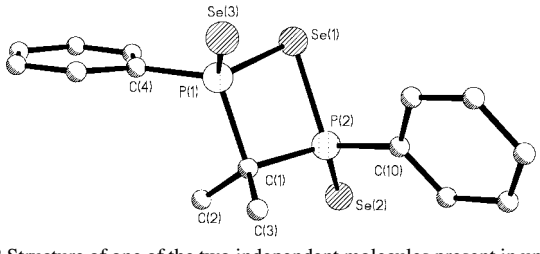

Fig. 2 Structure of one of the two independent molecules present in unit cell of **3**. H atoms omitted for clarity. Selected bond lengths (Å) and angles (°) for the molecule with less folded central heterocycle: P(1)–C(1) 1.915(7), P(2)–C(1) 1.910(6), P(1)–Se(1) 2.279(2), P(2)–Se(1) 2.283(2), P(1)–C(4) 1.825(7), P(2)–C(10) 1.817(7), P(1)–Se(3) 2.096(2), P(2)–Se(2) 2.101(2), P(1)–C(1)–P(2) 96.9(3), P(1)–Se(1)–P(2) 77.73(7), Se(1)–P(1)–C(1) and Se(1)–P(2)–C(1) 91.4(2), C(1)–P(1)–Se(3) 114.4(2), C(1)–P(2)–Se(2) 115.1(2), C(1)–P(1)–C(4) 110.2(3), C(1)P(2)–C(10) 108.9(3), C(4)–P(1)–Se(3) 112.3(2), C(10)–P(2)–Se(2) 113.0(3), Se(1)–P(1)–C(4) 109.0(2), Se(1)–P(2)–C(10) 107.5(3), Se(1)–P(1)–Se(3) 117.70(9), Se(1)–P(2)–Se(2) 118.74(9), C(2)–C(1)–C(3) 113.2(6). For parameters of second molecule in the independent unit see crystallographic data in CIF format.

Studies to employ new soluble P–Se heterocycles in our reagent program for C=O to C=Se transformations are now underway.

We are grateful to the EPSRC for financial support.

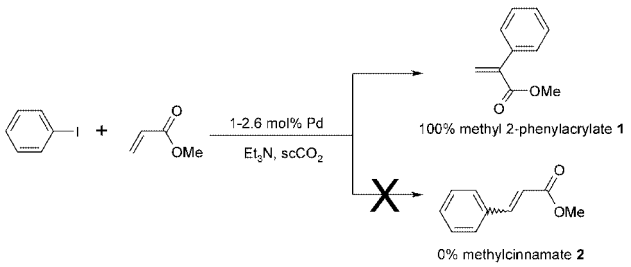
First published as an Advance Article on the web 17th October 2001

Dendrimer-encapsulated nanoparticles are shown to be versatile catalysts for both the hydrogenation of styrene and Heck heterocoupling of iodobenzene and methacrylate in supercritical CO_2 ($scCO_2$).

Here we present the first examples of catalysis in pure liquid or supercritical CO_2 ($scCO_2$) using soluble metal nanoparticles. The catalysts are composites consisting of functionalized poly(propylene imine) (PPI) dendrimers and Pd(0) nanoparticles. The perfluoropolyether-functionalized dendritic host is responsible for solubilizing the 1–2 nm diameter catalytic Pd(0) nanoparticles in $scCO_2$. The versatility of these dendrimer-encapsulated catalysts (DECs)[1] is illustrated by performing two very different chemical reactions. First, in the presence of hydrogen, the catalyst is effective for the hydrogenation of olefins, such as the reduction of styrene to ethylbenzene. Second, iodobenzene can be coupled with methylacrylate, which is a benchmark reaction for the synthetically useful Heck coupling,[2] to yield exclusively methyl 2-phenylacrylate **1** (Scheme 1). The selectivity for **1** is remarkable when compared with standard palladium complexes[2] or colloidal nanoparticles[3–6] used for Heck couplings in organic solvents, which result in only *cis*- and/or *trans*-cinnamate **2** (Scheme 1). When used in hydrocarbon/fluorocarbon solvents the same Pd-based DECs yield only *trans*-formylcinnamate.[7]

The use of liquid or $scCO_2$ as an alternative to hydrocarbon solvents is attractive because CO_2 is both inexpensive and environmentally benign.[8] Additionally, by changing the density, and thus the 'solvent power' of $scCO_2$, the reaction rates, product distribution,[9] and yields can be tuned,[10–12] and therefore there is intense interest in catalysts and chemical processes that are compatible with this 'green solvent'.[13] There are two approaches for the utilization of liquid and $scCO_2$ as a solvent for both hydrogenation[14–19] and Heck[20–22] reactions. One of these involves the use of CO_2-soluble coordination complexes, and the other utilizes Pd metal on a solid substrate such as carbon.



Scheme 1

The DECs used for both the hydrogenation and Heck chemistry described here consisted of Pd(0) nanoparticles sequestered within fifth-generation poly(propylene imine) (PPI) dendrimers having perfluoro-2,5,8,11-tetramethyl-3,6,9,12-tetraoxapentadecanoyl perfluoropolyether chains covalently attached to their periphery.[23] The general method used to prepare these materials has previously been reported and the specific procedures used in this work are provided in the ESI†.[1,7] Importantly, the dark-brown DECs (dry) could be easily solublized in liquid- and $scCO_2$ (dull-orange solution), and there were no obvious signs of aggregation or precipitation. Note that we and others have recently prepared and characterized Ag[24,25] and CdS[26] nanoparticles in $H_2O/scCO_2$ microemulsions as well as in pure CO_2 solvent[27] utilizing perfluorinated surfactants as either the sole emulsifier or as a co-surfactant.

Although synthetically trivial, the hydrogenation of styrene to ethylbenzene is a convenient example for demonstrating the catalytic activity of DECs.[11] With the novel catalyst (1–2.6 mol% Pd), the progress of styrene reduction was followed by capillary gas chromatography (GC) and shown to be complete in under 4 h (Fig. 1). Evidence of catalyst decomposition, such as Pd(0) precipitation, was not apparent at the end of the reaction. The ethylbenzene could be recovered after depressurization of the reaction vessel and was confirmed by NMR spectroscopy to be the only product.

To demonstrate the versatility of $scCO_2$-soluble DECs, the same catalyst was shown to be active for a Heck-type coupling reaction. In the presence of triethylamine (TEA) and the DEC (1–2.6 mol% Pd), methylacrylate (MA) reacted with iodobenzene (PhI) at 75 °C and 5000 psi, forming methyl 2-phenylacrylate **1**. The progress of the reaction was followed by GC using *n*-decane as an internal reference (Fig. 2). The DECs stopped producing **1** after about 24 h when 57% of the iodobenzene was consumed. This corresponds to a turnover number (TON) of *ca.* 22 (TON = mol of substrate/mol of Pd).

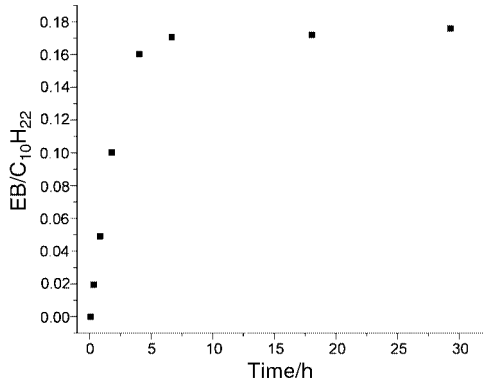


Fig. 1 Gas chromatographic data showing the appearance of ethylbenzene (EB) from the DEC catalyzed reduction of styrene in a supercritical H_2/CO_2 mixture with *n*-decane ($C_{10}H_{22}$) as an internal standard.

† Electronic supplementary information (ESI) available: DEC synthesis and specific reaction conditions used for the hydrogenation and Heck reactions. See http://www.rsc.org/suppdata/cc/b1/b106594g/

 DOI: 10.1039/b106594g

Although this TON does not approach values obtained in other solvent systems,[28] it is comparable to previous reports of Heck catalysis in $scCO_2$ using both soluble complexes and heterogeneous catalysts.[20–22]

Importantly, even after 52 h the $scCO_2$ Heck reaction solution did not show evidence of Pd(0) precipitates or other catalyst decomposition products. The DECs and product were recovered by slowly venting the CO_2 followed by washing the depressurized reaction vessel with 1,1,2-trichlorotrifluoroethane (CFC-113). ^{1}H NMR analysis of the extract revealed a mixture of the *n*-decane internal GC reference, the starting materials (PhI and MA), and methyl 2-phenylacrylate **1**, but no evidence of byproducts or other impurities[29,30]

Prior to drying and loading into the CO_2 reactor, the CFC-113 DEC solution is dark-brown. However, the recovered CFC-113 solution was dull-orange in color, reminiscent of the color of the Pd(II)-containing PPI dendrimers [from which the Pd(0)-containing DECs were prepared].[1] This color change suggests that the Pd is oxidized from Pd(0) to Pd(II) during the course of the Heck reaction. Indeed, upon treatment of the recovered Pd(II)-containing DEC solution with an excess of $NaBH_4$, the solution turned dark-brown, UV-VIS spectroscopy indicated the formation of intradendrimer nanoparticles, and the solution remained precipitate free. We also noted that the Pd-containing DEC can be subjected to the reaction conditions described above, but in the absence of substrate, and then recovered without signs of Pd(0) oxidation. These findings provide a reasonable hypothesis for the cause of reaction termination and the low TON.

It is widely accepted that the last step in the catalytic Heck cycle involves the reductive elimination of the halide from the Pd metal and neutralization of the resulting acid.[31,32] Moreover, the use of excess tertiary amine has led to rate enhancements for a Heck-type coupling reaction resulting from both the neutralization effect of the base and weak ligand–complex stabilization.[33] We propose that at the start of the reaction in $scCO_2$, the inherently more basic[34] and proximal tertiary amines of the dendrimer neutralize the eliminated acid more effectively than the slightly less basic TEA. However, an equilibrium develops in which the interior tertiary amine hydrogen iodide salt disproportionates back to the free amine and acid, resulting in Pd(0) oxidation and halting the catalytic cycle. In fact, past studies have shown that stronger bases lead to increased rates and completion of Heck reactions because dissociation to the free base and acid is not a concern.[32,35]

To summarize, we have described the first example of catalytically active nanoparticles solublized in environmentally benign $scCO_2$. This versatile catalyst is able to reduce styrene exclusively to ethylbenzene and to catalyze the carbon–carbon bond forming Heck reaction. Although the conditions have not been optimized, it is clear that DECs can select for particular products (*e.g.*, methyl 2-phenylacrylate for the Heck reaction). The high selectivity is due in part to the steric environment the dendrimer template imposes on the reaction intermediates, but primarily results from the $scCO_2$ solvent in view of our recent finding that the same DEC in an organic/fluorocarbon solvent system yields exclusively the *trans*-coupled isomer.[7]

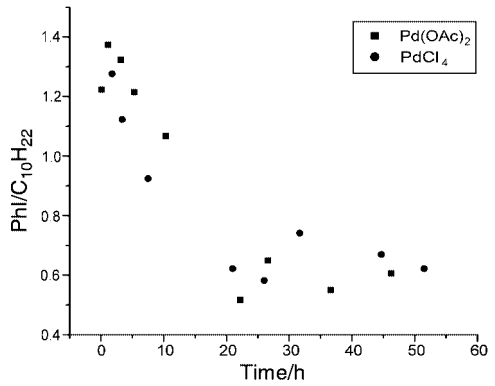

Fig. 2 Gas chromatography data showing the disappearance of the limiting reagent (PhI) for the Heck reaction as a function of time. The two sets of data correspond to independently run reactions using DECs prepared from different molecular sources of palladium, $Pd(OAc)_2$ and K_2PdCl_4.

We gratefully acknowledge support from the Office of Naval Research (R. M. C.) and the STC program of the NSF under Agreement No. CHE-9876674 (K. P. J.). We also acknowledge Prof. Victor Chechik (University of York) whose preliminary work with DECs in $scCO_2$ contributed greatly to our progress in this area.

The stabilisation and reactivity of indium trihydride complexes

Cameron Jones

Department of Chemistry, University of Wales, Cardiff, P.O. Box 912, Park Place, Cardiff, UK CF10 3TB

Received (in Cambridge, UK) 10th August 2001, Accepted 4th September 2001
First published as an Advance Article on the web 3rd October 2001

Indium trihydride complexes were unknown prior to 1998. This article focuses on the development of this field over the last 4 years. Emphasis is placed on strategies employed to stabilise such complexes, their structure, properties and use in inorganic and organic synthesis. Throughout, comparisons are drawn with the chemistries of related lighter group 13 metal trihydride complexes. A number of similarities and differences have been observed in these comparisons which have been rationalised in terms of the properties of the group 13 elements involved.

Introduction

The importance of boron trihydride complexes to organic[1] and inorganic[2] synthesis is unquestionable and thoroughly documented. It was not really until the early seventies that the chemistry of corresponding aluminium trihydride (alane) and gallium trihydride (gallane) complexes received any significant attention[3] and even then this waned towards the end of that decade. In the late 1980s a resurgence of interest in alane and gallane coordination chemistry occurred, probably because of an increased accessibility to routine X-ray crystallography around that time. The resulting systematic study of these compounds allowed an understanding of their properties that was not previously possible. This area has been covered by several reviews which revealed that major differences exist between the coordination chemistry of alane and gallane.[4–6] These differences revolve around the fact that, although of a similar size, aluminium is more electropositive than gallium as a result of a 'd-block' contraction of the electron cloud in the latter (Table 1). Therefore, the AlH_3 unit is more Lewis acidic than the GaH_3 unit and thus it prefers coordination numbers of 5 or 6 as opposed to 4, or in rare instances 5, for GaH_3. Correspondingly, the M–H bonds in gallane complexes are more covalent (less hydridic) than in alane complexes. These properties, and others, have been exploited in recent years to the point where Lewis base adducts of alane and gallane are now widely utilised in a variety of areas which include organic, inorganic[4–6] and materials chemistry. With regards to the latter, the potential volatility and clean decomposition pathways of the complexes have led to them becoming commercially available as precursors to the pure group 13 metal or to 13/15 semiconductor materials (*e.g.* AlN). This area has been recently reviewed.[7]

Table 1 Some properties of the Group 13 elements

	B	Al	Ga	In	Tl

M–C/kJ mol^{-1}[a]	365	274	245	162	125

[a] Ref. 6. [b] Ref. 27.

It seemed logical that if stable InH_3 (indane) complexes could be prepared they may find a range of applications similar to their lighter group 13 congeners. Despite this and until our involvement in the field no such complexes had been reported, probably because of a general belief that they would not be stable species under normal conditions, given the frailty of the In–H bond (Table 1). This is at odds with early reports from Wiberg *et al*. that indane and indeed thallane (TlH_3) can exist at room temperature, albeit in an associated form, $[(MH_3)_n]$.[8] However, based on theoretical studies[9] which predict In_2H_6 to be thermodynamically unstable in the gas and solid states, these claims are thought to be doubtful. It is noteworthy that monomeric indane has been synthesised in a solid argon matrix and a number of its properties investigated.[10] The results of this study generally mirrored those predicted by earlier theoretical work.

Although no well characterised indane complexes had been reported prior to 1998, a handful of compounds containing In–H bonds, **1**–**6**, had been previously crystallographically characterised.[11–16] These are mentioned here for purposes of comparison but also because they show that compounds containing In–H bonds are not necessarily only low temperature stable species. This point is perhaps best illustrated by the intramolecularly base stabilised complex, **4**, which is neutral and contains a terminal In–H bond but still is stable in the solid state until 90 °C.[14] Other compounds containing In–H bonds that have been reported include $MInH_4$, M = Li–Cs;[17] $Li[InH_{4-n}Ph_n]$, n = 1 or 2[18] and $[InCl_2H(THF)]$[19,20] though the degree of characterisation of these compounds is variable. In addition, in the last two years the Downs and Himmel group at Oxford have made major advances into the understanding of indium hydride chemistry by preparing and studying a variety of unusual organo-, chloro-, amido- and phosphido-complexes in solid argon matrices.[21–26]

This review covers our efforts since 1997 to stabilise and explore the reactivity of indium trihydride complexes. We

Cameron Jones was born in Perth, Australia in 1962. He completed both his BSc (1982) and BSc (Hons.) (1984) degrees at the University of Western Australia. From 1985–1987 he worked as a Research Officer at the University Department of Surgery at Royal Perth Hospital. His PhD degree (1989–1992) was gained from Griffith University, Brisbane, under the supervision of Professor Colin L. Raston. He then moved to a postdoctoral research assistantship (1992–1994) at Sussex University under the supervision of Professor John F. Nixon FRS. From 1994–1998 he held a lectureship at The University of Wales, Swansea before moving to a Readership in Inorganic Chemistry at Cardiff University where he remains. His research interests include the chemistry of the heavier group 13 hydrides and the low coordination chemistry of heavier group 15 elements.

originally became interested in this area as we were intrigued by what structural and reactivity differences these complexes would show to their aluminium and gallium counterparts, especially considering the larger covalent radius of indium and its intermediate electronegativity (Table 1). Moreover, the thermal stability of compounds such as **4** gave us encouragement and it seemed that given the right ligand environment some success could be had. This proved to be the case and what we have found is that the coordination chemistry of indane can be similar but also significantly different to that of alane and gallane.

Stabilisation strategies

It is perhaps a misconception that the paucity of indium hydride complexes is wholly due to the weakness of the In–H bond (Table 1). This must be part of the reason but as pointed out by Downs and Pullham, the In–H bond is actually stronger than the In–C bond and indium trialkyls and their complexes are common place and generally thermally stable.[27] These authors suggested that the facile decomposition of the heavier group 13 binary hydrides may be partly kinetic in origin in that M–H–M bridges are easily formed, much more so than M–C–M bridges, and that such intermolecular association could lower the energy barrier to decomposition to $M_{(s)}$ and $H_{2(g)}$.

This argument could also be applied to indane complexes, [L → InH_3], if comparisons are drawn with their alane analogues, [L → AlH_3]. These are well known to associate through hydride bridges[4,5] and it is quite possible that such an associative process could occur prior to ligand (L) loss which in the case of indane complexes would invariably lead to decomposition to indium metal and H_2 gas. It has been calculated that the strengths of the bonds between normal donors (*e.g.* tertiary amines) and the InH_3 unit should be weak (< 100 kJ mol^{-1}) and certainly less than the strength of the In–H bond.[28] This situation would favour ligand loss in the aforementioned associative decomposition mechanism but also in a dissociative mechanism involving ligand loss from monomeric [L → InH_3]. It seems likely that a dissociative pathway is more likely given the relative instability of gallane complexes [L → GaH_3] for which intermolecular hydride bridges are not favoured.

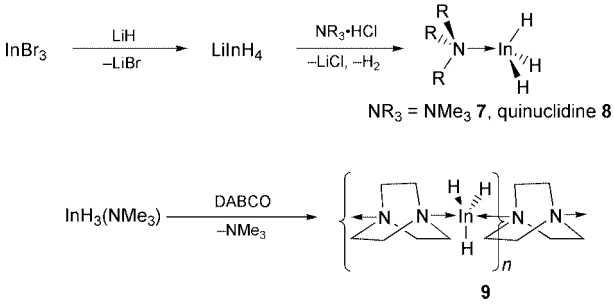
It was thought logical that the formation of room-temperature stable indane complexes would require the use of a ligand with two major characteristics. Firstly, it would have to be a strong Lewis base. This would allow the formation of a relatively strong L–In bond, thus disfavouring ligand loss. This, in turn, would help circumvent the formation of intermolecular hydride bridges as the indium centre would be more electronically satisfied. Secondly, the ligand would need to be sterically bulky. This would help prevent the formation of intermolecular hydride bridges while at the same time protecting the InH_3 unit from attack from oxygen and moisture.

Preparation and properties

Group 15 donor complexes

Our original strategy was to employ ligands that had been successfully used to stabilise the AlH_3 and GaH_3 fragments, *viz.* tertiary amines and phosphines. With regards to tertiary amines, a theoretical study had suggested these would be far superior to phosphines as ligands with respect to their binding energy to the InH_3 unit (*e.g.* [$InH_3(NH_3)$] 91 kJ mol^{-1}, [$InH_3(PH_3)$] 35 kJ mol^{-1}).[28] Two synthetic routes to tertiary amine complexes were employed which involved (i) salt elimination from the reaction of $LiInH_4$ with a trialkylammonium chloride or (ii) ligand displacement from *in-situ* generated [$InH_3(NMe_3)$]. It is noteworthy that in route (i) $LiInH_4$ is generated *in-situ* (from the reaction of $InBr_3$ and LiH) and the by-product, LiBr, is soluble in diethyl ether. These reactions do not appear to work when NaH or KH are used, or if they are carried out in THF.

The only success achieved with tertiary amines was in the preparation of complexes **7**–**9** (Scheme 1), none of which are

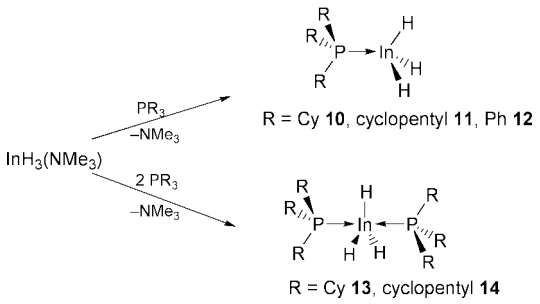


Scheme 1

stable at room temperature. In fact **7** is only stable below −30 °C and in dilute solutions (< 0.1 M) and so could not be properly characterised.[29,30] Compounds **8** and **9** are unstable below *ca.* 0 °C in the solid state, decomposing to In metal, H_2 gas and returning the free tertiary amine.[31] This is perhaps surprising considering the alane analogues of these compounds are very thermally stable and do not decompose until 170 °C (mp 110–112 °C)[32] and > 200 °C respectively.[33] Little data could be obtained on either compound but their IR spectra display very strong, broad In–H stretching absorptions at 1640 cm^{-1} and 1650 cm^{-1} which are at considerably lower frequency than normally seen for tertiary amine–alane complexes (*ca.* 1700–1800 cm^{-1}).[4,5] This is in line with the relative strengths of the M–H bonds. It is noteworthy that very stable ionic aluminium hydride complexes, *e.g.* $[AlH_2(L)]^+[AlH_4]^-$, L = tetramethylcyclam (decomp. 243–246 °C) or pmdeta (decomp. 182 °C),[34] can be formed from the reaction of [$AlH_3(NMe_3)$] with polydentate tertiary amines. Interestingly, a number of similar reactions have been carried out with [$InH_3(NMe_3)$] but all led to decomposition below < −15 °C.[31] It is not known why this occurs but it is clear that indane is different to alane in this respect.

Although tertiary phosphines are much poorer donors than tertiary amines towards alane, both ligand types have a similar donor ability toward gallane. Despite theoretical studies which have predicted that tertiary phosphines would be poorer donors than amines toward indane,[28] the preparation of a series of complexes was attempted (Scheme 2). It was found that both 1:1 and 2:1 complexes could be prepared using a ligand displacement route but reactions of PR_3/HCl with $LiInH_4$ proved fruitless even though a similar route can be used to form gallane complexes.[35]

In general, the phosphine–indane complexes possessed remarkable thermal stability (*cf.* gallane chemistry) that



Scheme 2

increased with the σ-donating and steric properties of the phosphine ligand. The 1 : 1 and 2 : 1 PCy_3 adducts were the most stable in the solid state (**10** decomp. 50 °C and **13** decomp. 37 °C) though all complexes decomposed to indium, $H_{2(g)}$ and the free phosphine.[36] Remarkably, crystalline samples of **10** proved to be completely stable to the atmosphere at room temperature over a 24 hour period. The apparently greater stability of phosphine–indane adducts over their amine analogues is probably due to a combination of factors. Firstly, the phosphines that have been employed are much bulkier than the amines used. Secondly, the electronegativity of In, intermediate between that of Al and Ga, and its greater covalent radius might make the InH_3 unit a softer Lewis acid than alane and therefore prefer phosphine coordination, as does gallane. However, unlike gallane, indane appears to take on higher coordination numbers, which is a well documented feature of alane chemistry. Indeed, it appears that indane prefers even higher coordination numbers than alane as the latter cannot form a 2 : 1 adduct with PCy_3 (*cf.* **13**). These trends were further examined with the attempted preparation of an arsine–indane complex, $[InH_3(AsCy_3)]$, however, not surprisingly, no stable adduct could be obtained.[31]

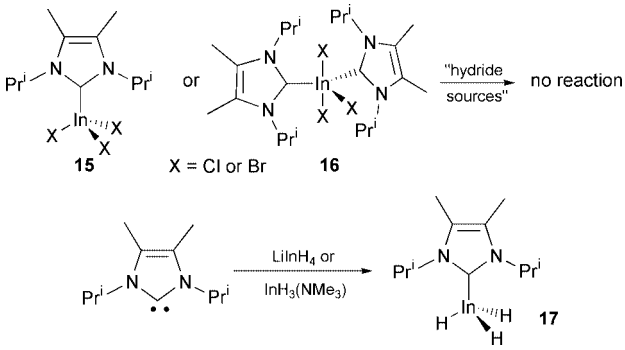
Both **10** and **13** have been crystallographically characterised and in the case of **10** the hydride ligands were located. Although not terribly accurate, the average In–H distance was found to be 1.68 Å which is significantly longer than M–H bonds in alane and gallane adducts (*e.g.* $[AlH_3(PCy_3)]$ 1.53 Å and $[GaH_3(PCy_3)]$ 1.48 Å).[4] Most significantly, the geometry around the indium centre is a flattened tetrahedron (av. P–In–H 101.4°; av. H–In–H 116.2°). Similar flattenings are common for alane and gallane complexes and imply that the MH_3 units are relatively weak Lewis acids. In **13** the phosphine donors take up the axial positions of a trigonal bipyramid and the In–P bond lengths are some 0.34 Å longer than in **10**. This significant difference was put down to a combination of steric and electronic factors.

All the phosphine–indane complexes mentioned here displayed strong In–H stretching absorptions in what is now known to be the normal region for InH_3 complexes (*ca.* 1630–1690 cm^{-1}). Of the data obtained so far there seems to be an inverse correlation between the strength of the donor ligand and the position of this band. In several cases the resonances for the hydride ligands were observed in ^1H NMR spectra of the complexes though these were significantly broadened due to the quadrupolar nature of the indium centre to which they are bonded (^{115}In 95%, I = 9/2; ^{113}In 5%, I = 9/2). Again, a trend is emerging which points to these resonances occurring at *ca.* 1 ppm to lower field than for corresponding Al and Ga complexes, *e.g.* $[MH_3(PCy_3)]$, M = Al δ 4.32 ppm; Ga δ 4.25 ppm; In δ 5.61 ppm. At present there is no explanation for this observation.

Carbene complexes

Although phosphine complexes such as **10** and **13** are stable at room temperature in the solid state they are not in solution which makes an investigation of their further chemistry difficult. We began looking at the use of imidazol-2-ylidenes, or 'Arduengo carbenes' as they are sometimes known, for this purpose. These room temperature stable carbenes were seen as potentially ideal in that they are extremely nucleophilic, easy to prepare, can incorporate bulky N-substituents and are known to behave like classical Lewis bases in combination with main group Lewis acids.[37] These properties have led to their use in the stabilisation of a variety of main group complexes including $[AlH_3(IMes)]$, IMes = $:CN(Mes)C_2H_2N(Mes)$, Mes = mesityl, which melts at 246 °C.[38] This is *ca.* 100–150 °C greater than the decomposition temperatures of normal tertiary amine–alane complexes.[4,5] To predict if these carbenes would have a similar stabilising effect toward the InH_3 fragment DFT studies have been carried out on the model carbene–indane adduct, $[InH_3\{CN(H)C_2H_2N(H)\}]$, and have found the ligand binding energy to be 110.8 kJ mol^{-1} which can be compared to values of 64.5 kJ mol^{-1} and 58.2 kJ mol^{-1} for $[InH_3(NMe_3)]$ and $[InH_3(PMe_3)]$ respectively.[39] Therefore it seemed likely that carbene–indane adducts might well be more stable than either tertiary amine or phosphine adducts.

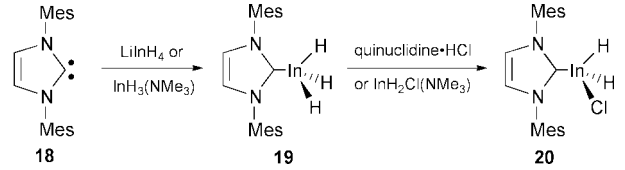
Our initial approach was to carry out hydride/halide exchange reactions on 1 : 1 and 2 : 1 carbene adducts of indium halides. Several of these adducts, **15** and **16**, were prepared and structurally characterised[40] but when treated with a variety of hydride sources, *e.g.* LiH, $LiInH_4$, $LiAlH_4$ *etc.* no reaction was observed (Scheme 3). More success was had when the same



Scheme 3

carbene was treated with $LiInH_4$ or $[InH_3(NMe_3)]$ which afforded the first carbene–indane adduct, **17**.[29,30] The latter reaction was a simple ligand displacement but in the former a thermally unstable by-product, thought to be a complex indium hydride species, was formed. Despite the aforementioned theoretical predictions, complex **17** proved to be disappointingly unstable in that it decomposed above −5 °C in the solid state and −20 °C in solution. However, the decomposition products did not include the free carbene, but a complex mixture of products that contained organoindium species. Therefore it was thought that in this case decomposition proceeded *via* metallation of the carbene isopropyl substituents by the InH_3 unit.

Accordingly the mesityl substituted carbene, IMes **18**, was employed in identical reactions as it was thought that it would be sterically less viable for any formed adduct to decompose *via*. metallation of the N-substituents. This indeed proved to be the case and the reactions depicted in Scheme 4 yielded **19** in up to a 86% yield.[41] Interestingly in the reaction of **18** with $LiInH_4$,



Scheme 4

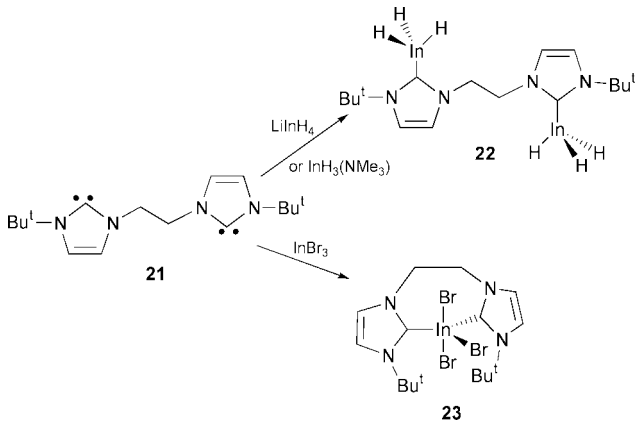
LiH was the by-product which contrasts with the previously mentioned reaction. Moreover, when $[InH_3(NMe_3)]$ was reacted with two equivalents of either IMes or $:CN(Pr^i)C_2H_2N(Pr^i)$ only the 1:1 adducts were formed. This is perhaps not surprising on steric grounds but contrasts with the formation of the 2:1 indium halide adducts, **16**, and is evidence for the weaker Lewis acidity of the InH_3 unit relative to InX_3, X = Cl or Br.

Complex **19** proved to be remarkably stable in that it remained intact in the solid state up to 115 °C (*cf.* $[AlH_3(IMes)]$ mp 246 °C,[38] $[GaH_3(IMes)]$ 214 °C decomp.[41]) and can be heated as a toluene solution for up to 2.5 hours before decomposition is complete. The decomposition of **19** in solution has been studied and in no case does this occur *via* metallation reactions (*cf.* the facile decomposition of **17**). In fact, this decomposition is solvent dependent. For example, heating toluene solutions of **19** afforded In metal, H_2 gas and returned the free ligand in a similar manner to the decomposition of Lewis base adducts of alane and gallane.[4,5] However, in THF and in the presence of a catalytic amount of indium metal, decomposition occurs *via* hydrogen transfer from the InH_3 unit to the carbene ligand to give indium metal and the dihydroimidazole, $H_2CN(Mes)C_2H_2N(Mes)$. More surprising is the decomposition of **19** in CH_2Cl_2 which gives high yields of $[InCl_3(IMes)]$ as a result of chloride abstraction from the solvent.

The crystal structures of both **17** and **19** have been reported though in both the hydride ligands were not located. Both are monomeric with In–C bond lengths in the normal region for indium alkyls. In each there is a degree of delocalisation over the NCN fragment of the carbene ligands which is manifested by an opening of this angle relative to that in the free carbene. The NMR and IR data for the compounds confirmed the presence of the hydride ligands and the latter revealed the In–H stretching absorptions (**17** 1640 cm^{-1}; **19** 1640 cm^{-1}) to be at the low end of the normal range. This observation is in line with the highly nucleophilic nature of the ligands which should weaken the In–H bonds in the complexes relative to phosphine–indane complexes for example. In addition, the deuteride analogue of **19**, $[InD_3(IMes)]$, has been prepared and its IR spectrum shows a strong In–D stretch at 1180 cm^{-1}, which is shifted by the expected amount from the corresponding In–H stretch. Finally, if one of the hydride ligands of **19** is substituted with a chloride, the resulting complex, **20** (Scheme 4), shows an In–H stretch at a significantly higher frequency (1737 cm^{-1}) which is no doubt a result of the chloride ligand drawing electron density away from the In centre, thus strengthening the two In–H bonds relative to those in **19**.

Recently we have extended this work to investigate the interaction of bidentate carbenes with indane. The rationale here was that alane forms very stable ionic species of the type $[AlH_2(L)]^+[AlH_4]^-$ with polydentate donors[34] and we thought a similar outcome might result with indane. However, the reaction of **21** with either $[InH_3(NMe_3)]$ or $LiInH_4$ only gave the indane rich 2:1 adduct, **22** (Scheme 5) under any stoichiometry of reactants.[31] This is in line with our previous observation that the InH_3 fragment will only form four-coordinate adducts with nucleophilic carbene ligands. By contrast, when the same carbene is reacted with $InBr_3$ in any stoichiometry it forms a five-coordinate chelate complex, **23**, which again implies that InH_3 is a weaker Lewis acid than indium trihalides.

Unfortunately, **22** did not prove to be very thermally stable as it decomposes slowly above 0 °C. However, in its crystal structure the hydride ligands were located for the first time in a carbene–indane complex. As expected, the tetrahedral geometry about the In centres is much less flattened (C–In–H 105.7° av., H–In–H 112.9° av.) than in the phosphine adduct, **10**, which gives evidence for the relative strength of the donors (carbene > phosphine) in these complexes. The In–H distances (1.72 Å av.) are close to those in **10**.

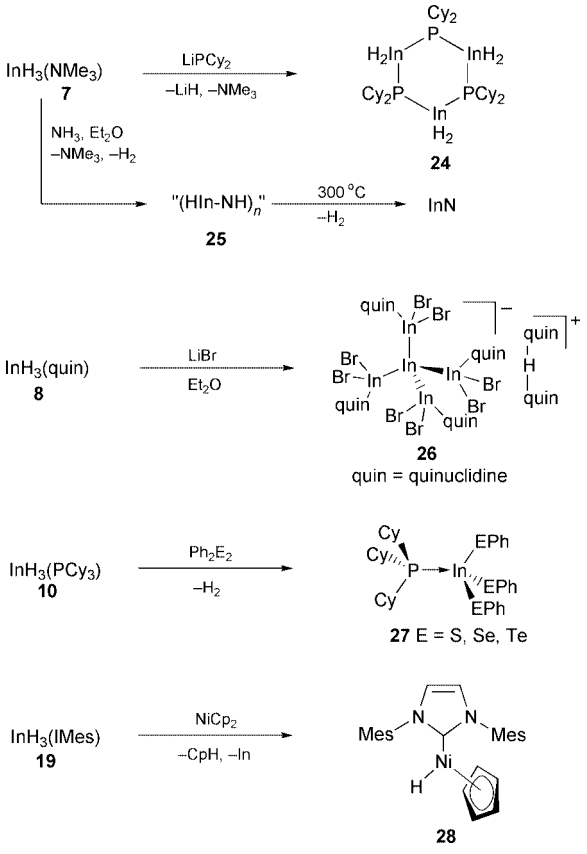


Scheme 5

Reactivity

Use in inorganic synthesis

Now that room temperature stable indane complexes have been developed it is of great interest to investigate their further reactivity and compare it to alane and gallane chemistry. To date only preliminary and largely unconnected steps have been made in this direction which, in the case of inorganic synthesis, are summarised in Scheme 6. There is no doubt that a more complete picture will soon emerge in this respect.



Scheme 6

The *in-situ* generated indane complex, **7**, reacts with $LiPCy_2$ to give the trimeric phosphido–indium hydride complex, **24**.[36a] This proved to be moderately stable in the solid state (decomp. 64 °C) but did not decompose in solution as hoped to give InP and cyclohexane but instead afforded $In_{(s)}$, H_2 and PCy_2H. X-Ray crystallography confirmed its structure and the location of the hydride ligands gave an average In–H bond length of 1.71 Å for the complex. When NH_3 was passed through an ethereal

solution of **7** at −30 °C an amorphous white precipitate immediately deposited which is thought to be some form of imido–indane polymer, **25**. This is stable at room temperature but when heated at 300 °C yields relatively pure nanocrystalline InN as determined by X-ray powder diffractometry.[31] This result mimics similar work with alane and gallane complexes[7] and with development could offer a facile route into other group 13–15 materials, *e.g.* InP from the reaction of **7** with PH_3.

One of the most interesting reactions we have encountered is the controlled decomposition of [InH_3(quinuclidine)] **8** at −30 °C in the presence of LiBr, the by-product in the synthesis of the $LiInH_4$ precursor to **8**. At this temperature over 5 days the solution slowly changes from colourless to deep orange and orange diamagnetic crystals of **26** deposit in 15% yield. These are unstable above 0 °C and probably form from a combination of H_2 elimination and H/Br exchange.[31] The crystal structure shows the anion to consist of a tetrahedron of 4 indium atoms around a central In. Each of the outer indium atoms is coordinated by two bromides and a quinuclidine giving an average In oxidation state of 1.4. The cation consists of two quinuclidine molecules coordinated to a proton in a linear fashion. Interestingly, a neutral gallium relation of this complex, [$Ga_5Cl_7(OEt_2)_5$], has been reported by Schnöeckel and coworkers to have arisen from the controlled decomposition/redistribution of metastable [$Ga^{I}Cl(OEt_2)$].[42] There is no precedent for the formation of **26** in alane or gallane chemistry and it offers the exciting possibility of preparing sub-valent indium hydride compounds *via* the controlled decomposition of indane complexes.

Other reactions that have been investigated include the use of the phosphine–indane complex, **10**, in the formation of a series of monomeric tris(chalcogenolato)indium complexes, **27**, all of which were crystallographically characterised.[36a] Finally, the interaction of the carbene–indane complex, **19**, with transition metal complexes is being systematically examined in the hope that low valent transition metal fragments can be oxidatively inserted into the In–H bond. Although no indium containing products have yet been obtained, a noteworthy result from this study has come from the reaction of **19** with nickelocene.[39] This effected both a hydride and a carbene transfer to the nickel centre with a concomitant loss of cyclopentadiene to form **28**.

Use in organic synthesis

Boron and aluminium hydride complexes are invaluable reducing agents in organic synthesis. Even gallium trihydride complexes have found a niche as chemoselective reductants as a result of the lesser polarity of the Ga–H bond relative to the Al–H bond.[43] It was of considerable interest to us to examine the exploitation of indane complexes as selective reducing agents given the chemical and physical differences they show to their lighter group 13 analogues. This seemed especially timely considering the recent emergence of indium and its complexes as reagents in organic synthesis.[6,44] Indeed, the selective reducing abilities of several indium hydride complexes had been previously confirmed though in these instances the active species were invariably prepared *in-situ*, were not thermally stable and were poorly characterised.[18–20,45] It was apparent that if easily prepared, room temperature stable indane complexes did show selectivity in organic reductions they might be of real use to organic chemists.

Indium has an electronegativity between that of Al and Ga. Therefore it might be expected that the In–H bond has a polarity between that of Al–H and Ga–H bonds. As a result, indane complexes could display a degree of chemoselectivity in the reduction of organic functionalities. This proved to be the case as both **10** and **19** readily reduce ketones but showed no activity towards a variety of ester functionalities that are readily reduced by alane complexes.[46] In addition, the debromination qualities of **10** toward 2,4′-dibromoacetophenone (57% C–Br cleavage) are mid way between those of alane complexes, which quantitatively effect α C–Br cleavage, and gallane complexes which show only minimal activity towards alkyl bromides. It is noteworthy that [$BH_3(NMe_3)$] is completely inactive towards this substrate. In addition, the reduction of styrene oxide by **10** highlights an intermediate regioselectivity of this reductant (reduction product mixture: 56% 1-phenylethanol, 44% 2-phenylethanol) over [$GaH_3(PCy_3)$] which gives 99% of the secondary alcohol and [AlH_3(quinuclidine)] which yields 37% of the primary alcohol as a reduction product.

Indium has a greater covalent radius (1.50 Å) than either aluminium or gallium (1.25 Å) which means that like alane but unlike gallane, indane should form hypervalent complexes as has been demonstrated with the preparation of **13**. It was thought this preference could lead to indane complexes showing diastereoselectivity in the reduction of potentially chelating bifunctional substrates. This has been confirmed with the reductions of benzoin, benzil and benzoin methyl ether by **10**, all of which occur with >99% disastereoselectivity. These results suggest a chelation of the substrate to the indium centre of the complex which allows a directed hydride delivery leading to the observed result.[46]

Efforts have also been made to examine the enantioselectivity of indane reductions using the *in-situ* generated complexes [InH_3{PPh_2((+)-neomenthyl)}] and [InH_3((−)-sparteine)]. Unfortunately, when a range of prochiral ketone substrates were employed no significant enantiomeric excesses were observed.[31] This work is now moving towards the use of chiral carbene–indane complexes for this purpose.

Outlook

In the past 4 years the stabilisation of indane complexes has been achieved and their structure, bonding, properties and reactivity have begun to be explored and understood. This work has showed that indane complexes display many similarities to their alane and gallane counterparts but also significant differences which can often be accounted for by examining the properties of the group 13 elements themselves. Now that reasonably stable indane complexes have been developed their further chemistry should be systematically explored. Areas in which they might be especially useful include their employment as precursors to sub-valent indium hydride complexes (*cf.* **26**) which are currently unknown. In addition, our preliminary work suggests they might find valuable use as materials precursors, as have alane and gallane complexes.

Of course the obvious question for the future is can stable TlH_3 (thallane) or other thallium hydride complexes be formed? It would perhaps be thought that the weakness of the Tl–H bond and the potential for thallane complexes to undergo reductive elimination of hydrogen would argue against this. However, we have recently prepared the first carbene–thallium complexes, *e.g.* [$TlCl_3$(IMes)] (decomp. 208 °C), which are remarkably stable under normal conditions and show little desire to undergo reductive decomposition processes.[47] This again raises the question, would a complex such as [TlH_3(IMes)] be isolable under normal conditions? Only time will tell.

Acknowledgements

Thanks go to my current and former postgraduate students and postdoctoral colleagues who made this work possible through their perseverance and attention to detail. The results reported in this article would not have been possible without them. Their names are cited in the references. Funding for this work was

from the EPSRC who I must thank for their continuing support.

First published as an Advance Article on the web 22nd October 2001

Electroconductivity along a long DNA strand (*ca.* 10 μm length) in a DNA-aligned cast film of DNA–lipid complex was measured on a comb-type electrode (5 μm distance), and it could be reversibly regulated by temperatures across 70 °C.

DNA is interesting as a conducting molecule along double strands. There have been many approaches to study the electric conductivity along a DNA strand.[1–9] Barton and co-workers reported in pioneer work that photoinduced charge transfer between donors and acceptors immobilized at both ends of DNA strands could be observed in homogeneous aqueous solution.[1] Photoinduced or long range charge transfer along DNA molecules has also been studied in aqueous solution.[2,3] Conductivities of a DNA monolayer on Au electrode have been studied by cyclic voltammogram[4] or atomic force microscopy (AFM)[5] in aqueous solution. Fink and Schonenberger measured directly the electrical conductivity of dry DNA fibers across two electrodes separated by the very short distance of 8 nm.[6] Recently, superconductivities of DNA fibers across a sub-micronic slit on mica plate has been reported.[7] The conductivity values obtained in these studies are roughly in the wide range of 1–10^{-5} S cm^{-1} and are still a matter of controversy. This is due to the widely spread measurement methods or media depending on different sample preparations. We have reported that a large, self-standing DNA film (10 × 10 cm, 20–100 μm thick), in which DNA strands aligned in one direction, could be prepared by casting from organic solution of DNA–cationic lipid complexes.[8] We observed high anisotropic conductivity along the DNA strands in the film.[9] The DNA-aligned film has many advantages as an electric conducting material, being large, flexible, self-standing and thermo-stable.

In this communication, we report molecular level evidence of *electron* conductivity through DNA strands in the DNA-aligned cast film prepared from two different length of DNAs (*ca.* 0.2 and 10 μm per molecule), by measuring direct or alternating currents on a comb-type electrode plate (5 μm distance between two electrodes) at different temperatures.

The DNA-aligned cast film was prepared as follows.[8,9] Two different lengths of DNA were extracted and purified from salmon testes: *ca.* 0.2 μm length, average *M* 3 × 10^5, 500 bps *ca.* 10 μm length, *M* 2 × 10^7, 30 000 bps. An aqueous solution of DNA^{n-} $n Na^+$ and an aqueous solution of 1.1 eq. mol of a cationic amphiphile (**1**) were mixed at rt and the precipitated DNA–lipid polyion complex (1 : 1 ratio of phosphate anion to cationic lipid) was collected and solubilized in chloroform–ethanol (4 : 1 v/v). The solution (40 mg mL^{-1}, 4 wt%) was cast on a Teflon plate and the solvent was evaporated slowly under saturated vapor at rt. The obtained self-standing film (*ca.* 60 μm thick) was transparent, water-insoluble, and physically stable below 150 °C. The DNA film could be stretched mechanically 3–5 times in length at rt. From X-ray diffraction, polarized microscopy, and polarized absorption spectra measurements, DNA strands were aligned with a distance of 41 Å along the stretching direction as shown schematically in Fig. 1.[8] The distance between stacked base pairs of DNAs in the film was 3.4 Å, similar to the native DNAs in aqueous solution. The stretched film was still transparent and physically strong. The orientation of DNA strands in the film disappeared on heating to 150 °C (glass transition temperature, T_g = 135 °C).

The stretched DNA film (5 × 5 mm, 20 ± 5 μm) was put on a comb-type electrode plate, in which the distance between two electrodes is 5 μm. The dc conductivity was measured using an ammeter (R8340A, Advantest, Co., Tokyo) at 20 °C in a dry box. Typical results are shown in Fig. 2. When the stretched DNA film prepared from long DNA strands (10 μm length, 30,000 bps) was put on the comb-type electrodes with the DNA strand axis aligned perpendicularly to the electrodes, large ohmic currents (0–0.7 mA) were observed that increased linearly with increasing applied voltage in the range of −0.5–+0.5 V. The conductivity was calculated from the slope to be 5 × 10^{-3} S cm^{-1}. The currents were constant during measurements and did not decrease for at least 10 min. In contrast, when the same film prepared from the long DNA was placed with DNA strands aligned *parallel* to the two electrodes, electric current was hardly observed even at voltages up to 100 mV (less than 0.001 mA or 10^{-6} S cm^{-1}, data not shown).[9] When the DNA-aligned film prepared from the short DNA molecules (0.2 μm length, 500 bps) was put perpendicularly to the electrodes, very small ohmic currents (0–1 μA, 10^{-6} S cm^{-1}) were observed depending on applied voltage, and the current diminished within 5 s (Fig. 2B). The constant, large, and ohmic currents along the long DNA strands indicate electron conduction along DNA strands aligned in the film, since one 10 μm DNA molecule can be expected to bridge the distance of 5 μm between two electrodes in the film. In contrast, the short 0.2 μm DNA strands could not bridge two electrodes and only very small and immediately-diminished currents were observed due to the rate-limiting diffusion of impurity ions between inter-molecular short DNA strands in the film.

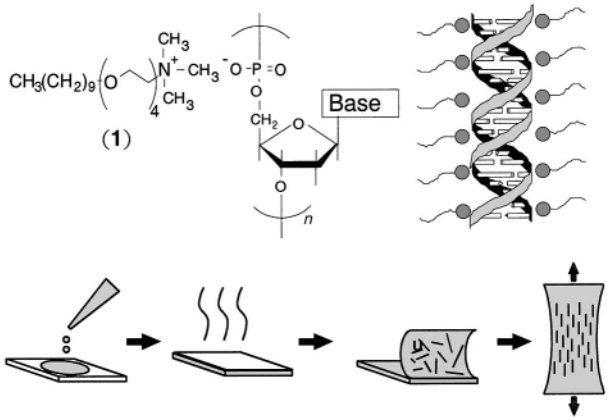

Fig. 1 Schematic illustration of a DNA aligned film prepared from casting organic soluble DNA–lipid (**1**) complex with subsequent uniaxial stretching.

 DOI: 10.1039/b107228e

Fig. 3 shows temperature dependences of Cole–Cole plots of DNA-aligned cast film with the DNA strands placed perpendicularly to the two comb-type electrodes. Alternating currents were measured by using a universal impedance analyzer (Model 53131A, Hewlett Packard, CO. Tokyo) by changing the frequencies from 10 Hz to 10 MHz at 20–100 °C in a dry box. With the film prepared from the long DNA (10 μm molecular length), the apparent resistances at the zero imaginary of impedance were constant at 400 Ω independent of temperature from 25 to 60 °C (Fig. 3A). When the film prepared from the short DNA (0.2 μm length) was employed, in which DNA molecules cannot bridge two electrodes, the resistance was greatly increased to 100–650 kΩ depending on temperature (Fig. 3B). The conductance (σ) obtained from the resistance is plotted against temperature in Fig. 4. The conductance obtained from the long DNA film was 10^{-3} S cm^{-1}, consistent with that obtained by direct current measurements (Fig. 2), and was independent of temperature from 20 to 60 °C. In contrast, the conductance of the short DNA film was very small and increased linearly with increasing temperatures (10^{-7} to 10^{-5} S cm^{-1}). Thus, the temperature-independent conductance of the long DNA film again indicates electron conductance along intramolecular DNA strands. The temperature-dependent conductance of the short DNA film shows the small ionic transportation between short DNA molecules.

When the film prepared from the long DNAs was heated above 60 °C, the conductance decreased drastically to 10^{-6} S cm^{-1}, but reverted to the original value when the temperature was decreased to below 60 °C (curve A in Fig. 4). When the film was heated above 135 °C, the conductivity diminished and did not revert to the original value, since the orientation of the DNA strands in the film disappeared above T_g = 135 °C. This indicates that the anisotropic conductivity along DNA strands can be switched *on* and *off* reversibly depending on whether the temperature is below or above 70 °C. Since the intermolecular orientation of DNA strands in the film does not change below 135 °C, this reversible conductivity change can be explained by reversible changes in intramolecular stacking of base pairs of DNA strands aligned in the film.

In summary, we could directly observe the switchable electron conduction along intramolecular DNA strands by using DNA-aligned cast film on a comb-type electrode. This was possible because of the large area and self-standing, physically strong, and thermotropic liquid crystalline nature of the DNA-aligned cast film.

Configurational ordering of a cationic dinuclear triple helicate by chiral TRISPHAT anions†

Jérôme Lacour,* Jonathan J. Jodry and David Monchaud

Département de Chimie Organique, Université de Genève, quai Ernest Ansermet 30, CH-1211 Genève 4, Switzerland. E-mail: Jerome.Lacour@chiorg.unige.ch; Fax: (41-22) 328-73-96

Received (in Cambridge, UK) 10th September 2001, Accepted 25th September 2001
First published as an Advance Article on the web 22nd October 2001

Chiral TRISPHAT anions behave as efficient asymmetric hosts controlling with high efficiency the configuration of a cationic dicobalt(II) triple helicate—de up to 82%.

Helicate derivatives made by the self-assembly of polydentate organic ligands and metal ions have received much attention over the last two decades.[1] They are chiral and the helical enantiomers are characterized by their *plus* (*P*) or *minus* (*M*) handedness. To obtain chiral helicates in a predominant *P* or *M* configuration, the most common strategy, apart from resolution, has been to add stereogenic elements to the backbone of the ligands. Intramolecular diastereoselective interactions occur between the enantiopure strands and lead to the preferred formation of one diastereomer.[2] To date, there are several examples of high selectivity in the formation of double and triple helicates, in which enantiopure ligands completely control the configuration. The stereogenic elements are introduced either on the coordinating units, on the bridging elements or on a chiral template linking the strands together.[3]

An alternative strategy to control the configuration of the charged chiral complexes is to consider their asymmetric ion pairing with chiral counter-ions; intermolecular diastereoselective interactions controlling the stereoselectivity (Pfeiffer effect). However this approach, although efficient, has been essentially used with small molecules and simple coordination complexes.[4] Recently, Raymond *et al*. reported the asymmetric induction of chiral pyridinium cations onto an anionic dinuclear Ga(III) triple-stranded helicate, the extent of the diastereoselectivity being determined by chiroptical measurement.[5]‡ Herein, we report that the asymmetric induction of chiral counter-ions onto a triple helicate can be indeed an efficient process, a good level of configurational ordering from TRISPHAT **1** anions onto a cobalt(II) dinuclear triple helicate being observed in solution (diastereomeric excess (de) ≤ 82%, determined by ^{1}H NMR).

Previously, we reported the synthesis and resolution of D_3-symmetric tris(tetrachlorobenzenediolato)phosphate(V) anion **1** or TRISPHAT.[6] Associated with mononuclear ruthenium(II) or iron(II) tris(diimine) complexes, it is an efficient NMR chiral shift, resolving and asymmetric inducing agent.[7] However, in these studies, D_3-symmetric mononuclear complexes were used. It was then debatable whether **1** would behave as a good asymmetric inducer for cationic polynuclear helicates of more complex structure and geometry.

Chiral di- and polynuclear helicates of Fe(II), Ni(II) and Cu(I) racemize more slowly (factor 10^{-6}) than their mononuclear equivalents.[8] Their association with chiral anions has therefore led to their resolution into separated enantiomers rather than an asymmetric induction from the anions.[9] To perform our projected study, we thus derived a known configurationally stable helicate—Elliott's dinuclear iron(II) derivative **2** (Fig. 2, $[Fe_2(\mathbf{L})_3]^{4+}$, **L** = 1,2-bis[4-(4′-methyl-2,2′-bipyridyl)]-ethane)—into a configurationally labile dinuclear cobalt(II) derivative (**3**, $[Co_2(\mathbf{L})_3]^{4+}$).[10]

The synthesis of complexes [**3**][Δ-**1**]$_4$ was achieved in a single step as follows.† Treatment in hot water of $CoSO_4{\cdot}7H_2O$ with 1.5 equiv. of ligand **L** afforded a yellow solution of [**3**][SO_4]$_2$. Extraction of the cationic helicate **3** from the aqueous layer into the organic layer [CH_2Cl_2–acetone (25 : 1)], using 2 equiv. of [cinchonidinium][Δ-**1**], gave the desired complex [**3**][Δ-**1**]$_4$ as the major product, which was further purified by recrystallization.

The efficiency of anions **1** as chiral inducers was then simply demonstrated by ^{1}H NMR. Solutions of [**3**][Δ-**1**]$_4$ (0.50 mM) were prepared in mixtures of $CDCl_3$ and [D_6]-DMSO (100% to 20%) and analyzed. Due to the presence of the chiral TRISPHAT anions, we were able to distinguish between the diastereomeric pairs [*P*-**3**][Δ-**1**]$_4$ and [*M*-**3**][Δ-**1**]$_4$ as the spectra showed partial or complete separation for the signals of the chiral cation.§·¶ The diastereoselectivity of the asymmetric ion pairing between [*P*-**3**][Δ-**1**]$_4$ and [*M*-**3**][Δ-**1**]$_4$ was then directly calculated by the integration of the respective signals (Fig. 3). Upon decreasing solvent polarity (lower % DMSO), one diastereomer became predominant up to 82% de (diastereomeric ratio 10.1 : 1 in 20% [D_6]–DMSO–$CDCl_3$, Table 1). The study could not be performed in lower polar mixtures as compound [**3**][Δ-**1**]$_4$ precipitated in such solvent conditions.

So, with the decrease of the polarity of the solvent combination, a highly asymmetric induction took place in solution.‖ The equilibrium ([*P*-**3**][Δ-**1**]$_4$ ⇄ [*M*-**3**][Δ-**1**]$_4$) was

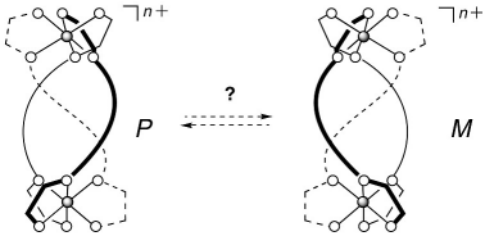

Fig. 1

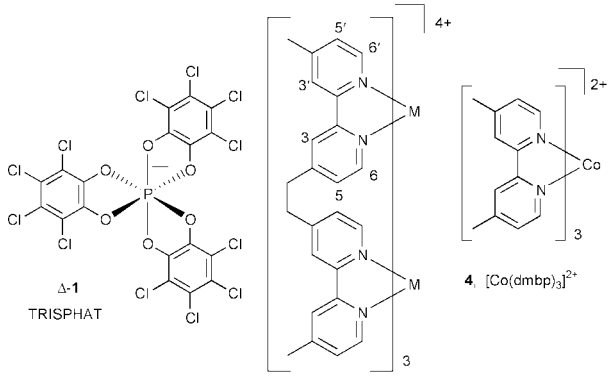

2, $[Fe_2(L)_3]^{4+}$
3, $[Co_2(L)_3]^{4+}$

Fig. 2

† Electronic supplementary information (ESI) available: synthesis and analytical data for compounds [**3**][Δ-**1**]$_4$ and [**4**][Δ-**1**]$_2$. See http://www.rsc.org/suppdata/cc/b1/b108110a/

 DOI: 10.1039/b108110a

consequently shifted towards the preferred diastereomer. The increase in diastereoselectivity as the polarity decreases is interpreted as the result of closer interactions between the ions.[11] Unfortunately, despite our efforts, we did not succeed in obtaining reliable solution CD spectra of complex [**3**][Δ-**1**]$_4$.†† Finally, to evaluate the efficiency of the chiral recognition of dinuclear helicate **3** by TRISPHAT anions, we measured the asymmetric induction of anions **1** onto mononuclear $[Co(dmbp)_3]^{2+}$ equivalent (Fig. 2, **4**, dmbp = 4,4′-dimethyl-[2,2′]bipyridinyl). Association of **4** with TRISPHAT was realized in a similar manner to **3**.† ^{1}H NMR analysis of salt [**4**][Δ-**1**]$_2$ in mixtures of [D$_6$]-DMSO–$CDCl_3$ revealed two sets of signals and, as for helicate **3**, a strong dependence of the diastereoselectivity as a function of the polarity of the solvent medium was observed (Table 1). In rather low-polar solvent conditions (7.5% DMSO–$CDCl_3$), only one of the two diastereomers was observed by ^{1}H-NMR (dr > 96%); its absolute configuration being [Δ-**4**][Δ-**1**]$_2$ as determined by CD analysis (0.1% DMSO–$CHCl_3$, 4.5 × 10^{-6} M).

Although the comparison of the diastereoselectivity of the association of TRISPHAT anions **1** and cations **3** and **4** was limited to a rather small range of solvent polarity, interesting observations could be made. In 20% [D$_6$]-DMSO–$CDCl_3$, a higher selectivity for complex [**3**][Δ-**1**]$_2$ (dr 10.1 : 1) than that for [**4**][Δ-**1**]$_2$ (dr 4.0 : 1) (Table 1) was determined. The stronger electrostatic attraction, due to the higher charge of the helicate, and the synergy resulting from mechanical coupling at both metal centers, all contribute to a higher asymmetric induction.

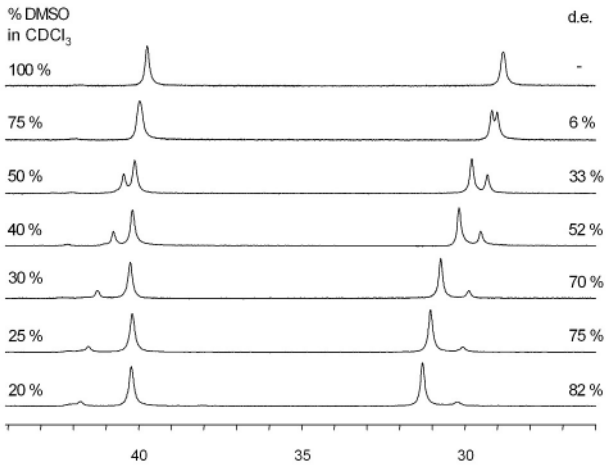

Fig.3 ^{1}H NMR spectra (δ 44–27 ppm) of [**3**][Δ-**1**]$_4$ in mixtures of [D$_6$]DMSO–$CDCl_3$.

[a] Not measured.

In conclusion, we have shown that the association with chiral triple helicate **3** and a stoichiometric amount of four chiral counterions **1** is sufficient to lead to an efficient asymmetric induction ^{1}H NMR allowing an unambiguous determination of the diastereoselectivity.

We thank the Swiss National Science Foundation, the Federal Office for Education and Science (COST D11), the 'Société Académique de Genève' for financial support, and more particularly the 'Fondation de Famille Sandoz' for a professorship.

Notes and references

‡ A correlation between solid-state and solution circular dichroism (CD) spectra was used to determine the extent of the diastereoselectivity.

§ In lower polar solvent conditions, contact ion pairs are formed between **1** and **3**, and the resulting short-range diastereomeric interactions lead to a non-equivalence of the enantiomers of the cation.

¶ Due to the broadening of the signals induced by paramagnetic metal centers, only two sets of signals could be analyzed properly (δ ~41 and ~30 ppm).

‖ Low-temperature experiments—which possibly have led to an improved selectivity—could not be performed due to the low solubility of the complex and the use of DMSO as co-solvent.

†† Complex [**3**][Δ-**1**]$_4$ seems to decompose in 20% DMSO–$CHCl_3$ at the 5 × 10^{-6} M concentration required for accurate solution CD measurements. As helicate **3** is formally an 'extended dimer' of mononuclear complex **4**, for which we have observed a high homochiral asymmetric induction in favor of [Δ-**4**][Δ-**1**]$_4$, we believe that [*P*-**3**][Δ-**1**]$_4$ is the preferred diastereomeric ion pair.

Received (in Cambridge, UK) 1st August 2001, Accepted 1st October 2001
First published as an Advance Article on the web 24th October 2001

Compounds of type $[(Ph_3P)_2AgIn(SC\{O\}R)_4]$ (R = Me (1), Ph (2)) are excellent single-source precursors for $AgInS_2$ bulk materials by pyrolysis and $AgIn_5S_8$ films by aerosol assisted chemical vapour deposition (AACVD).

In the past two decades chemists have been interested in synthesizing effective molecular precursors for various metal chalcogenides.[1–4] However, the possibility of single-source precursors for silver indium sulfide materials has been unexplored. Both $AgInS_2$ and $AgIn_5S_8$ are known to be semiconducting.[5–8] $AgInS_2$ finds applications as linear and nonlinear optical materials. The band gap of $AgIn_5S_8$ is 1.80 eV (300 K) and has been identified as making it a suitable candidate for photovoltaic solar cell applications.[9] Thin films of these sulfides have been obtained by spray pyrolysis[10,11] which also deposits Ag_2S.[10] Various metal monothiocarboxylates have been used as single-source precursors for metal sulfides.[12–14] Hence we attempted to synthesize bimetallic thiocarboxylate compounds as single-source molecular precursors to silver indium sulfides. Here we report the synthesis and characterization of compounds of the type $[(Ph_3P)_2AgIn(SCOR)_4]$ [R = Me (**1**), Ph (**2**)] along with the results of AACVD experiments.

The compounds were synthesized by reacting $[(Ph_3P)_2AgCl]_2$ and $InCl_3{\cdot}4H_2O$ with four molar equivalents of $Na^+RC\{O\}S^-$.† The structure of compound **2** (as its chloroform solvate) has been determined unequivocally by X-ray crystallography.‡

A view of **2** is shown in Fig. 1. Compound **2** consists of $(Ph_3P)_2Ag$ and $In(SC\{O\}Ph)_2$ units bridged by two $PhC\{O\}S^-$ ligands through μ-*S* bridging. The Ag(I) centre has distorted tetrahedral geometry with a P_2AgS_2 core while In(III) adopts distorted octahedral coordination geometry with two terminal $PhC\{O\}S^-$ anions chelating to In(III). The $AgInS_2$ ring is essentially planar with the two benzoyl groups attached to the S atoms in *anti* fashion.

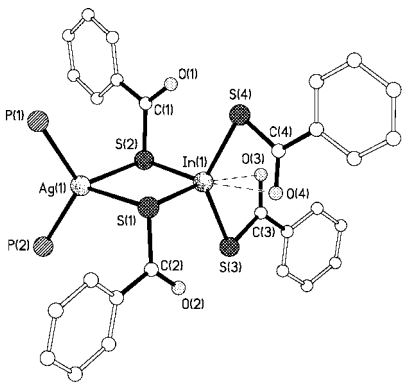

Fig. 1 Molecular structure of compound **2**. All hydrogen atoms and the phenyl rings on the triphenylphosphine ligand have been deleted for clarity. Selected bond distances (Å) and angles (°): Ag(1)–S(1), 2.7032(8); Ag(1)–S(2), 2.7173(8); Ag(1)–P(1), 2.4649(8); Ag(1)–P(2), 2.4573(1); In(1)–S(1), 2.5421(8); In(1)–S(2), 2.5352(2); In(1)–S(3), 2.4594(9); In(1)–S(4), 2.4571(9); In(1)–O(3), 2.672(2); In(1)–O(4), 2.664(3); S(1)–Ag(1)–S(2), 87.20(2), P–Ag(1)–S, 104.47(3)–117.61(3); P(2)–Ag(1)–P(1), 122.44(3); S(2)–In(1)–S(1), 87.20(2); S(3)–In(1)–S(1), 108.76(3); S(4)–In(1)–S(1), 101.05(3); S(3)–In(1)–S(2), 99.53(3); S(4)–In(1)–S(2), 111.23(3); S(4)–In(1)–S(3), 134.75(3); S–In–O, 59.98(6)–170.67(6); In(1)–S(1)–Ag(1), 89.05(2); In(1)–S(2)–Ag(1), 88.88(2).

The residual weights observed for **1** and **2** in thermogravimetric analyses indicate the formation of $AgInS_2$. The decomposition occurs in unresolved multiple steps in the temperature range 132–315 °C for **1** and 175–328 °C for **2**. X-Ray powder diffraction (XRPD) of the final residue obtained from pyrolysis of compounds **1** and **2** indicated the formation of orthorhombic $AgInS_2$, JCPDS: 25-1328 (Fig. 2).§ I-III-VI_2 materials are known to prefer tetragonal structures and hence the formation of the high temperature orthorhombic $AgInS_2$ phase is interesting.[4,15]

However, aerosol assisted chemical vapour deposition (AACVD) of a THF solution of compound **1** yielded $AgIn_5S_8$.¶ Films on glass deposited at 400 and 450 °C from the precursor were found to be transparent and adherent (Scotch tape test) with a dark red colour.

XRPD analysis (step size; 0.04° per 2 s) confirmed that the films were found to be cubic-$AgIn_5S_8$ (JCPDS 25-1329) with a preferred orientation along (311) (Fig. 3). Scanning electron

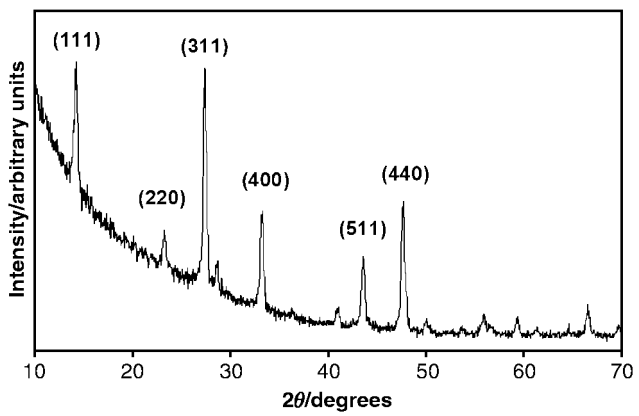

Fig. 3 X-Ray powder diffraction of $AgIn_5S_8$ thin films formed from compound **1**.

 DOI: 10.1039/b106923c

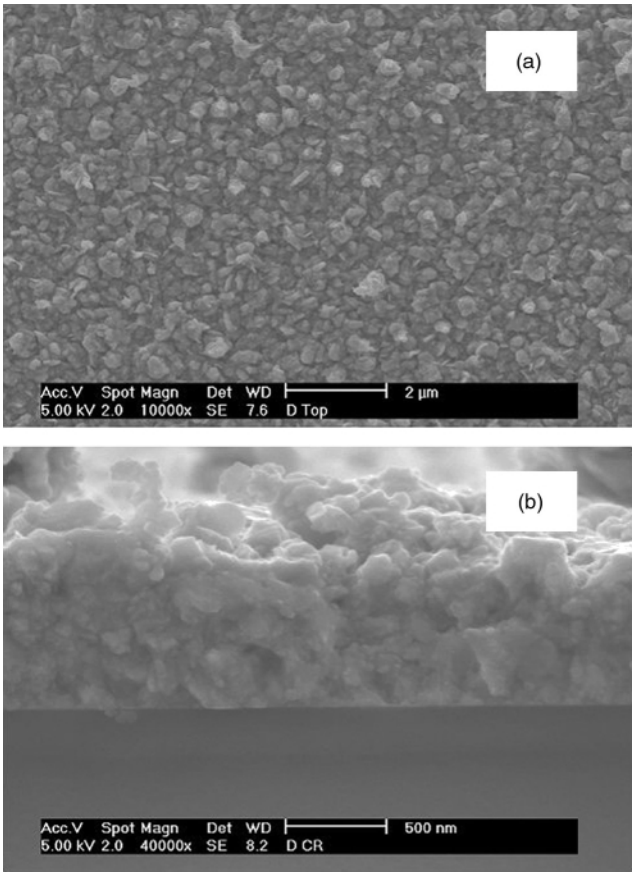

Fig. 4 SEM images of the film on glass grown at 400 °C from compound **1** (a): top view, (b): cross view.

microscopy (SEM) studies showed there is a dramatic change in the morphologies of films grown at 400 and 450 °C. The morphology of films grown at 450 °C consists of thin plate-like particles, perpendicularly laid down onto the substrate with random orientation. However, with decreasing growth temperature from 450 to 400 °C, the morphology was dense and no longer were plate-like particles formed (Fig. 4). Growth rate and average particle size of the films grown at 400 °C were *ca*. 0.3 μm h^{-1} and *ca*. 0.5 μm.

In conclusion, $[(Ph_3P)_2Ag(\mu\text{-}SC\{O\}Me\text{-}S)_2In(SC\{O\}Me)_2]$ (**1**) is shown to be a suitable single-source precursor for the deposition of cubic $AgIn_5S_8$ films on glass substrates by AACVD at 400 and 450 °C. The films grown at 400 °C were dense on a glass substrate. Similar results have also been obtained for **2**.

The significance of the current study is two fold. First of all, we have isolated and characterized bimetallic compounds containing In(III) and Ag(I) for the first time. Secondly, their potential use as single source precursors to silver indium sulfide has been clearly demonstrated. To the best of our knowledge no single-source precursors have been reported for silver indium sulfides previously in the literature. Further studies of novel single-source precursors for the growth of I–III–VI thin films are in hand.

J. J. V. would like to thank the National University of Singapore for a research grant (Grant No. R-143-000-084-112) and P. O. B. thanks EPRSC, UK for support.

Notes and references

† *Synthesis* of **1** and **2**: indium chloride tetrahydrate (0.10 g, 0.34 mmol) dissolved in 12 mL MeOH was added to a CH_2Cl_2 solution (25 mL) of $\{(PPh_3)_2AgCl\}_2$ (0.23 g, 0.17 mmol). To this solution was added NaSC{O}Me prepared *in situ* by mixing 97.5 μL (1.36 mmol) of CH_3\{O\}CSH and 0.031 g (1.36 mmol) of sodium in 15 mL of MeOH. The solvents were removed by a flow of N_2. The product was extracted into 20 mL of CH_2Cl_2, filtered immediately, layered with 40 mL of petroleum ether (bp 35–60 °C) and allowed to stand at 5 °C overnight. The creamy precipitate thus formed was filtered off and washed with petroleum ether (bp 35–60 °C) and Et_2O and dried under vacuum. Yield: 0.37 g (76%). Anal. Calc. for $C_{44}H_{42}O_4S_4P_2AgIn$ (*M* 1047.71): C, 50.44; H, 4.02; S, 12.24. § Pyrolysis experiments were performed in a quartz or Pyrex glass reactor using a horizontal tube furnace. The samples were heated to 300 °C under a dynamic vacuum of *ca*. 0.5 Torr.

¶ Thin films of silver indium sulfide were grown on borosilicate glass slides by AACVD. The growth apparatus consisted of a flask containing the solution with a pipette connected to an argon flow which was used as the propellant and carrier gas. The flask was attached, *via* reinforced tubing, to a silica tube containing the glass substrates, which were heated in a tube furnace. $[(Ph_3P)_2Ag(\mu\text{-}SCOMe)_2In(SCOMe)_2]$ (**1**) (~20 mg) was dissolved in tetrahydrofuran (20 mL) at room temperature, and injected into the growth apparatus, with the substrate at 400 or 450 °C. The system was allowed to run for 1 h, with a constant argon flow rate of 140 sccm (carrying the precursor from flask to substrate), at which point the substrates, thin coatings, were collected.

Received (in Cambridge, UK) 20th July 2001, Accepted 27th September 2001
First published as an Advance Article on the web 24th October 2001

Mesoporous MCM-41 silica immobilized aluminium chloride shows high catalytic activity and selectivity in the Friedel–Crafts alkylation of naphthalene with isopropanol.

Liquid phase Fridel–Crafts isopropylation of naphthalene over $AlCl_3$ catalysts is widely used in the chemical industry to manufacture 2,6-diisopropylnaphthalene (2,6-DIPN), an important chemical intermediate for making monomers of advanced polymers.[1] While $AlCl_3$ is catalytically efficient and readily available commercially, it has a number of drawbacks: (1) $AlCl_3$ catalyzes the formation of the desired 2,6-DIPN and the undesired 2,7-diisopropylnaphthalene (2,7-DIPN) in a thermodynamic ratio (2,6-:2,7-DIPN = 1:1), requiring a costly separation step to isolate the 2,6 isomer; (2) significant quantities of other isopropylated derivatives such as 2-isopropylnaphthalene (2-IPN) are formed, which must also be separated and removed or recycled; (3) $AlCl_3$ is a stoichiometric reagent that cannot be regenerated and has to be hydrolyzed and disposed of, resulting in a large volume of solid waste. As a result, there has been an interest in finding environmentally friendly alternative catalyst systems.[1–3]

Immobilization of aluminium chloride onto inorganic support materials has been studied previously.[4–8] Of particular interest is the observation that aluminium chlorides immobilized on silica gel and on mesoporous HMS are highly active in the liquid-phase alkylation of aromatic molecules while the selectivity towards the formation of monoalkylates is considerably better than under homogeneous conditions, and the immobilized catalyst systems are recoverable and reusable.[7,8] Therefore, we initiated our investigation on the immobilization of aluminium chloride on mesoporous MCM-41[9] for the liquid-phase alkylation of naphthalene.

The pure-silica MCM-41 support was prepared using cetyltrimethylammonium bromide† as the template according to the method described by Beck *et al.*[9] Two immobilized catalysts designed as $AlCl_x$/MCM-41 and $AlCl_x$/MCM-41(ESM) (ESM refers for external surface modification) respectively were prepared. The preparation of $AlCl_x$/MCM-41 was similar to that reported by Clark *et al.*[8] The procedures of preparing catalyst $AlCl_x$/MCM-41(ESM) are described as follows. The external surface of the MCM-41 support was modified by silylation, using trimethylchlorosilane. It was achieved by modifying the as-synthesized MCM-41 sample before template removal (the template acts as protecting species equivalent to the protecting groups in the organic synthesis). The detailed modification procedures have been described previously.[10] After modification of the external surface, the surfactant template was removed by solvent extraction using 1 M HCl in ethanol at 50 °C under stirring (1 g of MCM-41 in 50 ml of solution), followed by calcination at 450 °C to achieve the maximum density of internal surface silanol groups[11] while maintaining the external surface-attached trimethylsilyl groups without burning off (according to thermogravimetric analysis, the thermal decomposition temperature of the trimethylsilyl species is about 650 °C). Aluminium chloride was grafted onto the internal surface of the MCM-41 support by refluxing benzene (99.99%) containing anhydrous $AlCl_3$ (BDH) and the support ($AlCl_3$:support:benzene = 2 g:5 g:100 ml) at room temperature for 4 h. No reaction occurred on the external surface because the silanol groups on the external surface had already been poisoned during the silylation step. The solid was filtered off, washed with benzene and dried at 110 °C. Other catalysts involved in this study included H/MCM-41 (Si:Al = 15:1) and H/Mordenite (Si:Al = 13:1).

The catalysts were characterized using the techniques of ICP-AES (Spectroflame Model P), XPS (PHI Model 560 XPS/SAM/SIMS I), XRD (PW 1050 diffractometer, Cu Kα radiation), Nitrogen adsorption (NOVA 1200, Quanta Chrome), and solid-state NMR (Bruker MSL 300 spectrometer). The properties of the catalysts are shown in Table 1.

The isopropylation of naphthalene was carried out in a Parr batch reactor equipped with a temperature controller. Naphthalene (0.02 mol), isopropanol (0.04 mol) and fresh catalyst (1.5 g) were loaded in an autoclave containing 200 ml of cyclohexane (solvent). The reaction temperature was 200 °C and the pressure was autogenous. After 4 h, the reactor was cooled to room temperature, and the liquid products were analyzed using a GC-FID with a DB-17 column (30 m × 0.25

Table 1 Physical and chemical properties of catalysts

Sample	Surface area/$m^2\ g^{-1}$	Pore volume/ml g^{-1}	Pore diameter/nm	Atomic ratio[a]		
				$Al:Si_{Bulk}$	$Al:Si_{XPS}$	$Cl:Al_{XPS}$
$AlCl_x$/MCM-41	723	0.67	2.3	0.019	0.023	1.56
$AlCl_x$/MCM-41(ESM)	778	0.70	2.0	0.020	0.021	2.08
Parent MCM-41	1230	1.2	3.0	Nil	Nil	N/A
H/MCM-41	1040	1.1	3.0	0.058	0.064	0
H/Mordenite	444	0.32	0.65 × 0.70[12]	0.076	0.075	0

[a] The atomic ratio of Al:Si was measured using both ICP-AES (denoted $Al:Si_{Bulk}$) and XPS (denoted $Al:Si_{XPS}$) while the atomic ratio of Cl:Al was measured using XPS only.

 DOI: 10.1039/b106499c

Table 2 Catalytic properties of catalysts

Catalyst	Conv.[a] (mol%)	DIPN yield (mol%)	DIPN selectivity (mol%)			Other products[c] (mol%)
			2,6	2,6:2,7	Other[b]	
$AlCl_x$/MCM-41	88.5	65.5	41.0	2.20	40.4	34.3
$AlCl_x$/MCM-41(ESM)	85.2	72.3	60.9	2.82	17.5	27.7
$AlCl_3$	96.4	56.3	36.7	0.986	26.1	43.7
H/MCM-41	60.4	38.4	38.6	1.64	37.9	61.6
H/Mordenite	84.8	44.5	44.3	2.00	33.6	55.4

[a] Conversion of naphthalene. [b] Other DIPN isomers. [c] Other products except DIPNs including MIPN, tri-, and tetra-IPNs, *etc*.

mm). Product identification was carried out using a GC/MS system. Comparisons of the catalytic performance of the catalysts are summarized in Table 2.

Table 1 shows that both the pure-silica and the aluminosilicate MCM-41 materials are of high quality with a pore diameter of 3.0 nm. As expected, immobilization of aluminium chloride on MCM-41 silica resulted in a reduction of surface area, pore volume, and pore diameter. The chemical analysis data further prove the attachment of aluminium chloride on the surface of the MCM-41 silica. The Al contents analyzed using ICP-AES are consistent with that analyzed using XPS.

It can be seen from Table 2 that the highest activity was observed on $AlCl_3$ while the lowest activity was observed on H/MCM-41. The two immobilized catalysts exhibit a reasonable catalytic activity, similar to that of H/Mordenite. Despite a slightly lower activity for catalysts $AlCl_x$/MCM-41 and $AlCl_x$/MCM-41(ESM) compared to $AlCl_3$, there are significant differences in the yield and selectivity of products. With $AlCl_x$/MCM-41 and $AlCl_x$/MCM-41(ESM) as the catalysts, DIPNs were the major products, whereas the other catalysts produced a large amount of other products. Very remarkably, $AlCl_x$/MCM-41(ESM) catalyzed the formation of 72.3% DIPNs with a selectivity of 2,6-DIPN of 60.9% while $AlCl_x$/MCM-41 produced 65.5% DIPNs with a selectivity of 2,6-DIPN of 41.0%. The significant enhancement of selectivity towards 2,6-DIPN after modification of the external surface of the MCM-41 support is explicable only in terms of the differences in the pore-opening size and the nature of the external surfaces of the two catalysts. The selective modification of the external surface of the MCM-41 support resulted in a reduction of the pore-opening size (see Table 1) and the poisoning of the external catalytically active sites. The former probably enabled shape-selectivity while the latter led to the avoidance of the catalytic reaction taking place on the external surface of the $AlCl_x$/MCM-41(ESM) catalyst.

After the 4 h reaction, catalyst $AlCl_x$/MCM-41(ESM)† was filtered off, washed with hot benzene and calcined at 450 °C for 2 h. Subsequent characterization using ^{27}Al NMR and catalytic tests were carried out. The chemical shifts of ^{27}Al before and after the 4 h reaction were found to be about 53.0 and 52.2 ppm, respectively, indicating that the immobilized aluminium chloride species had hardly changed. It was also observed that both the activity and selectivity towards 2,6-DIPN remained unchanged.

Overall, the results discussed above demonstrate that immobilization of aluminium chloride on mesoporous MCM-41 silica can create substantial density of acidic sites, which are catalytically responsible for the liquid-phase isopropylation of naphthalene. Most remarkably, a significant increase in selectivity towards 2,6-DIPN can be achieved through the use of external surface-silylated MCM-41 support. The immobilized catalyst system is recyclable and reusable without observable loss in activity and selectivity, demonstrating its promise as an environmentally friendly alternative catalyst for the isopropylation of naphthalene.

We thank the University of Queensland for partial financial support and the Australian Academy of Science for traveling support (*via* the program Scientific Visit to North America for Young Australian Scientists). X. S. Z. wishes to acknowledge Ms Lim Hwee Ling for her help during manuscript revision.

Bidentate lactate binding in aqueous solution in a cationic, heptadentate lanthanide complex: an effective chiral derivatising agent

Rachel S. Dickins,* Christine S. Love and Horst Puschmann

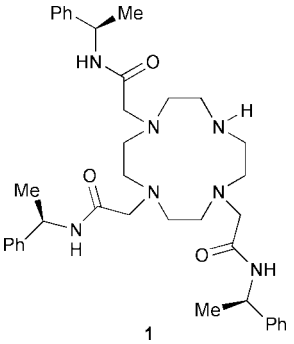
Received (in Cambridge, UK) 13th July 2001, Accepted 1st October 2001
First published as an Advance Article on the web 16th October 2001

The X-ray crystal structures of cationic, heptadentate lanthanide complexes of holmium and ytterbium bound to lactate are reported and the observed bidentate chelation in the solid state is consistent with near-IR CD (Yb) and solution NMR measurements; the complexes are shown to act as aqueous chiral derivatising agents for α-hydroxy acids.

In vivo detection of lactate is of prime importance in the diagnosis, grading and therapeutic monitoring of diseases such as cancer, stroke and heart disease.[1] Magnetic resonance spectroscopy (MRS) offers a non-invasive means of analysing lactate concentration *in vivo* but suffers from limitations due to insensitivity and the requirement of long acquisition times for a good signal to noise ratio. Furthermore the lactate resonances are often masked by overlapping lipid resonances for example, which has severely limited the role of MRS in the clinic. In order to improve the diagnostic potential of MRS it would be highly advantageous to utilise the enhanced shifting and relaxation properties of paramagnetic shift reagents, designed to bind strongly and selectively to lactate, to effect spectral resolution and also allow rapid acquisition times to be implemented giving increased signal intensity.

Lanthanide complexes of heptadentate ligands *e.g.* **1**, possess two bound water molecules and have been reported to show high affinity for oxy-anions, and in particular lactate.[2]



1

They form well-defined, relatively stable complexes in aqueous solution, are amenable to NMR and luminescence studies and are good candidates for assessment as MRS reagents for lactate. With this model in mind we set out to examine the shifting ability of a series of such lanthanide complexes. Herein we report the crystal structures of the first examples of lactate-bound lanthanide complexes and describe preliminary near-IR CD and ^{1}H NMR studies of [Yb.**1**]$^{3+}$($CF_3SO_3^-$)$_3$.†

There are only 13 examples of metal-containing lactate species reported and none involves a rare earth ion.[3] The ytterbium complex of (*RRR*)-**1** in the presence of lactate crystallised in the *P*1 space group in the triclinic system with the unit cell comprising of [Yb.**1**]$^{3+}$, one lactate molecule, two triflate counter ions and three water molecules. The complex adopts a monocapped square antiprismatic geometry (twist angle = 40°) with the tetraazacyclododecane ring in the usual [3333] conformation in which the four nitrogen atoms are roughly coplanar, directed towards the lanthanide ion and occupy four coordination sites (average Ln–N 2.573 Å) (Fig. 1).

The oxygen atoms of the pendent arms lie approximately in the same plane (average Yb–O 2.299 Å) and define three coordination sites. The average values of the macrocyclic N–C–C–N and the pendent arm N–C–C–O torsion angles are +57.6 and −26.4 respectively, showing the complex has crystallised in the Λ(δδδδ) form. The lactate binds in a bidentate manner with the hydroxyl oxygen occupying the axial position above the lanthanide ion (Yb–O 2.461 Å)[4] and one of the carboxylate oxygens binding in the same plane as the O3 face (Yb–O 2.278 Å) completing the nine-coordinate sphere. The lactate bound holmium complex was isostructural with lactate–[Yb.**1**]$^{3+}$ with Ho–O distances of 2.469 and 2.317 Å to the lactate OH and carboxylate oxygens, respectively.

The local coordination environment about the lanthanide centre may be probed by CD. Yb absorbs in the near-IR region and exhibits sensitive CD bands centred around 980 nm due to magnetically allowed $^2F_{7/2} \rightarrow {}^2F_{5/2}$ transitions.[5] The CD spectrum of [Yb.**1**]$^{3+}$ (20 mM, H_2O) exhibited two peaks at 972.5 and 996.0 nm (Fig. 2). On the addition of ten equivalents of sodium lactate (100 mM, H_2O) the peak at 972.5 nm was shifted to longer wavelength, increased in intensity by 80% and was resolved into two peaks at 975.0 and 979.5 nm. The peak at 996.0 nm displayed a 40% increase in intensity and was shifted to a shorter wavelength of 990.5 nm. Changing the nature of the donor atom, on lactate addition, from a neutral water to a charged carboxylate greatly affects the electronic properties of the lanthanide ion resulting in modulation of the crystal field splitting and hence the observed changes in CD.

Analysis of [Yb.**1**]$^{3+}$ by ^{1}H NMR spectroscopy (293 K, D_2O, 200 MHz) revealed eight broadened singlet resonances to high frequency corresponding to the four most shifted axial and

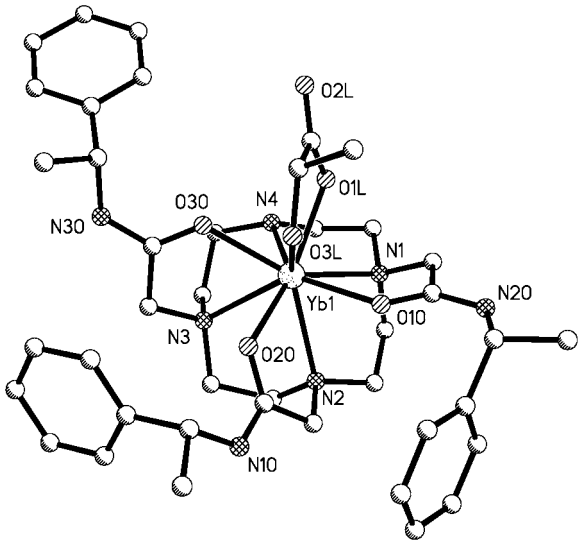


Fig. 1 Structure of [Yb.**1**]$^{3+}$ showing bidentate chelation of (*S*)-lactate.

 DOI: 10.1039/b106262j

equatorial ring protons [Fig. 3(a)]. On the addition of 0.25 equivalents of Na (*S*)-lactate to [Yb.**1**]$^{3+}$ an additional set of axial and equatorial ring resonances appeared which may be attributed to the lactate bound species which is in slow exchange on the NMR timescale with the free form [Fig. 3(b)]. Subsequent incremental additions of lactate resulted in an increase in the bound to free ratio and after addition of 1.0 equivalent only the bound form was observed [Fig. 3(c)]. Two additional singlet resonances were also evident at +58 ppm, integrating to one proton and attributed to the CH of the bound lactate, and at +20 ppm, integrating to three protons and subsequently attributed to the methyl resonance of the bound lactate.[6] The expected Me doublet was not resolved due to the broadening effect of the paramagnetic ion. The induced paramagnetic shift, which for Yb is largely due to dipolar contributions and can be approximated to having a $(3\cos^2 - 1)$ r^{-3} dependence, suggests the lactate CH lies closer to the principal axis of the complex than the Me group. This is consistent with the X-ray data.[7]

Following addition of 2.5 equivalents of racemic lactate to [Yb.**1**]$^{3+}$, a 1:1 mixture of diastereomeric complexes was observed by ^{1}H NMR [Fig. 3(d)], consistent with the very similar formation constants measured for (*R*)- and (*S*)-lactate with [Eu.**1**]$^{3+}$.[2] The CH and Me lactate resonances are clearly resolved for the *R* and *S* diastereoisomers ($\Delta\Delta\delta \sim 10$ ppm) and

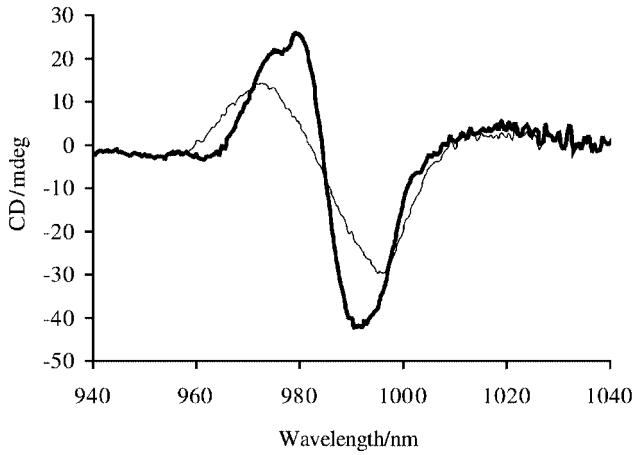

Fig. 2 Circular dichroism spectra of [Yb.**1**]$^{3+}$ (diaqua species) and in the presence of 10 equiv. (*S*)-lactate (bold).

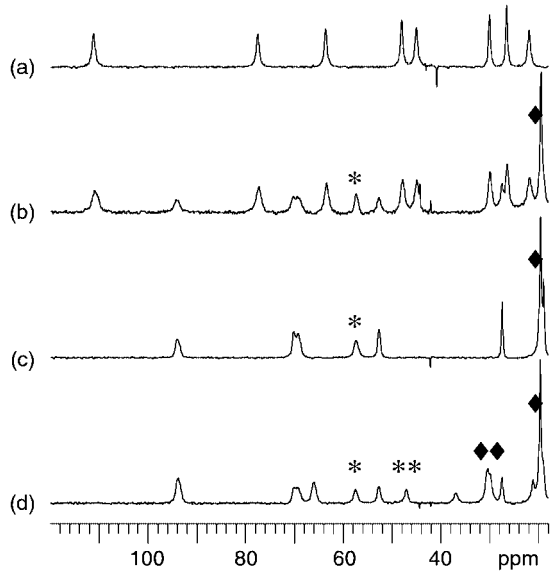

Fig. 3 Partial ^{1}H NMR spectra of (a) [Yb.**1**]$^{3+}$ (diaqua species) showing four axial and four equatorial ring protons; (b) in the presence of 0.25 equiv. (*S*)-lactate [(*) (*S*)-lactate CH, (◆) (*S*)-lactate CH_3]; (c) 1 equiv. of (*S*)-lactate; (d) 2.5 equiv. of racemic lactate [(**) (*R*)-lactate CH, (◆◆) (*R*)-lactate CH_3].

experienced large lanthanide induced shifts; the CH resonating at +48 and +58 ppm (*cf.* +4.1 ppm in the free form) and the Me resonating at +30 and +20 ppm for (*R*)- and (*S*)-lactate, respectively (*cf.* +1.3 ppm in the free form). A lack of enantioselectivity in complex formation was also observed following addition of the sterically more demanding (*R*)- and (*S*)-mandelic acid to [Yb.**1**]$^{3+}$. Similar behaviour is exhibited with related alkyl and aryl α-hydroxy acids. A difference of 16 ppm was observed for the mandelic *ortho*-phenyl ring protons which appeared at +37.0 and +20.5 ppm for the *R* and *S* complexes, respectively.[6] The very large shifts and chemical shift non-equivalence for this unique NMR 'chiral derivatising agent' may be compared to the much smaller $\Delta\Delta\delta$ values reported for shift reagents which are generally around 1 ppm and often < 0.1 ppm. Moreover there are very few examples of water-soluble chiral shift reagents,[8] the majority of studies being performed in organic media and those reported are mainly based around neutral and anionic systems. Sasaki and coworkers, for example, has reported an aqueous cationic chiral lanthanide shift reagent to separate enantiomeric signals based upon bpba[9] which exhibits $\Delta\Delta\delta$ values of < 0.15 ppm.

In summary, the substituents alpha to the α-hydroxy acid in the Ln-bound complex fall within the 'McConnell' cone and so are susceptible to large dipolar shifts. The apparent absence of kinetic resolution in complex formation with racemic α-hydroxy acids substrates augurs well for the development of such complexes as NMR chiral derivatising agents. By reducing the effective charge demand at the Ln centre chiral shift reagents (*i.e.* lower affinity and fast exchange on the NMR timescale) may also be envisaged.

We thank the University of Durham for support, Prof. J. A. K. Howard for use of crystallographic facilities and the Royal Society for a Dorothy Hodgkin Fellowship (RSD).

The first zinc-promoted, environmentally friendly, and highly efficient acetoxyallylation of aldehydes in aqueous ammonium chloride

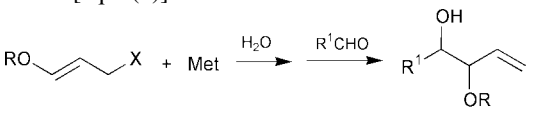
Marco Lombardo,* Rugiada Girotti, Stefano Morganti and Claudio Trombini*

Dipartimento di Chimica 'G.Ciamician', University of Bologna, Bologna, Italy.
E-mail: trombini@ciam.unibo.it; Fax: +39 051 2099456; Tel: +39 051 2099513

Received (in Cambridge, UK) 9th August 2001, Accepted 20th September 2001
First published as an Advance Article on the web 15th October 2001

An exceptionally mild acetoxyallylation of aldehydes in water promoted by zinc is reported, using 3-bromo-1-acetoxyprop-1-ene as starting material; simple diastereoselectivity mainly depends on the nature of the aldehyde.

In any synthetic plan, carbon–carbon bond forming reactions are the most important and valuable transformations. If the construction of a carbon–carbon bond is carried out in water at ambient temperature, we also meet some basic requirements of green chemistry,[1] such as preventing hazardous waste (organic solvents), optimising synthetic efficiency by reducing derivatisation reactions (protection–deprotection *etc*.) and minimising energy consumption. The Henry nitroaldol reaction[2] has been known for a long time as a prototype of these reactions, allowing for example the direct use of unprotected aldoses,[3] but only in the 1980s did the use of water in organic chemistry enjoy an outbreak in terms of studies and applications.[4] A lot of attention has been devoted to the allylation of carbonyl compounds in water,[5] by generating allylic organometallic reagents, particularly tin, zinc, indium and even magnesium[6] species, and reacting them with carbonyl compounds. Two general protocols are available: the *in situ* Barbier procedure where the allylic species is formed in the presence of the carbonyl compound, or the stepwise Grignard procedure where the organometallic compound is preformed and then added to the aldehyde. Again, sugars may be used without derivatisation, as demonstrated by the synthesis of higher sugars,[7] sialic acid derivatives,[8] and *C*-branched sugars in water.[9] To the best of our knowledge, no report is available in the literature on Barbier reactions in water using 3-halo-1-alkoxyprop-1-enes **1**, which could ensure a straightforward access to 3-alkoxy-1-en-4-ols **2**,[10] attractive building blocks for the synthesis of polyoxo compounds [eqn. (1)].

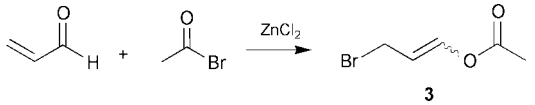


(1)

1 **2**

A possible reason why chemists are discouraged from attempting this reaction could be based on the sensitivity towards acidic conditions of the enol ether functionality in **1**. In fact, both Barbier protocols involving zinc and indium operate in acidic media; zinc requires the NH_4Cl–H_2O system to give the best results, while indium salts formed during the oxidative addition undergo acidic hydrolysis which lowers the pH by up to 3.

Considering that enol esters are supposed to be somewhat more stable than enol ethers under acidic conditions, we envisaged 3-bromo-1-acetoxyprop-1-ene (**3**) as a promising candidate for the acetoxyallylation of aldehydes. Preparation of **3** as a 35:65 *E*/*Z* isomer mixture,† was carried out by the $ZnCl_2$ catalysed 1,4-bromoacetylation of propenal with acetyl bromide [eqn. (2)].[11]



(2)

3

We were delighted by the observation that **3** was compatible with aq. ammonium chloride solutions and that the reaction of **3** with zinc was very rapid and exothermic. On this basis, a simple, fast and environmentally benign Barbier protocol was developed (Scheme 1);‡ preliminary results are collected in Table 1.

As shown in the reaction mechanism, once **4** is formed in water at pH = 5, a few reaction channels are possible: *E*/*Z* metallotropic isomerisation, protonation, Wurtz-like dimerisation, addition to an electrophile, if present. In the presence of an aldehyde, nucleophilic addition to the carbonyl group is faster than protonation or dimerisation. Of course, in the absence of the aldehyde, **4** completely decomposes within 30 min. Data presented in Table 1 deserve a few comments: i) with reference to the general economy criteria, the overall procedure is simple, fast and makes use of inexpensive reagents; ii) the procedure is based on **3**, an easily available starting material obtained in 70% yield in multigram scale, iii) side-products are limited to some Wurtz coupling product (< 10% based on **3**), and iv) the product is a selectively monoprotected diol, namely a 3-acetoxy-1-en-4-ol **5**, a straightforward precursor of the parent 1-en-3,4-diol by simple hydrolysis (quantitative in 2 h using K_2CO_3 in MeOH–H_2O 9:1). All these features make **3** highly competitive with alkoxylated organometallic derivatives **6a–f**,[12] whose forma-

6d : RO = TBSO, ML_n = $SnBu_3$
6e : RO = sugarO, ML_n = $SnBu_3$
6f : RO = sugarO, ML_n = $AlEt_3$

Indium may replace zinc (Table 1, run 1) but the overall process is slower and does not produce a significant improvement both in terms of yield and selectivity. With indium a Grignard protocol in THF seems to represent a more appropriate reaction system and results will be published independently.

Even though the stereochemical outcome of these reactions, in terms of simple diastereoselectivity, is not exceptional, an interesting difference comes out with respect to the use of **6a–f**. In fact, all the **6a–f** species are denoted by a remarkable *syn*-selectivity, independent of the aldehyde used, with *syn–anti* ratios in the 70 : 30–99 : 1 range. Invariably, the stereopreference for the formation of the *syn*-adduct is discussed in terms of a preferred formation of a *Z*-configurated organometallic species **6**, stabilised by internal coordination, which adds to the aldehyde following the classical chair-like Zimmerman-type transition state.

Results reported in Table 1 show that, starting from **3**, the simple diastereopreference depends on the nature of the aldehyde, saturated aldehydes mainly affording *anti* adducts (runs 6–10), and aromatic or α,β-unsaturated aldehydes leading to *syn* adducts (runs 1–5). No attempt was made to detect the actual structure of the intermediate **4**, anyway, in analogy to **6**, we believe that (*Z*)-**4** should enjoy thermodynamic stabilisation by zinc–oxygen coordination and should represent the most abundant isomer in the reaction mixture. On a purely speculative basis, we believe that the most important contribution to the observed diastereoselectivity is given by twist–boat transition states (TSs) **A** and **B** (Fig. 1) rather than by Zimmerman chair-like TSs which could not enjoy the through space stabilising O → Zn interaction present in **A** and **B**. **A** holds the sterically demanding R group in the *anti* position relative to the acetoxy group, so leading to the *anti* adduct, while **B** eclipses the unsaturated substituent with the acetoxy group with a likely stabilisation by π–π stacking interaction.

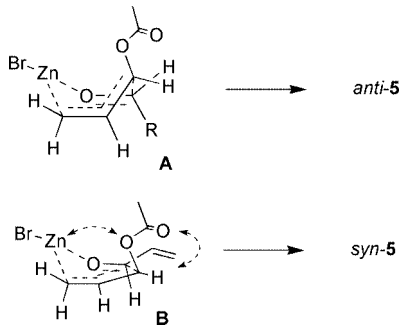

Fig. 1 Proposed transition states for the addition of **4** to aldehydes.

In conclusion, a new promising route to monoacetylated 1-en-3,4-diols based on 3-bromo-1-acetoxyprop-1-ene (**3**) is reported; this protocol joins an excellent efficiency in terms of yield, cost and time, to the use of typical environmentally benign conditions, such as the use of water as a solvent at room temperature.

Notes and references

† Anhydrous $ZnCl_2$ (0.068 g, 0.5 mmol) was added at −20 °C to a solution of freshly distilled propenal (3.32 mL, 50 mmol) and acetyl bromide (3.73 mL, 50 mmol) in anhydrous CH_2Cl_2 (40 mL). The reaction was stirred for 2 h at 0 °C and quenched at 0 °C by addition of aq. $NaHCO_3$. After extraction (CH_2Cl_2), 3-bromo-1-acetoxyprop-1-ene (**3**) was isolated by distillation (bp = 69–71 °C/22 mmHg) as a 35 : 65 mixture of *E*/*Z* isomers in 70% yield. (*Z*)-**3**. ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.22 (s, 3H), 4.09 (dd, J = 0.3, 8.1 Hz, 2H), 5.24 (dt, J = 6.3, 8.1 Hz, 1H), 7.19 (dt, J = 0.3, 6.3 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 20.5, 23.5, 109.3, 136.9, 166.9. (*E*)-**3.** ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.16 (s, 3H), 3.99 (dd, J = 0.3, 8.1 Hz, 2H), 5.70 (dt, J = 8.1, 12.3 Hz, 1H), 7.19 (dt, J = 0.3, 12.3 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 20.5, 28.4, 111.1, 139.0, 167.2.

‡ In a typical experimental procedure, an aldehyde (1 mmol) and **3** (1.5 mmol) are added to a sat aq. solution of NH_4Cl (5 ml). Zinc powder (1.5 mmol) is added and completely dissolves within 2 min. The reaction is checked after 15 min and products are extracted with ether after 30 min. The monoacetylated diol **5** is isolated by flash-chromatography in the 75–90% yield range. All new compounds were fully characterised by ^{1}H NMR, ^{13}C NMR and high resolution mass spectrometry; *syn–anti* stereorelationships were assigned after hydrolysis to 1-en-3,4-diols (Ref. 12).

First published as an Advance Article on the web 24th October 2001

Two types of multiporphyrin arrays, mediated by $PdCl_4^{2-}$ complex ions at the air–water interface, were alternately transferred onto solid supports to form three-dimensional organized multilayers by a layer-by-layer method.

The architecture of multiporphyrin arrays has attracted much attention in the developing biomimetic chemistry of photosynthetic reaction centers, as well as in developing potential materials for optical, photoelectrochemical and sensor applications.[1,2] The methodology commonly used for preparing multiporphyrin arrays is *via* linkages including ethyne-type organic groups and transition metal ions between porphyrins and/or metal ions.[3,4] Recently, efforts have been made on the preparation of three-dimensional (3D) organized multiporphyrin arrays. One interesting strategy by Sharma *et al*. was using solvent molecule inclusion in crystals of multiporphyrin arrays to control the interlayer separation of 2D layers.[5] However, examples of 3D multiporphyrin arrays prepared and characterized are much rarer.

In the present communication, a layer-by-layer (LBL) technique, developed from the Langmuir–Blodgett (LB) method, was used to build 3D multilayers of two types of multiporphyrin arrays. The 2D multiporphyrin arrays were prepared by using $PdCl_4^{2-}$ complex ions as linkages between porphyrins at the air–water interface. Compared to synthesis in solution, the present method is more rapid and efficient in forming multiple porphyrins with network structure, and more easily available and controllable in building 3D layered multilayers.

The used porphyrins were 5,10,15,20-tetrakis(4-pyridyl)-21*H*,23*H*-porphine (TPyP) and 5,10,15,20-tetrakis(4-carboxymethyloxyphenyl)-21*H*,23*H*-porphine (TCPP), as shown in Fig. 1. Preparation of 2D multiporphyrin arrays and LBL deposition were performed with the use of a KSV 5000 minitrough at 20 °C. Since the monolayer could not be transferred by the vertically dipping method, we used a horizontal lifting technique.[6]

Fig. 2 shows the π–A isotherms for TPyP and TCPP monolayers on pure water and 0.3 mM K_2PdCl_4 subphase surfaces. By extrapolating the tangent on the isotherms at a fixed point (20 mN m^{-1}) to zero surface pressure ($A_{\pi\rightarrow 0}$), the mean TPyP and TCPP molecular areas were obtained and are summarized in Table 1. Based on single-crystal structures of simple tetraarylporphyrins, the expected mean molecular areas of Langmuir monolayers would be about 0.9 nm^2 if the porphyrin rings lie vertical to the aqueous surface, and about 2.25 nm^2 if the porphyrin rings lie parallel.[7] Here, the mean TPyP and TCPP areas are about 0.55–0.65 nm^2 on pure water surface, smaller than 0.9 nm^2, which may be ascribed to a tilted and overlapped arrangement of the porphyrin rings.[8] On the other hand, the mean TPyP and TCPP areas are about 1.4–1.8 nm^2 on the 0.3 mM K_2PdCl_4 subphase surfaces, a value between 0.9 and 2.25 nm^2, which may be ascribed to the formation of Pd–TPyP and Pd–TCPP multiporphyrin arrays.[9] The Pd–TPyP multiporphyrin array is based on a coordination of Pd to N atoms of pyridyl groups of TPyP, and that of Pd–TCPP on reaction of Pd with $-CO_2H$ groups of TCPP.[10]

Layer-by-layer deposition was performed by alternately transferring monolayers of the Pd–TPyP and Pd–TCPP multiporphyrin arrays onto a hydrophobic glass substrate surface by the horizontal lifting technique.[6,11] Fig. 3 shows the absorption spectra of 1–8 layers of the assembled 3D Pd–TPyP and Pd–TCPP LBL multilayers. Each spectrum consists of a strong Soret band (425–465 nm) together with several Q-bands ranging from 500 to 700 nm. Table 1 summarizes the spectral data. We have reported that the TPyP Soret band in dilute solution appears at 417 nm, and that in its LB film transferred from a pure water surface, it red shifts to 442 nm.[9] Here, the TPyP Soret band in the LBL multilayers of Pd–TPyP multiporphyrin arrays red shifts to 430 nm. That is, there is a smaller red shift for the Pd-mediated multiporphyrin arrays than that for the LB films from a pure water surface. Similar red shift results

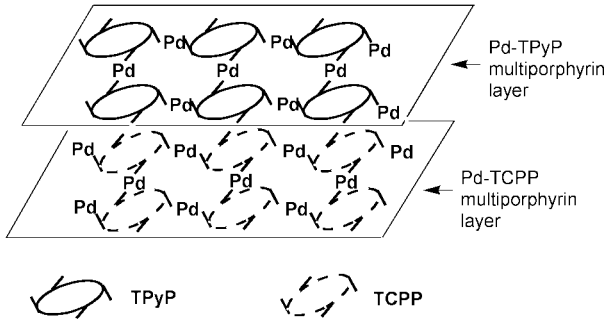

Fig. 4 Schematic model of LBL multilayers of Pd–TPyP and Pd–TCPP multiporphyrin arrays.

are also observed from the absorption spectra of TCPP in solution, LB film and Pd–TCPP LBL multilayers. It is clear that the porphyrins exist in a monomer form in dilute solution and that a peak shift of the Soret band corresponds to the formation of aggregates, which can be explained by exciton theory.[12] This theory points out that the red shift of the Soret band relates to the side-to-side electronic coupling between the respective porphyrins; the stronger the electronic coupling the larger the red shift. Thus, the electronic coupling is weaker in the LBL multilayers of the Pd–TPyP and Pd–TCPP multiporphyrin arrays than that in the TPyP and TCPP LB films from a pure water surface. This weakened electronic coupling is due to the linkage of Py–Pd–Py or CO_2–Pd–CO_2 between two porphyrin rings, which enlarges the porphyrin–porphyrin distance in the Pd-mediated multiporphyrin arrays as indicated in their π–A isotherms.

Close inspection of Fig. 3 reveals that there is a large increase at 430 nm between each even layer due to the deposition of a Pd–TPyP multiporphyrin array, and a large increase at 460 nm between each odd layer due to the deposition of a Pd–TCPP multiporphyrin array. The absorption at 460 nm corresponds to protonated TCPP.[13] If we define the absorption intensity at 430 nm, $A_{sum} = A_i + A_{i+1}$ (number of layers, i = 1, 3, 5 and 7), we observe a linear growth of A_{sum} with increasing number (i + 1) of the deposited layers. Thus, we conclude that 3D multiporphyrin arrays can be constructed by the LBL method. Furthermore, the fact that spectral features of either Pd–TPyP or Pd–TCPP multiporphyrin arrays are retained separately in their LBL multilayers indicates that the electronic coupling among the interlayers of Pd–TPyP and Pd–TCPP multiporphyrin arrays is weak.

The orientation of TPyP and TCPP rings, commonly expressed by the tilted angle, θ, between the mean porphyrin plane and the substrate surface, plays an important part in the description of the organization of the LBL multilayers, and was estimated by measuring polarized UV–VIS spectra of the transferred monolayers at different incidence angles.[14] According to the equation by Yoneyame *et al.*,[14] we calculated that θ_{LBL} was *ca.* 42 and 51° for TPyP and TCPP rings in the LBL multiporphyrin multilayers and 30 and 32° for TPyP and TCPP LB monolayers from a pure water interface, respectively. That is, θ_{LBL} is larger than θ_{LB}, from which, if there were no linkage between porphyrin rings, the mean porphyrin area in LBL multilayers should be smaller than that in LB monolayers from a pure water surface ($\cos\theta_{LBL} < \cos\theta_{LB}$). However, from the π–A isotherms, quite large TPyP or TCPP areas are observed in the LBL multilayers. Thus, we conclude that not the orientation angle but the Py–Pd–Py or CO_2–Pd–CO_2 linkages dominate the arrangement of TPyP or TCPP in the multiporphyrin arrays. On the basis of the monolayer properties, spectral characteristics and orientation angles, we propose a schematic organization of the 3D LBL multilayers of multiporphyrin arrays (two layers) in Fig. 4. Each Pd ion coordinates with two Py or CO_2^- from different porphyrins, leading to the formation of Pd–TPyP or Pd–TCPP multiporphyrin arrays with unlimited numbers of porphyrin macrocycles.[5,10,15] An electrostatic interaction between the layers of Pd–TPyP and Pd–TCPP might dominate the formation of the 3D LBL multilayers of multiporphyrin arrays.[16]

In summary, we have demonstrated a layer-by-layer method to prepare 3D well-defined, organized multiporphyrin arrays with virtually unlimited numbers of porphyrin macrocycles, features that are relevant to the design of light harvesting model systems and to the development of potential materials for optical and photoelectrochemical applications.

The ionic liquid [bmim][PF_6] was found to provide extra stability to the air-sensitive chiral catalyst Rh–MeDuPHOS in asymmetric hydrogenation of enamides.

One of the most versatile routes for preparing optically active compounds is asymmetric synthesis, particularly by the use of enantioselective catalysts.[1] Various chiral catalysts including biocatalysts (enzymes and/or microorganisms),[2] chiral transition-metal complexes[3,4] and heterogenized chiral catalysts have been used for the conversion of a prochiral substrate into a chiral product. The chiral complex Rh–DuPHOS[5] has been found to be particularly efficient as a homogeneous catalyst in the asymmetric hydrogenation of enamides. However, as good as its performance is, the rather expensive Rh–DuPHOS is very sensitive to oxidation; hence, an inert atmosphere is required for its preparation and handling, and separation of the complex from reagents and products and recovery of the complex are not easy.

Possible solutions to these drawbacks have focused on the engineering of chiral 'heterogenized' catalysts. Heterogenization of chiral complexes by immobilization in various organic and inorganic supports has been successful, but leaching and stability of the complex still remain severe problems.[6] Another approach was the use of two-phase systems, in which the phase of preference of the complex differs from that of the substrate,[7,8] but only limited success has been achieved.[9,10] In most cases, the activity and enantioselectivity of the chiral complexes are lower than those of the identical homogeneous system as a result of mass transfer limitations. The immobilization of chiral metal complexes in molten salts (ionic liquids) has recently been reported for some enantioselective hydrogenations[10,11] and for the epoxidation of alkenes.[12] Room-temperature ionic liquids (RTIL) have gained increasing interest as 'green' solvents in organic syntheses.[13,14] An ionic liquid such as [bmim][PF_6] (Fig. 1), which has poorly coordinating ions and which is highly polar, nonvolatile, stable in air, and immiscible with both water and nonpolar solvents can serve as a good and environmentally friendly medium for asymmetric hydrogenations. First earlier examples that have appeared in the literature are the asymmetric-catalyzed hydrogenation of 2-phenylacrylic acid in a [bmim][BF_4]–iPrOH system[10] and the Rh–DIOP-catalyzed hydrogenation of α-acetamidocinnamic acid in [bmim][SbF_6] as an ionic liquid to produce (*S*)-phenylalanine (64% ee).[11]

Our approach to performing hydrogenation reactions with the unstable air-sensitive Rh–DuPHOS catalyst was based on 'immobilizing' the Rh–MeDuPHOS complex (Fig. 2) in the air-stable molten salt [bmim][PF_6] (Fig. 1). This ionic liquid was not only a good host for the chiral catalyst, but it also protected the complex from attack by atmospheric oxygen and facilitated easy recycling. Hydrogenation of two model enamide compounds to optically active α-amino acid derivatives was performed in the biphasic system [bmim][PF_6]–iPrOH (Scheme 1). The chiral complex was totally soluble in the ionic liquid phase, and the products were easily recovered in the upper iPrOH phase.†

Results of the asymmetric hydrogenations of methyl α-acetamidoacrylate (**1a**) and of methyl α-acetamidocinnamate (**1b**) with Rh–MeDuPHOS in the [bmim]PF_6–iPrOH system are presented in Table 1. In the first run (entry 3), the enantioselectivities obtained for the two substrates in the ionic liquid were high, the values being similar to those obtained in the homogeneous reaction. Note that for the homogeneous reactions, the transfer of the catalyst into the reactor without an inert atmosphere brought about a significant decrease in the enantioselectivity of the hydrogenation of **1a** (57% ee *vs*. 97% ee) and the conversion dropped almost completely. Two cycles of recycling of the catalyst were performed for both substrates (entries 3 and 4), with the recycling procedure being continued with substrate **1b** for three further cycles (entries 5–7), since the activity and enantioselectivity of the immobilized catalyst after the second run were remarkable. Although the activity of the catalyst decreased after the first cycle, it remained almost constant upon successive cycles, without significant loss of enantioselectivity, even though the fifth cycle was performed after the heterogenized catalyst had been exposed to air for 24 h. It thus appears that the combination of the particularly efficient chiral complex (Rh–MeDuPHOS)[6] with the ionic liquid system used in this study [(bmim)PF_6–iPrOH] provides a promising route to facile asymmetric hydrogenations.

In summary, as an extension of our ongoing efforts to heterogenize chiral catalysts, this work focused on the perform-

7	Heterogeneous Fifth cycle[c]			58	94 (*R*)

Reaction conditions for homogeneous catalyst: 25 °C, 2 atm H_2, 7 g iPrOH; reaction time = 5 min. In the heterogeneous system, 5 g of ionic liquid was added; reaction time = 20 min. [a] Preparation of the catalyst and of feeding into the reactor were performed under nitrogen. [b] Catalyst prepared in an inert atmosphere and exposed to air for a few minutes during feeding into the reactor. For cycles 3–7, all manipulations were performed in air. [c] Left to stand in air for 24 h.

ance of the 'immobilized' Rh-DuPHOS complex in an ionic liquid such as [bmim][PF_6] for the asymmetric hydrogenations of enamides. Recycling of the catalyst was possible. Entrapment of the air-sensitive complex in an ionic liquid facilitated its handling without loss of enantioselectivity. At the end of the reaction, the products were easily separated by decantation of the upper iPrOH phase.

We thank the Magneton program for financial support.

Notes and references

† The salt 1-butyl-3-methylimidazolium chloride was prepared under nitrogen according to the method of Huddleston *et al*.[15] with small changes. The [bmim][PF_6] salt was prepared by dropwise addition of HPF_6 (65%) into a precooled aqueous solution of the crude imidazolium salt. After stirring for a few hours, the lower phase was washed with water (×3) until the pH was about 6–7. After separation, the ionic liquid was dissolved in methylene chloride and dried over anhydrous $MgSO_4$. After the methylene chloride was evaporated off, the ionic liquid was characterized by ^{1}H-NMR spectroscopy.

The Rh–MeDuPHOS homogeneous catalyst was prepared as previously described.[5] Homogeneous and biphasic reactions were performed with magnetic stirring in a specially designed 25 ml reactor. In the homogeneous reactions, 10 μmol of the prepared complex were dissolved in 5–7 g of iPrOH. In the biphasic reactions, 5 g of ionic liquid were added to the solution of the complex under nitrogen. The reaction mixture was added to the reactor together with the substrate. The reaction took place at 20–25 °C at a reactor pressure of 2 bars of highly pure hydrogen (99.995%). Re-use of the catalyst was achieved by replacing the iPrOH and insertion of fresh substrate dissolved in iPrOH. Conversion and enantiomeric excess were determined with a Hewlett Packard GC equipped with an Astec Chirasil-Val-L capillary column.

Rhodium catalysed addition of boronic acids to anhydrides: a new method for the synthesis of ketones

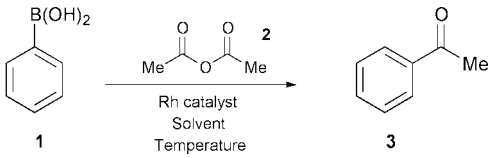
Christopher G. Frost* and Kelly J. Wadsworth

Department of Chemistry, University of Bath, Bath, UK BA2 7AY. E-mail: c.g.frost@bath.ac.uk; Fax: 01225 826231; Tel: 01225 826142

Received (in Cambridge, UK) 22nd August 2001, Accepted 26th September 2001
First published as an Advance Article on the web 24th October 2001

The efficient transmetalation from boron to rhodium is exploited in a new synthesis of aryl and alkenyl ketones.

The rhodium catalysed addition of boronic acids to organic electrophiles has recently emerged as an important tool for organic synthesis.[1] An efficient transmetalation between boron and rhodium permits the addition of organoboronic acids to a range of activated olefins.[2] Significant advances have also been made in the coupling of unactivated olefins in aqueous media.[3] Further to this the addition of aryl boronic acids to aldehydes and imines has been achieved.[4] The mechanism of these transformations is proposed to involve transmetalation between the boronic acid and the rhodium(I) complex to afford an R–Rh(I) species. The nucleophilic R group then adds to the coordinated electrophile yielding either a Rh bound enolate or alkoxide which is subsequently hydrolysed. As part of our research programme developing catalysts for the functionalisation of aromatics, we were interested in the boron–rhodium transmetalation process as a means to promote the equivalent of a Friedel–Crafts acylation reaction of deactivated aryl derivatives. This is a demanding transformation which is not readily achieved by even the most effective Lewis acid catalysts.[5] In this communication we wish to report our development of an efficient rhodium catalysed addition reaction that allows the synthesis of ketones from boronic acids under mild conditions.



Scheme 1 Rhodium catalysed acylation.

Table 1 Rhodium catalysed addition of **1** to acetic anhydride **2**

Entry	Catalyst	Solvent (Temp./°C)	Yield of 3 (%)
1	—	Dioxane (100)	0
2	[Rh(acac)(ethylene)$_2$]	Dioxane (100)	0
3	[Rh(acac)(ethylene)$_2$]	DME–H_2O (65)	0[a]
4	[Rh(acac)(cod)]	Dioxane (100)	16
5	[Rh(acac)(cod)]	DME–H_2O (65)	18[a]

17	[Rh(ethylene)Cl]$_2$	DME (20)	76[c]

[a] DME–H_2O (6:1). [b] Yield after 2 hours. [c] Yield after 16 hours.

To demonstrate this concept, initial experiments examined the reaction of phenylboronic acid (1.6 equiv.) **1** with acetic anhydride **2** in the presence of 5 mol% of various rhodium complexes (Scheme 1).[6] As summarised in Table 1, the formation of acetophenone **3** is symptomatic of an effective protocol for ketone synthesis.

The first point to note is that in the absence of catalyst no product formation is observed. It was interesting to learn that the Rh(acac) complexes favoured for addition to activated olefins, were not particularly effective in this case (entries 2–7). Similarly, the use of [Rh(OAc)$_2$]$_2$ and $RhCl_3·3H_2O$ afforded disappointing results (entries 10 and 11). Gratifyingly, the use of [Rh(alkene)Cl]$_2$ complexes showed more promise (entry 9)

resulting in the formation of **3** in excellent overall yield in the best case (entry 12). The choice of solvent had a clear effect on the efficiency of the reaction (entries 12–16) with the reaction proceeding smoothly in dioxane and 1,2-dimethoxyethane (DME). The insensitivity of this protocol towards air and water (entry 13) is extremely beneficial from a practical perspective. At 65 °C in DME the reaction was complete within two hours, whilst at room temperature the reaction required 24 hours to afford comparable yields (entries 16 and 17). Furthermore, the catalyst loading could be lowered to 1.5 mol% with the product **3** being obtained in an 87% yield after 16 hours. Upon lowering to 0.1 mol% of catalyst, a modest 33% of **3** was isolated after the same period of time.

Under the optimised conditions the reaction was examined with respect to the scope of the boronic acid (Table 2).† An attractive feature of this methodology is the commercial availability of a wide range of boronic acids. An important point to note about the presented reaction is the regiospecific formation of product with the electrophile substituting the boronic acid group. Therefore, whilst electronic effects (inductive and resonance) may influence the rates of the reactions, as a consequence of the nucleophilicity dictating the transmetalation and transfer processes, the composition of product is unaffected by the nature and position of substituent in the starting boronic acid. This offers a significant tactical advantage over Lewis acid catalysed electrophilic substitution processes. Thus, the reaction can be designed to mirror typical electrophilic substitution reactions (Table 2, entry 3). Conversely, the formation of *meta*- or *para*-substituted deactivated aromatics can be achieved in excellent isolated yield (Table 2, entries 1, 2 and 4). The results also confirm the scope of the reaction with the alternative electrophile, benzoic anhydride (Table 2, entries 6–10). Furthermore, the reaction can be extended to alkenylboronic acids with no significant loss in efficiency. At the present time, difficulties have been encountered in extending the methodology to acid chlorides.[7] Further investigations are directed towards accomplishing this and the addition of organoboronic acids to other electrophiles.

In summary, a new rhodium catalysed addition of boronic acids has been developed that allows the synthesis of ketones. This transformation proceeds in good yield for a range of boronic acids. Importantly, this new methodology offers specific advantages over traditional Lewis acid catalysed acylation reactions in that it allows the regiospecific functionalisation of activated, unactivated and deactivated aromatics.

Notes and references

† *General experimental procedure*: to a pressure tube charged with $[Rh(ethylene)Cl]_2$ (0.006 mmol, 1.5 mol%) was added 1,4-dioxane (4 ml), boronic acid (0.56 mmol) and anydride (1 ml of 0.4 M solution). The tube was sealed, placed in a cold oil bath which was then heated to the required temperature and stirred for 16 hours. The mixture was allowed to cool to room temperature then worked up by extracting with ethyl acetate, washing with brine, drying over magnesium sulfate and concentrating *in vacuo*. The crude product was then purified by flash chromatography (ethyl acetate–hexane, 1:8 by volume). All the products have been satisfactorily characterised by ^{1}H NMR, ^{13}C NMR and IR spectroscopy.

A convenient imino aldol reaction in ethyl alcohol catalyzed by a cation-exchange resin

Makoto Shimizu,* Susumu Itohara and Emi Hase

Department of Chemistry for Materials, Mie University, Tsu, Mie 514-8507, Japan

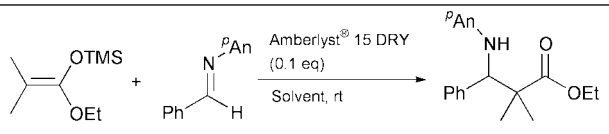
Received (in Cambridge, UK) 24th July 2001, Accepted 26th September 2001
First published as an Advance Article on the web 25th October 2001

Imino aldol reaction of ketene silyl acetals with imines proceeds smoothly to give β-amino esters in good yields under the influence of a cation-exchange resin in ethanol, and the work-up of the reaction consists only of a simple filtration followed by concentration of the crude mixture and purification.

Cation-exchange resins have been found to be excellent activators for imino aldol reaction of ketene silyl acetals with imines in dichloromethane or in some cases in isopropyl alcohol.[1] Although a variety of activators for such transformations have been reported,[2] polymer supported catalysts such as ion-exchange resins have not received much attention for promotion of imino aldol reaction until recently.[3] Use of ion-exchange resins offers several advantages in organic synthesis,[4] *e.g.* simplification of reaction procedures, easy separation of products without discharging harmful waste water, repeated use, and so on. In our previous report, a cation-exchange resin, in particular Amberlyst® 15 DRY, having a large surface area (45 m^2 g^{-1}), was found to be one of the most useful resins that promoted aldol type reaction, where the addition reactions proceeded with high chemoselectivity in the presence of two kinds of imines and/or nucleophiles. From an environmental point of view, however, this reaction needs modifications, because it is carried out in dichloromethane as a solvent and an equimolar amount of a cation-exchange resin is needed in most cases. Recent papers describing imino aldol reaction carried out in water or organic solvent–water as a convenient system[5] prompted us to report our approach which reduces harmful wastes such as waste water containing metal ions and organic wastes. We wish to report herein a convenient imino aldol reaction using a cation-exchange resin as a recyclable catalyst in ethanol as a solvent.

First, reaction of the imine **2a** and the ketene silyl acetal **1a** was chosen as a model for comparison of solvents, and the results are shown in Table 1. Among the alcohols examined the use of ethyl alcohol proved to be the most effective, whereas in methyl alcohol the ketene silyl acetal **1a** hydrolized to some extent and in *tert*-butyl alcohol the desired reaction proceeded very slowly.

Table 1 Effects of solvent[a]



1a **2a** **3aa**

Entry	Solvent	Time/h	Yield (%)[b]

3[c]	*t*-BuOH	11.5	30
4	MeOH	12.5	66

[a] The reaction was carried out according to the typical experimental procedure. [p]An = *p*-anisyl (*p*-methoxyphenyl). [b] Isolated yield. [c] Amberlyst® 15 DRY (0.2 eq.) was used.

Examples of the Amberlyst® 15 DRY catalyzed imino aldol reactions of ketene silyl acetals with imines in ethyl alcohol are shown in Table 2.† In the reactions of ketene silyl acetal **1a** with the imines derived from aromatic amines, the addition reaction proceeded smoothly to afford β-amino esters **3** in moderate to high yields. However, the imine derived from benzyl amine did not give the addition product in good yield (entry 7). A moderate diasteroselectivity was observed in the reaction of the ketene silyl acetal **1b** derived from propionate (entry 8). Ketene silyl thioacetals also worked well to give the corresponding adducts in good yields (entries 9 and 10).

The present reaction conditions were also effective for the addition of ketene silyl acetal **1a** to the imine equivalent **2h** derived from formaldehyde,[6] and the β-amino ester was obtained in 66% yield. As shown in Scheme 1, the *in situ* preparation of a relatively unstable imine could be used for the present addition, and the adduct was formed in good yield.

Furthermore, Amberlyst® 15 DRY was recovered by simple filtration after the reaction, and could be reused at least four times without loss of activity.‡ The results are shown in Table 3.

Regarding the chemoselectivity, the ketene silyl acetal **1a** reacted with the anisyl imine **2a** preferentially even in the presence of benzaldehyde to give β-amino ester **3aa** in 83% yield, and none of the adduct **4** arising from benzaldehyde was detected.[7]

Competition reactions between two kinds of imines were examined next. Amberlyst® 15 DRY selectively promoted the

addition to anisyl imine in the presence of the tosyl **2j** or ethoxycarbonyl imine **2k** with an electron-withdrawing *N*-substituent. One of the reasons for the chemoselectivity may be due to the difference in the ability of the imino nitrogen to be protonated by the catalyst. A better chemoselectivity between the imines **2a** and **2k** was observed in the present case than that in the previous report, showing that the present reaction conditions are much milder than the previous ones.

Notes and references

† A typical experimental procedure is as follows: to a suspension of Amberlyst® 15 DRY (4.3 mg, 0.02 mmol of the sulfonic acid portion, washed with EtOH and dried *in vacuo* at 100 °C) and aldimine **2a** (42.3 mg, 0.2 mmol) in EtOH (1.0 ml) was added a solution of ketene silyl acetal **1a** (45.2 mg, 0.24 mmol) in EtOH (1.0 ml) at room temperature under an argon atmosphere. After being stirred at room temperature for 10.5 h, the suspension was filtered through a Celite pad. The filtrate was concentrated *in vacuo* to afford a crude oil. Purification on preparative silica gel TLC (*n*-hexane–AcOEt = 10 : 1, as an eluent) gave the adduct **3aa** (64.7 mg, 99%) as a colorless oil.

‡ The sulfonic acid groups on the recovered resin are involved in the salt formation with amine moieties,[8] and therefore, such salts may be also responsible for the present imino aldol reaction. We are currently investigating such salt formation in more detail.

Ferrimagnetic-like ordering in a unique three-dimensional coordination polymer featuring mixed azide/carboxylate-bridged trinuclear manganese(II) clusters as subunits†

Hong-Ji Chen,[ab] Zong-Wan Mao,[a] Song Gao*[c] and Xiao-Ming Chen*[a]

Received (in Cambridge, UK) 16th July 2001, Accepted 11th September 2001
First published as an Advance Article on the web 25th October 2001

The crystal structure of the coordination polymer $[Mn_3(N_3)_2(nta)_4(H_2O)_2]_n$ (nta = nicotinate) consists of trinuclear subunits bridged by mixed μ-1,1-azide and μ-carboxylate-*O,O* groups, which are linked by μ_3-nta-*N,O,O* ligands into a three-dimensional network exhibiting ferrimagnetic-like ordering.

The family of azide-bridged transition metal complexes has been investigated widely in the past decade due to its magnetic properties and potential applications.[1–3] A number of synthetic strategies utilizing different organic spacers for propagating new motifs have been used to produce a large number of azide-bridged complexes.[1–4] Among them the end-to-end (EE) coordination mode affords antiferromagnetic exchange interactions,[2] the end-on (EO) coordination mode shows ferromagnetic exchange interactions,[3] and some alternating azide-bridged modes give interesting magnetic properties.[1] These complexes include dinuclear,[1a] trinuclear[4] and tetranuclear[3a] species, as well as one-,[1b] two-[1c,2a,3b–d] and three-dimensional[2b] coordination frameworks. So far no azide-bridged trinuclear Mn^{II} complex has been documented; in contrast, carboxylate-bridged trinuclear manganese complexes have been widely investigated as models for a variety of metalloenzymes[5] and often show antiferromagnetic interactions.[6] Meanwhile, very few complexes containing mixed azide and carboxylate bridges have been reported.[7] In this communication, we report the synthesis, crystal structure and magnetic properties of a unique three-dimensional complex $[Mn_3(N_3)_2(nta)_4(H_2O)_2]_n$ (**1**)‡ featuring mixed azide/carboxylate-bridged trinuclear Mn^{II} clusters as subunits.

Single-crystal X-ray diffraction§ shows that **1** consists of a three-dimensional covalent network constructed by linear Mn^{II}_3 subunits (Fig. 1), in which each Mn^{II} atom is coordinated in a distorted octahedral geometry. The central Mn(1) atom, being located at a crystallographic inversion centre, is coordinated by two *trans*-related nitrogen atoms [Mn(1)–N(3) 2.184(2) Å] from two azide groups and four carboxy oxygen atoms [Mn(1)–O(2B) 2.212(2) Å and Mn(1)–O(4) 2.257(2) Å] from nta groups. Each of the two terminal Mn^{II} atoms is coordinated by a μ-1,1-azide nitrogen atom [Mn(2)–N(3A) 2.233(2) Å], two nitrogen atoms [Mn(2)–N(1C) 2.292(3), Mn(2)–N(2D) 2.321(2) Å] from two nta ligands, two oxygen atoms [Mn(2)–O(1) 2.150(2), Mn(2)–O(3) 2.194(2) Å] from two other nta ligands, and an aqua ligand [Mn(2)–O(1W) 2.206(2) Å]. The central Mn^{II} atom is linked to each terminal Mn^{II} atom by a μ-azide and a *syn-syn* μ-carboxylate bridge [Mn···Mn 3.861(1) Å, Mn–N–Mn 118.6(1)°]. The aqua ligand is hydrogen bonded [O(1W)···O(4) 2.772(3), O(1W)···O(1E) 3.003(3) Å] to two oxygen atoms from adjacent nta ligands [O(1W)···O(4B) 2.772(3), O(1W)···O(1E) 3.003(3) Å]. The nta ligands act in two kinds of tridentate-*N,O,O′* modes, either utilizing the pyridyl nitrogen atom and the two carboxy oxygen atoms (*syn-anti*) to bridge Mn^{II} atoms from adjacent trinuclear units to form a two-dimensional sheet (Fig. 1S),† or using both carboxy oxygen atoms (*syn-syn*) to bridge a pair of intracluster metal atoms and the pyridyl nitrogen atom to link a metal atom from an adjacent sheet, which link layers into a three-dimensional network (Fig. 2). The shortest intercluster Mn···Mn distance is 6.771(1) Å.

The EPR spectrum of powdered **1** at room temperature shows a broad isotropic signal at $g = 2.018$. The variable-temperature magnetic susceptibility of **1** from 5 to 300 K was measured at 5 kOe, as shown in Fig. 3(a). The magnetic susceptibility above 18 K obeys the Curie–Weiss law with a Weiss constant, $\theta = -19.26$ K, and a Curie constant, $C = 14.49$ cm^3 mol^{-1} K. The C value is slightly higher than the value (13.1 cm^3 mol^{-1} K) of three non-interacting Mn^{II} ions with $g = 2.0$. The $\chi_m T$ decreases continuously with decreasing temperature and reaches a minimum of 6.64 cm^3 mol^{-1} K near 12 K. Upon a further decrease of temperature, however, the $\chi_m T$ rises quickly. This is a characteristic ferrimagnetic-like behavior. Usually the EO azide bridge should promote ferromagnetic interaction for an angle between 100 and 105°.[1a] In **1**, however, the Mn–N–Mn angle of the EO azide bridge is 118.63(9)°, which is much larger than the above-mentioned range of bond angles, giving an antiferromagnetic interaction within the trinuclear unit. In addition, the *anti-anti* carboxylate bridges also promote an antiferromagnetic interaction.[5] Therefore, the ferrimagnetic-like behavior ought to arise from competitions between intra-

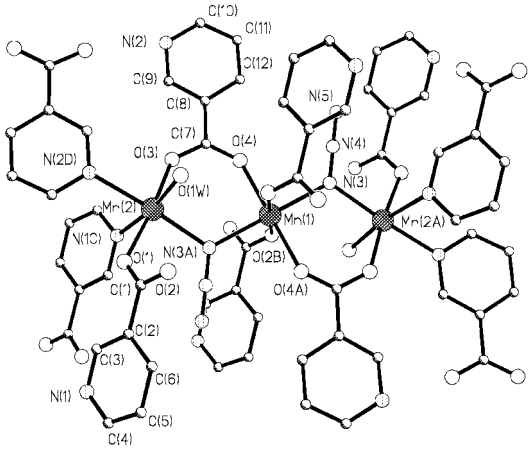

Fig. 1 Perspective view of the trinuclear unit in **1** projected approximately along the *a*-axis.

† Electronic supplementary information (ESI) available: the theoretical expressions of the intra-/inter-molecular magnetic interactions, two-dimensional view of **1**, temperature dependence of ac magnetic susceptibility and field dependence of magnetization at 1.97 K.  DOI: 10.1039/b106314f

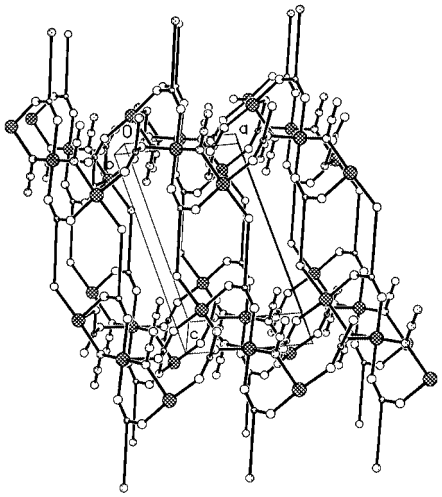

Fig. 2 Perspective view of the three-dimensional framework of **1** viewed along the *b*-axis. The aromatic rings are simplified by sticks for clarity.

cluster antiferromagnetic and inter-cluster ferromagnetic interactions.

To evaluate the intra- and inter-cluster super-exchange coupling constants in **1**, a trinuclear Mn^{II} model[8] including a mean field approximation term was used, with the J and J' referring to the intra- and inter-cluster coupling constants, respectively.† The experimental data fitted well [Fig. 3(a)], and led to the following parameters: $J/k = -2.20$ K, $J'/k = 0.326$ K, $g = 2.01$ and $R = 7.16 \times 10^{-4}$ ($R = \Sigma[(\chi_m)_{obs} - (\chi_m)_{calc}]^2/\Sigma[(\chi_m)_{obs}]^2$). The negative value of J and the small positive value of J' imply that there is an antiferromagnetic exchange interaction within the trimers and a ferromagnetic exchange interaction among the trimers through nta bridges, respectively.

The temperature dependence of the magnetization measured in a low field of 100 Oe showed an abrupt increase in M at *ca.* 3.7 K, indicating a long-range magnetic ordering occurring [Fig. 3(b)]. The temperature dependence of *ac* magnetic susceptibilities verifies the magnetic phase transition at almost the same temperature 3.7 K (T_c), defined as the point where non-zero out of phase χ appears distinctly. The field dependence of the magnetization (0–70 kOe) measured at 1.97 K shows a rapid increase of the magnetization, expected for a magnet, reaching 4.98 $N\beta$ per Mn_3 at 25 kOe, very close to the expected value of 5 $N\beta$ for an anti-parallel alignment of three Mn^{II} magnetic moments in a linear Mn_3 cluster with $S_T = 5/2$. The magnetization increases further above 25 kOe as the spins begin to deviate from antiferromagnetic coupling and align with the applied field. No detected hysterestic loop was observed, typical of a soft magnet.

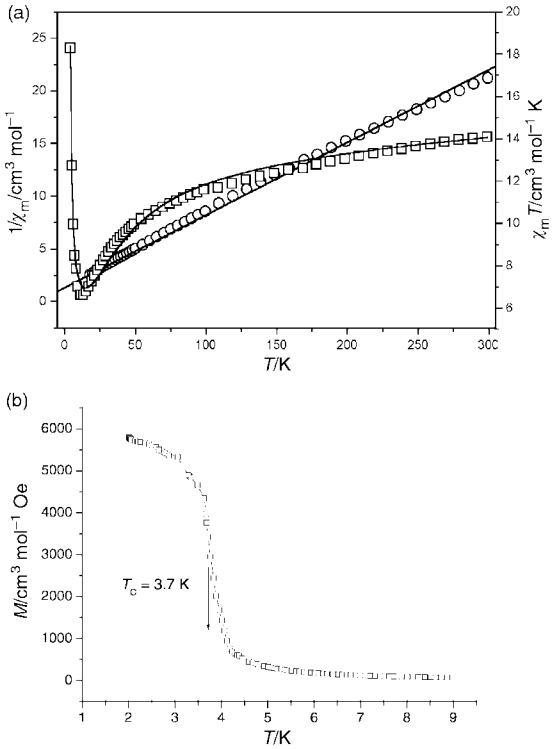

Fig. 3 Temperature dependence of the magnetic susceptibility of **1** (a) measured at 5 kOe and of magnetization (b) of **1** measured at 100 Oe.

In summary, weak ferrimagnetic interactions among the antiferromagnetically correlated Mn_3 clusters lead to a long-range ferromagnetic-like ordering: this is essentially due to increasing structural dimensions when going from an isolated cluster to a supercluster.[8]

Stereospecific oxidation by Compound I of Cytochrome P450 does not proceed in a concerted synchronous manner

Sam P. de Visser, François Ogliaro and Sason Shaik*

First published as an Advance Article on the web 25th October 2001

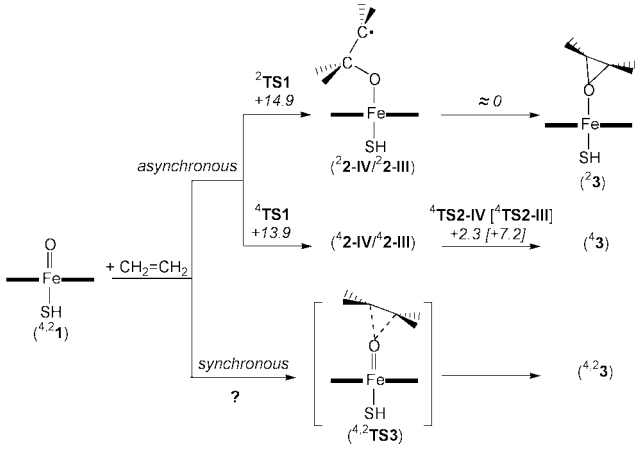
Calculations show that the transition structure for the synchronous oxygen transfer by Compound I is a second order saddle point. The process is unlikely.

Cytochrome P450 specializes in vital oxygen transfer reactions such as alkane hydroxylation and alkene epoxidation.[1,2] One of the attractive features of the enzyme is its overwhelmingly stereospecific reactions. However, the stereospecifity is occasionally incomplete resulting in some loss of stereochemical integrity of the alkene or alkane.[1] These findings led to the formulation of mechanistic schemes that involve competing concerted and stepwise monooxygenations mediated by the primary active species of the enzyme, so called Compound I (Cpd I),[1,2] and/or by secondary oxidants, *e.g.* the iron-hydroperoxo species.[3] The concerted reactions are generally described in terms of *a synchronous oxygen insertion* (Scheme 1, bottom), while the formation of an intermediate carbon radical remains a controversial issue since the estimated lifetime of the putative species is too short.[1,4] Using alkene epoxidation as an archetypal mechanism, this paper addresses the feasibility of synchronous mono-oxygenations[3] by Cpd I *vis-à-vis* the alternative mechanistic hypothesis that invokes the existence of radical species in the reaction process.

Cpd I is a high valent iron-oxo species that possesses three unpaired electrons, coupled to closely lying quartet and doublet spin states. The adjacency of the states renders Cpd I prone to two state reactivity (TSR). Indeed, our recent study of ethene epoxidation (Scheme 1),[5] revealed TSR in which the two spin states are close throughout the reaction path. The bond activation was found to occur along an *asynchronous trajectory of oxygen insertion*. On the quartet spin surface this trajectory leads to a stable intermediate radical complex, in two different oxidation states of iron; Fe^{IV} and Fe^{III} (^{4}**2-IV** and ^{4}**2-III**). Ring closure of these radical complexes to produce the epoxide complex (^{4}**3**) proceeds with substantial barriers. These barriers, especially for ^{4}**2-III**, endow the intermediates with a finite lifetime, sufficient to undergo loss of stereochemistry of the olefin and other side reactions.[5] The doublet state reaction proceeds along the same asynchronous trajectory, but exhibits tiny barriers (if at all existent) for the ring closure step. As such, it is essentially an '*effectively concerted*' process, leading to stereospecific epoxidation. The question now is whether there exists a competitive concerted synchronous mechanism that can also account for the observed stereospecifity? *An answer to this question can decide between the two alternative mechanistic hypotheses* and is expected to shed light on mechanistic puzzles generated by use of radical clocks and mutant enzymes.[1–4]

To answer this question we performed density functional calculations.[6] We used both restricted and unrestricted B3LYP hybrid density functional methods. The Los Alamos effective core potential (ECP) was employed and coupled with the double-ζ LACVP basis set for iron and an all-electron 6-31G basis set for C, H, O and N.[7] We also investigated the availability of concerted oxygen insertion in CH_4 hydroxylation,[8] as well as in C_2H_4 epoxidation by dioxygen.

The transition state for the concerted ethene epoxidation (^{4}**TS3**) is depicted in Fig. 1. It was further ascertained that the transition state ^{4}**TS3** is indeed connected to the ground states of the reactants (^{4}**1** + CH_2=CH_2) and product ^{4}**3**. Alongside we show the corresponding transition states for the asynchronous process (^{4,2}**TS1**). Underneath the drawings we indicate the corresponding barriers. The barrier for the synchronous reaction is 7.2 kcal mol^{-1} higher than the one for the asynchronous process. Inclusion of zero point energy correction leads to a difference of 4.1 kcal mol^{-1}, in favor of the asynchronous reaction. The free energy barrier at 298 K is 3.6 kcal mol^{-1} in



Scheme 1 Asynchronous and synchronous reaction paths. The barriers of the transition states are written above the arrows in kcal mol^{-1}.

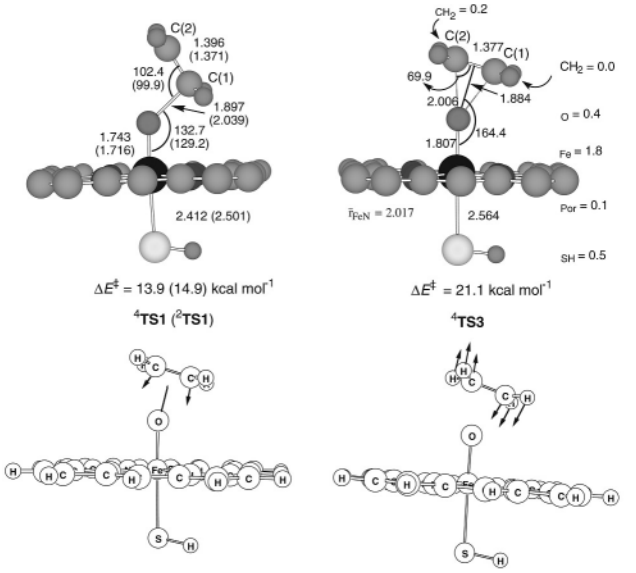


Fig. 1 Optimized geometries (Å and degrees) of ^{4,2}**TS1** and ^{4}**TS3** and imaginary modes of ^{4}**TS3** (bottom). Group spin densities (ρ) of ^{4}**TS3** are noted near the structure.

 DOI: 10.1039/b105571m

favor of the asynchronous processes. Thus, ^{4}**TS3** may become accessible only at high temperatures (T > 600 K), certainly unavailable in the enzymatic reaction. All attempts to locate ^{2}**TS3** failed, and upon removal of the synchronous constraints the structure collapsed into ^{2}**TS1**.

A frequency analysis on ^{4}**TS3** revealed two imaginary modes (see Fig. 1) with magnitude i607 cm^{-1} and i44 cm^{-1}. The first mode is the motion that connects ^{4}**TS3** to the epoxide product by a synchronous formation of two C–O bonds. The second one is a cartwheel rotation of C_2H_4. This vector drives the system towards the asynchronous ^{4}**TS1** transition state, and subsequently to the radical intermediate (^{4}**2–IV**/^{4}**2-III**, in Scheme 1) in which only one C-O bond is formed. The instability of ^{4}**TS3** toward conversion to ^{4}**TS1** is apparent in fact from the electronic structure. As shown in Fig. 1, even though the two C–O bonds are identical (2.006 Å), nevertheless the radical character on C(2) is larger than on C(1), in accord with the fate of ^{4}**TS3** to collapse to the radical intermediate on C(2) (by C(1)–O bond formation).

The epoxidation of C_2H_4 by dioxygen reveals clearly the problem with the synchronous concerted mechanism. Two synchronous pathways were explored in C_{2v} symmetry; an in-plane attack and a side-on attack, along with the asynchronous path (see definitions given in Scheme 2 for Cpd I + C_2H_4). The resulting two transition states for the synchronous paths were found to be geometrically similar to the one found for Cpd I + C_2H_4 (^{4}**TS3**). More so, both exhibit the same types of imaginary frequencies. Here too, the barrier for the asynchronous stepwise mechanism is lower, by 11.3 and 10.7 kcal mol^{-1}, respectively, than the barriers for the concerted attacks. In fact, this is a general finding among analogous mono-oxygenation processes. Thus, in water formation by the reactions of O_2 with H_2, and of FeO^+ with H_2, the concerted oxygen insertion transition states are second-order saddle points; one of their imaginary modes leads to the stepwise asynchronous transition state.[9] Notably, in both reactions, the barrier for the asynchronous path is lower than the corresponding barrier for the synchronous process by 15 and 2 kcal mol^{-1}.[9] Finally, we explored the concerted hydroxylation of CH_4 by Cpd I. Here too, structures leading to synchronous oxygen insertion into the C–H bond were extremely high. They invariably collapsed onto the asynchronous transition state for the hydrogen abstraction, reported before,[8] and were found to be analogous to Groves' rebound mechanism in its TSR formulation.

The existence of a second imaginary frequency in the concerted transition states of such processes is rooted in electronic structure. This instability derives from the fact that the addition of O to C_2H_4 (or H_2) is a forbidden process.[10] Sevin and Fontecave used molecular orbital arguments to show that this 'forbiddeness' remains effective in the C_{2v} reaction paths of Cpd I with C_2H_4.[11] Additional insight is provided by valence bond (VB) arguments in Scheme 2. The Fe=O bond of Cpd I possesses the same bonding as the dioxygen molecule, with two unpaired electrons in π* type orbitals made from d_{xz}–p_x and d_{yz}–p_y overlaps.[8] In each of the two major resonance structures, the oxygen carries one electron in p_x and two in p_y or *vice versa*. In addition, there is a lone pair along the FeO axis (z-axis). When the alkene approaches the oxygen to make two bonds synchronously as in **a**, the transition state will encounter a repulsive 4-electron interaction. In the side-on approach as in **b** the concerted transition state encounters with either one of the two resonance structures of FeO a repulsive 4-electron interaction and an unfavorable 3-electron interaction. The latter shown in **b** involves a 3-electron/3-center structure in a cyclic orbital array, which is an unstable situation (recall the D_{3h} form of H_3 is on top of a conical intersection and of high energy compared with the linear structure). Faced with these two evils, the transition state assumes the open structure **c** which resembles a radical attack on the π-CC bond and is the **TS1**structure.[5] *There is then, a fundamental reason why the concerted oxygen insertion processes are less favorable than the stepwise mechanisms.*

Since the synchronous pathway is unavailable, the stereospecifity of P450 oxidations[1–4] must originate in the *effectively concerted but asynchronous mechanism* of the doublet state (Scheme 1). Occasional loss of stereochemistry and side products originate, in turn, in the asynchronous and stepwise quartet state process. The interplay of the low-spin and high-spin components of the TSR provide also a lucid rationale[5,8] for the ultrashort lifetime observed in radical probe experiments in these mechanisms.[1–4] Furthermore, the observed *cis* selectivity[1] can also be accounted for by an asynchronous side-on transition state, obtained from ^{2,4}**TS1** by a 90° rotation around C–O.

In conclusion, therefore, the computational results make a choice between mechanistic alternatives and provide support for the asynchronous nature of olefin epoxidation and the C–H hydroxylation by the primary oxidant of P450 and generally by Cpd I iron-oxo species.[5,8]

The research was supported by the Israel Science Foundation (ISF) and the Ministry of Science, Culture and Sport. F. O. thanks the European Union for a Marie Curie Fellowship.

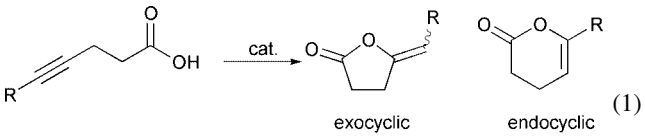
Received (in Cambridge, UK) 24th July 2001, Accepted 27th September 2001
First published as an Advance Article on the web 25th October 2001

The σ-enynyl complex [TpRu{C(Ph)=C(Ph)C≡CPh}(P-Me^{i}Pr$_2$)] efficiently catalyses the regioselective cyclization of α,ω-alkynoic acids to yield endocyclic enol lactones having ring size up to 12 atoms.

Enol lactones are present in a number of biologically active natural products. Whereas some compounds contain the exocyclic enol lactone substructure,[1] other natural products contain an endocyclic enol lactone ring, *e.g.* eresmofarfugin A,[2] and all products containing the isocoumarin ring system.[3,4] Endocyclic enol lactones are useful intermediates in the synthesis of more complex natural products such as the alkaloid (−)-aspidospermidine.[5] The cyclization of α,ω-acetylenic acid precursor represents one effective synthetic approach to enol lactone systems.[6] Silver salts and mercuric salts have been used as catalysts, but their utility suffers from limited scope, drastic conditions and poor selectivity.[7] Transition metal complexes have shown to catalyse efficiently the cyclization of α,ω-alkynoic acids to give enol lactones of 5- and 6-member rings, with variable degree of regio- and stereoselectivity depending upon the catalyst used and the particular alkynoic acid [eqn. (1)].[8–11]



(1)

In the case of terminal alkynoic acids (R = H), the metal-catalysed cyclization reaction yields exclusively exocyclic enol lactones. This can be interpreted in terms of the regioselective Markovnikov addition of the carboxylic acid to the terminal alkyne.[12] Alternatively the *anti*-Markovnikov addition would produce the corresponding endocyclic enol lactone. However, *anti*-Markovnikov addition products have never been observed to any significant extent, hence the use of this synthetic route for the general preparation of enol lactones seems to be very limited. We have recently reported the σ-enynyl complexes [TpRu{PhC=C(R)C≡CPh}(PMe^{i}Pr$_2$}] [R = Ph, H; Tp = hydrotris(pyrazolyl)borate(1−)] and their ability to catalyse the dimerisation and even cross-coupling of alkynes.[13] We have now found that [TpRu{PhC=C(Ph)C≡CPh)(PMe^{i}Pr$_2$}] (**1**) catalyses the regioselective cyclization of HOOCCH$_2$(CH$_2$)$_n$C≡CH (*n* = 1, 2, 3, 7) to the corresponding endocyclic enol lactones. Results are shown in Table 1 (entries 1–4).‡ The cyclization takes place smoothly in refluxing toluene in 6 h, and 2% catalyst load. Analytical samples of the lactones were isolated by solvent removal followed by preparative HPLC. In the case of larger lactone rings, the catalyst load and reaction time were increased to 10% and 24 h respectively, diluting the substrate concentration to *ca.* 0.05 M in order to prevent the formation of linear oligomers. As shown in Table 1, endocyclic enol lactones were the only product generated when catalyst **1** was used. So far, our catalyst has proven to be able to cyclize ring systems of up to 12 atoms. This constitutes an efficient method for the synthesis of macrocyclic enol lactones, with the potential ability for accessing even larger cyclic systems. In these cases, the cyclization is not stereoselective, and mixtures of the endocyclic *Z*- and *E*-enol lactones are obtained (entry 4).§ The complex [TpRuH(PPh$_3$)$_2$] (**2**)[14] can also cyclize alkynoic acids to enol lactones (Table 1, entries 5–8). However, with pentynoic acid the only exception, the cyclization is not regioselective, and mixtures of endocyclic (*anti*-Markovnikov) and exocyclic (Markovnikov) enol lactones are obtained. Detailed studies carried out on rhodium and iridium complexes, supported by X-ray crystal structure determinations of some iridium model catalytic intermediates,[11] have led to a mechanistic proposal for the catalytic cyclization of alkynoic acids leading to exocyclic enol lactones.[10,11] Based upon these observations, we can propose in our case a similar catalytic cycle to account for the formation of exocyclic enol lactones (Scheme 1, pathway A). Compound **2** dissociates one PPh$_3$ molecule followed by insertion of the alkynoic acid into the Ru–H bond. The resulting alkenyl complex releases alkenoic acid (10-undecenoic acid has been isolated from runs

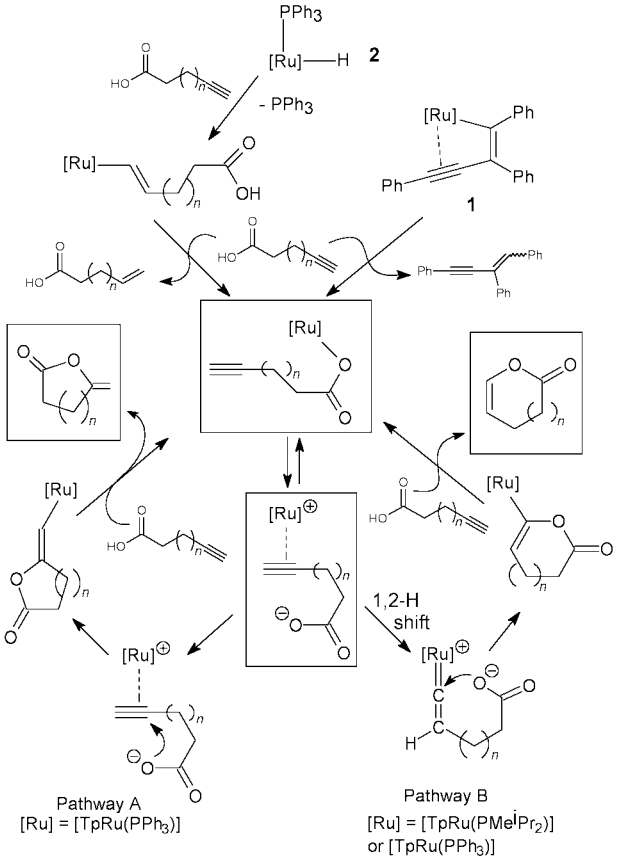

Scheme 1 Proposed mechanism for the cyclization of alkynoic acids to exocyclic enol lactones (pathway A) or endocyclic enol lactones (pathway B) catalysed by the complexes **1** and **2**.

involving undecynoic acid) upon reaction with another alkynoic acid molecule, furnishing a coordinatively unsaturated carboxylate complex which seems to be the actual catalytic species. An alternative pathway must be figured out in order to explain the regioselective formation of endocyclic enol lactones. Dixneuf and co-workers have developed ruthenium-based catalysts which can give either Markovnikov or *anti*-Markovnikov addition of acids or other organic substrates to terminal alkynes in a regioselective fashion.[12] The *anti*-Markovnikov addition takes place when the terminal carbon atom of the alkyne becomes electrophilic, this being feasible if a ruthenium–vinylidene intermediate species is generated at some stage during the catalytic process.[12] Therefore, we assume that in our case, a fast alkyne to vinylidene rearrangement takes place, most likely *via* a concerted 1,2-hydrogen shift (Scheme 1, pathway B).[15] In this fashion, the terminal carbon of the alkyne becomes electrophilic, and hence the carboxylate group attacks at this position. Ring closure yields an endocyclic alkenyl complex. As in pathway A, reaction with another alkynoic acid molecule releases the enol lactone and regenerates the coordinatively unsaturated carboxylate complex. It appears that the fast isomerization to vinylidene prior to carboxylate attack is the key step in the regioselective formation of endocyclic enol lactones. In the case of catalyst **1**, the presence of highly basic phosphine PMe^iPr_2 prompts the fast alkyne to vinylidene tautomerisation. In fact, we have already observed that facile alkyne to vinylidene rearrangement takes place at the $\{[TpRuCl(PMe^iPr_2)]\}$ moiety furnishing neutral vinylidene complexes $[TpRu{=}C{=}CHR(Cl)(PMe^iPr_2)]$ (R = Ph, Bu^t, $SiMe_3$).[13] For catalysts **2**, the alkyne to vinylidene rearrangement possibly occurs at a slower rate, similar to that of the attack of the carboxylate on the π-alkyne, so both pathways A and B of Scheme 1 might operate simultaneously. Further investigations are currently in progress in order to expand the applicability of these catalytic reactions, and in order to find additional information in support of our proposal for the reaction sequence in the catalytic cycle.

We thank the M.E.C./M.C.Y.T. of Spain (DGICYT, Projects PB97-1357, PB97-1360) for financial support, and Johnson Matthey plc for generous loans of ruthenium trichloride.

Notes and references

‡ *General procedure*. A round bottom flask fitted with a condenser was loaded with 0.02 equiv. of the catalyst and dry toluene (5 mL), and the mixture was heated at 100 °C under argon. Then, 1 equiv. of alkynoic acid dissolved in dry toluene (2 mL) was added. The reaction mixture was refluxed for 6 h and then allowed to cool to rt. Cyclohexane (5 mL) was added and the solvent removed using reduced pressure. In the case of octynoic and undecynoic acids, the catalyst load and reaction time were increased to 10% and 24 h respectively, diluting the substrate concentration to *ca*. 0.05 M in order to prevent the formation of linear oligomers. The ratio of the different products present in the crude was established by integration of the signals in the ^{1}H NMR spectrum. Pure samples of the lactones were obtained by preparative HPLC.

§ There is evidence for the formation of *Z*- and *E*-stereoisomers also in case of the 8-membered lactone ring, but the *E*-stereoisomer is strained, and tends to open up during the purification process yielding 7-oxoheptanoic acid (Table 1, entry 3).

The tetramethylpiperidinyl-1-oxide anion (TMPO$^-$) as a ligand in lanthanide chemistry: synthesis of the per(TMPO$^-$) complex $[(ONC_5H_6Me_4)_2Sm(\mu\text{-}ONC_5H_6Me_4)]_2$

William J. Evans,* Jeremy M. Perotti, Robert J. Doedens and Joseph W. Ziller

Received (in Purdue, IN USA) 28th July 2001, Accepted 14th September 2001
First published as an Advance Article on the web 25th October 2001

$(C_5Me_5)_3Sm$ reacts with the free radical 2,2,6,6-tetramethylpiperidinyl-1-oxy (TMPO) to form $(C_5Me_5)_2$ and the per nitroxide $[(\eta^1\text{-}ONC_5H_6Me_4)_2Sm(\mu\text{-}\eta^1:\eta^2\text{-}ONC_5H_6Me_4)]_2$

Recent studies of the chemistry of $(C_5Me_5)_3M$ complexes[1] have shown that these sterically crowded molecules can function as reducing agents, even though the metal is not redox active. This sterically induced reduction[2] is likely to occur *via* a half reaction like that shown in equation (1). For example, $(C_5Me_5)_3Sm$ reduces C_8H_8 according to equation (2).[3]

$$(C_5Me_5)_3M \rightarrow e^- + 1/2\ (C_5Me_5)_2 + [(C_5Me_5)_2M]^+ \quad (1)$$

$$2(C_5Me_5)_3Sm + C_8H_8 \rightarrow (C_5Me_5)Sm(C_8H_8) + (C_5Me_5)_2 + (C_5Me_5)_3Sm \quad (2)$$

To probe the mechanism of the Sm(III) reduction reaction and to explore the possibility that radical intermediates are involved, the reaction of $(C_5Me_5)_3Sm$ with the commonly-used free radical trapping agent 2,2,6,6-tetramethylpiperidinyl-1-oxy (TMPO)[4–10] was studied. We report here the unexpected result that TMPO can replace all of the C_5Me_5 groups in $(C_5Me_5)_3Sm$ to form an unusual per(TMPO$^-$) metal complex.

Reaction of $ONC_5H_6Me_4$ with $(C_5Me_5)_3Sm$ in toluene gave crystals of a yellow complex, **1**.† Examination of the mother-liquor by ^{1}H NMR spectroscopy revealed the formation of the reduction byproduct expected from equations (1) and (2), namely, $(C_5Me_5)_2$, but no signals were observed which could be attributed to products such as $(C_5Me_5)_2Sm(ONC_5H_6Me_4)$ or $(C_5Me_5)ONC_5H_6Me_4$. Instead, X-ray crystallography† revealed that $ONC_5H_6Me_4$ had been reduced with formation of a bimetallic homoleptic samarium complex, $[(\eta^1\text{-}ONC_5H_6Me_4)_2Sm(\mu\text{-}\eta^1:\eta^2\text{-}ONC_5H_6Me_4)]_2$ **1**, Fig. 1, in which TMPO$^-$ anions were the sole ligands, equation (3). Although several metal complexes of TMPO and TMPO$^-$ have been reported in the literature,[5–11] to our knowledge this is the first example

$$2(C_5Me_5)_3Sm + 6\ ONC_5H_6Me_4 \rightarrow Sm_2(ONC_5H_6Me_4)_6 + 3(C_5Me_5)_2 \quad (3)$$

of a per(TMPO$^-$) metal complex and the first example in which TMPO is a ligand for the large electropositive lanthanide elements. The only homoleptic TMPO system we could find in the literature is the boron system, $B(ONC_5H_6Me_4)_3$.[9]

Complex **1**, which has a center of inversion, has four terminal TMPO$^-$ ligands bound only through oxygen. Two bridging TMPO$^-$ units connect the two samarium centers *via* bridging oxygen atoms and each also coordinates to one samarium with its nitrogen atom. This gives each samarium a formal coordination number of 5. Both of these coordination modes are precedented in $ONC_5H_6Me_4$ metal chemistry.[5–10] The overall structure of **1** is reminiscent of bimetallic alkoxide-bridged lanthanide and yttrium structures such as $[(Ph_3CO)_2Ln(\mu\text{-}OCPh_3)]_2$, and $[(Ph_3SiO)_2Ln(\mu\text{-}OSiPh_3)]_2$.[11] This comparison indicates that the TMPO$^-$ anion is comparable in steric bulk to large alkoxide ligands. The 2.110(5) and 2.124(5) Å terminal Sm–O ($ONC_5H_6Me_4$) bond lengths are shorter than the 2.295(4) and 2.354(4) Å bridging Sm–O distances as expected. The 2.537(6) Å Sm–N bond length is significantly longer than the Sm–O bonds in **1** as expected for a Sm ← NR_3 donor bond. The Sm–N bond is shorter than typical bonds of this type in samarium metallocenes,[12] which is consistent with the fact that the formal coordination number of samarium in $Sm_2(ONC_5H_6Me_4)_6$ is much less than in the metallocenes. The difference in length between the Sm–N bond and the bridging Sm–O distances is similar to that observed in several high valent transition metal complexes in which TMPO$^-$ is bound side-on.[7,8,10] The three N–O bond lengths in **1** (1.434(7), 1.433(8), and 1.427(8) Å) are similar and are nearly 0.15 Å longer than the corresponding 1.283(9) Å bond length in the structure of the isolated free radical,[4] which is consistent with the formation of TMPO$^-$ anions.[7,8]

The isolation of **1** shows that $ONC_5H_6Me_4$ readily replaces C_5Me_5 in organolanthanide complexes and the reduced nitroxyl can function as the sole ligand in lanthanide compounds.

We thank the National Science Foundation for funding.

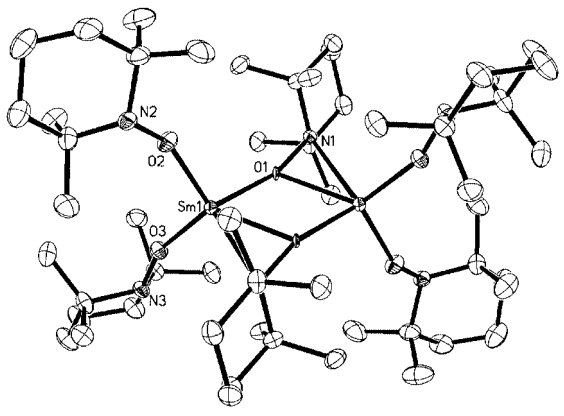

Fig. 1 Thermal ellipsoid plot for $[(\eta^1\text{-}ONC_5H_6Me_4)_2Sm(\mu\text{-}\eta^1\text{:}\eta^2\text{-}ONC_5H_6Me_4)]_2$, **1**, with ellipsoids drawn at the 50% probability level (all hydrogen atoms have been omitted for clarity).

Notes and references

† *Synthesis* of **1**: under a N_2 atmosphere, an H-shaped reaction vessel was charged in one side-arm with $(C_5Me_5)_3Sm$ (42 mg, 0.075 mmol), dissolved in 12 mL of toluene and with neat $ONC_5H_6Me_4$ (71 mg, 0.45 mmol) in the other. The H-tube was evacuated to the vapor pressure of the solvent and the $ONC_5H_6Me_4$ containing side-arm was placed in an 80 °C bath. $(C_5Me_5)_3Sm$ reacted with the $ONC_5H_6Me_4$ vapor over several days to form yellow crystals (32 mg, 68% yield) and $(C_5Me_5)_2$ (21 mg, 99%). Received (in Cambridge, UK) 27th July 2001, Accepted 8th October 2001
First published as an Advance Article on the web 25th October 2001

Cyclodextrin media are used to achieve photochemical water addition to isolated, acyclic double bonds *via* intramolecular interaction with excited arenes.

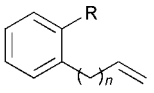
Cyclodextrins (CD) are known to form inclusion complexes with a variety of organic guests, whose chemical reactivity may become significantly modified due to interaction with the CD hosts. In particular, the photochemical properties of a number of substrates are sensitive to the CD microenvironment. In this context, the modified polarity inside the cavities and the imposed steric constraints are among the main factors governing the photoreactivity of CD inclusion complexes.[1,2]

Most of the photochemical processes performed within the CD microvessels involve formation of radicals or radical pairs. These include the Norrish type I or type II photoreactions[1,3,4] and the photo-Fries and photo-Claisen rearrangements.[1,5,6] Inside CD, some of these processes appear to occur with remarkable chemo- and/or regio-selectivity. The potential of CD as chiral reaction media, to bring about enantioselective photoreactions (albeit with modest ee) has also been explored.[7,8]

Photochemical processes involving generation of polar intermediates inside CD (for instance, carbocations, radical cations or zwitterions) are much less common. This is not surprising, as the interior of CD cavities is markedly hydrophobic. Actually, when these charged intermediates are formed in the CD microenvironment, their escape to the bulk of the aqueous solution occurs in the nanosecond timescale.[9]

With this background, the purpose of the present work was to investigate the photochemical behaviour of the CD complexes of a series of arene/olefin bichromophoric compounds; their structures are shown in Chart 1.

In organic solution, compounds **1a** and **1c** are known to photocyclise to 5-membered ring products,[10–13] while **1b** undergoes di-π-methane photorearrangement[14] and compound **1d** is essentially unreactive.[15]



1a-d

b: R = OCH_3, *n* = 1
c: R = NH_2, *n* = 1
d: R = OH, *n* = 2

Chart 1

By contrast, it will be shown that the photoreactivity of the β-CD inclusion complexes of the allyl derivatives in aqueous media is dramatically modified. Under these conditions, a novel hydration of the acyclic olefin moiety is by far the predominating photoprocess.

Compound **1a** was purchased from Merck, while **1b–d** were prepared by known procedures.[13,16,17] Irradiation of **1a–d** was carried out using the quartz-filtered light of a medium pressure mercury lamp for 1 h. Parallel experiments were performed in homogeneous solution (hexane or acetonitrile, 5 mM) and in β-cyclodextrin–water (*ca.* 1.5 mM **1a–d** and 7 mM CD). The results are shown in Table 1 and Chart 2.

Photolysis of **1a** in hexane afforded dihydrobenzofuran **2a** (Table 1, entry 1).[18] In acetonitrile (Table 1, entry 2), a 4:1 mixture of **2a** and the cyclopropane **3a** was obtained. Photoproduct **2a** is known to arise *via* intramolecular proton transfer,[10,12] while **3a** is the di-π-methane photorrearrangement product.[19] Formation of **3a** in acetonitrile is consistent with the previously reported enhancement of the rearrangement in polar solvents.[20] Irradiation of **1a** in β-CD–water resulted in a much higher conversion, together with a dramatic change in the product distribution (Table 1, entry 3). In this case, cyclisation to **2a** was totally suppressed, to the benefit of alcohols **4a** and **5a**, the hydration products of **3a** and **1a**, respectively. Lower amounts of **3a** were also obtained. The same trend was observed with α and γ-CD (Table 1, entries 4 and 5), although photohydration was less efficient than with β-CD. Control experiments were run leaving **1a**–CD in the dark and irradiating emulsions of **1a** in water for 1 h. Under these conditions, **1a** remained unreacted.

Table 1 Photochemistry of compounds **1a–c**

				Product yield (%)[b]

[a] A: Hexane, B: acetonitrile, C: β-CD–water, D: α-CD–water, E: γ-CD–water. [b] The photoproducts were identified by comparison of the GC retention times and MS spectra with those of authentic samples and quantitated by GC, using adequate standards.

 DOI: 10.1039/b106847b

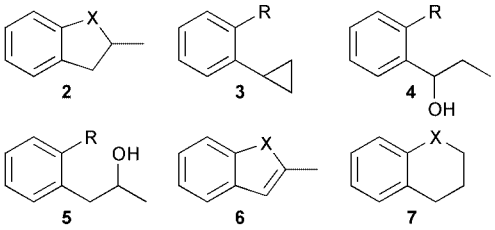

Chart 2

Photohydration of the allylic double bond is a remarkable result. Monosubstituted, non-conjugated acyclic olefins are unable to absorb light of $\lambda > 200$ nm, employed under the usual irradiation conditions. Neither direct nor sensitized irradiation of acyclic or large ring cyclic alkenes results in addition of protic solvents;[21] the only reported process is *E*/*Z* isomerization, which is a hidden non-observable process in the case of monosubstituted olefins such as **1a–d**. Only tri- or tetraalkyl substituted olefins (through their Rydberg excited states), medium-ring cycloalkenes and conjugated aryl olefins undergo addition of nucleophilic solvents *via* photoprotonation.[21–23]

Obviously, although the reacting moiety involved in photohydration is the isolated double bond, the phenolic substructure is the only light-absorbing chromophore. On the other hand, the phenolic singlet (*ca*. 103 kcal mol^{-1}) lies well below the lowest olefin singlet.[24] Thus, excitation of the allyl group by simple singlet–singlet energy transfer is thermodynamically disfavoured.

A possible pathway leading to **5a** could involve excited state proton transfer from the phenolic hydroxy group to the allylic double bond. The resulting zwitterion might undergo either cyclisation to **2a** or nucleophilic attack of water to the cationic center. This is reasonable and would be closely related to the behaviour of **1a** in homogeneous solution. However, if this were the only operating mechanism, methylation of the OH group should result in the suppression of photoproduct **5a**. In order to check this possibility, the photochemistry of **1b** was studied under the same conditions. Irradiation of **1b** in hexane and acetonitrile (Table 1, entries 6 and 7 respectively) gave rise to cyclopropane **3b** as the only product. By contrast, in cyclodextrin media (Table 1, entry 8) the alcohols **4b** (36%) and **5b** (37%) were obtained. These results indicate that in homogeneous solution the di-π-methane photorrearangement is the only occurring process, while inside β-CD it has to compete with photohydration. To make sure that **4b** is formed by secondary photohydration of **3b**, this compound was irradiated in the presence of β-CD. As a matter of fact, alcohol **4b** was the only product under these conditions.

A comparison between the results given in entries 3 and 8 (Table 1) clearly shows that excited state proton transfer is not the only operating mechanism. As photohydration also occurs in the case of the methylated derivative **1b** there must be other pathway(s) leading to **5**. In this context, photohydration might involve an intramolecular charge transfer exciplex. Although such a species was not detected when recording the fluorescence spectra of **1b**, intramolecular exciplex emission has been observed in closely related systems.[25] Moreover, it is generally assumed that non-detectable intramolecular exciplexes are involved in a variety of arene/alkene photoreactions.[26]

As allyl anilines undergo intramolecular electron transfer (rather than proton transfer) in their excited states,[13] **1c** was selected as a probe to check whether this type of process also contributes to photohydration. As expected,[13] direct photolysis of **1c** in hexane (Table 1, entry 9) afforded indoline **2c**, together with its secondary oxidation product **6c**. In acetonitrile (Table 1, entry 10), the same two products were obtained, although in a different ratio. However, when photolysis of **1c** was carried out in β-CD–water **5c** was the major product. Lower amounts of **2c**, **6c** and the tetrahydroquinoline **7c** were also obtained (Table 1, entry 11). These results indicate that intramolecular excited state electron transfer also contributes to photohydration, although to a lesser extent than proton transfer.

Finally, to gain some insight into the influence of the interchromophoric distance on the efficiency of photohydration, the photochemistry of **1d** was investigated in organic solution as well as in aqueous medium, in the presence of β-CD. Under these conditions, **1d** was found to be photostable.[27] This shows that increasing the distance between the phenol and the allyl moieties prevents the intramolecular excited state interaction required for photohydration.

In summary, a novel photohydration of non-conjugated aryl/olefin bichromophores has been observed in constrained media. Intramolecular excited state interaction (most likely exciplex formation) is responsible for activation of the otherwise unreactive olefin. The occurrence of photohydration inside the hydrophobic CD pockets might indicate that the olefin moiety is directed towards the bulk of the solution, remaining accessible to water. Current studies are aimed at disclosing this point, at extending the reaction to other systems and to investigate a possible stereoselectivity of CD-mediated photohydration.

We thank support from the Spanish DGES (PB97-0339).

First published as an Advance Article on the web 25th October 2001

Poly-β-leucines have been evaluated as catalysts for the Juliá–Colonna asymmetric epoxidation of enones; the β³-isomer was found to be an effective catalyst for the epoxidation of chalcone (70% ee) and some analogues.

Peptides, generated from α-amino acids, can adopt a number of stable conformations such as the α-helix and β-sheet. In combination these secondary structural units allow a protein to adopt a defined tertiary structure, which can lead to catalytic behaviour. Recent work by Seebach,[1] Gellman[2] and others,[3] as well as earlier studies,[4] has shown that peptides generated from β-amino acids (so called β-peptides) show similar secondary structural characteristics to their natural counterparts. This suggests that, in principle, the β-analogues of proteins may exhibit related catalytic behaviour. It is notable that short β-peptides show promise as therapeutic agents as they can exhibit similar biological profiles to α-peptides with increased stability to peptidases, leading to improved bioavailability.[5] Careful tuning of β-amino acid structure has allowed a wide range of structural units to be reliably prepared using the β-peptide backbone.

Work initiated by Juliá and Colonna[6a] has shown that polyamino acids, typically containing 30 or more identical residues of α-leucine or α-alanine, are capable of catalysing the Weitz–Scheffer epoxidation of enones with remarkable levels of asymmetric control.[6] More recently, modifications have been made to the original reaction conditions[6b] and as a result the method is now applicable to a wide range of *trans*-enones.[6c] As part of an ongoing program investigating and developing this transformation, β-analogues of the Juliá–Colonna poly-α-leucine catalysts have been prepared, in order to evaluate their potential as asymmetric catalysts.

The addition of a methylene unit to an α-amino acid generates two possible structurally-isomeric β-amino acids. Seebach has termed these β² and β³ depending on which carbon bears the side chain.[1] In order to prepare the two isomeric β-leucine polymers, the monomer amino acids β²-(**1**) and β³-leucine (**2**) were required in enantiomerically enriched form (Fig. 1).

Following the method of Seebach, β²-leucine **1** was prepared by amidomethylation of **3** with *N*-(chloromethyl)benzamide using the Evans auxiliary to control the formation of the stereocentre (Scheme 1).†[7] The β³ isomers are generally synthesised using an Arndt–Eistert homologation of the corresponding α-amino acids.[8] Thus, we were able to prepare protected β³-leucines **6a** and **6b** from the corresponding α-amino acids **5a** and **5b**. Compound **6a** was then deprotected to afford **2** {$[\alpha]_D^{22}$ +35 (*c* 1.0, H_2O) lit.[9] +34.7 (*c* 1.0, H_2O}} (Scheme 1).

Poly-α-amino acids are typically prepared from the corresponding monomers by activation as the *N*-carboxyanhydride, followed by polymerisation using a nucleophilic initiator.[10] This approach is less effective in the case of β-amino acids[10] and even employing recent synthetic improvements[11] a pure sample of the β³-leucine *N*-carboxyanhydride could not be prepared.

We have shown that a 20-mer of poly-L-α-leucine, prepared using solid phase synthesis, exhibits similar catalytic activity to material generated by polymerisation of L-leucine NCA.[12] Moreover, Seebach has shown that solid phase techniques can be used to prepare β-peptides.[8] Thus, solid phase automated peptide synthesis was carried out using the two isomeric Fmoc protected β-leucines† to afford two 20-mer peptides β²-Leu_{19}-α-Leu-R **7** and β³-Leu_{19}-α-Leu-R **8**.‡[13]

The polymers **7** and **8** were tested under two sets of reaction conditions; first, a triphasic protocol, consisting of aqueous NaOH and H_2O_2 and a solution of the substrate in toluene,[6a] and

[a] Determined by HPLC. [b] Determined by chiral HPLC, major enantiomer **11**. [c] Substrate (0.24 mmol), urea–H_2O_2 (28 mg), DBU (56 μl), catalyst (100 mg) in THF (1 ml). [d] Substrate (0.24 mmol), catalyst (100 mg), 30% aq. H_2O_2 (0.7 ml), 4 M aq. NaOH (0.5 ml) and PhMe (1 ml). [e] Catalyst (100 mg) stirred with 4 M aq. NaOH (0.5 ml) and toluene (1 ml) for 70 hours, then filtered and dried. [f] Catalyst (100 mg) stirred with DBU (56 μl) in THF (1 ml) for 16 hours then reagents for reaction added directly.

secondly, biphasic conditions, employing urea–H_2O_2 and DBU in THF.[6b] Like their α-analogues, the poly-β-leucines proved to be insoluble in both organic and aqueous solvents.§

In the first instance, the poly-β-amino acids were tested as catalysts for the epoxidation of chalcone (**10a**) (Scheme 2). Under the biphasic conditions, with catalysis by α-Leu_{20}-R, the (2*R*,3*S*)-epoxide **11a** was obtained (66% conversion, 89% ee) after 1.5 hours (Table 1, entry 1). Catalysis using β^2-Leu_{19}-α-Leu-R **7** afforded essentially racemic epoxide under the same conditions; moreover, the rate of reaction was considerably diminished (entry 2). On the other hand, the β^3-Leu_{19}-α-Leu-R catalyst **8** gave a significant ee of (2*R*,3*S*)-**11a** under both biphasic (23% ee) and triphasic (25% ee) reaction conditions, albeit still with a decreased rate (entries 3 and 4 respectively).

Previous studies have shown that the activity of poly-α-amino acid catalysts can be improved by various washing procedures.[14] Two such activations were investigated with the catalyst **8** and a third 20-mer: β^3-Leu_{20}-R **9**. In the first procedure the catalyst was stirred for 70 hours in a mixture of 4 M aq. NaOH and toluene, before filtering, washing and drying;[14] in the second it was stirred with DBU in toluene for 16 hours before adding the reagents for epoxidation directly. Both activation procedures significantly increased the enantioselectivity of the catalysed epoxidation reaction. For example, NaOH–PhMe-activated **8** catalysed the epoxidation of **10a** with 92% conversion and 70% ee under the triphasic conditions (entry 5).¶

The catalyst **9** was tested against a range of other substrates **10b–d**. Using DBU–PhMe-activated **9** the ees for the epoxidation of the β-ethyl enone **10b** were somewhat lower than for chalcone (entries 6, 8 and 9); under the biphasic conditions the ethyl epoxide **11b** had an ee of 28% (entry 9). On the other hand, under similar conditions the *tert*-butyl ketone **10c** was epoxidised in a high ee (entry 10), however the reaction rate was significantly retarded, with only 10% conversion to the epoxide **11c** being obtained after 24 hours. The final substrate investigated was 2-benzylidene-3,4-dihydronaphthalen-1(2*H*)-one (**10d**). In this case the triphasic reaction conditions gave an ee of 22%; however the reaction was again slow (entry 11).

In conclusion, peptides generated from β-amino acids exhibit catalytic behaviour analogous to that shown by poly-α-amino acids. Specifically, poly-β^3-leucine catalyses the epoxidation of (*E*)-α,β-enones with significant enantioselectivity. Although this methodology is not competitive with the poly-α-amino acid analogues it is possible that variation of the β-amino acid monomer may lead to altered catalytic behaviour. Results of such studies and approaches to preparing poly-β-amino acids *via* polymerisation reactions will be reported in due course.

Notes and references

† Fmoc β^2-leucine was prepared from **1** using FmocCl under standard conditions {$[\alpha]_D^{22}$ = +12 (*c* 1.0, $CHCl_3$) lit.[8] +10.8 (*c* 0.6, $CHCl_3$)}.

‡ The oligoleucines were linked *via* a hydroxymethylphenoxyacetic acid linker to PEG and thence to polystyrene resin (loading 0.18 mmol g^{-1}). These oligomers are represented as Leu_n-R where R = linker–PEG–resin.

§ The poly-β-amino acids remained attached to the support; the solubility of the non-immobilised material was not investigated.

¶ Ees using activated β^2-Leu_{19}-α-Leu-R **7** remained below 10%.

First published as an Advance Article on the web 25th October 2001

Tris(benzene-1,2-dithiolate)molybdenum(VI) reacts rapidly and quantitatively with tetrabutylammonium hydroxide to yield the corresponding Mo(V) and Mo(IV) complexes and hydrogen peroxide; the reaction has been executed in dry tetrahydrofuran where the reaction rate shows a fair dependence on complex and OH^- concentrations.

Tris(dithiolene) complexes of transition metals have been the subject of considerable attention since they were first reported.[1] While early interest focused primarily on the facile one-electron redox reactions which these complexes undergo, more recently the scope has expanded to areas ranging from bioinorganic chemistry to materials science.[2]

Surprisingly little is known about the interaction of this class of compounds with hydroxide ions. Kawashima *et al.*[3] first reported the reduction of neutral $M(tdt)_3$ complexes (M = Re, Mo, and W; tdt = toluene-3,4-dithiolate) dissolved in acetone or THF by aqueous NaOH, but little more than the formation of the corresponding one-electron reduced complex was described. Confirmation of the occurrence of this reaction was subsequently provided by Sellmann *et al.*[4] who reacted $Mo(bdt)_3$ (bdt = benzene-1,2-dithiolate) with NaOH in methanol. The reaction yields the $[Mo(bdt)_3]^-$ or $[Mo(bdt)_3]^{2-}$ complex, depending upon the ratio in which NaOH and $Mo(bdt)_3$ are mixed, and it was thought to proceed by oxidation of methanol to methanal, although this hypothesis has not been tested.

We were surprised to find that addition of n-Bu_4NOH to a THF solution of neutral $Mo(bdt)_3$ caused its conversion to the monoanionic $[Mo(bdt)_3]^-$ complex and then to the dianionic $[Mo(bdt)_3]^{2-}$ complex. All these complexes have been thoroughly characterised elsewhere in solid[5] and in solution.[4] Because the whole reaction was complete in less than 20 s in excess of base, both reduction processes have been studied by stopped-flow spectrophotometry. A general treatment of spectrophotometric data has been used to investigate the kinetics of the reaction. The solution absorption spectra of authenticated Mo(VI), Mo(V), and Mo(IV) complexes were fitted to a Gaussian function basis set within the 400–800 nm region.[6] The calculated optical densities $\varepsilon_i(\lambda)$ were used to analyse the $Mo(bdt)_3$–n-Bu_4NOH system spectrum at each time and to deduce the variation of molybdenum complex concentrations with time.† In all cases the sums of the Mo complex concentrations were equal to the initial $Mo(bdt)_3$ concentration and the resulting c_i *vs.* time curves were subject to further kinetic analysis by using a non-linear least-squares method.[7]

The monitoring of an equimolecular $Mo(bdt)_3$–n-Bu_4NOH reaction system is presented in Fig. 1a. On the basis of comparisons with authentic samples of $Mo(bdt)_3$ and $[Mo(bdt)_3]^-$, it was concluded that the latter complex is the only molybdenum product formed. This was further supported by HPLC which enabled the separation of $Mo(bdt)_3$ from $[Mo(bdt)_3]^-$ in a reaction mixture where no other peaks were detected. Finally, GC–FID did not show peaks other than that from the THF, indicating that this solvent is not involved in the redox process.

All evidence indicates that no absorbing intermediates are formed in appreciable quantities. First, as can be seen in Fig. 1, repetitive UV–Vis scans show tight isosbestic behaviour. Secondly, and more significantly, the kinetics treatment

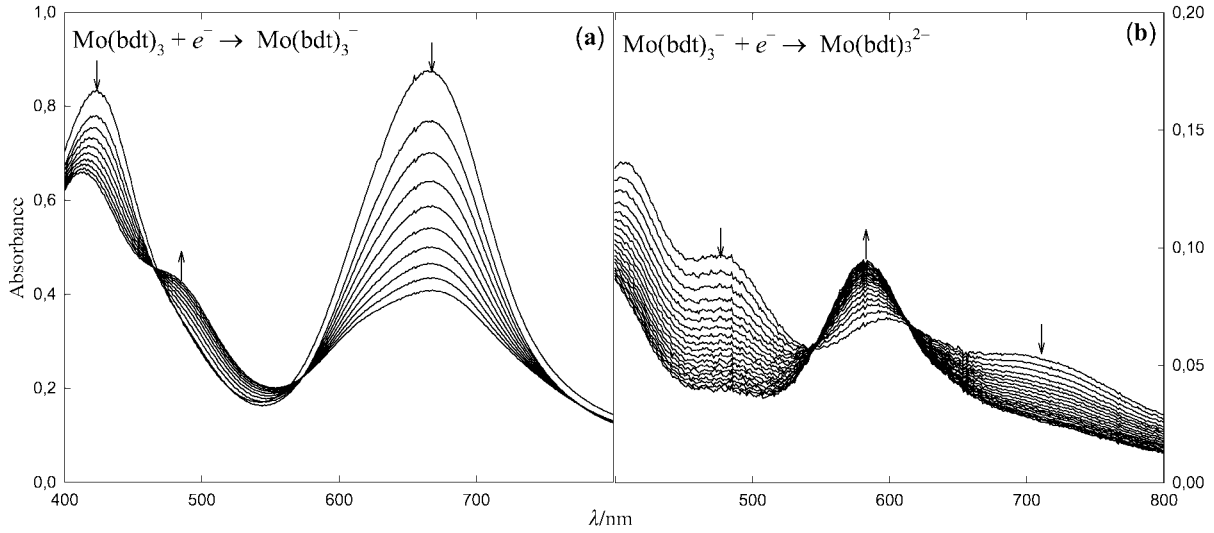

Fig. 1 Repetitive diode-array UV-scans from reaction mixtures in dry THF containing: (a) $Mo(bdt)_3$ 3.38×10^{-5} mol dm^{-3} and n-Bu_4NOH 3.38×10^{-5} mol dm^{-3} (spectra taken every 0.2 s, shown every 1 s, T = 300.2 K). (b) $Mo(bdt)_3^-$ 1.16×10^{-5} mol dm^{-3}, n-Bu_4NOH 3.28×10^{-4} mol dm^{-3} (spectra taken every 0.5 s, shown every 10 s, T = 301.2 K).

 DOI: 10.1039/b106123m

described here is capable of reproducing any of these experimental spectra satisfactorily by using only the component Gaussian functions of the $Mo(bdt)_3$ and $Mo(bdt)_3^-$ spectra.

The kinetics of the Mo(VI)–Mo(V) transformation were investigated with Bu_4NOH–$Mo(bdt)_3$ mole ratios of 0.4–1.3. At higher ratios, a further reduction of the formed Mo(V) complex with excess *n*-Bu_4NOH led to the Mo(IV) complex. Because of this limitation on the ratio of reactants, the kinetics data were treated in complete form, fitting the Mo(VI) and Mo(V) concentration *vs.* time curves to the integrated form of the $d[Mo^{VI}]/dt = -k[Mo^{VI}]^p[OH^-]^q$ equation by using non-linear regression methods. An excellent fit was obtained over a wide range of conditions for $p = 2$, $q = 1$, and $k = (5.0 \pm 0.2) \times 10^8$ s^{-1} mol^{-2} dm^6 at 27 °C. Reaction orders were also corroborated by applying the initial rate method.

The second-order dependence on $[Mo(bdt)_3]$ suggests a two-electron reduction of hydroxide ions to hydroperoxide ions that were actually identified in separate experiments [reaction (1)].

$$2\ Mo(bdt)_3 + 3\ OH^- \longrightarrow 2\ Mo(bdt)_3^- + HO_2^- + H_2O \quad (1)$$

The experiments were performed in biphasic systems by dissolving $Mo(bdt)_3$ in the organic phase and extracting the produced H_2O_2 as HO_2^- in the aqueous basic phase. Thus, when a 2.0×10^{-3} M solution of $Mo(bdt)_3$ in THF–toluene mixture (70:30) was added to a 0.1 M aqueous solution of NaOH over a period of 4 h, H_2O_2 could be detected and spectrophotometrically analysed by reacting an aliquot of the aqueous phase with a solution of $TiOSO_4$ in 25% H_2SO_4–H_2O. The transmittance at 405 nm due to the yellow peroxotitanyl cation indicated the presence of H_2O_2 in yields of 80–90% based on the initial $Mo(bdt)_3$ concentration, while no formation of H_2O_2 was detected in the absence of $Mo(bdt)_3$.

The second-order dependence on $[Mo(bdt)_3]$ is consistent with a mechanism having a bimolecular Mo complex interaction as the rate-limiting step. Taking into account that the current spectrophotometric results do not show that OH^- binds to Mo through the oxygen, we suggest as a reasonable pathway the association of one hydroxide ion with two neutral $Mo(bdt)_3$ molecules by hydrogen bonding to the co-ordinated sulfur atoms of the ligands.‡[1,2] The μ-hydroxo $Mo(bdt)_3\cdots HO^-\cdots Mo(bdt)_3$ species thus formed may pass through a highly concerted transition state in which the interaction with another OH^- ion would lead to a polar group-transfer reaction,[8] dominated by HO···OH bond making and metal reduction, to yield the $[Mo(bdt)_3]^-$ radical ($<g> = 2.006$; $<A>$ ($^{95,97}Mo$) $= 26.6 \times 10^{-4}$ cm^{-1}) and H_2O_2‡[3] which in basic solution forms the HO_2^- ion. An Eyring plot of the rate constant k determined at a series of temperatures gives an excellent straight line from which $\Delta H^{\neq} = 37.9 \pm 0.8$ kJ mol^{-1} and $\Delta S^{\neq} = -39 \pm 3$ J K^{-1} mol^{-1} are deduced. The $\Delta S^{\neq}$ value is consistent with the proposed associative transition-state.

As estimated from standard reduction potential data, the overall reaction (1) must be exergonic at least in acetonitrile solution. In fact, the redox potential for the reduction of HO_2^- to OH^- ions has been reported to be −0.11 V *vs.* ENH, [1 M $(Bu_4N)OH$, pH 30.4],[8] whereas the measured redox potential for the $Mo(bdt)_3$–$Mo(bdt)_3^-$ pair was found to be +0.610 V by cyclic voltammetry.[5] Thus, reaction (1) lies indeed far to the right.

However, the $[Mo(bdt)3]^{1-/2-}$ reduction potential is considerably more negative (−0.040 V) than that of the $[Mo(bdt)_3]^{0/1-}$ couple, and thus the former reduction must have a smaller driving force and a relatively slower reactivity. This was confirmed by monitoring the reaction of (Bu_4N)-$[(Mo(bdt)_3]$ with Bu_4NOH, which also proceeds cleanly with well-defined isosbestic points upon addition of excess base (Fig. 1b). By using the procedure indicated above, these spectra were simulated and the concentration of each complex evaluated as a function of time. The disappearance rate of $[Mo(bdt)_3]^-$ parallels the appearance rate of $[Mo(bdt)_3]^{2-}$ for all runs, but it should be noted that both rates become negligible a few seconds after the reaction starts (*ca.* 15 s), and also that a complete conversion does not take place even when an excess of *ca.* 20 equivalents of base are initially present. These observations can be plausibly explained when the equilibrium shown in reaction (2) is assumed.

$$2\ Mo(bdt)_3^- + 3\ OH^- \rightleftharpoons 2\ Mo(bdt)_3^{2-} + HO_2^- + H_2O \quad (2)$$

Support for the occurrence of this equilibrium comes from the fact that final complex concentrations are dependent on the initial Bu_4NOH concentration ($K = (1.2 \pm 0.3) \times 10^3$ mol^{-1} dm^3 at 298 K). A first analysis of the kinetic data seems to indicate a reversible process in which the rate of $[Mo(bdt)_3]^-$ reduction is first-order in both $[Mo(bdt)_3]^-$ and $[Mo(bdt)_3]^{2-}$ concentrations, being the rate constants dependent on the concentration of base.

In summary, on the basis of this and other works,[3,4] it should no longer be considered unusual to react a higher valent molybdenum tris(dithiolene) compound with hydroxide ions to produce a lower valent molybdenum tris(dithiolene) compound. Moreover, such electron-transfer processes have also been observed to occur with tungsten, *e.g.* $W(bdt)_3$, and this will be the basis of a later publication. Further investigations of the reactivity of $Mo(bdt)_3$ and related compounds in solvents other than THF may clarify whether the observed reactivity is relevant to that of molybdenum cofactor (Moco).[2]

Notes and references

† The molybdenum complex concentrations were calculated by minimising the following least-squares equation with respect to the concentration of the Mo(VI–IV) complexes:

$$\phi(c_1, c_2, \ldots, c_n; \lambda) = \sum_{k=1} (A(\lambda_k) - l \sum_{i=1} \varepsilon_i(\lambda_k) c_i)^2$$

where $A(\lambda)$ is the reaction mixture absorbance at wavelength λ, l is the optical pathway, and $\varepsilon_i(\lambda)$ and c_i, $i \in \{1\ldots3\}$, are the optical densities and concentrations of $Mo(bdt)_3$, $Mo(bdt)_3^-$, and $Mo(bdt)_3^{2-}$ species. The calculations were performed using the C++ Linux programs GssKin and GssFit. Free copies of the program are supplied under request.

Direct oxidation of sulfur-containing fuels in a solid oxide fuel cell

Hyuk Kim, John M. Vohs and Raymond J. Gorte*

Department of Chemical Engineering, University of Pennsylvania, Philadelphia, PA 19104, USA. E-mail: gorte@seas.upenn.edu

Received (in Purdue, IN, USA) 27th June 2001, Accepted 27th September 2001
First published as an Advance Article on the web 25th October 2001

Solid-oxide fuel cells with Cu–ceria anodes are shown to provide stable power generation through the direct oxidation of hydrocarbon fuels having sulfur levels similar to that in gasoline and can be regenerated by steam after being poisoned with higher sulfur levels.

The economical development of fuel cells for the near future depends on the use of hydrocarbon fuels, usually through the reforming of those fuels to hydrogen. However, most hydrocarbon fuels available today contain significant levels of sulfur. For example, approximately 10 ppm of sulfur-containing compounds are added to natural gas as an odorant. In the case of gasoline, regulations in most of the US allow 300 ppm of sulfur.[1] Even with new regulations to avoid poisoning the automotive catalytic converter, gasoline will still contain at least 20 ppm for the foreseeable future.[1] For military applications, logistical fuels can be as high as 10 000 ppm S. This sulfur represents a serious complication for fuel-cell developers, since sulfur levels must be in the ppb range for a reasonable lifetime in proton-exchange membrane (PEM) fuel cells and <1 ppm for many solid-oxide fuel cells (SOFC).[2] Indeed, for SOFC operation at 1023 K and lower, it is reported that the H_2S concentration must be below 0.05 ppm.[3] Depending on the fuel, removal of sulfur can require a complex hydrodesulfurization reactor and always requires a trap that must be periodically serviced.[2]

Direct, electrochemical oxidation of hydrocarbons, without first reforming them to H_2, is theoretically possible in an SOFC because O^{2-} is the species that diffuses through the electrolyte. An SOFC generates electricity through the reduction of O_2 to O^{2-} anions at the cathode, transfer of the anions through an electrolyte that is an electronic insulator (usually yttria-stabilized zirconia, YSZ), and finally the oxidation of the O^{2-} anions by the fuel at the anode. The anode in conventional designs is a ceramic–metallic (cermet) composite of Ni and yttria-stabilized zirconia (YSZ) which is an electronic conductor due to Ni and ionic conductor due to YSZ. However, Ni catalyzes formation of graphite from hydrocarbons; and, except for a narrow range of operating temperatures and only for methane,[4] carbon formation with Ni-based anodes is unavoidable unless steam or oxygen is fed along with the hydrocarbon.

By substituting Ni with Cu, we were able to show that carbon formation is essentially eliminated for hydrocarbon fuels,[5,6] including fuels that are liquids at room temperature such as *n*-decane, toluene and synthetic diesel.[6] While Cu provides the high electronic conductivity necessary for good anode performance, Cu–YSZ anodes are not active for the oxidation of hydrocarbons.[7] To provide activity for hydrocarbon oxidation, we have found it necessary to add ceria to the anode.[5–7] Ceria appears to help catalyze the oxidation reactions.

The fuel cells used in this study were prepared by tape-casting methods according to procedures described elsewhere.[7] Briefly, a YSZ wafer was prepared having a dense layer, 60 μm thick, supported by a porous layer, 400 μm thick. A 50:50 mixture of YSZ and LSM ($La_{0.8}Sr_{0.2}MnO_3$, Praxair Surface Technologies) powders was pasted onto the dense side of the wafer to form the cathode. Cu and ceria were then added to the porous side of the YSZ wafer, in separate steps, using wet impregnation of aqueous nitrate solutions to a final concentration of 10 wt% ceria and 20 wt% Cu, followed by heating in air at 750 K to form the oxides. Au was used to form the electrical contacts at the anode so as to avoid questions about catalytic activity. Finally, the cell with an active surface area of 0.25 cm^2 was sealed onto a 1.2 cm alumina tube using a zirconia-based adhesive.

As described in a previous paper, room-temperature liquids were introduced into the anode compartment using a syringe pump, and the liquids were vaporized in the oven used to maintain the temperature of the cell at 973 K.[6] The effect of fuel concentration and hydrocarbon type on the curves of potential *vs.* current are shown elsewhere.[6] In order to simulate a realistic, sulfur-containing fuel, this study used pure *n*-decane to which thiophene was added to achieve the desired level of sulfur. The sulfur contents are reported as the weight fraction of S in ppm. Because of the low surface area of the anode, it was not possible for us to reduce the flow rates to the point where fuel conversion was high. In the experiments reported here, the liquid flow rate was maintained at 1.0 ml h^{-1}, implying that the conversion to CO_2 and H_2O was never higher than 3%. Analysis by gas chromatography of the effluent from the cell showed that CO_2 was formed in an amount equal to the O^{2-} flux through the electrolyte.[5,6]

To control the composition of the fuel in the anode compartment and to maintain flow, dry N_2 was introduced into the anode compartment with the liquids. The fuel concentration was either 50 mol% *n*-decane in N_2 or 5 mol% *n*-decane. These correspond to the *n*-decane concentrations that would be obtained at 10 and 50% conversion if pure *n*-decane were fed to the anode and only CO_2 and H_2O were formed by reaction.

The effect of sulfur on the Cu is shown in Fig. 1. Here, the resistance between the two Au wires, pasted on opposite sides of the Cu cermet, 0.5 cm apart, was measured as a function of time. Initially, the resistance was high because the Cu was in the form of an oxide. As the temperature of the cermet was ramped in flowing H_2, the resistance dropped to metallic levels. At 16 h, while holding the sample at 973 K, the fuel was switched to 50 mol% *n*-decane (5000 ppm S), while the resistance was measured for an additional 24 h. The results demonstrate that

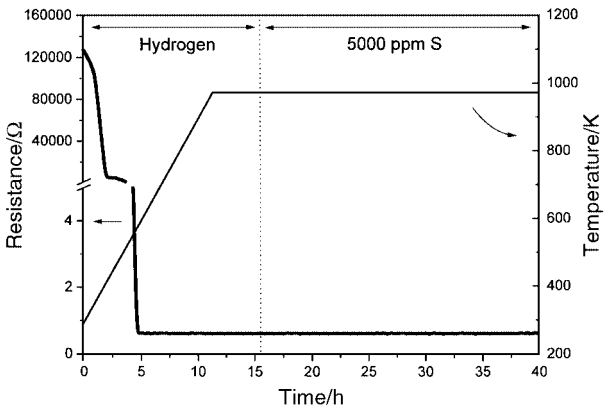

Fig. 1 The resistance measured across 0.5 cm of the Cu–ceria–YSZ cermet as a function of time. The feed to the anode was pure H_2 for the first 16 h and was then switched to 50 mol% *n*-decane containing 5000 ppm S.

 DOI: 10.1039/b105713h

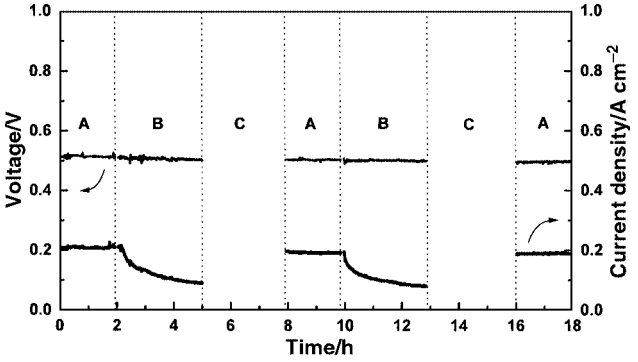

Fig. 2 Single cell performance as a function of time at 973 K, holding the cell potential at 0.5 V. The feed to the anode was: (A) 50 mol% *n*-decane in N_2; (B) 50 mol% *n*-decane, having 5000 ppm S; (C) 50 mol% H_2O in N_2.

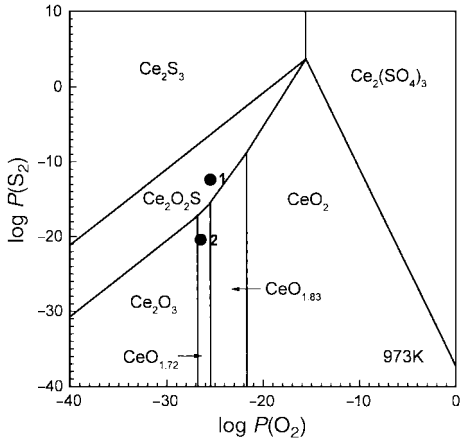

Fig. 3 The Ce–O–S phase diagram at 973 K. Points 1 and 2 correspond to the experimental conditions described in the text.

the presence of sulfur at these levels gave rise to no measurable changes in the resistance, implying that the Cu was not strongly affected. This result is not surprising, given that equilibrium calculations demonstrate that Cu_2S formation is not favorable under these conditions. While surface sulfides are reported to be more stable than bulk Cu_2S,[8] their presence would probably have no effect on anode performance, since the role of Cu appears to be only that of providing electronic conductivity.[7] It is also noteworthy that Cu has been added to the anodes of molten-carbonate fuel cells to improve the sulfur tolerance.[9]

As discussed elsewhere, ceria is an important component in the anode, probably because of its catalytic properties for hydrocarbon oxidation, and is essential for achieving good power densities for hydrocarbon fuels.[7] Fig. 2 shows the performance of the cell upon switching from 50 mol% *n*-decane (0 ppm S) to 50 mol% *n*-decane (5000 ppm S), while holding the cell potential at 0.5 V. The current density began to drop dramatically upon the introduction of sulfur and could not be restored by simply switching back to the sulfur-free fuel. However, the cell could be completely restored to its original performance level by introducing steam (50 mol% in N_2) at 973 K. As shown in Fig. 2, the cell could be poisoned and restored, repeatedly, using this procedure.

The phase diagram for ceria, calculated from the data of Dwivedi and Kay and shown in Fig. 3,[10] shows the likely cause for the sulfur poisoning. To calculate the equilibrium O_2 pressure at the anode, we used the equation for the complete oxidation of *n*-decane to CO_2 and H_2O and the conversion calculated from the current density, 1.5%. The equilibrium S_2 pressure was determined from the reaction $C_4H_4S + 2H_2 = \frac{1}{2}S + C_4H_4$, using literature values for C_4H_4S.[11] We further assumed that $P(H_2)$ and $P(C_4H_8)$ were present at the same

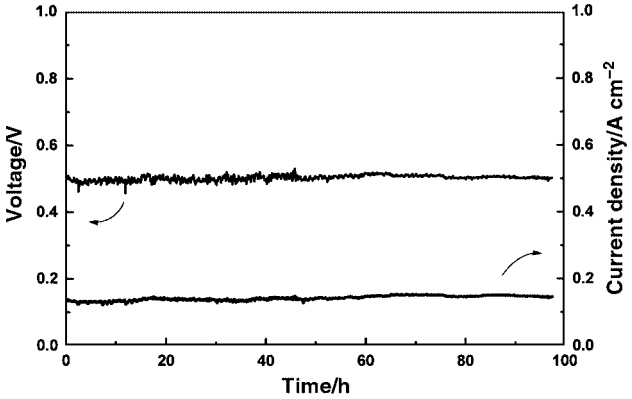

Fig. 4 Single cell performance as a function of time at 973 K, holding the cell potential at 0.5 V. The feed to the anode was 5 mol% *n*-decane containing 100 ppm S.

concentrations as *n*-decane. With these assumptions, $P(O_2)$ and $P(S_2)$ would be $10^{-25.5}$ and $10^{-12.6}$ atm, respectively, and cerium should exist as Ce_2O_2S, point 1 in Fig. 3. Heating Ce_2O_2S in steam should remove sulfur and restore CeO_2.

An obvious implication of the phase diagram is that a more modest level of sulfur should not affect the ceria in the anode. This is demonstrated in Fig. 4, which shows the cell performance in 5 mol% *n*-decane (100 ppm S). The calculated $P(O_2)$ and $P(S_2)$ for this experiment ($10^{-26.6}$ and $10^{-20.3}$ atm) are shown in point 2 of Fig. 3. Holding the cell potential at 0.5 V, Fig. 4 shows that the current density was slightly lower because of the lower fuel concentration,[6] but remained constant for 100 h in this fuel mixture. Even though the total exposure of the ceria to sulfur over this period was significant, sulfur at this concentration seems to have no effect on anode performance.

The results are extremely encouraging in that they demonstrate that fuels with moderate levels of sulfur can be used in SOFCs having anodes made from Cu and ceria. For applications with natural gas and low-sulfur gasoline, it will probably not be necessary to desulfurize or trap the sulfur before introducing it to the anode. Even for high-sulfur, logistical fuels, it may be necessary to remove only some of the sulfur. Furthermore, we have shown that a cell which has been poisoned by sulfur-containing fuels can be restored by passing steam over the anode. The implications of this for distributed-power and portable-power applications, where complex and bulky fuel-processing equipment is difficult to incorporate, are enormous.

We are grateful to the Office of Naval Research for funding.

Manganese as a template: a new synthesis of corrole

Martin Bröring* and Christian Hell

Institut für Anorganische Chemie, Universität Würzburg, Am Hubland D-97074. Würzburg, Germany. E-mail: Martin.Broering@mail.uni-wuerzburg.de

Received (in Cambridge, UK) 14th August 2001, Accepted 2nd October 2001
First published as an Advance Article on the web 22nd October 2001

The reaction of 2,2′-bisdipyrrins 1, 2, and 3 with manganese(II) acetate tetrahydrate and molecular dioxygen yields the manganese(III)corroles 4, 5 and 6, which are readily demetalated to the respective free-base corroles.

The chemistry of corrole, the one-carbon short analogue of porphyrin, is currently one of the most flourishing fields in the porphyrin area.[1] Ever since the unexpected observation by Vogel *et al.* in 1994, that this trisanionic ligand stabilises unusually high oxidation states of transition metal centers like Fe(IV), Cu(III), and Co(IV),[2] the interest in this particular macrocycle has continuously increased. The synthetic pathways leading to corroles, however, are still rather small in number, albeit a large body of work has been conducted in recent years towards general approaches to differently substituted corroles, mainly by the groups of Paolesse[3] and Gross.[4] Very recently, the first applications of corroles as ligands in catalytically active transition metal complexes have appeared in the literature,[5] and the first multi-macrocyclic architectures using corroles as building blocks have also been achieved.[6] Today, the major methods used for the preparation of corroles are the oxidative cyclization of α,ω-didesoxybiladienes-*a*,*c* as described by Murakami,[7] and the strategy of Gross *et al.*, who developed the non-catalysed condensation of pyrrole and aromatic aldehydes as a one step procedure.[4] In the course of studies towards a synthetic entry into the corrole and corrin field, Johnson *et al.* attempted to cyclize 2,2′-bisdipyrrin complexes of Pd(II) as early as 1960, but received a palladium(II)-10-oxacorrole instead.[8] Here we report, that by simply changing the metal ion to manganese the desired formation of corroles from 2,2′-bisdipyrrins[9] can in fact be observed.

As 3,3′,4,4′,8,8′,9,9′-octaethyl-10,10′-dimethyl-2,2′-bisdipyrrin **1** is treated with manganese(II) acetate tetrahydrate under aerobic conditions in boiling DMF, varying amounts of **4** build up over the course of several hours. Purging the hot reaction mixture with dioxygen accelerates the reaction significantly, so that within five minutes the cyclization is complete. After chromatography and recrystallization from diethyl ether–*n*-hexane, **4** is obtained as violet crystals in 23% yield (Scheme 1). The material obtained this way is identical in every respect with the manganese(III)octaethylcorrole reported earlier.[10] When applying the very same conditions to other α,ω-dimethyl-2,2′-bisdipyrrins,[9] substituted manganese(III)corroles can be prepared. For example, *meso*-diphenyl- and *meso*-di-*p*-tolyl-2,2′-bisdipyrrins **2** and **3** are cyclized to the manganese(III)-5,15-diarylcorroles **5** and **6** in 18 and 19% yield, respectively.[11,12]

As we experienced at an initial stage of the project, the manganese(III)corroles appear remarkably prone to oxidation by chlorinated solvents (Scheme 2). Thus, simply performing the chromatographic work-up of **4** on silica with a dichloromethane–methanol mixture as the eluent directly gave the known chloro-manganese(IV) complex **7**[1b] as the only product, albeit in diminished yield (17%). This observation provides yet another example for the ease of stabilisation of high oxidation states through the trisanionic corrole ligand.

Free base corroles are readily released from the manganese complexes by simple acid induced demetallation. For example, treatment of **4** with HBr in acetic acid yields the well-known octaethylcorrole **8** quantitatively within 10 min (Scheme 3).[7] This clean demetalation protocol makes the newly found manganese induced cyclization a useful synthetic tool towards

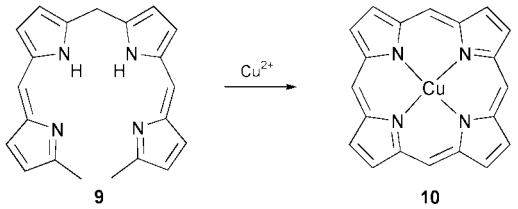

Scheme 4

substituted corrole ligands, some which are hardly or not at all accessible by any other of the corrole forming reactions known today.

Although the mechanistic details of the Mn(II)–O_2 induced cyclization of 2,2′-bisdipyrrins are still in question, the formation of **4**–**6** points to an analogous oxidative transformation in the porphyrin field, namely the reaction of *a*,*c*-biladienes **9** with several metal salts or oxidants to yield porphyrins **10** (Scheme 4). This valuable transformation, initially found by Johnson *et al*.,[13] has been thoroughly investigated and mechanistically explained by Smith.[14] It appears highly probable, that a related sequence of steps occurs also in the case of 2,2′-bisdipyrrin cyclization. As a major difference to the macrocyclization of *a*,*c*-biladienes we believe, that in our case a templating action of the metal ion—prior to or after partial oxidation—is crucial to the reaction. Most probably, the 2,2′-bisdipyrrin unit will not stabilise the tense, helical conformation necessary for ring closure on its own, but rather retain the ability of an almost free rotation around the central pyrrole–pyrrole axis. Additionally, it is quite questionable, whether the terminal methyl groups of a 2,2′-bisdipyrrin in a closed, quasi-macrocyclic conformation would have sufficient overlap without being forced by a central metal ion.

Further studies towards an understanding of the C_1 extrusion, the use of other metal ions and/or co-oxidants, and the application of the new macrocyclization in the synthesis of tailor-made and functionalized corroles and metallocorroles are currently in progress.

This work was funded by the Deutsche Forschungsgemeinschaft (Emmy-Noether-Programm) and the Fonds der Chemischen Industrie. We thank Professor Helmut Werner for his generous support.

Received (in Cambridge, UK) 6th September 2001, Accepted 9th October 2001
First published as an Advance Article on the web 25th October 2001

Novel dimeric fullerenes incorporated in a 2,3-diazabicyclo[2.2.2]oct-2-ene framework, with and without direct inter-fullerene-cage bonds, were synthesized and fully characterized spectroscopically; the electronic communication between the two fullerene cages was clarified by differential pulse voltammetry.

Dimeric fullerene compounds are attracting current interest not only from the structural curiosity but also concerning their electrochemical properties, as the partial structure of fullerene polymers.[1] In some of such compounds having direct C–C bond(s) between the fullerene cages has been reported the occurrence of electronic communication between the fullerene units upon electroreduction.[2,3] We recently reported electronic communication in a dimeric compound without the direct C–C bond between the fullerene cages.[4] Herein we report the synthesis and properties of new dimeric fullerenes incorporated in a 2,3-diazabicyclo[2.2.2]oct-2-ene framework, with and without the covalent bonds directly between the two cages.

The synthesis of dimeric compound **2** was conducted by the solid-state reaction of fullerene C_{60} with 0.5 equiv. of di(2-pyridyl)-1,2,4,5-tetrazine (Scheme 1). The key intermediate **1**[4a,5] was found to be formed quantitatively under the high-speed vibration milling (HSVM) conditions[4,6] for 30 min. The [4 + 2] cycloaddition of resultant **1** with C_{60} was achieved by heating the solid mixture of **1** and C_{60} at 150 °C for 2 h. After flash chromatography over SiO_2, the dimeric compound **2**† without inter-cage bonds was obtained in 27% yield along with 40% of recovered C_{60}. This dimeric compound **2** was obtained only by the solid-state reaction, in which the highest concentration of the reactants without any solvation can cause the closest contact of the reacting species. The reaction in solution has been reported to result in only hydrogenation of **1**.[5,7]

The structure of **2** was determined based on the following spectral data.† The MALDI-TOF MS spectrum showed a molecular ion peak at *m*/*z* 1649 with the isotopic distribution pattern identical to the calculated one for $C_{132}H_8N_4$ as shown in Fig. 1. The ^{1}H NMR exhibited only one type of 2-pyridyl group. The ^{13}C NMR showed 33 signals (one signal overlapped) in the sp^2 carbon region and 2 signals in the sp^3 carbon region. These data support the structure of **2** having C_{2v} symmetry with two C_{60} cages rigidly fixed in close proximity by incorporation in a 2,3-diazabicyclo[2.2.2]oct-2-ene framework. Although it was expected that extrusion of a nitrogen molecule from **2** and the addition of another molecule of C_{60} would give a C_{60} trimeric compound, like triptycene having fullerene instead of benzene, **2** was found to be stable in the solid state at temperatures as high as 250 °C. Such nitrogen extrusion was observed only under the MALDI-TOF MS conditions as shown in Fig. 1.

When a solution of **2** in *o*-dichlorobenzene (ODCB) was irradiated with room light for 3 h, a novel C_{60} dimer **3**‡ with direct inter-cage bonds was formed quantitatively by the intramolecular [2 + 2] cycloaddition[8] (Scheme 1). This reaction was monitored by UV-vis spectra which displayed decreasing absorption at 329 nm and increasing absorption at 441 nm with isosbestic points at 312, 353, and 535 nm as shown in Fig. 2. The ^{1}H NMR spectrum of **3** showed two types of 2-pyridyl groups and the ^{13}C NMR spectrum exhibited 61 signals (five signal overlapped) in the sp^2 carbon region and 6 signals in the sp^3 carbon region. These data support the structure of **3** having

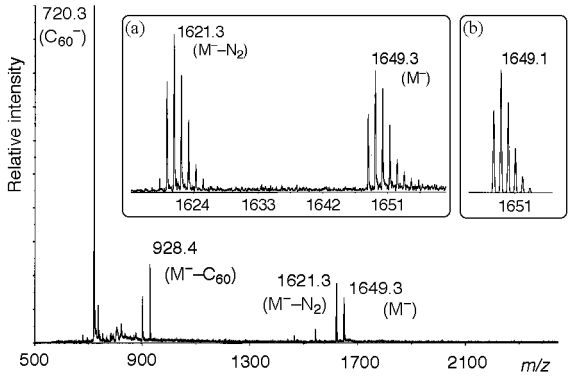

Fig. 1 MALDI-TOF MS spectrum of **2** in a dithranol matrix (negative-ion reflector mode); inset (a) molecular-ion region, (b) a theoretical isotropic pattern for $C_{132}H_8N_4$.

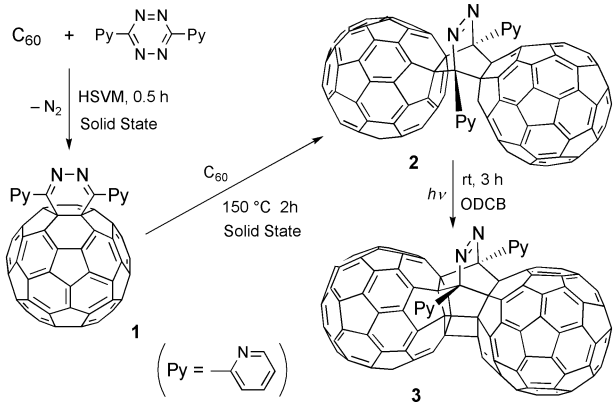

Scheme 1

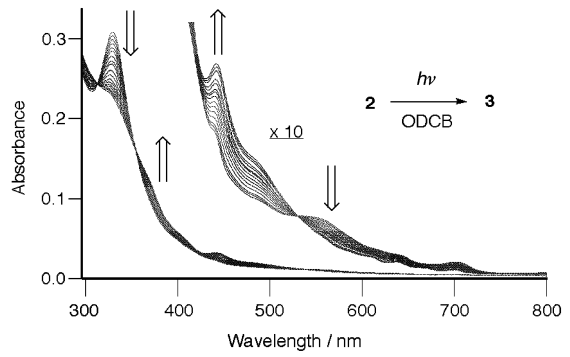

Fig. 2 Time-dependent UV-vis spectral changes observed upon irradiation of **2** (in ODCB, 3.06×10^{-5} M) with room light for 3 h.

 DOI: 10.1039/b107922k

C_s symmetry with two C_{60} cages directly connected by sharing a newly formed cyclobutane ring. It was found that dimeric compound **3** does not revert to **2** either under the thermal (in ODCB, 100 °C, 2 h) or photochemical (visible light) conditions. This observation was supported by theoretical calculations which show that the relative energy of **3** is lower than that of **2** by 4.24 kcal mol^{-1} at the B3LYP/3-21G level of theory.[9]

The redox properties of these dimeric compounds were studied by differential pulse voltammetry in ODCB in order to investigate the possible electronic communication between the two fullerene cages closely located to each other.[2–4] As shown in Fig. 3, **2** displayed three sets of reduction peaks, each of which consisted of two closely located reduction peaks (−1.09, −1.15, −1.52, −1.58, −2.11, and −2.19 V *vs*. Fc/Fc$^+$), indicating that the reduction takes place stepwise on each fullerene cage due to the small but clear electronic communication between two cages. However, **3** showed two sets of two reduction peaks (−1.11, −1.20,−1.56, and −1.63 V) and then two isolated reduction peaks at −2.03 and −2.32 V. The difference in voltage between the fifth and sixth reduction peaks for **3** is quite large, suggesting that the electronic interaction is large after the fifth reduction because of the effects of Coulombic repulsion between the negatively charged fullerene cages. Although the reason for the close distance between the third and fourth reduction peaks compared with that between the first and second peaks is not clear, the overall reduction profile of **3** is quite similar to that of C_{121} reported by Dragoe.[3]

In summary, novel fullerene dimers **2** and **3** were synthesized using a solid-state reaction as a key technique. The intramolecular [2 + 2] reaction in **2** forming a cyclobutane ring readily took place photochemically to give **3**. The newly formed cyclobutane ring was found to be thermally and electrochemically stable, which is in sharp contrast to the ready cleavage of the [2 + 2] bonds upon heating[6c,8] or reduction[4b,6c] in dimer C_{120} and in compounds with a related structure.

This work was supported by a Grant-in-Aid for COE Research on Elements Science (No. 12CE2005) from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

Chelating alkoxy-N-heterocyclic carbene complexes of silver and copper†

Polly L. Arnold,* Andrew C. Scarisbrick, Alexander J. Blake and Claire Wilson

School of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: Polly.Arnold@nott.ac.uk

Received (in Cambridge, UK) 31st August 2001, Accepted 27th September 2001
First published as an Advance Article on the web 22nd October 2001

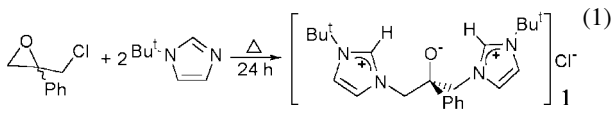
Incorporation of an alkoxide functional group into an N-heterocyclic carbene (NHC) ligand allows the synthesis of the first anionic NHC chelating ligands, which react to give the first neutral, molecular silver(I) alkoxide carbene complex, and a copper(I) derivative containing the first non-macrocyclic, square planar Cu(I) centres.

The surge in recent research focused on stable N,N′-dialkylated heterocyclic carbenes (NHC) has been fuelled in part by results that show that these strong σ-donor ligands can significantly increase the reactivity of many homogeneous catalysts.[1] The straightforward synthesis of the imidazolium precursors has pushed these phosphine replacements to the forefront of catalyst design.

To date, almost all NHC ligand tuning has involved N-functionalisation with chiral hydrocarbyl groups, or other pendant neutral donor ligands (a second NHC or pyridyl, phosphine, carbonyl or ether groups).[2] These derivatives have been used almost entirely to enhance the catalytic properties of the platinum group metals. Surprisingly, only monodentate NHC 'solvated' adducts of more electropositive metals have been characterised.

We have targeted the first NHC-based chelate ligand that incorporates a hard, anionic functional group, in this case an alkoxide. Despite the calculated strength of the Cu(I)–carbene bond (319 kJ mol^{-1}) and the involvement of the copper carbene fragment in a number of important catalytic processes,[3] remarkably few copper carbene complexes have been reported, and their synthesis is not always trivial.[4] We report herein a one-pot synthesis of the imidazolium precursor to a mixed alkoxide/carbene ligand, and the observation that the combination of the anionic binding site with the NHC provides easy access to stable silver and copper carbene complexes.

Simplicity and atom efficiency is achieved by using functionalised epichlorohydrin as the source of the anionic alkoxide binding site. The combination of an imidazolium and alcohol group has been achieved in two previous instances, but neither targeted a metal–alkoxide product.[5] The zwitterionic diimidazolium salt **1** (the proligand) is accessible as a hygroscopic cream-coloured powder from the one-pot reaction of two equivalents of *N-tert*-butylimidazole with 2-chloromethyl-2-phenyloxirane at 100 °C for 24 h, followed by washing with dry THF, eqn. (1).‡ Recrystallisation from CH_2Cl_2–THF



(1)

produces colourless crystals of **1**·HCl·3H_2O, the structure of which, as determined by X-ray crystallography, is shown in Fig. 1.§

Ionic silver NHC adducts, already recognised as valuable transmetallation reagents in NHC chemistry, may be directly

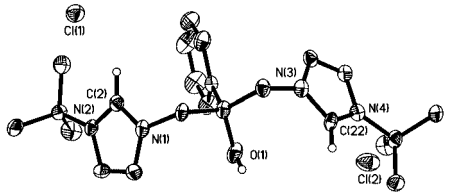


Fig. 1 Ellipsoid plot of the molecular structure of [**1**H]$^+$Cl$^-$, solvent H_2O and peripheral hydrogens omitted for clarity, 30% probability. Selected distances (Å) and angles (°); O1–C10 1.433(8), N–C(2, 22) range 1.301(7) to 1.338(7), N–C(2, 22)–N 109.4(5), 109.1(5).

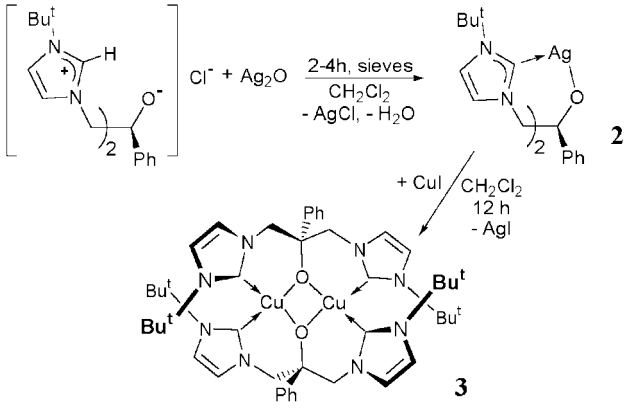
accessed by treating the imidazolium precursor salt with a basic silver salt such as silver oxide.[6] The diimidazolium **1** is readily deprotonated upon treatment with Ag_2O to afford the neutral silver(I) alkoxide carbene **2** within 4 h at room temperature in dichloromethane, if activated 4 Å molecular sieves are added, Scheme 1.‡ Complex **2** is modestly light and air sensitive ($t_{1/2}$ ~ 12 h for a powdered sample on the bench).

The halide-free, neutral, silver alkoxy-carbene **2** Ag–NHC complex should be an ideal vehicle for the transfer of the alkoxide-functionalised carbene to other metals using the driving force of silver halide precipitation. Noting the failure of copper halides and simple derivatives to react with other ionic Ag–NHC reagents,[4] we looked to copper halides as a suitable test for the transmetallation reactions of **2**.

Accordingly, treatment of a concentrated dichloromethane solution of **2** with one equivalent of copper iodide furnishes a red solution from which, after filtration to remove silver iodide, dark red crystals of the neutral copper alkoxide-carbene **3** may be isolated in 85% yield, see Scheme 1.§ Upon deprotonation, as expected, the chemical shift of the carbenoid C shifts to higher frequency by about 40 ppm, to the characteristic $C_{carbene}$ values of 179 (**2**) and 181 ppm (**3**). It is broadened in **2**, presumably due to coupling to the silver nuclei and non-rigidity in the complex (the ^{1}H NMR spectrum of **2** also shows broadening of the shifts at 300 K).

A single crystal X-ray structure determination of the copper complex **3** shows the dinuclear solid-state structure, Fig. 2, and confirms that the copper centre is co-ordinated by both the alkoxide and two carbene centres.



Scheme 1 Synthesis of the copper carbene complex **3**.

† Electronic supplementary information (ESI) available: spectroscopic data for **1**–**3**, cyclic voltammetry. See http://www.rsc.org/suppdata/cc/b1/b107855k/

 DOI: 10.1039/b107855k

The most notable feature in the structure is that the Cu(I) centres exhibit nearly square planar geometry, the angle between the CuO_2 and CuC_2 planes is 14.0(2)°. We can find only two four-co-ordinate Cu(I) complexes in the literature which achieve this degree of planarity. Each is found as one metal of an M_2O_2 core in the centre of a dinucleating compartmental macrocycle; the analogous plane–plane angle in each is 11.9°.[7]

The average Cu–$C_{carbene}$ distance of 1.963(4) Å is at the upper end of the C(sp^3)–Cu(I) bond distance range, confirming the absence of π-character in the bond.[8] In comparison to the imidazolium geometries, each carbene ring displays a lengthened $C_{carbene}$–N bond and narrowed N–$C_{carbene}$–N angle, concomitant with the increase in p character of the N–C bond after deprotonation.[9]

Since the Cu(I)–alkoxide bond is not regarded as particularly stable, it is interesting that this tridentate ligand, which combines hard alkoxide and soft NHC functionalities, is so effective in stabilising the Cu(I) centres, and in such an unexpected geometry. The near planarity of each Cu(I) centre suggests the oxidation to Cu(II) might be accessible. The cyclic voltammogram of a CH_2Cl_2 solution shows two irreversible oxidations at +0.435 and +0.850 V *vs*. Fc^+/Fc, whilst that in acetonitrile shows a quasireversible first oxidation at +0.717 V, and a second irreversible oxidation at 1.06 V *vs*. Fc/Fc^+. The proximity of the *tert*-butyl groups appears not to allow absolute square planarity of a smaller Cu(II) ion, but how the peculiar electronic structure of the carbenes influences the frontier MOs of the complex **3** clearly needs to be addressed.

Importantly, deprotonation of the imidazolium protons in **1** with Ag_2O is completely selective and does not require forcing conditions. The use of silver carbenes instead of free NHCs is becoming increasingly widespread, both as a method to avoid unselective deprotonations of N-functionalised NHCs, and due to the tolerance to air and moisture of both precursors and the silver salts.[10] The synthesis of **2** is driven by precipitation of silver chloride which is readily removed. Thus this neutral silver alkoxycarbene contrasts with previously reported silver–carbene salts (which tend to retain silver halide, forming $[NHCAg]^+[AgHal_2]^-$ ion pairs) and should provide access to a range of alkoxide-supported NHC metal complexes.[10]

To conclude, we have described a one-pot reaction to combine two imidazolium heterocyclic cations with an alkoxide anion. Deprotonated, this forms the first chelating ligand to bind to a metal through an anionic alkoxide bond as well as through the N-heterocyclic carbene group. Structural studies have shown an unusual near-planar conformation for the copper(I) derivative—unprecedented in non-macrocyclic complexes.

Intercalation and controlled release of pharmaceutically active compounds from a layered double hydroxide†

Aamir I. Khan, Lixu Lei, Alexander J. Norquist and Dermot O'Hare*

Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR. E-mail: dermot.ohare@chem.ox.ac.uk

Received (in Cambridge, UK) 20th July 2001, Accepted 10th October 2001
First published as an Advance Article on the web 19th October 2001

A series of pharmaceutically active compounds including diclofenac, gemfibrozil, ibuprofen, naproxen, 2-propylpentanoic acid, 4-biphenylacetic acid and tolfenamic acid can be reversibly intercalated into a layered double hydroxide, initial studies suggest that these materials may have application as the basis of a novel tuneable drug delivery system.

In order for drug therapy to be most effective the desired pharmacological response must be obtained at the target without harmful interactions at other sites.[1] This requires the correct amount of drug to be absorbed into the body and transported to the target with control of the drug rate input in order to produce the correct dosage. Ideally the delivery of the drug to other tissues should be minimised or prevented, however this is rarely achieved owing to the complex nature of these processes.[2] Modern controlled release systems are usually polymer based with mechanisms of release regulated by diffusion, bioerosion, degradation and swelling or the production of osmotic pressure. Exposing the polymer–drug mixture to the gastrointestinal fluid results in the diffusion of the drug from the tablet or capsule and the polymers are excreted. Certain polymer–drug complexes undergo bio-erosion or degradation when they pass through the gastrointestinal tract. Swelling or the generation of osmotic pressure occurs with other polymer–drug formulations upon contact with gastrointestinal fluid resulting in the release or expulsion of the drug.[3]

Controlled release systems have many advantages but also have disadvantages. The main advantage is the decreased fluctuation in drug concentration resulting in reduced toxicity. In addition, the reduction in the number of doses may lead to lower patient care time and also to the use of a smaller amount of drug. However, disadvantages include the increased amount of time required to achieve therapeutic blood concentrations, dose dumping and usually an increase in the cost.[3] Not all drugs are suitable for controlled release systems—those not suitable are drugs with very short or very long half lives, poor absorption through the gastrointestinal tract and low solubility.[4] Controlled release systems are most useful for drugs that are taken on an extended basis such as drugs used to treat cardiovascular disorders and arthritis. Layered double hydroxides (LDHs) represented by the general formula $[M^{II}_{(1-x)}M^{III}_{x}(OH)_2]$-$[A^{n-}_{x/n}]\cdot zH_2O$ or $[M^{I}M^{III}_2(OH)_6][A^{n-}_{1/n}]\cdot zH_2O$, where M^{I}, M^{II} and M^{III} are mono-, di- and tri-valent metal cations, respectively, are now well established as excellent anion-exchange materials and their extensive intercalation chemistry has widespread applications in areas such as heterogeneous catalysis,[5,6] optical materials,[7,8] biomimetic catalysis,[9,10] separation science[11,12] and as DNA reservoirs.[13,14]

Here we report the reversible intercalation of a number of active cardiovascular and anti-inflammatory agents into a layered double hydroxide and the results of an initial study into the use of these drug–inorganic hybrid materials as a novel tuneable drug delivery system.

As a number of well known cardiovascular, anti-inflammatory and analgesic agents are either carboxylic acids or carboxylic derivatives we were interested in investigating whether these compounds could be ion-exchange intercalated in a layered double hydroxide. $[LiAl_2(OH)_6]Cl\cdot H_2O$ reacts with 2 equivalents of either the sodium salts of diclofenac, gemfibrozil, ibuprofen, naproxen, 2-propylpentanoic acid, 4-biphenylacetic acid or tolfenamic acid (Table 1) in H_2O at 60 °C for 1–2 h to give a LDH–drug intercalation compound. The solid products are isolated by filtration and then washed with an excess of deionised water and then acetone. In each case full anion exchange of the interlayer Cl^- anions and intercalation of these pharmaceutically active compounds has taken place. In each case the products are first stage intercalation compounds and they have all been fully characterised using X-ray powder diffraction (XRD), elemental microanalysis, IR spectroscopy and thermogravimetric analysis. The observed interlayer spacings for the drug–LDH intercalates are shown in Table 1, the values are consistent with the formation of bilayer arrangement for all the drug molecules with the positively charged $[LiAl_2(OH)_6]^+$ layers of the host lattice. In all cases the intercalated anions can be quantitatively recovered from the host lattice by treatment of the intercalates with either an aqueous solution of M_2CO_3 (M = Na or Li) or addition of dilute HCl. In the case of treatment with an alkali metal carbonate, the alkali metal salt of the organic guest ions goes into solution and

Table 1 Summary of the guest molecule used and the analytical and structural data of the LDH–drug intercalation compounds

Guest	Molecular structure of guest[a]	Interlayer spacing/Å[b]	Elemental analysis: found (calc.)[c]
4-Biphenylacetic acid ($C_{14}H_{12}O_2$)		20.4	C, 30.77 (30.77); H, 5.16 (5.20); $x = 0.58$, $y = 2$
Diclofenac ($C_{14}H_{10}Cl_2NaNO_2$)		22.3	C, 30.91 (30.92); H, 4.12 (3.91); N, 2.60 (2.58); $x = 0.72$, $y = 1$
Gemfibrozil ($C_{15}H_{22}O_3$)		23.2	C, 35.35 (35.36); H, 6.56 (6.65); $x = 0.69$, $y = 1$
Ibuprofen ($C_{13}H_{18}O_2$)		22.7	C, 31.92 (31.98); H, 6.15 (5.99); $x = 0.75$, $y = 3$
Naproxen ($C_{14}H_{14}O_3$)		21.5	C, 27.91 (28.08); H, 4.98 (4.99); $x = 0.48$, $y = 1$
2-Propylpentanoic acid ($C_8H_{16}O_2$)		18.7	C, 14.78 (14.82); H, 5.77 (6.04); $x = 0.35$, $y = 1$
Tolfenamic acid ($C_{14}H_{12}ClNO_2$)		21.9	C, 23.24 (23.18); H, 5.25 (5.29); N, 1.90 (1.93); $x = 0.46$, $y = 3$

[a] Neutral guest molecules were converted to the sodium salt prior to intercalation. [b] Based on hexagonal cell: $\alpha = \beta = 90$, $\gamma = 120°$, $a = b = 5.1$ Å and $c = 2 \times d_{(002)}$ [c] Based on the general formula $Li_xAl_2(OH)_6[drug]_x \cdot yH_2O$

the solid phase is quantitatively converted to $[LiAl_2(OH)_6](CO_3)_{0.5}\cdot H_2O$ as indicated by the XRD data which shows a series of 00*l* reflections corresponding to an interlayer spacing of 7.51 Å. Addition of dilute aqueous HCl solution to the LDH–drug complex results in dissolution of the inorganic host and precipitation of the neutral form of the guest acid.

Given that these ions could be recovered intact from the LDH host we were interested to see if this could form the basis of a drug reservoir and controlled release system. Therefore, we performed a series of experiments in order to quantitatively monitor the kinetics of release of the guest ions under conditions which would resemble physiological conditions. Deintercalation of the drugs from the LDH was performed by the addition of the drug–LDH complex to 250 ml of phosphate buffer solution at 37 °C of pH 7 or pH 4. A mass of 0.025 g of the LDH–drug complex was used for 4-biphenylacetic acid, diclofenac and tolfenamic acid and a larger amount of 0.1 g for naproxen and gemfibrozil. Aliquots were removed from the reaction mixture at regular intervals and solution UV–Vis absorption spectroscopy was used to quantify the concentration of the de-intercalated ions in the aqueous phase. Fig. 1 shows release profile plots for the deintercalation of diclofenac and of gemfibrozil on addition of phosphate buffer at pH 4 and pH 7. At pH 4 the measured release of diclofenac and gemfibrozil is very fast with almost full deintercalation observed in less than 10 min. Surprisingly, the release curve for gemfibrozil at pH 7 is almost identical to the profile recorded at pH 4. At pH 7 the release of diclofenac is much slower and only after 28 min is 90% of the drug released into solution. Table 2 is a summary of the release profiles for all the different guest ions that we have intercalated in $[LiAl_2(OH)_6]Cl\cdot H_2O$.

In summary, the results show that the intercalation of pharmaceutically active compounds that form stable anions is a feasible approach for the storage then subsequent controlled release of bioactive agents. We anticipate that there will be tremendous scope for fine tuning the intercalation and de-intercalation kinetics in these materials by employing different LDHs with differing charge densities and basicities.

Table 2 Release profile data

	Release times/min[a]			
	pH 4		pH 7	
Guest molecules	t_{50}[b]	t_{90}[b]	t_{50}[b]	t_{90}[b]
Diclofenac (λ_{max} = 279 nm)	1	4	1	28
Naproxen (λ_{max} = 317, 330 nm)	1	9	1	17
Gemfibrozil (λ_{max} = 275 nm)	1	5	1	5
Tolfenamic acid (λ_{max} = 290 nm)	1	21	1	23
4-Biphenylacetic acid (λ_{max} = 290 nm)	1	2	1	35

[a] Release (%) = $(I_t/I_{max}) \times 100$, at λ_{max}. [b] t_{50} and t_{90} are the times for 50 and 90% release, respectively.

Unusual electronic absorption changes in the 800–2200 nm region by intramolecular dimer radical cations from photoirradiated *meso*-2,4-bis[4-(4′-nitrostyryl)pyridinium]pentane ditetraphenylborates during storage in the dark

Received (in Cambridge, UK) 23rd August 2001, Accepted 8th October 2001
First published as an Advance Article on the web 26th October 2001

Electronic absorption spectra were remarkably changed in the broad near-infrared region for photoirradiated *meso*-2,4-bis[4-(4′-nitrostyryl)pyridinium]pentane ditetraphenylborates during storage in the dark, which was attributed to conformational changes of the intramolecular dimer radical cations between sandwich and partially overlapped types.

We have been studying absorption spectra changes in the visible and near-infrared (NIR) regions due to photoinduced electron transfer.[1–12] We reported, for the first time, a charge resonance (CR) band as a broad absorption with a peak in the NIR region upon steady photolysis of 4-substituted styrylpyridinium tetraphenylborate (TPB^-) in organic solutions at rt as a result of electronic interaction between a photogenerated styrylpyridinyl radical and a parent styrylpyridinium cation.[4] The CR band characterized by its absorption spectrum in the NIR region had been known for dimer radical cations only between the neutral aromatic compound and its oxidized form as a transient species or a stable one at near 77 K, until we reported the CR band between a substituted styrylpyridinium cation and its photoreduced form.

The peak wavelength of the CR band corresponding to twice the stabilization energy of dimer radical cations is affected by many factors such as the extent of overlapping of two chromophores, the conformation, or the electronic distribution. Intramolecular dimer radical cations are especially interesting since it is possible to control the CR band by the structure of the connecting unit. The intramolecular dimer radical cation is one of the promising candidates for materials with large refractive index and/or absorption changes in the 1300–1600 nm region together with fast responses, which are greatly needed for near future all-optical data processing.

Recently we reported the formation of intramolecular dimer radical cations in 1,3-bis[4-(4′-nitrostyryl)pyridinium]propane ditetraphenylborates (SPPr).[7] Two types of intramolecular CR bands, sandwich and partially overlapped, were observed in SPPr upon steady photolysis. Two chromophores connected by a trimethylene bridge in SPPr showed much more efficient intramolecular CR interactions compared with those having shorter or longer alkyl bridges, *e.g.*, ethane, butane and hexadecane.[7,9] A shift of the peak wavelength was observed from 1742 to 1505 nm in 3 h after steady photolysis of SPPr, although the absorbance at each wavelength was very weak.[7] Yamamoto *et al.* studied the intramolecular CR band for several chromophores linked with a tri-methylene chain in organic solutions at rt by ns laser photolysis.[13–17] They observed sandwich and partially-overlapped dimer radical cations for carbazole, pyrene, naphthalene, anthracene and phenanthrene as transient species with lifetimes of a few ms. Peak wavelengths of the intramolecular CR band observed in these measurements are between 1050 and about 2000 nm depending on chromophores and the type of overlapping.[13–17] No shift of the CR band was, however, observed after flash photolysis to indicate any change in conformation or overlapping of the two chromophores.

We now report unusual absorption changes in 800–2200 nm due to the intramolecular CR band of styrylpyridinyl radicals, formed by steady photolysis of newly synthesized *meso*-2,4-bis[4-(4′-nitrostyryl)pyridinium]pentane ditetraphenylborates (*m*-SPPe), during storage in the dark in solutions at rt, clearly indicating a change in conformation and overlapping of the two chromophores in dimer radical cations.

Synthesis of tetraphenylborate (TPB^-) salts of *m*-SPPe will be published elsewhere. The purity was confirmed by 300 MHz NMR and HPLC. Absorption spectra were recorded on a Hitachi U-3500 spectrophotometer upon irradiation *in vacuo* by a Hamamatsu 150 W Hg-Xe lamp through a band pass filter (λ_{ex} = 405 nm) at rt. All absorption spectra reported were the difference between those after and before irradiation. Fig. 1 shows absorption spectra just after irradiation of *m*-SPPe in acetonitrile (ACN) at room temperature. The visible absorption band was assigned to styrylpyridinyl radical formation[3–8] by photoinduced electron transfer from TPB^- which is known to be decomposed after oxidation.[4,10,11] Two bands at 920 and 1734 nm in the NIR region were attributed to a sandwich form and a partially overlapped one of intramolecular dimer radical cations, respectively, in comparison with those observed in SPPr[7] and from the fact that both of them disappeared upon introduction of air. Two chromophores in the sandwich form I and II as shown in Fig. 2 can interact with each other to give the CR band at 920 nm. An example of the partially overlapped form is shown in Fig. 2 III, which will give the CR band at 1734

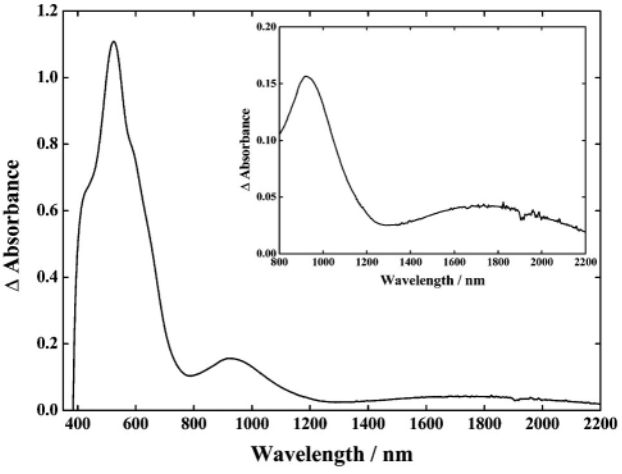

Fig. 1 Difference absorption spectra in 400–2200 nm region after irradiating *m*-SPPe in ACN solution (0.25 mM) through a band pass filter (405 nm) for 4 min. The inset shows the enlarged spectra in the 800–2200 nm region.

 DOI: 10.1039/b107504g

nm with a lower stabilization energy (34.4 kJ mol^{-1}) than the sandwich form (64.8 kJ mol^{-1}). The overlap of π-orbitals of both chromophores at the trimethylene bridge is maximized, and known as Hirayama's rule.[18] The CR bands of *m*-SPPe are stronger by a factor of 1.3 at 920 nm and of 2.1 at 1734 nm as compared with those of SPPr studied under the same conditions.[7] These results clearly indicate that two additional methyl groups in *m*-SPPe contributed to the conformational confinement of both sandwich-type and partially overlapped intramolecular dimer radical cations formed just after irradiation.

Very interestingly, the absorption spectra of *m*-SPPe irradiated for 4 min changed dramatically during storage in the dark at rt as shown in Fig. 3. The strong band at 920 nm decayed monotonically and a very broad band with a peak at 1559 nm and a shoulder at 1300 nm appeared concomitantly. The less stabilized partially overlapped dimer radical cation with a peak at 1734 nm, which is most probably caused by the excess energy in photoreaction products, also seemed to shift to 1559 nm at the initial stage of storage in the dark. The absorbance of the new band increased gradually until 20 h at the expense mostly of the band at 920 nm with an isosbestic point at 1060 nm for spectra **b–d**. Then it decayed very slowly in the dark due to radical reactions, surviving even after 100 h as shown in Fig. 3 (**e**). The maximum absorbance of the newly observed CR band at 1559 nm was about 4.5 times larger than that at 1734 nm and exceeded even the initial absorbance of the sandwich form at 920 nm. This broad band with a peak at 1559 nm can be assigned to thermodynamically stabilized partially overlapped dimer radical cations which were formed from both the non-thermalized partially overlapped one and from the sandwich-type formed just after photoinduced electron transfer. Such change from the sandwich-type to the partially overlapped is most probably due to electronic repulsion. These changes in the NIR region during storage in the dark showed strong temperature dependences. No changes were observed below 15 °C, most probably because of a high energy barrier. Similar spectral changes were observed in SPPr, but absorbance of the new band at 1505 nm was smaller, about 80%, than the band at 1742 nm and was less than a half of the sandwich form.[7] The lifetime of the new band in SPPr was much shorter.[7] These results confirmed again the remarkable effect of two methyl groups at the 2- and 4-positions of *m*-SPPe on the conformational confinement of two chromophores forming dimer radical cations.

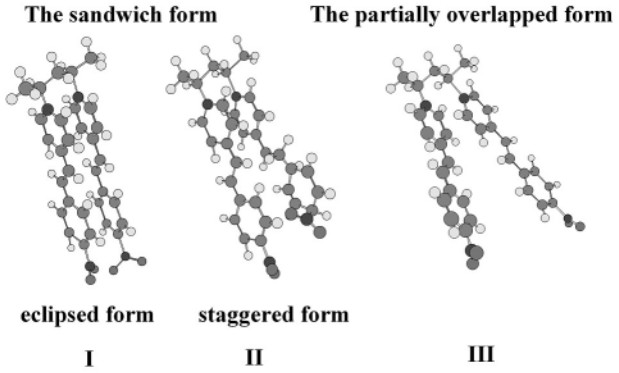

Fig. 2 Proposed models of the sandwich (I and II) and partially overlapped (III) forms of imtramolecular dimer radical cations in *m*-SPPe.

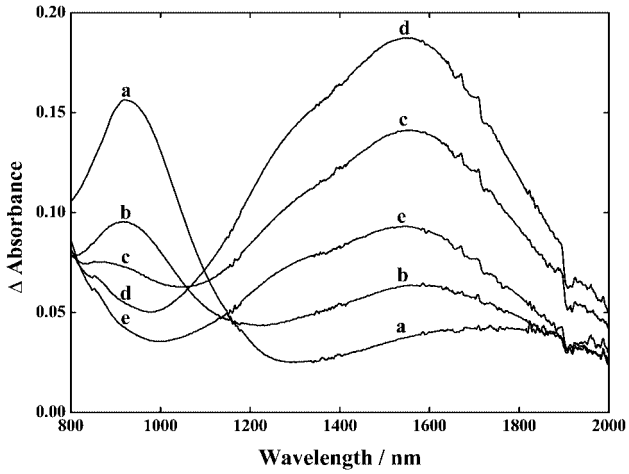

Fig. 3 Difference absorption spectra changes in 800–2000 nm region of *m*-SPPe irradiated for 4 min. (**a**) Just after irradiation, (**b–e**) after storing in the dark for (**b**) 2 h, (**c**) 6 h, (**d**) 20 h, and (**e**) 100 h.

Unusual spectral changes in the NIR region were reproducible in successive cycles of photoexcitation at least several times, because each photoreaction was limited to only a small conversion of less than 10%. The change of a counter ion from TPB$^-$ to bromide, which shows reversible transient electron transfer, will give a totally reversible system upon pulsed laser excitation.

In conclusion, we have achieved unusual absorption changes in the broad NIR region, which finally gave an absorption with a peak at 1559 nm, by newly synthesized *m*-SPPe during storage in the dark at rt. Two methyl groups at the 2- and 4-positions of *m*-SPPe greatly contributed to the conformational confinement of two chromophores in the intramolecular dimer radical cation between a photogenerated styrylpyridinyl radical and a parent styrylpyridinium cation. The absorbance and stability of the CR band were remarkably increased as compared with the 1,3-propane derivative. Such strong absorption change in the NIR region can be used to control the complex refractive index in the molecular photonic device proposed by us[19–23] at the wavelength compatible with the present light communication.

This work was partly supported by the Grant-in-Aid for Scientific Research on Priority Areas 'Molecular Synchronization for Design of New Materials System' (No. 11167242, 13022230) from the Ministry of Education, Science, Sports and Culture, Japan.

Received (in Cambridge, UK) 26th July 2001, Accepted 4th October 2001
First published as an Advance Article on the web 26th October 2001

A novel, three-dimensional copper diphosphonate $Cu_4\{CH_3C(OH)(PO_3)_2\}_2(C_4H_4N_2)(H_2O)_4$ (1) incorporating an organic pyrazine ligand has been hydrothermally synthesized, which exhibits antiferromagnetic ordering below 4.2 K and metamagnetic behavior.

Continuous attention has been paid to the porous materials based on metal phosphonates owing to their potential applications in exchange, sorption and catalysis, *etc*.[1] Several approaches, including the direct reaction between metal ions and suitable mono- or di-phosphonic acids[2–6] and the reaction through template influences,[7,8] have been employed to explore novel phosphonate compounds with porous or open framework structures. The approach using a second ligand, either inorganic or organic, however, has not been well documented. Only a few zirconium phosphonates have been prepared by introducing small anions of phosphate (PO_4^{3-}) or phosphite (HPO_3^{2-}) into the inorganic layers and thus creating large pore sizes.[9,10] A vanadium copper phosphonate containing a terminal organic ligand (2,2′-bipyridine) has also been reported recently.[11] Based on 1-hydroxyethylidenediphosphonate [$CH_3C(OH)(PO_3)_2^{4-}$, $hedp^{4-}$] and a pyrazine (pz) bridging ligand, herein we describe the synthesis and crystal structure of a novel copper phosphonate compound $Cu_4\{CH_3C(OH)(PO_3)_2\}_2(C_4H_4N_2)(H_2O)_4$ (**1**) with an open framework structure. The magnetic properties of this compound have been investigated.

The hydrothermal reaction of $Cu(NO_3)_2$, 50% $hedpH_4$, pyrazine, NaOH and H_2O in a molar ratio of 1:1.3:1:4:444 (pH ≈ 3) at 140 °C for 48 h afforded blue, needle-like crystals of **1** as a single phase. Thermal analysis showed a one-step weight loss (9.3%) below 230 °C, corresponding to the removal of four water molecules (calc. 8.9%). Single crystal structural determinations‡ reveals a three-dimensional open framework structure composed of $\{Cu_4(hedp)_2(H_2O)_2\}_n$ layers connected by pyrazine bridges (Fig. 1). The copper(II) phosphonate layer consists of $\{Cu_3(hedp)_2(H_2O)_2\}$ double chains linked by $\{CuO_4\}$ units (Fig. 2). Within the double chain, two types of Cu atoms are found. The Cu(1) atom, sitting on an inversion center, is chelated by two equivalent $hedp^{4-}$ groups using two of its six phosphonate oxygens [O(1) and O(4)]. Each $hedp^{4-}$ group behaves as a bis(chelating) ligand to bridge Cu(1) and Cu(2) atoms, forming $\{Cu_3(hedp)_2\}$ trimer units. The neighboring trimers are fused together by the coordination of the phosphonate oxygen O(3) to the equivalent Cu(2) atom, hence forming an infinite chain along the [100] direction with a ladder-like motif. The chain is reminiscent of that observed in $(NH_4)_2Cu_3(hedp)_2(H_2O)_4$.[12] These chains are connected through $\{Cu(3)O_4\}$ units by sharing the remaining phosphonate oxygen [O(6)] of hedp. The remaining two sites of $\{Cu(3)O_4\}$ are filled with two water molecules. The Cu(3) atom sits on an inversion center. Consequently, a two-dimensional network structure of copper phosphonate is constructed with zigzag fluctuation in the *ab* plane (Fig. 2). The layers are linked by pyrazine bridging ligands, leading to a three-dimensional open framework structure (Fig. 1). All the Cu–O and Cu–N bond lengths are normal, although the Cu(2)–O(1w) distance is longer than usual [Cu(2)–O(1w) 2.368 Å].

The temperature dependent molar magnetic susceptibilities of **1** are shown in Fig. 3. The observed $\chi_M T$ value per Cu_4 unit at 280 K is 1.8 cm^3 K mol^{-1}, slightly higher than the value of

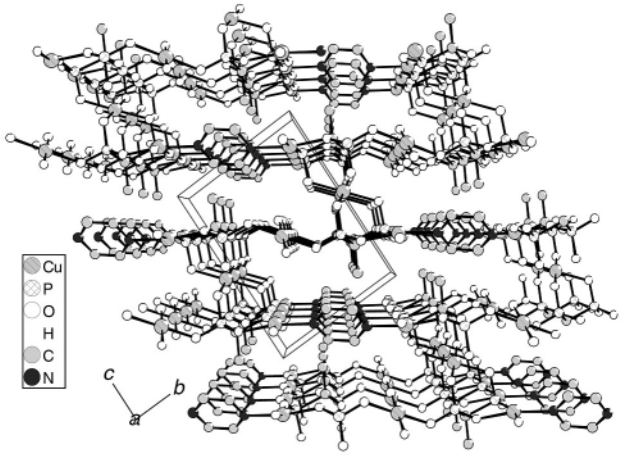

Fig. 1 Structure **1** viewed along the *a*-axis.

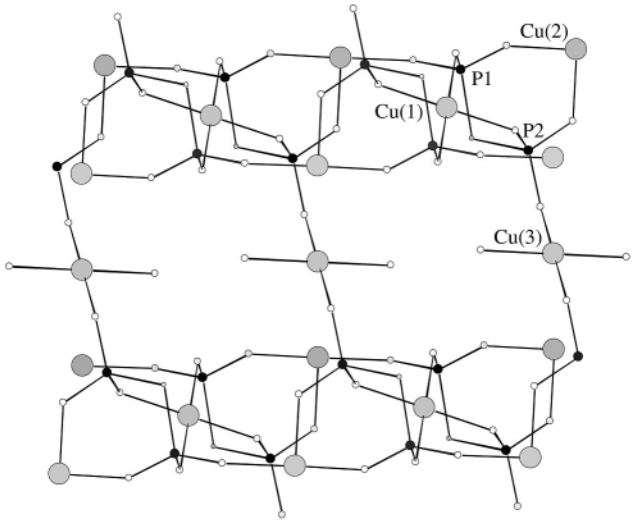

Fig. 2 One layer of copper phosphonate in structure **1**. For clarity, the atoms are shown with arbitrary radii and the C2, O7 and all H atoms are omitted.

† Electronic supplementary information (ESI) available: views of structure **1**, temperature dependence of ac magnetic susceptibility and field dependence of magnetization of **1**. See http://www.rsc.org/suppdata/cc/b1/b106780j/

 DOI: 10.1039/b106780j

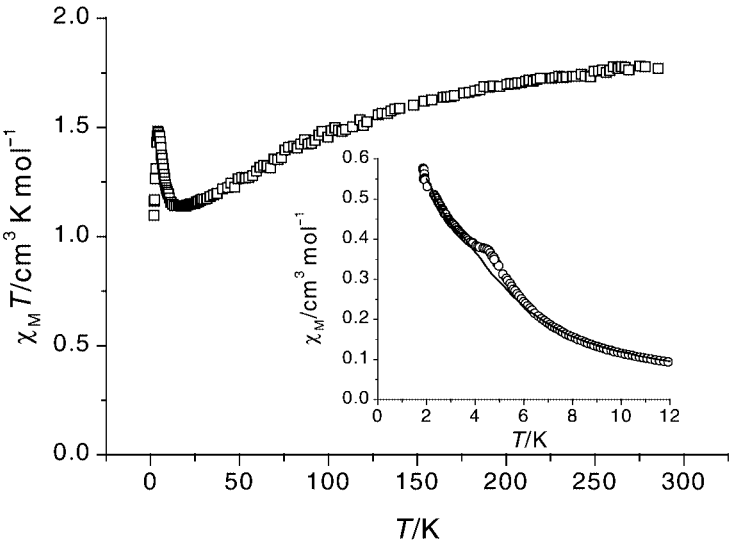

Fig. 3 Temperature dependence of the magnetic susceptibility of **1** [$\chi_M T$ at 10 kOe (□); χ_M at 10 kOe (—); χ_M at 500 Oe (○)].

1.5 expected for four spin-only Cu(II) ions with S = 1/2, g = 2.0, and correspond to g = 2.2. Upon cooling down, the $\chi_M T$ decreases regularly and reaches a minimum of 1.14 cm^3 K mol^{-1} at 17.7 K. This is characteristic of a dominant ferrimagnetic behavior. Below 17.7 K, a sharp maximum of 1.48 cm^3 K mol^{-1} is found at 4.2 K followed by a drop to 1.1 cm^3 K mol^{-1} at 2 K, suggesting a magnetic phase transition. As shown in the inset of Fig. 3, there appears a shoulder peak around 4.5 K in the χ_M *vs*. T curve measured at low field (500 Oe) while without any anomaly at high field (10 kOe, line), which indicates the antiferromagnetic (AF) ordering at low field. The AF transition is further evidenced by the in phase of zero-field ac magnetic susceptibility $\chi_M'(T)$, which has a peak at *ca*. 4.2 K under H_{ac} = 5 Oe and frequencies of 111, 199, 355, 633 and 1111 Hz. No detected out-of-phase signal and frequency dependence were observed, excluding any ferromagnetic phase and glassy behavior.

Low-dimensional ferrimagnetism is generally related to uncompensated sublattices giving a net magnetic moment in the ground state. Although more common in bimetallic systems, ferrimagnetic behavior has also been observed in homometallic chain systems containing discrete species with an odd number of interacting metal ions or complicated alternating sequences of ferro-/antiferro-magnetic interactions.[13,14] With regard to structure **1**, the Cu···Cu distance over the pyrazine bridge (6.8 Å) is much longer than that over the O–P–O bridges (*ca*. 4.7 Å). The magnetic behavior of **1** is mainly attributed to the phosphonate layer which is composed of $\{Cu_3(hedp)_2(H_2O)_2\}$ double chains linked by $\{Cu(3)O_4\}$ units. The saturation magnetization of **1** at 1.93 K is 2.3 $N\beta$ per Cu_4 unit, far from the value of 4.4 $N\beta$ anticipated for four independent S = 1/2 spins with g = 2.2, but close to the value of 2.2 $N\beta$ based on the assumption that the exchange within the $\{Cu_3(hedp)_2(H_2O)_2\}$ double chain is antiferromagnetic and the exchange between the chain and the Cu(3) atom is ferromagnetic (Fig. 2). At very low temperature, the inter-layer antiferromagnetic couplings through the pyrazine bridge and/or the space must be considered. It is this interaction that yields a weak, three-dimensional AF ordering state below 4.2 K. By carefully looking at the M *vs*. H curve in the low field range, a metamagnetic behavior was observed with a critical field of *ca*. 2–3 kOe at 1.93 K. Compound **1** switches from an AF ground state to a ferrimagnetic-like state when a field is larger than the critical field.

Conjugate addition of arylsilanes to unsaturated carbonyl compounds catalyzed by rhodium in air and water

Tai-Sheng Huang and Chao-Jun Li*

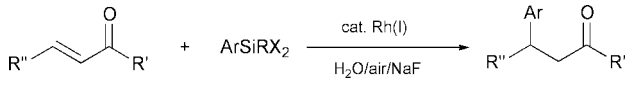
First published as an Advance Article on the web 22nd October 2001

$ArSiCl_3$ and Ar_2SiCl_2, believed to be unstable in aqueous media, reacted efficiently with α,β-unsaturated ketones and esters in air and water (in the presence of sodium fluoride and a rhodium catalyst), giving good to excellent yields of the desired conjugate addition products.

Currently, there is a wide interest in searching for alternative media and processes for chemical and organic synthesis. As a result of the natural abundance of water as well as the inherent advantages of using water as a solvent, interest has been growing in studying organic reactions in water.[1] Recently, in our ongoing 'green' chemistry research program, namely, the use of environmentally friendly reagents, solvents, and processes for organic reactions, we have been interested in developing transition-metal catalyzed carbon–carbon bond formations under the quasi-natural conditions of air and water.[2] Such reactions have the advantages of simplifying protection–deprotection steps, easy recycling of the catalyst solution, and convenient conducting of the reaction. A general requirement for performing such reactions is that the reagent is air- and water-stable, readily available, and less toxic (nontoxic if possible).

Conjugate addition of organometallic reagents to α,β-unsaturated carbonyl compounds is an important means for C–C bond formation in organic synthesis.[3] This reaction was once limited to organocopper chemistry but now is possible with other organometallic compounds through the use of transition metal catalysts.[4] Recently we found that, in the presence of a rhodium catalyst, α,β-unsaturated esters and ketones reacted with arylbismuth, aryltin (and vinyltin), and aryllead reagents in aqueous media to give the corresponding conjugate addition products in an air atmosphere.[5] The method has been used in synthesizing natural and unnatural α-amino acids.[6] However, organotin, organolead, and organobismuth reagents are rather toxic in spite of the fact that they are very efficient in the quasi-natural conditions of water and air. Therefore we felt it was highly desirable to search for the less toxic reagents instead of tin, lead, or bismuth.

Silicon has drawn the attention of chemists for many years due to its low cost, large abundance, and nontoxic properties. The application of silicon and organic silicon compounds for synthetic purposes has been growing in scope due to their relatively high stability and the ability to tailor chemo-, regio-, and stereoselectivities by combining these reagents with appropriate catalysts. Widely recognized reactions attributed to the use of silicon include organosilane based reduction chemistry,[7] cross-coupling reactions,[8] allylsilanes chemistry,[9] as protecting groups,[10] and the chemistry of silyl enolates.[11] Recently, transition-metal catalyzed conjugate additions involving allylsilanes were studied under an inert gas atmosphere and anhydrous conditions.[12] However, conjugate addition with arylsilicon compounds has not been reported due to their lower reactivity, especially in the presence of air and water. Herein we wish to report a highly efficient conjugate addition reaction with arylsilanes in air and water in the presence of sodium fluoride and catalyzed by rhodium catalysts (eqn. 1).



(1)

Initially, phenyltrimethylsilane was chosen to react with 2-cyclohexen-1-one in the presence of a catalytic amount of $(COD)_2RhBF_4$ in water because of its high stability in aqueous media. However no reaction was observed, even after refluxing for several days in the presence of sodium fluoride. Knowing that arylsilyl halides undergo transmetalation with palladium complexes with the aid of fluoride ions *via* five-coordinate silicates in the cross-coupling reaction with aryl- or alkenylhalides,[13] we selected phenyltrichlorosilane as a phenylating reagent despite the fact that phenyltrichlorosilane was thought to be unstable in water. Subsequently, it was discovered that, when cyclohex-2-en-1-one was stirred with phenyltrichlorosilane and a catalytic amount of $(COD)_2RhBF_4$ in the presence of an excess amount of NaF at refluxing conditions overnight in water, a smooth reaction occurred to give the conjugate addition product in 54% isolated yield. Unlike the triphenylbismuth reaction, virtually no biphenyl product was observed with the silicon reagent. No reaction was observed without the catalyst or fluoride. At room temperature the reaction also ceased to proceed completely. Interestingly, the use of different fluoride salts also affected the reaction progress. Fluoride salts such as lithium fluoride, sodium fluoride and potassium fluoride were tested, and sodium fluoride appeared to be the most effective for this reaction. Among the rhodium catalysts screened, $(COD)_2RhBF_4$ and $(COD)_2RhCl$ were effective while others such as $[(CO)_2RhCl]_2$, $(PPh_3)_3RhCl$, and $(C_2H_4)_2Rh(acac)$ were not. It is noteworthy that the yield of this reaction was dramatically improved to almost 100% when (4 equivalents) Ph_2SiCl_2 was used instead of $PhSiCl_3$ (Table 1). The use of 1 equivalent of the silicon reagent decreased the yield somewhat (67%). It is noteworthy that essentially identical results were obtained with either Ph_2SiCl_2 or $Ph_2Si(OH)_2$ as the phenylating reagent, which implies that hydrolysis of the silyl chloride does

Table 1 Effects of reagents and catalyst on conjugated addition of cyclohex-2-en-1-one

[a] All reactions were carried out at refluxing conditions with isolated yields after column chromatography on silica gel.

not affect the reaction. Under the same reaction conditions, no reaction was observed with analogous germanium compounds. With the optimal reaction conditions in hand, several α,β-unsaturated carbonyl compounds were examined with Ph_2SiCl_2 (or $TolSiCl_3$ for entry 11) under these conditions (Table 2). Both ketones (linear and cyclic) and esters were effective as the electron-withdrawing functional groups. Compounds bearing a hydroxy group reacted as expected without the need of protection.

The following procedure is representative. A mixture of cyclohex-2-en-1-one (0.25 mmol), diphenyldichlorosilane (253 mg, 1.0 mmol), NaF (210 mg, 5.0 mmol) and $(COD)_2RhBF_4$ (5.6 mg, 0.013 mmol) in 5 mL of water was stirred at 100 °C for 12 h under an air atmosphere. The reaction mixture was extracted with ethyl acetate. After the combined solvent was dried and concentrated *in vacuo*, the residue was purified by silica gel chromatography eluting with hexanes–ethyl acetate (5 : 1) to give 42.2 mg (97%) of the desired product.

In conclusion, a highly effective conjugate addition of diphenyldichlorosilane to α,β-unsaturated ketones and esters was achieved by using a rhodium catalyst in the presence of sodium fluoride in air and water. The scope (such as asymmetric synthesis), mechanism, and synthetic applications of this reaction are currently under investigation.

We are grateful to the NSF (CAREER) and the NSF-EPA Joint Program for a Sustainable Environment for partial support of this research.

First chiral selenium ylides used for asymmetric conversion of aldehydes into epoxides

Hiroya Takada,[a] Patrick Metzner*[a] and Christian Philouze[b]

[a] *Laboratoire de Chimie Moléculaire et Thio-organique (UMR CNRS 6507), ISMRA-Université, 6, boulevard du Maréchal Juin, 14050 Caen, France. E-mail: metzner@ismra.fr; Fax: +33 231 452 877*
[b] *LEDSS (UMR CNRS 5616), Université Joseph Fourier, BP 53, 38041 Grenoble 9, France*

Received (in Cambridge, UK) 9th July 2001, Accepted 8th October 2001
First published as an Advance Article on the web 26th October 2001

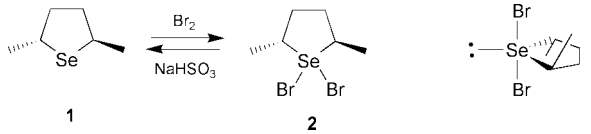
Enantioenriched selenonium ylides have been generated by addition of benzyl bromide to C_2 symmetric (2*R*,5*R*)-2,5-dimethylselenolane in the presence of NaOH, and subsequently reacted with a variety of aldehydes to give oxiranes with excellent enantiomeric excesses (a catalytic version has been achieved); also, an aliphatic cyclic hypervalent dibromoselenurane structure has been demonstrated by X-ray analysis.

The reaction of selenium ylides with carbonyl compounds provides epoxides.[1,2] Since the initial report by Krief and his group[3] in 1974, it has rarely been exploited[4,5] and, to our knowledge, no asymmetric version is available. We wished to introduce a chiral selenide for the conversion of aldehydes into oxiranes with absolute stereocontrol. This raises several challenges. Few enantioenriched selenides have been synthesized so far.[6] An interesting question is the stereochemical course: will it differ, due to the possible [2 + 2]cycloaddition for the key step, leading to 4-membered ring intermediates with a hypervalent selenium atom (oxaselenetanes),[7] or will it be similar to that of the sulfur analogue,[8] with classical betaines as intermediates?[9,10]

We anticipated favourable kinetics of the epoxidation sequence as compared to the sulfur series. For the first step, a high nucleophilicity of selenides towards benzyl halides has been reported.[11] Deprotonation of the selenonium salt will probably be facilitated,[12] as a result of the higher polarizability of selenium. For the third step, addition of the ylide to the carbonyl group, we found no accurate data in the literature, but a fair reactivity was hoped for in relation to polarizability, bond lengths and dissociation energies.

Our study has been based on our results[13,14] with C_2 symmetric sulfur ylides, prepared from (+)-(2*R*,5*R*)-2,5-dimethylthiolane and possible comparisons. Therefore we embarked on the synthesis of the selenium analogue and its use for the epoxidation reaction.

Enantiopure selenolane **1** has been prepared in two easy steps from commercially available (2*S*,5*S*)-hexanediol.† Activation of both hydroxy groups into mesylates and subsequent double nucleophilic substitution with lithium selenide[15,16] (generated *in situ* from selenium and $LiBEt_3H$) provided the crude selenolane quantitatively. Isolation of **1** proved problematic in relation to volatility and azeotrope formation with solvents. We converted **1** by addition of bromine into a stable crystalline 'dibromide'[17,18] **2** (Scheme 1). A selenurane structure was suggested by the single NMR signal observed for the two methyl groups. We were able to grow single crystals (mp: 93.5–94.5 °C) and the X-ray analysis demonstrated the Se^{IV} hypervalent[19] arrangement (Fig. 1). A trigonal bipyramid[20] was observed with the two electron withdrawing groups (bromine atoms) in apical positions, a reduced C–Se–C angle[21,22] of 89.9° and the lone pair in equatorial position. To our knowledge, this is the first structural determination of an aliphatic cyclic dibromoselenurane.



1 2

Scheme 1

Selenolane **1** was regenerated by reaction with aqueous sodium hydrogensulfite in 70% overall yield.

The expoxidation reaction was carried out in a very simple, one pot procedure. Selenolane **1**, benzyl bromide, an aldehyde, and sodium hydroxide were reacted at ambient temperature in a 9 : 1 mixture of Bu^tOH and water as solvent (Scheme 2).‡ With a stoichiometric amount of selenide (Table 1), the reaction time is shorter than for the corresponding sulfide: after 2 h, a 51% yield of stilbene oxide was isolated. After 24 h, oxiranes were obtained in 71–97% yields (Table 1, entries 2–4). Excellent enantiomeric excesses were attained: 92–93%.

8		65[c]	1 : 1	92
9	2-Thiophenecarboxaldehyde	72	1 : 1	94
10		86[c]	1 : 1	94

[a] All reactions were performed with selenolane **1** (0.020 mmol, 20 mol% to aldehyde), benzyl bromide (0.40 mmol), aldehyde (0.20 mmol) and NaOH (0.40 mmol) at rt for 7 days. [b] Enantiomeric excesses were determined by chiral HPLC using a Daicel AD column. [c] Reaction time: 4 h.

These results led us to achieve a catalytic procedure.[23–25] Using 0.2 equivalent of selenolane **1** and eight aldehydes, at ambient temperature for a maximum of 7 days, good to excellent yields of oxiranes (65–97%) were obtained (Table 2). For the more reactive heteroaromatic aldehydes (entries 8, 10) the reaction time could be optimized to 4 h. Enantiomeric excesses were 91–94% (entries 1–3, 6–10), except for aldehydes bearing electron-withdrawing groups (entries 4, 5).

As compared to the sulfur analogues,[13,14] this series leads to enhanced reactivity and higher asymmetric induction, with the same absolute configuration.

Another feature is the diastereoselectivity,[26] which has almost not been addressed so far in the selenium series.[1,2] Under stoichiometric conditions, the *trans* oxirane was the major isomer but to a much lesser extent than with sulfides (for the example of benzaldehyde: excess of 18–34% instead of 86%). The catalytic series provides an equal abundance of *trans* and *cis* oxiranes, for most cases. This trend towards the *cis* isomer is reminiscent of the reaction of unstabilized sulfur ylides with aliphatic aldehydes, and of the Wittig reaction of unstabilized phosphoranes with aldehydes. The higher reactivity observed here with selenonium ylides leads us to propose early transition states, and possible hypervalent oxaselenetane intermediates.[7,27]

In conclusion this first report of chiral selenium ylides demonstrates that they can provide efficient asymmetric induction for the synthesis of epoxides. They exhibit marked differences with sulfur ylides. The catalytic version is competitive with previous methods in the sulfur series.[23–25,28–30]

The radical-chain addition of aldehydes to alkenes by the use of *N*-hydroxyphthalimide (NHPI) as a polarity-reversal catalyst

Shinya Tsujimoto, Takahiro Iwahama, Satoshi Sakaguchi and Yasutaka Ishii*

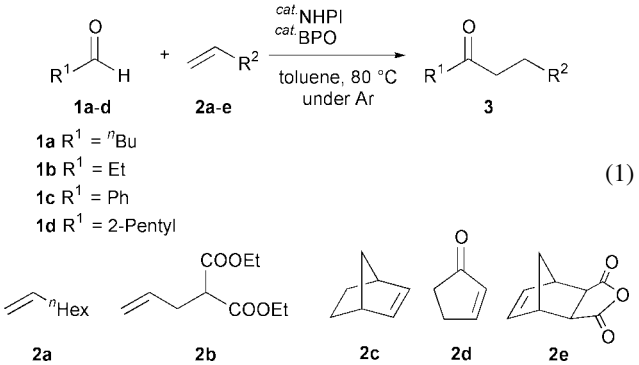
Received (in Corvallis, OR, USA) 20th August 2001, Accepted 3rd October 2001
First published as an Advance Article on the web 29th October 2001

Hydroacylation of simple alkenes with aldehydes *via* a radical process was successfully achieved by the use of *N*-hydroxyphthalimide (NHPI) as a polarity-reversal catalyst. Thus, 5-tridecanone was obtained by the reaction of oct-1-ene with pentanal in the presence of small amounts of NHPI and dibenzoyl peroxide (BPO).

Intermolecular radical-chain addition of aldehydes to alkenes is the simplest methodology for the synthesis of long-chain unsymmetrical ketones, but employment of this method is usually difficult for the synthesis of simple aliphatic ketones.[1–3] The hydroacylation between alkenes and aldehydes *via* a radical process involves the following reaction sequences: (i) hydrogen abstraction from an aldehyde by a radical initiator to form an acyl radical (**A**), (ii) addition of the acyl radical to alkene leading to a β-oxocarbon radical (**B**), and (iii) abstraction of the aldehydic hydrogen atom from another aldehyde by **B,** generating ketone and acyl radical **A** (Scheme 1).

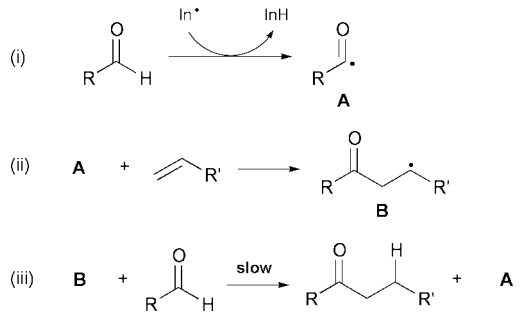
In this radical-chain reaction, if the R′ is an alkyl or an electron-donating group (EDG), step (iii) becomes a sluggish process, since the abstraction of the aldehydic hydrogen atom by nucleophilic radical **B** (Nu·) proceeds with difficulty. In contrast, if the R′ is an electron-withdrawing group (EWG), this step proceeds smoothly because of the ease of aldehydic hydrogen abstraction by an electrophilic radical **B** (El·).[2] Acyl radicals, which are nucleophilic in nature, are known to add more easily to electron-deficient alkenes than normal alkenes.[3] As a result, the hydroacylation of simple alkenes with aldehydes *via* a radical process proceeds with difficulty. Recently, the hydroacylation of alkenes, particularly electron-rich alkenes, with aldehydes has been reported to be achieved by the use of methyl thioglycolate ($HSCH_2CO_2Me$) which acts as a polarity-reversal catalyst. For instance, the addition of butanal to isopropenyl acetate using di-*tert*-butyl hyponitrite (TBHN) as an initiator and methyl thioglycolate as the polarity-reversal catalyst at 60 °C produces 1-acetoxyhexan-3-one in good yield.[4,5]

In a previous paper, we reported that NHPI under dioxygen serves as an efficient carbon radical generation catalyst from alkanes. In this reaction, we found that the hydrogen atom attached to the hydroxyimide moiety of NHPI is easily abstracted by a radical species to generate phthalimide *N*-oxyl (PINO) which abstracts the hydrogen atom from alkanes to give alkyl radicals.[6] Therefore, if the adduct radical **B** in Scheme 1 can abstract the hydrogen atom from NHPI, NHPI is expected to serve as a polarity-reversal catalyst in analogy with methyl thioglycolate. The hydrogen atom of the hydroxylimide moiety adjacent to two carbonyl groups may be easily abstracted by a nucleophilic radical rather than an electrophilic one, and the resulting PINO would behave as an electrophilic radical that can efficiently abstract the aldehydic hydrogen atom. In this paper, we wish to report the radical-chain hydroacylation of simple alkenes with aldehydes assisted by NHPI [eqn. (1)].



(1)

A solution in dry toluene (0.5 mL) containing pentanal (**1a**) (6 mmol), oct-1-ene (**2a**) (2 mmol), NHPI (0.2 mmol) and dibenzoyl peroxide (BPO) (0.1 mmol) was stirred at 80 °C under argon. After 12 h, additional BPO (0.1 mmol) in toluene (0.5 mL) was added to the reaction system and the mixture was allowed to react at that temperature for 12 h.† The reaction gave tridecan-5-one (**3aa**) in 78% yield at 77% conversion (Table 1, Run 1). In the absence of NHPI, the reaction gave **3aa** in lower conversion and yield (Run 2). This indicates that the NHPI enhances the chain transfer reaction of step (iii) shown in Scheme 1.



Scheme 1

Table 1 Reaction of pentanal (**1a**) with oct-1-ene (**2a**) using various catalysts in toluene at 80 °C in the presence of BPO[a]

Run	Catalyst	Conv. (%)	Yield (%)[b]
1	NHPI	77	78
2	—	63	48
3	3F-NHPI[c]	79	80
4	4Cl-NHPI[d]	72	78
5	NHSI[e]	78	65
6[f]	NHPI	67	75
7[g]	NHPI	72	88
8[g]	—	53	58

[a] Reaction was run as described text. [b] Based on **1a** reacted. [c] 3F-NHPI = 3-fluoro-*N*-hydroxyphthalimide. [d] 4Cl-NHPI = 4-chloro-*N*-hydroxyphthalimide. [e] NHSI = *N*-hydroxysuccinimide. [f] BPO (0.2 mmol) was added at once at the start of the reaction. [g] BPO (0.2 mmol) was added over 18 h using a syringe pump.

 DOI: 10.1039/b107548a

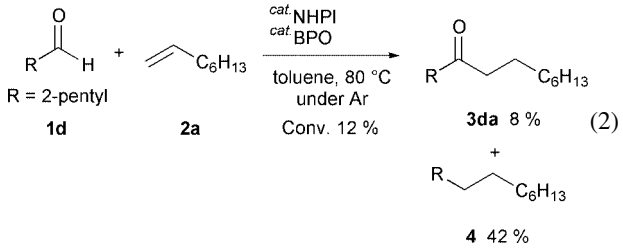
Table 2 Hydroacylation of alkenes with aldehydes catalyzed by NHPI[a]

Run	Aldehyde	Alkene	Conv. (%)	Product	Yield (%)
1	**1a**	**2b**	91	**3ab**	67
2[b]	**1a**	**2b**	91	**3ab**	80
3	**1a**	**2c**	90	**3ac**	73
4	**1a**	**2d**	>99	**3ad**	53
5	**1a**	**2e**	>99	**3ae**	92
6	**1b**	**2a**	58	**3ba**	73
7	**1c**	**2a**	30	**3ca**	90
8[c]	**1c**	**2a**	33	**3ca**	83

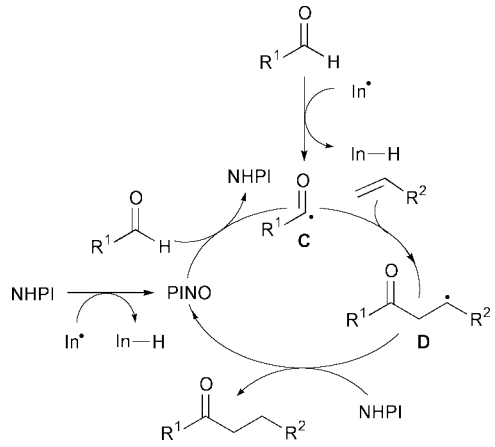
[a] See Table 1a. [b] Chlorobenzene was used as a solvent. [c] Reaction condition was 90 °C.

Several NHPI derivatives and *N*-hydroxysuccinimide (NHSI) were examined as catalysts (Runs 3 to 5). Among them, 3-fluoro-*N*-hydroxyphthalimide (3F-NHPI) gave the best result (Run 3). When the radical initiator BPO (0.2 mmol) was added in one portion, **3aa** was formed in slightly lower yield (Run 6). It was found that the gradual addition of BPO (0.2 mmol) in toluene (0.5 mL) using a syringe-pump over a period of 18 h afforded **3ab** in higher yield (88%) in 72% conversion (Run 7).

On the basis of these results, the reactions of various aldehydes with alkenes were run under the same conditions as Run 1 in Table 1 (Table 2). Diethyl allylmalonate (**2b**) and norbornene (**2c**) were reacted with **1a** giving the corresponding adducts, **3ab** and **3ac**, respectively, in good yields (Runs 1–3). α,β-Unsaturated ketone, **2d**, afforded the 1,4-adduct **3ad** in slightly lower yield.‡ 5-Norbornene-2,3-dicarboxylic anhydride (**2e**) resulted in adduct **3ae** in high selectivity (Run 5).§ The reaction of benzaldehyde (**1c**) with **2a** produced 1-phenyloctan-2-one (**3ca**) in high selectivity, although the conversion was not high (30%) (Run 7). Treatment of 2-methylpentanal (**1d**) with **2a** catalyzed by NHPI gave the corresponding coupling product **3da** (8%) and 4-methyldodecane (**4**) (42%) [eqn. (2)]. It is reported that the isoamylacyl radical was easily decarbonylated to an isoamyl radical and CO.[7] Therefore, **4** would be produced by the addition of an isoamyl radical, which is generated by decarbonylation of **1c**, to **2a**.



A possible reaction path for the NHPI-catalyzed hydroacylation of alkenes with aldehydes is shown in Scheme 2. The reaction may be initiated by the hydrogen atom abstraction from aldehyde by the radical initiator (In·), giving an acyl radical **C** which then adds to an alkene to afford a β-oxocarbon radical **D**. The resulting radical **D** having a nucleophilic character abstracts the hydrogen atom from NHPI leading to ketone and PINO. The abstraction of the hydrogen atom from aldehyde by the PINO forms the acyl radical **C** and NHPI. An alternative formation of PINO from NHPI and radical initiator (In·) may also be possible.



Scheme 2

In conclusion, we have developed a facile catalytic method for hydroacylation of alkenes using NHPI which acts as a polarity-reversal catalyst. Further extension of this method is now underway.

This work was partly supported by a Grant-in-Aid for Scientific Research (S) (No. 13853008) from Japan Society for the Promotion of Science (JSPS).

The first bismuth phosphonate cluster. X-Ray single crystal structure of $[(Bu^tPO_3)_{10}(Bu^tPO_3H)_2Bi_{14}O_{10}\cdot 3C_6H_6\cdot 4H_2O]$†

Michael Mehring* and Markus Schürmann

Received (in Cambridge, UK) 9th August 2001, Accepted 8th October 2001
First published as an Advance Article on the web 26th October 2001

The reaction of triphenylbismuth and *tert*-butylphosphonic acid gives the bismuth phosphonate phase $(Bu^tPO_3H)_3Bi$ and the first bismuth phosphonate cluster $[(Bu^tPO_3)_{10}(Bu^tPO_3H)_2Bi_{14}O_{10}\cdot 3C_6H_6\cdot 4H_2O]$.

In the past three decades phosphate and phosphonate ligands have been widely used to prepare polynuclear oxo anions such as vanadates and molybdates.[1] A fascinating example of this class of compounds is the cluster $[V_{18}O_{25}(H_2O)_2(PhPO_3)_{20}Cl_4]^{4-}$.[2] In addition to the soluble metallaoxo anions, poorly soluble oxo–vanadium phosphonates such as $[VO(PhPO_3)\cdot H_2O]_n$ have also been reported.[3] The latter phosphonate forms a layered structure with well-defined internal void spaces and coordination sites which are accessible for organic molecules such as alcohols. Similarly, zirconium phosphates and phosphonates are composed of two-dimensional layered structures and show properties which make them useful as ion exchangers, sorbents, sensors, proton conductors, non-linear optical materials, photochemically active materials, catalysts, and hosts for the intercalation of a broad spectrum of guests.[4] Several other metal phosphonates which exhibit two- and three-dimensional structures in the solid state have been reported, including recent examples of Al, Zn, Cu, and Ga, among others.[4,5] The only bismuth phosphonate characterised by a single crystal X-ray structure analysis is $Bi(O_3PC_2H_4CO_2)\cdot H_2O$ which has a two-dimensional layered structure.[6] The chemistry of uncharged organophosphonate clusters which are soluble in common organic solvents and serve as molecular models for phosphate and phosphonate based materials is more recent.[7,8]

Herein we report our results on the reaction of $BiPh_3$ with $Bu^tPO_3H_2$ which was undertaken initially in order to obtain soluble organobismuth phosphonate compounds *via* the elimination of benzene. A 1 : 1 mixture of $BiPh_3$ and $Bu^tPO_3H_2$ was heated at 50 °C for three days in THF to give a suspension. The solid material was filtered off and the solvent removed *in vacuo*. The residue was dissolved in $CHCl_3$/benzene and by slow evaporation of the solvent colourless single crystals of $[(Bu^tPO_3)_{10}(Bu^tPO_3H)_2Bi_{14}O_{10}\cdot 3C_6H_6\cdot 4H_2O]$‡ (**1**) were obtained in low yield. The major product was identified as $(Bu^tPO_3H)_3Bi$ (**2**) which can be prepared almost quantitatively by choosing the appropriate stoichiometry. EDX analysis of analytically pure **2** shows a phosphorus-to-bismuth ratio of approximately 3 : 1 and in the ^{31}P MAS NMR only one signal at δ 36.0 is observed. The IR spectrum of **2** shows a broad absorption (3100 cm^{-1}) in the ν(P–OH) region. In the PO_3 vibration domain three strong absorption bands at 1066, 1017 and 934 cm^{-1} are observed. The absorption band at 1192 cm^{-1} is indicative for a P=O group. The TGA shows a weight loss of 4.7% in the temperature range 230–320 °C as a result of a condensation reaction of the Bu^tPO_3H moieties (weight loss calc. for 1.5 H_2O 4.6%). In the range 400–470 °C cleavage of the C–P bonds occurs (weight loss 27.9%; calc. for three Bu^t groups 27.6%). Additional weight loss in the temperature range 320–400 °C (1.8%) and 480–550 °C (2.7%) was observed giving a ceramic yield at 550 °C of 62.9% which is lower than the calculated ceramic yield for $Bi(PO_3)_3$ of 71.9%. The X-ray powder diffraction data show broad diffraction peaks which are indicative for the bismuth phosphonate phase **2** to be amorphous.

The single crystal X-ray structure analysis of **1**§ revealed the formation of a bismuth phosphonate oxo cluster containing 14 bismuth atoms and 12 *tert*-butylphosphonate groups (Fig. 1). In the crystal structure of **1** (space group *Immm* with $Z = 2$) the cluster, the water and the benzene molecules show *mmm* symmetry.

Two of the phosphonate groups are not fully deprotonated and give two Bu^tPO_3H units which form strong hydrogen bonds to adjacent Bu^tPO_3 groups with O(2')–O(2'E) and O(2'A)–O(2'D) distances of 2.327 Å. The molecular formulation $[(Bu^tPO_3)_{10}(Bu^tPO_3H)_2Bi_{14}O_{10}\cdot 3C_6H_6\cdot 4H_2O]$ (**1**) was confirmed by elemental analysis. The 10 μ_3-oxygen atoms are most likely the result of partial hydrolysis of $BiPh_3$ caused by residual water present in $Bu^tPO_3H_2$. The difficulty to obtain water-free $Bu^tPO_3H_2$ was previously noticed in context with the synthesis of *tert*-butylphosphonate clusters of titanium.[8,9] Cluster **1** shows D_{2h} symmetry which results in the observation of only two crystallographically independent phosphonate groups, four independent bismuth atoms, Bi(1)–Bi(4), and three independent μ_3-oxygen atoms, O(3)–O(5). The μ_3-oxygens O(3)–O(5) are incorporated inside the cluster and show Bi–O distances in the range 2.093(16)–2.237(9) Å. The oxygen O(3) is trigonal planar coordinated which is indicated by the sum of the O–Bi–O angles Σ 360.0°, whereas the μ_3-oxygens O(4) and O(5) show sums of the O–Bi–O angles of Σ 342.7 and 339.2°, respectively. The coordination geometry both at Bi(2) and Bi(4) is best described as a square pyramid with four phosphorus-bonded oxygen

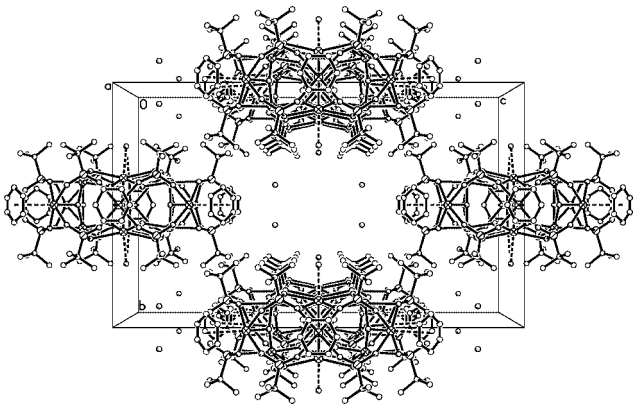

Fig. 2 Packing diagram of **1**. The view along the *a*-axis highlights the channels which are partially filled with water molecules. A one-dimensional copolymer of the bismuth-containing cluster and benzene extends along the *a*-axis.

atoms occupying the corners of the base. The corresponding bond distances Bi(2)–O(P) and Bi(4)–O(P) are in the range 2.212(11)–2.439(11) Å. The apex of each of the pyramids is occupied by an oxygen atom with Bi(2)–O(3) and Bi(4)–O(5) bond distances of 2.093(16) and 2.119(12) Å, respectively. In addition, both Bi(2) and Bi(4) are each coordinated to a benzene molecule with Bi–C distances in the range 3.428–3.459 and 3.376–3.564 Å, respectively, which is comparable with the bismuth–benzene coordination in $BiCl_3 \cdot C_6H_6$ with Bi–C distances in the range 3.219–3.621 Å.[10] The benzene molecules coordinated to Bi(2) link adjacent clusters to give a linear polymeric arrangement with a Bi–benzene$_{centroid}$ distance of 3.194 Å. A similar polymeric structure with collinear bismuth atoms and arene centers was recently reported for $[Bi_2(O_2CCF_3)_4](C_6Me_6)$.[11] The benzene molecules coordinated to Bi(4), Bi(4A), Bi(4B) and Bi(4C) and having an occupancy of 0.5 occupy a void built up by four chains of the bismuth clusters. The coordination geometry at Bi(1) is best described as that of a strongly distorted square pyramid with four phosphorus-bonded oxygen atoms occupying the corners of the base (Bi–O(P) 2.237(9)–2.577(10) Å). The O(1)–Bi(1)–O(1A) angle of 147.8(5)° deviates strongly from the ideal value of 90° indicating a stereochemically active lone pair. The apex of the pyramid is occupied by a μ_3-oxygen with a Bi(1)–O(3) distance of 2.228(6) Å. In addition, a water molecule is weakly coordinated to Bi(1) with a Bi(1)–O(31) distance of 3.066 Å. The coordination environment of Bi(3) consists of four phosphonate-oxygens and three μ_3-oxygens. The Bi–O(P) distances are in the range 2.555(10)–2.664(10) Å and the Bi–O distances amount to 2.208(13)–2.231(7) Å. In the crystal lattice huge voids extend along the *a*-axis at (0,0,0) and (0,1/2,1/2) which are partially filled with water molecules (Fig. 2). The IR spectrum of **1** shows a broad absorption band in the region 3000–3500 cm^{-1} which is indicative for OH vibrations in agreement with the single crystal X-ray structure analysis. Only two strong and relatively broad absorption bands are observed at 1059 and 970 cm^{-1}, which are assigned with caution to ν(P–O–Bi) vibrations. A ν(P=O) absorption band is observed at 1190 cm^{-1}.

In conclusion, the single crystal X-ray structure analysis of the first bismuth phosphonate cluster **1** is reported which, to the best of our knowledge, is the largest bismuth containing cluster reported so far and a rare example of a linear π-coordination copolymer of a main group metal cluster and an arene molecule. We have shown that novel hybrid organic–inorganic bismuth compounds are easily accessible under mild reaction conditions starting from a commercially available organobismuth compound and phosphonic acids.

We are grateful to Professor Dr K. Jurkschat (Universität Dortmund, Lehrstuhl für Anorganische Chemie II) for his generous support.

‡ *Synthesis* of $[(Bu^tPO)_3)_{10}(Bu^tPO_3H)_2Bi_{14}O_{10} \cdot 3C_6H_6 \cdot 4H_2O$ (**1**) and $(Bu^tPO_3H)_3Bi$ (**2**): to a solution of $BiPh_3$ (900 mg, 2.04 mmol) in 20 mL of THF was added $Bu^tPO_3H_2$ (282 mg, 2.04 mmol). The reaction mixture was stirred at 50 °C for three days to give a cloudy solution. The precipitate was isolated by filtration and dried *in vacuo* to give 280 mg (66%) of **2** as a colourless solid. The solvent was removed to give a slightly yellow oil which was dissolved in a $CHCl_3$/benzene mixture. Slow evaporation of the solvent afforded colourless crystals of analytically pure **1** (20 mg). A second crop of crystals (25 mg) contained small amounts of the starting material $BiPh_3$ as impurity. **1**: Decomp. > 200 °C. § *Crystal data for* **1**: $C_{66}H_{136}Bi_{14}O_{50}P_{12}$, M = 5027.11, crystal size 0.05 × 0.03 × 0.03 mm^3, orthorhombic, space group *Immm*, Z = 2, a = 15.628(1), b = 17.977(2), c = 30.189(3), V = 8481.4(13) $Å^3$, D_c = 1.968 g cm^{-3}, $F(000)$ = 4548, μ(Mo-Kα) = 0.7107 mm^{-1}, T = 171(1) K, $3.31 \leqslant 2\theta \leqslant 25.35$, Completeness to 2θ: 99.2%, max./min. residual electron density: 1.516/−1.244 e $Å^{-3}$. Data were collected on a Nonius Kappa CCD diffractometer. Of a total of 18370 reflections collected, 4236 reflections were independent (R_{int} = 0.098). The structure was solved by direct methods (SHELXS97)[12] and successive difference Fourier syntheses. Refinement applied full-matrix least-squares methods SHELX97.[13] Final $R1$ = 0.054 (for 4236 reflections $I > 2\sigma(I)$) and $wR2$ = 0.130 (all data). The H atoms were placed in geometrically calculated positions using a riding model with U_{iso} constrained at 1.2 for non-methyl groups and 1.5 for methyl groups times U_{eq} of the carrier C atom. Disordered solvent molecules of benzene and water were found with occupancies of 0.25 (O(21)) and of 0.5 (C(41), C(42), C(43)), whereas all solvent molecules, except O(31), were refined isotropically. CCDC 162527. See http://www.rsc.org/suppdata/cc/b1/b107220j/ for crystallographic data in CIF or other electronic format.

Two alternative products from the intercalation of alkali metals into cation-defective Ruddlesden–Popper oxysulfides

Sophie G. Denis and Simon J. Clarke*

Inorganic Chemistry Laboratory, Department of Chemistry, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: simon.clarke@chem.ox.ac.uk

Received (in Cambridge, UK) 23rd August 2001, Accepted 9th October 2001
First published as an Advance Article on the web 26th October 2001

Sodium may be topotactically inserted into the perovskite layers (under thermodynamic control) or the rock-salt layers (under kinetic control) of the cation-deficient $n = 2$ Ruddlesden–Popper oxysulfides $Ln_2Ti_2O_5S_2$ with concomitant reduction of Ti^{IV}.

Intercalation is important in the modification of materials properties. Reductive topotactic insertion of alkali metals into transition metal oxides[1] and sulfides[2] is central to battery technology.[3] Layered sulfides and oxyhalides,[2,4] and layered oxides such as Ruddlesden–Popper (R–P) phases consisting of perovskite slabs separated by rock-salt layers, accept non-redox intercalants to increase the separation of the slabs[5] or exfoliate them.[6] Some R–P phases, such as $Sr_3Ru_2O_7$,[7] undergo topotactic *oxidative* intercalation of fluorine into the rock-salt layers.

Oxysulfides contain anions with different sizes and chemical requirements which order crystallographically, often resulting in layered structures. Two groups[8,9] have reported the cation-defective $n = 2$ R–P oxysulfides $Ln_2Ti_2O_5S_2$ (Ln = Pr–Er, Y). These contain vacant sites 12-coordinated by oxygen in perovskite slabs, which are separated by LnS rock-salt layers (**1**). Here we show that lithium and sodium intercalate into the vacant sites in the perovskite slabs with reduction of Ti^{IV}. While reductive intercalation of alkali metals into partially filled rock-salt layers of R–P oxides is known,[10] we show here that reductive intercalation of sodium into *new sites* in filled rock-salt layers is also possible in the oxysulfides. The synthetic conditions determine the destination of the Na intercalants: thermodynamic control favours insertion into the perovskite slab, whereas kinetic control favours insertion into the rock-salt layers.

All manipulations were carried out in an argon-filled dry box or under nitrogen using Schlenk techniques. The brown oxysulfides were prepared† on the 5 g scale for Ln = Nd, Y by reacting stoichiometric amounts of Ln_2O_3, TiO_2 and TiS_2 in evacuated silica tubes at 1100 °C. Lithium intercalation was carried out by reacting the powders with excess *n*-BuLi (2.5 M in hexane) or lithium naphthalide (0.05 M in THF) at between 20 and 50 °C for 0.5–11 days. Sodium intercalation was carried out either by exposing the oxysulfide to excess sodium vapour at 600 °C in a sealed nickel container for 4–10 days, or by reacting the powder with excess sodium naphthalide (0.05 M in THF) at 50 °C for 3–7 days. The products were black or blue-black powders and were analysed chemically† and using powder X-ray diffraction (PXRD) and powder neutron diffraction (PND).‡ Magnetic susceptibility measurements§ were carried out on the products of intercalation into diamagnetic $Y_2Ti_2O_5S_2$, **1** (Fig. 1).

The PXRD patterns of the Na intercalates and the products of Li intercalation at 50 °C were indexed on the tetragonal unit cell of the starting material in space group *I*4/*mmm* suggesting that intercalation is topotactic. The products of lower temperature Li intercalation were less Li-rich and were orthorhombic (*Immm*); lattice parameters and compositions are given in Table 1. In the products of reaction with *n*-BuLi or Na vapour, the *a* parameter increases by 2–3 % whereas the *c* parameter decreases by 1–2 %, consistent with reduction of Ti^{IV} and insertion into the perovskite slabs (**2**). The products of Na intercalation using Na naphthalide (**3**) are dramatically different: the *a*-axis decreases by 1% and the *c*-axis increases by 25% (6 Å). The only topotactic change which can give rise to this involves insertion into the rock-salt layers.[7] The products of Li intercalation using Li naphthalide or *n*-BuLi were indistinguishable from one another. This suggests that Na is too large to intercalate into the perovskite blocks under mild conditions to give the thermodynamic product; the product of Na naphthalide intercalation may be converted into a product indistinguishable from the product of Na vapour intercalation by annealing for 6 days at 600 °C in an evacuated silica tube. The Li intercalates are the most air sensitive, and the brown colour of the starting material was apparent after a few seconds' exposure to air. Decomposition of the Na naphthalide intercalate was apparent after a few minutes, and the product had a PXRD pattern characteristic of $Ln_2Ti_2O_5S_2$, but enhanced 00*l* reflection intensities with the sample mounted in flat plate geometry showed that deintercalation exfoliates the crystallites. The products of Na vapour intercalation are air stable for many days.

Rietveld refinements against PND data of the structures of the $Na_xY_2Ti_2O_5S_2$ phases **2** and **3** are shown in Fig. 2. The structures‡ are compared in Fig. 1 with that of the parent $Y_2Ti_2O_5S_2$, **1**. Insertion into the perovskite slabs to produce **2** was predicted[9] based on the reactivity of Ti^{IV} and other early transition metal oxides. Reductive intercalation into completely new sites to produce **3** is, to our knowledge, unprecedented, and is surprising as it involves a change in the Y^{3+} ion coordination from 9 [4 × S at 2.8048(2) Å, 1 × S at 2.9395(6) Å and 4 × O at 2.4277(2) Å] to 8 [4 × S at 2.9404(7) Å and 4 × O at 2.3008(5) Å] with cleavage of the longest Y–S bond. The Ti coordination also changes substantially: in **1**, Ti can be considered 6-coordinate [4 × O at 1.9427(1) Å, 1 × O at 1.7941(4) Å and 1 × S at 2.8741(6) Å]. The long axial Ti–S bond is broken completely on intercalation of sodium into the rock-salt layers, increasing to 3.312(1) Å, and in **3** Ti is unambiguously in square pyramidal coordination by O [4 × O at 1.9814(6) Å and 1 × O at 1.809(1) Å]. On intercalation of Na into the perovskite slabs (**2**), the Ti–O bonds lengthen [4 × O at

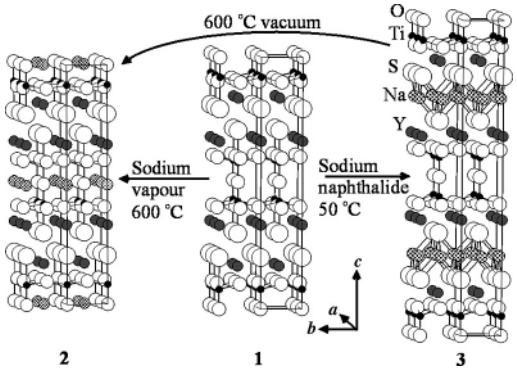

Fig. 1 Structures of $Y_2Ti_2O_5S_2$, **1**, and its sodium intercalates.

 DOI: 10.1039/b107659k

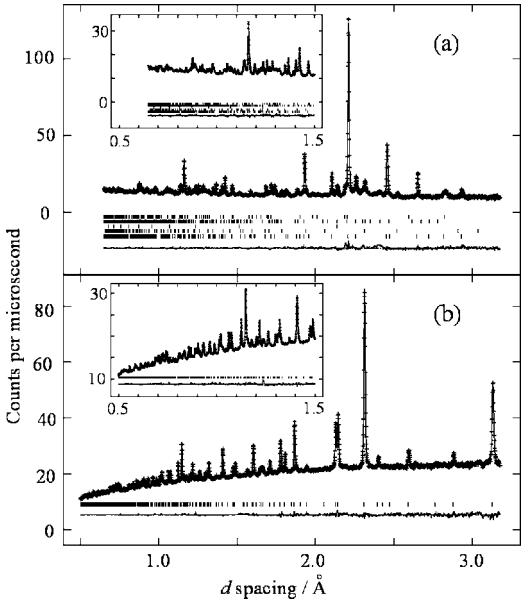

Fig. 2 Rietveld refinements against powder neutron diffraction data (2θ = 145°) for: (a) **2** (Na vapour): χ^2 = 1.62, wR_p = 0.018, $R(F^2)$ = 0.055; tick marks are for $NaY_2Ti_2O_5S_2$ (bottom-most), and impurities $Y_2Ti_2O_7$, vanadium sample holder, and poorly crystalline $YTiO_3$ and $NaYS_2$ (topmost); (b) **3** (Na naphthalide): χ^2 = 1.31, wR_p = 0.007, $R(F^2)$ = 0.086.

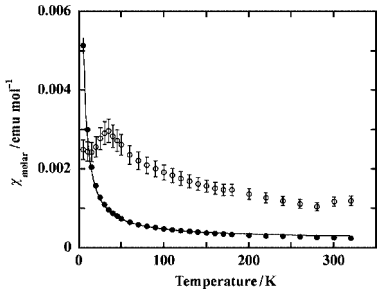

Fig. 3 Magnetic susceptibility of **2** (Na vapour intercalation) (○) and **3** (Na naphthalide intercalation) (●). The fit is to $\chi = \chi_0 + C/T$ with χ_0 = 2.2(1) × 10^{-4} emu mol^{-1} and a Curie constant corresponding to 5% of Ti ions behaving as S = ½ moments. The anomaly in the susceptibility of **2** is an artefact of the correction§ for the $YTiO_3$ impurity.

1.9699(4) Å, 1 × O at 1.883(2) Å] and the Ti–S bond shortens to 2.732(3) Å. In **2** Na is surrounded by four O atoms at 2.7282(1) Å in the *ab* plane; the eight more distant O atoms in the TiO_2 sheets were best modelled as a split site such that on average four would be located 2.772(1) Å from Na. In the Na naphthalide intercalate, **3**, Na is tetrahedrally coordinated by four S atoms at 2.796(1) Å. Refinement of the Na occupancy for **2** indicated a composition of $Na_{1.04(1)}Y_2Ti_2O_5S_2$ with the vacant site in the perovskite slab fully occupied. The composition of **3** refined to $Na_{1.02(1)}Y_2Ti_2O_5S_2$ with the tetrahedral site 50% occupied by Na so that short Na–Na contacts of 2.64 Å across shared tetrahedral edges are avoided. Compound **3** is poorer in Na than suggested by chemical analysis (Table 1). This discrepancy is under investigation: while no additional crystalline phases were observed in diffraction studies of **3**, the sloping background in Fig. 2(b) shows that an H-containing species remains after washing with THF. Rietveld refinement showed that the site in the perovskite blocks was 4(1)% occupied in **3**.

Compounds **2** and **3** both have Ti in a formal oxidation state of +3.5. The main contribution to both magnetic susceptibilities§ (Fig. 3) is a temperature-independent term comparable in magnitude to that of reduced metallic titanates that lie close to the metal–insulator boundary, such as $LaTiO_3$.[11]

Compound **3** bears some similarity to the oxysulfides prepared by Zhu and *et al.*[12] in which transition metal-containing perovskite slabs are separated by Cu_2S_2 layers. We are currently investigating further the synthesis, properties and ion-exchange chemistry of the intercalates described here.

Notes and references

† Y_2O_3 (Aldrich 99.99%), Nd_2O_3 (ALFA 99.99%), TiO_2 (Aldrich 99.9+%); TiS_2 was prepared by reacting Ti (ALFA 99.99%) with S (ALFA 99.9995%) at 600 °C for 3–4 days in evacuated silica tubes. Analysis for lithium and sodium (Table 1) was carried out using a Thermo Elemental Atomscan 16 ICP analyser. The alkali metal ions were leached out by boiling the materials in 20% nitric acid solution.

‡ PXRD data were collected using a Siemens D5000 diffractometer operating with CuKα radiation in Debye–Scherrer geometry and the sample sealed in a glass capillary. PND data were collected using the Polaris diffractometer at ISIS, UK; 0.25–2 g samples were sealed in vanadium containers. Rietveld refinement was carried out against neutron data collected at 35, 90 and 145° 2θ ($0.5 < d < 8$ Å) using GSAS: A. Larson and R. B. von Dreele, *The General Structure Analysis System*, Los Alamos National Laboratory, Los Alamos, NM, 1985. *Crystal data*: for $Y_2Ti_2O_5S_2$ **1**: T = 25 °C, tetragonal, space group *I*4/*mmm* (no. 139), a = 3.76956(1) Å, c = 22.80557(9) Å, Z = 2; Y (0 0 0.333589(9)), Ti (0 0 0.07867(2)), O1 (0 0.5 0.099313(8)), O2 (0 0 0), S (0 0 0.20469(2)). For $NaY_2Ti_2O_5S_2$ **2** (Na vapour): T = 25 °C, tetragonal, space group *I*4/*mmm* (no. 139), a = 3.85823(8) Å, c = 22.5926(6) Å, Z = 2; Y (0 0 0.33258(4)), Ti (0 0 0.08335(8)), O1 (0 0.4371(3) 0.40264(5)) (50% occupied split site), O2 (0 0 0), S (0 0 0.20429(8)), Na (0 0 0.5). For $NaY_2Ti_2O_5S_2$ **3** (Na naphthalide): T = 25 °C, tetragonal, space group *I*4/*mmm* (no. 139), a = 3.73088(5) Å, c = 28.8193(5) Å, Z = 2; Y (0 0 0.36732(2)), Ti (0 0 0.06278(5)), O1 (0 0.5 0.08596(3)), O2 (0 0 0), S (0 0 0.17774(5)), Na (0 0.5 0.25) (occupancy 0.509(5)).

§ Magnetic susceptibility data were measured using a Quantum Design MPMS2 SQUID magnetometer. The susceptibility of **2** was determined from the differences in moments measured at 4.5 and 5.0 T due to the presence of 4 mol% of ferromagnetic $YTiO_3$[13] impurity. Compound **3** contained a small Ni impurity and was measured at 2.0 and 3.0 T.

First published as an Advance Article on the web 29th October 2001

NH_3-treated mesoporous silica (FSM-16) contains $SiNH_2$ sites which exhibit basic catalytic activity for Knoevenagel condensation; $SiNH_2$ and SiOH pair sites formed at lower NH_3-treatment temperatures exhibit higher turnover frequencies (TFs) in comparison with $SiNH_2$ single sites.

The development of solid base catalysts is now becoming active[1–5] to replace liquid bases for the production of fine chemicals in industrial processes, since solid bases are easy to recycle and are environment friendly.[6]

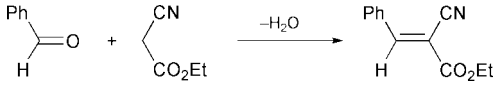
Mesoporous silica materials such as FSM-16[7] and MCM-41[8] developed in the last decade have high surface area (*ca.* 1000 m^2 g^{-1}) and regular nanometer size pores (2–10 nm), and thus provide suitable fields for functional guest components and large reaction spaces. It was reported that amino functionalised MCM-41 obtained by silylation catalysed the Knoevenagel condensation,[1] a typical base catalysed reaction.[1–6] However, this method requires complicated manipulation, and produces a waste solution. In order to obtain basic catalysts, simple routes have been reported *e.g.*, thermal treatments at above 1023 K for amorphous aluminophosphates[2] or zeolites[3] in a flow of NH_3, leading to the formation of $–NH_2$ and/or –NH– sites. We report here a new simple method to obtain basic mesoporous silica catalysts through NH_3 adsorption on evacuated silica surfaces. The present method can lead to pair sites of $SiNH_2$ and SiOH, which exhibit higher TFs in comparison with $SiNH_2$ single sites.

Siliceous mesoporous silica (Si/Al > 5000), FSM-16, was prepared in the same manner as in previous reports,[9] and the structure was confirmed by its XRD pattern and N_2 adsorption isotherm; the BET surface area was 850 m^2 g^{-1}.

FSM-16 was treated in O_2 (100 Torr, 1 Torr = 133 Pa) at a given temperature for 1 h and evacuated for 1 h at the same temperature (pre-evacuation). Then NH_3-treatment was carried out; evacuated FSM-16 was exposed to 30 Torr gaseous NH_3 for 30 min at 473 or 923 K in a closed system, and evacuated for 30 min at the same temperature. The sample after NH_3-treatment is denoted as FSMN. FSMN samples showed almost the same clear XRD pattern as that of FSM-16.

For the measurement of FTIR spectra, sample powders were pressed (30 kg cm^{-2}) into self-supported disks of 5–10 mg cm^{-2}. Temperature programmed desorption (TPD) was carried out for FSMN at a rate of 5 K min^{-1} in a flow of He (60 ml min^{-1}).

The Knoevenagel condensation [eqn. (1)] was carried out as follows. The powder catalyst was added to a toluene (2.5 ml)



(1)

solution of benzaldehyde (0.7 mmol) and ethyl cyanoacetate (0.5 mmol), then the reaction mixture was stirred at 323 K. Products were analyzed by gas chromatography (GC) employing dodecane as an internal standard.

Table 1 shows the results of the Knoevenagel condensation. The reaction occurred on all FSMN samples (entries 1–6), while reaction did not occur over unmodified FSM-16 (entry 7). ^1H NMR and GC did not detect any by-products, confirming the progress of the selective reaction. Moreover, basic species did not elute during the reaction, since the filtrate after the reaction over the active catalyst did not exhibit any activity (entry 8). These results indicate that NH_3 molecules are stabilised on FSM-16 to function as base catalytic sites.

The catalytic activity of FSMN increased with increasing the pre-evacuation temperature for FSM-16 prior to NH_3-treatment at 473 K (entries 1–3). Increase of the pre-evacuation temperature from 923 K (entry 4) to 1073 K (entry 5) prior to NH_3-treatment at 923 K also enhanced the activity. These results suggest that the sites on which NH_3 molecules are stabilised would be generated by evacuation at higher temperature. NH_3-treatment temperature also influenced the catalytic activity. Increase of the treatment temperature from 473 K

Table 1 Results of the Knoevenagel condensation[a]

Entry	Sample		Pre-evacuation temperature/K	NH_3-treatment temperature/K	Reaction		$SiNH_2$[b]/μmol g^{-1}	TF/h^{-1}
	Name	Weight/g			Time/h	Yield (%)		
1	FSMN-1	0.1	673	473	0.5	4.0	1.06	283[e]
2	FSMN-2	0.1	873	473	0.5	12	15.3	78.6
3	FSMN-3	0.1	1073	473	0.5	16	21.2	75.5
4	FSMN-4	0.1	923	923	0.5	30	124	24.1
5	FSMN-5	0.1	1073	923	0.5	35	140	25.0
6	FSMN-5[c]	0.05	1073	923	0.5	19	140	27.1
7	FSM-16	0.1	1073	—	18	0.0	0.0	0.0
8	filtrate[d]	—	—	—	72	0.0	—	0.0

[a] The reaction mixture (2.5 ml toluene as solvent, 0.7 mmol benzaldehyde, 0.5 mmol ethyl cyanoacetate and 100 mg powdered catalyst as standard) was stirred at 323 K. [b] Values were estimated by using the absorption coefficient of the $SiNH_2$ band at 1553 cm^{-1}. The coefficient was calculated in terms of molar amount of desorbed NH_3 in NH_3-TPD above 923 K per decreased amount of the integrated intensity of the $SiNH_2$ band for FSM-16N-5 above 923 K. [c] This sample was the same as that in entry 5 but the sample weight used for the reaction was halved (50 mg). [d] The filtrate was isolated from the mixture after the reaction for 30 h over FSM-16N-5. [e] Very high TF would be due to the underestimation of the $SiNH_2$ band.

 DOI: 10.1039/b107131a

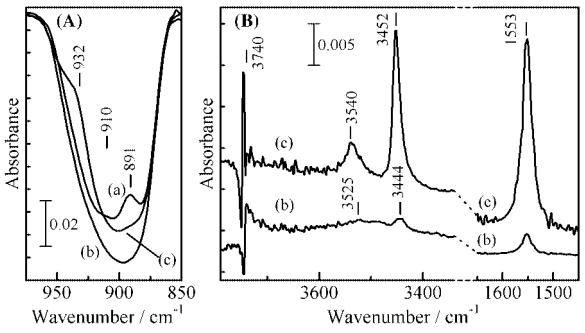


Fig. 1 (A) FTIR spectra of FSM-16 after evacuation at 1073 K (a), followed by NH_3-treatment at 473 K (b) and 923 K (c). (B) Difference spectra (b) and (c) obtained by subtraction of the spectrum (Aa) from (Ab) and (Ac), respectively. The intensity was normalised by the sample weight.

(entries 1–3) to 923 K (entries 4 and 5) enhanced the activity significantly. When a half amount of the sample of FSMN-5 (entry 5) was used, about half activity was observed (entry 6).

Fig. 1 shows the FTIR spectra of FSM-16. Evacuation at high temperature such as 1073 K gave rise to the absorption band at 891 cm^{-1} with a small band at 910 cm^{-1} (Fig. 1Aa). These bands were assigned to the strained siloxane bridge formed by dehydroxylation of the isolated hydroxy groups [eqn. (2)].[10]

(2)

Intensities of the strained siloxane bands increased with increasing the evacuation temperature above 673 K. After NH_3-treatment at 473 K, the strained siloxane bands at 891 and 910 cm^{-1} completely disappeared (Fig. 1Ab), and new absorption bands were generated at 1553 and 3444 cm^{-1} with a very weak band at 3525 cm^{-1} (Fig. 1Bb). These new bands could be assigned to bending, symmetric stretching and asymmetric stretching vibrations of $SiNH_2$, formed by dissociative chemisorption of NH_3 on the strained siloxane bridges [eqn. (3)].[10]

(3)

At the same time, the intensity of the SiOH band at 3740 cm^{-1} increased (Fig. 1Bb) upon NH_3-treatment, indicating that the reaction of eqn. (3) occurred during NH_3-treatment at 473 K. We confirmed that the reaction of eqn. (3) occurs even at r.t. as reported previously.[10] In the present study, NH_3-treatment was performed at 473 K to exclude physisorption of NH_3. No N–H bands other than the $SiNH_2$ bands were observed.

Higher temperature NH_3-treatment at 923 K resulted in generation of three intense bands at 3540, 3452 and 1553 cm^{-1} (Fig. 1Bc). These could be also assigned to $SiNH_2$ bands.[10] Also the Si–N stretching of $SiNH_2$ was observed at 932 cm^{-1} (Fig. 1Ac). Morrow *et al*. proposed that reaction can occur to form $SiNH_2$ [eqn. (4)] at high temperatures such as 923 K.[10] In the present case, much stronger $SiNH_2$ bands were formed (Fig. 1Bc) than at 473 K (Fig. 1Bb). However, the SiOH band intensity did not increase so much (Fig. 1Bc), and the strained siloxane band at 891 cm^{-1} decreased only partially (Fig. 1Ac). These results suggest that the reaction of eqn. (4) should mainly occur at 923 K rather than that of eqn. (3).

(4)

The amounts of $SiNH_2$ sites were estimated by using NH_3-TPD (see footnote *b* in Table 1) and are listed in Table 1. The yield in the Knoevenagel condensation increased with increasing the amount of $SiNH_2$ sites (Table 1), suggesting that $SiNH_2$ sites are the basic active sites catalysing this reaction.

Fig. 2 shows a plot of the product yield in the Knoevenagel condensation *vs*. the amount of $SiNH_2$. It is noteworthy that the

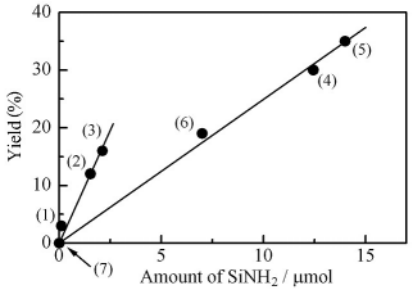

Fig. 2 Product yield for Knoevenagel condensation *vs*. the amount of $SiNH_2$ sites. The numbers in the plots correspond to the entry number in Table 1.

plot gives two straight lines (Fig. 2) the slopes of which are dependent upon the NH_3-treatment temperature. A steep slope was obtained by NH_3-treatment at 473 K (entries 1–3), while the less steep slope was obtained at 923 K (entries 4–6). The activity per amount of $SiNH_2$ (TF) was three times higher for the former than for the latter as shown in Table 1.

As mentioned above, pair sites of $SiNH_2$ and SiOH were formed at 473 K (Fig. 1Bb), while $SiNH_2$ sites with only few SiOH were formed at 923 K (Fig. 1Bc). Angeletti *et al*. proposed that the Knoevenagel condensation over propylamine catalyst bound on a silica surface was promoted by participation of residual surface silanols.[4] Therefore, in the present study, higher TFs for FSMN treated at 473 K (entries 1–3) would be attributed to the presence of SiOH with neighbouring $SiNH_2$ basic sites.

It can be concluded that NH_3-grafted mesoporous silica, FSMN, exhibits base catalytic activity for Knoevenagel condensation. The active basic site is $SiNH_2$ and higher pre-evacuation temperature and higher NH_3-treatment temperature are effective to form larger amounts of $SiNH_2$. Higher TFs were obtained for the FSMN on which pair sites of $SiNH_2$ and SiOH were formed by low temperature NH_3-treatment [eqn. (3)] in comparison with that for $SiNH_2$ single sites formed by high temperature NH_3-treatment [eqn. (4)].

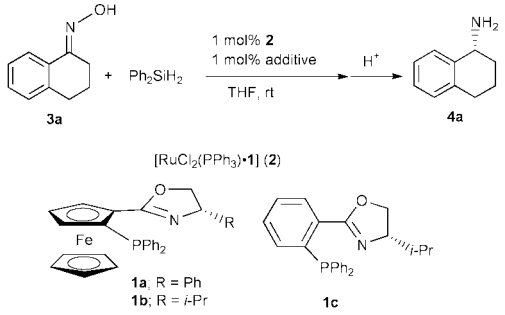
First published as an Advance Article on the web 22nd October 2001

Chiral ruthenium(II) complexes, $RuCl_2(PPh_3)$(oxazolinylferrocenylphosphine), have been found to be effective catalysts for asymmetric hydrosilylation of ketoximes to give the corresponding primary amines in good yields with high enantioselectivities (up to 89% ee) after acid hydrolysis.

Optically active *primary* amines are one of the most useful synthetic intermediates of natural compounds and pharmaceutical drugs.[1] However, the *direct* enantioselective synthesis of optically active *primary* amines with high enantioselectivities is limited only to the hydroboration of ketoxime ethers[2] and the kinetic resolution of *racemic primary* amines.[3] A catalytic hydrogenation of ketoximes producing directly the chiral *primary* amines has been reported by several groups, but no sufficient results have been achieved until now.[4] This is in sharp contrast to the enantioselective hydrogenation and transfer hydrogenation of imines catalysed by transition metal complexes with chiral ligands to afford the corresponding *secondary* amines with high enantioselectivities.[5,6] As an alternative *direct* enantioselective synthesis of chiral *primary* amines, Brunner and co-workers developed the rhodium-catalysed asymmetric hydrosilylation of ketoximes using DIOP (2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane) as a chiral ligand, but enantioselectivities of the produced *primary* amines were moderate (up to 36% ee).[7] On the other hand, we have recently disclosed that the ruthenium(II)- and iridium(I)-catalysed asymmetric hydrosilylation of imines by using oxazolinylferrocenylphosphines[8] (**1**) as chiral ligands gave the corresponding *secondary* amines with high enantioselectivities after acid hydrolysis (up to 89% ee).[9] As an extension of our studies, we have now investigated the ruthenium(II)-catalysed asymmetric hydrosilylation of ketoximes by using **1** as chiral ligands and have found that the corresponding chiral *primary* amines were produced successfully. Preliminary results are described here.

Treatment of 1-tetralone oxime[10] (**3a**) with 3 equiv. of diphenylsilane in THF in the presence of [$RuCl_2(PPh_3)$·**1a**] (**2a**) (1 mol%) at rt for 24 h afforded 1,2,3,4-tetrahydro-1-naphthylamine (**4a**) in 46% GLC yield with 74% ee (*R*) after acid hydrolysis (Scheme 1; Table 1, run 1).[11] The ee value of **4a** was determined by GLC analysis of the corresponding trifluoroacetamide. The relatively low yield of **4a** to the high conversion of **3a** is considered to be due to the formation of unidentified side products together with 1-tetralone, which was probably formed after the hydrolysis of some intermediates. The addition of AgOTf (1 mol%; OTf = OSO_2CF_3) to the reaction system slightly increased the yield of **4a** (Table 1, run 2). The use of **2b**, bearing *i*-Pr substituted oxazoline, in place of **2a** caused a decrease of the catalytic activity (Table 1, run 3). The ruthenium complex having an oxazolinylphenylphosphine[12] (**1c**) without planar chirality showed a quite low enantioselectivity (Table 1, run 4), compared with that having an oxazolinylferrocenylphosphine (**1a** and **1b**). Reaction in the presence of 2 mol% of **2a** and AgOTf in DME (1,2-dimethoxyethane) gave the best enantioselectivity (up to 83% ee) (Table 1, runs 5 and 6). It is noteworthy that none of the oxazolinylphosphines (**1a**, **1b**, and **1c**) worked effectively as chiral ligands for the rhodium- and iridium-catalysed asymmetric hydrosilylation of ketoximes. For example, the ee values of **4a** obtained by using rhodium and iridium catalysts having **1a** were only 8% (*S*) and 5% (*R*), respectively. Furthermore, no reaction occurred when the ruthenium complex with DIOP was employed under the same reaction conditions, in contrast to Brunner's results[7] described above (Rh-catalysed: up to 36% ee).

Asymmetric hydrosilylation of other ketoximes with diphenylsilane was investigated in the presence of **2** and AgOTf.[13] Typical results are summarised in Table 2. Reactions of 1-indanone oxime (**3b**) and 1-benzosuberon oxime (**3c**) proceeded smoothly, but only moderate enantioselectivities were obtained (Table 2, runs 3–5). In the case of acetophenone



Scheme 1 Asymmetric hydrosilylation of ketoximes.

Table 1 Ruthenium-catalysed asymmetric hydrosilylation of 1-tetralone oxime (**3a**)[a]

Run	Catalyst/ mol%	Additive/ mol%	Reaction time/h	Conv. of **3a** (%)	Yield of **4a** (%)[b]	ee of **4a** (%)[c]
1	**2a** (1)	—	24	>95	46	74 (*R*)
2	**2a** (1)	AgOTf(1)	18	>95	50	78 (*R*)
3	**2b** (1)	AgOTf(1)	80	>95	45	74 (*R*)
4	**2c** (1)	AgOTf(1)	40	77	44	23 (*R*)
5	**2a** (2)	AgOTf(2)	15	>95	71	79 (*R*)
6[d]	**2a** (2)	AgOTf(2)	24	>95	65	83 (*R*)

[a] All reactions were carried out in the presence of a catalyst and an additive using ketoxime **3a** (1.0 mmol) and Ph_2SiH_2 (3.0 mmol) in THF (5 ml) at rt.[b] GLC yield.[c] Determined by GLC analysis of the corresponding trifluoroacetamide.[d] DME was used in place of THF.

 DOI: 10.1039/b106435p

11	**3h**	**2a**	THF	90	>95	6	12 (*R*)

[a] All reactions were carried out in the presence of catalyst (0.010 mmol) and AgOTf (0.010 mmol) using ketoxime **3** (0.50 mmol) and Ph_2SiH_2 (2.0 mmol) in solvent (5 ml) at rt.[b] GLC yield.[c] Determined by GLC analysis of the corresponding trifluoroacetamide.

oxime (**3d**),[14] the best enantioselectivity of 89% ee was achieved (Table 2, run 7). Introduction of a *p*-halogeno or *p*-methyl substituent to the aromatic ring of acetophenone oxime slightly decreased the enantioselectivity (Table 2, runs 8–10). When **2b** was used in place of **2a** as catalyst, a slightly better enantioselectivity was obtained in several cases (Table 2, runs 7–10). Dialkyl ketoxime (**3h**) was also converted into the corresponding dialkyl amine, but unfortunately in low yield with low enantioselectivity (Table 2, run 11).

In summary, we have developed the highly enantioselective ruthenium(II)-catalysed hydrosilylation of ketoximes to give the corresponding *primary* amines with high enantioselectivities (up to 89% ee) after hydrolysis. This may provide a versatile method for the straightforward synthesis of chiral *primary* amines because of the ready accessibility of ketoximes by reaction of ketones with hydroxylamine. Further work is currently in progress aiming at the elucidation of the reaction mechanism and broadening the scope of this asymmetric hydrosilylation.

This work was supported by Grant-in-Aid for Scientific Research (Nos. 09102004 and 12750747) from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

10 In the present study, the prochiral ketoximes were used as formed from the corresponding ketones and hydroxylamine liberated from hydroxylammonium chloride.[7] A single isomer of each ketoxime was tentatively assigned as (*E*)-form from the following arguments: G. L. Karabatsos and N. Hsi, *Tetrahedron*, 1967, **23**, 1079; K. Maruoka, T. Miyazaki, M. Ando, Y. Matsumura, S. Sakane, K. Hattori and H. Yamamoto, *J. Am. Chem. Soc.*, 1983, **105**, 2831; D. L. Boger and W. L. Corbett, *J. Org. Chem.*, 1992, **57**, 4777; K. D. Sugi, T. Nagata, T. Yamada and T. Mukaiyama, *Chem. Lett.*, 1997, 493.

11 When the reaction of **3a** (2.50 mmol) with diphenylsilane (10.0 mmol) was carried out under the same reaction conditions, **4a** was isolated in 67% yield (70% GLC yield) with 80% ee.

12 G. Helmchen and A. Pfaltz, *Acc. Chem. Res.*, 2000, **33**, 336 and references cited therein.

13 A typical procedure for ruthenium-catalysed asymmetric hydrosilylation of ketoximes is as follows. In a 20 ml flask were placed catalyst **2a** (10.3 mg, 0.010 mmol; 2.0 mol%) and AgOTf (2.6 mg, 0.010 mmol; 2.0 mol%) under N_2. Anhydrous DME (5 ml) was added, and then the mixture was magnetically stirred at rt for 1 h. After the addition of 1-tetralone oxime (**3a**) (80 mg, 0.50 mmol), diphenylsilane (2.0 mmol) was slowly added at rt and the mixture was stirred at rt for an appropriate time. The mixture was then quenched with MeOH (1.0 ml), stirred at rt for 30 min, and subsequently hydrolysed by the addition of 1 N HCl aq. The mixture was extracted with water (50 ml), and 3 N NaOH aq. (20 ml) was added to the aqueous solution to obtain a free amine. This solution was extracted with diethyl ether (50 ml × 3) and the extract was dried over anhydrous $MgSO_4$. For GLC analysis of the yield of **4a**, *n*-tetradecane was added as an internal standard. The optical purity was determined by GLC analysis of the corresponding trifluoroacetamide on a cyclodextrin phase (Chiraldex GT-A, 30 m). The absolute configuration of **4a** was determined by an optical rotation..

14 Acetophenone oxime (**3d**) was assigned as the (*E*)-isomer by ^{1}H NMR; F. G. Bordwell and G.-Z. Ji, *J. Org. Chem.*, 1992, **57**, 3019.

Multi-component coupling reactions: synthesis of a guanidine containing analog of the hexahydropyrrolo[3,2-*c*]quinoline alkaloid martinelline

Robert A. Batey* and David A. Powell

A multi-component coupling reaction is used to synthesize a highly functionalized guanidine containing pyrroloquinoline analog of martinelline that displays bradykinin B2 receptor antagonist activity.

The martinelline alkaloids **1**[1] (Fig. 1) have attracted a considerable amount of interest from the synthetic community,[2–4] much of which stems from the unique biological activity and unprecedented (in nature) hexahydropyrrolo[3,2-*c*]quinoline core of these natural products. Martinelline was the first naturally occurring, non-peptidic bradykinin receptor antagonist to be identified and antagonists of the bradykinin B2 receptor have been implicated as potential therapeutics for pain, rhinitis, shock and asthma.[5] Hence martinelline and derivatives thereof offer significant potential as novel pharmaceutical agents. Despite considerable work towards the synthesis of the tricyclic core,[2] only recently has a 29 step total synthesis of (−)-martinellic acid **1b** been achieved.[3] Furthermore, there are no reported structure–activity relationship studies on synthetic analogs of **1a** and **1b**.

We recently reported a one pot protocol towards the hexahydropyrrolo[3,2-*c*]quinoline core of martinelline utilizing a lanthanide triflate[6,7] catalyzed formal hetero Diels–Alder reaction (Povarov reaction)[8] between an aniline, aldehyde and a protected endocyclic enamine component (*N*-CBz 2-pyrroline).[4] In all cases an approximate 1:1 mixture of *endo*:*exo* diastereomers[9] was observed using $Dy(OTf)_3$ in MeCN. Moreover, conversion of the deprotected pyrrolidine nitrogen to a trisubstitued guanidine proved to be problematic. An alternative strategy to introduce the *N*-1 guanidine from an appropriately functionalized 2-pyrroline was thus required. We now report the first use of a synthetic equivalent to a 2-pyrroline, which employs an *N*-thiocarbamoyl group to improve the *exo*-selectivity of the hetero Diels–Alder reaction and provides a means to introduce the challenging *N*-1 trisubstituted guanidine functionality. A simplified analogue of **1a** which displays similar biological activity to the natural product is synthesized using this strategy.

One approach to improve the diastereoselectivity of the key 3-component Povarov reaction is to modify the *N*-substituent on the 2-pyrroline component. This approach initially appears to be problematic, as the synthesis and isolation of the requisite *N*-substituted-2-pyrrolines by dehydration of the corresponding hemiaminals requires harsh conditions (acid catalysis with reflux) and often proceeds in low yields. We considered that cyclic hemiaminals could however serve as *in situ* equivalents of *N*-substituted-2-pyrrolines under the mildy Lewis acidic conditions employed for the 3-component coupling reaction. Since thioureas are useful guanidine precursors, a *N*-thiocarbamoyl group was considered an ideal choice for this purpose. Synthesis of the pyrrolidine carbothioic acids (Scheme 1) was accomplished through reaction of the sodium anion of 2-pyrrolidinone with benzylisothiocyanate. The resulting lactam was reduced with 1.5 equiv. of DIBAL-H in CH_2Cl_2 at −78 °C to furnish the lactamol **2**. Lactamol **2** was found to be unstable when stored for extended periods of time and was converted to the methyl ether **3**, which could be stored for up to 8 months at room temperature without significant decomposition.

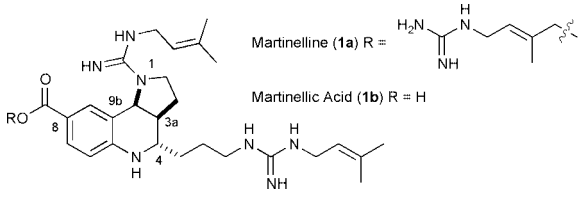

Fig. 1 Martinelline alkaloids (IUPAC numbering).

As desired, both **2** and **3** serve as endocyclic enamine equivalents in the lanthanide triflate catalyzed Povarov reaction. Lewis acid promoted loss of water from **2** or MeOH from **3** generates *in situ N*-substituted-2-pyrroline which reacts with the 2-azadiene, generated *in situ* from the aldehyde and aniline components, affording pyrroloquinoline **4** as a 7:3 mixture of *exo*:*endo* diastereomers (Table 1). This is the first example, to our knowledge, of the use of N-protected hemiaminals as dienophile precursors in hetero Diels–Alder reactions of this type and offers a significant improvement in both the range of protected endocyclic enamines and facility with which they can be employed as dienophiles.[10] This observation is of potential importance for combinatorial applications of such 3-component coupling reactions.

We envisioned the conversion of thiourea **4** to the trisubstituted guanidine through a modified Rathke procedure. Accordingly, 3-component coupling product *exo*-**4b** was ethy-

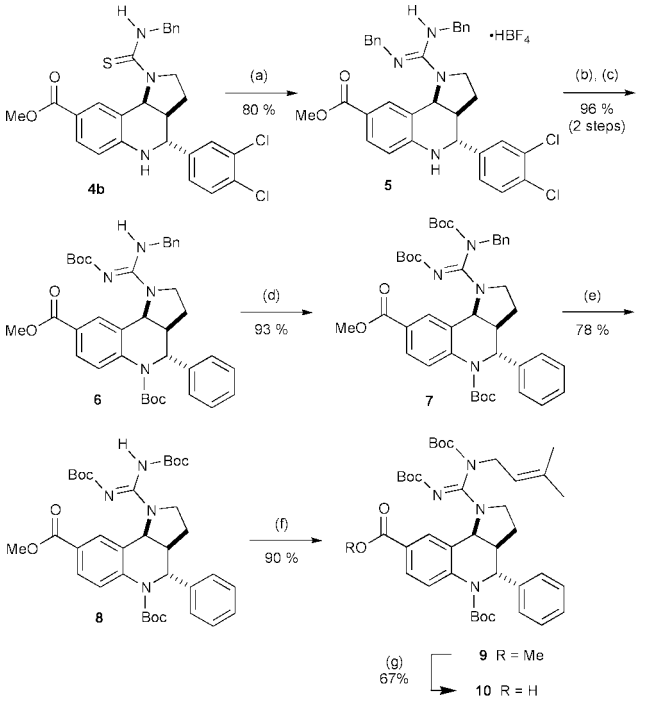
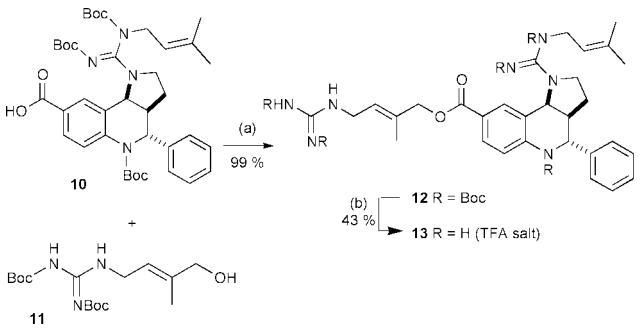


Scheme 2 *Reagents and conditions*: (a) i) $Et_3O^+BF_4^-$ (1.0 equiv.), CH_2Cl_2, rt, 1 h; ii) $BnNH_2$, MeCN, 75 °C, 20 h; (b) Boc_2O, DMAP, Cs_2CO_3, CH_2Cl_2, rt, 24 h; (c) $Pd(OH)_2$ (10 mol%), H_2, Et_3N, MeOH, rt, 5 h; (d) Boc_2O, DMAP (5 mol%), CH_2Cl_2, 4 h; (e) $Pd(OH)_2$ (50 mol%), H_2, Et_3N, MeOH, rt, 24 h; (f) 4-bromo-2-methylbutene, K_2CO_3, MeCN, 50 °C, 4 h; (g) *t*-BuOK, H_2O, THF, 70 °C, 5 h.

lated with 1.0 equiv. of triethyloxonium tetrafluoroborate[11] and the crude mixture refluxed with benzylamine in MeCN for 20 h to afford guanidinium salt **5** in 80% yield (Scheme 2). Debenzylation of the guanidine was accomplished through a modification of a procedure first outlined by Isobe.[12] First the guanidine and aniline nitrogens were acylated with Boc_2O under basic conditions. The benzyl groups were then removed sequentially with hydrogenation over Pearlman's catalyst. Treatment with catalytic $Pd(OH)_2$ and Et_3N in MeOH gave the monodebenzylated guanidine **6** in quantitative yield. Perhaps not surprisingly, the aryl chloride was also reduced under these conditions. Acylation of the guanidine at the more nucleophilic nitrogen gave **7**, which on hydrogenation gave the fully protected guanidine compound **8**. The isoprenyl side chain was installed through nucleophilic displacement of bromide from 4-bromo-2-methylbutene under basic conditions. Finally, the methyl ester **9** was hydrolyzed with *t*-BuOK–H_2O in THF[13] to afford carboxylic acid **10** in 67% yield.

The side chain **11** was installed through Mitsunobu coupling with acid **10** to give ester **12** which was deprotected with TFA–CH_2Cl_2 to yield the highly functionalized model compound **13** as its TFA salt (Scheme 3).[14] The binding affinities of (±)-**13** against human bradykinin B1 and human and rat B2 receptors were determined with IC_{50} values of >10 μm, 1.7 μm and 2.4 μm respectively. Similar selectivity for the B2 over the B1 receptors is shown for (±)-**13** and martinelline.[1] The B2 binding affinity of (±)-**13** is between that of martinelline and martinellic acid, suggesting that the guanidine containing C-8 ester side chain is of greater importance for B2 receptor antagonist activity than the C-4 aliphatic guanidine side chain.

In conclusion, these model studies have demonstrated the convergent synthesis of a highly functionalized derivative of martinelline containing 2 of the 3 guanidine side chains and a phenyl group in place of the C-4 aliphatic guanidine side chain. In addition, the first biological studies reported on a synthetic analog of martinelline are presented. Further application of this methodology towards the synthesis of martinelline, martinellic acid and analogs thereof will be reported in due course.



Scheme 3 *Reagents and conditions*: (a) **11** (1.2 equiv.), PPh_3, DEAD, THF, rt, 2 h; (b) TFA, CH_2Cl_2, rt, 24 h.

We thank Paul D. Simoncic for preliminary studies and the synthesis of **11** and Joanne Butterworth at AstraZeneca for ligand binding studies on **13**. We also thank Dr A. B. Young for mass spectrometric analyses and Dr T. Burrow for NMR analysis of **13**. AstraZeneca, the Natural Science and Engineering Research Council (NSERC) of Canada and the Ontario Research and Development Challenge Fund supported this work. D.A.P. thanks AstraZeneca and NSERC for an Industrial Postgraduate Scholarship.

Received (in Cambridge, UK) 30th August 2001, Accepted 2nd October 2001
First published as an Advance Article on the web 31st October 2001

The activation energy for hydrogen abstraction from imidazolium-based ionic liquids is significantly higher than that observed in conventional solvents.

The photochemistry of benzophenone (Bp) has been widely investigated over the past 50 years. Its ability in its excited state to act as an energy transfer donor, electron acceptor or hydrogen atom abstracting agent has been exploited in numerous studies.[1] As part of a continuing study of the influence of ionic liquids[2] on photochemical processes,[3] we now report our initial results on hydrogen abstraction from these solvents by triplet excited state benzophenone (^{3}Bp*). Although ionic liquids are finding increasing use in a wide range of applications, there have been only a few reports on the behaviour of excited state species or reactive intermediates in these media.[3,4] Furthermore, only a handful of photochemical systems have been studied in ionic liquids to date, often with results that are quite different from those observed in conventional solvents.[5]

The ionic liquids used in this study were based on the cations 1-butyl-3-methylimidazolium ([bmim]$^+$), 1-methyl-3-octylimidazolium ([omim]$^+$) and 1-butyl-2,3-dimethylimidazolium ([bmmim]$^+$), combined with the anions $[PF_6]^-$ and $[Tf_2N]^-$ (Tf = CF_3SO_2), chosen to give a moderate degree of structural variation. All are immiscible with water, facilitating their preparation in a 'spectroscopically pure' form.‡ Hydrogen abstraction was studied in five different ionic liquids and three conventional solvents using laser flash photolysis methods.§ Laser excitation (λ_{ex} = 355 nm) of N_2-saturated 5 mM solutions of Bp gave rise to a broad feature with a maximum at λ = *ca.* 525 nm, entirely typical of ^{3}Bp*.[6] This species decayed *via* first order kinetics over several microseconds forming a second, long-lived species that exhibited a slight solvent dependence in its absorption maximum (λ_{max} = 530–550 nm), suggesting formation of the hydrogen abstraction product benzophenone ketyl radical (KR). An example of the spectra obtained is given in the ESI†. The short–lived component formed initially was quenched by naphthalene at a diffusion controlled rate,[7] forming triplet excited state naphthalene (λ_{max} = 425 nm). The decay rate of both components was strongly dependent on oxygen concentration. We are therefore very confident of the assignment of both species (see Scheme 1). The hydrogen abstraction product, benzophenone ketyl radical (KR) is known to exhibit a λ_{max} value around 540 nm (±10 nm), depending on the solvent.[8] The lifetime of KR was orders of magnitude longer than that of ^{3}Bp*.

It is clear that the values of the first order decay rate constant of ^{3}Bp*, k_{obs}, determined in ionic liquids are an order of magnitude *lower* than those observed in the conventional solvents (see Table 1) despite the clear availability of abstractable alkyl hydrogen atoms on the cation substituents. In cyclohexane, toluene and butan-1-ol, we found that the relative amplitudes of absorbances from KR relative to those of ^{3}Bp* were independent of temperature, indicating that ^{3}Bp* decays entirely *via* the hydrogen abstraction process in these solvents. However, the amplitude of the KR signals increased relative to those of ^{3}Bp* with increasing temperature in the ionic liquids. This indicates that not all ^{3}Bp* species decayed *via* a single process in these media. There are two possible mecanisms responsible for this temperature dependence of KR quantum yield: competing decay pathways of the ^{3}Bp* or geminate recombination of the KR and solvent radicals competing with cage escape. The latter seems unlikely despite the high viscosities of the ILs because there is no correlation between the yield of KR and solvent viscosity, η. Consequently it seems more likely that the former mechanism is responsible for the yield effects.

As Scheme 1 shows, ^{3}Bp* can decay *via* two competing processes: H-atom abstraction from the solvent (rate constant k_H) to form KR, and intersystem crossing (ISC, rate constant k_T) giving the ground state. The observed first order rate constant is the sum of these two rate constants (*i.e.*, $k_{obs} = k_H + k_T$). Based on the assumption that the absorbance measured directly after the laser pulse arises entirely from ^{3}Bp*, while the absorbance after several μs arises from KR only, it is possible to calculate the values of k_H and k_T from the intensities of the transient absorption bands for ^{3}Bp* and KR. Values of k_H were then calculated using eqn. (1) where ΔA_H and ΔA_T are the absorbance signals at 530 nm due to KR and ^{3}Bp*, respectively, and $\varepsilon_T/\varepsilon_H$ is the ratio of the molar absorptivities of ^{3}Bp*:KR at 530 nm. The value of $\varepsilon_T/\varepsilon_H$ was taken as 2.4 in all cases.[9]

$$k_H = k_{obs}(\Delta A_H/\Delta A_T)(\varepsilon_T/\varepsilon_H) \quad (1)$$

The values of k_{obs} (and thus k_H) were recorded over the temperature range 3–70 °C in each solvent, and the Arrhenius parameters for H-abstraction were determined. The results are summarised in Table 1.¶

The k_T values listed for the ionic liquids are comparable to that observed in benzene (*ca.* 1.7 × 10^5 s^{-1} at 298 K), an electrophilic solvent in which no hydrogen abstraction occurs. The cationic components of the ILs are also of course electrophilic, suggesting that similar solvation effects are responsible for controlling ^{3}Bp* deactivation in both solvent types. The Arrhenius data for hydrogen abstraction clearly show that the low k_{obs} values in ionic liquids arise from the lower values of k_H in these solvents compared with conventional solvents. It is also clear that there is a significant difference in E_a values between the ionic liquids and those in conventional

solvents (*ca.* 25 and 15 kJ mol^{-1} respectively). Despite the uncertainty in $\varepsilon_T/\varepsilon_H$, our results indicate that the uniformly low k_H values in ionic liquids arise as a consequence of uniquely high E_a values in these solvents rather than systematic variation in A_H values. The similarities in A_H values suggest that the transition state geometries for H-abstraction are similar in all the solvents in this study.‖ The results show that the activation parameters for H abstraction in the ionic liquids are essentially independent of the anionic component and the availability of the hydrogen atom at the 2-position on the imidazolium ring. Also, the values of k_H are larger for the [omim]$^+$ salts than those with [bmim]$^+$ or [bmmim]$^+$ cations. We therefore conclude that it is more likely that an alkyl chain H atom is being abstracted in the ionic liquids, but cannot currently discriminate its precise location. It should be noted that abstraction of a benzylic H atom would result in the formation of a resonance stabilised radical cation.

Several factors are known to influence the rate constant for H abstraction by aromatic ketone excited states. Firstly, the nπ* or $\pi\pi$* character of the ketone excited state can be influenced by solvent polarity. UV–VIS spectra suggest that no unique interactions are observed in ionic liquids compared with the conventional solvents (see ESI†). Furthermore, there is no evidence that the differences in E_a can be attributed to differences in bond strength of the C–H bonds involved in the abstraction process as has been noted previously.[10] IR and ^{1}H NMR spectra suggest that alkyl CH bonds in the 1,3-dialkylimidazolium salts display essentially the same properties as alkanes, with the exception of the CH_2 group bonded directly to the ring. Finally, there is no evidence for the influence of a charge transfer interaction in the excited state, as the spectra of ^{3}Bp* and KR are essentially identical to those in conventional solvents.

Thus, there is no spectroscopic evidence for uniquely strong interactions between the ILs and Bp or ^{3}Bp*. The similarity in pre-exponential factors for H-abstraction in all solvents suggests that the transition state structure is solvent independent. It is possible that electrostatic interactions between the solvent ions must be broken or disrupted in order to arrive at the common transition state geometry. Small movements of either ion could then result in significant energy costs resulting in the raising of the transition state energy and thereby E_a.

Finally, these results show that the effect of an ionic liquid on a relatively well understood chemical reaction involving low polarity reactants and transition states may be very significant and yet have a subtle origin. We have observed that significant lowering of rate constants for hydrogen abstraction from the solvent can occur despite the absence of any direct solvation effects on reactants. These results also show, however, that ionic liquids cannot be regarded as entirely 'innocent' solvents in the presence of reactive species.

We would like to thank the EPSRC (Grant No. GR/M56852) for financial support and the award of a studentship (M. J. M.), the Royal Society of Edinburgh for the award of a BP Research Fellowship (C. M. G.), and 3M (Minneapolis, MN) for a gift of Li(Tf_2N).

Notes and references

‡ The liquids were prepared following standard literature procedures (see ESI† for details of purification of starting materials).[11]

§ The laser flash photolysis set-up is described elsewhere.[12] All ILs were dried by heating at *ca.* 70 °C under vacuum for several hours prior to preparation of the solutions. Bp (Aldrich) was purified by sublimation. All solutions were thoroughly degassed with nitrogen prior to data collection.

¶ It should be noted that variation from the value of 2.4 estimated for the relative molar absorptivity values does not affect the calculated value of $E_a{}^H$, but only the value of A_H. Arrhenius plots for the ionic liquids may be found in the ESI†.

‖ We cannot directly compare solvent *A* values because of our assumptions regarding the ε ratio and also our lack of current knowledge as to which H atoms are being abstacted from RTILs. Before such comparisons can be made for different solvents, it is necessary to carry out a statistical correction for the relative number of identical, abstractable hydrogen atoms present in each solvent. In this case we cannot 'normalise' the *A* values for the RTILs as we can the conventional solvents. However, were alkyl substituent H atoms being abstracted slightly *higher* values of *A* in RTILs would be calculated than those of the conventional solvents. Were benzylic hydrogen atom abstraction to be dominant, similar values of *A* would be obtained in all solvents. Further research is currently under way in order to clarify this point.

A by-product using TIPS protection—a warning

David J. Barden and Ian Fleming*

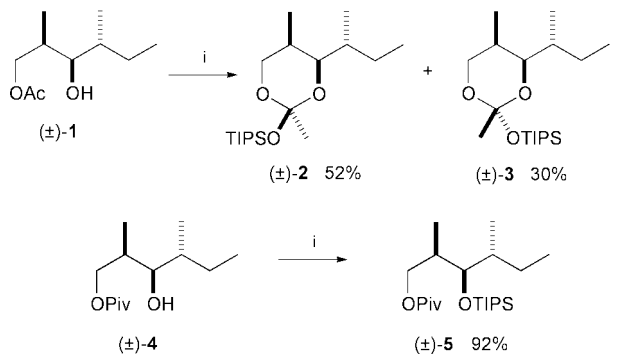
Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: if10000@cam.ac.uk; Fax: +44 (0)1223 336362; Tel: +44 (0)1223 336372

Received (in Cambridge, UK) 16th August 2001, Accepted 9th October 2001
First published as an Advance Article on the web 31st October 2001

The TIPS derivatives of alcohols are contaminated with more or less of the diisopropyl(*n*-propyl)silyl derivative, which can be a major product when a bad batch of reagent is used, a large excess of reagent is used, and/or the reaction is not taken to completion.

We reported elsewhere a half-expected problem that we met when using the triisopropylsilyl (TIPS) protecting group—the alcohol **1** gave the ortho esters **2** and **3** on attempted silylation.[1] We had expected that acyl migration might be a problem, but we had not expected that it would be the most hindered of the possible alcohol components in equilibrium with each other that would be selected, although there had been two precedents in the silylation of the tetrahedral intermediate produced by intramolecular attack of a secondary alcohol on the carbonyl group of a cyclic imide.[2] The problem was easily overcome in our case by using the pivalate (±)-**4** instead of the acetate, when we obtained cleanly the derivative (±)-**5** with the pivalate on the primary alcohol and the TIPS on the secondary. We now report an entirely different and more general problem when using the TIPS protecting group.

The reactions in Scheme 1 were carried out with racemic material. More recently we have repeated the sequence[3] with enantiomerically enriched material. All the intermediates in the synthetic sequence up to and including the alcohol (+)-**4** were identical (^{1}H-NMR, ^{13}C-NMR, IR, TLC) to the samples prepared earlier, except of course for their optical rotation. We were dismayed, however, when its TIPS derivative gave ^{1}H-NMR and ^{13}C-NMR spectra that were slightly different from those we had measured before. Careful inspection of the ^{1}H-NMR spectrum revealed, downfield of the diagnostic signal from the C-3 proton, a similar signal from a minor component corresponding exactly to the compound (±)-**5** observed in the racemic series. This meant that there was a new product **6** in addition to a little of the right compound (Scheme 2), and that the anomalous spectra were not caused by some unlikely association phenomenon that might have made the enantiomerically enriched materials give different NMR spectra from their racemic counterparts. Furthermore, the next two intermediates in our synthetic sequence also had spectra with the same features—a major product and a slightly different minor product matching the corresponding intermediates in the racemic series.



Scheme 1 *Reagents and conditions*: i, Pr$^i_3$SiOTf, 2,6-lutidine, CH_2Cl_2, rt, 30 min.

The presence of a new product might have meant that our enantiomerically enriched material was a diastereoisomer of the alcohol (+)-**4**, with the difference showing up only after TIPS protection; it might have meant that the TIPS and pivalate had exchanged places in this work, even though we knew they had not in the earlier work; finally, it might have meant that there was something wrong with the TIPS reagent. We have now found that it is the last of these explanations—we were the victims of an unfortunate batch of contaminated TIPS triflate.[4] When we repeated the TIPS protection with a different batch of TIPS triflate, the product (+)-**5** now had NMR spectra that were identical to those in the racemic series, and the merest trace of the byproduct was all that we could detect. Order was restored.

We might have left the problem there, but we have noticed that *all* batches of TIPS triflate that we have been able to test have the same problem, usually to a lower extent, making it less noticeable. It is, however, unlikely that we will be the last people to meet this problem, and so we have investigated its nature.

We used 2,4-dimethylpentan-3-ol **7** as a test compound—a secondary alcohol with a similar degree of steric hindrance to that of the alcohol **1**. It too gave two products with the contaminated batch of TIPS triflate, but essentially only one **8** with a good batch of TIPS triflate.[5] The two products could easily be detected in their ^{1}H-NMR spectra by the carbinol proton on C-3, the triplet from the TIPS derivative was at δ3.47 and that from the byproduct at δ3.33. GC-MS showed that the two compounds were isomers. The next clue about what might be wrong came when we found that we could easily control the proportions of the two products by varying the molar proportions of the alcohol **7** and the TIPS triflate reagent. If the contaminated triflate was used in ever larger excess, the amount of byproduct **9** went up proportionately (Scheme 3). We estimate, using the proportion 4:96 of **8**:**9** from the run with the

largest excess of triflate reagent, that the contaminant was reacting nearly 300 times faster than the TIPS triflate.[6] Evidently it was a less hindered silylating agent, and it seemed plausible that it would prove to have a *n*-propyl group in place of one or more of the isopropyl groups.

We confirmed this supposition from the ^{1}H-NMR and ^{13}C-NMR spectra of the silyl ether **9** prepared using the highest ratio of TIPS triflate to alcohol **7**.[7] The ^{13}C-NMR spectrum using the attached proton test showed two methylene signals at δ 15.3 and 17.3 and one methyl signal at δ19.0 from C-1′, C-2′ and C-3′, in addition to the methines and methyls of the isopropyl groups and the carbinol carbon. The ^{1}H-NMR spectrum showed a clear but imperfectly resolved 3-proton triplet at δ0.98 from the 3′ protons of the n-propyl group. In addition there was a 2-proton multiplet at δ 1.42 from the 2′ protons, and a 2-proton multiplet at δ 0.66 from the 1′ protons, neither of which was first-order. An HMQC spectrum showed that the signals assigned to the protons and the carbons of the *n*-propyl group were correlated. None of these signals was present in the spectrum of the pure TIPS derivative **8**. The integrals in the ^{1}H-NMR spectrum showed that there was one *n*-propyl group and not two, a conclusion that was supported by the ^{13}C-NMR spectrum, which showed *two* signals for the methyl groups in the isopropyl groups on silicon, which can only be diastereotopic if there are two isopropyl groups.

When we used an excess (1.5 : 1) of the alcohol **7**, instead of an excess of triflate, the ratio of **8** : **9** was 92 : 8, indicating that our batch of TIPS triflate had been contaminated with about 8% of diisopropyl(*n*-propyl)silyl triflate. A similar experiment with the better reagent indicated that it contained 4% of the impurity, but when this reagent was used in tenfold excess, the ratio of **8** : **9** was a noticeable 42 : 58. It is obviously unwise ever to use an excess of the TIPS reagent. Our original problem with the alcohol (+)-**4** arose, not because we had used a notably large excess of silyl triflate, but because we had failed to allow the reaction to go to completion, another pitfall. We also tested a primary alcohol, 2-methylbutanol, and found that it too gave both silyl ethers. With a tenfold excess of the bad batch, the ratio of TIPS ether to diisopropyl(*n*-propyl)silyl ether was 70 : 30, significantly better than the corresponding ratio 13 : 87 found for the secondary alcohol **7**, as might be expected for a less hindered and therefore less selective nucleophile.

We have been unable to find out how the reagent is made, having been informed only that the method is 'proprietary'. Corey made TIPS triflate by treating triisopropylsilane with triflic acid.[8] The triisopropylsilane had in turn been made by Cunico and Bedell from trichlorosilane and isopropylmagnesium chloride.[9] It seems likely that the alkyl halide used to make the Grignard reagent (or whatever is used commercially) might not always be purely isopropyl. It is also conceivable that the isopropyl Grignard might slowly rearrange to give some *n*-propyl Grignard, and that old batches of Grignard reagent might not reflect the alkyl halide composition that went into them. Furthermore, there is a multiplying factor that makes 1% of the *n*-propyl contaminant in the Grignard reagent lead statistically to 3% of the *n*-propyl impurity in TIPS triflate. It might well be worse than that if there is any selective reactivity in favour of the primary Grignard reagent.

In conclusion, *you are likely to find a byproduct whenever you use TIPS protection*. The problem is worst when (a) an inferior batch of reagent is used, (b) a large excess of reagent is used, (c) the reaction is not taken to completion (d) the alcohol is relatively hindered, and presumably, although we have not tested this, (e) the alcohol is added to the triflate instead of the triflate being added to the alcohol. In our experience, the diisopropyl(*n*-propyl)silyl derivatives have the carbinol proton between 0.05 and 0.14 ppm upfield of the signal from the corresponding signal in the TIPS derivative, and there is always a characteristic multiplet, which is not a first-order triplet, close to δ0.66 from the $SiCH_2$ protons.

Electronic origin of the structural versatility in linear trichromium complexes of dipyridylamide

Noureddine Benbellat, Marie-Madeleine Rohmer* and Marc Bénard*

Laboratoire de Chimie Quantique, UMR 7551, CNRS and Université Louis Pasteur, 4 rue Blaise Pascal, F-67000 Strasbourg, France. E-mail: benard@quantix.u-strasbg.fr; rohmer@quantix.u-strasbg.fr

Received (in Cambridge, UK) 10th July 2001, Accepted 2nd October 2001
First published as an Advance Article on the web 31st October 2001

Spin unrestricted DFT calculations on $Cr_3(dpa)_4Cl_2$ (dpa = dipyridylamide) suggest that the linear $(Cr_3)^{6+}$ metal framework could adopt either a symmetric conformation, or a strongly nonsymmetric one, depending on the nature of the spin coupling between the localized metal electrons.

In a series of recent articles, Cotton, Murillo and co-workers have shown that the linear trimetallic framework of complexes belonging to the $M_3(dipyridylamide)_4L_2$ family (Fig. 1) exhibits an unprecedented structural variability when the metal is Co^{II},[1,2] or Cr^{II}.[3] The case of cobalt complexes, and more especially $Co_3(dpa)_4Cl_2$, has been most extensively documented. It was proved that the same compound can exist with either a symmetrical (*s*) Co3 chain, or an unsymmetrical (*u*) one, solely depending on the crystal form in which it is found.[1] The structural behavior of the chromium complexes $Cr_3(dpa)_4L_2$ and $Cr_3(dpa)_4LL'$ presents strong analogies, and some differences. Complexes with identical axial ligands, including $Cr_3(dpa)_4Cl_2$ (**1**), show a clear preference for the *s* conformation, even though two types of moderately unsymmetrical arrangements (Δd_{Cr-Cr} = 0.064 Å and 0.118 Å at −60 °C) reminiscent of the *u* conformation of $(Co_3)^{6+}$ complexes, were observed in one of the reported crystal structures.[3] However, the two $Cr_3(dpa)_4LL'$ compounds with different ligands in axial position (L = Cl; L′ = BF_4^-, PF_6^-) exhibit extremely unsymmetrical arrangements, with Cr–Cr distances of the order of 2.00 Å and 2.62 Å, respectively. Magnetic measurements confirm that the ground state should be a quintet (*S* = 2), whether the complex is completely symmetrical or extremely unsymmetrical.[3]

$M_3(dpa)_4L_2$ molecules synthesized with other metals (M = Ni, Cu, Ru, Rh) have been structurally characterized in the symmetrical form only.[3] The structural documentation presently available on this family of complexes therefore raises the hypothesis of a common electronic origin to the structural versatility observed for the linear frameworks of $(Co_3)^{6+}$ and $(Cr_3)^{6+}$. Spin unrestricted DFT calculations have therefore been carried out on $Cr_3(dpa)_4Cl_2$ using the ADF program with the BP86 functional and Slater basis sets of triple-ζ plus polarization quality for the valence shells.[4] The obtained results have been compared with those of similar calculations previously reported on the cobalt complexes.[5]

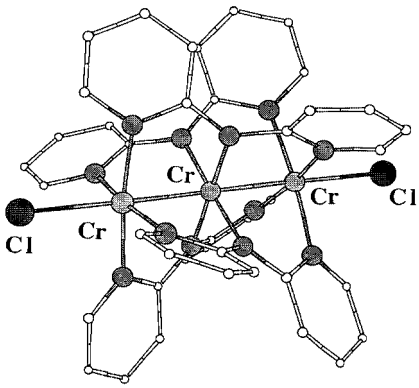

Fig. 1 Schematic representation of $Cr_3(dpa)_4Cl_2$ in the symmetric conformation (D_4 point group).

As for the homologous complex of cobalt, the ground state conformation of an isolated molecule of $Cr_3(dpa)_4Cl_2$ was found to be symmetric (D_4 point group), with optimized structural parameters (Cr–Cr = 2.350 Å; Cr–Cl = 2.560 Å; Cr_{term}–N = 2.094 Å; $Cr_{central}$–N = 2.010 Å) very close to the distances observed in the *s* conformations. A schematic representation of the metal orbitals obtained in the *s* form of the $(Co_3)^{6+}$ and $(Cr_3)^{6+}$ complexes, with their relative ordering, their occupancies and the spin orientation of the d electrons, is displayed in Fig. 2.[6] In both systems, a covalent σ linkage is delocalized over the whole metallic framework by means of a *three-electron three-center bond* involving an all-bonding, doubly occupied σ orbital (σb), and a singly occupied nonbonding orbital (σnb) (Fig. 2). This type of bonding is reminiscent of the π system of the allyl radical and generally yields a delicate balance between symmetry and distortion for the nuclear framework.[5b,7] The overlap between the 3d π and δ orbitals at a distance of 2.350 Å is not sufficient to induce a clear separation between the bonding, nonbonding and antibonding MOs of these types. The six π and the three δ levels[8] are therefore clustered between the σb and the σnb levels. In the cobalt complex, these nine levels are all equally occupied with two electrons, which implies a localization of these 18 d electrons on the metal atoms. In the chromium complex, the nine non-σ d electrons are also equally distributed among the π and δ orbitals, but the occupancy is now one electron per MO

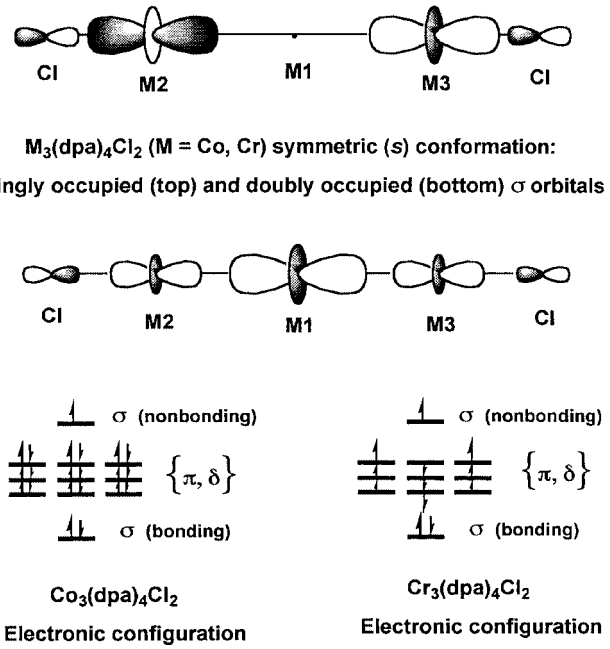

Fig. 2 $M_3(dpa)_4Cl_2$ (M = Co, Cr); symmetric form: sequence of the metal orbitals and their occupancies.[6] Scheme of the doubly occupied, σ-bonding MO and of the singly occupied, σ-nonbonding MO.

Nonsymmetric $\Delta d_{Cr-Cr} = 0.106$	2	↑↑↑—↓↓↓—↑↑↑ 3.60 −3.00 3.44	+0.97	Type *a*
Nonsymmetric $\Delta d_{Cr-Cr} = 0.679$	2	↑↑↑↓↓↑↑ 3.79 −2.27 2.50	+4.25	Type *a*
Nonsymmetric $\Delta d_{Cr-Cr} = 0.679$	2	↑↑↑↑↓↓ 3.84 2.17 −2.09	+10.12	Type *b*
Symmetric $\Delta d_{Cr-Cr} = 0$	5	↑↑↑—↑↑↑—↑↑↑ 3.50 2.93 3.50	+30.8	Type *c*

The total molecular spin *S* is defined as $0.5[n(\alpha)-n(\beta)]$, where $n(\alpha)$ and $n(\beta)$ represent the number of electrons with α and β spin, respectively.

(Fig. 2). These nine localized electrons—and the unpaired σ electron—are spin-coupled. The most favorable coupling is antiferromagnetic, with 3.5 electrons with α spin on each terminal chromium atom and three electrons with β spin localized on the central chromium (Table 1, coupling type *a*). The resulting molecular spin state is a quintet ($S = 2$) in agreement with the magnetic measurements. The energetic stabilization due to the antiferromagnetic coupling was estimated by computing the energy associated with the electronic configuration of maximum spin ($S = 5$) assuming the same symmetric structure as optimized for the quintet ground state. The high spin state is destabilized by 30.8 kcal mol^{-1} (Table 1, coupling type *c*).

As for the cobalt complex,[5] the ground state potential energy curve has been calculated with respect to an imposed distortion of the metallic framework by constraining the metal–metal distances to keep fixed, nonsymmetric values, while optimizing all other geometric parameters. The molecule in the distorted conformation belongs to the C_4 point group, and the calculations have been carried out with the C_2 constraints. The obtained curve is very shallow: the destabilization is less than 1 kcal mol^{-1} when Δd_{Cr-Cr} is equal to 0.106 Å and reaches 4.25 kcal mol^{-1} only when the extreme framework distortion observed in $Cr_3(dpa)_4LL'$ complexes is imposed to $Cr_3(dpa)_4Cl_2$. In the latter case, the spin populations assigned to the atoms involved in the 'supershort' Cr–Cr linkage (2.27β and 2.50α for $Cr_{central}$ and for Cr_{term}, respectively) evolve toward values typical of a quadruple bond between two chromium atoms, calculated in the broken symmetry formalism (Table 1). The potential energy curve calculated for $Cr_3(dpa)_4Cl_2$ is practically the same as that calculated in the same conditions for the equivalent complex of cobalt.[5] This should be traced to the identity in both complexes of the driving force to covalent bonding, namely the three-electron three-center linkage. It should therefore be assumed that the strength of the antiferromagnetic interaction, superimposed to the σ bond in the chromium system, is not significantly modified by a distortion of the metal framework.

A different spin arrangement of the unpaired electrons was also found when the observed structure of $Cr_3(dpa)_4Cl(BF_4)$ was taken as an initial guess for the geometry of $Cr_3(dpa)_4Cl_2$ (Table 1, coupling type *b*). The molecular electronic state remains a quintet and the calculated spin density distribution appears quite consistent with the electronic structure proposed by Clérac, Cotton and co-workers for the strongly distorted systems: a metal–metal quadruple bond flanked with an isolated chromium atom accommodating four unpaired spins.[3] At variance with the antiferromagnetic—type *a*—coupling, however, this arrangement of spins is basically nonsymmetric and should favor a distorted structure. In fact, a geometry optimization of $Cr_3(dpa)_4Cl_2$ assuming this electronic configuration resulted in a conformation very close to that reported for $Cr_3(dpa)_4Cl(BF_4)$.[3] The calculated geometrical parameters are as follows: Cr1–Cr2 = 2.671 Å; Cr1–Cr3 = 1.992 Å; Cr2–Cl = 2.526 Å; Cr3–Cl = 2.574 Å; Cr2–N = 2.111 Å; Cr3–N = 2.097 Å; Cr1–N = 2.006 Å. From the energetic viewpoint, the type *b* coupling corresponds to a low-lying excited state for $Cr_3(dpa)_4Cl_2$: at its optimal distorted geometry, this electronic configuration is destabilized by 10.1 kcal mol^{-1} with respect to the symmetric ground state. It is still higher by 5.9 kcal mol^{-1} than the symmetric coupling at the distorted geometry (Table 1), which means that the potential energy surface (PES) of the quintet *ground state* only displays a single minimum, corresponding to the symmetric conformation.

Calculations on $Cr_3(dpa)_4Cl(BF_4)$ are in progress to confirm that the change in axial coordination modifies the energy ordering of the two electronic configurations. It is not excluded in this case that both configurations appear as separate minima on the ground state PES. The structural behavior of the complex would therefore be relevant to the much debated issue of *bond-stretch isomerism*.[9]

Calculations have been carried out in part at the Centre Universitaire et Régional de Ressources Informatiques (CURRI, Université Louis Pasteur, Strasbourg, France) and in part at the IDRIS computer center (CNRS, Orsay, France). We are pleased to thank Professor F. A. Cotton and C. A. Murillo for stimulating discussions and for communicating their most recent results and structures.

Direct electrochemistry of pentachlorophenol hydroxylase

Weihong Xie,* John P. Jones, Luet-Lok Wong and H. Allen O. Hill*

Central Chemistry Laboratory, University of Oxford, South Parks Road, Oxford UK OX1 3QH.
E-mail: allen.hill@chem.ox.ac.uk; zxn@pentium.whiov.ac.cn

Received (in Cambridge, UK) 30th August 2001, Accepted 9th October 2001
First published as an Advance Article on the web 31st October 2001

The direct electrochemistry of the flavin-containing monooxygenase, pentachlorophenol hydroxylase (PCPH), at an edge plane graphite electrode was observed and a catalytic response, linear with concentration, was found with the substrate pentachlorophenol (PCP).

Pentachlorophenol hydroxylase (PCPH) isolated from *Sphingomonas chlorophenolica* strain ATCC 53874 is a flavin containing monooxygenase.[1–5] The monomeric enzyme possesses one FAD prosthetic group, and converts pentachlorophenol (PCP) to 2,3,5,6-tetrachlorohydroquinone (TeCH). The enzymatic reaction requires two equivalents of NADPH and one molecule of dioxygen to hydroxylate one molecule of PCP [eqn. (1)].

$$2NADPH + H^+ + O_2 + PCP \rightarrow 2NADP^+ + H_2O + Cl^- + TeCH \quad (1)$$

Herein we describe the direct electrochemistry of PCPH. We hope that the exploitation of PCPH using electrochemical techniques can be used in sensing PCP or converting the pollutant to a less, or non-toxic, substance.

Cyclic voltammetry was performed in a two-compartment electrochemical cell with a working volume of 0.5 ml. The working compartment accommodated the platinum gauze counter electrode in addition to the edge plane pyrolytic graphite working electrode (diameter = 5 mm). A saturated calomel electrode (SCE) was used as a reference in a sidearm, which connected to the working compartment *via* a Luggin capillary. An Autolab PG STAT10 potentiostat (Eco Chemie B.V.) was used to record and control the potential of the working electrode.

The cyclic voltammogram of PCPH in Tris buffer is shown in Fig. 1(a). A redox couple with E_{pc} at −536 mV and E_{pa} at −487 mV ($E_{1/2}$ = −512 mV) is observed. The peak current increases linearly with the square root of the scan rate indicating a diffusion controlled process. A diffusion coefficient of 5.4×10^{-7} cm^2 s^{-1} for PCPH was estimated, which is similar to values observed for other proteins (1.1×10^{-7} cm^2 s^{-1} for *p*-cresolmethylhydroxylase,[6] and 4.5×10^{-7} cm^2 s^{-1} for spinach [2Fe–2S] ferredoxin[7]). The k^0 calculated for the electron transfer between PCPH and the EPG electrode was 7.2×10^{-4} cm s^{-1} which is in the rate constant region for a quasi-reversible process ($10^{-1} > k^0 > 10^{-5}$ cm s^{-1}).[8] In order to be sure that the electrochemical response observed from the enzyme solution was not due to the dissociated coenzyme, the electrochemistry of free FAD was also examined under identical experimental conditions. The cyclic voltammogram [Fig. 1(b)] of free FAD shows two redox couples at −501 and −639 mV. The peak current of the first couple is proportional to the square root of the scan rate only up to 20 mV s^{-1}. A diffusion coefficient estimated from the linear part was 7.1×10^{-6} cm^2 s^{-1}, near the literature values of 4.5×10^{-6} cm^2 s^{-1} [9] and 3.8×10^{-6} cm^2 s^{-1}.[10,11] This value is an order of magnitude larger than that calculated for PCPH. The heterogeneous rate constant k^0 is *ca.* 8.3×10^{-3} cm s^{-1}, which broadly agrees with the literature values of 1.6×10^{-3} cm s^{-1} [11] and 2.0×10^{-3} cm s^{-1}.[12] The peak current of the second couple has a linear relationship with the potential scan rate, indicating that it is likely an adsorption process. The different electrochemical behaviour between PCPH and free FAD therefore suggests that the direct electrochemistry of PCPH observed at the bare EPG electrode was not due to the dissociated coenzyme, FAD.

Electrochemistry of PCPH in the presence of substrate PCP was performed with the enzyme immobilised on the electrode surface. The EPG electrode was protected by a dialysis membrane (MW cut-off 3500 Da) which was fixed on the electrode by an 'O' ring. Modification the electrode was performed by depositing 4 mL (2 mL each time) of the concentrated PCPH (>80 mM) on to the top of the electrode. The enzyme layer was allowed to slightly dry at room temperature, then covered by the membrane. The electrode was then dipped into a solution containing PCP. Cyclic voltammograms were recorded in the presence of the substrate at a scan rate of 10 mV s^{-1}. As shown in Fig. 2, a catalytic response is

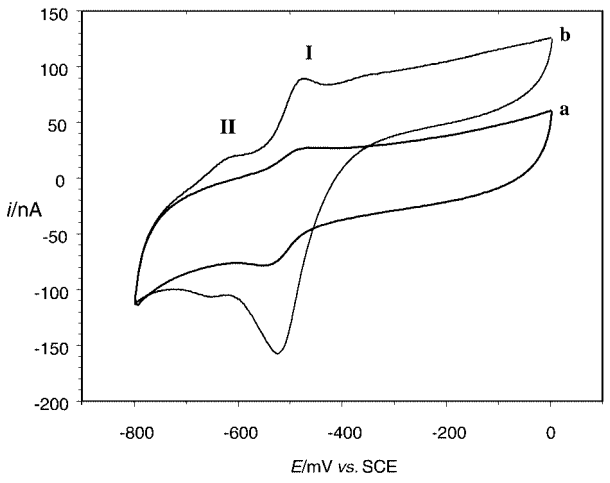

Fig. 1 Cyclic voltammograms recorded at a bare EPG electrode with a scan rate of 20 mV s^{-1} in 50 mM Tris buffer, pH 8.0: (a) 10 μM PCPH, (b) 10 μM FAD.

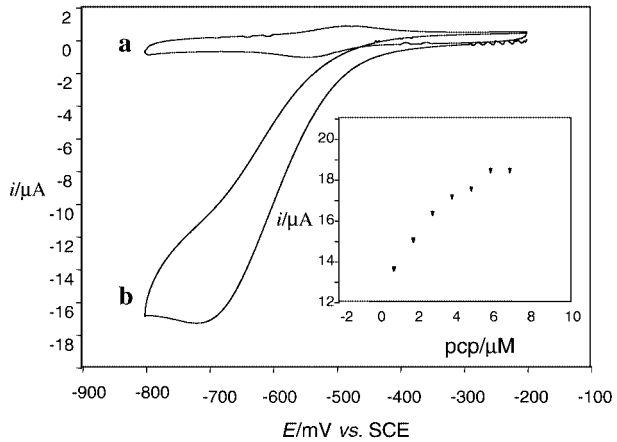

Fig. 2 Cyclic voltammograms of PCPH (4 μl of 200 μM PCP immobilized at an EPG electrode with dialysis membrane (MW cut-off 3500 Da) recorded at a scan rate of 10 mV s^{-1}: (a) in absence of PCP, (b) in the presence of 5 μM PCP; the PCP concentration dependence curve is shown in the inset.

 DOI: 10.1039/b107740f

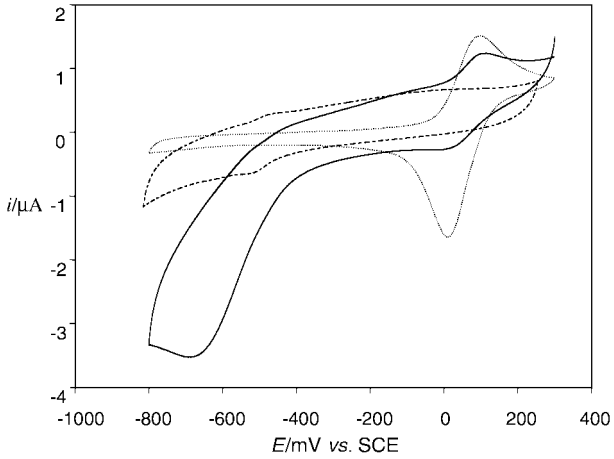

Fig. 3 Cyclic voltammograms recorded at an EPG electrode in 50 mM Tris buffer, pH 7.0, at a scan rate of 20 mV s^{-1}: (1) CV (–·–) was recorded in 45 μM PCPH solution prior to electrolysis, (2) CV (—) was recorded in solution (1) after the electrolysis had been carried out for 120 min, (3) CV (·····) was recorded in 0.1 mM of TeCH solution.

observed and the catalytic current increases with the increase of the concentration of PCP. Cyclic voltammetry carried out at a FAD modified electrode, which was constructed in the same manner as used in the enzyme experiment, showed that the reduction current decreased when PCP was added into the solution. This suggested that free FAD alone could not take part in a catalytic reaction with PCP. The addition of PCP into a deoxygenated enzyme solution did not stimulate a catalytic reaction, while in the present of dioxygen, the addition of PCP aroused a catalytic response, thereby demonstrating the mono-oxygenase function of PCPH.

The electrochemical conversion of PCPH was performed using a 5 mm diameter EPG electrode in a 50 mM Tris buffer solution containing 45 μM PCPH and 80 μM PCP. Prior to electrolysis, the enzyme solution was deoxygenated using Ar. During the reduction, the flow of Ar was stopped, enabling dioxygen to diffuse gradually into the electrochemical cell. The potential of the working electrode was fixed at −800 mV *vs.* SCE for 2 h and the cyclic voltammogram was recorded every 30 min. The measured cyclic voltammogram showed a new redox couple with a mid-point potential of 60 mV after the electrolysis. The peak current of this couple increased slightly when the electrolysis time was prolonged. In order to identify this response, cyclic voltammetry of a 0.1 mM TeCH solution (in 50 mM Tris buffer at pH 7.0) was recorded at the EPG electrode with a scan rate of 20 mV s^{-1}. The response of TeCH is identical to that obtained in the electrolysis experiment (Fig. 3) suggesting that the oxidised product of the reaction is formed. The observation of hydroxylation product at the electrode shows the possibility of designing a bioreactor, which could make use of this electroenzymological process to drive the conversion of PCP.

The author thanks the K. C. Wong Foundation for a Scholarship.

Preparation, structure and catalytic properties of a binuclear Pd(0) complex with bridging silylene ligands

Alois Fürstner,* Helga Krause and Christian W. Lehmann

Max-Planck-Institut für Kohlenforschung, D-45470 Mülheim/Ruhr, Germany.
E-mail: fuerstner@mpi-muelheim.mpg.de; Fax: +49-208-306-2994

Received (in Cambridge, UK) 10th September 2001, Accepted 9th October 2001
First published as an Advance Article on the web 31st October 2001

In contrast to the N-heterocyclic carbene (NHC) 1, the homologous N-heterocyclic silylene (NHS) 4 acts as a bridging ligand to Pd(0), giving rise to the dinuclear complex 5 which is catalytically active in Suzuki reactions.

Applications of transition metal complexes bearing N-heterocyclic carbene (NHC) ligands to catalysis have recently met with considerable success,[1,2] with olefin metathesis[3] and cross coupling chemistry being the most pertinent examples.[4,5] Thereby the strong σ-donor properties of the NHC account for the observed gain in activity and stability, while the fact that many catalysts can be conveniently prepared *in situ* from readily accessible precursors renders the procedures particularly user-friendly. Some of the resulting complexes, however, have also been isolated and structurally characterized. Thus, it has been shown that the sterically hindered NHC **1** readily displaces PAr_3 from Pd(0), leading to the formation of the homoleptic, mononuclear 14-electron complex **2** which is catalytically competent for Suzuki cross-coupling reactions (Scheme 1).[6]

As part of our project aiming at the design of novel metal catalysts and their applications to advanced organic synthesis,[7] we became interested in the properties of the homologeous N-heterocyclic silylenes (NHS)[8] as ancillary ligands. Although they promise to exhibit a similarly favorable profile, the catalytic performance of transition metal–NHS complexes is as yet largely unexplored. Outlined below is an exploratory study into palladium chemistry which resulted in the discovery that NHS **4** leads to an entirely different structural motif than its NHC-analogue **1**, without compromising the catalytic activity of the resulting Pd(0) template.

For the preparation of the required NHS, the procedure described by West *et al*. has been modified.[9] Rather than refluxing the dichlorosilane **3** in THF with a large excess of potassium chunks for extended periods of time, its treatment with C_8K[10,11] in THF at ambient temperature turned out highly beneficial (Scheme 2).† Not only does this method lead to the formation of **4** in high yield, but also gives much better reproducible results and requires neither large excess of the reducing agent nor the monitoring of the reaction progress by NMR as recommended in the original publication.[9]

Scheme 2 *Reagents and conditions*: [a] C_8K (2.2 equiv.), THF, rt, 18 h, 67%; [b] $Pd(PPh_3)_4$, rt, 1 h, 50%.

Having secured good access to multigram amounts of **4**, this ligand was reacted with $Pd(PPh_3)_4$ in THF at ambient temperature. ^{31}P NMR spectroscopy revealed the rapid release of PPh_3 accompanied by the virtually quantitative formation of a single new product which was isolated as dark red, air-sensitive crystals in 50% yield (Scheme 2).‡ Its structure in solution can be deduced from the spectroscopic and analytical data. Particularly diagnostic is the ^{29}Si NMR signal which appears as a triplet at δ = 109.5 ppm ($J_{P,Si}$ = 21.5 Hz) indicating a highly symmetrical structure containing *two* PPh_3 ligands at degenerate positions. MS indicates the presence of a dimeric species which was unambiguously identified by X-ray crystallography. Fig. 1 depicts the molecular structure of **5** in the solid state, showing that the silylene moieties act as bridging ligands between two 14-electron Pd(0) centers.§

The dimer is situated upon a crystallographic inversion center. The distance between the Pd atoms (2.65005(17) Å) is shorter than that of Pd(0) in the bulk metal (2.7511 Å), but slightly longer than the distances observed in structurally related, bridged dinuclear Pd(I)-complexes with a linear R_3P–Pd–Pd–PR_3 entity.[12] The co-ordination of the Pd atoms is planar, the sum of the Pd bond angles is 359.8°. The 1,3-diaza-2-silacyclopentene is also essentially planar (with a mean deviation of 0.005 Å) and is oriented perpendicular to the Pd1, Si1, Pd1*, Si1* plane (interplanar angle 94.1°). Its geometry reflects the silylene character of this ligand, with the N–Si–N

angle being even more acute than in dicarbonyl-bis(1,3-diaza-2-silacyclopentene)nickel[13] and the Si–N distances being also slightly longer.

Although the propensity of silylenes to act as bridging ligands in a variety of stable binuclear complexes is well established,[14] we are not aware of any precedence involving Pd(0). Moreover, the synthesis of **5** favorably compares with that of most other silylene bridged metal(0) complexes¶ which are usually prepared by less convenient indirect routes. Finally, complex **5** seems to be the first case of a NHS–metal complex used as catalyst in organic synthesis. Specifically, it was found to effect Suzuki reactions[15] of aryl boronic acids with bromoarenes in high yield. Two representative examples are depicted in Scheme 3.

Generous financial support by the Deutsche Forschungsgemeinschaft (Leibniz award program) and the Fonds der Chemischen Industrie is gratefully acknowledged. We thank Professor K. Pörschke for a valuable discussion.

Notes and references

† *Preparation* of **4**: To a stirred solution of dichloride **3** (6.04 g, 22.6 mmol) in THF (100 mL) under Ar is added C_8K (6.7 g, 49.7 mmol)[10] in several portions. The resulting suspension is stirred at ambient temperature for 18 h during which its color changes from bronze to black. The insoluble residues are filtered off under Ar and are repeatedly rinsed with THF, the combined filtrates are evaporated and the crude product is purified by sublimation *in vacuo* (bath temperature 60–75 °C, 10^{-1} torr) thus affording silylene **4** as a colorless solid (2.97 g, 67%). Its spectroscopic and analytical data are in full agreement with those reported in the literature.[9]

‡ *Preparation of complex* **5**: To a solution of silylene **4** (345 mg, 1.75 mmol) in THF (40 mL) under Ar is added a solution of $Pd(PPh_3)_4$ (1.69 g, 1.46 mmol) in THF (60 mL) over a period of 30 min and stirring is continued for another 30 min after the addition is complete. The resulting dark red solution is evaporated, the residue is suspensed in hexane (15 mL), the precipitate is filtered off under Ar and is carefully rinsed with hexane in several portions. Drying *in vacuo* affords complex **5** as a dark-red solid (824 mg, 50%). ^{1}H NMR (THF-d_8): δ = 7.21–7.44 (m, 30H), 6.86 (s, 4H), 1.25 (s, 36H); ^{13}C NMR (THF-d_8): δ = 139.8, 139.7, 139.5, 135.2, 135.1, 134.8, 134.7, 129.2, 129.0, 128.8, 128.7, 128.6, 128.4, 121.3, 54.6, 33.8; ^{31}P NMR (THF-d_8): δ = 31.4; ^{29}Si NMR (THF-d_8): 109.5 (t, J = 21.5 Hz); MS (EI): *m*/*z* (rel. intensity) 1130 (0.5, [M$^+$]), 350 (10), 263 (20), 262 (100), 261 (14), 184 (13), 183 (58), 154 (14), 121 (14), 108 (23), 84(4), 77(3), 57(7), 51(4).

§ *Crystal data* for **5**: $C_{56}H_{70}N_4P_2Pd_2Si_2$, M = 1130.12 g mol^{-1}, red–brown, crystal dimensions 0.17 × 0.13 × 0.09 mm, triclinic $P\bar{1}$ (no. 2), at 100 K a = 10.2277(2), b = 10.8525(2), c = 13.8201(2) Å, α = 66.897(1), β = 73.515(1), γ = 89.888(1)°, V = 1342.51(4) Å^3, Z = 1, ρ = 1.398 Mgm^{-3}, μ = 0.814 mm^{-1}, λ = 0.71073 Å. ω-Scans covering reciprocal space up to θ_{max} 33.18° with 93.7% completeness, total of 13730 reflections (9616 unique) with R_{int} = 0.034. Structure solution SHELXS-97, full matrix least-squares based on F^2 using SHELXL-97, final R = 0.026, wR = 0.071, $\triangle\rho_{max}$ 0.7 eÅ^{-3}. CCDC 168806. Hydrogen-bonded capsules in polar, protic solvents

Alexander Shivanyuk and Julius Rebek, Jr.*

A kinetically stable, dimeric capsule is formed by tetrahydroxyresorcinarene in methanol; it encapsulates tropylium and tetramethylammonium cations.

Molecular capsules held together by hydrogen bonds are stable in organic solvents that do not compete well for donors and acceptors.[1] Ordinarily, the addition of small amounts of highly polar solvents disrupts these capsular hosts and releases their guests. A few monomeric cavitands are able to form inclusion complexes in methanol and in water,[2] and a number of well-defined molecular capsules involving metal co-ordination are stable in alcohols and water.[3] But the presence – even requirement – of water in the assemblies of resorcinarene **1a**[4] is anomalous. Water is an integral part of its hexameric capsules in the solid state, and in wet organic solvents large, polar guests can be encapsulated. [5] Enough additional space is available to co-encapsulate sizable, neutral molecules (Fig. 1). A similar hexameric structure is reported for **1b**[6] in the solid state. Its additional hydroxy groups offer greater possibilities for self-assembly in competitive media and we describe here the behavior of the closely related **1c** in protic solvent mixtures. We have found that **1c** forms dimeric capsules in solution and in the solid state.

Compound **1c** is insoluble in water or dry acetonitrile, but readily dissolves in **wet** acetonitrile (10–20% water), in methanol, or in mixtures of acetonitrile and methanol. Colorless crystals were grown from aqueous acetonitrile. These were unstable without the mother liquor but were, nonetheless, suitable for single crystal X-ray analysis.†

The molecule adopts a slightly distorted cone conformation, stabilized by intramolecular hydrogen bonds. Two molecules of **1c** form a centrosymmetric dimer linked through no less than 16 hydrogen-bonded water molecules (Fig. 2). The overall structure resembles the dimeric capsular assembly known for resorcinarene **1e**,[7] and encapsulates four acetonitrile molecules. Two of them are positioned to engage in CH–π interactions with the aromatic rings; the remaining two are nearly parallel to the plane of bridging carbon atoms and are disordered over two positions. The dipoles of the two ordered acetonitrile molecules are antiparallel and their intermolecular distances are consistent with dipole–dipole interactions. The distances between nitrogen atoms of acetonitrile molecules and selected oxygens of **1c** indicate host–guest hydrogen bonding.
