The application of supramolecular concepts such as self-assembly to the solid state offers an approach to crystal design and crystal engineering, namely supramolecular synthesis of solids, that is based upon the design of infinite networks. Self-assembly of more than one molecular component, modular self-assembly, is particularly attractive since it can be accomplished in one-pot reactions with existing molecular components and allows for facile fine-tuning of structural and functional features. The challenges and opportunities that face crystal engineering are illustrated by concentrating on the superstructural diversity that has been exhibited in 2D network structures. Despite the observed superstructural diversity, which can manifest itself in the form of supramolecular isomerism, and the range of molecular components that have been utilized, these structures have in common an inherent ability to mimic clays by intercalation of guest molecules.

From molecules to crystal engineering and design

That the physical and chemical properties of crystalline solids are as critically dependent upon the distribution of molecular components within the crystal lattice as the properties of its individual molecular components has provided impetus for research into crystal design and engineering. In such a context, it is probably more than coincidental that the late 1980s represents a watershed for research in this area. A provocative statement by Maddox[1] highlighted the issue as follows: '*One of the continuing scandals in the physical sciences is that it remains in general impossible to predict the structure of even the simplest crystalline solids from a knowledge of their chemical composition*'. It is reasonable to assert that Maddox's statement still holds true, especially for organic solids. Nevertheless, it has not precluded a seemingly exponential growth in research activity devoted to the subjects of crystal design and crystal engineering. This should be unsurprising since the implications of crystal engineering go beyond materials science. Indeed, the term crystal engineering was first coined in a contribution by G. M. J. Schmidt concerning the subject of organic solid-state photochemistry.[2] An important consequence of Schmidt's research into solid-state reactions is that it is implicit by use of the term crystal engineering that crystals can be thought of as the sum of a series of molecular recognition events, self-assembly, rather than the result of the need to 'avoid a vacuum'. In other words, crystal engineering uses the concepts of supramolecular chemistry. It is now evident that supramolecular chemistry, defined by Lehn as chemistry beyond the molecule,[3] and 'supramolecular assemblies' are inherently linked to the concepts of crystal engineering. Therefore, crystal engineering has implications that extend into areas as diverse as pharmaceutical development and synthetic chemistry. In the context of the former, there are important processes and intellectual property implications related to polymorphism.[4,5] In the context of synthetic chemistry, solid-phase organic synthesis can be solvent free and offer significant yield and regioselectivity advantages over solution phase reactions,[6] including some that cannot be effected in solution.[7–9]

The field of crystal engineering developed further in the 1980s thanks to a series of papers and monographs by Desiraju[10,11] and Etter[12] that concentrated upon applying the Cambridge Structural Database for analysis, interpretation and design of noncovalent bonding patterns in organic solids. In this contribution, we focus upon how these supramolecular concepts have been exploited to rationally generate laminated architectures in the solid state. Particular emphasis is placed upon supramolecular isomerism and how it affords superstructural diversity in two classes of compound: coordination polymers and organic networks.

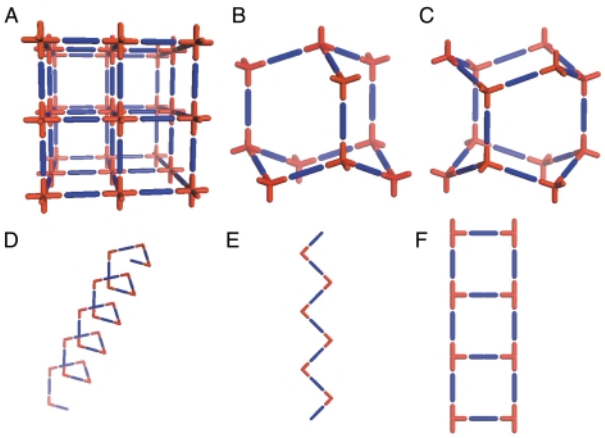
Coordination polymers: networks from first principles

Coordination polymers exemplify how crystal engineering has become a paradigm for the design of new supramolecular architectures. In this context, the work of Wells[13,14] serves as an excellent reference point. Wells defined crystal structures in terms of their topology by reducing them to a series of points (nodes) of a certain geometry (tetrahedral, trigonal planar, *etc.*) that are connected to a fixed number of other points. The resulting structures, which can also be calculated mathematically, can be either discreet (zero-dimensional) polyhedra or infinite (one-, two-, and three-dimensional) periodic nets. It is perhaps surprising that it was not until the 1990s that the

Michael John Zaworotko was born in South Wales in 1956 and attended Bedwellty Grammar School and Imperial College, where he received a B.Sc. in 1977. His doctoral research was conducted at the University of Alabama under the supervision of Prof. Jerry L. Atwood and the Ph.D. was granted in 1982. This was followed by post-doctoral research in structural and organometallic chemistry with Prof. S. R. Stobart at University of Victoria, Canada. He joined the faculty at Saint Mary's University, Halifax, Canada in 1985, where he remained until 1998. His interest in crystal engineering was developed during a sabbatical leave at the Frank J. Seiler Research Laboratory at the United States Air Force Academy in Colorado Springs, USA. He moved to the University of Winnipeg, Canada in 1998, where he served as Dean of Arts and Science and to the University of South Florida, Tampa, USA in September 1999, where he currently serves as Chairperson of the Department of Chemistry. His current interests focus upon expanding the field of crystal engineering further into the nanoscale by concentrating upon biological and synthetic supermolecules.

DOI: 10.1039/b007127g

approach of Wells began to bear fruit in the laboratory. Discrete coordination compounds that are based upon Platonic or Archimedean polyhedra have attracted considerable interest in recent years[15–17] and are conceptually related to the 'Wellsian' approach. However, we shall focus upon infinite architectures, for which Robson and coworkers[18] delineated principles that facilitated rapid development of the field of coordination polymers. In effect, Robson extrapolated Wells' work on inorganic network structures into the realm of metal–organic compounds and coordination polymers. In this context, the 'node and spacer' approach has been remarkably successful at producing predictable network architectures. Scheme 1 illustrates some of the simplest architectures that can be generated by using commonly available metal moieties and linking them with linear 'spacer' ligands.



Scheme 1 A schematic representation of some of the simple 3D and 1D network architectures that have been structurally characterized for metal–organic polymers: A. octahedral; B. cubic diamondoid; C. hexagonal diamondoid; D. helix; E. zigzag chain; F. molecular ladder.

These network structures are salient from a design perspective as follows:

- Each of the networks illustrated in Scheme 1 is based upon at least two components (*i.e.* the metal node and the ligand spacer) and the components can be pre-selected for their inherent ability to self-assemble. These network structures can therefore be regarded as blueprints for the construction of networks that, in principle, can be generated from a diverse range of chemical components, *i.e.* they are prototypal examples of modular frameworks. It should be noted that the construction of networks from single component systems also represents an important area of activity but that there are conceptual differences between the two approaches.
- The architecture alone often affords information that allows the chemist to predict some of the bulk properties. For example, most of the structures in Scheme 1 inherently generate cavities that are based upon the size and length of the spacer ligand. The 3D architectures A–C represent in some ways the ultimate challenge in terms of crystal engineering since they lead directly to crystal structure prediction. It should therefore be unsurprising that diamondoid[19] and octahedral[20–22] frameworks have attracted considerable attention. In general, for 3D architectures one would expect rigidity to be coupled with porosity, *i.e.* analogies to zeolites may be drawn. In the case of 1D structures one would normally expect close-packing variability in the context of how adjacent networks pack with respect to one another.
- We have coined the term 'supramolecular isomerism'[23] to define the existence of more than one superstructure for a given set of molecular components. This concept is illustrated by structures B and C, which represent cubic and hexagonal diamondoid structures, respectively, and structures D and E, which are also supramolecular isomers of one another. It is important to note that, although supramolecular isomerism affords superstructural diversity, it also limits the number of possible architectures to those that can be generated rationally from the molecular components that are present in a network.

The diversity of network structures that can result from supramolecular isomerism is the focus of this article. In the case of 2D architectures, one would anticipate that networks would possess an inherent ability to intercalate guest molecules, *i.e.* clay-like properties will be expected. As revealed herein, this is indeed the case for many of the 2D networks that have been studied by us and other groups. We also highlight the surprising degree of diversity that can exist in 2D structures.

Square-grid coordination polymers

Square-grid networks exemplify a particularly simple and commonly reported example of a predictable 2D metal–organic network. Square grid coordination polymers are based upon 1 : 2 metal:ligand complexes with linear bifunctional spacer ligands. They were first reported using cyano ligands[24–26] and have recently been expanded in terms of chemical type and cavity size to include pyrazines,[27–30] 4,4′-bipyridine(bipy)[30–35] and longer analogues of bipy.[23,36] These compounds can indeed be regarded as being analogues of clay minerals since they also have an ability to intercalate guest molecules. However, they have added features that are not likely to be present in clays and they are complementary to 'organoclays',[37] which are chemically modified inorganic clays or calixarene 'organic clay mimics',[38,39] that are based upon calix[4]arenesulfonate salts that form alternating hydrophobic and hydrophilic layers. For example, cavities lie within the plane of the structure and they are suitable for either interpenetration or enclathration of a wide range of organic guest molecules. Furthermore, since they are designed from first principles, it is possible to design the cavities to be inherently hydrophobic or hydrophilic and to tune their dimensions, although interpenetration can mitigate against the existence of frameworks with very large cavities.[40] Finally, it should be noted that the metal sites can possess chemical as well as structural properties. Indeed, catalytically active sites have been incorporated into square-grid structures.[32]

Square-grid networks generated with bipy spacer ligands were first reported by Fujita *et al.*[32] Fujita's compounds are based on Cd(II) and related structures were subsequently reported for other transition metals, including Co(II) and Ni(II) and Zn(II). Although these 2D coordination networks are isostructural within the coordination grid (effective dimensions of the diagonals are *ca.* 1.3 × 1.3 nm), the crystal structures of compounds can differ in the manner in which the networks stack with respect to each other. In particular, interlayer separations can lie in the range 0.6–0.8 nm and the quantity of guest molecule can vary. $[M(bipy)_2(NO_3)_2]\cdot$guest (M = Co, Ni)[41–43] exhibits three basic packing modes (Fig. 1). These packing modes are similar in that the square-grid networks are parallel to one another but they differ in the manner in which the square grids pack with respect to one another and the relative proportion of guest molecule that is present. Type A compounds exhibit 2 : 1 guest : host stoichiometry and interplanar separations of *ca.* 0.6 nm, type B compounds generally crystallize with 2.5 guest molecules per metal center and interlayer separations are *ca.* 0.8 nm. Type C compounds have interlayer separations that are similar to those seen for type B compounds and have 3 : 1 stoichiometry.

In all of these compounds the proportion of the crystal that is occupied by guest molecules is *ca.* 50% by volume. In such a situation it becomes reasonable to question whether interactions between the guest molecules determine the cavity shape and crystal packing of the square grid polymers rather than *vice versa.* Careful examination of the crystal packing in $\{[Ni(bipy)_2(NO_3)_2]\cdot 2pyrene\}_n$ reveals that the pyrene molecules

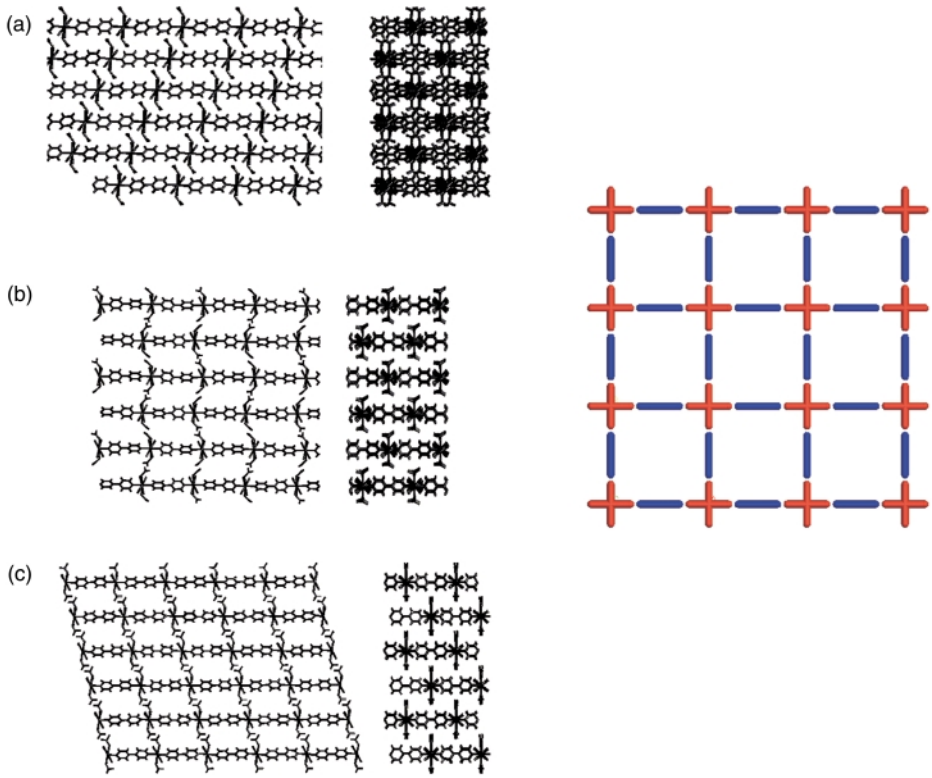


Fig. 1 Perspective views of the stacking of square-grid network architectures of formula $[M(bipy)_2(NO_3)_2]$: (a) A type grids; (b) B type grids; (c) C type grids. The square grid is represented schematically.

form an independent noncovalent network that is complementary from a topological perspective with the square-grid coordination polymer. Indeed, the resulting crystal represents what is to our knowledge the first compound in which it has been revealed that two very different types of 2D net interpenetrate. The square-grid coordination networks [Fig. 2(a)] possess inner cavities of *ca.* 0.8 × 0.8 nm and stack in such a manner that they lie parallel to one another with an interlayer separation of *ca*. 0.79 nm.

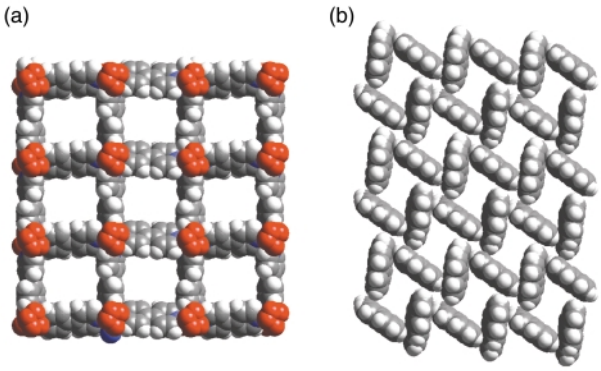

Fig. 2 Space-filling illustrations of the two independent networks in $[M(bipy)_2(NO_3)_2]\cdot 2pyrene$: (a) the metal–organic coordination polymer square-grid, and (b) the noncovalent (4,4) net of pyrene molecules.

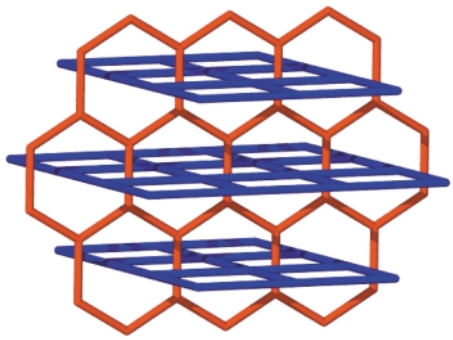
The pyrene nets [Fig. 2(b)] are sustained by edge-to-face interactions and contain cavities of dimensions *ca.* 0.65 × 0.35 nm. The planes of the neighboring molecules intersect at an angle of *ca.* 60° and there are no face-to-face stacking interactions between the molecules. The pyrene nets can be regarded as distorted (4,4) nets (if the node is the point in space at which the vectors of the four pyrene planes intersect) or as a distorted brick wall form of a (6,3) net (if the nodes exist at the point of the edge-to-face interactions). It is important to note that, as revealed by Scheme 2, a (6,3) planar net is also complementary from a topological sense with the (4,4) coordination polymer net and that the coordination polymer nets



Scheme 2 A schematic diagram that illustrates how honeycomb (6,3) and square (4,4) nets can interpenetrate.

must pack in a staggered manner if they are to fit with the noncovalent net.

That the crystal structure can be viewed as coexistence of interpenetrating covalent and noncovalent nets is potentially important in the context of understanding the structure and stoichiometry of other compounds that are based upon interpenetrated covalent and noncovalent nets. It also illustrates how polarity in crystals can be generated from subtle packing of achiral components, since the pyrene molecules form chiral nets.

This mode of packing is not unique to $\{[Ni(bipy)_2(NO_3)_2]\cdot 2pyrene\}_n$. Indeed, its naphthalene analogue, $\{[Ni(bipy)_2(NO_3)_2]\cdot 3C_{10}H_8\}_n$,[43] can be interpreted as being the result of interpenetration of hexagonal and square nets and a study of a series of related compounds has revealed the presence of noncovalent nets in every compound.[44] The noncovalent hexagonal nets formed by naphthalene and veratrole are illustrated in Fig. 3.

Coordination polymers in which identical (4,4) planar networks interpenetrate have been observed to exhibit two types of interpenetration, both of which are examples of *inclined interpenetration*.[40] The most commonly encountered form might be described as *diagonal/diagonal inclined interpenetration* and was observed in the prototypal $[M(bipy)_2X_2]_n$

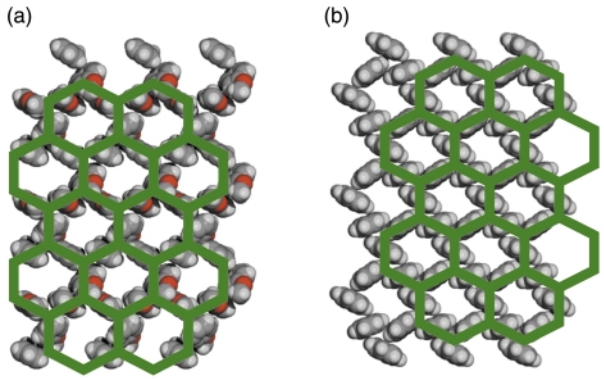


Fig. 3 Space-filling illustrations of the hexagonal (6,3) networks formed by (a) veratrole, and (b) naphthalene in the intepentrated structures [Ni(bipy)$_2$(NO$_3$)$_2$]·3aromatic.

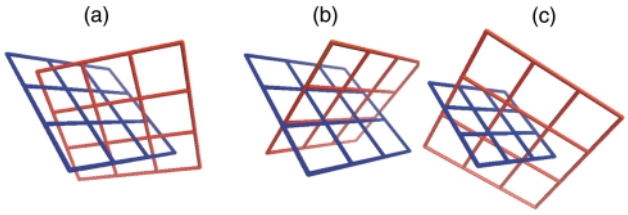
compound [Zn(bipy)$_2$(H$_2$O)$_2$]SiF$_6$.[32] The other mode of interpenetration might be described as *parallel/parallel inclined interpenetration* and to our knowledge has only been reported for two compounds.[45,46] These types of interpenetration are illustrated in Scheme 3(a) and 3(b), respectively, and differ in how the networks orient and cut through each other.



Scheme 3 A schematic that illustrates the three modes of inclined interpenetration that have been observed for square-grid networks: (a) diagonal/diagonal, (b) parallel/parallel, and (c) parallel/diagonal.

Parallel refers to a structure in which a 'spacer' ligand from one network threads through the cavity of the other, *diagonal* refers to a structure in which a 'node' from one network (*e.g.* the metal moiety) is within the cavity of the other. One would anticipate that the structure that is adapted by a particular compound would be influenced by several geometric factors: the relative size of the cavity; the distance between adjacent nodes within a network; the thickness of the layers and how this limits the interlayer separation of adjacent networks; the steric bulk of the node. In this context, it is important to note that, with all other things being equal, the diagonal/diagonal mode of interpenetration facilitates an interlayer separation that is 41.4% greater than that of the parallel/parallel mode. Furthermore, the diagonal/diagonal mode ensures a staggered orientation of parallel layers whereas an eclipsed orientation is necessary if the parallel/parallel structure is present. Therefore, in terms of steric considerations, it would be expected that the diagonal/diagonal mode would be most favored. However, circumstances where the interlayer separation would ideally be shorter, or where the metal atoms in adjacent layers would be eclipsed (*e.g.* to maximize interlayer interactions) could favor the parallel/parallel mode.

The structures we have studied that are based upon complementary covalent and noncovalent networks exhibit a third mode of inclined interpenetration that is a hybrid of the modes described above: *parallel/diagonal inclined interpenetration*. The noncovalent (4,4) arene networks exhibit parallel inclined interpenetration with respect to the (4,4) metal–organic coordination networks, whereas the covalent coordination networks demonstrate diagonal inclined interpenetration with respect to the arene networks [Scheme 3(c)]. This structural feature means that the nitrate groups of adjacent parallel coordination polymer grids are staggered and that the interlayer separation is a consequence of the size of the arene network. It should therefore be unsurprising that Type A grids result when templated by the smallest arenes (benzene and derivatives) as they exhibit smaller interlayer separations than type B and C packing. Grid types B and C occur in the presence of larger or more arenes.

A question that cannot yet be answered with certainty concerns whether or not the noncovalent networks of aromatic molecules can exist in the absence of the coordination polymers. In this context, the existence of a 1 : 1 binary compound between ferrocene and pyrene[45] represents an important prototype since pairs of ferrocene molecules are stacked inside a pyrene 2D network that is sustained by noncovalent C–H···π interactions (Fig. 4). This pyrene network is a slightly distorted version of that observed in {[Ni(bipy)$_2$(NO$_3$)$_2$]·2pyrene}$_n$.

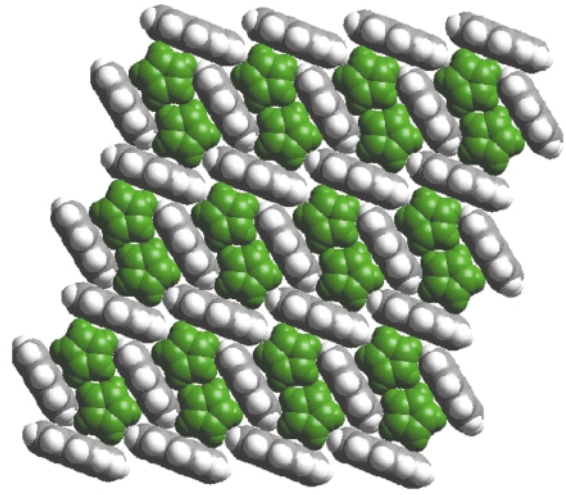


Fig. 4 A space-filling illustration of the crystal structure of the cocrystal formed by ferrocene (green) and pyrene.

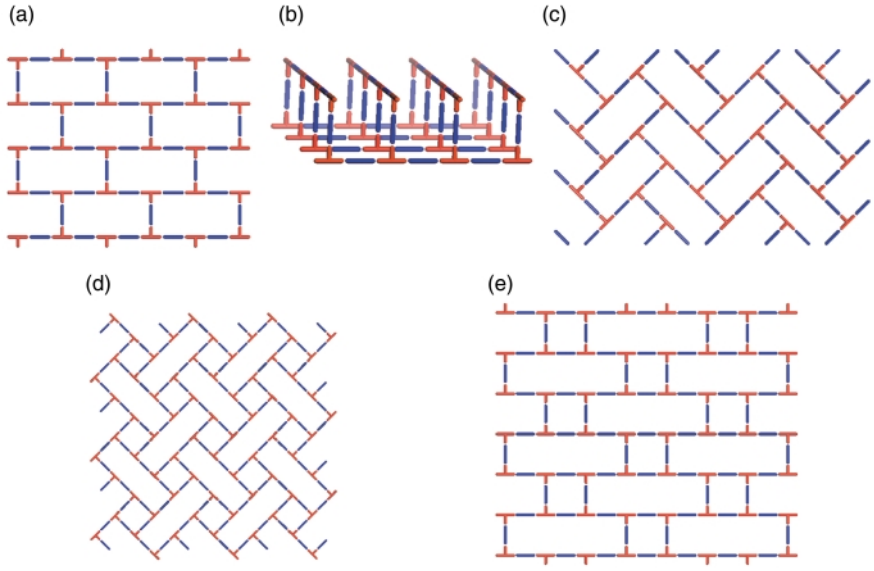
From the above it should be clear that even for the relatively narrow class of compounds of formula [M(bipy)$_2$X$_2$]$_n$, there are many permutations of metal, anion and guest. It should be noted that grids in which there are two types of spacer ligand, rectangular grids, have also been reported.[29,30] It therefore seems likely that square and rectangular grids will represent a generic class of synthetic clay mimic.

Other 2D architectures

The existence of supramolecular isomerism is well exemplified by the diverse range of architectures that can be generated by self-assembly of T-shaped nodes. In the context of coordination polymers, this effectively means linking of *mer*-substituted octahedral metal moieties or trisubstituted square-planar metal centers. In such a situation the stoichiometry is based upon a 1 : 1.5 metal : spacer ligand ratio. The T-shape node has thus far produced examples of 1D, 2D and 3D networks. There are three distinct 2D supramolecular isomers: brick wall,[45,48–55] herringbone,[51,56–58] and bilayer.[59–61] Schematic illustrations of these structures are presented in Scheme 4(a)–(c), respectively. It is interesting to note that, if one calculates the possible 2D networks that are possible for T-shaped nodes (Scheme 4), three of the five possibilities have already been realized.

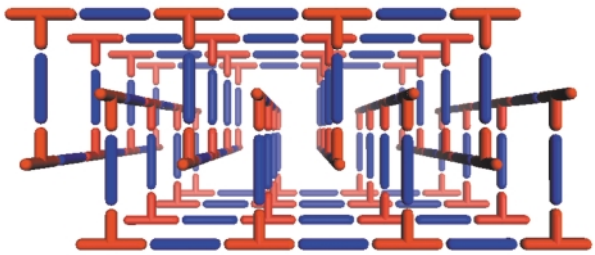
The brick architecture was first observed as the product of the reaction between heptacoordinate Cd(II) and 1,4-bis[(4-pyridyl)methyl]-2,3,5,6-tetrafluorophenylene.[35] The T-shape geometry is the result of two nitrate ligands chelating in a bidentate manner, thereby occupying four of the seven coordination sites. The structure is triply interpenetrated and, as such, does not have channels or cavities. Interestingly, in a similar system using the non-fluorinated pyridyl-based ligand, a 1D ladder structure was observed. In several of the compounds that exhibit the herringbone or 'parquet floor' architecture the coordination sphere is similar to that of the brick architectures: heptacoordinate Cd(II) or Co(II), with two terminal bidentate



Scheme 4 A schematic illustration of 2D nets that can be generated for T-shape building blocks: that have been characterized or might be expected to occur: (a) brick wall; (b) bilayer; (c) herringbone; (d) long-and-short brick; (e) basket weave; (d) and (e) are yet to be realized.

nitrate ligands and coordination to one end of three 4,4′-azopyridine bridging ligands; an isostructural example has also been reported with 1,2-bis(4-pyridyl)ethyne as the bridging ligand.[60]

The bilayer architecture has been observed in at least three compounds.[59–63] Interestingly, it has been observed as the product from the reaction of $Co(NO_3)_2$ and bipy, which also generates ladder, square-grid and herringbone architectures. The bilayer form of $[Co(bipy)_{1.5}(NO_3)_2]$ is observed if crystallization occurs in the presence of CS_2[59] or H_2O.[61,63] The bilayers pack by partial interdigitation (Scheme 5), which



Scheme 5 A schematic that illustrates how porosity can be generated by partial interdigitation of bilayer networks.

allows 1D channels to run through the structure. This structure is somewhat relevant since it represents one of the first reported examples of a synthetic compound that might be regarded as a metal–organic zeolite, *i.e.* the structure is porous and stable to loss of guest.[63] The bilayer architecture has also been reported for systems using 1,2-bis(4-pyridyl)ethane.[64]

The number of supramolecular isomers already observed in the $Co(NO_3)_2$/bipy system indicates the importance of template and crystallization conditions. It seems reasonable to assert that it is only a matter of time and effort before the weave and long-and-short brick motifs, Scheme 4(d) and 4(e), respectively, will also be realized.

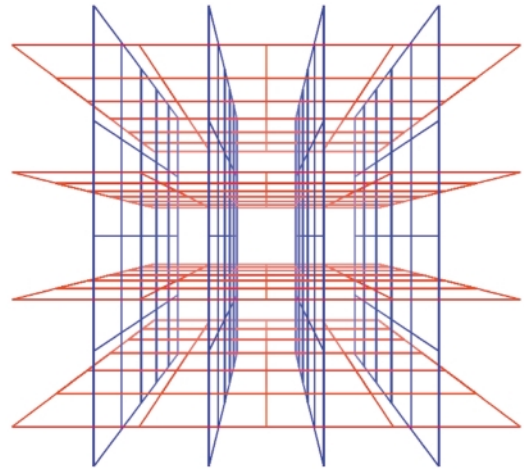
In terms of topology, it should be noted that brick and herringbone motifs are both examples of (6,3) nets and can therefore be regarded as being closely related to honeycomb (6,3) nets. Honeycomb networks are quite common in organic structures because of the availability of trigonal nodes (*i.e.* 1,3,5-trisubstituted benzenes such as trimesic acid and species such as the guanadinium cation) but they seldom occur in the context of metal–organic polymers because trigonal and trigonal-bipyramidal coordination geometries are relatively rare. However, $[Cu(pyrazine)_{1.5}]BF_4$[65] is based upon trigonal Cu(I) and it should therefore be unsurprising that it crystallizes as a honeycomb (6,3) net. That there now exist a number of ligands with trigonal geometry means that it is likely that a wider range of honeycomb structures will be generated in the near future.

3D structures *via* 2D structures

Manipulation of 2D structures represents a possible entry into the generation of 3D architectures. In such a context, there are two relatively simple strategies: cross-linking of 2D structures and interpenetration of identical or different 2D networks.

Cross-linking becomes feasible if one selects an appropriate 2D structure that has functionality in the axial direction. Such an approach has been widely used by clay chemists and hence the term ‘pillaring’ might be applied to describe such a process. $[M(bipy)_2(SiF_6)]$ could be used as a prototype in the context of coordination polymers since it can be regarded as having been generated from square-grid coordination polymers that are cross-linked by μ-SiF_6 anions.[20,22]

Interpenetration is a widely encountered phenomenon[40] that can mitigate against the existence of frameworks with very large cavities. However, Scheme 6 reveals that there are



Scheme 6 A schematic diagram that illustrates how square-grids can interpenetrate and generate channels.

situations in which interpenetration can occur, generate porosity and afford 3D structures. Square-grid polymers that are based upon longer spacer ligands such as 1,2-bis(4-pyridyl)ethane

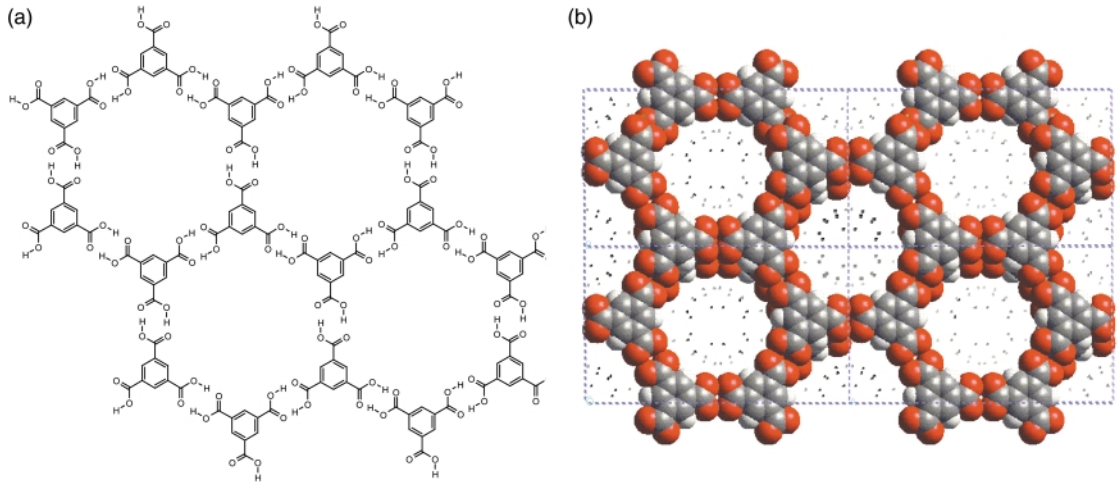


Fig. 5 Schematic (a) and space-filling (b) views of the open-framework phase of trimesic acid.

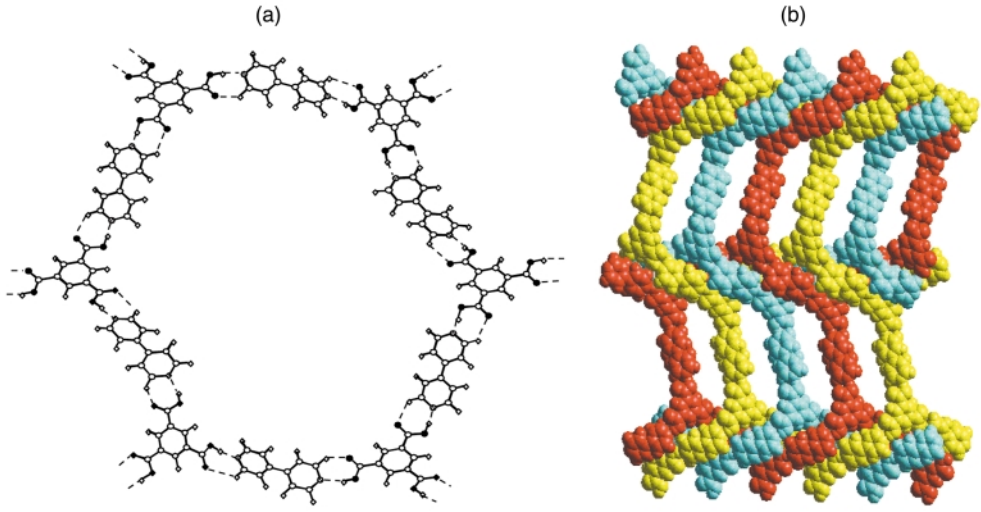

Fig. 6 The cocrystal formed by trimesic acid and 4,4′-bipyridine: (a) a single 'expanded trimesic acid' honeycomb network and (b) a space-filling view of how the puckered honeycomb networks interpenetrate.

(bipy-eta) or 1,2-bis(4-pyridyl)ethylene (bipy-ete) can interpenetrate in such a fashion.[40,41]

Organic networks–molecular and ionic structures involving trimesic acid

It is possible in both principle and practice to draw a number of analogies between organic networks and coordination polymers. In particular, the 'node and spacer' approach can be employed equally well with noncovalent interactions as with coordinate covalent bonds. This is especially true for hydrogen bonds, for which the donor (*i.e.* a protic hydrogen atom) and the acceptor (*i.e.* a region of electron density) can be compared with metal atoms and ligands, respectively. Furthermore, as noted by Etter,[12] in cases where there are multiple hydrogen bonding sites, there is a fair degree of predictability concerning which donors and acceptors will engage. In this context, networks that involve NH···O and/or OH···O hydrogen bonds, including those that exploit the carboxylic dimer or its deprotonated form, represent a wide range of reliable and ubiquitous supramolecular synthons that already have been applied in a broad range of systems.

Molecular networks sustained by trimesic acid

Hydrogen-bonded 2D networks are well exemplified the well known structure of trimesic acid (1,3,5-benzene tricarboxylic acid, H_3TMA), a polyfunctional carboxylic acid that is inexpensive and chemically robust. It possesses trigonal exodentate functionality that facilitates self-assembly into two dimensions. Fig. 5 illustrates how the hydrogen-bonding pattern in 2D networks formed by H_3TMA generates cavities of predictable size (*ca.* 1.4 nm diameter). In pure H_3TMA[66] the honeycomb grid is puckered and the cavities are filled by self-inclusion, or interpenetration, of other networks. However, subsequent reports revealed that there are methods for preparing the non-interpenetrated or open framework form of H_3TMA.[67,68] If crystallized in the presence of alkanes, H_3TMA forms open-framework honeycomb layers that align in such a manner that adjacent sheets are almost eclipsed with respect to each other [Fig. 5(b)]. The resulting architecture observed in the crystal structure is essentially identical to that depicted in Fig. 5(a).

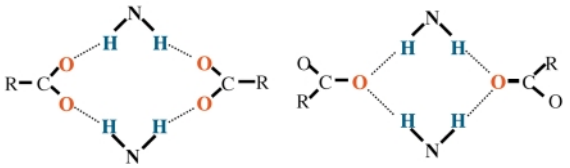
H_3TMA represents an example of a self-assembled motif. However, this limits options in terms of supramolecular synthesis, especially when compared to modular systems. The H_3TMA network can be modified in several ways if modular approaches are employed. For example, $[H_3TMA][bipy]_{1.5}$ would be expected to exist as an expanded form of H_3TMA since the pyridine–carboxylic acid supramolecular synthon appears to be more stable than the carboxylic acid dimer itself.[69] As depicted in Fig. 6, the anticipated expanded honeycomb structure indeed occurs and the cavities are large (*ca.* 2.6 × 3.5 nm). However, the cavities are filled by the interpenetration of three independent networks [Fig. 6(b)], thereby affording a close-packed structure with no cavities. This type of interpenetration, *parallel interpenetration*, resembles weaving, is

facilitated by puckering of the pseudohexagons that form the network. Indeed, the hexagons resemble the chair conformation of cyclohexane.

Rao and coworkers recently reported a related structure that is based upon modular self-assembly:[70] an organic network formed by trithiocyanuric acid (TCA) and bipy. Adjacent layers are aligned parallel to each other and there is no interpenetration.

Networks sustained by anions of trimesic acid

Anionic forms of H_3TMA also represent an appropriate node for generation of 2D superstructures. Ammonium salts of the deprotonated forms of H_3TMA offer a simple entry into such systems.[71–73] Scheme 7 illustrates two motifs that demonstrate how the ammonium moiety might extend anionic forms of H_3TMA into honeycomb networks.



Scheme 7 The two supramolecular isomers that have been seen for self-assembly of carboxylate and ammonium moieties in $[NH_2(c\text{-}C_6H_{11})_2]_3$[TMA].

In the case of TMA^{3-} and the dicyclohexylammonium cation, supramolecular isomers A[74] and B[75] have both been observed to generate laminated structures. The generation of A or B appears to be solvent dependent. It has also been shown that self-assembly of the lamellar structure can occur on surfaces.[74] An important feature of architectures that are sustained by A and B is that some of their components and features can be fine-tuned without destroying the basic architecture. For example, the ammonium cation substituents can be changed without influencing the basic molecular recognition properties in the context of motifs A and B. For secondary amines, organic substituents would extend above and below the network, and in appropriate circumstances would preclude interpenetration.

If alkyl substituents are present on the ammonium cation and the stoichiometry is 1 : 2 then the typical result is a laminated material with poor ability to adsorb molecules because of interdigitation of the alkyl substituents.[72] However, use of dibenzylamine mitigates against interdigitation and promotes reversible incorporation of aromatic guest molecules.[73] The resulting compounds are structurally related to clays, but they are inherently hydrophobic and have generic affinity for a wide range of aromatic guests over alcohols or water. In a series of host–guest compounds, the stoichiometry remains constant, $[NH_2(CH_2Ph)_2]_2$[HTMA], but there is variation in the geometry of the hydrogen bond layer and in the manner in which guest molecules are incorporated. In general, the benzyl groups form a plethora of aromatic C–H$\cdots\pi$ interactions to the surrounding guest molecules. The unit cell lengths are typically multiples of *ca.* 1.2 $\times$ 1.7 $\times$ 2.1 nm (stacking axis, short axis and long axis, respectively). The length of the stacking axis represents the interlayer separation and a doubling of the length of the stacking axis occurs when adjacent layers are not related by translation. Multiples of short and long axes also occur because of differences in the arrangement of guest molecules between benzyl groups. In effect, guest molecules and/or benzyl groups do not necessarily repeat with the asymmetric unit of the H-bonded layer. The crystal structures might be classified based upon the stacking axis as being of one of two types: (a) identical packing of adjacent layers (*i.e.* related by translation); (b) adjacent layers which are different from each other. The hydrogen bonded sheets can be either flat or corrugated. In effect, the host matrix is a flexible, generic host material for aromatic molecules. A representative series of structures is illustrated in Fig. 7 and, as should be clear, there is no interdigitation of benzyl groups.

A series of related structures that is based upon two-dimensional layers resulting from hydrogen bonding of the trigonal guanidinium cation, $C(NH_2)_3^+$, and organic sulfonate ions RSO_3^- has been extensively studied by the Ward group.[76] Interdigitation of the organic substituent of the sulfonate ions on

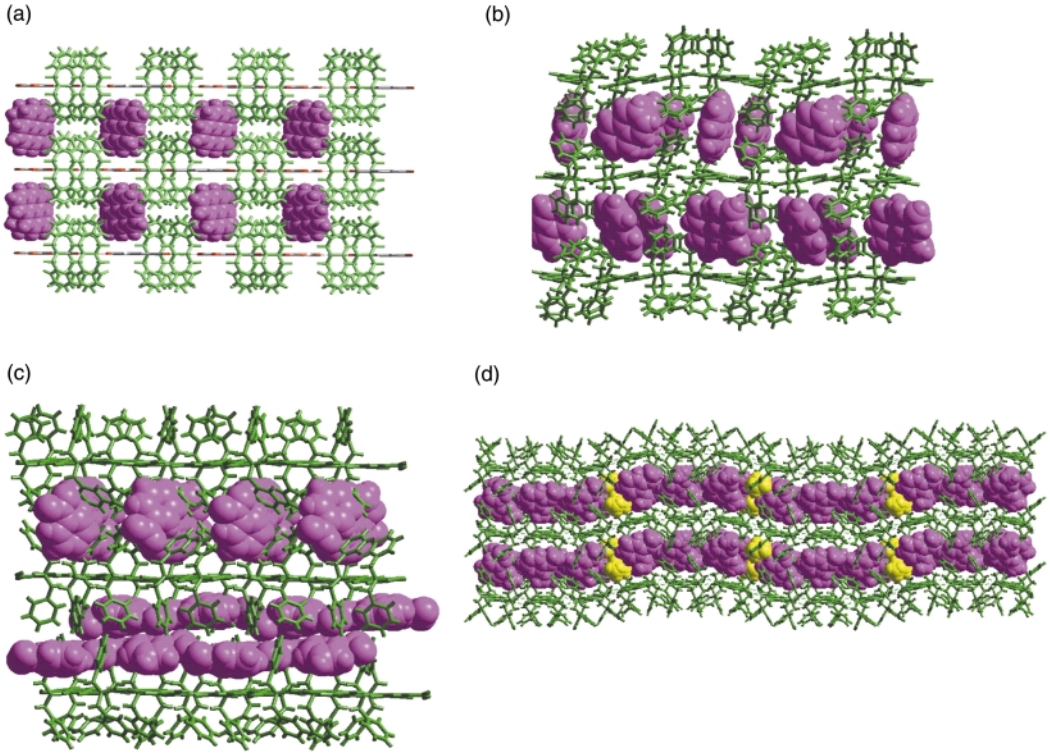


Fig. 7 The crystal structures of four 'organic clays' sustained by [(trimesate){$NH_2(CH_2Ph)_2$}$_2$]. The benzyl moieties preclude interdigitation and facilitate reversible sorption of aromatic molecule: (a) pyrene; (b) naphthalene; (c) nitrobenzene; (d) veratrole.

adjacent layers and ionic hydrogen bonding predictably leads to a series of laminar architectures.

Summary and conclusions

The fundamental precept of crystal engineering is that all information necessary for design of extended 1D, 2D and 3D structures is already present at the molecular level in existing chemical species. However, crystal engineering does not address the important issues of crystal structure prediction, crystal growth and crystal nucleation. In the case of growth and nucleation, the role of kinetic factors and inhibitors in controlling morphology, polymorphs and supramolecular isomers is critical. Crystal engineering does not yet address control of such factors, rather it afford 'recipes'. Based upon this understanding and the results described herein one can make several assertions:

Prediction *vs.* design

It is important to stress the significant conceptual difference between crystal engineering and crystal structure prediction. They are not synonymous. In short, crystal structure prediction is precise (*i.e.* space group and exact details of packing are defined) and deals primarily with known molecules, many of which are not disposed to predictable self-assembly.[77,78] Crystal engineering is far less restrictive from a conceptual perspective since it focuses more broadly upon the design of new and existing network architectures. In effect, the principles of design are based upon a blueprint, in many cases a blueprint that is first recognized *via* a serendipitous discovery, and they allow the designer to select components in a judicious manner. Therefore, a desired network structure or blueprint can be limited to chemical moieties, in many cases commercially available moieties, that are predisposed to a successful outcome. In short, crystal engineering represents a paradigm for supramolecular synthesis of new solid phases and there are no real limits in terms of chemical moieties that can be involved.

What does self-assembly mean in this context of crystal engineering?

That one can exploit self-assembly principles to design new solid phases has important implications. First and foremost, all the information necessary to build networks is already stored in known molecules. In the context of the results reported herein, all structures are air- and water-stable and were generated in one-pot reactions using commercially available reagents. Second, if one uses a modular self-assembly approach then fine-tuning of structures is both facile and can be effected broadly. It should be intuitive that most molecules are not self-complementary, *i.e.* their molecular recognition sites cannot be fully satisfied by self-assembly. It therefore follows that modular structures, *i.e.* those based upon more than one component, are often going to be both more diverse and more controllable than single component phases.

Relevance to 0D structures

The principles of self-assembly have also been applied towards the design and isolation of discrete molecular structures. Such structures are exemplified by molecular squares[79–81] and, more recently, by striking examples of new high molecular weight compounds that can be described as spheroid organic[82,83] or coordination architectures.[15–17,84] The design principles behind the isolation and development of these new classes of compound are based upon applying the concept of self-assembly in the context of geometric considerations found in regular (Platonic) and semi-regular (Archimedean) solids.[82] Interestingly, such structures are also known in zeolites (*e.g.* Linde A, which is based upon an edge-skeleton generated by fused, truncated octahedra[85]) and in biological self-assembled systems such as mammalian picornaoviruses.[86–89]

It is reasonable to expect a great deal of synergy between these two areas of research. In the context of how self-assembly of discrete structures will influence crystal engineering, it is reasonable to assert that a wide range of nanosized molecular species will become available for self-assembly of synthetic clay-like and zeolite-like architectures. Such structures would be unprecedented and offer nanoscale channels and cavities in addition to novel functionality. The hierarchy of such systems, which is inherently a consequence of self-assembly approaches, and the interesting possibilities that exist for use of such 'secondary building units' in materials science have already been highlighted by others.[90,91]

Acknowledgements

I gratefully acknowledge the generous financial support of the NSERC during 1986–99 and Saint Mary's University. I am also indebted for the contributions to this work by a group of talented, hard-working students and coworkers, many of who were undergraduates when they were active in my group. Thanks to them I never need to be reminded that the primary benefit of research is that it is for people and by people. I will only accept a small part of the blame for the contributions that these individuals are now making to science and society.

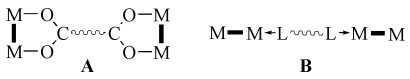
Received (in Columbia, MO, USA) 6th September 2000, Accepted 20th October 2000
First published as an Advance Article on the web 12th December 2000

As determined by X-ray crystallography, tetranuclear metal–metal bound molecular loops $[Rh_2(DAniF)_2]_2(O_2CCH_2CO_2)_2$ (DAniF = *N*,*N*′-di-*p*-anisylformamidinate) react with 2-*N* donor linkers to give a tubular structure $\{[Rh_2(DAniF)_2]_2(O_2CCH_2CO_2)_2(NC_5H_4CHCHC_5H_4N)_2\}_n$ 1, and a sheet-like structure with interstitial dichloromethane molecules for $[Rh_2(DAniF)_2]_2(O_2CCH_2CO_2)_2(NCC_6H_4CN)_2\}_n$ 2; when the assembly unit was changed from $[Rh_2(DAniF)_2(O_2CCH_2CO_2)]_2$ to the square $[Rh_2(DAniF)_2(O_2CCO_2)]_4$ and the linker $NCC_6F_4C_6F_4CN$ was used, the compound $\{[Rh_2(DAniF)_2]_4(O_2CCO_2)_4(NCC_6F_4C_6F_4CN)_4\}_n$ 3, was formed, in which there are infinite tubes of square cross section having entrained CH_2Cl_2 molecules.

Oligomers and polymers in which a key organizing element is a coordinated metal atom, for example, a square-coordinated Pd^{II} or Pt^{II} atom or a tetrahedral zinc atom, are currently the subjects of vigorous study in many laboratories.[1] This work is driven by the search for novel materials, distinguished by special magnetic properties,[2] micro- and meso-porous structures,[3] or catalytic properties.[4]

Several years ago we began to explore the possibilities of employing strongly bonded dimetal units, such as Mo_2^{4+} and Rh_2^{4+}, that can be suitably complexed to control their reactivity and then linked to form linear,[5a,b] square,[5c,d] triangular[5c] and polyhedral[5e] structures. The linking process entails the use of di- and tri-carboxylic acids which attach themselves to adjacent pairs of equatorial sites in the M_2^{4+} entities, as shown



schematically in **A**. The arrays that can be built up in this way have as great a range of sizes as those previously made[2] but differ from most of those in forming initially as neutral species rather than as highly charges ones. However, charge may readily be introduced—in a controlled, stepwise fashion[5b,d]—by oxidation of the Mo_2^{4+} units.

Here we report that by using axial linking, as shown schematically in **B**, it is possible to take simple oligomers and connect them to form one- and two-dimensional polymers. These, again, are initially neutral but can be oxidized. This is the first time such architectures have been created by using dimetal building blocks. We also show how the nature of the polymeric structure can be controlled by choosing axial linkers of the right length, a principle that will be of importance in all future work.

In the examples reported here we have utilized dirhodium, Rh_2^{4+}, building blocks shown as **II** and **III** in Fig. 1. The square, **III**, has been reported before[5c] but the loop, **II**, is a new unit, not reported before, though it is somewhat similar to loops that have been made with Mo_2^{4+} units.[6] Dirhodium units were used here because they have a strong affinity for axial ligands, unlike Mo_2^{4+} units. As axial linkers we have employed **IV**, **V**, and **VI**, (Fig. 1).

With **IV**, $\{[Rh_2(DAniF)_2]_2(O_2CCH_2CO_2)_2(NC_5H_4CHCHC_5H_4N)_2\}_n$ **1** is obtained.‡ It has a tubular structure shown in Fig. 1(a). In Fig. 1(b) there is a schematic representation of this structure§ showing how the rings (**II**) are related alternately by centers of inversion and two-fold axes.

While the formation of such tubes might be considered the 'obvious' outcome of linking units of type **II** by axial bridges, it can only result when the linkers are long enough to keep the bulky *p*-anisyl groups from clashing with each other. With a shorter linker, **V**, major clashes would occur and therefore a different structure arises in $\{[Rh_2(DAniF)_2]_2(O_2CCH_2CO_2)_2(NCC_6H_4CN)_2\}_n$ **2**. This sheet-like structure is shown as 2(a), where dichloromethane molecules are omitted, as 2(b) where the sheets are viewed edge-on and the CH_2Cl_2 molecules are included, and in schematic form as 2(c). The CH_2Cl_2 molecules were well ordered and refined without difficulty. The sheet belongs to the two-dimensional space group C*mm*, the highest symmetry possible in a rectangular sheet structure.

When the assembly unit was changed from **II** to **III** and the linker **VI** was used, the compound $\{[Rh_2(DAniF)_2]_4(O_2CCO_2)_4(NCC_6F_4C_6F_4CN)_4\}_n$, **3** was formed, in which there are infinite tubes of square cross section. A portion of the entire structure is shown as 3(a) while 3(b) shows a portion of one of the units, including one of the entrained CH_2Cl_2 molecules; 3(c) shows a schematic representation of this structure.

Other studies of these compounds and the syntheses of other assemblies of different topologies containing different dimetal units and axial ligands are in progress.

We are grateful to the National Science Foundation for support of this work, and to Johnson Matthey for a generous loan of $RhCl_3$.

Notes and references

‡ The general experimental conditions were described in ref. 1. Elemental analyses were satisfactory for all compounds. The following procedure describes the preparation of $\mathbf{1}\cdot 3CH_2Cl_2\cdot 0.5Et_2O$. A CH_2Cl_2 solution (10 mL) of **II** (82 mg, 0.05 mmol) was carefully layered with a CH_2Cl_2–Et_2O solution (1:1, 20 mL) of *trans*-1,2-bis(4-pyridyl)ethylene (18 mg, 0.10 mmol). Red crystals formed after several days. A similar method was used for $\mathbf{2}\cdot 4CH_2Cl_2$ and $\mathbf{3}\cdot 12.36CH_2Cl_2$. The yields are essentially quantitative.

§ *Crystal data*: for $\mathbf{1}\cdot 3CH_2Cl_2\cdot 0.5Et_2O$: $C_{95}H_{95}Cl_6N_{12}O_{16.5}Rh_4$, M = 2293.17, monoclinic, space group $C2/c$, a = 56.521(4), b = 19.016(2), c = 19.564(2) Å, β = 103.053(2)°, V = 20484(3) Å^3, Z = 8, μ(Mo-Kα) = 0.857 mm^{-1}, T = 213(2) K. The structure, refined on F^2, converged for 13458 unique reflections and 613 parameters to give $R1$ = 0.082 and $wR2$ = 0.182 and a goodness-of-fit = 1.031.

For $\mathbf{2}\cdot 4CH_2Cl_2$: $C_{86}H_{80}Cl_8N_{12}O_{16}Rh_4$, M = 2232.86, triclinic, space group $P\bar{1}$, a = 12.708(2), b = 14.378(2), c = 14.997(3) Å, α = 65.810(3), β = 72.693(3), γ = 74.766(3)°, V = 2355.0(7) Å^3, Z = 1, μ(Mo-Kα) = 0.984 mm^{-1}, T = 213(2) K. The structure, refined on F^2, converged for

† Most of the results reported here were presented in a poster at *Contemporary Inorganic Chemistry, II*, March 12–15, 2000, College Station, TX, USA.

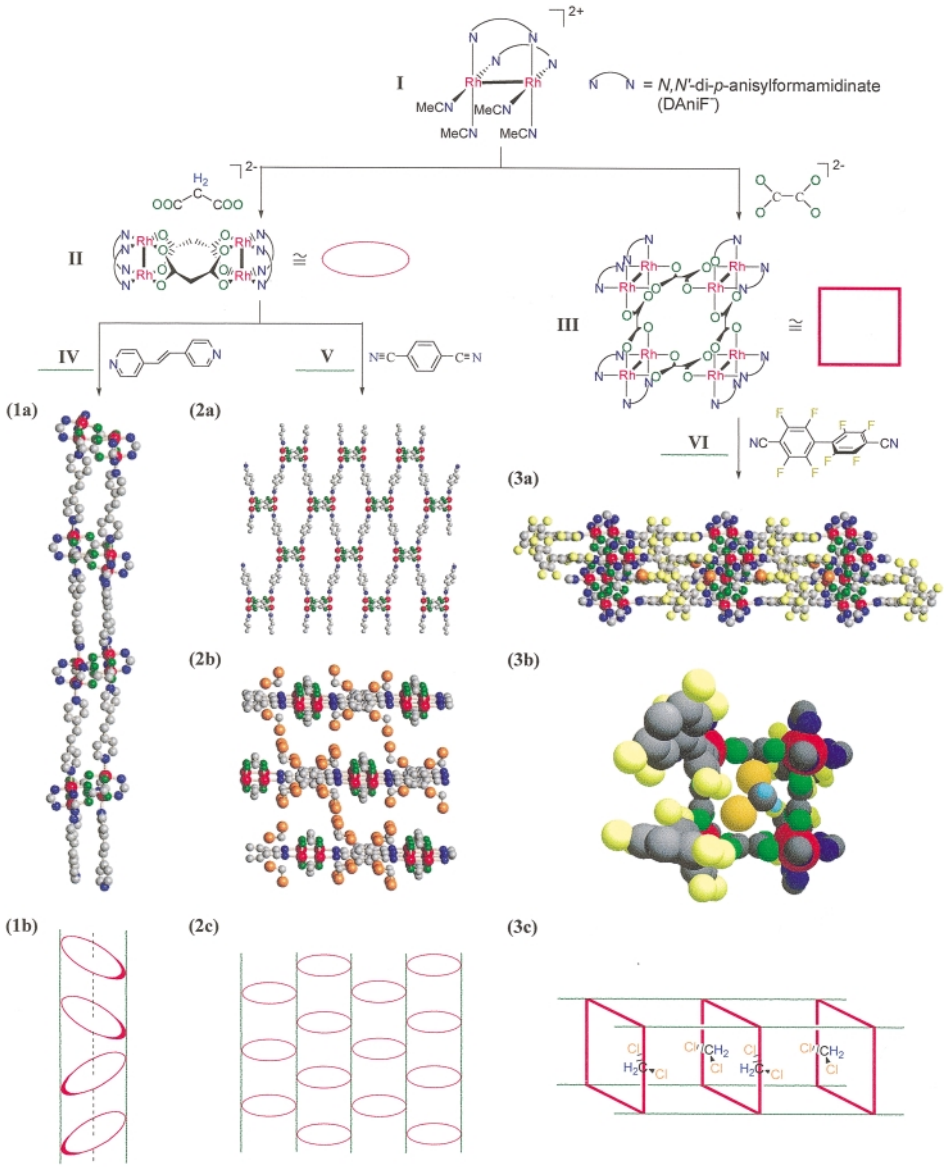


Fig. 1 Synthesis of compounds **1**·3CH_2Cl_2·0.5Et_2O, **2**·4CH_2Cl_2 and **3**·12.36CH_2Cl_2. Views of the extended structures are given in the middle section as follows: (1a) structure of **1**; (2a) structure of **2**; (2b) intercalating architecture in **2**; (3a) structure of **3** and (3b) a space filling drawing of **3** showing CH_2Cl_2 molecules inside the square tube. A schematic view of the corresponding structure is shown in the lower section. In the top section, there are axial CH_3CN molecules (not shown for clarity) at each Rh atom in **I** and **III**. For **II**, there are two CH_3CN molecules distributed on the four Rh atoms. The *p*-anisyl or DAniF groups have also been omitted for clarity. Color labels: Rh, red; N, blue; O, green; C, gray; F, yellow; Cl, orange; H, turquoise.

6163 unique reflections and 578 parameters to give $R1$ = 0.051 and $wR2$ = 0.119 and a goodness-of-fit = 1.010.

For **3**·12.36CH_2Cl_2: $C_{196.36}H_{144.72}Cl_{24.72}F_{32}N_{24}O_{32}Rh_8$, M = 5660.01, triclinic, space group $P\bar{1}$, a = 18.235(6), b = 18.430(6), c = 18.665(6) Å, α = 81.839(7)°, β = 81.775(6), γ = 80.742(7)°, V = 6082(3) Å^3, Z = 1, μ(Mo-Kα) = 0.891 mm^{-1}, T = 223(2) K. The structure, refined on F^2, converged for 15333 unique reflections and 814 parameters to give $R1$ = 0.094 and $wR2$ = 0.211 and a goodness-of-fit = 1.014. CCDC 182/1852. Easily prepared, cone-like, extended cavity calix[6]pyrrole is shown to form strong complexes with iodine and other halide ions as well as with trihaloalkanes and electron deficient aromatic systems.

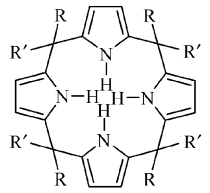
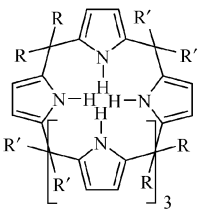
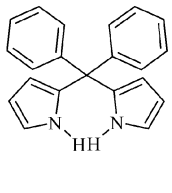
The host–guest chemistry of calixpyrroles has been the subject of intensive research aimed at gaining both understanding and control on guest recognition and binding.[1] Recently, Sessler and coworkers[2] reported that calix[4]pyrroles **1** are effective and



1



2: R = Ph; R′ = Me



3

selective receptors for anions and neutral guest species. Calixpyrroles that have been tailored to the size, shape and binding modes of target guests were shown to exhibit improved binding ability.[3] Here we report the selective binding of anions, haloalkanes and aromatic guests by recently reported, cone-like, extended-cavity 1,1,3,3,5,5-*meso*-hexaphenyl-2,2,4,4,6,6-*meso*-hexamethylcalix[6]pyrrole.[2,4] Calix[6]pyrroles are a new class of molecules characterized by a six-pyrrolemethane rim. The cross section of the hexapyrrolemethane rim is significantly larger than that of calix[4]pyrroles, *ca.* 110 *cf.* 24 Å^2. Additionally, in the stable conformation of calix[6]pyrroles, such as **2**, three of the *meso* phenyl substituents form a trigonal cavity with a volume of *ca.* 500 Å^3. Such extended-cavity receptors may allow efficient and selective binding of electron defficient aromatic guests as well as large anions such as I^-. These substrates can not be efficiently recognized nor complexed by the smaller calix[4]pyrrole systems.[3b,5]

Calix[6]pyrrole **2** was prepared using a modification of a previously reported method.[4a] Benzophenone (5 g, 27.4 mmol), pyrrole (5 mL, 72.3 mmol) and BF_3·OEt (5 mL, 39.5 mmol) were dissolved in dry ethanol (250 mL) and stirred at room temperature for 5 days under an inert atmosphere. The precipitate was then filtered off and washed with cold ethanol, offering di(phenyl)di(pyrrol-2-yl)methane **3** as a colorless solid (40% yield). An additional crop of **3** could be isolated from the mother-liquor using column chromatography [silica, dichloromethane–hexane (1:10), 50% total yield for **3**]. Calix[6]pyrrole **2** was obtained by stirring a solution of **3** (300 mg, 1 mmol) in 60 mL of dry acetone–ethanol (1:1) containing CF_3CO_2H for 5 days under inert atmosphere. The product was isolated by filtration (43% yield). An additional crop of **2** could be isolated from the mother-liquor using column chromatography [silica, dichloromethane–hexane (3:7), 52% total yield for **2**].

Similarly to earlier studies by Sessler and coworkers on the complexation of calix[4]pyrroles with different guest species, proton NMR spectroscopy was found to be a useful tool for the determination of binding constants between different guests and calix[6]pyrrole, **2**.[6] Quantitative assessments of anion binding constants were made by following the induced shifts in the ^{1}H NMR spectra of the host as a function of the concentration of the guest in an acetonitrile–chloroform (1:9) solution at room temperature (298 K). Table 1 lists the association constants between **2** and the different guests. For comparison, the complexation of octamethylcalix[4]pyrrole with the same guest species was studied under the same conditions (Table 1).

In accordance with previous studies performed by Sessler and coworkers octamethylcalix[4]pyrrole displays a clear preference towards fluoride ions over larger anions, the binding order being $F^- >> Cl^- > Br^- > I^-$. In contrast, probably due to its extended cavity, **2** exhibits a clear preference to iodide over smaller halides. Here the binding order switches to $I^- > F^- >> Cl^- > Br^-$. We interpret this binding order and the high affinity towards iodide in terms of the geometrical fit between the extended cavity of **2** and the iodide ion, allowing full binding of the anion by up to six pyrrole rings. Being the smallest halide, the fluoride ion may fit and bind efficiently to only part of the pyrrolemethane ring. Similar effects have previously been reported for the binding of cations to the cavities of crown ethers.[7]

Calix[6]pyrrole **2** is found to bind also to trihalogenated species such as trichloroethanol, trifluoroethanol, tetrafluoroborate and trifluoroacetate and forms significantly stronger complexes with such guests than with their nonhalogenated ananolgs (Table 1). The reason for this is revealed from the crystal structure† of such a complex between 2,2,2-trichloroethanol and **2** (Fig. 1). Unlike simple calixpyrroles that bind their guests predominantly through X$^-$···H–N bonds,[2,3b] **2** anchors the 2,2,2-trichloroethanol guest through one (disordered) H–O···H–N hydrogen bond with the hydroxy group, *d*(O84b···H–N18) = 2.411 Å; α(O–H–N) = 169.11°; *d*(O84a···H–N70) = 2.412 Å; α(O–H–N) = 175.95°; *d*(O84a···H–N44) = 2.725 Å; α(O–H–N) = 156.97°, and three π_{phenyl}···Cl–C bonds between the Cl atoms of the guest and the three π electron clouds of the three axial *meso*-phenyl groups forming

Table 1 Binding constants of calix[6]pyrrole **2** and 1,2,3,4-*meso*-octamethylcalix[4]pyrrole **1**, with different guest molecules

DOI: 10.1039/b007788g

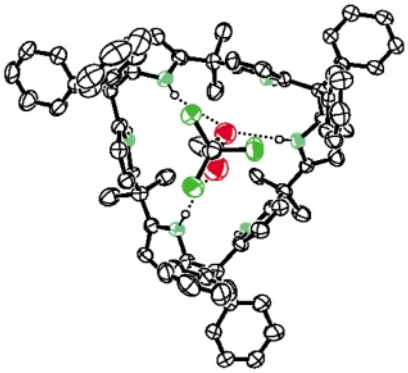

Fig. 1 The molecular structure of the complex between 2,2,2-trichloroethanol and calix[6]pyrrole **2**. Solvent and other molecules not situated in the cavity of the host have been omitted for clarity.

the pseudo-threefolded cavity of **2**: *d*(Cl79–π(C34–C39)) = 3.38 Å; *d*(Cl80–π(C60–C65)) = 3.00 Å; *d*(Cl81–π(C8–C13)) = 3.45 Å.

The stable conformation of **2** brings two electron-rich pyrrole rings, situated in a 1,4 position to one another, into a parallel and cofacial orientation. These two rings are spaced *ca*. 7.1 Å apart. Being an electron rich ring system, the hexapyrrolemethane ring is suitable for hosting electron poor conjugated species in between a pair of cofacial pyrrole rings. The additional four pyrrole rings are capable of forming multiple hydrogen bonds with appropriate guests, making the system an interesting host for different nitro- and carboxy-aromatic compounds. Fig. 2 shows the crystallographic structure† of a complex between *p*-nitrotoluene/nitrobenzene and **2**. Interestingly, though crystallized from a solution containing nitrobenzene and *p*-nitrotoluene in a 10 : 1 ratio, the crystal structure clearly indicates the 1 : 1 inclusion of nitrobenzene and *p*-nitrotoluene within the cavity of **2**. As can be seen in Fig. 2, the nitroaromatic guest is fixed to the cavity of the host through short range π–π interactions between the nitro group of the guest and the two sandwiching pyrrole rings of the host, *d*(nitro(plane)···pyrrole-(plane)) = 3.55 Å. Three of the other four pyrrole rings are involved in hydrogen bonding with the nitro group of the encapsulated guest, *d*(NH1···O80) = 2.23 Å, *d*(N1···O80) = 3.06 Å, *α*(O–H–N) = 172.94°, *d*(NH31···O80) = 2.38 Å, *d*(N31···O80) = 3.18 Å, *α*(O–H–N) = 143.67°, *d*(NH19···O81) = 2.45 Å, *d*(N19···O81) = 3.23 Å, *α*(O–H–N) = 165.11°.

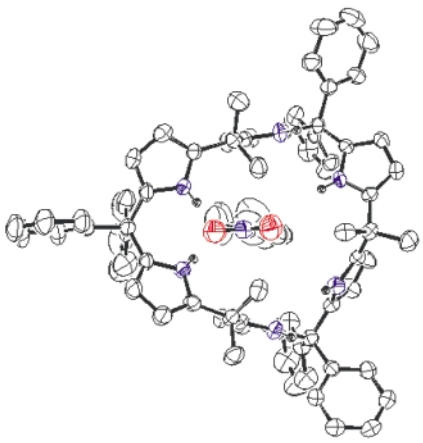

Fig. 2 The molecular structure of the complex between calix[6]pyrrole and nitrotoluene/nitrobenzene. Molecules that are not situated in the cavity of the host have been omitted for clarity.

In conclusion, calix[6]pyrrole **2** shows a wealth of binding modes to different substrates, ranging from simple anions to aromatic derivatives. The axial *meso* phenyl groups form a genuine preorganized cavity and actively participate in binding trihalogenated compounds. The application of calix[6]pyrroles to the separation and identification of such compounds is under investigation.

† *Crystal data*: for **2**·2.5CCl_3CH_2OH·1.5$CHCl_3$·3CH_3CH_2OH·5.5H_2O: grown in the dark from 2,2,2-trichloroethanol–chloroform–ethanol. A single crystal was mounted on the Nonius Kappa CCD diffractometer,[8] and cooled to 170 K under a nitrogen stream. Data were collected with graphite-monochromated Mo-Kα radiation (λ = 0.71070 Å) by applying φ and ω rotations. Data reduction was performed using DENZO-SMN software.[9] The structure was solved using direct methods (SHELXS-97[10]) and refined by SHELXL-97.[11] All non-H atoms of the macrocycle and the trichloroethanol inside the cavity, excluding the disordered hydroxy oxygen, were refined anisotropically. Hydrogen atoms of these moieties were placed at calculated positions and refined as riding on their carbon and nitrogen atoms. Difference Fourier maps based on the macrocycle and the guest inside, revealed another moderately disordered trichloroethanol bound to the macrocycle outside the cavity, and another four sites of severely disordered molecules such as trichloroethanol, chloroform, ethanol and water. All the disordered positions of the solvent molecules were refined isotropically. 38 hydrogen atoms belonging to some of the disordered solvent molecules were not allocated. M_r = 1804.83, monoclinic, space group $P2_1/n$, a = 17.773(10), b = 20.2090(10), c = 26.2590(10) Å, β = 107.730(3)°, V = 8983.6(8) Å^3, T = 170.0(1) K, Z = 4, μ = 0.076 mm^{-1}, 14 385 relections measured, 14 385 unique which were used in all calculations. The final $R(F^2)$ was 0.1168 [$I > 2\sigma(I)$].

For **2**·2.5$C_6H_5NO_2$·0.5$C_7H_9NO_2$: grown in the dark by slow evaporation of a chloroform solution. A single crystal was mounted on the Nonius Kappa CCD diffractometer, at 293 K. Data collection and reduction as above. The structure was also solved and refined as above. All non-H atoms of the macrocycle and the guests were refined anisotropically. Hydrogen atoms were placed at calculated positions and refined as riding on their carbon and nitrogen atoms except for the N–H hydrogen atoms of the pyrrole rings which were localized on a Fourier difference map and refined isotropically. M_r = 1392.66, monoclinic, space group $P2_1/n$, a = 19.455(1), b = 19.762(1), c = 22.027(1) Å. β = 115.405(2)°, V = 7649.8(5) Å^3, T = 293 K, Z = 4, μ = 0.076 mm^{-1}, 16 018 relections measured, 15 694 unique which were used in all calculations. The final $R(F^2)$ was 0.0740 [$I > 2\sigma(I)$].

Selective formation of rectangular grid coordination polymers with grid dimensions 10 × 15, 10 × 20 and 15 × 20 Å

Kumar Biradha* and Makoto Fujita*

Department of Applied Chemistry, Graduate School of Engineering, Nagoya University and CREST, Japan Science and Technology Corporation (JST), Chikusaku, Nagoya 464-8603, Japan. E-mail: kbiradha@org.mol.nagoya-u.ac.jp; mfujita@apchem.nagoya-u.ac.jp

Received (in Cambridge, UK) 29th August 2000, Accepted 23rd November 2000
First published as an Advance Article on the web 15th December 2000

Using four linear bifunctional ligands of different lengths and $Ni(NO_3)_2$, three coordination polymers containing big rectangular cavities were shown to form selectively, despite the fact that all the four ligands are known to form square grid coordination polymers when they are reacted independently with $M(NO_3)_2$.

The utility of linear bifunctional ligand such as 4,4′-bipyridine **1** has been well explored in the studies of crystal engineering of coordination polymers.[1–4] Although there are a considerable number of reports dealing with designing square grid coordination polymers, their rectangular counterparts are not explored to that extent. The synthesis of rectangular grids at will allows the modulation of size and function of the cavity. Only few rectangular grid polymers have been designed either using two charged ligands or using charged and neutral ligands.[6–9] However using two neutral ligands to date only one rectangular grid coordination polymer has been reported.[10] In this structure the rectangular cavities are too small to enclatharate guest molecules. Recently we have shown that the higher analogues of **1**, 1,4-bis(4-pyridyl)benzene **2** and 4,4′-bis(4-pyridyl)biphenyl **3**, can also be used in designing open square grid polymers with dimensions of 15 × 15 and 20 × 20 Å.[11,12] Herein we show that one can employ these longer ligands to design their rectangular counterparts.

Single crystals of $\{Ni(\mathbf{1})(\mathbf{2})(NO_3)_2\cdot 6C_6H_6\}_n$ **4** in 62% yield were obtained by layering a MeOH solution (2 ml) of $Ni(NO_3)_2$ (6 mg, 0.002 mmol) over a benzene solution (7 ml) of **1** (3.2 mg, 0.002 mmol) and **2** (4.6 mg, 0.002 mmol). Similarly single crystals of $\{Ni(\mathbf{1})(\mathbf{3})(NO_3)_2\cdot 8C_6H_6\}_n$ **5** were prepared in 76% yield by using **3** instead of **2**. The crystal structures of **4** and **5** revealed the selective formation of rectangular grids with the entrapment of benzene molecules.[13]† In both the complexes the Ni atom has octahedral geometry with four pyridyl groups at the equatorial and two nitrates at the apical positions.

Complex **4** forms 2D-network containing rectangular grids of dimension 11.3 × 15.6 Å and encloses six benzene molecules per metal, two of them are embodied in the rectangular cavities while the other four exist between the layers [Fig. 1(a)].[14] Ligands **1** and **2** bridge the metal atoms in the (010) and (001) directions, respectively. The rectangular grid planes sit in (011) plane and pack in the direction of (100). Benzene molecules form a two-dimensional layer [Fig. 1(b)] which is similar to that of naphthalene molecules in the crystal structure of $\{M(4,4'\text{-bipy})_2(NO_3)_2\cdot 3C_{10}H_8\}_n$ (M = Co or Ni).[15] The network of benzene molecules can be described as one of the semi-regular planar networks, which are described by Wells,[16] when benzene molecules are depicted as nodes and aromatic interactions as node connections. The packing of the grids is as follows: the moieties of **1** deposit on each other such that 2,6 and 2′,6′-C–H groups of **1** form C–H···O hydrogen bonds (C···O 3.126, 3.568 Å; C–H···O 151,148°) with the uncoordinated O atoms of the $Ni(NO_3)_2$ moiety. As a result this leads to a C–H···O hydrogen bonded layer that divides the whole structure into an infinite number of two-dimensional compartments with a width of the longer ligand [Fig. 1(c)]. Each of these compartments accommodates two benzene layers which interpenetrates through the moieties of **2** such that each molecule of **2** interacts with 12 benzene molecules *via* edge-to-face aromatic interactions.

Complex **5** also formed 2D-network containing rectangular grids of dimension 19.9 × 11.3 Å and enclosed eight benzene molecules per metal. Similarly to **4**, only two benzene molecules were encapsulated in the cavities while the remaining six exist between the layers (Fig. 2). Ligands **1** and **3** bridge

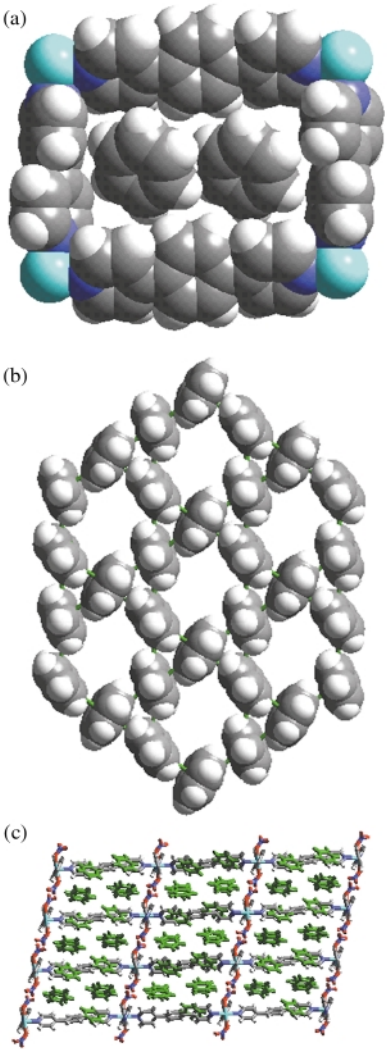

Fig. 1 Space filling representations for (a) rectangular grid unit of **4** containing two benzene molecules; (b) layer of benzene molecules exhibited by complex **4**; (c) side view (101) of the packing of grids and benzene layers in **4**. Note that the C–H···O bonded layers and benzene layers (110) are parallel to each other but perpendicular to grid planes (011).

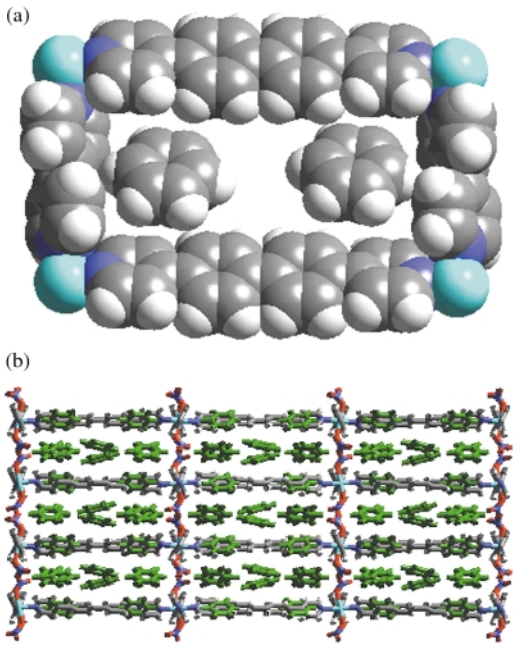

Fig. 2 (a) Space filling representation of rectangular grid unit in **5** containing two benzene molecules. (b) Packing of the grids in **5**. Note that each compartment accommodates three layers of benzene (disorder of the benzene molecules in the middle layer is not shown).

metal atoms in (001) and (100) directions, respectively, and the grid planes pack in the (010) direction. The packing of the grids is similar to that of **4** but now there are three layers of benzene molecules accommodated in each compartment as the width of the compartment is increased from 15.6 to 19.9 Å [Fig. 2(b)]. In this triple layer the outer layers have the same topology as shown in Fig. 1(b) and are linked together by a middle layer, (6,3) net, that is generated by two disordered benzene molecules. In effect each moiety of **3** is surrounded by 18 benzene molecules *via* edge-to-face aromatic interactions.

Our attempts to prepare a 15 × 20 Å grid polymer by using ligands **2** and **3** and $Ni(NO_3)_2/Cu(NO_3)_2/Co(NO_3)_2$ were futile as single crystals suitable for X-ray studies were not obtained. Hence we considered 9,10-bis(4-pyridyl)anthracene **6** as a replacement for **2**. The layering of an MeOH solution of $Ni(NO_3)_2$ over a benzene solution of ligands **3** and **6** resulted in single crystals of the complex $\{Ni(\mathbf{3})(\mathbf{6})(NO_3)(H_2O)\cdot 2C_6H_6\cdot NO_3\}_n$ **7** (yield 55%).† Single crystal analysis reveals

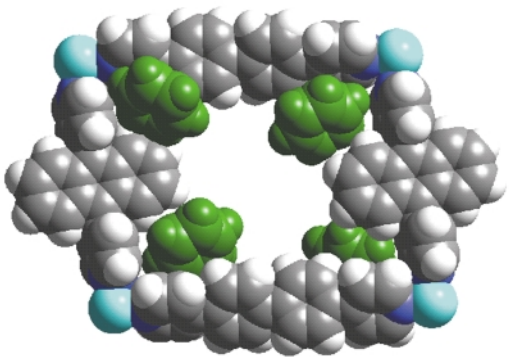

Fig. 3 (a) Space filling representation of a rectangular grid unit in **7**. Note that this contains four benzene molecules.

the formation of a coordination polymer containing rectangular grids of dimension 20 × 15.7 Å (Fig. 3). Each grid accommodates four benzene molecules (two are only partly in the cavity), disordered nitrates and H_2O. Unlike **4** (8 Å) and **5** (7.8 Å), **7** has an interlayer separation of only 4 Å as no guests exist between the layers. The packing of the grids is different from that of the above structures as the layers here deposit on each other in an offset fashion over the two ligands. It is interesting that the rectangular grids formed selectively from two different ligands although ligands **1**–**3** and **6** are known to form square grids when they reacted independently with $M(NO_3)_2$. Given the big size of these rectangular cavities it is also noteworthy that these grid layers are non-interpenetrated.

First published as an Advance Article on the web 11th December 2000

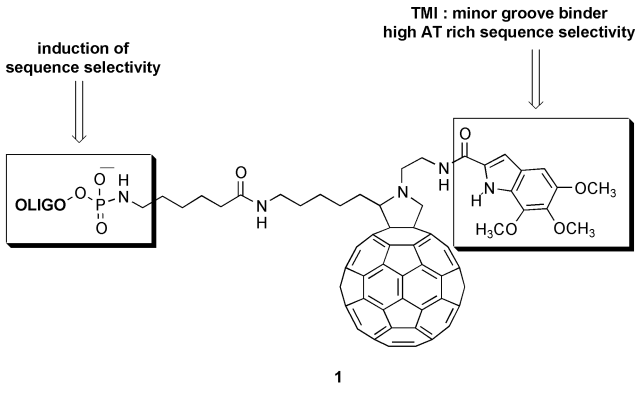
The synthesis of novel functionalized fullerene derivatives is reported: a DNA minor groove binder such as trimethoxyindole-2-carboxylate (TMI) and an oligonucleotide chain have been covalently linked to C_{60} with the aim of duplicating DNA interactions for increasing sequence selectivity.

Fullerene C_{60} and its organofunctionalized derivatives have recently become a topic of interest in bioorganic and medicinal chemistry. This class of compounds has shown high potential in a wide variety of biological activities, such as DNA photocleavage, HIV protease inhibition, neuroprotection and apoptosis.[1] In particular, the excited state properties of C_{60} may offer viable routes to novel pharmacological tools.[2]

One of the problems of photodynamic therapy is the addressed delivery of a photoactive agent to its target. That is why conjugates of fullerene with molecules possessing biological affinity to certain nucleic acids, proteins, cell types, organelles, *etc.*, might be of particular interest. Additionally, C_{60} itself might facilitate the interactions of certain biologically active molecules with lipophilic membranes of living cells and consequently improve cellular uptake due to its high hydrophobicity.

Recently, some conjugates between C_{60} and nucleic acid-specific agents (acridine,[3] netropsin[4] and complementary oligonucleotides[5,6]) have been reported, with the aim of better understanding the mechanism of action and to increase their cytotoxic properties and specificity. Coupling of fullerene to an intercalator or a minor groove binder already leads to higher affinity and specificity of the derivatives towards target DNA.[4] The next step envisages the improvement of the photocleavage efficiency of the conjugates, possibly by stabilizing their duplexes and triplexes and increasing their sequence selectivity.

In order to achieve these goals, we have designed derivative (**1**) of fulleropyrrolidine linked to trimethoxyindole (TMI) and

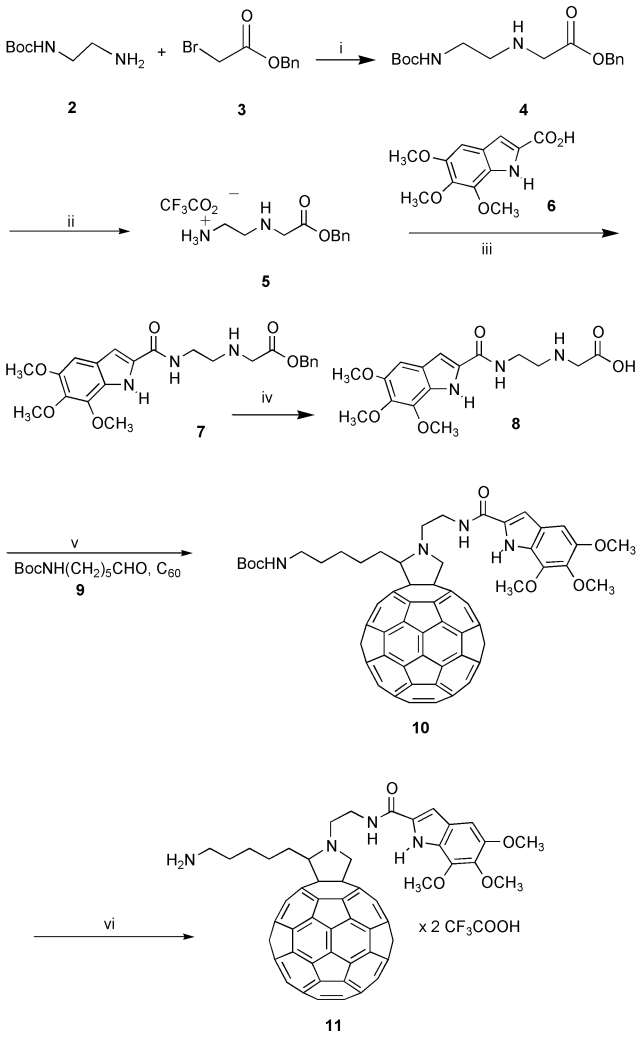


1

OLIGO = 5'-TTT-TC*T-TTT-C*C*C*-C*C*C*-T-3'
C* = Methylated Cytosine

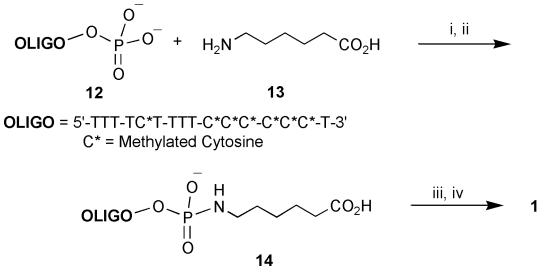
an oligonucleotide chain simultaneously. The rational design of this derivative was based on a synergistic effect of two different linkers such as TMI and oligonucleotide. The TMI unit is characteristic of a class of natural antibiotics named duocarmycins, possessing antitumor activity in the picomolar range, in part due to high affinity and selectivity of the TMI group for the minor groove in AT-rich sequences of DNA.[7] The effect of the oligonucleotide chain could be considered both to induce high sequence-selectivity and to increase water solubility, one of the main problems of C_{60} derivatives for biological application.

The designed compound **1** was prepared following the general synthetic strategy summarized in Schemes 1–2, according to the known procedure for the synthesis of fulleropyrrolidines, based on the 1,3-dipolar cycloaddition of azomethine ylides to C_{60}.[8,9]



Scheme 1 *Reagents*: i, dioxane, 0 °C, then rt 18 h; ii, TFA, CH_2Cl_2, rt, 20 min; iii, NMM, HOBT, EDC, CH_2Cl_2; iv, Pd/C 10%, H_2, MeOH; v, toluene, reflux, 50 min; vi, TFA, CH_2Cl_2, rt, 1 h.

DOI: 10.1039/b008744k



Scheme 2 *Reagents*: i, PPh_3, DMSO, DMAP, Py_2S_2; ii, DMSO; iii, PPh_3, DMSO, Py_2S_2; iv, Et_3N, DMSO, **11**.

The appropriate *O*-benzylaminoacid **4** was prepared by alkylation of the mono protected (Boc) ethylenediamine **2** with benzyl α-bromoacetate **3** (Scheme 1).

Deprotection of the amino functionality by TFA in **8** led to amine **5**, which was coupled to trimethoxyindole-2-carboxylic acid **6**[10] to afford amino ester **7**. The latter was deprotected at the carboxylic function by catalytic hydrogenation and the resulting acid **8** was allowed to react with C_{60} and *N*-Boc-6-aminohexanal **9** to yield the desired multifunctional fulleropyrrolidine **10**.† The latter compound was in turn deprotected to obtain the desired salt **11** by treatment with TFA (Scheme 1).

The designed product **1** was synthesized following a general synthetic strategy for the preparation of oligonucleotide conjugates previously reported[11–13] and summarized in Scheme 2, but the new procedure contained several modifications. Originally the reaction was initiated by activation of the oligonucleotide terminal phosphate by means of Mukaiyama reagents, triphenylphosphine–dipyridyl-2,2′-disulfide in the presence of DMAP.[14] However, it appeared that interaction of the activated phosphate with the amino group of the fullerene derivative did not lead to satisfactory yields of conjugation. Thus, it was necessary to use 6-aminocaproic acid as a spacer between the two moieties.

The phosphorylated oligonucleotide (16-mer) **12** was activated at its terminal phosphate, precipitated by lithium perchlorate in acetone according to the method described by Knorre *et al.*[11] and attached to the ε-amino group of 6-aminocaproic acid **13** in water in the presence of triethylamine to afford the carboxylic acid derivative of oligonucleotide **14** in quantitative yield. Coupling of **14** with fullerene derivative **11** was performed in a similar way, by activation of the carboxylic group with Mukaiyama reagents in organic media to obtain the desired conjugate **1**. Purification of **1** was performed by electrophoresis in 1% agarose–0.1% triton X-100 gel using tris-acetate buffer, followed by excision of the colored band and electroelution, or digestion of agarose with β-agarase.[5,6]

In summary, we have described the synthesis of the bis-functionalized fulleropyrrolidine **1** containing two different linkers capable of modulating and inducing high sequence selectivity. Results on duplex and triplex helicex DNA formation and the synthesis of an enlarged series of compounds for structure–activity relationship studies will be reported in due course.

First published as an Advance Article on the web 11th December 2000

A catalytic antibody has been discovered that degrades oligomeric ester substrates.

A topic of current interest to both the chemical and global community alike concerns the development of readily degradable polymers and benign agents necessary for polymer breakdown.[1,2] From an environmental perspective, microbial/enzymatic approaches for polymer breakdown are very attractive, and while a number of commercially used polymers are sensitive to biodegradation, a large variety of commonly used materials are essentially resistant.[3–5] Furthermore, our current understanding is not sufficient to fully predict a degradability profile or to specifically target an enzyme/microorganism that could degrade a man-made, synthetic polymer.[6]

Antibodies bind biological macromolecules or haptens with high affinities and specificities.[7] We and others have reported antibodies that bind phosphorus transition-state analogues can catalyze the hydrolysis of carbonate, ester, carbamate and amide substrates.[8] Yet, to date there have been no reports of antibody catalysts that accept oligomeric versions of these simple substrate classes. Herein we report the first example of a catalytic antibody capable of degrading synthetic oligomeric esters.

Several tactics could be envisioned in a hapten design for an antibody-catalyzed hydrolysis of an oligomer. Among the ones we considered include: (1) a transition-state analogue used as a repeating unit, and (2) a pseudo-symmetric transition-state analog. Both approaches have merit, but to date no methodology for antibody-catalyzed oligomer degradation has been disclosed.[8] We recently synthesized the new transition-state analogue phosphorodithioate hapten **1** and used this molecule attached to keyhole limpet hemocyanin (KLH) to obtain antibodies with excellent catalytic activity for the hydrolysis of carbonate **2a** (k_{cat} 2.7 min^{-1}) and good activity to ester **2b** (k_{cat} 0.27 min^{-1}).[9] Based on the carbonate and esterolytic activities seen from antibodies derived from **1** and its pseudo-symmetric structure we reexamined this panel of antibodies for possession of 'deoligomerase' activity. Our objective was thus to see if an antibody could perform either a stepwise degradation from an oligomer's terminus or mediate nonselective endo-cleavage on a starting oligomer and resulting subunit structures.

Before antibody screening could be engaged a set of oligomers that could be recognized based on **1**'s haptenic structure needed to be prepared. While aromatic oligocarbonate structures were deemed to be the most highly congruent substrates for antibody library recognition we found such molecules to be unstable for screening. As a second choice, consideration was given to oligoesters. Polyesters are notoriously insoluble in both aqueous and organic solvents.[2] However, we found that smaller molecular weight oligoesters could be synthesized in a controlled stepwise and highly pure manner.[10] Furthermore, these oligomers displayed good stability and workable solubility parameters for the kinetic analysis of the appearance and disappearance of distinct oligomeric subunits. Based on these considerations (*vide supra*), and the need for maximal antibody substrate recognition, 4-hydroxyphenylacetic acid **3** was chosen as our monomer for oligomeric synthesis.

Twenty-five monoclonal antibodies (mAbs) were screened against tetramer **4**, where the term 'tetramer' refers to the total number of aromatic residues, that contained distinct terminal units (Fig. 1). Though **4** was only soluble up to 250 μM in aqueous buffer (50 mM PIPES, 50 mM NaCl, pH 6.7, 5% DMSO cosolvent), we were still able to conduct the assay at 500 μM of **4** under heterogeneous conditions using an orbital shaker. Three mAbs were found that cleaved the tetramer by cutting at

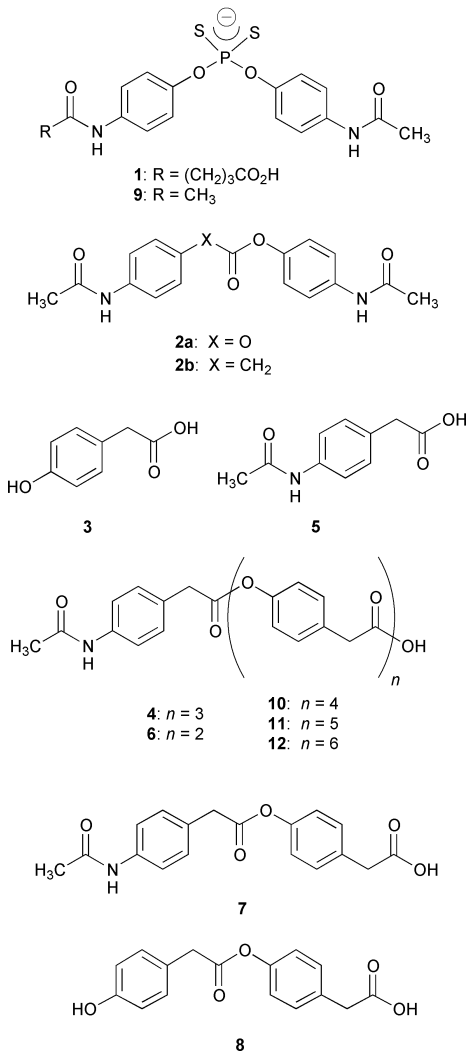

Fig. 1 Structures of hapten **1**, inhibitor **9**, carbonate **2a**, oligoesters **4**, **6**, **10**–**12**, simple esters and products derived from hydrolysis, **2b**, **3**, **5**, **7** and **8**.

† Electronic supplementary information (ESI) available: experimental procedures are provided including kinetic assays, and full characterization (^{1}H and ^{13}C NMR, HRMS, HPLC traces) of the compounds under discussion (**4, 6**–**8**, **10**–**12**). See http://www.rsc.org/suppdata/cc/b0/b008065i/

DOI: 10.1039/b008065i

all three ester linkages. Interestingly, none of these antibodies were noted previously to be catalysts for the hydrolysis of the simple carbonate **2a**, hence they had not been previously examined as catalytic antibodies for monoester hydrolysis.[9] The most impressive mAb, OB2-48F8, was studied in greater detail since it degraded **4** to the products **3**, **5**, **6**, **7** and **8** (Fig. 1) with the best overall rate estimated semi-quantitatively from the sum of product concentrations measured by HPLC. Thereafter, the antibody was freshly prepared and extensively purified by protein G affinity chromatography followed by MonoQ ion exchange chromatography. Notably, the antibody specific activity increased upon purification, as required. Also, the Fab fragment of OB2-48F8 was prepared, purified, and displayed a similar activity compared to the whole IgG. Hence, we ruled out contamination by esterases as a source of the deoligomerization reaction.

Due to the solubility limitations of **4**, the trimer **6** was used as a substrate to quantitatively obtain an assessment of antibody activity. The upper limit of solubility of **6** in the above buffer–cosolvent system was 750 μM and allowed a full kinetic analysis of the formation of **3** and **7** by OB2-48F8 (k_{cat} = 2.2 × 10^{-2} min^{-1}, K_m = 580 μM, k_{cat}/k_{uncat} = 1.5 × 10^3). The phosphorodithioate **9** was a competitive inhibitor (K_i = 6.2 μM) for this route of trimer degradation.[11,12] Concurrently, the antibody also catalyzed the cleavage of **6** to subunits **5** and **8** (k_{cat} = 1.5 × 10^{-3} min^{-1}, K_m = 520 μM, k_{cat}/k_{uncat} = 1.2 × 10^2). The observed activity was interesting in the light of the haptenic structure for which conventional wisdom would predict a preferred hydrolysis to yield **5** and **8**. We also tested the antibody-catalyzed hydrolysis of **2b**,[9] the ester most congruent to **1** and **9**, as well as the cleavage of the two primary ester products **7** and **8**. OB2-48F8 catalyzed the hydrolysis of **2b** (k_{cat} = 1.0 × 10^{-2} min^{-1}, K_m = 289 μM, k_{cat}/k_{uncat} = 3.3 × 10^2) and was competitively inhibited by **9** (K_i = 16.5 μM). The antibody also cleaved **7** (k_{cat} = 1.7 × 10^{-3} min^{-1}, K_m = 695 μM, k_{cat}/k_{uncat} = 1.1 × 10^2) and **8** (k_{cat} = 2.0 × 10^{-3} min^{-1}, K_m = 940 μM, k_{cat}/k_{uncat} = 90). Thus, mAb OB2-48F8 was capable of completely degrading **6** to its component monomeric building blocks. Unexpectedly, the trimer **6** was a better substrate than ester **2b** for reasons that remain unclear. Additional studies employing the novel phosphorodithioate moiety might reveal unusual features with regard to the correlation between hapten and substrate structures.

Finally, to investigate the capabilities of OB2-48F8 for degrading larger oligomers approaching 'real' polymers, we synthesized polyesters **10**–**12** that contained additional repeating units (Fig. 1). The pentamer **10** (MW 729) was sparingly soluble (less than 30 μM) in our aqueous buffer conditions, however using a 500 μM heterogeneous mixture of **10** degradation still occurred into subunit structures (Fig. 2). As detailed in Fig. 2, there was an initial increase in the dimers **7** and **8** followed by a decrease as monomers **3** and **5** increased. This was rationalized based on the above cleavage preferences and consecutive-reaction kinetics. Over a one month period near neutral pH at ambient temperature in the presence of antibody, approximately 200 mM of **3** was formed from degraded **10**. Without antibody, less than 3% occurred. In a similar fashion, OB2-48F8 also broke down polyesters **11** (MW 863) and **12** (MW 997) that were virtually insoluble under our assay conditions, yet cleavage occurred at multiple sites to yield suboligomers as primary products (data not shown). Significantly, the antibody was stable for more than a month under heterogeneous conditions while the progress of these reactions was being monitored.[13] All the observations and data confirmed that the antibody performed oligomer degradations by 'multimer' processing using nonregioselective, kinetically biased endo-cleavage, rather than a stepwise deoligomerization through cleavage of monomers from a terminus.

In conclusion, a catalytic antibody has been discovered that degrades oligomeric esters. Our findings are of fundamental importance as now catalytic antibodies share another trait thought only to be associated with enzymes, the biodegradation of oligo and polymeric materials.[1]

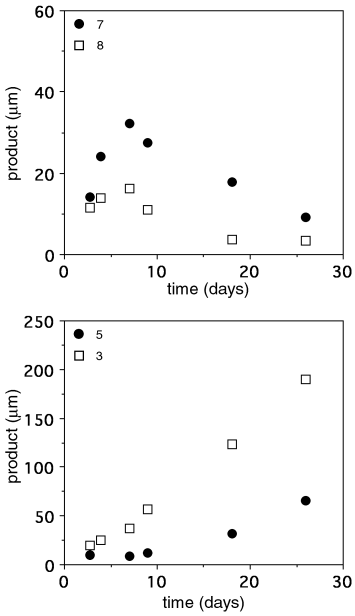

Fig. 2 Reaction profiles showing products from the antibody-catalyzed hydrolysis of oligoester **10**. Reactions were carried out in 50 mM PIPES, 50 mM NaCl, pH 6.7, 5% DMSO at 21 °C in the presence of 500 μM **10** and 20 μM OB2-48F8. The uncatalyzed reactions were carried out under the same conditions in the absence of antibody and the rates subtracted.

We thank Dr Peter Wirsching for reviewing the manuscript. Financial support was provided by The National Institute of Health (GM 43858) and The Skaggs Institute of Chemical Biology.

Cellulose: a new bio-support for aqueous phase catalysts

Françoise Quignard and Agnès Choplin*

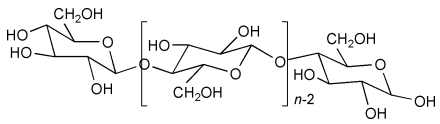
Institut de Recherches sur la Catalyse-CNRS, 2 avenue A. Einstein, 69 626 Villeurbanne Cedex, France. E-mail: choplin@catalyse.univ-lyon1.fr

Received (in Cambridge, UK) 25th September 2000, Accepted 20th November 2000
First published as an Advance Article on the web 11th December 2000

The choice of a hydrophilic bio-polymer, such as cellulose, as the support of the water soluble $Pd(OAc)_2$/5 TPPTS system, leads to a new and efficient heterogeneous catalyst for the Trost Tsuji allylic alkylation reaction.

The heterogeneous catalysts designed for the synthesis of fine chemicals are usually supported either on inorganic oxides (silica, carbon..) or on organic synthetic polymers.[1] If one excludes the case of supported metal particles modified with the appropriate asymmetric inductor (tartaric acid, cinchona alkaloids…),[2–5] most of these catalysts are anchored metal complexes; the anchoring bond links a surface atom either to the metal centre or to an atom of one of the ligands at a position as remote as possible from the active metal centre. The control of the selectivity of the surface anchoring reactions is one of the major difficulties; yet this affects directly the selectivity of the target organic reaction.

About ten years ago, the so-called Supported Aqueous Phase Catalysts were developed for the heterogenization of biphasic water/organic catalysts.[6] This immobilisation procedure takes advantage of the hydrophilicity and of the high specific surface area of an inorganic support. The former character is necessary to maintain the catalyst-containing water film on the solid, the latter is responsible for the substantial activity increase as compared to that achieved in a biphasic medium. Silica is the most used support; mesoporous glass beads of controlled pore size distribution are the favourite, although the precise role of the porosity is so far not unambiguously demonstrated. This methodology is particularly well suited to the reactions non-feasible under conventional biphasic conditions such as, for example, those which involve water non-soluble reactants[7] or water-sensitive reactions.[8] We wish to report here the first example, to our knowledge, of a catalyst supported in an aqueous film on a natural polysaccharide, cellulose.



This polymer, which has unlimited availability as a renewable agro-resource and is biodegradable, presents a number of interesting structure related properties[9] which have so far, to our knowledge, never been explored in the field of catalysis. Here, we have used its high hydrophilic character, induced by the presence of numerous hydroxy groups. Thus, we have immobilised on a cellulose powder the water soluble catalytic precursor $Pd(OAc)_2$/5 TPPTS [TPPTS = $P(m\text{-}C_6H_4SO_3Na)_3$] using the SAP methodology and we have tested the catalytic properties of this solid for the allylic substitution of (*E*)-cinnamyl ethyl carbonate by morpholine [eqn. (1)].

The cellulose powder (a generous gift from Institut Textile de France, Ecully, France, particles size: 80 μm) is characterised by a degree of crystallinity of 53% (determined by XRD), a specific surface area equal to 1.35 $m^2\ g^{-1}$ (from the isotherm of N_2 adsorption of the solid evacuated at 108 °C) and a wetting volume equal to 4.5 mL g^{-1} (defined as the volume of water which can be added to 1 g of solid before a drop of liquid can be visualised). All the manipulations are performed under inert atmosphere using classical Schlenk tube techniques. The catalyst is synthesised following the so-called incipient wetness method as described in ref. 10. Typically, $Pd(OAc)_2$ (52.5 mg, 0.23 mmol) and TPPTS (732 mg, 1.3 mmol) are dissolved in de-aerated water (12 mL) under magnetic stirring (30 min, 40 °C). This solution is then poured onto cellulose (2.5 g, pre-evacuated at 120 °C (10 h, 10^{-4} Torr)) and the mixture stirred at 40 °C for 30 min. Water is then evacuated at rt (2 h at 10^{-1} Torr, 2 h at 10^{-4} Torr). The dry mustard yellow solid (CELL–SAP-Pd) is characterised by a 0.75% Pd content (determined by ICP) and a 3% wt water content (determined by TGA). The latter parameter is varied by addition of the desired quantity of water directly onto the solid with a syringe under magnetic stirring (rt, 30 min).

The catalytic tests are performed as described in ref. 10 under the following conditions: solvent: PhCN, T = 50 °C, [**1**]–[**2**]–[Pd] = 25:30:1; [**1**] = 30 mmol L^{-1}. The reaction is followed by GPC (HP 5890, HP5 column, T_{inj} = 240 °C, $T_{det.}$ = 280 °C), calibrated against authentic samples. Analysis of the palladium content of the organic solutions at the end of each catalytic test is performed by ICP or ICP-MS when necessary.

The activity of CELL–SAP-Pd is strongly dependent on its water content (Fig. 1), a phenomenon which has already been observed with most silica–SAP catalysts.[10–13] For these latter, one maximum is generally observed which seems to depend on the precise reaction (catalyst, reactants) under investigation. With CELL–SAP-Pd, two maxima of activity are evidenced. The first corresponds to a water content of 26 wt% or 0.5 g H_2O/g CELL; **1** is converted after 100 min to a 60% level with a 100% selectivity for **3**. The second is with 66 wt% H_2O or 6 g H_2O/g CELL; then the solid is much more active and **1** is fully converted to **3** within 100 min.

For the most active solid (66 wt% H_2O), we tested the influence of the method of introduction of water on the solid.

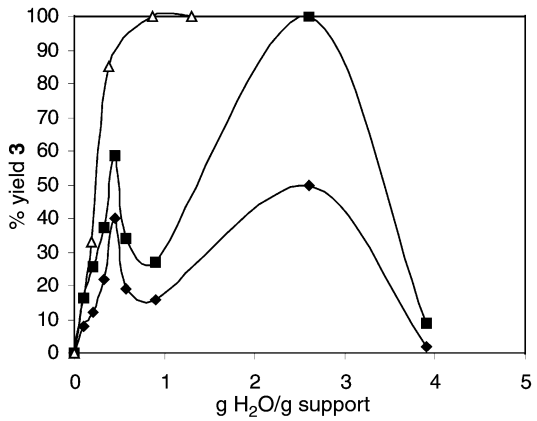

Fig. 1 Influence of the water amount (g H_2O/g CELL) on the catalytic activity of ($Pd(OAc)_2$/5 TPPTS) supported on CELL, ◆: t_R = 50 min; ■: t_R = 100 min and on silica Δ (t_R = 10 min. Exp. cond.: solvent: PhCN, T = 50 °C, [**1**] = 30 mmol L^{-1}, [**1**]–[**2**]–[Pd] = 25:30:1.

DOI: 10.1039/b007776n

For this purpose, we added the desired water amount to the benzonitrile solution of the reactants. This biphasic solution is then poured on the 'dry' CELL–SAP-Pd sample. Instantaneously, the solution becomes monophasic but remains colourless; this confirms the high hydrophilicity of the surface of cellulose and suggests that palladium remains essentially on the solid. The activity of this sample is lower than that obtained with the general method (60 *vs*. 95% yield **3** after 100 min). But, we suspect that the main origin of this discrepancy is the uncontrolled agglomeration of the solid particles under the catalytic conditions; this necessarily induces major problems of diffusion of the reactants to the active centres. Accordingly, we observe also some irreproducibility of the activity of the solid CELL–SAP-Pd as soon as its water content lies above 1 g H_2O/g CELL.

In none of these catalytic tests, is the presence of palladium detected in the organic catalytic solutions once the reactants are fully converted: the leaching of palladium, if any, is below 0.6%. This result is very encouraging because it is the first condition which must be met before one can envisage the possibility of recycling a supported catalyst, one of the advantages which is expected from the heterogenization of any molecular catalyst. It is then worth finding a way to improve the dispersion of the solid particles in the liquid organic medium.

In water, the surface of cellulose is anionic;[9] therefore cationic surfactants should easily interact with the outer surface of the particles, and confer on them a hydrophobic character. This should facilitate their dispersion in an organic medium such as benzonitrile. When a small amount of cetyltrimethylammmonium bromide (CTAB) is added to the solution of the reactants, the dispersion of the solid particles CELL–Pd-SAP (2.6 g H_2O/g CELL) is *de visu* excellent and concomitantly their activity increases sharply (Fig. 2). The increase of the concentration of CTAB (given as the initial concentration in PhCN) is beneficial for the activity, but concomitantly the palladium leaching increases up to an unacceptable level (Table 1). The addition of triethylpropylammonium bromide NEt_3PrBr, which is not a surfactant but a common phase transfer agent in catalysis, improves neither the activity of the same solid, (Fig. 2) nor its dispersion, but simultaneously the palladium leaching is less severe (Table 1). Finally, we observe that CTAB, even at low concentrations, kills the activity of the related silica–SAP-Pd (40 wt% H_2O) (Fig. 2).

The interpretation of all these data clearly needs a more detailed investigation; yet, some important comments can already be made. The increase of the activity of CELL–SAP-Pd

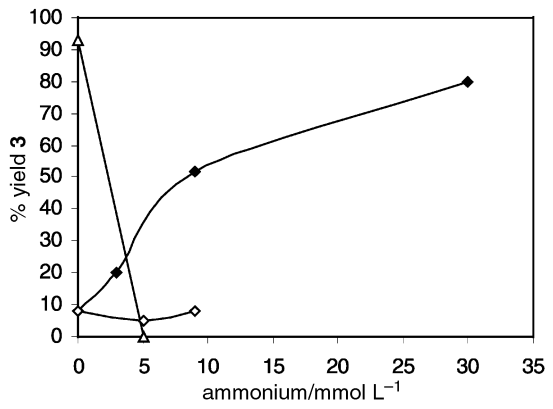

Fig. 2 Influence of NEt_3PrBr (◇) and of CTAB (◆) on the activity of CELL–SAP-Pd (2.6 g H_2O/g CELL and of CTAB on the activity of silica–SAP-Pd (0.87 g H_2O/g silica) (Δ). t_R = 5 min. Exp. cond.: solvent: PhCN, T = 50 °C, [**1**]: 33 mmol L^{-1}, [**1**]–[**2**]–[Pd] = 25:30:1.

Table 1 Palladium leaching from CELL–SAP-Pd (2.6 g H_2O/g CELL) into the organic solvent after the catalytic tests performed under the conditions given below Fig. 1 and 2

Ammonium bromide Nature	Conc/mmol L^{-1}	Pd/ppm	% Pd
CTAB	0	1.2	0.6
	3	9	3
	9	14	8
	30	47	20
NEt_3PrBr	9	9	5

with its water content may be related to a greater mobility of the complex with increasing thickness of the water layer on the surface. But some properties must clearly be correlated to the nature of the support itself: water induces a swelling of the cellulose,[9] a property which increases the surface accessibility. Thus for example, it is known that the specific surface of a cotton powder is very low when determined from the adsorption isotherm of N_2, and raises values two orders of magnitude larger when determined from the adsorption of H_2O.[9] The double maximum may also reflect the structure of cellulose and more specifically the fact that the amorphous part is more accessible to the reactants than the crystalline part. Finally, CTAB clearly has a complex role, but it acts definitely as a surfactant, favouring the dispersion of the cellulose particles in the organic reaction medium and most probably also its swelling.

These data are very encouraging; they show the potential of cellulose as a support for the immobilisation of water soluble catalysts for fine chemical synthesis, these latter reactions are generally compatible with the thermal stability of this natural polymer. We are currently exploring the many other means of immobilisation of complexes which are possible on this type of solid, so as to take advantage of the specific chemical and structural properties of these polysaccharides as compared to the inorganic oxide supports traditionally used in the field of catalysis.

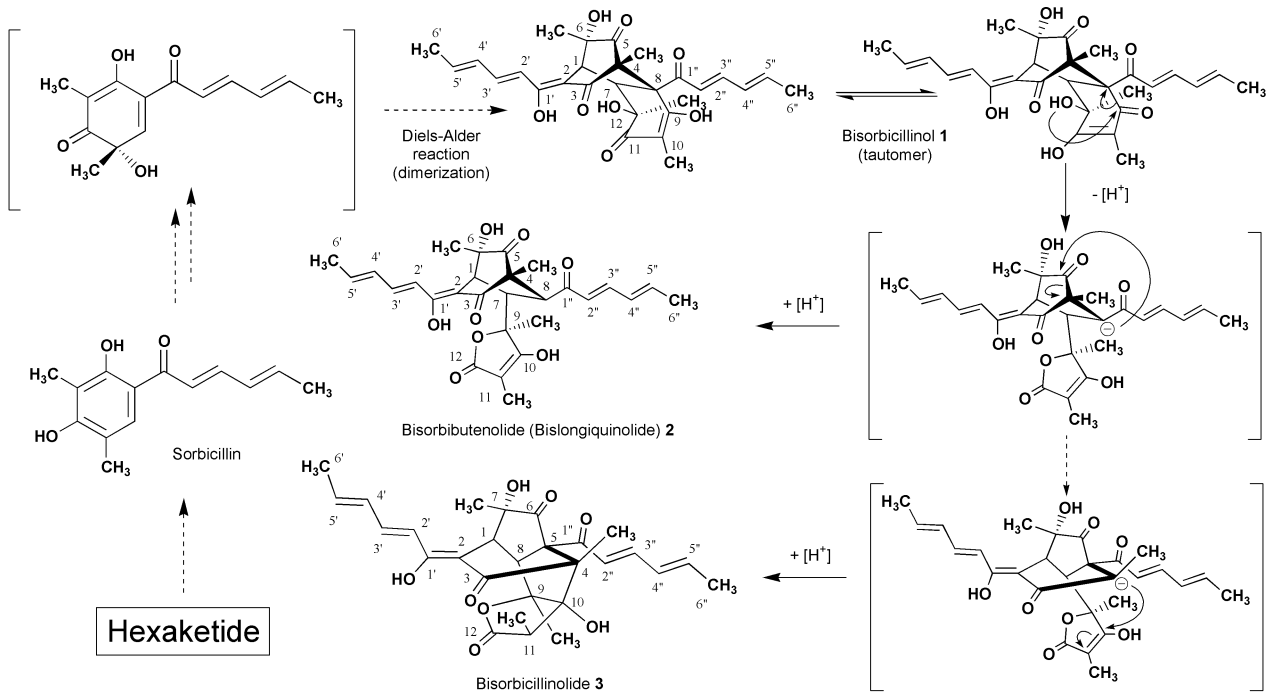
Biosynthetic incorporation of labelled sodium acetates into bisorbicillinol in *Trichoderma* sp. USF-2690 suggests that bisorbicillinol is derived from 12 acetate units. Successful bioconversion of the labelled bisorbicillinols to bisorbibutenolides (bislongiquinolides) and bisorbicillinolides using the washed mycelium of the strain suggests that there are biosynthetic routes from bisorbicillinol to bisorbibutenolide and from bisorbicillinol to bisorbicillinolide.

The 'Bisorbicillinoids', comprised of dimeric sorbicillin-related natural products, have recently been described by Nicolaou *et al*.[1] Several compounds in the group, possessing complex structures, exhibit interesting biological activities, *e.g.*, inhibition of the production of TNF-α by macrophages and monocytes,[2] inhibition of β-1,6-glucan biosynthesis,[3] and scavenging of the 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical.[4–7] The biosynthesis of bisorbicillinoids is of interest to many investigators[5,8–10] and, recently, biomimetic total synthesis has been investigated.[11–13] In particular, the biosynthetic pathway of bisorbibutenolide[5] (bislongiquinolide, **3**)[14] has been proposed to involve several distinct routes.[5,10] We recently reported that *Trichoderma* sp. USF-2690 produced seven bisorbicillinoids, including bisorbicillinol **1**, bisorbibutenolide **2**, and bisorbicillinolide **3**,[4,5] with presumed biogenetic routes from **1** to **2** and from **1** to **3** through a branch point as a common intermediate anion (Scheme 1).[5] The routes were postulated based on the finding that ^{13}C-labeled sodium acetate was incorporated into **1** *via* a polyketide pathway prior to incorporation into **2** and **3**. We wished to establish the biosynthetic relationship between **1**, **2**, and **3**, and report herein the result of a preliminary labelling experiment that provides evidence of the biosynthetic routes from **1** to **2** and from **1** to **3**.

Trichoderma sp. USF-2690 was first cultivated on a reciprocal shaker at 30 °C for 2 d.† The washed mycelium from the fermentation broth was then suspended in five 0.5-liter flasks each holding 150 mL of the medium (pH 7) containing 0.1% sodium [1-^{13}C]acetate or 0.1% sodium [2-^{13}C]acetate and 0.5% polypeptone, and again fermented with reciprocal shaking at 30 °C for 2 d. The filtered broth (1 L) was extracted with ethyl acetate (0.5 L × 2) at pH 3. The organic extract, concentrated *in vacuo*, was applied to a Sephadex LH-20 column and eluted with methanol. The fraction including **1** was rechromatographed using medium-pressure liquid chromatography (MPLC) under the following conditions: support, YMC-ODS-AQ 120-S50; solvent, acetonitrile–H_2O (1 : 1, containing 0.1% trifluoroacetic acid); detection, UV at 370 nm. Two types of labelled bisorbicillinol **1** were obtained. The experiment using sodium [1-^{13}C] acetate gave **1** ([1-^{13}C]-**1**) with 10 ^{13}C-enriched carbons (C-1, C-3, C-5, C-7, C-1′, C-3′, C-5′, C-1″, C-3″, and C-5″) in the ^{13}C-NMR spectrum. The expected incorporations at C-9 and C-11 were not observed. We previously reported that bisorbicillinol **1** had a keto–enol tautomation between C-9 and C-11 in solution, and the ^{13}C signals of C-9 and C-11 did not appear in the ^{13}C-NMR spectrum.[4] Therefore, the lack of peaks at C-9 and C-11 did not necessarily mean that the ^{13}C atoms from sodium [1-^{13}C]acetate were not incorporated at C-9 and



Scheme 1 Biosynthetic pathway from bisorbicillinol **1** to bisorbibutenolide (bislongiquinolide **2**) and bisorbicillinolide **3**.

DOI: 10.1039/b007181l

C-11. On the other hand, the feeding experiment using sodium [2-^{13}C]acetate enhanced the peak strength of 12 carbons (C-2, C-4, C-6, C-8, C-10, C-12, C-2′, C-4′, C-6′, C-2″, C-4″, and C-6″) in the ^{13}C-NMR spectrum of **1** ([2-^{13}C]-**1**). These results suggested that **1** was formed by the dimerization of six acetate units, which combined in the head-to-tail manner typical of fatty acids and polyketides, to give linkages between C-1 and C-7 and between C-4 and C-8 according to the Diels–Alder reaction.

The incorporation study employing each labelled bisorbicillinol **1** as a precursor of bioconversion was accomplished in the following manner. The fungus, inoculated in 0.5 L flasks containing 150 mL of the medium (pH 7) composed of 2.0% glucose and 0.5% polypeptone, was preincubated on a reciprocal shaker at 30 °C for 9 d. Mycelia were washed with sterilized water and then the washed mycelium was inoculated in 0.5 L flasks containing 150 mL of sterilized water with 10 mg of non-labelled and 5 mg of ^{13}C-labelled bisorbicillinol **1**. The cultures for isolation of bisorbibutenolide **2** and bisorbicillinolide **3** were incubated for 72 and 10 h, respectively. The filtrate obtained from each broth was adjusted to pH 3 and extracted with ethyl acetate. LH-20 column chromatography and repetitive MPLC yielded **2** and **3**, respectively.

The ^{13}C-NMR spectrum of bisorbibutenolide **2** obtained from the broth fed with [1-^{13}C]-**1** had 12 ^{13}C-enriched peaks at C-1, C-3, C-5, C-7, C-10, C-12, C-1′, C-3′, C-5′, C-1″, C-3″, and C-5″. This definitive result established the existence of a biological synthetic route from **1** to **2**, as we had proposed previously.[5] In addition, the enrichment of C-10 and C-12 of **2** meant that the two invisible carbons in the ^{13}C-NMR spectrum of **1** were enriched by sodium [1-^{13}C]acetate. Furthermore, the consecutive feeding study of [2-^{13}C]-**1** confirmed the validity of bioconversion from **1** to **2** in the fungal strain. This finding was consistent with the expectation based on a typical polyketide pathway that the ^{13}C–enrichments at C-2, C-4, C-6, C-8, C-9, C-11, C-2′, C-4′, C-6′, C-2″, C-4″, and C-6″ were observed in the ^{13}C-NMR spectrum of **2**.

Proof of biosynthesis of bisorbicillinolide **3** *via* bisorbicillinol **1** as a precursor, was then performed in the same manner. The bisorbicillinolide **3** obtained from the broth fed with [1-^{13}C]-**1** gave the characteristic ^{13}C-NMR spectrum of **3**, which had 12 peaks enhanced at C-1, C-3, C-6, C-8, C-10, C-12, C-1′, C-3′, C-5′, C-1″, C-3″, and C-5″. The continued experiment using [2-^{13}C]-**1** led to the expected **3**, into which excess ^{13}C-atoms were incorporated at C-2, C-4, C-5, C-7, C-9, C-11, C-2′, C-4′, C-6′, C-2″, C-4″, and C-6″. The results of a feeding study using [1-^{13}C]-**1** and [2-^{13}C]-**1** ascertained that bisorbicillinolide **3** was biosynthesized from bisorbicillinol **1** as a precursor.

To examine the possibility that the biosynthesis from bisorbicillinol **1** to bisorbibutenolide **2** occurred *via* bisorbicillinolide **3**, or from **1** to **3** *via* **2**, time course studies on bioconversion of products in the washed mycelium were performed using high performance liquid chromatography analysis. Non-labeled bisorbibutenolide **2** or bisorbicillinolide **3** was added to the washed mycelium prepared above, and the culture broth was incubated at 30 °C for 72 h. No other products were detected in either experiment.

These observations from the ^{13}C-feeding studies indicate that there are biosynthetic routes from **1** to **2** and from **1** to **3** in *Trichoderma* sp. USF-2690. The supporting experiments might rule out the possibility of biosynthesis from **1** to **2** *via* **3** or from **1** to **3** *via* **2** and the reverse biosynthesis from **2** or **3** to **1**. These results suggest the presence of the first anion as a branch point and the second anion following the C–C bond cleavage. Further incorporation studies will clarify the detailed biosynthetic mechanisms through the two precursor anions.

Water in supercritical carbon dioxide microemulsions are examined as a new medium for the extraction of metal ions from contaminated surfaces, and are shown to extract > 99% of the copper from a spiked filter paper with as little as a two-fold excess of surfactant.

Supercritical carbon dioxide ($scCO_2$) has many advantages as a solvent for extractions in environmental remediation including enhanced diffusivity (mass transfer), chemical stability, and pressure-dependent solvation properties that facilitate simple separations. The absence of a liquid–vapor interface above the critical temperature (31 °C) results in zero surface tension, and is particularly advantageous for extraction from solid surfaces since $scCO_2$ may easily penetrate the pores of solid matrices. The challenge for extracting metal ions comes from the fact that supercritical carbon dioxide has no permanent dipole moment and a low dieletric constant (*ca.* 1.5). Hence, hydrophiles and metal salts typically have near zero solubility. Ligands such as β-diketones, dithiocarbamates, and organophosphorus reagents have been used to solubilize metals into $scCO_2$.[1] The solubility of the ligands is quite good in some cases, but solubility of the metal–ligand complexes remains low, limiting practical applications. Solubility of the metal complexes can be enhanced with highly fluorinated ligands,[2] but complexes that have moderate CO_2 solubility often require a large excess of ligand for efficient extraction.[1e,g,i,2e] Yazdi and Beckman have shown that attaching 'CO_2-philic' tails, consisting of either highly fluorinated or polysiloxane groups, to ligands increases the solubility of the metal complexes and results in moderately efficient metal extractions (up to 87%) in liquid CO_2.[3] The approach of designing specific fluorinated ligands has the drawback that efficient extraction depends on the metal being present as a simple metal salt in a specific oxidation state.

Our approach differs significantly from strategies to date in that we solubilize the metal ion with water in CO_2 microemulsions. Johnston *et al.*[4] and Eastoe *et al.*[5] first demonstrated that a perfluoropolyether ammonium carboxylate surfactant was effective in forming water microemulsion droplets (< 10 nm in diameter) in supercritical carbon dioxide. We report here on using these water-based microemulsions as a new medium for metal extraction from contaminated surfaces. The nanodroplets of water suspended in CO_2 take advantage of both the high solubility of metal ions in water and the high difussivity of CO_2 to penetrate pores that are inaccessible to bulk water. The pressure-dependent solvent strength of CO_2 can be used to control formation and disruption of the nanodroplets. This extraction scheme is particularly attractive for remediation of heterogeneous waste in which small amounts of metal contaminants are dispersed throughout a large volume of solid waste. Typically, such extractions require an amount of water or solvent proportional to the volume of solid material. With microemulsions, CO_2 is effectively used as a diluent and the amount of water need only be proportional to the amount of metal to be extracted, making it possible to decontaminate grams of waste with μL of water.

Water in carbon dioxide microemulsions were formed in a stainless steel variable volume view cell.[6] The standard amounts of material added for microemulsion formation were 0.2 g PFPE-NH_4, 10 g CO_2 and 60 μL water. Selected experiments were done with 0.122 g PFPE-NH_4, 10 g CO_2 and 42 μL water (data in Table 1). All extractions were conducted at 207 bar and 45 °C. Filter paper was spiked by two different methods. A 42.5 mm diameter filter paper was submerged in aqueous 1 M copper nitrate for at least 48 h (method 1). After drying, the filter paper was cut into quarter sections and extractions were conducted on one section of the paper. For method 2, 5–6 mg of $Cu(NO_3)_2$ was dissolved in 30 μL of water and the entire solution was added dropwise to a piece of filter paper. Each filter paper was dried for at least 24 h and placed in a small extraction cell (ISCO, 3 mL cell). The microemulsion was recirculated through the extraction cell at a flow rate of 10 mL min^{-1}. The kinetics of extraction from the filter paper were followed with UV–VIS spectroscopy (Hewlett–Packard model 8453). At the completion of the extraction, at least 50 mL of neat CO_2 was passed through the extraction cell (207 bar, 25 °C) to remove residual fluorinated surfactant from the filter paper. The filters were digested and copper concentrations were determined by ICP-AES.

The extinction coefficient for the 733 nm band of $Cu(NO_3)_2$ in the water/CO_2 microemulsion was determined to be 59.3 M^{-1} cm^{-1}.[7] The low energy absorption band is blue shifted compared to copper nitrate in nitric acid (810 nm) at ambient conditions (Fig. 1). We attribute this shift to two factors: copper binding to the surfactant head groups and a decrease in the polarity of water in the micelle core. The maximum solubility of copper in the microemulsion was found to be 3 M.

Extractions of copper from spiked filter paper were conducted to examine the effectiveness of the microemulsion in removing metal contaminates from solid surfaces (Table 1). More than 99% of the copper is extracted in one step from smaller pieces of filter paper. Extraction efficiency decreases when a larger piece of filter paper is used, but following with a second extraction improves the efficiency to 82–99%. The kinetics of extraction from a spiked filter paper (method 1) were followed by UV–VIS spectroscopy (Fig. 1). The absorption from copper reached a maximum after 60 min of exposure to the microemulsion, with no further increase after an additional 90 min. The kinetics of extraction with microemulsions are much

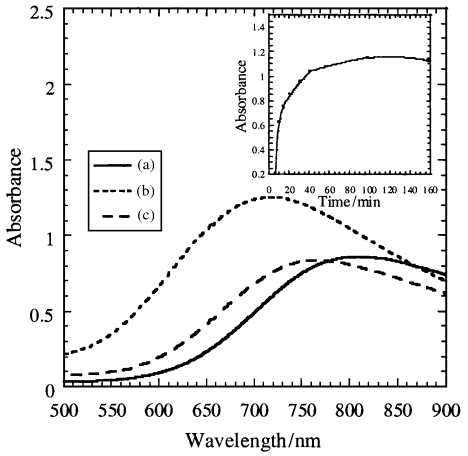

Fig. 1 The absorption spectra of copper(II) from: (a) copper nitrate dissolved in nitric acid at ambient conditions, (b) copper nitrate dissolved in the water/CO_2 microemulsion, and (c) aqueous copper acetate at ambient conditions. The inset shows the intensity at 733 nm *vs.* time for extraction of copper.

faster than those observed recently with CO_2-soluble polymers that required many hours to days for extraction.[8] In addition to improved kinetics, the microemulsions have improved efficiency compared to previous studies with CO_2-soluble chelating agents. In general, past extractions have required a tremendous excess of ligand to achieve reasonable metal extractions (> 1000 fold).[1] By comparison, at the maximum solubility of copper, the molar ratio of surfactant to copper in the microemulsion is approximately 3.

Europium fluorescence lifetimes and emission spectra were examined to probe ion solvation in the water in CO_2 microemulsions. The relative heights of the europium emission bands at 593 and 615 nm provide information on the first solvation sphere around the europium ion.[9,10] In the microemulsion, the 615 nm band gains in intensity, indicating that the center of inversion around europium is removed by displacement of water in the first hydration sphere by another ligand.[11] Two possible ligands are available in the microemulsion core: the carboxylate head group of the surfactant or carbonic acid, formed by CO_2 dissolved in the aqueous phase. As a control, europium chloride was dissolved in D_2O and the headspace over the solution was pressurized to 3000 psi with carbon dioxide to introduce bicarbonate with no surfactant present. The europium emission spectra appeared the same as in water at ambient conditions, suggesting that the carboxylate head group of the surfactant is solely responsible for the changes in the emission spectra of europium ion dissolved in the microemulsion.

Futher evidence for surfactant binding comes from lifetime experiments using H_2O- and D_2O-based microemulsions. The isotope effect provides a way to determine the number of water molecules surrounding the europium ion using the equation: $n = C^*(1/\tau_H - 1/\tau_D)$, where n is the number of water molecules, C is a constant (1.05 for Eu), τ_H is the fluorescenece lifetime in H_2O, and τ_D is the fluorescence lifetime in D_2O (lifetimes in milliseconds).[9] The lifetime of europium(III) ion in the water in supercritical CO_2 microemulsion was found to be 120 μs and increased to 274 μs when the microemulsion was formed with D_2O. Using the above equation with the measured lifetimes gives *ca.* 5 water molecules in the first hydration sphere of the europium ions. As the fully hydrated ion has 8 to 9 water molecules,[12] this result suggests that the surfactant displaces 3 or 4 water molecules from around the europium ion.

Radioactive and heavy metal contaminants are often present as water-insoluble metal oxides in heterogeneous waste. To demonstrate the versatility of the microemulsion in metal extraction, the microemulsion was formed with a 20 wt% nitric acid solution instead of pure water. The increase in acidity was confirmed by dissolving methyl orange indicator in the microemulsion. The indicator appeared bright red when the microemulsion was formed with 20% nitric acid as opposed to orange when distilled water was used. The ability of the acidic microemulsions to extract metal oxides was examined with europium oxide. Based upon visual observation, 10 mg of europium oxide completely dissolved into a microemulsion formed with 20 wt% nitric acid after stirring for 1 h.

Water in supercritical carbon dioxide microemulsions are effective for extraction of metals from solids. At maximum solubility, a 3 M solution of copper can be obtained within the microemulsion core. The nanodroplets offer the advantages of rapid and efficient extractions with a versatile environment. Making the microemulsion with 20 wt% nitric acid rather than pure water allowed europium oxide to be solubilized. Agents that oxidize low valent metal oxides or water-soluble chelating agents could also be introduced into the microemulsions to expand the types of metals that may be extracted and to provide selectivity in mixed metal extractions. Metal is readily recovered by simply dropping the CO_2 pressure below the cloud point, causing the water to coalesce into a single droplet with all of the metal and some surfactant. Initial experimental work has indicated that surfactant recycle should be possible by adding excess water and reducing pressure to destabilize the microemulsion while maintaining surfactant solubility. An additional 270 μL of water was added to a copper-saturated microemulsion at 207 bar, and then pressure was reduced to 101 bar. At 101 bar, phase separation occurred and the aqueous phase settled to the bottom of the cell, while a significant fraction of the surfactant remained in the upper phase. No copper was observable in the upper phase by UV–VIS. The ability of the microemulsion to concentrate the metal into a small volume of water makes it particularly attractive for extractions from contaminated solids that often have small amounts of metal dispersed over a large volume of solid waste.

First published as an Advance Article on the web 11th December 2000

The α-effect for the reaction of a sulfonyl ester exhibits a bell-shaped dependence of the α-effect on solvent composition as do the corresponding reactions with a carbonyl and a phosphinyl ester, and the magnitude of the α-effect is found to be dependent on the magnitude of the β_{nuc} value, suggesting TS stabilization as the cause of the α-effect.

Since the α-effect term was given by Edwards and Pearson in 1962 to the abnormally enhanced reactivity shown by nucleophiles having a pair of unshared electrons adjacent to the nucleophilic center,[1] numerous studies have been performed to account for this phenomenon.[2–11] However, the cause of the α-effect has not been clearly understood.[2–11] One of the intriguing aspects in α-effect studies has been the finding that the magnitude of the α-effect is dependent on the nature of the electrophilic center, generally increasing as $sp^3 < sp^2 < sp$ for carbon centers,[2–4] though some exceptions exist.[5] Equally interesting, as well as controversial, has been the effect of solvent on the α-effect.[6–9]

In order to shed light on the effect of solvent on the α-effect, we initiated systematic studies and in 1986, we investigated the reaction of *p*-nitrophenyl acetate (PNPA) with butane-2,3-dione monoximate (Ox^-) and *p*-chlorophenoxide ($ClPhO^-$), as the α- and corresponding normal-nucleophile, respectively, in DMSO–H_2O mixtures of varying compositions.[6a] We found, unexpectedly, a bell-shaped dependence of the α-effect (k^{Ox^-}/k^{ClPhO^-}) on solvent composition.[6a] A similar bell-shaped trend was observed for the corresponding reaction of *p*-nitrophenyl diphenylphosphinate (PNPDPP).[6b] However, Moss reported that the reaction of PNPA with *o*-iodosylbenzoate (IBO^-) and $ClPhO^-$ in DMSO–H_2O mixtures shows no maximum α-effect but exhibits a decreasing α-effect trend.[7] More surprisingly, a contrasting solvent behaviour was found recently:[8] the reaction of PNPA with Ox^- and $ClPhO^-$ in MeCN–H_2O mixtures exhibits an increasing α-effect trend as the mol% MeCN in the medium is increased.[8a] Similarly, the α-effect for the reaction of PNPA with benzohydroxamates and *m*-chlorophenoxide in MeCN–H_2O mixtures also resulted in an increasing α-effect behaviour as the concentration of MeCN in the reaction medium was increased.[8b]

It appeared to us as potentially highly informative, in investigation of the α-effect, to vary the electrophilic center systematically and to couple that with variation of solvent. We report herein such a study for the reaction of a sulfur centered substrate, *p*-nitrophenyl benzenesulfonate (PNPBS), with Ox^- and $ClPhO^-$ in DMSO–H_2O mixtures as shown in eqn. (1), and compare the results with the data for the corresponding reactions of PNPA and PNPDPP.

$$C_6H_5SO_2\text{-}OC_6H_4NO_2\text{-}p + Nu^- \rightarrow C_6H_5SO_2Nu + {}^-OC_6H_4NO_2\text{-}p \quad (1)$$

$Nu^- = CH_3C(O)C(CH_3)=NO^-$ (Ox^-), an α-nucleophile
$p\text{-}ClC_6H_4O^-$ ($ClPhO^-$), a normal nucleophile

As shown in Fig. 1, the second-order rate constant increases as the mol% of DMSO in the medium increases for both Ox^- and $ClPhO^-$ systems: the rate enhancement upon solvent change from 10 to 90 mol% of DMSO is 2190 and 3330 for Ox^- and $ClPhO^-$, respectively. Interestingly, the plot of log k^{Ox^-} *vs.* mol% of DMSO shows downward curvature, while that of log k^{ClPhO^-} *vs.* mol% DMSO exhibits upward curvature. As a result, the difference in rate constant between Ox^- and $ClPhO^-$ increases up to *ca.* 50 mol% DMSO but decreases beyond this point. Such a differential solvent effect on rates leads to the solvent dependent α-effect profile, shown in Fig. 2; *i.e.* the sulfonyl system exhibits maximum α-effect at *ca.* 50 mol% DMSO, as do the carbonyl and phosphinyl systems. Therefore,

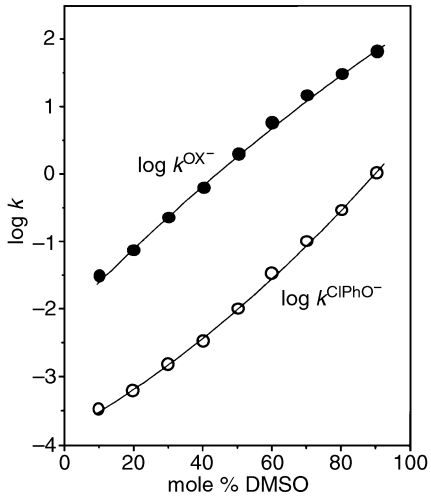

Fig. 1 Plots showing the effect of solvent on second-order rate constants for the reaction of PNPBS with Ox^- and $ClPhO^-$ in DMSO–H_2O mixtures at 25.0 ± 0.1 °C.

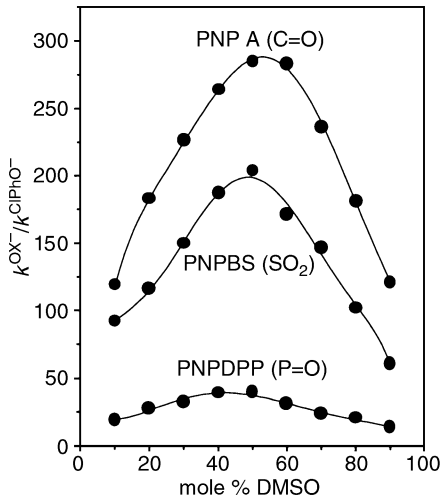

Fig. 2 Plots showing the effect of solvent on the α-effect for the reaction of PNPA, PNPDPP and PNPBS with Ox^- and $ClPhO^-$ in DMSO–H_2O mixtures at 25.0 ± 0.1 °C.

† Electronic supplementary information (ESI) available: Tables of rate constants. See http://www.rsc.org/suppdata/cc/b0/b007000i/

DOI: 10.1039/b007000i

the bell-shaped α-effect behaviour has been found to be general for the reactions of the three different electrophiles with Ox^- and $ClPhO^-$ in DMSO–H_2O mixtures.

Moreover, interestingly, the magnitude of the α-effect is strongly dependent on the electrophilic center; *i.e*. the α-effect in 50 mol% is *ca*. 300, 40 and 200 for the carbonyl, phosphinyl and sulfonyl systems, respectively. The small α-effect for the phosphinyl system compared to the carbonyl and sulfonyl systems is striking. Bruice showed that the magnitude of the α-effect is dependent on the magnitude of the β_{nuc} value for reactions of a variety of substrates with hydrazine and glycylglycine: the α-effect decreases with decreasing β_{nuc} value.[10] Similarly, Bernasconi observed no α-effect for the addition reaction of primary amines including hydrazine and *o*-methylhydroxylamine to Meldrum's acid, a system for which $\beta_{nuc} = 0.22$.[11a]

The β_{nuc} values for the reactions of PNPA with substituted phenoxides in various DMSO–H_2O mixtures are available,[12] but the ones for the reaction of the phosphinyl and sulfonyl systems have not been reported. Therefore, we performed the reaction of PNPDPP and PNPBS with a series of substituted phenoxides in 50 mol% DMSO, in which the maximum α-effect is observed. The plots of log $k^{ZC_6H_4O^-}$ *vs.* pK_a (ZC_6H_4OH) exhibit good Brønsted type correlation: β_{nuc} values are 0.64, 0.21 and 0.54 for the carbonyl, phosphinyl and sulfonyl systems, respectively. Thus, the β_{nuc} value for the phosphinyl systems is much smaller than for the carbonyl and sulfonyl systems, and, moreover, the β_{nuc} value follows the same order as the α-effect in magnitude. Therefore, one can suggest that the small β_{nuc} value is responsible for the small α-effect exhibited by the phosphinyl system. This argument is consistent with our recent report that the reaction for an sp hybridized carbon center exhibited an unexpectedly small α-effect in which the β_{nuc} value was 0.32.[5]

As demonstrated in Fig. 2, the effect of solvent on reactivity is significant. Such a solvent effect on rate can be achieved by destabilizing the ground-state (GS) and/or stabilizing the transition-state (TS). We recently found that the GS of Ox^- and $ClPhO^-$ becomes destabilized upon addition of DMSO to the reaction medium,[6c] however, the GS energy difference between Ox^- and $ClPhO^-$ is constant for the three systems. Therefore, if the GS energy difference between Ox^- and $ClPhO^-$ were mainly responsible for the α-effect, the magnitude of the α-effect should be about the same, regardless of the nature of the electrophilic center. However, our results show that this is not the case. Therefore, the present results clearly suggest that the difference in the GS energy is not solely responsible for the α-effect.

The magnitude of the β_{nuc} value has been understood as a measure of bond formation between the nucleophile and the substrate in the TS of the rate-determining step; hence the TS structures of the carbonyl, phosphinyl and sulfonyl systems would vary according to the different β_{nuc} values. One can expect that the TS stabilizing effect would be smaller for the reaction system in which the degree of bond formation between nucleophile and substrate in the TS is less advanced (reactant-like TS), and *vice versa*. Accordingly, one can suggest that the TS stabilizing effect would be developed to a lesser extent for the phosphinyl system compared with the carbonyl and sulfonyl systems, based on the smaller β_{nuc} value obtained for the former, which would explain the small α-effect observed for the phosphinyl system.

More systematic studies are underway including theoretical investigation for better understanding of solvent effect on the α-effect.

Pd-catalysed arylation of propan-1-ol and derivatives: oxidative role of the arylating agent

Laurence Bagnell, Ulf Kreher and Christopher R. Strauss*

Received (in Cambridge, UK) 3rd July 2000, Accepted 15th November 2000
First published as an Advance Article on the web

With excess PhI under Pd catalysis, 1-PrOH was converted to a mixture of 3,3-diphenylpropenal and *trans*-2,3-diphenylpropenal by a concerted, oxidative sequence that involved two arylative couplings and an olefinic aldehyde that was generated *in situ*.

Recently in our laboratory, Pd on porous glass was developed as a heterogeneous catalyst[1] for promoting Glaser-type and Heck arylative couplings[2] without the need for solubilising or activating ligands. Significantly, with excess allyl alcohol and with PhI in air, Pd on porous glass gave *trans*-cinnamaldehyde (**1**) along with 3-phenylpropanal (**2**; see entry 2, Table 1).[1] Consistent with literature reports,[3,4] in the absence of air, and without the addition of Ag^+ salts, **2** predominated and **1** was not obtained (entry 1, Table 1).

With PhI in excess, the diarylated compounds **3** and **4** appeared as major products from allyl alcohol, along with **1** and **2** (entry 3, Table 1). This diarylation appeared to contrast with a wealth of literature data on the Pd catalysed arylation of that alcohol.[3] Without Ag^+ salts,[4] one might expect that the first arylation of allyl alcohol would be accompanied by rapid migration of the olefinic bond to afford mainly 3-phenylpropanal (**2**), thereby removing the opportunity for a second Heck arylation to occur.

Although air facilitated the dehydrogenation for the reaction in entry 2 of Table 1,[5] the results in entry 3 and co-formation of biphenyl suggested that the arylating agent may have had an additional role. To support this contention, we now report that 1-PrOH with excess PhI can afford a mixture of 3,3-diphenylpropenal (**4**) and *trans*-2,3-diphenylpropenal (**5**), *even under an inert gas atmosphere* (see entry 9). This remarkable transformation has been performed with either $Pd(OAc)_2$ or Pd on porous glass as catalyst[6,7] (which was used for all entries in Table 1) includes microwave heating[8] in a reactor of our design.[9]

A comparable stepwise process would require oxidation of the hydroxy function of 1-PrOH, dehydrogenation of the hydrocarbon chain and two Heck-like arylative couplings of the resultant olefin. However, for the one reaction, successive intermolecular Heck arylative couplings onto the same olefin are rare.[10] Intramolecular examples usually have involved mono-arylations of more than one carbon–carbon double bond.[11]

Mono-arylated products were not observed in the reaction of 1-PrOH, rendering as unlikely, a multi-step sequence involving successive intermolecular Heck arylative couplings with an olefin formed by dehydrogenation *in situ*.[12] The absence of detectable intermediates implies that the process was concerted and may constitute a new reaction.

Formation of biphenyl and benzene as by-products indicates that PhI served as both an oxidant and a reactant. Buchwald and Palucki observed similar behaviour of their arylating agent in the 'Pd' catalysed reaction of cyclohexanol with 4-*tert*-butylbromobenzene to produce the corresponding α-arylated cyclohexanone and *tert*-butylbenzene.[13] They surmised that some of the haloarene was simultaneously reduced during oxidation of the alcohol to cyclohexanone.

Although variations in the order of transformations and alternative routes are possible for the present reaction, the pathway in Scheme 1 appears to account for the products, by-products and their relative proportions.

Preliminary investigations (see Table 1) into the process utilised cinnamaldehyde (**1**),[14] cinnamyl alcohol (**6**), 3-phenylpropanol (**7**) and 3-phenylpropanal (**2**). Cinnamyl alcohol (**6**) afforded diarylenal **4** as a major product (along with **3** and the 2,3-diphenylpropenol isomer **8**), *irrespective of whether or not the atmosphere contained air* (entries 5 and 6). Under argon, 3-phenylpropanal (**2**) gave 2,3-diphenylpropanal (**9**) and products of higher oxidation state, including **1**, **4** and **5** (entry 7). 3-Phenylpropanol (**7**) afforded **4** and **5** as major products, along with traces of **1** and **2** (entry 8). The product distributions obtained from Pd catalysed reactions of excess PhI with **6**, **7** and **2** suggest that several competing processes were operating, including α-arylation,[13] Heck-like arylative coupling of olefinic bonds[2] as well as the new process described herein and illustrated by Scheme 1.

These outcomes may have depended on whether or not coordination of the olefin to Pd occurred in conjunction with the establishment of a strong Pd–O bond, leading to a chelation controlled reaction. Such bonds have been suggested for palladium catalysed oxidation of alcohols.[15] Scheme 1, proposed for the reaction of 1-PrOH commences with Pd–O chelation and proceeds preferably through metallaoxetane intermediates,[16] which account for the observed products and their relative distribution. In the case of allyl alcohol (entry 3), it appears that the double bond and the hydroxy group of the

6 **A** Into a dry, two-necked flask fitted with a reflux condenser and an inert gas (Ar) bleed line was placed a solution of 1-PrOH (0.784 g; 13.06 mmol) and PhI (12.674 g; 62.12 mmol) in dry, deoxygenated *N*,*N*-dimethyl acetamide (DMA; 50 mL). Anhydrous NaOAc (5.80 g; 70.70 mmol) and $Pd(OAc)_2$ (0.564 g; 2.51 mmol) were added and the mixture was heated at 125 °C for 16 h, then cooled, quenched with 80 mL H_2O and extracted with Et_2O (1 × 80 mL, 2 × 50 mL). The ether extract was washed thrice with water, dried with $MgSO_4$ and the ether removed *in vacuo*. Unconverted PhI was recovered by vacuum distillation at 40 °C and 1×10^{-2} mbar and biphenyl was removed by sublimation (80 °C and 1×10^{-2} mbar). Flash chromatography (silica gel 60, dichloromethane : pentane 1:1) afforded pure product **4** (395 mg). **B** Into a dry, two-necked flask fitted with a reflux condenser and an inert gas (Ar) bleed line was placed a solution of 1-PrOH (749 mg; 12.48 mmol) and PhI (6.971 g; 34 mmol) in dry, deoxygenated *N*,*N*-dimethyl acetamide (DMA; 50 mL). Anhydrous NaOAc (4.127 g; 50 mmol) and Pd on porous glass (containing 19 μmol Pd)[1] were added and the mixture was heated at 125 °C for 16 h, then cooled. Work up as above yielded pure product **4** (73 mg).
7 Although $Pd(OAc)_2$ undergoes thermal decomposition to give finely divided Pd metal and gases including CO_2, methane and ethane (see M. T. Reetz and M. Maase, *Adv. Mat.*, 1999, **11**, 773; M. T. Reetz and G. Lohmer, *Chem. Commun.*, 1996, 1921), no evidence was obtained to associate that redox process with the present reaction.
8 Into a dry PTFE vessel under nitrogen was placed a solution of 1-PrOH (0.803 g; 13.4 mmol) and PhI (6.853 g; 33.6 mmol) in dry, deoxygenated *N*,*N*-dimethyl acetamide (DMA; 50 mL). Anhydrous NaOAc (4.19 g; 51.0 mmol) and $Pd(OAc)_2$ (50.4 mg; 0.22 mmol) were added and the mixture was heated for 10 min at 220 °C in a microwave batch reactor[9] (MBR), then cooled. Work up as in footnote 6 yielded pure product **4** (280 mg). For other examples of Pd catalysed reactions under microwave heating, see M. Larhed and A. Hallberg, *J. Org. Chem.*, 1996, **61**, 9582; U. Bremberg, M. Larhed, C. Moberg and A. Hallberg, *J. Org. Chem.*, 1999, **64**, 1082; M. Larhed, M. Hoshino, S. Hadida, D. P. Curran and A. Hallberg, *J. Org. Chem.*, 1997, **62**, 5583.

Grignard reagent mediated reaction of Cp_2Zr(II)–ethylene complex with imines†

Tamotsu Takahashi,* Yuanhong Liu, Chanjuan Xi and Shouquan Huo

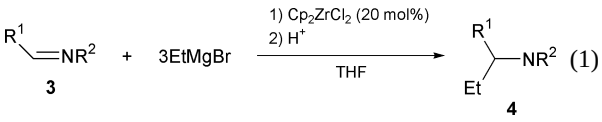
Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University; and CREST, Science and Technology Corporation (JST), Sapporo 060-0811, Japan. E-mail: tamotsu@cat.hokudai.ac.jp

Received (in Cambridge, UK) 13th September 2000, Accepted 2nd November 2000
First published as an Advance Article on the web 11th December 2000

Imines which do not react with Grignard reagents reacted with EtMgBr in the presence of a catalytic amount of Cp_2ZrCl_2 to give ethylated products in excellent yields; the stoichiometric reaction of the imines and the zirconocene–ethylene complex did not give the ethylated product, whereas addition of MeMgBr or BuMgCl to the mixture afforded the ethylated product after hydrolysis.

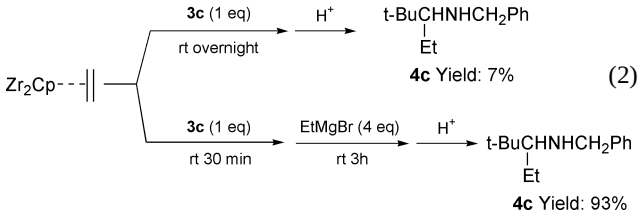
We have found that a zircononcene–ethylene complex $Cp_2Zr(CH_2{=}CH_2)$ (**2**)[1] and its ate complex $[Cp_2ZrEt(CH_2{=}CH_2)]MgBr$[2] prepared from Cp_2ZrEt_2 (**1**) and zirconacyclopentanes[1] were involved in the zirconium-catalysed reaction of olefins with EtMgBr[3] which was first reported by Dzhemilev.[4] In order to extend this type of reaction we investigated a catalytic and a stoichiometric reaction of imine with EtMgBr in the presence of zirconocene. In this paper we would like to report a zirconium-catalysed reaction of imine with EtMgBr and the unusual effect of addition of Grignard reagents on the formation of a new C–C bond in the stoichiometric reaction of imines with the zirconocene–ethylene complex.

Imines **3a**–**d**, easily prepared from the corresponding aldehydes and amines, do not react with EtMgBr in THF at even 50 °C to give addition products. When 20 mol% Cp_2ZrCl_2 was added to the mixture of the imines and EtMgBr in THF, the reaction proceeded smoothly at rt to produce substituted amine derivatives **4** in excellent yields after hydrolysis. The results are shown in Table 1. At least 3 eq. of EtMgBr was needed to finish the reaction, and the use of 10 mol% of Cp_2ZrCl_2 decreased the yield of products **4** [eqn. (1)].



(1)

We investigated the stoichiometric reactions of imines with the zirconocene–ethylene complex. And quite surprisingly, we found that the stoichiometric reaction of **3c** with **2** did not give the coupling product (only 7% of **4c**) after hydrolysis. It puzzled us, however, that when an additional amount of EtMgBr (1 eq.) was added to the reaction mixture, the desired product **4c** was obtained in 64% yield. Moreover, addition of 4 eq. of EtMgBr to the mixture gave an excellent yield of **4c** (93%) [eqn. (2)].



(2)

It is noteworthy that the use of different Grignard reagents also afforded only the same ethylated product **4c**, with improved yields as shown in Table 2.

It is interesting that the reaction of **3a** with **2** gave the ethylated product **4a** in 57% yield after hydrolysis. This indicates that the azazirconacylopentane **5a** was formed in the case of **3a**. A similar effect of addition of a Grignard reagent was also observed. In fact, addition of 1 eq. of MeMgBr to the mixture of **3a** and **2** afforded **4a** in 75% yield after hydrolysis. When 4 eq. of EtMgBr was added to the mixture of **3a** and **2**, the product **4a** was formed in 97% yield after hydrolysis.

These results suggest that there is an equilibrium between azazirconacyclopentane **5** and imine **3** and that the position of the equilibrium lies to the left under the conditions used here. If an irreversible step such as ring-opening and β-hydrogen abstraction is involved in the reaction, in other words, when additional Grignard reagents are added, the reaction goes to the right as expected to give the ethylated products. Deuterolysis instead of hydrolysis of the reaction mixture after addition of 4 eq. of MeMgBr to a mixture of **3c** and **2** afforded deuterated product **4c** DCH_2CH_2(t-Bu)$CHNDCH_2Ph$ (65% D) [eqn. (3)]. This strongly suggests that the complex **6c** is the reaction product of MeMgBr with a mixture of **3c** and **2**. When **6c** was treated with 2 eq. of CuCl for 6 h at rt, ethylated imine tBu(Et)CHN=CHPh (**7**) was obtained in 48% yield after hydrolysis.

We also carried out the reactions of a mixture of Cp_2ZrEt_2 and imine **3a** with various electrophiles[5,6] and the results are summarized in Table 3.

Table 1 Zirconium-catalysed addition of EtMgBr to imines[a]

Imines	R^1	R^2	*T*/°C	*t*/h	Products	Yield (%)[b]
3a	Ph	Bn	20	1	**4a**	96
3b	Ph	Bu	20	12	**4b**	89
3c	t-Bu	Bn	20	1	**4c**	97
3d		Bn	20	1	**4d**	(87)

[a] 20 mol% Cp_2ZrCl_2 and 3 eq. of EtMgBr were used. [b] GC yields: isolated yield is given in parenthesis.

Table 2 The effect of addition of Grignard reagents under stoichiometric conditions

Grignard reagents	Yield of **4c** (%)[a] 1 eq. of $RMgX$[b]	Yield of **4c** (%)[a] 4 eq. of $RMgX$[b]
MeMgBr	40	70[a]
EtMgBr	64	93
n-BuMgCl	38	64
sec-BuMgCl	22	96
t-BuMgCl	7	15

[a] GC yields of ethylated product **4c**. [b] Amount of addition of RMgX.

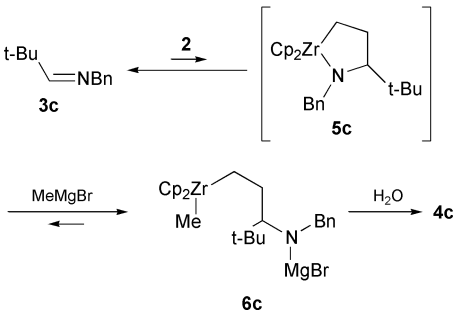
Table 3 Reactions of a mixture of Cp_2ZrEt_2 and **3a** with electrophiles[a]

Entry	Additives	Electrophile	*T*/°C	*t*/h	Product[a]		Yield (%)[b]
1	CuCl		r.t.	3		(**8a**)	56 (48)
2	—	C_2H_5COCl	0	1		(**8b**)	79 (57)
3[c]	(1) — (ii) CuCl	C_2H_5COCl (2 eq) —	0 50	1 12		(**8c**)	70 (56)
4[c]	(i) — (ii) CuCl	C_2H_5COCl 	0 r.t.	1 6		(**8d**)	82 (63)

[a] GC yields; isolated yields are given in parenthesis. [b] Reaction products were isolated after hydrolysis. [c] The mixture was treated with (i) and then (ii).



(3)

We have developed several zirconium-catalyzed reactions, in which a zirconocene–olefin complex acts as the key catalytic species. In the light of our previous work, a plausible mechanism for this catalytic addition of EtMgBr to imines is shown in Scheme 1, which involves: (1) generation of zirconocene–ethylene complex **2** from Cp_2ZrCl_2 and two eq. of EtMgBr; (2) coupling with imine **3** to form azazirconacyclopentane **5**; (3) ring-opening reaction by EtMgBr; and (4) β-elimination to regenerate zirconocene–ethylene complex **2** and to release metalated amine **9**.[7] The ring-opening reaction occurred exclusively on the Zr–N bond, because no deuterium incorporation was found in the Et group of products **4** in the catalytic reaction when the reaction mixture was quenched with MeOD. As expected, this catalytic reaction did not proceed with MeMgBr. When higher magnesium alkyls, namely, n-PrMgBr and n-BuMgCl, were used, the formation of addition products was not observed from the reaction with imine **3a**, indicating no coupling reaction between the zirconocene-substituted olefin complex and the imine.

The allylic oxidation of unsaturated steroids by *tert*-butyl hydroperoxide using homogeneous and heterogeneous cobalt acetate†

Jorge A. R. Salvador and James H. Clark

Clean Technology Centre, Chemistry Department, University of York, York, UK YO10 5DD

Received (in Liverpool, UK) 8th September 2000, Accepted 14th November 2000
First published as an Advance Article on the web 11th December 2000

Cobalt acetate is an effective catalyst for the selective allylic oxidation of unsaturated steroids using *tert*-butyl hydroperoxide especially when used in a supported form when it can be easily recovered and reused.

Allylic oxidation is a reaction of fundamental importance in organic chemistry with applications in areas ranging from agricultural products to pharmaceuticals.[1,2]

The allylic oxidation of unsaturated steroids such as Δ^5-steroids has traditionally been carried out with chromium reagents such as CrO_3–pyridine complex,[3] chromium trioxide and 3,5-dimethylpyrazole,[4] pyridinium chlorochromate, (PCC),[5,6] pyridinium dichromate (PDC),[6] sodium chromate,[7] sodium dichromate in acetic acid[8] and pyridinium fluorochromate.[9] However the large excess of reagent used in these procedures along with a difficult work-up and production of environmentally hazardous chromium residues, makes these reactions increasingly unacceptable on a commercial scale. Of greater preparative interest has been the use of hydroperoxides combined with different types of catalysts.[10–17] Despite the good yields reported with CrO_3,[10] hexacarbonylchromium $Cr(CO)_6$,[11,12] pyridinium dichromate[13] and $RuCl_3$[14] to prepare allylic oxidation products from Δ^5-steroids, the toxicity of the chromium compounds and the high cost of the ruthenium catalyst renders the procedures unsuitable for commercialisation and led us to recently report the use of cuprous salts, CuBr, CuCl, CuI, and a cupric salt $CuCl_2$, as well as copper metal as catalysts for this type of reaction.[17]

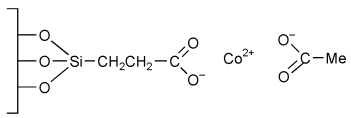
Allylic oxidation of steroids, particularly at the 7-position, has attracted interest over many years. The Δ^5-steroids can be oxidised to 5-en-7-ones, which are known as inhibitors of sterol biosynthesis and have some use in cancer chemotherapy.[18] This has encouraged us to find new, more environmentally acceptable methods for this reaction. The heterogenisation of inorganic reagents and catalysts useful in organic reactions is a very important area in clean technology.[19] In this communication we report the use of cobalt acetate in homogeneous, ($Co(OAc)_2 \cdot 4H_2O$), and more importantly, heterogeneous forms (catalysts **1**, **2**, and **3** prepared as reported previously[20,21]) for this type of allylic oxidation reaction.

Using Δ^5-steroids **4**–**7** and **12** as substrates (Scheme 1) allylic oxidation products **8**–**11** and **13** were obtained in very high, isolated yields, 70–86% (Table 1). Apart from the reaction with substrate **6** which required benzene as solvent and a temperature of 70 °C all the reactions were performed in acetonitrile using a milder temperature of 50–55 °C. The best results were obtained using the supported catalyst **3** which may be a result of its greater organophilic character. No significant reaction occurs in the absence of catalyst or in the presence of the catalyst support only.

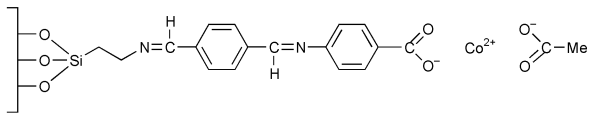
In a typical reaction to a solution of 17-oxoandrost-5-en-3β-yl acetate **4** (660.90 mg 2 mmol) in acetonitrile (12 ml) under nitrogen, catalyst **3** (60 mg, cobalt loading 0.41 mmol g^{-1}) and *tert*-butyl hydroperoxide (*ca.* 2.4 ml 12 mmol) were added. After 24 h under magnetic stirring at 50 °C, the catalyst was removed by filtration and the solution was poured into sodium sulphite solution (10% aq.) and extracted with diethyl ether. The extract was washed with aq. saturated solution of $NaHCO_3$, water, dried and evaporated to dryness to give 7,17-dioxoandrost-5-en-3β-yl acetate. These reactions are very selective compared to those carried out using $Fe(acac)_3$ as catalyst reported by Kimura *et al.*[15,16] $Mo(CO)_6$ has also been described as catalyst for this reaction, but this led to epoxidation of the cholesteryl acetate under similar oxidative conditions.[16]

$Co(OAc)_2/SiO_2$

catalyst **1**



catalyst **2**



catalyst **3**

While the product yields of the allylic oxidations are very similar under homogeneous and heterogeneous conditions, the easier recovery of the catalyst in the heterogeneous reactions make these more environmentally friendly processes. Furthermore using the heterogeneous catalysts **2** and **3** it was possible to reuse the catalyst with only a small reduction in the product yields, under similar experimental conditions (80% for recycled catalyst **2** and 81% for recycled catalyst **3**, Table 1). Our catalytic method is also effective for other unsaturated steroids. Thus the Δ^4-steroid **14** gives the testosterone acetate **15**, in a yield of 70% (Scheme 2). Furthermore, the method is also effective in the presence of an oxidatively vulnerable secondary alcohol group. The steroid **16** is oxidised to the alcohol product **17** with impressive selectivity (71%) (Scheme 2).

In summary we have discovered a new efficient and relatively environmentally friendly method for the preparation

Received (in Liverpool, UK) 28th July 2000, Accepted 15th November 2000
First published as an Advance Article on the web 11th December 2000

First evidence of the *in vitro* oxidation of 1,2,3,4,6-penta-galloylglucose to the ellagitannins, tellimagrandin II and 1,4,6-tri-*O*-galloyl-2,3-*O*-hexahydroxydiphenoyl-β-D-glucose, has been obtained with a partially purified enzyme from leaves of *Tellima grandiflora* (fringe cups, Saxifragaceae).

It was already recognized in the mid 1950's that ellagitannins, a widespread subclass of hydrolyzable plant tannins, were characterized by 3,4,5,3′,4′,5′-hexahydroxydiphenic (HHDP) acid residues (**5**) that occur in Nature in the form of various glucose esters and which, after hydrolytic release, spontaneously rearranged to the dilactone, ellagic acid (**6**). It was discussed very early on that the biogenesis of such ellagitannins in plants should originate from 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose (**1**) as the principal precursor,[1] a view that was corroborated and refined later by Haslam and coworkers. It was proposed by these authors that the energetically preferred $^4C_1$ conformer of **1** was sequentially oxidized to tellimagrandin II (**2**) and casuarictin (**3**).[2,3] The recently recognized role of ellagitannins as promising chemotherapeutic agents[4,5] has stimulated remarkable success in the challenge of chemically synthesizing such compounds.[6,7] The biosynthesis of ellagitannins, in contrast, still remained completely obscure. The present situation was illustrated in a recent review article[8] with the statement that 'the *in vitro* biaryl coupling of **1** has yet to be achieved by an isolated enzyme.' In several attempts to elucidate the mechanism of such a transition with the enzyme systems laccase/O_2 or peroxidase/H_2O_2[9] only free ellagic acid (**6**) had been detected, while the formation of true ellagitannins, characterized by glucose-bound HHDP residues, has never been achieved.

We concluded that inadequate analytical techniques represented the decisive obstacle in such investigations, which suffered from minimal enzyme reaction rates yielding numerous structurally closely related reaction products and unspecific by-products, and particularly from the inherent risk of contamination with *in vivo* formed ellagitannins that had been transferred into the enzyme assays by complexation with proteins. Such problems are eliminated by using radioactively labeled compounds, a technique that dramatically increases both the sensitivity and specificity of test systems. We therefore produced [*U*-^{14}C]pentagalloylglucose by photoassimilation of $^{14}CO_2$ in leaves of the gallotannin synthesizing plant *Rhus typhina* (staghorn sumac) in >99% purity.[10] This compound was used as standard substrate in an extended screening program for enzymes that formed reaction products liberating [^{14}C]ellagic acid (**6**) upon hydrolysis, thus providing a general probe for the *in vitro* synthesis of ellagitannins of widely differing structures.

By this strategy we were able to discover a novel soluble enzyme in leaves of *Tellima grandiflora* (Pursh) Lindley (fringe cups, Saxifragaceae), a weed that is known as a rich source of ellagitannins. The partially purified protein[11] was found to catalyze the conversion of [*U*-^{14}C]pentagalloylglucose to several radioactively labeled products, while no reaction occurred in the presence of denatured enzyme (Fig. 1). The most prominent peak among these compounds coincided with authentic tellimagrandin II (**2**) in two different HPLC systems with acetonitrile and MeOH gradients, respectively. This fraction was isolated and hydrolyzed (4 M HCl, 100 °C, 4 h) to afford glucose, gallic acid and ellagic acid (**6**) as sole ^{14}C-labeled degradation products as determined by HPLC and liquid-scintillation counting of the eluates, thus indicating the *in vitro* synthesis of a true ellagitannin.

Under the conditions given in Fig. 1, the enzyme reaction proceeded linearly for 30 min and had pH and temperature optima at pH 5 and 45 °C, respectively. Normal Michaelis–

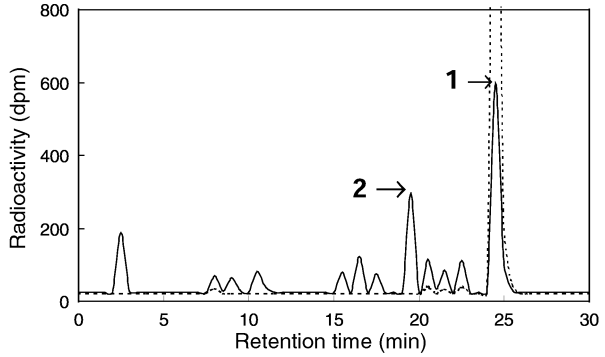

Fig. 1 RP-18 HPLC analysis of *in vitro* formed oxidation products of [^{14}C]pentagalloylglucose with an enzyme from *Tellima grandiflora* leaves. Assay mixtures, containing 12.5 μg (2,500 dpm) **1** and enzyme (4 pkat) in 50 μl HEPES buffer (50 mM, pH 5.0), were incubated at 30 °C for 60 min, stopped by heat-denaturing of enzyme, and analyzed by RP-18 HPLC. (—), Enzyme assay; (···), blank with acid-denatured enzyme. (**1**), Pentagalloylglucose; (**2**) tellimagrandin II. HPLC conditions: Reprosil NE, 5 μm, 250 × 4 mm i.d.; solvent A = 0.05% aq. H_3PO_4, B = 0.05% H_3PO_4, in MeOH; gradient 0–1 min 10% B, 1–3 min 10–30% B, 3–20 min 30–40% B, 20–40 min 40% B; flow rate 0.7 ml min^{-1}. Radioactivity was determined by fractionation of eluates and subsequent liquid-scintillation counting.

Menten kinetics were observed for the substrate, pentagalloylglucose (**1**), up to a maximal concentration of 320 μM, while increasing substrate inhibition occurred above this value. Replots of this data according to Lineweaver-Burk revealed a K_m value of 110 μM (V_{max} = 33 pkat [0.12 μmol h^{-1}]).

For the unequivocal determination of the structure of the reaction product, 100 mg of unlabeled pentagalloylglucose (**1**), chemically synthesized from triacetylgalloylchloride and β-D-glucose[12]) was incubated in a scaled-up enzyme assay, affording 1.7 mg pure reaction product of > 93% purity after semi-preparative HPLC.[13] Negative FAB-MS of this substance revealed prominent peaks for the deprotonated molecular ion $[M - H]^-$ at *m/z* 937 (tellimagrandin II **2**, M_r 938) and *m/z* 635 (trigalloylglucose, M_r 636).[14] Proton NMR spectroscopy (500 MHz) displayed signals that corresponded to those of an authentic sample of tellimagrandin II (**2**). In particular, three characteristic singlets at δ ppm (TMS) 6.91 (2H), 6.94 (2H) and 7.05 (2H) were detected in d_4-MeOH that corresponded to the aryl-2,6 hydrogens at C-1, C-2 and C-3 of **2**, respectively, while the singlets at δ 6.47 (1H) and 6.60 (1H) were due to the 2,2′-hydrogens of diphenic acid (**5**) bound at C-4,6. Also the chemical shifts for the glucose moiety were in full agreement with those of authentic **2**.

The reaction product displayed, however, strong additional singlets at 6.61 (1H) and 6.63 (1H) ppm that apparently were due to a different compound with a C-2,3 linked HHDP unit, as concluded by comparison with ^{1}H NMR data from authentic samples of 2,3-*O*-hexahydroxydiphenoylglucose, casuarictin (**3**) and pedunculagin (structure as **3**, but with a free anomeric OH-group at C-1). Evidently, the enzyme preparation had catalyzed the simultaneous synthesis of both tellimagrandin II (**2**) and isomeric 1,4,6-tri-*O*-galloyl-2,3-*O*-hexahydroxydiphenoyl-β-D-glucose (**4**) that had not been separated by RP-HPLC. This latter, unusual ellagitannin is not known as a natural product; it has been recently obtained, however, by total synthesis in two enantiomerically pure forms, mahtabin A and pterocarinin C, characterized by 2,3-*R*- and *S*-HHDP residues, respectively.[15,16] (An earlier report proposing this structure for a compound named cercidinin A from *Cercidiphyllum japonicum*[17] has been questioned by these authors.) Detection of such a compound raises questions about the specificity of the enzyme(s) catalyzing such transformations that prompt considerations on the eventual cooperation of product-specificity guiding enzymes, analogous to the recently reported 'dirigent' protein involved in lignan biosynthesis.[18]

In summary, first evidence has been provided by our results that the long sought clue to unravel the old enigma of ellagitannin biosynthesis is now available.

We thank Angelika Müller (Ulm) for excellent technical assistence, Dr G. Schmidtberg (Ulm) for MS analyses, and Dr A. Scalbert (Clermont-Ferrand, France) and Professor T. Yoshida (Okayama, Japan) for reference samples of ellagitannins. Financial support from the Deutsche Forschungsgemeinschaft (Bonn), the Fonds der Chemischen Industrie (Frankfurt/M) and from research grants of the University of Ulm is gratefully acknowledged.

13 The reaction mixture (400 ml vol., pH 5, containing 100 mg **1** and 850 mg protein) was incubated for 60 min at 30 °C. After stopping the reaction by heat-denaturing the enzyme, the mixture was extracted with EtOAc. The contents of the dried organic phase were subjected to semi-preparative RP-18 HPLC on Kromasil (5μ, 250 × 20 mm i.d.; gradient: solvent A = 0.05% aq. H_3PO_4, B = acetonitrile; 0–1 min 5% B, 1–2 min 5–18% B, then isocratic at 18% B; flow rate 22 ml min^{-1}). Relevant fractions were immediately neutralized, depleted of organic solvent *in vacuo*, extracted with EtOAc and rechromatographed twice by RP-18 HPLC on Reprosil NE (5 μm, 250 × 8 mm i.d.; solvents and gradient as in Fig. 1; flow rate 2.4 ml min^{-1}). The purified product was neutralized, depleted of MeOH and applied to a column of Sephadex LH-20 (60 × 12 mm i.d., in water). After rinsing with water to remove H_3PO_4, the product was eluted with MeOH and lyophylized, affording 1.7 mg material of > 93% purity as determined by analytical HPLC under the conditions given in Fig. 1.

Olefin metathesis in non-degassed solvent using a recyclable, polymer supported alkylideneruthenium†

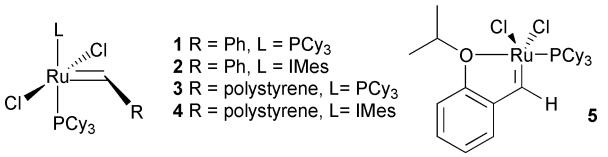
James Dowden* and Jelena Savović

Wolfson Laboratory of Medicinal Chemistry, Department of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath, UK BA2 7AY. E-mail: J.Dowden@bath.ac.uk

Received (in Liverpool, UK) 6th September 2000, Accepted 16th November 2000
First published as an Advance Article on the web 11th December 2000

Polystyrene-supported ruthenium complex 8 is a robust pro-catalyst for olefin metathesis that can be used in non-degassed solvents and recycled without added stabilisers.

Recent enthusiastic interest in olefin metathesis has been fuelled by the development of well-defined transition metal catalysts.[1] These catalysts have found wide application because they provide facile alkene exchange, often late in a synthetic sequence.[2] Grubb's alkylideneruthenium **1**[3] is particularly



popular because it is easy to handle. Undesirable features of these systems are that they are not amenable to recycling and that they give rise to high levels of ruthenium contamination. Recent work has sought to address these problems.[4–7] Hoveyda and co-workers established **5**[6,7] as a remarkably robust complex that was stable to silica gel chromatography using non-degassed eluent and could therefore be recovered and recycled. Recently, Barrett's group reported a 'boomerang' system **3**[8] for sequestering the catalytic species onto vinyl polystyrene. Indeed **3** could be reused, as long as an alkyl alkene additive was added to intercept the unstable catalytic methylidene carbene ($Cl_2(PCy_3)_2Ru{=}CH_2$).[8] Complex **2** can be transferred to vinyl polystyrene in the same way, with corresponding benefits.[9]

We are interested in developing a robust immobilised catalyst for olefin metathesis that can be readily modified to operate in a range of solvent environments. The ability to utilise non-degassed solvent offers practical simplicity and could widen the scope of this reaction. The reported stability of **5** was attractive and we reasoned that a suitably modified version could be attached to a range of polymer supports. In this communication, we describe initial studies leading to a recyclable, polystyrene-supported analogue of complex **5** that promotes olefin metathesis in non-degassed solvents.

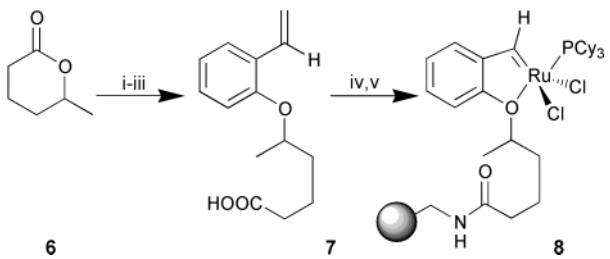
We envisaged that the isopropyl portion of the phenol ether could be extended to accommodate some functional handle that would allow attachment to any chosen support (Scheme 1). Thus, opening of racemic δ-hexanolactone **6** with sodium methoxide,[11] subsequent Mitsunobu reaction with 2-vinylphenol[12] and saponification provided **7**. Treating the pendant acid of **7** with aminomethyl polystyrene under standard conditions afforded the polystyrene supported ligand. Direct formation of the alkylideneruthenium[7] would be expected to be more efficient but we reasoned that reaction of styrene **7** with **1** would generate **8** more simply and in sufficient quantities to permit our initial study. One disadvantage of this approach is that the accumulation of free phosphine effectively inhibits olefin metathesis.[10] This is reflected in the fact that treatment of resin **7** with stoichiometric Grubb's complex afforded loadings of only 0.12 mmol g^{-1} (as determined by phosphorus analysis), while treating the resin with five successive portions of 10 mol% of **1** essentially doubled the loading to 0.20 mmol g^{-1}. Simple filtration and washing of the resin gave **8** as dark brown beads that could be dried, stored in air and used more than a month later with no apparent decrease in activity. In all cases no colour change, or corresponding decomposition was observed during the loading of the catalyst[8] even after extended reaction times.

Polymer-supported complex **8** was then tested for activity using representative diene substrates for ring closing metathesis (Table 1). It is notable that the rates of reaction were somewhat slower than those reported using homogenous Grubb's alkylidene **1**, so that reaction of benchmark substrates such as diethyl diallylmalonate (entry 2) was only 42% complete after 90 min. All of these reactions however, provided good to quantitative yield of product within 5 h. Preparative scale transformation (153 mg, 5 mol%, 4 h) of benzyl *N*,*N*-diallylcarbamate (entry 1) gave isolated product in 91% yield after chromatography.

The easy manipulation of **8** is noteworthy. In each case, general laboratory grade dichloromethane (DCM) was used *without* degassing, in an air atmosphere, so that substrates were simply dissolved and added to the resin in a plastic solid phase organic synthesis tube fitted with a glass frit. The tube was then sealed and subjected to agitation by 360° rotation at rt. Filtration and washing with DCM afforded the product and the remaining resin used for further transformations.

Recycling of **8** was tested by treatment of the same batch of resin with equal, successive portions of benzyl *N*,*N*-diallylcarbamate, without addition of stabilising alkene (Table 2).[8] Indeed **8** proved to be remarkably robust providing good yields over five successive runs at 5 mol% catalyst. In subsequent runs yields declined steadily and the beads turned from dark brown to black.

We have also demonstrated the ability of **8** to perform cross metathesis. Heating a two-fold excess of (*Z*)-1,4-diacetoxybut-2-ene[13] with 4-allylanisole and **8** in DCM under reflux for 9 h furnished the cross-coupled product (33%) along with the anisole homodimer (18%). The recovered resin retained its brown colouration, rather than turning black. Subsequent ring



Scheme 1 *Reagents and conditions*: i, sodium methoxide, MeOH, 0 °C to rt, 6 h, 95%; ii, 2-vinylphenol, diisopropyl azodicarboxylate, PPh_3, THF, 0 °C to rt, 14 h, 64%; iii, 1 M NaOH, dioxane, rt, 12 h, 88%; iv, polystyrene-NH_2, DIC, HOBt, CH_2Cl_2–DMF (1 : 1), rt, 12 h; v, $Cl_2(PCy_3)_2Ru{=}CHPh$, DCE, rt, 12 h.

DOI: 10.1039/b007304k

closing metathesis of benzyl *N*,*N*-diallylcarbamate using this resin afforded the cyclised product in 85% yield over 90 min, confirming the retention of catalytic activity.

Olefin metathesis using **1** is typically performed in degassed solvent, for example, previous studies of **5** were performed in argon-saturated solvent and atmosphere (only chromatography using non-degassed solvent was reported).[7] We believe that this communication is notable because studies involving non-degassed solvent have not been widely reported. We also found, however, that for reactions corresponding to entries 1 and 5 using non-recyclable complex **1** in non-degassed DCM proceeded in good yield and draw attention to recent discussion relating to the oxidative decomposition of alkylideneruthenium.[14] In the case of Barrett's boomerang system **3** however, it is necessary to add 10 mol% hex-1-ene to prevent decomposition.[8] It is therefore interesting that **8** promotes olefin metathesis for up to five cycles, without added stabiliser.

Table 1 Olefin metathesis using polymer supported complex **8**[a]

Entry	Substrate[b]	Product[cd]
1		 91% (95)
2		 43% (88)[5]
3		 77% (>95)[8]
4		 >95% (>95)[16]
5		 33%[e]  18%
6		 31%[f]

91[c]	81	68	67	63	46	40
81[d]	69	68	33	21	11	—

[a] All runs performed in non-degassed CH_2Cl_2 for 90 min. [b] Relative integration of ^1H NMR. [c] 5 mol% **8**. [d] 1.5 mol% **8**.

The ability to perform olefin metathesis in polar protic solvents is a desirable goal that has so far been addressed by the development of water-soluble phosphine ligands.[14,15] We therefore investigated the effect of a different polymer support on the solubility and catalytic activity of the complex. Thus, amine-functionalised TentaGel (0.3 mmol g^{-1}) was converted into TentaGel-**8** and in preliminary experiments we observed ring-closing metathesis in non-degassed MeOH, although there was significant variation between batches of resin. The best reaction proceeded in 31% yield after 6 h of reaction (entry 6) and the worst gave 18% after overnight reaction with double the quantity of resin (100 mg). The lower yield of this transformation presumably reflects the much lower loading offered by this TentaGel resin but does suggest that modification of the supporting polymer is a viable strategy.

In summary, we have reported a novel polymer supported pro-catalyst for olefin metathesis that is robust and easy to use. That **8** is stable to non-degassed solvents and can be recycled without the use of stabilising additives is notable and interesting. An attractive feature of the precursor **7** is that it can be attached to any solid support.

We are grateful to the University of Bath for a studentship (to J. S.) and to Professor B. V. L. Potter for helpful advice and encouragement.

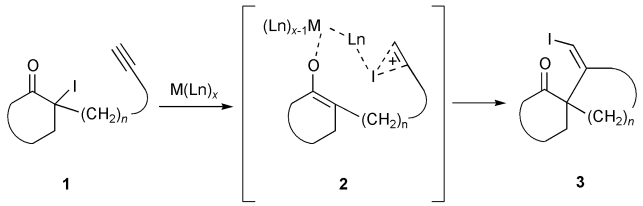
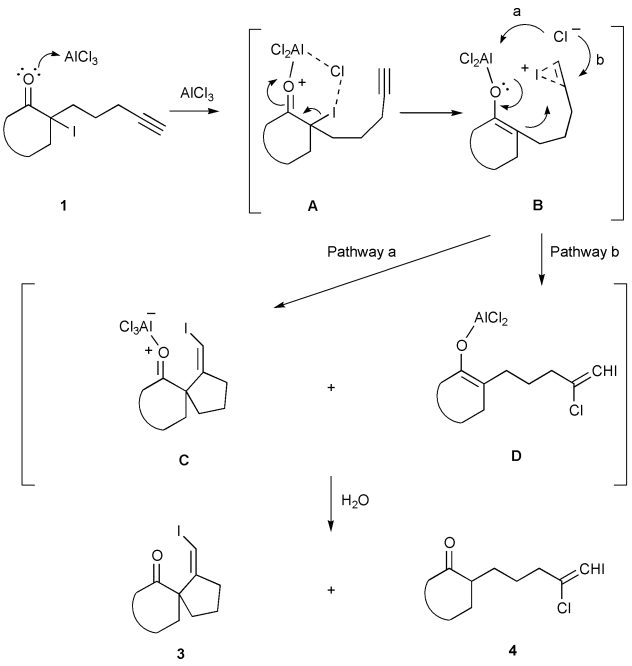
Received (in Cambridge, UK) 9th October 2000, Accepted 20th November 2000
First published as an Advance Article on the web 11th December 2000

Treatment of α-iodo cycloalkanones bearing an acetylenic side chain with $AlCl_3$/ICl afforded spirocyclic ketones in good yields.

Spirocyclic systems are core skeletons of several important natural products, such as gloiosiphone A[1] and ginkgolide B.[2] They also constitute the main frameworks of spirocyclic chiral auxiliaries having a C_2 axis of symmetry.[3] During our work on radical cyclization of α-iodo ketones,[4] we became interested in developing a general method for synthesis of spirocyclic ketones from α-iodo ketones. We envisaged that iodo-carbocyclization of α-iodo ketones, as depicted in Scheme 1, could be exploited for annulation of five- and six-membered rings. Generation of enolate from α-iodo ketone **1** with simultaneous transfer of I^+ to the acetylenic moiety might be effected with a Lewis acid, $M(Ln)_x$, to give intermediate **2**. Subsequent cyclization of the intermediate **2** would afford spirocyclic ketone **3**. In the past decade, free-radical atom-transfer cyclization of iodo substrates mediated with hexabutylditin[5] or other reagents[6] has emerged as a routine method. Ionic iodo-carbocyclization of iodo malonates[7] and ionic seleno-carbocyclization of seleno ketones[8] have also been described. In this communication, we report results obtained from our investigation of iodo-carbocyclization of α-iodo ketones.



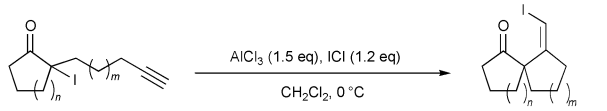
Scheme 1



Scheme 2

We first sought appropriate Lewis acids that could effect formation of an enolate from α-iodo ketones. Many Lewis acids including $TiCl_4$, BCl_3, $AlMe_3$, Me_2AlCl, $SnCl_4$, $MgBr_2$ and $AlCl_3$ were examined. We found that $AlCl_3$, Me_2AlCl and $TiCl_4$ effect the desired transformation of **1** to **3** in dichloromethane, although in low yield (10–20%). A plausible mechanism is proposed for the reaction using $AlCl_3$ as catalyst, Scheme 2. $AlCl_3$ reacts with α-iodo ketone to generate an aluminium

Table 1 Ionic iodo-carbocyclization of α-lodo cycloalkanones



Entry	α-lodo Cycloalkanone	Reaction Time	Product[a]	Yield (%)
1	 **5**	45 min	 **11**	83
2	 **6**	50 min	 **12**	81
3	 **7**	40 min	 **13**	70
4	 **8**	30 min		94
5	 **9**	60 min	 **15**	74
6	 **10**	60 min	 **16**	77

[a] The stereochemistry of the vinyliodide moiety in each product was tentatively assigned as *Z*.

enolate[9] and ICl. The acetylenic moiety on the side chain then complexes with ICl to give intermediate **B**. Cyclization of **B** (pathway a) would afford $AlCl_3$-complex **C**. In principle, $AlCl_3$ is catalytic and gets regenerated at this stage. Because it would complex with the product, one equiv. of $AlCl_3$ is needed. Upon aqueous work-up, complex **C** is hydrolyzed to spiro ketone **3**. According to this mechanism, ICl is generated in the first step and participates in the subsequent cyclization. Therefore, we felt that addition of ICl from an external source might facilitate cyclization. Indeed, we found that treatment of iodo ketones **5**–**10**[10] with a mixture of $AlCl_3$ (1.5 equiv.) and ICl (1.2 equiv.) in dichloromethane at 0 °C afforded spirocyclic products **11**–**16** in good yield.[11] The results are summarized in Table 1. Products **11**–**16** are all obtained as a single geometric isomer and are tentatively assigned to be *Z* isomers.[12] Presumably, the conformation of intermediate **B**, as depicted in Scheme 2, favors the formation of the exclusive *Z* isomers. Annulation of both five-membered rings (entries 1–3) and six-membered rings (entries 4–6) is achieved. In entries 1–3, by-product **4** is formed in trace amount ($< 5\%$) from direct addition of Cl^- to the iodonium moiety, pathway b in Scheme 2.[13] Since addition of an external source of ICl significantly enhances the yield of the carbocyclization process, an alternative mechanism involving enolate formation with simultaneous complexation of ICl to the acetylene unit is also possible.

In conclusion, we have demonstrated that an ionic iodo-carbocyclization of α-iodo cycloalkanones can be effected with Lewis acid, $AlCl_3$. Addition of ICl greatly enhances yields of spirocyclic ketones. In comparison with free-radical atom-transfer cyclization, the present method has two distinct advantages: (i) as tin reagents are not used, tedious separation of products from tin residues is avoided; (ii) whereas free-radical atom-transfer cyclization is only useful for synthesis of the five-membered ring, this method allows annulation of both five- and six-membered rings. Applications of this reaction for total synthesis of natural products are under investigation in our laboratory.

11 A representative procedure for iodo-carbocyclization: to a solution of compound **5** (200 mg, 0.72 mmol) in CH_2Cl_2 (7.2 mL) was added $AlCl_3$ (150 mg, 1.08 mmol) at 0 °C. The mixture was stirred at 0 °C for 15 min, during which the color turned orange red. A solution of ICl in CH_2Cl_2 (1 M, 0.87 mL, 0.87 mmol) was added dropwise at 0 °C. The color became dark brown. The reaction mixture was stirred at 0 °C for 45 min and then quenched with H_2O (20 mL), saturated $Na_2S_2O_3$ solution (10 mL) and saturated $NaHCO_3$ solution (10 mL). The mixture was extracted with EtOAc (3 × 15 mL). The combined organic layers were washed with brine and dried ($MgSO_4$). Concentration and silica gel column chromatography (hexane–EtOAc, 50 : 1) gave product **11** (160 mg, 83%) as a pale yellow liquid. δ_H(300 MHz; $CDCl_3$) 6.32 (s, 1H), 2.70−2.60 (m, 1H), 2.60−2.34 (m, 1H), 2.34−1.86 (m, 6H), 1.77−1.59 (m, 1H), 1,59−1.15 (m, 3H); δ_C(75 MHz; $CDCl_3$) 211.2, 137.0, 73.4, 55.9, 40.7, 38.0, 34.4, 25.3, 19.5 (two carbons); IR (neat) 3069, 2953, 1732, 1602; MS (EI): *m*/*z* 277 ($M + H^+$), 214 (13), 185 (52), 149 (31), 127 (47), 97 (45), 84 (100), 79 (34), 41 (55); HRMS (EI): Calc. for $C_{10}H_{14}IO$ ($M + H^+$) 277.0090. Found 277.0087.

12 For purposes of comparison, *E* isomers of **11** and **13** were prepared from compounds **5** and **7** according to the photolytic hexabutylditin method (ref. 5). ^{1}H NMR spectra of **11** and **13** were found to be different from those of *E* isomers. Therefore, all products **11**–**16** are tentatively assigned to be *Z* isomers.

13 When the reactions of entries 1 and 2 were performed at −78 °C, products **11** and **12** were both obtained along with some by-product **4**, in ratios of 1 : 0.9 and 1 : 0.8 respectively.

An alternative synthesis method for zeolite Y membranes

A new approach for the synthesis of supported zeolite Y membranes is presented, using a synthesis gel containing seeds to avoid any unnecessary *ex situ* pre-treatment of the support.

Zeolitic membranes can be applied in many separations of either liquid or gaseous components. It is important to be able to draw from a large number of different zeolite membranes to enhance the scope of this approach further. Various procedures have been proposed for the synthesis of membranes with different zeolites, *e.g.* for MFI membranes a direct synthesis method has been reported[1–3] as well as a synthesis route involving pre-adsorption of zeolite crystals and subsequent secondary growth.[4,5] However, in some cases membranes become efficient only after many repeated syntheses steps.[2] In another example vapour phase transport was used to synthesise mordenite and ferrierite membranes.[6] Here we report a conceptually new and improved method for membrane preparation.

Owing to its large pore system and its specific counter-ion-dependent adsorption properties, zeolite Y is an interesting material for a membrane and/or a catalytic membrane reactor. Although zeolite Y membranes have been synthesised previously, the methods used involve the deposition of pre-formed crystals employed as seeds on the support[7] or rubbing of the support with zeolite crystals.[8,9] These *ex situ* synthesis methods work well on a laboratory scale, but are unlikely to be applicable for larger scale uses.

We showed recently that a coating of zeolite Y on common stainless steel could be achieved with a new synthesis procedure, using a seeded synthesis mixture.[10] We report here that this method can be successfully employed to synthesise a zeolite Y membrane *in situ*. The behaviour of this material as a membrane was tested in the separation of the light molecules N_2 and CO_2, since membranes able to separate these technologically important gases are not common nor readily available.

Two different synthesis mixtures were prepared. The first mixture, prepared in two steps with sodium silicate as the silica source and sodium aluminate as the alumina source, was seeded according to the procedure described previously,[10] by ageing a mixture highly concentrated in NaOH and incorporating it in a gel of general molar composition 10 SiO_2 : Al_2O_3 : 5.2 Na_2O : 180 H_2O (G1). A second type of gel, unseeded, was prepared in one step using colloidal silica (Ludox HS-40, DuPont) as the silica source with a general molar composition 10 SiO_2 : Al_2O_3 : 4 Na_2O : 180 H_2O (G2). Porous stainless steel disks, coated with a 15 μm thick porous titania layer (Trumem™) were used as supports. They were calcined at 300 °C prior to use to ensure they were free of organic deposits. Synthesis took place at 100 °C under rotational conditions (180 rpm) for 7 h in a Teflon-lined autoclave. During the synthesis, only the titania side was in contact with the synthesis mixture, the stainless steel side being protected by a Teflon disk. After synthesis the coated supports were washed and dried at 120 °C. Permeation measurements using single components of CO_2 and N_2 and binary mixtures of CO_2/N_2 were performed by the Wicke–Kallenbach method at 30 °C. The feed and permeate sides were kept at atmospheric pressure while helium was used as sweep gas with a flow rate of 100 ml min^{-1}. Feed, retentate and permeate streams were analysed with a mass spectrometer. The zeolite layer on the support faced the feed side in the permeation measurements. Characterisation of the materials was performed by XRD and SEM. The Si/Al ratio was measured by ICP-AES of the powder and was equal to 2.

In agreement with previous observations on stainless steel plates,[10] the use of the unseeded synthesis mixture (G2) resulted in a very low coverage of the titania layer even after 24 h of synthesis. Accordingly, no separation of the gas mixture could be observed. By contrast, when using the seeded mixture (G1), a good coverage of the support was obtained, although XRD could not evidence the presence of zeolite Y, probably owing to the thickness of the layer. However, the system did not show any real separation of N_2 or CO_2. When single component experiments were carried out, fluxes of N_2 and CO_2 were 8.58 $\times 10^{-7}$ and 6.05 $\times 10^{-7}$ mol m^{-2} s^{-1} Pa^{-1}, respectively. The ideal selectivity and the selectivity measured for a 1 : 1 mixture were nearly equal, at 0.7 and 0.63, respectively. Besides, large amounts of the sweep gas were found in the retentate. This indicates the presence of pinholes in the membrane. SEM showed that individual crystals were still present. This implies that crystal intergrowth was not achieved.

A second synthesis step can induce the intergrowth of the zeolite crystals supported after the first synthesis, however, when using the same seeded mixture (G1) for the second synthesis, degradation of the first layer occurred and impurities, namely zeolite P, were formed on the surface. This might be caused by the high pH of the synthesis mixture. To avoid the degradation of the zeolite Y layer, the second synthesis was performed, using the *unseeded synthesis* mixture (G2) of lower alkalinity. In this case, XRD evidenced that zeolite Y was present on the surface, and that impurities were not present. SEM images showed that the layer was well intergrown (Fig. 1). This layer was *ca.* 0.7 μm thick and permeation measurements confirmed that a closed layer had been synthesized.

Fig. 2 shows the fluxes of N_2 and CO_2 in the single- and binary-component measurements as a function of CO_2 partial pressure for the latter material. Both curves cannot be explained by the Knudsen diffusion mechanism, since N_2 diffuses faster than CO_2 in the Knudsen diffusion region. The effect of the surface diffusion of CO_2 should be taken into account. When plotting the separation factors of the CO_2/N_2 mixture *vs.* the CO_2 partial pressure, the separation factor is greater than the ideal separation factor calculated with the single component fluxes. This indicates that adsorbed molecules of CO_2 partly blocked the pores and depressed the permeation of N_2. The separation factor CO_2/N_2 increased with increasing partial

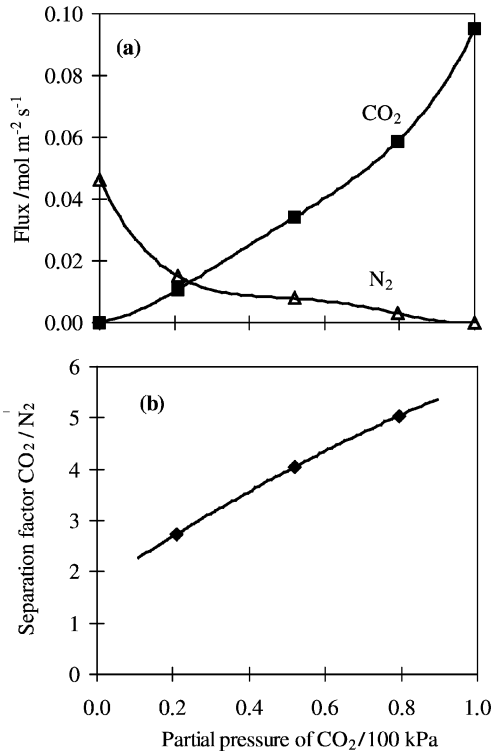

Fig. 2 CO_2/N_2 permeation measurements. (a) fluxes, (b) separation factor (CO_2/N_2).

pressure of CO_2, showing that the effect of pore blocking caused by adsorbed CO_2 is more pronounced when the CO_2 content in the feed stream is higher. This trend is in good agreement with the data obtained for the separation of other gas mixtures such as *n*-butane/methane,[1] *n*-butane/isobutane[11] and ethane/methane[12] over silicalite membranes. Although the separation behaviour was much improved, the fluxes did not decrease significantly (fluxes of N_2 and CO_2 were respectively 4.59×10^{-7} and 9.41×10^{-7} mol m^{-2} s^{-1} Pa^{-1} in single-component experiments). The presence of a dense amorphous phase is thus not likely as this would manifest itself in a lowering of fluxes. Furthermore, this interpretation is consistent with SEM characterisations (Fig. 1).

We have shown that a high quality zeolite Y membrane can be synthesised by combining two synthesis steps. With this method a *seeded gel* layer is first deposited on the support upon dipping it in the synthesis mixture. The seeds initially present in the synthesis mixture are also part of the supported gel layer.[13] Therefore their growth occurs directly on the support and this gives rise to a dense layer when exposing the system to a second synthesis step.

In conclusion, we have shown that seeds on the support are necessary to allow the growth of a supported Y membrane. Unlike previous reports,[8,9] seeds can easily be brought to the support during synthesis. This method simplifies the process of attaching nuclei onto the support and opens up new vistas for supported zeolite membranes.

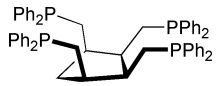
The *cis,cis,cis*-1,2,3,4-tetrakis(diphenylphosphinomethyl)-cyclopentane/$[PdCl(C_3H_5)]_2$ system catalyses allylic amination in good yields with a very high substrate/catalyst ratio; a turnover number of 680 000 and a turnover frequency of 8125 h^{-1} can be obtained for the addition of dipropylamine to allyl acetate in the presence of this catalyst.

Allylamines are fundamental building blocks in organic synthesis and their preparation is an important industrial goal.[1] Allylic amination is an efficient method for the formation of allyl–nitrogen bonds.[2] The classical method to perform this reaction is to employ palladium complexes associated with mono-[3] or di-phosphine[4] ligands. Phosphine-amine[5] ligands have also been used successfully. Even if the catalysts formed by association of these ligands with palladium complexes are efficient in terms of yield of adduct, the efficiency in terms of the ratio of substrate/catalyst is low. In general 1–5% of these catalysts must be used. With one of the most active catalysts based on a polystyrene–phosphine–palladium complex the reaction can be performed with as little as 0.018% catalyst (TON: 3200).[6] Nevertheless, very high values of ratio substrate/catalyst have not been reported for this reaction.

Our aim was to obtain complexes capable of very high turnover numbers in catalysis. The nature of the phosphine ligand on complexes has a tremendous influence on the rate of catalysed reactions. Recently a tetraphosphine based on a cyclobutane ring led to the formation of palladium catalysts for copolymerization that are more efficient than those of dppe by a factor of ten.[7] In order to find more efficient palladium catalysts we decided to study the influence of the new tetrapodal phosphine ligand, *cis,cis,cis*-1,2,3,4-tetrakis(diphenylphosphinomethyl)cyclopentane (Tedicyp **1**)[8,9] in which the four



Tedicyp 1

diphenylphosphinoalkyl groups are stereospecifically bound to the same face of the cyclopentane ring, on the rate of allylic amination reaction.

Our first objective was to evaluate the difference of efficiency for allylic amination between a monophosphine ligand such as triphenylphosphine, a diphosphine ligand such as 1,2-bis(diphenylphosphino)ethane (dppe) and our tetraphosphine **1**. We observed that the addition of dioctylamine **8** to allyl acetate **2** in the presence of 0.001% catalyst, led to the addition product **14** in 1 and 3% conversion when PPh_3 and dppe, respectively, were used as ligand and 99% conversion with Tedicyp (Scheme 1, Table 1). A similar tendency was observed for the addition of diallylamine **9** to allyl acetate **2**. In the presence of 0.001% catalyst, only 7% conversion was observed with dppe. With Tedicyp the conversion was 73% in the presence of 0.0001% catalyst.

Next we tried to evaluate the scope and limitations of Tedicyp–palladium complex for this reaction. The addition rate was slightly decreased for the addition of morpholine **11** to **2**. A conversion of 93% is observed in the presence of 0.01%

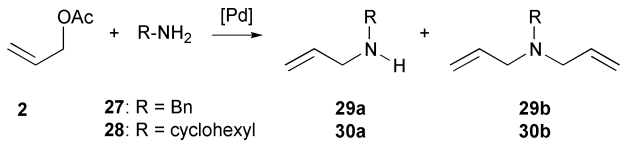
DOI: 10.1039/b007860n

catalyst. A turnover number (TON) of 57 000 and a TOF of 1111 h^{-1} were obtained in the presence of 0.001% catalyst. On the other hand, a significant steric effect was observed with the bulky diisopropylamine **12**. In the presence of 0.1% catalyst only 81% conversion was obtained after three days.

The complex formed by association of Tedicyp and $[PdCl(C_3H_5)]_2$ seems to be more stable and less sensitive to temperature and poisoning than the complexes formed with diphosphines.

These results prompted us to investigate the allylation of amines with substituted allyl acetates. When we used cinnamyl acetate **3** in the presence of 0.1% catalyst high yields were obtained for the addition of dipropylamine **7** and diallylamine **9**. A TON of 4400 has also been observed with morpholine **11**. We noted a good regioselectivity for the amination of cinnamyl acetate **3** in favour of the linear isomer. Similar selectivities were observed for the addition of diethylamine **6**, dipropylamine **7** and dioctylamine **8** to (*E*)-hex-2-en-1-yl acetate **4**. (*E*)-*N*,*N*-dialkylhex-2-enylamines **21a**–**23a** were obtained regio- and stereo-selectively in good yield. The regioselectivity of the addition of cyclic amines **10** and **11** is slightly lower; 6 and 8% of the branched products **24b** and **25b** are obtained with pyrrolidine **10** and morpholine **11**. Much lower TON and TOF were observed in the course of the amination of hindered 3-acetoxy-1,3-diphenylprop-1-ene **5**.

With primary amines, we obtained mixtures of monoaddition and diaddition products (Scheme 2). Benzylamine **27** led to the monoaddition product **29a** in 83% conversion and 90% selectivity in the presence of 0.001% catalyst with a TOF of 1229 h^{-1}. The addition rate of cyclohexylamine **28** is slower with a TOF of 49 h^{-1} and a lower selectivity in favour of the monoaddition product **30a** is observed.



Scheme 2

Finally, we tried to gain some information on the structure of the palladium–Tedicyp complex formed. Addition of 1 equiv. of Tedicyp to 0.5 equiv. of the dimer $[PdCl(C_3H_5)]_2$ gave a clean ^{31}P NMR spectrum which shows two broad signals at δ 19 and 25 (*vs.* H_3PO_4). The characteristic signals of the free phosphine at δ −16.3 and −17.7 were not observed. Addition of 1 equiv. of Tedicyp to 1 equiv. of $[PdCl(C_3H_5)]_2$ gave an identical ^{31}P NMR spectrum. Addition of 2 equiv. of Tedicyp to 0.5 equiv. of $[PdCl(C_3H_5)]_2$ led to a more complicated spectrum; mainly four signals of free phosphines at δ −16.9, −18.2 , −19.3 and −20.9 and some broad peaks between δ 40 and 10 were observed in ^{31}P NMR. In the first case, addition of 1 equiv. of Tedicyp to 0.5 equiv. of the Pd complex, produced broad signals at δ 19 and 25 suggesting that this complex is involved in a succession of equilibria due to a fast coordination–dissociation process of the four phosphines of the ligand. The absence of peaks of free phosphines probably arises from the equilibrium rate which seems to be of the order of the NMR time scale. Similar results have already been described; for example, $Pd(PPh_3)_3$ is largely dissociated and the equilibrium rate is of the order of the NMR time scale even at low temperature.[12] Addition of 10 equiv. of allyl acetate or addition of 10 equiv. of allyl acetate with 10 equiv. of dipropylamine to this Pd–Tedicyp complex (ratio Pd-dimer/Tedicyp = 0.5) has no influence on the ^{31}P NMR spectrum; the two broad signals observed at δ 19 and 25 are unchanged.

We have also examined the importance of the ratio palladium/Tedicyp for the catalysis. We observed that if the reaction is performed with Pd-dimer/Tedicyp ratios of 0.5, 1 and 2, the rate of the reaction decreases. The TONs after 40 min were, respectively, 8100, 4000 and 1300 for the addition of dipropylamine **7** to allylacetate **2** with a ratio substrate/catalyst of 100 000. These results seems to indicate that the active palladium catalyst requires one tetraphosphine for one palladium centre.

In conclusion, the Tedicyp–palladium complex obtained by addition of Tedicyp to $[Pd(C_3H_5)Cl]_2$ provides a convenient catalyst for the allylic amination reaction. This catalyst seems to be more stable and less sensitive to poisoning than the complexes formed with mono- and di-phosphine ligands. This stability probably arises from the presence of the four diphenylphosphinoalkyl groups stereospecifically bound to the same face of the cyclopentane ring. All four phosphines probably cannot bind at the same time to the same palladium centre, but the presence of these four phosphines on the ligand close to the metal centre, along with steric factors, seems to increase the coordination of the ligand to the palladium complex. In the presence of this catalyst the amination reaction can be performed with as little as 0.0001% catalyst. These results represent an inexpensive, efficient, and environmentally friendly synthesis. Further applications of this ligand will be reported in due course.

We thank F. Berthiol for experimental work and the CNRS for providing financial support.

The ligands cyanate and di-2-pyridyl ketone (dpk) are used to construct a tetranuclear cobalt(II) complex involving $\mu_{1,1}$-cyanate bridges: $[Co_4(dpk\text{-}OH)_2(dpk\text{-}OMe)_2(NCO)_4]$, which shows a dicubane-type structure, with two missing vertices, and having ferromagnetic interactions.

A considerable ongoing research has been directed at the preparation of molecule-based magnets over recent years. In this area, great activity has been focused on obtaining nanoscale magnets in which each microcrystal behaves as a single domain. A way to deal with the preparation of nanomagnets concerns single molecules having ground electronic states with a large number of unpaired electrons.[1] In relation to the ligands for the preparation of those clusters, a variety of blocking organic compounds has been used, most of them providing oxo-bridges between metallic centers.[2]

An efficient way for the generation of interactions between metallic centers concerns the use of pseudohalide ligands. Among these, azide has been undoubtedly one of the most interesting magnetic coupling species found so far in molecular magnetism.[3] One of the latest findings found for this ligand is its incorporation into *cubane-type* systems and those exhibiting $\mu_{1,1}$-azido bridges have been observed to be ferromagnetic.[4] The cyanate pseudohalide is a more unusual ligand, its chemistry and bonding properties have been the subject of several studies[5] which focussed upon its ability to coordinate to metals, and its ability and adaptability as a bridging ligand.[6] It shows preference for the end-on bridging mode, through the nitrogen atom. In this kind of bridging, the cyanate ligand has been shown to be able to mediate ferromagnetic interactions.[7]

As mentioned above, in most of the clusters for nanomagnets, the intermetallic connections take place through oxo-bridges. In this way, the coordination behavior of di-2-pyridyl ketone (dpk) as a ligand has also attracted much attention.[8] Its hydrolyzed derivatives, namely, the *gem*-diol[9] and its respective mono- and di-anions, are potential chelating or chelating-bridging ligands. In fact, a number of mononuclear[10] and oligomeric polynuclear[11] complexes derived from these ligands have been isolated and crystallographically characterized. Solvolysis reactions are also observed to occur in contact with other solvents thus widening the possibilities in structural arrangement.

For the indicated reasons above, the simultaneous use of dpk and cyanate ligands could be expected to enhance the formation of intermetallic bridges. Thus, taking into account these considerations, this work reports on a ferromagnetic tetranuclear cobalt(II) system of formula $[Co_2(dpkOH)(dpkOMe)(NCO)_2]_2$, the structural core of which can be described as that of a 'dicubane' having two missing vertices. Very few examples of cobalt(II) dicubanes are known[12] and no cobalt–$\mu_{1,1}$-cyanate polynuclear compound has been characterized structurally and magnetically to date. Furthermore, as far as we are aware, this is the first example of a 'cubane-type' system involving cyanate ligands.

Reaction of dpk, $Co(NO_3)_2{\cdot}4H_2O$ and KNCO yielded,† after evaporation, a brown-red crystalline material, the composition of which was consistent with the formula $[Co_2(C_{23}H_{20}N_4O_4)(NCO)_2]$ **1**. The X-ray crystal structure determination of **1** (Fig. 1)‡ revealed that it consists of centrosymmetric tetranuclear units in which the cobalt(II) ions are connected through the ligands NCO, dpkOH, and dpkOMe (the latter tworesulting from solvolysis of the dpk ligand) to give a face-shared dicubane-like coordination core containing two missing vertices (Fig. 1).

The Co(II) ions exhibit slightly distorted octahedral $[CoN_3O_3]$ and $[CoN_4O_2]$ environments, with the Co–N distances ranging from 2.024(6) (dpk) to 2.146(4) Å (cyanate) and the Co–O distances ranging from 2.025(3) to 2.244(3). The EO cyanate bridges form an angle with the metal of 101.8(2)°, while the Co–O–Co angles range from 97.1(1) to 100.6(2)°. The Co···Co distance through the combined cyanate and oxo bridges is 3.283(2) Å, while those corresponding to the oxo-bridges alone are 3.144(1) and 3.238(2) Å.

The temperature dependence of the magnetic susceptibility χ_m of **1** has been investigated in the range 4–300 K. The product $\chi_m T$ continuously increases upon cooling and its value, per 4 Co atoms, at room temperature is 11.7 $cm^3\ K\ mol^{-1}$, which is larger than the 7.5 $cm^3\ K\ mol^{-1}$ expected for four isolated spin-only $S = 3/2$ ions. This larger value is the result of contributions to the susceptibility from orbital angular momentum at high temperatures, which produces effective moments per cobalt atom in the range 4.7–5.2 μ_B.[13] A maximum of 18.3 $cm^3\ K\ mol^{-1}$ appears at 12 K. After this maximum, $\chi_m T$ decreases [Fig. 2(a)]. This behavior is characteristic of a system exhibiting intramolecular ferromagnetic interactions; while the sudden decrease must be associated to spin–orbit coupling and/or the existence of intermolecular interactions. It is not possible to fit the behavior of an array of four high-spin Co^{II} centers given current theory, even if the centers are orbitally degenerate. Besides, in the present compound the environment of the Co(II) centers which are in distorted octahedra, probably removes the degenereracy. Taking into account that, even for the simplest of the possible Co(II) tetranuclear systems (*i.e.* a square planar cluster with a single *J* value[14]), fitting has not been carried out, the extreme difficulty of modeling a four-*J* system (see Scheme 1) for this cation that should include aspects such as spin–orbit coupling, magnetic anisotropy, orbital degeneracy, *etc*, should be appreciated.

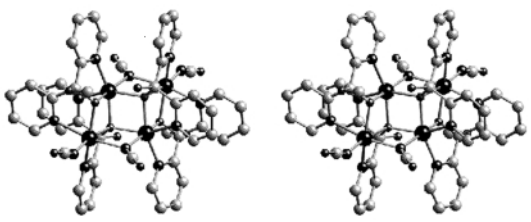

Fig. 1 Stereoview of the tetranuclear structure of compound **1**. Sizes of spheres is in the order Mn > C > N > O. Hydrogen atoms have been omitted for clarity.

DOI: 10.1039/b008256m

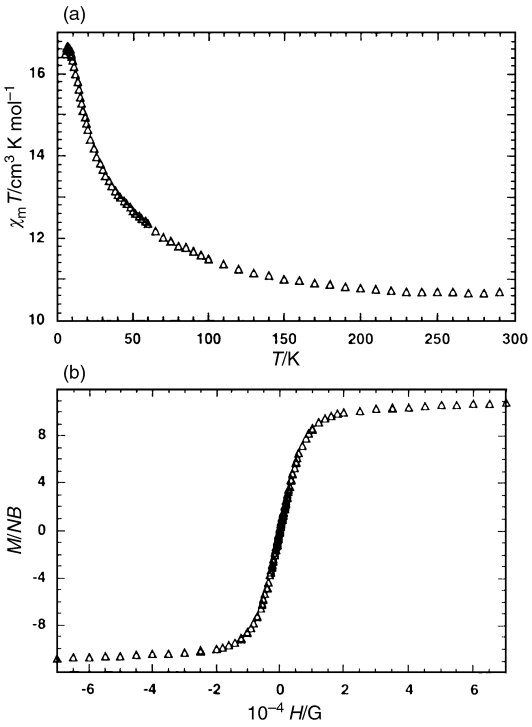

Fig. 2 (a) Thermal variation of $\chi_m T$ for **1**, per tetranuclear unit. (b) Representation of the magnetization *vs.* magnetic field at 5 K.

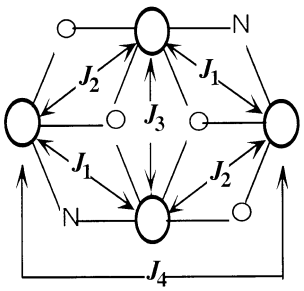

Scheme 1

In order to gain more information on **1**, we investigated the variation of the magnetization *M vs.* the applied magnetic field *H*, in the field range $0 < H/T < 7$ at 5 K and results are shown in Fig. 2(b), where it can be observed that the magnetization reaches the saturation value expected for a tetranuclear ferromagnetic cobalt(II) compound, *i.e.* $N\beta g/2$ ($\approx$ 12). Further studies are being undertaken to thoroughly characterize this system.

The ferromagnetic behavior of this compound can be explained by the existence of *end-on* cyanate bridges, with angles close to 100°, which gives rise to moderately strong ferromagnetic interactions.[7] In addition, the oxo bridges in the compound also promote ferromagnetic interactions, as has been observed in related cubane oxo-bridged compounds.[11b]

In conclusion, the combination of dpk and cyanate ligands has been shown to be a good strategy for obtaining 'cubane-like' systems and related nickel, cobalt and manganese systems are now under investigation. The resulting compound **1** shows a tetranuclear molecular structure of dicubane type which is unprecedented for cyanate ligand. The bridging ligands connecting the cobalt(II) ions provide global ferromagnetic exchange interactions.

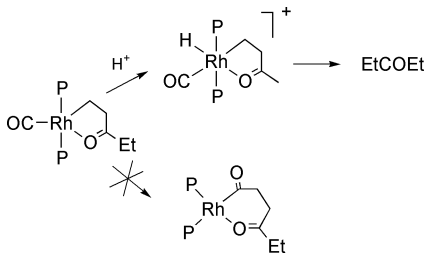
Using rhodium complexes of tertiary phosphines with carbonyl groups β to the P atom, ethene and CO react in methanol to give products involving increased chain growth (octane-3,6-dione, methyl 4-oxohexanoate) compared with PEt_3 complexes and unsaturated products (methyl propenoate, penten-3-one and 1-methoxypentan-3-one from addition of methanol to penten-3-one); mechanistic studies suggest that the ligand carbonyl group prevents coordination of the keto group in the growing chain.

Reactions between ethene and CO in methanol generally give perfectly alternating polyketones or methyl propanoate (MP), with the best catalysts being based on palladium complexes of mono- or ditertiary phosphines,[1,2] although we have recently reported that highly electron rich rhodium phosphine complexes can give high selectivities to pentan-3-one (DEK), with the two extra H atoms required being derived from methanol, which forms methyl formate (MF).[3] We presented evidence that the selectivity to pentan-3-one (DEK) arose because of binding of the keto-oxygen atom in the growing chain to the rhodium atom to give an η^2-3-oxopentyl intermediate. Since this complex has 18e, it more readily protonates and reductively eliminates pentan-3-one than undergoing further insertion to give chain growth (Scheme 1).[3]

One of our interests is in the production of CO/C_2H_4 oligomers for use as low-volatility solvents containing relatively high oxygen content, so we were interested in the possibility of encouraging chain growth and hence of preventing the formation of the η^2-3-oxopentyl intermediate. We, therefore, synthesised a range of phosphines which themselves contain carbonyl groups β to the P atom in the hope that these carbonyl groups might compete with coordination of the keto group in the growing chain and encourage chain growth.

The ligands shown in Table 1 were synthesised by the reaction of R_2PH (R = Et, Bu^t, Cy) with the appropriate bromo compound, R′$COCH_2Br$. (R′ = Ph, Et, OEt), followed by removal of HBr with base (Scheme 2). Catalytic reactions were then carried out, synthesising the active catalyst *in situ* from the ligand and $[Rh(acac)(CO)_2]$ (Hacac = pentane-2,4-dione). The results of these reactions are shown in Table 1 and indicate that, apart from the complex derived from $Bu^t_2PCH_2C(O)Ph$, which does not give an active catalyst, catalysts based on these ligands show quite different selectivities compared with those involving PEt_3. In particular, chain growth to octane-3,6-dione (OD) and methyl 4-oxohexanoate (M4OH) has become significant and the unsaturated products, penten-3-one (EVK) and methyl propenoate (MA) are observed. A further product, 1-methoxypentan-3-one (1M3P)† is a major product. We have shown in separate experiments that this is formed by addition of methanol to penten-3-one (EVK) in an uncatalysed reaction under the experimental conditions employed. The selectivity to medium chain products (≥7 chain atoms) can be as high as 57.6%,



Scheme 1 Proposed role of an η^2-3-oxopentyl intermediate in determining the selectivity of ethene carbonylation to pentan-3-one catalysed by Rh/PEt_3 complexes.[3]

Scheme 2 Sythesis of β-ketophosphine ligands. R″ = H, R = Et, R′ = Ph, OEt, Et; R″ = H, R = Bu^t, R′ = Ph, OEt; R″ = H, R = Cy, R′ = Ph; R″ = Me, R = Et, R′ = Me. *Reagent*: i, NaOH.

Table 1 Products obtained from the carbonylation of ethene catalysed by rhodium complexes of β-ketophosphines and related ligands[a]

Ligand	MA	MP	EVK	DEK	1M3P	M4OH	OD	Total turnover	MCP(%)

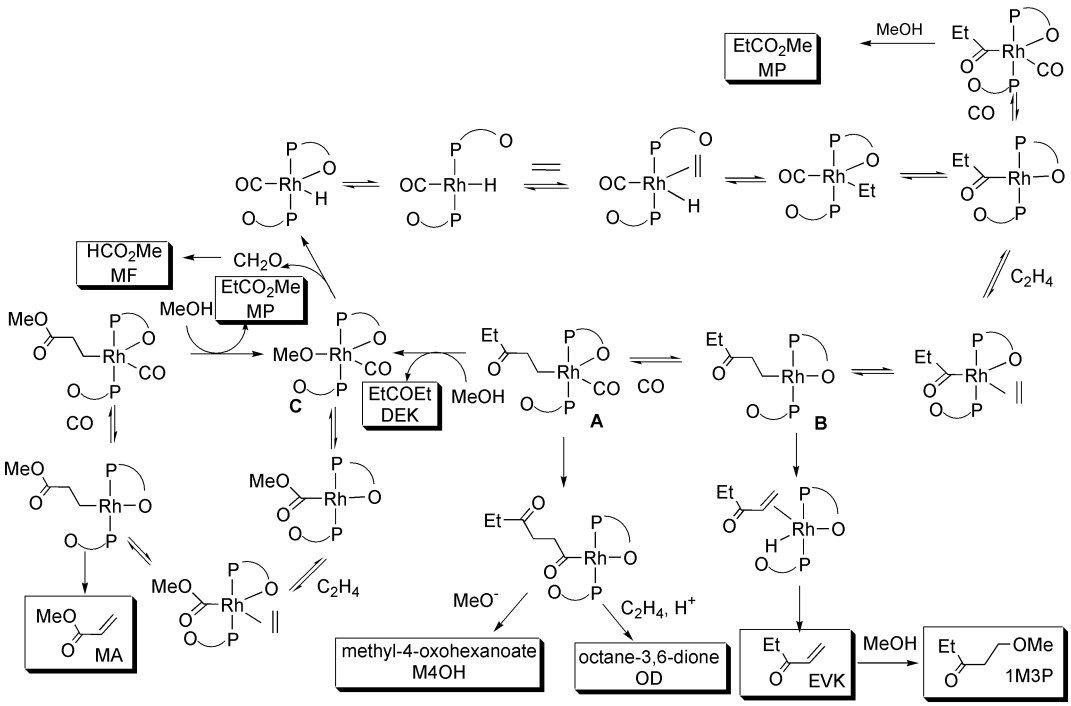
[a] $[Rh(acac)(CO)_2]$ (0.1 mmol), phosphine (0.4 mmol), CO (35 bar), ethene (35 bar), methanol (10 cm^3), 110 °C, 24 h. Amounts expressed as catalyst turnovers. [b] 2 equivalents of ligand used, *i.e.* (0.2 mmol). MA (methyl propenoate, methyl acrylate), MP (methyl propanoate), EVK (penten-3-one, ethyl vinyl ketone), DEK (pentan-3-one, diethyl ketone), 1M3P (1-methoxypentan-3-one), M4OH (methyl 4-oxohexanoate), OD (octane-3,6-dione), MCP (medium chain products, 7+ atoms in backbone).

DOI: 10.1039/b007989h



Scheme 3 Proposed mechanism of ethene carbonylation catalysed by Rh/β-ketophosphine (P⁀O) complexes. The products shown in boxes have been observed (Table 1), but the assignments of the metal containing intermediates are tentative.

whereas with PEt_3 the selectivity to pentan-3-one (DEK) can be >80% with only traces of medium chain products being formed. Similar results to those for the β-ketophosphines are obtained (Table 1) using other ligands with O γ to the P atom such as $Me_2PCH_2P(O)Me_2$, or $Et_2PCH_2CH_2OMe$, but not with N in this position; $Et_2PCH_2CH_2NEt_2$ behaves more like PEt_3, although the rate is lower.

We have also carried out the reaction using $PhCOCH_2PEt_2$ in CD_3OD and find that the methyl groups of pentan-3-one (DEK) and of methyl propanoate (MP) contain 0 or 1 D atoms.‡ This contrasts with reactions involving PEt_3,[3] where multiple deuteriation of the methyl groups of pentan-3-one (DEK) is observed.

These results point to the conclusion that, in these systems, the carbonyl group in the growing chain does not coordinate, presumably because the coordination site is blocked by the carbonyl group β to the phosphine (Scheme 3). Intermediate **A** in Scheme 3 is an 18e complex, so may protonate and reductively eliminate pentan-3-one (DEK). Alternatively, CO may insert leading to chain growth. We have shown that multiple D incorporation into the methyl group of pentan-3-one (DEK) in the Rh/PEt_3 catalysed reactions carried out in CD_3OD occurs *via* β-H abstraction in the η^2-3-oxopentyl intermediate to give an enolate. A similar β-H abstraction in the η^1-3-oxopentyl intermediate, **B** in Scheme 3, would lead to penten-3-one (EVK) bound only through the double bond and it appears that this decoordinates to give free penten-3-one (DEK), rather than undergoing reversible C–H bond breakage and multiple D incorporation.

The formation of methyl propenoate (MA) is also of considerable interest, not only because it indicates that acrylates can be products from CO/C_2H_4 reactions under non-oxidative conditions, but also because it indicates that a carbomethoxy mechanism[1] is operating in addition to the hydride mechanism which is responsible for the other products. This suggests that CO insertion into the Rh–OMe bond competes with β-H abstraction and CO can insert in the 18e complex (**C** in Scheme 3). Acrylates can be products of CO/alkene reactions in the presence of oxygen.[5,6]

In conclusion, all of the products obtained from the reaction of CO with ethene in methanol in the presence of rhodium complexes containing phosphine ligands with a carbonyl β to the P atom can be explained as in Scheme 3 if one carbonyl group in the phosphine is coordinated to the rhodium.

We thank BP and the EPSRC for funding (R. A. M. R.) and Dr E. Ditzel and Mr P. Howard for helpful discussions.

Notes and references

† Since this product has seven atoms in the chain and contains two O atoms (bp 62 °C at 24 Torr),[4] it may be a suitable component of a low volatility solvent mixture, so is included when calculating the percentage of medium-chain products produced in the reaction.

‡ The methylene groups contain from 0 to 2 D atoms on account of post-reaction exchange with the solvent.[3]

Compound 1, containing an octamethylferrocene donor linked to a nitrothiophene acceptor *via* an ethenyl linker, shows a static first hyperpolarisability β_0 of 95(±10) × 10^{-30} esu, which is reduced to 10(±2) × 10^{-30} esu on oxidation of the octamethylferrocene unit; this provides for a simple redox-based switching of the NLO characteristics of the compound.

Compounds displaying non-linear optical (NLO) properties are of considerable interest because of their possible applications in the emerging technologies of optoelectronic and photonic devices.[1] Second-order NLO effects, including second-harmonic generation, and especially electro-optic modulation are important in interfacing massive amounts of electronic data to wideband optical communication. At the molecular level, the efficiency for electro-optic modulation is determined by the second-order non-linear polarisability, also called the first hyperpolarisability, β. A large value of β is generally associated with molecules which have a donor/conjugated bridge/acceptor (D-π-A) structure, such that there is a long-range charge-transfer transition from one end to the other and consequently a substantial difference between the ground-state and excited-state dipole moments.

The ability to switch the NLO response of a molecule 'on' and 'off' reversibly by a simple controllable perturbation would add significant value to the utility of NLO molecules, from the point of view of developing molecular photonic devices whose properties can be switched by modifying one of the component parts.[2] Despite the large number of molecules with large first hyperpolarisabilities, there are remarkably few examples in which such reversible switching has been demonstrated. Of these the majority depend on isomerisation or tautomerisation of the molecule, such that the nature of the conjugated bridge linking the donor and acceptor termini undergoes a substantial change.[3] A more appealing method of controlling the second-order NLO response of a molecule would be a reversible redox change, in which either the donor (D) unit is oxidised or the acceptor (A) unit is reduced. The result in either case would be a loss of the charge-transfer capability and a consequent drop in the hyperpolarisability β.[2] To date there is a single example of this in the literature, from the group of Coe, comprising a $\{Ru(NH_3)_5\}^{2+}$ donor linked to a viologen-like acceptor; the value of β decreased by an order of magnitude on one-electron oxidation of the Ru terminus. Subsequent re-reduction of the Ru terminus completely restored the SHG properties of the compound.[4]

We describe here a new molecule for second-order NLO applications (**1**) which contains an octamethylferrocene donor unit and a nitrothiophene acceptor, linked by an ethenyl bridge. The reversible octamethylferrocene–octamethylferrocenium couple, at modest potential, provides an ideal route for redox-based switching of the hyperpolarisability. Compounds which contain ferrocene units as the electron donor, with a single conjugated side-arm linked to an acceptor unit, have been exceptionally popular for studying SHG in the last decade.[5] The redox activity of the ferrocene donor unit however has not until now been exploited for switching purposes; use of the octamethylferrocene unit in **1** will both enhance its electron-donor properties compared to ferrocene, and will reduce the redox potential to make redox-based switching more facile.

Compound **1** was prepared in good yield† by a Wittig reaction between 1′,2,2′,3,3′,4,4′,5-octamethylferrocenylmethyltriphenylphosphonium bromide[6] and 5-nitro-2-thiophenecarbaldehyde in tetrahydrofuran (THF); the crystal structure is in Fig. 1.‡ The cyclopentadienyl ring of the donor, the ethenyl bridge, and the nitrothiophene acceptor are essentially coplanar which will clearly optimise end-to-end charge-transfer *via* the conjugated system. The electronic spectrum in CH_2Cl_2 (Fig. 2)

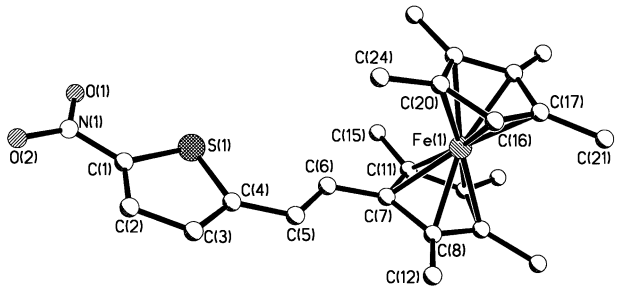

Fig. 1 Crystal structure of **1** together with selected bond distances. The structure of the complex cation of $[\mathbf{1}]^+(PF_6)\cdot CH_2Cl_2$ is essentially identical, and the bond distances for this are given in square parentheses after the corresponding value for **1**. DOI: 10.1039/b008056j

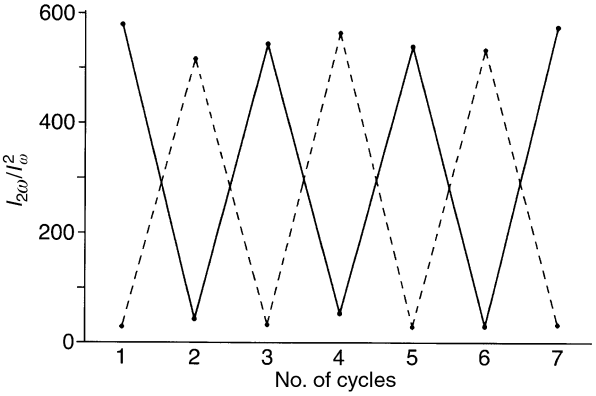

Fig. 3 Redox switching of the hyper-Raleigh scattering response between **1** and $[\mathbf{1}]^+$ in CH_2Cl_2 (concentration of samples, 4×10^{-5} M). The solid line shows the response obtained starting with **1** and then alternately oxidising and re-reducing it; the dotted line shows the response obtained starting with $[\mathbf{1}]^+(PF_6)$ and then alternately reducing and re-oxidising it. The parameter plotted on the *y*-axis ($i_{2\omega}/I^2_{\omega}$) is proportional to β^2.

shows transitions at 644 nm and 447 nm which we ascribe to the two relevant D $\rightarrow$ A charge-transfer transitions;[7] in agreement with this, both transitions are strongly solvatochromic, with the absorption maxima changing from 586 and 409 nm respectively in hexane, to 655 and 453 nm respectively in dimethyl sulfoxide. Compound **1** undergoes a reversible octamethylferrocene–octamethylferrocenium redox interconversion at -0.30 V *vs.* the ferrocene–ferrocenium couple in THF. Accordingly, one-electron oxidation of **1** by treatment with 1 equiv. of ferrocenium hexafluorophosphate in MeCN afforded $[\mathbf{1}]^+(PF_6)$ in high yield.§ This complex has also been structurally characterised,‡ and the structure of the complex cation $[\mathbf{1}]^+$ is essentially identical to that of **1** apart from minor changes in the Fe–C bond distances (see caption to Fig. 1). In the oxidised complex $[\mathbf{1}]^+$ the charge-transfer transitions of **1** are absent, replaced by the characteristic weak LMCT transition of the ferrocenium unit at 851 nm (Fig. 2).

We used the hyper-Raleigh scattering method[8] to measure the first hyperpolarisability β of **1** and $[\mathbf{1}]^+$ in CH_2Cl_2 solution using a 1064 nm laser. The value of β obtained for **1** [316 ($\pm$32) $\times$ 10^{-30} esu] is much greater than that for $[\mathbf{1}]^+$ [25 ($\pm$5) $\times$ 10^{-30} esu], as we would expect based on the above arguments. Part of this change is however ascribable to the fact that the value of **1** is resonantly enhanced due to absorption by the CT transitions in the region of the second harmonic of the excitation laser at 532 nm; this effect is not so significant for $[\mathbf{1}]^+$ whose absorbance at this wavelength is much lower. Consequently the two-level model[9,10]¶ was used to derive the static hyperpolarisability (β_0) in each case, and β_0 values of 95 ($\pm$10) $\times$ 10^{-30} and 10 ($\pm$2) $\times$ 10^{-30} esu were obtained for **1** and $[\mathbf{1}]^+(PF_6)$ respectively. Thus, compound **1** has a SHG efficiency about one order of magnitude greater than does $[\mathbf{1}]^+$.

The redox interconversion of **1** and $[\mathbf{1}]^+$ thus provides a basis for an effective switch of the second-order NLO properties of the complex. The switching effect is illustrated in Fig. 3, which shows (solid line) the alternation in the value of the first hyperpolarisability as a sample of **1** is alternately oxidised (by addition of Bu_4NBr_3) and then reduced (by addition of hydrazine). Exactly similar results were obtained starting with $[\mathbf{1}]^+$ and alternately reducing and oxidising it (dotted line). Given the large number of D–π–A complexes based on ferrocenyl donors which have been prepared for NLO studies,[5] this redox-based switching is clearly of wide applicability for the development of switchable NLO materials.[2]

§ To a solution of **1** (0.15 g, 0.33 mmol) in N_2-purged dry MeCN was added ferrocenium hexafluorophosphate (0.107 g, 0.32 mmol) and the mixture was sonicated in an ultrasound cleaning bath for 15 min. After evaporation of the solvent the residue was washed several times with ether until the filtrate was colourless, and was then dried yielding pure $[\mathbf{1}]^+(PF_6)$ (0.18 g, 91%). Found: C, 47.9; H, 5.1; N, 2.3%; $C_{24}H_{29}FeF_6NO_2PS$ requires C, 48.3; H, 4.9; N, 2.4%. FABMS: *m/z* 451 ($M^+ - PF_6$, 100%).

¶ One of the referees has pointed out that the two-level model (ref. 9) cannot be applied with accuracy to ferrocenyl-based systems such as these in which two charge-transfer processes contribute to β (ref. 7). This is true, however because of its simplicity and the lack of readily applicable alternatives it remains in wide use as long as its limitations are understood (ref. 10).

First published as an Advance Article on the web

The values of the $^1J(^{199}Hg^{199}Hg)$ coupling constant in solution of the asymmetric dimercury(2+) complexes with the stoichiometries Hg_2^{2+}/18-crown-6 and Hg_2^{2+}/18-crown-6/15-crown-5 are 220 300 and 284 100 Hz, respectively, representing the largest scalar couplings measured.

Very large scalar coupling constants have been observed between heavy metal nuclei and have been attributed to relativistic effects. The largest value known at present is the one-bond $^{199}Hg^{199}Hg$ coupling in the polycation $[Hg–Hg–Hg]^{2+}$ **1** with a magnitude of 139 600 Hz.[1] The largest coupling constant between two different nuclei is a 71 060 Hz $^1J(^{195}Pt^{205}Tl)$ coupling observed for the compound $[(NC)_5Pt–Tl]$.[2]

The use of solid-state ^{199}Hg NMR for the determination of the $^{199}Hg^{199}Hg$ coupling of $[Hg–Hg]^{2+}$ salts involving magnetically inequivalent mercury atoms, has been proposed,[3] but appears not to have been carried out. We report here on the synthesis of asymmetric dimercury(2+)–crown ether complexes which are kinetically stable on the NMR time scale at low temperatures and provide straightforward access to the $^{199}Hg^{199}Hg$ coupling constants.

Treatment of $[Hg–Hg]^{2+}$ with 1 equiv. of 18-crown-6 in CH_2Cl_2 produces the dimercury(2+) complex **2** in which one Hg is complexed to the macrocyclic crown ether.† The mixed ligand complex $[Hg_2(18\text{-crown-6})(15\text{-crown-5})(Me_2SO)](O_3SCF_3)_2$ **3a** containing one 18-crown-6 and one 15-crown-5 co-ordinated to dimercury(2+) was formed upon reaction of **2** with 1 equiv. of 15-crown-5.†

The ^{199}Hg NMR spectra of **2** and **3** consist of a superposition of the patterns of the two isotopomers with one ^{199}Hg nucleus (abundance 14.00% each) and the isotopomer containing two ^{199}Hg nuclei (abundance 2.84%). The latter arises from an AB spin system. The outer transitions of the AB system could not be observed because of very low probabilities (*e.g.* 0.3% of the inner transitions as calculated for **3b**) and because of linewidths of *ca.* 60–80 Hz for **2** and **3**, which are attributed to chemical shift anisotropy (CSA) relaxation. The coupling constant is readily derived from the distances of the inner lines of the AB system and of the shifts ν_a and ν_b which are obtained from the patterns of the isotopomers containing one ^{199}Hg nucleus. The value of the $^1J(^{199}Hg^{199}Hg)$ coupling constant in **2** is 220 300 Hz. An even larger $^{199}Hg^{199}Hg$ coupling constant (263 200 Hz) is observed for the mixed 18-crown-6/15-crown-5 complex **3a** in CH_2Cl_2. The ^{199}Hg NMR spectrum of a solution of **3a** in MeOH at 223 K shows the presence of two asymmetric dimercury(2+) complexes. The parameters of one of these species correspond to those of $[Hg_2(18\text{-crown-6})(15\text{-crown-5})(Me_2SO)](O_3SCF_3)_2$ **3a** in CH_2Cl_2, the other species is assigned to $[Hg_2(18\text{-crown-6})(15\text{-crown-5})(MeOH)](O_3SCF_3)_2$ **3b**, which is thought to be formed according to the equilibrium (1).

$$\underset{\textbf{3a}}{[Hg_2(18\text{-crown-6})(15\text{-crown-5})(Me_2SO)]^{2+}} + MeOH \rightleftharpoons \underset{\textbf{3b}}{[Hg_2(18\text{-crown-6})(15\text{-crown-5})(MeOH)]^{2+}} + Me_2SO \quad (1)$$

The size of the Hg–Hg coupling constant of **3b** is 284100 Hz, and we believe that this represents the largest scalar coupling constant recorded so far. The ^{199}Hg shifts of the mercury atoms complexed to 18-crown-6 macrocycles appear at low frequencies compared with the Hg atoms coordinated by 15-crown-5 or bridging Me_2SO.

The complexes **2** and **3c** (all attempts to isolate **3a** gave **3c**) were characterised by single crystal X-ray diffraction:‡ as can be seen from Fig. 1, **2** exists as a dimer $\{[Hg_2(18\text{-crown-6})(Me_2SO)(\mu\text{-}Me_2SO)](O_3SCF_3)_2\}_2$ in the solid state. Curiously, the crystals of **3c** are built from two different complexes: the asymmetric unit contains one $[Hg_2(18\text{-crown-6})(15\text{-crown-5})(Me_2SO)](O_3SCF_3)_2$ and one $[Hg_2(18\text{-crown-6})(15\text{-crown-5})(H_2O)](O_3SCF_3)_2$ species which is shown in Fig. 2. In **2** and **3c** the coordination geometry of the mercury atoms complexed to a 18-crown-6 is hexagonal-bipyramidal with the other Hg atom and one oxygen of Me_2SO or H_2O in axial position and the crown oxygens in the equatorial sites. The 18-crown-6 ligands are located slightly off-centre with respect to the mercury atoms, presumably as a result of the steric demands of the Me_2SO ligand coordinated to the same Hg atom. The mercury atoms reside slightly off the 18-crown-6 plane which is shifted towards the terminal Me_2SO ligands. The 15-crown-5 macrocycle is coordinated in a 'half-sandwich' manner.

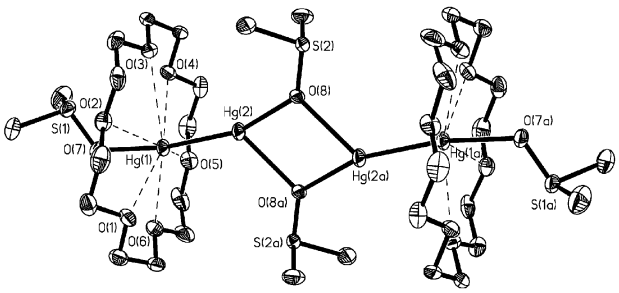

Fig. 1 Structure of $\{[Hg_2(18\text{-crown-6})_2(Me_2SO)(\mu\text{-}Me_2SO)]\}_2^{4+}$ (cation of **2**). Thermal ellipsoids are shown at the 20% probability level.

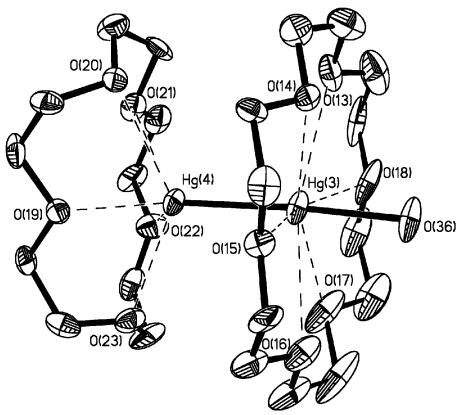

Fig. 2 Structure of $\{[Hg_2(18\text{-crown-6})(15\text{-crown-5})(H_2O)]^{2+}$ (part of **3c**). Thermal ellipsoids are shown at the 20% probability level.

Crystal structures of (*R,R*)-{[Ph(Me)CH]$_2$NLi·pmdeta} and {[PhC(=CH$_2$)NH]Na·pmdeta}$_2$: alkali metal amides derived from (*R,R*)-bis(α-methylbenzyl)amine†

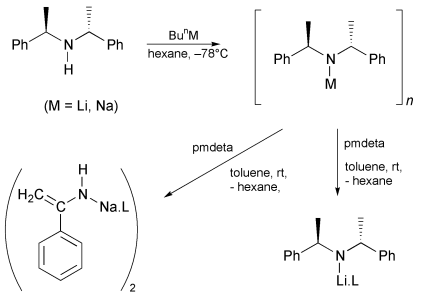
First published as an Advance Article on the web

The reaction of Bu^{n}M (M = Li, Na) with [(*R,R*)]-bis(α-methylbenzyl)amine in the presence of pmdeta results in the formation of the chiral lithium amide complex (*R,R*)-{[Ph(Me)CH]$_2$NLi·pmdeta} and, remarkably, the sodium enamide, {[PhC(=CH$_2$)NH]Na·pmdeta}$_2$; both compounds have been authenticated by single crystal X-ray diffraction.

Our knowledge of the structural chemistry of alkali metal amides is now firmly established and indeed, many of the structural features found in these complexes have become largely predictable. As a result of their widespread applicability in synthesis most of our understanding has come from detailed solution and solid state studies on lithium amides, though there has been a steady increase in the study of the heavier metal (Na, K) complexes.[1,2] Limited hydrocarbon solubility, increased reactivity and possible reductions in selectivity are the reasons often quoted for the limited use of Na and K complexes, though implicit within this is also the belief that while structural differences will occur as a result of increasing cation size, the complex formed and the resulting chemistry will be essentially similar to that of the lithium counterpart. While most structural studies have indicated this is probably the case, there is also the possibility that the change in metal can effect dramatic and unexpected structural outcomes, which is important given that many alkali metal reagents are generated and used *in situ*.[3]

We reported recently that in the presence of pmdeta (*N,N,N′,N′,N″*-pentamethylethylenetriamine), α-(methylbenzyl)benzylamido lithium will produce the expected monomer, (*R*)-[(Ph(Me)CH)(PhCH$_2$)NLi·pmdeta], **1**,[4] while the sodium complex will undergo the facile low-temperature transformation to a 2-azaallylic anion system, {[Ph(Me)C⋯N⋯C(H)Ph-]Na·pmdeta} **2**,[6] as has also been described, in detail, for the analogous alkali metal complexes of dibenzylamine.[7] In comparing the Li complexes, the added methyl group increased the stability of the amide complex to azaallyl formation. We also noted the surprising paucity in solid and solution state structural information which is available on enantiomerically pure chiral alkali metal amides,[4] especially in light of their important role in synthesis.[5] With this in mind, we extended our studies to the complexes of [*R*-(*R**,*R**)]-bis(α-methylbenzyl)amine and herein report the solid state structure of (*R,R*)-{[Ph(Me)CH]$_2$NLi·pmdeta}, **3**, and the remarkable transformation of the amide to an enamide with crystallisation of {[PhC(=CH$_2$)NH]Na·pmdeta}$_2$ **4**. Both structures have been determined by single crystal X-ray diffraction.

The preparative methods towards **3** and **4** are shown in Scheme 1. Complex **3** was prepared by the addition of Bu^{n}Li to a hexane solution of (*R,R*)-bis(α-methylbenzyl)amine at −78 °C. Ligand pmdeta (1 equiv.) was added to the bright orange solution on reaching ambient temperature, resulting in a yellow precipitate which was redissolved on addition of toluene. Cooling the pale brown solution to −20 °C resulted in a large crop of pale yellow prismatic crystals, yield 67%.†



Scheme 1 Synthesis of (*R,R*)-{[Ph(Me)CH]$_2$NLi·pmdeta} **3** and [PhC(=CH$_2$)N(H)Na·pmdeta]$_2$ **4** (L = pmdeta).

Synthesis of **4** was by essentially the same method, the difference being that the amine was added to a hexane suspension of Bu^{n}Na at −78 °C.† Pale yellow crystals of **4** were obtained at room temperature after *ca*. six days, but only after reduction of solvent to a minimum (*ca*. 5 ml for 5 mmol reaction).†

Complex **3** crystallises in the orthorhombic space group $P2_12_12_1$ and is monomeric, as shown in Fig. 1.‡ In general, the structure is similar to that previously described for **1**;[4] the Li centre is four coordinate, bonding with the three available N atoms of pmdeta and N$_{amido}$, is in a distorted tetrahedral environment and with comparable Li–N bonding distances. The most interesting feature of the structure though is the arrangement of the methyl groups, both in terms of their location in relation to the metal centre and their close proximity to the plane defined by C9, N1 and C1. Close H$_3$C⋯Li interactions of 2.74 and 2.78 Å in the dimer (*R,R*)-{[Ph(Me)CH]$_2$NLi·thf}$_2$ are described as being of possible importance in explaining stereochemical outcomes in deprotonation reactions.[8] Given the similarity in the conformations adopted by the amido moieties

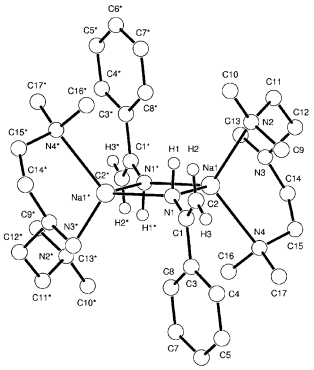

Fig. 2 Molecular structure of $[PhC(=CH_2)N(H)Na{\cdot}pmdeta]_2$ **4**; all H except those on CH_2 and NH omitted for clarity. Selected bond distances (Å) and angles (°); Na1–N1* 2.430(3), Na1–N1 2.406(3), Na1–N2 2.518(4), Na1–N3, 2.577(3), Na1–N4 2.578(4), N1–C1 1.365(4), C1–C2 1.368(5); N1–Na1–N1* 92.9(1), Na1–N1–Na1* 87.1(1), N1–Na1–N2 89.5(1), N1–Na1–N3 160.7(1), N1–Na1–N4 116.7(1), N1–Na1–N2 126.5(1), Na1–N1–C1 128.0(2), Na1–N1–C1 135.4(2), N1–C1–C2 126.5(4), N1–C1–C3 114.3(3).

in the dimeric thf and monomeric pmdeta complexes of $[(Ph(Me)CH)(PhCH_2)NLi]$ it might have been expected that such close interactions and amide conformations would be carried through from (R,R)-$\{[Ph(Me)CH]_2NLi{\cdot}thf\}_2$ into the structure of **3**. As such, in viewing the solid state structure of **3** and the location of the Me groups it would be easy to conclude that the metal centre is dictating the orientation of the Ph(Me)CH moieties. However, while the asymmetry in $Li{\cdots}CH_3$ interactions observed in (R,R)-$\{[Ph(Me)CH]_2NLi{\cdot}thf\}_2$ remains, the analogous distances in **3** are significantly longer at 2.989 Å (C2–Li), and 3.325 Å (C10–Li). The closest distance is therefore only comparable with that observed in **1**, of 3.04 Å. Also, the amido moieties in the thf and pmdeta structures of (R,R)-$[Ph(Me)CH]_2NLi$ do not adopt a similar orientation. In **3** the Me carbons and N_{amido} are almost coplanar, which is evident if we consider a plane defined by N1, C9, C1 above which C10 and C2 lie 4.2 and 15.5°, respectively.

While the monomeric nature of **3** in the solid state was somewhat predictable the crystalline product and subsequent structure obtained from the Na reaction was not. We were probing whether the additional Me groups on the benzylic carbons would effect the formation of an azaallylic anion, as such the formation of the sodium enamide dimer, **4**, was entirely unexpected.

Complex **4** crystallises in the triclinic space group $P\bar{1}$ and is, as evident in Fig. 2, dimeric.‡ What is initially striking about the complex is that it is an amide, with a formal M–N bond, rather than a 1-azaallyl complex in which the Na cation is located above the N∴C∴C fragment as observed in similar systems,[9] and which may have been anticipated on metalation of a primary enamine. The propensity noted for ketimides to undergo a 1, 3 sigmatropic rearrangement to 1-azallyl complexes may hint at a possible mechanism for the formation of **4** involving the formation of [PhC(Me)=NNa] and $PhC(H)=CH_2$ as intermediates. Whether this involves the formation and subsequent cleavage of a C∴N bond from a 2-azaallyl intermediate complex is under investigation. A proton shift from Me onto N as found in $[\{CH_2{\therefore}C(^tBu){\therefore}N(H)Li{\cdot}hmpa\}_2]$[10] with subsequent stabilisation of the enamide over the 1-azallyl structure *via* dimerisation in the solid state would result in **4**. The ^1H and ^{13}C NMR do not give a conclusive answer as to whether the complex in solution adopts a 1-azaallyl arrangement, though the chemical shift of the CH_2 doublet, centred on δ 2.65, is significantly upfield from the region expected for $PhC{=}CH_2$ and is perhaps indicative of a reduction in the double bond character.

The main features of **4** are the central cyclic $(NNa)_2$ ring core about which the amide moieties adopt a *trans* configuration. This is wholly consistent the two other structurally characterised sodium primary amides with which **4** can be compared, $[PhN(H)Na{\cdot}pmdeta]_2$ **5**,[11] and $[2\text{-}PhOC_4H_6N(H)Na{\cdot}pmdeta]_2$,[12] and is a common feature of many sodium secondary amides.[13] In all three cases the Na cation is five coordinate, however the tripodal connectivity of pmdeta in **5** makes it more closely related to **4**. In **5** the anilino moieties tilt at an angle of 65° relative to the $(NNa)_2$ ring plane, whereas in **4** the amide ligands are directly perpendicular, influenced no doubt by the sp^2 nature of C1.

We thank the Australian Research Council and Monash University for financial support.

Using vesicular polymerization, water-soluble polyelectrolyte nanocapsules have been prepared, that are able to undergo a reversible swelling transition upon changing the pH and/or salt concentration.

In recent years considerable progress has been made in developing synthetic methods that allow preparation of materials with precise control over size and morphology at the nanometer level. One typical example is the formulation of hollow nanoparticles. For such nanocontainers a widespread range of applications such as confined reaction vessels, drug carriers or protective shells for cells or enzymes have been proposed. Similar and very effective nanometer sized containers, *viz.*, micelles and vesicular structures, are already used by nature in biological systems. However, due to the non-covalent interactions responsible for their formation, these objects have only a limited stability and may undergo structural changes. Many applications (*e.g.* in drug delivery) require more stable particles. Mechanically stable polymer nanocapsules can be prepared using a variety of different techniques (see for example refs. 1–9). In view of their high stability and low permeability it is, however, generally rather difficult to load polymeric capsules after formulation or to release substances from their interior in a controlled way at the desired target. Consequently prior to any application of such polymer shells ways have to be found to control their permeability.[10] One possibility to realize this is nicely demonstrated by a naturally occurring polymeric nanocontainer: the protein shells of the cowpea chlorotic mottle virus (CCMV) show a reversible, pH-induced structural transition.[11] Increasing the pH from *ca.* 5 to 7 leads to a swelling of the protein shells by *ca.* 10%. During this swelling gated pores are opened in their shells which allow free molecular exchange between the interior of the virion cages and the bulk medium. Recently this gating transition of the virion particles has been used for host–guest encapsulation.[12] Practical applications of virion cages on a technical scale are not feasible due to the difficulties in handling and producing larger quantities. Here our aim is to find a fairly simple synthetic mimetic of these virion cages able to undergo a similar structural transition.

The conformation of polyelectrolytes is very sensitive towards changes in ionic strength, pH and other external factors. Hence water-soluble polymer hollow spheres formed by a covalently crosslinked polyelectrolyte shell could be a suitable model system. The carboxylate groups of nanocapsules based, for example, on poly(acrylic acid) dissociate increasingly with increasing pH. As a result of the associated electrostatic repulsion between the identically charged carboxylate anions along the polymer backbone the particles should swell considerably. Similar to the virion cages, the permeability of the swollen poly(acrylate) shells should increase and enhance molecular exchange between the interior of the particles and the bulk medium. Here we describe a synthetic route to nanometer-sized poly(acrylic acid) hollow spheres. To demonstrate their potential for host–guest encapsulation and controlled release their swelling behavior in aqueous media of different pH and ionic strength, has been investigated.

Recently we succeeded in preparing hydrophobic polymer hollow spheres with diameters ranging from several nanometers up to hundreds of micrometers by polymerization of hydrophobic monomers in the lipid bilayer of vesicles or liposomes.[5] While the size and shape of the resulting polymer particles are directly determined by the templating vesicles, the polymer scaffold can be modified fairly easily, using conventional chemical reactions.

The preparation of hydrophobic polymer hollow spheres has already been described elsewhere.[5] Therefore we just recall briefly the individual steps. We prepared small unilamellar vesicles from the synthetic surfactant dimethyldioctadecylammonium chloride (DODAC) by ultrasonification of aqueous lipid dispersions (2.1 g DODAC in 97.9 g bidistilled water). This yields unilamellar vesicles with an average diameter of 100 nm, however, with a rather high polydispersity. The lipid bilayers of the vesicles were swollen by incubating them in the presence of hydrophobic monomers (0.52 g, *i.e.*, 25 wt% with respect to the lipid) for 2 h at 60 °C. A crosslinking polymerization of the monomers was initiated by UV-irradiation (2 h) at room temperature. Afterwards the resulting polymer particles were isolated from the vesicles by repeated precipitation in a large excess of methanol–water (3 : 1) until ^{1}H NMR spectroscopy indicated complete removal of the surfactant (yield: 81%). As hydrophobic monomers we used mixtures of *tert*-butyl acrylate (t-BUA) and ethylene glycol dimethacrylate (EGDMA) as the crosslinking agent. For selective saponification of the *tert*-butyl ester groups[13] the crosslinked poly(*tert*-butylacrylate) hollow spheres were dissolved in dioxane and stirred for 8 h at 80 °C in the presence of a catalytic amount of hydrochloric acid. The resulting poly(acrylic acid) particles were precipitated in diethyl ether and finally dried by lyophilization from dioxane (yield 89%). ^{1}H NMR spectroscopy indicates full conversion of the poly(*tert*-butyl acrylate) under these conditions.

The resulting poly(acrylic acid) particles are dispersable in aqueous media. Fig. 1 shows a characteristic cryogenic electron micrograph (cryo-TEM) of a representative sample in an aqueous phosphate buffer at pH = 7. The micrograph shows clearly that the polymer particles are hollow. Although we

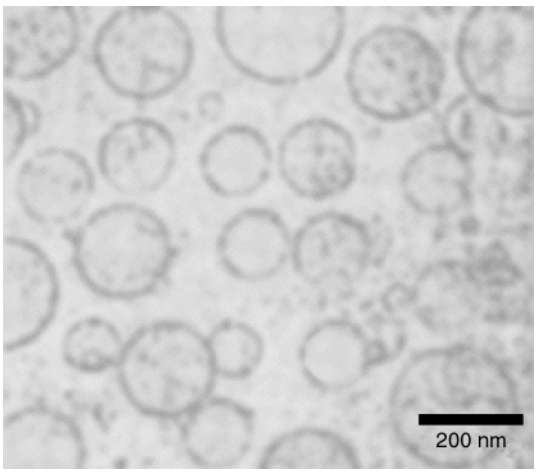

Fig. 1 Cryo-transmission electron micrograph of poly(acrylic acid) hollow spheres in an aqueous phosphate buffer at pH = 7.

DOI: 10.1039/b007118h

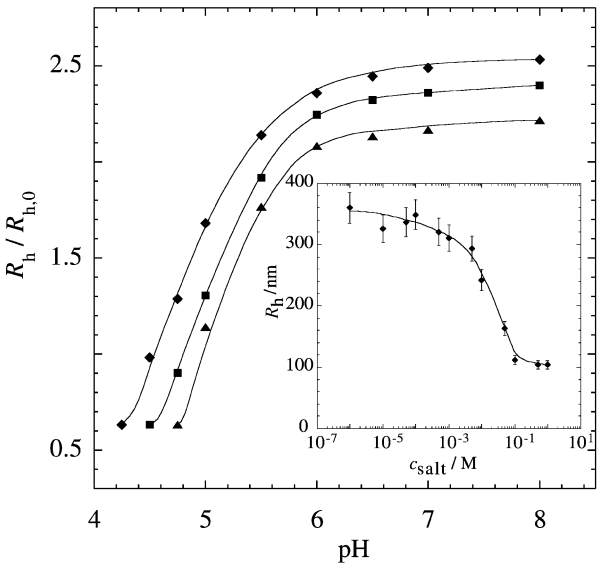

Fig. 2 Reduced hydrodynamic radius $R_h/R_{h,0}$ as a function of pH. The different curves correspond to particles with a different molar fraction of crosslinking comonomers: (◆) 3 mol% EGDMA ($R_{h,0}$ = 49 nm), (■): 5 mol% EGDMA ($R_{h,0}$ = 55 nm), (▲) 10 mol% EGDMA ($R_{h,0}$ = 60 nm). Inset: hydrodynamic radius R_h of poly(acrylic acid) hollow spheres (5 mol% EGDMA) as a function of salt concentration c_{salt} of the buffer.

cannot completely exclude their presence due to the limited resolution of the method, no solid latex particles or fragments of the shells can be detected. The size of the particles is in good agreement with dynamic light scattering experiments (see below) and they are polydisperse as are the parent DODAC vesicles. This reflects that the newly formed poly(acrylic acid) hollow spheres have survived intact the isolation and saponification procedure.

The sensitivity of the particles towards changes of the pH and/or ionic strength of the buffer is the basic requirement for their use as controlled release devices. Therefore we investigated in a first set of experiments the behavior of the poly(acrylic acid) hollow spheres in phosphate buffers of varying pH. It has to be emphasized that the ionic strength of the buffers used for these experiments was carefully kept constant at 0.1 M by addition of sodium chloride. Although electrostatic interactions are shielded considerably this salt concentration is close to physiological conditions (*ca.* 150 mM), the relevant range for most pharmaceutical applications. Additionally the systems are quite insensitive towards small ionic impurities at this concentration.

The pH-induced dimensional changes of the particles were investigated by dynamic light scattering and Fig. 2 shows the results. To take into account small variations in the average radius of different batches of the precursor vesicles we plotted a reduced hydrodynamic radius $R_h/R_{h,0}$ (R_h = hydrodynamic radius of poly(acrylic acid) hollow spheres; $R_{h,0}$ = hydrodynamic radius of the polymer containing vesicular precursors) as a function of pH. As can directly be seen the dimensions of the particles increase considerably with increasing pH. In the range pH 4–8 their radius increases by a factor of about 4 (*i.e.*, their encapsulated volume increases by a factor of 64!). It should be emphasized that this swelling is completely reversible. The different curves in Fig. 2 refer to nanocapsules of different crosslinking density which was controlled by the molar fraction of the crosslinker EGDMA in the particles. With increasing crosslinking density, the maximum swelling decreases and the swelling transition is shifted towards higher pH, which is a result of the increasing fraction of the non-ionic EGDMA comonomers. The same effect has also been observed for other polyelectrolyte gels.[14] It is important to note that the poly(acrylic acid) hollow spheres precipitate at low pH. The first points of the different curves in Fig. 2 represent the lowest pH values for which stable particle dispersions were obtained. Such a pH-induced precipitation could be highly interesting for applications since it represents a convenient way to separate the particles after their loading from the solution.

The effect of varying salt (NaCl) concentration is shown in the inset of Fig. 2. Throughout this series of measurements we kept the pH constant at 6 where the poly(acrylic acid) is highly ionized. As can directly be seen with decreasing salt concentration the swelling of the particles increases and tends towards a saturation value, which is due to decreasing electrostatic shielding effects. Similar observations have been made with macroscopic poly(acrylic acid) based gels.[15] It is interesting that we can conclude from these data an increase of the radius of the poly(acrylic acid) hollow spheres by up to a factor of 10 (*i.e.* the encapsulated volume increase by a factor of 1000!) at low salt concentrations.

In conclusion, we have presented a convenient way to prepare new, pH-sensitive nanocapsules based on crosslinked polyelectrolyte shells. These particles undergo a reversible swelling transition upon changing the pH and/or the salt concentration of the system which reversibly changes their dimensions. We expect that this swelling will have considerable influence on the permeability of the shells of these nanocapsules which makes these systems highly interesting for applications in areas such as drug delivery. Initial preliminary results indicate that this 'gating transition' can successfully be used for controlled encapsulation and release of biopolymers such as enzymes.

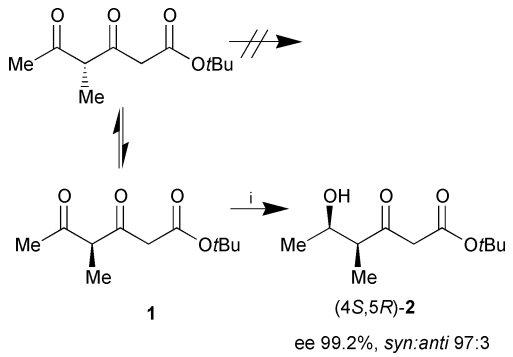
An entirely new method for the dynamic kinetic resolution of a racemic, 2-methyl substituted, unsymmetrical 1,3-diketone *via* enzymatic reduction to give an enantiomerically pure compound is introduced.

The dynamic kinetic resolution of α-substituted β-keto esters by chemical[1] or biocatalytical[2] reduction is particularly useful due to the simultaneous introduction of two stereogenic centres into the molecule in combination with a theoretical maximum yield of 100%. Although this method has proven broad applicability in stereoselective synthesis, the corresponding dynamic kinetic resolution of 2-substituted 1,3-diketones is rarely found in the literature.[3] Our aim is directed toward extending dynamic kinetic resolution to enantio- and regioselective reduction of alkyl-substituted 3,5-dioxoesters, which would enable the introduction of up to four stereogenic centers by two consecutive reduction steps.

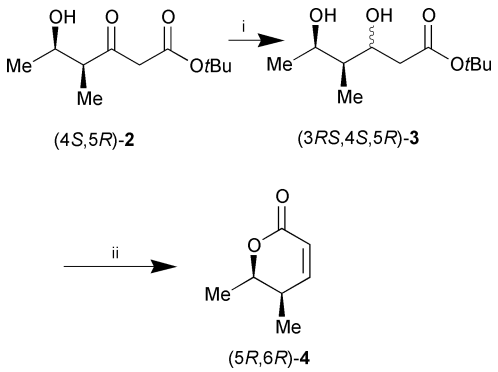
The attempted enantioselective ketone reduction of 3,5-dioxohexanoate esters by chemical methods[4] or biotransformation[5] usually results in complex mixtures of several stereo- and regioisomeric products with one or both keto groups reduced. We figured out that this difficult transformation can be accomplished by using isolated enzymes to afford optically pure 5-hydroxy-3-oxohexanoates in high yield.[6] Herein we wish to report in preliminary form on the first enantio- and regioselective enzymatic reduction of 4-alkyl-3,5-dioxohexanoates resulting in formation of one out of a total of 8 monoreduction and 8 bisreduction products.

tert-Butyl 4-methyl-3,5-dioxohexanoate (**1**) was prepared by acylation of the bisenolate of *tert*-butyl 3-oxovalerate with commercially available Weinreb acetamide.[7] For the enzymatic reduction recombinant alcohol dehydrogenase from *Lactobacillus brevis* (recL*B*ADH) was chosen, which has been cloned and overexpressed in *E. coli*.[8] recL*B*ADH exhibits a broad substrate range and considerable stability even towards highly reactive compounds like 6-chloro-3,5-dioxohexanoates.[6,8] Cofactor (NADPH) regeneration succeeds *via* a coupled-substrate process. Propan-2-ol (200 mM) was applied in excess to the reaction mixture as an auxiliary substrate in order to shift the equilibrium of the reaction towards the desired direction (Scheme 1).[9]

NMR data of the major product (4*S*,5*R*)-**2** which was obtained in 66% isolated yield, clearly proved the regioselective monoreduction of the keto group at C-5. Additionally, from GC-MS data of the crude product after derivatisation with $(F_3CCO)_2O$, pyridine, no evidence could be found for the reduction of the keto group at C-3. In order to verify the proposed absolute configuration and to enable precise determination of the enantiomeric excess, (4*S*,5*R*)-**2** was transformed through sodium borohydride reduction into lactone **4** *via* diol (3*RS*,4*S*,5*R*)-**3**. Lactonisation and dehydration gave the unsaturated lactone (5*R*,6*R*)-**4** which is known in racemic form[10] (Scheme 2).



Scheme 1 *Reagents and conditions*: i, **1** (20 mM), propan-2-ol (200 mM), $NADP^+$ (1 mM), pH 6.5, recL*B*ADH (360 U), 23 h, rt (66%).



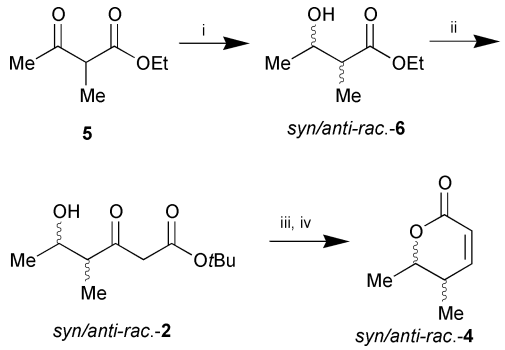
Scheme 2 *Reagents and conditions*: i, $NaBH_4$, EtOH, 0 °C; ii, cat. TsOH, toluene, reflux, 2 h (60% over two steps).

As a standard a racemic 1:1 mixture of *syn*- and *anti*-lactone *rac*-**4** was synthesised from keto ester **5** by sodium borohydride reduction, subsequent chain elongation, and, finally, lactone formation as described above (Scheme 3). The four stereoisomers of *syn/anti-rac*-**4**, which were formed in equal amounts, can be separated by HPLC on chiral stationary phase (Daicel Chiracel OB).

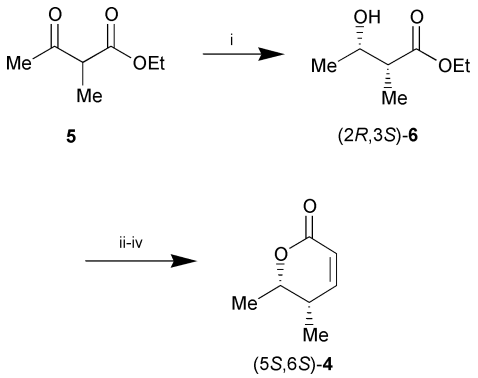
An authentic sample of the enantiomeric *syn*-lactone (5*S*,6*S*)-**4** was synthesised by the same sequence starting from bakers' yeast reduction of **5** *via* the known[11] ethyl (2*R*,3*S*)-2-methyl-3-hydroxybutyrate (2*R*,3*S*)-**6** (Scheme 4).

The spectroscopic data (^{1}H-NMR, ^{13}C-NMR, MS) of (5*S*,6*S*)-**4** and of (5*R*,6*R*)-**4**, produced *via* enzymatic (recL*B*ADH) reduction of **1**, are identical. Comparison of the CSP-HPLC data of both lactones revealed the (4*S*,5*R*)-absolute configuration for the product **2** of the recL*B*ADH reduction. This product is formed in almost enantiomerically pure form (99.2% ee, HPLC data); the diastereomeric ratio of *syn*:*anti* 97:3 is likewise very high (NMR and HPLC data).

DOI: 10.1039/b007448i



Scheme 3 *Reagents and conditions*: i, $NaBH_4$, EtOH, 0 °C (83%); ii, CH_2=C(OLi)O*t*Bu, THF, −30 °C (53%); iii, $NaBH_4$, EtOH, 0 °C; iv, cat. TsOH, toluene, reflux, 2 h (60% over two steps).



Scheme 4 *Reagents and conditions*: i, bakers' yeast, 10% aq. EtOH, (50%); ii, CH_2=C(OLi)O*t*Bu, THF, −30 °C; iii, $NaBH_4$, EtOH, 0 °C; iv, cat. TsOH, toluene, reflux, 2 h (53% over three steps).

In summary, we have shown the regio- and enantioselective reduction of *tert*-butyl 4-methyl-3,5-dioxohexanoate *via* dynamic kinetic resolution to give an almost enantiomerically and diastereomerically pure compound introducing two stereogenic centers can be done efficiently by enzyme-catalysed reduction. This method represents a novel entry into the chemistry of polypropionates based on a biomimetic approach *via* polyketides. This method should be extendable towards dynamic kinetic resolution of other 2-alkyl-substituted unsymmetrical 1,3-diketones.

9 Enzymatic transformation: A solution of recLBADH was prepared by mechanically disrupting wet cells of recombinant *E. coli* strain recADH-HB101+.[8] One unit (U) enzyme activity is defined as the amount of recLBADH that catalyses the oxidation of 1 μmol NADPH per minute when incubated with acetophenone (10 mM) and NADPH (0.25 mM) at 25 °C and pH 6.5 (100 mM phosphate buffer, 1 mM $MgCl_2$). In a round bottom flask, a solution of diketo ester **1** (0.53 g, 2.5 mmol) in propan-2-ol (1.9 mL, 25 mmol) was added to 120 mL phosphate buffer (100 mM, pH 6.5) containing 1 mM $MgSO_4$, and the mixture was ultrasonicated for 1 minute. The reaction was started by addition of $NADP^+$ (105 mg, 120 μmol; FLUKA Nr. 93210, 90%) and recLBADH (360 U). After slowly stirring for 23 h at ambient temperature, 20 g NaCl were added and the solution was extracted with ethyl acetate three times. The combined organic phases were dried over $MgSO_4$ and evaporated. The crude product was purified by flash chromatography (silica, ethyl acetate isohexane 40/60 (v/v)), yielding 0.35 g (66%) hydroxyketo ester (4*S*,5*R*)-**2** as a colourless oil.

Asymmetric cyclopropanation in protic media conducted by chiral bis(hydroxymethyl-dihydrooxazolyl)pyridine–ruthenium catalysts

Seiji Iwasa, Futoshi Takezawa, Yasunori Tuchiya and Hisao Nishiyama*

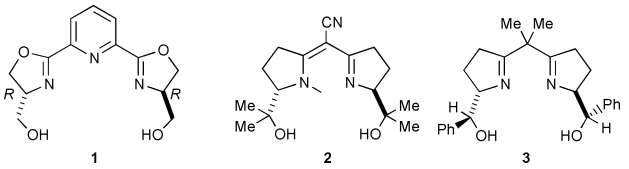
School of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 441-8580, Japan. E-mail: hnishi@tutms.tut.ac.jp

Received (in Liverpool, UK) 23rd October 2000, Accepted 20th November 2000
First published as an Advance Article on the web 14th December 2000

Cyclopropanation of styrene with diazoacetates, performed in aqueous/organic biphasic media or homogeneous alcoholic media in the combination of toluene by using chiral bis(hydroxymethyldihydrooxazolyl)pyridine–ruthenium catalyst, resulted in high enantiomeric excess up to 96–97% and *trans*:*cis* stereoselectivity to 97:3.

Enantioselective reactions of olefins and diazoacetates catalyzed by a variety of metal complexes to provide chiral cyclopropane materials have been well investigated.[1] We have reported ruthenium catalysts of chiral bis(dihydrooxazolyl)pyridine [pybox] for that purpose and their prominent feature of high *trans*-stereoselectivity with higher enantioselectivity.[2,3] Very recently, we reported a characteristic derivative of pybox, *hm*-pybox **1**, having two hydroxymethyl groups as the symmetric chiral stems of the oxazoline rings.[4] We observed that *hm*-pybox exhibits high solubility in water. One of the recent demands for organic synthesis and catalysis, with environmental concerns in mind, has been for the reactions to be carried out in non-halogenated solvents or in aqueous and protic media.[5] We therefore had expectations of developing a new process in aqueous media for asymmetric catalytic cyclopropanation using our water-soluble bis(hydroxymethyldihydrooxazolyl)pyridine–ruthenium catalyst. In addition, however, we demonstrated the tolerance of the catalysis to protic media, such as alcoholic mixtures.

We surveyed previous research related to the catalytic cyclopropanation of olefins and diazoacetates but we could find no systems effective *in aqueous media or protic solvents.*[4] However, we discovered that the existence of a free hydroxy group on chiral ligands does not interfere with the smooth running of cyclopropanation for copper catalyzed reactions, for example, in the case of bis(oxazoline) ligands **2**[6] or **3**[7]. It had also very recently been reported that although a small amount of water in the reaction solvent diminishes enatioselectivity of cyclopropanation with rhodium catalyst, the unfavorable effect of water was reduced by addition of an appropriate phosphite ligand.[8] Accordingly, we were intrigued to examine the catalysis with *hm*-pybox **1** and $[RuCl_2(p\text{-cymene})]_2$ **4**.



First, we tried an aqueous media for the cyclopropanation of styrene and (+)-menthyl diazoacetate **5a** with *hm*-pybox in the presence of co-solvent THF or toluene (Scheme 1). (+)-Menthyl ester was chosen on the basis of better matching to the (*R*,*R*)-absolute configuration of pybox, which ought to give higher enantioselectivity according to our previous work.[2b] The use of a single organic solvent resulted in lower yields and lower enantioselectivities (run 1 and 2 in Table 1). Surprisingly, addition of water to both media in runs 1 and 2 dramatically improved the enantioselectivities and slightly the yields (runs 4 and 5). This phenomenon can be simply accounted for by the increase of the solubility of the active catalyst Ru(*hm*-pybox)Cl_2(vacant or solvent) derived from *hm*-pybox **1** and pre-catalyst $[RuCl_2(p\text{-cymene})]_2$ **4**. It could easily be seen from the dark-violet coloring of the bottom phase that most of the catalyst was dissolved in the aqueous phase. Into the two-phase system of water and organic solvent (initial ratio = 1:2), a solution of the diazoacetate **5** was slowly added under vigorous stirring to give the desired cyclopropanes **6** in moderate yields with higher enantioselectivity (88% for **6t**, runs 3 and 4). The

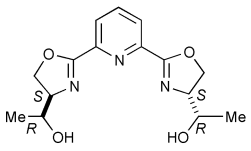
[a] The reaction scale and procedures were the same as those described in Table 1. [b] Absolute configuration: **6t** for all runs, (1*S*,2*S*); **6c** for run 2 and 6, (1*R*,2*S*); **6c** for runs 1,3,4,5 and 7, (1*S*,2*R*). [c] At 30 °C. The cyclopropanation did not proceed at 20 °C. [d] In place of (+)-menthyl diazoacetate, (−)-menthyl ester **5b** was used.

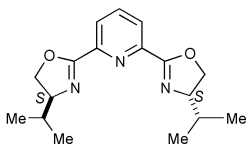
organic layer was extracted with degassed (or absolute) diethyl ether and concentrated to give the products. As the active species remained in the aqueous phase, the second run was carried out by addition of styrene and diazoacetate to give a similar result (run 5). We are now further investigating the optimization and multi-time reuse of the catalyst.

In this aqueous system, addition of phase-transfer reagents such as $(n\text{-Bu}_4N)(HSO_4)$ (10 mol% of **5a**) into the system of run 4 resulted in no improvement upon the reaction and the selectivities. On the other hand, when alcohols such as ethanol, isopropyl alcohol, and *tert*-butyl alcohol in place of water were adopted to provide a homogeneous protic media, isopropyl alcohol resulted in the best enantioselectivities, up to 96% ee for *trans*-**6t** and 88% ee for *cis*-**6c** at 30 °C (Table 2, run 4). (−)-Menthyl diazoacetate **5b** showed a decrease of ee to 90% for *trans*-product (run 5), because of the unmatched steric pair toward *R*,*R*-absolute configuration of the ligand. Single use of isopropyl alcohol gave moderate ees (run 7). We have thus found that the choice of alcoholic solvents apparently influences the enantioselectivity. However, at present we cannot define the origin of the stereochemical outcomes for protic solvents.

We next intended stereochemical tuning of the hydroxymethyl group of **1** using *hydroxyethyl*-pybox **7** [*he*-pybox] synthesized from (−)-threonine (Scheme 2).† However, in aqueous biphasic media, toluene–H_2O, the enantioselectivities with ruthenium–**7** catalyst were not increased by using (−)-menthyl diazoacetate at 40 °C: 80% ee for *trans* and 50% ee for *cis*, in 96:4 *trans*:*cis* ratio (75% yield). In toluene–*i*-PrOH the enantioselectivities increased to 91% for *trans* and 78% ee for *cis*, in 94:6 *trans*:*cis* ratio (78% yield). In comparison, classic *ip*-pybox **8** with similar bulkiness to **7** was



7



8

found in toluene–*i*-PrOH media to give 93% ee for *trans* and 90% ee for *cis*, in 97:3 *trans*:*cis* ratio (84% yield). *He*-pybox **7** thus proved to be inferior to *iso*-pybox **8**.

In conclusion, the hydroxymethyl derivative of pybox can provide excellent stereoselectivities for cyclopropanation of styrene, compared to the hydroxyethyl or isopropyl derivatives, in moderate yields in aqueous and protic media. We hypothesize that appropriate solvation of water or alcohols around the hydroxy group causes a more favourable stereochemical environment around the active site for the cyclopropanation. Work is now under way to investgate the mechanism of reaction and on applications to other catalytic reactions performed in aqueous media.

First published as an Advance Article on the web 15th December 2000

The reaction of 2 equivalents of 1,3-dimesitylimidazolium chloride with Cp_3Yb affords the salt [bis(1,3-dimesitylimidazolium)cyclopentadienide] [bis(cyclopentadienyl)dichloroytterbate]; the T-stacked cation is composed of two imidazolium fragments that are C–H···C(π) hydrogen bonded to the bridging cyclopentadienide anion.

N-Heterocylic carbene transition-metal complexes have been the subject of intense study in recent years.[1] Öfele,[2] and more recently Tilset and coworkers,[3] and our group[4] have demonstrated the utility of imidazolium salts for the preparation of transition-metal (TM) carbene complexes *via* protonolysis of Cp–TM and other suitable ligand-TM bonds. Encouraged by the fact that *N*-heterocyclic carbene complexes of the type Cp'_2M-(carbene) (M = Sm, Yb; Cp′ = $EtMe_4C_5$) have been prepared by traditional methods,[5] we were prompted to seek a new route to such compounds by treatment of lanthanocenes with imidazolium salts. However, the outcome of one of these experiments was unexpected and resulted in the formation of a remarkably persistent T-stacked cation. There is considerable current interest in such X–H···π systems, not only from the structural and theoretical standpoints, but also because of the recognition of this type of interaction in peptide and protein structures[6] and supramolecular architectures.[7] Furthermore, the reactivity patterns of imidazolium salts are of interest because of their use as ionic liquids.[8]

The reaction of 2 equivalents of 1,3-dimesitylimidazolium chloride (ImidCl) with Cp_3Yb in refluxing tetrahydrofuran afforded the golden-orange salt [bis(1,3-dimesitylimidazolium)(μ-cyclopentadienide)][bis(cyclopentadienyl)dichloroytterbate], $[Imid_2Cp][Cp_2YbCl_2]$, upon recrystallisation from toluene.[9] Although the spectroscopic data were consistent with the proposed formulation, unambiguous identification of the structure of the salt required an X-ray crystallographic experiment.‡ The most remarkable structural feature is the unprecedented geometry of the complex cation, $[Imid_2Cp]^+$ (**1**$^+$) which can be regarded as two "interlocked" cationic 1,3-dimesitylimidazolium fragments encapsulating a cyclopentadienide anion (Fig. 1). Interestingly, the "glue" that binds this cation together appears to be two C–H···C(π Cp) hydrogen bonds complemented by interionic attractions. The confined cyclopentadienide anion, which is slightly disordered, has an average C–C bond distance of 1.341(10) Å and an average C–C–C bond angle of 108.0(6)°. Both values are close to those reported for a typical "free" $[C_5H_5]^-$ anion.[10] Likewise, the metrical parameters for the 1,3-dimesitylimidazolium moieties are virtually identical to those reported for 1,3-dimesitylimidazolium chloride.[11] The only significant difference is the slight shortening of the C(1)–H bond in **1**$^+$ [0.819(9) *vs.* 0.944(9) Å for ImidCl] which is an expected consequence of the weaker C–H···Cp hydrogen bond (*vs.* C–H···Cl). The C–X (X is the Cp ring centroid) distance is 3.086(8) Å which is significantly shorter than the 3.85 Å distance in *e.g.* the neutral T-stacked 4-methylpyridine hexamer.[7] Likewise, the H···X distance is 2.295(9) Å and lies at the short end of the range of C–H···Cp contacts reported recently by Harder for ammonium and phosphonium cyclopentadienide salts (2.30–2.63 Å).[12] The C–H–X and H–X–H angles are 162.4(5) and 167.9(5)°, respectively. The average H–C(Cp) distance ($< d >$ = 2.561 Å) and the average C(1)–H–C(Cp) angle ($< \psi >$ = 150.9°) yield a relatively high value of 341 for each of the hydrogen bonds using Harder's C–H···Cp hydrogen bonding scale.[13] Somewhat surprisingly, the two 1,3-dimesitylimidazolium moieties are not mutually orthogonal but are arranged at an angle of 70° with respect to each other. This structural feature is most likely a consequence of crystal packing effects. For example, there is a somewhat close interaction of H(3) with Cl(1) on an adjacent $[Cp_2YbCl_2]^-$ anion (2.662 Å) as shown in Fig. 2. Although the structure of

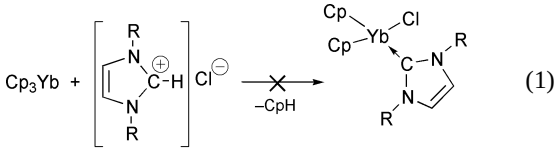
† Electronic supplementary information (ESI) available: DFT calculations. See http://www.rsc.org/suppdata/cc/b0/b005450j/

DOI: 10.1039/b005450j

$[Cp_2YbCl_2]^-$ has not been reported previously, the metrical parameters are unexceptional and are not commented on here.

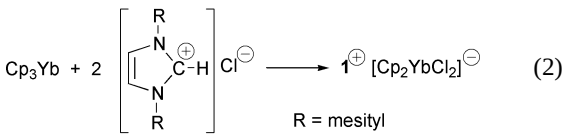
Interestingly, the complex cation persists in toluene solution. Unfortunately, **1**$[Cp_2YbCl_2]$ is virtually insoluble in aromatic solvents after initial crystallisation and decomposes rapidly in coordinating solvents hence ^{13}C NMR experiments were not informative. However, it was possible to demonstrate the persistence of $\mathbf{1}^+$ by means of an electrospray ionization (ESI) mass spectrum of a saturated toluene solution of **1**$[Cp_2YbCl_2]$ which exhibited an envelope with the anticipated isotopic intensity distribution in the region of *m/z* 674–678. This experiment confirmed the presence of $\mathbf{1}^+$ in solution and revealed that the only other major peak in the positive mode corresponds to the 1,3-dimesitylimidazolium cation. As expected, electron impact (EI) and chemical ionization (CI) mass spectra of solid samples of **1**$[Cp_2YbCl_2]$ did not evidence significant peaks attributable to $\mathbf{1}^+$, presumably because the high energy required to volatilize the solid exceeds the weak binding interactions of the complex cation.

The reaction clearly proceeds differently than had been expected and, although the mechanism remains unclear, some insight into the process can be gleaned from the nature of the products. Instead of protolytic cleavage of a Cp ligand and formation of CpH [eqn. (1)], Cp_3Yb can be regarded as



(1)

undergoing nucleophilic attack by two chloride anions to eliminate a Cp^- anion which, in turn, associates with two imidazolium cations to form **1**$[Cp_2YbCl_2]$ [eqn. (2)]. Such



(2)

imidazolium salt reactivity may offer additional insights into the solution structure and catalytic behavior of imidazolium-based ionic liquids.[8]

Interestingly, density functional theory (DFT) calculations (see ESI for details†) indicate that the reaction of Cp^- with a model imidazolium cation (R = Me) is highly exothermic (91.4 kcal mol^{-1}). However, we have not yet calculated the activation energy for such a process; moreover, no account has been taken of solvent effects. Single-point DFT calculations on a model system (R = Ph) predict the bond energy of the imidazolium–Cp interaction to be 31.4 kcal mol^{-1}. As such, this interaction is of a similar magnitude to H···O–R hydrogen bonding and represents the strongest C–H···C(π) bond yet reported.

In conclusion, the formation and persistence of the T-stacked cation $\mathbf{1}^+$ stems both from electrostatic attractions and also from the appreciable acidity of the imidazolium protons which facilitates rather strong C–H···Cp (π) hydrogen bonding. In a sense, $\mathbf{1}^+$ can be regarded as an organic analogue of an "inverse sandwich" complex.

We are grateful to the National Science Foundation, the Robert A. Welch Foundation, the Natural Sciences and Engineering Research Council (Canada) and Acadia University for financial support. We would also like to thank the Atlantic Region Magnetic Resonance Center (Dalhousie University) for the acquisition of some NMR spectra.

Notes and references

‡ *Crystal data* for **1**$[Cp_2YbCl_2]$. Formula (half of each cation and anion in the asymmetric unit): $C_{28.5}H_{32.5}Cl_1N_2Yb_{0.5}$, M_w = 525.04, orange blocks, orthorhombic, space group *Pnma*, a = 16.785(4), b = 19.727(6), c = 15.847(3) Å, V = 5247(2) Å^3, Z = 8, D_c = 1.329 g cm^{-3}, μ(Mo-Kα) = 1.923 mm^{-1}. A single crystal of **1**$[Cp_2YbCl_2]$ was covered with perfluoro(poly)ether and mounted on a Nonius KAPPA CCD diffractometer at 153(2) K. A total of 29 722 reflections were collected in the range of 2.39 < θ < 29.12° using Mo-Kα radiation (λ = 0.71073 Å). Of these, 7037 independent reflections (R_{int} = 0.0859) were used to solve (direct methods, SHELXS) and refine (full matrix, least squares on F^2, SHELXL) the structure of **1**$[Cp_2YbCl_2]$; $wR2$ = 0.0664, R = 0.0403. Note: all hydrogen atoms except those on the encapsulated Cp ring were found in the Fourier difference maps; those on the said Cp ring were placed in calculated positions. CCDC 182/1848. ***N*-Bound α-cyanocarbanion complexes $Ru^+Cp(NCCH^-R^1)(PPh_3)_2$ 1 react with electron deficient olefins to afford the conjugate adduct $Ru^+Cp(NCC^-R^1CHR^2CR^3R^4)(PPh_3)_2$ 2, kinetic studies of which revealed that complex 1-catalyzed Michael reactions of nitriles proceed *via* transformation of 1 to 2 and subsequent ligand exchange with nitriles.**

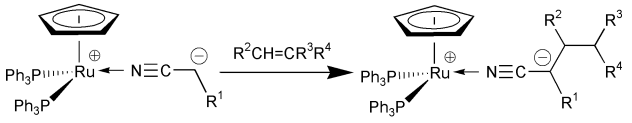
Transition metal α-cyanocarbanions have attracted much attention as active species for stoichiometric[1] and catalytic[2,3] carbon–carbon bond formations of nitriles, and studies on their structure and reactivity[4,5] are particularly of importance to develop novel transformations of nitriles bearing high selectivities, atom efficiency and sustainability.[6] In 1989 we presented a new methodology for catalytic carbon–carbon bond formation of nitriles initiated by α-C–H activation of nitriles with low-valent transition metal catalysts.[2a] Capture of the α-cyanocarbanion intermediate with electrophiles provides a family of catalytic C–C bond formations at the α-position of nitriles under neutral conditions.[2] *N*-Bound α-cyanocarbanion complexes, *mer*-$Ru^+H(NCCH^-CO_2R)(NCCH_2CO_2R)(PPh_3)_3$, derived by α-C–H activation of alkyl cyanoacetates with $RuH_2(PPh_3)_4$, have proven to be reactive species and active catalysts for the $RuH_2(PPh_3)_4$-catalyzed aldol and Michael reactions of nitriles.[2b,7] Further studies revealed that a variety of *N*-bound transition metal α-cyanocarbanion complexes act as efficient catalysts for the aldol and Michael reactions of nitriles.[8]

One of the most important aspects of this chemistry is to clarify and control the C–C bond forming process on the α-cyanocarbanion intermediates. Direct nucleophilic attack of zwitterionic *N*-bound α-cyanocarbanions to carbon electrophiles has been postulated for the crucial step in these catalytic aldol and Michael reactions.[2b,3b,7,8] Isomerization to *C*-bound α-cyanocarbanions[5] and subsequent carbometallation[1] are alternative possibilities for this process; however, precise mechanistic information on this step still remains to be explored. During the course of our systematic studies on the structure and reactivity of transition metal α-cyanocarbanions[5] we have succeeded in the isolation of intermediate for catalytic Michael reactions of nitriles. We describe here the conjugate addition of *N*-bound α-cyanocarbanions, $Ru^+Cp(NCCH^-R)(PPh_3)_2$ **1** to electron deficient olefins, and mechanism of the catalytic Michael reactions of nitriles.[9]

When a 25.0 mM solution of *N*-bound α-cyanocarbanion $Ru^+Cp(NCCH^-SO_2Ph)(PPh_3)_2$[5] **1a** in benzene was allowed to react with dimethyl ethylidenemalonate (1.0 equiv.) at room temperature under argon atmosphere, conjugate addition and subsequent 1,3-hydrogen shift occurred to give the corresponding *N*-bound α-cyanocarbanion $Ru^+Cp[NCC^-(SO_2Ph)CHMeCH(CO_2Me)_2](PPh_3)_2$ **2a** in 99% isolated yield. Complex **2a** was characterized by ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ NMR, IR, mass spectra and elemental analysis.§ Characteristic downfield shifts of the IR absorption (2153 cm^{-1}) and ^{13}C NMR signal (δ 143.7) of the cyano group indicate that the α-cyanocarbanion is *N*-bound,¶ and the zwitterionic structure has been unequivocally established by a ^1H–^{13}C HMBC experiment.‖ Similar treatment of cyanoacetate and ketonitrile analogs **1b** (R^1 = CO_2Et)[8d] and **1c** (R^1 = $COBu^t$) gave the corresponding adducts **2b**, **c** in 98 and 98% isolated yields. Various electron deficient olefins such as dimethyl benzylidenemalonate, benzylidenemalononitrile, pent-3-en-2-one, and acrylonitrile reacted smoothly with **1a** at room temperature to afford **2d**–**g** in 98, 99, 31 and 36% yields, respectively.



1 **2**

a: R^1 = SO_2Ph, R^2 = Me, R^3 = R^4 = CO_2Me
b: R^1 = CO_2Et, R^2 = Me, R^3 = R^4 = CO_2Me
c: R^1 = $COBu^t$, R^2 = Me, R^3 = R^4 = CO_2Me
d: R^1 = SO_2Ph, R^2 = Ph, R^3 = R^4 = CO_2Me
e: R^1 = SO_2Ph, R^2 = Ph, R^3 = R^4 = CN
f: R^1 = SO_2Ph, R^2 = Me, R^3 = COMe, R^4 = H
g: R^1 = SO_2Ph, R^2 = H, R^3 = CN, R^4 = H

As well as complex **1**,[8d] complex **2** shows comparable catalytic activity for the Michael additions of nitriles. Typically, the reaction of (phenylsulfonyl)acetonitrile **4** (4.00 M) with dimethyl benzylidenemalonate **3** (4.40 M) in the presence of **1a** or **2d** catalyst (0.120 M) in THF at 25 °C for 24 h gave adduct **5** in 86 and 88% isolated yields, respectively. In order to obtain insight into the mechanism of the complex **1**-catalyzed Michael addition of nitriles, kinetic studies on the reaction of **1a** with an excess amount of **3** in THF-d_8 were carried out by means of ^1H NMR (500 MHz) analysis using an internal standard (bibenzyl). The consumption rate of **1a** exhibited clean pseudo-first-order dependence on the concentration of **1a** (k_{obs} = 6.61 ± 0.04 × 10^{-4} s^{-1} at 25.0 °C, $[\mathbf{1a}]_0$ = 2.00 × 10^{-2} M, $[\mathbf{3}]_0$ = 2.00 × 10^{-1} M), and the k_{obs} values showed linear dependence on the initial concentration of **3** ranging from 2.00 to 4.00 × 10^{-1} M, indicating the second-order rate constant k_1 as 2.9 ± 0.1 × 10^{-3} dm^3 mol^{-1} s^{-1} at 25.0 °C. Dependences of k_{obs} *vs.* $[\mathbf{3}]_0$ at 25.0–45.0 °C are shown in Fig. 1. The rate data correlate well (R^2 = 0.990) with the Arrhenius relationship of ln(k_1) *vs.* 1/*T*, where the $\Delta H^‡$ and $\Delta S^‡$ values were determined as 41 ± 3 kJ mol^{-1} and −148 ± 8 J mol^{-1} K^{-1}, respectively. The second-order kinetics and the large negative value of $\Delta S^‡$ clearly indicate that the conjugate addition of **1a** to **3** proceeds *via* a direct ionic pathway without any contact of olefins with the metal center. $Ru^+Cp[NCCH(SO_2Ph)CHMeC^-(CO_2Me)_2](PPh_3)_2$ could not be detected during ^1H NMR experiments, indicating that the process involves a fast 1,3-hydrogen shift after the conjugate addition. When complex **2d** was allowed to react with nitrile **4** at room temperature in THF-d_8,

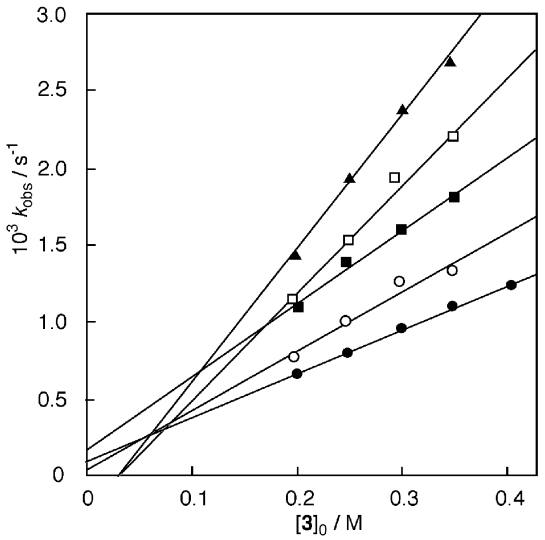

Fig. 1 Dependence of k_{obs} *vs.* $[\mathbf{3}]_0$ for the reactions of **1a** with **3** in THF-d_8 at 25.0 °C (●), 30.0 °C (○) 35.0 °C (■), 40.0 °C (□) and 45.0 °C (▲).

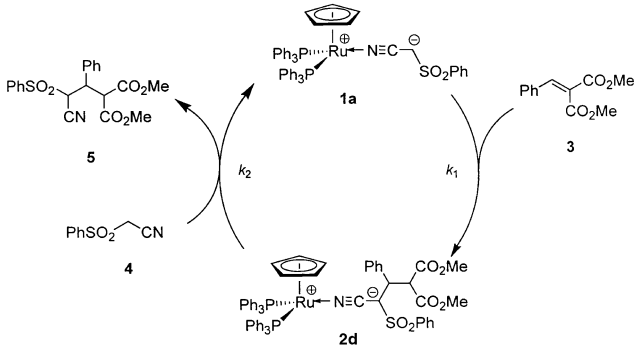
dissociation of Michael adduct **5** and regeneration of complex **1a** can be monitored by ^{1}H NMR spectroscopy. The consumption rate of **2d** was first-order on the concentration of **2d** ($[\mathbf{2d}]_0 = 2.00 \times 10^{-2}$ M, $[\mathbf{4}]_0 = 2.00 \times 10^{-1}$ M) and independent on the concentration of **4** ($[\mathbf{4}]_0 = 2.00$–3.50×10^{-1} M). The first-order rate constant k_2 was determined to be $7.3 \pm 0.3 \times 10^{-6}$ s^{-1} at 25.0 °C. The observed first-order kinetics on the ligand exchange process is ascribed to rate-determining formation of the 16-electron complex $[RuCp(PPh_3)_2]^+$ which would be followed by fast rebound process of the carbanion of **4** from outer sphere of the metal.

The complex **1a**-catalyzed Michael reaction of nitrile **4** with olefin **3** can be rationalized by the mechanism shown in Scheme 1. Direct ionic addition of **1a** to **3** and a subsequent 1,3-hydrogen shift affords complex **2d**, which undergoes a rate determining process of ligand exchange with **4** to form adduct **5** and regenerate catalyst **1a**. In order to verify this mechanism, kinetics on the overall catalytic Michael reaction of **4** with **3** were carried out at 25.0 °C in THF-d_8 using the same NMR technique. The initial rate of the formation of **5** was constant ($d[\mathbf{5}]/dt = k_{obs} = 1.44 \pm 0.03 \times 10^{-7}$ dm^3 mol^{-1} s^{-1}), when the reaction was started at an initial concentration of $[\mathbf{1a}]_0 = 2.00 \times 10^{-2}$ M, $[\mathbf{3}]_0 = 2.00 \times 10^{-1}$ M and $[\mathbf{4}]_0 = 2.00 \times 10^{-1}$ M. Almost the same k_{obs} value of $1.49 \pm 0.03 \times 10^{-7}$ dm^3 mol^{-1} s^{-1} was obtained when complex **2d** was employed as the catalyst ($[\mathbf{2d}]_0 = 2.00 \times 10^{-2}$ M). These rate constants are first-order on the concentration of catalyst **1a** or **2d**, and zero-order on the concentration of both nitrile **4** and olefin **3**. Thus, the rate law for the catalytic reaction can be expressed as $d[\mathbf{5}]/dt = k_3[\mathrm{Ru}]$ ($[\mathrm{Ru}] = [\mathbf{1a}]_0 = [\mathbf{2d}]_0 = [\mathbf{1a}] + [\mathbf{2d}]$), which leads to the relation $k_3 = k_{obs}/[\mathrm{Ru}]$. The calculated k_3 value of $7.7 \pm 0.9 \times 10^{-6}$ s^{-1} (25.0 °C) is well in accord with that of k_2; the rate constant of rate-determining step of the proposed catalytic cycle.



Scheme 1

In summary, we have identified the active species of the catalytic Michael reactions of nitriles, and presented a definitive mechanism for the reactions. This is a rare case because most reported mechanistic investigations for catalytic Michael reactions of nitriles deal mainly with substrate and product analysis while speculating on the crucial step of carbon–carbon bond formation. Efforts are currently underway to investigate more fully the dynamic behavior of transition metal α-cyanocarbanion intermediates in a variety of carbon–carbon bond forming processes of nitriles.

Ruthenium-catalysed oxidation of alkanes with peracetic acid in trifluoroacetic acid: ruthenium as an efficient catalyst for the oxidation of unactivated C–H bonds

Naruyoshi Komiya, Satoru Noji and Shun-Ichi Murahashi*

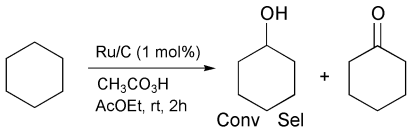
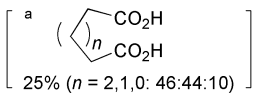
Received (in Cambridge, UK) 22nd August 2000, Accepted 3rd November 2000
First published as an Advance Article on the web 14th December 2000

The role of ruthenium catalysts for the oxidation of alkanes with peracetic acid in trifluoroacetic acid has been confirmed.

During the course of simulation of the functions of cytochrome P-450 enzyme with transition metal complexes, we have found that transition metal-catalysed oxidations of various substrates can be performed highly efficiently.[1] In 1994 we reported that ruthenium-catalysed oxidation of alkanes with peracetic acid in ethyl acetate gives the corresponding ketones and alcohols.[2] Furthermore, the $RuCl_3$-catalysed oxidation of cyclohexane in TFA proceeds highly efficiently to give cyclohexyl trifluoroacetate and cyclohexanone with high conversion and high selectivity.[2] Recently, Moody and O'Connell reported that the oxidation of cyclohexane using urea hydrogen peroxide (UHP) in TFA without a metal catalyst gives cyclohexyl trifluoroacetate,[3] which was originally reported by Deno *et al.*[4] They obtained the rate constants ($k = 3.3 \times 10^{-5}$ M^{-1} s^{-1}) for the oxidation of cyclohexane with UHP in TFA in the presence or absence of $RuCl_3$ catalyst, indicating that the system is not ruthenium dependent. They claimed our system (peracetic acid–Ru) is not ruthenium dependent. However, our system using peracetic acid is quite different from that of UHP oxidation. Here, we describe our ruthenium-catalysed oxidation of alkanes with peracetic acid, which is very fast and an efficient ruthenium dependent reaction. The kinetics show the rate is 10^5 times faster than previously reported.

As described in our previous paper,[2] the oxidation of cyclohexane with peracetic acid in the presence of ruthenium on charcoal (Ru/C) or $RuCl_3$ (1 mol%) catalyst in ethyl acetate gives cyclohexanone along with a small amount of cyclohexanol [eqn. (1)]. No oxidation takes place without a catalyst.

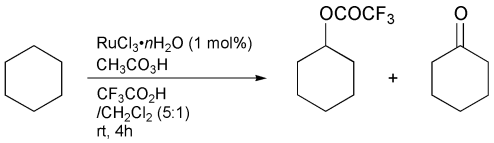




(1)

Treatment of cyclohexane with 0.5 eq. of peracetic acid proceeds in the presence of Ru/C catalyst to give cyclohexanol and cyclohexanone (4:93) with 97% selectivity (conv. 8%). In contrast, treatment of cyclohexane with 3 eq. of peracetic acid afforded cyclohexanol and cyclohexanone (2:68) with 70% selectivity along with dicarboxylic acids (adipic acid–glutaric acid–succinic acid = 46:44:10), which are derived from the oxidation of cyclohexane-1,2- and -1,3-diones under the reaction conditions, with 25% selectivity (conv. 51%). Peracetic acid is quite effective for the ruthenium-catalysed oxidation of alkanes, while hydrogen peroxide does not give any oxidation product because of the decomposition of hydrogen peroxide to give O_2 and H_2O by the contact with $RuCl_3$, indicating that peracetic acid is clearly different from hydrogen peroxide in the present non-TFA system.

In order to generate more active oxo-metal species which may lead to high conversion and high selectivity for the oxidation of alkanes,[5–7] we used TFA. As described in our previous paper,[2] the $RuCl_3$-catalysed oxidation of cyclohexane with peracetic acid in a mixture of TFA and CH_2Cl_2 (5:1) for 4 h gave cyclohexyl trifluoroacetate and cyclohexanone with 90% selectivity (85:15) and 90% conversion [eqn. (2)]. However,



(2)

the same reaction in the absence of $RuCl_3$ for 24 h gave cyclohexyl trifluoroacetate only in $< 3\%$ yield.

The present catalytic oxidation can be applied to a variety of alkanes. The representative results of the ruthenium-catalysed oxidation of alkanes with peracetic acid in a mixture of TFA and CH_2Cl_2 are shown in Table 1. Both linear and cyclic alkanes can be converted into the corresponding esters of trifluoroacetic acid along with ketones. The reaction of adamantane gave adamantan-1-ol, which was formed by hydrolysis of 1-adamantyl trifluoroacetate.

Kinetic experiments on the reaction of cyclohexane with peracetic acid in TFA were carried out. In the presence of a large excess of cyclohexane, the rate was first-order with respect to

Table 1 Ruthenium-catalysed oxidation of alkanes with peracetic acid in TFA[a]

Alkane	Conversion[b] (%)	Product	Yield[c] (%)
Cyclohexane	90	Cyclohexyl trifluoroacetate	77
		Cyclohexanone	13
Cyclooctane	81	Cyclooctyl trifluoroacetate	40
		Cyclooctanone	10
Adamantane[d]	70	Adamantan-1-ol[e]	89
		2-Adamantyl trifluoroacetate	9
Norbornane[f]	90[g]	*exo*-2-Norbornyl trifluoroacetate	61
Hexane	nd	Hexyl trifluoroacetates[h]	24[b]
		Hexanones[i]	6[b]

[a] To a mixture of alkane (2.5 mmol), $RuCl_3$ (0.025 mmol), TFA (5 mL) and CH_2Cl_2 (1 mL) was added dropwise a 30% peracetic acid (5.0 mmol) solution in ethyl acetate over a period of 2 h. After stirring for 2 h, the reaction was quenched by adding 5% aqueous sodium sulfite solution. [b] Determined by GC based on the starting alkane using an internal standard (acetophenone). [c] Determined by GC based on the converted alkane. [d] TFA (5 mL), CH_2Cl_2 (10 mL) and acetic acid (5 mL) were used as a solvent. [e] 1-Adamantyl trifluoroacetate was readily hydrolyzed to give adamantan-1-ol during the work up. [f] The IUPAC name for norbornane is bicyclo-[2.2.1]heptane. [g] Not determined. [h] 2-:3-Hexyl trifluoroacetate = 45:55. [i] 2-:3-One = 34:66.

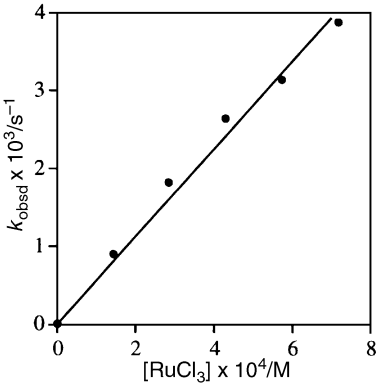

Fig. 2 Dependence of the first-order rate constants k_{obsd} on the concentration of $RuCl_3$. Solvent, TFA–CH_2Cl_2–AcOEt = 5:1:1; [CH_3CO_3H] = 1.4×10^{-2} M; [cyclohexane] = 3.6×10^{-2} M; 20 °C.

the concentration of peracetic acid (Fig. 1). The first-order rate constant increased with an increase in the concentration of $RuCl_3$ (Fig. 2), but the rate constant was independent of the concentration of cyclohexane. The rate law for the ruthenium-catalysed oxidation of cyclohexane with peracetic acid in TFA and CH_2Cl_2 was expressed by the equation $(-d[\text{cyclohexane}]/dt = k[RuCl_3][CH_3CO_3H])$. The second-order rate constant was determined to be $k = 5.4\ M^{-1}\ s^{-1}$. In contrast, the rate constant for the oxidation of cyclohexane without a metal catalyst is very small ($k < 10^{-6}\ s^{-1}$). These results clearly show that the oxidation of cyclohexane is catalysed by $RuCl_3$ catalyst dramatically.

Intermolecular deuterium isotope effect (k_H/k_D) of the ruthenium-catalysed oxidation of cyclohexane–cyclohexane-d_{12} in TFA was determined to be 2.9, which is smaller than the value (6.8) obtained from the same oxidation in ethyl acetate, indicating that a more reactive species is involved in the oxidation in TFA. The oxidation can be rationalized by assuming the mechanism which involves oxo-ruthenium species. The reaction of L_nRu^{III} with peracetic acid would give $L_nRu^{III}OOC(O)CH_3$ which undergoes heterolytic cleavage[8] to give the L_nRu^{V}=O species. Hydrogen abstraction with the oxo-ruthenium species and recombination would give an alcohol. Under the reaction conditions, an alcohol can be converted into either the corresponding trifluoroacetate or ketone. Actually, control experiments show that cyclohexanol is readily converted to a mixture of cyclohexyl trifluoroacetate and cyclohexanone under the reaction conditions.[9] The ruthenium-catalysed oxidation with peracetic acid is quite different from the oxidation with hydrogen peroxide in TFA, where electrophilic reaction of perfluoroacetic acid is involved. It is noteworthy that cyclohexanone has never been obtained from the reaction of H_2O_2–TFA.[3,4]

In summary, the oxidation of alkanes with peracetic acid in TFA proceeds efficiently in the presence of ruthenium catalyst to give the corresponding trifluoroacetic acid ester.

Received (in Cambridge, UK) 10th October 2000, Accepted 17th November 2000
First published as an Advance Article on the web 14th December 2000

A novel microporous solid acid, the phosphonic acid modified polysilsesquioxane $[(HO)SiCH_2CHPO(OH)_2\text{-}CH_2CH_2SiO_2(OH)]_n$ P2, from the new single precursor compound $[(EtO)_3SiCH_2CHPO(OCH_2CH_3)_2CH_2CH_2\text{-}Si(OEt)_3]$ 1, is reported, along with the catalytic activity of P2 for the pinacol–pinacolone rearrangement.

The development of functionalised porous silicas[1a,b] and polysilsesquioxane materials[1c,d] for various applications is proceeding at great pace as evidenced by recent reviews and reports on synthesis and applications in this area. Functional groups or their precursors may be attached to silica *via* compounds $(RO)_3Si(CH_2)_nX$ where X may be further modified if required. Such materials offer a wide spectrum of potential applications for example as acid, base, or oxidation catalysts or asymmetric carbon–carbon coupling catalysts, or as biocompatible surface groups.[1a,b,2] In the context of the present report efforts are also being directed towards the synthesis of functionalised porous polysilsesquioxanes, where the functional group is an integral part of a single framework precursor. Examples include polysilsesquioxanes with built-in NLO and luminescence chromophores,[3a,b] built-in crown-ether[4] or cyclam[5] groups for ion sensing applications or ferrocenyl groups for electrochemical applications.[6]

It occurred to us that phosphonic acid functionalised silicas and polysilsesquioxanes might offer a new class of solid acid materials with wide-ranging potential to act as catalysts, ion exchange and separation materials. There were no examples of such materials previously reported in the literature.

We report here on unique examples of the uniformly modified phosphonate and phosphonic acid polysilsesquioxanes $[(HO)SiCH_2CHPO(OCH_2CH_3)_2CH_2CH_2SiO_2(OH)]_n$ **P1** and $[(HO)SiCH_2CHPO(OH)_2CH_2CH_2SiO_2(OH)]$ **P2** prepared from the new precursor compound $[(EtO)_3SiCH_2CH\text{-}PO(OCH_2CH_3)_2CH_2CH_2Si(OEt)_3]$, **1**, 1,4-bis(triethoxysilyl)-2-(diethylphosphonato)butane. Compound **1** was formed‡ as shown in eqn. (1) by radical addition of $HPO(OEt)_2$ to the *ene* fragment in 1,4-bis(triethoxysilyl)but-2-ene[7] and was fully characterised by solution phase NMR, mass spectrometry and elemental analysis.

$$HPO(OEt)_2 + [(EtO)_3SiCH_2CH{=}CHCH_2Si(OEt)_2] \xrightarrow{Bu^tOOBu^t} [(EtO)_3SiCH_2CHPO(OCH_2CH_3)_2CH_2CH_2Si(OEt)_3] \quad (1)$$

1

P1 was obtained as a transparent monolith after acid-catalysed sol–gel processing of **1** in THF.§ The solid state ^{13}C CP MAS NMR spectrum of **P1** had peaks close to those observed for compound **1**; the ^{29}Si spectrum showed one broad resonance at −63 ppm consistent with predominantly T^2 type silicon sites while the ^{31}P NMR showed a single peak at 35 ppm similar to that of **1**. Treatment of **P1** with concentrated hydrochloric acid gave the corresponding phosphonic acid modified material **P2**.¶ The absence of any Q^n type resonances in the ^{29}Si CP MAS NMR of **P2** indicates that the transformation from ester to acid occurred without any Si–C cleavage. The decrease in C : P ratio and changes in the NMR spectra from **P1** to **P2** (in particular the disappearance of the signals due to the phosphonate ester group $-PO(OCH_2CH_3)_2$ at 63 ppm, see Fig. 1), is consistent with the formation of the phosphonic acid from the ester. Average formulae for these materials derived from C : P ratios and based on predominantly T^2 environments (66% condensation) are $[(HO)SiCH_2CHPO(OEt)_2CH_2CH_2\text{-}SiO_2(OH)]_n$ **P1** and $[(HO)SiCH_2CHPO(OH)_2CH_2CH_2\text{-}SiO_2(OH)]_n$ **P2**.

The material **P2** was found to be microporous by nitrogen sorption porosimetry with very narrow pore size distribution.

It is our intention initially to utilise the phosphonic acid functionality in these and related materials we have prepared for various catalytic transformations. Preliminary experiments based on catalytic pinacol–pinacolone rearrangement and dehydration of cyclohexanol were used to test the reactivity of the phosphonic acid functionality in **P2**. A range of solid acid catalysts have been reported to catalyse pinacol–pinacolone rearrangements; examples include metal substituted aluminophosphates,[8] lanthanide substituted zeolites,[9] heteropolytungstates,[10] various SAPOs (silicoaluminophosphates)[11] and polyphosphoric acid.[12]

A reaction between **P2** (0.2 g) and pinacol (6.0 g) at 140 °C (no solvent) resulted in 80% conversion to pinacolone after 12 h. Control experiments‖ using mesoporous or microporous silicas under the same conditions afforded no rearranged product. Attempted dehydration reactions using **P2** (0.25 g) and cyclohexanol (25 cm^3) ($C_6H_{11}OH : PO(OH)_2$ = 60 : 1) at 120 °C resulted in about 15% conversion to cyclohexene (^1H NMR of the cooled reaction mixture) after 12 h. In control experiments using mesoporous or microporous silica under the same conditions no cyclohexene was produced. Industrial processes for production of cyclohexene require high temperature and pressure whereby cyclohexanol is fed to activated catalysts such as silica, alumina or zinc aluminate at 380–450 °C (see ref. 13 for example). Neat phosphoric acid used in large excess is also active between 160–170 °C. [14]

A detailed systematic study of both reaction types will be carried out to optimise the catalyst performance.

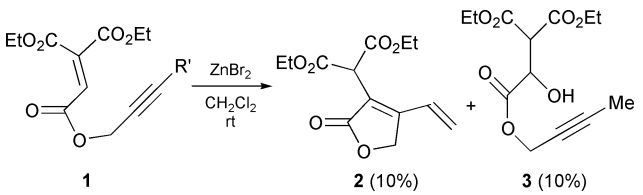
Received (in Cambridge, UK) 6th October 2000, Accepted 31st October 2000
First published as an Advance Article on the web 15th December 2000

A novel cycloisomerization reaction of enynes 4 in the presence of $ZnBr_2$ and THF (1 eq.) in CH_2Cl_2 at −40 °C gave *exo*-methylenic 1,3-dienes 5 in moderate to good yield.

Lewis acid-promoted reactions are an important part of modern synthetic chemistry.[1] Recently, prototropic cycloisomerization reactions of enynes and dienes have been recognized as atom-economic tools to construct rings, and transition metal-catalyzed cycloisomerizations in particular have received much attention.[2] However, only a few examples of Lewis acid-promoted cycloisomerizations (intramolecular ene reactions) have been reported so far.[3,4a,b]

The design of a Lewis acid-promoted enyne cyclization requires that a highly electrophilic alkene (or alkyne) has coordination sites for a Lewis acid and that the other component (alkyne or alkene) works as a nucleophile. Alkenes with three ester groups are considered to be highly electrophilic and very reactive towards nucleophilic olefins,[5] and they may react intramolecularly with alkynes which are relatively unreactive nucleophiles.[6]‡ We thus examined Lewis acid-promoted intramolecular cyclization of the designed triester-substituted alkene **1**. Reaction of **1** in the presence of $ZnBr_2$ at rt gave cyclized product **2** and H_2O-adduct **3** in 45% and 10% yields, respectively (eqn. (1)).



(1)

The formation of **2** can be explained as shown in Scheme 1.§ Nucleophilic attack of the alkyne moiety to the electrophilic olefin complexed with $ZnBr_2$ in **A** gives intermediate **B**.¶ A 1,3-hydride shift then leads to complex **C**, which isomerizes and then forms diene **2** with Et_3N. The formation of hydrated product **3** is presumed to result from attack by trace amounts of water on complex **A**.

If the isomerization step in **C** is prevented, *exo*-methylenic 1,3-dienes should be the primary products in this process. The enyne **4**, which is prevented from undergoing isomerization due to the lack of a proton, was designed and Lewis acid mediated reactions examined. After several conditions were examined (see below), reaction of **4** in the presence of $ZnBr_2$ (1.2 eq.) and THF (1 eq.) in CH_2Cl_2 at −40 °C for 17–19 h gave *exo*-methylenic 1,3-dienes **5** in 29–67% yields (eqn. (2), Table 1).‖ The γ-lactone structure of **5** was suggested by the presence of a characteristic C=O absorption (1771–1779 cm^{-1}). ^1H, ^{13}C, ^1H/^{13}C-HSQC, HMBC and NOESY spectra were in agreement with the lactone structure drawn in eqn. (2). The crystal structure of **5a** was elucidated by X-ray diffraction analysis (Fig. 1).** The diene is slightly twisted from the plane in order to reduce steric repulsion between the ester and HPhC= groups; the torsion angle of the diene moiety (∠C5-C3-C2-C12) is 21.9°. This *cisoid* diene may be effective as an acceptor in the inverse electron demand Diels–Alder reaction (see below).

Scheme 1

Table 1 Cycloisomerization of **4** to **5**

Substrate[a]	R^1	R^2	Ar	Product (yield)
4a	H	Et	Ph	**5a** (67%)
4b	H	Et	*p*-Tol	**5b** (58%)
4c	H	Et	*p*-MeO-C_6H_4	**5c** (41%)
4d	Me	Et	Ph	**5d** (53%)
4e	*n*-Propyl	Et	Ph	**5e** (46%) (**4e** recovered 36%)
4f	H	Me	Ph	**5f** (29%)
4g	H	^{i}Pr	Ph	**5g** (50%)[b]

[a] All reactions were carried out using 0.30–0.58 mmol of **4**, 1.2 eq. of $ZnBr_2$, and 1.0 eq. of THF at 0.41 M for **4** in CH_2Cl_2 at −40 °C for 17–19 h, unless otherwise noted. [b] THF was not added. Addition of THF gave **5g** in 40% yield along with recovered **4g** (24%).

† Electronic supplementary information (ESI) available: experimental procedures and spectral data for described compounds and crystallographic data for **5a**. See http://www.rsc.org/suppdata/cc/b0/b008103p/

DOI: 10.1039/b008103p

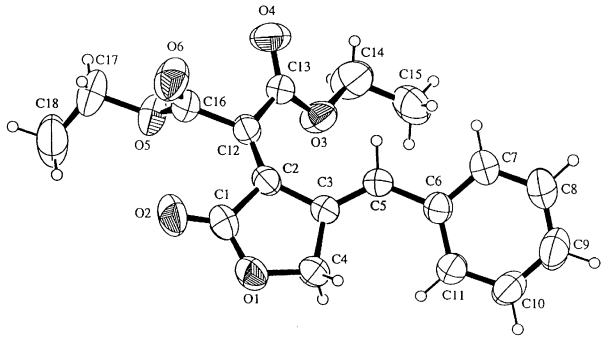


Fig. 1 ORTEP drawing of **5a** (50% probability ellipsoids). Selected bond lengths (Å) and torsion angle (°): C1–C2 = 1.499(3); C2–C3 = 1.460(2); C3–C4 = 1.501(2); C1–O1 = 1.344(2); O1–C4 = 1.444(2); C2–C12 = 1.345(2); C3–C5 = 1.344(2); ∠C5–C3-C2–C12 = 21.9(3). More detailed structure data are given in the supplementary data.

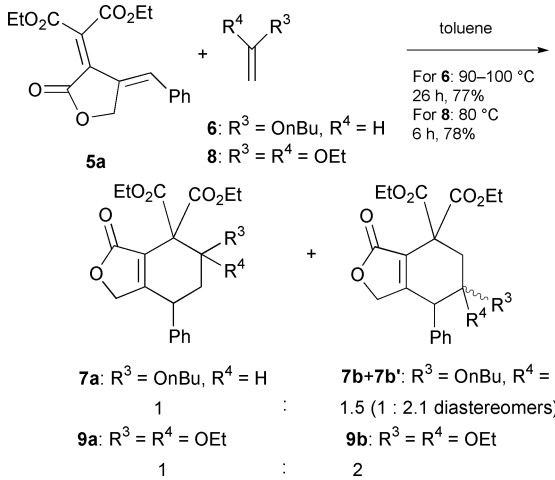
With **4a**,**b**, the yield of **5** decreased when THF was omitted from the reaction (for **5a** to 11–36%, for **5b** to 11–25%).†† The effect of THF is presumed to be that coordination of THF to Zn adjusts the strength of the Lewis acid and prevents side reactions.‡‡ For **4g**, the reaction without THF gave a slightly better yield (see Table 1).

Use of ZnI_2–THF instead of $ZnBr_2$–THF gave **5a** in 62% yield. Use of $SnCl_4$ (−78 °C) or $ZnCl_2$–THF (−40 °C) gave **5a** in lower yield (24–39% including inseparable complex mixtures). The reaction of **4a** with $ZnBr_2$–THF was also performed at a higher temperature (0 °C to rt), however, the yield of **5a** decreased (32%), probably because of the instability of the diene product. The reaction of **4a** using 0.3 eq. of $ZnBr_2$–THF afforded 19% of **5a** along with recovered **4a** (62%), therefore the reaction requires a stoichiometric amount of Lewis acid.§§

Thermal reactions of **4a** and **1** (CH_3CN, 80 °C, 24 h or toluene, 110 °C, 24 h) without Lewis acid only afforded complex mixtures along with recovered starting materials (38–87%). A $RuClH(CO)(PPh_3)_3$-catalyzed reaction (toluene, 110 °C, 7 h) of **4a** was examined but did not proceed.[8]

Only a few examples of synthesis of heterocycles by cycloisomerization using transition metal catalysts have been reported.[9] Therefore, the present method should provide an efficient alternative to transition metal-catalyzed cycloisomerizations. Also, the product cyclic dienes are electron-deficient and suitable for cycloadditions such as inverse electron demand Diels–Alder reaction[10] and transition metal-catalyzed [4 + 3] cycloadditions.[11] The inverse electron demand Diels–Alder reactions of **5a** with the electron rich dienophiles **6** and **8** were thus examined (eqn. (3)). C–C bond formation proceeds readily, however, the observed regio- and stereoselectivity was low.¶¶



(3)

In summary, a novel Lewis acid-promoted enyne cycloisomerization to give cyclic dienes has been developed. This new reaction provides a highly efficient means to prepare electron-deficient cyclic dienes. The application of this methodology towards the construction of carbocycles and diverse heterocycles is under investigation.

‡ Thermal ene reactions[6a,b] and $FeCl_3$-promoted chlorinated cyclizations[6c] of allylic and propargylic esters of ethylenetricarboxylic acid have been reported.

§ The alternative mechanism is that **1** undergoes an ene reaction initially to give a cyclic allene that rearranges to **2**.

¶ The coordination of a Lewis acid to a C≡C bond was reported recently.[12] The intermediate **A** (Scheme 1) can be drawn as shown above.

‖ Cyclizations were also examined using **10a**–**c** as substrates. Using similar conditions, only starting material was recovered.

** *Crystal data*: $C_{18}H_{18}O_6$, M = 330.34, monoclinic, a = 8.1206(3), b = 10.5914(3), c = 19.7984(7) Å, β = 100.513(1)°, V = 1674.2(1) Å^3, T = 296 K, space group $P2_1/c$ (no. 14), Z = 4, μ(Mo-Kα) = 0.099 mm^{-1}, number of reflections measured = 4062, number of independent reflections = 3845 (R_{int} = 0.025), R, R_w = 0.047, 0.052 for 2473 observed reflections ($I > 2\sigma(I)$). CCDC 182/1839. See http://www.rsc.org/suppdata/cc/b0/b008103p/ for crystallographic files in .cif format.

†† The reaction of **4a** in THF as a solvent did not proceed.

‡‡ Use of propylene oxide instead of THF in the reaction of **4a** gave **5a** in lower yield (28%), along with recovered **4a** (21%). The combination of Lewis acid and Lewis base is used in some Lewis acid-mediated reactions.[7]

§§ Formation of cyclic dienes is in marked contrast with the $FeCl_3$-promoted reaction of dimethyl ester analog of **1** and **4d** giving chlorinated cyclization products.[6c] Investigation of the difference in Lewis acids is underway.

¶¶ The stereochemistries of **7a**, **7b** and **7b′** were tentatively assigned as shown in the supplementary information by the observed NOE's.

First published as an Advance Article on the web 14th December 2000

The high-pressure rate coefficient for the formation of the new peroxide $FC(O)OO(O_2)SF$ from recombination of $FC(O)O$ and $FS(O_2)O$ radicals has been determined by laser flash photolysis at 296 K; density functional theory calculations indicate peroxide stabilization and allow estimation of an O–O bond dissociation energy of 20.6 ± 3 kcal mol^{-1}.

Early syntheses of fluorinated peroxides involved the coupling of oxy-radicals to form the peroxide bond.[1] In fact, the co-photolysis of the mixtures of peroxides SF_5OOSF_5/CF_3OOCF_3 and $SF_5OOSF_5/FS(O_2)OO(O_2)SF$ have been employed by Cady and coworkers to prepare SF_5OOCF_3 and $SF_5OO(O_2)SF$.[1] The fluorinated peroxides allow study of the role that the electron-withdrawing effect of electronegative groups plays on their reactivity, energetics and conformation. Here we report the determination of the rate coefficient for the recombination of $FC(O)O$ and $FS(O_2)O$ radicals to form the new peroxide $FC(O)OO(O_2)SF$ at 296 K. In addition, the rate coefficient for the reaction of $FS(O_2)O$ with CO has been determined for the first time.

A laser flash photolysis–absorption spectroscopy configuration described in detail elsewhere,[2–7] was employed in the present experiments. Typically, samples of 30–40 mbar of $FS(O_2)OF$ in the presence of 130–300 mbar of CO, 15 mbar of O_2 and up to 900 mbar of SF_6 were irradiated with the emission of an excimer laser operating on the 193 nm ArF transition. No more than 30 single shot experiments from fresh samples were averaged and analysed up to 5 ms for each set of conditions. In the photolysis, electronically excited $FS(O_2)O$ radicals in the B ^2E state are initially formed and afterwards collisionally deactivated to the X $^2A_2$ ground state *via* a manifold of low-lying vibrationally excited states.[4,5] After *ca.* 250 μs the excited radicals are thermalized.[5] On the other hand, photolytically generated F atoms are rapidly consumed by recombination with CO to form FCO radicals, which subsequently recombine with O_2 and yield $FC(O)O_2$ radicals. Finally, these radicals form $FC(O)O$ radicals by self-reaction. The whole reaction mechanism is detailed in refs. 6–9. FCO and $FC(O)O_2$ are almost quantitatively consumed at 200 μs. Thus, the well established mechanisms involved in the $FS(O_2)O$[2–5] and $FC(O)O_x$ (x = 0, 1, 2)[6–9] radical chemistries lead to the conclusion that over 300 μs only $FS(O_2)O$ and $FC(O)O$ survive and the mechanism reduces to eqns. (1)–(5)

$$FC(O)O + FC(O)O \rightarrow FC(O)OO(O)CF \quad (1)$$

$$FS(O_2)O + FS(O_2)O \rightarrow FS(O_2)OO(O_2)SF \quad (2)$$

$$FC(O)O + FS(O_2)O \rightarrow FC(O)OO(O_2)SF \quad (3)$$

$$FS(O_2)O + CO \rightarrow FSO_2 + CO_2 \quad (4)$$

$$FS(O_2)O + FSO_2 \rightarrow FS(O_2)O(O_2)SF \quad (5)$$

Under the present conditions, reactions (1) and (2) are pressure independent with high-pressure rate coefficients of $k_{\infty,1}$ = 5.5 × 10^{-13} [8] and $k_{\infty,2}$ = 4.6 × 10^{-14} cm^3 molecule^{-1} s^{-1}, respectively.[3] Second-order plots of the absorbance monitored at 450 nm after photolysis of $FS(O_2)OO(O_2)SF/CF_4$ and $FS(O)_2OF/CO/O_2/SF_6$ mixtures are depicted in Fig. 1. In the first case, the generated $FS(O)_2O$ radicals [absorption cross-sections $\sigma(FS(O_2)O)$ = 3.64 × 10^{-18} cm^2 molecule^{-1}[3]] react exclusively according to reaction (2). In the latter case, a fast component due to the above mentioned thermalization of excited $FS(O_2)O$ radicals is followed by a second component with a slope much higher than the observed for the first mixture. Absorbance *vs.* time profiles were numerically fitted employing the mechanism described by reactions (1)–(5). The modelling leads to radical concentrations such that the absorbance may be mostly attributed to $FS(O)_2O$ absorption with a small contribution due to $FC(O)O$ radicals [$\sigma(FC(O)O)$ = 6.7 × 10^{-19} cm^2 molecule^{-1} [8]]. Moreover, the calculations show that the higher slope observed in signal (B) of Fig. 1 is predominantly due to $FS(O_2)O$ consumption by reaction (3). At longer times and higher CO pressures these radicals are also consumed in reaction (4). However, the low FSO_2 concentration precludes the determination of k_5, for which reasonable values ranging from 2 × 10^{-12} to 7 × 10^{-11} cm^3 molecule^{-1} s^{-1} do not affect the modelling results. Between *ca.* 175 and 1060 mbar the rate coefficients determined for reaction (3) remain independent on total pressure such that they can be certainly ascribed to the limiting high pressure value. All experimental results are very well reproduced using the $k_{\infty,1}$, $k_{\infty,2}$ and k_5 values given above as well as $k_{\infty,3}$ = (1.2 ± 0.3) × 10^{-12} cm^3 molecule^{-1} s^{-1} and k_4 = (1.8 ± 0.7) × 10^{-17} cm^3 molecule^{-1} s^{-1} for reactions (3) and (4). The errors quoted are 2σ. The value of $k_{\infty,3}$ is normal for this type of reaction[10] while the low value of k_4 is quite consistent with the measured activation energy of 7 kcal mol^{-1}.[11] The experimental study is supplemented by density functional theory thermochemical computations to determine the bond dissociation energies of O–O, C–O and O–S bonds in $FC(O)OO(O_2)SF$. For this, standard enthalpies of formation of the peroxide and the relevant radicals were calculated. The value for $FC(O)OO(O_2)SF$ was estimated using the isodesmic reaction: $FOOF + FC(O)OH + HSO_3F \rightarrow FC(O)OO(O_2)SF + 2FOH$. Energy calculations were carried out on optimized geometries and harmonic frequencies evaluated employing the hybrid B3LYP density functional with the 6-311++G(d,p) basis

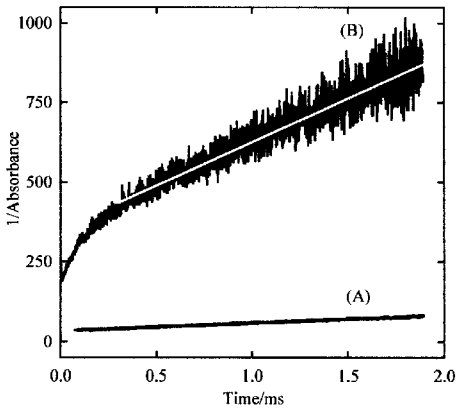

Fig. 1 Plot of the inverse of the absorbance *vs.* time. (A) 8.1 mbar of $FS(O_2)OO(O_2)SF$ and 16.4 mbar of CF_4; (B) 29.3 mbar of $FS(O_2)OF$, 132.4 mbar of CO, 14.3 mbar of O_2 and 890.0 mbar of SF_6. The solid line is the result of the modelling described in the text.

DOI: 10.1039/b006272n

set.[12] Unless otherwise indicated, the experimental enthalpies of formation of the species involved in this and other isodesmic reactions given here are from ref. 10. According to the experimental uncertainties, an error level for all derived thermochemical properties of this work of ±3 kcal mol^{-1} is estimated. From the calculated enthalpy of the isodesmic reaction of ΔH^0_r = 44.7 kcal mol^{-1}, the value $\Delta H^0_{f,298}$(FC(O)OO(O_2)SF) = −229.4 kcal mol^{-1} was derived. The enthalpy of formation for FS(O_2)O was estimated from the experimental bond dissociation energy, D_e(FS(O_2)O–F) = 33.1 kcal mol^{-1},[2] and $\Delta H^0_{f,298}$(FS(O_2)OF) = −136.9 kcal mol^{-1} obtained from the isodesmic reaction FO_2 + HSO_3F → FS(O_2)OF + HO_2 (ΔH^0_r = 40.0 kcal mol^{-1}). In this way, $\Delta H^0_{f,298}$(FS(O_2)O) = −122.8 kcal mol^{-1} results. Using the above enthalpies of formation for FC(O)OO(O_2)SF and FS(O_2)O together with $\Delta H^0_{f,298}$(FC(O)O) = − 86.0 kcal mol^{-1},[13] we obtain the enthalpy change ΔH^0_{298}(FC(O)O–O(O_2)SF) = 20.6 kcal mol^{-1} which is similar to the value measured for the FS(O_2)O–O(O_2)SF bond of 22.1 kcal mol^{-1}.[3]

Finally, using $\Delta H_{f,298}$(FS(O_2)OO) = −110.2 kcal mol^{-1}, estimated using the isodesmic reaction FO_2 + HSO_3F → FS(O_2)OO + FOH (ΔH^0_r = 40.4 kcal mol^{-1}), and $\Delta H^0_{f,298}$(FCO) = 44.6 kcal mol^{-1},[7] $\Delta H^0_{f,298}$(FC(O_2)OO) = −76.1 kcal mol^{-1},[6] and $\Delta H^0_{f,298}$ (FSO_2) = −96.2 kcal mol^{-1},[14] dissociation energies for other bonds in FC(O)OO(O_2)SF were evaluated. The resulting values are: ΔH^0_{298}(FC(O)OO–(O_2)SF) = 57.1 and ΔH^0_{298}(FC(O)–OO(O_2)SF) = 74.6 kcal mol^{-1}. These results indicate that no energetically feasible exit channels for the peroxide decomposition exist. The minimum-energy pathways for the recombination reaction (3) and for FC(O)–OO(O_2)SF and FC(O)OO–(O_2)SF dissociations show a smooth energy profile without a maximum: no transition state was found on the B3LYP/6-311 + G(d) surface. Thus the enthalpy changes can be assimilated to the respective bond dissociation energies. Scarcely probable is the competition between the reaction FC(O)O + FS(O_2)O → CO_2 + FS(O_2)OF and reaction (3). This assumption is supported by the fact that most fluorine abstraction reactions by either FS(O_2)O or other radicals exhibit relatively large activation energy values (*ca.* 10–30 kcal mol^{-1}) and consequently very small room temperature rate coefficients. In particular, for the similar reaction FNO_2 + FS(O_2)O → NO_2 + FS(O_2)OF an activation energy of *ca.* 30 kcal mol^{-1} can be estimated from the measured value of 10 kcal mol^{-1} for the reverse reaction,[15] the enthalpies of formation of FNO_2 and NO_2 molecules[10] and the above values for FS(O_2)O and FS(O_2)OF. The present results indicate that after formation by reaction (3), the new peroxide is mostly collisionally stabilized at room temperature. However, the low O–O bond dissociation energy leads to significant decomposition as temperatures rises, such that a gaseous sample of FC(O)OO(O_2)SF finally degrades to the more stable peroxide FC(O)OO(O)CF.[6–9]

Further experimental and theoretical work on FC(O)OO(O_2)SF is underway.

First published as an Advance Article on the web 14th December 2000

The α-ketocarbene 2-oxocyclohexa-3,5-dienylidene (λ_{max} = 360, 375 and 388 nm) is detected upon laser flash photolysis of 2-bromophenol in aqueous solution; its formation is confirmed by photoproduct studies.

para-Substituted halogenophenols have been shown to undergo heterolytic photodehalogenation in polar protic solvents.[1–10] The mechanism of this process could be clarified by demonstration of the formation of the carbene 4-oxocyclohexa-2,5-dienylidene (λ_{max} = 370 and 384 nm), which is long-lived enough to be detected by nanosecond laser flash photolysis experiments in aqueous solution.[1]

This intermediate arises from HCl elimination; its characteristic reactivity is governed by its triplet multiplicity: the addition of oxygen yields the *para*-benzoquinone *O*-oxide (λ_{max} = 460 nm) and subsequently *para*-benzoquinone, and the reduction by H-donor molecules such as alcohols gives rise to a phenoxyl radical (λ_{max} = 385 and 400 nm) and subsequently to phenol. Reactions with water and the halogenophenol itself produce hydroquinone and 5-chloro-2,4′-dihydroxybiphenyl respectively, in agreement with earlier studies.[2–5] This mechanism of the photoreactivity of 4-halogenophenols was later confirmed by several studies using transient absorption spectroscopy, EPR, and photoproduct analysis.[6–10]

In the case of aqueous 2-chlorophenol (2-ClP) or 2-bromophenol (2-BrP), UV irradiation leads to photocontraction into cyclopentadienic acids and to photohydrolysis.[11,12]

The ring contraction corresponds to a Wolff rearrangement;[13] it is also observed in the photolysis of α-diazoketones.[14] The similarity of the two reactions led to the proposal of intermediate formation of the α-ketocarbene, 2-oxocyclohexa-3,5-dienylidene, in both cases.[12,14] However, this carbene has not until now been detected, the first intermediate reported in aqueous solution on a nanosecond time scale being the ketene fulvene 6-oxide (λ_{max} = 255 nm), which subsequently adds a water molecule to yield fulvene 6,6-diol (λ_{max} = 295 nm).[15,16]

The photo-Wolff rearrangement is expected to proceed on the excited singlet surface.[13,17] A putative singlet α-ketocarbene arising as an intermediate on the reaction coordinate of ring contraction might have a lifetime in the subnanosecond range, as indicated by time-resolved studies of α-diazocarbonyl compounds.[18,19] On the other hand, α-ketocarbenes may have triplet ground states.[17] Currently available evidence indicates that the photoinduced dehalogenation of 4-halogenophenols proceeds on the excited triplet surface.[1,10] The formation of triplet α-ketocarbenes in the analogous reaction of 2-halogenophenols is therefore conceivable, either preceding ring contraction or in competition to it. A recent photoproduct study of the degradation of 2-ClP in aqueous surfactant solutions indicated that both singlet and triplet pathways may contribute to product formation.[20]

The transient spectrum obtained by laser flash photolysis of aqueous 2-ClP (Nd:YAG laser, Quanta-Ray DCR-1, pulse duration 7 ns, λ_{exc} = 266 nm) is dominated by the strong and broad absorption of the species resulting from ring contraction,[16] which mask a possible contribution from a carbene which, in analogy to that derived from 4-halogenophenols, is expected in the 350–420 nm range. However, careful examination of the transient spectrum in oxygenated solution revealed a very weak band with a maximum around 475 nm ($\varepsilon \times \Phi$ = 11 ± 3 M^{-1} cm^{-1}), reminiscent of the quinone oxide resulting from addition of O_2 to 4-oxocyclohexa-2,5-dienylidene.[1] Upon addition of propan-2-ol (0.085 M), an equally weak new species with a two-band absorption (λ_{max} = 380 and 400 nm, $\varepsilon_{400} \times \Phi$ = 9 ± 3 M^{-1} cm^{-1}) could be detected, indicating the formation of a phenoxyl radical[21] in these conditions.

These results suggested the transient formation of a triplet α-ketocarbene in the photochemistry of aqueous 2-ClP, but a direct proof of its presence was still lacking. Based on the hypothesis that the photoinduced reactions proceed on the triplet surface, it could be argued that 2-BrP, because of its intrinsically faster intersystem crossing, might be better suited as a substrate molecule to detect the carbene.

Laser flash photolysis of aqueous 2-BrP (10^{-3} M) yielded the ring contraction products, ketene and enol, just as with 2-ClP. However, an additional transient absorbing within the wave length range 350–400 nm (λ_{max} = 360, 375 and 388 nm, Fig. 1, spectrum 1) was also observed. This species decayed by first-order kinetics with k_d = 2.5 × 10^5 s^{-1}. In deoxygenated solutions containing propan-2-ol (0.17 M), it was converted into the phenoxyl radical with a formation rate of 1.6 × 10^6 s^{-1} (Fig. 1, spectrum 2). In oxygen-saturated solutions we found again the broad band with maximum around 475 nm (Fig. 1, spectrum 3), which had a formation rate of 9.0 × 10^6 s^{-1}.

As seen in Fig. 2, all these transients derived from monophotonic processes. We deduced from the slopes of the linear relationships of absorbance *vs.* laser pulse energy the following values of $\varepsilon \times \Phi$: 90 ± 20 M^{-1} cm^{-1} for the end-of-pulse transient at 388 nm, 130 ± 25 M^{-1} cm^{-1} for the phenoxyl radical at 400 nm and 175 ± 30 M^{-1} cm^{-1} for the transient observed in oxygenated solution at 475 nm.

Table 1 Quantum yields of photolysis (Φ_d) and of formation of products in neutral aqueous medium

	Conditions	Φ_d	$\Phi_{cyclopentadienic\ Acids}$	$\Phi_{pyrocatechol}$	Other products detected
2-ClP	N_2 or O_2	0.065 ± 0.007	0.042 ± 0.008	0.012 ± 0.001	none

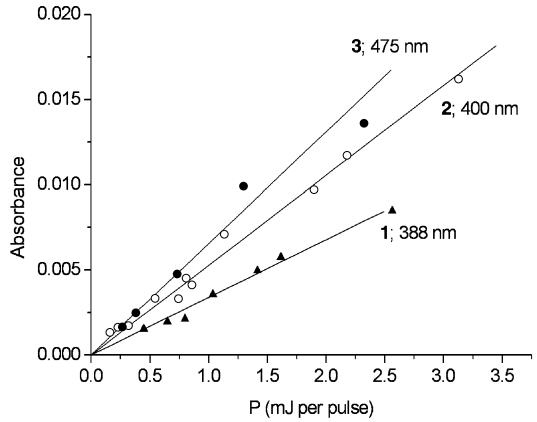

Fig. 2 Dependences of transient absorbances on pulse energy.

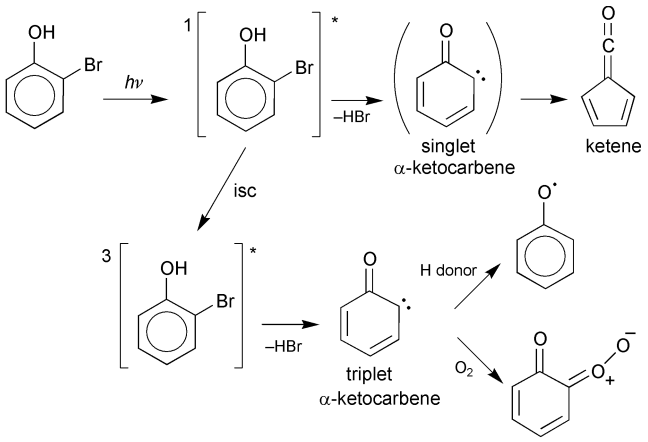
The complete analogy of the transients shown in Fig. 1 with those observed in the photochemistry of 4-halogenophenols[1] prompted us to assign the end-of-pulse transient to the α-ketocarbene formed by dehalogenation of 2-BrP. The reactivity with propan-2-ol and O_2 demonstrate the triplet character of this carbene; the 475 nm transient is therefore assigned to the *ortho*-benzoquinone *O*-oxide resulting from addition of O_2. Based on ε = 3000 M^{-1} cm^{-1} for the phenoxyl radical at 400 nm[21] and assuming complete conversion of the α-ketocarbene into the phenoxyl radical, values of Φ = 0.04 ± 0.01 and Φ = 0.003 ± 0.001 are found for the quantum yields of carbene formation from 2-BrP and 2-ClP, respectively. The molar extinction coefficient of the α-ketocarbene at 388 nm is estimated as ε = 2100 ± 500 M^{-1} cm^{-1}.

Product studies were undertaken to confirm the occurrence of an additional reaction pathway in the case of 2-BrP, besides that leading to ring contraction. The substrate (5×10^{-4} M 2-ClP or 2-BrP in neutral aqueous solution) was irradiated at 280 nm with low light intensities and the irradiated solutions were analysed by HPLC (Table 1). Within detection limits, only photocontraction and photohydrolysis are observed in the case of 2-ClP; the reaction is not measurably affected by the presence of O_2 or of propan-2-ol (0.017 M). In the case of 2-BrP, the formation of phenol and of three new products eluted after 2-BrP are observed in deoxygenated solutions. One of them, also obtained by bromination of 2,2′-dihydroxybiphenyl, is likely to be 2-bromo-6-(2′-hydroxyphenyl)phenol. In oxygenated solution biphenyls and phenol are not formed and the quantum yield of 2-BrP photolysis is reduced. The addition of propan-2-ol (0.17 M) clearly favours the formation of phenol, decreases the quantum yield of 2-BrP photolysis and inhibits drastically the formation of biphenyls. These results demonstrate that the photoproduct distribution of 2-BrP is indeed different from that of 2-ClP. The presence of biphenyls and of phenol among the photoproducts is indicative of the characteristic triplet carbene reactions, addition to the substrate and H abstraction, in analogy to the photoproducts from 4-halogenophenols.[1] Quinoid compounds are absent, which is not surprising in view of the instability of *ortho*-benzoquinone.



Scheme 1

To summarize, we have been able to characterize a hitherto unknown triplet α-ketocarbene by means of transient absorption spectroscopy and characteristic reactivity. The yield of this carbene is over ten times higher from 2-BrP than from 2-ClP, in agreement with the hypothesis that intersystem crossing at the molecular level precedes its formation. The relatively long triplet α-ketocarbene lifetime, of the order of microseconds, excludes the possibility of it being an intermediate on the way to ring contraction. It is therefore likely that ring contraction and formation of the triplet carbene are competing reactions, as indicated in Scheme 1.

The compound (η^5-C_5Me_5)Al→Al(C_6F_5)$_3$, which is the first valence isomer of a dialane, has been prepared by treatment of [Al(η^5-C_5Me_5)]$_4$ with Al(C_6F_5)$_3$ and characterized by X-ray crystallography and NMR spectroscopy.

Compounds with aluminium–aluminium bonds are attracting considerable recent attention. The simplest such compounds are the dialanes, R_2AlAlR_2, and a number of these have now been structurally authenticated.[1] It occurred to us that valence isomers of dialanes, *viz.* $RAl{\rightarrow}AlR_3$, might be capable of existence if the appropriate substituents were employed. DFT calculations[2] on the prototypical dialane, H_2AlAlH_2, revealed that the valence isomer $HAl{\rightarrow}AlH_3$, is less stable than H_2AlAlH_2 by 9.17 kcal mol^{-1}. However, replacement of one of the dialane hydride substituents by cyclopentadienide inverted this order and (η^5-C_5H_5)Al→AlH_3 **1** is more stable than the dialane (η^2-C_5H_5)(H)Al→AlH_2 by 10.79 kcal mol^{-1}. In view of the foregoing, [Al(η^5-C_5Me_5)]$_4$ [65 mg, 0.40 mmol of Al(η^5-C_5Me_5) units][3] was treated with Al(C_6F_5)$_3$·$PhCH_3$[4] (250 mg, 0.40 mmol) in 30 mL of toluene at 25 °C. After being stirred for 4 h at 25 °C, the yellow reaction mixture was heated to 50 °C for 30 min. Upon cooling to 25 °C, the reaction mixture was filtered and the solvent and volatiles were removed from the filtrate to afford a dark amber oil from which yellow crystalline (η^5-C_5Me_5)Al→Al(C_6F_5)$_3$ **2** (220 mg, 80% yield, mp 131–133 °C) deposited over a period of 24 h. The mass spectral data† for **2** are consistent with the proposed dialane isomer formulation. The presence of (η^5-C_5Me_5)Al and Al(C_6F_5)$_3$ moieties in **2** is evident from the ^{1}H, ^{13}C, and ^{19}F NMR spectroscopic data,† noting however that the equivalence of the C_5Me_5 ring carbon and Me resonances could be due to the well known fluxional behaviour of cyclopentadienyl–aluminium systems.[5] The ^{27}Al NMR spectrum of **2** comprises singlet resonances at δ −115.7 and 106.9. Given that the ^{27}Al chemical shifts for the model compound **1**, as computed by the GAIO method,[2b,6] are δ −107.9 and 109.0 for the (η^5-C_5Me_5)Al and AlH_3 centres, respectively, analogous assignments have been made for **2**.† Further support for the proposed assignments stems from the experimentally observed ^{27}Al chemical shifts for monomeric (η^5-C_5Me_5)Al (δ −150)[7] and Al(C_6F_5)$_3$·arene [δ 52 (benzene); δ 61 (toluene)].[4] The overall trend of ^{27}Al chemical shifts is consistent with the transfer of electron density from the alanediyl to the Al(C_6F_5)$_3$ fragment upon formation of the Al→Al donor acceptor bond of **2**.

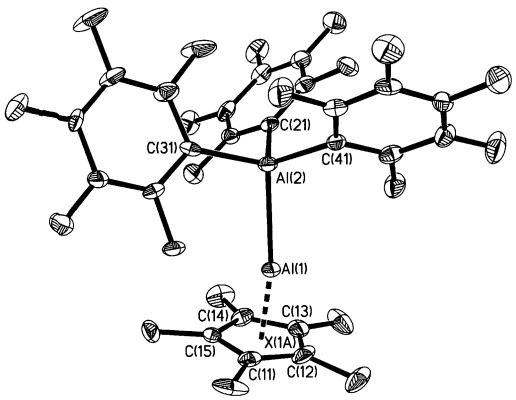

Fig. 1 Thermal ellipsoid plot (30% probability level) for (η^5-C_5Me_5)-Al→Al(C_6F_5)$_3$ **2**. Selected bond lengths (Å) and bond angles (°): Al(2)–Al(1) 2.591(2), Al(1)–X(1A) 2.591(8), Al(1)–C(11) 2.172(7), Al(1)–C(12) 2.162(6), Al(1)–C(13) 2.165(7), Al(1)–C(14) 2.200(7), Al(1)–C(15) 2.189(6), Al(2)–C(21) 1.982(7), Al(2)–C(31) 1.999(7); Al(2)–C(41) 1.997(7); Al(2)–Al(1)–X(1A) 170.1(3), C(21)–Al(2)–C(41) 111.0(3), C(21)–Al(2)–C(31) 108.5(3), C(41)–Al(2)–C(31) 113.5(3), C(21)–Al(2)–Al(1) 104.1(2), C(41)–Al(2)–Al(1) 111.2(2), C(31)–Al(2)–Al(1) 108.0(2).

The foregoing spectroscopic conclusions were confirmed by X-ray crystallography.‡ Compound **2** crystallizes in the *C*2/*c* space group with Z = 8; the solid state consists of individual molecules of the dialane isomer and there are no unusually short intermolecular contacts. The pentamethylcyclopentadienyl substituent is attached in an η^5 fashion and the ring centroid–Al–Al moiety deviates only modestly from linearity [170.1(3)°]. The Al–Al bond length in **2** [2.591(3) Å] is shorter than those in the dialanes {(Me_3Si)$_2$CH}$_4$Al$_2$ [2.660(1) Å],[1a] {2,4,6-Pr^i_3-C_6H_2}$_4$Al$_2$ [2.647(3) Å],[1b] and {Bu^t_3Si}$_4$Al$_2$ [2.751(2) Å][1c] but identical to that in [RIAl–AlClR] {R = [(Me_3Si)$_2$C(Ph)C(Me_3-Si)N]) [2.593(2) Å]}[1d] within experimental error. The average Al(1)–C bond length of 2.178(7) Å [Al–centroid 1.810(8) Å] is considerably shorter than those reported for Al(η^5-C_5Me_5) [2.388(7) Å][8] and [Al(η^5-C_5Me_5)]$_4$ (2.344 Å, av. Al–centroid 2.011 Å).[7] Such a shortening is anticipated as the partially antibonding aluminium 'lone pair' orbital of Al(η^5-C_5Me_5) is transformed into the donor–acceptor bond with the concomitant development of positive and negative charges on the aluminium centres.[9] The same trend is evident for other group 13 (η^5-C_5Me_5)M→acceptor complexes[10] and is true for both main-group and transition element acceptors.

In conclusion, we have prepared (η^5-C_5Me_5)Al→Al(C_6F_5)$_3$, a valence isomer of a dialane. This compound also features the first example of an Al→Al donor acceptor bond.

Metal ion catalysis in chemisorption and dehydrogenation of alkanes on aluminium hydroxide clusters, revealed by theoretical calculations

Dan Fărcaşiu* and Povilas Lukinskas

Department of Chemical and Petroleum Engineering, University of Pittsburgh, 1249 Benedum Hall, Pittsburgh, PA 15261, USA. E-mail: dfarca@pitt.edu

Received (in Cambridge, UK) 17th August 2000, Accepted 25th October 2000
First published as an Advance Article on the web 14th December 2000

Electron-correlated DFT calculations with a large basis set show that propane adds to coordinatively unsaturated aluminium, as in the clusters $(HO)_3Al(OH_2)_x$ (x = 0, 1), by aluminium insertion into a C–H bond, followed by hydrogen migration to an oxygen atom and predict correctly experimental observations; the alternative pathway involving alkyl–oxygen interaction has a much higher energy barrier and does not predict correctly the experimental results.

Following the progress of superacid chemistry, the reactions of hydrocarbons on aluminosilicates, including zeolites, have been interpreted as involving the activation by hydron transfer to form carbocations as intermediates or transition structures.[1] This type of activation, characteristic of superacids in solutions, *e.g.* $HF–SbF_5$,[2] $HF–TaF_5$,[3] or $H_2O–AlX_3$,[4] is not found for trifluoromethanesulfonic acid (TFMSA), which activates alkanes by an oxidative mechanism.[5] Yet, TFMSA is a much stronger acid than the zeolite catalysts.[6] This paradox, observable to an outsider, has been lost to the researchers in the field.

The computations on the activation of alkane C–H bonds have attempted to describe the accepted mechanism and sought mostly pathways based on hydron transfer.[7] The same held for the hydrogen chemisorption on alumina, responsible for the high-temperature H_2/D_2 exchange,[8] which was thought to involve heterolysis of the H–H bond, with the hydron going to the oxygen (base) and the hydride to aluminium (acid).[9]

Standard *ab initio* (MP2) and DFT (B3LYP) geometry optimizations with large basis sets and search of the reaction coordinate without the imposition of a pathway have shown, however, that hydrogen chemisorption occurs through the interaction of H_2 with the aluminium (metal ion catalysis) until both hydrogen atoms are bonded to Al, after which one hydrogen migrates to oxygen.[10] The reactivity of aluminium centers varied in the order: tri- > tetra- > penta-coordinated and the tetracoordinated aluminium in a silica-alumina cluster chemisorbed hydrogen by the same mechanism.[10*b*]

Alumina catalyzes the H–D exchange of saturated hydrocarbons as well,[11] a reaction also classified as acid–base catalysis.[11] Like the hydrogen chemisorption, the reaction of methane with $Al(OH)_3$ was described as a heterolytic reaction with an acid–base pair on the surface, with a hydron going to the negative oxygen and a methyl anion to the metal.[12] A computational search in which the reaction pathway was not presupposed was, therefore, in order. We studied the reaction of propane with aluminium hydroxide clusters, $(HO)_3Al(OH_2)_x$ (**1**, x = 0; **2**, x = 1).

B3LYP/6-31G** geometry optimizations and frequency analyses (giving also the zero point energy corrections, ZPE),[13] transition structure searching by the STQN (Synchronous Transit-Guided Quasi Newton) method,[14] and reaction pathway identification by intrinsic reaction coordinate (IRC)[15] tracking were conducted with the Gaussian 98 program,[16] as described before.[10] Pathway **b** (defined below) for chemisorption on **1** was also examined by MP2/6-31G**, to check the agreement between the two methods (as done in previous work).[10*a*] To model the alumina surface, the geometry of the tricoordinated aluminium reactant **1** was the optimized geometry of **2**, with the water ligand removed.[10] In the reaction of **1** with propane, the O1–O2–Al–O3 dihedral angle was kept constant. The alternative of freezing the outer atoms of the cluster and allowing the aluminium atom a breathing movement gave a similar potential energy barrier (PEB) for H_2 chemisorption.[10*a*] Our goal was to explore the existence of a reaction pathway, rather than to determine accurately the relative energies of reactants, intermediates, and transition structures.

Weak complexes of propane with **1** (**3**) and **2** (**4**) were located and two types of chemisorption products were identified, with C–Al bond (**5** and **6**, respectively) and with C–O bond (**7** and **8**, respectively), shown in eqns. (1) and (2). The relative reactivities of primary and secondary C–H bonds were also tested [series **a** and **b** in eqns. (1) and (2)]. The O–alkyl complexes were less stable than the Al–alkyl complexes by 5–7 kcal mol^{-1}.

$$\underset{\mathbf{1}(x=0),\ \mathbf{2}(x=1)}{(OH)_3Al(OH_2)_x} + PrH \longrightarrow \underset{\mathbf{5}(x=0),\ \mathbf{6}(x=1)}{(OH)_2Al(OH_2)_{x+1}(R)} \quad (1)$$

$$\mathbf{1}, \mathbf{2} + PrH \longrightarrow \underset{\mathbf{7}(x=0),\ \mathbf{8}(x=1)}{(HO)_2Al(OH_2)_x(H)\text{-}O(R)H} \quad (2)$$

a: R = CH_2Et **b**: R = $CHMe_2$

All chemisorption products react further to form hydrogen and propene, complexed with the aluminium cluster. The energies of intermediates and products, relative to the starting materials, are shown in Table 1.

It is seen that chemisorption and dehydrogenation are catalyzed by both tricoordinated and tetracoordinated aluminium centers. The former are more reactive, just as for the hydrogen chemisorption.[10] For the aluminium–alkyl pathway, eqn. (1), a primary C–H bond (**a**) is more reactive than a secondary C–H bond (**b**). Only option **b** was studied for the O–alkyl pathway [eqn. (2)], because the alkyl group acquired a positive charge. On the aluminium–alkyl pathway, the barrier for alkane chemisorption (TS1) is much smaller than the barrier (TS2) for the dehydrogenation step, whereas in the oxygen–alkyl pathway, TS1 is higher in energy than TS2. The O–alkyl pathway is higher in energy than the aluminium–alkyl pathway. In the second step of the reaction on **2**, the cleavage of an Al–O bond is easier than the elimination of propene. If the cluster was part of a solid, the lattice rigidity would determine the degree of Al–O bond separation. Therefore, the elimination step was followed at two lengths of the labile Al–O bond: the same as in the intermediate (**6** or **8**) and extended by 0.2 Å. Both values are given in Table 1, for each reaction pathway; the latter are smaller.

The transition structure for the chemisorption step on the aluminum–alkyl pathway,[14] shown in Fig. 1 (left)[17] for the reaction **1** → **5a**, was similar to that for hydrogen chemisorption. The imaginary frequency was the bending of the Al–H

Table 1 Relative energies of intermediates, products, and transition structures for the reaction of propane with aluminium hydroxide clusters **1** and **2**[a,b]

[m] Decomposition to **5b** occurred. [n] **2** → **8b**, eqn. (2). [o] d(Al–OH_2) = 2.00 Å, see text. [p] d(Al–OH_2) = 2.20 Å, see text. [q] 48.14 kcal mol^{-1} if the hydrogenated cluster is a product.

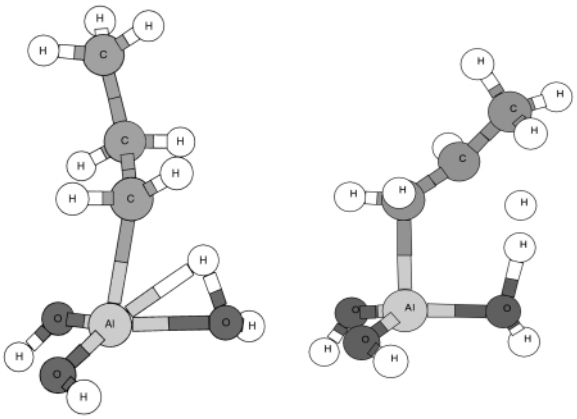

Fig. 1 Left: transition structure (TS1) for the chemisorption of propane (primary C–H) on a tricoordinated aluminium cluster (**1** → **5a**). Right: transition structure (TS2) for the elimination of propane from the chemisorbed complex **5a**.

bond toward O (migration of hydrogen from Al to O).[18] Thus, the reaction mechanism consists of the insertion of aluminium into the C–H bond, followed by hydrogen migration from Al to O, just as for hydrogen chemisorption.[10] In the elimination step, there is less cleavage of the Al–C bond than of the C–H bond at the transition state (Fig. 1, right).[19] For the elimination step of the O–alkyl pathway, the hydrogen is transferred to another oxygen atom.

The reactivity order prim > sec and the prediction that hydrogen exchange [reverse of eqn. (1)] is faster than further reaction of the olefin (*e.g.* on acid sites) agrees with the experiment. (The exchange of H_2 with the clusters has lower barriers than the exchange of the C–H bonds.[10]) The described mechanism is relevant for the hydrogen exchange[11,19] and alkene hydrogenation/alkane dehydrogenation.[20] These reactions have been described as catalyzed by Brønsted acid centers, with carbocations as intermediates or transition structures.[7,9,12,21] The cleavage of H–H and C–H bonds by insertion of metal atoms and ions (metal and metal ion catalysis), known for heavy metals, particularly noble metals, was not considered for aluminium. We show now that Al(O–)$_n$ sites with n = 3 and 4, are active in metal ion catalysis. An increase in reactivity for 'broken lattices' of zeolites or for extraframework aluminium species in steamed zeolites is predicted.

Aluminium-containing ring systems and N-heterocycle formation *via* nitrile insertions into Al–N bonds

Reactions of Me_3Al with 1,2-diaminobenzene [1,2-$(H_2N)_2C_6H_4$] or anthranilic acid, [1,2-$(H_2N)(HO_2$- C)C_6H_4], followed by treatment with acetonitrile, afford tetranuclear and hexanuclear aluminium-containing ring systems; a single crystal X-ray structure on the hexametallic product reveals the construction of quinazoline ligands arising *via* insertion of acetonitrile into Al–N bonds.

It is well over one hundred years since the trimerisation of nitriles to triazines by organometallic reagents was first noted, by Hofmann[1] using sodium, and by Frankland[2] in his studies on Et_2Zn. During the 1960s, Wade[3] and Lappert[4] did much to advance the understanding of nitrile binding and insertion reactions at main group centres; however, the potential of such reactions for synthesising useful heterocycles and interesting metal-containing ring systems has remained largely undeveloped.

Recently, we described the synthesis of large aluminium-containing ring systems *via* treatment of Me_3Al with hydrazines;[5] these included a highly unusual octa-aluminium structural analogue of a tetrapyrrole. The key macrocycle-forming step revolves around the insertion of acetonitrile into the aluminium–nitrogen bonds of intermediate amide species. With a view to probing the generality of this approach for the synthesis of aluminium-containing macrocycles, and also to evaluate the potential of this methodology for constructing nitrogen heterocycles, we have extended the study to other classes of amine substrate. Here, we describe the reactivity of Me_3Al towards 1,2-diaminobenzene [1,2-$(H_2N)_2C_6H_4$] and anthranilic acid [1,2-$(H_2N)(HO_2C)C_6H_4$]. The former gives rise to a tetranuclear complex, the latter to an unprecedented hexanuclear species incorporating N-heterocyclic ligands.

Slow addition of a solution of Me_3Al (2 equivalents) in toluene to 1,2-$(H_2N)_2C_6H_4$, followed by a 12 h reflux, afforded a pale brown solution. After removal of the solvent under reduced pressure, the residue was dissolved in acetonitrile and heated to reflux for 2–3 min. Slow cooling of this solution, followed by standing at room temperature for 2 days, gave colourless needles of **1** in 40% yield (Scheme 1). The ^{1}H NMR spectrum‡ of **1** consists of four equal intensity singlets in the Al–methyl region (δ −0.37 to −0.75) together with a similar intensity singlet at δ 1.29 attributable to carbon-bonded methyl groups. X-Ray analysis§ reveals the product to be the C_i symmetric twelve-membered macrocyclic complex **1** comprising four aluminium atoms (two bridging and two chelating), six nitrogen atoms and two carbon atoms, The structure of this product is closely related to that obtained from the reaction of $MePhNNH_2$ with Me_3Al,[5] and is not described in further detail here.

In the absence of acetonitrile, the 2 : 1 reaction of Me_3Al and 1,2-$(H_2N)_2C_6H_4$ (in toluene) has been shown to afford the asymmetric complex $[(Me_2Al)_2AlMe(C_6H_4(NH)_2)_2]\cdot AlMe_3$ **2**.[6] This, or a closely related derivative, is the likely precursor to **1**. Formation of the 12-membered ring product is brought about by insertion of two acetonitrile molecules into the Al–N bonds, in a related manner to that postulated for the reaction of hydrazines with Me_3Al/MeCN.[5]

Similar treatment of anthranilic acid, [1,2-(NH_2)-$(HO_2C)C_6H_4$] (twice sublimed) with 2 equivalents of a toluene solution of Me_3Al affords, after work-up in acetonitrile, large yellow prisms for which the ^{1}H NMR spectrum possesses nine distinct singlets in the Al–methyl region. The X-ray analysis§ of the product revealed the chiral trimeric hexanuclear complex $[(Me_2AlL)(MeAl)(\mu_3\text{-}O)(\mu\text{-}O)]\}_3$ **3** (L = quinazoline) shown in Fig. 1. The central Al_3O_3 ring has a twisted boat conformation, whereas the three attached Al_2O_2CN rings each have a folded envelope geometry. All six aluminium atoms exhibit marked departures from ideal tetrahedral geometry with angles in the range 100.9(2)–124.4(3)°. Although not possessing strict C_3 symmetry [the methyls on Al(2) and Al(4) are 'up', whilst that on Al(6) is 'down'], the pattern of bonding throughout the structure is essentially three-fold symmetric. It is interesting to note that whilst all of the Al–O bond lengths within the central Al_3O_3 ring and also those to O(2), O(4) and O(6) are all essentially the same [1.770(4)–1.794(4) Å], those to Al(1), Al(3) and Al(5) are all significantly longer [1.811(4)–1.827(4) Å]. As **3** is not the product of a chiral synthesis, the presence in the crystals of molecules of only one chirality is a consequence of spontaneous resolution upon crystallisation.

Whereas the formation of **1** can be rationalised in terms of acetonitrile insertion into the aluminium–nitrogen bonds of **2**, the carboxylic acid group of anthranilic acid contributes oxygen atoms to the Al_3O_3 core around which the quinazoline ligands are clustered. The reaction reproducibly affords **3** in *ca.* 45% yield; its hydrolysis then readily releases the 2-methyl-4(3*H*)-quinazolinone heterocycle **4** (identified by comparison of NMR data with those of an authentic sample) in excellent yield. We

note that the formation of N-heterocycles by this methodology is related to the intramolecular Ritter reaction[7–9] in which nitrilium salts, generated in the presence of Friedel–Crafts reagents, react with a second nitrile molecule to give quinazoline ring systems.[9]

Future studies will focus on further exploiting nitrile insertions into aluminium (and gallium) bonds to access unusual inorganic ring systems and nitrogen heterocycle products.

The EPSRC and the Leverhulme Trust (for a Research Fellowship to C. R.) are thanked for financial support. Professor Charles Rees is thanked for helpful discussions.

Received (in Corvallis, OR, USA) 18th October 2000, Accepted 14th November 2000
First published as an Advance Article on the web 14th December 2000

Two *C*-glucosyl porphyrins are prepared using Ramberg–Backlund and Lindsey methods for the key conversions, and thiosugars are shown to react with perfluorophenylporphyrins.

Photofrin®, a mixture of hematoporphyrin oligomers, is currently used clinically for the photodynamic therapy (PDT) of cancers, but suffers from a variety of problems including solubility and dosing.[1] Because of their potential selective binding to various cell types, porphyrins appended with a variety of saccharides have been examined as possible agents for PDT.[1,2] Most recently, sugar-specific binding to rat hepatoma cells by porphyrin glycoconjugates has been described.[2] Their efficacy as antibiotics and anti-viral agents is also under intense investigation.[1] Since metalloporphyrins are well-established catalysts, the attachment of sugars to effect regio- and stereo-selective oxidations has also been examined, albeit with limited success.[3] Additionally, there are several requirements for the successful commercialization of any of these adducts: (a) effective synthesis in high yields, (b) stable products, in this case to hydrolysis, and (c) highly pure compounds.

It is interesting that with few exceptions,[4–6] the glycoconjugate has been oxygen linked *via* a glycosidic bond to a phenolic aryl porphyrin. When the syntheses of these O-linked materials are examined, one finds that disappointingly low yields are reported, considering that the Lindsey porphyrin synthesis yields are typically 45–65%.[7] We believe that one problem may be that the frequently used *O*-glycosyloxybenzaldehyde starting materials, when subjected to the Lindsey porphyrin synthesis using BF_3 catalysis, can undergo a competing and yield-reducing Suzuki *O* to *C*-glycoside rearrangement.[8] Additionally, a perceived problem with the *O*-glycosides is the inherent possibility for glycosyl cleavage by acids, and in biological systems by glycohydrolases. We wish to describe our preliminary results, which provide possible solutions to both the issues of poor yields and hydrolytic instability, namely the preparation of *C*- and *S*-glycosylated aryl porphyrins in high yields. Both yield and stability are crucial factors for the successful incorporation of sugar moieties into porphyrin combinatorial libraries, since the linkage must be stable both during the formation, subsequent reactions, and in the presence of a variety of functional groups.

For the *C*-glycoside series, we chose to exploit earlier work from our laboratory where the Ramberg–Backlund synthesis is used to link sugars to aglycones.[9,10] Thus, after screening several alternative functional equivalents of *p*-bromomethylbenzaldehyde, we settled on α,α′-dibromo-*p*-xylene as an inexpensive starting material. This was condensed with 1-thio-β-D-glucose tetraacetate[11] to afford thioglucoside **1**. Then conversion to the silylated material **2** was accomplished by treatment of **1** with *tert*-butyldimethylsilanol in the presence of silver triflate and 2,6-di-*tert*-butylpyridine.[12] The replacement of the acetyl groups with benzyl ethers to obtain **3** was achieved by deprotection of **2** with sodium methoxide, followed by benzylation. The sulfide **3** was oxidized to the sulfone **4** with monoperoxyphthalic acid (MMPP). The resulting sulfone was employed in the Ramberg–Bäcklund synthesis of the *exo*-glucal **5** under Chan's conditions.[13] The two isomers (*Z*)-**5** and (*E*)-**5** in the ratio 8 : 2 were identified by NOE measurements, which showed an effect between H-1 and H-3 in the case of the *E*-isomer. In some cases the intermediate α-bromosulfone **6** was isolated from the reaction mixture and then converted to the *exo*-glucal **5** by treatment with base. The hydrogenation of **5** with palladium 5% on alumina afforded the β-*C*-glucoside **7**, identified by the coupling constant J = 9.2 Hz, indicating an anti-diaxial configuration of the anomeric H-2 with respect to H-3. The cleavage of the silyl ether **7**, followed by Swern[14] oxidation gave the aldehyde **9**, which was utilized in the synthesis of the porphyrins **10** and **11** in 15 and 53% yields respectively, under Lindsey conditions.[7] The materials obtained showed the expected spectroscopic data. The hydrogenolysis of the benzylic protecting groups yielded the porphyrins **12** and **13**, without reduction of the porphyrin. *S*-Glycosides were chosen as worthy conjugates because they are considered to be good mimics of *O*-glycosides with enhanced stability toward enzymatic hydrolysis.[15]

The second reaction sequence begins with 5,10,15,20-tetra(perfluorophenyl)porphyrin which can be routinely made in gram quantities in high yields by the Lindsey procedure.[7] The reactivity of the *para*-fluoro group toward a large variety of nucleophilic substitution reactions has been well established.[4,16] The tetrakis(thiogalactosyl) and tetrakis(thioglucosyl) derivatives of this fluorinated porphyrin are formed in > 85 and 90% yields, respectively, by modifications of previously described procedures.[16] Specifically, the porphyrin is dissolved in amine-free DMF, five equiv. of the sodium salt of the thiosugar added, and the mixture stirred at rt for 4 h. Purification is accomplished on silica-gel using an ethanol–ethyl acetate gradient as eluent.

DNA photocleavage assays are widely used to evaluate the photoreactivity of porphyrin compounds, though DNA is not the primary site of Photofrin activity.[1,5,6] Thus we used standard plasmid photocleavage assays to evaluate the photoreactivity and compare these results with those for other porphyrins. The conditions used to evaluate the photodamage to plasmid DNA caused by porphyrin compounds varies, but our analysis (see

Table 1

Compound	Partition coeff. octanol–water	DNA photocleavage
5-glu-triPP **12**	68	Fair
Tetra glu PP **13**	30	Poor
Tetra thio glu F4PP	50	Poor
Tetra thio gal F4PP	38	Fair
DiMePy + MeOHP[a]	7	Excellent

Table 1 indicates the compounds reported herein exhibit poor photoreactivity which is consistent with other glycosylated porphyrins.[1,5,6] The amphipathic character of the macrocycle derivative has been shown to correlate to cell toxicity *in vitro*,[1] so the partition coefficients are reported. To date, for this class of compounds, the activity is much poorer than the 5,10-bis(4-methylpyridinium)-15-(4-methylphenyl)-20-(4-hydroxyphenyl)porphyrin (DiMePy$^+$MeOHP) found by combinatorial methods,[17] and for some other tetraphenylporphyrin derivatives.[1]

In conclusion, both the C and S linked glycoporphyrins can be synthesized in high yields exceeding 50% based on starting aldehydes using more efficient synthetic strategies. These compounds are stable to hydrolysis and show some photoactivity. Despite significant efforts by a large number of groups, there are few effective photodynamic therapy (PDT) agents, thus there remains a need to further develop the chemistry and the structure–activity relationships of this class of compounds. In contrast to the present clinical use of Photofrin® for the PDT of cancers, it may be found that different porphyrinic compounds are needed to more effectively treat different cancerous tissues, or for other therapeutic uses.

We report on the fabrication of a polypyrrole/poly(methyl methacrylate) coaxial nanocable through the sequential polymerization of methyl methacrylate and pyrrole monomers inside the channels of mesoporous SBA-15 silica, followed by the removal of the silica template.

There has been tremendous interest in the development of conducting structures with nanometer dimensions. These nanostructured conducting materials could find many attractive applications such as electromagnetic interference shielding, electrochromic devices, supercapacitors, polymeric electrodes and sensors.[1] Recently, many nanotubules and nanowires of polymers, metals and carbons have been produced through template approaches with various membranes,[2] layered inorganic solids,[3] zeolites and mesoporous materials.[4] Generally conducting polymers themselves, however, possess poor mechanical properties, and are very difficult to process. To overcome these drawbacks, much research effort has been focused on the development of processes to combine conducting polymers and polymer matrices with good tractability.[5] Although many different conducting polymer composites have been developed, no nanostructured conducting-polymer/polymer composites have, as yet, been reported. Herein, we report the preparation of polypyrrole/poly(methyl methacrylate) coaxial nanocable using mesoporous silica as a template.‡

In the synthesis, mesoporous SBA-15 silica was utilized as a template. Mesoporous SBA-15 silica with regular hexagonal pores of 7.5 nm was prepared by the reported method.[6] To synthesize tubular PMMA within the pores of SBA-15, methyl methacrylate (MMA) was incorporated into the pores of SBA-15 silica and MMA was subsequently polymerized. The amount of MMA was precisely controlled so that the polymerization could occur selectively on the inner surfaces of mesopores of SBA-15, resulting in a tubular structure of PMMA. Pyrrole monomer was polymerized using $FeCl_3$ as an oxidant inside the tubular holes of the PMMA/SBA-15 composite, resulting in a PPy/PMMA/SBA-15 nanocomposite. The removal of SBA-15 silica template by etching using an aqueous HF solution produced a PPy/PMMA nanocomposite.

The pore size distribution (PSD) curves of SBA-15, PMMA/SBA-15 and PPy/PMMA/SBA-15 were derived from nitrogen adsorption isotherms and are presented in Fig. 1. The pore size of SBA-15 silica (7.5 nm) was decreased to 6.2 nm when the polymerization of MMA was conducted and the TEM image of PMMA incorporated SBA-15 exhibited a nearly hexagonal arrangement of pores, demonstrating the formation of tubular PMMA inside the mesopores of SBA-15 silica. The pore volumes of SBA-15, PMMA/SBA-15, and PMMA/PPy/SBA-15 are 0.63, 0.23, and 0.07 $cm^3\ g^{-1}$, respectively. Thermogravimetric analysis (TGA) showed the weight ratio of SBA-15: PMMA : PPy = 50 : 27 : 23 in the PPy/PMMA/SBA-15 composite. Elemental analysis of the PMMA/PPy nanocomposite revealed a 1 : 1 weight ratio of PMMA and PPy, which matches well with the TGA data. The weight ratio can be also calculated from the change of pore volumes after considering the bulk densities (1.2 g cm^{-3} for PMMA and 1.5 g cm^{-3} for PPy) and the weight increases from the consecutive addition of two polymers. The ratio was calculated to be PMMA : PPy = 1 : 0.8. When the weight ratio was derived simply from the decrease in the pore sizes of the composites, the weight of PMMA is much lower (PMMA : PPy = 0.4 : 1). However, this discrepancy can be explained by the incorporation of PMMA into the complementary pores (micropores) of SBA-15 silica. Recently, Kruk *et al.* revealed that many micropores in the walls of SBA-15 silica interconnect primary mesopores.[7] When polymerization of MMA occurs, PMMA might fill these micropores in addition to partial filling of the mesopores. Therefore, the actual amount of PMMA incorporated into SBA-15 is larger than the calculated amount of PMMA derived solely from the partial filling of mesopores.

Small angle X-ray scattering (SAXS) patterns were obtained at various times during the synthesis. The diffraction pattern of SBA-15 showed typical *hk*0 reflections (100, 110 and 200) from the hexagonal arrangement of pores. The peak intensity in the SAXS of PMMA/SBA-15 and PPy/PMMA/SBA-15 decreased compared with that in SBA-15 silica, but the peak positions of the XRD patterns were nearly identical. These results show that the SBA-15 structure remained intact during the synthesis, demonstrating the usefulness of SBA-15 silica as a nanoreactor.

The PPy/PMMA nanocomposite was obtained by HF etching of the SBA-15 silica template. It has been reported that acid treatment does not decrease the electrical conductivity of PPy.[8] The resulting polymer/polymer nanocomposite was dried at 100 °C under vacuum to obtain the dry powder which was analyzed by FTIR spectroscopy. The IR spectrum of the nanocomposite exhibited characteristic peaks from both PMMA and PPy. One very unusual observation is that there are two carbonyl peaks associated with PMMA. The curve-fitted

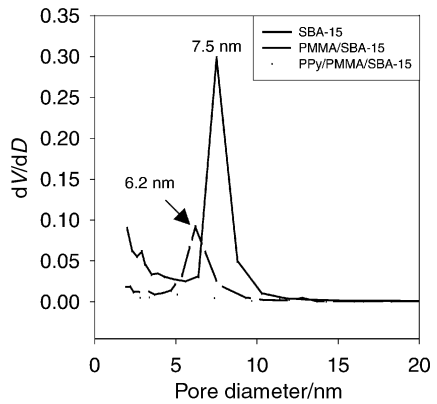

Fig. 1 The pore size distribution curves of SBA-15, PMMA/SBA-15 and PPy/PMMA/SBA-15. The curves were obtained from the adsorption branch of the nitrogen isotherm calculated by the BJH method. The isotherms were collected at 77 K on a Micrometrics ASAP2010 Gas Adsorption Analyzer after degassing at 250 °C at 30 μTorr for 5 h.

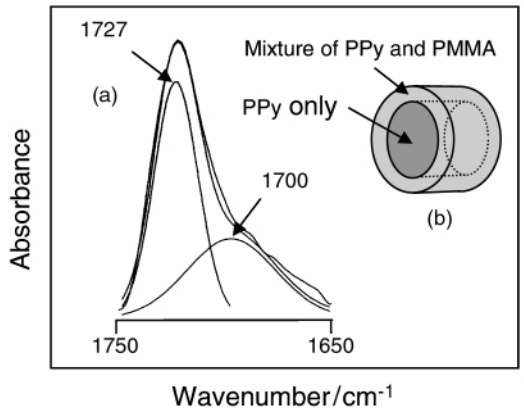

Fig. 2 (a) Curve-fitted IR spectra of the PMMA carbonyl peak for the PPy/PMMA nanocomposite. (b) A schematic illustration of coaxial nanocable of PPy/PMMA.

spectra of the carbonyl region of the PPy/PMMA nanocomposite exhibited one major peak at 1727 cm^{-1} and a shoulder at 1700 cm^{-1} [Fig. 2(a)]. The carbonyl peak at 1700 cm^{-1} indicates hydrogen bonding interactions between PMMA carbonyl groups and PPy N–H groups. On the other hand, the peak at 1727 cm^{-1} arise from the free carbonyl groups of PMMA. Such a strong interaction between PPy and PMMA has not been reported before in the micrometer-sized PPy/PMMA composites. Judging from these data, it seems that the outer PMMA layer is intimately mixed with PPy at the nanometer-scale [Fig. 2(b)].

The PPy/PMMA nanocomposite could be easily molded by compression under 25 kN cm^{-2} at 220 °C for 10 min using a pelletizer. Interestingly, the AFM image of the compression-molded PPy/PMMA composite revealed highly oriented and unidirectional structures (Fig. 3). The well aligned structure was observed nearly all over the sample, which seems to result from template synthesis inside regular hexagonally arranged mesopores of SBA-15. The compression-molded PPy/PMMA nanocomposite exhibited an electrical conductivity of 1.7 S cm^{-1}. Considering that the typical conductivity of chemically synthesized PPy lies in the range 1–10 S cm^{-1}, the conductivity of our PPy/PMMA composite seems to be low. However, when we consider that the PPy wires in the PPy/PMMA nanocomposite are surrounded by insulating PMMA tubules, limiting full exposure of the conducting surface of PPy, the conductivity is relatively high which might result from the good alignment of the PPy chains.

We are grateful to the Brain Korea 21 Program supported by the Korean Ministry of Education for the financial support.

‡ *Experimental details*: SBA-15 was prepared by the reported method. 1 g of methyl methacrylate (MMA) was incorporated into the pores of SBA-15 silica (2 g) by heating for 5 h at 90 °C under reduced pressure. MMA was polymerized with 10 mg of benzoyl peroxide under an argon atmosphere at 70 °C for 2 days and then 120 °C for 2 h, followed by evacuating in a vacuum oven at the same temperature for 18 h. 0.4 g of pyrrole was loaded into the pores of the PMMA/SBA-15 (1.3 g) using the same conditions as in the MMA incorporation, and then polymerized with 20 mL of 0.81 M aqueous $FeCl_3$ solution for 3 h. The resulting solid was retrieved by filtration, followed by drying under vacuum at room temperature for 12 h. To remove the silica template, the PPy/PMMA/SBA-15 composite was dispersed in an aqueous HF solution (48 wt%), and was stirred overnight. The PPy/PMMA nanocomposite was retrieved by vacuum filtration. To fabricate a thin film, the powder form of PPy/PMMA was compression-molded using a pelletizer under 25 kN cm^2 at 220 °C for 10 min.

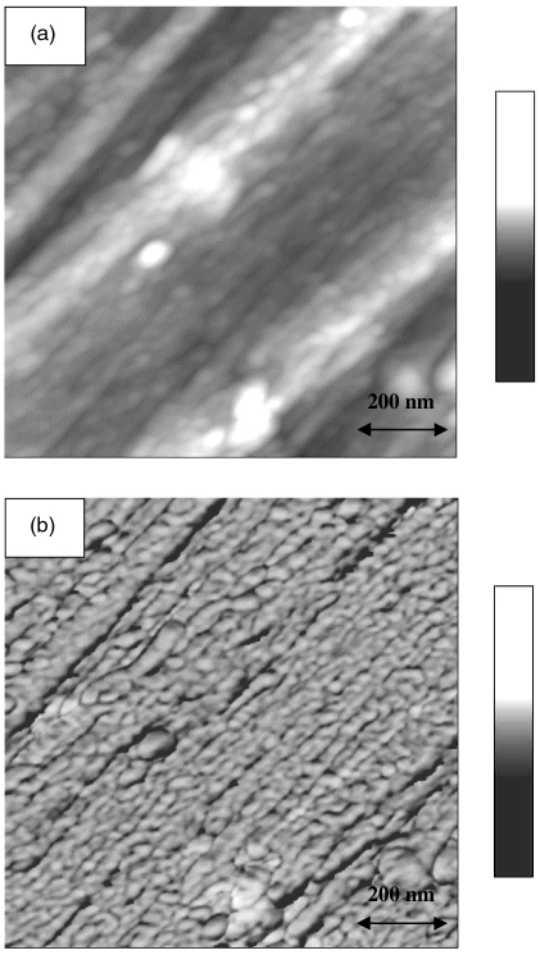

Fig. 3 AFM images of PPy/PMMA nanocomposite: (a) height image and (b) phase image. The film was fabricated by compression-molding of the PPy/PMMA nanocomposite at 220 °C under 25 kN cm^{-2} for 10 min. The images were obtained with Nanoscope IIIa Dimension 3100 SPM (Digital Instruments) in tapping mode.

Received (in Liverpool, UK) 17th October 2000, Accepted 16th November 2000
First published as an Advance Article on the web 14th December 2000

A hydrolytically stable sugar phosphonate coupled to a steroid *via* a long and semi-rigid spacer (synthesized *via* a 12-step sequence) binds both to the mannose-6-phosphonate receptors of certain cancer cells and to the lipid bilayer of vesicles, thereby serving as a multivalent adhesive between cell and vesicle surfaces.

Mannose-6-phosphate plays a key role in the intracellular retention and secretion of lysosomal hydrolytic enzymes.[1] Thus, this sugar residue inserted on the enzymes directs the transport of the newly synthesized enzymes from the Golgi apparatus to the lysosomes. Membrane-bound mannose-6-phosphate receptors assist in both the secretion and internalization of the lysosomal enzymes. It has been demonstrated that the population of mannose-6-phosphate receptors is increased abnormally in breast cancer cells as compared to those of benign breast disease.[2] The receptors can, therefore, provide a handle with which to attack the cells.[3] For example, drugs and vesicles endowed with mannose-6-phosphate moieties could, in principle, bind selectively to cancer cells owing to the enhanced presence of mannose-6-phosphate receptors. It is this potential vulnerability of the cancer cells which motivates the present paper. A recent paper describing vesicles containing phospholipids bearing a sugar-binding boronic acid that adhere to erythrocytes embodies a similar philosophy.[4]

Actually, the use of mannose-6-phosphate moieties to target bioactive molecules is not as attractive as it might seem. The problem lies in the susceptibility of sugar phosphates to hydrolysis by various phosphatase enzymes. To circumvent this problem, we have recently developed synthetic routes to two phosphonate analogs of mannose-6-phosphate (M6-P); one is isosteric with the phosphate moiety while the other is not.[5] Both, however, are hydrolytically stable. Upon submitting the analogs for biological testing, it was found that the isostere (but not the non-isostere) binds to M6-P receptors as effectively as does M6-P itself.[5]

Encouraged by the results of our biological testing, we proceeded to construct a molecule (**14**) that could bind both to cancer cells and to vesicles and, in this manner, serve as an 'adhesive' between the living and chemical systems. Our interest in attachment to cancer cells arose from the widespread attention given to vesicles (also called 'liposomes') as drug delivery vehicles in cancer therapy.[6]

Vesicles are spherical objects composed of one or more lipid bilayer shells surrounding an aqueous interior. Their diameter ranges from 30 nm ('small') to 10–200 μm ('giant'), and we have had considerable experience with both types.[7] Often in our vesicle research we add cholesterol, owing to its high affinity for lipids bilayers and to its strengthening effect upon the vesicles. It was for these properties that a cholesterylamine unit was selected as the vesicle-adhering unit. All told, about a dozen steps were required to synthesize the cell/vesicle adhesive (Scheme 1). Reactions were generally run at the 50 mg level because scale-up often reduced the yields. Great attention to purification by chromatography was necessary throughout.

4-Nitrophenyl-α-D-pyranoside **1** was used to initiate the synthesis (Scheme 1). Compound **1** was first selectively protected on the primary hydroxy with a 4-methoxytrityl group to give **2**. The secondary hydroxys were then protected with benzoyl groups (**2** to **3**). Attempts to benzylate these hydroxys instead of benzoylating them led to degradation. Compound **3**, fully protected, was selectively deprotected only at C-6 with the

DOI: 10.1039/b008446h

aid of a redox reaction involving ceric ammonium nitrate. The resulting primary alcohol **4** was then subjected to a Swern oxidation and converted into a product that gave two spots when developed with rhodanine. Both products showed the presence of an aldehyde proton in the NMR (one at 9.70 ppm and the other at 9.28 ppm in a ratio of 37 and 63 respectively). Purification of the mixture by chromatography gave the latter aldehyde whose NMR spectrum indicated the occurrence of a E1cb-type elimination of a benzoate during the Swern oxidation. In the course of the actual synthesis, however, the aldehyde mixture (**5** and **5′**) was used without separation in a Wittig–Horner reaction to produce two phosphonates (**6** and **6′**) in 25% and 40% yields, respectively. At this point, phosphonate **6** was isolated by chromatography and hydrogenated to **7**, a reduction that both removed the unsaturation and converted the nitro group into an amino group. Meanwhile, in this convergent synthesis, chemistry was being performed on the steroidal portion of the molecule starting with cholesterol **8**. Thus, cholesterol was transformed into α-cholesterylamine **10** using a literature procedure with only slight modification.[8] We now had in hand the necessary two amines which were joined together *via* a succinoyl unit by first acetylating **10** with succinic anhydride to give **11**. Carbodiimide coupling of **11** with **7** then gave **12** which needed only to be deprotected to produce the final compound.

Deprotection was accomplished by first debenzoylating **12** with methanolic ammonia. The phosphonate diester **13** was used to obtain the disodium phosphonate salt with the aid of trimethylsilylbromide; purification of **14** was performed by chromatography on silica gel. An overall yield of only 2.6% is indicative, in part, of the difficulties in preparing and purifying this large and bipolar molecule.

Microscopically visible giant vesicles, comprised of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), compound **14** or its phosphate counterpart,[9] and 1-palmitoyl-2-oleoyl-3-phosphoglycerol (POPG) were prepared in Hepes solution (1 mM) by the hydration method,[7] using ratios from 87:5:8 to 75:17:8, respectively. An aliquot of the vesicle suspension was added to a petri dish containing MCF-7 breast cancer cells (half-confluent) in Dulbecco's phosphate buffer solution (DPBS, Sigma). The petri dish was gently swirled and placed under a light microscope. Giant vesicles adjacent to cancer cells were grasped with a micropipet under suction and slowly withdrawn from the cells. The majority of the giant vesicles containing **14** or its phosphate counterpart failed to release the cells but continued to stick to them. When such vesicles were pulled away from the cancer cells, either the cell (Fig. 1) or the vesicle (Fig. 2) was substantially distorted. Fig. 1 shows how a withdrawn vesicle retains its contact with the cancer cell *via* an elongated fiber originating from the cancer cell. Fig. 2 shows how a spherical giant vesicle, attached to a cancer cell *via* **14**, deforms into an ellipsoid upon application of a lateral force. Control runs, carried out with identical vesicles except that their bilayers possessed a non-adhesive steroid, the succinate derivative of cholesterylamine, failed to produce a similar effect in the majority of cases. These experiments suggest that **14** does indeed serve as a chemical adhesive.

Submicroscopic vesicles (100 nm in diameter) were prepared by hydration of a film of POPC–14–POPG mixture with a 0.96 mM solution of a water-soluble fluorescent dye (Lucifer Yellow CH, dipotassium salt), followed by 19 extrusions through a 100 nm polycarbonate filter. Elution through a Sephadex G-50 column removed all dye not bound in or on the small vesicles. The fluorescent vesicles were then added to a cancer cell culture in medium and allowed to sit for 40 min. At the end of this period, medium and unbound vesicles were washed away with DPBS, and epifluorescence microscope pictures were taken of the cancer cells (Fig. 3). The cancer cells are seen to display a fluorescence consistent with surface binding of the fluorescent vesicles. As a control experiment, the chemical adhesive **14** was omitted from the vesicles, and the cancer cells failed to display fluorescence. This again suggests the efficacy of the chemical linkage between vesicle and cell. Definite experiments including flow cytometry are being planned. Yet even at this stage of our work the steroidal phosphonate appears to be a promising tool in selective targeting of breast cancer cells.

First published as an Advance Article on the web 14th December 2000

The electro-oxidation of water-immiscible liquid aliphatic acids (RCO_2H) leading to decarboxylation to afford a hydrocarbon (R–R) may be achieved using an emulsion formed *via* insonation so that the organic phase continuously extracts the products; in complete contrast to conventional monophasic electrolyses, the type and yield of products obtained from this biphasic Kolbe electrolysis are independent of the electrode material used.

The introduction of power ultrasound into homogeneous solutions has a considerable effect upon mass transport processes due to macroscopic streaming and microscopic interfacial cavitational events;[1] the sonication of biphasic media can result in the formation of an *in situ* emulsion,[2–4] primarily due to cavitational events that occur preferentially at the phase boundary.[3] These mechanical forces act to divide droplets again and again forming microdroplets and effectively 'homogenising' the heterogeneous system.

Electrosynthesis in emulsion media is long established.[5,6] Sono-emulsion systems have considerable potential for application in electrosynthesis because (i) there is no need for emulsion stabilising reagents, (ii) the separation of products is facile, (iii) aqueous solutions may be co-emulsified with a sparingly soluble liquid depolariser, resulting in a medium of high conductivity, (iv) high rates of mass transport can be achieved, and (v) the electrode surface is continually activated.[7]

We report the use of sono-emulsion media to study the electro-oxidation of hexanoic acid (Kolbe reaction). Previous sono-electrosynthetic studies[8–12] have focussed upon the effects of ultrasound on Kolbe electrolysis, exclusively under monophasic conditions, and with seemingly contradictory data. In this work it is shown that under biphasic conditions, although Kolbe electrolysis is conducted at a potential far beyond that required for solvent decomposition, an efficient conversion of hexanoic acid into decane is achieved at both platinum and boron-doped CVD (chemical vapour deposited) diamond film anodes. Surprisingly, the anode material does not affect the type or ratio of products formed.

An electrochemical cell equipped with an ultrasonic probe§ was used as reported earlier.[13] With an ultrasound intensity of 190 W cm^{-2}, this configuration leads to forceful mixing and emulsification of two-phase systems such as water | decane. The biphasic emulsion systems of hexanoic acid (*ca.* 5 mL) in aqueous 1.0 M NaOH (*ca.* 15 ml) had a conductivity of *ca.* 20 mS cm^{-1} and pH of 6.1. These values were kept more or less constant throughout the electrolysis by the reduction of water at the platinum counter electrode, and the gradual dissolution of the organic acid into the aqueous solution phase.

Power ultrasound was used to emulsify *ca.* 15 mmol of hexanoic acid in an aqueous 1.0 M NaOH biphasic system. After the passage of 1 Faraday (per mole of hexanoic acid) of charge (*ca.* 1500 C, sufficient to quantitatively convert hexanoic acid assuming a one-electron oxidation process) the reaction was stopped, excess hydroxide neutralised with acid, and the organic products extracted with ethyl acetate and analysed by GC–MS and NMR spectroscopy. Data summarised in Table 1 describe the conditions used and the yields of the main product, decane—the Kolbe dimer, generated in this electrolysis process. At platinum electrodes, it can be seen that a threshold current density (or applied potential) exists below which the Kolbe process cannot compete against background processes such as oxygen evolution. As in the monophasic case,[14] increasing the temperature at which the reaction takes place causes a decrease in current efficiency; decreasing the aqueous electrolyte concentration also has this effect. The effect of the current density can be rationalised as follows. Initially, increasing the current density causes the current efficiency to improve, and good yields of decane are observed at current densities in the range 0.2–0.3 A cm^{-2}; at values of 0.35 A cm^{-2} and higher, the current efficiency decreases. This can be rationalised in terms of the flux of hexanoate towards the electrode surface. The ultrasound-determined mass transport limiting current (I_{lim}) in homogeneous solution is given by[1] eqn. (1):

$$I_{lim} = \frac{nFADc}{\delta} \quad (1)$$

where n refers to the number of electrons transferred at the electrode, F is the Faraday constant (96485 C mol^{-1}), A is the area of the platinum working electrode (1.1 cm^2), D and c refer to the diffusion coefficient and the concentration of hexanoate in the emulsion respectively, and the Nernstian diffusion layer thickness,[1] δ is *ca.* 5 μm. Using the Wilke–Chang method[15] for estimation of diffusion coefficients, and further assuming the viscosity of the emulsion to be not too different from that of water, a hypothetical mass transport controlled limiting current

density of up to *ca.* 1 A cm^{-2} may be inferred. Hence, the oxidation is a mass transport controlled process and not limited by electrode kinetics. Increasing the current density beyond the mass transport limit gives rise to additional oxygen evolution rather than the desired Kolbe process, resulting in loss of efficiency. Decreasing the current density below a critical value of *ca.* 0.1 A cm^{-2} causes the Kolbe process to stop as the anode potential falls below the threshold required for Kolbe electrolysis.

The Kolbe dimer is not produced exclusively: GC–MS and NMR analysis of the electrolytic products permits the identification of the ester, amyl caproate, formed in $< 5\%$ yield. The absence of any pentenes and pentanols is novel and surprising. This is indicative of a trapping of the initial reaction intermediates at the electrode surface; the pentyl carbocation is unlikely to be formed as a free intermediate during electrolysis.

It is widely known that ultrasound damages the surface of platinum electrodes.[1] Recently, boron-doped CVD diamond electrodes have been employed in the presence of ultrasound with negligible damage to the electrode surface.[16] Furthermore, diamond surfaces are chemically inert under hostile conditions and after long-term electrolysis at very positive potentials.[17] The level of boron doping is high, typically *ca.* 10^{20} cm^3, corresponding to a B:C atom ratio of 1:1000, allowing a resistivity of 0.3 mΩ m to be achieved.[18]

Galvanostatic electrosynthesis experiments employing a boron-doped CVD diamond anode were conducted at different current densities, and the products analysed as before. The products observed in conventional Kolbe electrolyses suggest that the electrode material exerts a strong control, with products predominantly derived from carbocation intermediates detected at carbon anodes.[14] Surprisingly, electrosynthesis at a boron-doped CVD diamond anode under sono-emulsion conditions again gives rise to the detection of predominately the Kolbe dimer (see Table 1). Current efficiencies and yields are only slightly lower than those observed at platinum electrodes. Interestingly, the ester, amyl caproate is again the sole by-product, suggesting that a mechanism similar to that at platinum electrodes is operative.

In summary, Kolbe electrolysis has been accomplished under the novel conditions of an emulsion generated *in situ* by power ultrasound. This method of electrosynthesis renders good yields of product and is highly charge efficient. For the first time in 150 years,[19] the electrode material used and conditions employed are observed to have only little effect upon the type of products formed. Although the mechanism of the reaction is unclear, it may involve encapsulation of intermediates within the organic component of the emulsion. This type of electrosynthetic methodology shows promise for wider application.

We thank the Royal Society for financial support through a University Research Fellowship (F. M.), and DeBeers Industrial Diamond Division, UK and the EPSRC (GR/N 12051) for supporting this work.

Notes and references

§ The ultrasound generator employed was a VCX400 model immersion horn (Sonics and Materials, USA) equipped with a 3 mm diameter stepped titanium-alloy tip (electrically insulated) emitting 20 kHz sound with power level set to 190 W cm^{-2} (calorimetrically determined). The horn-to-electrode distance was maintained at 7 mm. Galvanostatic electrosynthesis was undertaken in the thermostatted cell (volume *ca.* 20 cm^3) using a PAR 173 (EG&G) galvanostat fitted with a PAR 178 (EG&G) digital coulometer. The cathode employed was a coil of platinum wire; the anode was either a 12 mm diameter platinum disc (Aldrich) or a 5 $\times$ 5 mm free-standing polycrystalline boron-doped CVD diamond plate (DeBeers Industrial Diamond Division, UK). Chemical reagents and NaOH (Aldrich) were of the highest commercially available purity.

Solvothermal synthesis of $[Cr_{10}(\mu\text{-}O_2CMe)_{10}(\mu\text{-}OR)_{20}]$ 'chromic wheels' with antiferromagnetic (R = Et) and ferromagnetic (R = Me) Cr(III)··Cr(III) interactions

Two decanuclear cyclic Cr(III) complexes have been synthesised in high yield by solvothermal techniques: magnetic susceptibility studies reveal ferromagnetic Cr···Cr exchange in one, and antiferromagnetic Cr···Cr exchange in the other.

The synthesis and magnetic characterisation of molecules with large numbers of unpaired electrons have attracted intense study since the discovery that molecular aggregates stabilising high ground spin states can display the phenomenon of single-molecule magnetism.[1] Cyclic complexes are of particular interest as models of infinite one-dimensional chain compounds and in the study of quantum-size effects,[2,3] and are known for several first row d-transition ions.[4] Among these, Fe(III) rings have received most attention[5] and can generally be made under ambient conditions. By contrast, few cyclic chromium complexes have been reported,[6] and require much harsher synthetic conditions owing to the kinetic inertness of Cr(III).[7]

Solvothermal techniques allow high reaction temperatures in low boiling solvents, whilst maintaining the advantages of solution chemistry (*e.g.* crystallisation of products). However, there are few reports of solvothermal syntheses of molecular clusters.[8] We report here the solvothermal synthesis of $[Cr_{10}(\mu\text{-}O_2CMe)_{10}(\mu\text{-}OR)_{20}]$ (R = Me **1**, Et **2**) in high yield. These are the highest nuclearity *cyclic* clusters yet reported for Cr(III), and **1** displays the rarely observed phenomenon of ferromagnetic Cr(III)··Cr(III) exchange.

Heating trinuclear basic chromium acetate, $[Cr_3(\mu_3\text{-}O)(\mu\text{-}O_2CMe)_6(H_2O)_3]Cl{\cdot}6H_2O$ (100 mg), in MeOH or EtOH (10 ml) in a Teflon-lined autoclave at 200 °C for 1 d followed by slow (0.1 °C min^{-1}) cooling to room temperature over *ca.* 2 d yields large, dark-green crystals of **1** or **2**, respectively (60–70%). Single-crystal X-ray diffraction analyses[9] reveal cyclic decanuclear structures (Fig. 1), similar to the 'molecular ferric wheels' reported by the groups of Lippard[5a] and Winpenny.[5b] The Cr_{10} rings are close to planar, with each pair of neighbouring Cr(III) ions bridged by one μ-acetate and two μ-alkoxide groups. In both compounds the rings are closely aligned perpendicular to the crystal {1 0 −1} plane. In **1**, the Cr_{10} rings in any given layer adopt a staggered configuration relative to those in adjacent layers (Fig. 2), while in **2** they are more closely 'eclipsed'.

The magnetic behaviour of **2** is relatively straightforward: χT *vs.* T decreases slowly from 300 to 120 K and then more quickly to 2 K (Fig. 3). This is indicative of weak, intra-ring antiferromagnetic exchange between Cr(III) ions. The best simulation[10] is obtained with J = +0.9 cm^{-1} (Fig. 3). Introduction of inter-cluster or zero-field splitting (ZFS) effects do not improve the simulation. Corroboration of this number comes from fitting $1/\chi$ *vs.* T (linear to low temperature, data not shown) to the Curie–Weiss law, giving a Curie constant of C = 18.8 $cm^3\ mol^{-1}$ K and a small Weiss constant of Θ = −3.4 K. The Cr··Cr exchange can then be calculated from Θ,[6b] giving J = +0.94 cm^{-1}.

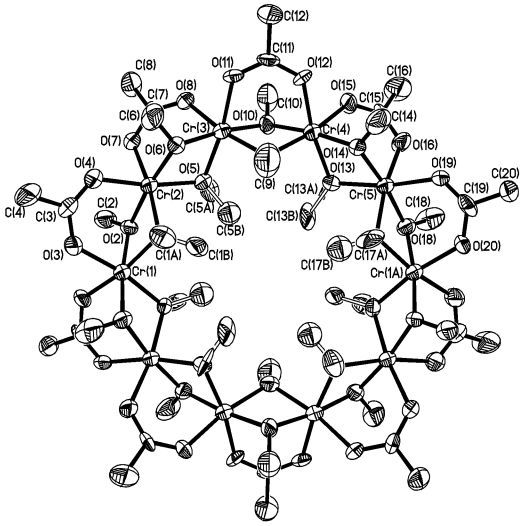

Fig. 1 Molecular structure (50% thermal ellipsoids) of $[Cr_{10}(O_2CMe)_{10}(OMe)_{20}]$ **1**. Bond length ranges: Cr–O(Me) 1.935(7)–1.985(8) Å, Cr–O(acetate) 1.969(8)–2.005(7) Å. Cr··Cr distances: 2.985(3)–2.994(3) Å. Bond angle ranges: Cr–O(Me)–Cr 98.0(3)–100.3(4)°. The analogous ranges for **2** are: Cr–O(Et) 1.951(6)–1.980(6) Å, Cr–O(acetate) 1.981(7)–1.998(7) Å, Cr··Cr 2.992(2)–2.997(2) Å, Cr–O(Et)-Cr 98.5(3)–100.1(3)°.

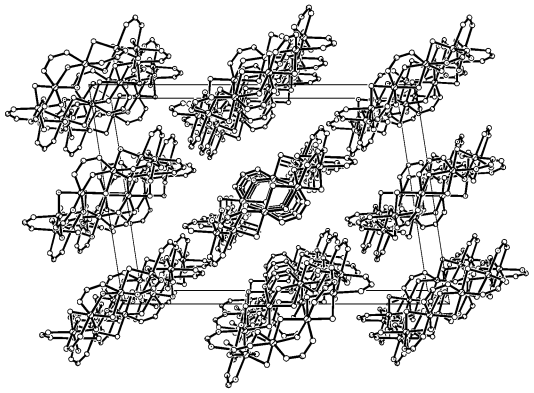

Fig. 2 Packing diagram of **1** viewed down the crystallographic *b* axis. All Me groups have been omitted for clarity.

The magnetic behaviour of **1** is more complicated. χT *vs.* T *increases* from 18.3 to 20.0 $cm^3\ mol^{-1}$ K between 300 and 22 K, indicating the presence of *ferro*magnetic interactions, before decreasing down to 2 K (Fig. 4). The high-temperature data (above 50 K) can be fitted to the Curie–Weiss law with C = 18.2 $cm^3\ mol^{-1}$ K and Θ = +4.1 K. The decrease of χT below

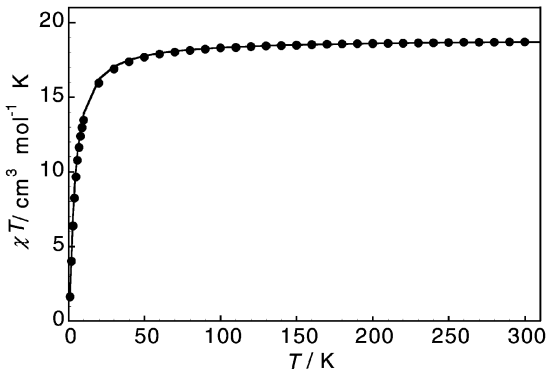

Fig. 3 χT *vs.* T for **2** (●) and best fit with $J = +0.9$ cm^{-1} (——).

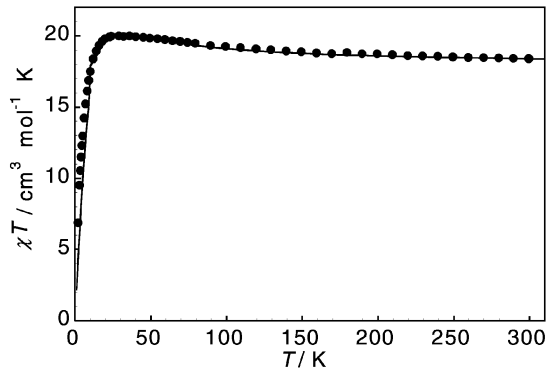

Fig. 4 χT *vs.* T for **1** (●) and best fit with $J = -4.5$ cm^{-1} and $J_{inter} = +0.26$ cm^{-1} (——).

20 K is indicative of an antiferromagnetic contribution to χT. The χT *vs.* T curve can be modelled with a ferromagnetic *intra*-molecular exchange between neighbouring Cr(III) ions of $J = -4.5$ cm^{-1} and a weak antiferromagnetic *inter*-molecular exchange of $J_{inter} = +0.26$ cm^{-1} (see Fig. 4). It is worth noting that it is the ferromagnetic nature of the *intra*-ring coupling in **2** that allows detection of an antiferromagnetic *inter*-ring interaction at temperatures below 20 K: a similar inter-ring coupling in **1** would be barely detectable. The ferromagnetic interaction is predominant as evidenced by the initial increase in χT down to 20 K. The decrease of χT below 20 K could not be modelled by inclusion of ZFS effects, or by having ferromagnetic exchange in one of the two independent molecules of **1** and antiferromagnetic exchange in the other.

The magnetic behaviour of **2** (antiferromagnetic intra-ring exchange, resulting in a non-magnetic $S = 0$ ground state) is common for cyclic complexes. However, $J = +0.9$ cm^{-1} is very weak compared to other cyclic Cr(III) complexes (typically +6 to +10 cm^{-1}).[6] The ferromagnetic interactions observed in **1** are highly unusual: there are very few previous examples of ferromagnetic Cr(III)··Cr(III) exchange in molecular systems[11] and, furthermore, only two previous examples of *ferro*magnetically coupled cyclic complexes of any metal ion.[12]

The so-called GHP model[13] correlates the exchange constant in 'planar' {$Cr_2(\mu\text{-}OR)_2$} dimers with (i) Cr–O(R)–Cr bridging angle (ϕ), (ii) Cr–O(R) bond length (r) and (iii) dihedral angle between the bridging plane and the O–R vector (θ). Our systems are complicated by the non-planarity of the {$Cr_2(\mu\text{-}OR)_2$} bridges imposed by the μ-O_2CMe groups: these bridges are also likely involved in the exchange pathways. However, we note that both **1** and **2** have an average $\phi \approx 99°$ and in the GHP model are in the 'crossover' region between (weak) antiferromagnetic and ferromagnetic coupling regimes. This is consistent with the observed small values of $|J| \approx 0.9$–5 cm^{-1}. Furthermore, the smaller average θ values observed in **2** than in **1** are consistent with the more antiferromagnetic exchange in the former: this effect has been observed previously in ethoxide *vs.* methoxide bridged Cr(III) dimers.[14] Thus, we attribute the differing magnetic behaviour of **1** and **2** to a combination of the above effects.

We thank the EPSRC and Italian MURST for financial support. This work was also supported by 3MD EU network contact no. ERB 4061 PL 97-0197.

Eight of the 20 (O)Me groups in **1** showed two-fold disorder, while many of the (O)Et groups in **2** were highly disordered. Non-hydrogen atoms were refined anisotropically, except for carbon atoms of minor disorder components; hydrogen atoms were placed in calculated positions. CCDC 182/1858. See http://www.rsc.org/suppdata/cc/b0/b007773i/ for crystallographic files in .cif format.

10 Magnetic susceptibilities for **1** and **2** were measured on a SQUID magnetometer in the temperature ranges 2–60 and 2–300 K in applied fields of 0.1 and 1 T, respectively, and diamagnetic corrections applied. Corrected χT values for **1** and **2** at 300 K were 18.3 and 18.7 cm^3 mol^{-1} K, respectively. The expected value for 10 Cr(III), $S = 3/2$ ions is 18.4 cm^3 mol^{-1} K. In order to calculate χT for 10 interacting $S = 3/2$ ions we must diagonalise the Heisenberg spin-Hamiltonian matrices ($H = \sum J_{ij} S_i S_j$) for the 116304 spin states of the cluster: the largest matrix (19425 × 19425) is beyond our present computational capabilities. Therefore, we have extrapolated the results from calculations on 6 and 8 interacting $S = 3/2$ ions. An average g-value of 1.98 was assumed for all simulations. Here, a *positive* J value implies an *anti*ferromagnetic interaction.

Porphyrins acting as external and internal ligands: preparation of conjugated trimetallic dimeric porphyrins

Sébastien Richeter, Christophe Jeandon, Romain Ruppert* and Henry J. Callot*

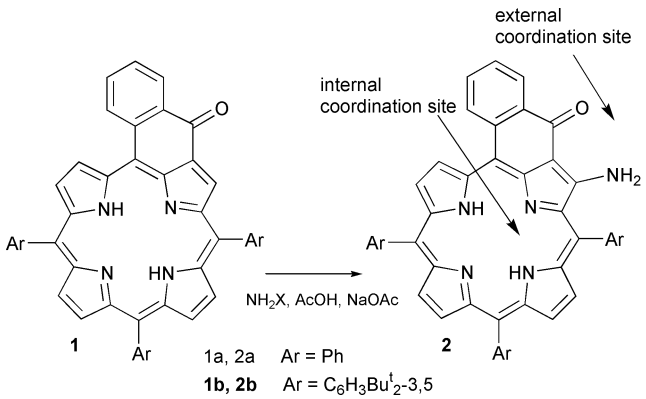
A porphyrin bearing a peripheral enaminoketone function allows the preparation of conjugated dimeric porphyrins linked through metal ions.

Multiporphyrin assemblies are involved in several biological processes such as photosynthesis or electron transfer. Mimicking those assemblies and their activity has been a challenge for chemists and numerous examples of multiporphyrin compounds have been described in recent years.[1–22] The connection between porphyrin nuclei may involve C–C bonds, hydrogen bonds, direct metal–metal or μ-X bonds, catenation of porphyrin *ansa*-derivatives, coordination of appropriate peripheral substituents to metal centers, *etc.* More recently, after the molecular wires described earlier by Crossley and Burn,[8] several groups are pursuing efforts to obtain conjugated oligoporphyrinic molecules directly linked through one, two or even three covalent bonds.[10–13] This covalent approach suffers some drawbacks: synthetic and separation problems, iterative reactions to obtain larger molecules, variations of the linking bonds limited to C–C or C–N.

The use of coordination bonds[15–21] has the advantage of offering an additional choice: each metal center may present its own geometry and coordination number depending on the element and its oxidation level, in addition to the variations due to the nature of the internal coordination sites of the porphyrins.

Here we describe a substituted porphyrin acting both as an internal (with the four pyrrole nitrogens) and as an external (with an enaminoketone moiety) ligand. The external coordination site is coplanar and fully conjugated to the porphyrin aromatic system.[22] In contrast to most systems assembled with metal ions, where little or no interaction is observed in the ground state between the porphyrins, the porphyrin–porphyrin conjugation in our dimers linked by metal ions will be illustrated by their electronic spectra and electrochemical behaviour.

meso-Tetraarylporphyrins bearing a keto group located on an additional ring attached to an aryl substituent and a pyrrolic β-carbon have been known since 1980 but their reactivity has been little investigated.[23–26] In the course of a search for extended



porphyrin chromophores we reacted ketone **1** with nitrogen nucleophiles. Under mild acid catalysis, reagents of the general composition $H_2N–X$ (X = OH, NHTs, OSO_3H) gave in variable yield enaminoketone **2**, the highest yield (90%) being observed with hydroxylamine *O*-sulfonic acid–AcOH–NaOAc in refluxing CH_2Cl_2. Enaminoketone **2a** showed a UV–VIS similar to the starting material (λ_{max} = 451, 568, 614 and 709 nm). The β-N–H NMR signals could be detected at δ 9.0 (N–H involved in a hydrogen bond with the carbonyl group) and δ 5.48 (free N–H, shielded by a vicinal phenyl ring).

Enaminoketone **2** presents remarkable coordinating properties: in addition to the internal 4N tetradentate macrocyclic coordination site, the enaminoketone group is a potential N+O chelating external site (an analog of the acetylacetonate ligand) that might couple porphyrins to form homo- or heteropolymetallic complexes. One would predict that the coordination at the enaminoketone site should be favoured over the introduction of metal ions in the core of the porphyrin, but one also expects the stability of the internal complex to be of orders of magnitude higher for the same metal ion; in particular with first row transition metals the porphyrin–metal–porphyrin connection is expected to be of low stability. Accordingly, heterometallation may be performed along two routes by using as an intermediate either an internal complex or the porphyrin base dimer (Scheme 1).

Metallation of **2a** (R = Ph) with nickel acetylacetonate (one or more equiv.) rapidly gave a highly insoluble product containing one metal and two porphyrins formulated as **3a** (M^1 = Ni; M^2 = M^3 = H_2). Treatment with acetic acid, which is unable to remove nickel from the 4N site of a porphyrin, quantitatively regenerated the starting material. However, on prolonged reaction in refluxing toluene with a 1:1 porphyrin/nickel ratio, metallation of the porphyrin occurred and gave mononuclear **Ni**–**2a**, while excess reagent gave trinuclear **3a** (M^1 = M^2 = M^3 = Ni). The formation of **Ni**–**2a** is best explained by the low stability of the nickel bridge—it did not survive chromatographic conditions—and the slow formation of the most stable metallation product. The same trinuclear compound **3a** (M^1 = M^2 = M^3 = Ni) was formed when **Ni**–**2a** was treated with an excess of nickel acetylacetonate. Similarly, several trimetallic bisporphyrins were prepared (Ni/Cu/Ni; Ni/V=O/Ni; Ni/Pd/Ni).

There remained the question of the relative arrangement of the porphyrins around the metal, since the dimers may have a center or a plane of symmetry. COSY and NOESY experiments

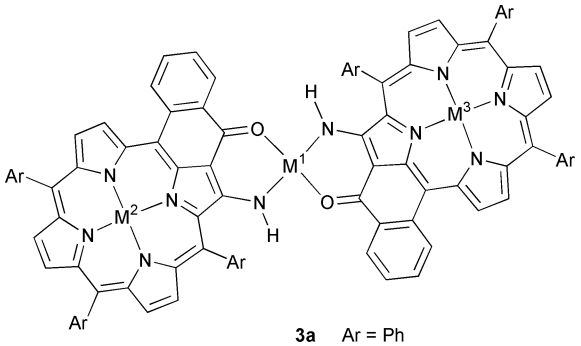
DOI: 10.1039/b008740h



3a Ar = Ph
3b Ar = $C_6H_3Bu^t_2$-3,5

confirmed the structure and the dimeric nature of **3**. Additional information was obtained when we turned to the more soluble *meso*-tri(3,5-di-*tert*-butyl)phenylporphyrin series. Heating equimolecular amounts of palladium(II) acetate and enaminoketone **2b** in refluxing toluene for 3 h led almost exclusively to **3b** (M^1 = Pd; M^2 = M^3 = H_2). Again, NMR experiments (ROESY) confirmed the relative position of the porphyrins: HH ROESY cross signals were observed between two protons of the cyclised phenyl ring and the *para* proton and the *tert*-butyl protons of a *meso*-aryl group belonging to the other porphyrin. This compound survived chromatographic purification and is a good starting material for heterometallic dimer preparation. Indeed, metallation with zinc acetate gave the mono- and bis-metallated **3b** (M^1 = Pd; M^2 = Zn; M^3 = H_2 or Zn).

These new porphyrin dimers all showed similar electronic spectra and an electrochemical behaviour indicative of the conjugation introduced through the connecting metal between the two aromatic rings. For example, the lowest energy band of **3a** ($M^{1–3}$ = Ni) shifts to 700 nm (ε = 33000 dm^3 mol^{-1} cm^{-1}) in comparison to the band observed at 649 nm (ε = 18500 dm^3 mol^{-1} cm^{-1}) for **Ni**–**2a** (Fig. 1). The HOMO–LUMO gap estimated from these data is reduced to 1.77 eV in the dimer **3a** ($M^{1–3}$ = Ni) compared to 1.91 eV for the monomer **Ni**–**2a** (already a very low value compared to the gap reported for nickel porphyrins, $E \approx 2.3$ eV). The corresponding bases such as **3b** (M^1 = Pd; M^2 = M^3 = H_2) display bands at even longer wavelengths (730 nm, ε = 39000 dm^3 mol^{-1} cm^{-1}), which can be compared with that of **2b** (711 nm, ε = 8500 dm^3 mol^{-1} cm^{-1}).

The monomer **Ni**–**2a** showed two one-electron oxidations at 0.46 and 0.83 V *vs.* Fc/Fc$^+$. In trimetallic **3a** ($M^{1–3}$ = Ni), the first oxidation is split into two one-electron oxidation waves (one electron per porphyrin) at 0.32 and 0.50 V, indicative of a strong interaction between the two porphyrins. The removal of the first electron therefore occurs at a potential 0.14 V lower than for the monomer (a value equal to the difference between the gaps taken from the electronic spectra). A two-electron oxidation (or rather twice a one-electron oxidation of each porphyrin ring) is further observed at 0.68 V. It seems that the

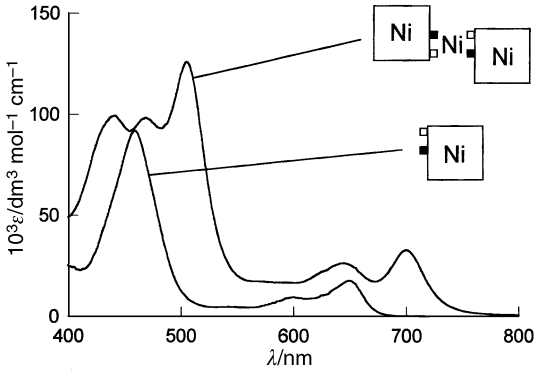


Fig. 1 UV–VIS spectrum of **3a** ($M^{1–3}$ = Ni) and **Ni**–**2a**.

removal of the first two electrons from the dimer has led to a disruption of the conjugation between the two rings. The dimer (already oxidised by two electrons) now behaves like two independant nickel monomers. All waves are quasi-reversible (ΔE_p = 60–90 mV), showing that dimer **3a** ($M^{1–3}$ = Ni) remains intact during this overall four-electron oxidation–reduction process.

In conclusion, we confirmed that efficient porphyrin–porphyrin interaction could be achieved *via* metal coordination. The synthesis of bis-enaminoketoporphyrins where two external coordination sites are located in divergent directions is in progress. These compounds should allow the preparation of more highly conjugated oligomers.

We thank R. Graff for the NMR experiments.

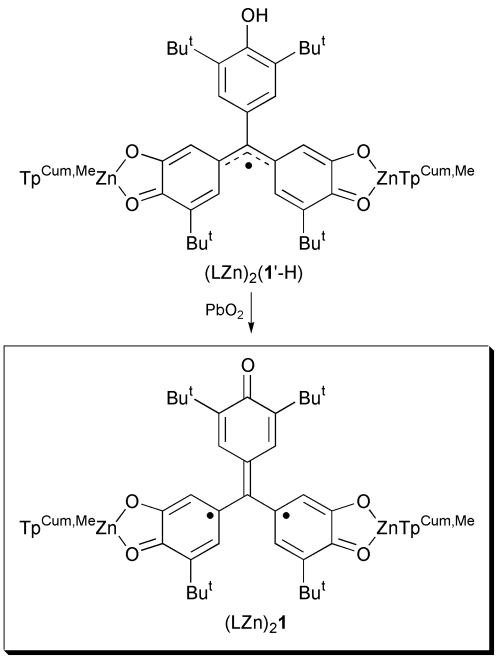
Received (in Irvine, CA, USA) 29th September 2000, Accepted 30th October 2000
First published as an Advance Article on the web

The first example of a structurally characterized, rationally designed, triplet ground-state bis(semiquinone) complex is presented; the intramolecular exchange coupling is ferromagnetic with $J = +209$ cm^{-1}.

Molecular structures of organic biradical ligands are important to those concerned with construction of molecule-based magnetic materials using the metal-radical approach,[1,2] and to those with an inherent interest in electronic properties of open-shell organic molecules.[3]

Recently, we reported several semiquinone-type ligands to be used as building blocks for high-spin molecules and open-shell materials.[4,5] Among these new ligands is $S = 1/2$ quinonemethide-semiquinone (QMSQ) present in the complex $(LZn)_2$(**1′**-H), the structure of which has been reported as well as its



conversion to both a mixed-valent species and to a biradical, $(LZn)_2$**1**, shown below.[5,6] Herein, we report both the molecular structure and magnetic properties of $S = 1$ $(LZn)_2$**1** [Tp^{Cum,Me} = hydrotris(3-cumenyl-5-methylpyrazolyl)borate].

For clarity, we will refer to the mono-oxygenated rings of $(LZn)_2$(**1′**-H) and $(LZn)_2$**1** as A-rings, and the dioxygenated rings as either the dioxolene- or the B-rings. Structural changes that accompany conversion of $(LZn)_2$(**1′**-H) to biradical $(LZn)_2$**1** are consistent with the Lewis structures above.

The crystal structure of biradical $(LZn)_2$**1** shows that the asymmetric unit contains two symmetry-independent molecules that differ primarily in torsion angles of A- and B-rings (and cumenyl ring torsions), and are therefore different conformers that also have an opposite sense of chirality.† An ORTEP of $(LZn)_2$**1** is shown in Fig. 1, where hydrogens and cumenyl groups have been omitted for clarity. Bond lengths, angles, and torsions are summarized in Table 1 and Fig. 2.

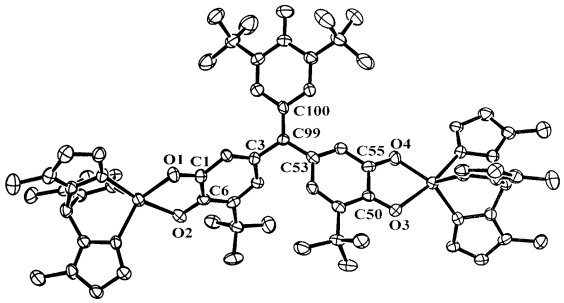


Fig. 1 50% ORTEP of $(LZn)_2$**1**. Hydrogen atoms, cumenyl groups and THF molecules have been omitted for clarity.

Table 1 Average bond lengths and torsion angles for $(LZn)_2$**1**[a,b]

Bond	R_{av}/pm
C1–O1, C55–O4	129.35, 128.35
C6–O2, C50–O3	128.15, 127.15
C1–C6, C50–C55	146.05, 146.55
C3–C99, C53–C99	148.30, 146.95
C99–C100	137.65
Ring	**Average torsion angles**
C1–C6, C50–C55	50.33, 42.68
C100–C105	18.05

[a] Averages for conformers I and II, the two symmetry-independent molecules in the asymmetric unit. [b] Torsion angles are relative to the plane made by atoms C3–C53–C99–C100.

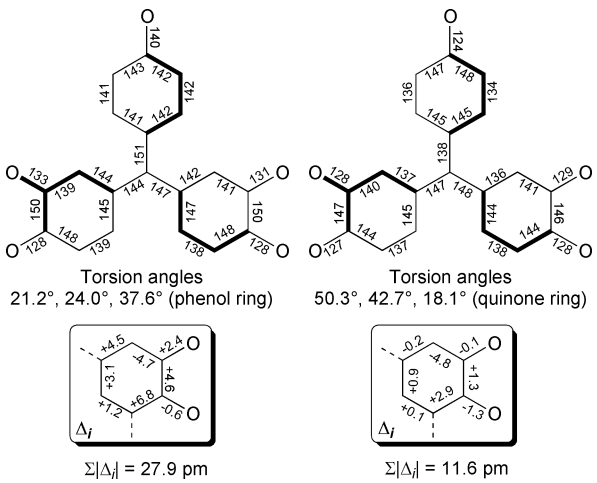

Fig. 2 Comparison of structural features of $(LZn)_2$(**1′**-H) (left) and $(LZn)_2$**1** (right). Averaged bond lengths (in pm) are shown for $(LZn)_2$**1**. See text for details.

DOI: 10.1039/b008037n

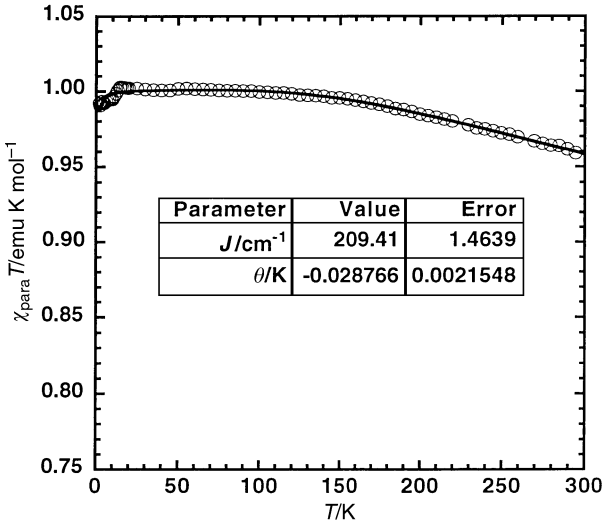

Fig. 3 Temperature dependence of $\chi_{para}T$ for biradical $(LZn)_2$**1**.

The A-ring C–O bond of $(LZn)_2$**1** (*ca.* 124 pm) is substantially shorter than the A-ring C–O single bond of $(LZn)_2$(**1′**-H) (140 pm),[5] consistent with carbonyl character for the former. In fact, as seen in Table 1 and Fig. 2, the pattern of long and short bond lengths for the A-ring in $(LZn)_2$**1** confirms its quinoidal character.

The A-ring of $(LZn)_2$**1** is twisted 18° while the dioxolene rings are twisted *ca.* 46° from the plane made by atoms C3, C53, C99 and C100, allowing conjugation of the dioxolene rings with the A-ring.

Fig. 2 shows bond length deviations ($\Sigma|\Delta_i|$) of the B-rings from a 3,5-di-*tert*-butylorthosemiquinone ring.[7,8] As we pointed out previously, the dioxolene rings of $S = 1/2$ $(LZn)_2$(**1′**-H) are quite different from those of a semiquinone ($\Sigma|\Delta_i| = 27.9$ pm) due to the QMSQ bond formulation.[5] However, $\Sigma|\Delta_i| = 11.6$ pm for the dioxolene rings of $(LZn)_2$**1** indicating a greater similarity to a semiquinone, but also consistent with some delocalization of spin/charge into the A-ring, since we maintain that $\Sigma|\Delta_i| \neq 0$ is an indication of a delocalized electronic structure.

The magnetic susceptibility of microcrystalline $(LZn)_2$**1** was measured from 2 to 300 K using a SQUID magnetometer, and is plotted as $\chi_{para}T$ *vs.* T in Fig. 3. Modeling the temperature-dependent $\chi_{para}T$ product of $S = 1$ molecules can be achieved by fitting to a modified Bleaney–Bowers expression:[9,10]

$$\chi_{para}T = \frac{2Ng^2\beta^2T}{k(T-\vartheta)\left[3+\exp\left(\frac{-2J}{kT}\right)\right]}$$

where, g is the isotropic Landé constant ($g = 2.0023$), β is the Bohr magneton, T is temperature in Kelvin, k is Boltzmann's constant, ϑ is the Weiss constant representing a weak intermolecular interaction, and $2J$ is the singlet–triplet energy gap ($J > 0$ for triplet ground-state and $J < 0$ for singlet ground-state).

The best fit of the data give $J = +209 \pm 1$ cm^{-1} and $\vartheta \approx -0.03$ K. The very small Weiss constant is consistent with negligible intermolecular interactions due to the large, insulating hydrotrispyrazolylborate ligand, while the moderately large, positive exchange parameter, J, indicates that $(LZn)_2$**1** is a triplet ground-state biradical consistent with its π-connectivity. The symmetry of the bis(semiquinone) ligand of $(LZn)_2$**1** precludes degeneracy of the SOMOs, nonetheless, delocalization of spin into the quinone-methide unit (A-ring) gives rise to a substantial exchange integral, stabilizing the triplet state relative to the singlet state. However, the different spin distribution, lower symmetry, and therefore attenuated delocalization into the A-ring results in a slightly smaller J for $(LZn)_2$**1** than for Yang's biradical ($J \geqslant +245$ cm^{-1}).[11,12]

This work is funded by the National Science Foundation. D. A. S. thanks the Camille and Henry Dreyfus Foundation for a Camille Dreyfus Teacher-Scholar Award, and Professor Frank Tsui (Department of Physics, UNC-CH) for the use of his SQUID magnetometer.

Coordination networks derived from antimony(III) halide complexes with thio- and seleno-ether ligation

Andrew J. Barton, Nicholas J. Hill, William Levason, Bhavesh Patel and Gillian Reid*

Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ. E-mail: gr@soton.ac.uk

Received (in Cambridge, UK) 26th September 2000, Accepted 27th November 2000
First published as an Advance Article on the web

Antimony(III) halides form highly unusual infinite one- or two-dimensional networks when coordinated to dithio- or diseleno-ether ligands or macrocyclic selenoethers. The structures adopted are contrasted with those observed for related bismuth(III) species.

We have been interested for some time in the coordination chemistry of group 16 donor ligands. The vast majority of compounds involving thio-, seleno- or telluro-ether coordination incorporate d-block elements.[1] Also, we have shown that σ-donation towards low valent metal centres increases significantly as group 16 is descended.[2] However, there are relatively few examples of complexes involving p-block elements with these ligands. We have therefore extended our work to investigate the interaction of thio-, seleno- and telluro-ether ligands with p-block metalloids. These elements exhibit very different electronic environments compared to d-block elements and π-bonding effects are unimportant. Specifically in this communication we report the synthesis and structural characterisation of three antimony(III) halide complexes involving group 16 donor ligands, including the first examples containing selenoether ligation. Antimony(III) thioether complexes are rare, the only structurally characterised examples being $[SbCl_3$(1,4-dithiacycloheptane)], $[(SbI_3)_2$(1,4-dithiane)], $[SbX_3([9]aneS_3)]$ (X = Cl or I) and $[(SbCl_3)_2([18]aneS_6)]$ ([18]aneS$_6$ = 1,4,7,10,13,16-hexathiacyclooctadecane).[3]

Reaction of $SbBr_3$ with 1 mol equiv. of the dithioether $MeS(CH_2)_3SMe$ in anhydrous MeCN solution yields a pale yellow solid of empirical formula $[SbBr_3\{MeS(CH_2)_3SMe\}]$.† Crystals were obtained by slow evaporation from a solution of the compound in MeCN. The structure shows (Fig. 1)‡ that this species adopts a two-dimensional sheet array derived from distorted octahedral Sb(III) centres coordinated to three mutually *fac* terminal Br ligands and three S-donor atoms from different dithioether ligands, two of which, S(1) and S(1*), may be regarded as μ-bridging since they also form weak interactions to an adjacent Sb centre. While the Sb–Br distances are normal for primary Sb–Br ligation, the Sb–S distances are *ca.* 3.2 Å, suggesting secondary interactions. The second sulfur in each dithioether coordinates to a nearby, symmetry-related Sb centre to generate the infinite array. The *cis* angles at Sb lie in the range 80.3(1)–104.49(7)° and the angle at the bridging thioether, S(1), is 104.4(7)°. The Sb–S distances reported for known Sb(III) thioether species span a considerable range, *e.g.* in $[SbX_3([9]aneS_3)]$, X = Cl (chain structure with seven-coordinate Sb) has *d*(Sb–S) = 3.156(3)–3.409(3), while X = I (discrete monomer with distorted octahedral Sb and *fac* [9]aneS$_3$) gives *d*(Sb–S) = 2.840(2)–2.895(2) Å, while for $[(SbI_3)_2$(1,4-dithiane)] (infinite chain with five-coordinate Sb} *d*(Sb–S) = 3.274 and 2.336 Å.[3] The Sb–S distances in our complex are comparable with those above.

The selenoether analogue $[SbCl_3\{MeSe(CH_2)_3SeMe\}]$ was obtained similarly,† although this species is rather less stable, turning black over a period a few days even when stored in a N_2 purged dry-box. The structure of this complex (Fig. 2)‡ is markedly different from the thioether analogue above, adopting an infinite one-dimensional chain. The Sb centres exhibit a distorted octahedral coordination environment comprising two *cis* terminal Cl, two μ-Cl and two mutually *cis* Se atoms from different diselenoethers. Thus the chains are derived from weakly associated, asymmetric Sb_2Cl_6 units linked by bridging diselenoether ligands, Sb–Cl(2) 2.451(3), Sb–Cl(2*) 3.236(3) Å. Indeed, the Sb–Cl(2) distance is very similar to the terminal Sb–Cl(1) and Sb–Cl(3) distances, with a weak secondary Sb–Cl(2*) interaction. The Sb–Se distances of *ca.* 3.2 Å are very similar to the Sb–S distances in the dithioether species above, again suggesting rather weak, secondary interactions.

The coordination of Sb(III) to the tetraselenoether macrocycle [16]aneSe$_4$ (1,5,9,13-tetraselenacyclohexadecane) was also probed to investigate the effect of the constrained cyclic ligand,

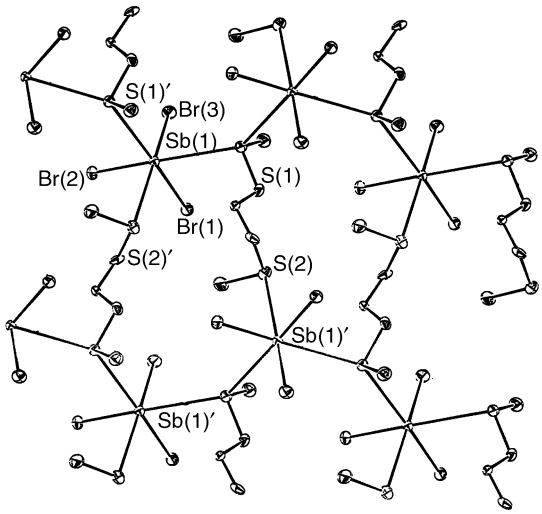

Fig. 1 View of a portion of the two-dimensional structure of $[SbBr_3\{MeS(CH_2)_3SMe\}]$ with the atom numbering scheme. Selected bond lengths (Å): Sb–Br(1) 2.572(2), Sb–Br(2) 2.503(2), Sb–Br(3) 2.575(2), Sb–S(1) 3.253(5), Sb–S(2*) 3.155(5), Sb–S(1*) 3.291(5).

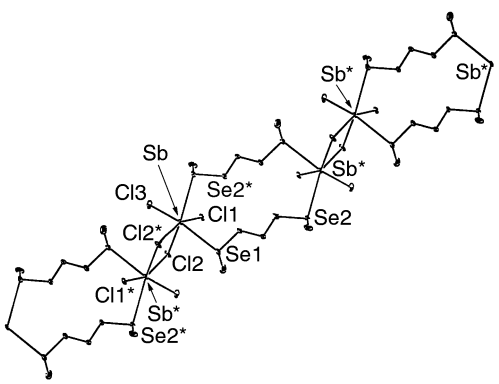

Fig. 2 View of a portion of the one-dimensional structure adopted by $[SbCl_3\{MeSe(CH_2)_3SeMe\}]$ with the atom numbering scheme. Selected bond lengths (Å) and angles (°): Sb–Cl(1) 2.388(3), Sb–Cl(2) 2.451(3), Sb–Cl(3) 2.424(3), Sb–Cl(2*) 3.236(3), Sb–Se(1) 3.204(2), Sb–Se(2) 3.244(2) Å; Cl(2)–Sb–Cl(2*) 76.8(1).

DOI: 10.1039/b007805k

while retaining the trimethylene linkage between the donor atoms. Reaction of $SbBr_3$ with [16]aneSe_4 in MeCN affords a yellow powder of stoichiometry [$(SbBr_3)_2$([16]aneSe_4)].† The crystal structure of this species shows (Fig. 3)‡ a two-dimensional sheet array derived from [16]aneSe_4 molecules coordinated in an exocyclic configuration to four Sb centres each of which bridge to another selenacrown. The geometry at Sb can be described as five-coordinate *via* primary interactions to three *fac* terminal Br and secondary interactions to two *cis* Se atoms from different macrocycles to give a distorted square-pyramidal coordination environment. The Sb–Se distances in [$(SbBr_3)_2$([16]aneSe_4)] are shorter than those in [$SbCl_3${MeSe$(CH_2)_3$SeMe}] above, although this may be due to the lower coordination number at Sb in the former. The weak Sb–Se interactions in these systems are considerably longer than normal Sb–Se bond distances in, for example, [$Sb(SeMe)_3$] which average 2.580 Å.[4]

The main features which these new compounds have in common are the retention of the pyramidal SbX_3 unit observed in the parent antimony trihalide[5] and the occurrence of weak, secondary Sb–S or Sb–Se interactions on the opposite face which leads to the S or Se atoms occupying mutually *cis* coordination sites.

The very low solubilities exhibited by the new compounds, presumably associated with their polymeric nature, has severely hindered attempts to obtain solution NMR spectra, however the IR spectra show features associated with coordinated dithio- or diseleno-ether and ν(Sb–X).

Surprisingly, the structures of the three new antimony species are each quite different from their bismuth(III) analogues. The thioether compound [Bi_4Cl_{12}{MeS$(CH_2)_3$SMe}$_4$]·H_2O forms a three-dimensional open-framework lattice incorporating pseudo-cubane Bi_4Cl_{12} units linked by bridging dithioether ligands, while [$BiBr_3${MeE$(CH_2)_3$EMe}] (E = S or Se) and [$BiCl_3${MeSe$(CH_2)_3$SeMe}] all adopt an infinite two-dimensional sheet array derived from planar Bi_2X_6 units linked by bridging dithio- or diseleno-ether ligands. Finally, [$BiBr_3$([16]aneSe_4)] adopts a one-dimensional ladder structure derived from almost planar Bi_2Br_6 'rungs', which are linked by bridging [16]aneSe_4 'uprights', leaving two mutually *trans* Se atoms within each crown uncoordinated.[6] These differences are unexpected given the subtle change from Bi(III) to Sb(III) and serve to extend further the diverse range of structures identified for thio- and seleno-ether complexes with p-block elements.

We thank the EPSRC for support.

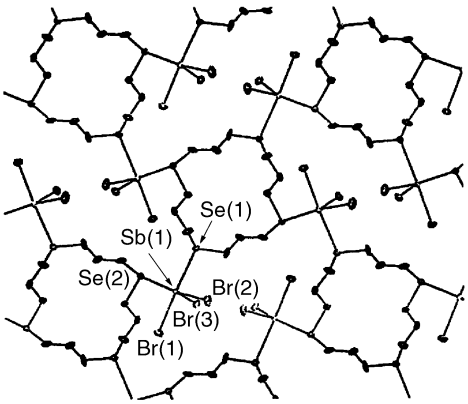

Fig. 3 View of a portion of the two-dimensional sheet adopted by [$(SbBr_3)_2$([16]aneSe_4)] with the atom numbering scheme. Selected bond lengths (Å) and angles (°) Sb–Br(1) 2.687(1), Sb–Br(2) 2.537(1), Sb–Br(3) 2.601(1), Sb–Se(1) 2.989(1), Sb–Se(2*) 3.193(1) Å; Se(1)–Sb–Se(2*) 82.55(3).

Notes and references

† Satisfactory elemental analyses and IR spectroscopic data were obtained for the new compounds.

‡ Colourless {or yellow: [$(SbBr_3)_2$([16]aneSe_4)]} crystals were obtained by slow evaporation from a solution of the appropriate compound in MeCN. X-Ray crystallographic data were collected on a Rigaku AFC7S four-circle diffractometer, T = 150 K. Structure solution and refinement were routine.[7–10]

Crystal data: for [$SbBr_3${MeS$(CH_2)_3$SMe}]: $C_5H_{12}Br_3S_2Sb$, M = 497.73, orthorhombic, space group $Pna2_1$, a = 14.105(2), b = 9.446(1), c = 9.781(1) Å, V = 1303.2(3) Å^3, Z = 4, D_c = 2.537 g cm^{-3}, μ(Mo-Kα) = 116.11 cm^{-1}. 1364 unique reflections of which 1022 with $F > 4\sigma(F)$ were used in all calculations. Final R = 0.041, R_w = 0.049.

For [$SbCl_3${MeSe$(CH_2)_3$SeMe}]: $C_5H_{12}Cl_3SbSe_2$, M = 458.18, monoclinic, space group $P2_1/c$, a = 9.622(5), b = 12.882(3), c = 10.376(4) Å, β = 101.89(4)°, V = 1258.5(8) Å^3, Z = 4, D_c = 2.418 g cm^{-3}, μ(Mo-Kα) = 85.59 cm^{-1}. 2344 unique reflections of which 1934 with $F > 4\sigma(F)$ were used in all calculations. Final R = 0.041, R_w = 0.053.

For [$(SbBr_3)_2$([16]aneSe_4)]: $C_{12}H_{24}Br_6Sb_2Se_4$, M = 1207.08, monoclinic, space group $P2_1/n$, a = 10.276(2), b = 13.340(3), c = 10.755(2) Å, β = 113.71(1)°, V = 1370.1(4) Å^3, Z = 2, D_c = 2.926 g cm^{-3}, μ(Mo-Kα) = 160.58 cm^{-1}. 2536 unique reflections of which 1724 with $F > 4\sigma(F)$ were used in all calculations. Final R = 0.035, R_w = 0.039.

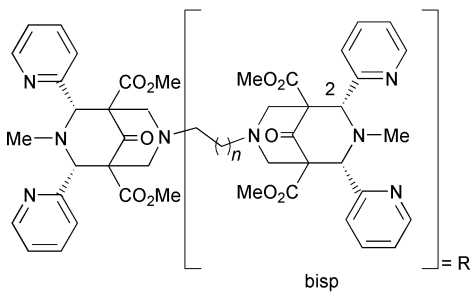
Received (in Cambridge, UK) 30th October 2000, Accepted 24th November 2000
First published as an Advance Article on the web 15th December 2000

The X-ray crystal structures of three low molecular weight models of catechol oxidase with three different coordination modes are reported; and the compound with a bridging catecholate is shown to be the catalytically most active form.

A range of biological dicopper sites have similar structures, with three histidine donors for each of the two Cu sites and Cu–Cu distances of *ca.* 3.5 Å. These include the oxygen transport protein hemocyanin, the oxygenation enzyme tyrosinase and the oxidation enzyme catechol oxidase. The active sites of these dicopper proteins are structurally well characterized;[1–6] thorough spectroscopic studies, combined with computational investigations, have defined the electronic structures of the active sites,[7,8] and extensive kinetic studies[9,10] have led to the proposal of mechanisms for oxygen transport and activation, as well as oxygen and electron transfer. The assumption of a bridging catecholate as the active species in catechol oxidase[7] was recently challenged on the basis of crystallographic data, which suggested an active state with a monodentate catecholate.[6]

Low molecular weight model compounds have helped to understand structural, electronic and mechanistic features and are expected to be useful for the development of new catalysts. A number of Cu^{II}-based models with catechol oxidase activity have been reported,[11–16] but only few relevant experimental structures with coordinated catecholate have appeared so far.[11] In particular, there is no example where the various coordination modes of catecholate, including the putative intermediates with bridging or monodentate catecholate, have been analyzed with identical coligands, and for some relevant coordination models there have not been any structural data available so far.

We have successfully used mono- and di-nuclear Cu^{I} and Cu^{II} compounds with bispidine-type ligands to stabilize μ-peroxodicopper(II) compounds.[17,18] We now present preliminary results on the catechol oxidase activity of the corresponding Cu^{II} compounds with 3,5-dtbc in MeOH (3,5-dtbc = 3,5-di-*tert*-butylcatechol; spectrophotometric analysis of the *o*-quinone product).[14,15] The mononuclear Cu^{II} complex of L^1 is inactive, in contrast to the dinuclear compounds with L^2 and L^3.



L^1: R = Me, **L^2**: R= bisp, *n* = 1; **L^3**: R = bisp, *n* =2;
L^4: R = bisp, *n* = 2, carbon atoms 2 inverted

One equivalent of $[Cu_2(L^3)(solv)_2]^{4+}$ (solv = solvent) produces in a stoichiometric process 2 equivalents of quinone, while 13 equivalents of quinone are produced per h in a catalytic reaction with $[Cu_2(L^2)(solv)_2]^{4+}$. It emerges that the catalytic activity is a function of the catechol binding mode and stability, and this may differ for all three Cu^{II} compounds.

To examine this, the electronically deactivated substrate $tccH_2$ ($tccH_2$ = tetrachlorocatechol) was added in various concentrations to methanolic solutions of the three Cu^{II} compounds, and substrate binding was monitored spectrophotometrically. For $[Cu(L^1)(solv)]^{2+}$ a strong absorption band appeared at *ca.* 450 nm; for $[Cu_2(L^2)(solv)_2]^{4+}$ and $[Cu_2(L^3)(solv)_2]^{4+}$ equilibria between species with absorptions at *ca.* 450 nm and *ca.* 530 nm were established; with L^2 the species with the lower energy transition was more stable than with L^3, where it disappeared with an excess of catechol (see ESI†). These results are in accord with the assumption that $[Cu_2(L^2)(solv)_2]^{4+}$ and $[Cu_2(L^3)(solv)_2]^{4+}$ lead to catecholate-bridged active compounds, while $[Cu(L^1)(solv)]^{2+}$ leads to a mononuclear catecholate compound. A molecular model[19] (see Fig. 1) indicates that the ethylene-bridged dicopper(II) compound is suitable and highly preorganized for a bridging catecholate.

Single crystals of $[Cu(L^1)(tccH)](ClO_4)$ **1**, $[Cu(L^1)(tcc)]$ **2** and $[Cu_2(L^3)(tcc)](ClO_4)_2$ **3** were obtained by reaction of the Cu^{I} precursors with the fully chlorinated quinone (tcbq) or with $tccH_2$ and O_2, followed by slow evaporation of the solvent (full experimental details, including synthetic procedures, crystal growth, spectroscopic (IR, UV–VIS) and elemental analytical data, are given as ESI†).[20,21] ORTEP plots are shown in Fig. 2. The structure of **1** is of poor quality, but catecholate binds unambiguously as a monodentate, monoprotonated ligand (see analytical data in the ESI†). Also shown in Fig. 2 is an ORTEP plot of $[Cu_2(L^4)(tcc)_2]$ **4**. L^4 has a non-coordinating pyridyl substituent at each copper center and, therefore, leads to copper(II) chromophores with the usual in-plane chelating catecholate coordination mode.

The C–C and C–O bond lengths of tcc^{2-} and $tccH^{-}$ confirm the assignment as coordinated catecholate in all four structures.

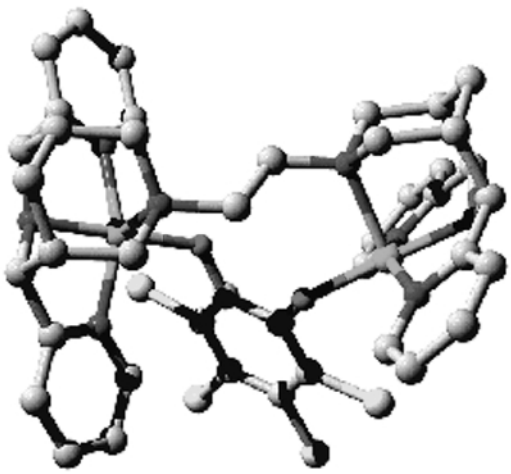


Fig. 1 Molecular model of $[Cu_2(L^2)(tcc)]^{2+}$.

DOI: 10.1039/b008714i

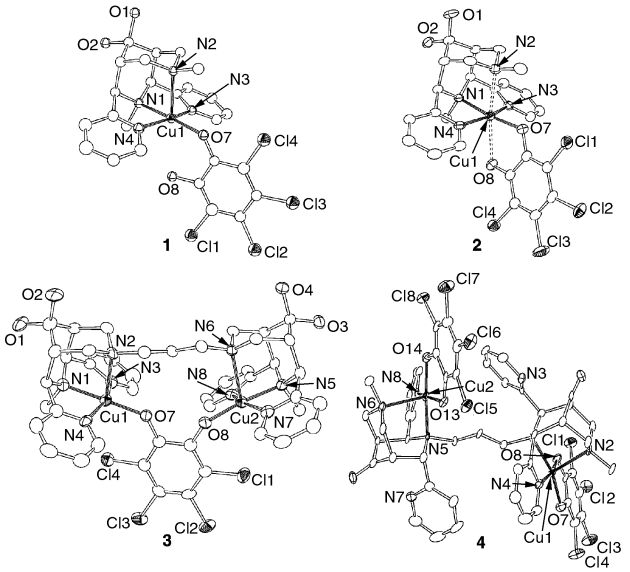

Fig. 2 ORTEP plots of $[Cu(L^1)(tccH)]^+$ **1**, $[Cu(L^1)(tcc)]$ **2**, $[Cu_2(L^3)(tcc)]^{2+}$ **3** and $[Cu_2(L^4)(tcc)_2]$ **4** (50%) probability level). H-atoms, ester groups and counter ions have been omitted for clarity. Selected bond lengths (Å) and angles (°) for **1**; **2**; **3**; **4**; Cu(1)–N(1): 2.020(11); 2.042(2); 2.027(5); 2.094(5). Cu(1)–N(2): 2.320(12); 2.433(2); 2.359(5); 2.293(5). Cu(1)–N(3) 1.987(11); 2.009(2); 2.004(6); —. Cu(1)–N(4) 1.989(11); 2.031(2); 1.985(6); 1.995(5). Cu(1)–O(7) 1.915(9); 1.909(2); 1.898(4); 1.947(4). Cu(1)···O(8) 2.76; 2.46; —; 1.898(4). N(1)–Cu(1)–N(2) 84.06(44); 80.97(8); 83.93(19); 82.24(17). N(1)–Cu(1)–N(3) 81.71(44); 80.56(9); 81.5(2); —. N(1)–Cu(1)–N(4) 81.94(44); 82.15(9); 82.4(2); 80.37(18). N(1)–Cu(1)–O(7) 176.85(47); 172.97(8); 178.1(2); 164.10(18). N(2)–Cu(1)–N(3) 96.66(44); 91.42(8) 95.6(2); —. N(3)–Cu(1)–N(4) 161.28(48); 161.58(9); 161.7(2); —. **4**: O(8)–Cu(1)–O(7) 86.70(17).

The geometry around the Cu^{II} centers can be described as square pyramidal, with N1, the pyridine N-atoms and one of the catecholate O atoms in the square plane and N2 at the axial position; in **2** O8 completes the coordination sphere to an elongated octahedron, and in **4** the second catecholate-O substitutes one of the pyridine-N atoms. **2** is only sparingly soluble in most solvents; the UV–VIS spectrum of a very dilute solution (MeCN) indicates an equilibrium between the mono- and bidentate coordination modes of catecholate, *i.e.* structures **1** and **2** (Fig. 2).

The most prominent structural difference between **3** and the other known structure of a catecholate-bridged dicopper(II) complex is the orientation of the catecholate bridge (angle between the line through the two metal ions and the line through the two catecholate O-atoms: 13.6° in **3**, 32.0° in $[Cu_2(L^2)(TCC)]^{2+}$ (computed), 63.1° in[11]). It is interesting that the increasing puckering of the catecholate bridge correlates with the catalytic activity in the 3,5-dtbc to 3,5-dtbq reaction.

For the model reactions involving bispidine-based ligands it appears that catecholate oxidation occurs at a catecholate-bridged dicopper(II) site by electron transfer from the catechole to the Cu^{II} ions; reoxidation of the Cu centers by molecular oxygen produces water and the active catalyst (the absence of H_2O_2 has been checked by reaction with KI). An interesting question is how thermally stable copper(II) peroxo compounds, generated during the catalytic process, affect the reaction. This and a thorough analysis of the electronic structures of the various structural modes are the subject of further studies in this area.

Generous financial support by the German Science Foundation (DFG), the Fonds of the Chemical Industry (FCI) and the Landesgraduiertenförderungsprogramm of Baden-Württemberg (fellowship to H. B.) is gratefully acknowledged.

A photo-responsive gas separation membrane modified by an organic azo derivative in a porous glass tube shows decreased gas permeance upon stimulation with an Xe-lamp, which returns the starting level upon stopping the irradiation.

It is well known that azobenzene derivatives show photo-reversible *cis–trans* isomerization.[1,2] Such conformational change leads to many chemically photoinduced changes so that many applications can be envisaged; among these is the possibility to control the chemical functions by 'on–off switching'. Several investigations considering this concept have been reported.[3–5] In addition, there are many researchers that are attempting to develop membranes with stimuli–response functions. For example, polymeric separation membranes with stimulation–response functions such as pH ultrafiltration membranes[7,8] or liquid membrane separating the intended ions by light[9] are now actively investigated.

On the other hand, porous glass membranes which possess relatively sharp pore size distributions are now actively investigated because of their high gas selectivity, ease of control of the pore size and easier molding.[6] However, the pore size of all such membranes is fixed rigidly so no such membranes can respond to physical and/or chemical stimuli.

In this study, as a new concept, the preparation of a porous glass membrane surface modified by an azo derivative was carried out for use of gas flow control. Furthermore, control of the gas permeability by the photoinduced *cis–trans* switching property of the compound under light irradiation was investigated.

Porous glass tubes were prepared and gas permeance measurements at 300 K were carried out according to the procedure reported elsewhere.[10] The chemicals which were used in this study were purchased either from Wako Pure Chemical Industries Co., Ltd. and Aldrich Inc. or used without any purification. The azo derivative, 11-[4-[(4′-hexylphenyl)-azo]phenoxy]undecanoic acid (6Az10CO_2H) was synthesized using the route reported by Seki *et al.*[11] Initially, a porous glass surface treated with 3-aminopropyldimethylethoxysilane as a coupling agent was placed into a solution of 6Az10CO_2H and THF and refluxed at 373 K for 20 h. Subsequently, the porous glass was refluxed in THF for > 24 h and then washed with THF several times. The azo modification membrane tube (one end was sealed by epoxy resin) was attached to the Pyrex glass tube by epoxy resin and then the support tube with the membrane was placed inside a stainless steel permeation cell equipped with a silica window through a flange connection, after drying at 348 K in vacuum for 1 h. Using the prepared membrane, gas permeances of pure N_2 and He were measured by a mass flow meter. The single feed gas of N_2 and He was passed continuously outside of the membrane under a pressure of *ca.* 3.03×10^5 Pa (3.0 atm) at room temperature (300 K). Light irradiation from a Xe lamp (500 mW cm^{-2}) was directed to the quartz window which could be covered with a thick board to interrupt irradiation. The pore size distribution of the sample after drying at 348 K under vacuum for several hours was measured by a nitrogen adsorption isotherm using a conventional volumetric apparatus (BELSORP 28SA, BEL JAPAN, inc.). Absorption spectra were recorded on a Shimadzu model 2501 instrument controlled by a personal computer.

The pore size distributions of the porous glass membranes before and after modification with the azo derivative were measured by nitrogen adsorption isotherms. As shown in Fig. 1, a main peak at *ca.* 1.7 nm (radius) for the non-modified and azo modified glass tubes was observed. The surface area of the azo modified glass tube (surface area: 108.9 $m^2\ g^{-1}$, pore volume: $9.10 \times 10^{-4}\ m^3\ g^{-1}$) was *ca.* 30% lower than that of the non-treated sample (surface area: 152.0 $m^2\ g^{-1}$, pore volume: $1.36 \times 10^{-3}\ m^3\ g^{-1}$). This suggested that 6Az10CO_2H is mainly located on the surface of the porous glass and not in the pores.

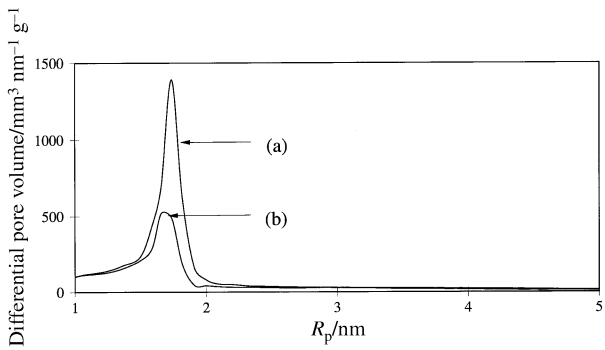

Fig. 1 Pore size distribution for the porous glass tube (a) before and (b) after surface modification with 6Az10CO_2H.

By using the modified membrane, changes of N_2 flow before and after Xe-lamp irradiation were investigated at 300 K. As shown in Fig. 2, the flow of each gas drastically decreased during Xe-lamp irradiation while the flow increased by stopping irradiation. These cycles could be continued > 30 times. Furthermore, there was no light response when similar experiments were performed using non-treated porous glass or porous glass treated with the silane coupling agent only. The increase in temperature close to the modified membrane in the apparatus upon Xe-lamp irradiation was 3–5 K. Thus thermal vibrations around the pores of the glass tube gradually increased the amplitude of N_2 permeance. The length of the folded

DOI: 10.1039/b007749f

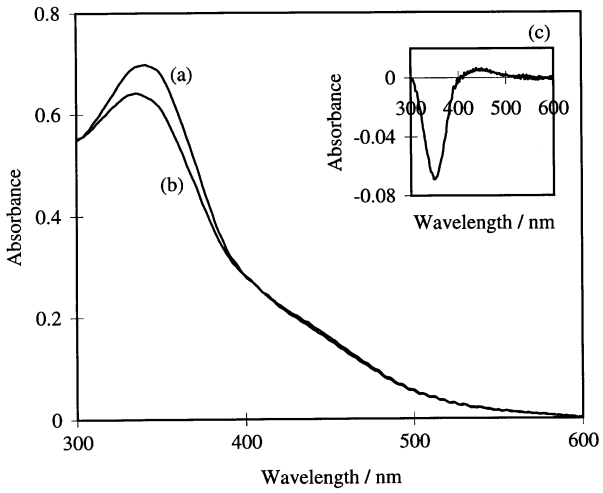

Fig. 3 Absorption spectra of the surface modified glass membrane (a) before irradiation, (b) under Xe-lamp irradiation and (c) differential spectrum (b) − (a).

$=NC_6H_4C_6H_{13}$ moiety of the modifier is 2.377 nm and from these results reorientation of this part of the modifier upon isomerization would reduce the gas permeance by covering the entrance of the pores of the glass substrate.

The absorption spectrum of the azo modified sample under Xe-lamp irradiation is plotted in Fig. 3 which shows a peak at *ca*. 360 nm from the *trans* form and a broad peak at *ca*. 480 nm from the *cis* form with a *trans/cis* ratio of 90/10. On the other hand, this ratio was reduced to 75/25 when UV light (low pressure Hg lamp) was used as a light source and no light response to gas flow was observed. Variation in the permeance relates to rapid *cis* to *trans* isomerization with the *cis* form of the derivative being resistant to permeance (see results of pore size distribution), however, a detailed mechanism could not be established in this study.

Thus, further experiments are now being performed to establish the detailed mechanism of the permeation in an attempt to obtain finer regulation for several gases by considering the interplay between the molecular size of the azo derivative and the pore size of the substrate.

We wish to acknowledge Dr K. Tawa for her assistance in measuring the UV–VIS spectra of the sample. We also thank Mrs H. Kobayashi and Y. Tatematsu for their help on every experiment in this study.

A simple one-pot synthesis of size and shape controlled ZnTe nanocrystals using a monomeric molecular precursor, [Zn(TePh)$_2$][TMEDA], has been studied by varying the growth temperature or the templating surfactants.

In recent years, nanomaterials have drawn enormous interest from the scientific community because of their special characteristics that are different from the bulk such as quantum confined electronic band structures,[1,2] novel optical,[3] catalytic,[4] and electronic properties.[5] Since novel properties in nanoscale materials depend on their size and shape, one of the frontier issues of nanochemistry research is morphology controlled synthesis of nanocrystals.

While sulfur and selenium based II/VI nanocrystals such as CdS and CdSe are widely explored,[6–9] there have not been many reports on the preparation of metal telluride nanocrystals. Furthermore, while there are some examples of Cd and Hg based tellurides,[10–14] studies on ZnTe are very limited. ZnTe, an attractive semiconductor with a direct gap of 2.26 eV (*ca.* 548 nm) in the green region of the electromagnetic spectrum, can be a useful material in several applications such as green light-emitting diodes, buffer layers for HgCdTe IR detectors, or as the first unit in a tandem solar cell.[15] Until now, only two reports on the preparation of colloidal ZnTe nanocrystals exist; however the resulting nanocrystals were either large (length 500–1200 nm, width 30–100 nm)[16] or only their optical properties were investigated without isolation or characterization of the nanocrystals.[17] In fact, there have not been any reports on isolated ZnTe nanocrystals < 10 nm. When ZnTe particles are on the order of 10 nm, quantum size effects appear and control of the optical properties is possible by simply changing the particle size. It is then feasible to have tunability of the opto-electronic properties from the green to the UV region.

In this report, we describe a simple one-pot synthesis of morphology controlled ZnTe nanocrystals using a single molecular precursor, [Zn(TePh)$_2$][TMEDA]. Upon thermolysis, this precursor produces ZnTe nanocrystals which are either spherical or of rod-like structure depending on the growth conditions and the choice of stabilizing surfactants. Furthermore, the size of the spherical ZnTe nanocrystals is controlled by the growth temperature and quantum confinement effects are observed. To the best of our knowledge, this paper reports the first isolated and well characterized ZnTe nanocrystals with quantum confined properties.

Even though metal chalcogenolato complexes have been widely studied previously as single-source precursors to group 12 chalcogenide semiconductor materials,[6,12,18] the development of zinc tellurolate molecular chemistry is still limited.[19–21] A pyridine adduct of a mesityltellurolate zinc complex prepared by Bochmann *et al.*[22] and the dimeric compound [Zn{TeSi(SiMe$_3$)$_3$}$_2$]$_2$ prepared by Bonasia and Arnold[23] have been known to generate ZnTe upon pyrolysis. In our study, we synthesized a polymeric phenyltellurolate zinc complex using a dealkylsilation process that was similarly employed to obtain a organotellurolato cadmium compound.[24] The reaction of dimethylzinc with 2 equiv. of PhTeSiMe$_3$ gives the pale yellow product Zn(TePh)$_2$, which was then reacted with TMEDA to give [Zn(TePh)$_2$][TMEDA].[25] X-Ray crystallographic studies of [Zn(TePh)$_2$][TMEDA][26] shows that it is monomeric and that the zinc center adopts a distorted tetrahedral geometry with a large Te–Zn–Te angle of 118.29(6)° and a small N–Zn–N angle of 84.1(4)° (Fig. 1).[27]

A one-pot synthesis of ZnTe nanocrystals was carried out by the thermolysis of [Zn(TePh)$_2$][TMEDA]. According to TGA, it is observed that the thermolysis of [Zn(TePh)$_2$][TMEDA] begins with the dissociation of the TMEDA donor ligand, with ZnTe and Ph$_2$Te produced in the following thermolysis step at higher temperatures.[28] As similarly observed by Yamamoto and Steigerwald in related work on alkyl- or phenyl-chalcogenolate ligand systems,[12,29] the thermolysis of its complexes cleanly produces the desired nanocrystals.

In a typical synthesis of spherical ZnTe nanocrystals, upon injection of the precursor (0.50 g, 0.88 mmol) dissolved in 5 ml of trioctylphosphine into the hot dodecylamine solvent (8.17 g, 44.1 mmol), immediate formation of nanocrystals was observed by the appearance of a pale yellow color. The crystal growth temperature was kept at either 180 or 240 °C for 2 h and the resulting solution was pale yellow in both cases. The solution was treated with butanol and centrifuged to isolate the yellow nanocrystals as a solid product.

Using the same conditions and procedures, the injection of the precursor into the mixed surfactant solvent trioctylamine (20 ml)–dimethylhexylamine (5 ml) and leads to a shape change of the nanocrystals from spherical to rod-like and after 2 h a gray precipitate of ZnTe nanocrystals was obtained from the initially pale yellow solution at 180 °C. It is believed that the combination of the two different surfactants provides rod-like micelles during the one-dimensional crystal growth process.[30]

The obtained spherical ZnTe nanocrystals are moderately monodispersed and their sizes can be controlled by changing the growth temperature. Relative to the position of the 548 nm (2.26 eV) absorption band edge of bulk ZnTe, blue shifts of 0.53 and 1.31 eV are found for the nanocrystals grown at 180 and 240 °C, respectively with larger shifts being seen for samples grown at higher growth temperature (Fig. 2A).[31] Similar blue shifts are also observed in the photoluminescence spectra: band maxima are 451 and 377 nm, respectively, for samples grown at 180 and

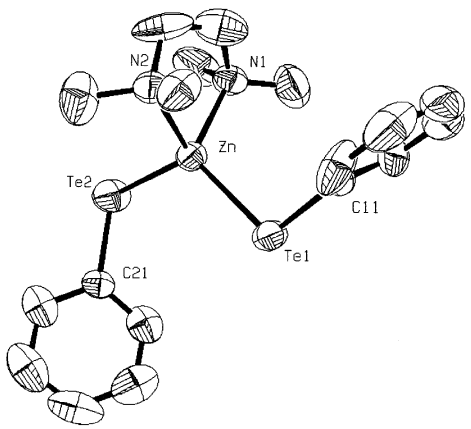

Fig. 1 ORTEP drawing of [Zn(TePh)$_2$][TMEDA]. Selected bond distances (Å) and angles (°): Te(1)–Zn(1) 2.5769(14), Te(2)–Zn(1) 2.5876(15), Zn(1)–N(1) 2.126(9), Zn(1)–N(2) 2.145(9); Te(1)–Zn–Te(2) 118.29(6), N(1)–Zn(1)–N(2) 84.1(4).

DOI: 10.1039/b008376n

240 °C (Fig. 2B). These results suggest that smaller nanocrystals are produced at higher growth temperatures where more nucleation sites exist and relatively less available ZnTe material is present for each nucleus during the growth process.

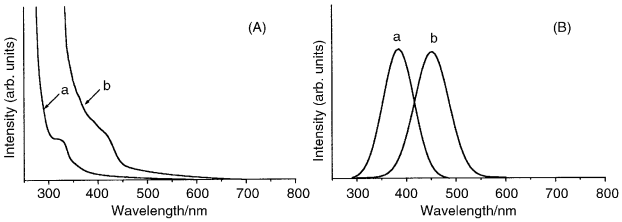

Fig. 2 Optical spectra of ZnTe nanocrystals grown at (a) 240 and (b) 180 °C; (A) UV–VIS absorption spectra, (B) Photoluminescence spectra.

High resolution transmission electron micrographs (HRTEM) show that the spherical ZnTe nanocrystals have average sizes of 4.2 (±1.1) and 5.4 (±0.9) nm for samples grown at 240 and 180 °C, respectively (Fig. 3A). Powder X-ray diffractometry (XRD) and selected area diffractometry (SAED) reveal patterns corresponding to (111), (220) and (311) of the cubic phase of ZnTe nanocrystals (Fig. 3C, D). This result is similar to that of TOPO-capped spherical ZnSe nanocrystals described in a previous report.[31] TEM of the rod-like ZnTe nanocrystals show that the diameters of the rod-like nanocrystals are quite uniform (*ca.* 25 nm) with lengths of several hundred nanometers (200–700 nm) giving an aspect ratio from 8 to 30 (Fig. 3B). The rod-like ZnTe nanocrystals are also cubic phase as confirmed by XRD and SAED analysis.

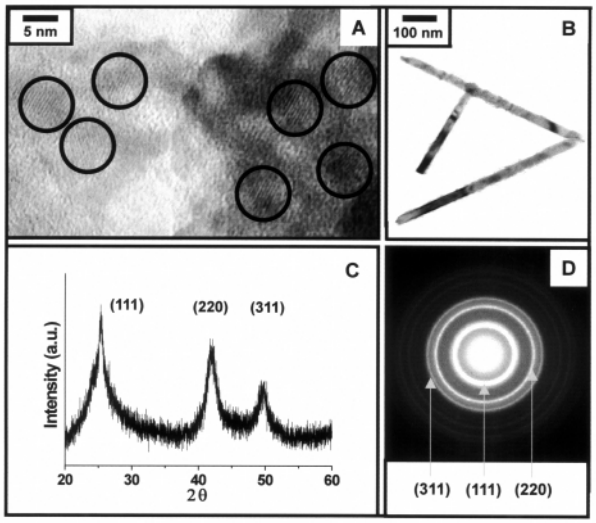

Fig. 3 (A) HRTEM analysis of spherical ZnTe nanocrystals grown at 240 °C, (B) TEM analysis of rod-like ZnTe nanocrystals, (C) powder X-ray diffraction and (D) selected area diffraction patterns of 4.2 nm ZnTe nanocrystals.

In conclusion, the results here constitute a simple and convenient one-pot synthesis of morphology controlled ZnTe nanocrystals using a monomeric molecular precursor, $[Zn(TePh)_2][TMEDA]$. By varying the growth temperature or the choice of the templating surfactants, the size and shape of the nanocrystals are controllable and quantum size effects are observed. We believe that this strategy can be extended to the facile synthesis of nanocrystals of other materials.

This work was supported by the Tera Level Nanodevices National Program of KISTEP. We thank KBSI for the TEM analyses and Professor S. J. Kim and Dr Y.-M. Kim of Ewha Womans' University for X-ray crystallographic analysis of the sample.

CCDC 182/1854. See http://www.rsc.org/suppdata/cc/b0/b008376n/ for crystallographic files in .cif form.
27 The Te–Zn–Te angles are slightly smaller than those reported for related compounds with larger ligands such as $[Zn(mesityl)_2(py)_2]$ and $[Zn\{TeSi(SiMe_3)_3\}_2(py)_2]$, (126.9 and 131.9°, respectively). The steric repulsions between these bulkier ligands are responsible for the larger angles as compared to compact phenyl ligands. This trend is clearly shown by the gradual increase of angle from 118.29 to 126.9 to 131.9° as the ligand size increases from phenyl to mesityl to sitel. The Zn–Te and Zn–N bond lengths are 2.5822(65) and 2.136(5) Å which are almost identical to those of $[Zn\{TeSi(SiMe_3)_3\}_2(py)_2]$ and $[Zn(mesityl)_2(py)_2]$ and similar to those seen for other zinc complexes with organochalcogen and amine ligands.[19–21]
28 In TGA, we observed that the dissociation of TMEDA and the generation of Ph_2Te and ZnTe occur at 158 and 178 °C, respectively.

One-step self-assembly organometallic molecular cages from 11 components†

Shih-Sheng Sun and Alistair J. Lees*

Department of Chemistry, State University of New York at Binghamton, Binghamton, NY 13902-6016, USA. E-mail: alees@binghamton.edu

Received (in Irvine, CA, USA) 18th September 2000, Accepted 15th November 2000
First published as an Advance Article on the web 15th December 2000

Two self-assembly organometallic molecular cages, each comprising 11 components and two different bridging ligands, were prepared from one-step reactions; both of these cages exhibit relatively high affinity and shape-selectivity toward planar aromatic compounds.

Self-assembly has been recognized as a most efficient process that organizes individual molecular components into highly ordered supramolecular species.[1] Relying on strong metal–ligand interactions, the design and study of well arranged metal-containing macrocycles or three-dimensional cage molecules has emerged as a promising research area in modern supramolecular chemistry.[2]

To date, most of the one-step self-assembly transition-metal containing supramolecular species reported in the literature have been synthesized from the same metal components and bridging ligands.[2,3] The incorporation of different metal components or more than two different types of bridging ligands are much rarer.[4] In most cases, such supramolecules were prepared from two or more steps.[5]

Recently, we have prepared a series of self-assembly molecular squares and triangles that incorporate photoactive chromophores. We have demonstrated that the geometry, length and electronic properties of the bridging ligand play an important role in determining the shape of the final self-assembly products and their resultant photophysical, photochemical and electrochemical properties as well as their binding capabilities in molecular sensing applications.[3a,b,6] As an extension of our previous work, we set out to design and synthesize self-assembly cage-type molecules that comprise two different types of ligands, which require more precise bonding directions between the metal components and the bridging ligands in order to avoid the formation of undesired oligomeric species. During the progress of our work, two communications have appeared that describe the two-step preparation of rectangular structures utilizing 2,2′-bipyrimidine (BPM) or bisbenzimidazolate and 4,4′-bipyridine as bridging units.[5a,d]‡ We report, herein, the synthesis of two new cage molecules, each involving two different bridging ligands and assembled from eleven individual components, including a route that involves only one stage and yet leads to high yield. Their photophysical properties and binding behavior toward electron-rich aromatic compounds are also described.

Two synthetic routes to these cage molecules have been investigated (see Schemes 1 and 2). The first involved synthesis of the BPM bridged Re(I) dimer and subsequent replacement of the bromo ligand by triflate (OTf) in acetone to isolate complex **1**.[5d] Subsequent reflux of **1** and the corresponding tridentate ligands, 1,3,5-tris(2′-ethynyl-4″-pyridyl)benzene (TEPB)[7] or 2,4,6-tris(4′-pyridyl)-1,3,5-triazine (TPTA)[8] in THF for 3 days afforded reddish products with general formula {[*fac*-$Re(CO)_3]_2$(μ-BPM)}$_3$(μ-L)$_2$$(OTf)_6$ (**2**, L = TEPB; **3**, L = TPTA).†§

Cages **2** and **3** were characterized by several different analytical techniques including IR, NMR, elemental analysis, and electrospray ionization mass spectrometry (ESI-MS). IR spectra of both cages **2** and **3** indicate typical tricarbonyl patterns with facial arrangements.[9] Elemental analyses confirmed the proposed stoichiometry. ^{1}H NMR spectra of both cages **2** and **3** exhibit very clean and simple chemical shifts, ruling out the possible existence of other oligomeric species. The ESI-MS measurements have provided a straightforward identification of the cage structures of **2** and **3**.† The excellent agreement between the observed and simulated isotopic distributions for the molecular ion unambiguously confirms the proposed molecular structures for **2** and **3**.

After successful isolation of the desired cages **2** and **3**, we wondered if it was possible to prepare them in a simpler one-step process. The synthesis was initiated by refluxing (OTf)-$Re(CO)_5$, BPM and L (TEPB or TPTA) in a 6 : 3 : 2 ratio in THF for one week and, subsequently, cages **2** and **3** were isolated in 47 and 41% yield, respectively. The BPM bridged dimer, $[(CO)_3ReOTf]_2$(μ-BPM), would be expected to form first in the solution considering the extra stabilization through the chelation effect of BPM. Indeed, the formation of one precursor, which is more thermodynamically stable than the other possible intermediates, is important for a self-assembly process that comprises more than one bridging ligand. Subsequently, the thermodynamically driven self-assembly process between $[(CO)_3ReOTf]_2$(μ-BPM) and the corresponding TEPB and TPTA ligands afforded the final cage products.

The absorption spectra of **2** and **3** in MeCN feature intense bands in the near-UV region and a low-energy band at 470 nm, tailing past 600 nm.§ This low energy band is assigned to the

Table 1 Association constants (K_a/M^{-1}) of **2** and **3** with different guests[a]

Guest	**2**	**3**
o-Dimethoxybenzene	0.81×10^2	0.99×10^2
m-Dimethoxybenzene	5.9×10^2	6.1×10^2
p-Dimethoxybenzene	4.5×10^2	4.2×10^2
1,3,5-Trimethoxybenzene	8.9×10^2	9.1×10^2
2-Naphthalenesulfonic acid, sodium salt	11.2×10^2	11.6×10^2
1,5-Naphthalenedisulfonic acid, disodium salt	26.4×10^2	20.7×10^2
2,6-Naphthalenedisulfonic acid, disodium salt	15.6×10^2	13.8×10^2
Sodium tetraphenylborate	0.75×10^2	0.60×10^2
p-Dimethoxycyclohexane	$< 0.01 \times 10^2$	$< 0.01 \times 10^2$

[a] Binding was monitored by following the phenyl proton of TEPB for cage **2** and β proton of TPTA for cage **3**. The spectra were recorded at 300 MHz in DMSO-d_6 solution at 298 K.

Re(d_π) to BPM (π^*) charge-transfer transition (MLCT). Both **2** and **3** are non-emissive in room-temperature MeCN solution. Several BPM-bridged Re(I) tricarbonyl complexes have been reported that exhibit a lack of emission.[5d,10] These observations have been attributed to the energy gap law effect,[11] resulting in the low-energy ^{3}MLCT excited state undergoing very efficient nonradiative decay. However, it is also possible that an emission band is present but is too red-shifed to detect on our instrumentation.

According to MM2 molecular modeling results, the interplanar distances between the two tridentate ligands in **2** and **3** are 3.5 and 4.2 Å, respectively.[12] These interplanar distances are comparable to the recently reported rectangular structures[5a,d] and the molecules are considered to have very effective π–π stacking that contributes to the highly thermodynamically stable structures.[4a,c] The nearly co-planar arrangement between the two tridentate ligands and the overall six positive charges in **2** and **3** render them promising hosts for electron-rich planar aromatic compounds. Table 1 summarizes the association constants (K_a) of **2** and **3** with different aromatic compounds. Not surprisingly, there is virtually no association between *p*-dimethoxycyclohexane and either **2** or **3** and only a very small association between spherical sodium tetraphenylborate and **2** or **3**. On the other hand, both **2** and **3** showed relatively strong association toward planar aromatic compounds. There are no clear binding differences between **2** and **3**. The shape selectivity, however, deserves more attention and is being further investigated. A significant difference in K_a values was observed for the isomers of dimethoxybenzene, where *m*- and *p*-dimethoxybenzene >> *o*-dimethoxybenzene. A similar trend of shape selectivity has also been observed for Pd and Pt based square complexes.[13]

We are grateful to the U.S. Department of Energy (Grant DE-FG02-89ER14039) for support of this research.

Notes and references

‡ After submission of our manuscript, an article describing the preparation of cages **2** and **3** using a similar two-step procedure appeared.[5e]

§ Two possible geometrical isomers of **1** can exist, namely *syn*- and *anti*-isomers in terms of the mutual arrangement of two triflate ligands. The formation of subsequent cage compounds requires the presence of *syn*-isomers in solution. The high yields (> 50%) of both cage-compounds suggests that either **1** existed mainly as the *syn*-isomer or a mixture of both *syn* and *anti*-isomers where the latter subsequently rearranges to the *syn*-isomer due to more favorable thermodynamic processes.

The first pillared three-dimensional structure constructed by carboxylate ligands bridging heterometallic trilayers

Long Pan, Bruce S. Finkel, Xiaoying Huang and Jing Li*

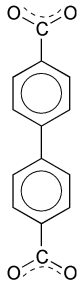
First published as an Advance Article on the web

Reaction of an aqueous solution of Na_2bpdc (H_2bpdc = biphenyldicarboxylic acid) with an organic solution of $Co(NO_3)_2$ *via* a diffusion route leads to a pillared three-dimensional structure in which the heterometallic sodium(I)–cobalt(II) trilayers are connected by carboxylate groups of the pillared ligand $bpdc^{2-}$.

One of the challenges in crystal engineering is to predict the crystal packing from molecular structures. A reasonable approach to build three-dimensional structures based on layered structural motifs is to control the packing of layers by organic pillars of changeable length and/or type. This approach has been demonstrated to be effective towards assembly of both non-covalent and covalent pillared networks.[1] Pillared structures are potentially important for applications in absorption, separation and catalysis.[2] A variety of pillar-layered structures including positively and negatively charged or neutral layers have been synthesized.[3] Organically templated molybdenum oxides MOXI-1, -8, -24, -37 and indium phosphate (InPO) involve nitrogen donor pillars that connect to oxide layers.[4] Metal phosphonates of the type $M^{z+}{}_{4/z}(O_3P–R–PO_3)$ use phosphonate pillars $O_3P–R–PO_3$ where R is an alkyl or aryl group.[5] However, only a few pillared structures are built upon ligands containing carboxylate groups. Limited examples include exo-bicarboxylate in bilayer[6] and isonicotinate (with a carboxylate group and a pyridine nitrogen) in three-dimensional pillared structures.[7] In this contribution, we report a three-dimensional structure consisting of sodium(I)–cobalt(II) heterometallic trilayers and biphenylenecarboxylate pillars, **1**. It is interesting to



1

note that this structure represents the first example of carboxylate pillared structures containing heterometallic layers.

The title compound was synthesized by mixing organic and aqueous solutions *via* slow diffusion techniques. A DMF solution of $Co(NO_3)_2$ (0.1 M, 1 mL) was carefully layered on an aqueous solution of Na_2bpdc (0.1 M, 1 mL), through a 2 mL mixed (buffer) solution of EtOH–water (2:3). Pink block crystals of $Na_2Co(bpdc)_2(H_2O)$ **2**, suitable for X-ray diffraction analysis,† appeared after several days. Single crystal X-ray analysis revealed that each sodium ion has a distorted triangular bipyramidal (tbp) coordination. The apical positions of the tbp are occupied by two carboxylate oxygen atoms (O1, O2) from two $bpdc^{2-}$, while the equatorial positions are occupied by a η^2-oxygen atom (O5) of a water molecule and two carboxylate oxygen atoms (O3, O4) from another two $bpdc^{2-}$. Each sodium metal is connected with four adjacent sodium atoms located in the same plane through four carboxylate groups *via anti–anti* mode, leading to a two-dimensional grid-like metal network with Na···Na distances of 6.083 Å (along the *b*-axis) and 6.809 Å (along the *c*-axis). Two of these topologically identical Na planes are interconnected by Co. The octahedrally coordinated cobalt ion is located at the inversion center as a node, connected to four adjacent sodium ions through four O atoms at equatorial positions, two of which are *trans* η^2-oxygen atoms (O5, $O5^i$) of water molecules, and the other two, *trans* carboxylate η^2-oxygen (O1, $O1^i$). The remaining two (axial) positions around Co(II) are occupied by terminal water molecules (O6, $O6^i$). This arrangement results in a heterometallic metal slab consisting of a Na(I)–Co(II)–Na(I) trilayer running parallel to the *bc* plane, with the edge-shared sodium(I) and cobalt(II) separated by 3.397(2) Å. A view of the metal slab is illustrated in Fig. 1. This metal trilayer is quite different from that of a pillared zinc biphenylylenebis(phosphonate) $Zn_2(O_3PC_{12}H_8PO_3)\cdot 2H_2O$,[8] in which not only the metal atoms are connected to five neighboring metals by four PO_3 groups, but also they form a monometallic single layer.

The unique heterometallic trilayers in **2** are cross-linked by $bpdc^{2-}$ ligands to form a pillared three-dimensional structure (Fig. 2). Two CO_2^- groups of each bicarboxylate attach the adjacent metal layers as a stud. Each group adopts a different coordination mode. One binds a metal layer through its two oxygen atoms to two sodium ions in a bidentate *anti–anti* mode. The other, at the opposite end of the $bpdc^{2-}$, forms tridentate bonds with the neighboring layer through its two oxygen atoms, coordinating to two sodium ions (in an *anti–anti* mode) and to one cobalt ion (with the η^2-oxygen). The twisting of the $bpdc^{2-}$ ligand is a result of orientation adjustment to achieve a stable coordination geometry for both carboxylate and the metal ions from the layers above and below the pillar, and the *skew–skew* mode of the CO_2^- groups. The width of the heterometallic

DOI: 10.1039/b007344j

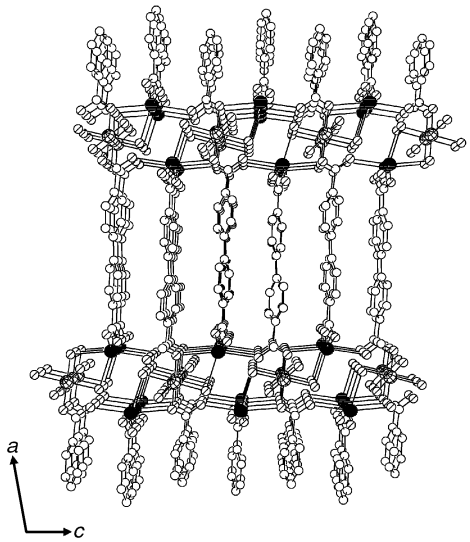

Fig. 2 Perspective view of **2** down the *b*-axis, The same labeling scheme as in Fig. 1 is used. The width of heterometallic trilayer is 3.75 Å and the interlayer distance is 11.5 Å.

trilayer is 3.75 Å. The distance between the two neighboring trilayers is 11.5 Å. The shortest average distance between neighboring benzene rings is 3.75 Å, falling in the range of π–π interactions. This non-covalent interaction may stabilize the pillared structure. However, the closely packed biphenylene groups in the title compound are too close to accommodate guest solvent molecules. The connectivity of $bpdc^{2-}$ (μ_5) in this heterometallic structure cannot be obtained by mixing different ratios of aqueous solutions of Na_2bpdc (0.1 M) and $Co(NO_3)$ (0.1 M), ($V_{Na_2bpdc}/V_{Co(NO_3)_2}$ = 1 : 1, 1 : 5, 1 : 10, 10 : 1, 5 : 1; *V* = volume). The product from these reactions is a one-dimensional structure with a single Co ion center, $^1_\infty[Co(bpdc)(H_2O)_2]$,[9] which was confirmed by powder XRD. The one-dimensional chain in this structure was formed by connecting six-coordinated Co ions through the four μ-H_2O, and two *trans* μ-bpdc.

The present work has shown that heterometallic pillared structures can be effectively synthesized using a bicarboxylate as a pillar molecule. Furthermore, it is likely that other transition metal elements with similar coordination habits and pillars of different length may replace Na/Co and $bpdc^{2-}$, respectively, to form other related pillared structures. Suitable choices of ligands may also lead to porous, 3D pillared networks.

This work is generally supported by the National Science Foundation (Grant DMR-9553066).

Synthesis of hyperbranched polymers from commercially available A_2 and BB'_2 type monomers

Chao Gao and Deyue Yan*

College of Chemistry and Chemical Engineering, Shanghai Jiao Tong University, Shanghai 200240, Peoples Republic of China. E-mail: dyyan@mail.sjtu.edu.cn

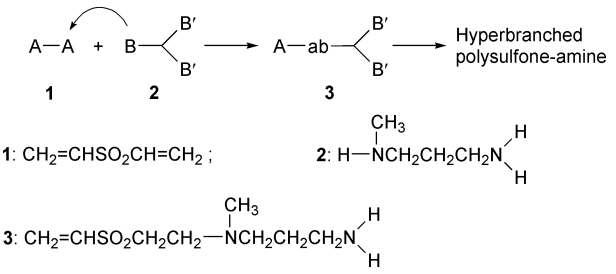
Received (in Cambridge, UK) 26th July 2000, Accepted 30th October 2000
First published as an Advance Article on the web

This work describes a new strategy for the preparation of hyperbranched polymers from commercially available A_2 and BB'_2 type monomers without any catalysts; the rapid reaction of A groups with B groups results in the formation of dimers that can be regarded as a new sort of AB'_2 type monomer; further polymerization of AB'_2 gives hyperbranched polymers; through this approach a new kind of water-soluble hyperbranched polysulfone-amine was synthesized by polyaddition of *N*-methylpropane-1,3-diamine (BB'_2) to divinyl sulfone (A_2).

Hyperbranched polymers have received attention for about 10 years due to their unique chemical and physical properties.[1–9] It is known that hyperbranched polymers are prepared mainly by polycondensation of AB_x type monomers.[10–14] Most AB_x type monomers are unavailable commercially. A significant approach to hyperbranched polymers, therefore, would be the polymerization of commercially available difunctional and trifunctional monomers. Unfortunately, the polycondensation of A_2 and B_3 type monomers usually leads to the formation of a three-dimensional network.[1] Interestingly, Kakimoto and coworkers[15] reported that hyperbranched aromatic polyamides were synthesized by polycondensation of diamines (A_2) with trimesic acid† (B_3) at low monomer concentration in the presence of special catalysts. The hyperbranched polymers were accessible only when the feed monomer ratio was 1 : 1. Gelation occurred within 10–20 min when the feed ratio of A_2 to B_3 was 3 : 2.[15,16]

This work found that gelation can be avoided at different feed ratios if A_2 monomers and BB'_2 (instead of B_3) monomers are used. Both B and B′ can react with A, and B is more active than B′. The difference in reactivity may be due to the distinction in chemical environment or chemical structure of the two functional groups. If the reaction between B and A is much faster than that between B′ and A, the predominant intermediate formed at the initial stage of the polymerization is the dimer ($AA–BB'_2$), which can be regarded as a new kind of AB'_2 type monomer. Further polymerization of AB'_2 gives a hyperbranched polymer. The approach for synthesis of hyperbranched polymers from two types of reactive monomers is essentially different from that invented by Davis and coworkers in which the new functional group A is formed by reacting a B_3 monomer with a reagent.[17]

To test the aforementioned concept, two kinds of monomers were selected as the raw materials (Scheme 1). Monomer **1** is attractive due to its strong electron-withdrawing group (SO_2) linking double bonds. The sulfone group may guarantee the high reactivity of vinyl groups in the nucleophilic addition, which results in fast reaction without catalyst.[18] The structure of **2** is interesting since it contains an active hydrogen atom in the secondary-amino group and two active hydrogen atoms in the primary-amino group. The former is more active than the latter in the nucleophilic addition due to the effect of the electron-donating group attached to the secondary-amino group.[19,20] At the start of the polymerization, secondary-amino groups of **2** react rapidly with vinyl groups of **1** to afford **3**. Species **3** is now an AB'_2 monomer with one double bond and two active hydrogen atoms. Further polymerization of **3** leads to higher species and finally to a hyperbranched polymer.



Scheme 1 Polymerization mechanism of A_2 and BB'_2 monomers.

FTIR has been used to investigate the reaction process. For the polyaddition of **1** to **2** with a mole ratio of 1 : 1 (Fig. 1), the area integration of the absorption band from 1625 to 1602 cm^{-1} (assigned to double bonds) decreases to approximately a half of feed **1** during the initial 12 s. However, little change can be observed for the absorption bands from 3240 to 3450 cm^{-1} (assigned to primary-amino groups; the secondary-amino groups can not be observed in the IR spectrum). Then, the peaks of primary-amino groups and double bonds gradually decrease with the reaction. At about 5 h, the peak owing to the double bonds disappears completely, while that of the primary-amino groups is still observed (Fig. 2). These data fully support the polymerization mechanism shown in Scheme 1. Close monitoring of this polymerization by HPLC further demonstrates the reaction is initially very fast. The corresponding peak of monomer **1** vanished after about 10 s. Moreover, in the mass spectrum of the reaction mixture at the initial reaction stage, the molecular ion peak of the AB'_2 monomer (M = 206.3) is observed at m/z = 207.1 (M + 1), and the fragment ion peak (M = 190.3) for AB'_2 losing its primary-amino group is found at m/z = 190.1. These data suggest that dimer **3** is indeed generated by the reaction of the secondary-amino groups with vinyl groups.

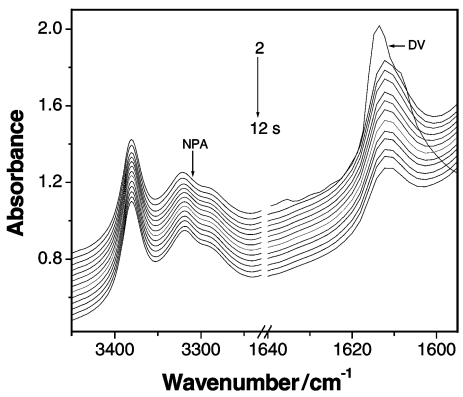


Fig. 1 *In situ* FTIR spectra of the reaction mixture of dinvinyl sulfone (DV) and *N*-methylpropane-1,3-diamine (NPA) with the feed ratio of 1 : 1 in chloroform within initial 12 s.

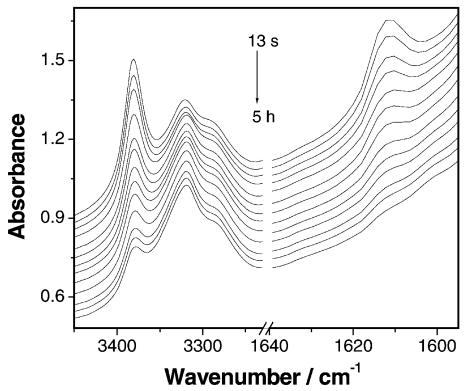

Fig. 2 *In situ* FTIR spectra of the reaction mixture of dinvinyl sulfone and *N*-methylpropane-1,3-diamine with the feed ratio of 1 : 1 in chloroform from 13 s to 5 h.

When the initial mole ratio of A_2 to BB'_2 is equal to 1, the hyperbranched polymer was synthesized through the following procedure (P1 in Table 1): Under vigorous stirring and nitrogen atmosphere, divinyl sulfone (3.5445 g, 30 mmol) was added to a solution of *N*-methylpropane-1,3-diamine (2.6445 g, 30 mmol) in 15 ml of chloroform. The reaction mixture was kept at 40 °C for 96 h. Precipitation of the reaction mixture with 500 ml of MeOH and 8 M aqueous HCl (10 ml) gave the white hyperbranched polymer in 90% yield, which has a molecular weight, M_n, of 18530 (vapour-pressure osmometer) and a glass transition temperature of −22.8 °C (measured on a PE Pyris-1 DSC thermal analyzer under nitrogen at a heating rate of 20 °C min^{-1} from −80 to 200 °C). The resulting polymer shows good solubility in water and polar organic solvents such as DMF, NMP and DMSO, which provides further support for the polymerization mechanism without network formation. A combination of IR, ^1H and ^{13}C NMR spectra confirmed the structure of the hyperbranched polymer. For hyperbranched polymers, the degree of branching (DB)[21] is calculated from the ratio of branched units (N_b) and terminal units (N_t) to the total units (branched units, terminal units and linear units). In this work, the branched unit is the tertiary-amino group, the terminal unit is the primary-amino group, and the linear unit (N_l) is the secondary-amino group. In the ^1H NMR spectrum, the peaks of N_b, N_l and N_t were found at 3.58, 3.31 and 3.19 ppm, respectively. Additionally, a tertiary-amino group is also formed during the reaction of the A group and B group. Since there is a methyl group (CH_3) attached to the tertiary nitrogen, the peaks of the formed tertiary-amino group (N_B) are different from that of the branched tertiary-amino group in the ^1H NMR spectrum. The peak of the methylene group (CH_2) attached to N_B was found at 3.75 ppm, and that of the methyl group at 2.9 ppm. Therefore, N_B has no influence on the calculation of DB. The DB calculated from the integration ratio of corresponding peaks (N_b, N_l and N_t) is summarized in Table 1.

When the feed ratio is equal to 3 : 2, it is more difficult to avoid gelation for the polycondensation systems of A_2 and B_3 monomers.[13,19] In this article, no gelation occurred during the polymerization with the 3 : 2 ratio in organic solvent. The end-capped polymer with benzoyl chloride is soluble in chloroform and other polar solvents such as DMF, NMP, and DMSO. Examination of the FTIR and HPLC showed the expected

Table 1 Direct polymerization of divinyl sulfone with *N*-methylpropane-1,3-diamine

Sample	Ratio[a]	Solvent	Time/h	Yield (%)	DB (%)	η_{inh}[b]	M_n
P1	1 : 1	$CHCl_3$	96	90	58.7	0.17	18530
P2	3 : 2	$CHCl_3$	120	94	71.8	0.15	15385
P3	1 : 1	NMP	96	92	57.4	0.18	19860
P4	3 : 2	NMP	120	95	73.5	0.16	17110

[a] The initial mole ratio of divinyl sulfone to *N*-methylpropane-1,3-diamine. [b] The inherent viscosity (dL g^{-1}) of the resulting polymer measured at a concentration of 0.5 g dL^{-1} in water solution at 25 °C.

reaction mechanism as given in Scheme 1. For the resulting hyperbranched polymer with 3 : 2-feed ratio, the terminal units should contain vinyl groups and primary-amino groups. The peaks of the vinyl groups were observed at 6.4 (CH_2=) and 6.8 (CH=) ppm in the ^1H NMR spectrum.

In conclusion, a novel approach for synthesis of hyperbranched polymers was presented. Water soluble hyperbranched polysulfoneamines were prepared by polyaddition of *N*-methylpropane-1,3-diamine (BB'_2) to divinyl sulfone (A_2). It is likely that the simplicity of this process and the generality of the method will make this new approach attractive for the synthesis of larger scale hyperbranched polymer materials.

We report the use of supercritical carbon dioxide ($scCO_2$) to create a diverse range of polymeric composites incorporating thermal and solvent labile guest materials such as proteins; no additional co-solvents are required; the entire process can be carried out at near ambient conditions; polymer morphology is controllable; high loadings of guest species can be achieved and the protein function is retained.

Tissue engineering scaffolds and controlled drug delivery devices are polymeric composites designed to release precise amounts of guest species, *e.g.* growth factors and biotechnology drugs, at rates matching the physiological need of the tissue.[1] The challenge is to incorporate such biologically active guest species, without loss or change of activity, into a polymer host. There are well documented problems in maintaining protein conformation and activity under conventional processing methods due to either the presence of an organic/aqueous solvent interface (*e.g.* double emulsion particle formation), elevated temperatures (*e.g.* polymer melt processing), or mechanical agitation of solutions.[2] A further challenge in producing these composites is to control the morphology of the composite, *e.g.* to generate a pore size distribution that promotes cell infiltration or a controlled porosity to influence polymer degradation and controlled release characteristics.

Here, we report a supercritical fluid mixing technology that overcomes both of these limitations in one processing step. The combination of gas-like and liquid-like properties makes $scCO_2$ a unique polymer-processing medium.[3,4] $scCO_2$ has long been proposed as the ideal medium for preparation of polymer based materials containing bioactive species, primarily because no solvent residues would remain in the final product. Progress has been slow because $scCO_2$ is generally a poor solvent for polar guest species[5] and for polymers.[6] and this has resulted in extensive use of $scCO_2$ as an anti solvent.[7,8]

However, $scCO_2$ does interact with a broad range of amorphous polymers leading to depression of the glass transition temperature (T_g).[4] Under these conditions the polymer is plasticised, substantially lowering the viscosity and allowing efficient incorporation of insoluble guest particles into the polymer (see Contents Page illustration). Briefly, powdered samples of polymer and bioactive guest are placed in the autoclave and $scCO_2$ added. Neither the guest, nor the polymer, dissolves in $scCO_2$. The precise conditions of temperature and pressure required to plasticise the polymer are determined by the composition of the polymer. For the biodegradable polymers poly(DL-lactide) (PLA), poly(lactide-*co*-glycolide) (PLGA) and polycaprolactone (PCL), near ambient temperature (35 °C) and modest pressures (200 atm) are sufficient. Efficient agitation of the $scCO_2$ swollen polymer leads to homogeneous distribution of the guest particles throughout the polymer matrix. The vessel is then depressurised to produce either monolithic samples or encapsulated particles. For monoliths, the composite material is formed inside the autoclave. For particles, the entire contents of the vessel are forced out under pressure through a computer controlled orifice. Depressurisation is rapid, and is controlled by the action of a flush valve. The encapsulated particles are retrieved from a cyclone collector and the CO_2 may be repressurised and recycled. The methodology is based on the technique of particle generation from supercritical suspension (PGSS) and was initially developed for the preparation of powder coatings for paint applications, with the aim of decreasing processing temperatures.[9] The whole process can be performed in < 1 h at near ambient temperatures on a gram to multi kg scale in a single processing step. No solvent residues remain after processing and a wide range of loadings (up to 70% by weight), morphologies, and porosities are accessible.

To demonstrate the principle we have prepared porous composites of PLGA (75% DL-lactide : 25% glycolide, M_w = 26 kDa, intrinsic viscosity = 0.6) incorporating a high loading of calcium hydroxyapatite (HA). Such materials are required for bone regeneration applications (Fig. 1A, B). A PLGA composite incorporating the enzyme catalase at 50% w/w loading is also shown (Fig. 1C) The catalase particle morphology is totally unchanged after processing, the protein is intimately mixed with

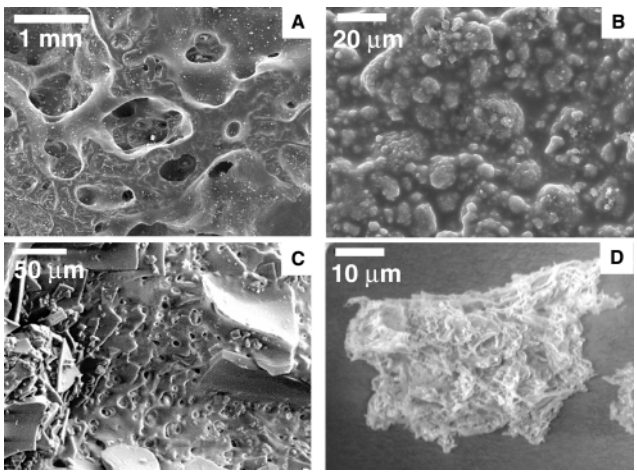

Fig. 1 SEMs of composites. (A and B) Images of internal fracture surface of composite of HA (40 wt%) and PLGA (60 wt%). At low magnification the distribution of HA and the porosity is evident, at higher magnification the intimate mixing of HA and PLGA is observed. (C) Catalase (50 wt%) incorporated into a PLGA matrix (50%). Micron-scale pores in the polymer and the distinctive protein particle morphology are evident. (D) High-surface area microparticle composite [fluorescein (sodium salt) (8 wt%) and PCL (92 wt%)] produced by direct atomisation.

† Electronic supplementary information (ESI) available: methods and measurement of ribonuclease A activity. See http://www.rsc.org/suppdata/cc/b0/b008188o/

DOI: 10.1039/b008188o

the biodegradable polymer, and porosity in the polymer phase is clearly evident.

The ability to plasticise such polymers at close to 37 °C and the inherently low solubility of proteins in $scCO_2$ provides a key processing advantage; thermal and solvent labile species can be processed easily whilst preserving protein structure and function. We have demonstrated this for three enzymes; ribonuclease A, catalase and β-D-galactosidase. For ribonuclease A, a number of investigators have studied the activity after exposure to a wide range of solvents and environments using a standard assay.[10] Using $scCO_2$ (170 atm; 37 °C for 10 min), we have prepared composites of ribonuclease A (10 wt%) and PLA (M_w 30 kDa). The enzyme was then released to a Tris buffer at 37 °C for 5 min and analysed (see ESI†). The total concentration of protein released was verified by a Coomassie protein assay and the activity of the released protein was measured. The data presented in Fig. 2 demonstrate that the activity of the enzyme is preserved. Thus $scCO_2$ behaves in a similar manner to conventional anhydrous solvents, with the advantage that no solvent residues are introduced. Indeed, $scCO_2$ processing even removes the conventional solvent residues that are almost always found in guest and polymer materials. Clinical use of such composites requires controlled release of the guest from the polymer host. Release of ribonuclease A from the PLA composites over a 70 day period revealed an initial burst release of < 10% of the dose over the first 2 days followed by close to zero-order release kinetics until the delivery device was exhausted.

We have also demonstrated that this $scCO_2$ mixing technology leads to fine control of the morphology of polymer composites. Others have demonstrated that $scCO_2$ can be used to create microcellular foams of amorphous polymers, and that control of the magnitude of pressure drop and the rate of depressurisation influence strongly the porosity and pore size.[11,12] The data in Fig. 3A were recorded following a 'slow' (over a 2 h period), whereas Fig. 3B shows the effect of a 'fast' (2 min) depressurisation. SEM images show that the 'slow' material possesses a small population of large pores (diameter 100–500 μm) whereas the 'fast' material has higher porosity and the pore size distribution, within the resolution of SEM, is more heterogeneous. Mercury porosimetry reveals significant differences in the pore size distribution of small pores that are not visible in the SEM images. 'Slow' depressurisation produced micropores between 50 and 100 nm diameter and no pores in the 500 nm to 5 μm range. Conversely, 'fast' depressurisation produced no micropores in the 50–100 nm range, but many in the 500 nm to 5 μm range. Thus, supercritical mixing offers a mechanism of controlling both macro- and micro-porosity without the addition of porogens[13] and *via* a one-step process. We have also observed such macro- and micro-porosity in protein loaded composites.

For many applications, the polymer/drug composite is required as micron-scale particles particularly for controlled release and lung or subcutaneous delivery systems.[1] Our technique can also produce such micron-scale composite particles. After the mixing step, direct atomisation is achieved

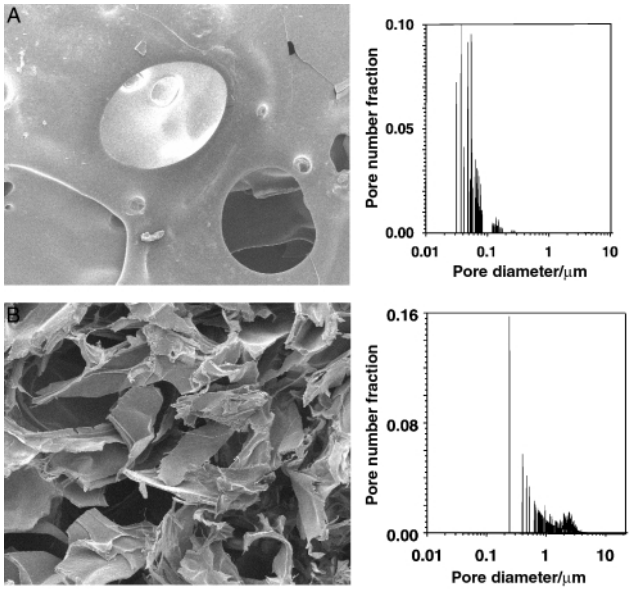

Fig. 3 Controlling PLA pore structure. A, 'slow' depressurisation over a 2 h period. B, 'fast' depressurisation over a 2 min period.

by releasing the pressure of the system across an orifice of known diameter, with particles forming as the CO_2 expands rapidly. The image in Fig. 2D shows an example of the type of particle morphology generated when processing a model system. The composite particles have a high surface area and their size may be fine-tuned by control of the orifice diameter. Typically the mean diameters fall in a range between 24 and 50 μm, a range that has been shown to be suitable for lung delivery of low density particles.[14]

The novel supercritical mixing process described here requires neither the guest nor the polymer to dissolve in $scCO_2$. The process is performed at near ambient temperature and conventional solvents are not required.[15] Hence, it is especially applicable to thermally labile or solvent sensitive guest species and polymers. Most importantly we have demonstrated that protein functioning is retained for a range of enzymes after the processing. The technique is applicable to production of composites for any technology requiring thermally labile materials dispersed throughout a polymer host.

Metal ion complexation by a new, highly sterically hindered, bowl-shaped carboxylate ligand†

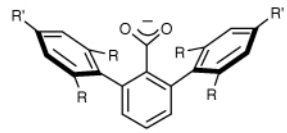
Department of Chemistry and Center for Metals in Biocatalysis, University of Minnesota, 207 Pleasant St. SE, Minneapolis, Minnesota 55455, USA. E-mail: que@chem.umn.edu; tolman@chem.umn.edu

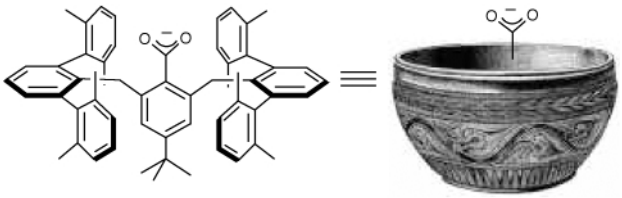
Received (in Irvine, CA, USA) 7th August 2000, Accepted 14th November 2000
First published as an Advance Article on the web 15th December 2000

A carboxylate encapsulated by arene groups arranged in a bowl-like shape coordinates to Fe(II), Co(II) and Cu(II) to form mononuclear complexes with atypical structures enforced by the extreme steric demands of the ligand.

Carboxylate groups (from Asp or Glu side chains or C termini) play key roles as supporting ligands in a diverse array of metalloprotein active sites.[1] Such carboxylates are notable for the facility with which they adopt different binding modes,[2] in particular during the catalytic cycles of dioxygen-activating mono- and di-iron enzymes.[3] In efforts to synthesize models of these metalloprotein active sites, we[4] and others[5,6] have begun using sterically bulky carboxylate ligands in order to control coordination geometry, mimic the hydrophobic active site environment, and access coordinatively unsaturated species akin to those implicated during enzymatic catalysis. For example, novel biologically relevant structures and reactivity have been discovered for iron complexes of carboxylates **1**[4] and



1 (R = R′ = Me)
2 (R = H, R′ = Me)



3

2,[5] which contain arene substituents on the benzoate unit that provide a high degree of hydrophobic 'shielding'. In expectation of even greater encapsulation of metal sites in model complexes, we targeted **3**, a carboxylate derivative of the known irregular 'bowl-shaped' 4-*tert*-butyl-2,6-bis[(2,2″,6,6″-tetramethyl-*m*-terphenyl-2′-yl)methyl]phenyl (Bmt) fragment that was used to isolate various species BmtX (X = Br, SH, SO, SI, SO_2H, AlH_3).[7] Herein we report the successful synthesis and X-ray crystallographic characterization of $BmtCO_2H$ (**3**-H) and Fe(II), Co(II) and Cu(II) complexes of **3**, which adopt atypical structures owing to the extreme steric bulk of the new carboxylate ligand.

The synthesis of $BmtCO_2H$ was achieved by lithiation of BmtBr,‡ addition of CO_2(g), acidification, and then column chromatography. The product was identified using spectroscopic (ESI†) and X-ray diffraction§ data. Treatment of $BmtCO_2H$ with Bu^nLi in thf afforded the lithium carboxylate ($BmtCO_2Li$·2thf) that was isolated as an analytically pure solid for use as the starting material for the preparation of metal complexes.

Reaction of $BmtCO_2Li$·2thf (2 equiv.) with MCl_2 in MeOH afforded $[M(BmtCO_2)_2(MeOH)_n]$·*m*MeOH [M = Fe(II), Co(II), $n = m = 4$; M = Cu(II), $n = 2$, $m = 0$]. Use of > 2 equiv. of the carboxylate yielded the same products, indicating that only two of these bulky ligands may be accommodated. The X-ray crystal structures§ of the Fe and Cu complexes are shown in Figs. 1 and 2, respectively. The Co structure is isomorphous with that of Fe, so only data for the Fe case is presented. Common to all of the complexes is a *trans* disposition of two

DOI: 10.1039/b006647h

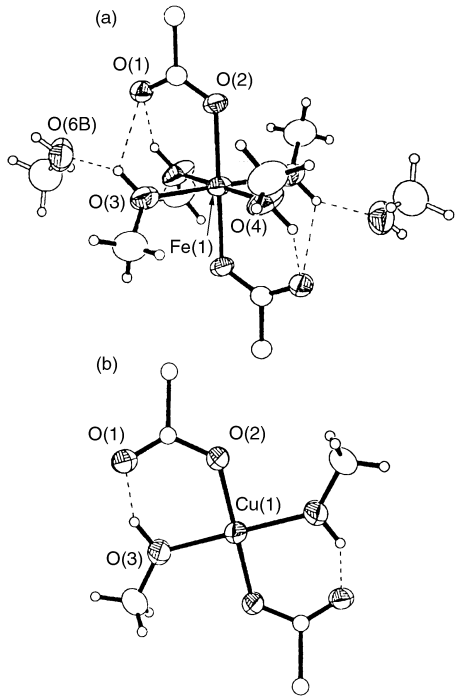

Fig. 3 Coordination spheres of (a) $[Fe(BmtCO_2)_2(MeOH)_4]\cdot 4MeOH$ (showing two of the MeOH solvent molecules; the other two are highly disordered) and (b) $[Cu(BmtCO_2)_2(MeOH)_2]$, with hydrogen bonding interactions indicated by dashed lines. Relevant interatomic distances (Å): (a) O(1)···O(4a) 2.582(3), O(1)···O(3) 3.199(3), O(3)···O(6b) 2.718(7), (b) O(1)···O(3) 2.511(3) Å.

$BmtCO_2^-$ ligands that coordinate in a *syn* monodentate fashion. The noncoordinating carboxylate oxygen atoms participate in hydrogen bonding with the bound MeOH ligands (Fig. 3). Additional hydrogen bonding occurs in the Fe and Co complexes involving included solvent MeOH molecules. Similar intramolecular hydrogen bonding patterns have been seen in other Fe(II)[8] and Cu(II)[9] carboxylate complexes and have been suggested to play a role in stabilizing their structures.

Mononuclear bis(carboxylato) iron(II) complexes possessing *trans* carboxylates are rare,[4a,c,10] and $[Fe(BmtCO_2)_2(MeOH)_4]$ is a unique example with an all-oxygen donor set. The O_{carb}–Fe–O_{carb} angle of 180° presumably results from the tendency of the $BmtCO_2^-$ ligands to position themselves as far apart as possible. This angle in the other two known bis(carboxylato) iron(II) complexes with *trans* monodentate carboxylate groups deviates significantly from linearity [168.5(2) and 154.74(8)°].[4a,c,10] The small space remaining in the equatorial plane of the octahedral $BmtCO_2^-$ complex is ideal for accommodation of small donors such as MeOH.

A Cu(II) complex possessing the same donor set as $[Cu(BmtCO_2)_2(MeOH)_2]$ has been reported,[9a] but in this complex of a functionalized benzoate ('furosemide') there are additional weak axial interactions between the Cu(II) center and the carboxylate oxygen atoms from adjacent molecules [Cu–O 2.720(4) Å]. In the $BmtCO_2^-$ compound, no other potential donor ligand is within bonding distance to the square-planar Cu(II) center due to blocking of the apical site by the carboxylate xylyl groups. The mononuclear structure of the complex contrasts with the familiar dinuclear paddlewheel[11] or other common topologies in which carboxylates bridge between multiple Cu(II) centers.[12] The discrete structure of $[Cu(BmtCO_2)_2(MeOH)_2]$ is also unusual insofar as many Cu(II) carboxylate complexes which exist as monomers in solution form intermolecular hydrogen bonded extended structures in the solid state.[13]

In conclusion, we have developed a synthesis of the carboxylate **3** in which the ligating unit is encapsulated in an irregular 'molecular bowl'. The extreme steric demands of the ligand have been illustrated through characterization of the monomeric Fe(II), Co(II) and Cu(II) complexes comprising two molecules of **3** coordinated *trans* in a *syn* monodentate mode. Further studies will explore the potential for the use of **3** and the complexes described herein for accessing unusual structures pertinent to nonheme, carboxylate rich metalloprotein active sites.

We thank Dr Katherine Aubrecht and Dr Victor G. Young, Jr., for the structural determination of $BmtCO_2H$ (**3**-H), Jamie Schneider for her efforts in improving the synthesis of BmtBr, and the NIH (GM38767 to L. Q.) for financial support.

Notes and references

‡ The precursor BmtBr was synthesized *via* the method described in ref. 7(*e*), but improvements were made that allowed the product to be isolated in higher yield (70% *vs*. 32%). For detailed procedures for the syntheses of BmtBr, $BmtCO_2H$ and $BmtCO_2Li$, see ESI.†

§ *Crystal data* for $BmtCO_2H$ (**3**-H): $C_{171}H_{174}O_6$, M = 2325.10, triclinic, space group $P\bar{1}$, a = 13.2288(7), b = 21.7697(11), c = 26.0770(13) Å, α = 76.040 (1), β = 82.286(1), γ = 84.717(1)°, V = 7208(1) Å^3, T = 173(2) K, Z = 2, μ(Mo-Kα) = 0.062 mm^{-1}, 63 469 reflections measured, 32 161 unique (R_{int} = 0.027) which were used in all calculations. The final $wR(F^2)$ was 0.1298 (all data), $R1$ = 0.0541. For $[Fe(BmtCO_2)_2(MeOH)_4]\cdot 4MeOH$: $C_{122}H_{146}O_{12}Fe$, M = 1860.24, monoclinic, space group $P2_1/n$, a = 21.1152(13), b = 13.3988(9), c = 21.1719(13) Å, β = 115.0900(10)°, V = 5424.7(6) Å^3, T = 173(2) K, Z = 2, μ(Mo-Kα) = 0.198 mm^{-1}, 27 850 reflections measured, 9562 unique (R_{int} = 0.0481) which were used in all calculations. The final $wR(F^2)$ was 0.1772 (all data), $R1$ = 0.0558. For $[Cu(BmtCO_2)_2(MeOH)_2]$: $C_{116}H_{122}O_6Cu$, M = 1675.68, monoclinic, space group $P2_1/n$, a = 15.2154(7), b = 11.1085(5), c = 27.7956(12) Å, β = 97.9700(10)°, V = 4652.6(4) Å^3, T = 173(2), Z = 2, μ(Mo-Kα) = 0.292 mm^{-1}, 23 238 reflections measured, 8203 unique (R_{int}) = 0.0439) which were used in all calculations. The final $wR(F^2)$ was 0.1795 (all data), $R1$ = 0.0598. CCDC 182/1859. See http://www.rsc.org/suppdata/cc/b0/b006647h/ for crystallographic files in .cif format.

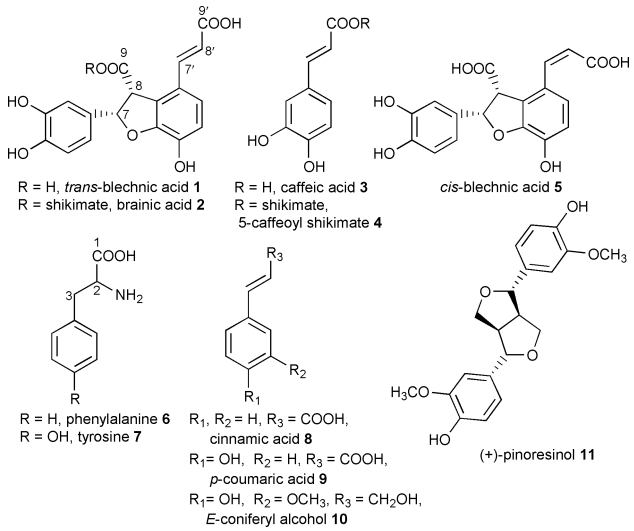
***In vivo* administration experiments using stable (^{13}C) and radio (^{14}C) labeled precursors provide further evidence for vascular plant proteins engendering specific but distinct phenolic coupling modes, *i.e.* in this case for stereoselective 8–2′ coupling leading to the optically active lignans, (–)-blechnic and (–)-brainic acids.**

The ferns (*Pteridophytes*) are evolutionary forerunners of the gymnosperms and angiosperms. They contain various phenolic natural products which may represent some of the earliest examples *in planta* of control of stereoselective phenolic coupling. For example, *Blechnum spicant* (deer fern) and *B. orientale*[1] accumulate the unusually linked, optically active, 8–2′ lignans, (−)-blechnic **1** and (−)-brainic **2** acids.



Gymnosperm and angiosperm lignans are frequently derived from stereoselective 8–8′ coupling of two monolignol (hydroxycinnamyl alcohol) radicals,[2] and the recent discovery of dirigent proteins (Latin: *dirigere*, to guide or to align) and their corresponding genes gave a new perspective into how free radical coupling is controlled in plants *in vivo*.[3–5] There have been no reports on the stereoselective control of other coupling modes, and hence establishing the mechanism of 8–2′ linked lignan formation in the Blechnaceae would be instructive.

The MeOH extract of *B. spicant* contains as its principal metabolites, caffeic acid **3**, 5-caffeoyl shikimate **4**, (−)-*trans*-blechnic acid **1** and (−)-brainic acid **2**. An unknown compound **5** was also isolated, which on standing in open solution (in CH_3CN or H_2O) over 72 h, was converted into (−)-*trans*-blechnic acid **1**. Compound **5** ($[\alpha]_D$ −128°, *c* 0.58, MeOH) had a molecular formula of $C_{18}H_{14}O_8$ as evidenced from its HR-MS (381.7373 $[M+Na]^+$); furthermore, comparison of its ^{1}H and ^{13}C NMR spectral data with those of (−)-blechnic acid (−)-**1** revealed that both structures were very similar, except for a *cis*-double bond in **5** [^{1}H NMR: 6.74 (1H, d, J = 12.7 Hz, H-7′), 5.88 (1H, d, J = 12.7 Hz, H-8′); ^{13}C NMR: 139.7 (C-7′) and 120.2 (C-8′)] *vs.* the *trans* double bond in blechnic acid **1** [^{1}H NMR: 7.57 (1H, d, J = 16.1 Hz, H-7′), 6.27 (1H, d, J = 16.1 Hz, H-8′); ^{13}C NMR: 143.3 (H-7′) and 117.8 (H-8′)]. Correlations (or connectivities) for compound **5** were determined by 2D-NMR (^{1}H-^{1}H COSY, HMQC, HMBC) spectroscopic analyses conducted at low temperature (−25°C), and the configuration of the *cis*-double bond was further confirmed by both NOE experiments and a comparison to that of (−)-*trans*-blechnic acid **1**.

The precursor relationships to the optically active 8–2′ linked lignans was examined through deployment of radiolabeled Phe **6**, Tyr **7**, cinnamic **8**, *p*-coumaric **9** and acetic acids as potential precursors over extended durations (Table 1). Thus, caffeic acid **3**, 5-caffeoyl shikimate **4**, (−)-*cis*-blechnic **5**, (−)-*trans*-blechnic **1** and (−)-brainic **2** acids, were individually isolated with the relative total radiochemical incorporation for each estimated by liquid scintillation counting (see Table 1). Significantly, a rapid incorporation into (−)-*cis*-blechnic acid **5** (~3%) was noted within 8 h, relative to that of (−)-*trans*-blechnic **1** and (−)-brainic **2** acids (≤0.1%). This indicated that (−)-*cis*-blechnic acid **5** was the initial coupling product, since it was apparently further metabolized into (−)-*trans*-blechnic **1** and (−)-brainic **2** acids based on the trends of total incorporation noted for **1** and **2** which approached *c.* 1–2 and 3–4% over 48–84 h, respectively. A less likely interpretation is that **5** might be a shunt metabolite and not directly involved in the formation of **1** and **2**. For each time frame examined, the relative incorporation into (−)-brainic acid **2** was higher than that into (−)-blechnic acid **1**, suggesting that *cis*-blechnic acid **5** was more effectively channeled into (−)-brainic acid **2** rather than into (−)-blechnic acid **1**. In a somewhat analogous manner, both [3-^{14}C]cinnamic **8**, and [2-^{14}C]*p*-coumaric **9** acids served as precursors, whereas neither [*U*-^{14}C]tyrosine **7** nor [2-^{14}C]NaOAc were incorporated into any of the various metabolites of *B. spicant* examined, (data not shown).

L-[3-^{13}C], [2-^{13}C] and [1-^{13}C] phenylalanine **6** (1.0 mM) were next individually administered to *B. spicant* fronds for 5 days, with the resulting (−)-brainic **2** and (−)-*trans*-blechnic **1** acids isolated by preparative μBondapak C18 column HPLC and subjected to ^{13}C-NMR spectroscopic analyses (see Fig. 1a–d). Only the data for (−)-brainic acid **2** are presented. Fig. 1a shows the natural abundance NMR spectrum and the corresponding assignments for (−)-brainic **2** acid; these are based on 2-D NMR spectroscopic analyses (HMQC, HMBC and ^{1}H-^{1}H COSY) and previous assignments by Wada *et al.*[1] The (−)-brainic **2** acid obtained following administration of [1-^{13}C]Phe **6** displayed carbon-13 enriched resonances for C-9 and C-9′ at 170.5 and 170.6 ppm, respectively (Fig. 1b). In a

† Electronic supplementary information (ESI) available: ^{13}C-NMR spectra of (a) natural abundance (−)-*trans*-blechnic **1** acid, as well as (−)-*trans*-blechnic acids **1** obtained following administration of (b) [1-^{13}C], (c) [2-^{13}C] and (d) 3-^{13}C]-phenylalanine **6** (1 mM) to *B. spicant* fronds for 5 days; all spectra were recorded under identical conditions.

The relative carbon-13 enrichments noted were higher for (−)-brainic acid **2** than for (−)-*trans*-blechnic **1** due in large part to the much higher endogeneous levels of the latter in *B. spicant*. See http://www.rsc.org/suppdata/cc/b0/b008174o/

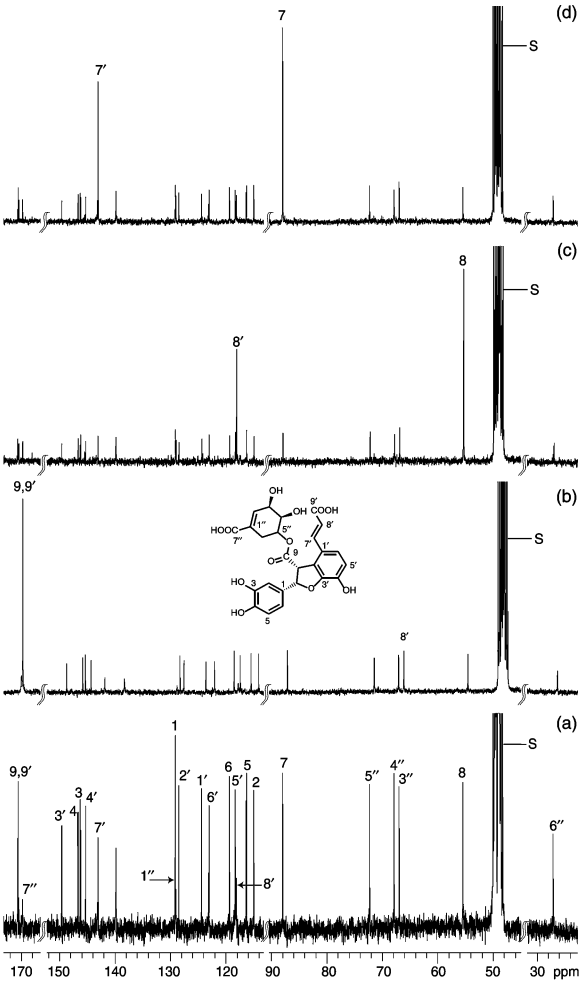

Fig. 1 ^{13}C-NMR spectra of (a) natural abundance (−)-brainic **2** acid, as well as (−)-brainic acids **2** obtained following administration of (b) [1-^{13}C], (c) [2-^{13}C] and (d) [3-^{13}C]phenylalanine **6** (1 mM) to *B. spicant* fronds for 5 days; all spectra were recorded under identical conditions.

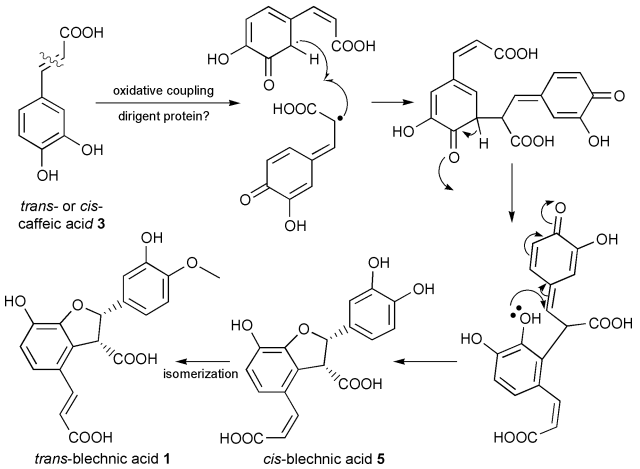
similar manner, administration of [2-^{13}C]Phe **6** gave enhanced signals for the C-8 and C8′ resonances of (−)-brainic **2** acid at 55.4 and 118.2 ppm (Fig. 1c), whereas with [3-^{13}C]Phe **6**, the corresponding enhanced signals at C-7 and C7′ were at 88.0 and 142.7 ppm (Fig. 1d). Comparable results were observed for (−)-*trans*-blechnic acid **1** biosynthesis (see ESI†).

We propose that the 8–2′ linked lignans, (−)-blechnic **1** and (−)-brainic **2** acids, result from oxidative coupling of caffeic acid **3** as depicted in Scheme 1. Based on the trends of relative incorporations into **5**, **1** and **2**, this conversion is likely to result *via* stereoselective coupling of two molecules of either *cis*- or



Scheme 1 Proposed stereoselective coupling of caffeic acid **3** leading to (−)-*trans*-blechnic acid **1**.

trans-caffeic acid **3** to first afford (−)-*cis*-blechnic acid **5**. Less likely, stereoselective coupling could involve *p*-coumaric acid **9** with subsequent hydroxylation of the aromatic ring to ultimately afford the corresponding catechols **1** and **2**. In any case, by comparison to the dirigent mediated stereoselective bimolecular coupling of coniferyl alcohol **10** affording (+)-pinoresinol **11**, it is tempting to suggest that the formation of the blechnates **1** and **2** may involve a comparable process.[4,5] This will be established in the future by isolation and characterization of the relevant proteins and enzymes involved in the biosynthesis of (−)-*trans*-blechnic acid **1** and its derivatives in *B. spicant*; nevertheless both 8–8′ and 8–2′ linked phenylpropanoid coupling products are under full proteinaceous control thereby stipulating the outcome of stereoselective coupling.

The authors thank the USDOE (DE-FG03-97ER20259) and the NSF (MCB-9976684), as well as the L. B. and D. Cullman and G. T. Hargrove Center for Land Plant Adaptation.

Ternary complexes of formula [Gd–DO3A–L–(H_2O)] (where L is a carboxylate-containing ligand) display exchange lifetimes of the metal-coordinated water that can be modulated as a function of L.

Paramagnetic Gd(III) chelates are currently under intense scrutiny for their use as contrast agents (CAs) for magnetic resonance imaging (MRI).[1] Their efficiency is usually expressed in terms of relaxivity (r_1), which represents the relaxation enhancement of the water protons at mmol concentration of the paramagnetic agent. The relaxivity is the result of a complex interplay of several structural, dynamic and electronic parameters. Recently, it has been shown that the exchange lifetime of the coordinated water, τ_M, may have a key role in determining the relaxivity of a Gd(III) complex.[2] In fact,it has been found that τ_M covers a whole range of values ranging from few ns in the aqua-ion[3] up to several μs in complexes of octadentate neutral macrocyclic ligands.[4] In systems containing one coordinated water only (q = 1) it has been shown that the exchange process occurs through a dissociative mechanism and the relative exchange rate is dependent upon the energy difference between the nona-coordinate ground state and the octa-coordinate transition intermediate.[5] Thus, an increased encumbrance in the ground-state structure results in a smaller energy jump to reach the intermediate state with a consequent increase in the water exchange rate.[6] Moreover, it has been found that in DOTA-like systems, the isomer possessing a twisted antiprismatic structure displays an exchange rate of the bound water that is *ca*. 50 times faster than that observed for the isomer endowed with a more compact square antiprismatic geometry.[7,8] Thus, minor structural variations may have remarkable effect on the exchange lifetime of the coordinated water in lanthanide(III) chelates.

As far as the use as CA for MRI is concerned, optimal values of τ_M for the attainment of high relaxivities [once the Gd(III) is part of a slowly moving macromolecular substrate] fall in the range of few tenths of ns.[9] Thus, it is relevant to gain more insight into the structural factors which are responsible of the exchange rate of the coordinated water. Recently, it has been shown that coordinatively unsaturated Gd(III) chelates with q > 1 are able to readily form ternary complexes with suitable ligands such as carboxylates. The formation of such adducts involves the replacement of one or more Gd-bound water molecules by the ligand.[10,11] Herein, we show that the mixed complexes [Gd–L–L′–(H_2O)], where L is the heptadentate ligand DO3A[12] and L′ is a carboxylate-containing ligand, display exchange lifetimes of the metal coordinated water which can be modulated as a function of the added ligand.

The formation of ternary adducts has been followed by analyzing the changes of relaxivity upon L′ concentration. The [Gd–DO3A] complex has a relatively high r_1 value (6.0 mM^{-1} s^{-1} at 20 MHz and 25 °C[14]) as the largely dominant isomer[13] displays two metal-bound water molecules (average q value = 1.8). Upon adding sodium propionate or L-alanine to a solution of [Gd–DO3A], a progressive decrease of r_1 was observed (Fig. 1). This effect is related to the replacement of one Gd-coordinated water molecule by the entering ligand. The fitting of these data according to the PRE (proton relaxation enhancement) theory[15] allowed us to estimate either the relaxivities of the ternary complexes, which are consistent for Gd(III) chelates of the expected molecular size and q = 1, or the binding constant between the paramagnetic complex and the ligand (Table 1).

As a further check, we evaluated, by luminescence measurements, the metal complex–substrate affinity as well as the hydration state of the resulting mixed complexes. The comparison between the rate constants of the luminescence decay for [Tb–DO3A] adducts in H_2O and D_2O assures about the presence of a residual lanthanide bound water molecule, whereas by looking at the changes in the intensity of the emission spectra at 545 nm [corresponding to the ΔJ = 1 transition of Tb(III) ion] upon the addition of the substrates, K_A values in agreement with those measured by the PRE analysis were obtained (Table 1).

The exchange rate of the metal bound water molecule in this class of paramagnetic complexes may be conveniently deter-

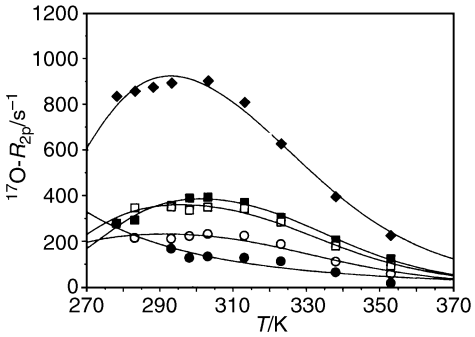

Fig. 2 ^{17}O-R_{2p} *vs.* T of 27.3 mM solutions of [Gd–DO3A–$(H_2O)_2$] (◆), [Gd–DO3A–propionate–(H_2O)]$^-$ (●), [Gd–DO3A–alanine–(H_2O)] (■), [Gd–DO3A–α-aminobutyrate–(H_2O)] (□) and [Gd–DO3A–β-aminobutyrate–(H_2O)] (○); 7.1 Tesla, pH 7.

mined by measuring the temperature dependence of water ^{17}O-R_{2p}.

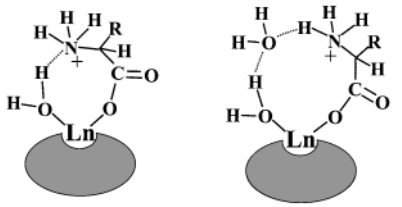
In fact, the R_{2p} values are basically a function of q, τ_M and the electronic relaxation times of the metal ion T_{ie} (i = 1,2). Two different regimes can be met, one occurring at low temperatures, in which the changes in R_{2p} are mainly determined by τ_M (slow exchange region) and one at higher temperatures, essentially dominated by T_{ie} (fast exchange region). For many systems displaying τ_M in the range of few hundreds of nanoseconds R_{2p} displays a bell-shaped curve (as shown in Fig. 2 for [Gd–DO3A–$(H_2O)_2$] at 7.05 T, τ_M^{298} = 80 ns). The ^{17}O-R_{2p} values for the ternary complexes [Gd–DO3A–propionate–(H_2O)]$^-$ and [Gd–DO3A–alanine–(H_2O)] are significantly smaller than those of the parent chelate owing to the reduction of q in the ternary adduct. Interestingly, the observed behaviour is consistent with the occurrence of a fast exchange of the metal bound water molecule in the case of [Gd–DO3A–propionate–(H_2O)]$^-$ (τ_M^{298} = 8 ns). Thus on going from [Gd–DO3A–$(H_2O)_2$] to [Gd–DO3A–propionate–(H_2O)]$^-$ there is a considerable shortening of the residence lifetime of the inner sphere water molecule. Furthermore, the observed τ_M is much shorter than that of [Gd–DOTA–(H_2O)]$^-$ and, interestingly, it is in the range of optimal values for providing the highest relaxivities for MRI applications.[9]

Surprisingly, the profile for the [Gd–DO3A–alanine–(H_2O)] adduct displays a different shape, indicative of a longer τ_M value (τ_M^{298} = 180 ns). This may reflect the occurrence of a hydrogen-bonding interaction between the metal bound water molecule and the positively charged α-amino group of the amino-acid, which could also be mediated by a solvent water molecule (Scheme 1).

In order to further check this hypothesis ^{17}O-R_{2p} *vs.* T profiles of the adducts between [Gd–DO3A–$(H_2O)_2$] and aminobutyrate anions differing in the position of the protonated amino group were recorded (Fig. 2).

The ^{17}O-R_{2p} values for the adduct with α-aminobutyrate are similar to those of the L-alanine adduct (τ_M^{298} = 120 ns). However, when the $-NH_3^+$ group is shifted to the β-position, the exchange lifetime decreases significantly (τ_M^{298} = 80 ns).

Therefore, these results clearly suggest that the position of the protonated amino group plays a key role for controlling the water exchange rate of the metal bound water molecule.



Scheme 1 Proposed representations of the ternary [Ln–DO3A–alanine–(H_2O)] adduct. The elongation of the residence lifetime of the metal bound water molecule may result from the occurrence of the hydrogen bonding network.

In summary, though it is difficult to foresee a MRI application for the Gd(III) based ternary complexes investigated in this work, the results here reported indicate a novel route to the modulation of the exchange rate of the coordinated water in Gd(III) complexes. Moreover, one may seek for the formation of ternary complexes between suitably functionalized Gd(III) chelates and endogenous substrates containing carboxylate functionalities.

Financial support from MURST and CNR (Biotechnology PF and L. 95/95) is gratefully acknowledged. This work was carried out under the framework of the COST-D18 action.

A molecular photoswitch based on an 'axial-bonding' type phosphorus(v) porphyrin

Reversible isomerization of the two axial azobenzene subunits leads to modulation of the fluorescence due to the basal tetrapyrrolic chromophore in a new hexa-coordinated phosphorus(v) porphyrin 3, illustrating its utility as a molecular photoswitch.

'Emitter–quencher' assemblies based on porphyrin building blocks are attracting increasing attention because of their importance as either model compounds in photosynthetic research or photoswitches in the fabrication of molecular electronic/optical devices.[1,2] While a great variety of covalently or non-covalently bound porphyrin–acceptor motifs are now known to closely mimic the initial, photoinduced electron transfer (PET) events of natural photosynthetic reactions,[1] the utility of such motifs as photoswitches has not been firmly established. In this regard, it is interesting that a key recurring theme of most earlier attempts to construct porphyrin-based photoswitches involves intramolecular PET coupled to isomerization (*E*/*Z*) of the azobenzene group.[3–8] This theme is an appealing one, and especially so, in view of the ready availability of PET-based non-porphyrinic photoswitches that incorporate azobenzene moieties in their architecture.[2] However, barring a recent exception,[4] photoswitching function has not been demonstrated in any of the porphyrin–azobenzene conjugates reported so far. Herein, we describe the luminescence on/off behavior observed in a novel, metalloid porphyrin-based photoswitch **3**, which is constructed by utilizing the 'axial-bonding' capability of a phosphorus(v) porphyrin- (Fig. 1).

The hydroxide salt of photoswitch **3** was synthesized in 70% yield by reacting [5,10,15,20-tetra(tolyl)porphyrinato]phosphorus(v) dichloride **1** and 4-hydroxyazobenzene (excess) **2**, in refluxing pyridine and purifying by column chromatography [silica gel, $CHCl_3$–MeOH 10 : 1, v/v)].[9] The ^{1}H NMR spectrum of this 'axial-bonding' type metalloid-porphyrin shows characteristic, porphyrin ring-current-induced upfield shifts for the protons on the axial aromatic ligands,[10] with the magnitude of shift for a given proton being a function of its separation distance from the porphyrin π-plane (see Fig. 1). On the other hand, effects due to the substitution of axial chlorides by the aryloxo ligands are minimal for the porphyrin pyrrole-β and meso-aryl proton resonances. However, in the ^{31}P NMR spectrum, the signal due to the central phosphorus ion of **3** was seen to be shifted downfield (δ −194.9, 85% H_3PO_4 external reference) compared to that of **1** (δ −229.4) but is within the typical range expected for hexa-coordinated diaryloxo phosphorus(v) porphyrins.[9] Further support for the structural integrity of **3** arises from the appearance of its molecular ion peak at *m/z* = 1093 ([M]$^+$) in the FAB mass spectrum.

The UV/VIS spectrum of **3** is essentially a summation of the spectra of **1** and **2** (1 : 2 molar ratio), with the porphyrin Q- and B-bands [λ_{max}/nm (log ε): 610 (4.03), 566 (4.28), 436 (5.36)] clearly distinguishable from the absorption due to the two *trans* azobenzene moieties in their *E* isomeric form [λ_{max}/nm (log ε): 341 (4.86)] [Fig. 2 (top curve)]. These spectral features suggest that there is no electronic communication between the porphyrin and the azobenzene chromophores and, more importantly, that it is possible to individually address the photochemistry of these two subunits in this bichromophoric system. Accordingly, continuous irradiation of $\mathbf{3}_E$ (5.9×10^{-5} M, MeCN) at 345 ± 5 nm resulted in the time-dependent decrease of its absorption band centered at 341 nm concomitant with a slight increase of absorption in the B-band region, suggesting isomerization of the porphyrin-bound azobenzene subunits to produce $\mathbf{3}_Z$.[11] The reverse thermal reaction was also spectrally monitored and the *E* form could be recovered quantitatively (Fig. 2).

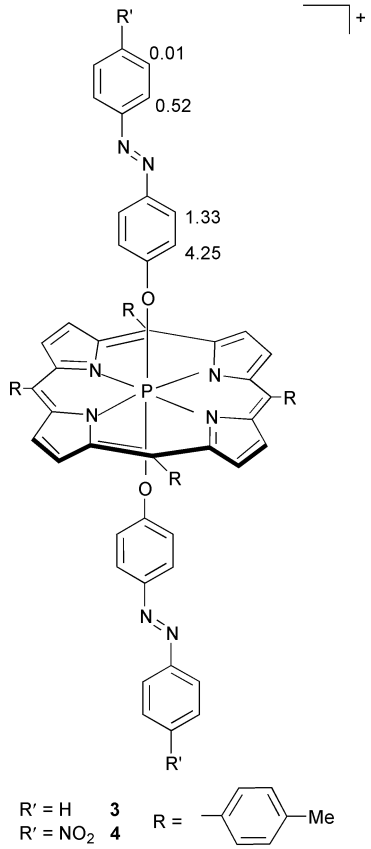

Fig. 1 Molecular structure of photoswitches investigated in the present study. The numbers indicated adjacent to protons on the azobenzene moiety are the corresponding porphyrin ring-current-induced ^{1}H NMR chemical shifts [*i.e.* $\Delta\delta$ (free − bound)] observed for $\mathbf{3}_E$.

Excitation of a MeCN solution of $\mathbf{3}_E$ at 345 nm resulted in no fluorescence emanating from the azo chromophore as is the case with the precursor **2**. On the other hand, the porphyrin component of the complex showed a fluorescence spectrum (λ_{exc} = 465/565 nm) typical of a hexa-coordinated phosphorus(v) porphyrin.[9] The fluorescence quantum yield [Φ_f, estimated using (5,10,15,20-tetraphenylporphyrinato)zinc(II), Zn^{II}TPP, as the standard] of $\mathbf{3}_E$ (0.01) is less than that of [5,10,15,20-tetra(tolyl)porphyrinato]phosphorus(v) dihydroxide {[P^V(TTP)$(OH)_2$]$^+$, Φ_f = 0.045}. Interestingly, the fluorescence intensity due to $\mathbf{3}_Z$ (produced by continuous irradiation at 345 ± 5 nm) is only 60 ± 5% of that due to $\mathbf{3}_E$, and the thermal back reaction regenerates the fluorescence of $\mathbf{3}_E$ as illustrated in Fig. 2 (inset). This *E*/*Z* interconversion was repeated 5–6 times

DOI: 10.1039/b007784o

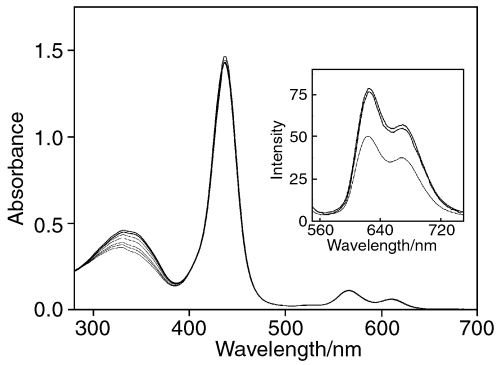

Fig. 2 Time-dependent UV/VIS spectral changes observed upon continuous irradiation of $\mathbf{3}_E$ (solvent: MeCN, [$\mathbf{3}_E$] = 5.9×10^{-5} M). Top curve represents the initial spectrum with the subsequent lower ones resulting from continuous irradiation of the solution at 345 ± 5 nm at 25 °C for 1, 2, 5, 7, 9, 12 and 16 min, respectively (PTI 150 W Xe-arc lamp model A1010, PTI model 1366-MONO monochromator). The dotted curve close to the top curve is the spectrum obtained after keeping the irradiated solution in the dark for several hours. Inset: fluorescence spectra of (——) unirradiated $\mathbf{3}_E$, (– – –) $\mathbf{3}_Z$ obtained upon irradiating $\mathbf{3}_E$ and of (· · · ·) $\mathbf{3}_E$ resulting from the back thermal reaction of $\mathbf{3}_Z$ (solvent: MeCN; λ_{exc} = 465 nm).

with < 5% loss of the material (UV/VIS and fluorescence), thus establishing the ability of **3** to be an effective and stable photoswitch.

What is the origin of weak fluorescence observed for **3** and what is the mechanism of its photoswitching function? Among the various possible mechanisms considered by us,† an intramolecular PET from the axial azobenzene donors to the singlet excited state of the basal phosphorus(v) porphyrin seems to be the most probable pathway for the quenching of fluorescence in $\mathbf{3}_E$. This interpretation is consistent with not only the exoergicity for such a PET reaction (ΔG_{PET} = −0.16 ± 0.03 eV‡), but also a similar interpretation made earlier for the quenching observed in a series of aryloxo phosphorus(v) porphyrins reported by us.[9b] Moreover, Φ_f for complex $\mathbf{4}_E$ (Fig. 1), which is endowed with the electron withdrawing nitro group at the axial azobenzene ligand, was seen (Φ_f = 0.035) to be more than that of $\mathbf{3}_E$.§ Thus, accepting that PET is occurring between the axial ligand and the singlet porphyrin in this donor–acceptor complex, the photoswitching function demonstrated here can be rationalized in terms of the distance dependence of PET. As schematically represented in Fig. 3, the distance between the basal porphyrin and the axial ligand in $\mathbf{3}_Z$ is shorter than that in $\mathbf{3}_E$ explaining the additional fluorescence quenching observed for the former isomer.

Recently, electro-switch and proton-switch properties of an supramolecular ensemble comprising of Zn^{II}TPP and *axially* ligated 4-(phenylazo)pyridine has been reported but, the effect of *E/Z* isomerization on the luminescence properties of this system was not observed.[3] Similarly, studies on the covalently

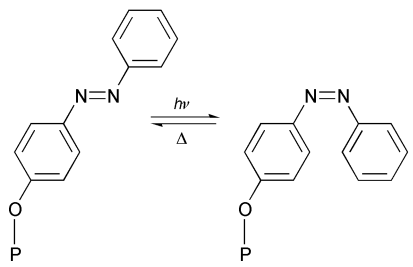

Fig. 3 Reversible *E/Z* isomerization in **3** (P = porphyrin).

connected azobenzene–porphyrin conjugates reported by Hunter and Sarson revealed that photochemistry of the porphyrin components of these novel chromophoric assemblies is essentially unaltered but, the photochemical isomerization of their azobenzene components could not be detected.[5] On the other hand, fluorescence properties of the early azobenzene–porphyrin systems reported by several groups were not investigated in detail.[6–8] While this work was in progress, photoswitching features of an azobenzene-linked diporphyrin complex have been described.[4] However, because of the extensive absorption by the two dissimilar porphyrin chromophores in the UV/VIS region, spectral detection of the *E/Z* isomerization in this system was not as facile as demonstrated here for **3**.

In summary, the new phosphorus(v) porphyrin **3** is an effective and stable photoswitch. Its photoswitching ability is a result of the isomerization-induced modulation of the PET between the axial azobenzene subunits and the basal porphyrin scaffold. Further studies on **3** and other closely related 'axial-bonding' type photoswitches are currently in progress.

We thank the CSIR (New Delhi) for financial support of this work.

Notes and references

† Excitation of **3** at 345 nm resulted in weak fluorescence in the range 550–750 nm but control experiments have suggested this to be entirely due to the residual absorption by the porphyrin chromophore. Moreover, the excitation spectrum of the compound (emission collected at the porphyrin fluorescence band maximum) did not show absorption corresponding to the azobenzene chromophore. In a separate set of experiments, neither the fluorescence of $[P(TTP)(OH)_2]^+$ was found to be quenched by compound **2** nor was any rate enhancement observed for the thermal back reaction of $\mathbf{3}_Z$ in the presence of externally added **2**. Thus, fluorescence quenching observed here for **3** is not due to the energy transfer between the azobenzene and porphyrin subunits or the photochemical disscociation of azobenzene ligands.

‡ Estimation of ΔG_{PET} is based on the electrochemical redox potential data [E_{ox} (axial ligand) = 1.52 V, E_{red} (basal porphyrin) = −0.35 V] and singlet energy of the porphyrin (2.03 eV[9c]).

§ The presence of an electron withdrawing nitro group on the axial ligand is expected to decrease its donor capacity. Indeed, ΔG_{PET} for **4** is close to 0.0 eV, consistent with its high Φ_f value.

Optically clear thin mesoporous films with covalently attached fluorescein entities are shown to exhibit very fast response pH sensing.

Dye-doped mesostructured compounds are currently attracting interest with respect to possible optical applications such as materials exhibiting amplified spontaneous emission and lasing.[1–3] The mesoporous forms are also promising for optical applications when doped with dyes. Dyes can be attached covalently to the matrix by introducing hydrolysable units onto the dye molecules.[4] Principally this should allow one to remove the surfactants quantitatively, leaving behind a porous matrix with anchored dye molecules. The porous structure is especially important for optical sensing applications where fast diffusion of the molecules towards the sensing species is of interest.

Previous investigations on optical sensors has focused predominately on sol–gel glasses. The attractive points of sol–gel glasses are their ease of processibility as well as thermal and mechanical robustness. A few examples include oxygen sensing by Ru-complexes,[5] pH sensing,[6] and ion sensing.[7] As far as pH sensing is concerned, the diffusion of the molecules into the dried glass is sometimes a limiting factor, usually leading to rather long response times (up to minutes),[7] a task which could be improved with mesoporous materials. Here, we show that mesosporous thin films[8] prepared by acidic sol–gel chemistry and low-temperature block-copolymer extraction[9] can function very effectively as pH sensors. The pH sensitive dye is covalently anchored to/within the mesoporous SiO_2 wall in order to prevent leaching during optical pH measurements. We also demonstrate that the response of the dye-modified mesoporous silica thin films is very fast, indicating the possibility of using these materials in sensor devices.

Fluorescein isothiocyanate (FITC) was used as the pH sensitive dye and was derivatized with 3-aminopropyltriethoxysilane (APTS). Typically, 7 mg of FITC was dissolved in 20.4 g of EtOH and was allowed to react with 10 mg APTS for 3 h. Afterwards, 2.0 g of the block-copolymer F127 [poly(ethylene oxide)-*block*-poly(propylene oxide)-*block*-poly(ethylene oxide), $(PEO)_{106}(PPO)_{70}(PEO)_{106}$, BASF], 1.6 g H_2O, 0.25 g HCl (2 M) and 8.5 g tetraethylorthosilicate (TEOS) were added. This solution with a molar composition of TEOS–F127–H_2O–HCl–FTIC–APTS–EtOH = $1:4 \times 10^{-3}:2.5:0.012:4.4 \times 10^{-4}:1.1 \times 10^{-3}:10.9$ was refluxed for 1 h. After the solution had cooled to rt, thin films were prepared by dip coating. Films were withdrawn from solutions with 10 cm min^{-1}, resulting in ~900 nm thick films on an area of 2.5×2.5 cm^2. The films show a considerable thickness variation when prepared by dip-coating. Apart from the fact that the ends are swelled thick, the film thickness increases along the dipping direction. When the same solutions are spin-coated (3000 rpm, 30 s), more homogenous thin films (~1500 nm) are produced, with a thickness variation of 5% (apart from the edges which are also swelled thick).

A typical X-ray pattern of an as-synthesized thin film is depicted in Fig. 1(a), showing several peaks in the region between 0.8 and 3.5 $2\theta°$. The peaks can be indexed in the $P6_3/mmc$ space group indicating that the composite thin film consists of a hexagonally packed arrangement of cages (a = 113, c = 181 Å, c/a = 1.60).[8] One further non-indexable peak is observed at a d spacing of 51 Å; this peak may be attributed to the 200 reflection of a cubic $Im3m$ phase which can also be derived under similar conditions with F127 as a block-copolymer.[8] The 110 reflection is hidden by the intense reflection of the hexagonal structure at ~1° 2θ. From the relative intensities we conclude that the hexagonal phase is the major part, whereas the cubic phase is only present in small amounts. However, as both structures are composed of cage-like entities, and porosity itself determines the sensing properties, the presence of minor amounts of a second phase is not of significant importance. We note also that the use of higher concentrations of APTS did not result in ordered mesostructures. This fact is attributed to the pH increase brought about by the basic amine. Hence, we adjusted the concentration of APTS carefully, in order to have an access for complete dye derivatization but still having a pH resulting in thin films with mesostructural order.

A key point is the low temperature removal of the surfactants. Fresh films (~1 d old) show severe cracking when treated in EtOH at 80 °C. The same is true, even when the films are aged for several days at rt. However, we observed that when the films had first been aged at rt for about 10 d and afterwards for 3–5 d at 70 °C, the stability of these films is sufficiently high to allow surfactant removal by extraction without decrease of the optical transparency.

The extraction time itself was optimized in order to completely remove the surfactants. IR spectroscopy was used to

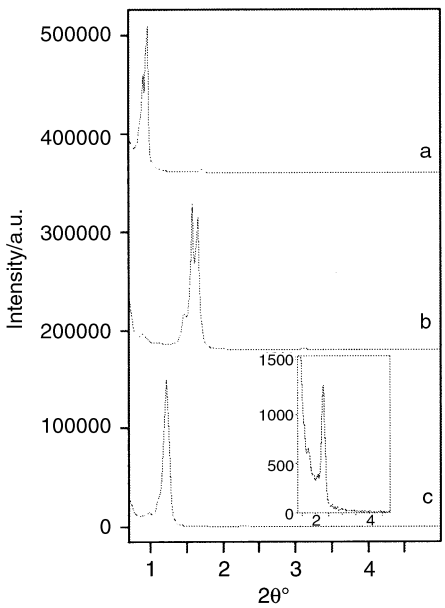

Fig. 1 X-Ray diffraction patterns of fluorescein-doped thin mesostructured/mesoporous films prepared with F127. (a) As-synthesized, (b) after calcination, and (c) after extraction. The inset in (c) shows a magnification of the higher $2\theta°$ range.

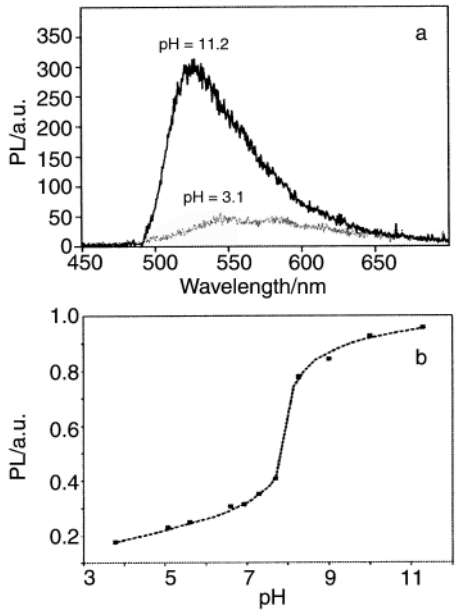

Fig. 2 (a) Photoluminescence of fluorescein doped mesoporous thin films at low and high pH values, (b) typical titration curve.

follow the surfactant removal during extraction by monitoring the C–H vibrations in the range 2700–3000 cm^{-1}. Within the first 4 h of extraction, the intensity of these bands steadily decreased, until finally only weak bands in this wavelength region remained. These bands were still present after 24 h of extraction and may be attributed to vibrations due to the occluded dye and the excess APTS used for the dye derivatization. X-Ray patterns showed that prolonged treatment in EtOH at 80 °C results in a decrease of the unit-cell constants compared to the as-synthesized material (Fig. 1c). The unit-cell parameters (a = 90.1, c = 144.6 Å, c/a = 1.60) are larger than those of a calcined thin film made from the same composition (a = 69.8, c = 111.8 Å, c/a = 1.62), showing a lower contraction of the SiO_2 framework when employing extraction for block-copolymer removal. We note that even after prolonged treatment in EtOH (24 h) not only the optical transparency and the mesostructure are retained but also the X-ray patterns exhibit all reflections seen for the as-synthesized material.

For the demonstration of pH sensing, we chose a simple configuration in which the thin films were excited by the 488 nm line of an Ar^+ ion laser at 45° and the photoluminescence (PL) was detected normal to the film surface. Typical PL spectra are depicted in Fig. 2a at a pH of and 3.1 and 11.2. As expected, the PL intensity of the thin films is dependent on the pH and is stronger under basic conditions. A typical titration curve is depicted in Fig. 2b. Compared to solution, the titration curve is relatively broad. This may be attributed to an inhomogeneous dye environment. Moreover, fluorescein possesses three pK values which can hardly be distinguished in solution (pK_1 = 2.08, pK_2 = 4.31, pK_3 = 6.43) and which might also cause some broadening.[10]

The response time of the mesoporous films upon changing the pH is fast, being in the range of a few seconds. Fig. 3 depicts a typical set of data which was obtained by exchanging the solution from pH 3.8 to 9.4. We attribute the fast response to the fact that the porous structure facilitates the diffusion of H_3O^+ (OH^-). While it is possible the dye is located both at the pore interface and incorporated within the SiO_2 wall, this does not hinder the anchored fluorescein entities to respond rapidly to changes in pH. From time dependent measurements we evaluated the time for the change in the PL signal to 95% of the final value to be in the range of ~7 s. We note that with the exception of small capillaries coated with sol–gel glass,[11] this is faster than in purely sol–gel based optical pH sensors.[7,12]

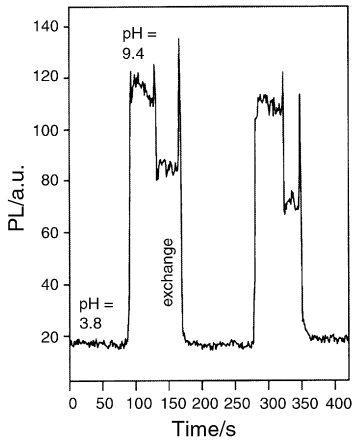

Fig. 3 Time dependent photoluminescence response of a fluorescein doped mesoporous thin film upon change of the pH value.

Here, we have demonstrated that dye-doped mesoporous thin films are suitable candidates for optical solid-state pH sensors. An important point is the careful optimization of the processing conditions which are necessary to obtain thin mesoporous films with high optical quality. As expected, the response time is very fast, due to the mesoporosity of the thin films. On the other hand, the high processibility of the solid state precursor solution should allow one to extend this chemistry to other sensing arrangements, *e.g.* to evanescent wave optical fibers[13] or to pH sensing microtips.[14]

This work was supported by the NSF under grant DMR 95-20971, DMR 9634396, the U.S. Army Research Office under grant DAAH04-96-1-0443 and made use of the Materials Research central facilities supported by the NSF under award DMR-9632716.

During review of this manuscript, Fau *et al.*[15] reported pH sensing in patterned mesoporous materials where the sensing agent was attached by post-synthesis modification.

First published as an Advance Article on the web

Novel W–Nb–S composite inorganic nanotubes have been generated by replacing W in the S–W–S sandwich layers of WS_2 by Nb. The tubes are uniform, with the Nb concentration 10 atom%. Raman spectral features of the tubes are described.

Inorganic fullerene (IF) nanotubes, *e.g.* MX_2 (M = W, Mo; X = S, Se), first reported by Tenne *et al.*,[1] have engendered considerable scientific interest because they are good semiconductors and display excellent wear-resistant properties. To date, various approaches to the synthesis of these materials have been developed, such as chemical transport,[2] gas–solid reactions[3] and *in situ* heating,[4] leading to pure MX_2 nanoparticles, short and long tubes, bundles, and even microtubes. The structural features, lubricating properties and electronic behaviour of the IF nanotubes have been widely investigated.[5–8] For example, a single WS_2 nanotube has been used successfully as a microscope probe.[3,9] Recently, Levy and coworkers showed that small amounts of noble metals (Au and Ag) could be intercalated between WS_2 tube walls.[10,11] Akin to their bulk crystals, IF nanotube band gaps are dependent upon tube diameter.[12] It is therefore interesting to prepare doped nanotubes and to assess their electronic and mechanical performance. Here, we describe the generation of a novel $W_xNb_yS_2$ IF nanotube containing *ca.* 10 atom% Nb.

We prepared needle-like WO_x (mainly $W_{18}O_{49}$) nanotubes by the previously described procedure.[13] The needles were then covered with a suspension of Nb_2O_5 (Aldrich, 99.9% pure, particle size < 2 μm) in acetone, and the acetone was allowed to evaporate leaving Nb_2O_5 uniformly distributed over the needles. The sample was then reheated to *ca.* 1100 °C under 200 Torr H_2S. Using a scalpel, the grey needle-like deposit was removed from the quartz surface, subjected to high resolution transmission electron microscopy (HRTEM, JEOL-4000) and to energy dispersive X-ray (EDX, element > B) and Raman spectroscopic (Renishaw system 1000, λ_0 = 514.5 and 632.8 nm) analysis.

Previously, we had refined the oxide–sulfide conversion method[7] and successfully created very long pure WS_2 nanotubes by forming WO_x nanorods prior to oxide–sulfide conversion.[4] We have now found that the constituent atoms of Nb_2O_5-coated WO_x nanorods easily diffuse at high temperature (*ca.* 1100 °C), particularly through materials possessing substantial vacancies. Thus Nb probably occupies some of the W positions within $W_{18}O_{49}$, leading to $W_xNb_yO_z$. This replacement process is reminiscent of the behaviour of the bulk oxides, but in this case the nanorod templates and the suboxide features were retained. The presence of gaseous H_2S in the chamber facilitated oxide-to-sulfide conversion in an identical manner to that found for the synthesis of pure WS_2 or MoS_2 nanotubes,[1,3,4] resulting in homogeneous W–Nb–S composite nanotubes. These tubes are straight, *ca.* 5–10 μm long and *ca.* 20–100 nm in diameter. HRTEM images of the tubes are not different from those of WS_2 nanotubes. The majority have hollow cores, less than 30% of them being fully or partly filled with elongated WO_x crystals. Concentric nanotubes (layer separation *ca.* 0.62 nm) are observed. The outer layers are smooth and appear to be free of lattice defects. All the tubes are closed, *ca.* 20% by flat caps, forming a *ca.* 90-degree connection with the cylinders. Dislocations at the cap–cylinder junctions are apparent [Fig. 1(a), arrowed]. EDX revealed the presence of Nb [Fig. 1(b)] within the nanotubes. Measurements on ten isolated hollow nanotubes revealed a *ca.* 9:1 W to Nb atomic ratio, the metal:sulfur ratio being *ca.* 1:2. The overall stoichiometry of the nanotubes is $W_xNb_yS_2$ (x = 0.9, y = 0.1, 5% uncertainty). The flat tip feature (*ca.* 90-degree angle with the body) of the nanorods is determined by their intrinsic crystalline nature.[13] Hence, the flat nanotube tips probably form as a result of oxide–sulfide template conversion. This conjecture is supported by supplementary experiments, which showed that NbS_2 nanotubes could not be prepared directly from Nb_2O_5 powder alone. These results confirm that the suboxide plays a key role in the IF nanotube formation, and the process can be written in terms of eqns. (1) and (2):

$$WO_{x\,(\text{nanorod})} + Nb_2O_{5\,(\text{particle})} \rightarrow W_{0.9}Nb_{0.1}O_{x\,(\text{nanorod})} \quad (1)$$

$$W_{0.9}Nb_{0.1}O_{x\,(\text{nanorod})} + H_2S_{\,(\text{gas})} \rightarrow W_{0.9}Nb_{0.1}S_{2\,(\text{nanotube})} + H_2O_{\,(\text{gas})} \quad (2)$$

In order to ascertain whether or not Nb was present as an intercalate within the WS_2 tube walls, or as a dopant in the WS_2 structure, we undertook additional EDX analyses. The results showed that the W:Nb:S ratio remained nearly constant, independent of nanotube diameter and position. This behaviour is consistent with the EDX mapping, and implies that the nanotubes are fairly uniform. When intercalated Au and Ag are present, the nanotubes are heterogeneous, irrespective of their diameter and length.[10,11] Heterogeneous intercalation is likely to lead to internal stresses owing to the different atomic diameters of W and Nb, resulting in significant defects. In fact,

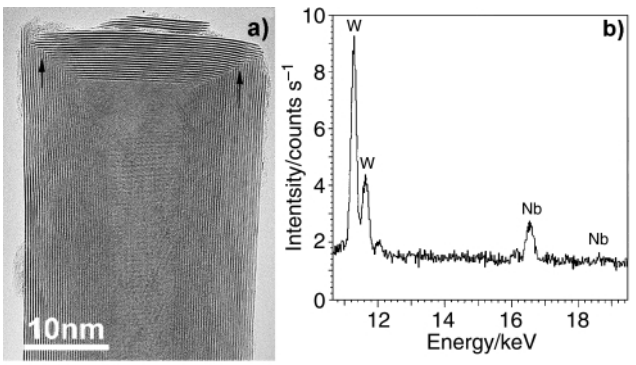

Fig. 1 (a) HRTEM image showing a *ca.* 90-degree flat cap, layer separation = 0.62 nm. Dislocations at the cap-cylinder junctions are apparent (arrowed); (b) EDX of an isolated hollow tube, revealing the presence of W and Nb. S signals are omitted from this profile.

† Electronic supplementary information (ESI) available: HRTEM image of a typical 10-layered $W_{0.9}Nb_{0.1}S_2$ nanotube, layer separation = 0.62 nm and Raman bands of $W_{0.9}Nb_{0.1}S_2$ and WS_2 nanotubes and their assignments. See http://www.rsc.org/suppdata/cc/b0/b007074m/

DOI: 10.1039/b007074m

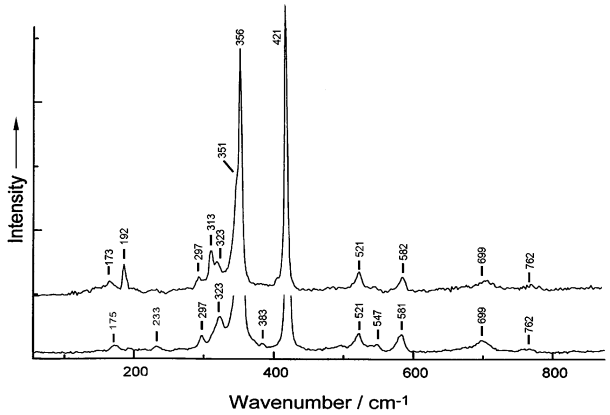

Fig. 2 Raman spectra (λ_0 = 514.5 nm) of $W_{0.9}Nb_{0.1}S_2$ (upper) and WS_2 (lower) nanotubes.

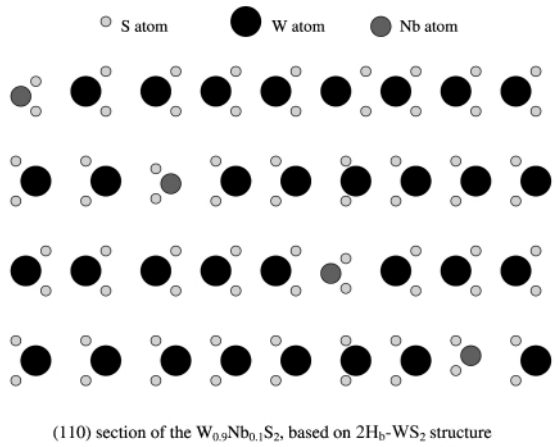

Fig. 3 Proposed model for the layered $W_{0.9}Nb_{0.1}S_2$ structure.

our HRTEM observations show that the distance between layer fringes is *ca*. 0.62 nm [Fig. 1(a)], identical with that in pure WS_2; only a few defects are present. Furthermore, expanded layer separations, *i.e*. > 0.62 nm, would be expected if Nb were to be intercalated between the WS_2 layers. However, very few crystals were found with expanded layer separations. Thus our nanotubes are Nb-doped and not intercalated.

Additional experiments have revealed that the W : Nb ratio can be altered by applying various amounts of Nb_2O_5 coating to the WO_x nanorods, prior to passage of H_2S during heating. The Nb concentration (*ca*. 10% atom%) can be doubled in the nanotubes; however, our results showed that Nb-dominated W–Nb–S tubes are difficult to construct.

The Raman spectrum of $W_{0.9}Nb_{0.1}S_2$ nanotubes taken with 632.8 nm excitation is identical to that of WS_2 nanotubes. The 514.5 nm spectrum of the Nb-doped tubes, however, does show some differences from that of WS_2 (Fig. 2), notably the appearance of a medium intensity band at 313 cm^{-1}, a shoulder on the low wavenumber side of the e_{2g}^1 band at 356 cm^{-1} and an increase in the relative intensity of the 192 cm^{-1} band. The intensity of the 192 cm^{-1} band is *ca*. half that of the disorder-induced zone-edge phonon [LA(M)] band at 173 cm^{-1} for WS_2, whereas its intensity for the Nb-doped tubes is *ca*. 5 times that of the 173 cm^{-1} band. The 192 cm^{-1} band has been observed in the Raman spectra of 2H-bulk and nanotubes of WS_2, but has not been assigned.[14] Its increase in relative intensity on going from pure WS_2 nanotubes to Nb-doped WS_2 nanotubes implies that it is caused by scattering from a disorder-induced zone-edge phonon. The band at 313 cm^{-1} has not previously been seen in the Raman spectra of any form of WS_2, and is also probably due to the increased disorder in the lattice owing to the presence of Nb. The shoulder at 351 cm^{-1} is the first overtone of the LA(M) band, with its apparent intensity enhanced by its proximity to the strong band at 365 cm^{-1}. The Raman bands and their assignments are summarised in Table 1 of ESI.†

The formation of $W_{0.9}Nb_{0.1}S_2$ nanotubes can be accounted for by considering the layered structure of the $W_{0.9}Nb_{0.1}S_2$ crystals. According to our EDX analysis, only *ca*. 10% of the W atoms are replaced by Nb. Therefore, we suggest that the Nb-doped material remains as the $2H_b$-type WS_2 structure, rather than becoming the $2H_a$-type NbS_2 structure. We propose a model for layered $W_{0.9}Nb_{0.1}S_2$ (Fig. 3). In this structure, the doped Nb atoms (medium circles) should not cause severe lattice defects and can easily be stabilised by neighbouring atoms. This suggestion is supported by our Raman spectra; the spectra of the Nb-doped and pure WS_2 tubes are identical using 632.8 nm excitation, whereas new bands attributable to increased lattice disorder are seen using 514.5 nm excitation. The crystal lattice spacing, particularly *c*/2, remains almost unchanged when compared with that of pure WS_2 layers. If a nanotube is to be formed by rolling up such composite layers, one would not expect a significant *c*/2 change. This conjecture is also supported by the facts that the composition of our nanotubes is uniform and that we did not observe severe defects on the tube walls.

We thank the Royal Society, the JFCC, the EPSRC and the ULIRS, for financial support. We are grateful to J. Thorpe and D. Randall (Sussex) for assistance with TEM and SEM facilities. We thank M. Mayne and I. Maurin for helpful discussions.

Stable pyrano[2,3-*b*]quinoxalines and pyrano[2,3-*g*]pteridines related to molybdopterin

Ben Bradshaw, David Collison, C. David Garner† and John A. Joule*

Chemistry Department, The University of Manchester, Manchester, UK M13 9PL. E-mail: j.a.joule@man.ac.uk

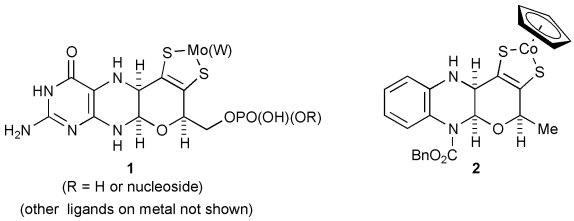
The syntheses of the quinoxaline and pteridine proligands (3 and 4) related to molybdopterin are described and 3 has been characterised complexed *via* its dithiolene group to a CpCo(III) centre (5). Each of 3–5 has the sensitive hemiaminal unit of molybdopterin, unprotected, verifying its stability *in vitro*.

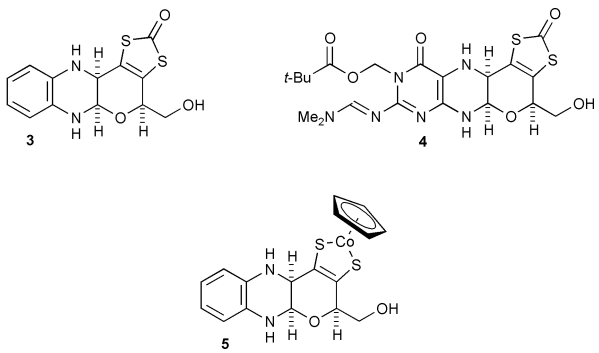
The pioneering studies on representatives of the molybdenum enzymes by Garrett and Rajagopalan[1] showed that each contained a prosthetic group that comprises a pteridine carrying a C_4-side-chain at pteridine C-6, having two sulfur atoms which ligate molybdenum. A series of X-ray crystallographic determinations on molybdenum and tungsten enzymes[2] further clarified the structure of the cofactor and its mode of ligation to Mo and W. Thus, the metals are chelated by an ene-1,2-dithiolate (dithiolene) which is part of a tricyclic system, in which a



dihydropyran ring is fused to a partially reduced pteridine, **1**. The pterin (2-aminopteridin-4(3*H*)-one) moiety is generally known as molybdopterin.

We have previously described[3] the synthesis of CpCo(III) (where Cp = η^5-cyclopentadienyl) complex **2** which involves ligation of the metal by a dithiolene moiety as part of a dihydropyran fused to a partially reduced pyrazine, as in **1**. However, **2** differs from **1** in several key respects. Firstly, **2** has a benzene ring instead of a pyrimidine ring; secondly the terminal primary hydroxy (phosphate) is absent; and thirdly, and crucially it retains a urethane at the nitrogen of the hemiaminal unit. It was far from certain that, freed from this protection against possible cleavage of the N–C–O system, the cyclic aminal would be stable, especially during the process of ligand release and complexation to a metal centre. Thus, to assess whether there are any special effects operating in the natural system which maintain the hemiaminal linkage, it was essential that structural analogues of **1** without the urethane be prepared. We describe here the synthesis of just such model compounds, the proligands **3** and **4** and the cobalt complex **5** derived from **3**.

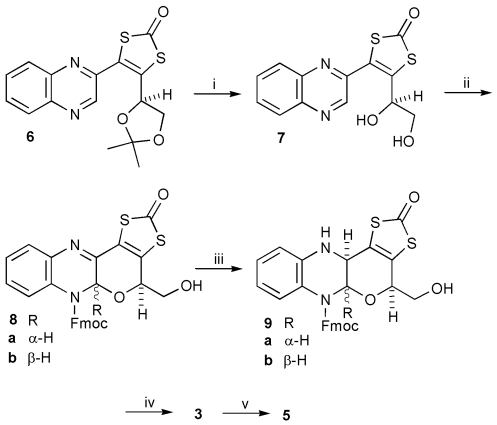
We have previously described syntheses of quinoxaline **6**[4] and protected pteridine **10**.[5] Hydrolysis of the acetal in **6** then reaction of **7** with fluoren-9-ylmethyl chloroformate (Fmoc-Cl), under carefully defined conditions gave a high yield of a 2:1 mixture of *cis*[6] (the desired) and *trans* tetracyclic products **8** which could not be separated by chromatography. Reduction of the mixture with sodium cyanoborohydride proceeded stereoselectively producing **9a**[6] and **9b**[6] which could be separated. It



is notable that there were no problems associated with the presence of a second alcohol group—neither cyclisation to give an oxepino[2,3-*b*]quinoxaline nor acylation of the primary hydroxy occurred.

Release of the Fmoc nitrogen protection, most efficiently using diethylamine,[7] gave the unprotected compound **3** *which retained the hemiaminal unit*. It remained to verify that this sensitive functionality would survive conditions to release the enedithiolate and form a metal complex. This indeed proved to be possible for, using caesium hydroxide for hydrolytic ligand release, with subsequent trapping by reaction with $CpCoI_2$, complex **5** was produced (Scheme 1).

A comparable sequence led to the isolation of a pyranopteridine having an unprotected hemiaminal unit. Thus, treatment of pteridine **10** with trifluoroacetic acid allowed selective removal of the acetal protection giving diol **11** then reaction of this with Fmoc-Cl produced a separable mixture of pyran-containing products in which the ratio of *cis*-**12a**[6] (desired) to *trans*-**12b**[6] (2:1) was comparable to that in the quinoxaline series. Conducting the cyclisation reaction at rt produced a more favourable ratio (4:1) of products but the reaction was much slower, not being complete after 1 week. *N*-Deprotection of the 'wrong' isomer **12b** led cleanly back to **11** (incidentally



Scheme 1 *Reagents and conditions*: i, $TsOH{\cdot}H_2O$, MeOH, reflux (92%); ii, Fmoc-Cl, 1,4-dioxane, 35 °C, 14 h (92%); iii, $NaB(CN)H_3$, AcOH, CH_2Cl_2, MeOH, rt (92%); iv, **9a**, Et_2NH, THF, rt (80%); v, CsOH, $CHCl_3$, MeOH, rt then $Cp(Co)I_2$ (55%).

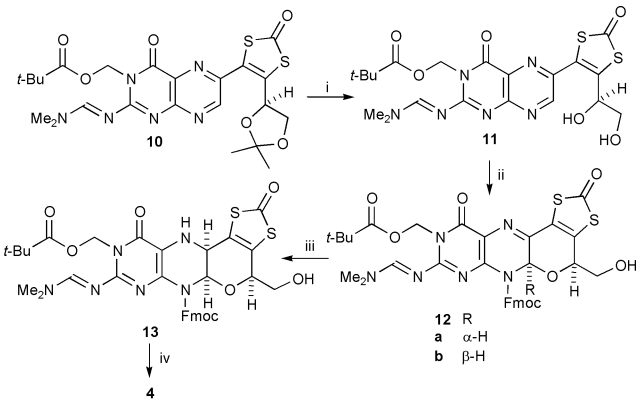
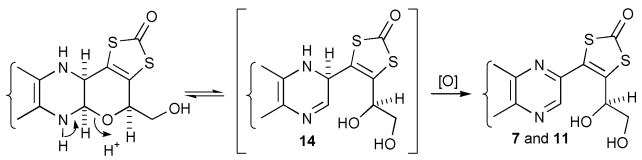
DOI: 10.1039/b008544h



Scheme 2 *Reagents and conditions*: i, TFA, CH_2Cl_2, 0 °C→rt (90%); ii, Fmoc-Cl, 1,4-dioxane, H_2O, 35 °C, 14 h (84%); iii, **11a**, $NaB(CN)H_3$, AcOH, CH_2Cl_2, MeOH, rt (92%); iv, Et_2NH, THF, rt (85%).

confirming the lability of the N–C–O unit) which could thus be recycled. Cyanoborohydride reduction of the *cis* isomer proceeded stereoselectively in high yield and removal of the N-8-protection from **13** gave pro-ligand **4**[6] with the hemiaminal unit intact and having the same relative stereochemistry[8] as the prosthetic groups in the natural cofactors (Scheme 2).

Both **3** and **4** are relatively stable compounds. However, after several weeks at rt, and without protection from moisture or oxygen, each reverted to the corresponding ring opened diol, **7** and **11**. This must involve reversible proton-catalysed cleavage of the N–C–O system revealing dihydro-systems **14** and then irreversible aerial oxidation (Scheme 3). The stabilities of the pyranoquinoxalines and pyranopteridine established in this work make it unlikely that any special properties of the enzyme environment need to be invoked to explain the tricyclic form of molybdopterin found in all the crystal structure determinations,[2] save that it must be protected from oxidation. The proton-catalysed cleavage of the N–C–O system, which we have



Scheme 3

suggested[9] may be intimately involved with catalysis at the metal centre, can now be studied *in vitro* with the compounds described herein. We shall be reporting on such studies in due course.

We thank the EPSRC for post-graduate (B. B.) and post-doctoral (B. B.) support for this work.

Bimetallic μ-cyanoimide complexes prepared by NCN group transfer†

Daniel J. Mindiola, Yi-Chou Tsai, Ryuichiro Hara, Qinghao Chen, Karsten Meyer and Christopher C. Cummins*‡

Department of Chemistry, Room 2-227, Massachusetts Institute of Technology, Cambridge, MA 02139-4307, USA. E-mail: ccummins@mit.edu

Received (in Irvine, CA, USA) 8th August 2000, Accepted 9th October 2000
First published as an Advance Article on the web

A cyanoimide [NCN] transfer reagent has been developed and applied to the synthesis of the μ-NCN systems (μ^2;η^1,η^1-NCN) {M[N(R)Ar]$_3$}$_2$ (Ar = C$_6$H$_3$Me$_2$-3,5; M = V or U, R = Bu^t; M = Mo, R = Pr^i).

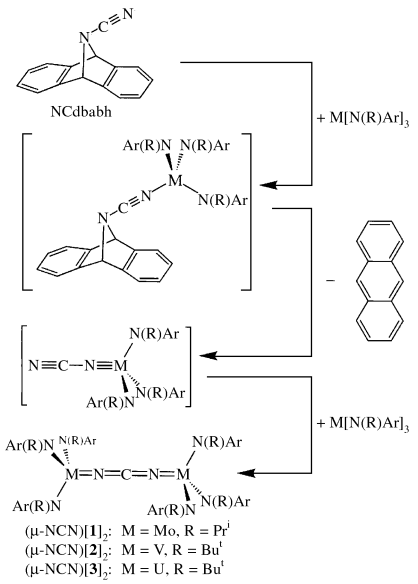
Small molecules or ions comprised of combinations of the elements C, N and O hold inherent fascination due to their simplicity and their importance with respect to the global cycles that involve them. Studies in which reactive metal complexes are employed for small molecule activation can shed light on manifolds of processes that permit such substrates to be manipulated. Recent reports involving dinitrogen, nitrous oxide, carbon monoxide, and cyanate ion serve to exemplify this approach. The present work is concerned with cyanoimide ion, $[NCN]^{2-}$, the attributes of which as a ligand in coordination chemistry currently are not well understood. To this end has been developed a new reagent for the synthesis of cyanoimide complexes, a reagent based on the bicyclic amine 2,3 : 5,6-dibenzo-7-azabicyclo[2.2.1]hepta-2,5-diene (Hdbabh). For references relating to this work see ESI.†

As reported by Carpino *et al.*, the synthesis of Hbdabh proceeds *via* an *N*-bromo derivative, Brdbabh or alternatively from the hydrobromide salt BrH$_2$dbabh.[1,2] Treatment of Brdbabh with trimethylsilyl cyanide in DMF has been found to provide the desired *N*-cyano derivative NCdbabh in essentially quantitative yield as colorless leaflets subsequent to recrystallization from diethyl ether.[3] Cyano-dbabh thus prepared constitutes a reagent for transfer of the neutral [NCN] fragment to reducing metal complexes under mild conditions, the reactions being two-electron redox events that occur with concomitant release of anthracene.[4] Methodology based on the ability of the dbabh skeleton to effect group transfer coupled with anthracene formation has been documented previously in the case of $[N]^-$ transfer to form chromium(VI) nitrido complexes.[5]

Several metal complexes have been found to effect smooth [NCN] abstraction from cyano-dbabh. Treatment of a molybdenum metallaziridine–hydride complex known to serve as a source of the relatively unhindered three-coordinate molybdenum(III) fragment Mo[N(Pr^i)Ar]$_3$ **1** (Ar = C$_6$H$_3$Me$_2$-3,5),[6] with 0.5 equiv. of NCdbabh in diethyl ether at 25 °C led to rapid and essentially quantitative formation of the diamagnetic dinuclear μ-cyanamide derivative (μ-NCN)[**1**]$_2$. Anthracene removal was effected by filtration of the reaction mixture through activated charcoal, and orange crystals of (μ-NCN)[**1**]$_2$ were obtained in 63% yield by storing a concentrated Et$_2$O solution at −35 °C (Scheme 1). Prepared analogously using the ^{13}C-labeled reagent N^{13}Cdbabh[3] was the isotopomer (μ-N^{13}CN)[**1**]$_2$, an isotopomer of interest due to its ^{13}C NMR quintet ($^1J_{CN}$ 24 Hz) at 176 ppm and its strong IR ν_{NCN} stretch appearing at 2061 cm^{-1}, this value being red-shifted by 61 cm^{-1} relative to that for its unlabeled counterpart.[3] A low energy band at 475 nm in the visible spectrum of (μ-NCN)[**1**]$_2$ is assigned tentatively to a fully allowed transition from the molecule's e$_u$ HOMO to its e$_g$ LUMO, assuming idealized D_{3d} symmetry for the complex. Calculation of the HOMO–LUMO gap for a model system, using NH$_2$ in place of N(Pr^i)Ar ligands, gave a value (1.38 eV) well in accord with the experimentally observed quantity.[3,7]

Based on the orbital scheme developed for diamagnetic (μ-NCN)[**1**]$_2$, an analogous divanadium complex was expected to exist as a ground-state triplet. Such a complex was obtained upon reaction of V[N(R)Ar]$_3$ **2**[8,9] (R = Bu^t) with 0.5 equiv. of NCdbabh (Scheme 1). The purple–black microcrystalline solid thus obtained analyzed correctly for (μ-NCN)[**2**]$_2$, exhibited the expected strong ν_{NCN} at 2037 cm^{-1} {(μ-N^{13}CN)[**2**]$_2$ had an IR stretch at 1982 cm^{-1}}, and was found to possess a μ_{eff} of 3.01 μ_B in solution at 25 °C.[3] Purification of (μ-NCN)[**2**]$_2$ was accomplished as for the molybdenum derivative, the isolated yield being 91%. The divanadium complex (μ-NCN)[**2**]$_2$ shows an interesting electrochemistry. Two reversible reduction processes can be observed at −1.61 and −2.42 V (*vs.* [FeCp$_2$]$^{0/+}$). An oxidation event at −0.68 V was found to be in a range convenient for chemical oxidation. Oxidation of (μ-NCN)[**2**]$_2$ thus was accomplished using silver triflate, a regimen providing paramagnetic {(μ-NCN)[**2**]$_2$}[O$_3$SCF$_3$] in 56% yield. Oxidized (μ-NCN)[**2**]$_2$ was characterized fully, including its magnetochemistry and X-band EPR spectrum in solution.[3]

That complex (μ-NCN)[**1**]$_2$ contains a linear 5-atom MoNCNMo chain was confirmed by single-crystal X-ray crystallography (Fig. 1(a)),§ the molecular structure in question being found to incorporate a crystallographic center of inversion at the cyanoimide carbon along with a Mo–N–C angle of 176.6(4)° (two crystallographically independent molecules were confined



Scheme 1 Reaction scheme for 0.5 equiv. of NCdbabh with the metal complexes M[N(R)Ar]$_3$ to form the μ-cyanoimide complexes of the type (μ-NCN)[M{N(R)Ar}$_3$]$_2$ (M = Mo, R = Pr^i; M = V or U, R = Bu^t). Intermediate complexes have not been observed.

(b) Structural diagram of (μ-NCN)[**3**]$_2$ with thermal ellipsoids at the 35% probability level. Selected distances (Å) and angles (°): U–N(4) 2.226(7), U–N(1) 2.219(6), U–N(2) 2.225(6), U–N(3) 2.291(6), N(4)–C 1.189(8), U–C(21) 2.787(8); C–N(4)–U 162.6(5).

in the asymmetric unit, one of which possessed an inversion center about the cyanoimide carbon). As for the μ-nitrido dimolybdenum complex (μ-N)[**1**]$_2$ studied previously,[6] the six isopropyl substituents are directed to the molecule's interior, the six aryl residues consequently occupying polar positions. Given the properties of vanadium-containing (μ-NCN)[**2**]$_2$, its structure presumably likewise incorporates a linear 5-atom chain with metal termini.[3]

In contrast is the structure of the diuranium derivative (μ-NCN)[**3**]$_2$§ derived from the reaction of (THF)U[N(R)Ar]$_3$ **3**-THF[10,11] with 0.5 equiv. of NCdbabh (Scheme 1). X-Ray crystallography revealed in this case a *bent* geometry at the cyanoimide nitrogens [U–N–C 162.6(5)°], the molecule exhibiting again, however, inversion symmetry at the cyanoimide carbon atom (Fig. 1(b)).[12] The bent geometry adopted by the cyanoimide nitrogens in (μ-NCN)[**3**]$_2$, taken together with the observation of a congruence in the U–N_{amide} and U–$N_{cyanoimide}$ distances, may be indicative of relatively little π bonding in the uranium–cyanoimide interaction. In contrast, the transition-metal derivative (μ-NCN)[**1**]$_2$ exhibits a Mo–$N_{cyanoimide}$ distance shorter by 0.115(6) Å than the Mo–N_{amide} distance in the same complex. Recently it has been suggested that the high nodality of its valence 5 f orbitals renders mid-valent uranium less effective at π bonding than its transition-metal counterparts.[13,14] Using the ^{13}C-labeled reagent N^{13}Cdbabh, it was found that the isotopomer (μ-N^{13}CN)[**3**]$_2$ evinces a broad ^{13}C NMR resonance at 133 ppm.

It is believed that the ultimate step in formation of these μ-cyanoimide systems is the combination of a putative terminal cyanoimide complex with unreacted complex. Formation of the bridged-cyanoimide complexes most likely occurs *via* mononuclear reduction of NCdbabh, a process evidently being slow relative to consumption of unreacted metal complex. This work establishes NCdbabh as an efficient source of the [NCN] moiety, its implementation having led to smooth assembly of dinuclear cyanoimide-bridged complexes of vanadium, molybdenum and uranium. In addition to showing that dbabh represents a versatile platform for group transfer reactions, the present work makes available for study a new class of cyanoimide-bridged dimetal complexes. Mononuclear complexes featuring a *terminal* cyanoimide ligand remain attractive as synthetic targets.[15,16]

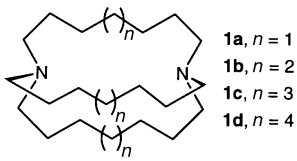
Received (in Columbia, MO, USA) 15th September 2000, Accepted 8th November 2000
First published as an Advance Article on the web

The first crystal structure of a 10.10.10 cryptand has been determined, during which an unusual single crystal phase transition was observed; at room temperature, crystals of macrobicycle 1d are monoclinic (α) but undergo a first-order topotactic phase change at 207 K to a triclinic (β) lattice; full structure determinations at 150 and 210 K were carried out and show that both phases adopt the *in–in* cryptand conformation.

The foundations of modern host–guest chemistry were laid in two papers published by independent research groups in 1967 and 1968. The former was the first report of alkali metal complexes of a polyether macrocycle,[1] and the latter the first report of guest inclusion in a diaza macrobicycle.[2] The first result gave birth to the crown ethers, the second to the cryptands, both 'household' words in the field of supramolecular chemistry.[3]

We became interested in the all-hydrocarbon bridged cryptands **1** originally described by Simmons and Park[2] from the point of view of isolating the effects of the two N (or HN^+) sites to produce linear inclusion complexes with various neutral and ionic guests. Although the 'original' crown ether, dibenzo 18-crown-6, has itself been the subject of no less than ninety X-ray crystal structures,[4] only one crystallographic study has been



1a, *n* = 1
1b, *n* = 2
1c, *n* = 3
1d, *n* = 4

published on an 'original' cryptand, *i.e.* **1c**.[5] In this work, the bis(hydrochloride) cryptate $[H_2(\mathbf{1c})Cl]^+ Cl^-$ co-crystallizes with the unusual polyaqua cation $H_{13}O_6^+$, the latter species being the main focus of the paper. However, no satisfactory representation of the cage itself was derived from the data, owing to the presence of extensive disorder.

Taking into account the respective melting points in the **1** series indicates that the *n.n.n* cryptands are conformationally mobile where *n* is odd, while those where *n* is even will be conformationally stable.[6] This may explain the difficulties the previous workers experienced with **1c**. We thus prepared the 10.10.10 cryptand **1d**[7] and undertook first to obtain an X-ray crystal structure of the empty, neutral receptor. In the course of the determination, we observed a single-crystal phase transition, and now report on the structure of **1d**, the first of a 10.10.10 cryptand,[8] and this unusual occurrence of polymorphism.

Crystals of **1d** (from light petroleum) were prismatic, but most of them displayed a peculiar form, with a large recess on one of the faces of the prism, often reducing the crystal to a hollow 'box' open on one side. A similar crystal habit has been observed for triethylenetetramine $[H_2N(CH_2)_2NH(CH_2)_2NH(CH_2)_2NH_2]$ and could be attributed to the presence of $N[(CH_2)_2NH_2]_3$, a by-product of the synthesis, which selectively inhibited the development of certain faces.[9]

At ambient temperature crystals of **1d** are monoclinic (α-**1d**), but undergo a sharp phase transition at 207 K. Of several crystals tested, all crumbled to powder or converted to polycrystalline blocks at this temperature, except one which was initially of exceptionally good quality and on which a full structure determination was performed at 210 K in space group *I*2/*a* (a non-standard setting of *C*2/*c*, no. 15). At the moment of transition (monitored by rotational diffractograms taken after every 1 K cooling step) a part of the crystal split off and the remainder appeared to become a non-merohedral twin. Its reflections were indexed on a triclinic lattice (β-**1d**), which was confirmed by a full structure determination at 150 K in space group $P\bar{1}$ (no. 2). No further phase transformations were observed on cooling to 100 K.

The molecular structure of **1d** in the α and β phases is shown in Fig. 1 (ESI†). In the former, monoclinic phase, the molecule lies across a crystallographic twofold axis, which is perpendicular to the N···N′ vector. Two of the decamethylene chains, C(1)– C(10) and C(1′)–C(10′), are related by this axis. In each chain, two atoms [C(7) and C(8) or their equivalents] are disordered over two positions with occupancies of 0.779(8) and 0.221(8). The third decamethylene chain is bisected by the twofold axis, and its four central C atoms are equally disordered over two conformations which are symmetrically related by this axis, but neither of which possesses C_2 symmetry. In the β phase the molecule has no crystallographic symmetry. The average volume per non-hydrogen atom, 24 Å^3 (α-**1d**) or 23 Å^3 (β-**1d**), is considerably higher than the typical value for an organic

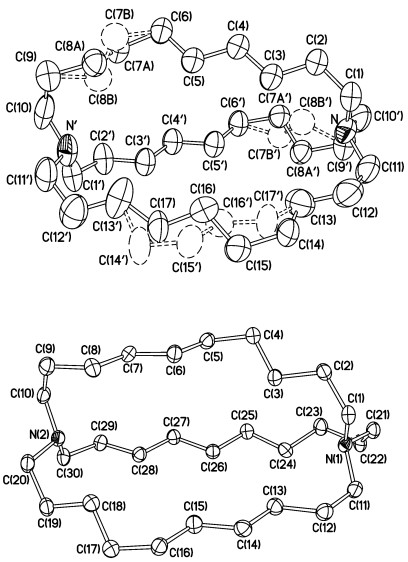


Fig. 1 Molecular structure of **1d** in the monoclinic (α, top) and triclinic (β, bottom) polymorphs, shown in the same crystallographic aspect and scale. Displacement ellipsoids are drawn at the 50% probability level. In α-**1d**, primed atoms are related to their equivalents by the operation of the twofold rotation axis. H atoms are omitted.

compound of 18 Å^3, but close to the value of 22 Å^3 found in the nearest structurally studied analogue, N[$(CH_2)_4$]$_3$ N.[10,11]

In both structures the lone pairs on the nitrogen atoms point into the cavity, the pro-cryptate '*in-in*' conformation of macrobicyclic hosts.[12] The bond distances are not unusual, while the torsion angles within the chains represent *anti* or *gauche* conformations and their patterns are different in the two structures. The molecule is slightly more elongated in the β than in the α phase, the transannular N···N distances being 9.14 and 9.01 Å, respectively. No significant empty volume was found in either structure or in any disorder component.[13]

As such topotactic phase changes between single crystal phases are relatively rare for molecular crystals, we sought to identify and describe the transformation between the high temperature α form and the low temperature β form, as illustrated in Fig. 2. The β phase is generated from the α form by first transforming the *I*-centered monoclinic lattice onto its primitive trinclinic one by application of the transformation matrix ($-\frac{1}{2}\,\frac{1}{2}\,-\frac{1}{2}\,/\,\frac{1}{2}\,\frac{1}{2}\,-\frac{1}{2}\,/\,0\;0\;-1$), then by an origin shift of *ca.* $a'/2$, and finally a considerable shear of the lattice, roughly along the c' ($=c$) axis, widening all three lattice angles by 7–13°. In both structures the molecules are packed in layers, parallel to the (0 1 0) plane in α-**1d** or the (1 1 0) plane in β-**1d** (Fig. 2 shows the projections on these planes). The intramolecular N···N vector is coplanar with the layer, rigorously in α-**1d**, and within 3° in β-**1d**. The interlayer separations are essentially equal in the α and β forms (8.32 and 8.36 Å, respectively). In either case the adjacent layers are shifted against each other along the *c* axis (which forms the same angle of 15.5° with the N···N vector). In α-**1d** the shift is exactly *c*/2 (*ca.* 7 Å), each molecule fitting the gap in the adjacent layer. In β-**1d** the shift is only 4 Å (*ca.* 0.3*c*) and the molecule adopts an asymmetric conformation to accommodate to a partial overlap.

Although this degree of reorganization could be considered incompatible with a topotactic transition, it is not unprecedented: Gougoutas has identified examples where considerable molecular motions appear to be necessary to effect the observed phase transformations.[14] The difficulties we encountered in retaining singularity suggest that in the present case we were operating at the limits of topotaxy.

The unit cell parameters of **1d** change remarkably between 210 and 293 K (Table 1), while the Laue symmetry and systematic absences remain the same. With increasing temperature, the unit cell actually contracts in the direction of the twofold axis (*b*) by 0.286 Å (1.72%) while expanding in the perpendicular directions, again implying substantial conformational changes. Unfortunately, at room temperature the crystals decay completely in the X-ray beam within a few hours, hence a full structure determination was not possible.

Organic polymorphism is a frequently observed but poorly understood phenomenon which is rarely examined in detail.[15] Despite this, it is of substantial relevance to biomolecular and pharmaceutical sciences.[16] Here we have sought to describe an occurrence of polymorphism in the first structurally characterized 10.10.10 cryptand, requiring a significant degree of molecular reorganization. The historically[2] and practically[7] important Simmons and Park cryptand **1d** has also been shown to reside in the '*in-in*' pro-cryptate macrobicycle conformation in the solid state.

Palladacyclic phosphinite complexes as extremely high activity catalysts in the Suzuki reaction

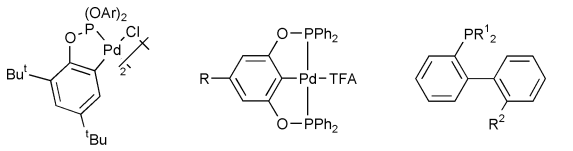
Robin B. Bedford* and Samantha L. Welch

School of Chemistry, University of Exeter, Exeter, UK EX4 4QD. E-mail: R.Bedford@ex.ac.uk

Received (in Cambridge, UK) 18th October 2000, Accepted 16th November 2000
First published as an Advance Article on the web

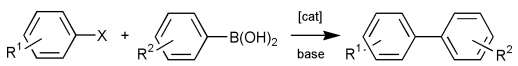
Phosphinite based palladacycles show extremely high activity in the Suzuki coupling of both sterically hindered and electronically deactivated aryl bromides, especially in the presence of one equivalent of free ligand.

There has recently been considerable interest in the synthesis of new, high activity palladium-based catalysts that can be used in low concentration in the Suzuki reaction (Scheme 1) since such catalysts have the potential to be used in industrial systems. In particular, palladacyclic catalysts in which a ligand coordinates to the metal centre through both a donor atom and metallated carbon have shown considerable promise. Beller and co-workers demonstrated that palladated phosphine complexes show good activity[1] whilst we have shown that the palladated triaryl phosphite complex **1** and the bis(phosphinite) PCP-



1: Ar = 2,4-^{t}Bu$_2$C$_6$H$_3$ **2**: R = H, Me **5**: R^1 = Cy, ^{t}Bu; R^2 = H, Me, ^{i}Pr, NMe$_2$

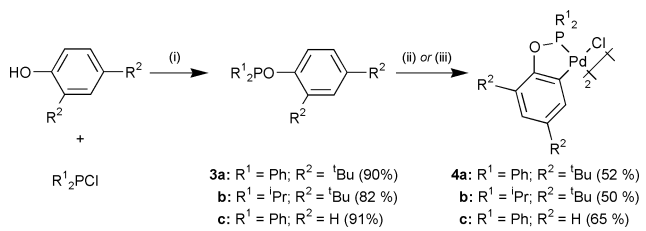
pincer complexes **2** show excellent activity.[2,3] High activity is not limited to metallated phosphorus donor systems—Milstein and co-workers have shown that a palladated imine complex shows excellent activity,[4] whilst Zim *et al*. have shown that palladated thioether complexes can also be used.[5]



Scheme 1 The Suzuki biaryl coupling reaction.

To the best of our knowledge, the use of *P,C*-bidentate phosphinite palladacycles as catalysts in the Suzuki reaction has not been investigated. We report here the synthesis of such complexes, the remarkable activity they show in the Suzuki reaction and present preliminary evidence that suggests that the active catalysts are likely to be low coordinate palladium(0) species.

The reactions of the ligands **3a** and **b** with palladium chloride in toluene at reflux temperature gives the complexes **4a** and **b** in good yields. Complex **4c** is best prepared by the reaction of [$PdCl_2(NCPh)_2$] with **3c** in THF at reflux temperature. All the complexes **7** are obtained as a mixture of *cis* and *trrans* isomers.[2]



Scheme 2 (i) Et_3N, toluene, reflux temperature, 18–20 h; (ii) For **4a** and **b**: $PdCl_2$, toluene, reflux temperature 18–20 h; (iii) For **4c**: [$PdCl_2(NCPh)_2$], THF, reflux temperature, 20 h.

The application of the complexes **4a**–**c** as catalysts in the Suzuki reaction was studied and the results are summarised in Table 1. The complexes **4a** and **b** prove to be extremely active catalysts for both the 'easy to couple' substrate 4-bromoacetophenone and the more challenging, electronically deactivated substrate 4-bromoanisole. To the best of our knowledge, the activity shown by the catalyst mixture of **4b** and one equivalent of added ligand **3b** (entry 13) is the highest reported for any Suzuki reaction—over five times higher than for the analogous reaction catalysed by palladium complexes of the phosphine ligands **5**.[6] By contrast, the previous highest reported activity with a palladacyclic catalyst in this reaction was with complex **1** which gave a turn-over number (TON) of 1 million.[2] More importantly with the electronically deactivated substrate 4-bromoanisole the catalyst systems reported here show up to 45 times higher activity than the previous best catalysts—the related bis(phosphinite) pincer complexes **2**.[3] Similarly the activities seen with the sterically hindered, electronically deactivated substrates 2-bromotoluene and 2-bromo-*m*-xylene are over an order of magnitude higher than any catalyst systems in the literature.[3]

Complex **4b** generally shows higher activity than **4a**, presumably due to the higher electron density that the phosphinite ligand confers on the palladium centre—this increase in electron density facilitates oxidative addition of the aryl bromide. The observation that **4a** seems to show very little difference in activity in the coupling of phenylboronic acid with either 4-bromoacetophenone or 4-bromoanisole indicates that the oxidative addition of the aryl bromide may not be the rate determining step in the catalytic cycle. Comparing entries 3 and 7 it can be seen that decreasing the steric profile of the metallated ring has a deleterious effect on the rate of reaction, however **4c** still shows substantially higher activity than its previously reported bis(phosphinite) PCP pincer counterpart, **2** (R = H).[3] The importance of the metallation in the pre-catalysts is demonstrated by comparing entries 3, 8 and 9. The addition of a second phosphinite ligand to the metallated complex gives an increase in activity, by contrast the formation of bis(phosphinite) complexes *in situ* leads to substantially *reduced* reactivity. In other words addition of a second phosphinite is only beneficial if there is a metallated ring in the complex, otherwise it is deleterious. This demonstrates that the orthometallation of the pre-catalyst is extremely important; the possible role it plays is addressed below.

By contrast with the extraordinary results obtained with the deactivated aryl bromide 4-bromoanisole, complex **4b** proved to be a very poor catalyst when 4-chloroanisole was used as a substrate, indeed substantial deposition of palladium metal was observed almost immediately upon heating. Interestingly, we found that rapid decomposition of all three complexes **4a**–**c** occurs even if the 4-chloroanisole is left out of the reaction mixture. To gain evidence for the mechanism of decomposition a reaction was performed between **4c**, $PhB(OH)_2$ (4 molar equiv./Pd) and K_2CO_3 (5 molar equiv./Pd) in toluene at reflux temperature. The reaction was performed over 24 h, although decomposition started within seconds of the reaction reaching about 50 °C. After this time the supernatant liquid contained a mixture of compounds which included some unreacted **4c**. A GC-MS spectrum of the mixture revealed the presence of some

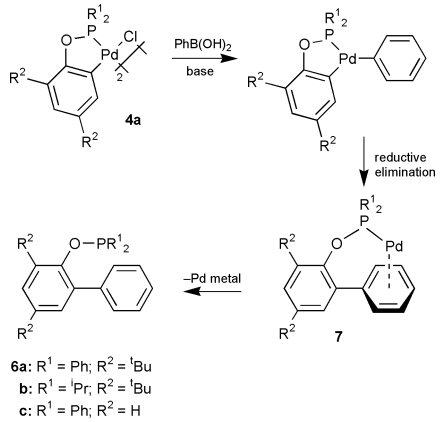

Scheme 3

of the new phosphinite species **6c**, this was confirmed by comparison with the spectrum obtained for a genuine sample of **6c**. In addition, hydrolysis of the reaction mixture led to the formation of 2-phenylphenol, again demonstrated by GC-MS and compared with an authentic sample. A plausible mechanism of decomposition which results in the liberation of **6c** and palladium metal is shown in Scheme 3.

Since the complexes **4** show no reactivity with aryl bromides or chlorides in toluene at reflux temperature it is possible that the transmetallation and reductive elimination steps outlined in Scheme 3 also occur as initiation steps in the catalytic cycles of Suzuki reactions catalysed by these species and that the low coordinate mono-phosphinite species **7** represent the active catalysts in these reactions. Similar low coordinate species have been postulated as being the active catalysts in high activity Suzuki systems which employ palladium complexes of the phosphines **5**.[6] Part of the explanation given for the high activity of these latter complexes is that transient π-coordination of the secondary aryl ring of the ligand to the palladium centre may help to stabilise the low coordinate complex. The introduction of the oxygen atom into the ligands gives a higher degree of flexibility, thus it would be expected that the secondary aryl functions of the ligands **6a**–**c** would participate in π-complexation with the metal centre even more readily than those in the ligands **5**. Furthermore, due to higher π-acidity of the phosphorus donors, the ligands **6** would stabilise the zero-valent palladium complexes better than the ligands **5**.

In summary, the catalysts described here show by far the highest activities yet reported in any Suzuki coupling reactions. These complexes are ideal catalysts for the coupling of deactivated and sterically hindered aryl bromides as they are comparatively inexpensive, very easily synthesised and can be used to give high conversions at extremely low concentrations. In addition preliminary results suggest that the active catalysts in these reactions may be low coordinate Pd(0) species.

We thank the EPSRC for funding and Johnson Matthey Chemicals for funding, the loan of palladium salts and access to their rapid catalyst screening programme.

Square-wave voltammograms of the complex Mo(His-N_ε-$C_2H_4CO_2Me$)(η-allyl)$(CO)_2$ (His = N_δ,*N*,*O*-L-histidinate) 2 recorded at variable temperatures establish the existence of two isomers in solution in both the reduced and the oxidized paramagnetic form of 2; a complete analysis yields thermodynamic parameters such as equilibrium constants, Δ*G* and Δ*H* for all species.

Fluxionality is frequently observed in organometallic complexes in solution.[1,2] In the course of our studies on the labelling of biomolecules with organometallic complexes we have reinvestigated the compound Mo(His)(η-allyl)$(CO)_2$ **1** (His = N_δ,*N*,*O*-L-histidinate). The synthesis of this complex was first reported by Beck and coworkers twenty years ago.[3,4] Since that time, fluxionality in diamagnetic complexes of the general formula M(η-allyl)$(CO)_2L_2X$ (M = Cr, Mo, W) has been studied in some detail by NMR spectroscopy in solution.[5–7] For some derivatives, a good stability of the one-electron oxidized species was demonstrated,[8,9] but related fluxionality was never mentioned. There seems to be no obvious method for investigations of this kind on the paramagnetic species $[M(\eta\text{-allyl})(CO)_2L_2X]^+$.

We were intrigued by the excellent stability of complex **1** and its potential as a covalent marker for biomolecules, in particular by IR or electrochemical detection. In complex **1**, three different orientations of the His ligand with respect to the (allyl)$(CO)_2$ plane are possible. The stereochemical implications of fluxional processes in M(η-allyl)$(CO)_2L_2X$ have been discussed, but all complexes investigated so far were either achiral or racemic mixtures.[7] Here, we report the synthesis of the enantiomerically pure methyl propionate derivative Mo(His-N_ε-$C_2H_4CO_2Me$)(η-allyl)$(CO)_2$ **2** and its complete characterization. The presence of two isomers of **2** is shown by NMR and electrochemical investigations. An unusual case of coalescence in temperature-dependent square-wave voltammograms is reported and we demonstrate how a complete analysis of the electrochemical data gives detailed quantitative information on both isomers of the paramagnetic, one-electron oxidized $\mathbf{2}^+$. This information is difficult to obtain otherwise with such accuracy.

Compound **2** was synthesised in 65% yield by reacting Mo(His)(allyl)$(CO)_2$[3] with 3-bromomethylpropionate in the presence of equimolar amounts of Cs_2CO_3 in DMF, under an atmosphere of Ar. Compound **2** is completely stable under Ar and can be stored in air on the benchtop for several days without decomposition.

X-Ray quality single crystals of **2**·2MeOH were grown by slow pentane diffusion into MeOH at +4 °C. An ORTEP representation of **2**·2MeOH§ is depicted in Fig. 1. The chirality around the metal atom is clearly determined by the known stereochemistry of the amino acid L-His. The Mo(allyl)$(CO)_2$ moiety is in a facial arrangement, with the terminal carbon atoms of the allyl ligand oriented towards the carbonyl ligands. Such a conformation has been shown to be energetically favourable[10] and is observed in all solid-state structures of this type reported thus far.[6,7,11–13] The allyl ligand is located *trans* relative to the histidine-N_δ atom [N(8)] and bound symmetrically to the Mo atom, with Mo–C distances of 2.328(3) Å [Mo(1)–C(17) and Mo(1)–C(19)] and 2.209(2) Å [Mo(1)-C(18)]. The two MeOH molecules form hydrogen bonds with the carboxylato group, with O···O contacts of 2.750(10) Å [O(14)···O(20)] and 2.800(10) Å [O(13)···O(30)].

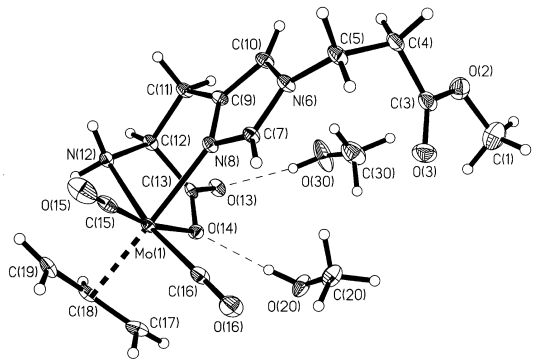

Fig. 1 ORTEP plot for **2**·2MeOH, with thermal ellipsoids at 50% probability level. Selected bond distances (Å): Mo(1)–N(8) 2.216(2), Mo(1)–N(12) 2.256(2), Mo(1)–O(14) 2.214(2), Mo(1)–C(15) 1.945(3), Mo(1)–C(16) 1.944(3), Mo(1)–C(17)=Mo(1)–C(19) 2.328(3), Mo(1)–C(18) 2.209(2).

In solution, the situation is more complex. Two sets of signals are observed in the ^1H NMR as well as in the ^{13}C NMR spectrum of **2**, indicating the presence of two isomers (**2a** and **2b**, see Scheme 1) in solution. The ratio between both isomers is solvent dependent [DMSO 53:47, MeCN (293 K) 57:43, MeOH 77:23]. The presence of two isomers in the special case of Mo(allyl)$(CO)_2L_2X$ with L_2X = cyclopentadienyl (Cp) has been explained by rotation of the allyl group. In the more general case where L_2X comprise heterodonor atoms (N, O, P *etc*.) fluxionality is brought about by a trigonal twist of the L_2X plane with respect to the Mo(allyl)$(CO)_2$ core.[12] Recently, we reported the presence of *two different* allyl orientations in the same crystal structure of a CpMo(allyl)$(CO)_2$ derivative.[14] For **2**, if one of the isomers has the conformation observed in the solid-state structure, the other detectable isomer could either have the NH_2 or the carboxylato group *trans* to the allyl ligand. In accordance with NMR data (*vide infra*), preliminary results from DFT calculations show the latter is the energetically favoured conformer of the two,[15] with the third isomer being too high in energy to be observed by NMR spectroscopy (< 0.1% at

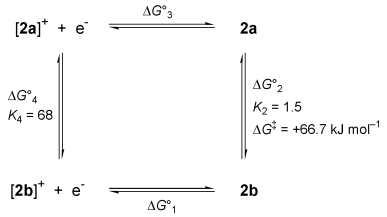

Scheme 2 Square scheme showing the redox reactions and rerrangements of **2**. At −60 °C: ΔG^0_1 = −40.1 kJ mol^{-1}, ΔG^0_2 = −0.72 kJ mol^{-1}, ΔG^0_3 = +48.3 kJ mol^{-1}, ΔG^0_4 = −7.5 kJ mol^{-1}. From electrochemical experiments at variable temperatures: ΔH^0_2 = −2.5 kJ mol^{-1}, ΔH^0_4 = −8.3 kJ mol^{-1}.

500 MHz ^{1}H NMR). The chemical shift of the imidazole proton signals are at δ 8.62 and 7.12 in isomer **2a** and δ 8.02 and 6.92 in isomer **2b**. We assume that the imidazole nitrogen atom is *trans* to the allyl ligand in isomer **2a** and *trans* to a CO in **2b**. The chemical shift difference may then be rationalized by the different *trans* influences of the allyl and CO ligands. Variable temperature measurements in MeCN yielded $\Delta G^{\ddagger}$ = 66.7 ± 0.5 kJ mol^{-1}, consistent with a trigonal twist mechanism of interconversion.[11,12]

The cyclic voltammogram (CV) of **2** in MeCN (scan rate of 0.1 V s^{-1}, 25 °C) shows a wave with reversible appearance at $E_{1/2}$ = +86 mV *vs.* Fc/Fc$^+$. This value is in the range reported for several other analogous pseudo-octahedral Mo complexes.[8,9] Controlled potential coulometry (at +0.5 V *vs.* Fc/Fc$^+$) reveals that the wave arises from a one-electron oxidation of **2**. However, the oxidation of **2** does not proceed *via* an uncomplicated reversible single electron process. At slow scan rates, the peak separation increases with increasing scan rates from 85 mV at 0.025 V s^{-1} to 140 mV at 0.8 V s^{-1}, but at even faster scan rates (up to the highest value measured of 25 V s^{-1}) it remains almost constant (±10 mV). This behaviour can be accommodated in a 'square scheme' shown in Scheme 2, assuming the presence of two isomers in *both* the oxidized and reduced form of **2**.

The presence of two species was readily detected by square-wave voltammetry (SWV). Square-wave voltammograms at four different temperatures are shown in Fig. 2. At −60 °C, the anodic and cathodic scans are fully symmetric [curve (d)]. This shows that the equilibrium composition of the reduced form (the starting material **2**) is maintained after the oxidation for the time period of equilibration at +0.6 V and during the time of the scan, *i.e.* for at least a few seconds. Because the equilibrium constants for the oxidized and reduced forms are quite different (see below), the isomerisation reaction must be correspondingly slow at −60 °C. At −20 °C anodic and cathodic scans are different [curve (b)] and it is observed that oxidized **2**$^+$ exhibits a preference for the state with the lower redox potential. At even higher temperatures two components are no longer discernible by SWV and a situation analogous to coalescence in NMR

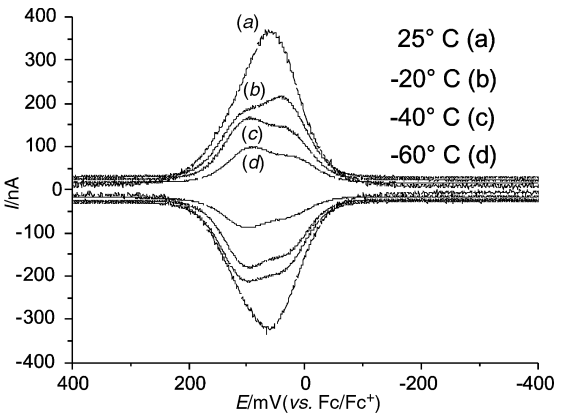

Fig. 2 Square-wave voltammograms of **2** at 25 °C [(a), scan rate 60 Hz], −20 °C [(b), scan rate 20 Hz], −40 °C [(c), 20 Hz] and −60 °C [(d), 20 Hz]. Concentration of **2** 1 mM, 0.1 M NBu_4PF_6 in EtCN, *vs.* Fc/Fc$^+$ as reference.

experiments is reached [curve (a)]. Curve fitting (COOL kinetic software) to the model of reversible oxidation of two independent species with equal diffusion coefficients was performed. At −60 °C the values E_1(1/2) = +15 mV and E_2(1/2) = +100 mV *vs.* Fc/Fc$^+$ were obtained, with relative contributions of 40 and 60% for the species with E_1(1/2) and E_2(1/2), respectively in accordance with ^{1}H NMR data. From the equilibrium data at −60 °C the following ΔG^0 and K values of Scheme 2 are calculated [counter-clockwise direction, starting with the reduction reaction and assuming E°(Fc/Fc$^+$) = 0.400 V *vs.* NHE]: $\Delta G_1{}^0$ = −40.1 kJ mol^{-1}, $\Delta G_2{}^0$ = −0.72 kJ mol^{-1}, $\Delta G_3{}^0$ = +48.3 kJ mol^{-1}, $\Delta G_4{}^0$ = −7.5 kJ mol^{-1}, K_2 = 1.5 and K_4 = 68. It should be noted that in reduced **2** the form with the *higher* redox potential is slightly favoured, whereas the oxidized form exhibits a strong preference for the species with the *lower* redox potential. Analysis in terms of the van't Hoff isochore yields standard reaction enthalpies $\Delta H_2{}^0$ = −2.5 kJ mol^{-1} and $\Delta H_4{}^0$ = −8.3 kJ mol^{-1} for the reduced and the oxidized forms of **2**, respectively. Small values are expected because the same types of bonds and presumably similar geometric parameters are present in all species. The difference of *ca.* 6 kJ mol^{-1} may well be attributed to increased solvation of the oxidized species as a consequence of their positive charge.

Poli and coworkers have investigated stable paramagnetic organometallic Mo compounds in some detail.[16,17] As shown herein, electrochemical measurements provide valuable information about equilibrium constants and thermodynamic parameters for fluxional paramagnetic species. This information cannot easily be derived by other common analytical techniques in organometallic chemistry. Currently, detailed calculations are performed to reveal the structure of all isomers and the mechanism of interconversion along with applications of compound **2** for the labelling of biomolecules.

We are grateful to Professor K. Wieghardt for his support of this work.

Enantioselective hydrolysis of amino acid esters by apomyoglobin: perfect kinetic resolution of a phenylalanine derivative

Katsuhiko Tomisaka, Yasuhiro Ishida, Katsuaki Konishi and Takuzo Aida*

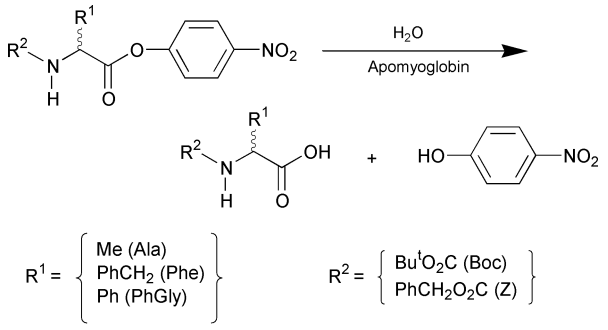
Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. E-mail: aida@macro.t.u-tokyo.ac.jp; Fax: +81-3-5841-7310

Received (in Cambridge, UK) 18th October 2000, Accepted 20th November 2000
First published as an Advance Article on the web

Apoprotein of horse-heart myoglobin promoted enantioselective hydrolysis of 4-nitrophenyl esters of amino acids, which allowed nearly perfect kinetic resolution of racemic *N*-Boc-phenylalanine ester (Boc-Phe-ONp).

Protein catalysis has a potential for asymmetric synthesis.[1] Apoproteins of cofactor-dependent proteins have attracted attention as the new candidates, since they possess a chiral hydrophobic cavity which can bind asymmetric substrates stereoselectively.[2,3] However, the successful examples are limited. Recently, we have found that the apoprotein of cytochrome b_{562} binds chiral porphyrins enantioselectively[4] and catalyzes template-assisted metalation of porphyrins.[5] Herein we report a novel asymmetric catalysis of apomyoglobin in hydrolysis of amino acid esters,[6] and wish to highlight an extremely high enantioselectivity for *N*-Boc-phenylalanine 4-nitrophenyl ester (Scheme 1).

Apomyoglobin is one of the most extensively studied apoproteins,[7] and has been reported to catalyze hydrolysis of 4-nitrophenyl alkanoates.[8] Horse-heart myoglobin was treated with dilute hydrochloric acid and butanone to give apomyoglobin, which was subjected to extensive dialysis against phosphate buffer (pH = 7.0, 10 mM).[9] Hydrolysis of *N*-Boc-phenylalanine 4-nitrophenyl ester (Boc-Phe-ONp) (Scheme 1) was investigated in a phosphate buffer containing 1% dioxane at 4 °C,[10] where the uncatalyzed hydrolysis ([Boc-Phe-ONp]$_0$ = 6.25 μM) proceeded sluggishly (Fig. 1d; △) to furnish only 11% conversion even after 240 min.[11] On the other hand, addition of apomyoglobin to the system resulted in a considerable acceleration of the reaction, where the L-isomer was preferentially hydrolyzed over the D-isomer. For example, when racemic Boc-Phe-ONp (12.5 μM) was mixed with apomyoglobin (62.5 μM), the hydrolysis proceeded smoothly to reach 60% conversion in only 8 min. Upon mixing of the reaction mixture with ether or ethyl acetate, the products (Boc-Phe-OH and 4-nitrophenol) and unreacted Boc-Phe-ONp were completely extracted into the organic phase. Chiral HPLC analysis of the organic phase with Chiralcel™ OD-H or Sumichiral™ OA-4700 showed that unreacted Boc-Phe-ONp is predominantly the D-isomer with an L : D ratio of 1 : 99 (98% ee), while the hydrolyzed product (Boc-Phe-OH) has an L : D ratio of 18 : 82. Thus, the hydrolysis with apomyoglobin enables nearly perfect kinetic resolution of racemic Boc-Phe-ONp.



Scheme 1

The hydrolysis of Boc-Phe-ONp (62.5 μM) also proceeded to attain 100% conversion by using an equimolar amount of apomyoglobin. Furthermore, upon addition of a fresh feed of the substrate (0.2 equiv.) to this reaction mixture, the hydrolysis ensued without significant loss of the activity, indicating that the reaction turns over catalytically with respect to apomyoglobin. The hydrolysis most likely occurs *via* acyl transfer to an imidazole group located within the heme pocket. In fact, the reaction was not accelerated by holomyoglobin, whose heme pocket is blocked by the native guest.[8] On the other hand, when imidazole was used as a reference catalyst, Boc-Phe-ONp was hydrolyzed much more slowly than with apomyoglobin. For example, the hydrolysis in the presence of 10 equiv. of imidazole (62.5 μM) with respect to Boc-Phe-ONp proceeded to 4% conversion in 20 min (Fig. 1c; □), where the pseudo first-order rate constant (k_{obs} = 1.4 × 10^{-3} min^{-1}) was only 2.7 times as high as that of the uncatalyzed reaction (k_{uncat} = 5.2 × 10^{-4} min^{-1}) (Fig. 1d; △).[12]

In order to obtain further insight into the enantioselective catalysis of apomyoglobin, the kinetics of the hydrolysis of the L- and D-isomers of Boc-Phe-ONp (12.5 μM) were investigated in the presence of apomyoglobin (62.5 μM). When Boc-L-Phe-ONp was the substrate, the hydrolysis took place smoothly to give Boc-L-Phe-OH and 4-nitrophenol quantitatively within only 10 min (Fig. 1a). The pseudo first-order rate constant (k^L_{obs}) was 4.9 × 10^{-1} min^{-1}, which is 940 times larger than that in the absence of the apoprotein. In contrast, hydrolysis of the D-isomer proceeded very slowly (Fig. 1b) with a rate constant (k^D_{obs}) of only 3.1 × 10^{-2} min^{-1} (k^D_{obs}/k_{uncat} = 59), which is 16 times smaller than that of the L-isomer under the same conditions.

Upon increasing the initial concentration of the apoprotein from 25 to 125 μM, the hydrolysis rates of Boc-L-Phe-ONp and

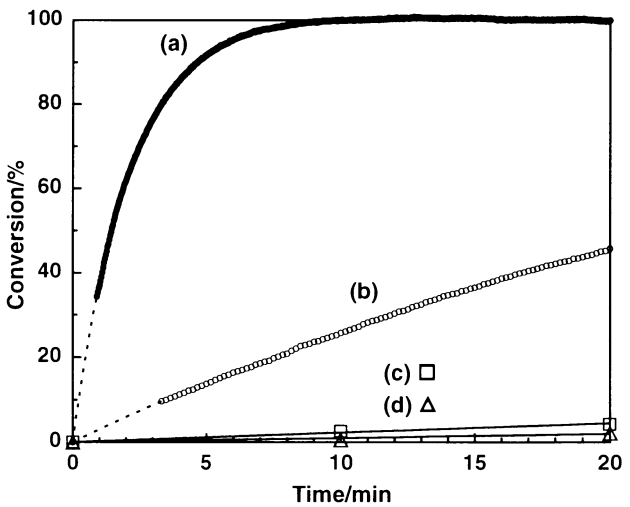


Fig. 1 Time courses of the hydrolysis of Boc-Phe-ONp in phosphate buffer (pH 7.0, 10 mM) containing 1% dioxane at 4 °C: (a) Boc-L-Phe-ONp–apomyoglobin (12.5 : 62.5 μM), (b) Boc-D-Phe-ONp–apomyoglobin (12.5 : 62.5 μM), (c) Boc-Phe-ONp–imidazole (6.25 : 62.5 μM) and (d) Boc-Phe-ONp (6.25 μM) without catalyst.

DOI: 10.1039/b008403o

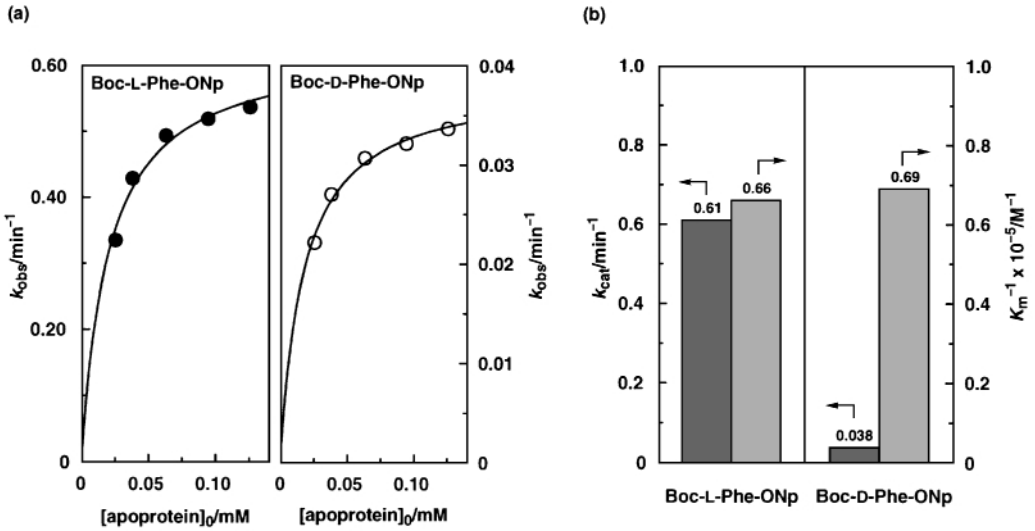

Fig. 2 Hydrolysis of Boc-L-Phe-ONp and Boc-D-Phe-ONp (12.5 μM) in the presence of apomyoglobin (2–10 equiv.) in phosphate buffer (pH 7.0, 10 mM) containing 1% dioxane at 4 °C: (a) plots of hydrolysis rate constant (k_{obs}) *vs.* initial concentration of apomyoglobin, and (b) association constants of the Michaelis complexes (K_m^{-1}) and maximum rate constants (k_{cat}).

Boc-D-Phe-ONp both showed a saturation signature (Fig. 2a), indicating that the apoprotein and Boc-Phe-ONp form a complex which serves as a reactive intermediate. Lineweaver–Burk plots[11,13] gave a maximum rate constant for the L-isomer (k^L_{cat}) of 6.1×10^{-1} min^{-1}, which is approximately 16 times larger than that for the D-isomer ($k^D_{cat} = 3.8 \times 10^{-2}$ min^{-1}) (Fig. 2b).[14] On the other hand, the K_m value for the hydrolysis of Boc-L-Phe-ONp (K^L_m) was evaluated to be 1.5×10^{-5} M, which is comparable to that of the D-isomer ($K^D_m = 1.4 \times 10^{-5}$ M).[12] Thus, the high stereoselectivity of the hydrolysis is not due to the enantioselective binding of the substrate ($K^L_m{}^{-1}/K^D_m{}^{-1} = 0.95$) but is more likely due to the large difference in reactivity between the L- and D-isomers of Boc-Phe-ONp within the heme pocket.

The enantioselectivity of the apomyoglobin-mediated hydrolysis was found to be highly sensitive to the substrate. For example, when the N-protecting Boc group (R^2) of the substrate was replaced with benzyloxycarbonyl (Z-Phe-ONp, 12.5 μM), the rate constant of the hydrolysis of the L-isomer with apomyoglobin (62.5 μM) was considerably decreased ($k^L_{obs} = 5.5 \times 10^{-2}$ min^{-1}, $k^D_{obs} = 3.1 \times 10^{-2}$ min^{-1}) to furnish a $k^L_{obs}:k^D_{obs}$ of only 1.8.[15] Lower enantioselectivities were also observed when Boc-PhGly-ONp (R^1 = Ph, $k^L_{obs}/k^D_{obs} = 1.8$)[16] and Boc-Ala-ONp ($R^1$ = Me, $k^L_{obs}/k^D_{obs} = 1.9$)[16] were the substrates in place of Boc-Phe-ONp, although the L-isomers were again preferentially hydrolyzed.

In conclusion, through the present studies on the utilization of the apoprotein of horse-heart myoglobin as a potential chiral catalyst, we have demonstrated a highly enantioselective hydrolysis of a phenylalanine 4-nitrophenyl ester (Boc-Phe-ONp), whose selectivity is one of the highest reported to date. Exploration with other natural and mutated apoproteins is one of the subjects worthy of further investigation for extending the scope of reactions.

14 Maximum acceleration factors for the hydrolysis of the L- and D-isomers of Boc-Phe-ONp (k_{cat}/k_{uncat}) were 1200 and 73, respectively.

15 The uncatalyzed reaction was not examined due to a limited solubility of Z-Phe-ONp.

16 Boc-PhGly-ONp: $k^L_{obs} = 1.3 \times 10^{-1}$ min^{-1}, $k^D_{obs} = 7.1 \times 10^{-2}$ min^{-1}, $k_{uncat} = 6.4 \times 10^{-4}$ min^{-1}; Boc-Ala-ONp: $k^L_{obs} = 5.1 \times 10^{-2}$ min^{-1}, $k^D_{obs} = 2.7 \times 10^{-2}$ min^{-1}, $k_{uncat} = 3.1 \times 10^{-4}$ min^{-1}.

Task-specific ionic liquids for the extraction of metal ions from aqueous solutions

Imidazolium cations, such as those commonly used in preparing ionic liquids (ILs) can easily be derivatized to include task-specific functionality, such as metal ligating groups that when used as part of the solvent or doped into less expensive ILs, dramatically enhance the partitioning of targeted metal ions into the IL phase from water; the strategy of preparing task-specific ILs is applicable to a wide range of designer solvent needs.

Owing to their unique chemical and physical properties, ionic liquids (ILs) have received recent attention for applications as solvent alternatives,[1–4] where, for example, ILs can be used in place of organic solvents in synthesis, catalysis, electrochemistry and liquid/liquid extractions. The formulations commonly reported for ILs have relied on pyridinium or imidazolium cations bearing simple alkyl appendages as the cation. Changes in IL physical properties have been accomplished by altering the length of the alkyl groups on the rings[4–6] allowing for fine-tuning their viscosity, hydrophobicity and melting points.[6,7] More recently, ionic liquid formulations have been expanded in scope to include other heterocyclic aromatic molecules as well as ions with structurally and functionally complex side chains.[8–10]

It has been demonstrated that organic solutes (*e.g.* aromatic molecules such as simple benzene derivatives)[1,2,4] can be partitioned to specific ILs based on the hydrophobicity of the solute and IL. In contrast, the partitioning of metal ions into an IL extracting phase in liquid/liquid systems is negligible owing to the tendency of the metal cations to remain hydrated and in the aqueous phase, thus necessitating the use of an extractant molecule that forms complexes directly with metal ions to increase their hydrophobicity.[11–15] The drawbacks associated with this approach lie in finding extractant molecules that remain exclusively in the IL under all process conditions and also in understanding the increased complexity of the system upon the addition of solutes. Here, we report the first use of task-specific ILs, *i.e.* those with targeted functionality designed into the IL solvent. In the present example, new compounds which have been designed specifically to both be ionic liquids and to extract heavy metal ions (*e.g.* Hg^{2+} and Cd^{2+}) are reported.

Mercury(II) and cadmium(II) were targeted in this study as part of our ongoing efforts to find alternative separations strategies for removing these toxic, easily transported metal ions from the environment.[16] The bases for the modified ILs were 1-alkyl-3-methylimidazolium, $C_n$mim$^+$ (n = 4, 6, 8) salts of PF_6^- which form two-phase systems when contacted in equal volume with water.[2] ILs that incorporated thiourea, thioether and urea into derivatized imidazolium cations were thus prepared,† that when combined with the PF_6^- anion, functioned as both the hydrophobic solvent and metal ion extractant in liquid/liquid separations. The new ILs (Fig. 1) may either be used directly as the bulk solvent or may be doped‡ as an extractant into less expensive ILs, such as [C_4mim][PF_6].

The distribution ratios§ of Hg^{2+} and Cd^{2+} between our chosen standard for this study, [C_4mim][PF_6], and an aqueous phase at pH = 7 were 0.84 (Hg^{2+}) and 0.03 (Cd^{2+}), indicating a preference for these metal ions to be retained in the aqueous phase. The thioether-appended IL **1**, as either the extracting phase or in 50 : 50 mixtures with [C_4mim][PF_6] at pH = 1 or 7, is effective in partitioning both metal ions to the IL phase (Table 1). The thiourea derivative **2** extracts Hg^{2+} from water comparably to **1**, however distribution ratios are much lower when **2** is diluted with [C_4mim][PF_6]. IL **2** is much less effective at extraction of Cd^{2+} (D values of 20 and 23 at pH of 1 and 7, respectively) and when diluted with [C_4mim][PF_6], IL **2** does not extract Cd^{2+} at all.

IL **3** (another thiourea derivative), and **4**–**6** (urea derivatives) were prepared and their behavior as extractants for Hg^{2+} and Cd^{2+} when mixed in equal mass ratios with [C_4mim][PF_6] measured as a function of aqueous phase pH (Fig. 2). The results are similar, in that each of these ILs {as 1 : 1 (mass) mixtures with [C_4mim][PF_6]} efficiently extract Cd^{2+} and Hg^{2+}, as shown in Fig. 2. In general, the distribution ratios of Cd are

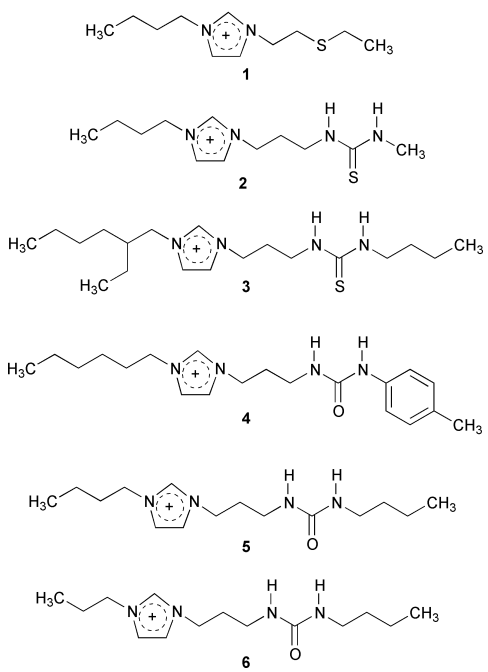

Fig. 1 Structures of the cations combined with PF_6^- to make the ILs utilized in these studies.

DOI: 10.1039/b008041l

Table 1 Distribution ratios for Hg^{2+} and Cd^{2+} in systems incorporating ILs **1** and **2**

IL	M^{2+}	pH (aq)	Distribution ratio	System
1	Hg^{2+}	1	200	**1** only
	Cd^{2+}	1	330	**1** only
1	Hg^{2+}	1	170	**1** + $[C_4mim][PF_6]$ (1 : 1)
	Cd^{2+}	1	310	**1** + $[C_4mim][PF_6]$ (1 : 1)
1	Hg^{2+}	7	210	**1** only
	Cd^{2+}	7	380	**1** only
1	Hg^{2+}	7	210	**1** + $[C_4mim][PF_6]$ (1 : 1)
	Cd^{2+}	7	360	**1** + $[C_4mim][PF_6]$ (1 : 1)
2	Hg^{2+}	1	350	**2** only
	Cd^{2+}	1	20	**2** only
2	Hg^{2+}	1	74	**2** + $[C_4mim][PF_6]$ (1 : 1)
	Cd^{2+}	1	0.0086	**2** + $[C_4mim][PF_6]$ (1 : 1)
2	Hg^{2+}	7	340	**2** only
	Cd^{2+}	7	23	**2** only
2	Hg^{2+}	7	100	**2** + $[C_4mim][PF_6]$ (1 : 1)
	Cd^{2+}	7	0.0074	**2** + $[C_4mim][PF_6]$ (1 : 1)

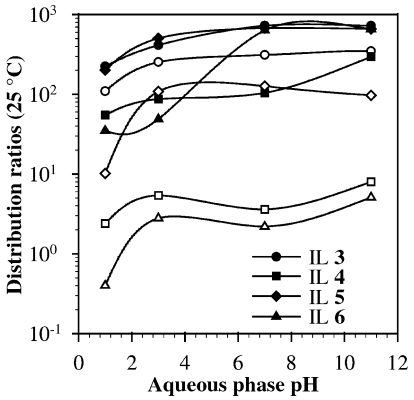

Fig. 2 Distribution ratios for Hg^{2+} (filled symbols) and Cd^{2+} (open symbols) with ILs **3**–**6** utilized in a 1 : 1 weight ratio with $[C_4mim][PF_6]$ and contacted with aqueous phases of variable pH.

lower than observed for Hg, and in the case of ILs **4** and **6**, the differences are over an order of magnitude. ILs **3** and **5** give the highest distribution ratios for each metal ion, and the extraction using IL **6** is the most affected by lowering the pH (although all four ILs exhibit lower distribution rations at the lowest values of pH studied). In comparing these results with those in Table 1, it is to be noted that distribution ratios as high as 710 (Hg^{2+}, IL **3**) were observed in this latter study, even though the ILs were utilized as 1 : 1 mixtures with $[C_4mim][PF_6]$.

Both the appended functional group and the alkyl group appear to affect the extraction. The extended alkyl 'tail' near the thiourea group in **3** results in a significant increase in *D* values for both metals. For the various functional groups, the *D* values for Hg^{2+} are the highest with urea > thiourea with the 'tail' > thioether > thiourea, while those for Cd^{2+} decrease from thiourea with the 'tail' > thioether > urea > thiourea.

We are currently investigating additional series of task-specific ILs with each functional group to elucidate the trends in both structure and function of the IL and to control the physical properties of these new extracting solvents. Additional studies are also required to determine if the metal ions can be effectively stripped from these solvents, although they are currently also being investigated for their ability to retain metallic catalysts in the IL for synthetic applications.

Notes and references

† All chemicals were obtained as reagent grade from Aldrich and used without further purification. 1-(3′-aminopropyl)imidazole (20.0 g, 0.160 mol) was mixed with 100 mL of acetonitrile under an atmosphere of dry nitrogen. To the stirred solution was added in a dropwise fashion 15.5 g (0.156 mol) of *n*-butyl isocyanate dissolved in 25 mL of acetonitrile. The combined solution was stirred overnight followed by removing the solvent *in vacuo*. The residue was then dried overnight *in vacuo*. Proton NMR spectroscopy confirmed the structure of the product as being the desired urea-appended imidazole, and the crude material was used in the next step without further purification.

Under a nitrogen atmosphere, the reaction residue was redissolved in acetonitrile (100 mL) and 28.0 g (0.164 mol) of propyl iodide was added. The mixture was then heated gently without refluxing. After stirring with heating overnight, the acetonitrile was removed *in vacuo*, leaving a sticky residue. The residue was washed in water and the aqueous layer washed twice with 100 mL of diethyl ether. To the aqueous solution was added a solution of 36.0 g (0.194 mol) KPF_6 in 100 mL of water. The mixture was stirred overnight at 40 °C, during which time a biphasic system formed comprised of an upper aqueous phase and a lower product phase. (Anion exchange for each of the ureas can also be accomplished using $AgPF_6$ in acetone.) The aqueous phase was decanted and the product was washed four times (2 h contacts) with 100 mL water to remove any remaining KPF_6. After the last water wash, the ionic liquid was dissolved in acetonitrile and toluene was added to aid in the azeotropic removal of water. Any solids were removed by filtration and the solution was then rotary evaporated. The isolated product was dried *in vacuo* for 24 h while being heated to 60 °C. Unoptimized yield: 45.2 g (68%). The general procedure for the preparation of the urea-functionalized ionic liquids **5** and **6** and the thiourea-functionalized ionic liquids **2** and **3** is analogous, each being formed in similar yield.

‡ When preparing the 1 : 1 mixtures of the solid samples with $[C_4mim][PF_6]$, solutions of **5** and **6** were prepared as a 1 : 1 ratio of the cations and added to $[C_4mim][PF_6]$ followed by sonication and gentle heating for 30 min to form the solution. Solutions of **1**–**4** were prepared as 1 : 1 weight ratios in $[C_4mim][PF_6]$ followed by thorough mixing.

§ Metal ion distribution ratios were determined by mixing equal volumes of the IL and aqueous phases followed by vortexing (2 min) and centrifuging (2000 *g*, 2 min) to equilibrate the phases. Addition of either $^{203}HgCl_2$ or $^{109}CdCl_2$ (*ca.* 0.005 μCi, 5 μL) was followed by two intervals of vortexing (2 min) and centrifuging (2000 *g*, 2 min) to ensure that the phases were fully separated. The phases were separated and dispensed into shell vials from which 100 μL of each phase was removed for radiometric analysis. The results are reported as distribution ratios and are calculated as the radioactivity in the lower phase divided by the radioactivity in the upper phase. Each experiment was done in duplicate and the results agreed to within 5%.

Synthesis of new types of polysiloxane based surfactants

First published as an Advance Article on the web

New types of amphiphilic polysiloxane diblock copolymers containing a pure polysiloxane backbone were prepared by the functionalization of poly(dimethylsiloxane)-*block*-poly-(methylvinylsiloxane) copolymers, synthesized by 'living' anionic ring opening polymerisation of 1,3,5,7-tetramethyl-1,3,5,7-tetravinylcyclotetrasiloxane (D_4^v) and hexamethyl-cyclotrisiloxane (D_3).

Amphiphilic block copolymers find widespread technological applications especially as non-ionic polymeric surfactants. The coexistence of the dissimilar segments, which show a different solubility in a specific solvent, produces unique properties because of their ability to self-organize at interfaces and in solution and thus modify interfacial properties and enhance compatibility or separation.[1] Typically, purely organic backbones are found in this type of surfactant, nevertheless inorganic polymer segments, especially polysiloxanes show properties that are advantageous, such as biocompatibility, robustness, flexibility *etc*.[2] Although polysiloxanes have superior properties compared to common organic polymers their controlled formation as block copolymers is nearly unexplored.

In recent years the interest in amphiphilic block copolymers has grown especially due to their surface activity and their lyotropic behaviour.[3] Amphiphilic block copolymers with a hydrophobic polysiloxane part are predominantly known in combination with organic hydrophilic blocks such as poly(ethylene oxide) or polymethacrylates.[4] As far as we know there is only one example in literature citing a block copolymer with a pure polysiloxane backbone bearing carboxyl groups pendant to the polysiloxane chain.[5]

In this paper we present the formation and post-functionalization of block copolymers of poly(dimethylsiloxane) (PDMS) and poly(methylvinylsiloxane) by 'living' anionic ring opening polymerisation.

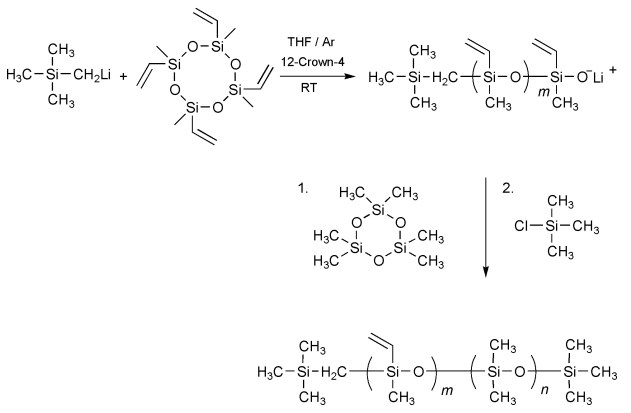
Valuable precursors for a post-functionalization are silane-bonded vinyl groups. For the preparation of a vinyl-functionalized block *via* anionic ring opening polymerisation a cyclic monomer with a sufficient reactivity is needed. The only commercially available monomer that fulfils this demand is 1,3,5,7-tetramethyl-1,3,5,7-tetravinylcyclotetrasiloxane (D_4^v). D_4^v did not show satisfactorily polymerisation initiated by butyllithium with the usual donor solvents (THF, DMF, DMSO, HMPA). Therefore another initiator with a higher basicity, *i.e.* trimethylsilylmethyllithium, $(CH_3)_3SiCH_2Li$, was used to transform the carbanionic acids into the silanolate species.[6] Usually polymerisations of unstrained cyclic siloxanes, such as cyclotetrasiloxanes or larger rings, are more difficult due to the presence of intra- and intermolecular reactions of the active ends leading to an equilibrium reaction between the ring, an oligomeric, and a polymeric species. It was shown that the equilibrium is shifted to the polymeric species if additives able to separate the ion pair between the oxidic end group and the lithium ion are added to the reaction solution. Typical additives are ethylenediamine, diglyme, cryptands and crown ethers like 12-crown-4.[7]

Block copolymers from 'living' ring opening polymerisations are obtained by using a polymer as macroinitiator and extending it with a second monomer. For the PDMS-*block*-poly(methylvinylsiloxane) we observed that the extension of a PDMS chain with poly(methylvinylsiloxane) only leads to the addition of up to five monomeric units until the final equilibrium between polymeric and ring species is reached, while the polymerisation of D_4^v first allows for a much better control of the equilibrium. Therefore, the polymerisation of vinylmethylcyclotetrasiloxane was initiated with trimethylsilylmethyllithium in a first step and the chain was extended by PDMS in a second step[8] (Scheme 1). With this procedure block copolymers with polydispersities around 1.40 and block lengths up to 10.000 with varying poly(methylvinylsiloxane) content were obtained (Table 1).

The resulting block copolymers have purely hydrophobic properties but the vinyl groups can easily be transformed into a variety of other functional groups. The double bonds of the methylvinylsiloxane blocks were modified either by hydrosilation[9] or by epoxidation.[10] In the latter case further modification reactions of the polyepoxide block were carried out[11] (Scheme 2).

The hydrosilation of the double bonds with Karstedt's catalyst at 70 °C worked quantitatively as confirmed by the disappearance of the vinylic protons in ^{1}H NMR. $HSi(OEt)_3$, $HSi(OMe)_3$ and $HSi(CH_3)_2Cl$ were used for this reaction to obtain a functionalized polysiloxane block. While the trialkoxysilane groups can be hydrolysed and used for cross-linking reactions, the chlorosilanes are able to react with a variety of nucleophiles, like alcohols, carboxylic acids, *etc.*

Another possibility of the double bond functionalization is the epoxidation[12] followed by the subsequent ring opening of the oxirane ring. The epoxide was quantitatively formed by a selective oxidation of the double bonds with *m*-chloroperoxybenzoic acid (MCPBA) in methylene chloride or toluene proved by ^{1}H NMR. SEC measurements of the epoxidised samples showed that only a small amount ($< 4\%$) of high molecular weight (cross-linked) polymer was formed. The cross-linking was almost quantitatively suppressed by working in high dilutions.[13] The obtained epoxide was opened with different mono- or difunctional nucleophiles, such as hydroxide ions, diamines, diols, dicarboxylic acids, hydroxy-functionalized ethers and carboxylic acid chlorides (Scheme 3). These reactions resulted in the formation of a hydroxide group at one carbon atom and the coupling product with the nucleophile at



Scheme 1

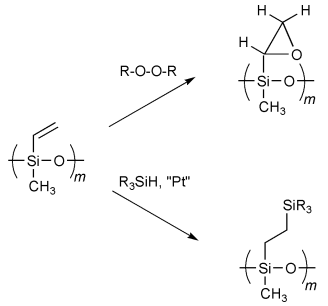
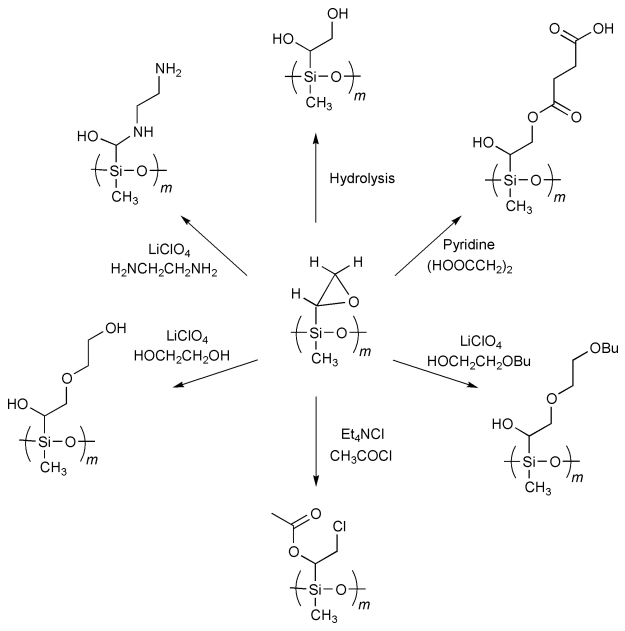


Scheme 2

the other. Modification of the epoxide block by reaction with amines or alcohols was catalysed by $LiClO_4$. Nucleophilic attack of the epoxide by the nucleophile on the more hindered carbon atom ($SiCH{=}CH_2$) was not observed in ^{1}H NMR spectra which indicates an almost quantitative attack on the terminal methylene carbon atom. In the case of modification with oxalic acid the reaction was performed in *N*,*N*′-dimethylformamide to dissolve the reactant and additionally catalysed by pyridine. Hydrolysis of the epoxidised block copolymers leads to the corresponding 1,2-diol side groups and may either be acid- or base-catalysed. Epoxide opening worked quantitatively, which was proved by ^{1}H NMR (disappearance of the signals of the epoxide protons at 2.2, 2.7 and 2.9 ppm). The processing parameters of the ring opening reactions allow for the preparation of different materials. High dilution of the block copolymers in the solvent during the ring opening leads to linear polymers while cross-linked hydrogels are formed in low dilution. To completely suppress cross-linking reactions using multifunctional nucleophiles a large excess of reactants is necessary and harsh purification conditions should be avoided. For a total prevention of cross-linking reactions it is advisable to use monofunctional protected ring opening agents and remove the protecting groups afterwards. Additional advantages of this procedure are simpler purification and analyses. In those cases in which hydroxy groups are formed during the ring opening or other functionalities are present, no elution in the SEC experiments was obtained due to interaction with the column material. This was avoided by protection of the free functional groups.



Scheme 3

In summary new methylvinyl-substituted polysiloxane diblock copolymers were prepared by 'living' anionic ring opening polymerisation. The vinyl group was used for a further functionalization to obtain silicon alkoxide substituted or amphiphilic block copolymers with a variety of functional groups.

We gratefully acknowledge the financial support by the Fonds zur Förderung der wissenschaftlichen Forschung Austria and Wacker-Chemie for their kind donation of chemicals.

8 Typical procedure: to a solution of D_4^v in THF $(CH_3)_3SiCH_2Li$ was added. The amount of the lithium compound was chosen depending on the target molecular weight of the poly(methylvinylsiloxane) $[I] = \frac{[M]_0}{DP}$ ([*I*] = initiator concentration; $[M]_0$ = monomer concentration; *DP* = degree of polymerisation). After stirring the solution at rt for 1 h 12-crown-4 was added. Propagation progress was determined during the polymerisation by taking samples, quenching the reaction with chlorotrimethylsilane at various reaction times and determining the molecular weights by size exclusion chromatography (SEC) analyses. By adding D_3 to the 'living' polymer the PDMS-blocks were formed. The diblock copolymers were quenched by chlorotrimethylsilane and analysed by SEC and NMR measurements. SEC was performed using a Waters 717 autosampler, 515 HPLC pump, 2410 RI detector and Styragel columns in THF at 40 °C at a rate of 1 ml min^{-1} applying linear polystyrene standards. The DP of each block was calculated by the SEC results of homopolymer and diblock copolymer and compared with the results of the composition determined by ^{1}H NMR. ^{29}Si NMR analyses allowed the determination of the sequence distribution of repeat units, which showed no random copolymerization of D_4^v and D_3.

12 General procedure: MCPBA was dissolved in toluene and dried over Na_2SO_4. Depending on the block length of the poly D_4^v block, a calculated amount of the solution was added to the block copolymer. The resulting mixture was stirred overnight at rt. The organic layer was extracted with an aqueous sodium bicarbonate solution and deionised water several times. The organic layers were collected and dried over Na_2SO_4. Afterwards the solution was filtered and evaporated.

The β-elimination route to stereodefined γ-alkylidenebutenolides†

Reinhard Brückner

Institut für Organische Chemie und Biochemie der Albert-Ludwigs-Universität, Albertstr. 21, D-79104 Freiburg, Germany. E-mail: reinhard.brueckner@organik.chemie.uni-freiburg.de; Fax: Int.+49-761-2036100

Received (in Cambridge, UK) 19th September 2000, Accepted 13th November 2000
First published as an Advance Article on the web 4th January 2001

γ-Alkylidenebutenolides are biologically significant compounds and comprise compounds as structurally and functionally diverse as the inhibitor dihydroxerulin (*Z*-61, Scheme 16) of cholesterol biosynthesis or the carotinoid peridinin (*Z*-18a, Scheme 5) which plays a dominant role in marine photosynthesis. For the stereo-controlled obtention of γ-alkylidenebutenolides *Z*-2 or *E*-2 with or without alkyl substituents at C-α or C-β, a general strategy has been developed (Scheme 1). The key step of this strategy is the stereospecific *anti*-elimination of water from diastereopure γ-(α-hydroxyalkyl)butenolides *lk*-1 or *ul*-1—be they racemic or enantiopure (*lk* = like, *ul* = unlike: γ-(α-hydroxyalkyl)butenolides *lk*-1 give γ-alkylidenebutenolides *Z*-2, while γ-(α-hydroxyalkyl)butenolides *ul*-1 furnish the isomeric γ-alkylidenebutenolides *E*-2. As dehydrating agents we used mixtures of triflic anhydride and pyridine or of diethyl azodicarboxylate and triphenylphosphine. Previous β-eliminations providing γ-alkylidenebutenolides exhibited in general little stereoselectivity and no stereospecifity at all (exception: Scheme 10), irrespective of whether this β-elimination was performed separately or took place *in situ*.

Introduction

Butenolides are γ-butyrolactones with a $C^{\alpha}=C^{\beta}$ bond. They abound in nature, revealing a great variety of substitution patterns.[1] Among many others, one finds γ-alkylidenebutenolides. The most prominent representatives of this class are vitamin C, the pulvinic acids [α-aryl-β-hydroxy-γ-(α-carboxybenzylidene)butenolides], the pulvinones [α-aryl-β-hydroxy-γ-(benzylidene)butenolides], and derivatives thereof. However, there are also γ-alkylidenebutenolides which are totally devoid of heteroatom substituents at C^{α} or C^{β}. Several such γ-alkylidenebutenolides are biologically significant.

Their simplest conceivable representative is γ-methylenebutenolide. This is a natural product ('protoanemonin'[2]) and known to be an antibiotic. The highly unsaturated γ-alkylidenebutenolides dihydroxerulin (*Z*-**61**, Scheme 16) and xerulin (*trans*,*Z*-**66**, Scheme 17) are structurally unique, intensely yellow fungal colorants.[3] Isolated as 90 : 10–65 : 35 mixtures, they were found to inhibit the biosynthesis of cholesterol without being cytotoxic; they prevent the incorporation of ^{14}C-acetate—but not of ^{14}C-mevalonic acid—into cholesterol produced from HeLa S3 cells (ID_{50} = 1 μg g^{-1}).[3] Suppressing a different step of the biosynthesis of cholesterol is what three

† Dedicated to Dr Klaus Brückner (retired from Cela-Merck, Ingelheim) on the occasion of his 75th birthday.

Reinhard Brückner prepared his doctoral thesis at the Ludwig-Maximilians-Universität München under the supervision of Professor Rolf Huisgen (1984) and was a postdoctoral fellow with Professor Paul A. Wender at Stanford University. After a habilitation with Professor Reinhard W. Hoffmann at the Philipps-Universität Marburg he became an associate professor at the Julius-Maximilians-Universität Würzburg (1990). He was a full professor at the Georg-August-Universität Göttingen (1992) and moved to the Albert-Ludwigs-Universität Freiburg in 1998. Being a dedicated teacher, he was a visiting professor at the Universities of Wisconsin / Madison and Santiago de Compostela / Spain. His research interests comprise the synthetic chemistry of dienediynes, 1,3,5,7,...-polyols, chiral butyrolactones and butenolides, and the stereochemistry of rearrangements of organolithium compounds.

DOI: 10.1039/b007590f

of the present top ten block busters of the pharmaceutical industry effect—namely Lipitor®, Zocor® and Pravachol®. The structurally most complex γ-alkylidenebutenolides of the substitution pattern under scrutiny are the carotinoids peridinin[4] (*Z*-**18a**, Scheme 5) and pyrrhoxanthin[5] (*Z*-**18b**, Scheme 5). Peridinin plays a key role in marine photosynthesis by dinoflagellates, which make up much of the sea plankton. Light harvesting by *Amphidinium carterae* is effected by a chromoprotein whose 2 active centers contain 2 × four molecules of peridinin, 2 × one molecule of chlorophyll A and 2 × one molecule of a (digalactosyl)diacylglycerol.[6] The conversion of light into chemical energy is a fundamentally important process.[7] Pyrrhoxanthin participates in algal photosynthesis.

Each of the γ-alkylidenebutenolides just mentioned has attracted synthetic attention in recent years[8] (Scheme references: *vide supra*), as have several others, too. The latter comprise the goniobutenolides A (*Z*-**27**) and B (*E*-**27**, Schemes 9, 29), the antibiotic lissoclinolide (*trans*,*Z*,*trans*-**52**, Scheme 14), the isomeric structure *trans*,*E*,*trans*-**52** once assigned to tetrenolin (Scheme 15), constituent *Z*-**72** of the roots of *Chamaemelum nobile* L. (Schemes 19, 22), the alkaloid pandamarilactam-3y (*Z*-**85**, Scheme 23), the cytotoxin nostoclide II (*Z*-**89**, Scheme 24), the wood constituent freelingyne (*Z*-**93**, Scheme 25), melodorinol (*Z*-**99**, Scheme 26), the antibiotic patulin,[9] and an eudesmanolide.[10]

The present article reflects the current interest in the preparation of such compounds.[11] Specifically, it compiles ways of assembling such γ-alkylidenebutenolides by means of

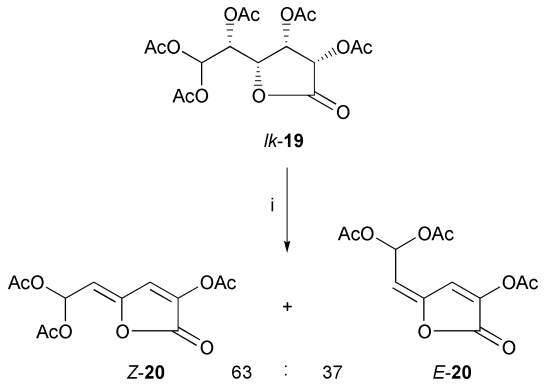
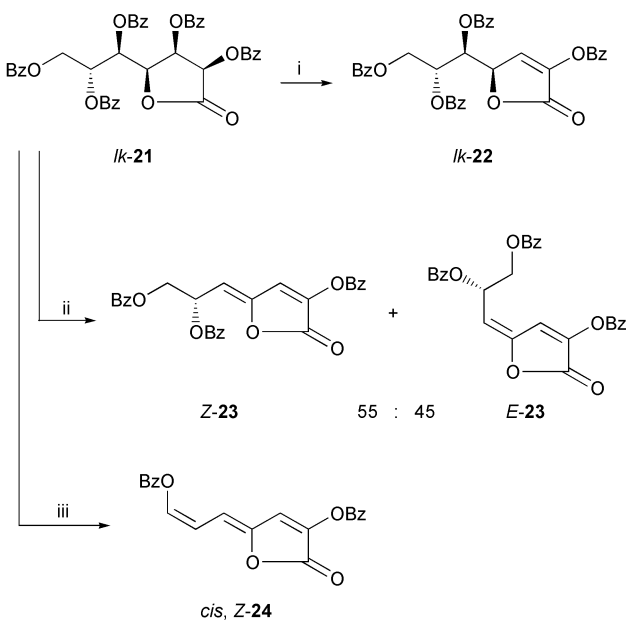
the strategy outlined in Scheme 1.[12] Its key step is an *anti*-elimination of a leaving group Het at C$^{\alpha\prime}$ and an adjacent proton at C$^{\gamma}$ from diastereopure γ-(α-heteroalkyl)-substituted butenolides **1**. If the latter possesses stereostructure *lk*-**1**, the *anti*-elimination of α′-Het and γ-H establishes *Z*-configured γ-alkylidenebutenolides *Z*-**2** while the isomeric starting materials *ul*-**1** serve as precursors of the stereocomplementary γ-alkylidenebutenolides *E*-**2**. In order for these eliminations to be stereo*specific*, there must not be competing *syn*-eliminations. Neither may the elimination products *Z*- and *E*-**2** equilibrate under the reaction conditions—*Z*-**2** is slightly or distinctly more stable than *E*-**2**.

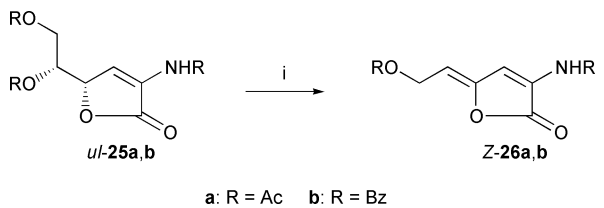
To the best of our knowledge, the earliest realization of a (fairly) *anti*-selective elimination of type *ul*-**1** → *E*-**2** is due to Font *et al*. in 1989.[13] As shown in Scheme 2, the dehydrobromination of the γ-(α-bromoethyl)-substituted butenolide *ul*-**6** with NEt_3 gave a 90 : 10-mixture of *E*- and *Z*-**5**.



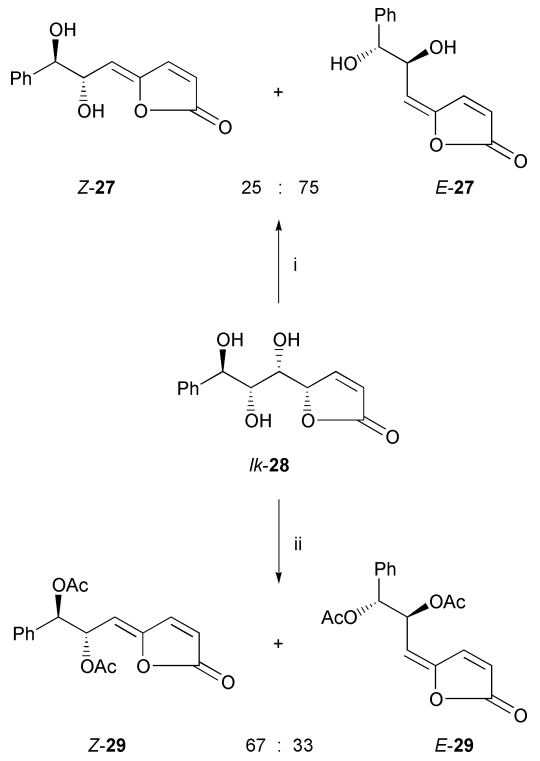
Scheme 6 *Reagents*: i, NEt_3, Ac_2O, 91%.



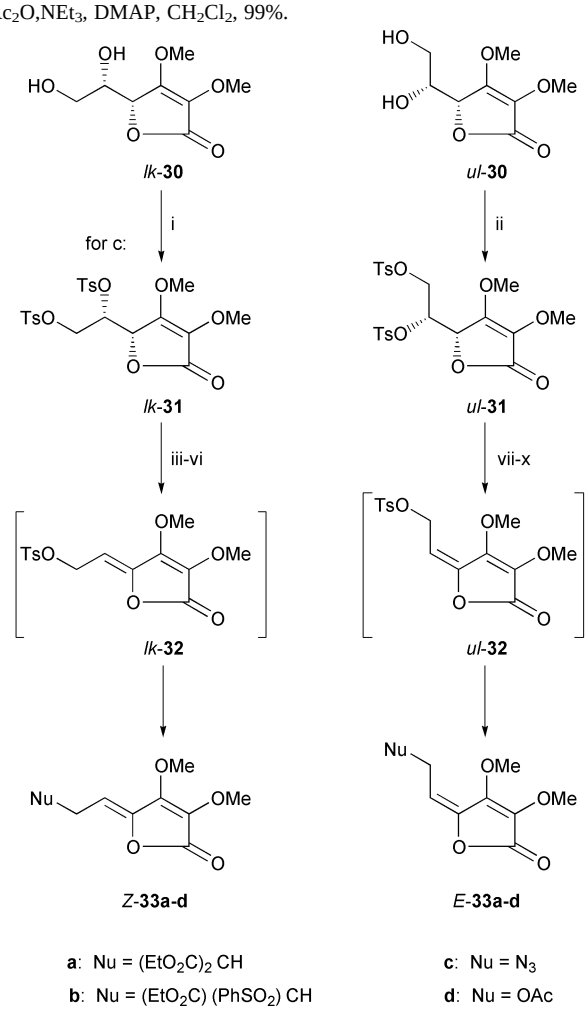
Scheme 7 *Reagents*: i, DBU, CH_2Cl_2, 67%;[18] ii, NEt_3, $CHCl_3$, 85% (experimental part)–90% (according to Scheme);[19] iii, NEt_3–$CHCl_3$, 59%.[20]



Scheme 8 *Reagents*: i, for **a**: DBU, CH_2Cl_2, 71%, for **b**: DBU, CH_2Cl_2, crystallization, 62%.



Scheme 9 *Reagents*: i, $(F_3C–CO)_2O$, NEt_3, CH_2Cl_2, then MeOH, 79%; ii, Ac_2O,NEt_3, DMAP, CH_2Cl_2, 99%.



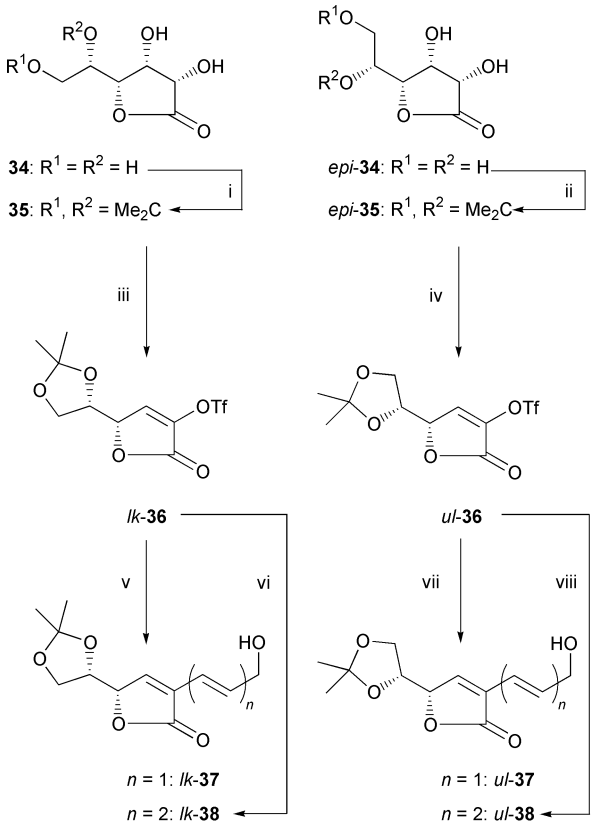
Scheme 10 *Reagents*: i, TsCl, pyridine, 86%; ii, same as (i), 86%; iii, for **a**: $(EtO_2C)_2CH^-Na^+$, THF, 78%; iv, for **b**: $(EtO_2C)(PhSO_2)CH^-Na^+$, THF, 82%; v, for **c**: NaN_3, DMF, 85%; vi, for **d**: NaOAc, DMF, 70%; vii, same as (iii), 70%; viii, same as (iv), 81%; ix, same as (v), 86%; x, same as (vi), 73%.

One must be aware that such an *E*-selectivity can easily be erased by an ensuing (partial or completely) $E \rightarrow Z$ isomerization. This is evidenced, for instance, by the DBU-mediated dehydroiodinations tabulated in Scheme 3.[14] The β-substituents R^2 of elimination products *Z*-**10b**–**e** destabilize the neighboring alkylidene substituents R^1 so much that substrate *ul*-**11e** undergoes a 100% *syn*-selective β-elimination.

Clearly, such a thermodynamically driven $E \rightarrow Z$ isomerization may be exploited for synthesizing *Z*-γ-alkylidenebutenolides selectively. This is underlined by the elaboration of the γ-[(trimethylsilyl)methylene]butenolides *E*-**10a** and **b** shown in Scheme 4.[14] The γ-(iodomethylene)butenolides *E*-**12a** and **b** obtained from these compounds by iodolysis provided the stereopure isomers *Z*-**12a** and **b** within 1 h at room temperature. Compound *Z*-**12b** underwent a Sonogashira–Hagihara coupling with alkyne **13** which proceeded with retention of configuration at the $C^{\alpha'}$=C^{γ} bond and provided the vitamin A lactone analog *Z*-**14** in 65% yield.

The fairly sophisticated β-eliminations of Scheme 5 allowed Ito *et al.* to achieve the first syntheses of the γ-alkylidenebutenolide carotinoids peridinin (*Z*-**18a**) and pyrrhoxanthin (*Z*-**18b**).[15] Benzenesulfonic acid was eliminated from the γ-(α-phenylsulfonyl)-substituted butenolides **17** which were formed *in situ* by the addition of the appropriate lithiated sulfone **15a** or **b** to the respective aldehydoester **16a** or **b**. This addition is expected to lack simple diastereoselectivity—like the first step of the Julia–Lythgoe olefination. Therefore, the corresponding intermediates **17** should arise as *lk*,*ul*-mixtures. The latter circumstance explains, in conjunction with the stereochemical relationships of Scheme 1, why the elimination products **18a** and **b** resulted as *Z*,*E*-*mixtures*.

One concludes that *stereospecific* β-elimination routes to γ-alkylidenebutenolides depend on the availability of diastereopure *lk*- and *ul*-configured γ-(α-heteroalkyl)-substituted butenolides **1**. These compounds have been prepared successfully from sugars, by (Mukaiyama) aldol additions, and by the route of Scheme 30, as specified in the following sections.

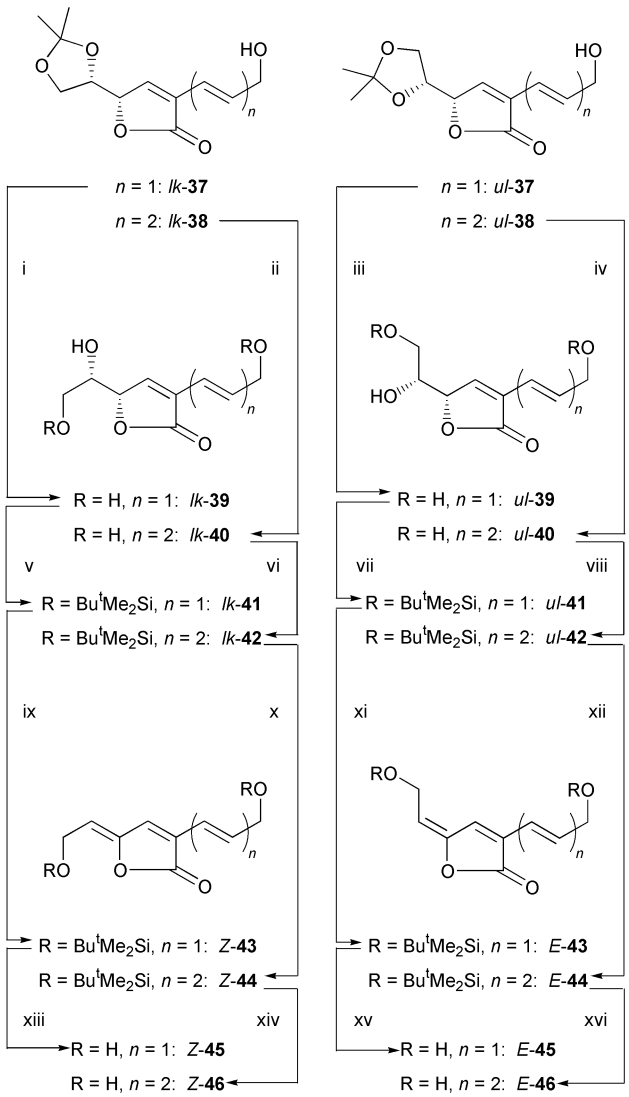


Scheme 11[24] *Reagents*: i, 2,2-Dimethoxypropane Amberlyst-15, DMF, 68% (ref. 25 60%, ref. 26 70%); ii, same as (i), 74% (ref. 25 77%); iii triflic anhydride, pyridine (4.0 equiv.), CH_2Cl_2, 74% (ref. 27 70%); iv, same as (iii), 70% (ref. 27 74%); v, *trans*-3-(tributylstannyl)prop-2-en-1-ol, $Pd_2(dba)_3$·$CHCl_3$, $AsPh_3$, LiCl, THF, 78%; vi, *trans*,*trans*-5-(tributylstannyl)penta-2,4-dien-1-ol, $Pd_2(dba)_3$·$CHCl_3$, $AsPh_3$, LiCl, THF, 57%; vii, same as (v), 68%; viii, same as (vi), 75%.

β-Eliminations from sugar lactones[16]

D-Glucurolactone and acetyl chloride react to give the saturated lactone *lk*-**19** shown in Scheme 6. Treatment with triethylamine in acetic anhydride induced two β-eliminations.[17] First, the C^{α}=C^{β} bond formed, as inferred from the analogous conversion *lk*-**21** → *lk*-**22** in Scheme 7.[18] Then, the $C^{\alpha'}$=C^{γ} bond was established. 57% of the *Z*-configured and 34% of the *E*-configured γ-alkylidenebutenolide **20** resulted,[17] *i.e.* the second elimination was non-stereoselective.

In a similar manner, the perbenzoate *lk*-**21** of D-seduheptulonolactone and triethylamine undergo multiple β-eliminations (Scheme 7).[18–20] As in the case of Scheme 6, the second elimination lacks stereocontrol since the γ-alkylidenebutenolide **23** forms as a 55 : 45 mixture of *anti*-elimination product *Z*-**23** and *syn*-elimination product *E*-**23**.[19] By a 10-fold increase of the reaction time, a third elimination of benzoic acid ensued. It



Scheme 12[24] *Reagents*: i, HCl (12 M), CH_2Cl_2, MeOH, 78%; ii, same as (i), 73%; iii, same as (i), 65%; iv, same as (i), 71%; v, Bu^tMe_2SiCl, imidazole, molecular sieves 4 Å, DMF, 73%; vi, same as (v), 48%; vii, same as (v), 70%; viii, same as (v), 51%; ix, triflic anhydride, pyridine, CH_2Cl_2, 81% of a 99 : 1 *Z*-**43** : *E*-**43** mixture; x, same as (ix), 69% of a 97 : 3 *Z*-**44** : *E*-**44** mixture; xi, same as (ix), 63% of a 96 : 4 *E*-**43** : *Z*-**43** mixture; xii, same as (ix), 73% of a 97 : 3 *E*-**44** : *Z*-**44** mixture; xiii, HF·pyridine, THF, 96% of a 94 : 6 *Z*-**45** : *E*-**45** mixture; xiv, same as (xiii), 92% of diastereopure *Z*-**46**; xv, same as (xiii), 86% of a 94 : 6 *E*-**45** : *Z*-**45** mixture; xvi, same as (xiii), 96% of a 95 : 5 *E*-**46** : *Z*-**46** mixture.

created the conjugated γ-alkylidenebutenolide **24** as a pure *cis*,*Z*-isomer.[20] Since the yield of this compound measured 60–80%, the $C^{\alpha'}$=C^{γ} bond of its precursor **23** (55 : 45 *Z* : *E* mixture, 85–90% yield if isolated) must have partly reverted to the *Z*-geometry under the influence of thermodynamic control.

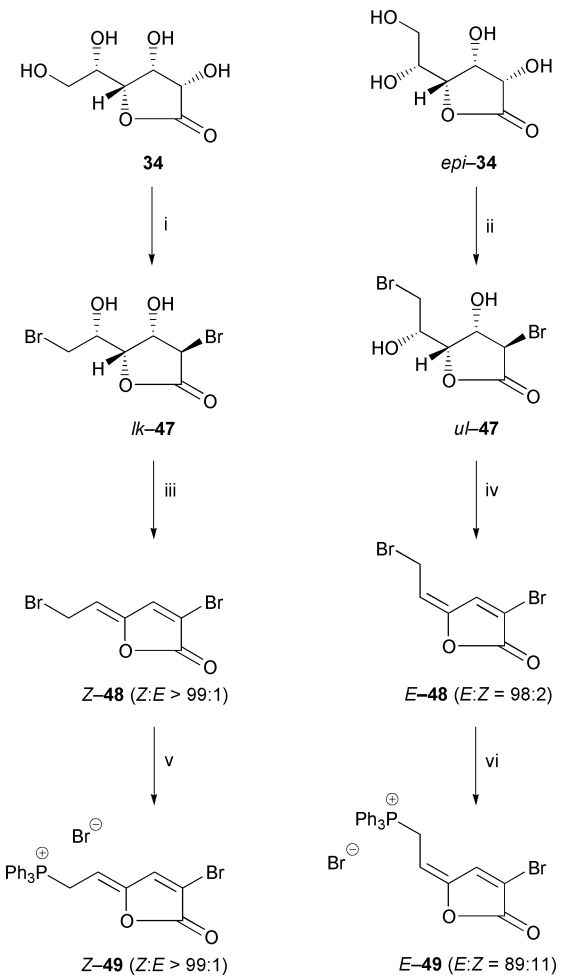
Thermodynamic control must also be responsible for the *syn*(!)-preference of the related, DBU-driven β-eliminations of acetic or benzoic acid from the acylamino-substituted sugar lactones *ul*-**25a** and **b**, respectively (Scheme 8).[21]

Why triethylamine and the tris(trifluoroacetate) derived from the butenolide *lk*-**28** shown in Scheme 9 give a 1 : 3 ratio of *anti*- and *syn*-elimination, while the analogous triacetate does so in a 2 : 1 ratio, is difficult to rationalize.[22] But clearly, the findings of Schemes 6–9 suggest that in γ-(α-heteroalkyl)-substituted butenolides which are to undergo a selective *anti*-elimination and provide sterically homogenous γ-alkylidenebutenolides thereby, the leaving group should *not* be a carboxylic acid. Presumably, a *better* leaving group is called for.

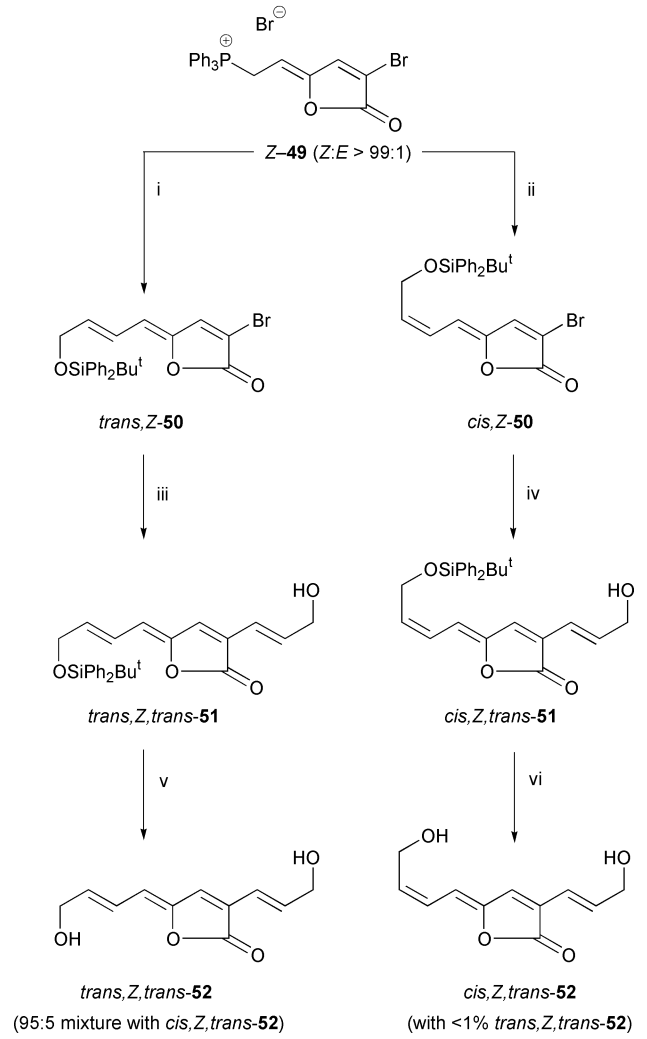
This thought represented *our* start into γ-alkylidenebutenolide syntheses.[12] However, it had already been considered by Khan and Adams in 1995 when they published the study displayed in Scheme 10.[23] The starting materials of these authors were two readily accessible sugar lactones, namely the dimethyl ether *lk*-**30** of L-ascorbic acid and the dimethyl ether *ul*-**30** of D-isoascorbic acid. Treatment of these species with tosyl chloride at room temperature in pyridine provided the diastereomeric ditosylates *lk*-**31** and *ul*-**31**, respectively, both in 86% yield. At 60–80 °C, these compounds became elimination substrates upon treatment with a variety of reagents acting as bases and nucleophiles simultaneously. Behaving as bases, they induced highly stereoselective *anti*-eliminations of toluene-*p*-sulfonic acid which established the homogeneously configured $C^{\alpha'}$=C^{γ} bonds of the presumed intermediates *lk*-**32** and *ul*-**32**, respectively. Then, the same reagents substituted the allylic tosyloxy group nucleophilically: 70–86% of the pure *Z*- and *E*-isomers of the γ-alkylidenebutenolides **33a**–**d** resulted.

Khan's and Adams' results encouraged us to develop *our* β-elimination route[12,24] from sugar lactones to stereodefined γ-alkylidenebutenolides (Schemes 11–17). Clearly, we felt more strongly their message 'this route in principle should work' than we anticipated how profoundly differently our materials behaved in comparison to theirs. We were to deal with 'true' α,β-unsaturated lactones while they had used α,β-unsaturated lactones, which, constituting vinylogous carbonates, are resonance-stabilized. Accordingly, none of our γ-alkylidenebutenolides could be heated overnight at 60–80 °C like theirs (*vide supra*) without suffering decomposition, not to speak of undergoing extensive *E*–*Z*-isomerization much earlier. Indeed, in each step following the installment of the crucial $C^{\alpha'}$=C^{γ} bond skillful experimentation was called for in our work lest the $C^{\alpha'}$=C^{γ} bond geometry be eroded.

Our methodology study (Scheme 11[24]) started from the hydrogenation products **34** ('L-gulonolactone') of L-ascorbic acid and *epi*-**34** ('D-mannonolactone') of D-isoascorbic acid. Acetonide formation, bis(triflate) formation, and *in situ* β-elimination furnished the butenolide-based enol triflates *lk*- and *ul*-**36**, respectively, as described earlier.[27] In the presence of 2 mol% $Pd_2(dba)_3$·$CHCl_3$, $AsPh_3$ and LiCl, these compounds underwent smooth Stille couplings with *trans*-3-(tributyl-



Scheme 13[28] *Reagents*: i, HBr, HOAc, afterwards addition of MeOH, 78% (ref. 29: 90%); ii, same as (i), 71% (ref. 30: 63%); iii, Tf_2O, pyridine, CH_2Cl_2, 95%; iv, same as (iii), 63%; v, Ph_3P, acetonitrile, 96%; vi, same as (v), 80%.



Scheme 14 *Reagents*: i, LDA, THF, $Bu^tPh_2SiOCH_2$–CH=O, −78 °C → 60 °C, 93%; ii, same as (i) but −78 °C → 25 °C, 72%; iii, *trans*-Bu_3Sn–CH=CH–CH_2OH, Pd_2dba_3·$CHCl_3$, $AsPh_3$, THF, 74%; iv, same as (iii), 78%; v, HF·pyridine, THF, 81%; vi, same as (v), 84%.

stannyl)prop-2-en-1-ol and *trans,trans*-5-(tributylstannyl)-penta-2,4-dien-1-ol. The α-alkenylated butenolides **37** and **38** resulted. They were liberated from their acetonide groups, furnishing the triols **39** and **40**, respectively (Scheme 12[24]). After selective *tert*-butyldimethylsilylation of their primary OH groups, the remaining secondary OH group of compounds **41** and **42** was poised to undergo the desired *anti*-elimination after activation with triflic anhydride. Pyridine accomplished this task at −25 °C. The α-alkenyl-γ-alkylidenebutenolides **45** and **46** resulted in 86–96% yield. Their isomeric purities were *Z*:*E* = 94:6 or 6:94 in the former case and *Z*:*E* = 100:0 or 5:95 in the latter. The viability of our strategy had thereby been demonstrated.

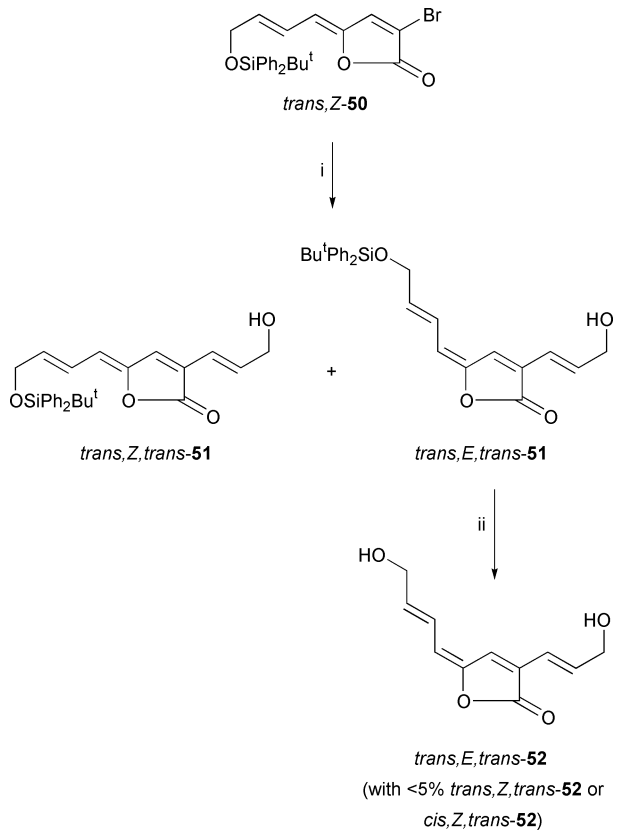
In two other sequences, the known[29,30] twofold S_N2-attack of HBr upon the primary and the activated secondary OH group of lactones **34** and *epi*-**34** delivered the dibromodihydroxylactones *lk*- and *ul*-**47** selectively (Scheme 13). Bistriflate formation in the presence of pyridine made possible two β-eliminations. They led to the bromine-containing γ-alkylidenebutenolides *Z*- and *E*-**48** as almost pure diastereomers. Allylic substitution by triphenylphosphine gave the corresponding phosphonium salts **49** with complete retention of the *Z*- and partial loss of the *E*-geometry.

The ylide derived from phosphonium salt *Z*-**49** reacted with $Bu^tPh_2SiOCH_2$–CH=O with complete retention of the $C^{\alpha'}$=Cγ bond geometry (Scheme 14[28]). The newly formed $C^{\beta'}$ = Cγ′ bond of olefination product **50** was either *trans*- or *cis*-configured, depending on whether the Wittig reaction was conducted at 60 or 25 °C. The bromoethylene moiety of the respective product *trans,Z*- or *cis,Z*-**50** could be coupled with *trans*-Bu_3Sn–CH=CH–CH_2OH in the presence of catalytic Pd_2dba_3·$CHCl_3$ and $AsPh_3$. All C=C bonds maintained their configurations under these conditions and did so, too, in the terminating desilylation step. It rendered, in the *trans,Z,trans*-series, the γ-alkylidenebutenolide *trans,Z-trans*-**52**, which had been described as the antibiotic lissoclinolide. This was the third and is the hitherto shortest synthesis of this compound. Two entirely different syntheses of lissoclinolide had been realized shortly before in the laboratories of Rossi[31] and Negishi.[32]

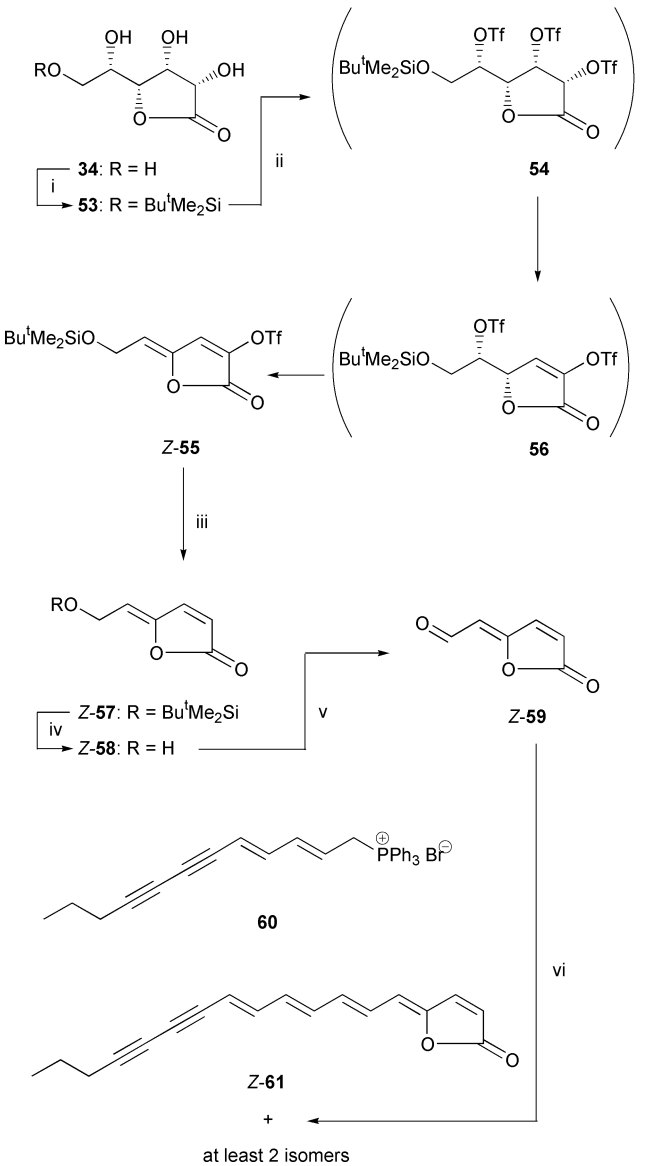
Disappointingly, the ylide derived from phosphonium salt *E*-**49** reacted with $Bu^tPh_2SiOCH_2$–CH=O with complete inversion of the $C^{\alpha'}$=Cγ bond geometry,[28] *i.e.* providing the same *Z*-configured condensation products *trans,Z*-**50** or *cis,Z*-**50** which we had already prepared starting from the isomeric phosphonium salt *Z*-**49** (Scheme 14). This means that the ylide in question underwent a thermodynamically driven *E*→ *Z*-isomerization.

Scheme 15 shows how we managed to get at least small amounts of the Stille coupling product *trans,E,trans*-**51** (which our Wittig approach had failed to give) from the bromoolefin precursor *trans,E*-**50** by a partial isomerization of the previously obtained (*cf.* Scheme 14) coupling product *trans,Z,trans*-**51**. A subsequent desilylation furnished isomer *trans,E,trans*-**52** of lissoclinolide (*trans,Z,trans*-**51**). This isomer was until then suspected to represent 'tetrenolin'.[33] However, having both isomers at hand, we proved by ^{1}H-NMR spectroscopy that "tetrenolin" possesses the structure of lissoclinolide.

Scheme 16 shows the first synthesis of dihydroxerulin (*Z*-**61**).[34] It allowed us to assign a *trans*-configuration to the C=C

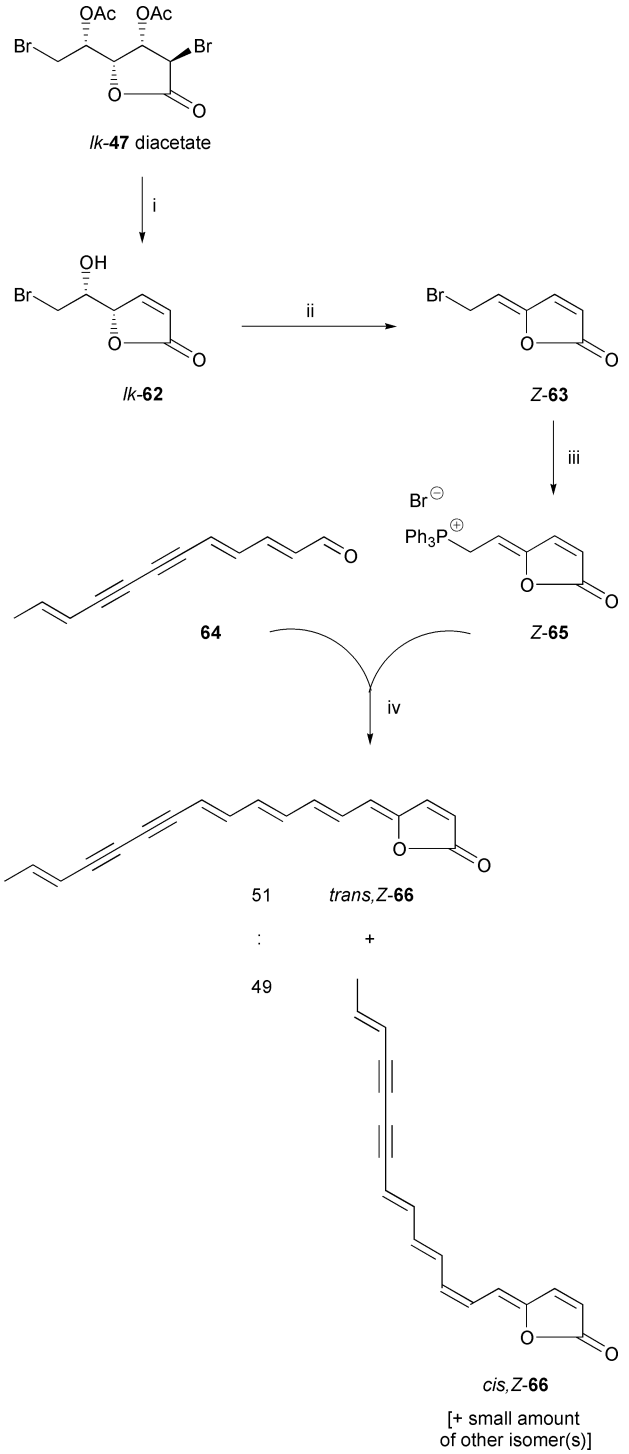


Scheme 15[28] *Reagents*: i, *trans*-Bu_3Sn–CH=CH–CH_2OH, Pd_2dba_3·$CHCl_3$, $AsPh_3$, THF, 71% *trans,Z,trans*-**51** + 20% *trans,E,trans*-**51**; ii, HF·pyridine, THF, 89%.



Scheme 16[34] *Reagents*: i, Bu^tMe_2SiCl, imidazole, DMF, 58%; ii, pyridine, triflic anhydride, CH_2Cl_2, 78% (*Z*:*E* > 99:1); iii, LiCl, $NiCl_2(PPh_3)_2$, THF, Bu_3SnH, 83% (*Z*:*E* = 94:6); iv, HF·pyridine, THF, 80% (*Z*:*E* = 96:4); v, Dess-Martin periodinane, CH_2Cl_2, 90% as a 95:5-mixture, recrystallized as a 98:2 *Z*:*E* mixture, 82%; vi, **60**, *n*BuLi, THF, *Z*-**59**, after repeated chromatographies 30% *Z*-**61** and 25% mixture of other isomers.

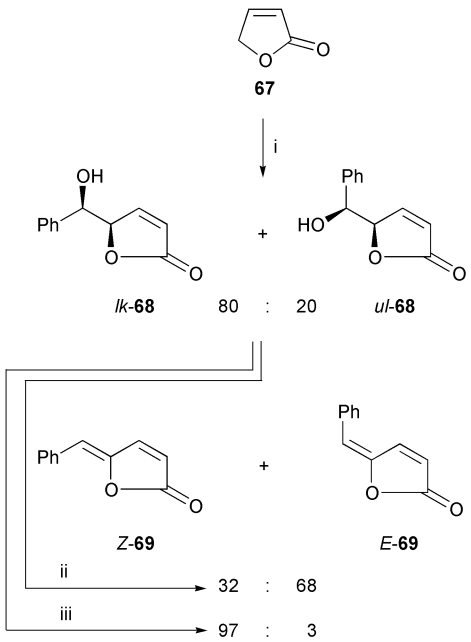
bond which could not be assigned by the spectroscopic study of the natural specimen[3] because of signal overlap with contaminating xerulin (*trans*,*Z*-**66**, Scheme 17). A conceptionally different synthesis of dihydroxerulin has since been elaborated by Rossi *et al*.[35] Initially, we sulfonylated the three OH groups of the O_{prim}-*tert*-butyldimethylsilyl protected L-gulonolactone **53** with triflic anhydride. The resulting tristriflate **54** underwent two *in situ* β-eliminations of triflic acid, the first elimination rendering butenolide **56**, the second leading to the isomerically pure alkylidenebutenolide *Z*-**55**. The enol triflate moiety of this compound was hydrogenolyzed readily to give lactone *Z*-**57** in the presence of catalytic $NiCl_2(PPh_3)_2$ and stoichiometric Bu_3SnH. A Wittig reaction of the derived aldehyde *Z*-**59** with



Scheme 17[36] *Reagents*: i, Na_2SO_3, $NaHSO_3$, MeOH, H_2O, crude product treated with MeOH–HCl, 92% overall (ref. 37: 64%); ii, triflic anhydride, pyridine, CH_2Cl_2, 63% (*Z*:*E* 97:3); iii, PPh_3, H_3C–CN, 100%; iv, K_2CO_3, **64**:*Z*-**65** 11:2, CH_2Cl_2, 28% *trans*,*Z*-**66** + 27% [*cis*,*Z*-**66** + small amount of isomer(s)].

the ylide corresponding to the phosphonium salt **60** followed but, unfortunately, exhibited no stereocontrol: it delivered 30% dihydroxerulin *Z*-**61** and 25% of at least two isomers. Yet, this synthesis encompasses only 2 × 5 consecutive steps in the linear sequences and a final converging step.

The first synthesis of xerulin (*trans*,*Z*-**66**) was also effected by our β-elimination strategy (Scheme 17).[36] We started with the diacetate of dibromolactone *lk*-**47** (preparation:[29,30] Scheme 13). A reductive elimination[37] established the $C^{\alpha}=C^{\beta}$ bond of butenolide *lk*-**62** and a subsequent base-promoted elimination the $C^{\alpha'}=C^{\gamma}$ bond of the γ-alkylidenebutenolide **63** (97% *Z*). An S_N2 reaction of this compound with triphenylphosphine provided the corresponding phosphonium salt **65** (96% *Z*). The terminating reaction of Scheme 17 was a Wittig olefination. It showed no more stereocontrol than the Wittig reaction of



Scheme 18[40] *Reagents*: i, LDA, THF, Ph–CH=O, 76%; ii, MsCl, pyridine, 0 °C → 80–90 °C, 87%; iii, same as (ii) but only rt, 96%.

opposite polarity used for synthesizing dihydroxerulin (*Z*-**61**; Scheme 16). Thus, it furnished equal, but separable, amounts of xerulin (*trans,Z*-**66**; 28% yield) and its isomer *cis,Z*-**66**. The recently published, differently tailored synthesis of xerulin by Negishi *et al*. is free from such a drawback.[38]

β-Eliminations from (Mukaiyama) aldol adducts

Aldol additions of type-**67** butenolides, *via* their quantitatively derived enolate (Schemes 18, 20) or *via* an equilibrium fraction of the same kind of enolate (Scheme 19), as well as the more widely used Mukaiyama aldol additions of the corresponding

% Yield **78**	70	95	94	90	92
% Yield **79**	90	91	94	96	92
E:*Z*	5:2	1:1	1:1	3:5	1:1

Scheme 21[43] *Reagents*: i, **76a**–**e**:**77** 1:1.2, $SnCl_4$, CH_2Cl_2, aqueous HCl; ii, Ac_2O, NEt_3, 4-pyrrolidinopyridine, CH_2Cl_2.

siloxyfurans (Schemes 21–25, 27–29) constitute versatile preparations of γ-(α-heteroalkyl)-substituted butenolides **1**. The addition of 5-lithio-2-(*tert*-butoxy)furans to an aldehyde followed by hydrolysis of the resulting heterocycle provides an altervative for attaining the same goal (Scheme 26).

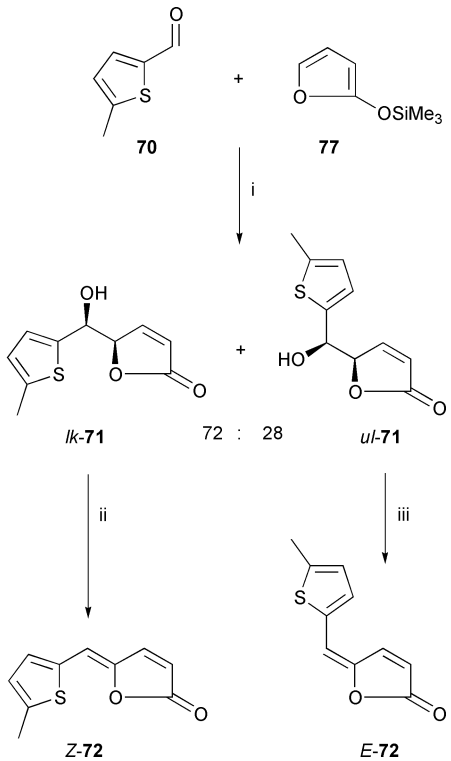
In general, a high degree of simple diastereoselectivity in such aldol additions is limited to the use of α-chiral aldehydes (where *lk*-selectivity of Mukaiyama aldol additions occurs[39]) whereas achiral aldehydes usually show little simple diastereoselectivity. Accordingly, the aldol additions shown in Schemes 18–21 provided the aldol addition products **68**, **71** (formed *in situ*, not isolated), **74** and **79** as *lk,ul-mixtures*. Not having separated them, the subsequent *stereoselective* formation of a γ-alkylidenebutenolide was observed in a single case (*lk*-/*ul*-**68** + mesyl chloride–pyridine → *Z*-**69**; Scheme 18) where thermodynamic control was achieved.

A somewhat related *Z*-preference occurred during the deketalization of the γ-alkylidenebutenolides *Z*- and *E*-**75** of Scheme 20: *Z*-**75** underwent this reaction with complete retention of configuration while *E*-**75** exhibited some *E*→*Z*-isomerization.

If the diastereomeric mixtures of (Mukaiyama) aldol addition products initially obtained are separated, the resulting *lk*-isomer, through an *anti*-elimination, gives a *Z*-configured alkylidenebutenolide and the *ul*-isomer, the *E*-alkylidenebutenolide. Thus, treatment of the thiophene-containing Mukaiyama products *lk*- and *ul*-**71** with Tf_2O and pyridine in dichloromethane provided the alkylidenebutenolides *Z*- and *E*-**72** as single isomers in 67 and 70% yield, respectively (Scheme 22). *Z*-**72** is a constituent of the roots of *Chamaemelum nobile* L.

The pyrrolidone-containing Mukaiyama product *lk*-**84** and an excess of both diethyl azodicarboxylate and PPh_3 gave the isomerically pure *Z*-configured alkylidenebutenolide pandamarilactam-3y *Z*-**85** (Scheme 23). It is noteworthy that the BF_3-promoted aldol addition leading to substrate *lk*-**84** was fairly diastereoselective starting from the (trimethylsiloxy)furan **81** (→ *lk*:*ul* = 88:12) and very diastereoselective starting from the (*tert*-butyldimethylsiloxy)furan **82** (→ *lk*:*ul* = 97:3).

The terminating elimination **88**→**89** in the synthesis of the γ-alkylidenebutenolide nostoclide II (*Z*-**89**, Scheme 24) was also



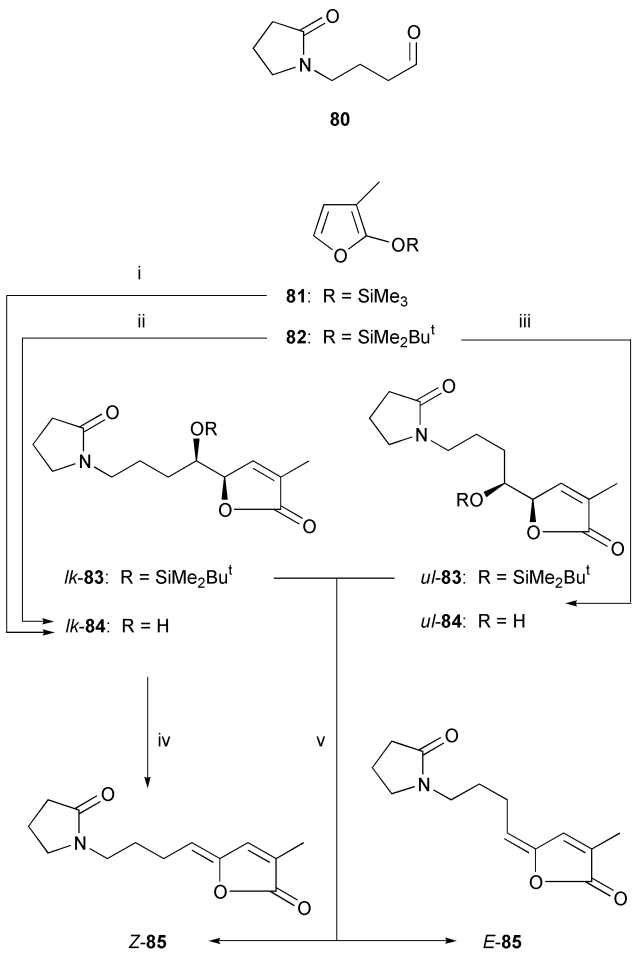
Scheme 22[44] *Reagents*: i, BF_3·OEt_2, aldehyde, CH_2Cl_2, 40%; ii, pyridine, CH_2Cl_2, triflic anhydride, 67%, *Z*-**72**:*E*-**72** 100:0; iii, same as (ii), 70%, *E*-**72**:*Z*-**72** > 99:1.

Z-selective, even when substrate **88** was a mixture (73 : 27) of *lk*- and *ul*-isomers. Probably, *E*-**89** is sterically too hindered to be formed under the reaction conditions (DBU, reflux temperature in chloroform).

Various (trimethylsiloxy)furans and β-iodomethacrolein (**90**) undergo Mukaiyama additions with much more diastereocontrol than simpler α,β-unsaturated aldehydes (*e.g.* crotonaldehyde, cinnamic aldehyde). In the presence of BF_3 etherate, (trimethylsiloxy)furans like compound **81** add to β-iodomethacrolein with > 99% *lk*-selectivity to furnish compounds like *lk*-**91**. Using $ZnBr_2$ as a promoter, the same reactants display an opposite 87 : 13 *ul*-preference. This also makes compound *ul*-**91** accessible as a single isomer (after chromatographic separation). Each of the aldol adducts *lk*- and *ul*-**91** was coupled with 3-ethynylfuran under Pd(0) catalysis (→ *lk*- and *ul*-**92**, respectively).

To our consternation, the *anti*-eliminations *lk*-**92** → *Z*-**93** and *ul*-**92** → *E*-**93** did not yield even trace amounts of product when tried with the elsewhere successful triflic anhydride–pyridine mixture. On the other hand, eliminations with excess diethyl azodicarboxylate–excess PPh_3[48] were high-yielding (94% *Z*-**93**, 87% *E*-**93**) and *anti*-selective. Thus, natural freelingyne (*Z*-**93**) resulted as a 92 : 8 *Z* : *E*- and the unnatural isomer *E*-**93** as a 98 : 2 *E* : *Z*-mixture. Two other stereoselective syntheses of freelingyne are known. They stem from Katsumura *et al.*[49] and Negishi and Liu[50] and are based upon the palladolactonization of a C≡C-containing carboxylic acid followed by a protonolysis of the resulting palladium–carbon bond.

The γ-alkylidenebutenolide syntheses compiled in Schemes 26–29 differ from those collected in Schemes 18–25 since now the $C^{\alpha'}$=C^{γ} bonds are formed through Brønsted (TsOH, HOAc/Δ) or Lewis acid (AgF) mediated β-eliminations. Using the Mukaiyama precursors as diastereomeric mixtures, only the E1-like elimination/fragmentation **96** → *Z*-**97** (Scheme 26) was selective. It furnished, through a subsequent benzoylation, melodorinol (*Z*-**99**).

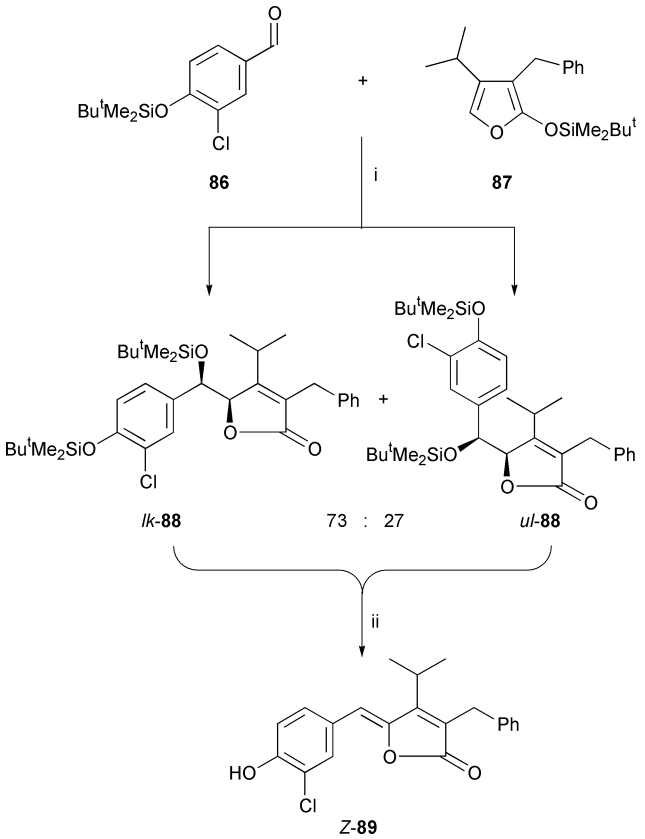


Scheme 23[45] *Reagents*: i, **80**, BF_3·OEt_2, 80% (*lk*-**84** : *ul*-**84** = 88 : 12); ii, **80**, BF_3·OEt_2, 48% **84** (*lk*-**84** : *ul*-**84** = 97 : 3) + 20% recovered **80**; iii, **80**, $Bu_4N^+F^-$ (10 mol%), Bu^tMe_2SiOTf, 37% **83** (*ul*-**83** : *lk*-**83** = 70 : 30) + 11% **84** (*ul*-**84** : *lk*-**84** = 70 : 30); iv, diethyl azodicarboxylate, PPh_3, 82%; v, DBU, 92% (*Z*-**85** : *E*-**85** = 90 : 10).

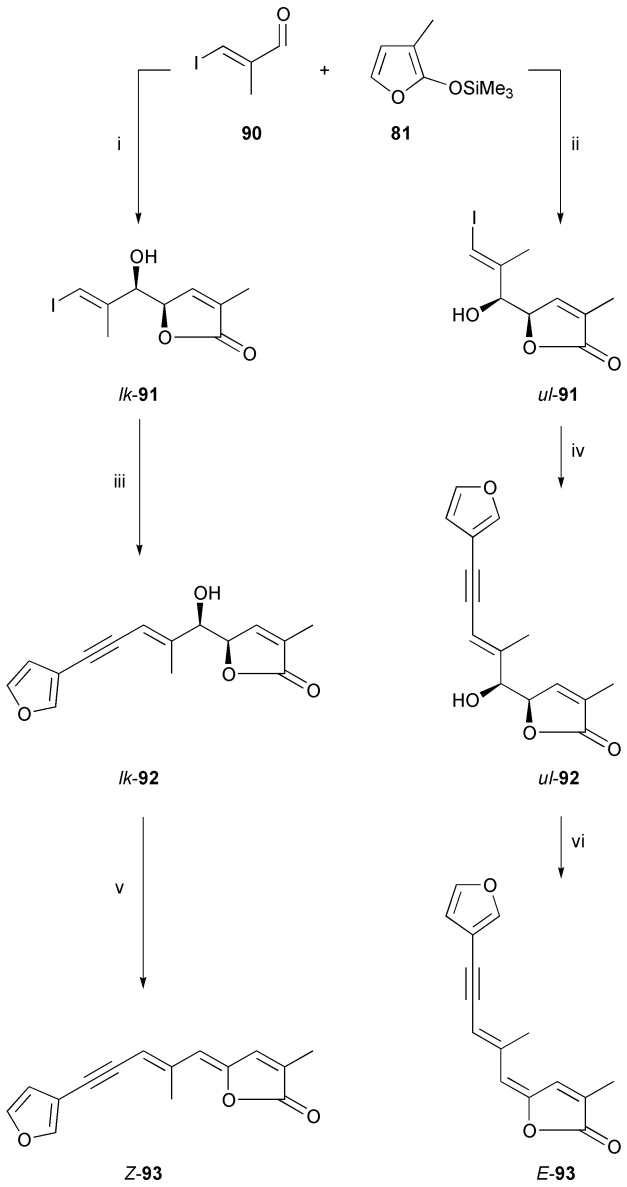
β-Elimination from a differently prepared γ-(α-hydroxyalkyl)butenolide

Our most recent approach to alkylidenebutenolides is presented in Scheme 30.[54] It is conceptually novel, remarkably stereoselective and, as far as the variablity of the substituents is concerned, potentially versatile. Therefore, it looks promising for an analogously shaped synthesis of peridinin (*Z*-**18a**). The latter is currently being pursued in these laboratories in collaboration with Professor de Lera (Universidade de Vigo, Spain). Peridinin plays a key role in the photosynthesis of marine algae.[6]

The starting point of Scheme 30 is the racemic trihalodiene **109**. So far, its 8-step synthesis[54] from the iodomethacrolein **90** is superior to potential short-cuts. Compound **109** was elaborated with a high degree of regio- and stereocontrol into the target butenolide **116**. First, it underwent a selective Suzuki coupling with the phenyl-substituted vinylboronic acid **110** at the less hindered C=C(–H)–I terminus—for steric and bond-energy reasons. Monocoupling product **111** was isolated in 56% yield. Under the same conditions, but using only 3% $Pd(PPh_3)_4$ rather than 5% as previously, compound **111** underwent a second Suzuki-coupling. Its reaction partner was now the ate-complex formed from the cyclohexyl-substituted vinylboronic acid **112** and aqueous NaOH. According to Roush *et al.*,[55] β-alkyl-*gem*-dibromoolefins undergo Suzuki couplings site-selectively with their *E*–C–Br bond. In agreement with that, we isolated the desired *Z*-configured monobromoolefin **113** in 79% yield. It was converted by Br/Li exchange into an organolithium compound. The latter was quenched by dropwise addition to an excess of neat ethyl chloroformate. This provided ethyl ester **114**. Upon exposure to HCl, the acetonide ring was cleaved and



Scheme 24[46] *Reagents*: i, Bu^tMe_2SiOTf (0.5 equiv.), CH_2Cl_2, 93% of the mixture; ii, DBU, $CHCl_3$; HCl, 96%.



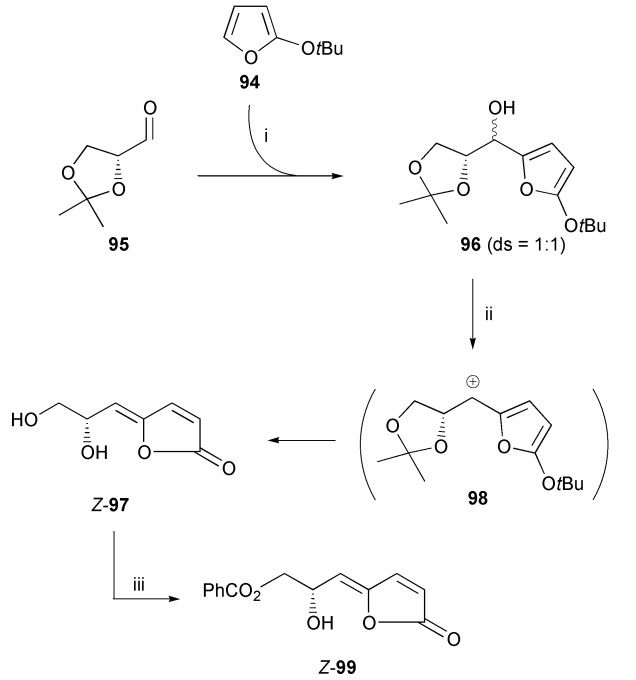
Scheme 25[47] *Reagents*: i, $BF_3{\cdot}OEt_2$–**90**–**81** 1 : 1 : 1, CH_2Cl_2, 56% (*lk*-**91** : *ul*-**91** > 99 : 1); ii, $ZnBr_2$–**90**–**81** 1 : 1 : 1, CH_2Cl_2, 61% (*ul*-**91** : *lk*-**91** = 87 : 13); iii, 3-ethynylfuran, $Pd(PPh_3)_4$, CuI, THF, iPr_2NEt, 70%; iv, same as (iii), 76%; v, diethyl azodicarboxylate, PPh_3, THF, 94% (*Z*-**93** : *E*-**93** = 92 : 8); vi, same as (v), 87% (*E*-**93** : *Z*-**93** = 98 : 2).

a spontaneous lactonization provided the γ-(α-hydroxyalkyl)-butenolide **115**. Its *anti*-selective dehydration was effected by treatment with excess PPh_3 and diethyl azodicarboxylate, *i.e.* by the established protocol of the dehydrations *lk*-**92** → free-lyngine (*Z*-**93**; Scheme 25) and *lk*-**84** → pandamarilactam-3y (*Z*-**85**, Scheme 23). In this way, we obtained butenolide **116** in 94% yield as a 95 : 5 *Z* : *E* mixture or, after recrystallization, in 90% yield as a pure isomer.

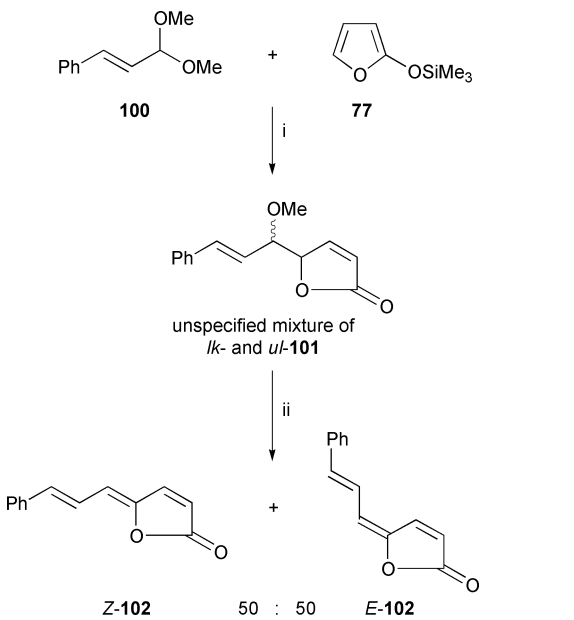
Other accesses to γ-alkylidenebutenolides

The best alternative to making *Z*-configured γ-alkylidenebutenolides by the β-elimination route of Scheme 1 is the metallocyclization/protonolysis strategy of Scheme 31. It has been pushed forward in recent years by the combined efforts of the Negishi, Rossi, and other groups.[31,32,35,38,49,50,56]

A reliable route to the less stable alkylidenebutenolides *E*-**119**, except the β-elimination route described, has yet to be developed. It seems conceivable, though, that the strategy of Scheme 32 could work. It represents a tandem metallocyclization/C,C-coupling approach and would start from pentenynoic acids **120** and unsaturated halides or triflates. While itself



Scheme 26[51] *Reagents*: i, Bu^{t}Li, **94**, THF, addition of **95**, 69%; ii, $TsOH{\cdot}H_2O$, THF, H_2O, 74%; iii, PhC(=O)CN, NEt_3, THF, 54%.



Scheme 27[52] *Reagents*: i, $TiCl_4$; ii, KOAc, HOAc, 80% over the two steps.

apparently unexplored, an analogous formation of *E*-configured γ-alkylidenebutanolides from pentynoic acids and aryl,[57] alkenyl,[58] or alkynyl halides (triflates) has been described.[59]

Palladium-catalysed isomerisation of vinyldisilanes to allyldisilanes

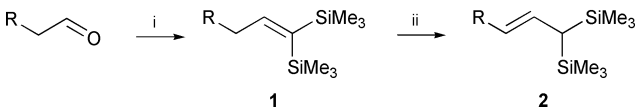
David M. Hodgson,* Sarah F. Barker, Laura H. Mace and Julian R. Moran

Dyson Perrins Laboratory, Department of Chemistry, University of Oxford, South Parks Road, Oxford, UK OX1 3QY. E-mail: david.hodgson@chem.ox.ac.uk

Received (in Liverpool, UK) 19th October 2000, Accepted 27th November 2000
First published as an Advance Article on the web 21st December 2000

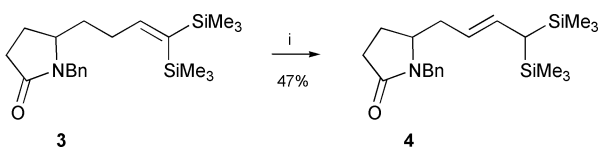
The isomerisation of vinyldisilanes 1 to allyldisilanes 2 catalysed by palladium-on-carbon in diethyl ether under hydrogen is described.

Three principle aspects of allylsilane chemistry have contributed to the tremendous utility of allylsilanes in organic synthesis.[1] Firstly, a variety of methods are available for preparing the allylsilane group with high regio- and stereocontrol.[2] Secondly, the allylsilane group is stable to many commonly used reagents, thus allowing the group to be carried through many synthetic sequences unchanged. Thirdly, is the ability of allylsilanes to act as allyl anion equivalents with a range of electrophiles (intramolecular C–C bond formation is particularly useful), generally with high and predictable stereo- and regio-control in the product alkene. Allyldisilanes **2** might be anticipated to possess broadly similar attributes to allylsilanes for use in synthesis. In contrast to allylsilanes however, allyldisilanes **2** are a relatively unexplored class of materials. A deterrent to investigating their chemistry is the lack of concise, general methods available for their preparation, particularly under mild conditions. Lautens and co-workers have developed a six step sequence to allyldisilanes from propargylic alcohols,[3] and Pornet *et al.* have reported a specific synthesis of the simplest allyldisilane [3,3-bis(trimethylsilyl)prop-1-ene] in two steps from 3-(trimethylsilyl)prop-1-yne.[4] The synthetic potential of allyldisilanes is indicated by observations from both Lautens and Pornet that disilylpropenes react with electrophiles (aldehydes and iminium ions) to give *trans*-vinylsilanes.



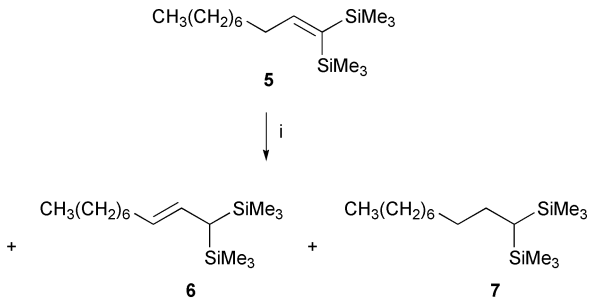
Scheme 1 *Reagents and conditions*: i, $Br_2C(SiMe_3)_2$, $CrCl_2$, DMF, 25 °C, 24 h; ii, see text.

We recently reported a one step highly chemoselective method for the preparation of vinyldisilanes **1** from aldehydes (Scheme 1).[5] During our investigations into the synthetic applications of vinyldisilanes,[5,6] we attempted debenzylation of lactam **3** using Pearlman's catalyst which, however, suprisingly generated the *trans*-allyldisilane **4** in an unoptimised 47% yield (Scheme 2). We communicate here our preliminary results concerning the development of this unusual isomerisation for the synthesis of allyldisilanes **2**.



Scheme 2 *Reagents and conditions*: i, 20% Pd)$OH)_2$/C, H_2 (1 atm.), AcOH, 25 °C, 12 h.

Double-bond migrations can occur during homogeneous or heterogeneous hydrogenation to an extent which is profoundly affected by the catalyst used (palladium catalysts being particularly active during heterogeneous hydrogenation),[7] but in many cases the process is not noticeable in the reduced product. Isomerisation of isolated olefins to allylsilanes has been reported under homogeneous catalysis by Matsuda and co-workers using cationic rhodium or iridium catalysts pre-activated with H_2.[8] Also, Mori *et al.* have recently reported the isomerisation of isolated olefins to allyl bis-metalated [$(SnR_3)_2$ and SnR_3/SiR'_3] compounds (formed as 1:1, *cis–trans* mixtures) using $RuClH(CO)(PPh_3)_3$.[9] However, application of Matsuda's conditions {using [Rh(norbornadiene)(dppb)]BF_4} or Mori's conditions to simple vinyldisilanes failed to generate any isomerisation and therefore our attention focused on the heterogeneous process. Initial experiments with Pearlman's catalyst under the original conditions using vinyldisilane **5** established that the presence of H_2 was essential for reaction to proceed, but that incomplete isomerisation was observed and reduction to the disilane **7** was a significant competing reaction (Scheme 3).



solvent	time	5 : 6 : 7
AcOH	4 h	18 : 61 : 21
hexane	2 h	0 : 24 : 76
CH_2Cl_2	3 h	3 : 88 : 9
Et_2O	2 h	6 : 87 : 7

Scheme 3 *Reagents and conditions*: i, 20% $Pd(OH)_2$/C, H_2 (1 atm.), solvent, 25 °C.

Although a number of different reaction variables with Pearlman's catalyst in acetic acid (and also 10% Pd/C in EtOH) were investigated for the isomerisation of vinyldisilane **5** to allyldisilane **6** (temperature, time, catalyst pre-activation, stirring and not stirring), the most notable variations were obtained by varying the solvent (Scheme 3), which is known to have a large influence on the extent of double bond migration.[7] For Pearlman's catalyst, hexane produced mainly reduction, whereas moving to DCM or ether resulted in a very encouraging ratio of isomerised to reduced material after 2–3 h (the proportion of reduced material increased at longer reaction times). Within the scope of the present study, 10% Pd/C in ether was found to give the best results (Table 1): complete conversion of vinyldisilane **5** to *trans*-allyldisilane **6** and (chromatographically inseparable) disilane **7** (94:6 respectively, 94% yield of allyldisilane **6**). These conditions also successfully isomerised other vinyldisilanes to allyldisilanes: **8** to **9** (88%) and **10** to **11** (91%), for which hydrogenated disilane was also observed at similarly low levels (6 and 7% respectively).

Reaction of vinyldisilane **5** using 10% Pd/C in ether under D_2 instead of H_2 gave allyldisilane **6** for which the ^1H NMR

$MeO_2C(CH_2)_3$, $SiMe_3$, $SiMe_3$ **8**	$MeO_2C(CH_2)_3$, $SiMe_3$, $SiMe_3$ **9**	88
$HO(CH_2)_4$, $SiMe_3$, $SiMe_3$ **10**	$HO(CH_2)_4$, $SiMe_3$, $SiMe_3$ **11**	91

[a] Hydrogenated disilane also observed (see text).

spectrum indicated that D had not been incorporated into either of the olefinic positions, but had been incorporated (51% by mass spectrometry) at the carbon atom bearing the two trimethylsilyl groups. One possible mechanistic sequence for the isomerisation consistent with this observation involves initial olefin coordination to palladium, followed by formation of a π-allylpalladium hydride which can undergo partial H/D exchange prior to hydride delivery selectively[3] to the more substituted end of the allylic system.

Density functional theory (DFT) calculations at the B3LYP/6-31+ G* level indicate that the vinyldisilane **1** (R = Et) is less stable than the allyldisilane **2** (R = Et) by 7.2 kJ mol^{-1} (a predicted ratio of 5:95 at 25 °C). The energy minimised structure for the vinyldisilane **1** (R = Et, Fig. 1) shows that the *cis* $SiMe_3$ group orients itself to minimize allylic strain (with the H of the allylic methylene that eclipses the double bond) at the expense of a 1,2-eclipsing interaction [Me–Si(*cis*)–C–Si(*trans*)]. In contrast, the *trans* $SiMe_3$ group has a relatively less demanding 1,3-allylic strain maximised (with the vinylic H) as this leads to the two $SiMe_3$ groups adopting a staggered arrangement of their Si–Me bonds with respect to each other. The 1,2-eclipsing interaction and allylic strain in vinyldisilane **1** (R = Et) could be the origin of its instability compared with the allyldisilane **2** (R = Et).

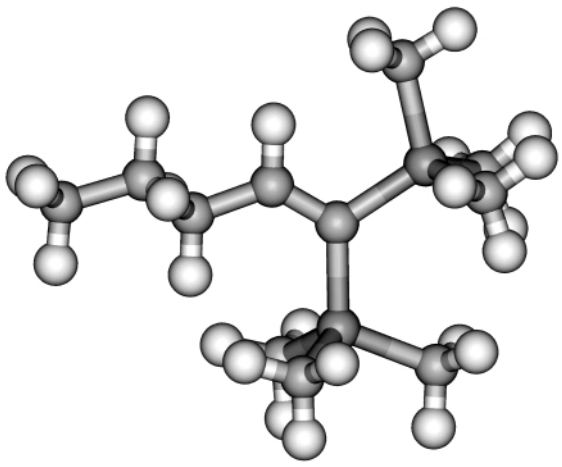

Fig. 1 The B3LYP/6-31+ G* optimised structure of vinyldisilane **1** (R = Et).

The energy minimised structure for the allyldisilane **2** (R = Et, Fig. 2) suggests that the presence of a $SiMe_3$ substitutent both above and below the plane of the double bond might retard (re)association with the catalyst and hence reduction; moreover, since the allylic H substituent [of $CH(SiMe_3)_2$] eclipses the C=C double bond it is now in an unfavourable orientation to reform the π-allylpalladium hydride suggested above.

As discussed earlier, Lautens and Pornet have shown that disilylpropenes undergo reactions with electrophiles. However,

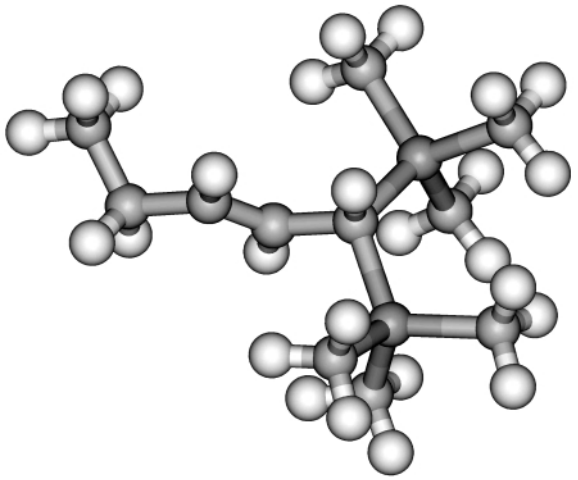

Fig. 2 The B3LYP/6-31+ G* optimised structure of allyldisilane **2** (R = Et).

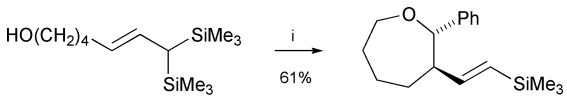
Lautens and co-workers also observed that higher 1,1-disilylalk-2-enes failed to undergo reaction with aldehydes using a range of Lewis acids.[3] Nevertheless, we have preliminary evidence that such allyldisilanes can undergo synthetically useful reactions. For example, following the conditions of Ito *et al*. for acetalisation–intramolecular allylsilane cyclisation[10] gave, with allyldisilane **11** and benzaldehyde the *trans*-2,3-disubstituted oxepane **12** ($J_{C(2)H\text{-}C(3)H}$ = 10 Hz)[10] possessing a *trans*-vinylsilane moiety ($J_{CH=CHSi}$ = 19 Hz) for further synthetic elaboration (Scheme 4).



11 **12**

Scheme 4 *Reagents and conditions*: i, PhCHO (1.4 equiv.), TMSOTf (2 equiv.), CH_2Cl_2, −78 °C, 3.5 h.

In summary, we have developed an experimentally straightforward method for the synthesis of allyldisilanes from vinyldisilanes; this allows access to allyldisilanes in two steps from aldehydes and should better allow the potential of allyldisilanes in organic synthesis to be realised.

We thank Dr G. H. Grant (University of Oxford) for performing the DFT calculations, Dr J. M. Goodman (University of Cambridge) for useful discussions and the EPSRC National Mass Spectrometry Service Centre for mass spectra.

Electronic effects in the thermal C^2–C^6 biradical cyclisation of enyne-allenes

Michael Schmittel* and Michael Maywald

FB 8 - OC1 (Chemie - Biologie), Universität GH Siegen, Adolf-Reichwein-Str., D-57068 Siegen, Germany. E-mail: schmittel@chemie.uni-siegen.de; Fax: +49-271-740-3270

Received (in Liverpool, UK) 19th September 2000, Accepted 29th November 2000
First published as an Advance Article on the web 4th January 2001

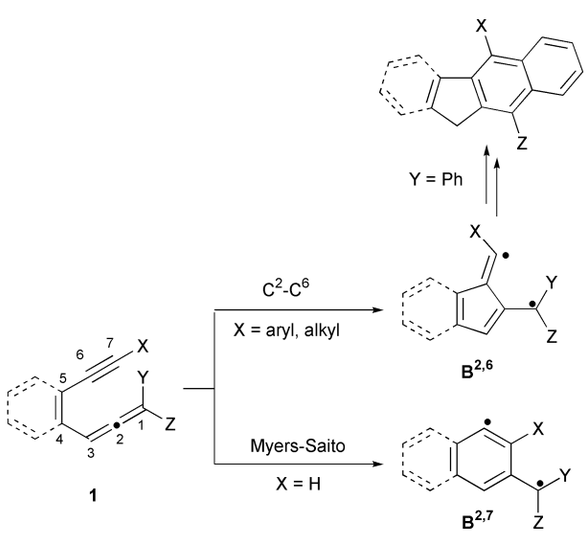
A comprehensive study on the influence of substituents at the alkyne terminus on the thermal biradical cyclisation of enyne-allenes shows a good agreement of the rates with $\sigma^{\cdot}$.

Although the cycloaromatisations of enediynes (Bergman)[1] and enyne-allenes (Myers–Saito)[2] play a fundamental role in the mode of action of the natural enediyne antitumor antibiotics[3] alternative thermal cyclisations with an altered regioselectivity have only been addressed recently. After the discovery of a novel cyclisation of enyne-allenes (C^2–C^6, see Scheme 1) in 1995,[4] this reaction has been studied extensively,[5] and ample evidence for the occurrence of the fulvene biradical **B**[2,6] has been collected through experimental[5f,6] and theoretical investigations.[7]

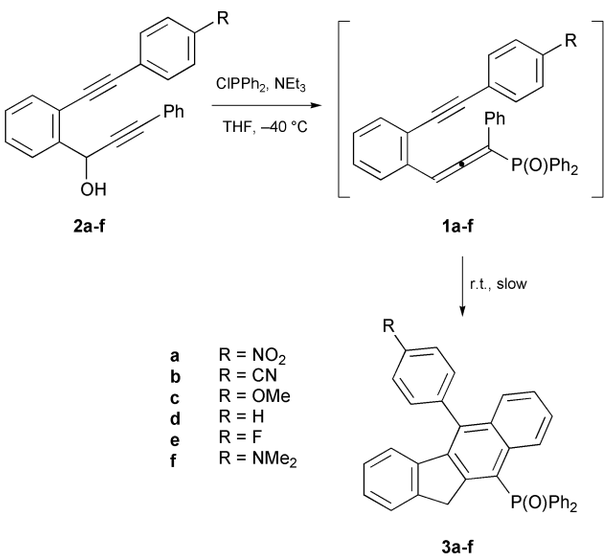
Moreover, the C^2–C^6 cyclisation has become a valuable synthetic tool for the construction of carbocyclic[8] and heterocyclic[9] ring systems as the intermediate biradical can undergo a second C–C bond formation followed by a formal 1,5-H shift to provide a convenient access to polyaromatic systems.

Engels *et al.*[7a] predicted on the basis of calculations that for **1** (Y,Z = H) the thermal C^2–C^6 cyclisation should be extremely accelerated with X = NH_2 in comparison to X = aryl, or ^{t}alkyl due to a special stabilisation of the biradical intermediate. In order to verify their prediction we decided to study the electronic effect of the substituent X in **1** on the thermal behaviour, which should also give some mechanistic insight in the polarity of the transition state. Herein, we describe the synthesis of the novel enyne-allenes **1a**–**f** and their kinetics.

The key step in the preparation of enyne-allenes **1a**–**f** is based on the rearrangement of the propargyl† alcohols[10] **2a**–**f** with $ClPPh_2$. (Scheme 2) Enyne-allenes **1a**–**f** were purified by low-temperature chromatography as far as possible, but their thermal instability precludes any elemental analysis. Some relevant IR and ^{1}H NMR data are presented in Table 1. Rapid cyclisation of **1f** even at rt prevented both isolation and a reliable kinetic analysis.



Scheme 1



Scheme 2 The reaction of **2a**–**f** with $ClPPh_2$, first at −40 °C and then at rt, leads directly to benzofluorenes **3a**–**f** (**3a**: 42%, **3b**: 47%, **3c**: 62%; **3d**: 68%, **3e**: 31%, **3f**: 45%).

Table 1 The IR (allene, alkyne) and ^{1}H NMR data of the desired enyne-allenes **1a**–**f**

	1a	**1b**	**1c**	**1d**	**1e**
IR (allene)/cm^{-1}	1924	1924	1923	1908	1924

^{1}H NMR/ppm[a]	6.75	6.26	6.78	6.80	6.83

[a] Allenic proton showing characteristic doublet with J = 10.1–10.7 Hz.

For the kinetic analysis the enyne-allenes were cooled and subjected to three DSC (differential scanning calorimetry) investigations. This method allows the recording of kinetic data over a range of temperatures in a single experiment.[11] To ensure that we monitor indeed the C^2–C^6 cyclisation, product studies were conducted for both preparative and DSC thermolyses. As rate constants determined at very low and very high temperatures proved to be unreliable, we resigned to make an Eyring analysis. Hence, only the cyclisation onset temperatures, reaction rates in the central temperature range (at 50, 60 and 70 °C) and $\Delta G^{\neq}_{60°C}$ are provided in Table 2. Data for enyne-allene **1g** was added for comparison.[12]

According to the data in Table 2 the lowest cyclisation temperature is found for enyne-allene **1f** with R = NMe_2, which unfortunately could not be isolated. The most stable representative is **1e** with R = F. Quite obviously the cyclisation rate constants do not follow a simple picture with electron-withdrawing substituents on one side, and electron-donating substituents on the other.

For a more detailed discussion we will concentrate on the rate constants at 60 °C that constitute the most reliable data due to the form of the DSC curves. In the above analysis we find a rate acceleration of 2.6 (at 60 °C) when going from R = F to NO_2.

DOI: 10.1039/b007811p

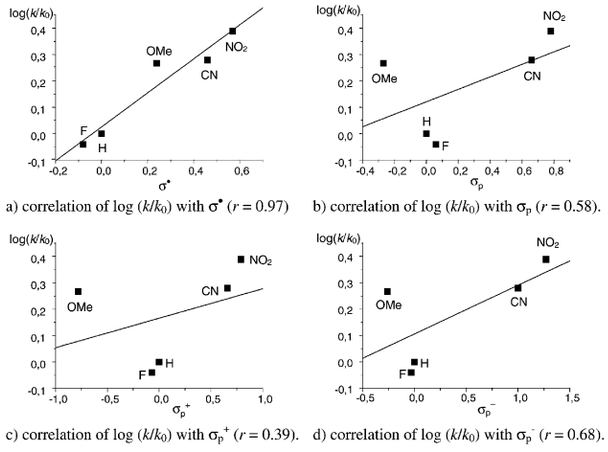
σ_p^+	0.79	0.66	−0.78	0	−0.07	−1.70	−0.31
σ_p^-	1.27	1.00	−0.26	0	−0.03	−0.12	−0.17

[a] Measured by DSC. [b] Onset temperature in the DSC. [c] Calculated from the correlation of the rate constants with $\sigma^{\cdot}$ (see Fig. 1a).



a) correlation of log (k/k_0) with $\sigma^{\bullet}$ (r = 0.97) b) correlation of log (k/k_0) with σ_p (r = 0.58).

c) correlation of log (k/k_0) with σ_p^+ (r = 0.39). d) correlation of log (k/k_0) with σ_p^- (r = 0.68).

Fig. 1 Correlation of the log (k/k_0)-values with the different substituent constants.[13]

Such accelerations are characteristic for radical reactions (2- up to 5-fold acceleration),[13] but much too low for reactions involving polar intermediates where the rates typically change over 2–7 orders of magnitude.

To further evaluate the data we correlated the log (k/k_H) values against the well-known substituent constants, $\sigma^{\cdot}$ (for radical reactions), and σ_p, σ_p^+ and σ_p^- (for polar reactions).[14]

The poor correlation with the polar substituent constants σ_p, σ_p^+ and σ_p^- (Fig. 1) clearly contradicts any polar intermediate in the thermal C^2–C^6 cyclisation, such as a zwitterion. On the contrary, a good correlation is obtained using $\sigma^{\cdot}$ values (reaction constant ρ = 0.643).[15] The latter correlation is strong support, together with earlier mechanistic evidence,[6] that the C^2–C^6 cyclisation is a biradical cyclisation. Moreover, it enables a good insight into the electronic structure of the transition state, as even *bona fide* radical reactions, but with a polar transition state, correlate with polar substituent constants, such as σ_p, σ_p^+ and σ_p^-.[13] Thence, the C^2–C^6 cyclisation of **1** proceeds *via* an extremely unpolar transition state (TS), in contrast to the Myers–Saito cyclisation, where the occurrence of unpolar and polar TS's is discussed.[16]

The reaction constant now allows us to predict the cyclisation rate and the free activation energy of **1f** and **1g** at various temperatures (Table 2). The higher rate constant for **1f** is in agreement with the fact that we have not been able to isolate it. The difference $\Delta\Delta G^{\neq 60°C}$ = −3.5 kJ mol^{-1} when going from R = H to R = NMe_2 is drastically smaller than predicted for **1** (no benzoannelation, Y,Z = H) upon changing from X = H to NH_2 ($\Delta\Delta G^{\neq 25°C}$ = −57 kJ mol^{-1}).[7a] Obviously, the substituent effect in our study is heavily attenuated because of the phenyl spacer between R and the alkynyl group.

In summary, the present study definitely rules out zwitterionic intermediates in the C^2–C^6 cyclisation and supports the biradical hypothesis. For the first time, a thermal biradical cyclisation was demonstrated to follow the radical substituent constant $\sigma^{\cdot}$. This finding is notable as calculations have as yet described the TS to contain no biradical character.[7]

We are indebted to the DFG, the Volkswagenstiftung and the Fonds der Chemischen Industrie for continued support. Additionally, we would like to thank Dr Kiau for providing the temperature onset for **1g**.

Highly stereoselective addition to alkoxy or hydroxy ketones using an α-stannyl ester–stannous chloride system in a chelation-controlled manner

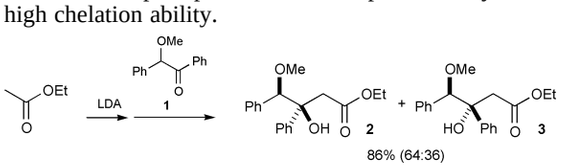
First published as an Advance Article on the web 4th January 2001

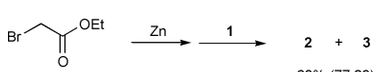
The reaction of an α-stannyl ester with α-alkoxy or hydroxy ketones in the presence of $SnCl_2$ gave aldol-type products with high selectivity in a chelation-controlled manner.

Stereoselective C–C bond formation is undoubtedly important for organic syntheses. Since the transition state of the reaction concerned demands a rigid structure for a selective reaction, chelation of a substrate bearing coordinative sites to a metal center often has a significant effect on the stereoselectivity. A number of selective reactions under chelation-controlled conditions have been reported for carbonyl addition by carbon nucleophiles.[1] Reetz has developed chelation-controlled aldol-type addition to α-alkoxy aldehydes using enol silane in the presence of Lewis acids.[2] However, chelation-controlled addition of a metal enolate or its equivalent to α-alkoxy ketones is scarcely known in spite of the fascinating structure of the products which would be tertiary alcohols bearing a stereocontrolled *O*-substituent. This is probably because the reaction conditions required to achieve the addition to ketones, which are much less reactive than aldehydes, would be too severe to control the selectivity. In this communication, we report a highly diastereoselective addition of an ester enolate equivalent to α-alkoxy or hydroxy ketones using an α-stannyl ester–stannous chloride system in a chelation-controlled manner.

In the initial trials, we obtained moderate selectivities of diastereomers **2** and **3** in the reactions of α-alkoxy ketone **1** with a lithium enolate[3] or zinc enolate equivalent[4] [eqns. (1) and (2)]. These results prompted us to develop a novel system having high chelation ability.



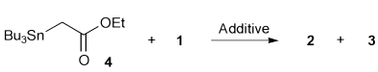
(1)



(2)

A stannyl nucleophile is often used for stereoselective organic synthesis.[5] Keck has reported chelation-controlled addition of allylic stannanes in the presence of $TiCl_4$.[6] We examined the reaction of α-stannyl ester **4** in the presence of metal halides, and the results are summarized in Table 1.

Table 1 Reaction of α-stannyl ester **4** with **1**[a]



Entry	Additive	Solvent	Conditions	Yield (%)	Ratio of **2**:**3**
1	$TiCl_4$	CH_2Cl_2	−78 °C → rt, 3 h	7	—
2	$BF_3{\cdot}OEt_2$	CH_2Cl_2	−78 °C → rt, 3 h	< 5	—
3	$SnCl_2$	CH_2Cl_2	rt, 3 h	40	> 99 : 1
4	$SnCl_2$	MeCN	rt, 3 h	86	> 99 : 1

[a] All reactions were carried out in solvent (1 mL) using **4** (1.2 mmol), alkoxy ketone **1** (1.0 mmol), and additive (1.2 mmol).

However, the use of $TiCl_4$ as an additive gave a complicated mixture with a small amount of the aldol-type product which was confirmed in a crude reaction mixture by NMR (entry 1). In the presence of $BF_3{\cdot}OEt_2$ almost no reaction took place and the starting ketone was recovered (entry 2). Recently, we have reported a carbonyl addition system using α-stannyl ester or tributylallylic stannane with $SnCl_2$ in which transmetallation occurs to generate an active species.[7] This activation methodology successfully attained the stereoselective reaction of **4** with **1** in the presence of $SnCl_2$ to give the product in 40% yield with excellent selectivity (entry 3). Changing the solvent from CH_2Cl_2 to MeCN improved the yield while retaining high selectivity (86% yield, > 99 : 1, entry 4).†

The relative configuration of the stereochemistry of **2** was unambiguously determined by its X-ray analysis and the ORTEP drawing is shown in Fig. 1.‡ It corresponds to the product which is formed by chelation-controlled alkylation.

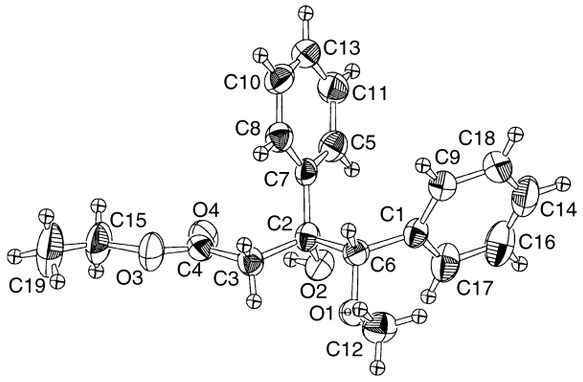


Fig. 1 Molecular structure of **2**.

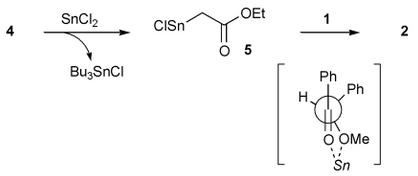
Although the reaction mechanism is now not clear, we assume that the active species is chlorinated stannous ester **5** which is generated by transmetallation between **4** and $SnCl_2$ (Scheme 1). The metal center has high Lewis acidity and thus high chelation ability to alkoxy ketone. The carbonyl addition proceeds *via* transition states which direct the selective addition by chelation. In fact, a transmetallation was confirmed by the following experiment. A mixture of α-stannyl ester **4** and $SnCl_2$ in MeCN at room temp. gave 71% yield of Bu_3SnCl which was confirmed by ^{119}Sn NMR. A lower yield (16%) of Bu_3SnCl was observed when CH_2Cl_2 was used as a solvent. This significant solvent effect on the transmetallation accounts for the difference in yields in entries 3 and 4 (Table 1). Unfortunately, the signal



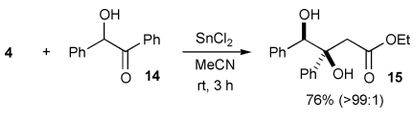
Scheme 1 Plausible path of chelation-controlled addition.

DOI: 10.1039/b008493j

corresponding to the generated nucleophilic tin(II) species was not detected probably because of its broadening in ^{119}Sn NMR.

Various alkoxy ketones were investigated and the results are shown in Table 2. The reaction with the α-ethoxy ketone **6** also gave the aldol product **7** in high selectivity and yield (entry 2). Even isopropoxy ketone **8**, which has a bulky substituent, was also subjected to this reaction system to afford **9** exclusively (entry 3). The reaction with 2-methoxypropiophenone **10** provided the selective aldol-reaction in >95:5 selectivity (entry 4). When the cyclic substrate **12** was used, **13** was selectively formed in a 92:8 ratio (entry 5). The relative configuration of the cyclic product **13** was determined by NOE experiment. The increased intensity at the carbonyl methylene protons was observed by irradiating the axial proton bonded to the methoxy-substituted carbon.

The chelation-controlled reaction using hydroxy carbonyl compounds without protection is a challenging problem because organometals for chelates are readily affected or quenched by the protic sites. Actually, the reaction with α-hydroxy ketone **14** performed under Reformatsky reaction conditions or using a lithium enolate according to the procedures employed in eqns. (1) or (2) did not effectively proceed and a significant amount of the starting ketone was recovered. Surprisingly, the stannyl ester–$SnCl_2$ system can provide high yield and high selectivity of **15** even with the use of hydroxy ketones **14** [eqn. (3)].[8] Other additives, $TiCl_4$ and $BF_3{\cdot}OEt_2$ for the reaction of **4** with **14** gave the recovered ketone **14** and low yields (9 and 26%) of **15**, respectively. The reaction with 2-hydroxypropiophenone **16** also gave the product **17** in high selectivity [eqn. (4)].[9] These results show the strong advantage of our system which tolerates protic conditions.

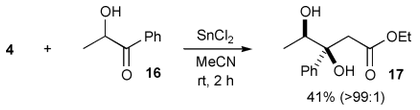


(3)

Table 2 Chelation-controlled reaction of α-stannyl ester **4** with alkoxy ketones in the presence of $SnCl_2$[a]

Entry	Alkoxy ketone	Product	Yield (%)	Dr
1			86	>99:1
2			87	>99:1
3			80	>99:1
4			31	>95:5
5			53	92:8

[a] All reactions were carried out in MeCN (1 mL) using **4** (1.2 mmol), alkoxy ketone (1.0 mmol), and $SnCl_2$ (1.2 mmol) at rt for 3 h.



(4)

In conclusion, we have shown a highly diastereoselective addition of an alkoxycarbonylmethyl group to α-alkoxy or hydroxy ketones, controlled by the chelation effect, using an α-stannyl ester–$SnCl_2$ system. The transmetallation between the α-stannyl ester and $SnCl_2$ generates an active species which has high Lewis acidity to form a chelate. Further investigation of the scope and limitations of the methodology, and the reaction mechanism is now under way.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture, of the Japanese Government.

9 The reaction was carried out using **4** (3.6 mmol), **16** (1.0 mmol), and $SnCl_2$ (3.0 mmol).

ChemComm

A molecular ‘hamburger’: bonded benzene in a bun

Douglas N. Butler,* Muhong Shang and Ronald N. Warrener

Centre for Molecular Architecture, Central Queensland University, Rockhampton, Queensland, 4702 Australia. E-mail: d.butler@cqu.edu.au

Received (in Cambridge, UK) 10th October 2000, Accepted 1st December 2000
First published as an Advance Article on the web 8th January 2001

The scaffold bis-succinimide 4 is shown to react twice with 1,2,4,5-tetrakis(bromomethyl)benzene 5 specifically at the *para*-related bromomethyl groups to form a multi-ring alicyclophane system 3 in which the benzene ring is sandwiched between the alicyclic frames to form a molecular ‘hamburger’.

In earlier work on proximity effects and structure–activity, one of us (DNB) demonstrated that the chemistry of an alkene π-bond could be completely negated by screening access to the π-system by suitably positioned benzene rings,[1] as in **1** where the alkene π-bond was situated in the valley between the two benzene rings. In this paper, we report another aspect of reactivity modification by proximity screening in which a benzene ring is positioned in the centre of a pair of extended alicyclic frames in a molecular equivalent of a hamburger, where the benzene ring corresponds to the ‘meat’ and the framework as the protective ‘bun’ (Fig. 1)†.

The synthesis of the molecular ‘hamburger’ **3** represents the second generation of our alicyclophanes[3] and draws on ideas expressed by Vögtle (aliphanes)[4] and the concept of stacked [2.2]cyclophanes (chochins) reported by Misumi[5] and Nakazaki[6]. By building a benzene ring into the alicyclophane and then attaching a second alicyclic spacer component onto the opposite face, it is possible to screen both sides of the benzene ring from reagent approach.‡

Reaction of the bis-succinimide **4**[3] with 1,2,4,5-tetrakis-(bromomethyl)benzene **5** in dimethylformamide containing solid potassium carbonate afforded a bromine free product having *m/z* = 1157.2590 (M + Na^+, calcd. 1157.2607) and thus confirming the 2:1-molecularity of the reaction. Comparisons of the N–N separation in **4** (AM1 6.30 Å) with the different bromomethyl C–C distances in **5** (AM1 C–C distances[8] are annotated on **5** in Scheme 1 and range from 2.91–5.77 Å) support preferential formation of the dual *para*-substituted product **3**§ since less deformation of the molecular frame is required to achieve cyclisation.¶ In order to gain evidence upon which to secure the ‘hamburger’ structure **3**, reactions were conducted between **4** and *o*-, *m*- and *p*-xylylene dibromides **6**–**8** as these subunits are each present in **5**. In all cases, reference to the N–N distances of starting scaffold **4** and product alicyclophanes **3**, **9**, **10** (see Table, Scheme 2) shows that significant frame deformation is required for cyclisation to occur, a feature

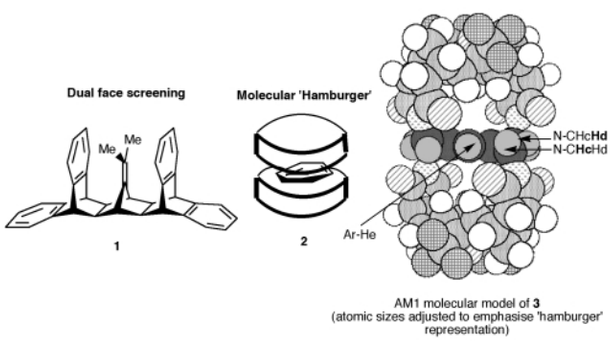

Fig. 1

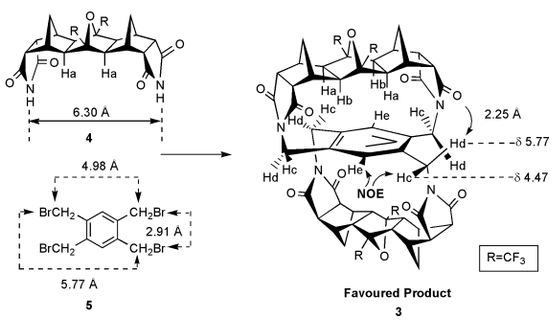
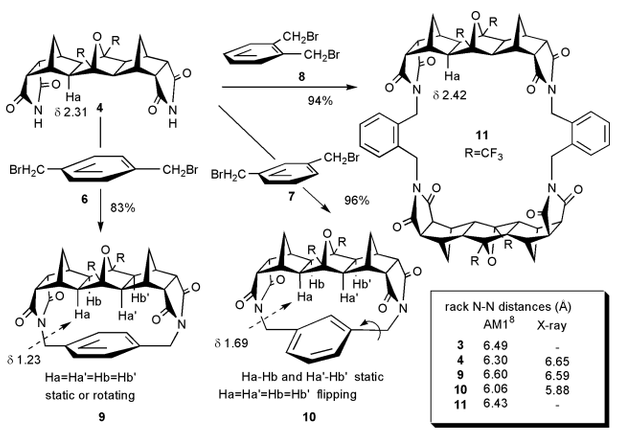


Scheme 1

somewhat surprising considering the expected rigidity in [*n*]polynorbornane frames comprised of fused norbornanes.‖

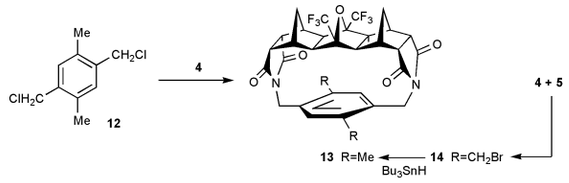
The product from bis-succinimide **4**** and *p*-xylylene dibromide **6** was assigned the alicyclophane structure **9**** on the basis of mass spectrometry (*m/z* 606.1591, calcd. 606.1589). Product **9**§ displayed ^1H and ^{13}C NMR spectra that reflected its *C*2*v*-symmetry. Similar reaction between *m*-xylylene dibromide **7** and spacer **4** produced an isomeric alicyclophane assigned structure **10**** (*m/z* = 606.1586). The ^1H NMR spectrum of **10** was also indicative of a compound with *C*2*v*-symmetry and was unchanged down to −70 °C supporting a facile ‘flipping’ motion of the *m*-phenylene bridge. By extrapolation, any *meta*,*meta*-linked structure for **3** is considered untenable since the N–CH_2 protons would not be diastereiotropic (as seen in **3**) owing to ring ‘flipping’. The reaction of *o*-xylylene dibromide **8** with **4** takes a different pathway and leads to production of a 2:2 product **11**§ (*m/z* 1212.3197, calcd. 1212.3179) resulting from dual intermolecular alkylation. Significantly, the *endo*-protons in **9** were more shielded than those in **10** and this offers further structural support for the *para*,*para*-structure of molecular ‘hamburger’ **3** in which the *endo*-protons occur at even higher field (δ 1.11, 1.21).

Conclusive chemical support for the structure of **3** was provided by the interrelation between alicyclophane **13**,§ prepared by the reaction of the dichlorodurene†† **12** with



Scheme 2

DOI: 10.1039/b008178g



Scheme 3

scaffold **4**, with the alicyclophane **14**§ which has been isolated as an intermediate in the preparation of 'hamburger' **3** (Scheme 3). This was achieved by debromination of **14** by treatment with tributyltin hydride. As the alicyclophane **13** must be *para*-linked (single aryl proton resonance at δ 7.51 is definitive), this shows that **13** has the same motif and the derived 'hamburger' **3** must be *para*,*para*-linked.

In order to assess the steric protection offered by the scaffold structures to reagent approach to the benzene ring in the 'hamburger' **3**, it was treated with hot nitric–sulfuric acid (1:1 v/v). No reaction occurred even at elevated temperatures however blank reactions, conducted on the alicyclophane **9**, produced a mono nitro derivative, while the related alicyclophane **10** produced a mixture of dinitro derivatives similar to that observed for *m*-xylene. This demonstrates that nitration will proceed on the benzene ring when only one face is screened by the scaffold, but that reaction is precluded by incorporation of the second scaffold-containing ring.

In conclusion, we have demonstrated that macrocycles can be produced by reaction of xylylene dibromides with the bis-succinimide **4** and that intramolecular cyclisation occurs to form alicyclophanes with *p*-xylylene dibromide **6** and *m*-xylylene dibromide **7**, whereas intermolecular reaction occurs linking two scaffold units when the shorter *o*-xylylene dibromide is employed. The double cyclisation of the bis-imide **4** with 1,2,4,5-tetrakis(bromomethyl)benzene produced the *para*,*para* substitution 'hamburger' product **3** in which the benzene ring is sandwiched between the alicyclic scaffolds, so much so that it resisted electrophilic substitution even under forcing conditions.

D. N. B. thanks the Centre for Molecular Architecture for a Research Fellowship 1998–2000, and the Central Queensland University merit grants scheme for partial funding. Dr Martin Johnston is thanked for his interest in the project and for conducting the NMR experiments. Dr Alan Lough (Chemistry, University of Toronto) is thanked for the X-ray structures** reported herein.

Notes and references

† Stoddart *et al*. have described[2] a catenated system in which the benzene ring is positioned centrally in a three-dimensional array. Their structure contains other aromatic rings which would make it difficult to conduct reactivity studies of the central aryl ring; further, it does not have the 'hamburger' appearance.

‡ We have recently shown that alicyclophanes containing an isobenzofuran subunit already display increased stability owing to the scaffold frame offering reagent approach control from one face.[7]

§ All new compounds gave appropriate high resolution mass spectra and consistent ^{1}H and ^{13}C NMR spectra.

¶ While there is literature precedent[2,9] for intramolecular cyclisation involving successive nucleophilic reactions at the benzylic bromide positions of 1,2,4,5-tetrakis(bromomethyl)benzene **5** occurring exclusively at the *para*-related sites, literature examples reveal that for more flexible bis-alkylating linkers, such as those forming bis-(crowns ethers), *ortho*- and *meta*-linked products are the preferred mode of cyclisation.[9] Indeed, our finding is one of the few examples in which *para*-linkage occurs and is a direct consequence of the compatibility of the N–N separation of the scaffold (6.30 Å) and the fixed positions of the benzylic carbons (5.77 Å), as mentioned in the text.

‖ The IUPAC name for norbornane is bicyclo[2.2.1]heptane.

Received (in Liverpool, UK) 27th September 2000, Accepted 13th November 2000
First published as an Advance Article on the web 4th January 2001

Quadruple hydrogen bonded fullerene dimer 8 with a very high dimerisation constant ($K_a \geqslant 1.0 \times 10^6$ M^{-1}) was synthesised and fully characterised.‡

Fullerenes have interesting properties that may be utilised in applications such as organic photovoltaic (PV) devices.[1] The bulk-heterojunction version of such cells especially has received much attention recently. In this type of device, a blend of an electron donor (for example a π-conjugated polymer) and an electron acceptor (for example a fullerene derivative) serves as the active PV layer.[2] Very recently, influencing the morphology of the bulk heterojunction layer by simply changing the spincoating solvent resulted in a substantial increase of the PV power conversion efficiency to a record value of 2.5%.[3] A more intimate mixing of the components most likely resulted in both a larger internal donor–acceptor interface area and increased percolation of at least one of the components. Charge carrier transport in the polymer phase was further improved on the nanoscopic scale due to enhanced polymer inter-chain interactions.

Another potential way to obtain desired bulk-heterojunction architectures is through supramolecular assembly of the constituents. Hydrogen bonding is particularly useful in the construction of supramolecular structures.[4] Strong non-covalent binding can be obtained using multiple hydrogen bond arrays, especially with Meijer's self-complementary 2-ureidopyrimidin-4-ones.[5] With this unit, ultra-strong non-covalent coupling can be achieved, reaching association constants of $> 10^8$ M^{-1}.[5c]

Here we report on the preparation of a [60]fullerene derivative bearing one 2-ureidopyrimidin-4-one moiety as the hydrogen bonding unit. This molecule serves as a model compound for supramolecular fullerene arrays based on multiple hydrogen bonding interactions.

The synthesis of target molecule **8** started from easily accessible 1,2-bis(hexyloxy)benzene.[6] Friedel–Crafts acylation yielded keto ester **1**,[7] which was transformed into the corresponding *p*-tosylhydrazone **2**. Subsequently, carboxylic acid **4** was prepared using the following one pot procedure:[8] first, heating the anion of **2** in the presence of [60]fullerene in *o*-dichlorobenzene (ODCB) at 80–90 °C gave fulleroid **3a**, together with methanofullerene **3b**, higher adducts and [60]fullerene. This crude mixture was photoisomerised quantitatively to a mixture of **3b**, higher adducts and [60]fullerene. Hydrolysis of this mixture yielded crude acid **4**, which was purified by column chromatography. The overall yield for the conversion of **2** into **4** was 36%. Carboxylic acid **4** was converted into the corresponding acid chloride **5**, after which reaction with sodium azide yielded the corresponding acyl azide **6**. Heating **6** in the presence of 6-methylisocytosine at 80 °C for 2 h afforded **8** in good yield.

Dimer **8** showed 29 signals for C_{60}-sp^2 carbons in ^{13}C NMR, in accordance with C_{2h} symmetry. The resonances at δ 172.8 (**a**), 156.5 (**b**) and 154.4 (**c**) are characteristic for the 2-ureidopyrimidin-4-one moiety.[5a] The signals at δ 80.6 and 52.4 are diagnostic for the cyclopropyl moiety.[8] The ^{1}H NMR spectrum recorded in $CDCl_3$ showed the typical resonances[5a] for the four dimer bonding hydrogen atoms of **8** at δ 11.81 (H_b) and δ 10.40 (H_c), a signal at δ 12.98 for the intramolecularly bonded H_a, and one at δ 5.75 for the vinylic proton H_d (Scheme 1). When the concentration of compound **8** was lowered to 1.0×10^{-5} mol l^{-1} no dissociation was observed, thus giving a lowest estimate of the dimerisation constant of 1×10^6 M^{-1}, in good agreement with the values obtained for other ureidopyrimidinone derivatives.[5a] To probe a possible influence of the fullerene core on the hydrogen bonding unit, equimolar amounts of dimer **8** and dimer **9** of *N*-butylaminocarbonyl-6-methylisocytosine (**9**)[5] were dissolved in $CDCl_3$. A statistical mixture of the possible dimers was obtained (Fig. 1) as was concluded from the integration of the absorptions of all protons

Table 1 Redox properties

Com.[a]	E^1_{red}[b]	E^2_{red}[b]	E_{1red}[c]	E^3_{red}[b]	E_{2red}[c]	E^4_{red}[b]
3b	−0.66	−1.04	—	−1.55	—	−2.00
4	−0.72	−1.09	—	−1.60	−1.80	−2.02
8	−0.68	−1.01	−1.15	−1.56	−1.84	−2.02
$\mathbf{C_{60}}$	−0.60	−1.09	—	−1.63	—	−2.07
9	—	—	−1.02	—	−1.60	—

[a] Experimental conditions: V: *vs.* Ag wire, GCE as the working electrode, Bu_4NPF_6 (0.1 M) as the supporting electrolyte, ODCB–MeCN (4 : 1) as the solvent, 100 mV s^{-1} scan rate. [b] Waves corresponding to the reduction processes of the C_{60} cage. [c] Waves corresponding to the reduction processes of the ureidopyrimidinone moiety.

$H_{a–d}$ in ^{1}H NMR. The most pronounced shift is observed for the resonance of H_c.

While **8** shows characteristic absorptions for a methanofullerene in UV-Vis, the FTIR-spectrum showed a peak pattern at 1695, 1658, 1586 and 1513 cm^{-1}, indicative of a pyrimidin-4(1*H*)-one dimer[9] and the typical fullerene absorption at 526 cm^{-1}. The MALDI-TOF spectrum of **8** featured a parent peak at m/z = 1217.8 for the monomer.

The redox behaviour of fullerene derivatives **3b**, **4, 8**, and that of **9**[5a] was determined by cyclic voltammetry (Table 1). The cyclic voltammogram of **3b** showed four reversible waves corresponding to reduction of the fullerene core, with values typical for methanofullerenes.[8] In the case of carboxylic acid **4** an additional wave was observed at −1.80 V, which was attributed to the reduction of the acid moiety. Finally, the cyclic voltammogram of **8** showed the similar four waves corresponding to reduction of the fullerene core as well as a weak wave at −1.84 V and a shoulder at −1.15 V. The latter two waves are related to the 2-ureidopyrimidin-4-one moiety as was confirmed upon comparison with **9**[5a] (−1.02 and −1.60 V).

In an exploratory experiment towards application in a PV device, the processability of dimer **8** was shown as follows: When filtered solutions of MDMO-PPV[10] and **8** [both 1.0 (m/v) % in chloroform] were mixed in a ratio of 1 : 4 and the mixture was subsequently spincoated on a glass substrate, an optical quality film was obtained.

Other supramolecularly interacting fullerene compounds have been reported recently.[11] The synthesis of **8**, however, represents the first example of a hydrogen bonded fullerene dimer. With both fullerene cages connected through the very strong quadruple hydrogen bonding motif, provided by the ureidopyrimidinone moiety, the application in supramolecular electronics is within reach. Non-covalent multifullerene arrays based on bis(ureidopyrimidinone) substituted fullerenes are currently under investigation.

These investigations were financially supported by the Dutch Ministries of EZ, O&W and VROM through the EET program (EETK97115) and by the Netherlands Organization for Energy and the Environment (NOVEM) through the NOZ-PV Program (146.120-008.3).

First published as an Advance Article on the web 4th January 2001

A C_{60}-dimer connected through a highly directional fourfold hydrogen bonding motif has been synthesized; photophysical measurements reveal a strong electronic coupling through the hydrogen bond edge.†

The design and synthesis of [60]fullerene dimers is currently attracting considerable attention.[1] Different strategies have been adapted for the construction of C_{60}-dimers: the net result is, however, that the two monomeric units are, in the resulting dimers, attached through diversified, covalent linkages.

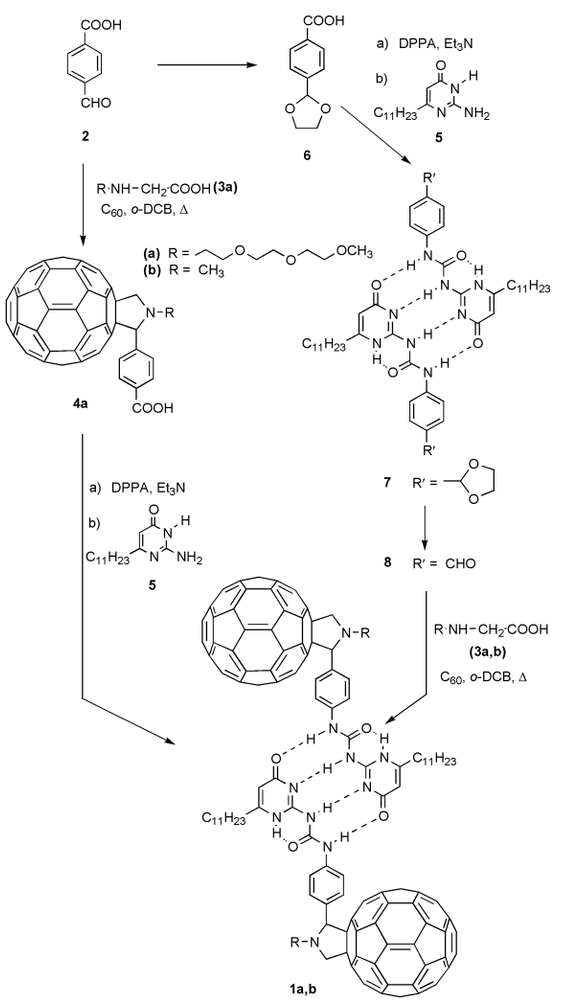
Sijbesma, Meijer *et al*. have reported the preparation of remarkably stable dimers ($K_s > 10^6$ M^{-1}) evolving from derivatives of the 2-ureido-4-pyrimidone moiety, *via* a self-complementary array of four hydrogen bonds.[2] The same strategy was afterwards employed for the synthesis of calix-[4]arene dimers.[3]

In this communication, we wish to report on the synthesis of the first, rigid noncovalent C_{60}-dimer system, in which both molecular subunits are linked by a self-complementary DDAA (donor–donor–acceptor–acceptor) array of hydrogen bonding.[4] The selected four-point hydrogen bond motif, based on a 2-ureido-4-pyrimidone moiety, guarantees the molecular recognition in solution and leads to a novel noncovalent constructed model system.

Two different routes, as summarized in Scheme 1, were pursued to synthesize dimers **1a**,**b**. In particular, *N*-substituted 2′,5′-dihydro-1′*H*-pyrrolofullerene **4a** was prepared from *p*-formylbenzoic acid (**2**) and *N*-(3,6,9-trioxadecyl)glycine (**3a**).[5] The polyether chain, located on the pyrrolidine ring, allows the sufficient solubility of compound **4a** in most organic solvents. In **4a**, the carboxy functionality was then transformed into the corresponding isocyanate by a Curtius rearrangement of the intermediate acyl azide generated with diphenylphosphoryl azide (DPPA).[6] Reaction with aminopyrimidone (**5**) afforded dimer **1a** in a 3% overall yield.‡ The poor yield for this three-step, one-pot process can be rationalized in terms of competitive reactions either of the azido group in DPPA or of the amino group in **5** with the C_{60} core of **4a**.

Performing first the C_{60}-based reaction with aldehyde dimer **8**, already containing the ureidopyrimidinone dimerization edge, successfully circumvented these interfering reactions. Accordingly, the reaction of acetal **6** with DPPA, followed by *in situ* reaction of the resulting isocyanate with aminopyrimidone **5**, afforded **7**. Subsequent deprotection of **7** with catalytic $HClO_4$ in 5 : 1 dioxane–$CHCl_3$ led to **8** in a 50% yield from **6**. Reaction of dimer **8** with C_{60} and *N*-substituted glycines **3a**,**b** under the same conditions used for the preparation of pyrrolidinofullerenes, gave the respective dimers (**1a**,**b**) in moderate yields (*ca.* 50%).

From the FTIR spectra characteristic evidence was derived for both subunits, namely, C_{60} and the heterocycle. It is worth mentioning that although a diastereomeric mixture should be formed, the ^{1}H-NMR spectra (500 MHz) show only the presence of a pure compound. Thus, the ^{1}H-NMR spectra of **1a**,**b** disclose the signals of the pyrrolidine protons at *ca*. 5.2 and 4.3 ppm (J = 9.6 Hz; geminal hydrogens) and a singlet at 5.1 ppm (CH), in good agreement with similar monoadducts. Large downfield shifts were found for the urea NH protons in compounds **1a**,**b**, at *ca.* 12.0 ppm, ($CDCl_3$). This observation is consistent with four DDAA hydrogen bonds in the noncovalent



Scheme 1

† See also the preceding paper in this issue: M. T. Rispens, L. Sánchez, J. Knol and J. C. Hummelen, *Chem. Commun.*, 2001, DOI: 10.1039/b008006n.

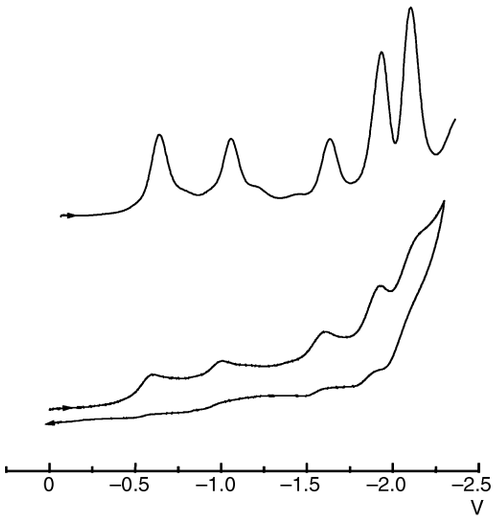


Fig. 1 Cyclic voltammogram and squarewave voltammogran (in V *vs* Ag/Ag^+) of compound **1a** in toluene : MeCN (4 : 1 *v*/*v*) solution containing 0.1 M *n*-Bu_4NClO_4 with glassy carbon; scan rate at 200 mVs^{-1}.

C_{60}-dimer system. In addition, the chelated NH at position 1 was observed at *ca.* 13.0 ppm.

The CV of dimers **1a**,**b** give rise to four reduction waves in deoxygenated CH_2Cl_2, while six reduction waves were found when a toluene–acetonitrile solvent mixture (4 : 1 v/v) was used (Fig. 1). As can be seen from an inspection of the parent C_{60} and related pyrrolidinofullerenes, the waves at −0.62, −1.01, −1.60, −2.08 V (in toluene–MeCN), and −0.69, −1.05, −1.61 V (in CH_2Cl_2) correlate to the one-electron reduction steps of the C_{60} moiety. These values are, nevertheless, cathodically shifted relative to those of C_{60}.[7]

However, it is important to point out that the voltammograms of dimers **1a**,**b** indicate that both fullerene moieties are reduced simultaneously. This observation, in conjunction with the above-listed spectroscopic characterization, supports the critical argument that there is little, if any, electronic interaction between the two C_{60} subunits in the dimers.

The remaining signals at −1.14 and −1.85 V (in toluene–MeCN) and −1.18 V (in CH_2Cl_2), are associated with redox processes of the heterocyclic ureido(oxo)pyrimidinyl addend.

The excited states properties of **1a** were studied by steady-state emission and time-resolved flash photolysis. Emission experiments, carried out with an excitation wavelength of 400 nm, gave rise to a distinctive solvent dependence. For instance, conditions that leave the hydrogen-bonded C_{60}-dimer intact (*i.e.* chlorobutane or CH_2Cl_2), led to an almost 50% quenching of the fullerene fluorescence around 710 nm relative to a 2′,5′-dihydro-1′H-pyrrolofullerene reference (see Table 1). This implies a markedly accelerated deactivation of the fullerene singlet excited state within the C_{60}-dimers and, hereby, resembling a trend established earlier for the most prominent fullerene dimer, namely, C_{120}.

Table 1 Fluorescence quantum yields[a] of **1a** in various solvents, a fulleropyrrolidine reference and C_{120} at room temperature

Compound solvent	Fluorescence quantum yields **1a**
Dichloromethane	3.05×10^{-4}
Chlorobutane/ethanol	3.3×10^{-4}
Chlorobutane/trifluoroethanol	3.65×10^{-4}
Chlorobutane/hexafluoroisopropanol	4.9×10^{-4}
Fulleropyrrolidine dichloromethane	6.0×10^{-4}
C_{120}[b] toluene	3.95×10^{-4}

[a] Measured at 710 nm. [b] See reference 8.

Upon adding protic solvents, such as ethanol, trifluoroethanol and hexafluoroisopropyl alcohol to a CH_2Cl_2 solution of **1a** a progressive enhancement of the fullerene fluorescence was observed. It should be noted that the solvents employed reveal different protic strengths and, therefore, different affinities to interfere in a disruptive manner with the hydrogen bonding along the following order: ethanol < trifluoroethanol < hexafluoroisopropyl alcohol. Importantly, in the most protic solvent (*i.e.* hexafluoroisopropyl alcohol), the emission quantum yield reached almost the value of a reference 2′,5′-dihydro-1′H- pyrrolofullerene. From this we may propose that under the experimental conditions probed the dissociation into monomer subunits is essentially complete. On the other hand, the quantum yield in the weakest protic solvent (*i.e.* ethanol) is close to the values determined in chlorobutane or CH_2Cl_2, suggesting a nearly dimeric appearance of **1a** under such conditions.

In conclusion, we have synthesized the first C_{60}-dimer linked *via* a highly directional fourfold hydrogen bonding motif. Electrochemical results indicate that there is no mutual interaction in the ground state between both C_{60} subunits. In contrast, the photophysical data, disclosing distinguishable differences between the monomer and the dimer, can be taken as first evidence for the strong electronic coupling mediated through the hydrogen bond edge.

Work is currently in progress directed to interface strong electron donor units with the C_{60} core through a self-complementary array of hydrogen bonds.

This work was supported by CICYT (projects PB93-0283 and PB98-0818) and in part by the Office of Basic Energy Sciences of the US Department of Energy. This is contribution NDRL-4280 of the Radiation Laboratory. This paper is dedicated to Professor José Barluenga on the occasion of his 60th birthday.

A tetraazaporphyrin (TAP) prepared by condensation of 1-ferrocenyl-1,2,2-tricyanoethylene in the presence of magnesium shows an intense, broad near-IR band in the 700–1300 nm region, which may be ascribed to charge-transfer transitions from the ferrocenyl moiety (substituents) to the TAP ligand.

Ferrocene (Fc)-modified porphyrins,[1] porphyrazines,[2] and phthalocyanines (Pcs)[3] have been reported over the past few decades. Although these compounds show characteristics ascribable to the Fc moiety such as the $Fe^{II/III}$ redox couple, their spectroscopic properties are generally similar to normal porphyrins and Pcs, except for a slight change in the shape or positions seen occasionally. In this regard, the TAP compound which we report here, *i.e.* 2,7,12,17-tetracyano-3,8,13,18-tetraferrocenyl-5,10,15,20-tetraazaporphyrinatomagnesium, **1**, is unusual in showing an intense, broad absorption band in the near-IR region (700–1300 nm), beyond the Q band. TAPs are structurally intermediate compounds between porphyrins and Pcs, and some porphyrins[4] and Pcs[5] are known to show near-IR absorption bands having much weaker intensity than the Q band, which can be assigned to either d–d transitions[6] in the central metal or charge-transfer (CT) transitions from the central metal to the ligands. Our compound **1**, on the other hand, has a broad, intense near-IR band, which may be assigned to charge-transfer from the iron in the substituent group to the TAP ligand, as described below.

Compound **1** was synthesized, in the presence of magnesium, by condensation of 1-ferrocenyl-1,2,2-tricyanoethylene, **2**, which was obtained from chloromercurioferrocene and tetracyanoethylene.[7] Fig. 1 shows the electronic absorption and magnetic circular dichroism (MCD) spectra of **1** and **2**. The starting material **2** showed two absorption peaks at 363 and 628 nm, while the TAP **1** had absorption maxima at 382, 623, and 962 nm. From the shape and intensity of the MCD band, the bands at 382 and 623 nm of **1** are assigned as the Soret and Q bands, respectively. The near-IR band can not be a π–π* transition in the TAP ligand, since the Q band corresponds to the HOMO–LUMO transition in the normal porphyrinic compounds. In addition, the possibility of this being a d–d transition is small because of the large absorption coefficient (ε = 13200 $dm^3\ mol^{-1}\ cm^{-1}$), which is a few orders of magnitude larger than normal d–d transitions ($0 < \varepsilon <$ *ca.* $10^2\ dm^3\ mol^{-1}\ cm^{-1}$; the d–d transition is a forbidden transition by the Laporte selection rule). The only feasible possibility appears to be CT transitions between the Fc moiety and the TAP ligand (the magnesium ion in the center of the TAP skeleton does not participate since it does not contain d electrons). However, since this kind of near-IR band has not been detected in Pcs and porphyrins having only a Fc moiety,[1,3] the presence of electron-withdrawing cyano groups in the close proximity may be of crucial importance. In accordance with this conjecture, the peak wavelength of the near-IR band changed from 962 nm in chloroform to 905 nm in ethanol and further to 888 nm in DMSO.

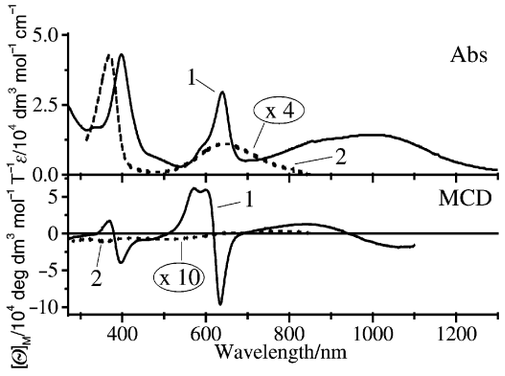

Fig. 1 Electronic absorption and MCD spectra of **1** (solid lines) and **2** (dotted lines) in chloroform.

In order to further gain some insight into the origin of the near-IR band, redox potentials of **1** and **2** were measured in *o*-dichlorobenzene, and the spectra of the electrolysed **1** have been recorded. Compound **2** showed one reversible oxidation peak at 0.38 V *vs.* Fc/Fc^+, which can be assigned to the $Fe^{II/III}$ couple, and one irreversible reduction peak at −1.35 V, which can be tentatively assigned to the formation of the tricyanovinyl-localized anion-radical.[8] The TAP **1** showed two reversible one-electron reduction processes at −0.84 and −1.28 V, and one reversible four-electron oxidation process at 0.06 V and one irreversible quasi one-electron oxidation process at 0.97 V. From the amount of the current and the position, the first oxidation is clearly assigned to the Fc moiety, *i.e.* $Fe^{II/III}$ and other couples are TAP-centered. Of course, an irreversible reduction peak tentatively assigned to the tricyanovinyl moiety in **2** disappeared in **1**, because the two cyano groups of the three cyano groups in **2** were used for the TAP core formation. The potential difference between the 1st oxidation and reduction potential of the TAP ligand (1.81 V) is much smaller than that of general tetraazaporphyrins (*ca.* 2.1–2.2 V)[9] due perhaps to the stabilization of the LUMOs by cyano groups. If the band in the near-IR region of **1** is associated with CT between the Fc moiety and the TAP ligand, the shape of this band should change significantly by electrolysis positive of the first oxidation potential. Accordingly, the solution of **1** was electrolysed at 0.21 V and the concomitant spectroscopic changes were monitored (ESI†). With the progress of electrolysis, the near-IR band faded away, the Soret band lost its intensity by one-third, and the Q band shifted to the red at 663 nm, in accord with the above expectations. From the linear relationship between the absorbance and concentration (Beer's law experiments, ESI†), the possibility of the near IR band being due to the aggregation can also be ruled out.

Furthermore, the molecular orbitals of the starting material **2** were calculated using the time-dependent DFT method, realized in the Gaussian 98W program (B3LYP functional and the SVP basis set).[10] The results of the first 10 lowest transitions are shown in Table 1. Transitions 1–3 and probably 5 correspond to a broad band between *ca.* 500 and 800 nm, and those 7–10 would be related to a strong band at *ca.* 350–400 nm. Taking into account that orbitals 76 (d_{yz}, E = −1.235 eV), 75

(LUMO+1, d_{xz}, −1.245), 73 (HOMO, d_{xy}, −6.486), 72 (d_{x2-y2}, −6.563), 71 ($a_1(\pi$, Fc, 47%) and d_{z2}(53%), −7.305), and 70 ($a_1(\pi$, Fc, 51%) and d_{z2}(43%), −7.459) are the iron ion or ferrocene-centered orbitals, while the orbital 74 (LUMO, −3.551) has 76% of its density on the tricyanovinyl fragment, the band to the longest wavelength between *ca.* 500 and 800 nm can be assigned to CT transitions from the filled iron ion orbitals in ferrocene to π* orbitals of the tricyanovinyl group. Unfortunately, similar calculations on **1** could not be performed, because the molecule was too large. However, considering that the Mössbauer parameters of **1** (isomer shift δ = 0.68 mm s^{-1}, quadrupole splitting ΔE_Q = 2.31 mm s^{-1}) and **2** (δ = 0.68, ΔE_Q = 2.06) are similar, and accordingly that the state of the iron ion in the two compounds is similar, the near-IR band of **1** may also be assigned as CT transitions between the Fc moiety and the TAP ligand with electron-withdrawing cyano groups[11] (*i.e.* the above CT transitions in **2** may correspond to the CT transitions from the iron ion in the Fc toward the nitrile groups in the TAP ligand of **1**). Thus, although the CT bands reported so-far on porphyrins and phthalocyanines have always been between the central metal and the ligands,[4,5] compound **1** appears to be the first porphyrin or phthalocyanine which shows a CT band from the metal in the substituent to the parent ligand.

11 Pcs with directly linked Fc units do not show near-IR bands beyond the Q band.[3a] Accordingly, this suggests that the near-IR band in **1** would not be observed unless cyano groups are not present in the periphery of **1**.

Thermal reactivities of isostructural d^{10} metalloenediynes: metal-dependent Bergman cyclization†

Isostructural d^{10} metalloenediynes of Cu(I), Pd(0) and Ag(I) exhibit metal-dependent variations in their thermal Bergman cyclization temperatures which correlate with differences in their alkyne termini separations.

The intriguing chemical reactivities and antitumor properties of the enediyne antibiotics[1] have generated considerable interest in controlling thermal Bergman cyclization reactions with simple synthetic motifs. Within this theme, structure/activity relationships for organic enediynes have documented the importance of the alkyne termini separation (*d*) as well as molecular strain in the ground and transition states.[2–5]

Recent work documenting that metal ions can greatly influence the conformation of the enediyne linkage thereby modulating the thermal reactivity of the resulting complex[6–8] broke ground for metal geometry control of Bergman cyclization reactions. It has now been shown that Bergman cyclization temperatures of metalloenediyne complexes of a given metal and enediyne ligand can be reduced by > 80 °C by variations in metal center geometry from tetrahedral to planar or tetragonal.[6,9–11] However, the influence of different metal ions on the Bergman cyclization temperature for a specific enediyne ligand within a well defined metal complex geometry has not been systematically evaluated. To this end, we report the X-ray structures and thermal reactivities of two homoleptic d^{10} metalloenediyne complexes [Cu(I) and Ag(I)] of 1,2-bis(diphenylphosphinoethynyl)benzene (dppeb, **1**). In conjunction with the Pd(dppeb)$_2$ analog **2**,[9] these complexes comprise a unique isoelectronic and isostructural set which exhibit significant differences in alkyne termini separation and consequently Bergman cyclization temperatures.

The Cu(I)‡ and Ag(I)§ metalloenediyne complexes were prepared by reacting 2 equivalents of **1** with the appropriate monovalent metal salt under N_2 to generate the $[M(dppeb)_2]^+$ d^{10} metalloenediyne cation.

Complexes **3** and **4** were isolated and purified by recrystallization from CH_2Cl_2–diethyl ether and MeCN–H_2O, respectively, as well as characterized in solution by NMR (^{1}H, ^{13}C) and mass spectrometry.

The X-ray crystal structures¶ of the cations of **3** (Fig. 1) and **4** (Fig. 2) reveal the isostructural identities of these complexes with respect to **2**.[9] Both d^{10} metal centers have local tetrahedral geometries with nearly idealized P–M–P angles (**3**: 107°, **4**: 108°). The tetrahedral geometries of these species promote a decrease in the alkyne termini separation *d*, relative to the free ligand but force an increase in *d* relative to square planar or tetragonal geometries.[10,11] For **2**–**4**, the average alkyne termini separation increases by 0.19 Å along the series Cu(I) (3.44 Å) < Pd(0) (3.47 Å) < Ag(I) (3.62 Å). For **2** and **3**, the differences in *d* are statistically insignificant. The average M–P bond lengths also increase from Cu(I) (2.33 Å) ≈ Pd(0) (2.33 Å) < Ag(I) (2.52 Å), reflecting contributions from both variations in atomic radii as well as metal–ligand covalency. Both structures exhibit bent alkyne units due to distortion of the enediyne unit induced by metal chelation. For **3**, the P–C≡C and C≡C–C angles are 166 and 170°, respectively, while for **4**, the same angles are 165 and 173°. The dppeb ligands in both complexes are also planar which minimizes out-of-plane structural contributions to the thermal reactivities of the complexes.

Off-resonance (λ = 785 nm) Raman spectra of **1**–**4** as a neat oil (for **1**) or solid states have been obtained in order to assess electronic contributions to the geometric structures which may influence thermal Bergman cyclization reactivities. The spectra (**1**, **3** in Fig. 3) are comprised primarily of alkyne (2150–2170 cm^{-1}), as well as phenyl ring and 1,2-disubstituted benzene group frequencies (500–1600 cm^{-1}).[12] The spectra of the metal complexes **2**–**4** are remarkably similar, indicating that with exception of the alkyne stretch, all of the ligand normal modes are relatively isolated from the effects of metal ion coordination. To this end, $\nu_{C\equiv C}$ for **1** (2160 cm^{-1}) is nearly degenerate with the average alkyne stretch for **3** (2168, 2155 cm^{-1}) and **4** (2165,

DOI: 10.1039/b008337m

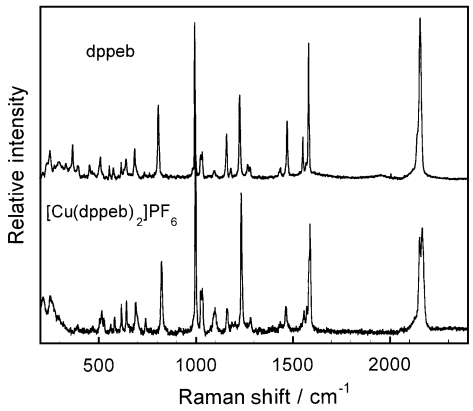

Fig. 3 Off-resonance Raman spectra of neat samples of dppeb **1** and $[Cu(dppeb)_2]PF_6$ **3** obtained with 1 mW at λ = 785 nm.

2153 cm^{-1}) which are comprised of two anisotropic vibrational components within the solid state. For **2** however, these values are shifted to lower energy by an average of 9 cm^{-1} (2155, 2149 cm^{-1}) indicative of only very modest back-donation from Pd(0) to the alkyne π-system through the empty p- and d-orbitals of the phosphine. This electronic contribution is not significant and likely does not strongly influence enediyne reactivity.

The Bergman cyclization temperatures for **2**–**4** have been determined by DSC in the solid state (Table 1) and show the following dependence on metal ion: Cu(I) (227 °C) ≈ Pd(0) (222 °C) < Ag(I) (266 °C). The DSC temperatures correspond to formation of the Bergman cyclized 1,4-phenyl diradical intermediate and rapid reaction to generate intractable black product complexes in the solid state. Unlike thermal cyclization reactions in the presence of H-atom donor in solution, the absence of a large excess of H-atom donor in the solid-state reaction inhibits quenching of the intermediate to specifically trap the disubstituted benzene product. In the absence of H-atom donor, we and others[13] have observed formation of black, insoluble polymeric products for various enediyne thermal cyclization reactions.

Table 1 Bergman cyclization temperatures of d^{10} metalloenediynes

Compound	Cyclization temperature/°C	Alkyne termini separation/Å
2	222[a]	3.47
3	227	3.44
4	266	3.62

[a] This value was originally reported as an onset temperature (209 °C).[9]

The Bergman cyclization temperatures directly correlate with the increased alkyne termini separation between **2** and **3**, and **4**. The 44 °C variation in the cyclization temperatures reflects the intimate relationship between the geometric structure of the metalloenediyne and the Bergman cyclization temperature of the resulting complex. Unlike previous examples of diverse structural variations in either metalloenediyne composition and/or geometry which strongly influence Bergman cyclization temperatures, in this case subtle variations in M–P bonding can introduce significant increases in *d* and consequently the thermal stabilities of the complexes. These results systematically reveal the prominent role that metal ions can play in affecting Bergman cyclization of the enediyne ligands and the intimate contribution that the specific metal ion has in modulating the reactivities of these metalloenediynes.

Received (in Cambridge, UK) 2nd October 2000, Accepted 11th December 2000
First published as an Advance Article on the web 4th January 2001

Dimeric aggregates are formed by the assembly of two tripodal moieties which are held together, both in solution and in the solid state, by a belt of 6 hydrogen-bonded urea functions.

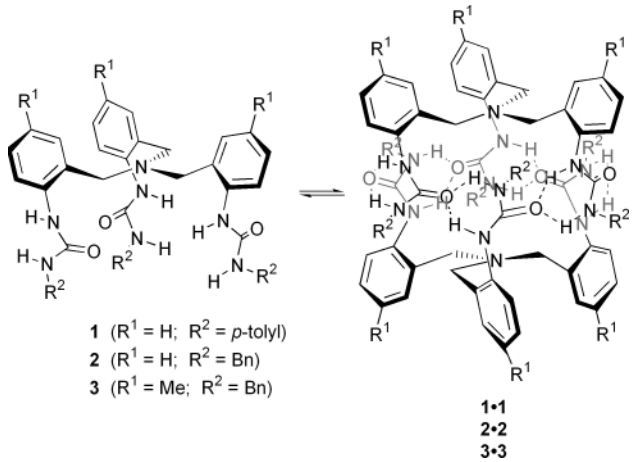
When two or more identical subunits are geometrically and functionally complementary, they may self-assemble to form a super molecule.[1] Urea or thiourea functionalities are excellent candidates to construct molecules that self-assemble by hydrogen-bonding not only in the solid state but are able to persist in solution.[2] Rebek[3] and Böhmer[4] have independently established that calix[4]arenes containing four urea functions at the upper rim form dimers by interdigitation of the all eight ureas in a head-to-tail directional array of 16 hydrogen bonds. Mendoza and coworkers have described dimeric capsules derived from tris(ureido)calix[6]arenes.[5] Herein we report a novel type of self-assembled dimeric aggregate derived from tris(*o*-ureidobenzyl)amines which resemble the structure of ureidocalixarenes.

The tris(ureas) **1**–**3**[6] shown in Scheme 1, easily available[7] from previously reported tris(*o*-azidobenzyl)amines,[8] showed dramatic differences in their ^{1}H NMR spectra when recorded in $CDCl_3$ or DMSO-d_6. While the spectra of **1**–**3** in DMSO-d_6 displayed the expected patterns consistent with averaged C_{3v} symmetries (Fig. 1a), by changing the solvent to $CDCl_3$ a new set of signals corresponding to a dimer (see below) emerged in each case. The ratio in which both species, monomer and dimer, were present in $CDCl_3$ depended on the substituent R^2 to a great extent. Thus, while for the tris(urea) **1** (R^2 = *p*-tolyl) only the signals attributed to the dimer were apparent, for the tris(ureas) **2** and **3** (R^2 = Bn) their spectra were interpreted as corresponding to equilibrium mixtures of both compounds (Fig. 1b).

The dimeric species featured two well separated doublets assigned to the diastereotopic methylenic protons of the $(ArCH_2)_3N$ fragment (J_{gem} = 14.5–15.7 Hz), instead of the singlet observed for the same nuclei in DMSO-d_6. In the dimers emerging from **2** and **3** the ABX systems formed by the three protons of the –CH_2NH– fragments were clearly evident. The signals assigned to the NH protons of the dimers (near 6.0 and 7.6 ppm, in **2·2** and **3·3**) appeared significantly sharp and shifted to lower field when compared to those attributed to the monomers (near 5.2 and 6.3 ppm). The involvement of the urea carbonyl groups as hydrogen bonding acceptors is supported by the δ value of their carbon atoms in the ^{13}C NMR spectra, which were shifted to downfield in $CDCl_3$ ($\Delta\delta$ = 2.8–3.2 ppm). FT-IR of $CHCl_3$ solutions of **1** (13.7 mM) and **2** (16.4 mM) revealed typical hydrogen-bonded NH-stretching bands[9] at 3317–3327 cm^{-1}.

All those data revealed that the dimers **1·1**, **2·2** and **3·3** should possess a highly ordered, hydrogen-bonded structure. Further indication of the existence of **1·1** and **3·3** in solution came from ESI-MS experiments. This technique was used in virtue of its gentle ionization and has been reported to reflect, at least qualitatively, solution phenomena.[10] The spectra in $CHCl_3$ showed the molecular ions of the protonated dimers **1·1** (1463) and **3·3** (1547).

Thus, monomers and their dimeric aggregates coexist in equilibrium in $CDCl_3$. Preliminary calculations of the dimerization constant of **1** by ^{1}H NMR experiments at three concentrations (in the range 1–10 mM in $CDCl_3$) following known equations[11] showed values (82518, 83832 and 84755 M^{-1}) which are comparable within the experimental error margin.



Scheme 1

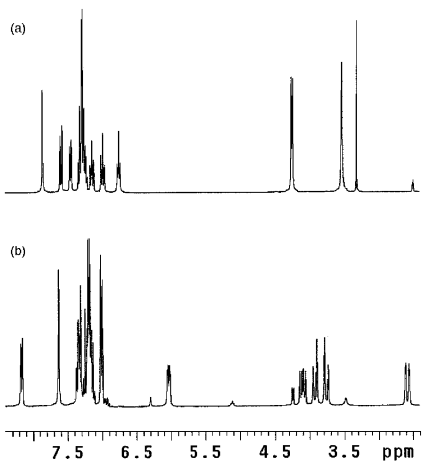


Fig. 1 (a) ^{1}H NMR spectrum (300 MHz) of the tris(urea) **2** in DMSO-d_6 (the singlet at 3.39 ppm is H_2O from the solvent), (b) ^{1}H NMR spectrum measured in $CDCl_3$ showing a mixture of **2** and **2·2**.

† Electronic supplementary information (ESI) available: ^{1}H NMR spectra. See http://www.rsc.org/suppdata/cc/b0/b007955n/

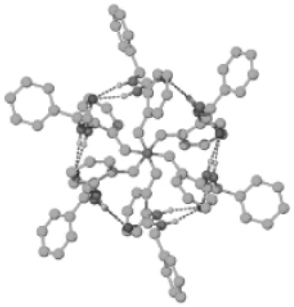

Fig. 2 A perspective view of the molecular structure **2·2**, as projected along the pseudothreefold axis containing the two pivotal nitrogen atoms.

Since DMSO-d_6 is able to disrupt the intermolecular hydrogen bonds, only the monomeric species could be observed in this solvent. The thermodynamic stability of the dimeric aggregate **1·1** proved to be higher than **2·2** and **3·3**. The dimer **1·1** is virtually the only species observed (⩾98%) in a 30 mM $CDCl_3$ solution of **1**. In contrast, the ^{1}H NMR spectra of **2·2** and **3·3** in $CDCl_3$ solutions of the same concentration displayed considerable amounts of their respective monomers (15–20%). These dimerization equilibria were concentration dependent, and could be shifted toward the monomer by decreasing the concentration. These equilibria could be also totally shifted to the monomeric tris(urea) by adding DMSO-d_6 (40%) to the $CDCl_3$ solution. Finally, the composition of a mixture of **2** and **2·2** was found to be temperature dependent; an increase in the temperature shifted the equilibrium toward the monomer. Thus, the 85:15 ratio of **2·2** to **2** measured at 296 K decreased to 72:28 at 323 K (38 mM in $CDCl_3$).

A single crystal X-ray structure[12] of **2·2** confirmed unambiguously the existence of the hydrogen-bonded dimers in the solid state, and provided an exact description of their geometry (Fig. 2). The dimer is composed of two enantiomeric units entangled *via* their urea residues, which form a belt of 12 hydrogen bonds with N···O distances ranging from 2.897(4) to 3.024(4) Å. The dimeric core is of approximate S_6 symmetry, although this is broken by the pendant phenyl substituents. The centre of the capsule is empty and is too small to contain any guest species, however extensive disordered solvent exists in external pockets formed by the aryl groups of the dimer. On the basis of the NMR data ($CDCl_3$) we believe that the conformation shown by the solid state structure of **2·2** is retained in solution.

The formation of heterodimers by the combination of two homodimeric species is a well-known phenomenon in ureidocalixarenes.[3,4] In our case, a mixture of equimolecular amounts of the dimers **1·1** and **2·2** in $CDCl_3$ did not show the formation of heterodimers. However, the ^{1}H NMR spectrum of an equimolecular mixture of **2·2** and **3·3** revealed the appearance of signals attributable to the heterodimer **2·3**, besides those of homodimers **2·2** and **3·3** and monomers **2** and **3**. In this experiment the region of the aryl-NH protons (7.45–7.80 ppm) was especially informative (Fig. 3). Thus, four NH singlets appeared (Fig. 3c), two of them due to the homodimers **2·2** (δ = 7.63 ppm) and **3·3** (δ = 7.61 ppm), and the other two to both aryl-NH protons of the heterodimer **2·3** (δ = 7.51 ppm and δ = 7.73 ppm). The integration revealed a nearly statistical mixture of the three dimers.

In summary, we have shown that tris(*o*-ureidobenzyl)amines **1**–**3** self assemble to form dimeric aggregates in which six urea groups constitute a cyclic array involving a closed network of 12 hydrogen bonds.

Received (in Cambridge, UK) 20th September 2000, Accepted 27th November 2000
First published as an Advance Article on the web 4th January 2001

Two new extended chromophoric systems, in which a 4-aminoazobenzene moiety is linked to a cyclo-bridged hexatriene electron withdrawing group, have been synthesized, and show large optical nonlinearities and unexpected blue-shifted absorption in comparison with shorter chain analogues.

Organic and polymeric second-order nonlinear optical (NLO) materials have been extensively studied for their potential applications involving optical signal processing and telecommunications.[1] One of the major challenges in this area of research is to design and synthesize second-order NLO chromophores simultaneously exhibiting large first molecular hyperpolarizability (β), high chemical and thermal stability, and good optical transparency.[2,3] Most attempts to design molecules with large β since the 1980s have been based upon 'push–pull' compounds,[4] in which a π-conjugated bridge is endcapped with an electron donor group and an electron acceptor group. From the two-level model,[5] the β value of this type of chromophore is a strong function of the absorption maximum (λ_{max}), leading to the so-called nonlinearity–transparency tradeoff.

Among all the attempts to solve this kind of trade-off, it has been proved that the nature of π-conjugated bridge of chromophores is one of the crucial factors in determining the linear and nonlinear optical properties of the chromophores. For example, Alain *et al*. recently reported[6] that chromophore **1** (Fig. 1), in which a biphenyl moiety is present between the diphenylpolyene unit, exhibits a 45 nm (2400 cm^{-1}) blue-shifted absorption and similar optical nonlinearity compared with its all diphenylpolyenic analogue (chromophore **2**, Fig. 1), though the conjugation bridge of **1** is much longer. It seems a worthwhile job to study further the linear and nonlinear optical properties of the chromophores by using a combination of different types of conjugation bridges.

Therefore, we have recently designed two new chromophores (**I** and **II** in Fig. 2)† in which the conjugation bridge of isophorone-protected triene with the terminal acceptors is linked to a donor-substituted azo benzene bridge.

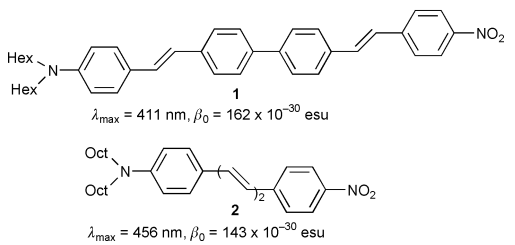

Fig. 1 Chemical structures and properties of chromophores **1** and **2**.

The first molecular hyperpolarizabilities of chromophores **I** and **II** were measured by Hyper-Rayleigh Scattering (HRS) in methanol using the fundamental excitation wavelength of 1064 nm; *p*-nitroaniline (PNA) was used as the external reference. The β values of **I** and **II** were found to be 2890×10^{-30} esu and 3490×10^{-30} esu, respectively, and by using the two-level approximation model, the zero-frequency hyperpolarizabilities β_0 of **I** and **II** were extrapolated to be 337×10^{-30} esu and 198×10^{-30} esu, respectively.

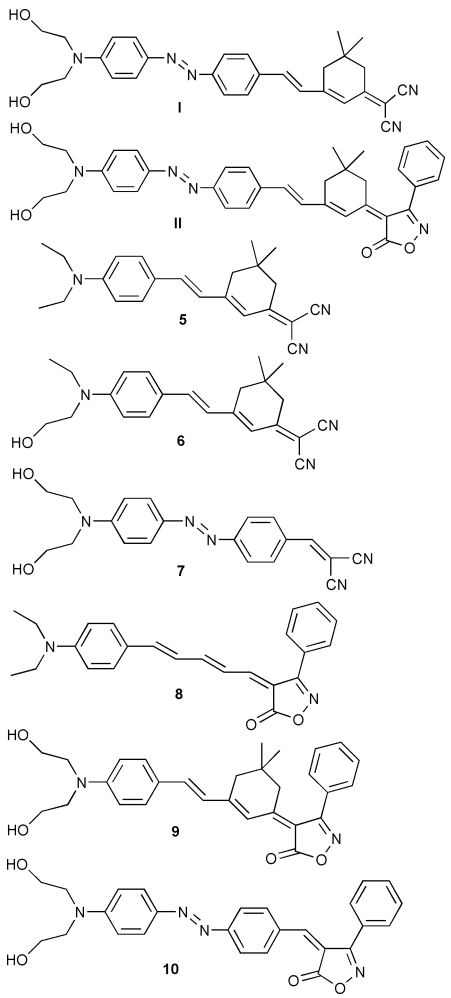

Fig. 2 Chemical structures of chromophores **I**, **II** and their corresponding triene-only and azo-only analogues (chromophores **5**–**10**).

[a] AcOEt: ethyl acetate, DMF: dimethylformamide, NMP: *N*-methylpyrrolidone. [b] AM1/FF results, in units of 10^{-30} esu. [c] ZINDO/S-CI results. [d] Dispersion-corrected β values (in units of 10^{-30} esu) of **I** and **II** were calculated by using an approximate two-level model. [e] β^0_{HRS} values are estimated from the data of β^0_{EFISH} previously reported[8] according to the following equation: $\beta^0_{HRS} = (6/35)^{1/2}\beta^0_{EFISH}$.

Besides the target chromophores **I** and **II**, the other six chromophores (**5**–**10**, see Fig. 2), which are the azo-only or triene-only analogues of **I** and **II**, respectively, will also be discussed below.[8,9]

The linear and the nonlinear properties of these chromophores are summarized in Table 1. It can be seen that **I** and **II**, two chromophores employing the combination of azo benzene and conjugated triene as their conjugation bridge, display unexpectedly blue-shifted absorption compared with the corresponding azo-only or triene-only analogues, although the length of their conjugation bridge is much longer. For instance, the absorption maxima of **I** is about 15 nm (500 cm^{-1}) blue-shifted compared with **5**, **6**, and **7** in different organic solvents. And as shown in Fig. 3, there is no significant broadening of the main absorption band for **I**, if another absorption band around 400 nm in their UV-Vis spectrum is taken into account, and this is also the case for **II**. All these results show that for **I** and **II**, the electron transmission process between donor and acceptor groups is affected, and the intramolecular charge transfer (ICT) efficiency is reduced. This reduction may occur through using different types of bridge with different energy orbitals other than the most efficiently conjugated bridge possible.

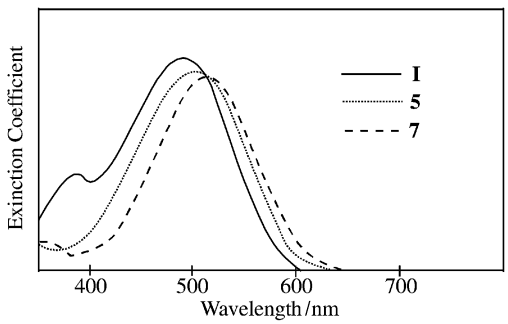

Fig. 3 Comparison of the absorption spectra of chromophores **I**, **5**, and **7** in methanol.

Although the π-electron delocalization efficiency of **I** and **II** is somewhat reduced, it should be noted that the β_0 values of **I** and **II** are quite competitive with those of their corresponding analogues from the theoretical investigation and the experimental results**.** This appears to be at variance with the predictions of the two-level model. However, besides the nonlinearity–transparency trade-off mentioned above, the two-level model also adduces that the β value is a strong function of the oscillator strengths (f) and $\Delta\mu$, the change of dipole moment upon excitation. Thus it can be phenomenologically deduced that the reduction of the ICT efficiency of chromophores **I** and **II** does not accompany a decrease in their f and/or $\Delta\mu$ values, and this has been partially verified by the experimental results. As shown in Table 1, the oscillator strengths (f) of **I** and **II**, respectively determined to be 1.0 and 1.1, are significantly higher than those of the corresponding azo-only or triene-only analogues. It seems that the larger oscillator strengths of **I** and **II** may be one of the major points for counterbalancing the effects of blue shifts. Further study is needed for a full interpretation.

In summary, we have explored two new NLO chromophores with combined conjugation bridges and found that they possess blue-shifted absorption and large molecular nonlinearities. Experimental results indicate that the combined conjugation bridge tunes the linear and nonlinear properties of the chromophores in a different style from those of common homologous chromophores. We expect this methodology to build up new molecular engineering, thereby providing a new opportunity for defeating the 'nonlinearity-transparency trade-off'. Design and synthesis of further chromophores with different types of combined conjugation bridge, and a detailed investigation of the origin of this new effect are currently in progress.

Nitroethylene, formed during the selective catalytic reduction (SCR) of NO_2 by C_2H_4 over H-ferrierite, was determined to be an intermediate in SCR due to its decomposition behavior in forming N_2.

In the selective catalytic reduction (SCR) of NO_x (NO and NO_2) by hydrocarbons, both spectroscopic observation and product analysis support the contention that HNCO and HCN are among the intermediates related to N_2 formation. However, the routes to the formation of these compounds are under discussion. Yokoyama and Misono[1] proposed that nitro compounds are precursors of HNCO and HCN, and Cowan *et al.*[2] speculated that $MeNO_2$ is an intermediate in the SCR of NO_x by CH_4 while Zuzaniuk *et al.* reported that HNCO is produced by nitromethane decomposition over Al_2O_3.[3] Joubert *et al.* also suggested that 2-nitropropane is an intermediate during SCR over a Pt-based catalyst.[4] In this study, we conducted a product analysis of the SCR of NO_2 by C_2H_4 over H-ferrierite, which shows activity for this reaction,[5] and attempted to elucidate the pathway of formation of the nitrogen-containing compounds.

The catalyst sample was obtained by wash-coating *ca.* 30 mg of H-ferrierite (Tosoh; HSZ-720HOA, SiO_2/Al_2O_3 = 17.0) onto a miniature cylindrical cordierite honeycomb (8 mm diameter × 9 mm length, 400 cells in^{-2}).[6] Catalytic activity tests were carried out under conventional flow reactor conditions at ambient pressure. The reactant gas for the SCR of NO_2 was composed of 1000 ppm NO_2, 1000 ppm C_2H_4 and 5% O_2 diluted in He. Products were analyzed with an FTIR spectrometer (Nicolet; Magna 560, resolution set at 0.5 cm^{-1}) equipped with a multi-reflection gas cell (Gemini Specialty Optics; optical path length = 2 m) and GC (Agilent; Micro GC).

Fig. 1(a) shows the gas-phase IR spectrum of the products of SCR at 473 K. To show the unknown band clearly, the absorption bands of coexisting NO_2 and C_2H_4 were subtracted from the original spectrum to an optimum extent. The absorption bands at 1562 and 1546 cm^{-1} were tentatively ascribed to nitro groups. To confirm this assumption, nitroethylene (NE), which was the most probable compound formed, was synthesized according to the literature,[7] and its gas-phase spectrum [Fig. 1(b)] was obtained. Characteristic bands appeared at 1562, 1546, 1384, 1377, 1365, 1355, 963, and 888 cm^{-1}. Comparison with the standard spectrum of 2-nitroethanol [Fig. 1(c)], used as a precursor for the synthesis, shows that this compound was not a contaminant in the synthesized NE. The unknown bands in Fig.1(a) agreed completely with those of NE. To our knowledge, this is the first report of the observation of a gas-phase NE IR spectrum. It is clear that NE is formed during the SCR of NO_2 by C_2H_4. As a comparison, the standard spectrum of nitromethane is shown in Fig. 1(d), which is clearly different from that observed during SCR.

Fig. 2 shows the effect of contact time with a reactant gas on the formation of NE and N_2 at 523 K. The concentration of NE in the product gas decreased drastically at contact times > 0.15 s, becoming negligible at contact times > 0.3 s; on the other hand, the N_2 concentration increased with increasing contact time. This result suggests that NE is an intermediate in the production of N_2. In similar experiments at 623 and 723 K, NE formation was not observed at any contact time, indicating that NE decomposition or a secondary NE reaction is very fast at higher temperatures.

Using the synthesized NE, we further investigated its reactivity over H-ferrierite. In the presence of 5% O_2, decomposition of diluted NE (*ca.* 230 ppm) became prominent above 600 K; CO_2 CO, NH_3 HCN and trace amounts of HNCO and N_2 were observed as the products. The formation of HCN and HNCO is in accord with theoretical calculation results for the thermal decomposition of NE through a four-membered-

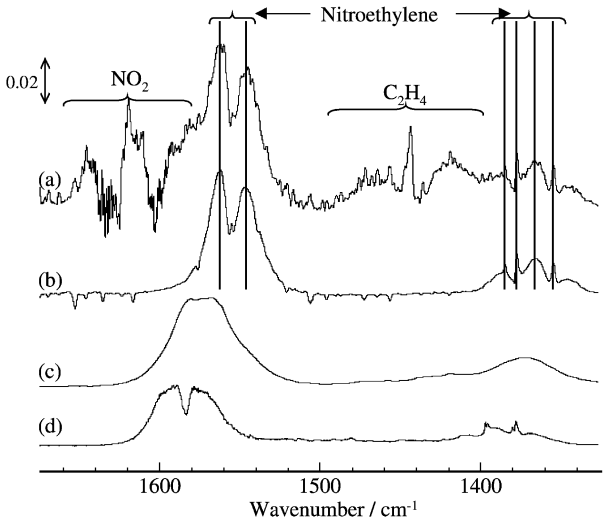

Fig. 1 Gas-phase IR spectra of (a) product gas of SCR of NO_2 by C_2H_4, (b) nitroethylene synthesized in this study, (c) standard 2-nitroethanol and (d) standard nitromethane.

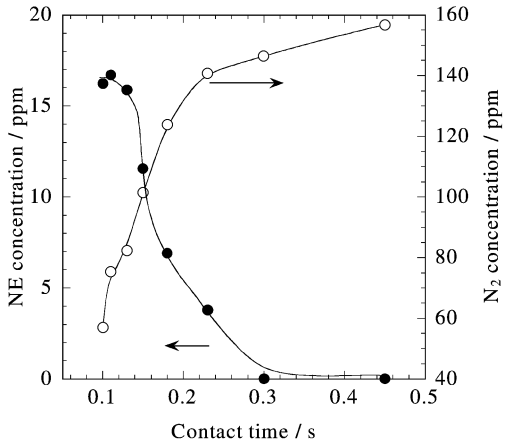

Fig. 2 Effect of contact time on NE and N_2 formation. Symbols indicate the concentration of NE (●) and N_2 (○) in the product gas.

ring structure (4*H*-oxazete *N*-oxide).[8] NH_3 is speculated to be produced by catalytic hydrolysis of HCN[9] and HNCO,[10] which simultaneously form CO and CO_2, respectively.

The formation of NH_3 led us to invoke successive occurrence of the conventional SCR reaction, *i.e.*, selective reaction of NO_x with NH_3 to form N_2 in the presence of excess O_2, over this proton-type zeolite catalyst.[9] Incidentally, under most reaction conditions, the product gas of the SCR of NO_2 with C_2H_4 contains more NO than NO_2; partial reduction of NO_2 to NO by C_2H_4 must have occurred, in addition to the total reduction process. To confirm the above possible role of NH_3 we conducted NE (230 ppm) decomposition over H-ferrierite in the presence of 1000 ppm NO and 5% O_2, as shown in Fig. 3. Conversions in this figure were defined as follows:

NO_x and NE conversion = (Inlet concentration – Outlet concentration)/(Inlet concentration) × 100 (%)

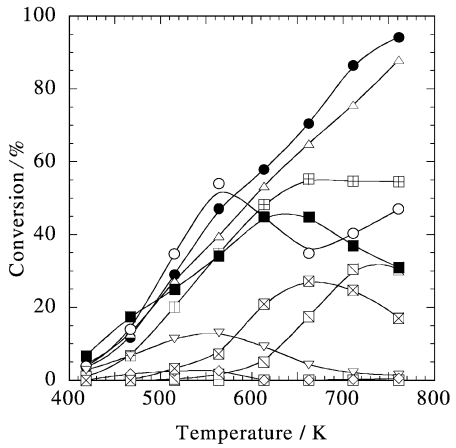

Fig. 3 Behavior of NE decomposition over H-ferrierite. The feed gas was composed of 230 ppm NE, 5% O_2 and 1000 ppm NO. The total flow rate was 160 ml min^{-1}, corresponding to 21 000 h^{-1}. Symbols indicate NE (●) and NO_x conversion (■), and conversion to CO_2 (△), NH_3 (□), N_2 (⊞), CO (○), HNCO (◇), N_2O (▽), HCN (⧅) and HCHO (⊠).

Conversion to products = (Product concentration)/(NE inlet concentration) × 100 (%)

In the presence of NO + O_2, NE decomposition became prominent above 425 K, and the conversion increased with increasing temperature. It is noteworthy that both the NO_x conversion and conversion to N_2 were almost equal to the NE conversion below 623 K. This result strongly suggests that both NE and NO_x molecules supplied, respectively, one nitrogen atom to form one N_2 molecule. The rather high conversion to CO at lower temperatures, amost equal to the NE conversion, might be produced by the decomposition of HCO_2H. We confirmed that HCO_2H is easily produced by the oxidation of HCHO with NO_2 and also decomposed to CO and H_2O over H-ferrierite under conditions similar to that for the present SCR reaction. Formaldehyde should be formed by NE decomposition, simultaneously with HNCO.[8]

To summarize these results, we conclude that the NE we detected is not merely a byproduct in HC-SCR but is very probably an intermediate in the formation of N_2, through conversion to HNCO or HCN followed by formation of NH_3.

Triple-decker main group cations†

Alan H. Cowley,* Charles L. B. Macdonald, Joel S. Silverman, John D. Gorden and Andreas Voigt

Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712 USA. E-mail: cowley@mail.utexas.edu

Received (in Columbia, MO, USA) 16th June 2000, Accepted 27th November 2000
First published as an Advance Article on the web 8th January 2001

The syntheses of the first main group triple-decker cations are described, namely, [(η⁵-C_5Me_5)Sn(μ-η⁵-C_5Me_5)Sn(η⁵-C_5Me_5)][Ga(C_6F_5)$_4$] and [(η⁶-C_7H_8)In(μ-η⁵-C_5Me_5)In(η⁶-C_7H_8)][(C_6F_5)$_3$BO(H)B(C_6F_5)$_3$], both of which have been characterized by X-ray crystallography; the former was prepared by the reaction of Sn(η⁵-C_5Me_5)$_2$ with Ga(C_6F_5)$_3$, while the latter was prepared by treatment of [In(η⁵-C_5Me_5)]$_6$ with an equimolar mixture of B(C_6F_5)$_3$ and H_2O·B(C_6F_5)$_3$.

An elegant approach to the formation of multidecker, sandwich-type anions of the heavier main group elements consists of the addition of cyclopentadienide anions to neutral metallocenes in the presence of weakly coordinating cations.[1,2] However, to our knowledge, the inverse of this approach has not been reported, *viz.* the synthesis of homonuclear multidecker p-block cations by the addition of positively charged fragments to neutral metallocenes in the presence of appropriate anions. We report two different but complementary reactions that demonstrate the viability of the latter approach.

Since it is known[3] that the reaction of Sn(η⁵-C_5Me_5)$_2$ with a variety of acidic reagents results in salts of [Sn(η⁵-C_5Me_5)]⁺, it was reasoned that, in principle, this cation should be able to add to Sn(η⁵-C_5Me_5)$_2$ to afford the desired triple decker cation [(η⁵-C_5Me_5)Sn(μ-η⁵-C_5Me_5)Sn(η⁵-C_5Me_5)]⁺ **1**⁺. Moreover, it was recognized that the choice of the gegenion would be important, bearing in mind that (a) the anion should be weakly coordinating, and (b) the chance of obtaining a crystalline product would be maximized if the anion and cation were of comparable size. Addition of a toluene solution of Sn(η⁵-C_5Me_5)$_2$[4] (0.38 g, 0.98 mmol) to a solution of Ga(C_6F_5)$_3$[5] (0.60 g, 1.0 mmol) in the same solvent at 0 °C resulted in a yellow precipitate which was recrystallized from hot toluene solution to afford 0.51 g (74.5% yield) of [**1**][Ga(C_6F_5)$_4$]. The positive and negative CI mass spectra for [**1**][Ga(C_6F_5)$_4$] revealed the presence of **1**⁺ and [Ga(C_6F_5)$_4$]⁻ ions, respectively.[6] The ^{1}H, ^{13}C and ^{119}Sn NMR spectra[6] evidenced only one type of C_5Me_5 group and a unique Sn center thus suggesting reversible dissociation of **1**⁺ into Sn(η⁵-C_5Me_5)$_2$ and [Sn(η⁵-C_5Me_5)]⁺. Definitive structural information was provided by a low-temperature X-ray crystal structure.[7] As shown in Fig. 1, the solid state consists of **1**⁺ and [Ga(C_6F_5)$_4$]⁻ ions[8,9] and there are no unusually short interionic contacts. The structure of **1**⁺ is such that a pentahapto C_5Me_5 ring serves as a bridging group for two Sn(η⁵-C_5Me_5) units. Within experimental error, the two Sn atoms are located equidistantly from the ring centroid [X(1C)] of the μ-(η⁵-C_5Me_5) group [2.644(19) Å] and the Sn(1)–X(1C)–Sn(2) angle is close to 180° [174.9(4)°]. The average distance from the Sn atoms to the ring centroids of the two terminal (η⁵-C_5Me_5) rings, X(1A) and X(1B), is shorter than that to the bridging (η⁵-C_5Me_5) moiety [2.246(18) Å] and lies between the values reported for Sn(η⁵-C_5Me_5)$_2$ (2.396 Å)[3c] and [Sn(η⁵-C_5Me_5)]⁺ (2.157 Å).[3c] The X(1A)–Sn–X(1C) and X(1B)–Sn–X(1C) angles of 154.6(7) and 151.8(7)°, respectively are very similar to the values reported for Sn(η⁵-C_5Me_5)$_2$ (av. 154.9°).[3c] An intriguing feature of the overall structure is that **1**⁺ adopts a cis-type geometry while the triple decker anions [(η⁵-C_5H_5)$_3$Tl$_2$]⁻ and [(η⁵-C_5H_5)Cs$_2$]⁻ possess transoid arrangements.[1b,2]

A second method of triple decker cation synthesis recognized the isolobal relationship of *e.g.* [Sn(η⁵-C_5H_5)]⁺ and [In(η⁶-C_6H_6)]⁺ thus suggesting that cations of the latter type should add to In(η⁵-C_5Me_5) units.[10] Since protolytic cleavage of In(η⁵-C_5Me_5) in the presence of an arene solvent represented a potential source of [In(arene)]⁺ cations, we treated In(η⁵-C_5Me_5) (0.1 g, 0.4 mmol) with equimolar quantities (0.195 mmol each) of B(C_6F_5)$_3$[11] and the Brønsted acid H_2O·B(C_6F_5)$_3$[12] in toluene solution at 0 °C. The reaction mixture afforded colorless crystals (0.25 g, 70.4% yield) upon storage at −30 °C for several days. Since the product could not be characterized unambiguously on the basis of spectroscopic data,[6] an X-ray crystallographic study was undertaken.[7] The solid state (Fig. 2) consists of [(η⁶-C_7H_8)In(μ-η⁵-C_5Me_5)In(η⁶-C_7H_8)]⁺ **2**⁺ and [(C_6F_5)$_3$BO(H)B(C_6F_5)$_3$]⁻ ions[8] with 1.5 additional toluene molecules per asymmetric unit. There are no unusually short interionic contacts. The central core of **2**⁺ features an η⁵-bonded In atom on each face of the (μ-C_5Me_5)

DOI: 10.1039/b005425i

group. The In–ring centroid [X(1A)] distances of 2.528(4) and 2.435(4) Å for In(1) and In(2), respectively are longer than those reported[10] for monomeric [2.288(4) Å] and hexameric [2.302(4) Å] In(η^5-C_5Me_5). As in the case of **1**$^+$, the metal–X–metal angle in **2**$^+$ is close to linear [176.0(4)°]. The triple decker structure of **2**$^+$ is completed by capping η^6-bonded toluene molecules. The In–ring centroid [X(1B) and X(1C)] distances of 3.490(4) and 3.325(4) Å for In(1) and In(2), respectively are considerably longer than those reported for [In(I)·2mesitylene]$^+$ (2.83 and 2.89 Å).[13] Nevertheless, it is interesting to note that, akin to **1**$^+$, the toluene–(μ-C_5Me_5)–toluene moieties are distinctly bent [124.4(4) and 130.3(4)° for X(1A)–In(1)–X(1B) and X(1A)–In(2)–X(1C), respectively] and that the overall cationic geometry is cisoid.

Part of the reason for the long arene distances in **2**$^+$ may relate to the fact that the net +1 charge is delocalized over two In centers. However, the bonding in **2**$^+$ can be interpreted in two different ways, namely (a) as a triple-decker sandwich cation or (b) a base-stabilized inverse sandwich cation. Density functional theory (DFT) optimization[14] of the model system [In(μ-η^5-C_5H_5)In]$^+$ predicts a D_{5h} symmetric structure with a computed In–X distance of 2.515 Å, close to the value observed experimentally for **2**$^+$. Moreover, the η^6-coordination of two benzene molecules to the [In(μ-C_5H_5)In]$^+$ moiety causes only a slight perturbation of the core thus lending credence to model (b). Furthermore, the benzene–In bond dissociation energy (6.6 kcal mol^{-1}) suggests a very weak interaction. In sharp contrast, calculations on [(η^5-C_5H_5)Sn(μ-η^5-C_5H_5)Sn(η^5-C_5H_5)]$^+$ as a model for **1**$^+$ predict a much more tightly bonded triple-decker sandwich environment—the weakest bond (36.6 kcal mol^{-1}) being that between [(η^5-C_5H_5)Sn(η^5-C_5H_5)] and [Sn(η^5-C_5H_5)]$^+$ fragments. Thus the (C_5Me_5) acidolysis methodology may be used to prepare isolobally related compounds with very different properties. We are currently investigating the utility of this technique for the synthesis of larger sandwich, cluster and mixed-metal compounds.

We are grateful to the National Science Foundation and the Robert A. Welch Foundation for financial support.

7 *Crystal data*: for [**1**][Ga(C_6F_5)$_4$]: $C_{54}H_{45}F_{20}GaSn_2$, monoclinic, space group *Cc*, yellow prisms, a = 22.147(4), b = 15.092(3), c = 17.352(4) Å, β = 115.11(3)°, V = 5252(2) Å^3, Z = 4, D_c = 1.747 g cm^{-3}, μ(Mo-Kα) = 1.561 mm^{-1}, R_1 = 0.063, wR_1 = 0.0823, GOF = 1.344. For [**2**][(C_6F_5)$_3$BO(H)B(C_6F_5)$_3$]·1.5C_7H_8: $C_{70.5}H_{44}B_2F_{30}In_2O_1$, monoclinic space group, $P2_1/c$, colorless blocks, a = 16.042(3), b = 20.771(4), c = 21.165(4) Å, β = 107.74(3)°, V = 6717(2) Å^3, Z = 4, D_c = 1.693 g cm^{-3}, μ (Mo-Kα) = 0.814 mm^{-1}, R_1 = 0.0411, wR_1 = 0.1138, GOF = 1.383. Both data sets were collected at 153 K on a Nonius-Kappa CCD diffractometer. CCDC 182/1871. See http://www.rsc.org/suppdata/cc/b0/b005425i/ for crystallographic files in .cif format.

8 The structures of the [Ga(C_6F_5)$_4$]$^-$ and [C_6F_5)$_3$BO(H)B(C_6F_5)$_3$]$^-$ anions are similar to those reported in the literature: K.-F. Tebbe, T. Gilles, F. Conrad and W. Tyrra, *Acta Crystallogr., Sect. C*, 1996, **52**, 1663; A. A. Danopoulos, J. R. Galsworthy, M. L. H. Green, S. Cafferkey, L. H. Doerrer and M. B. Hursthouse, *Chem. Commun.*, 1998, 2529.

9 Presumably, the initially formed anion is [Ga(C_6F_5)$_3$(C_5Me_5)]$^-$. However, since [B(C_6F_5)$_n$R$_{4-n}$]$^-$ anions are known to undergo facile redistribution reactions, a similar process can be postulated to explain the formation of [Ga(C_6F_5)$_4$]$^-$. See: V. K. Dioumaev and J. F. Harrod, *Organometallics*, 1997, **16**, 2798.

10 In(η^5-C_5Me_5) is a weakly-held hexamer in the solid state that undergoes facile dissociation to the monomer in solution and in the vapor phase: O. T. Beachley, Jr., R. Blom, M. R. Churchill, K. Faegri, Jr., J. C. Fettinger, J. C. Pazik and L. Victoriano, *Organometallics,*, 1989, **8**, 346.

Reversible voltammetry was achieved ($E^{\circ\prime}$ = −0.13 V *vs.* NHE at 25 °C at pH 7.1) for the Fe^{III}/Fe^{II} redox couple of mycobacterial KatG catalase–peroxidase in films of dimyristoyl phosphatidylcholine, which also catalyzed electrochemical reductions of hydrogen peroxide and oxygen.

The mycobacterial KatG catalase–peroxidase[1,2] oxidatively activates the prodrug isoniazid (isonicotinic acid hydrazide) used to treat tuberculosis. *Mycobacterium tuberculosis* catalase-peroxidase is a dimer of 80 kDa subunits, both of which contain an iron heme. Oxidative activation of isoniazid may occur through several possible pathways. The Fe^{III} form of the enzyme can react with peroxides to form an unstable intermediate peroxidase compound I that oxidizes isoniazid.[3] The catalase–peroxidase can oxidize isoniazid in the presence of dioxygen and a reductant, similar to cytochrome P450 catalysis.[4] The Fe^{III} enzyme receives one electron forming Fe^{II} enzyme, to which dioxygen binds to give an Fe^{II}–O_2 intermediate that is the precursor of a high-valent active oxidant.[5,6] Oxidation of isoniazid by the catalase–peroxidase can also be initiated by superoxide.[7] Knowledge of redox chemistry, oxidation kinetics, and reduction of H_2O_2 with the catalase–peroxidase is critical for elucidation of pathways for isoniazid oxidation. Here we report the first example of direct, reversible electron transfer between the Fe^{III}/Fe^{II} redox couple of the catalase–peroxidase from *M. tuberculosis* in thin films of dimyristoyl phosphatidylcholine (DMPC) on electrodes. These enzyme–lipid films catalyzed electrochemical reduction of H_2O_2 and of dioxygen.

Films of stacked lipid bilayers provide a biomimetic environment facilitating direct electrical communication between electrodes and redox sites of incorporated heme enzymes.[8,9] Fig. 1 shows a reversible cyclic voltammogram (CV) for the Fe^{III}/Fe^{II} redox couple of *M. tuberculosis* catalase–peroxidase (enzyme obtained as in ref. 3) in a DMPC film in pH 6.0 buffer. Films were made by spreading 10 μL of an aqueous vesicle dispersion of 1 mM DMPC and 0.05 mM enzyme evenly onto a basal plane PG disc electrode (area = 0.2 cm^2) and drying overnight.[10] The film thickness was *ca.* 0.5 μm.

Catalase–peroxidase/DMPC films in oxygen-free buffers gave symmetric CV peaks with equal reduction and oxidation peak heights that depended linearly on scan rate from 0.01 to 1 V s^{-1}. Peak widths at half-height were *ca.* 200 mV, and reduction–oxidation peak separations were *ca.* 50 mV, exceeding the 90/*n* mV peak width and 0 mV peak separation, respectively, predicted by theory for ideal thin layer voltammetry. Integration of CVs gave enzyme surface concentration of 2.1×10^{-10} mol cm^{-2}. Results are typical for non-ideal thin film protein voltammetry.[9] Formal potentials ($E^{\circ\prime}$) of the catalase–peroxidase obtained as midpoint potentials of reversible CVs are compared with other enzymes in Table 1.

Recently Wengenack *et al.*[11] reported irreversible voltammetry for the KatG catalase–peroxidase on graphite electrodes. Cyclic voltammograms with the enzyme in solution showed a Fe^{III} reduction peak, but no reverse oxidation peak, and reversibility of square-wave voltammograms was unsubstan-

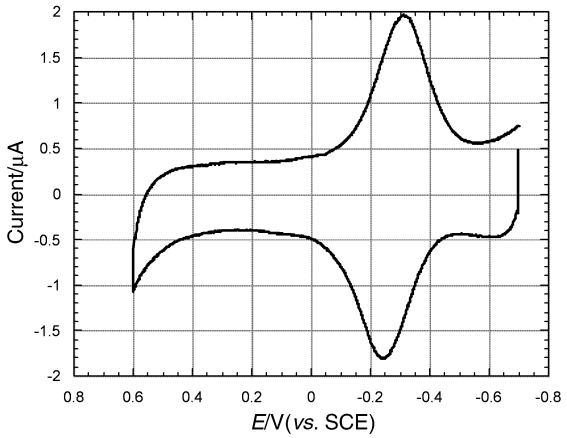

Fig. 1 Background subtracted cyclic voltammogram (CV) at 100 mV s^{-1} and 25 °C of catalase–peroxidase–DMPC film on basal plane PG electrode, in pH 6.0, 20 mM phosphate buffer purged with purified nitrogen for 20 min before CV. Note that *E*/V (*vs.* NHE) = 0.244 + *E*/V (*vs.* SCE).

Table 1 Electrochemical results for enzymes in DMPC films and water[a]

Enzyme	pH	$E^{\circ\prime}$[b]/V (*vs.* NHE)	Γ[c]/ mol cm^{-2}	Slope[d]/nA μM^{-1}	Rel. rates of H_2O_2 redn.[e]
Catalase–peroxidase film	6.0	−0.058	2.1×10^{-10}	1.3	0.06
Catalase–peroxidase film	7.1	−0.128	2.1×10^{-10}		
Catalase–peroxidase in water	7.6	−0.028	(from ref. 11, by titration)		
HRP film	6.0	−0.065	1.8×10^{-11}	1.8	1.0
Catalase film	6.0	−0.18	9.0×10^{-11}	0.11	0.01

[a] Average of at least two electrodes in 20 mM phosphate buffer at pH 6.0, 25 °C. Standard deviations were *ca.* ±5 mV for $E^{\circ\prime}$ and ≤15% for other quantities. [b] Estimated as midpoint potentials of reduction–oxidation peaks in CV. [c] Determined by integration of CV peaks at low scan rates and application of Faraday's law. [d] Calculated by linear regression of amperometric responses to various concentrations of hydrogen peroxide using rotating electrodes at 1800 rpm at 0.24 V *vs.* NHE. [e] From steady state currents as nA $nmol^{-1}$ enzyme at 1800 rpm at 0.24 V *vs.* NHE, proportional to turnover rate, relative to HRP = 1.

DOI: 10.1039/b009348n

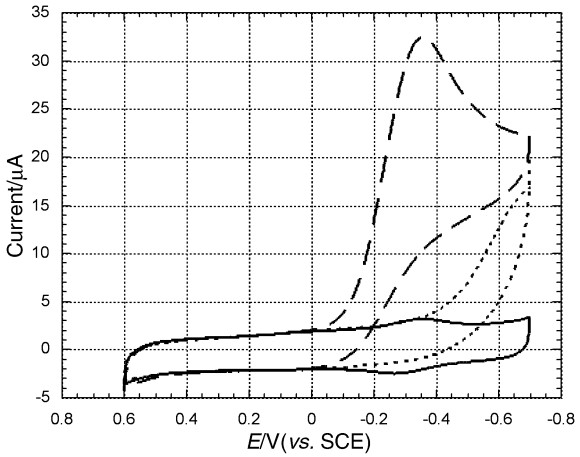

Fig. 2 CVs at 100 mV s^{-1} of KatG–DMPC films in pH 6.0 buffer saturated with air (– —) and without oxygen (—), and enzyme-free DMPC film in pH 6.0 buffer saturated with air (---).

tiated by the data.[11] The potentials of these irreversible redox peaks are controlled by kinetics and do not yield $E°'$ for the Fe^{III}/Fe^{II} couple of the enzyme.

The Soret absorbance band of catalase–peroxidase shifted slightly from 407 nm in pH 7 solution[12] to 409 nm in DMPC films, similar to myoglobin/DMPC films.[13] When the catalase–peroxidase was purposely denatured at pH 3.5, the Soret band disappeared and a new broad band at *ca.* 375 nm appeared. These results suggest that catalase–peroxidase in DMPC films at pH 6–7.5 is similar in secondary structure to the native enzyme.

If the Fe^{II} enzyme generated by reduction reacts with oxygen and product Fe^{II}–O_2 is reduced by the electrode, reduction current will increase due to the catalytic process, and the Fe^{II} oxidation peak will decrease or disappear. Fig. 2 shows such voltammetric behavior of catalase–peroxidase/DMPC in air-saturated buffer. Increased reduction current results from additional electrons injected into Fe^{II}–O_2, and the likely product is hydrogen peroxide as found for other iron heme enzymes.[9] This catalytic reduction is *ca.* 0.4 V more positive than direct reduction of oxygen on DMPC/PG electrodes (Fig. 2).

Catalase–peroxidase/DMPC films also catalyzed the reduction of hydrogen peroxide. Without H_2O_2, enzyme–DMPC films give similar cyclic voltammograms on quiet (*cf.* Fig. 1) and rotating electrodes [Fig 3(b),(d),(f)]. After adding H_2O_2, reduction current was greatly increased to give catalytic steady-state (limiting) currents for the catalase–peroxidase at 0.4 mM H_2O_2 (Fig. 3(a)] and for HRP at 0.05 mM H_2O_2 (Fig. 3(e)]. For catalase (bovine liver), partly reversible Fe^{III}/Fe^{II} redox peaks are still detected even at 1 mM H_2O_2 [Fig. 3(c)], and steady state was not achieved. The onset of catalytic current for reduction of H_2O_2 occurred at *ca.* 0.24 V *vs.* NHE for catalase–peroxidase, 0.14 V for HRP and 0.1 V for catalase. In no case was a direct Fe^{III} *oxidation* peak observed.

Amperometric responses for enzyme–DMPC films at 0.24 V *vs.* NHE to various concentrations of H_2O_2 were measured at rotating electrodes (Table 1). H_2O_2 presumably reacts with the Fe^{III} enzyme to give compound I,[3] which is reduced by the electrode in a catalytic cycle. Relative turnover rates from these steady-state currents[14] in nA $nmol^{-1}$ enzyme were in the order: HRP > catalase–peroxidase > catalase (Table 1).

Results presented above demonstrate direct, reversible electron transfer between electrodes and *M. tuberculosis* catalase–peroxidase in DMPC films. Catalytic reduction of oxygen involving the oxyferrous enzyme proceeded similarly to electrochemical catalytic cycles of cyt P450 enzymes.[8,9] For catalytic electrochemical reduction of H_2O_2, the catalase–peroxidase in DMPC films resembles HRP more than catalase.

Reversible voltammograms allowed estimation of a formal potential of −0.128 V *vs.* NHE in DMPC films at pH 7.1. An observed $E°'$–pH dependence of −53 mV pH^{-1} puts the value

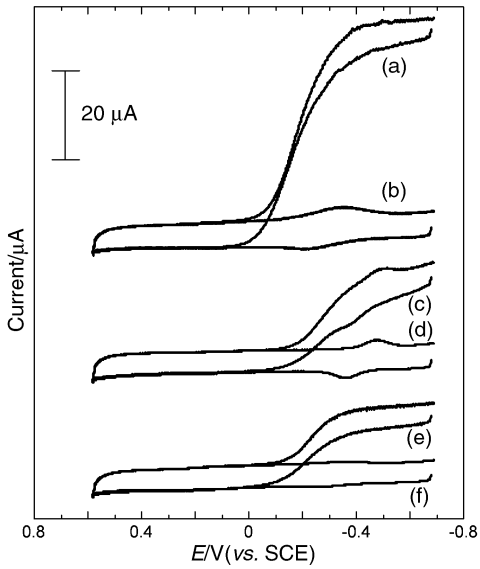

Fig. 3 Rotating disk CVs of enzyme–DMPC films on PG at 1800 rpm and 100 mV s^{-1} in pH 6 buffer illustrating catalytic electrochemical reduction of H_2O_2: KatG enzyme–DMPC films at (a) 0.4 mM H_2O_2, (b) 0 mM H_2O_2; Catalase-DMPC films at (c) 1.0 mM H_2O_2, (d) 0 mM H_2O_2; HRP-DMPC films at (e) 0.05 mM H_2O_2, (f) 0 mM H_2O_2. Buffer solution was purged with purified nitrogen for 20 min before CV; curves for different enzymes were offset for clarity.

at pH 7.6 in DMPC films at −0.155 V. This is significantly more negative than −0.028 V obtained recently in solution at pH 7.6 by spectroelectrochemical titration.[11] Results for other iron heme proteins suggest that $E°'$ values in DMPC films may differ from solution values by 100 mV or more as a result of lipid–enzyme and film–electrode interactions.[9] In comparison, HRP and the catalase–peroxidase have similar formal potentials in DMPC films (Table 1), even though the value for HRP in solution was reported at −0.278 V.[11] Thus, the previous conclusion[11] that the catalase–peroxidase $E°'$ is 200 mV higher than HRP may be modulated by enzyme environment.

Cooperative assistance in a very short O–H··O hydrogen bond. Low-temperature X-ray crystal structures of 2,3,5,6-pyrazinetetracarboxylic and related acids

Peddy Vishweshwar,[a] Ashwini Nangia*[a] and Vincent M. Lynch[b]

[a] *School of Chemistry, University of Hyderabad, Hyderabad 500 046, India. E-mail: ansc@uohyd.ernet.in*

Received (in Columbia, MO, USA) 30th August 2000, Accepted 7th November 2000
First published as an Advance Article on the web 4th January 2001

In contrast to the well documented role of charge- and resonance-assistance in very short hydrogen bonds, a very short O–H_{acid}···O_{water} hydrogen bond [O···O 2.4791(13) Å] in the title acid is ascribed to the cumulative stabilisation from σ- and π-bond cooperativity.

Very short (very strong) O–H···O hydrogen bonds are formed with unusually activated donors and acceptors, as between an acid and its conjugate base (O–H···O^-) or in the hydrates of strong acids (O^+–H···O). With H···O distances in the range 1.2–1.5 Å (O···O 2.2–2.5 Å), very short H-bonds have a significant covalent component (O–H ≈ H···O) and bond energies in the range 15–40 kcal mol^{-1}. The substantial covalent character of very short H-bonds, a result of three-centre–four-electron contribution, O•–•H···••O ↔ O••···H•–•O, is responsible for their distinctive properties: the near linear geometry (θ = 170–180°), the lengthening of O–H distance (up to 0.2 Å) and the very large IR bathochromic shifts (up to 2000 cm^{-1} in ν_s).[1] Typical examples are the intramolecular hydrogen bonds in monobasic salts of dicarboxylic acids.[2] Very strong hydrogen bonds are relevant in the context of proton transfer phenomena in chemical and biological systems and they have been studied with spectroscopic, crystallographic and computational methods.[1a] The overall picture that emerges from such studies is that very short H-bonds have a quasi-covalent character. This is in contrast to strong hydrogen bonds (H···O 1.5–2.2 Å, O···O 2.5–3.2 Å, energy 4–15 kcal mol^{-1}) that are largely electrostatic in nature.[1b]

In addition to charge-assisted hydrogen bonding (CAHB: O–H···O^-, O^+–H···O) in carboxylic acids, very short hydrogen bonds have been observed in the neutral β-diketone enol fragment, ···O=C–C=C–OH···, wherein resonance-assistance through π-bonds (RAHB) results in unusual bond shortening.[3] We show here that a composite array with σ- and π-bond cooperativity, O–H···O=C–O–H_{acid}···O_{water}–H···O, can shorten an *inter*molecular O–H_{acid}···O_{water} hydrogen bond into the regime of the very short H-bond (O···O < 2.50 Å). This kind of H-bond array has been referred to as 'polarisation enhanced hydrogen bonding' by Jeffrey.[1a] Our example of a very short hydrogen bond is: (i) intermolecular, (ii) not of the charge-assisted type,[4] (iii) not of the acid–conjugate-base type[5] and (iv) does not contain highly activated donor/acceptor groups.[6]

Recrystallisation of 2,3,5,6-pyrazinetetracarboxylic acid **1**† from 20% aqueous HCl afforded diffraction quality crystals of the dihydrate. Low-temperature (123 K) single crystal X-ray analysis of **1**·$2H_2O$ ($P\bar{1}$, Z = 1)‡ showed it to contain a very short O–H_{acid}···O_{water} H-bond [d = 1.50 Å, D = 2.4791(13) Å, θ = 170.3°]§ that is part of cooperative array **I** [Figs. 1 and 2(a)]. In this very short H-bond, both the carboxylic acid O–H donor ability and the water O atom acceptor basicity are simultaneously enhanced through polarisation, as shown in Fig. 2(b). Such a strong polarising effect involving water was noted recently in the complex, Ph_3P=O–1,4-diethynylbenzene–H_2O (4:1:2).[7] The other O–H···O/N bonds in the crystal are in the short to medium range (Table 1).

In order to probe such a polarisation-induced H-bond shortening in related acids, the crystal structures of pyrazine-2,3-dicarboxylic acid **2** and 5,6-dimethylpyrazine-2,3-dicar-

[a] *d* Values are neutron-normalised (O–H 0.983 Å). [b] This work. [c] Ref. 8.

boxylic acid **3** were analysed. Diacid **2** is reported as a dihydrate (*C*2/*c*).[8] Diacid **3** was also determined to be a dihydrate by low-temperature X-ray diffraction (*Pbcn*).‡ Both these crystal structures contain synthon **I** with O···O distances in the short (strong) regime [**2**·2H_2O 2.562, **3**·2H_2O 2.5269(12) Å]. The very short O–H···O bond in **1** compared to the short bond in **2** and **3** may be rationalised through differences in their extended arrays: the CO_2H donor in **1** [marked with # in Fig. 2(a)] is replaced by H_2O in **2** and **3**. The relative shortness of the O–H···O bond in **3** compared to **2** could be because the donor O–H_{acid} is more polarised by the stronger O–H_{water}···O = C–O–H bond in **3** [2.922 *vs.* 2.8747(12) Å].

Another reason for the very short O–H_{acid}···O_{water} bond in tetra-acid **1** compared to the short H-bond in diacids **2** and **3** is the presence of twice as many electron-withdrawing groups in the former structure. Thus, molecular (4 CO_2H groups on a *N*-heterocycle) and supramolecular (extended cooperative array **I**) features act in concert, resulting in the very short O–H···O bond in **1**. An analysis of the Cambridge Structural Database (April 2000 update) substantiates our observation. While CO_2H···OH_2 H-bonding is present in many carboxylic acids (*ca.* 150 contacts in the range O···O 2.40–2.80 Å),¶ the very short H-bond region (< 2.50 Å) contains mostly the oxalic acid dihydrates (11/13). In these crystal structures, activation of the donor O–H in the 1,2-dicarboxylic acid moiety results in very short O–H_{acid}···O-$_{water}$ bonds, a point not mentioned in the original publications.[9]

A novel feature of this work is the influence on H-bond shortening of cooperative stabilisation, a phenomenon hitherto not discussed in the extensive literature[1–6] on very short hydrogen bonds. Once again, akin to polarisation by water,[7] precedent for H-bond shortening through cooperative assistance comes from the weak C–H···O category, namely 2-ethynyladamantan-2-ol.[10] The presence of two types of CO_2H groups in the same crystal, one that engages in a very short H-bond and the other with a normal H-bond, permits an assessment of O–H bond lengthening (Table 1). Thus, the very short O–H···O bond in **1** displays the expected characteristics: near linear geometry (θ = 170.3°), O–H lengthening (0.1 Å) and O–H ν_s in agreement with the reported correlation (1398 cm^{-1}).‖

In order that our σ- and π-bond cooperativity argument through synthon **I** is tenable, the presence of tautomers **I′** and **I″** in tetra-acid **1** [Fig. 2(c)] must be rigorously excluded, because such motifs would contribute towards resonance stabilisation (**I** ↔ **I′**↔ **I″**), and in effect negate the present hypothesis. Carboxylic acid groups may be characterised as C=O and C–O or as a delocalised carboxylate by their single and double bond lengths.[11] A difference of > 0.1 Å implies a static CO_2H group while a smaller difference (< 0.02 Å) means a resonating or disordered carboxylate. The > 0.1 Å difference between C–O and C=O bond distances in **1**–**3** (Table 1) confirms that synthon **I** is present in their crystal structures, and not a resonance-stabilised motif.

In summary, we have shown that polarisation through a finite σ- and π-bond cooperative array can shorten an O–H···O bond into the very strong regime. This study adds to our knowledge of the traditional H-bond shortening phenomena, namely through charge- and resonance-assistance.

A binary metal system of nickel(0) and zinc(II) phenoxide catalyzed the chemo- and regioselective cyclotrimerization of monoynes.

There is considerable interest in organotransition-metal chemistry based on their wide application in organic syntheses. Over the past few years, we have studied the development of new organonickel chemistry.[1,2] In the course of this research, we found that cyclotrimerization (or [2 + 2 + 2] cycloaddition) of enones and alkynes occurred in the presence of both nickel(0) and some other metal species such as aluminum phenoxide or zinc halide.[3,4] Inspired by the synergistic effects of binary metal catalysts, we applied this concept to the cyclotrimerization of two or three different monoynes,[5] in which the control of chemo- and regioselectivity is a crucial problem. We report here the remarkable effects of a zinc(II) phenoxide co-catalyst in the nickel(0)-catalyzed cyclotrimerization of monoynes.[6]

We first investigated the reaction of methyl propargyl‡ ether (**1a**) with methyl propiolate (**2**) (Scheme 1). When a THF solution of **2** (2 eq.) was added dropwise with stirring over 5 min at rt to a THF solution of **1a** (1 eq.), $Ni(acac)_2$ (5 mol%), PPh_3 (10 mol%), Et_2Zn (50 mol%), and PhOH (80 mol%), a mixture of two regioisomeric cycloadducts **3a** and **4a**, which were formed by the chemoselective coupling of one molecule of **1a** and two molecules of **2**, was obtained in 78% yield (Table 1, run 1). The major isomer (95% selectivity) was determined to be **3a** by the spectral analyses. Other benzene derivatives such as **5**, **6**, and **7** were not obtained in this reaction. In contrast, when the reaction was carried out without both Et_2Zn and PhOH, chemoselectivity did not occur (runs 1 and 2 *vs.* run 3). While other metal species such as Et_2Zn itself, $ZnCl_2$, and aluminum phenoxides also assisted the nickel catalyst in the cycloaddition, a noticeable amount of **6** was detected by GC analysis (runs 5–8). The results indicate that the remarkable chemoselectivity is due to the effects of a zinc phenoxide prepared from Et_2Zn and PhOH *in situ.*[7,8]

We explored the scope of the chemo- and regioselective cyclotrimerization of various **1** with **2** in the presence of Ni(0)–PPh_3–Et_2Zn–PhOH (Scheme 2). In each reaction, competing self-trimerizations were suppressed. When **2** was added slowly over 60 min to the reaction medium involving hex-3-yne (**1c**),

Table 1 Catalytic cycloaddition of **1a** and **2**[a]

Run	Catalytic system	Yield[b] (%) (**3a** + **4a**)	**5**	**6**	**7**
1	$Ni(acac)_2$–PPh_3–Et_2Zn–PhOH[c]	81 (78)	0	0	0
2	$Ni(cod)_2$–PPh_3–Et_2Zn–PhOH[d]	(67)	0	0	0
3	$Ni(cod)_2$–PPh_3[e]	10	19	19	11
4	$Ni(acac)_2$–Et_2Zn–PhOH[f]	0	0	0	0
5	$Ni(acac)_2$–PPh_3–Et_2Zn[g]	30	0	8	4
6	$Ni(cod)_2$–PPh_3–Et_2Zn[h]	29	0	13	5
7	$Ni(cod)_2$–PPh_3–$ZnCl_2$[i]	38	0	26	4
8	$Ni(acac)_2$–PPh_3–Me_3Al–PhOH[j]	21	0	56	4

[a] All reactions were carried out as follows: a THF solution of **2** (2 eq.) was added dropwise over 5 min at rt to a THF solution of **1a** (1 eq.) and catalysts. [b] GC yield. Isolated yield is in parentheses. The yield of **7** is estimated on the basis of those of **3**–**6**. [c] $Ni(acac)_2$–PPh_3–Et_2Zn–PhOH = 0.05:0.1:0.5:0.8. [d] $Ni(cod)_2$–PPh_3–Et_2Zn–PHOH = 0.05:0.1:0.4:0.8. [e] $Ni(cod)_2$–PPh_3 = 0.05:0.1. [f] $Ni(acac)_2$–Et_2Zn–PhOH = 0.05:0.5:0.8. [g] $Ni(acac)_2$–PPh_3–Et_2Zn = 0.05:0.1:0.5. [h] $Ni(cod)_2$–PPh_3–Et_2Zn = 0.05:0.1:0.4. [i] $Ni(cod)_2$–PPh_3–$ZnCl_2$ = 0.05:0.1:0.4. [j] $Ni(acac)_2$–PPh_3–Me_3Al–PhOH = 0.05:0.1:0.5:0.8.

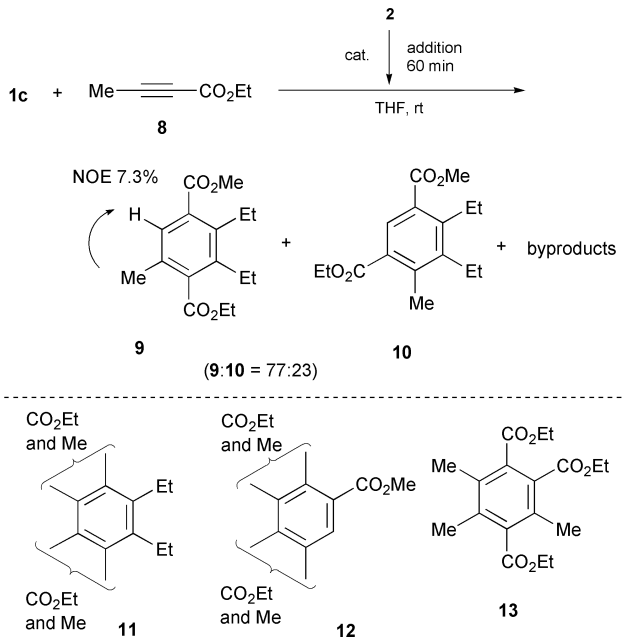
Table 2 Cylocotrimerization of **1** and **2** in the presence of $Ni(acac)_2$–PPh_3–/Et_2Zn–PhOH[a]

Entry	1	Add. time/min	Product(s)	Yield[b] (%)	Ratio[c] (**3**:**4**)
1	**1a**	5	**3a**, **4a**	78	95:5
2	**1b**	5	**3b**, **4b**	60	95:5
3	**1c**	60	**3c**	41	100:0
4	**1d**	60	**3d**, **4d**	50	92:8
5	**1e**	20	**3e**, **4e**	64	90:10
6	**1f**	10	**3f**, **4f**	53	94:6
7	**1g**	20	**3g**, **4g**	55	93:7
8	**1h**	60	**3h**	49	100:0
9	**1i**	20	**3i**, **4i**	68	93:7

[a] All reactions were carried out as follows: a solution of **2** (2 mmol) in THF (2 mL) was added dropwise with stirring to a mixture of **1** (1 mmol), $Ni(acac)_2$ (0.05 mmol), PPh_3 (0.1 mmol), Et_2Zn (1.0 M in hexane, 0.5 mL), and PhOH (0.8 mmol) in THF (5 mL) at rt. [b] Isolated yield. [c] Determined by integration of the aryl protons of ^1H NMR.

the cross-cyclotrimerization adduct **3c** was obtained as the sole product (Table 2, entry 3). *tert*-Butylacetylene (**1d**) and (trimethylsilyl)acetylene (**1e**) were also applied to the cyclotrimerization (entries 4 and 5). Biaryl compounds **3f**–**h** were synthesized from the reaction with the corresponding arylacetylenes **1f**–**h**, respectively (entries 6–8). The presence of an electron-withdrawing group on arylacetylene tended to increase the regioselectivity. A conjugated enyne **1i** reacted with **2** to give an α-methylstyrene derivative **3i** with an excellent regioselectivity (entry 9).

Interestingly, the cyclotrimerization of three different monoynes was also effectively promoted by the nickel(0) and zinc phenoxide system mentioned above. Thus, when **2** (1 eq.) was added dropwise over 60 min to a mixture of **1c** (1 eq.) and ethylbut-2-ynoate (**8**, 1 eq.) in the presence of the binary metal catalyst (Scheme 3), a mixture of three-component cycloadduct **9** and its regioisomer **10** was preferentially obtained along with small amounts of other benzene derivatives **3c**, **11**, and **12** (Table 3, run 1). On the other hand, in the reactions without zinc phenoxide, the desired **9** and **10** were obtained in lower yields (runs 2–4).



Scheme 3

The transition-metal-catalyzed cyclotrimerization of alkynes has been extensively studied by several research groups.[9] However, in contrast to intramolecular reactions,[10] a fully intermolecular reaction has not yet been established as a useful synthetic method. We have demonstrated that the binary metal system of nickel(0) and zinc(II) phenoxide effectively catalyzes

Table 3 Cyclotrimerization of **1c**, **2**, and **8**[a]

Run	Catalytic system	Yield[b] (%) (**9** + **10**)	Byproducts[c]
1	$Ni(cod)_2$–PPh_3–Et_2Zn–PhOH[d]	45 (48)	**3c** (4) + **11** (1) + **12** (8)
2	$Ni(cod)_2$–PPh_3[e]	(< 3)	**8** (> 90% recovery)
3	$Ni(cod)_2$–PPh_3–Et_2Zn[f]	(13)	**11** + **12** (total 5) + other products
4	$Ni(cod)_2$–PPh_3–Me_3Al–PhOH[g]	24 (27)	**3c** (5) + **6** (3) + **11** (2) + **12** (7) + **13** (13)

[a] All reactions were carried out as follows: a THF solution of **2** (1 eq.) was added dropwise with stirring over 60 min at rt to a THF solution of **1c** (1 eq.), **8** (1 eq.), and catalysts. [b] Isolated yield. GC yield is in parentheses. [c] The yield of **12** (*m/z* = 308) is estimated on the basis of that of **11**. [d] $Ni(cod)_2$–PPh_3–Et_2Zn–PhOH = 0.05:0.1:0.5:0.8. [e] $Ni(cod)_2$–PPh_3 = 0.05:0.1. [f] $Ni(acac)_2$–PPh_3–Et_2Zn = 0.05:0.1:0.5. [g] $Ni(cod)_2$–PPh_3–Me_3Al–PhOH = 0.05:0.1:0.4:0.8.

the chemo- and regioselective cyclotrimerization of two or three different monoynes. While the detail is being investigated further in our laboratory, the present finding should help address a longstanding problem in the cyclotrimerization.

This work was supported by Grants-in-Aid for Scientific Research on Priority Areas (A) (No. 283, 'Innovative Synthetic Reactions') from the Ministry of Education, Science, Sports and Culture, Government of Japan (Monbusho).

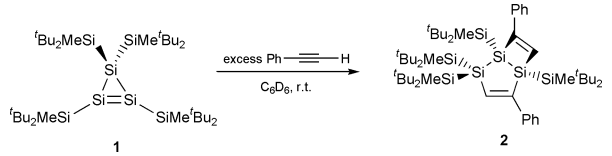
Cyclotrisilene, $(^tBu_2MeSi)_4Si_3$, was reacted with phenylacetylene to produce an unusual 1,2,5-trisilabicyclo[3.2.0]hepta-3,6-diene derivative, whose structure was determined by NMR spectroscopy and X-ray crystallography; a mechanism for its formation is proposed.

The synthesis and characterization of a number of isolable double bond species consisting of the heavier Group 14 elements has been accomplished since the first isolation of tetramesityldisilene by West *et al*. in 1981.[1,2] Cyclotrimetallenes (R_4M_3, M = Si, Ge, Sn), *i.e.* compounds with endocyclic metal–metal double bonds, have been prepared: cyclotrigermenes in 1995,[3] cyclotrisilenes in 1999,[4,5] and cyclotristannene in 1999.[6] Quite recently, we have succeeded in the preparation of the first mixed cyclotrimetallenes consisting of two different Group 14 elements: 1- and 2-disilagermirenes.[7] These compounds exhibit an enhanced reactivity arising from the combination of a highly reactive metal–metal double bond and a highly strained three-membered ring skeleton in one molecule, which gives access to new cyclic and bicyclic compounds by addition and cycloaddition reactions.[8] Recently, we have also succeeded in transforming the cyclotrigermenes and cyclotrisilene into the cyclotrigermenylium ions[9] and cyclotetrasilenylium ion,[10] which are free germyl and silyl cations, respectively. Herein, we report on the reaction of cyclotrisilene **1** with phenylacetylene to produce an unusual product with a bicyclo[3.2.0]hepta-3,6-diene skeleton, and report also on its reaction mechanism.

Cyclotrisilene **1** was allowed to react with excess phenylacetylene in C_6D_6 at rt. The orange colour of **1** disappeared within 15 h to give a 1,2,5-trisilabicyclo[3.2.0]hepta-3,6-diene derivative **2** in a 65% yield (Scheme 1). No reaction occurred with trimethylsilylacetylene, bis(trimethylsilyl)acetylene, or diphenylacetylene, and a complicated reaction mixture was formed with hex-1-yne.

The structure of **2** was determined by mass spectrometry, NMR spectra and X-ray crystallography. The mass spectrum of **2** showed a very weak parent ion at 916, with fragmentation peaks at 859 ($M^+ - {}^tBu$) and at 759 ($M^+ - SiMe^tBu_2$). The ^1H NMR spectrum showed two olefinic protons at 7.42 and 7.98 ppm, as well as peaks indicating the presence of four different $^tBu_2MeSi$ groups, and two phenyl groups. The ^{13}C and ^{29}Si NMR spectra were also consistent with this structure being a 1:2 adduct of **1** and phenylacetylene. As shown in Fig. 1, compound **2** has a bicyclo[3.2.0]hepta-3,6-diene skeleton, the formation of which can be explained by the consecutive addition of one molecule of phenylacetylene to the Si=Si double bond, and by the insertion of a second molecule of phenylacetylene into the Si–Si single bond in the resulting cyclotrisilane ring. The cycloaddition reaction of acetylenes with a Si=Si double bond to give the disilacyclobutene derivative is well known,[11] but the insertion of C–C multiple bonds into a Si–Si single bond at ambient temperature without the use of a catalyst has not been reported.



1 2

Scheme 1

The formation of **2** was quite interesting for us, and prompted us to investigate its formation mechanism. Under the same conditions as above, deuterium-labelled cyclotrisilene, **1**–$\mathbf{d}_6$,[12] in which the CH_3 groups in the di-*tert*-butyl(methyl)silyl substituents on the saturated silicon atom were replaced by a CD_3 group, was reacted with phenylacetylene to give **2a**–$\mathbf{d}_6$ and **2b**–$\mathbf{d}_6$ in a 1:1 molar ratio.[13] This result indicates that **2** is not formed *via* a simple [2 + 2] cycloaddition and insertion process. A more likely mechanism is as follows. First, the phenylacetylene undergoes cycloaddition to the Si=Si double bond of **1**–$\mathbf{d}_6$ to form the 1,4,5-trisilabicyclo[2.1.0]pent-2-ene derivative **3**–$\mathbf{d}_6$, which then isomerizes to the 1,2,3-trisilacyclopenta-3,5-diene derivative **4**–$\mathbf{d}_6$, which has a conjugated Si=C–C=Si system in a five-membered ring. Secondly, one $^tBu_2(CD_3)Si$ group on a saturated silicon atom migrates to an unsaturated silicon atom to give the 1,2,3-trisilacyclopenta-2,4-diene derivative **5**–$\mathbf{d}_6$, which has a conjugated Si=Si–C=C system in a five-membered ring.[14] Finally, the silole intermediate **5**–$\mathbf{d}_6$, is trapped by phenylacetylene *via* a [2 + 2] cycloaddition across

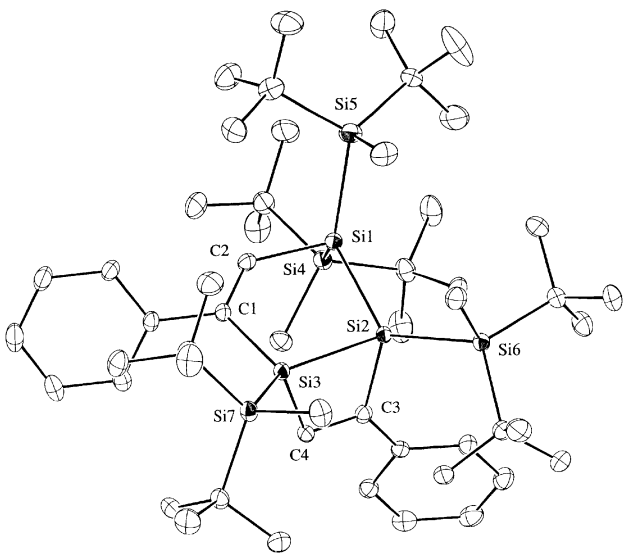


Fig. 1 Structure of **2** (hydrogen atoms are omitted for clarity). Selected bond distances [Å] are: Si1–Si2 2.477(1), Si1–C2 1.893(3), Si2–Si3 2.388(1), Si2–C3 1.943(3), Si3–C 11.909(3), Si3–C4 1.892(3), C1–C2 1.351(4), C3–C4 1.356(4). Selected bond angles [°] are: Si2–Si1–C2 95.8(1), Si1–Si2–Si3 92.6(0), Si3–Si2–C3 73.7(1), Si2–Si3–C1 101.7(1), Si2–Si3–C4 75.0(1), Si3–C1–C2, 119.0(2), Si1–C2–C1 130.5(2), Si2–C3–C4 104.7(2), Si3–C4–C3 106.5(2).

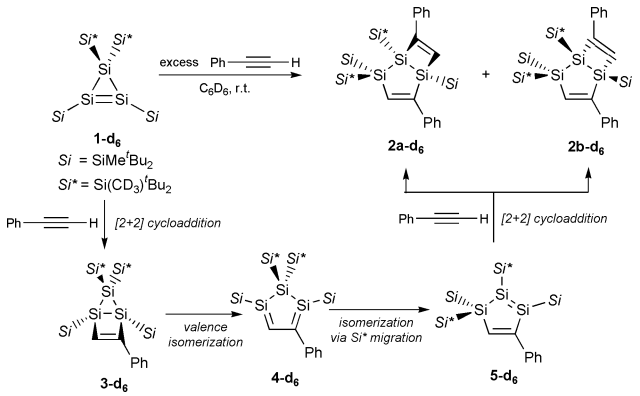
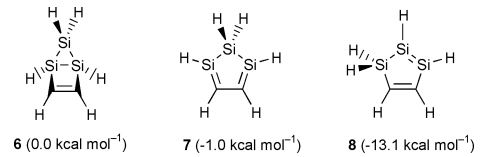
DOI: 10.1039/b008375p



Scheme 2

the Si=Si double bond to afford a mixture of **2a**–$\mathbf{d}_6$ and **2b**–$\mathbf{d}_6$ (Scheme 2). However, the silole intermediates **4** and **5** were not observed in monitoring the reaction of **1** with phenylacetylene using NMR spectroscopy, which is probably due to their high reactivity. Even with equimolar quantity of phenylacetylene, the product **2** was formed together with unreacted **1**.

To have a better understanding of the isomerization of **3** to **5**, *ab initio* calculations on the parent system (**6**–**8**) were carried out at the Beck3LYP/6-31G(d) level, and all isomers **6**–**8** were found as energy minimum structures. The bicyclic structure **6** was the most unfavourable, probably due to the highly strained three- and four-membered bicyclic structure, and the siloles **7** and **8** were more stable by 1.0 and 13.1 kcal mol^{-1} relative to



6, respectively. The conrotatory isomerization of **6** to **7** may be unfavourable because of the fixed bicyclic structure of **6**. The last compound consequently isomerizes by the migration of the hydrogen atom to give the thermodynamically most stable silole structure **8**, with a Si=Si–C=C conjugated system.

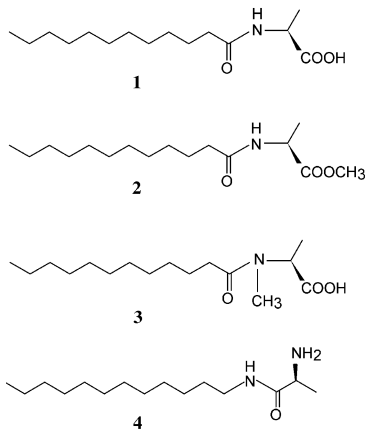
From a two-phase mixture of water and oil (either commercial fuel or pure organic solvent), a simple amino acid derivative, *N*-lauroyl-L-alanine has been shown to be able to gelate the oil phase selectively; SEM and FT-IR provided molecular level insights into the process of gelation.

Much has been achieved in the field of polymeric gels and their applications.[1] Although several excellent non-polymeric *low molecular mass* organogelators have been developed,[2,3] the ability of an organogelator to gelate one solvent in preference to another from a given mixture has still not been evidenced. This becomes an even more daunting task when one of the solvents in such a mixture is water. This is because, in contrast to their macromolecular counterparts, the network structure formed by low molecular weight organogelators are often held together by non-covalent interactions such as hydrogen bonding.[3] Understandably, water competes for the hydrogen bonding sites in the gelator molecule, thereby disrupting the self-association of the gelator and ruining gelation. We discovered that a fatty acid



derived amino acid, *N*-lauroyl-L-alanine, **1**, is a simple and effective system for the selective gelation of non-polar organic solvents such as aromatic and aliphatic hydrocarbons. Herein we report for the first time an organogelator, which is capable of achieving solvent-specific gelation from a two-phase mixture. To derive a proper structure–property correlation, related compounds **2**–**4** were also synthesized.‡

First the efficiency of **1** in gelating various aromatic and aliphatic hydrocarbon solvents was examined§ (Table 1). For a series of *n*-alkanes with $6 < n < 12$, the MGC passed through a maximum for $n = 8$, and another minimum was reached for $n = 16$, where n is the number of C-atoms in the aliphatic hydrocarbon. The gels formed in aliphatic hydrocarbons were translucent in nature while those formed in aromatic solvents were found to be transparent. Since the above solvents also form major constituents of petrol, we found that **1** could indeed gelate a wide range of commercial fuels (Table 1).

Representative SEM¶ of the gels of **1** obtained from either *n*-heptane (Fig. 1A) or toluene (Fig. 1B) shows the presence of a network of fibers of varying thicknesses. In the heptane gels, a profusion of thin fibers (0.5–1.5 μm) was seen while in toluene gels individual fibers of regular thickness (3.0 μm) appeared to merge into thicker fibers (6–15 μm). Solvent molecules get entrapped in the fibrous networks due to surface tension resulting in gelation.

We then investigated selective gelation of a discrete volume of such fuels by **1** when it is present in a two-phase system. A mixture of double-distilled water (2 mL) and an oil (2 mL) was taken in a test tube and **1** (10 mg) was added to the two-phase mixture. Compound **1** was solubilized either by heating or by injection of an ethanolic solution of **1** leaving the mixture to equilibrate. Remarkably, as soon as rt was attained, the oily layer was found to be completely gelated leaving the aqueous layer unaffected. Even upon standing for ~1 week, both the phases remained intact with their respective states of gelation and non-gelation. When the experiment was repeated with periodic or continuous violent agitation (a model 'oil-spill situation') the above mixture formed an emulsion which, upon cooling to rt, rapidly solidified into a mass where the phase

Table 1 Gelation properties of **1** (1 mmol) and minimum gelator concentration (MGC) in g L^{-1} (gelator/organic solvent) necessary for gelation of various organic solvents at 25 °C

† Also at the Chemical Biology Unit, JNCASR, Bangalore 560 064, India. This work was supported by the Swarnajayanti fellowship grant of the Department of Science and Technology (Government of India) awarded to S. B.

boundaries were indistinct. Heating of this gelled emulsion to > 50 °C resulted in the 'melting' of the mass which separated into discrete aqueous and organic layers. When this was allowed to cool undisturbed, as before only the organic layer was gelated selectively. Similarly, a given volume of commercially available petrol could be gelated from a two-phase mixture. Importantly the gelation was unaffected even in the presence of (a) NaCl (at various concentrations) or (b) chelation inducing metal salts (*e.g.* $CuSO_4$), or (c) oxidizing agents (*e.g.* $KMnO_4$) or (d) other impurities present in water from natural sources (not shown).

Next, the roles of various functional groups involved in the self-assembly process were investigated by blocking one by one the hydrogen bonding sites in **1** *via* chemical modification. First the carboxylic acid (-CO_2H) in **1** was converted to its methyl ester, **2**. Then the amide moiety (-NH-C(O)) in **1** was subjected to *N*-methylation to give **3**. Interestingly, neither **2** nor **3** induced any gelation. Thus the presence of both the -CO_2H and the secondary amide (-NH-C(=O)) appear to be essential for self-association of the monomer into fibers (Fig. 1) a necessary prerequisite for gelation.

In order to understand the precise roles of the -CO_2H and -NH-C(=O) residues in **1** in the process of gelation, detailed FT-IR studies were carried out.‖ First, FT-IR spectra of (a) the solid (KBr pellet) from a dried benzene gel of **1**, (b) solutions of **1** (c = 60 mg mL^{-1}) in benzene and (c) in a non-gelatable solvent such as $CHCl_3$ were compared (not shown). The amide and the –CO_2H moieties in **1** are as strongly hydrogen bonded in the gel state as they are in the solid state. Benzene does not interfere with the intermolecular association. The *amide I* band in the gel state was almost as strongly hydrogen bonded as in the solid (1646 cm^{-1}). However, in $CHCl_3$ the *amide I* band (1669 cm^{-1}) evidenced a weakly hydrogen bonded species probably between the oxygen of the amide carbonyl and the acidic H of $CHCl_3$. This is confirmed by efficient gelation of CCl_4 by **1**. Thus solvents capable of hydrogen bonding *suppress* gelation in these systems by disallowing the self-assembly process.

The -CO_2H sites of **1** in both solvents form dimers of comparable strength (1732 cm^{-1}). Thus the factor controlling gelation of **1** seems to be hydrogen bonding at the amide sites (-N–H···(O)=C–N–H···(O)=C-), which is significantly affected by the polarity and protic nature of the solvent. However, the strength of the *amide I* band is considerably weaker in $CHCl_3$ (1669 cm^{-1}) than in benzene (1648 cm^{-1}). It is this difference in strength that most probably determines whether the solvent promotes or inhibits perpetuation of the superstructure. In addition to the amide site, the availability of the free -CO_2H is mandatory for the dimer formation leading to gelation. This was confirmed with **4** where the free amine cannot form analogous dimers and despite the presence of amides, the gelation did not occur.

In summary, in order to exhibit gelation, the molecule must have the capacity to self-assemble in three-dimensions to form fibrous networks. Self-assembly of **1** is evident from SEM. IR studies show that this process involves at least two interactions (-CO_2H and (O)=C–N–H) where each residue promotes the formation of a supramolecular array. In water, due to the presence of a lipophilic alkyl chain, **1** exerts a hydrophobic effect[4] and excludes water. Additional stabilization of such aggregates most likely originates from Van der Waals contacts of the polymethylene chains. This promotes the self-organization of **1** and in the process it is able to gelate hydrocarbon-based fuels or solvents even in the presence of water. While the present system is interesting, the necessity to heat and cool the samples in order to achieve phase separation significantly limits its use for the containment of oil-spills. Clearly issues such as requirement of heating to achieve gelation have to be addressed before a real-life application is possible. Nevertheless the present system demonstrates its unique ability to confer phase-selective gelation of toxic solvents from complex mixtures.

Notes and references

‡ All new compounds, **1**–**4**, were synthesized from readily available precursors and were characterized by FT-IR, ^{1}H-NMR, LR-MS and elemental analysis. Selected data: *N*-*n*-dodecanoyl-(*S*)-alanine (**1**) was synthesized by the hydrolysis of **2** in MeOH with 1.0 eq. of 1 M NaOH for 2 h at ~5 °C followed by careful acidification in cold conditions. Isolated as a solid, mp: 84 °C (97% yield). $[\alpha]_D^{25}$ (c = 2 in $CHCl_3$) = +16.6°. IR (cm^{-1}): 3348, 1704, 1646, 1520. ^{1}H-NMR (300 MHz, $CDCl_3$) δ: 0.88 (t, J = 6.5 Hz, 3H), 1.25 (br m, 16H), 1.45 (d, J = 7 Hz, 3H), 1.61 (m, 2H), 2.22 (t, J = 8 Hz, 2H), 4.54 (m, 1H), 6.4 (d, J = 9 Hz, 1H). LR-MS: 271 (M^+, 2%). Anal. calcd. for $C_{15}H_{29}NO_3$: C, 66.38; H, 10.77; N, 5.16. Found: C, 66.62; H, 10.94; N, 4.92%. Methyl *N*-*n*-dodecanoyl-(*S*)-alaninate (**2**) was synthesized by reaction of L-alanine methyl ester hydrochloride (Fluka) with dodecanoyl chloride (1.1 eq.) in dry $CHCl_3$ and Et_3N (2.2 eq.). Isolated as a solid, mp: 65 °C, (97% yield). $[\alpha]_D^{25}$ (c = 2 in $CHCl_3$) = +14.0°. IR (cm^{-1}): 3300, 1732, 1650, 1537. ^{1}H-NMR (300 MHz, $CDCl_3$): δ: 0.88 (t, J = 7 Hz, 3H), 1.26 (br m, 16H), 1.41 (d, J = 6.5 Hz, 3H), 1.62 (m, 2H), 2.18 (t, J = 8 Hz, 3H), 3.73 (s, 3H), 4.56 (m, 1H), 5.93 (d, J = 9 Hz, 1H). LR-MS: 285 (M^+, 2%). Anal calcd. for $C_{16}H_{31}NO_3$: C, 67.33; H, 10.95; N, 4.91. Found: C, 67.52; H, 11.03; N, 5.05%. *N*-*n*-Dodecanoyl-*N*-methyl-(*S*)-alanine (**3**) was synthesized by the reaction of *N*-methyl-L-alanine (Fluka) in dry DMF with dodecanoyl chloride (Fluka) and Et_3N (1.1 eq.). Isolated as a solid, mp: 79 °C, (64% yield). $[\alpha]_D^{25}$ (c = 2 in $CHCl_3$) = +10.1°. IR (KBr) (cm^{-1}): 1701, 1645, 1541. ^{1}H-NMR (300 MHz, $CDCl_3$) δ: 0.87 (t, J = 6.5 Hz, 3H), 1.26 (br m, 16H), 1.44 (d, J = 7 Hz, 3H), 1.62 (m, 2H), 2.21 (t, J = 8 Hz, 3H), 2.91 (s, 3H), 4.53 (m, 1H). LR-MS: 285 (M^+, 2%). Anal. calcd. for $C_{16}H_{31}NO_3$: C, 67.33; H, 10.95; N, 4.91. Found: C, 67.22; H, 10.58; N, 4.74%. *N*-Dodecyl-(*S*)-alaninamide (**4**) was prepared by catalytic hydrogenation (10% Pd/C) in MeOH of *N*-benzyloxycarbonyl-*N*′-hexadecyl-(*S*)-alaninamide, a compound that was prepared by DCC coupling of (*S*)-*N*-Benzyloxycarbonylalanine (Fluka) and *n*-hexadecylamine (Fluka) in dry THF. Isolated as a hygroscopic solid, mp: 54 °C (87% yield). $[\alpha]_D^{25}$ (c = 2 in $CHCl_3$) = +12.8°. IR (KBr) (cm^{-1}): 3320, 1630, 1560. ^{1}H-NMR (300 MHz, $CDCl_3$) δ: 0.86 (t, J = 7 Hz, 3H), 1.2 (br m, 18H), 1.26 (m, 2H), 1.43 (d, J = 7 Hz, 3H), 3.2 (m, 2H), 4.09 (m, 1H), 7.5 (br s, 1H). LR-MS: 256 (M^+, 40%). Anal. calcd. for $C_{15}H_{32}N_2O{\cdot}0.25\ H_2O$: C, 69.04; H, 12.56; N, 10.74. Found: C, 69.36; H, 12.83; N, 10.48%.

§ The ability of **1** to gelate a given solvent was tested by solubilizing **1** (1 mmol) in the desired solvent (7.5 mL) by gentle heating and allowing the solution to spontaneously cool to rt. The gel was allowed to stand for *ca.* 15 min at rt. MGC was calculated as described in the literature.[3a]

¶ Scanning electron micrograph (SEM) was recorded using a Cambridge stereoscan S-360 SEM. A glass plate bearing a droplet of **1** dissolved in benzene or *n*-heptane was attached to the sample stage after completion of gelation and sputtered with gold to 100–150 Å.

‖ **1** was dissolved in the desired concentrations in benzene or $CHCl_3$ and loaded into a solution cell of a JASCO 410 FT–IR spectrometer. Spectra were corrected for solvent absorption.

First published as an Advance Article on the web 8th January 2001

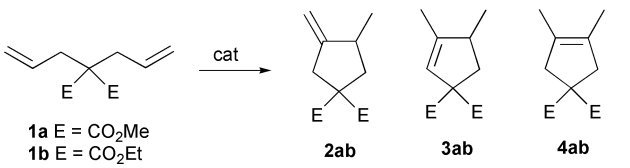
$[(MeCN)_3PdCl]^+$, generated *in situ*, reversibly disproportionates to give $[(MeCN)_2PdCl_2]$ and $[(MeCN)_4Pd]^{2+}$. The neutral species is a reactive and highly regioselective catalyst for 1,6-diene cycloisomerisation.

Early examples of transition metal-catalysed cycloisomerisation reactions[1] employed hepta-1,6-dienes (*e.g.* **1**) as substrates.[2–4] Since dialkyl diallylmalonates **1** may form cyclopentane **2** and cyclopentenes **3** and **4**, much of the focus in their cycloisomerisation has been the efficient control of regioselectivity (Scheme 1). A pioneer in this area was Grigg,[4] who reported regioselective $[(PPh_3)_3RhCl]$-catalysed isomerization of **1b** to **2b** ($CHCl_3$, reflux 8 h)‡ or **4b** (EtOH, reflux, 12 h).‡ Under palladium catalysis [5 mol% $Pd(OAc)_2$ or $PdCl_2$] isomeric **3b** and **4b** were obtained in good yields (80–88%) and with good regioselectivity (92−94%) for **3b** ($CHCl_3$, reflux 6–8 h).‡ Much more recently, a number of other catalyst systems have been developed for selective isomerisation of **1** to **2** or **4**,[5] although catalysts for selective conversion of **1** to **3** still remain rare.[4,6] Our attention was drawn to the recent report by Heumann and Moukhliss[7] on the use of $[(MeCN)_{(4-m)}Pd(Cl)_m]^{(2-m)+}$ {generated *in situ* from the neutral complex $[(MeCN)_2PdCl_2]$} for cycloisomerisation. By use of 1 or 2 equivalents of $AgBF_4$ (per Pd), **1b** was isomerised to **3b** (79%, 18 h, reflux, 5 mol% Pd, $CHCl_3$) or to **2b** (39%, 8 h, reflux, $CHCl_3$), respectively. This led the authors to conclude that it is the catalyst charge that controls the regioselectivity.[7]

We have recently been studying the mechanism by which $[(MeCN)_2Pd(allyl)]^+$ (5 mol%) in $CHCl_3$ cycloisomerises **1a**.[8] The primary and predominant product is **2a**, however, on co-addition of 1 mol% $[Cl_2Pd_2(allyl)_2]$, which is not itself an active catalyst, both **2a** and **3a** are generated at approximately equal rates. This suggested to us that it could be the presence of chloride, rather than the charge, that determines the regioselectivity in the Heumann system.[7] Consequently, we attempted to isolate $[(MeCN)_3PdCl]^+$ from a freshly prepared solution {AgOTf, MeCN, $CHCl_3$, $[(MeCN)_2PdCl_2]$, filter}. However, chloride redistribution through monomer/μ-halide dimer equilibrium resulted in crystallisation of the neutral dichloride $[(MeCN)_2PdCl_2]$,§ leaving the more soluble complex $[(MeCN)_4Pd][OTf]_2$¶ in solution. Since nearly all Pd-catalysed 1,6-diene cycloisomerisations employ cationic pro-catalysts[5b,c,6,7] there seems to be a general assumption that halide abstraction to generate a mono- or di-cation is a pre-requisite for activity. In fact, pure neutral $[(MeCN)_2PdCl_2]$ turned out to be a far more active catalyst than the analogous mono- or di-cationic complexes. For example, in the presence of 5 mol% $[(MeCN)_2PdCl_2]$, a $CHCl_3$ solution of **1a** was quantitatively cycloisomerised in just a few minutes at 60 °C. The catalyst was also active at lower temperatures, *e.g.* at 40 °C, 100% conversion was achieved in under 2 h with 97% regioselectivity for **3a** and no trace of **2a** evident by GC.‖

Neutrality and the presence of chloride appear to be important features in the activity of $[(MeCN)_2PdCl_2]$: simple salts** $[PdI_2, Pd(OAc)_2, Pd(O_2CCF_3)_2]$ failed to isomerise **1a** at 60 °C in the presence or absence of added MeCN (10 mol%) over a period of many hours. As indicated above, the cations are much less reactive and addition of 5 mol% NBu_4X (X = Cl, Br or I) to $[(MeCN)_2PdCl_2]$, to generate an anionic palladate-type species, completely inhibited catalysis. A stoichiometric reaction between **1a** and $[(MeCN)_2PdCl_2]$ in $CDCl_3$ was followed by ^1H NMR (500 MHz) at 25 °C. There were no observable complexation processes,†† just the slow consumption of **1a** and appearance of **3a**. To gain more information, the kinetics of the catalytic reaction (5 mol% Pd) were measured (HRGC) in $CHCl_3$, CH_2Cl_2 and 1,2-dichloroethane (DCE) at 23, 40 and 60 °C. In nearly all cases, an induction period was followed by a pseudo-zero-order rate profile over three to four half-lives (*ca.* 90% conversion).

The induction period indicates that $[(MeCN)_2PdCl_2]$ must be a pro-catalyst, however, there is no direct reaction between the complex and **1a** observable by NMR, *vide supra*, and although the induction period is followed by pseudo-zero order kinetics (*i.e.* steady-state catalyst concentration) no trace of any co-product from pro-catalyst reaction is evident by GC analysis.‡‡ We also prepared and evaluated $[(PhCN)_2PdCl_2]$, $[(Bu^tCN)_2PdCl_2]$, $[(DMSO)_2PdCl_2]$ and $[(PhCN)_2PdI_2]$ as cata-



Scheme 1 Transition metal-catalysed cycloisomerisation of 1,6-diene **1**.

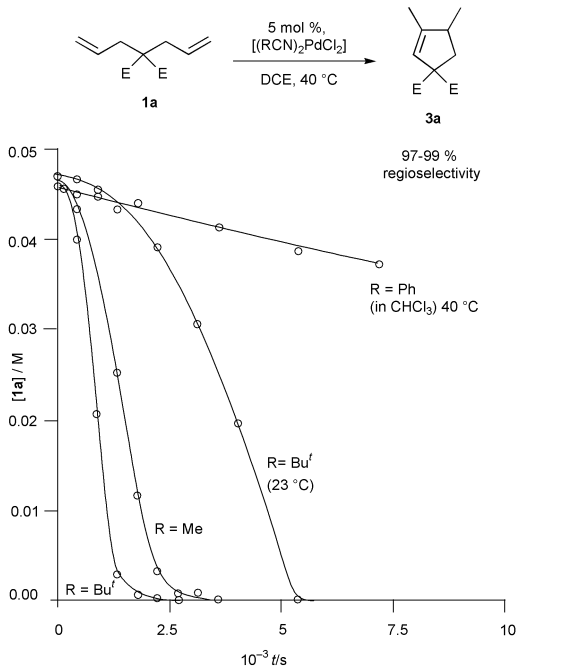


Fig. 1 Plot of variation of the concentration of 1,6-diene **1a** (M, *y*-axis) with time (*s*, *x*-axis) during cycloisomerisation by 5 mol% $[(RCN)_2PdCl_2]$ in 1,2-dichloroethane (DCE) or $CHCl_3$ at 23 or 40 °C. Concentration determined by GC analysis. For full details see ESI†.

† Electronic supplementary information (ESI) available: general experimental procedure, typical GC analyses and table of regioselectivities obtained with the various catalysts. See http://www.rsc.org/suppdata/cc/b0/b009356o/

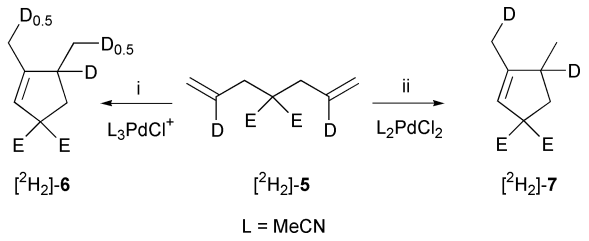
DOI: 10.1039/b009356o

lysts. Only the chloro-complexes were active for cycloisomerisation of **1a**. The rate of reaction of **1a** using the pro-catalysts of type $[(RCN)PdCl_2]$ were similar, with DCE proving the best solvent. The Bu^{t}CN-bearing complex generally showed the highest activity. With the more coordinating ligand, DMSO, the catalyst was substantially less active (*ca.* 70% conversion in 42 h at 40 °C in DCE). However, it was highly selective, giving a 110 : 1 ratio of **3a** over isomeric **2a** and **4a**. By preparing the μ-halide dimer, $[(DMSO)_2Pd_2(\mu\text{-}Cl_2)Cl_2]$ we obtained a more reactive catalyst (90% conversion, 22 h, 40 °C, DCE) which still displayed excellent regioselectivity for **3a** (99%).

The regioselectivity of the isomerisation of **1a** to **3a** mirrors, but far exceeds, that observed by Grigg using $PdCl_2$, *vide supra*. However, $PdCl_2$, being a relatively insoluble polymeric species, requires use of more vigorous conditions (8 h, reflux in $CHCl_3$).‡ In contrast, monomeric complexes $[L_2PdCl_2]$ (L = RCN or DMSO)[9] allow reaction at lower temperatures, under neutral conditions and extremely high regioselectivity is attained. For example, using $[(Bu^tCN)_2PdCl_2]$ as catalyst, > 99% conversion of **1a** occurred in 90 min at 40 °C in $CHCl_3$ and **3a** was isolated in 96% yield and high purity (97.5%) after chromatography. In summary, compared to the analogous cations $[(RCN)_3PdCl]^+$ and $[(RCN)_4Pd]^{2+}$, complexes of the type $[(RCN)_2PdCl_2]$, are far more active pro-catalysts for 1,6-diene cycloisomerisation.[10] Furthermore, most catalysts[4,6,7] generate isomeric **2** and **4** from **1**, whereas with the neutral catalysts the regioisomer **3** is obtained with very high selectivity. Ironically, $[(MeCN)_2PdCl_2]$ has been used as a precursor for $[(MeCN)_3PdCl]^+$ generation *in situ*, however, due to chloride redistribution, it remains present in the reaction mixture. Nonetheless, preliminary labelling experiments employing $[^2H_2]$-**5**,[11] demonstrate that catalysis by $[(MeCN)_2PdCl_2]$ is not the exclusive process when '$[(MeCN)_3PdCl]^+$' is employed (Scheme 2).

Of note is the finding that, unlike labelling studies of cationic Pd-catalysts that generate the regioisomer **2a**,[5c,8] no scrambling of ^2H is observed with the neutral chloride catalysts (*cf.* $[^2H_2]$-**7**, Scheme 2). This bodes well for elucidation of the complete pathway between **1** and **3** and detailed NMR, kinetic and isotopic labelling studies,[8] to distinguish hydropalladation, cyclometallation and C–H insertion pathways,[1–5] will be reported in full in due course. Additionally, novel chiral ligands allowing the generation of analogous neutral complexes are being tested for asymmetric induction.

We thank the University of Bristol and the EPSRC (GR/N05208) for support. We also thank Professor Ross A. Widenhoefer (Duke University, USA) for sharing results prior to publication.



Scheme 2 Conditions: *i*, 5 mol% $[(MeCN)_3PdCl][OTf]$ (prepared from $[(MeCN)_2PdCl_2]$ by halide abstraction in MeCN with 1 equivalent AgOTf, then removal of AgCl by filtration, evaporation and redissolution in $CHCl_3$), 40 °C, $CHCl_3$; *ii*, 5 mol% $[(MeCN)_2PdCl_2]$, 40 °C, $CHCl_3$.

Notes and references

‡ To effect catalyst activation, the solvent was pre-saturated with HCl gas before addition of the substrate and heating to reflux.

§ $[(MeCN)_2PdCl_2]$ was isolated in 66% yield (based on Cl) and its identity confirmed by comparison (FT-IR and mp) with an authentic sample.

¶ Such disproportionation to generate the achiral pro-catalyst $[(MeCN)_2PdCl_2]$ may well explain why cycloisomerisation of **1b** with 5 mol% '$[(MeCN)_3PdCl]^+$/sparteine' in $CHCl_3$, generates **3b** in essentially racemic form, but with '$[(MeCN)_4Pd]^{2+}$/sparteine', **2b** and **3b** are obtained in 60 and 37% ee respectively, see ref. 7.

‖ When pure **2a** was exposed to 5 mol% $[(MeCN)_2PdCl_2]$, no isomerisation could be detected (^1H NMR) over a period of 22 h at 40 °C. However, in some reactions small quantities of the isomer **2a** were generated. Most often, these disappeared in the later stages of reaction and the maximum level of **2a** reached during reaction was < 0.5% of the total mixture of alkenes.

** In contrast to $Pd(OAc)_2$ and $Pd(CF_3CO_2)_2$, it may be noted that PdI_2 is essentially insoluble in $CHCl_3$. However, the soluble complex $[(PhCN)_2PdI_2]$ was also found to be ineffective. Furthermore, the insoluble polymer $PdCl_2$ (or a combination of $Pd(OAc)_2$/HCl) generates a moderately active catalyst, see ref. 4(*c*).

†† However, in the last *ca.* 20% reaction a slight broadening of the signals of **1a** became apparent suggesting reversible and unfavourable complexation at the NMR timescale.

‡‡ This suggests the possibility of substrate-induced establishment of a pre-equilibrium (dissociation of nitrile or chloro-bridged dimers) or solvent–catalyst reaction to generate the active species. Ongoing studies will address this issue through full analysis of the kinetics.

Glycosyldisulfides: a new class of solution and solid phase glycosyl donors†‡

Benjamin G. Davis,* Sarah J. Ward and Phillip M. Rendle

Department of Chemistry, University of Durham, South Road, Durham DH1 3LE, UK.

Received (in Liverpool, UK) 24th October 2000, Accepted 22nd November 2000
First published as an Advance Article on the web 8th January 2001

Mixed glycosyl disulfides are not only glycomimetics but also glycosyl donors that may be readily constructed in either armed ether-protected or disarmed ester-protected and in soluble or solid-supported forms from corresponding glycosyl methanethiosulfonates and used in the glycosylation of a variety of representative acceptors.

Oligosaccharides and glycopeptides are essential tools for the investigation of the enormous variety of biological functions that require specific carbohydrate-containing structures.[1] Furthermore, their potential as therapeutic agents is clear.[2] As a result, the formation of the glycosidic linkage continues to be a dominant theme in carbohydrate chemistry.[3] Yet despite the development of many elegant strategies, there is still no generally efficient and stereoselective method available. To this end, a number of glycosyl donor systems have been developed in which differences in their anomeric leaving groups have an often critical effect upon reactivity. Of the variety of glycosyl donor systems available, thioglycosides **1** have proved one of

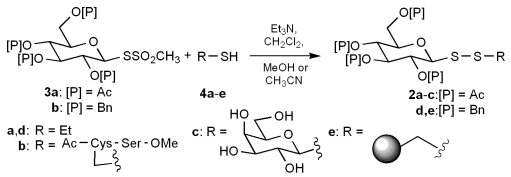
1 **2**

the most popular.[4] Strategies for tuning their reactivity, including armed/disarmed[5] donors, active/latent donors[6] or the use of bulky leaving groups,[7] have culminated in elegant one-pot glycosylation systems.[8]

With the goal of extending the scope of glycosyl donor reagents with sulfur at the anomeric centre, we have examined the utility of glycosyl disulfides **2**. These appeared attractive for several reasons: (i) the mixed disulfide linkage is a flexible one that may be cleaved for ready aglycon adjustment in reactivity tuning methods.[9] (ii) If used as a linker in solid-supported glycosylations, the anomeric mixed disulfide linkage would allow bidirectional (reductive or hydrolytic) cleavage, that would be of great advantage in both the analysis and use of solid supported glycosylation systems. (iii) The coordination of a potential thiophile by both sulfur atoms may offer enhanced reactivity over single sulfur thioglycoside systems.[10]

Remarkably, despite these positive indications and the high utility of thioglycosides **1**, the use of glycosyl disulfides **2** as glycosyl donors in *O*-glycoside bond formation is unexplored.[11] This neglect of glycosyl disulfides may in part be due to the lack of efficiency in existing syntheses.[12] We therefore set ourselves the goals of (a) developing efficient and general methods for the construction of glycosyl disulfides and (b) exploring their utility as glycosyl donors in *O*-glycoside formation.

Methanethiosulfonate (MTS) reagents allow the rapid and efficient formation of mixed disulfides.[13] We have previously demonstrated the utility of glycosyl methanethiosulfonates in the site-selective glycosylation or proteins.[14] In order to test fully the efficiency and scope of their use as reagents we



Scheme 1

prepared a representative range of glycosyl disulfides **2a**–**e** (Scheme 1) in which the structure of the coupling thiol **4** was varied. Thus, addition of ethanethiol **4a** to equimolar glucoMTS **3a**[14] gave ethyl glucosyl disulfide **2a**† in an excellent 96% yield. Similarly, more complex dipeptide glucosyl disulfide **2b**[15] (62% yield), as a potential glycopeptide mimic, or galactosyl glucosyl disulfide **2c** (60% yield), as a potential trehalose analogue, were also prepared in fair yield simply by reaction of the appropriate thiol **4b**,**c**, respectively, with **3a**. It should be noted that in all cases the β anomeric stereochemistry of the glucoMTS was preserved in the product disulfides. This also demonstrated the compatibility of this method with partially-, **4b**, or even un-protected, **4c**, thiols. To investigate the effect of protecting groups in the glucoMTS **3**, we prepared perbenzylated glucoMTS **3b**, which also reacted smoothly with ethanethiol to give **2d** (78% yield).[16]

Having demonstrated the efficient synthesis of several different glucosyl disulfides **2a**–**d**, we chose ethyl glycosyl disulfides **2a**,**d** as model systems in which to investigate their utility as glycosyl donors with the representative selection of glycosyl acceptors **5a**–**c** (Scheme 2). As Table 1 shows, glucosyl disulfide **2a** allowed the successful preparation of simple **6a**, disaccharide **6b**[17] and glycopeptide **6c**[18] *O*-glucosides. In all three cases exclusive β-stereoselectivity was observed. However, consistent with the disarmed and peracetylated nature of **2a**, moderate yields and acetyl migration side-products[19] were obtained under a variety of conditions. The disarmed nature of **2a** was further confirmed by the lack of reactivity with I_2 but the efficient conversion of **2a** to acetobromoglucose **7** using IBr.[20] With the aim of improving efficiencies, the activation of armed perbenzylated glucosyl disulfide **2d** was investigated next. We were delighted to find that under the optimal conditions elucidated for the activation of **2a** (NIS, TESOTf, CH_2Cl_2), **2d** rapidly and smoothly[21] gave methyl glucoside **8a** in an excellent 90% yield. Furthermore, reaction of **2d** with more hindered acceptors **5b**,**c** gave good yields of disaccharide **8b**[22] and glycopeptide **8c**[23] *O*-glucosides, respectively.

[a] All reactions at rt in CH_2Cl_2 unless otherwise stated. [b] All yields are for isolated products. [c] See ref. 19. [d] See ref. 23. [e] Yield over two steps: mercaptomethylpolystyrene **4e** with **3b** then glycosylation.

To test the applicability of glycosyl disulfides to solid-supported glycosylation strategies we used mercaptomethylpolystyrene **4e** as a suitable thiolfunctionalized support (Scheme 3). Such was the reactivity of **3b** that even with solid-supported thiol **4e** reaction proceeded rapidly (1 h) to give solid-supported glycosyl disulfide **2e**.[24] The cleavage of **2e** as a representative disulfide-linked glycoside from the support in a bidirectional manner was then demonstrated. Firstly, a small portion of **2e** was taken and treated with tributylphosphine to yield configurationally stable tetrabenzyl 1-thio-β-D-glucose **9**. The potential ability to retune **9** in a latent/active manner to create a glycosyl donor bearing an alternative aglycon (in this case bearing a methyl) was demonstrated by smooth conversion into **10**[25] using methyl methanethiosulfonate. This also showed the release of solid-supported glycosyl disulfide glycosyl donor **2e** from the resin in the form of a solution phase glycosyl donor **10**, thereby demonstrating the potential of the resin as a platform for the creation of solution-phase donors. Next, the ability of **2e** to act as a solid-supported glycosyl donor was clearly demonstrated by activation with NIS, TESOTf in the presence of glycosyl acceptor **5a** to yield methyl glycoside **8a** in a good overall yield (67% over 2 steps). This is also a traceless cleavage method that installs reducing end functionality.

In summary, we have demonstrated the ready and efficient preparation of a wide range of glycosyl disulfides using differently protected glycosyl methanethiosulfonates. Furthermore, we have shown for the first time that glycosyl disulfides may be used as efficient glycosyl donors in both solution- and solid-phase systems for the preparation of *O*-glycosides including disaccharides and glycopeptides. The disulfide linkage offers enhanced utility in aglycone alteration, use as a linker to solid supports and higher activation rates, the full potential of which is the subject of current investigations.

First published as an Advance Article on the web 8th January 2001

Oxidation of adamantane and 2,3-dimethylbutane by methyl(trifluoromethyl)dioxirane is accompanied by chemiluminescence (CL); formation of the emitter of CL, triplet excited trifluoropropanone, is proposed to occur *via* a concerted oxenoid mechanism of oxygen insertion into C–H bond of the hydrocarbons.

Chemiluminescence (CL) is a promising rapidly developing area of chemistry of new class of hyperenergetic molecules—dioxiranes.[1,2,3*a*,*b*,4] In 1981 it was suggested[1] that isomerization of dioxirane into the corresponding ester should lead to the electronic excitation of the latter. Recently it was revealed that decomposition of dioxiranes in the absence of reactive substrates under certain conditions really results in production of the light emission.[2,3*a*,*b*] Apart from the study of CL of isolated dioxiranes, dioxirane intermediate has been also postulated to explain luminescence in biochemical systems.[5]

On the other hand, dioxiranes are known to be highly effective yet selective oxidants in respect to various classes of organic compounds.[3] Some of these oxidation reactions are exothermic enough[6] to generate excited species and consequently to produce CL. The area of oxidative CL of dioxiranes seems to be highly perspective from the viewpoint of fundamental questions of chemistry of excited states since it could provide new valuable information not only on mechanisms of CL, but also on some aspects of generation of light in biochemical reactions as it has been suggested that dioxirane intermediates may be involved in biochemical oxidations.[7*a*] However, in spite of these promising perspectives, so far the literature contained only a single report on generation of CL in the course of oxidative reactions of isolated dioxiranes. In 1994 CL occurring during oxidation of olefin (9-arylmethylene-10-methyl-9,10-dihydroacridine) with isolated dimethyldioxirane (DMD) was reported.[4]

In this communication we report the observation of a novel type of CL of dioxiranes occurring during oxidation of saturated hydrocarbons, such as adamantane (Ad) and 2,3-dimethylbutane (DMB), with isolated methyl(trifluoromethyl)dioxirane (TFD).[7*a*] We also suggest a plausible mechanism of luminescence generation. To the best of our knowledge, CL in the reaction of alkanes with dioxiranes is unprecedented.

We have found that interaction of Ad and TFD is accompanied by light emission in the visible spectrum region (λ_{max} = 430–470 nm). Under air atmosphere, the maximum intensity of CL and the total amount of light (*S*) evolved in the reaction (18 °C, CCl_4, $[Ad]_o$ = 0.063 mol l^{-1}, $[TFD]_o$ = 0.0019 mol l^{-1}) were equal to 2×10^6 photon $s^{-1}ml^{-1}$ and 1.4×10^7 photon ml^{-1} respectively. However, significant increase in CL intensity (I_{CL}) was observed when the reaction was carried out under nitrogen atmosphere. This effect testifies in favour of the triplet nature of the CL emitter since it is known that oxygen quenches triplet excited states.

Reaction of Ad with TFD is known[7*a*,*b*] to obey a second order low (first order on each substrate):

$W = k_2[Ad][TFD]$

or, under pseudo-first order conditions:

$W = k_1[TFD]$, where $k_1 = k_2[Ad]$.

Indeed, under $[TFD]_o << [Ad]_o$, the plots $\ln(I_{CL})$ *vs.* time were found to be linear, yielding reproducible values of k_1. From this k_2 values were estimated at different temperatures (Table 1). The activation parameters for k_2 calculated from the data of Table 1 are equal to $E_a = 8.2 \pm 0.7$ kcal mol^{-1} and $\log A = 6.5 \pm 0.5$.

Under pseudo-first order conditions the rate of the reaction (*W*) is connected with the CL intensity by the following expression:

$$I_{CL} = \varphi_{CL} W = \varphi_{CL} k_2[Ad][TFD] = k_1[TFD] \qquad (1)$$

where φ_{CL} is yield of CL.

The value of φ_{CL} was estimated from eqn. (1) using k_2 values taken from Table 1. Thus, at 18 °C φ_{CL} is equal to 1.2×10^{-11} Einstein mol^{-1}. The yield of CL calculated from the ratio $S/[TFD]_o \approx 1.16 \times 10^{-11}$ Einstein mol^{-1} is in agreement with that obtained from eqn. (1).

CL occurring under interaction of dioxiranes with alkanes appeared to be a more general phenomenon. In fact, we have found that interaction of DMB with TFD is also accompanied by light emission. The yield of CL (estimated as $S/[TFD]_o$ ratio) is equal to 2.6×10^{-12} Einstein mol^{-1} (at 18 °C). It is important to note that the region of CL appeared to be the same as for the reaction of TFD with AD, *i.e.* λ_{max} = 430–470 nm.

What is the mechanism of CL occurring under reaction of TFD with Ad and DMB? Interaction of alkanes with dioxiranes is known[3,7] to result in the formation of the corresponding alcohol and ketone–dioxirane reduction product. In the course of previous studies it was shown[3,7] that oxidation of alkanes (including Ad and DMB) by TFD is a bimolecular reaction implying involvement of high-ordered (so-called butterfly) transition state (Scheme 1 (path (a)).†

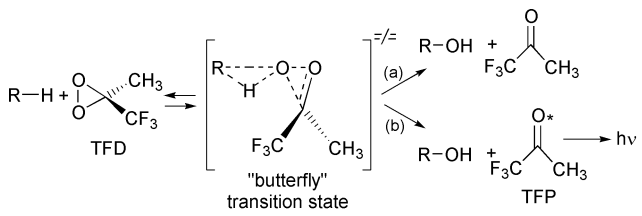
Therefore, it seems to be reasonable to attribute the light emission to the mechanism depicted in Scheme 1. According to the proposed mechanism only corresponding alcohol R–OH and trifluoropropanone (TFP) could be regarded as potential CL emitters. However, we can exclude alcohols from the consideration since they emit in the shorter wavelength region of spectrum than that recorded for CL in our system. Indeed, the range of CL observed upon oxidation of DMB and AD by TFD corresponds to the phosphorescence (PS) of TFP, testifying that

Table 1 Dependence of the rate constant of oxidation of Ad by TFD on temperature (solvent-CCl_4, N_2 atmosphere[*d*])

T/K	251	262	272	279.5	283.5	288.5	291.5
[*a*]k_2 ($l\ mol^{-1}\ s^{-1}$)	0.23[*c*] 0.51[*b*]	0.47	0.73	1.42	1.57	1.83	2.25

[*a*] Estimated as $k_2 = (k_1/[Ad]_o)$; k_1 values were obtained from pseudo-first order kinetic plots of CL damping with $[TFD]_o = 1.8–3.8 \times 10^{-3}$ mol L^{-1} and $[Ad]_o = 4–6.3 \times 10^{-2}$ mol L^{-1}; most data are averages (±5%) from duplicate or more runs. [*b*] Value of the rate constant obtained previously[7*a*] (in CH_2Cl_2–TFP mixture) under second-order rate conditions by non-CL method (GLC). [*c*] Extrapolated to 251 K from Arrhenius equation. [*d*] Replacing N_2 with O_2 atmosphere does not affect the rate constant of the reaction.

DOI: 10.1039/b008315l



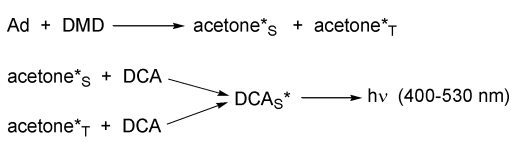
where R-H - adamantane or 2,3-dimethylbutane

Scheme 1

the latter in triplet excited state (TFP^*_T) is indeed an emitter of CL.‡ Recent calculations[5a] also favor the proposed mechanism of CL: oxygen insertion into C–H bonds of saturated hydrocarbons was shown to be about −65–−70 kcal mol^{-1} exothermic[6a] so that the sum of enthalpy and activation energy (according to our data *ca*. 8 kcal mol^{-1} for the reaction of Ad with TFD) should be sufficient for excitation (Scheme 1, path (b)) of, at least, triplet state of TFP. In fact, the energetic level of TFP^*_T is equal[8] to *ca*. 75 kcal mol^{-1}, whereas the singlet excited level of TFP[8] is about 9 kcal mol^{-1} higher and unlikely to be occupied in the reaction.

One may note that the yield of CL arising during oxidation of alkanes with TFD was found to be relatively low.§ This fact is not surprising since numerous oxidation reactions are characterized by rather low yields of CL (ultra-weak CL). In particular, this is characteristic for light emission recorded in certain biological systems.[9]

It is of interest that we failed to record CL upon interaction of Ad with less reactive DMD. This is despite the fact that DMD, similar to TFD, is known to oxidize Ad into the corresponding alcohol.[7e] Probably, the slower rate of Ad oxidation by DMD, compared with that of TFD,[7b] accounts for the impossibility of recording CL due to its low intensity and the quenching of excited acetone (formed by analogy with TFP) by molecules of solvents or other reagents. However, introduction of 9,10-dicyanoanthracene (DCA) in the system results in the appearance of light emission ($[DMD]_o = 3.1 \times 10^{-2}$ mol l^{-1}, $[Ad]_o = 4 \times 10^{-2}$ mol l^{-1}, $[DCA]_o = 6.6 \times 10^{-5}$ mol l^{-1}, CCl_4–acetone = 2:1, 20 °C). DCA was found to be the emitter of the CL observed. One may suppose, that in this case DCA serves as a CL activator and enhances CL intensity as a result of energy transfer from excited acetone, formed by analogy with the mechanism suggested for TFD oxidation of alkanes (Scheme 1, path (b)). However, in contrast to the TFD case, along with triplet ketone, significant contribution of singlet excited states of acetone seems to have taken place since only insignificant quenching (*ca*. 20%) of CL intensity by oxygen is observed in this reaction. Consequently, excitation of DCA is likely to be caused by transfer of energy from both singlet and triplet excited molecules of acetone (Scheme 2).



Scheme 2

Likewise, effect of CL enhancement is observed when reaction of TFD and AD is carried out in the presence of DCA, obviously due to transfer of energy from the TFP^*_T on the activator with subsequent radiative deactivation of the latter.

In conclusion, oxidation of alkanes by TFD is accompanied by CL.¶ We have proposed a plausible mechanism of CL (Scheme 1 (path b)) to explain our observations. We suggest to call this novel type of CL *butterfly chemiluminescence* or, in more general sense, *oxygen-transfer chemiluminescence*. To the best of our knowledge, this is a new mode of chemiexcitation not only for dioxiranes but also for other liquid-phase organic reactions with peroxide participation.

We thank Russian Foundation for Basic Research (project No 99-03-32140a) and program of Leading Scientific Schools Support (project No 00-15-97323) for financial support of this work. We are also grateful to Professor Curci (University of Bari, Italy) for supplying us with the first samples of TFD and critical reading of the manuscript.

Notes and references

† Oxidation of DMB by TFD (as 1:1 ratio) leads exclusively to the corresponding alcohol.[7a] Likewise, interaction of Ad and TFD (as 0.9 ratio) results in the formation of 94% of adamantan-1-ol (Ad-OH), 5% of adamantane-1,3-diol and trace amounts of adamantanone (as a result of further oxidation of Ad-OH).[7b] Apart from these compounds and TFP no other products or even intermediates were detected in the course of the reactions of alkanes with TFD.[7] Kinetics evidence and the other experimental data[3,7] also testify in favour of absence of any other routes (including those involving participation of radicals) of the reaction except that depicted in Scheme 1 (path (a)). In particular, very low frequency factor values (logA ~ 6.6–10) noted[7a,c] for oxidation of alkanes by TFD are regarded as support for the existence of a highly ordered transition state preceding the formation of reaction products.

‡ PS spectrum of TFP was recorded on Hitachi MPF-4 fluorimeter at 77K (λ_{exc} = 320 nm): the spectrum has a broad maximum in the region 400–490 nm (spectrum of PS of TFP recorded in gas phase[8] has a shift to longer wavelength region at *ca*. 30 nm).

§ Estimation of the yield of excitation of TFP_T^* was made on the assumption that the quantum yield of its PS is about equal to that of acetone, *i.e.* 10^{-5}. Under this approach, the yield of chemiexcitation of TFP was estimated to be 10^{-4} and 10^{-5}% for the reaction of TFD with AD and DMB respectively.

¶ We have observed CL occurring upon interaction of TFD and DMD with various types of organic compounds including some polyaromatic hydrocarbons, dyes (rhodamine 6G, eosine), europium chelates *etc*. CL intensities recorded in these reactions in many cases are significantly higher then those observed in the reaction of dioxiranes with Ad and DMB (unpublished results). The study of CL arising in reactions of organic compounds with dioxiranes is under progress in our laboratory.

Dissolution of small diameter single-wall carbon nanotubes in organic solvents?

Jeffrey L. Bahr, Edward T. Mickelson, Michael J. Bronikowski, Richard E. Smalley* and James M. Tour*

Department of Chemistry and Center for Nanoscale Science and Technology, MS 222, Rice University, 6100 Main Street, Houston, Texas 77005, USA. E-mail: tour@rice.edu

Received (in Columbia, MO, USA) 19th September 2000, Accepted 27th November 2000
First published as an Advance Article on the web 8th January 2001

The solubility of small diameter single-wall carbon nanotubes in several organic solvents is described, and characterization in 1,2-dichlorobenzene is reported.

Owing to their phenomenal electrical and mechanical properties, single-wall carbon nanotubes (SWNTs) have been an area of intense research since their discovery in 1991,[1] and a variety of potential applications have been proposed.[2] Many of these applications will likely require chemical modification to facilitate manipulation of the tubes. Consequently, there have been significant efforts to derivatize SWNTs.[3] These efforts, including our own, have been hampered by minimal or complete lack of solubility in common organic solvents. We report here a screening of organic solvents, many of which have previously been found advantageous towards the dissolution of C_{60} and C_{70} fullerenes.[4] Solubilization of SWNTs is expected to facilitate both their chemical derivatization and investigation of their photophysical properties.

The SWNT samples used for this study were produced by a gas-phase catalytic process developed by Smalley and coworkers.[5] This process is capable of producing SWNTs with diameters of *ca.* 0.7 nm, considerably smaller than SWNTs typically produced by laser oven methods.[5,6] The production material was used directly, with no purification. The material used for this investigation consisted of mostly carbon nanotubes, and contained *ca.* 5 atom% residual iron catalyst, as verified by scanning electron microscopy (Philips XL 30 ESEM) and EDAX (energy dispersive analysis with X-rays). An SEM image of the SWNTs is shown in Fig. 1

UV–VIS absorption spectroscopy was used to determine solubility as follows. Several different concentrations of SWNT solutions in 1,2-dichlorobenzene were prepared by sonication (Cole-Parmer B3-R, 55 kHz). The solutions were then filtered through glass wool until no visible particulate remained, and the absorption spectrum was recorded (Fig. 2). A 100.0 mL aliquot of each sample was placed in a warm water bath, and the solvent was removed with a gentle stream of nitrogen. The samples were dried in an oven at 130 °C for 1 h and then weighed to determine the mass of solubilized SWNT. This concentration (in mg L^{-1}) in conjunction with the absorbance at 500 nm, allowed preparation of the plot shown in the inset of Fig. 2. The slope of the linear-least-squares fit is then analogous to the familiar extinction coefficient of Beer's Law.[7] This value was used to determine the concentration of all subsequent samples, which were prepared in the following manner. Several mg of SWNT material were placed in a scintillation vial containing 10 mL of solvent. The amount of SWNTs used was sufficient to ensure undissolved material. The vial was capped and sonicated for 1 h. The solution was filtered through glass wool until no particulate remained, and the absorption spectrum was recorded. The concentration was determined as described above. The results are shown in Table 1. A single production batch was used to generate the results shown in Table 1. The stability of these solutions varied from *ca.* 4 h to more than 3 days for 1,2-dichlorobenzene. Since the solubility of SWNT samples might vary from batch to batch, two other batches of gas-phase grown material were checked for their solubility properties in 1,2-dichlorobenzene. The results were within *ca.* 10% of the original batch.

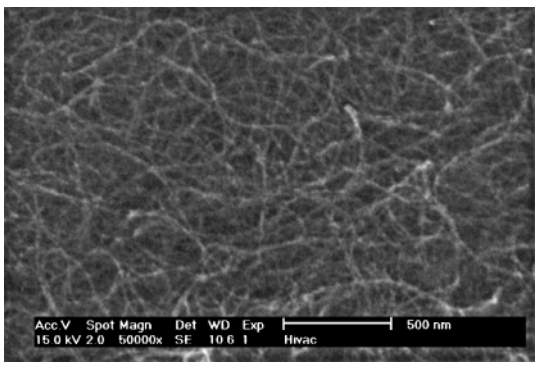

Fig. 1 SEM image of the SWNT material used for this investigation.

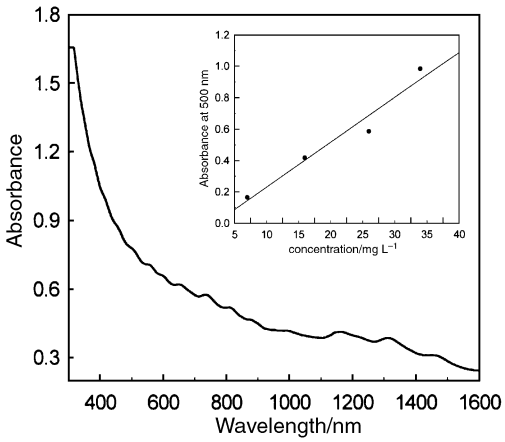

Fig. 2 Absorption spectrum of the SWNT material at a concentration of 27 mg L^{-1} in 1,2-dichlorobenzene. Inset: Optical density at 500 nm of the SWNT material in 1,2-dichlorobenzene at different concentrations. The straight line is a linear-least-squares fit to the data; slope = 0.0286.

Table 1 Room-temperature solubility of the SWNT material[a]

Solvent	mg L^{-1}
1,2-Dichlorobenzene	95
Chloroform	31
1-Methylnaphthalene	25
1-Bromo-2-methylnaphthalene	23
N-Methylpyrrolidinone	10
Dimethylformamide	7.2
Tetrahydrofuran	4.9
1,2-Dimethylbenzene	4.7
Pyridine	4.3
Carbon disulfide	2.6
1,3,5-Trimethylbenzene	2.3
Acetone	—[b]
1,3-Dimethylbenzene	—[b]
1,4-Dimethylbenzene	—[b]
Ethanol	—[b]
Toluene	—[b]

[a] The sonicator bath water temperature rose to *ca.* 35 °C over the course of 1 h. [b] Solubility in these solvents was < 1 mg L^{-1}

DOI: 10.1039/b008042j

1,2-Dichlorobenzene was found to be a reasonable solvent for the SWNTs. A photograph of the SWNT samples dissolved in 1,2-dichlorobenzene at differing concentrations is shown in Fig. 3. The 1,2-dichlorobenzene solutions could be filtered (0.2 μM PTFE, Sartorius), dried for 1 h at 140 °C, and then re-dissolved.

The issue of solution *vs.* suspension for SWNT in organic solvents is unresolved. Although there was no visible particulate in the solutions reported here, the terms 'metastable solution' or indeed even 'suspension' may be equally applicable. The question of whether solvation means exfoliation of nanotube ropes into individual nanotubes is perhaps inherent in this issue. In an attempt to determine whether these solutions/suspensions were comprised of individual tubes, we performed atomic force microscopy (Digital multi-mode SPM)[8] on samples deposited from 1,2-dichlorobenzene solutions. Samples from a *ca.* 5 mg L^{-1} solution showed mostly small bundles which are likely comprised of several nanotubes, based on height analysis of *ca.* 1.5–1.9 nm and lengths of *ca.* 500 nm. Analysis of samples deposited from more concentrated solutions revealed larger bundles or ropes with heights of *ca.* 6 nm and lengths of 1–3 μM. These bundles are a result of the significant van der Waals interaction between the sidewalls of the tubes. It is therefore possible that solubilization in 1,2-dichlorobenzene does not completely exfoliate the SWNT bundles to give individual nanotubes. Alternatively, individual tubes could be present when in solution, but these coalesce when spin-coated on the substrate for imaging.

Solutions in 1,2-dichlorobenzene did not pass through a 1.2 μM PTFE membrane (Sartorius). This does not conclusively mean that all tubes in the solution were longer than 1.2 μM. A few longer tubes may form a mat on the membrane, preventing passage of shorter tubes. In addition, these membranes are 'torturous path' filters, which may require significant solute deformation; a difficult task for these exceedingly rigid tubular structures. We also attempted to pass a *ca.* 30 mg L^{-1} 1,2-dichlorobenzene solution (this solution was sonicated for *ca.* 20 min) through a 3 μM, track-etched polycarbonate membrane (Poretics). The pores in these membranes are nearly 'straight' holes (relative to their diameter) which do not require significant solute deformation for passage. The filtrate contained 13 mg L^{-1} of SWNTs. This solution did not exhibit a Tyndall effect (632 nm) 20 min after filtration. This suggests that most particles in the solution are on the order of 0.6 μM in length or smaller, though this is of course an extremely crude estimate of particle size. In addition, at this concentration, the solution absorbs *ca.* 50% of the incident light at 632 nm. After *ca.* 1 h, the solution did exhibit a Tyndall effect, and particulates became visible shortly thereafter. It is then reasonable to suppose that individual tubes might indeed exist in the solution at low concentrations, but they eventually form ropes, then bundles of larger size. In more concentrated solutions, the tubes are likely to exist only as ropes or bundles. Whenever dealing with such large, rigid molecules however, the question of 'true' solubility persists.

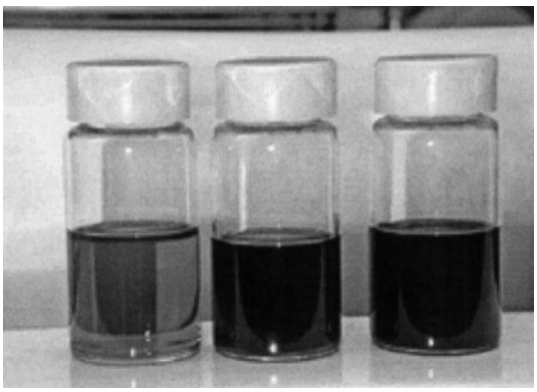

Fig. 3 SWNT solutions in 1,2-dichlorobenzene. From left to right: 10 mg L^{-1}, 25 mg L^{-1}, 95 mg L^{-1}.

A report recently appeared in the literature concerning dissolution of laser-oven produced SWNTs (diameter *ca.* 1.2 nm) in organic solvents.[9] The authors presented extensive spectroscopic characterization of the dispersions, and concluded that highly polar solvents such as dimethylformamide, *N*-methylpyrrolidinone, and hexamethylphorphoramide were the most attractive solvents. We have also investigated the solubility of laser-oven produced tubes (obtained from Tubes@Rice) in 1,2-dichlorobenzene, which was briefly touched upon in the aforementioned report. We found the raw production material to possess a solubility similar to that of the gas-phase catalytically grown tubes in 1,2-dichlorobenzene, at *ca.* 75 mg L^{-1}. However, this material consists of as little as 40% SWNTs, the remainder being comprised of amorphous carbon amd metal catalysts. We found purified material from Tubes@Rice (consisting of *ca.* 90% SWNTs) to be considerably less soluble in 1,2-dichlorobenzene, at 35 mg L^{-1}. It is therefore likely that impurities play a role in dissolution of the laser-oven grown SWNTs. Alternatively, the purification process may affect the integrity of the SWNTs, altering their solubility properties. Concerning the differences observed between the laser-oven produced material and the gas-phase catalytically produced material, it is not clear whether these arise from the nature of the tubes themselves (*i.e.* the diameter or possibly differing helicity mixtures), or merely arise from the different impurities or intermolecular packing characteristics of each production method.

We are currently seeking to take advantage of the dissolution ability of 1,2-dichlorobenzene to facilitate chemical derivatization of the gas-phase catalytically produced SWNTs.

We thank Dr Robert Hauge for helpful discussions. We gratefully acknowledge the financial support of NASA (NASA-JSC-NCC 9-77, OSR#99091801) and the NSF (NSR-DMR-0073046#) for this work.

Salt-free C–C coupling reactions of arenes: palladium-catalyzed telomerization of phenols[1]

A salt-free functionalisation of phenols with either butadiene or isoprene in the presence of palladium catalysts has been developed, which gives octadienyl- or decadienylphenols selectively.

Transition metal-catalyzed C–C coupling reactions of arenes with unsaturated organic compounds are of increasing importance for the synthesis of fine chemicals, agrochemicals and intermediates for pharmaceuticals.[2] However, a general problem in most arene transformation reactions is the production of at least stoichiometric amounts of salts due to the necessity of using Lewis acids or suitable activating groups, *e.g.* halides, on the aromatic ring. Despite considerable efforts in the past, only a few examples of direct atom-efficient functionalizations of aromatic compounds are known.[3] Hence, the development of efficient ecologically-favorable protocols for the construction of C–C bonds to aromatic rings is one of the important goals for catalysis.

In 1967 Smutny[4] described the first palladium-catalyzed telomerization reaction[5] of phenol with buta-1,3-diene, which yielded *O*-allylated octa-2,7-dienyl ethers. In the original paper Smutny also reported the observation of *C*-allylated phenols, although neither product yields nor the reaction conditions were given. Later on, telomerizations with phenol were studied by Weigert,[6] Beger[7] and Kaneda *et al.*[8] In all these studies only the corresponding *O*-allylated ethers were obtained.

In this paper we describe the catalytic salt-free reaction of naphthol and electron-rich phenols with buta-1,3-diene and 1,3-isoprene giving selectively *C*-allylated phenols.

While studying the telomerization of buta-1,3-diene with methanol,[1] we became interested in the reaction of 1,3-dienes with substituted phenols and naphthol. Applying our previously optimized conditions (0.1 mol% $Pd(OAc)_2$–1 eq. PPh_3 in THF at 90 °C) the reaction of 100 mmol β-naphthol with 200 mmol buta-1,3-diene yielded both of the expected *O*-allylated products (1-naphthoxyocta-2,7-diene **1**: 30% yield and 3-naphthoxyocta-1,7-diene **2**: 7% yield) as well as significant amount (25%) of the *ortho*-*C*-allylated product 1-(octa-2,7-dienyl)-2-naphthol **3** (Scheme 1).

By variation of the catalyst system, the reaction temperature and the ligand-to-metal ratio we discovered that it is possible to obtain the *C*-allylated products selectively (Table 1). Using optimized conditions (L : Pd = 3 : 1; addition of 1 mol% triethylamine) **3** was obtained in 84% yield (ratio C : O-allylated products = > 50 : 1).† Interestingly, this reaction, which resembles the classic Friedel–Crafts allylation, proceeds with high regioselectivity. Apart from **3**, only a small amount (< 3%) of a second *C*-allylated naphthol was obtained. The efficiency of the simple $Pd(OAc)_2$–PPh_3 catalyst is remarkable: even in the presence of only 0.01 mol% Pd-catalyst, a 76% yield of **3** was obtained (TON = 7600).

In order to understand the formation of the *C*-allylated telomerization product we studied the reaction of **1** in the presence of catalytic amounts (0.5 mol%) of $Pd(OAc)_2$–2 PPh_3 in toluene at 70–90 °C. After 30 min at 70 °C none of the *C*-allylated product **3** was observed. However, after 1.5 h at 90 °C the formation of **3** began, and after 6 h (90 °C) **3** was the main product in the reaction mixture, although other *C*-allylated products (*ca.* 5–10%) were detected. Based on detailed mechanistic studies of the telomerization of butadiene and methanol[9] we propose the following mechanism for the formation of **3** (Scheme 2).

The $Pd(0)$-catalyzed dimerization of buta-1,3-diene affords the L–Pd–(η^1,η^3-octadiendiyl) complex **4**. Subsequent protonation at C6 and attack of the oxygen atom at C1 or C3 yields the corresponding naphthyl allyl ethers **1** and **2**. Due to the improved leaving group ability of naphthol compared to an aliphatic alcohol, **1** and **2** are in equilibrium with **5** under the reaction conditions.[10] Allylation is also possible *ortho* to the hydroxy group, due to the ambident character of napthol. As this reaction step is irreversible, **3** is the main product of this reaction. The large influence of the P : Pd-ratio on the yield of **3**

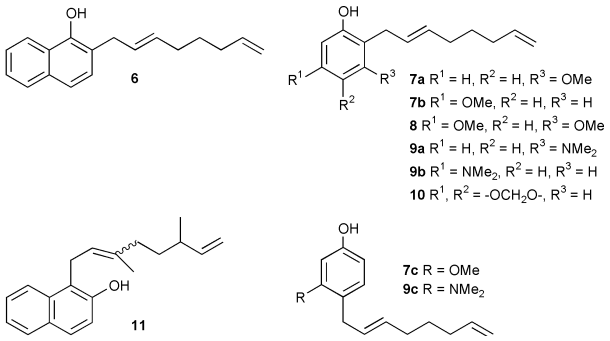
[a] 100 mmol ROH, 200 mmol buta-1,3-diene, 90 °C, 16 h, THF, 0.5 mol% $Pd(OAc)_2$, Pd : PR_3 1 : 3, NEt_3. [b] GC-purity > 98%. [c] Ratio of peak areas (GC). [d] 12 h. [e] 0.1 mol% $Pd(OAc)_2$. [f] GC-purity > 80%. [g] 12 h, toluene, 0.01 mol% $Pd(OAc)_2$. [h] 150 mmol ROH were used. [i] Isoprene was used instead of buta-1,3-diene, 100 °C, toluene, 1 mol% $Pd(OAc)_2$, isoprene–ROH 3 : 1.



is explained by a deactivation of the Pd catalyst at a low ligand concentration and an inhibition of the catalyst activity in the presence of an excess of phosphine ligand.

In order to demonstrate the generality of the palladium-catalyzed *C*-allylation of phenols we studied the reaction of buta-1,3-diene with electron-rich phenols and the reaction of β-naphthol with isoprene (Table 2). *C*-Allylations similar to β-naphthol are observed with 3-methoxyphenol, 3,5-dimethoxyphenol, α-naphthol, 3-dimethylaminophenol and 3,4-methylenedioxyphenol. In contrast phenol yielded only the corresponding *O*-allylated ethers.

Similar to electrophilic aromatic substitutions, the reaction of butadiene and 3-methoxyphenol, 3,4-methylenedioxyphenol and 3-dimethylaminophenol, gave not only the *ortho*-*C*-allylated products **6**–**10**, but also the *para*-allylated compounds **7c** and **9c**.

The reaction of β-naphthol with isoprene proceeds regioselectively to give the C1-substituted β-naphthol.

In conclusion, we have shown that electron-rich phenols react with 2 molecules of 1,3-dienes in the presence of Pd catalysts to give *C*-allylated phenols. After reduction with hydrogen and Pd/C the corresponding alkylated products are obtained in high yields. The telomerization of phenols with dienes constitutes a salt-free functionalisation of the aromatic nucleus, which proceeds with remarkable catalyst turnover numbers.

We thank Dr W. Baumann (IfOK, Rostock) for performing the NMR studies and Mrs K. Kortus and S. Buchholz for the GC analysis. This work was supported by the Alexander-von-Humboldt-Stiftung (grant for G. S.) and the State Mecklenburg-West Pomerania.

† To a solution of 79 mg (0.3 mmol) triphenylphosphine in 50 ml anhydrous THF in a 100 ml Schlenk tube under an argon atmosphere were added 23 mg (0.1 mmol) palladium acetate and 100 mg (1.0 mmol) triethylamine. The mixture was transferred into a steel autoclave charged with 14.4 g (100 mmol) β-naphthol. After cooling with dry ice 11.0 g (200 mmol) of butadiene were condensed in the autoclave. The reaction was carried out by stirring at 90 °C. After the reaction the resulting residue was purified by flash chromatography (hexane–ethyl acetate) to afford 21.1 g (84%) of **3**.

It is possible (and occasionally preferable) to define bond energies of polyatomic molecules by dissociation of the molecule at a given bond into two radical fragments, *e.g.* for a tetra-atomic molecule ABCD.

However it has long been recognized that the quantity derived in this manner will bear little relation to the actual energy content of the bond in the molecular ground-state equilibrium geometry, due to internal reorganization of the radical fragments. Clearly, a rigorous method for determining the distribution of bonding energy at the equilibrium geometry of a polyatomic molecule using its wavefunction or charge density would be highly desirable. In particular, it would provide a powerful analytical tool for quantum chemistry by enabling precise, quantitative statements to be made about the nature of bonds in a given environment, as an alternative to other indirect measures such as bond lengths; bond orders; charges or higher multipoles; or (in some cases) aromaticity indices.[1,2]

$$E\ (\mathrm{B–C}) \equiv E(\mathrm{ABCD}) – E(\mathrm{AB^{\cdot}}) – E(\mathrm{CD^{\cdot}}) \qquad (1)$$

Traditionally, the energies of specific bonds in a molecule have been estimated from its atomization energy ΣD_0 (if vibrationally corrected) or ΣD_e by making assumptions about other bonds in the molecule. For example, the energy of the C–C bond in ethyne, ethene or ethane may be calculated 'precisely' if the C–H bond energy is assumed to be either constant for all three compounds, or the same as the bond energy in methane (trivially $\Sigma D_e/4$). Other approaches to calculating bond energies which should be mentioned here include Grimme's idea of parameterizing the atomization energy in terms of bond critical point (topological) properties;[3] Bader's proposal of relating the bond energy to the integral of the energy density over the interatomic surface;[4] and Krygowski *et al*'s method of parameterizing the C–C bond energies as a single exponential function of experimentally observed bond lengths.[5]

Like Grimme's approach, the method outlined here does not make any assumptions about the constancy of C–C bond energies across any series of compounds, enabling *individual* bond energies to be derived for each such bond in a molecule. Our approach is to parameterize the potential energy surface for each bond in a way which best reproduces the atomization energies across a series of related compounds, assuming only that chemically similar types of atoms interact *via* the same potential.

Molecular geometries and total energies of benzene, naphthalene, five linear polyacenes (anthracene, tetracene, pentacene, hexacene and heptacene), five angular phenacenes (phenanthrene, chrysene, picene, fulminene and [7]phenacene) and four 'composite' benzenoid hydrocarbons (triphenylene, pyrene, perylene, coronene) were obtained at B3LYP/6-311G** level of theory, and used in the subsequent fitting procedure. Comparing the best experimental bond length values for benzene, naphthalene and anthracene, derived from low-temperature crystallographic studies and corrected for librational effects,[6] we find very good agreement with structures optimized at this level of theory, around 0.006 Å mean difference. Vibrationless atomization energies ΣD_e were derived from the molecular total energies by subtracting the energies of the free ground state atoms at the same level of theory, *i.e.* C(^3P) = −37. 85599 and H(^2S) = −0.50216, in Hartree atomic units. The parameterization procedure begins by defining a set of additive bond energies with respect to an estimated vibrationless atomization energy $\Sigma D_e{}^{\mathrm{calc}}$:

$$\Sigma D_e{}^{\mathrm{calc}} = \sum_{n_{\mathrm{CC}}} E(\mathrm{C–C}) + \sum_{n_{\mathrm{CH}}} E(\mathrm{C–H}) \qquad (2)$$

At first glance, the above partitioning of atomization energy seems inappropriate for the systems we have chosen to illustrate the method, namely π-electron molecules with conjugated π-bonds, and aromatic hydrocarbons in particular. An extension of the HMO model due to Longuet-Higgins and Salem[7] predicts the following bond-energy contribution for any pair of neighboring carbon atoms *m* and *n*

$$E_{mn}\ (\mathrm{C–C}) = -\{U(r) + 2p_{mn}\,\beta(r)\} \qquad (3)$$

where *r* is the C–C distance, $U(r)$ and $\beta(r)$ are the σ-bond potential energy and the resonance integral, respectively, and p_{mn} represents the π-electron bond order for atoms *m* and *n*. The latter quantity depends on the LCAO-MO coefficients of all the occupied MOs, and thus is a function of the whole molecular geometry, not just the *m*–*n* distance *r*. On the other hand at the *equilibrium* molecular geometry there is a simple linear relationship between the bond order $p^{\mathrm{e}}{}_{mn}$ and the equilibrium bond distance $r^{\mathrm{e}}{}_{mn}$:

$$p^{\mathrm{e}}{}_{mn} = p(r^{\mathrm{e}}{}_{mn}) = (R_1 - r^{\mathrm{e}}{}_{mn})/(R_1 - R_2) \qquad (4)$$

where R_1 (R_2) is the length of a 'pure' single (double) C–C bond of the sp^2–sp^2 type. It follows from eqs. (3) and (4) that for π-electron hydrocarbons at *equilibrium* there is a *universal* function $E(r)$ which defines bond energies as dependent of equilibrium bond distances $r^{\mathrm{e}}{}_{mn}$,

$$E_{mn}\ (\mathrm{C–C}) = E(r^{\mathrm{e}}{}_{mn}) \qquad (5)$$

The above result is valid providing that all the carbon atoms in the molecule are considered equivalent (a usual assumption in the HMO model). However, in aromatic molecules one finds two kinds of atoms: tertiary (with one hydrogen atom attached) and quaternary (with no hydrogen atom attached). Thus, up to three kinds of C–C bonds may be distinguished in these molecules (see below), with possible different bond-energy functions $E_i(r)$, (i = 1,2,3).

In our approach, the C–C bond energies are represented by one or more Morse functions, slightly modified to give E (C–C) = D_e at $r = r_e$ (rather than zero energy at $r = r_e$).

$$E_i\ (\mathrm{C–C}) = D_e{}^i\,\{1 - [1 - \exp\{-\alpha_i\,(r - r_e{}^i)\}]^2\} \qquad (6)$$

slightly modified to give E (C–C) = D_e at $r = r_e$, rather than zero energy at $r = r_e$ (here r_e and D_e correspond to the minimum of the Morse function, not to some equilibrium bond distance). The subscript/superscript i labels the Morse function to be applied. In fact it would be equally feasible to parameterize E_i(C–C) with a three parameter harmonic model, *i.e.*

† Electronic supplementary information (ESI) available: data for attempted fittings and exact and calculated atomisation energies for the final model. See http://www.rsc.org/suppdata/cc/b0/b007657k/

DOI: 10.1039/b007657k

$$E_i\,(\text{C–C}) = D_e^i\ \{1 - \alpha_i\,(r - r_e^i)^2\} \qquad (7)$$

but since the Morse function allows for anharmonicity without introducing any more parameters, we consider it superior for this application. At first, the bonds to terminal hydrogen atoms were also parameterized with Morse functions, but it was found essentially impossible to extract this data from the atomization energies (the optimized C–H bond lengths vary from just 1.084 to 1.086 Å over the whole data set). Thus the single value of E(C–H) for all such bonds was finally chosen as a parameter in the fitting procedure.

The next step is to define a normalized χ^2 statistic which will be minimized with respect to variations in the model parameters during the fitting procedure.

$$\chi^2 = \sum_{n_{\text{mols}}}\{\Sigma D_e^{\text{calc}} - \Sigma D_e\}^2 \qquad (8)$$

This statistic is minimised in a simple iterative algorithm employing numerical partial first derivatives of eqn. (5) with respect to the model parameters in ΣD_e^{calc}. This has been implemented as a *MATHEMATICA 4*[8] routine which is freely available from the authors, on request.

Topologically we can distinguish three types of C–C bond in polyacenes (see Fig. 1). These are (i) bonds between carbon atoms both bearing hydrogens; (ii) bonds between carbon atoms where only one of the carbons bears a hydrogen; and (iii) bonds between carbon atoms where neither bears a hydrogen. Thus it could be expected that the potential energy surface for these three types of bonds will differ, such that three independent Morse functions for each type of bond will be required to correctly describe all types of polyacene. However, we began the fitting procedure assuming that a single C–C potential energy surface might describe *all* types of C–C bonds, *i.e.* a four-parameter fit of {D_e, α, r_e} plus E(C–H) for all sixteen compounds. The result was quite poor reproduction of the 'exact' B3-LYP/6-311G** atomization energies by the model calculated ones: the average (percentage) accuracy $100(\chi^2/n_{\text{mols}})^{\frac{1}{2}}$ being just 0.5%. Subsequent improvement of the model by distinguishing between chemically distinct types of C–C bond led to a final model with ten parameters (three Morse functions as described above) reproducing the atomization energies with 0.04% average accuracy over all sixteen compounds. The fitted model parameters are as follows (in units of kJ mol^{-1}, Å^{-1} and Å): type (i) C–C bonds {D_e, α, r_e} = {530.83, 5.052, 1.3549}; type (ii) C–C bonds {D_e',α',r_e'} = {498.45, 6.448, 1.3922}; type (iii) C–C bonds {D_e'',α'',r_e''} = {490.49, 4.102, 1.3642}; and E(C–H) = 431.47 kJ mol^{-1}. The data for all of the fits attempted and the exact and calculated atomization energies for the final model are supplied as ESI.†. Here we will just mention that by far the worst agreement between any ΣD_e and ΣD_e^{calc} is found for septacene (ΣD_e = 25212 kJ mol^{-1} and ΣD_e^{calc} = 25232 kJ mol^{-1}, a 0.08% error). It should be noted that an error of 20 kJ mol^{-1} on the atomization energy represents < 1 kJ mol^{-1} error on the average C–C bond energy, since septacene has 30 C–C bonds.

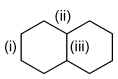

Fig. 1. Definition of C–C bond types.

The bond energies derived from the final model by substituting the optimized C–C bond lengths for r in eqn. (6) vary over a range of 438–531 kJ mol^{-1} in the sixteen compounds, with the C–C bond energy in benzene being at the upper end of this range. The complete distribution of C–C bonding energy is illustrated in Fig. 2 for just a few of the molecules: benzene, perylene and coronene. The values for perylene and coronene nicely demonstrate the Clar classification[9] of so-called 'empty rings' at the centre of composite polyacenes. The energies of innermost C–C bonds are much lower than those of the outermost bonds of the molecules, indicating that π-electron stabilization is concentrated in the peripheral rings (*e.g.* the difference in C–C bond energies between the peripheral rings and the central rings in perylene and coronene is 246 and 107 kJ mol^{-1}, respectively). It should also be mentioned that the bond energies reported here, and those derived by this method in general, will be slightly higher than any experimental estimates because by necessity we use ΣD_e values (*e.g.* the experimental ΣD_0 for benzene is 5464.8 kJ mol^{-1}, compared with our ΣD_e value of 5670 kJ mol^{-1}).

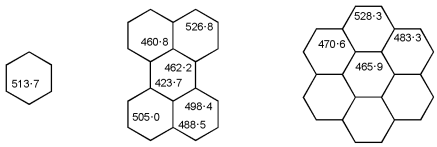

Fig. 2. C–C bond energies (kJ/mol^{-1}) for benzene, perylene and coronene.

To test whether the fitted parameters from our best model are sufficiently general to reproduce atomization energies and hence bond energies for polyacenes not in the fitting set of sixteen compounds, we have optimized four additional molecules at the same level of theory: benz[*a*]anthracene, benzo[*c*]-phenanthrene; benzo[*e*]pyrene and benzo[*g,h,i*]perylene. Indeed, we find that the ten-parameter Morse model reproduces the atomization energies of these compounds to the same accuracy obtained for the compounds present in the fit. So we may conclude that the parameters given here are sufficiently general to predict bond energies for most benzenoid hydrocarbons, with the possible exception of helicenes, where strong steric interactions may need to be explicitly treated in the model.

In addition to providing individual bond energy data, this parameterization procedure leads to a model of the molecules in question whose parameters also lend themselves to chemical interpretation. Consider the harmonic force constant $f = 2\alpha^2 D_e$ computed as the second partial derivative of eqn. (3) with respect to r. The model predicts f for type (i), (ii) and (iii) C–C bonds approximately in the ratio 1.6 : 2.5 : 1.0, information that probably has not been obtained before by any other method, experimental or theoretical.

In conclusion: the method for determining polyatomic molecule bond energies presented here should be applicable to essentially any series of related compounds (not only hydrocarbons); with the proviso that a more detailed treatment of the C–H bond and some types of steric or long-range interactions may be required for some families of compounds.

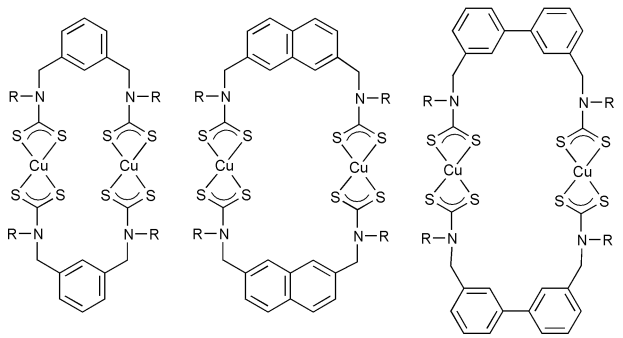
A novel family of redox-active dinuclear copper(II)-based macrocycles self-assembled from dithiocarbamate ligands has been synthesised; a naphthyl-spaced complex exhibits selective electrochemical recognition of perrhenate and dihydrogenphosphate anions.

The use of metal-directed self-assembly techniques provides a facile route to novel host macrocycles capable of binding charged and neutral guest substrates.[1,2] In some instances macrocycle formation can be templated by the guest and therefore the size and stability of the assembly is promoted by the complementarity between host and guest.[3]

We recently demonstrated the utility of the dithiocarbamate (dtc) moiety as a coordinating group[4] in the transition metal-directed construction of nano-sized resorcarene-based assemblies.[5] The incorporation of redox-active metal–ligand units into the macrocycle framework of a host introduces the possibility of using the host as an electrochemical sensor for guest substrates.[6] Herein, we describe the application of dithiocarbamate ligands in the construction of metal-directed self-assembled macrocycles. A range of copper-based, redox-active metallomacrocycles, their structural characterisation and preliminary electrochemical anion sensing results are presented.

The starting diamines were simply prepared by reaction of the appropriate bis(bromomethyl)aromatic compound with neat alkylamine. Dithiocarbamate copper(II) macrocycles were prepared in a one-pot synthesis from the parent secondary amines by reaction with carbon disulfide, potassium hydroxide and copper(II) acetate. The crude powders were recrystallised from dichloromethane–ethanol mixtures to afford the analytically pure metallomacrocycles **1**–**7** in yields of 40–70%.



Electrospray mass spectrometry (ESMS) in pure methanol solutions confirmed the presence of all dinuclear macrocyclic structures. Treatment of copper(II) macrocycle **1** with iron(III) chloride gave upon crystallisation the complex $[Cu_2L_2][FeCl_4]_2$ **8**.[7] The structure of **8** was characterised by X-ray crystallography‡ and is shown in Fig. 1. There is only one crystallographically unique copper(III) ion present, a centre of inversion relating the two copper ions. The copper–copper distance in **8** is quite short at 5.5 Å. In profile, the structure of **8** forms a step-like structure, the two aromatic phenyl groups remaining planar and the two dtc–Cu–dtc moieties twisting out of the plane at an angle to the plane of the aromatic rings. There are two tetrachloroferrate(III) anions associated with each macrocycle and each exhibits a single axial interaction *via* a chlorine atom to a copper(III) centre, Cu–Cl 3.00 Å. The nature of this solid-state association led us to consider the possibility of anion interactions with the oxidized macrocycles.

The electrochemical properties of the copper(II) metallomacrocycles **2**, **4** and **7** were investigated in CH_2Cl_2–MeCN (4 : 1) using cyclic and square-wave voltammetry with NBu_4BF_4 as the supporting electrolyte. The xylyl-spaced complex **2** exhibits two quasi-reversible oxidation waves at 0.06 and 0.20 V [Table 1 and Fig. 2(a)]. The observation of two oxidation potentials indicates either electrochemical coupling between the two proximal copper centres or that in solution the two copper centres are in different coordination environments. The naphthyl-spaced complex **4**, with more separated copper centres, exhibits a single, broad, quasi-reversible oxidation wave at 0.19 V suggesting two overlapping waves [Fig. 2(b)]. However interestingly, the biphenyl-spaced copper(II) complex **7** again exhibits two distinct reversible oxidation waves at 0.04 and 0.19 V respectively even though molecular models predict that this complex possesses the longest Cu···Cu distance [Fig. 2(c)].

The copper(II)/(III) redox couples of macrocycles **2**, **4** and **7** in the presence of anions (ReO_4^-, $H_2PO_4^-$, Cl^-, Br^-, NO_3^-) (Table 1) were investigated by square-wave and cyclic voltammetry. Notably, substantial cathodic shifts in oxidation potential are seen for naphthyl-based macrocycle **4** with tetrahedral anions such as dihydrogenphosphate and per-

[a] Obtained in CH_2Cl_2–MeCN (4:1) solution containing 0.2 mol dm^{-3} NBu_4BF_4 as supporting electrolyte. Solutions were *ca.* 1×10^{-3} mol dm^{-3} in receptor and potentials were obtained with reference to $Ag–Ag^+$ electrode at 293 K, scan rate = 100 mV s^{-1}. [b] Broad quasi-reversible oxidation wave: E_{pa} = 0.25 V, E_{pc} = 0.11 V, suggesting two overlapping waves. [c] Cathodic shift of $E_{1/2}$ oxidation potential produced by presence of 5 equiv. of anion added as their NBu_4^+ salts.

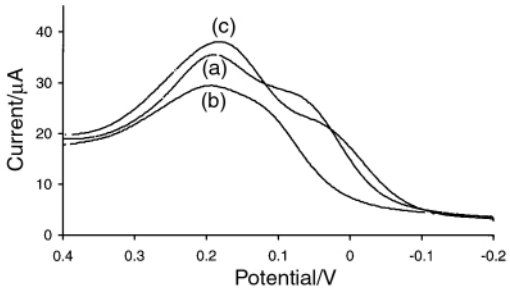

Fig. 2 Square-wave voltammograms of (a) **2**, (b) **4** and (c) **7** in CH_2Cl_2–MeCN (1:1), NBu_4BF_4 supporting electrolyte, Ref: Ag/AgCl.

rhenate.[8] For example with **4** the addition of five equivalents of tetrabutylammoniumperrhenate gave a cathodic shift of 85 mV in the Cu(II)/Cu(III) redox couple (see Fig. 3). The complexed anion effectively stabilises the copper(III) oxidation state. Interestingly no significant perturbations were observed with chloride, bromide or nitrate anions. In contrast the smaller xylyl-spaced macrocycle exhibits a noticeable cathodic perturbation to chloride (20 mV) but little response to nitrate, bromide or the larger anions such as perrhenate or dihydrogenphosphate. For the control bis(diethyldithiocarbamate)copper(II) a single quasi-reversible oxidation wave at 0.07 V is observed which exhibits no significant perturbations in oxidation potential on the addition of anions.

The interaction of **4** with perrhenate was investigated further by UV–VIS spectroscopy. Solutions of **2**, **4** and **7** in CH_2Cl_2–MeCN (0.1 M NBu_4BF_4) were oxidised with $NOBF_4$ to the corresponding dicationic copper(III) complexes.§ On addition of 5 equiv. of NBu_4ReO_4 to freshly prepared $[\mathbf{4}]^{2+}$ (λ_{max} = 421 nm) a bathochromic shift of 10 nm was observed in the maximum absorption. However, no such shifts were observed

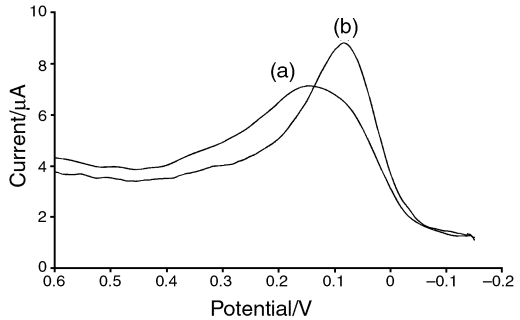

Fig. 3 Square-wave voltammograms of (a) **4** and (b) **4** plus 5 equiv. of NBu_4ReO_4; in CH_2Cl_2–MeCN (1:1), NBu_4BF_4 supporting electrolyte, Ref: Ag/AgCl.

on the addition of NBu_4ReO_4 to $[\mathbf{2}]^{2+}$, $[\mathbf{7}]^{2+}$ or the oxidised monocation of bis(diethyldithiocarbamate)copper(II).¶ Further evidence for the interaction of $[\mathbf{4}]^{2+}$ with ReO_4^- came from ES-MS studies.[9] Oxidation of copper(II) macrocycles in acetonitrile–dichloromethane mixtures with copper(II) triflate, perchlorate or tetrafluoroborate gave in all cases the doubly oxidised species, $[Cu_2L_2]^{2+}$ of the copper(III) macrocycles (L = ligand). Addition of ReO_4^- anions to solutions of macrocycle **4** oxidised with copper(II) triflate or tetrafluoroborate gave the ion corresponding to the doubly oxidised species $[Cu_2L_2][ReO_4]^+$, 1275.2.‖ This species was predominant even in the presence of a large excess of tetrafluoroborate anion. Space filling molecular models indicate anions such as ReO_4^- and $H_2PO_4^-$ may comfortably occupy the cavity and bridge the copper centres in **4**, but are too large for the xylyl-spaced **2** and too small for biphenyl-spaced **7**. This suggests this macrocyclic system may exhibit a measure of anion selectivity based upon the macrocycle ring size.[10]

In summary, copper(II) metallomacrocycles **1**–**7** are novel examples of redox-active macrocyclic hosts whose oxidation states and hence binding affinities can be chemically switched by redox control. In addition we have demonstrated the use of the dtc–copper(II)/(III) redox couple as an electrochemical anion-sensing unit. These preliminary electrochemical sensing results suggest anion selectivity is dictated by the size of dithiocarbamate copper(II) macrocycle.

Financial support for this work was provided by EPSRC, AWE Aldermaston and the Universities of Oxford and Reading.

First published as an Advance Article on the web

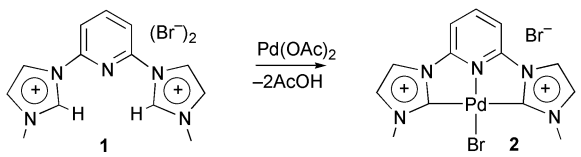
The bis-carbene precursor, 1, gives a thermally very robust Pd(II) catalyst for Heck coupling that maintains activity even in boiling diethylacetamide (bp 184 °C) in air.

One common and significant limitation of some homogeneous catalysts is their relatively rapid deactivation, particularly when high temperatures or harsh conditions are needed; this is often the case for cross-coupling reactions and alkane functionalization.[1] The facility of P–C bond cleavage reactions has been implicated in catalyst deactivation of phosphine complexes.[2] For example, the deactivation of the $[IrH_2(tfa)(P\{C_6H_4F\}_3)_2]$ catalyst in alkane dehydrogenation was shown to correlate with the appearance of C_6H_5F, the product of P–aryl hydrogenolysis.[3]

The recent discovery of imidazole-based carbenes[4] and of their effectiveness as ligands[5] offers an opportunity to develop phosphine-free homogeneous catalysis. These carbenes are not only excellent ligands for late transition metals but are also able to promote a variety of catalytic reactions, including C–C[6] and C–N[7] coupling and olefin metathesis.[8] The thermal stability of carbene complexes is often high and they lack sensitive bonds that might be cleaved in any deactivation process. Since thermal stability of phosphine complexes can be improved by incorporation into a chelating ligand, as in the well known 'pincer' phosphines,[9] the same strategy might be useful in enhancing stability in the carbene case. Several authors have recently reported thermally stable palladium complexes active for the Heck reaction either with carbene or with pincer phosphines of both mono- and multi-dentate types as ligands.[6b,d,e,i,j,10]

We now report that the known carbene precursor,[11] **1**, readily formed by an improved synthesis (95% yield), reacts with $Pd(OAc)_2$ to give a carbene complex, **2**, as shown in Scheme 1 (ESI†). The thermal stability of the product is emphasized by the fact that the final stage of the synthesis of **2** takes place at 160 °C.

Fig. 1 shows the structure and metric parameters of the resulting complex from an X-ray structure determination.‡ The molecule is flat with a ligand bite angle of 79°. Otherwise, the metric parameters are similar to those previously found for related complexes.[6b,d] The Pd–C distance (2.038(6) Å) indicates that the bond is essentially single with very little back donation, as expected for this strongly Fischer-type carbene. This Pd–C distance is somewhat longer than in most prior cases,[6b,d] probably because the two high *trans*-effect carbene ligands are mutually *trans*.



Scheme 1

† Electronic supplementary information (ESI) available: synthesis details and NMR data. See http://www.rsc.org/suppdata/cc/b0/b008038l/

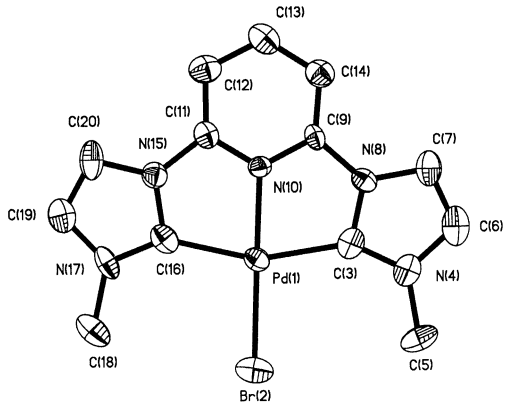


Fig. 1 ORTEP diagram of complex **2** showing the atom numbering scheme. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): Pd(1)–N(10) 1.979(4), Pd(1)–C(3) 2.033(6), Pd(1)–C(16) 2.044(6), Pd(1)–Br(2) 2.4099(7); N(10)–Pd(1)–C(3) 78.9(2), N(10)–Pd(1)–C(16) 79.6(2), C(3)–Pd(1)–C(16) 158.5(2), N(10)–Pd(1)–Br(2) 179.03(13), C(3)–Pd(1)–Br(2) 100.29(16), C(16)–Pd(1)–Br(2) 101.18(16). Thermal ellipsoids are drawn at 50% probability.

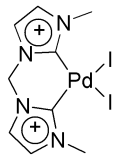
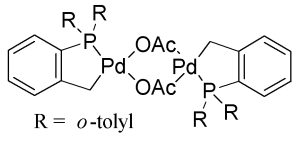
The stability that ligand **1** imparts to complex **2** is apparent from comparison with other Heck catalysts containing chelating ligands. Catalysts **3**[6d,e] and **4**[12] are very active for the Heck reaction when used under nitrogen at 140 °C. Complex **3**,



3



4

however, is reported[6e] to decompose in dimethylacetamide (DMA, bp 165 °C) above 70 °C. Our own work shows that in refluxing DMA in air, complex **3** begins to deposit Pd black after 8 h and complex **4** deposits Pd black after 17 h, while our complex, **2**, is unchanged (> 24 h). Other Pd pincer complexes, of PCP and SCS types, are also known as Heck catalysts.[10]

The new complex **2** shows catalytic activity under argon for a standard Heck reaction between PhI and styrene (Table 1, entry 1) in refluxing diethylacetamide (DEA, bp 184 °C) in the presence of NaOAc as base.§ We find that with 0.2 mol% catalyst, good yields and turnover frequencies are found. Complex **2** shows comparable activity to the Heck catalysts, **3** and **4**, at least for PhI (Table 1, entries 1–3). Bromobenzene and styrene can also be converted to *trans*-stilbene in essentially quantitative yield in the presence of 5 mol% catalyst, NaOAc, and refluxing DMA, within 1 h (Table 2, entry 1). Surprisingly, but not uniquely,[10b,c,e] the catalyst retains activity even under air (Table 2, entry 2). Iodobenzene and styrene can also be converted to *trans*-stilbene in near quantitative yield in the presence of 5 mol% **2**, NaOAc, and refluxing DMA in a reflux

Table 1 Comparison of yields for catalysts **2**–**4** for the reaction of PhI with styrene in refluxing DEA to form *trans*-stilbene (under Ar with 0.2 mol% catalyst and NaOAc)[a]

Entry	Catalyst	0.5 h	1 h	1.5 h	2 h	4 h
1[b]	**2**	48, 494	58, 298	67, 230	73, 188	85, 109
2	**3**	36, 370	48, 247	62, 213	72, 185	84, 108
3	**4**	50, 514	61, 314	67, 230	75, 193	90, 116

Table 2 Heck reaction between aryl halides and styrene to form *trans*-stilbene. All reactions carried out in refluxing DMA with NaOAc as base

Entry (air/Ar)	Aryl halide	**2** (mol %)	Reaction time/h	Stilbene yield (%)[a]	TOF [mol prod./ (mol Pd)(h)]
1 (Ar)	PhBr	5	1	> 99	20
2 (air)	PhBr	5	1	> 99	20
3 (air)	PhI	5	1	> 99	20
4 (air)	PhI	1	1	89	89
5 (air)	PhI	0.0001	20	33	16.500
6 (Ar)[b]	*p*-(CHO)C$_6$H$_4$Cl	5	20	75	15

[a] Yield determined by ^{1}H NMR based on amount of product *vs*. amount of starting material remaining. [b] In the presence of *n*-Bu$_4$NBr (20 mol% *vs*. Pd).

apparatus open to the air (Table 2, entry 3). A yield of 89% can still be obtained in only 1 h if 1 mol% of **2** is used (Table 2, entry 4). To see if the TOF could be improved at low loading, we find that as little as 10^{-4} mol% of **2** still gives a TOF of 16.500 after 20 h under air (Table 2, entry 5). Aryl chlorides react more slowly (Table 2, entry 6). Other alkenes react satisfactorily—for example, *n*-butyl acrylate and PhI give the Heck product in 99% yield after 1 h in refluxing DMA with 1 mol% catalyst.

In view of recent studies that find evidence that the active species can be metallic palladium,[13] we checked **2**–**4** for heterogeneity by the Hg drop test.[14] Heck catalysis with **2**–**4** was unaffected by the presence of Hg, and no induction period is observed for **2**, so a homogeneous active species is likely.

On the standard model of the Heck reaction, with [Pd(0){PR$_3$}$_2$] as the key intermediate, a pincer carbene might seem to be a poor choice, even if the carbene is an acceptable replacement for the tertiary phosphine of the standard system. On the Amatore–Jutand model,[15] however, [Pd(0)(OAc){PR$_3$}$_2$]$^-$ is the key intermediate. Our work supports this model if the pyridine part of the pincer ligand is considered as replacing the OAc group. It is true that [Pd(0)XL$_2$]$^-$ would normally be expected to adopt a trigonal geometry, but the presumed intermediate Pd(0) form of the metal being d^{10}, there should be no strong penalty to adopt the pincer geometry. Eisenstein and Clot[16] are currently looking at such mechanistic issues in detail.

The results are of interest not so much as an advance in Heck catalysis—other catalysts can be better[6,10]—but as an indication that chelating carbenes can provide ligand systems that give high catalytic activity with excellent stability, even in air. This approach should be widely applicable to the development of non-phosphine late metal homogeneous catalysis.

We thank US DOE (J. A. L.) and NSF (R. H. C.) for funding and Matthew Torres for some preliminary observations.

‡ *Crystal data for* **2**: $C_{11}H_7Br_2N_5Pd{\cdot}H_2O$, monoclinic, space group $P2(1)/n$, a = 8.7782(4), b = 14.3181(6), c = 13.5684(6) Å, α = 90, β = 107.1600(10), γ = 90°, Z = 4, D = 2.011 g cm^{-3}, μ = 6.044 mm^{-1}, 5300 measured reflections, 1467 [R(int) = 0.0310] independent reflections, R = 0.0225 [$F > 2\sigma(F)$]. Crystals were grown by diffusion of CH_2Cl_2 into a DMSO solution. Data collection: Siemens Smart CCD diffractometer (λ = 0.71073 Å). The structure was solved by direct methods and was refined using the SHELXTL 5.1 software package. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned to ideal positions and refined using a riding model. CCDC 182/1880. See http://www.rsc.org/suppdata/cc/b0/b008038l for crystallographic files in .cif format. The diffraction frames were integrated using the SAINT[17] package and corrected for absorption with SADABS.[18]

§ *General Heck procedure*: NaOAc (360 mg, 4.4 mmol) and the catalyst were placed in a 3-necked flask fitted with a reflux condenser and degassed. Aryl halide (4 mmol), styrene (640 μL, 5.6 mmol), and solvent (DMA or DEA, 5 mL), were added under Ar or air. The reaction vessel was placed into an oil bath preheated to the desired temperature. Aliquots (200 μL) were removed after fixed times and added to 10 mL CH_2Cl_2. The organic layer was extracted five times with 10 mL portions of water and dried with $MgSO_4$. The mixture was then filtered and the CH_2Cl_2 removed *in vacuo*. The residue was dissolved in $CDCl_3$ or CD_2Cl_2 and analyzed by ^{1}H NMR (400 MHz).

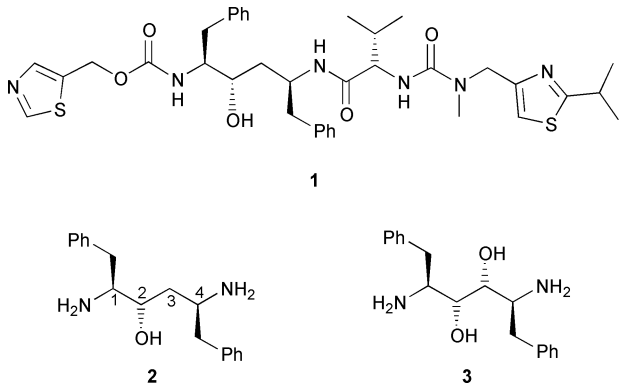
Received (in Liverpool, UK) 13th July 2000, Accepted 8th December 2000
First published as an Advance Article on the web

A stereoselective synthesis of the diaminoalcohol core of Ritonavir illustrates a novel approach to hydroxyethylene dipeptide isosteres, based on the regioselective reduction of amino acid-derived epoxyalcohols.

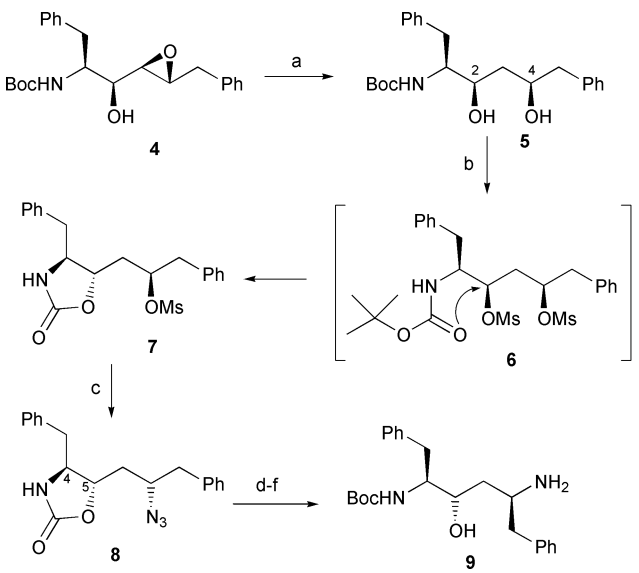
Ritonavir (**1**), approved in 1996,[1] is a potent and clinically effective peptidomimetic inhibitor of the protease of HIV, with high oral bioavailability.[2] The structure of Ritonavir was designed to target the enzyme's active site and is based on the hydroxyethylene dipeptide isostere **2**.[2a] In the original synthesis of the inhibitor,[3] the diaminoalcohol **2** was obtained from the corresponding diaminodiol **3** by a multi-step deoxygenation



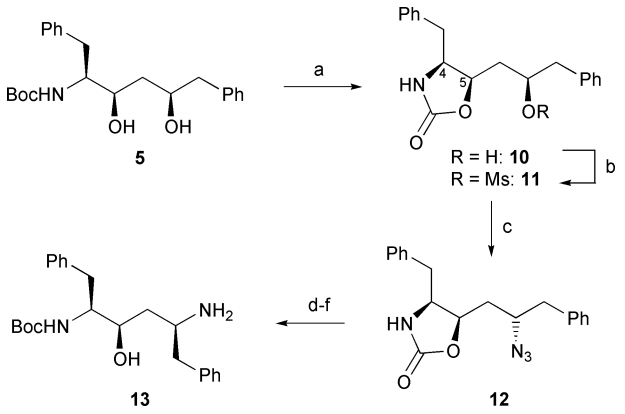
approach.[4] The core **2** was then statistically monoacylated to introduce the first side chain while the second flanking residue was introduced in the final step. This strategy has some drawbacks: loss of **2** through undesired bis-acylation, impossibility of introducing different residues on the isostere's C1 and C4, which originate from the Cα of the same aminoacid *via* the reductive dimerization of the corresponding aminoaldehyde,[4] and a less than optimal stereocontrol in the synthesis of **3**. Several approaches have been proposed to overcome these limitations, based on aminoacids as precursors from the chiral pool[5] or on enantioselective synthetic strategies.[6] In this communication we describe a short and efficient synthesis of the monoprotected Ritonavir core **9** which utilizes the amino-acid derived epoxyalcohol **4** as key intermediate (Scheme 1).

The epoxyalcohol **4** was obtained from phenylalanine, in four steps and 40% overall yield, as described previously.[7] 2,3-Epoxyalcohols are regioselectively converted into the corresponding 1,3-diols by Red-Al;[8] accordingly, when the epoxyalcohol **4** was treated with this reagent (3 equiv.) in THF at 50 °C for 24 h, attack of hydride took place selectively to give the Boc-protected aminodiol **5** {$[\alpha]_D^{25} = -18$ (*c* 0.2, MeOH)} in 60% yield after chromatography. In order to convert this compound into the required diaminoalcohol **9**, it is necessary to: i) selectively activate the hydroxy group on C4 towards displacement by a suitable precursor of the aminogroup and ii) invert the configuration of C2 which is opposite to that of **9**. Differentiation of the two secondary hydroxy groups, selective activation and inversion of the configuration of C2 were obtained in a single step by treating the diol with 3 equiv. of methanesulfonyl chloride and 6 equiv. diisopropylethylamine (DIPEA) in 1,2-dichloroethane, at 80 °C for 6 h. The dimesylate **6** initially obtained spontaneously cyclizes *via* S_N2 attack of the carbonyl oxygen of Boc on the neighbouring sulfonate ester to give the inverted oxazolidinone **7**. Displacement of the second mesylate was obtained by treating crude **7** with 1.5 equiv. NaN_3 in DMSO for 18 h at 50 °C, in the presence of 1 equiv. of 18-crown-6, affording the azide **8** {$[\alpha]_D^{25} = -35$ (*c* 0.2, MeOH)} in which all the stereocenters have the correct configuration (50% for the two steps). The stereochemistry of the oxazolidinone **8** was established from NOE experiments. These show a 3% enhancement between the ring H4 and H5, consistent with a *trans* relationship between these protons, while in the *cis*-oxazolidinone **12** (Scheme 2) a 11% enhancement is detected between the same protons. The Boc-protected amino group was then restored by treatment of **8** with equimolar amounts of Boc_2O and NaH in THF, at 25 °C for 12 h, followed by hydrolysis of the resulting N-Boc heterocycle with Cs_2CO_3 in MeOH–water at 25 °C for 2 h.[9] Finally, hydrogenation of the azide, in MeOH over 10% Pd/C, gave the monoprotected (*S*,*S*,*S*) hydroxyethylene dipeptide isostere **9** {$[\alpha]_D^{25} = -19$ (*c* 0.2, MeOH)} in 20% overall yield from the epoxyalcohol **4**.

The synthetic approach shown here can be expanded to obtain the epimeric Phe-Phe dipeptide isostere **13** with the opposite configuration at the alcoholic carbon (Scheme 2). In this case the diol **5** is treated with sodium hydride in THF at 25 °C for 12 h to give, in 85% yield, the *cis*-oxazolidinone **10** arising from a normal acyl transfer cyclization[10] {$[\alpha]_D^{25} = -42$ (*c* 0.2, MeOH)}. The NOE enhancement between the ring



Scheme 1 *Reagents and conditions*: (a) Red-Al, THF, 50 °C, 60%; (b) MsCl, DIPEA, 80 °C; (c) NaN_3, DMSO, 18-crown-6, 50 °C, 50%, 2 steps; (d) NaH, Boc_2O, THF; (e) Cs_2CO_3, MeOH–H_2O, 67%, 2 steps; (f) 1 atm H_2, 10% Pd/C, MeOH, 100%.



Scheme 2 *Reagents and conditions*: (a) NaH, THF, 25 °C, 85%; (b) MsCl, Et_3N, CH_2Cl_2, 0 °C; (c) NaN_3, DMSO, 18-crown-6, 50 °C, 75%, 2 steps; (d) NaH, Boc_2O, THF; (e) Cs_2CO_3, MeOH–H_2O, 58%, 2 steps; (f) 1 atm H_2, 10% Pd/C, MeOH, 100%.

protons (11%) is consistent with the *cis* stereochemistry of the ring substituents. With the first hydroxy group thus protected, the second OH can be activated as mesylate, in CH_2Cl_2 at 0 °C,[11] and the resulting oxazolidinone **11** is then converted into the selectively protected (*S*,*R*,*S*) isostere **13** {$[\alpha]_D^{25}$ = +1.0 (*c* 2, MeOH)} by the same sequence of reactions seen before for the synthesis of **9** (Scheme 2). The overall yield of **13** is 22%, from the epoxyalcohol **4**.

We have thus described a novel approach to the synthesis of the (*S*,*S*,*S*) dipeptide isostere of Ritonavir **9** and its (*S*,*R*,*S*) epimer **13**, based on the regioselective ring opening of an epoxyalcohol with aluminium hydride. This strategy leads to a mono-protected diaminoalcohol from which peptidomimetic protease inhibitors can be directly obtained by coupling with different peptide, or non-peptide, residues. The approach is not limited to isosteres with identical side chains, and it should thus be possible to extend this methodology to the synthesis of a repertoire of isosteres with different residues, starting from the corresponding, readily available epoxyalcohols.[7] The synthesis of dihydroxyethylene dipeptide isosteres from the same epoxyaminoalcohols **4** has been described previously;[7,12] the present extension to the synthesis of monohydroxyethylene isosteres further demonstrates the synthetic utility of these intermediates.

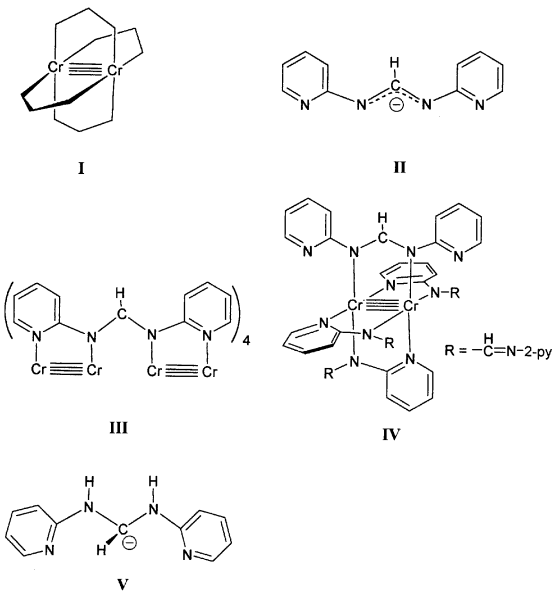
First published as an Advance Article on the web

In addition to a quadruply bonded dichromium(II,II) compound of unusual structure, we have obtained a dinuclear, antiferromagnetically coupled, Cr^{III} complex [Cr_2(μ-OMe)$_2$(η^3-*N,C,N′*-H_2DpyF)$_2Cl_2$·MeOH, H_2DpyF = CH(NH-pyridyl)$_2$] containing a transformed formamidinate group in which the central carbon atom has changed from sp^2 to sp^3 hybridization and Cr–C bonds have been formed; details of the crystal structure of the organometallic compound are given here.

The use of formamidinate ligands of the type RNC(H)NR and ArNC(H)NAr to bridge M_2^{n+} dinuclear units (M = various transition metal atoms, n = 4, 5, and 6) has been intensively studied.[1] Typically, paddlewheel structures, **I**, have been obtained. More recently there has been wide interest in creating longer chains of metal atoms.[2] Thus we decided to use amidinate ligands with more than two N atom donors. One such ligand is the anion of *N,N′*-di(2-pyridyl)formamidine, HDpyF, **II**, where the two Ar groups are 2-pyridyl groups. In this way chains of three and four collinear chromium(II) atoms, **III**, were obtained.[3]

After we recently found that dimolybdenum compounds of the DpyF ligand have many coordination isomers in solution,[4] we have carried out the reaction of $CrCl_2$ with LiDpyF in THF in the molar ratio of 1:2. This reaction affords the dinuclear species of Cr_2^{4+} as an unsymmetrical yellow isomer of the type **IV** as the major product.[5] During the work-up process, the



solvent from the reaction mixture was removed under vacuum and the solid residue, which also contained LiCl, was washed with methanol, a solvent in which **IV** is not significantly soluble but LiCl is. We noticed that upon the addition of very dry methanol, a deep red solution was produced above the solid **IV**. After filtration, the red methanol solution was layered with diethyl ether and red crystals of Cr_2(μ-OMe)$_2$(η^3-*N,C,N′*-H_2DpyF)$_2Cl_2$·MeOH were obtained in low yield.†

The structure‡ consists of two very similar but crystallographically independent molecules, one of which is shown in Fig. 1. It comprises an edge-sharing bioctahedral (ESBO) dichromium unit with two methoxy groups defining the shared edge. The Cr_2O_2 unit is planar in accordance with lying on a crystallographic inversion center. A chlorine atom on each chromium atom is *cis* to the methoxy groups. The other three coordination sites comprising a face of each octahedron are occupied by a carbon atom and two nitrogen atoms of a tridentate ligand derived from what was the usual form of the DpyF anion, **II**. The carbon atom is *trans* to the chlorine atom. The DpyF ligand has been transformed to the monoanion, **V**. Binding to the chromium atoms no longer occurs in the usual way, by bonds to the amidinate N atoms, but instead through the two pyridyl N atoms and the central C atom. Thus there are two fused five-membered rings with the N atoms *trans* to the methoxy groups. The methoxy bridges are but slightly asymmetric with Cr–O distances of 1.971(2) and 1.984(2) Å. They are very similar to those found in Cr^{III}–O(H)–Cr^{III} units of hydroxo-bridged amine complexes[6] and in some other compounds with Cr(μ-OMe)$_2$Cr cores[7] where they are in the narrow range of 1.95–1.99 Å. The Cr–N distances of 2.086(2) to 2.101(2) Å are also as expected.[8]

The Cr–C distances of 2.059(3) and 2.068(3) Å in the two nonequivalent molecules are within the normal range of 2.04–2.13 Å. The Cr–Cl distances of 2.4653(8) Å are more

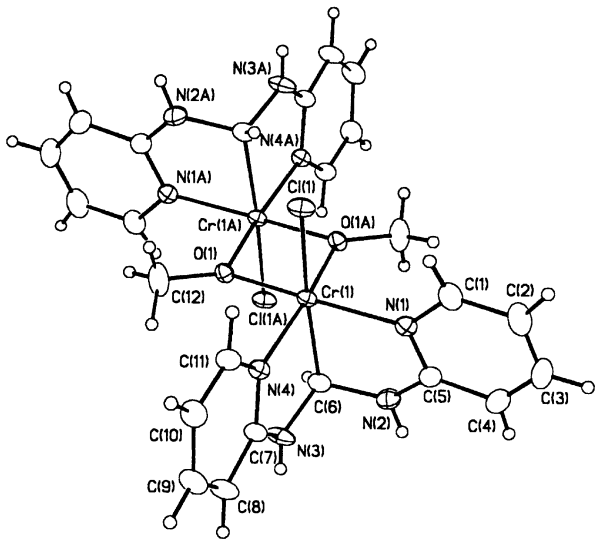


Fig. 1 Plot of one of the independent molecules in Cr_2(μ-OMe)$_2$(η^3-*N,C,N′*-H_2DpyF)$_2Cl_2$·MeOH. Hydrogen atoms refined during the X-ray diffraction study are shown as arbitrarily sized circles. Selected distances (Å) and angles (°) are Cr(1)···Cr(1A) 3.0751(8), Cr(1)–C(6) 2.059(3), C(6)–N(2) 1.444(4), C(6)–N(3) 1.455(4); N(2)–C(6)–N(3) 111.0(2), N(2)–C(6)–Cr(1) 108.8(2), N(3)–C(6)–Cr(1) 108.7(2), N(2)–C(6)–H(6) 105(2), N(3)–C(6)–H(6) 110(2).

DOI: 10.1039/b007813l

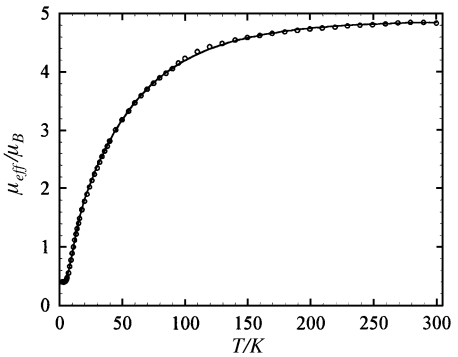

Fig. 2 Temperature dependence of the effective magnetic moment. The solid line is the best fit obtained with a dimer model of $S = 3/2$ magnetic spins (1% of an $S = 3/2$ paramagnetic impurity was taken into account to reflect the residual paramagnetism a low temperature).

difficult to compare with previous results because the presence of halide ions in six-coordinate Cr^{III} organometallic compounds is rare.[9] However, a comparison can be established with *fac*-Cl_3Cr(1,5-diamino-3-azapentane), a coordination compound which has three Cr–N distances varying from 2.08(1) to 2.11(1) Å and three Cr–Cl distances varying from 2.303(7) to 2.332(7) Å.[10] Clearly the Cr–Cl distances in the present case are significantly longer, by more than 0.13 to 0.16 Å. A large *trans* effect for carbon atoms in Cr^{III} organometallic compounds has previously been documented.[11]

All hydrogen atoms were found and refined. In the crystal there is extensive intermolecular hydrogen bonding involving pairs of nonequivalent molecules and also the interstitial methanol molecules. Thus, it is not surprising that the crystalline compound is stable towards exposure to oxygen and moisture.

The most remarkable feature of this compound is the transformation that occurs at the sp^2 methine C atom of the DpyF anion, **II**, whereby the hybridization is changed to sp^3 at the methanide C atom upon hydrogen atom capture by the inner N atoms giving the monoanion **V**. In **II**, the N–C(H)–N unit is typically planar with short C–N distances of 1.31–1.33 Å,[1,12] but in **V** those distances increase to 1.433(4)–1.455(4) Å. These are also *ca*. 0.1 Å longer than those of the corresponding N–$C_{pyridyl}$ bonds. Also consistent with the presence of a methanide group in **V** are the bond angles around the central C atom (including those involving the C–H bond) which are very close to those expected for a tetrahedral atom. Thus the internal consistency of all the structural data supports beyond any doubt the formulation given here.

To our knowledge this is an unprecedented transformation of a formamidinate group (although many other transformations are known[13]) with concomitant formation of a stable Cr(III) organometallic compound. Only one additional report exists of a transformation of an sp^2 C atom in a formamidinate to an sp^3 C atom. This was observed when dimerization of two formamidinate anions was induced by a tantalum compound giving the dianion PhNC(H)N(Ph)*C*(H)$(NPh)_2$,[13] but here the *C* atom has four bonds and is thus unable to bind to metal atoms.

Finally, magnetic measurements (Fig. 2)§ show antiferromagnetic coupling of the two chromium atoms through the methoxy bridges. The fitting of the data using an $S = 3/2$ dimer model[7,14] leads to an exchange interaction, J, of -18 K and a g value of 2.04. This is consistent with the magnetic behavior of other dinuclear Cr^{III}-organometallic compounds.[15]

We gratefully acknowledge the National Science Foundation for financial support and Dr. L. M. Daniels and Professor K. R. Dunbar for help with the crystallographic and magnetic measurements, respectively.

† For $Cr_2(\mu\text{-}OMe)_2(\eta^3\text{-}N,C,N'\text{-}H_2DpyF)_2Cl_2\cdot MeOH$: Anal. Calc. For $Cr_2C_{25}H_{32}N_8O_3Cl_2$: C, 44.98; H, 4.83; N, 16.79. Found: C, 44.52; H, 4.79; N, 16.51%. The process whereby the product is formed is not clear yet but a balanced equation can be written as follows:

$$2CrCl_2 + 4LiDpyF \xrightarrow[\Delta]{THF} \xrightarrow{4MeOH}$$

$$Cr_2(\mu\text{-}OMe)_2(\eta^3\text{-}N,C,N'\text{-}H_2DpyF)_2Cl_2 + 2LiCl + 2LiOMe + 2HDpyF$$

In three runs by two different people yields of 5–10% were obtained.

‡ *Crystal data*: $C_{25}H_{32}Cl_2Cr_2N_8O_3$, $M = 667.49$, monoclinic, space group $P2_1/c$, $a = 15.507(2)$, $b = 9.7562(6)$, $c = 19.920(2)$ Å, $\beta = 98.597(7)°$, $V = 2979.8(5)$ Å^3, $Z = 4$, $T = 213$ K, $\mu = 0.95$ mm^{-1}, 15663 measured/4711 independent reflections, R(int) = 0.056. The final $wR(F^2)$ were 0.093 ($I > 2\sigma$) and 0.098 (all). The positions of all H atoms were clearly indicated in the final difference Fourier maps. CCDC 182/1882. See http://www.rsc.org/suppdata/cc/b0/b007813l/ for crystallographic files in .cif format.

§ Magnetic susceptibility measurements were obtained with the use of a Quantum Design SQUID magnetometer MPMS-XL, from 1.8 to 300 K at 1000 G on a finely divided polycrystalline sample. Data were corrected for the sample holder and for the diamagnetic contributions estimated from Pascal's constants.[16]

Received (in Cambridge, UK) 17th October 2000, Accepted 27th November 2000
First published as an Advance Article on the web 4th January 2001

(*R*,*R*,*R*)-γ-Amino acids with side chains in the 2-, 3-, and 4-positions, prepared by addition of acyloxazolidinones to a nitroolefin and hydrogenation, have been coupled to γ-tetra-, and γ-hexapeptides which are shown to form (*M*)-2.6_{14} helices in the crystal state and in MeOH solution.

While there is a lot of activity in the field of β-peptides, their homologs, the γ-peptides, have received much less attention, so far.[1–3] It has been discovered that γ-peptides form helical secondary structures in solution, detectable by NMR spectroscopy, with chains as short as four residues, and that homologation of L-α-amino acids to L-β- and L-γ-amino acids leads to peptides, folding to helices of alternating polarity and helicity (α: N ↦ C (*P*), β: N ↤ C (*M*), γ: N ↦ C (*P*)), and of increasing stability. The γ-peptides studied hitherto consisted of γ^4-residues (side chains at C(4))[1,2] or of $\gamma^{2,4}$-residues (two side chains, one at C(2) and one at C(4)),[2,3] rel. configuration *l* or *u*.† Inspection of models leads to the conclusion that $\gamma^{2,3,4}$-peptides of type **1**/**2** (Fig. 1), built of (*R*,*R*,*R*)-amino acid residues, should be able to form a 2.6_{14}-helix without steric interference of the side chains within the helical backbone.

The required γ-amino-acid building blocks were prepared stereoselectively by *Michael* addition of the modified *Evans* acyloxazolidinones **3** to nitrobutene (→ **4**),[4] reductive cleavage (→ **5**), hydrolysis, and *N*-Boc or *C*-OBn protection (→ **6**, **7**) (Scheme 1). Coupling of amino acids **6** and **7** gave dipeptide **8**, which after appropriate deprotection yielded dipeptide building blocks which were coupled to tetra- and hexapeptides **1** and **2**, respectively.

Of the protected γ-tetrapeptide **1** we obtained crystals suitable for X-ray structure analysis.‡ The quality and size of the samples allowed only for isotropic refinement and the determined structure is shown in Fig. 2a. The structure is characterized by two consecutive 14-membered H-bonded rings, one between the NH of residue 3 and the C=O of the Boc-protecting group and the other between the NH of residue 4 and the C=O of residue 1. Thus, both intramolecular H-bonds fit into the typical pattern of the 2.6_{14}-helix (H-bond between NH of residue *i* and C=O of residue (*i* − 3)). The carbamate NH of residue 1 and the amide NH of residue 2 are involved in intermolecular H-bonding to the ester C=O and to the C=O of residue 3 respectively, resulting in a two-dimensional H-bonded network. Residues 1 to 3 show the typical backbone conformation found in the (*M*)-2.6_{14} helix ((−)-*sc* for the C(2)–C(3) and the C(3)–C(4) ethane moieties). The side chains at C(2) and C(4) are in lateral positions, while the C(3)–Me bonds form angles of approximately 35° with the helix axis. The C-terminal residue has an extended backbone conformation ((±)-*ap* for the C(2)–C(3) and the C(3)–C(4) ethane moieties). Since the C-terminal ester group has no NH-group which could form an

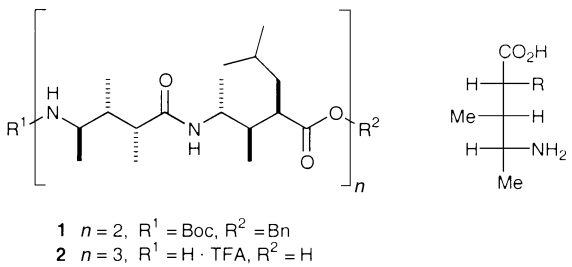

Fig. 1 $\gamma^{2,3,4}$-Tetra- and hexapeptide derivatives **1** and **2** used for the structure determinations and *Fischer* representation of the required amino acid building blocks.

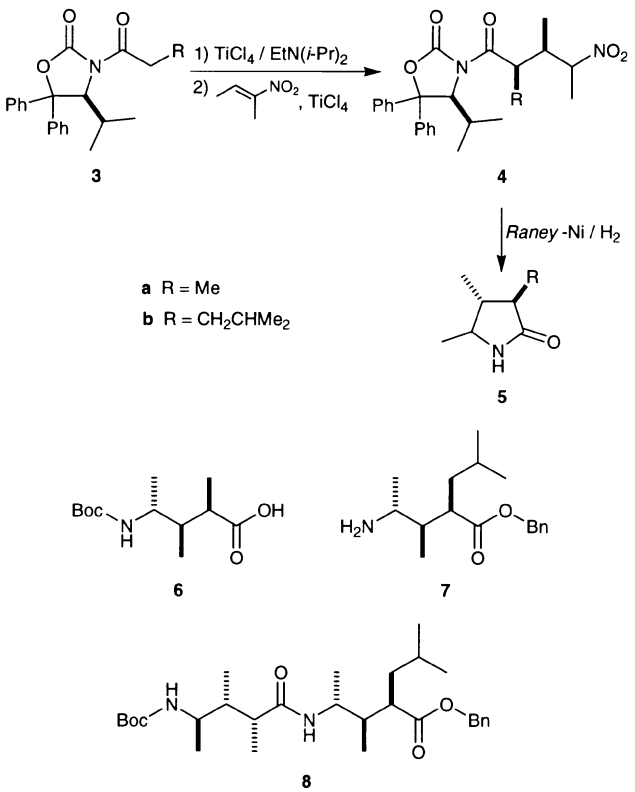

Scheme 1 Synthesis of the building blocks used for the preparation of peptides **1** and **2**. Hydrolysis of lactam **5a** in 6 M HCl and subsequent Boc-protection yielded amino acid **6**. The same procedure was applied with **5b**, followed by benzylation and Boc-deprotection to obtain **7**. Compounds **4** and **5** were used as mixtures of diastereoisomers, and separation was performed at the stage of the corresponding γ-amino acid. Coupling of amino acids **6** and **7** with HATU [*O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate] to dipeptide **8** proceeded smoothly. Appropriate deprotected derivatives of **8** were fragment coupled to tetrapeptide **1** and hexapeptide **2** using EDC (1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide·HCl)/DMAP as reagents.

DOI: 10.1039/b008377l

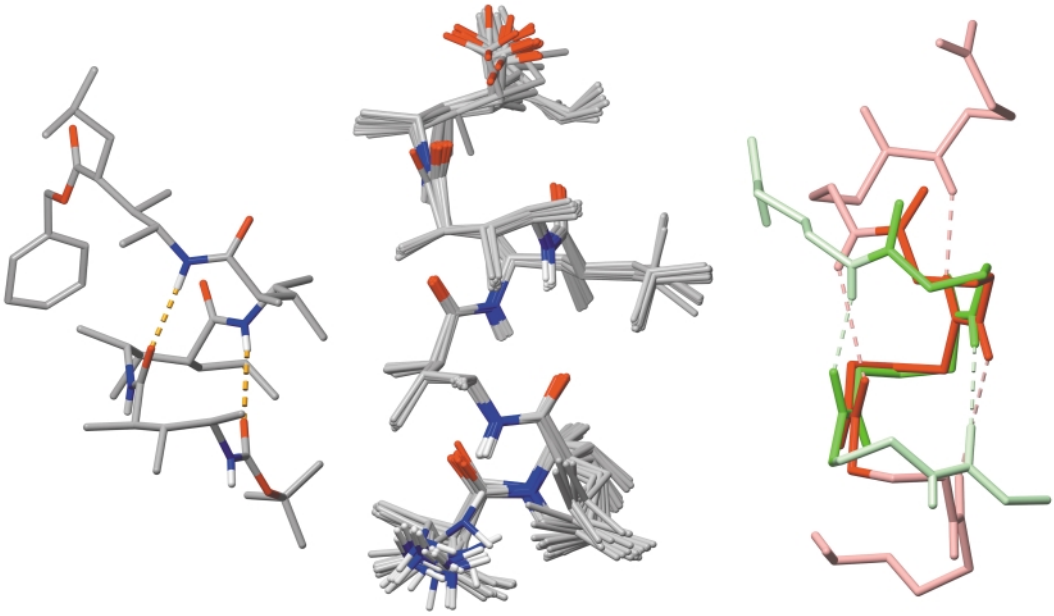

Fig. 2 (*M*)-2.6$_{14}$ Helical structures of γ-peptides **1** and **2**. a, Structure of γ-tetrapeptide **1** in the crystal state determined by X-ray structure analysis. b, Bundle of 20 conformers of hexapeptide **2** in MeOH obtained by simulated annealing calculations using restraints from NMR data. c, Superposition of the peptide backbones from the X-ray diffraction structure (blue) and NMR structure (red).

intramolecular H-bond the conformation of residue 4 may by determined by crystal packing factors.

The observation that γ-peptides with just four residues form a helical structure in the crystal state led us to examining γ-hexapeptide **2** by means of high-resolution NMR techniques. 2D-NMR Studies were carried out on a 500 MHz spectrometer with solutions in CD_3OH. We used DQF-COSY and TOCSY techniques to assign all ^1H resonances in their respective spin systems. HSQC and HMBC experiments led to the assignment of the amino acid sequence. ROESY spectra of **2** at different mixing times were acquired and NOEs were extracted from spectra with a mixing time of 300 ms.

The NOEs were classified according to their relative volume in three distance categories with the following upper bound distance limits: strong < 3.0, medium < 3.5 and weak < 4.5 Å. A total of 83 NOEs were used as distance restraints in simulated annealing, following the XPLOR protocol. This calculation yielded a set of 20 structures with low restraint violation and minimum energy (Fig. 2b). The structures show a well-defined left-handed helix with three 14-membered hydrogen-bonded rings from C=O of residue *i* to NH of residue *i* + 3. The helix has a pitch of *ca*. 5.0 Å and has *ca*. 2.6 residues per turn. An overlay of the backbone of one of the NMR-derived structures of **2** and the backbone from the crystal-structure of tetrapeptide **1** is shown in Fig. 2c. This superposition shows a good agreement between the central residues of the two molecules.

This study shows that γ^{2,3,4}-peptides constructed from (*R*,*R*,*R*)-trisubstituted γ-amino acid residues adopt well defined (*M*)-2.6$_{14}$-helices without steric interferences of the side chains, and allowed for the first time the characterization of this secondary structural motif by X-ray crystal structure analysis.

Notes and references

† Peptides built of γ^{2,4}-amino acids with rel. configuration *l* form 2.6$_{14}$ helical structures, while a tetrapeptide consisting of the corresponding *u* residues was found to form a turn motif.

‡ *Crystal data* for $C_{46}H_{80}N_4O_7$ **1**: M = 801.14, monoclinic, space group $P2_1$, a = 9.462(2), b = 20.472(6), c = 13.866(4) Å, β = 106.14(2)°, V = 2580.1(12) Å^3, Z = 2, D_c = 1.031 g cm^{-3}, μ(Cu-Kα) = 0.543 mm^{-1}, crystal size 0.30 × 0.20 × 0.02 mm. Data were collected on an Enraf Nonius CAD-4 diffractometer using graphite-monochromatized Cu-Kα radiation. A total of 4479 unique reflections (3.32 < 2Θ < 66.23°) were processed of which 1140 were considered significant with $I_{net} > 3\sigma(I_{net})$. Part of the structure was solved by direct method with SIR97,[5] the remaining non-H-atoms were found from a difference Fourier map. The non-H atoms were refined isotropically with SHELXL97.[6] The number of observed reflections did not allow anisotropic refinement. H-atoms were calculated at idealized positions and included in the structure factor calculation with fixed isotropic displacement parameters. Final residuals were R = 0.0898 and R_w = 0.1961 (GOF = 1.525) for 243 parameters. CCDC 182/1874.

The structure was determined by B. Schweizer of our X-ray service.

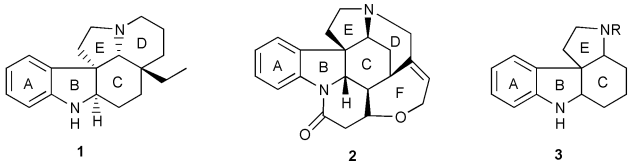
Received (in Liverpool, UK) 16th October 2000, Accepted 18th December 2000
First published as an Advance Article on the web

Reaction of indole 19 *via* the derived aryl radical gives the tetracycle 20 in 43% yield. This compound contains the ABCE-rings of both *Aspidosperma* and *Strychnos* alkaloids.

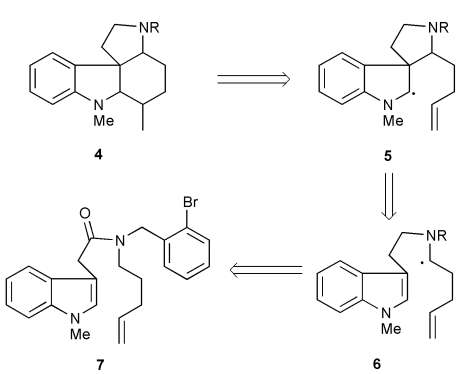
The pentacyclic *Aspidosperma* alkaloids such as aspidospermidine **1** and the heptacyclic *Strychnos* alkaloids such as



1 **2** **3**

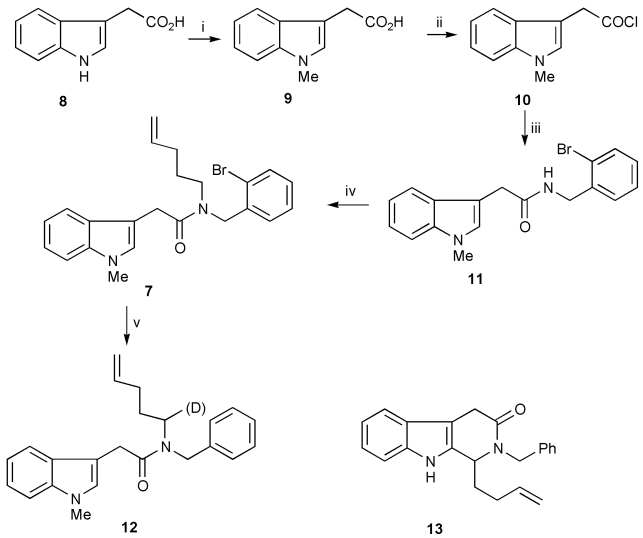
strychnine **2** remain interesting targets for synthetic chemists owing to their chemical architecture and their biological activities.[1] The tetracyclic sub-structure **3**, consisting of the ABCE-rings of both these series of natural products represents the core of these molecules and functionalised examples of this tetracycle have featured in the total synthesis of both *Strychnos* and *Aspidosperma* alkaloids.[2] Efficient approaches to **3** carrying appropriate functionality would allow not only the synthesis of these natural products but also related non-natural products. Some years ago, we commenced a programme of research based on a strategy of radical cyclisation to form oxindoles (indolin-2-ones) followed by carbanion cyclisation to create the B- and C-rings.[3] Murphy has disclosed a tandem radical cyclisation route to this tetracyclic structure in which the B- and E-rings are created by an aryl radical addition to a double bond followed by internal trapping of the resultant radical by an azide.[4] This provides an alternative to the 'radical-polar crossover' chemistry developed by the same group and utilised in a synthesis of (±)-aspidospermidine **1**.[5] Parsons has also reported a conceptually different approach to the *Aspidosperma* skeleton using aryl radicals.[6] We now wish to disclose a new route to the ABCE–tetracycle using a novel tandem radical route to create the C- and E-rings.

The new disconnection sequence is shown in detail in Scheme 1. The key features of this plan involve the addition of radical **6** to the indole 3-position to create the E-ring. The α-amino radical generated in this step can then be captured in a 6-*exo* manner to create the C-ring. In order to generate radical **6**, it was decided to take advantage of the well-known ability of aryl radicals to abstract hydrogen atoms *via* a 6-membered ring transition state.[7] This analysis led back to the tertiary amide **7** as the substrate for a series of radical reaction steps under the usual conditions of tributyltin hydride (TBTH) and a suitable initiator.



Scheme 1

The synthesis of radical precursor **7** commenced with indole-3-acetic acid **8** (Scheme 2). Treatment with sodium hydride and methyl iodide gave the *N*-methylindole-3-acetic acid **9** in 93% yield. Reaction of **9** with oxalyl chloride in THF at 0 °C gave the acid chloride **10** which was reacted immediately with 2-bromobenzylamine hydrochloride in the presence of excess diisopropylethylamine to give amide **11** in overall 86% yield. Alkylation of **11** with 5-bromopentene using potassium hydride as base in THF and tetrabutylammonium iodide as catalyst proceeded smoothly resulting in tertiary amide **7** in 73% yield. The ^{1}H NMR spectrum of **7** showed clearly the presence of two rotamers caused by restricted rotation about the amide bond. The minor rotamer possessed a singlet resonance at δ 4.72 assigned to the benzyl group in **7a** (Fig. 1) whilst the major rotamer displayed a singlet at δ 4.56 assigned to the benzyl group in **7b**. Integration of these signals revealed a ratio of 6:5 favouring **7b**. It is well known that the timescale for amide bond rotation to occur is considerably longer than the lifetime of radical intermediates which means that cyclisation of the translocated radical derived from major rotamer **7b** is unlikely.[8]



Scheme 2 *Reagents and conditions*: i, NaH, THF, 0 °C, then MeI warm to 20 °C, 12 h, 93%; ii, oxalyl chloride, THF, 0 °C to 20 °C, 20 h; iii, 2-bromobenzylamine hydrochloride, *N*,*N*-diisopropylethylamine, dichloromethane, 0 °C, 2 h, 86%; iv, KH, THF, 0 °C, then 5-bromopentene, tetrabutylammonium iodide, warm to 20 °C for 20 h, 73%, v, TBTH (or TBTD), AIBN, xylene, reflux, 10 h.

DOI: 10.1039/b008465o

With this problem in mind, reaction of **7** with TBTH at reflux in xylene under dilute conditions (0.02 M) was carried out. A complex mixture of products was obtained and to help determine the nature of the products, the reaction was repeated using tributyltin deuteride (TBTD). Extensive spectroscopy on the isolated products allowed assignment of the structure **12** (both rotamers) to the major product (50%) and structure **13** to one of the minor products (18%). Both products contained the intact alkene unit indicating that tetracycle formation had not occurred whilst the product **12** from reaction with TBTD contained deuterium adjacent to the nitrogen indicating successful radical translocation. Addition of the intermediate α-amido radical to the indole C-2 followed by rearomatisation to give **13** is not unreasonable given the results of Moody[9] and related work by Bowman[10] in other heteroaromatic systems. Product **12** could simply be arising from the major rotamer **7b** which cannot cyclise. However, the isolation of **13** indicates that the rather nucleophilic α-amido radical prefers to add to the indole ring at the C-2 position.

Following the precedent in the work of Fang,[11] we decided to introduce an electron-withdrawing group at the 2-position of indole **7** to encourage addition of the nucleophilic α-amido radical to C-3 of the indole. Reaction of 3-methylindole with triphenylphosphine–thiocyanogen has been reported to give 2-cyano-3-methylindole in 85% yield.[12] Treatment of **7** under these conditions led only to starting material. A variety of other studies to introduce a cyano-group at the 2-position were undertaken but eventually it was decided to develop a new route to the desired radical precursor (Scheme 2). The required secondary amine was prepared following the chemistry of Fukuyama and Bowman.[13] Reaction of 2-bromobenzylamine hydrochloride with sulfonyl chloride **14** gave sulfonamide **15** in 86% yield (Scheme 3). Alkylation using 5-bromopentene and caesium carbonate as base gave **16** in 93% yield and removal of the 2-nitrosulfonamide group was achieved in high yield using potassium carbonate and benzenethiol yielding secondary amine **17**. Reaction of **17** with the acid chloride **18** (derived from the acid[14] by reaction with oxalyl chloride in THF at 0 °C) gave the radical precursor **19** in 83% yield. Again the NMR revealed the presence of rotamers in a ratio of 1.1 : 1. Reaction of **19** with TBTH in refluxing 5-*tert*-butyl-*m*-xylene (*ca.* 200 °C) under syringe pump conditions gave some 50% of reduced product (**19** with Br = H) and 43% of **20** which had undergone the desired translocation–cyclisation–cyclisation sequence. Tetracycle **20** was isolated as a mixture of 4 diastereoisomers in a ratio of 8 : 3 : 2 : 1. The relative stereochemistry of the four diastereoisomers obtained cannot be assigned from their NMR spectra owing to the contiguous quaternary centres at the BC- and CE-ring junctions. Calculations show the *trans,trans* stereochemistry at these ring junctions to be of very high energy leaving 6 possible diastereoisomers, four of which possess the natural *cis* CE-ring junction stereochemistry and two of which possess the *trans* CE-ring junction stereochemistry. Although the transition state for the addition of the α-amido radical to the 3-position of the indole would seem to favour creation of a *cis* CE-ring junction, we cannot rule out the formation of isomers containing the *trans*-CE, *cis*-BC stereochemistry.

In summary, we have shown that the sequence of radical reaction steps shown in Scheme 1 is successful if a cyano group is present at the indole C-2. This short sequence to tetracycles such as **20** may provide a rapid entry into indole alkaloid natural products and related compounds and is under active investigation.

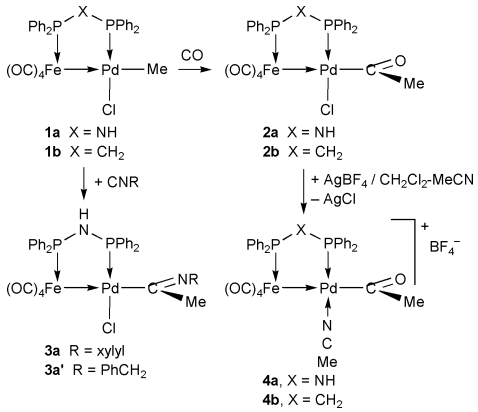
Received (in Cambridge, UK) 5th September 2000, Accepted 12th December 2000
First published as an Advance Article on the web

The reactivity of diphosphine-bridged heterobimetallic Fe–Pd alkyl complexes was evaluated for the insertion of CO, isonitriles, ethylene, methyl acrylate and norbornadienes and the crystal structures of the precursor alkyl complex, the iminoacyl derivative and the five-membered ring complex resulting from ethylene insertion into the palladium–acyl bond are reported.

The insertion of small molecules such as CO, isonitriles, olefins and alkynes into palladium–carbon bonds represents reactions of fundamental importance for stoichiometric organic synthesis and industrial catalysis.[1] An example of the latter is the alternating copolymerisation of CO and olefins, which has triggered considerable research on alkene insertion into the palladium–acyl bond.[1,2] Whereas previous studies have been concerned with the influence of the stereoelectronic properties of the (usually chelating) ligand bonded to the Pd centre on this chemistry, we present here a different approach aimed at evaluating the influence of a metal adjacent to the reactive Pd on its reactivity, with the hope that cooperativity effects may lead to beneficial bimetallic effects.[3]

In the alkyl complexes [$(OC)_4\overline{Fe(\mu\text{-dppx})}PdCl(Me)$] [**1a**, dppx = $Ph_2PNHPPh_2$ (dppa); **1b**, dppx = $Ph_2PCH_2PPh_2$ (dppm)], prepared by reaction of [$Fe(CO)_4$(dppx-*P*)] with [PdCl(Me)(cod)], the methyl ligand is *trans* to the formally dative Fe→Pd bond, both in solution, as deduced from the small $^3J(PH)_{cis}$ coupling constant (< 4 Hz) with the Pd-bound P atom, and in the solid state, as established by X-ray diffraction for **1b** (Scheme 1, Fig. 1).‡§



Scheme 1

These complexes react with CO under atmospheric pressure, more rapidly (3 h) in the case of **1b** because of its higher solubility, to form **2a**,**b**. Quantitative carbonylation of **1a** was achieved in CH_2Cl_2 in < 1 h under 20 atm CO. The *trans* arrangement of the acetyl ligand and the metal–metal bond suggested by the spectroscopic data is retained in the solid state, as shown by comparison with the spectroscopic data for the corresponding iminoacyl complexes **3a**,**a′** which were prepared by instantaneous reaction of **1a** with a stoichiometric amount of (xylyl)N≡C or $PhCH_2N{\equiv}C$, respectively, and characterised by X-ray diffraction in the case of **3a** (Fig. 2).‡§ As expected, the iminoacyl ligand is almost orthogonal to the palladium coordination plane.[4]

Since **2a** did not react with ethylene (at 1 atm), we turned our atttention to more electrophilic, cationic systems and prepared complex **4b** by chloride abstraction in CH_2Cl_2 in the presence of MeCN (Scheme 1). Interestingly, this reaction did not lead to CO deinsertion, a reaction often observed with Pd(II) acyl complexes. Complexes **4a**,**b** are more readily prepared by

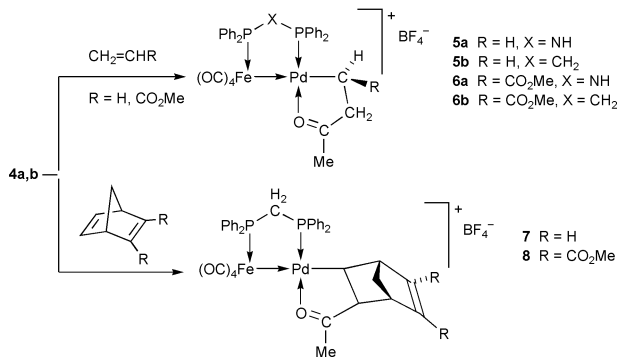

Scheme 2

halide abstraction from **1a**,**b** using $AgBF_4$ in CH_2Cl_2–MeCN, which generates $[(OC)_4Fe(\mu\text{-dppx})Pd(Me)(NCMe)]^+$, followed by instantaneous *in situ* reaction with CO. Complexes **4a**,**b** were indeed more reactive than **2a**,**b** since ethylene insertion into the Pd–acetyl bond occurred under atmospheric pressure to afford after *ca.* 15 h the stable complexes **5a**,**b** in quantitative spectroscopic yields (Scheme 2).‡ The latter represent rare examples of isolable insertion products of an unstrained alkene into a Pd–acyl bond.[5]

IR spectra show an absorption at 1634 cm^{-1} (**5a**) and 1633 cm^{-1} (**5b**) for the acetyl carbonyl coordinated to Pd. The crystal structure of **5a** (Fig. 3)§ established that the σ-bonded carbon atom is *trans* to the metal–metal bond. The BF_4^- counter ion weakly interacts with the N–H proton [d(N···F) = 3.105 Å]. To the best of our knowledge, there are only two precedents for the structural characterisation of a $-CH_2CH_2C(O)Me$ ligand, both in mononuclear Pd complexes.[5]

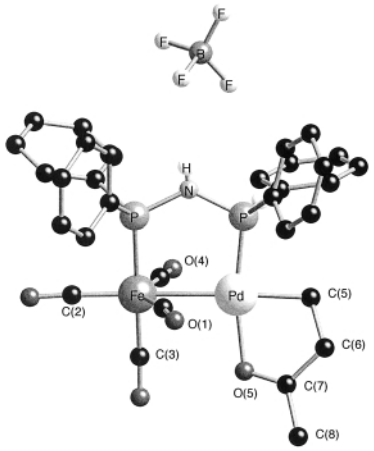

Fig. 3 View of the crystal structure of **5a**. Selected bond lengths (Å) and angles (°): Fe–Pd 2.7208(9), Pd–P(2) 2.1861(14), Pd–C(5) 2.054(6), Pd–O(5) 2.130(4), Fe–P(1) 2.240(2), Fe–C(1) 1.802(6), Fe–C(2) 1.791(7), Fe–C(3) 1.786(6), Fe–C(4) 1.806(6), C(7)–O(5) 1.256(8); O(5)–Pd–Fe 96.13(12), O(5)–Pd–C(5) 81.5(2), P(2)–Pd–C(5) 87.4(2), Pd–C(5)–C(6) 105.7(4), Pd–C(5)–N(1) 124.6(5), C(5)–Pd–Fe 172.5(2), Pd–O(5)–C(7) 112.7(4), Pd–Fe–P(1) 91.12(5), Fe–Pd–P(2) 95.48(5), O(5)–Pd–P(2) 167.93(12), C(6)–C(7)–O(5) 119.0(5), C(3)–Fe–Pd 88.9(2).

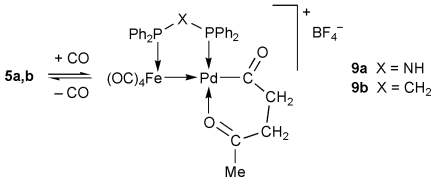
The stable methyl acrylate insertion products **6a**,**b** were isolated in *ca.* 90% yield after stirring **4a**,**b** for 18 h in the presence of 10 equiv. of methyl acrylate (Scheme 2). Insertion of norbornadiene or dimethyl norbornadiene-2,3-dicarboxylate into the Pd–C bond of **4b** occurred within *ca.* 30 min with complete regio- and stereo-selectivity to afford yellow **7** or orange **8**, respectively. The ^1H NMR data of **8** unambiguously indicate that insertion across the *exo*-face of the sterically less hindered CH=CH double bond is preferred over that of the more 'activated' $MeO_2C–C=C–CO_2Me$ double bond.

In order to mimic the next step in the alternating CO/olefin insertion chemistry, **5a**,**b** were reacted with CO under atmospheric pressure and the six-membered chelate complexes **9a**,**b** were obtained after *ca.* 4 h [eqn. (1)].



(1)

This reaction is reversible since **5a**,**b** are regenerated under reduced pressure. The lower reactivity of **5a**,**b** compared to $[(OC)_4Fe(\mu\text{-dppa})Pd(Me)(NCMe)]^+$ is most likely due to the presence of a chelating ligand at Pd, suggesting that opening of the dative ketone→Pd bond is necessary for CO insertion into the Pd–CH_2 bond to proceed. The reaction leading to **9a** is indeed much faster in the presence of a few drops of MeCN.

The bimetallic templates around which various C–C coupling reactions have been performed in this work do not appear, at the moment, to be more reactive than mononuclear cationic Pd(II) complexes reported recently.[5b] However, they have allowed the complete characterization of key intermediates, including in the chemistry of functional monomers.

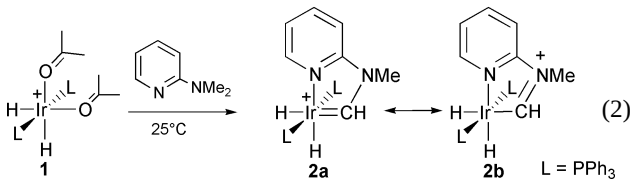
First published as an Advance Article on the web

2-Dimethylaminopyridine (pyNMe$_2$; py = 2-pyridyl) reacts with [$H_2Ir(OCMe_2)_2L_2$]$^+$ (L = PPh_3) to give a cyclic carbene complex [H_2Ir(=CHN(Me)py)L_2]$^+$ *via* an oxidative addition, reversible α-elimination sequence.

The conceptual conversion of eqn. (1) is highly endothermic (ΔH = 111 kcal mol^{-1}, triplet; 119 kcal mol^{-1}, singlet). If the carbene is sufficiently stabilized by a metal fragment and by π-donor heteroatom substitution in the α-position (Fischer carbene), however, such a conversion becomes thermodynamically allowed. For example, both alkene to carbene[1–3] and THF to carbene[4,5] rearrangements of this sort are known, but elevated temperatures may be required for satisfactory rates.[4–5]

$$CH_4 \rightarrow :CH_2 + H_2 \quad (1)$$

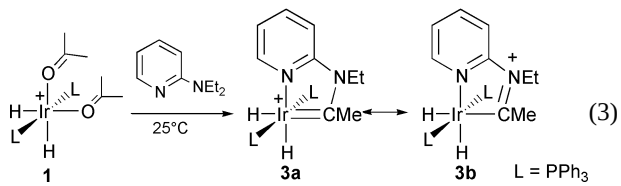
We now report a room-temperature route for the title reaction [eqn. (2)] *via* the activation of two geminal C–H bonds and liberation of H_2.



(2)

We find that 2-dimethylaminopyridine (pyNMe$_2$, 1 equiv.) reacts with [$IrH_2(OCMe_2)_2L_2$]BF_4 **1** in CH_2Cl_2 at 25 °C to give the cyclic heteroatom-stabilized carbene complex **2** (25 °C, 15 min, 78%), by a net reaction that resembles eqn. (1).† The identity of the product follows from the ^{1}H NMR spectrum, in particular the appearance of a low-field singlet of intensity 1H at δ 11.71 assigned to the CH=Ir proton. The NMe group of intensity 3H appears as a singlet at δ 3.50. The two inequivalent hydrides (1H each) resonate at δ −9.98 and δ −17.78 as triplets of doublets ($^2J_{PH}$ 16, $^2J_{HH'}$ 4 Hz), indicating each is *cis* to the two phosphines. The ^{13}C NMR shows a low-field resonance at δ 155.9 characteristic of Fischer carbenes.

The reaction is also possible for 2-diethylaminopyridine (pyNEt$_2$, 1 equiv.) to give the analogous product **3** (25 °C, 15 min, 80%), shown in eqn. (3). The spectral data for **3** is similar



(3)

to that for **2**, in particular, the ^{1}H NMR spectrum shows high-field resonances at δ −10.80 and δ −17.92, characteristic of terminal iridium(III) hydrides. The two hydrides ($^2J_{PH}$ 17 Hz, $^2J_{HH'}$ 4 Hz) are mutually coupled and coupled to the PPh_3 ligands. The formation of **3** was also confirmed by a crystal structure determination (Fig. 1).‡ The Ir–C distance of 2.018 Å is consistent with predominant single bond character while the C–N bond distance of 1.322 Å indicates some multiple bond character as expected from the resonance form **3b** generally preferred by Fischer carbenes. Even with β-hydrogen atoms available, we see only the α-elimination product **3**. Preferred α- *vs.* β-elimination in metal alkyls has been reported.[6,7]

The evidence discussed below suggests formation of **2** proceeds by initial C–H bond activation, perhaps to form an intermediate H_2 complex **5**. Loss of H_2 leads to an alkyl, **6**, which then rearranges to the observed carbene **2,** by α-elimination (Scheme 1).

Formation of an agostic C–H···M bond is typical in complexes related to **1**. For example, the known 2,6-di-

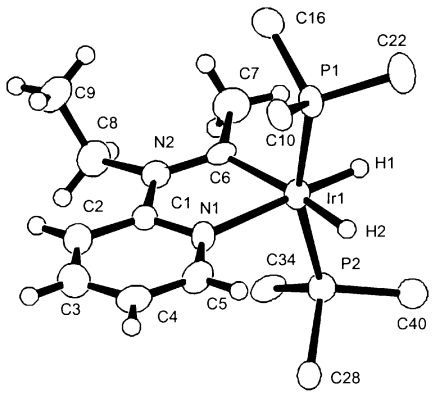


Fig. 1 An ORTEP view of the cation of [$Ir(PPh_3)_2$(pyNEtC-MeH_2]BF_4·CH_2Cl_2 **3**. Selected bond lengths (Å): Ir(1)–C(6) 2.018(5), Ir(1)–N(1) 2.142(4), N(2)–C(1) 1.410(6), N(2)–C(6), 1.332(7). Only the *ipso* carbons of PPh_3 are shown for clarity. The ligand H atoms are in calculated positions. The hydrides were refined with Ir(1)–H(1) 1.43(5) Å and Ir(1)–H(2) 1.47(5) Å, no doubt shortened by systematic error.

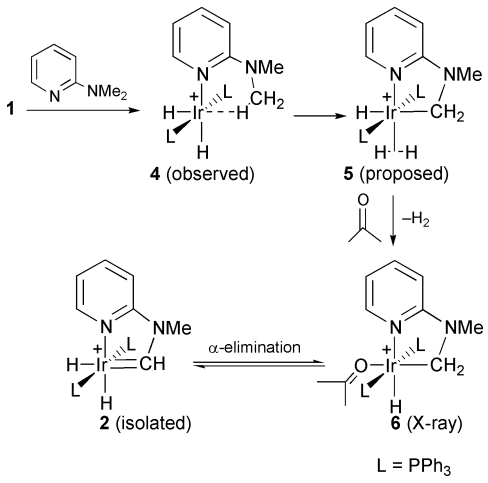
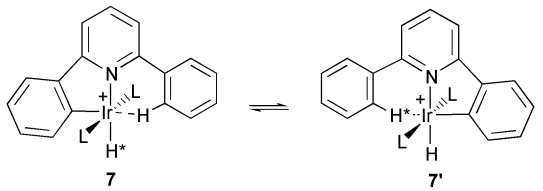


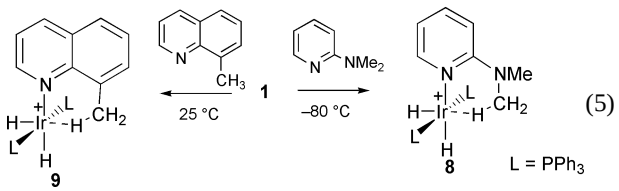
Scheme 1

phenylpyridine species **7**,[8] is fluxional [eqn. (4)] *via* a pathway analogous to that of Scheme 1. To probe the formation of a



(4)

possible agostic C–H···M intermediate **4** in the present case, we treated **1** in CD_2Cl_2 with $pyNMe_2$ at low temperature and monitored the reaction by ^1H NMR. At −80 °C, a new species, **8**, is seen that is too reactive to isolate [eqn. (5)]. After 40 min



(5)

at 0 °C, it converts to **2**. Comparison of **8** with the fully characterized, stable material **9**, made *via* the route of eqn. (5),[9] shows very close ^1H NMR spectral similarities, suggesting **8** has the agostic structure, **4**, shown in Scheme 1. For example, the inequivalent hydrides resonate as a pair of signals (**8**, δ −20.69, δ −29.84; **9**, δ −19.20, δ −28.60) coupled both to two *cis* phosphines (**8**, $^2J_{PH}$ 17 Hz; **9**, $^2J_{PH}$ 15 Hz) and to each other (**8**, $^2J_{HH'}$ 7 Hz; **9**, $^2J_{HH'}$ 8 Hz).

Net loss of H_2 occurs and free H_2 was detected (δ 4.2) in the ^1H NMR spectrum of the reaction mixture. After loss of H_2 to generate a vacant site *cis* to the newly formed iridium alkyl, an α-elimination gives the final product.

Reversible α-elimination is rare,[6] but remarkably, this process is facile in this system. Dissolving the carbene **2** in acetone rapidly gives **6** by reversal of the α-elimination step. The Ir–H of the product **6** resonates as a triplet at δ −16.14 ($^2J_{PH}$ 14 Hz). This colorless alkyl complex was crystallized from acetone–diethyl ether and characterized by a crystal structure (Fig. 2). The equilibration of **2** and **6** was further probed by ^1H NMR. The colorless alkyl complex **6** dissolved in fresh CD_2Cl_2 at 25 °C with loss of acetone to give the yellow carbene **2** within seconds. In a typical case, **6**:**2** occur as a 1:1 ratio (integration of the hydride peaks). Incremental addition of acetone to the solution then led to displacement of the equilibrium in favor of **6**. For example, when 2 and 3 equivalents of acetone were added, the mole ratio of **6**:**2** became 2:1 and 3.3:1, respectively.

Several factors may make the rearrangement of the agostic species (**8**) to the carbene (**2**) thermodynamically favorable, in contrast with the highly endothermic base case of eqn. (1). The metal complexation stabilizes the carbene but this is not sufficient on its own, as shown by the failure of the agostic 8-methylquinoline species **9** to convert to the corresponding carbene, a species that is as yet unknown. Heteroatom stabilization by the adjacent amino group is clearly an important stabilizing factor. In addition, carbene **2** can be considered as a metallacycle with 10 π-electrons, which could in principle benefit from aromatic stabilization.

In summary, we have a rare double C–H activation route that provides a mild and fast synthetic method to generate chelating Fischer carbene complexes.

We thank the NSF (R. H. C, J. W. F), the DOE (J. C.), and the Korean Research Foundation (D.-H. L., grant KRF-2000-015-DP0305) for funding.

Notes and references

† *Synthesis*: **2**: the BF_4 salt of **1** (280 mg, 0.3 mmol) was dissolved in degassed CH_2Cl_2 (4 mL) and 2-dimethylaminopyridine (37 mg, 0.3 mmol) was added. The resulting clear yellow solution was stirred for 15 min. Slow addition of diethyl ether (*ca.* 10 mL) gave a light yellow precipitate. The solution was then filtered and the light yellow powder was washed with diethyl ether (15 mL) and dried *in vacuo* to give pure **2**. Yield: 217 mg (78%). Complex **3** can be prepared similarly by treating **1** with 1 equiv. of 2-diethylaminopyridine. Satisfactory analytical and spectroscopic data were obtained for **2** and **3**.

Reaction of a diarylgermylene with a phosphaalkyne: formation of a germadiphosphacyclobutene with an exocyclic C=Ge double bond

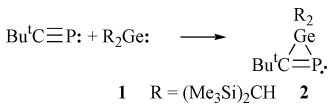
Frank Meiners, Wolfgang Saak and Manfred Weidenbruch*

Fachbereich Chemie, Universität Oldenburg, D-26111 Oldenburg, Germany

Received (in Liverpool, UK) 16th October 2000, Accepted 13th December 2000
First published as an Advance Article on the web

The reaction of bis(2-*tert*-butyl-4,5,6-trimethylphenyl)germylene (Ar_2Ge:) with *tert*-butylphosphaalkyne furnishes a germadiphosphacyclobutene derivative with an exocyclic –C(Bu^t)=GeAr_2 group at one phosphorus atom, which was characterised by an X-ray structure analysis.

The addition of dialkyl-silylenes and -germylenes to the P≡C triple bonds of thermally stable phosphaalkynes represents a simple method for the synthesis of three-membered ring systems containing a P=C double bond that are difficult to prepare by other routes. For example, the silylene R_2Si**:** (R = CMe_3) reacts smoothly with phosphaalkynes to afford the corresponding phosphasilirenes.[1] The dialkylgermylene **1**[2,3] also undergoes a [2 + 1] cycloaddition reaction with *tert*-butylphosphaalkyne from which the germaphosphirene **2** can be isolated (Scheme 1).[4] The diarylsilylene Mes_2Si**:** behaves differently and furnishes a phosphadisilacyclobutene *via* stepwise addition of two silylene molecules to the phosphaalkyne.[5]



Scheme 1

We have now addressed the question if, similar to the silylenes, the use of a diarylgermylene would furnish a different result. Thus, from the reaction of the germylene **4** (which, in analogy to **1**,[6] exists as the digermene **3** in the solid state)[7] with *tert*-butylphosphaalkyne gave orange-coloured crystals which were isolated in 59% yield. The analytical data for these crystals were indicative of a 1:1 adduct composed of **4** and the phosphaalkyne. However, the ^{31}P NMR spectrum revealed the presence of both two- and three-coordinated phosphorus atoms, thus excluding the formation of a three-membered ring system analogous to **2** and suggesting the presence of a larger ring system (Scheme 2).

In agreement with the analytical and spectral data, an X-ray crystallographic analysis (Fig. 1)‡ revealed that two molecules each of the phosphaalkyne and **4** had reacted to furnish compound **5**† comprised of a germadiphosphacyclobutene with an additional, exocyclic Ge=C double bond. The bond lengths of both the exocyclic Ge=C and the endocyclic P=C double bonds were in accord with those of previously reported, similar

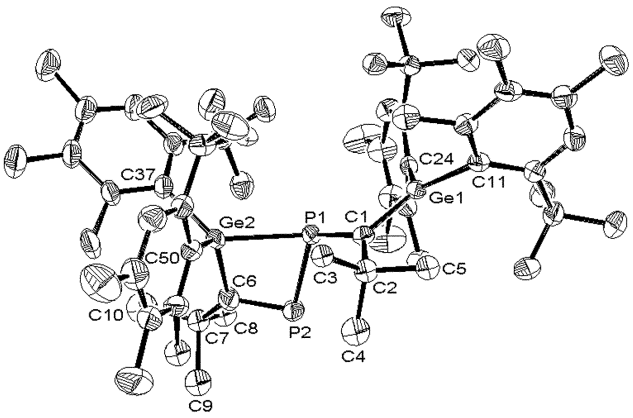


Fig. 1 Molecular structure of **5** (50% probability ellipsoids, hydrogen atoms omitted). Selected bond lengths (Å) and angles (°): P(1)–P(2) 2.1703(14), P(2)–C(6) 1.702(4), C(6)–Ge(2) 1.982(4), P(1)–Ge(2) 2.4351(9), P(1)–C(1) 1.822(3), C(1)–Ge(1) 1.833(4); P(2)–P(1)–Ge(2) 78.73(4), P(1)–Ge(2)–C(6) 79.15(11), Ge(2)–C(6)–P(2) 105.0(2), C(6)–P(2)–P(1) 93.39(15).

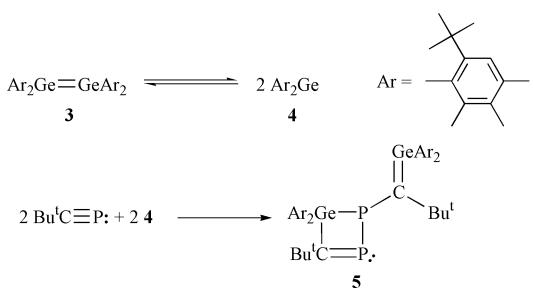
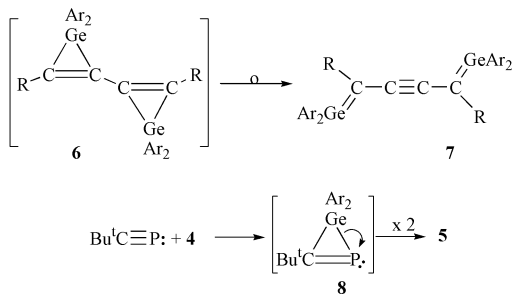
bonds. The remaining bond lengths and angles also did not reveal any unusual features.

The unexpected formation of **5** is without precedence in the chemistry of germylenes and phosphaalkynes. It is, at best, comparable with the addition of the germylene **4** to 1,3-diynes, a process proceeding through the C–C bridged bis(germacyclopropenes) **6** as the intermediate on the way to the rearranged, acetylene-linked bis(germaethenes) **7** (Scheme 3).[8] In analogy to the formation of **7**, it may be assumed that here also the reaction sequence is initiated by the addition of **4** to the phosphaalkyne to afford a three-membered ring system of type **8** with subsequent opening of the P–Ge single bond. Cyclodimerisation of this intermediate would then yield compound **5**.

A cyclodimerisation of this type should produce several conformers with varying orientations of the substituents on the exocyclic C atom. In fact, the ^{31}P NMR spectrum of **5** contains two doublets for two-coordinate phosphorus atoms at δ 269.0 and 271.5 as well as two doublets in the high-field region at δ −8.1 and −34.4. These signals remain unchanged even on heating a sample to 80 °C, presumably on account of the steric crowding at the exocyclic carbon atom. The existence of two conformers in solution is further supported by the observation



Scheme 2



Scheme 3

DOI: 10.1039/b008472g

of numerous, in part overlapping, signals in the ^{1}H and ^{13}C NMR spectra that cannot be assigned unambiguously. The $^{1}J_{PP}$ coupling constants of 16 and 21 Hz for the two conformers are inexplicably small; related ring systems[9] have values of *ca.* 250 Hz.

Financial Support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged. We thank Professor Marsmann, Paderborn, for the ^{31}P NMR spectra.

Notes and references

† *Preparation* of **5**: to a suspension of **3** (0.35 g, 0.41 mmol) in *n*-hexane (20 mL) was added a solution of *tert*-butylphosphaalkyne (0.30 g, 3.0 mol) in *n*-hexane (20 mL) and the mixture was stirred for 24 h at room temperature. The mixture was then filtered, the filtrate concentrated to a volume of 20 mL, and cooled to −30 °C to furnish 0.255 g (59% yield) of orange crystals of **5**, mp 118–120 °C. $^{31}P\{^{1}H\}$ NMR: δ 271.5, −34.4 ($^{1}J_{PP}$ 16 Hz), 269.0, −8.1 ($^{1}J_{PP}$ 21 Hz). ChemComm

A microporous framework from a magnetic molecular square: $[Co(HAT)Cl_2]_4$ (HAT = 1,4,5,8,9,11-hexaazatriphenylene)

José R. Galán-Mascarós and Kim R. Dunbar*

Department of Chemistry, Texas A&M University, College Station, TX 77842-3012 USA. E-mail: dunbar@mail.chem.tamu.edu

Received (in Columbia, MO, USA) 9th October 2000, Accepted 12th December 2000
First published as an Advance Article on the web

The neutral, paramagnetic molecular square $[Co(HAT)Cl_2]$ 1,4,5,8,9,11-hexaazatriphenylene (HAT) form stacks with large open, water-filled channels that constitute approximately 37% of the void space in the crystal.

The nitrogen heterocyclic molecule, 1,4,5,8,9,11-hexaazatriphenylene (HAT) and its derivatives have been studied in the context of supramolecular chemistry,[1] photochemistry[2] and organometallic chemistry.[3] The HAT molecule exhibits a symmetrical arrangement of three bidentate binding sites that resemble three fused 1,10-phenanthroline units. The topology of the coordination sites renders HAT an especially interesting ligand for paramagnetic metals due to the fact that the triangular geometries promote spin-frustration if the magnetic interactions between paramagnetic metals are antiferromagnetic. Given that superexchange through similar molecules such as pyrazine, bipyrimidine and pyrazino[2,3-*f*][4,7]phenanthroline (pap)[4] bridges are typically antiferromagnetic, we expect that HAT bridges will also promote antiferromagnetic exchange between paramagnetic metal centers. In terms of HAT coordination chemistry, one can envision the elaboration of a three-dimensional framework, *e.g.* the fascinating chiral compound $[Ag(HAT)ClO_4{\bullet}2MeNO_2]_\infty$,[5] but if fewer than three binding sites are occupied by metal ions, it is conceivable that cyclic oligomers such as molecular squares[6] or one-dimensional polymers will ensue.

In spite of the interest in the HAT molecule, its chemistry has not been widely explored. Presumably, this is due to the fact that it is not commercially available and is insoluble in nearly all common solvents. Two main synthetic approaches to HAT have been reported, one of which employs triaminotrinitrobenzene, a compound that is used as a mild explosive in military applications.[7] We have elected to use an alternative six-step procedure beginning with commercially available precursors that leads to HAT in low overall yields.[8] Colorless, prismatic crystals of HAT were grown from hot water and subjected to a single-crystal X-ray study.† As Fig. 1 clearly shows, HAT forms one-dimensional zigzag chains that run along the *c* axis. Adjacent HAT molecules in the same chain are rotated 180° from each other and engage in π–π interactions at distances of *ca.* 3.25 Å (sum of the van der Waals radii is 3.54 Å).[9] The orientations of HAT molecules between chains are tilted by *ca.* 38° from a parallel arrangement. The packing of the chains is pseudo-tetragonal, with vacancies between the chains being occupied by water molecules that assume close contacts to the nitrogen atoms of the HAT molecules (*ca.* 2.8–3.0 Å).

The title compound was prepared from the addition of aqueous solutions of HAT and $CoCl_2$ in a 1:1 ratio. Slow evaporation of the water led to the formation of orange prismatic crystals of the product in 65% yield.† The solid-state structure of $[Co(HAT)Cl_2]_4{\bullet}27H_2O$ revealed that the compound is a molecular square with four distorted octahedral Co(II) ions coordinated to *cis* HAT molecules (Fig. 2). Each HAT bridge is bound to only two Co atoms and forms an angle of 105° with respect to the plane of the metal atoms. The remaining coordination sites of the Co ions are occupied by two terminal Cl^- ligands. The distortion from a regular octahedron is evident

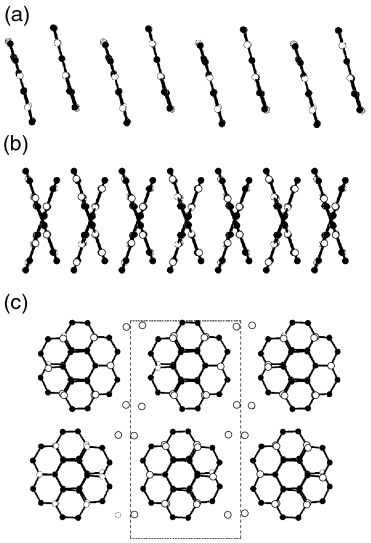

Fig. 1 Structure of $HAT{\bullet}2H_2O$: (a) side view of a dimerized chain, (b) side view of two adjacent chains and (c) projection in the *bc* plane.

from an examination of the Co–N distances [two each at 2.177(10) and 2.145(9) Å] and the Co–Cl distances [2.397(4) Å]. The angles about the Co atoms are *ca.* 90° with the exception of the chelating N–Co–N which is 77.8(3)°. The $CoCl_2(L–L)_2$ corners exhibit alternating chirality (Δ,Λ,Δ,Λ) which allows for the formation of a square rather than the open-chain analog. The individual squares pack in an eclipsed fashion along the *c* axis (Fig. 3) which results in the formation of large, open channels of 6 Å in diameter. The interactions between the stacks are dominated by π–π interactions between HAT ligands at 3.40 Å, a distance that is slightly longer than the interaction observed in $HAT{\bullet}2H_2O$, but shorter than the sum of the van der Waals radii.

It is worth mentioning at this point that the void space in this structure occupied by water molecules represents *ca.* 37%[10] of

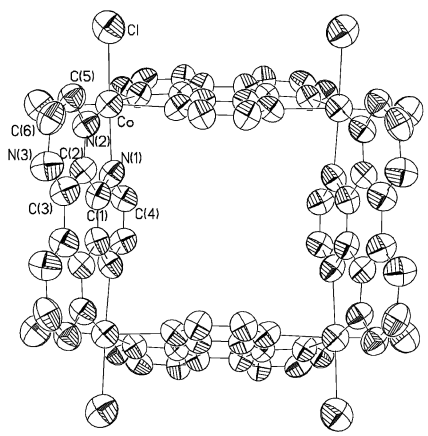

Fig. 2 Molecular structure of the $[Co(HAT)Cl_2]_4$ molecule.

DOI: 10.1039/b008209k

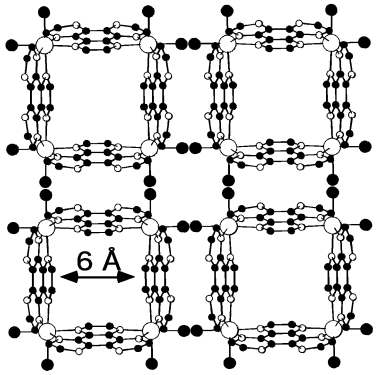

Fig. 3 Projection of the $[Co(HAT)Cl_2]_4 \cdot 27H_2O$ structure on the *ab* plane, showing the channels created by eclipsed stacking of the $[Co(HAT)Cl_2]_4$ squares (solvent molecules are omitted).

the total volume, which places this compound in the category of a microporous material. As many as 27 disordered water molecules were located in the channels created by the stacking of the squares and in the interstices between the stacks. The ability of this material to reversibly absorb and desorb water molecules and other molecules in the solid state is under investigation.

The magnetic properties of $[Co(HAT)Cl_2]_4 \cdot 27H_2O$ were investigated over the temperature range 2–300 K. The behavior of $\chi_m T$ is shown in Fig. 4. The room-temperature value of $\chi_m T$ is 10.41 emu K mol^{-1} which corresponds to four magnetically isolated Co ions ($S = 3/2$; $g = 2.34$). Below 150 K and down to 2 K, $\chi_m T$ steadily decreases which can be attributed to the well known zero-field splitting of high-spin Co(II) ions and also, possibly, to antiferromagnetic exchange between the Co centers. The anisotropy of these Co(II) systems precludes a quantitative analysis of these data, but it is possible to compare these data to the corresponding behavior of the model compound $Co(bpy)_2Cl_2$ with isolated Co ($S = 3/2$) centers. As indicated in Fig. 4, the decrease in χT observed for $Co(bpy)_2Cl_2$ below 150 K is essentially identical to that observed for $[Co(HAT)Cl_2]_4$, thus it must be concluded that the moment decrease is due exclusively to the zero-field splitting of the Co ions. Magnetic exchange through the HAT ligand in this particular case is negligible compared to the ZFS.

In conclusion, a novel magnetic molecular square composed of Co^{II} ions and HAT ligands has been prepared and characterized in the solid state. Several aspects of this molecular structure are particularly noteworthy. It is one of the few neutral molecular squares known to date, and it forms a microporous solid with channels of 6 Å diameter and 37% void space. Efforts to use the HAT ligand to produce new clusters as well as polymeric structures with paramagnetic metal centers are in progress.

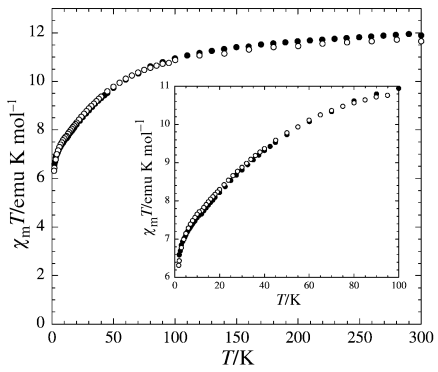

Fig. 4 The $\chi_m T$ *vs.* T plot ($H = 1000$ G) for $[Co(HAT)Cl_2]_4$ (●) compared to 4 × ($\chi_m T$) product for the model compound $Co(bpy)_2Cl_2$ (○).

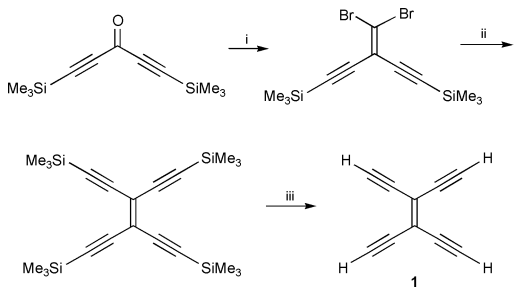
First published as an Advance Article on the web 16th January 2001

Derivatives of tetraethynylethene (TEE, 3,4-diethynylhex-3-ene-1,5-diyne) and (*E*)-1,2-diethynylethene ((*E*)-DEE, (*E*)-hex-3-ene-1,5-diyne) provide a unique class of π-conjugated building blocks for modular construction of one- and two-dimensional carbon-rich scaffolds such as monodisperse, linearly π-conjugated oligomers extending in length beyond 10 nm or large macrocyclic all-carbon cores. Lateral functionalisation of these novel chromophores with donor–acceptor substituents strongly enhances their advanced materials properties and leads to exceptional third-order optical nonlinearities. New photochromic molecules were prepared which undergo photochemical *cis* → *trans* and *trans* → *cis* isomerisation without competing thermal isomerisation pathways, thereby paving the way for applications as light-driven molecular switches in optoelectronic devices.

Introduction

Acetylenic scaffolding started in 1869 with the discovery of the oxidative alkyne coupling by Glaser.[1,2] Soon after, Baeyer recognized the potential of this reaction for forming infinite all-carbon chains, $[-C\equiv C-]_n$, known today as carbyne.[3] The advent of the Eglinton–Galbraith variant of the Glaser coupling reaction in 1956,[4] which uses cupric salts in donor solvents such as pyridine, paved the way for the pioneering work by Sondheimer and co-workers, who described the first synthesis of [18]annulene in 1959.[5,6] This milestone in physical organic chemistry, which provided experimental support for the Hückel rule defining aromaticity, was followed by the synthesis and investigation of a large number of macrocyclic π-electron perimeters, including many dehydroannulenes containing acetylenic bonds.[7–9] Methodological advances such as the Hay variant for oxidative homo-coupling[10] and the Cadiot–Chodkiewicz protocol for oxidative hetero-coupling[11] expanded the application of acetylenic scaffolding into the fields of polymer and natural product synthesis.[2] Today, progress in acetylene-based molecular construction is greatly fueled by the advent of powerful novel metal-catalyzed acetylenic homo- and cross-coupling protocols.[2,12,13]

In the mid 80s, the observation of fullerene formation by mass spectrometry[14] stimulated our research group to search for other, synthetic carbon allotropes.[15,16] We developed 'precursor' routes to the cyclocarbons (*cyclo*-C_n), *n*-membered monocyclic rings of sp-hybridised C atoms with unique electronic structures resulting from two perpendicular systems of conjugated π-orbitals, one in-plane and one out-of plane.[15–17] In collaborative efforts, we showed that these all-carbon molecules undergo ion-molecule coalescence reactions in the gas phase under clean formation of fullerenes.[18,19] At the same time, we identified two-dimensional all-carbon networks,[20] containing as repeat unit the cross-conjugated framework of tetraethynylethene (**1**, TEE, 3,4-diethynylhex-3-ene-1,5-diyne) (Scheme 1), as potential advanced materials and attractive synthetic targets.[15,16] While our hope of producing such networks with high crystallinity was not substantiated, it initiated the research featured in this article.



Scheme 1 Synthesis of tetraethynylethene (**1**).[38] i, CBr_4, PPh_3, 50%; ii, $Me_3Si–C\equiv C–H$, $[Pd(PPh_3)_4]$, CuI, $BuNH_2$, PhH, 88%; iii, K_2CO_3, wet MeOH, 87%.

Tremendous synthetic efforts are currently ongoing in the area of acetylenic scaffolding, targeting exceptional molecular architecture and functional advanced materials, and the reader is referred to review articles and monographs for a better appreciation of these developments.[21–32] Here, we describe how derivatives of tetraethynylethene (**1**) and (*E*)-1,2-diethynylethene (**2**, (*E*)-DEE, (*E*)-hex-3-ene-1,5-diyne) have been used to prepare a great diversity of functional carbon-rich compounds such as chromophores with high second- and third-order optical nonlinearities, molecular photochemical switches, large two-dimensional carbon cores, and linearly π-conjugated molecular rods extending in length beyond 10 nm.

† Dedicated to Professor Jean François Normant on the occasion of his 65th birthday.

François Diederich, born in 1952 in the Grand Duchy of Luxembourg, received his PhD degree in 1979 from the University of Heidelberg. Following postdoctoral studies at the University of California at Los Angeles (UCLA) from 1979–1981, he was a research associate at the Max-Planck-Institut für medizinische Forschung in Heidelberg. After his Habilitation in 1985, he joined the faculty of the Department of Chemistry and Biochemistry at UCLA where he became full professor in 1989. Since April 1992, he has been a professor of organic chemistry at ETH Zürich. His research interests encompass the development of covalent fullerene chemistry, the preparation of novel carbon allotropes and acetylenic carbon-rich advanced materials, the exploration of functional dendrimers as models for globular proteins and molecular recognition studies with synthetic and biological receptors.

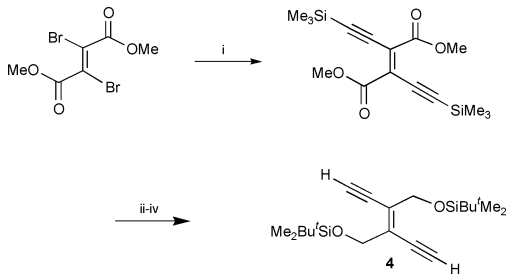
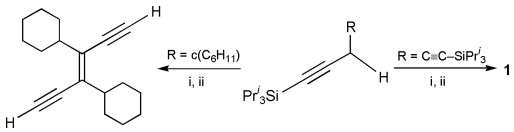
Synthesis and properties of tetraethynylethenes and (*E*)-1,2-diethynylethenes

Tetrakis(phenylethynyl)ethene (**3**) was the first TEE derivative synthesised by Hori *et al.* in 1969,[33,34] and the first peralkylated and persilylated derivatives were reported later in the 70s by Hauptmann.[35] Taking advantage of modern Pd(0)-catalyzed cross-coupling methods,[12] our research group introduced in the early 90s more general synthetic protocols, providing access not only to the parent compound **1**[36] but also to virtually any desired substitution pattern about the central ten-carbon TEE core. These methods have been comprehensively reviewed;[37] they are illustrated in Schemes 1 and 2 for the synthesis of TEE **1**[38] and (*E*)-DEE **4**.[39]



Scheme 2 Synthesis of (*E*)-1,2-diethynylethene **4**.[39] i, Me_3Si–C≡C–H, $[PdCl_2(PPh_3)_2]$, CuI, NEt_3, 20 °C, ≈50%; ii, DIBAL-H, CH_2Cl_2, 0 °C, 85%; iii, Me_2Bu^tSiCl, Et_3N, DMAP, 25 °C, 98%; iv, K_2CO_3, MeOH, 25 °C, 90%. DIBAL-H = diisobutylaluminum hydride, DMAP = 4-(*N*,*N*-dimethylamino)pyridine.

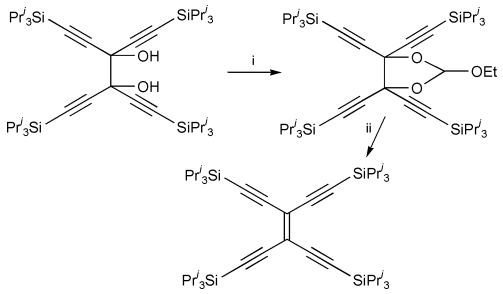
Recently, another general procedure for the synthesis of hex-3-ene-1,5-diynes was described by Jones and co-workers which does not rely on Pd(0)-catalyzed cross-coupling.[40] A large variety of (*E*)- or (*Z*)-DEE and TEE derivatives could be prepared using the carbenoid coupling–elimination strategy shown in Scheme 3.



Scheme 3 DEEs and TEEs by a carbenoid coupling–elimination strategy. i, LHMDS, HMPA, THF, −80 °C; ii, Bu_4NF, THF, 70% (DEE), 90% (**1**); yields over 2 steps.[40] LHDMS = lithium hexamethyldisilazane, HMPA = hexamethylphosphorous triamide.

Another synthesis of TEE derivatives results from the acid-catalyzed thermal elimination of an orthoester moiety from 1,1,2,2-tetraethynylethane (3,4-diethynylhexa-1,5-diyne) derivatives (Scheme 4).[41]

The stability of TEE and DEE derivatives largely depends on the number of free ethynyl residues in the molecule. If all

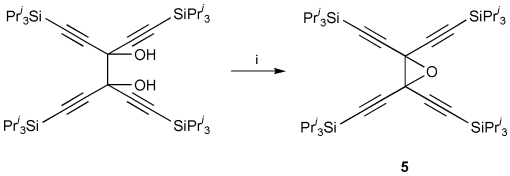


Scheme 4 TEEs by acid-catalysed orthoester thermolysis. i, $(EtO)_3CH$, cat. CSA, CH_2Cl_2, 94%; ii, CSA, 150 °C, 0.1 Torr, 5 min, 25–33%.[41] CSA = camphorsulfonic acid.

acetylene residues are silylated, alkylated or arylated, the compounds are kinetically very stable and display high melting points or decomposition points which in the case of arylated derivatives reach 200 °C and higher. With increasing number of free terminal alkyne groups, the stability rapidly decreases: derivatives with two ethynyl residues already are quite labile in the neat state and the parent TEE **1** rapidly decomposes at 25 °C. Remarkably, we never observed any Bergman cycloaromatisation of TEEs and DEEs;[42,43] at higher temperatures, other decomposition channels presumably become dominant.

Over 30 X-ray crystal structures of TEE and DEE derivatives have been solved.[44] They all revealed fully or nearly planar π-conjugated carbon cores, which in most cases, also include terminal aryl rings. In some solid-state structures, terminal aryl rings are not in plane with the central core, presumably due to crystal packing effects. In these cases, they adopt an orthogonal orientation, thereby maintaining conjugation with the second set of π-orbitals in the adjacent C≡C bond. The length of the central C=C double bond in TEE and DEE cores usually varies between 1.34 and 1.37 Å, whereas the C≡C triple bond lengths vary between 1.17 and 1.22 Å.[45]

One of the striking characteristics of TEE derivatives is the complete chemical inertness of the central olefinic bond. All attempts to add electrophiles, carbenes, 1,3-dienes or 1,3-dipoles to this electron-deficient[46] bond failed.[47] Thus, 1,3-dipolar cycloaddition with diazomethane occurred at one of the C≡C bonds rather than at the central C=C bond. Similarly, oxidations or epoxidations of this bond were unsuccessful and epoxide **5** could only be prepared in an indirect way as shown in Scheme 5.[48]

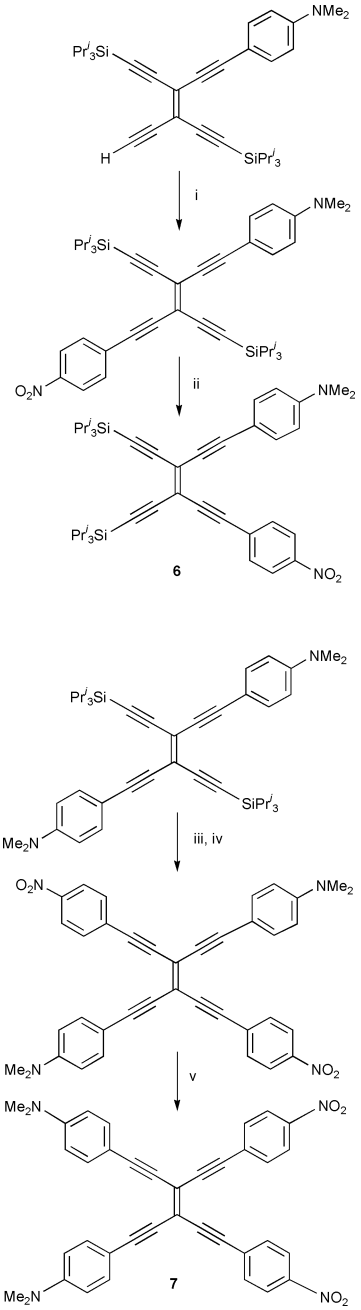


Scheme 5 Synthesis of epoxide **5**. i, $MeSO_2Cl$, NEt_3, CH_2Cl_2, −20 °C → 20 °C, 80%.[48]

Functional advanced materials based on arylated TEEs and DEEs

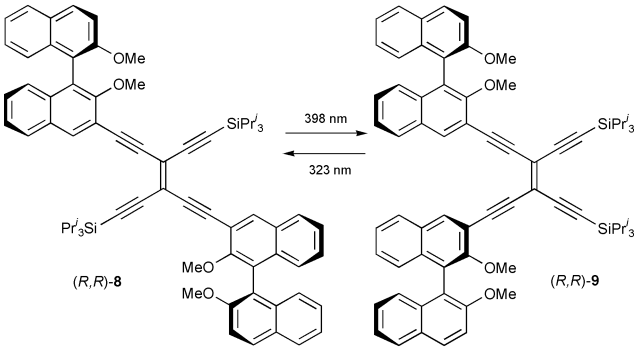
The physical properties of the TEE and DEE chromophores are further enhanced by arylation, generating a variety of desirable functional derivatives for advanced materials applications. Thus, the fully planar tetraphenyl derivative **3** and the π-acceptors 2,4,7-trinitrofluoren-9-one or (2,4,7-trinitrofluoren-9-ylidene)malononitrile form highly ordered donor–acceptor π-complexes of 1:2 donor–acceptor stoichiometry in the solid state.[49,50] The donor/acceptor orientation in the extended layer structures seen in the crystals is electrostatically controlled and shows a good correlation with the calculated atom-centered point charges on both components.

One of the most interesting properties of arylated TEEs and DEEs is their ability to undergo reversible, photochemical *trans* → *cis* and *cis* → *trans* isomerisation.[51] These isomerisations are not observed in the corresponding derivatives lacking aryl substituents. Since both *cis* and *trans* forms benefit from strain-free planarity—in contrast to azobenzenes[52] and stilbenes[53] which are nonplanar in the *cis* forms—the photochemical processes are not accompanied by undesirable thermal isomerisation, a quality reached only in a very small number of photochromic materials known today.[54] The photoisomerisation is of substantial preparative use and was applied to the synthesis of donor–acceptor substituted TEEs, such as **6** and **7**, for nonlinear optical studies (Scheme 6).[44c] A detailed investigation revealed a strong dependence of the quantum yields for photoisomerisation from the pattern and degree of aryl functionalisation, solvent polarity and excitation wavelength.[51] For a bis(4-nitrophenyl)-substituted DEE, the *trans–cis* isomerisation was also shown to occur electrochemically at the stage of the dianion.[45c]



Scheme 6 Synthesis of donor–acceptor substituted TEEs **6** and **7** by photochemical *trans–cis* isomerisation.[44c] i, *p*-O_2N-C_6H_4I, [$PdCl_2(PPh_3)_2$], CuI, NEt_3, 20 °C, 66%; ii, *hv* (366 nm), Et_2O, 37%; iii, Bu_4NF, wet THF; iv, *p*-O_2N-C_6H_4I, [$PdCl_2(PPh_3)_2$], CuI, NEt_3, 20 °C, 56% (2 steps); v, *hv* (366 nm), $CHCl_3$, 20%.

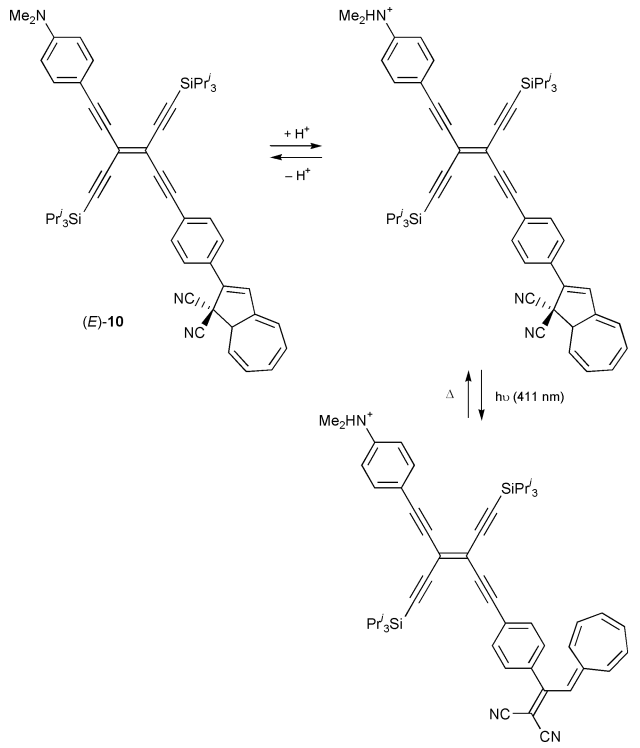
We have taken advantage of the photochemical *trans–cis* isomerisation process to construct light-driven molecular switches.[55] Compounds (*R*,*R*)-**8** and (*R*,*R*)-**9** are hybrid systems consisting of a TEE core with two attached (*R*)-configured 1,1′-binaphthalene moieties (Scheme 7).[56] They can be reversibly



Scheme 7 The couple (*R*,*R*)-**8**/(*R*,*R*)-**9** represents a novel, fully light-driven molecular switch.[56]

interconverted in CH_2Cl_2 solutions with light of λ = 398 or 323 nm. No thermal isomerisation was observed at room temperature, and the system displayed high resistance to photofatigue.

A further enhancement in complexity of molecular functions that can be expressed with TEE derivatives was achieved with the synthesis of the three-way chromophoric molecular switch (*E*)-**10** (Scheme 8).[57] This compound contains three addressable

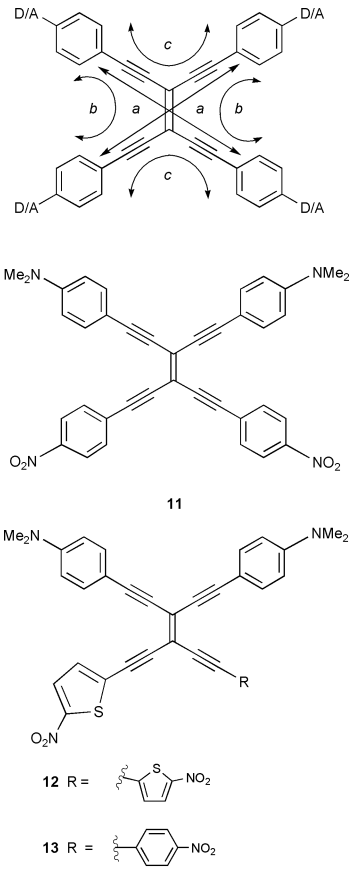


Scheme 8 Two of the three switching functions expressed by the three-way chromophoric molecular switch (*E*)-**10**.[57] The third one (not shown) is the *trans–cis* isomerisation of the TEE core.

subunits which undergo individual reversible switching cycles: (i) a central TEE core which can be reversibly photoisomerised between its *cis* and *trans* forms, (ii) a dihydroazulene unit that can be transformed upon irradiation into a vinylheptafulvene (vinyl-7-methylenecyclohepta-1,3,5-triene) moiety[58] and (iii) a proton-sensitive *N*,*N*-dimethylanilino group. Of the eight resulting possible interconverting states, a total of six could be detected. Individual interconversion processes such as three

'write–erase' processes and one process mimicking the function of an AND logic gate could be separatively addressed. The latter process relies on the interesting observation that the photochemical opening of the dihydroazulene to the vinylheptafulvene moiety occurs only after protonation of the dimethylamino group, as shown in Scheme 8. We are now investigating in interdisciplinary collaboration, whether TEE- and DEE-based molecular switches could find application in photoaddressable memory storage and readout devices or as waveguides.[59]

Donor–acceptor substituted TEEs display some of the highest known third-order optical nonlinearities[60] and in case of acentricity, also very large second-order nonlinear optical effects.[61] Comprehensive investigations by Günter, Bosshard and co-workers under non-resonant conditions helped to establish structure–property relationships which provide useful guidance for the future design of nonlinear optical materials.[60] In particular, these studies clearly demonstrated the important role of two-dimensional conjugation in enhancing third-order nonlinear optical effects.[62] The highest values of the second hyperpolarisability, γ, that describes molecular third-order nonlinear optical effects,[63] were measured for perarylated TEEs such as **7** (Scheme 6), **11**,[44c] **12**[44b] or **13**[44b] in which as many as six conjugation paths are effective (Scheme 9). In addition to

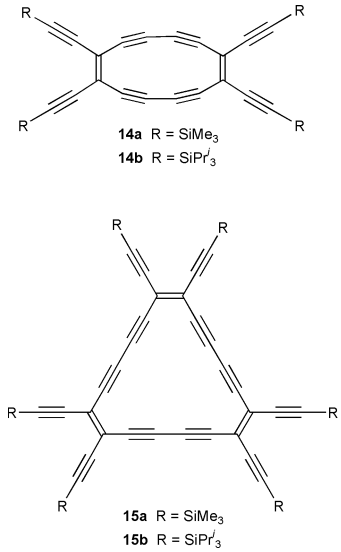


Scheme 9 Top: schematic representation of the possible conjugation pathways in perarylated TEEs. Paths *a* and *b* depict *trans*- and *cis*-linear conjugation, and path *c* depicts geminal cross conjugation. (D donor, A acceptor). Bottom: fully two-dimensionally conjugated chromophores with high second hyperpolarisabilities, γ.[60,64]

full two-dimensional conjugation, low molecular symmetry was also found to be of particular importance for enhancing third-order nonlinear optical effects. Thus, the lower-symmetrical nitrothienyl derivative **13** gave a higher value for γ than obtained for **7**, **11** or **12** possessing higher molecular symmetries. A theoretical model was derived to explain these experimental findings;[64] the reader is referred to the original literature for more details.

Two-dimensional scaffolding: expanded carbon cores

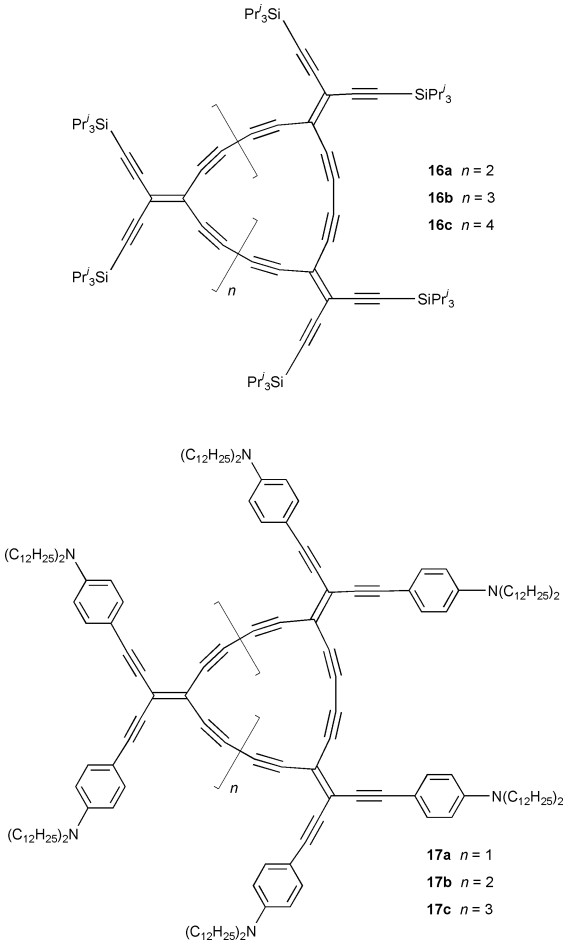
Two families of molecules featuring large all-carbon cores were constructed from suitably functionalised TEE derivatives, perethynylated dehydroannulenes and expanded radialenes. Oxidative Glaser–Hay macrocyclisation of *cis*-bis(trialkylsilyl)-protected TEEs yielded the per(silylethynylated) octadehydro[12]annulenes **14a**,**b** and dodecadehydro[18]annulenes **15a**,**b** with fully planar π-conjugated carbon cores as evidenced by X-ray crystallography (Scheme 10).[65,66] The yellow-colored



Scheme 10 Planar, perethynylated aromatic (**15a**,**b**) and antiaromatic (**14a**,**b**) dehydroannulenes.[65,66]

[18]annulenes **15a**,**b**, with a large HOMO–LUMO gap (2.57 eV in pentane) are aromatic, whereas the purple-colored [12]annulenes **14a**,**b**, with a smaller HOMO–LUMO gap (1.87 eV), are antiaromatic. Electrochemical studies[46,66] showed that [12]annulene **14b** undergoes stepwise one-electron reductions (E^o = −0.99 and −1.46 eV *vs.* Fc/Fc$^+$ (ferrocene/ferricinium couple) in THF) more readily than [18]annulene **15a** (E^o = −1.12 and −1.52 V). This redox behavior is best explained by the formation of an aromatic [4*n* + 2] π-electron dianion from antiaromatic **14b**, whereas **15a** loses its aromaticity upon reduction. Removal of the six silyl-protecting groups in **15a** yielded the perethynylated derivative with the molecular formula $C_{30}H_6$ which was stable in dilute solutions for a few days at −20 °C in the dark. All attempts, however, to prepare crystalline networks[15,16] by oxidative acetylenic coupling failed.

Formal insertion of ethynediyl[67] or buta-1,3-diynediyl moieties between each pair of vicinal *exo*-methylene units in the cyclic framework of radialenes leads to the carbon-rich expanded radialenes of which the perethynylated derivatives **16a**–**c** are the first representatives (Scheme 11).[66,68] They possess nanometer-sized carbon sheets with diameters, not including the SiPr$^i_3$ groups, of *ca.* 17 (**16a**), 19 (**16b**) and 22 (**16c**) Å. They are amazingly stable and readily soluble compounds with melting points above 220 °C and can be viewed as persilylated C_{40}, C_{50} and C_{60} isomers, respectively. Mass spectrometric analysis revealed that even larger carbon sheets extending to C_{120} cores are formed and, with the recent advances in gel permeation chromatographic (GPC) techniques, we are currently attempting their separation and characterisation. Electrochemical investigations showed that **16a**–**c** are powerful electron acceptors, capable of undergoing multiple reversible one-electron reductions, but are not readily oxidized. Both UV/Vis and electrochemical analyses suggested that cross-conjugation is not very effective in the macrocyclic perimeters and that the extent of π-electron delocalisation in all



Scheme 11 Expanded radialenes **16a**–**c** and **17a**–**c**.[66,68,69]

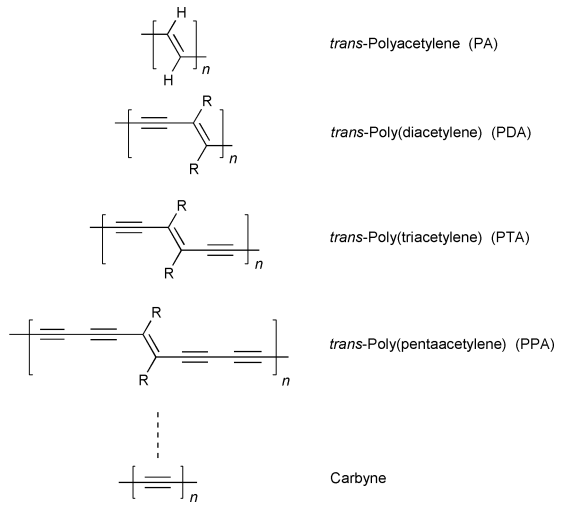
three compounds is limited to the longest linearly-conjugated π-electron fragment corresponding to a dodeca-3,9-diene-1,5,7,11-tetrayne-1,12-diyl moiety (–C≡C–CR=CR–C≡C–C≡C–CR=CR–C≡C–).

The materials properties of the expanded radialenes were greatly enhanced upon donor functionalisation, leading to the stable derivatives **17a**–**c** with fully planar π-chromophores.[69] These compounds exhibit large third-order nonlinear optical coefficients, can be reversibly reduced or oxidised, and form Langmuir monolayers at the air–water interface. Particularly intriguing is the UV/Vis spectrum of trimeric **17a**, which features a strong low-energy absorption band in the visible region with an exceptionally large molar extinction coefficient (ε = 171 000 dm^3 cm^{-1} mol^{-1} at λ_{max} = 646 nm). The studies with expanded radialenes executed so far suggest that π-electron delocalisation in these cross-conjugated macrocycles is not well understood, and high-level theoretical calculations of the structural and electronic properties of these large perimeters would be very desirable.

Novel linearly π-conjugated oligomers and polymers with all-carbon backbones

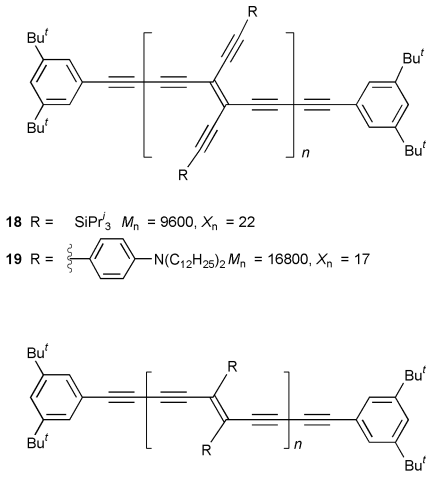
After the introduction of the Pd(0)-catalysed cross-coupling-based syntheses of TEEs and DEEs in 1991,[36] we rapidly became interested in applying these building blocks to the construction of novel oligomers[70] and polymers with linearly π-conjugated all-carbon backbones. In particular, we targeted the first synthesis of poly(triacetylene)s (PTAs),[71] thereby extending the progression of all-carbon polymer backbones which leads from polyacetylene[72] to poly(diacetylene)[73] and, ultimately, to carbyne[74] (Scheme 12).[39]

Starting from suitable TEE or DEE monomers, we prepared by oxidative acetylenic coupling under end-capping conditions



Scheme 12 Progression of linearly π-conjugated all-carbon backbones from *trans*-polyacetylene to carbyne.[39]

several larger-chain PTA polymers such as air-stable **18**–**20** (Scheme 13).[39,69] Deep red–brown **18** was soluble in hot $CHCl_3$

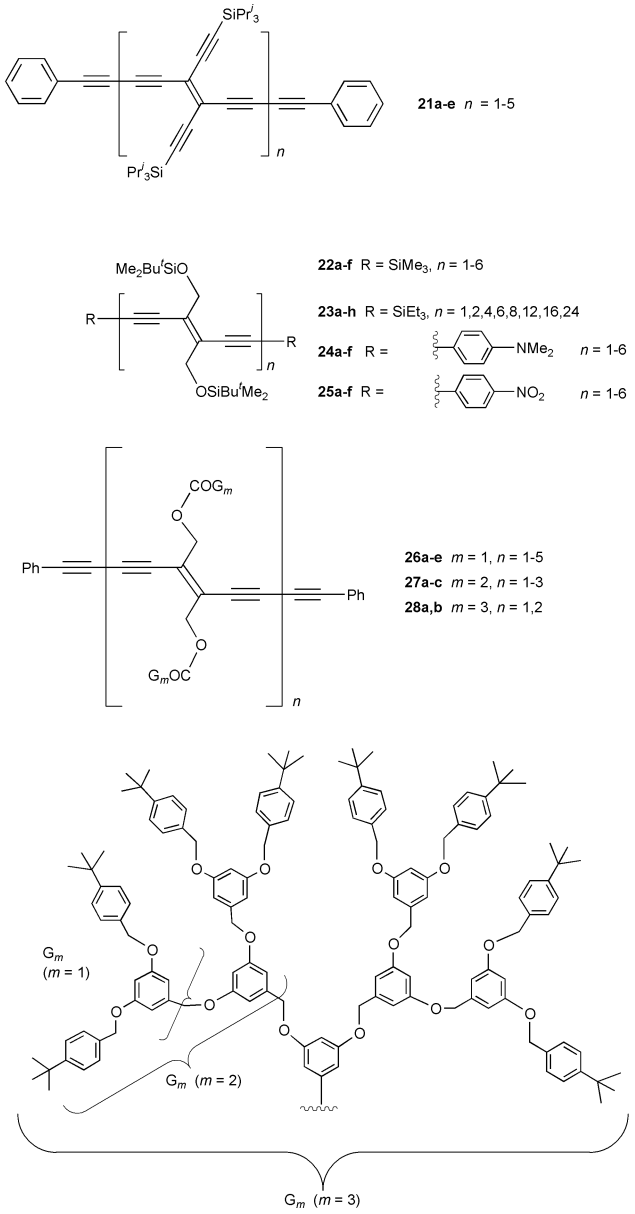


Scheme 13 Poly(triacetylene) polymers prepared by oxidative acetylenic coupling under end-capping conditions.[39,69] M_n = number-averaged molecular weight, X_n = degree of oligomerisation.

and in 1,2-dichlorobenzene above 65 °C and showed an optical gap of E_g = 2.0 eV which is in the range of the values measured for poly(diacetylene)s.[75] It can be reversibly reduced at the remarkably low potential of E = −0.65 V (*vs.* Fc/Fc$^+$).[39] In polymer **19**, with laterally appended donor groups, the optical gap is substantially reduced as compared to **18** and appears at E_g = 1.6 eV.[69] Lacking the laterally appended alkynyl groups, the optical gap in **20** is raised to E_g = 2.4 eV.

A particularly interesting accomplishment in the chemistry of poly(triacetylene)s is their first synthesis by topochemically controlled polymerisation of hexa-1,3,5-triynes in the crystal, which was recently described by Fowler and co-workers.[76] A highly original supramolecular control of spatial alignment and orientation of the hexa-1,3,5-triynes in the crystal lattice was required for this 1,6-polymerisation to occur.

In the largest body of our work on PTA rods, we focused on the preparation and study of monodisperse oligomeric series as models for the corresponding infinite polymers.[77] We first prepared by oxidative coupling under end-capping conditions the two oligomeric series **21a**–**e**[78,79] and **22a**–**f**,[80] extending in length up to 5 nm (Scheme 14). Compounds in series **21a**–**e** undergo facile one-electron reduction, with the number of reversible reduction steps being equal to the number of TEE moieties in each molecular rod. Thus, the first reduction of **21a**



Scheme 14 Poly(triacetylene) oligomers prepared by oxidative acetylenic coupling.[78–80,82,83,85,86]

occurs at $E = -1.57$ V (*vs.* Fc/Fc$^+$ in THF) whereas the first reduction of 49.2 Å long **21e** is much more facile, occurring at -1.07 V. The highly colored oligomers are amazingly stable to air and can be stored on the laboratory bench for months without decomposition. Correspondingly, no oxidation of these rods was observed in THF below 1.0 V (*vs.* Fc/Fc$^+$).

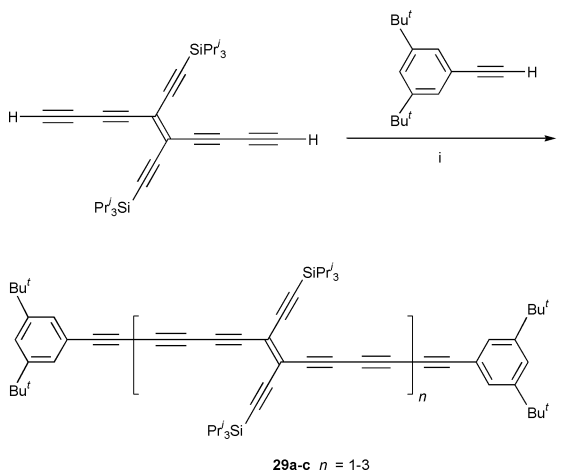
Of particular interest was the determination of the effective conjugation length (ECL)[81] in PTA oligomers and polymers. The effective conjugation length indicates the number of repeat units in a conjugated polymer that is required to furnish size-independent properties. From the chain-length dependence of the linear and third-order nonlinear optical properties of oligomers **22a**–**f** (Scheme 14), the effective conjugation length was extrapolated in the range of 7–10 monomer units, corresponding to 42–60 carbon–carbon bonds. It is noticeable that most linearly π-conjugated polymers show an ECL in this length range.[77a,81]

In more recent work, we prepared the series of stable monodisperse PTA oligomers **23a**–**h** (Scheme 14) which extend up to a 17.8 nm long 24-mer.[82,83] This is the longest known molecular rod featuring a fully conjugated non-aromatic carbon backbone. This series enabled for the first time the investigation of the evolution of the physicochemical properties of PTAs into the higher oligomeric regime where saturation of the properties becomes apparent. In good agreement with the extrapolative studies conducted with the previous oligomeric series **22a**–**f**, evaluation of linear (UV/Vis) and nonlinear (third-harmonic generation (THG) and degenerate four-wave mixing (DFWM)) optical properties, Raman scattering and electrochemical data supported an onset of saturation at about $n = 10$ monomeric units, corresponding to 60 carbon–carbon bonds. Based on the spectroscopic data, we had proposed a preference of the molecular rods for adopting a planar s-*trans* conformation (orientation of two adjacent double bonds with respect to the bridging buta-1,3-diynediyl linker) of the π-conjugated backbone.[82] Such a conformational preference was recently confirmed by an X-ray crystal structure analysis of 4-mer **23c**.[83] The nonlinear optical investigations showed a power law dependence ($\gamma \propto n^a$ with $a \approx 2.5$) of the second hyperpolarisability γ on the number of monomeric repeat units n until a smooth saturation is reached. The experimentally observed power law dependence as well as the measured upper boundary for electron delocalisation in a one-dimensional molecular wire (about 60 carbon–carbon bonds) were nicely reproduced in quantum-mechanical calculations using the Valence Effective Hamiltonian (VEH) method combined to a Sum-Over-States (SOS) formalism.[84]

These investigations were further extended to two families of monodisperse terminally donor–donor and acceptor–acceptor functionalised PTA oligomers **24a**–**f** and **25a**–**f** (Scheme 14).[85] A dramatic influence of the end-groups on the electronic properties of these materials was observed. As an example, saturation of the linear optical properties in the donor–donor series **24a**–**f** occurred already at the stage of 4-mer **24d**, whereas the properties of the acceptor–acceptor series **24a**–**f** resembled much more those of the Me_3Si-end-capped PTA oligomers **22a**–**f**.

In another approach,[86] the PTA oligomers were dendritically encapsulated[87] into shells of Fréchet-type[88] (**26**–**28**, Scheme 14) or carbosilane dendrons.[89] As an important result, UV/Vis studies demonstrated that the insulating dendritic layers do not alter the electronic characteristics of the PTA backbone, even at higher generation level. Electronic conjugation involving the acetylenic fragments in the PTA backbone is presumably best described as being cylindrical rather than resulting from orbital overlap within a distinct plane and is therefore maintained upon rotation about C(sp)–C(sp) and C(sp)–C(sp^2) single bonds. This conclusion, which requires further validation coming from other studies, is of substantial importance for the rich area of acetylenic scaffolding.[90]

Moving further along the progression from polyacetylene to carbyne (Scheme 12), we recently prepared the first series of monodisperse poly(pentaacetylene) (PPA) oligomers **29a**–**c** (Scheme 15).[86b] Compared to the corresponding PTA oligo-

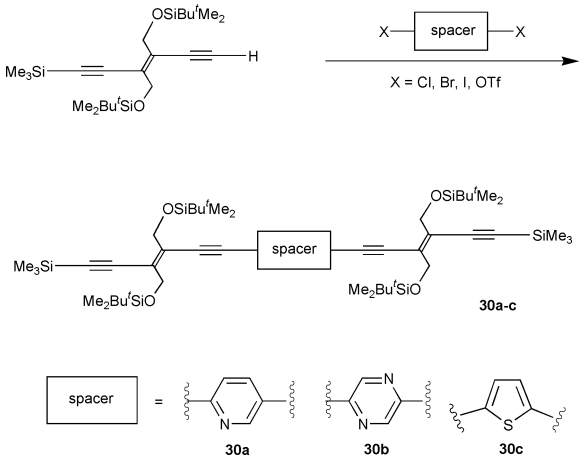


Scheme 15 Synthesis of the first poly(pentaacetylene) oligomers **29a**–**c**.[86b] i, CuCl, TMEDA, air, CH_2Cl_2, 20 °C, 10% (**29a**), 6% (**29b**), 3% (**29c**).

mers **21a**–**e**, we find the PPA derivatives much more delicate in terms of stability and processability. Therefore, it will be interesting to see how much further we will be able to move synthetically along the backbone progression leading to carbyne.

Hybrid systems

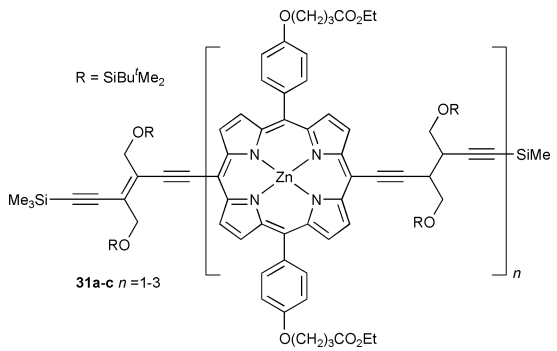
TEEs and DEEs are readily combined with other building modules for further enhancement of advanced materials properties. We prepared by Sonogashira cross-coupling a large series of mixed oligomers with a spacer inserted between two DEE moieties (Scheme 16) and found that the resulting hybrid



Scheme 16 Incorporation of spacer moieties into DEE oligomers.[91]

systems featured properties not displayed by the individual components.[91] Thus, the heterocyclic derivatives **30a**–**c** containing pyridine, pyrazine or thiophene spacers, respectively, showed a strong fluorescence emission (fluorescence quantum yields in $CHCl_3$ at 20 °C: Φ_F: 0.40 (**30a**), 0.65 (**30b**), 0.21 (**30c**)) which was present to a significant extent neither in DEE oligomers nor in the individual heteroaromatic spacer components. Pyridine derivative **30a** provided an interesting example of a molecular system, in which both the electronic absorption and emission characteristics can be reversibly switched as a function of pH. Upon protonation, the most intense electronic absorption band shifts from 337 to 380 nm and the fluorescence quantum yield decreases strongly from Φ_F = 0.40 to Φ_F = 0.07.

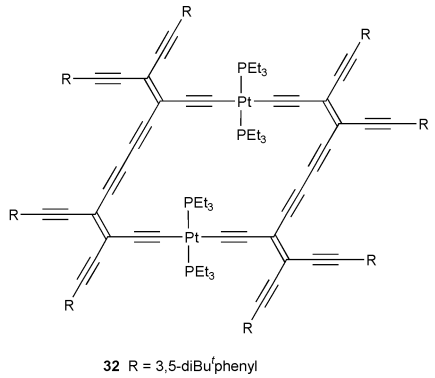
In another study, the porphyrin–DEE hybrid rods **31a**–**c**, extending in length from 2.3 (**31a**) to 3.8 (**31b**) and 5.3 nm (**31c**), were prepared by synthetic routes featuring Sonogashira cross-couplings between *meso*-iodinated porphyrin components and DEE moieties as key steps (Scheme 17).[92] Both UV/Vis and

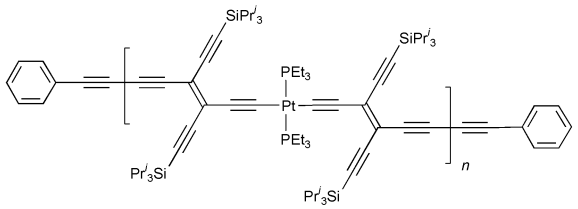


Scheme 17 Porphyrin–DEE hybrid molecular rods.[92]

electrochemical studies confirmed the existence of substantial electronic communication between the two porphyrins rings in **31b** across the *trans*-enediynediyl bridge. On the other hand, the spectra of **31b** and **31c** closely resemble each other, indicating that saturation of the optical properties in the oligomeric series already occurs at the stage of 'dimeric' **31b**. Stationary voltammetric investigations in CH_2Cl_2 showed that the terminal DEE substituents act as strong electron acceptors which induce large anodic shifts (up to ΔE = 190 mV) in the first, porphyrin-based reduction potential.

Finally, novel classes of organometallic macrocycles (such as **32**, Scheme 18)[93] and long molecular rods have become





Scheme 18 Novel organometallic macrocycles and molecular rods by Pt–TEE molecular scaffolding.[93,95]

available by Pt–TEE molecular scaffolding.[94,95] The series of stable oligomers **33a**–**f** was prepared by oxidative Glaser–Hay oligomerisation under end-capping conditions. They extend in length from 3.3 (monomeric **33a**) to 12.1 nm (hexameric **33f**). Both linear and nonlinear optical properties of these compounds revealed an almost complete lack of π-electron conjugation along the linear backbones due to the insulating character of the Pt centers and the absence of π-character in the Pt–C(sp) bonds. Purification, separation and characterisation of these remarkable organic–inorganic hybrid materials reached the performance limits of currently available analytical and preparative gel permeation chromatography.

Conclusions

Ten years after we started this research, tetraethynylethene (TEE) and (*E*)-diethynylethene ((*E*)-DEE) building blocks clearly represent one of the most versatile known molecular construction kits for the development of functional molecular architecture. Acetylenic scaffolding, starting from these modules, provided donor–acceptor substituted chromophores with exceptional optical nonlinearities, monodisperse poly(triacetylene) (PTA) oligomers with linearly π-conjugated all-carbon backbones expanding to unprecedented lengths, large carbon sheets with unusual chromophoric properties and a new class of light-driven molecular switches. This research has clearly contributed to expanding the limits in size and complexity of stable, monodisperse functional scaffolds that are accessible by organic synthesis. At the same time, it has advanced the fundamental knowledge of π-electron delocalisation in acetylenic molecular architecture. Only the tip of an immense 'iceberg' of structural diversity accessible through TEE and

DEE scaffolding has been explored today, and this chemistry will undoubtfully provide in the future many new classes of chromophores with multinanometer dimensions which could find use in optoelectronic devices and in the development of molecular-scale electronic circuitry.

I thank the many co-workers and collaborators for their enthusiastic contributions to this research; their names are included in the literature references. Funding for this work was provided by the Swiss National Science Foundation and the ETH research council (TEMA grant and joint grant with Professor P. Günter).

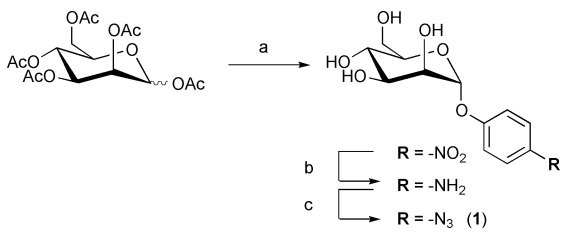
A new method to construct a fluorescent saccharide biosensor based on a lectin protein is successfully proposed using post-photoaffinity labeling modification coupled to aldehyde chemistry.

A biosensor is regarded as one of the ideal systems to monitor ions and molecules of biological importance both *in vivo* and *in vitro*,[1,2] since a protein framework can provide a superior molecular recognition scaffold. To carry out the rational coupling of a signal transduction device with the molecular recognition events on a protein scaffold, most examples rely upon site-directed mutagenesis,[3] GFP (green fluorescent protein) fusion strategy[4] and protein total-[5] or semi-[6]synthesis. In contrast to genetic technologies, however, chemistry-based versatile methods for the manipulation of biomacromolecules have not been satisfactorily developed. In fact, there are still limited numbers of procedures that are capable of the site-directed introduction of unique thiol[3] or ketone[7] groups into native proteins in order to tag unnatural signaling molecules.

We describe herein a new method named as '*post-photoaffinity labeling modification*' to construct a fluorescent saccharide-biosensor based on a naturally occurring saccharide-binding protein, concanavalin A (Con A). Con A, a kind of lectin family, can bind α-D-mannoside and α-D-glucoside derivatives selectively.[8] An active site-directed modification of the lectin was conducted by the photoaffinity-labeling technique using *p*-azidophenyl-α-D-mannopyranoside **1**. The subsequent oxidative degradation of the mannose part to produce aldehyde tags, followed by the chemical modification with a hydrazine derivative yields a fluorescent lectin.

The affinity ligand **1** which has both a α-mannoside unit, the strongest monosaccharide ligand for Con A, and a phenylazide group as a photoaffinity labeling group was synthesized as shown in Scheme 1. Peracetylmannose was glycosylated by *p*-nitrophenol in the presence of $BF_3{\cdot}Et_2O$,[9] followed by deacylation with NaOMe and conversion of the nitro-group to azide in the conventional manner to afford the target **1**.[10]



Scheme 1 Synthesis of photoaffinity labeling reagent **1.** *Reagents and conditions*: (a) (i) *p*-nitrophenol, $BF_3{\cdot}Et_2O$ (1 eq.), dry CH_2Cl_2, rt, 3 days; (ii) NaOMe, dry MeOH, rt, 2 h (55% for 2 steps). (b) 10% Pd/C, MeOH, rt, 30 min (95%). (c) (i) $NaNO_2$, 0.4 M HCl, 0 °C, 30 min; (ii) NaN_3, 0 °C, 20 min (61%).

The post-photoaffinity labeling modification for Con A is briefly outlined in Scheme 2. When the ligand **1** was bound to the binding pocket of Con A, photolabeling *via* nitrene generation was carried out by UV light irradiation (λ = 254 nm).[10] The labeled Con A was purified by gel chromatography (Biogel-P-30), followed by affinity chromatography (Sephadex G-100). Two fractions bearing the lessened affinity to the Sephadex column than native Con A were obtained.† The analysis by MALDI-TOF mass spectroscopy shows that the first fraction showing no affinity to Sephadex is a Con A homodimer, the monomer of which is modified with 1 mole of **1** (a mass peak appeared only at 25 850 ± 10 due to Con A plus **1**), and the second one showing moderate affinity is a heterodimer that comprises the modified Con A monomer (1 mole of **1** per 1 mole of Con A**)** and the unmodified monomer [two mass peaks appeared at 25 850 ± 10 and 25 583 (native Con A)]. The total yield of the modified Con A is about 30%. To determine the labeled site, the labeled Con A was digested by lysyl-endopeptidase (at 37 °C, pH 9.0 for 15 h in the presence of 3 M urea).[11] The HPLC (ODS column) and MALDI-TOF mass analyses of the digested peptides showed that only two fragments [the peptide 1 (A1-K30) and the peptide 6 (R60-K101)] among 10 fragments of the digested peptide were labeled with 1 mole of the ligand **1**. The crystal structure of Con A[12] shows that these two peptides are strongly involved in the sugar binding. Especially, Tyr12 in fragment 1 and Tyr100 in fragment 6 form a hydrophobic fence of the binding pocket. These reasonably suggest that the photoaffinity labeling reaction site-selectively proceeds under the present conditions. Subsequently, the mannose unit of **1** introduced by photoaffinity labeling can be converted by oxidation with periodate (IO_4^-) under mild conditions into unique aldehyde groups (CHO-Con A),[13] that can be chemoselectively labeled with hydrazine- or aminooxy-appended fluorophores [DCCH-Con A in the case of DCCH (a coumarin derivative)-hydrazine].[14]

Secondary structure of the modified Con As was monitored by CD spectroscopy. A negative Cotton peak at 218 nm, characteristic of the typical β-sheet, in all of the modified Con As (the labeled, CHO-, and DCCH-Con A), is comparable to that of native Con A,[15] suggesting that the secondary structure is not significantly disturbed by the present modification.

DCCH-Con A showed an absorption at 435 nm[16] (Fig. 1a) and a strong fluorescence at 485 nm (excitation at 435 nm), due to the coumarin unit, an environmentally sensitive fluorophore. Thus, we monitored emission spectral changes of DCCH-Con A by the addition of methyl-α-D-mannoside (Me-α-Man), the strongest mono-saccharide ligand for native Con A (inset of Fig. 1b). With increasing concentration of Me-α-Man, the emission intensity at 485 nm is gradually lessened and the change is saturated at less than 10 mM. The saturation curve (Fig. 1b) obtained by the fluorescent titration can be analyzed by a Benesi–Hildebrandt plot to give a binding constant of 1.9×10^3 M^{-1} for Me-α-Man. Similar saturation curves were observed in the fluorescent titration of other types of saccharides and the association constants are determined as summa-

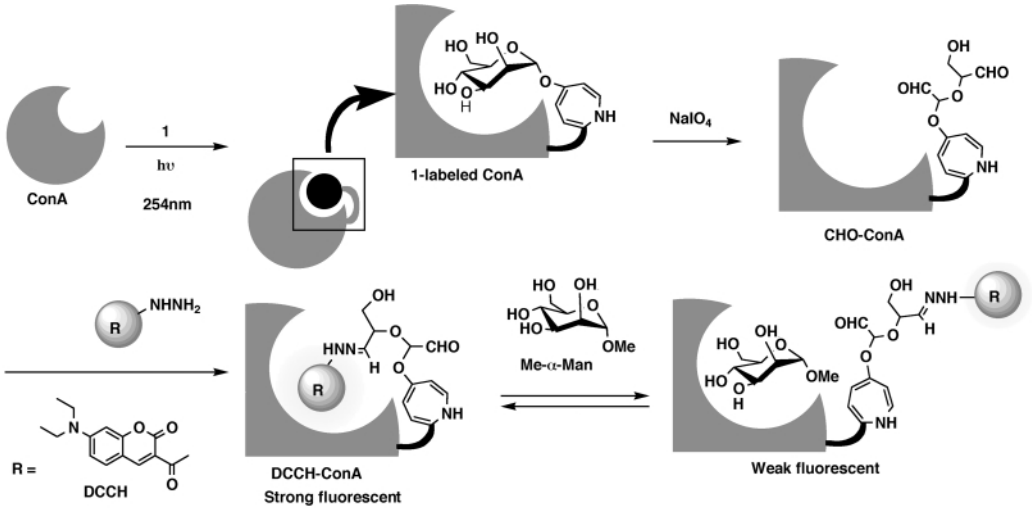

Scheme 2 Schematic illustration for semisynthesis of DCCH-ConA. The typical structures of the oxidative degradation of mannose are shown.

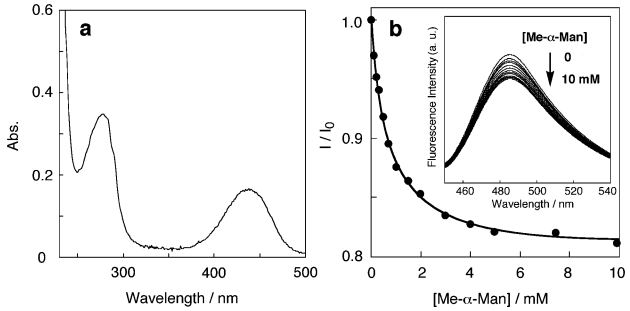

Fig. 1 (a) UV-vis spectrum of DCCH-ConA; (b) fluorescence titration curve of DCCH-ConA with Me-α-Man. [DCCH-ConA] = 3 μM, 50 mM HEPES buffer (pH 7.0), 1 mM $MnCl_2$, 1 mM $CaCl_2$, 0.1 M NaCl at 15 ±1 °C, λ_{ex} = 435 nm; inset: fluorescence spectral change of DCCH-ConA by the addition of Me-α-Man.

Table 1 The binding constants (*K*) of DCCH-ConA for saccharides

	K/M^{-1}	
Saccharide	DCCH-ConA	Native ConA
Me-α-mannoside	1900	11 000[a]
Me-α-glucoside	1450	3 000[a]
Me-β-glucoside	520	—[b]
Me-α-glactoside	570	—[b]

[a] Ref. 16. [b] The binding constants for Me-α-galactoside and Me-β-glucoside have not been reported because of their low affinity.

rized in Table 1. It is clear that the order of the affinity constants for various saccharides is the same as that of native Con A (Me-α-Man > Me-α-Glc > Me-α-Gal, Me-β-Glc), although the affinity constants are lower than the literature values of native Con A[17] determined by ITC (isothermal titration calorimetry) measurement. Significantly these results imply that the molecular recognition event occurring in the binding pocket of DCCH-Con A can be directly transduced by the fluorescence signal. This is the first step toward the rational design of fluorescent saccharide biosensors based on lectins. The reduced selectivity of DCCH-ConA might be due to the partial blocking of the sugar-binding pocket by the appended fluorophore and/or the structural disturbance of the binding site by the unnatural groups. Details are now under investigation in our laboratory.

We believe that this strategy is so general that other fluorescent biosensors may be produced showing different saccharide specificities by the simple replacement of the sugar part of **1** and the usage of the corresponding lectin.

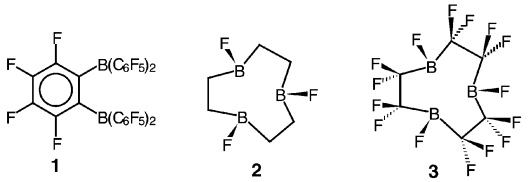
Density functional studies of model tribora-macrocyclic Lewis acids indicate extremely strong binding of the methyl anion, which in some cases exceeds that of $B(C_6F_5)_3$. In addition anion selectivity for the fluoride ion is implied by binding energies *ca.* 200 kJ mol^{-1} greater than those of other halides.

The formation of donor/acceptor complexes exploiting the well known Lewis acidic nature of organo-boranes and -alanes has been the subject of much recent research interest.[1] In part, this stems from the role of species such as MAO or $B(C_6F_5)_3$ as hydride or alkide abstractors in the generation of highly active cationic olefin polymerisation catalysts.[2] In such cases the activity and stability of catalysts are known to be strongly dependent on the extent of interactions between the cationic transition metal species and the anionic donor/acceptor complex.[3] Attempts have been made to manipulate the nature and strength of ion pairing interactions in solution, for example through the use of sterically more encumbered Lewis acids.[4] An alternative to the manipulation of the steric environment about the Lewis acidic centre is the incorporation of additional acceptor sites within a multidentate framework. By analogy with classical chelating agents such species offer the possibility for even stronger anion binding and the greater delocalisation of negative charge. Recently several groups have investigated this



approach using bifunctional Lewis acids such as **1**.[5] A logical extension of this strategy is the development of macrocyclic multidentate Lewis acids. Classical macrocyclic donor ligands are well noted for the formation of exceptionally stable metal complexes and for slow dissociation kinetics.[6] In addition, by the incorporation of acceptor sites into a medium-sized cyclic structure ring strain is released on anion binding *via* the pyramidalization of planar boron centres.

This work explores the nature of two such model compounds, 1,4,7-trifluoro-1,4,7-triboracyclononane **2** and perfluoro-1,4,7-triboracyclononane **3**, and their complexes with a number of anions (H^-, F^-, Cl^-, Br^-, CH_3^-). To facilitate quantitative interpretation of the results, the binding energy of tris(pentafluorophenyl)borane **4** with CH_3^- has also been computed at the same level of theory. Although there are some recent density functional studies of simple mono-functional boranes (BH_3 or BF_3) and their complexes with neutral Lewis bases,[7] studies of anion binding to boranes (either mono- or poly-functional) are limited to a recent high-level study of complexes of BH_3 with PH_2^-, OH^- and Cl^-,[8] and a semi-empirical investigation of anion complexes of macro-bi- and -tri-cyclic boranes.[9]

† Electronic supplementary information (ESI) available: geometry optimization details and results of calibration calculations. See http://www.rsc.org/suppdata/cc/b0/b007544m/

The geometries of **2**, **3** and their various donor–acceptor complexes were optimized at the Hartree-Fock level using 3-21G and 6-31+G* basis sets (Fig. 1 and 2) (see also ESI†). The minimum energy geometries for F^-, Cl^-, and Br^- complexes with both macrocyclic Lewis acids **2** and **3** feature symmetrical binding of the anion to all three boron centres (see Tables 1 and 2). For hydride anion, however, three different BH distances are observed in the minimum energy structure. The H^- anion bridges two boron centres in near symmetrical fashion {*r*(B–H) = 1.429, 1.414 Å for [**2**·H]$^-$; 1.351, 1.364 Å for [**3**·H]$^-$}, but interacts minimally with the third boron atom {*r*(B···H) = 2.668 Å for [**2**·H]$^-$; 2.813 Å for [**3**·H]$^-$}. Such a geometry is unsurprising given the small size of the hydride anion, the μ_2- bonding mode for bridging hydrogen atoms being far more common than the face-capping μ_3-mode in polyhedral boron hydrides, for example. BH distances can be compared to those determined by X-ray diffraction for hydride complexes of bidentate Lewis acids {*e.g.* with 'hydride sponge' [1,8-$(Me_2B)_2C_{10}H_6$·H]$^-$, *r*(B–H) = 1.20(5), 1.49(5) Å and [$(HBC_4H_8)_2$·H]$^-$, *r*(B—H) = 1.28(2), 1.31(2) Å}.[11] In general the closest BH contacts for [**2**·H]$^-$ and [**3**·H]$^-$ are somewhat longer (*ca.* 5–10%) than those determined experimentally. Conceivably this may reflect the anomalous shortening found for E–H bonds determined by X-ray diffraction, as the B···B distances to be spanned by the hydride 'ligand' in both the macrocyclic and bidentate complexes are very similar (2.473 and 2.535 Å for the macrocyclic complexes; 2.480 and 2.544 Å for the bidentate species).

The BCl distances in [**2**·Cl]$^-$ and [**3**·Cl]$^-$ (2.654 and 2.329 Å, respectively) are also somewhat longer than those found in the chloride complex of the bidentate Lewis acid 'chloride sponge', [1,8-$(Cl_2B)_2C_{10}H_6$·Cl]$^-$ [1.86(1)–2.10(1) Å].[12] In this case, however this reflects the significantly longer B···B distance to be spanned by the Cl^- ligand {3.373 and 3.311 Å for the macrocyclic complexes compared to 3.055 Å for [1,8-$(Cl_2B)_2C_{10}H_6$·Cl]$^-$}. Comparison with the structure of the known $B_2F_7^-$ ion shows a similar trend for the fluoride complexes of **2** and **3**.

Table 1 HF/6-31+G(d) calculated geometrical parameters for complexes of anions with macrocyclic Lewis acids **2** and **3**

	2			**3**		
Lewis base	r(B···X)/Å	d^a/Å	F–B–X/°	r(B···X)/Å	d^a/Å	F–B–X/°
H^-	1.429, 1.414, 2.668	—	—	1.351, 1.364, 2.813	0.413	—
F^-	1.832	0.721	101.9	1.805	0.516	103.8
Cl^-	2.654	1.803	99.7	2.329	1.330	103.4
Br^-	2.857	2.062	98.6	2.445	1.491	104.0
CH_3^-	1.659, 3.276, 3.221	—	—	1.651, 2.984, 3.016	—	—

[a] The perpendicular distance of the anion from the mean plane of the three boron acceptor atoms, as defined in Fig. 1.

Table 2 B3-LYP/6-311+G(d)//HF/6-31+G(d) calculated binding energies (E_b) and anion ↔ macrocycle charge transfers (ΔQ) for complexes of anions with macrocyclic Lewis acids **2** and **3**

	2		**3**	
Lewis base	$E_b{}^a$/kJ mol^{-1}	ΔQ	E_b/kJ mol^{-1}	ΔQ
H^-	359.0	0.90	692.3	0.85
F^-	307.9	0.49	595.7	0.60
Cl^-	107.3	0.52	385.4	0.72
Br^-	73.1	0.58	338.9	0.98
CH_3^-	298.3	0.03	555.3	0.09

[a] These include HF/3-21G harmonic thermal corrections (at 298 K) scaled by 0.893.[10]

The binding energies for F^- and Cl^- complexes of macrocycles **2** (307.9 and 107.3 kJ mol^{-1}, respectively) and **3** (595.7 and 385.4 kJ mol^{-1}, respectively) can be compared to values of 265.7 and 141.8 kJ mol^{-1} calculated by Boutalib and coworkers for the corresponding complexes with BH_3 at the G-2 level of theory.[8] For all the anions examined the binding energy is considerably enhanced by perfluorination of the triboramacrocycle. For the smaller anions H^- and F^- extremely high binding energies are observed for the perfluorinated macrocycle (692.3 and 595.7 kJ mol^{-1}). The weaker binding found for complexes of Cl^- and Br^- reflects a poorer size-match selectivity (anion/macrocycle) and the greater B···X distances (2.329 and 2.445 Å, respectively). Fluoride anion recognition is an area of much current interest,[13] and these data imply that [9]aneB_3 macrocyclic species have much potential in this regard.

The case of methyl anion binding is intriguing; although a strong overall attractive interaction is found for the symmetrically bound (C_3 symmetry) system, [**3**·CH_3]$^-$, reflected by a binding energy (492.9 kJ mol^{-1}) in excess of that calculated for the analogous complex of $B(C_6F_5)_3$ (*vide infra*), the global minimum for both [**2**·CH_3]$^-$ and [**3**·CH_3]$^-$ features less symmetrical anion binding. In each case, binding of the anion within the cavity is essentially monodentate, featuring a single short B···C distance {1.651 Å for [**3**·CH_3]$^-$} and two other B···C distances long enough to preclude any significant interaction {2.984 and 3.016 Å for [**3**·CH_3]$^-$}. For **3** the binding energy for the methyl anion in this asymmetric mode is found to be 555.3 kJ mol^{-1}; for each complex the less symmetrical C_1 binding geometry is found to be energetically more favourable than the C_3 mode of attachment by at least 60 kJ mol^{-1}.

Given the importance of methyl anion abstraction in the initiation of olefin polymerisation processes, we sought to compare the CH_3^- binding capabilities of **2** and **3** with that of the commonly used Lewis acid **4**. At the B3-LYP/6-311+G*//HF/6-31+G* level with a scaled HF/3-21G vibrational correction, we obtained a binding energy of 472.4 kJ mol^{-1} for [$B(C_6F_5)_3$·CH_3]$^-$, a value which is *ca.* 15% lower than the value found for [**3**·CH_3]$^-$. In terms of binding energies for the methyl anion, the value detailed herein for the perfluorinated macrocycle **3** is the highest absolute value yet to be reported in the literature.‡

In summary the calculations presented here reveal that the macrocycle **3** binds CH_3^- at least as strongly as the 'best' recently synthesised Lewis acids. Although binding of CH_3^- by a Lewis acid is only one step in the generation of the active species from metallocene dimethyl derivatives, other factors such ion pairing interactions are known to be important,[3] this result has clear implications in terms of the design of Lewis acids as activators in olefin polymerisation catalysis. With this in mind we are currently investigating anion binding by a range of multidentate and macrocyclic Lewis acids, including species featuring benzyl backbones which may prove to be more synthetically accessible. The results of these studies will be reported in due course.

Fluorodesilylation of alkenyltrimethylsilanes: a new route to fluoroalkenes and difluoromethyl-substituted amides, alcohols or ethers

Benjamin Greedy and Veronique Gouverneur*

University of Oxford, The Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY.

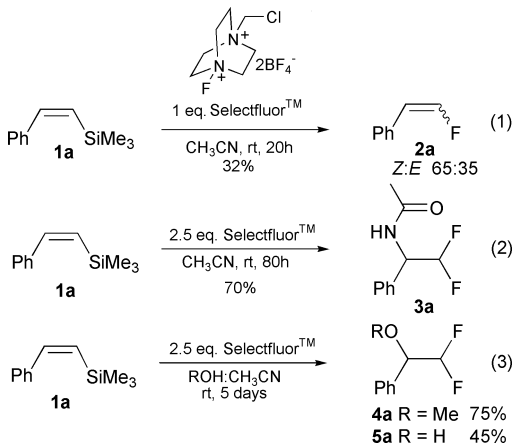
Received (in Liverpool, UK) 9th November 2000, Accepted 19th December 2000
First published as an Advance Article on the web 16th January 2001

A range of alkenyltrimethylsilanes are converted to alkenyl fluorides by reaction with one equivalent of Selectfluor™ (1-chloromethyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate)), or difluoromethyl-substituted alcohols, ethers or amides using an excess of Selectfluor™ in the presence of various nucleophiles.

In view of the unique features of fluorine-containing compounds, there has been an increasing interest in the development of novel methods for the synthesis of fluorinated molecules.[1] In particular, terminal fluoroalkenes have been used in the design of a number of mechanism-based enzyme inhibitors and other bioactive molecules.[2] Consequently, development of general methodologies for their preparation is an important challenge. Our studies were initiated in order to investigate the hypothesis that electrophilic N–F reagents[3] would react with alkenyltrimethylsilanes to give the corresponding alkenyl fluorides. Fluorodesilylations of aryltrimethylsilanes using xenon difluoride and elemental fluorine have been reported respectively by Lothian and Ramsden[4] and by Stuart *et al*.[5] Surprisingly, in contrast to chloro-, bromo- or iododesilylation,[6] fluorodesilylation has never been applied to alkenylsilanes. In addition, the reactivity of the N–F group of reagents has not been investigated for a fluorodesilylation processes. In this communication, we demonstrate a new and facile approach for the synthesis of alkenyl fluorides as well as difluoromethyl-substituted alcohols, amides and ethers.

The substrate trimethylstyrylsilane **1a** was prepared as a mixture of stereoisomers (*E*:*Z*/8:92).[7] The fluorodesilylation was attempted with several commercially available N–F reagents. The reaction of compound **1a** with 1 eq. of Selectfluor™ in acetonitrile at rt afforded the expected fluoroalkene **2a** with a conversion[8] of 47% after 20 h (Scheme 1, eqn 1 and Table 1, entry 1). Prolonged reaction times did not improve the yield of compound **2a** as the formation of a second product was observed instead. This product was identified as difluoroamide **3a** and is believed to result from further fluorination of **2a** followed by reaction with acetonitrile. When



Scheme 1

1-chloromethyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane bis-(trifluoromethanesulfonate) was allowed to react with an equimolar amount of compound **1a** in acetonitrile, fluorodesilylation occurred to afford the fluoroalkene **2a** with a conversion of 32%. In contrast, 1-fluoropyridinium pyridine heptafluorodiborate and *N*-fluorobenzenesulfonimide did not react with compound **1a**. These results prompted us to use Selectfluor™ for subsequent fluorodesilylation reactions. A series of alkenyltrimethylsilanes **1b–f** was thus prepared according to known literature procedures[7,9] in order to evaluate the scope and limitation of this reaction. The expected fluoroalkenes **2b**,**c** were obtained as *Z*:*E* mixtures in moderate to good yields (Table 1, entries 2 and 3). In terms of mechanism, the reaction of **1a** to form **2a** might involve an

Table 1 Fluorodesilylation of vinylsilane derivatives **1a–f**

addition–elimination pathway *via* a carbocationic intermediate. The formation of a mixture of geometrical isomers and the faster reaction with more nucleophilic vinylsilanes are consistent with this mechanism.

Treatment of alkenylsilanes **1a–d** with more than one equivalent of Selectfluor™ produced the corresponding vicinal difluoroamides **3a**, **3c** and **3d** in good yields by a Ritter-type fluoro-functionalisation with acetonitrile (Scheme 1, eqn. 2 and Table 1, entries 4, 6 and 7). The reaction could not be applied to **1b** since the corresponding primary product of the reaction, the fluoroalkene **2b**, failed to react any further (Table 1, entry 5). These results are consistent with the observation made earlier by Stavber *et al.*[10] who reported that monofluoroamides could be prepared from the corresponding alkene by a "fluoro-Ritter" reaction. More recently, Olah *et al.*[11] also reported the formation of difluoroamides by electrophilic fluorination of alkenyl boronic acids and trifluoroborates.

When the reaction was carried out in aqueous acetonitrile or in a mixture of methanol and acetonitrile, the product outcome was different (Scheme 1, eqn. 3). When the alkenyltrimethylsilanes **1a** and **1c** were treated with 2.5 eq. of Selectfluor™ in a 1:1 mixture of MeOH–CH_3CN, the corresponding difluoromethyl ether derivatives **4a** and **4c** were prepared in 75 and 79% yield respectively (Table 1, entries 8 and 10). Similarly, when compounds **1a** and **1c** were treated with 2.5 eq. of Selectfluor™ in a 1:1 mixture of H_2O:CH_3CN, the difluoromethyl alcohols **5a** and **5c** were obtained with chemical yields of 45 and 83% (Table 1, entries 9 and 11). The difluoroamides were always formed as side products but could be easily separated by silica gel chromatography. In addition, the methodology can also be applied to the preparation of the bis-fluorinated tetrahydrofuran **6e** and the tetrahydropyran **6f**† by treating the corresponding alkenyltrimethylsilanes **1e** and **1f** with 2.5 eq. of Selectfluor™ in acetonitrile (Table 1, entry 12).

In summary, substituted alkenylsilanes carrying electron-donating groups undergo smooth mono- or bis-electrophilic fluorination to afford fluoroalkenes or vicinal difluoroamides, alcohols or ethers. The present report opens new possibilities for the direct and effective preparation of alicyclic and cyclic difluorinated derivatives. Mechanistic investigations along with the evaluation of the scope and limitation of this novel methodology are in progress in our laboratory. The generous financial support of Rhodia Organique Fine is acknowledged. We also thank Dr J. M. Paris, Dr J. R. Desmurs, and Dr J. Russell for very helpful suggestions regarding this work.

Nitrene-transfer to olefins catalyzed by methyltrioxorhenium: a universal catalyst for the [1+2] cycloaddition of C-, N-, and O-atom fragments to olefins

Hee-Joo Jeon and SonBinh T. Nguyen*

Department of Chemistry, Northwestern University, 2145 Sheridan Road, Evanston, IL 60208, USA

Received (in Corvalis, OR) 28th September 2000, Accepted 5th December 2000
First published as an Advance Article on the web 16th January 2001

Methyltrioxorhenium (MTO) was found to catalyze the transfer of the nitrene unit of [*N*-(*p*-tolylsulfonyl)imino]-iodobenzene to a number of olefins providing aziridines in moderate to good yields, establishing MTO as a universal catalyst for the [1 + 2] cycloaddition of carbene, nitrene, and oxo units to olefins.

The metal-catalyzed [1 + 2] cycloaddition of small functional groups to olefins to yield 3-membered rings comprises a very important class of reactions in organic syntheses.[1,2] Most important among this class of reactions is the addition of isoelectronic second row (ISR) fragments, *e.g.* carbene, nitrene, and oxo species, to olefins to produce cyclopropanes, aziridines, and epoxides, respectively. From a valence-shell electron consideration, it is quite reasonable to propose that these ISR moieties may behave similarly toward olefins in the presence of the *same* metal catalyst. In particular, we were intrigued by the possibility that there may exist a "universal" catalyst which can transfer all three of these ISR species to olefins. The development of a common catalyst for multiple organic reactions is a powerful concept in synthesis. Its significance lies in the possibility that the ligand framework developed for one reaction may be applied to other reactions without further modification of the catalyst system. The advantages are most apparent in the case of enantioselective reactions catalyzed by soluble metal complexes, where the most labor-intensive research is the development of the required chiral ligands. Perhaps the most prominent example of this strategy is the work by Sharpless and coworkers on the osmium-catalyzed asymmetric olefin aminohydroxylation,[3–6] where a chiral alkaloid ligand used in the asymmetric olefin dihydroxylation reaction is applied to the synthesis of chiral β-aminoalcohols. In the area of [1 + 2] cycloadditions, the developers of Cu[2,7–9] and Rh[2,10] catalysts have utilized this strategy to some degree in that both aziridination and cyclopropanation can be carried out by the same metal catalyst.

We report herein the aziridination of olefins catalyzed by methyltrioxorhenium[11] (MTO). Combined with the known olefin epoxidation[12–14] and cyclopropanation[15] catalyzed by the same metal complex, our work establishes *the unique activity of MTO as a 'universal' catalyst for the [1 + 2] cycloaddition of carbene, nitrene, and oxo units to olefins*. To our knowledge, this is the first instance where a single catalyst can be used for three different [1 + 2] cycloaddition reactions.

In the olefin aziridination experiments, we utilized [*N*-(*p*-tolylsulfonyl)imino]iodobenzene (PhINTs) as the nitrene source. General experimental conditions involved the mixing of PhINTs (1 equiv.), olefin (5 equiv.), and MTO (10 mol% relative to PhINTs) in MeCN at the appropriate temperature (Table 1). Although the polymeric PhINTs was initially insoluble, the mixture became homogeneous as the reaction proceeded. The complete consumption of the nitrene source signaled the end of the reaction. In the absence of MTO no reaction occurred, as evidenced both by the lack of dissolution of PhINTs as well as by GC analysis of the reaction solution which shows trace $TsNH_2$ as the only nitrogen-containing product.

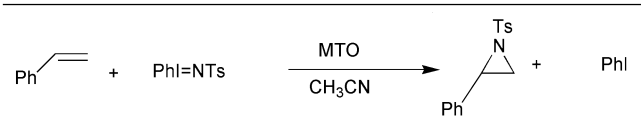
As depicted in Table 1, reaction conditions were varied to elucidate their effect on the catalyst activity with respect to the aziridination of styrene. In general, higher substrate concentrations gave better yields in shorter reaction times. A reaction of 40 equiv. of styrene relative to the nitrene source resulted in the highest yield of aziridine (45%, Table 1, entry 5). In refluxing MeCN (*ca.* 82 °C, Table 1, entries 6 and 7), the reaction was essentially instantaneous. There was no noticeable change in yield compared to those at room temperature.

Nitrile solvents (both MeCN and benzonitrile) were the most suitable for this system. In most other solvents, such as Et_2O, CH_2Cl_2 PhMe, THF, and pyridine, aziridine did not form, and all of the nitrene precursor was converted to $TsNH_2$. In the absence of nitrile solvents (neat conditions), the yield of aziridine was 27% based on PhINTs.

In all cases, $TsNH_2$ was the major side product of the aziridination reaction. To determine the hydrogen atom sources for $TsNH_2$ formation, a series of labeling experiments was conducted. A 10:1 mixture of styrene and PhINTs with MTO (10 mol% relative to PhINTs) in deuterated solvent (CD_3CN, rigorously dried and distilled) was allowed to react for 4 h, and the product mixture was analyzed by GC–MS. If the solvent was the major hydrogen source, $TsND_2$ or TsNDH would have been expected to form. However, the product from hydrogen abstraction was mostly $TsNH_2$ with a small amount of TsNDH. When styrene-d_8 in MeCN was used, the byproduct consisted mostly of $TsND_2$ (*m/z* 173) and TsNDH (*m/z* 172). Although both MeCN and styrene can supply hydrogen atoms for the $TsNH_2$ formation, the labeling experiments indicate that the substrate is the major hydrogen source leading to the formation of the $TsNH_2$ side product.

To investigate the scope of the MTO catalyzed aziridination reaction, several substituted olefins were examined using the conditions optimized for the aziridination of styrene (Table 2). In general, electron-withdrawing substituents at the *para* position of styrenes slowed down the overall reaction although yields remained essentially the same (Table 2, entries 1–4). For conjugated aromatic olefins, substitution patterns affected both

Table 1 Substrate concentration effect in the aziridination of styrene catalyzed by MTO

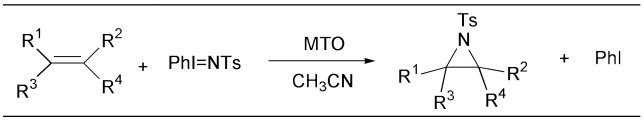


Entry	Substrate[a]	Temperature/°C	Reaction time[b]	Yield (%)[c]
1	5	rt	4–5 h	28
2	10	rt	2–3 h	33
3	20	rt	2–3 h	34
4	30	rt	1–2 h	39
5	40	rt	1–2 h	45
6	10	82	3 min	35
7	20	82	< 2 min	38

[a] Number of equiv. of substrate to PhINTs. [b] Time for complete dissolution of PhINTs. [c] HPLC yield (calibrated with an internal standard) based on the amount of PhINTs. All reactions were performed with PhINTs (0.2 mmol) and MTO (10 mol% relative to PhINTs) in CH_3CN (1 mL) at room temp.

DOI: 10.1039/b007906p

Table 2 Scope of the aziridination reaction catalyzed by methyltrioxorhenium (MTO)

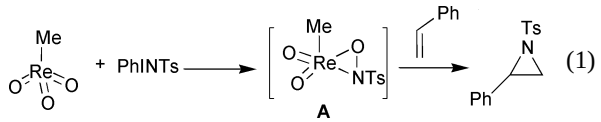


Entry	Substrates	Reaction time[a]/h	Aziridines	Yield (%)[b]
1		4–5		28
2		3		24
3		9–10		33
4		43		32
5		10		17
6		1		70[c]
7		4–5		43
8		4–5		12

[a] Time for complete dissolution of PhINTs. [b] HPLC yield based on the amount of PhINTs. All reactions were performed with PhINTs (0.2 mmol), MTO (10 mol% relative to PhINTs), and substrate (5 equiv. relative to PhINTs) in CH_3CN (1 mL) at room temp. [c] Isolated yield of a mixture of the desired aziridine and the rearranged *N*-Ts-2-phenylpropylidenimine product (*ca.* 4:3).

reaction time and yield. While (*E*)-β-methylstyrene only yielded 17% of the desired *trans*-product after 10 h (Table 2, entry 5), the *cis*-substituted 1,2-dihydronaphthalene showed faster conversion, producing 43% aziridine after 4–5 h (Table 2, entry 7). Aziridination of α-methylstyrene was fastest (1 h reaction time) among the substrates examined, and a mixture of aziridine and *N*-tosyl-2-phenylpropylidenimine was isolated (Table 2, entry 6). Finally, cyclohexene, a substrate known to be very sluggish in atom-transfer reactions, was transformed to the corresponding aziridine in low, but finite, yield (Table 2, entry 8).

Although identification of a complete mechanism accounting for the yields and products obtained from this family of reactions is beyond the scope of this initial communication, we believe that a 3-membered rhenoxaziridine intermediate **A**, formed from the coupling of [NTs] with MTO, is a reasonable common first intermediate (eqn. (1)).[15] This intermediate **A** could then react with olefins to form aziridines or undergo other transformations, such as hydrogen abstraction from the substrate to yield $TsNH_2$.



(1)

To summarize, we have demonstrated that MTO can act as a catalyst for the transfer of nitrene to olefins. This reactivity, taken together with the known MTO-catalyzed epoxidation[12–14] and cyclopropanation,[15] represents the first example of three different [1 + 2] cycloadditions of ISR fragments catalyzed by a single metal complex. Further studies, including the isolation and characterization of reaction intermediates, a complete elucidation of the reaction mechanism, the extension of the scope of this reaction to other rhenium(VII) oxo compounds and olefin substrates, as well as the asymmetric version of the MTO-catalyzed olefin aziridination are currently in progress and will be the topic of future reports.

Rhodium-catalyzed allylation of styrenes with allyl tosylate

Naofumi Tsukada,* Tetsuo Sato and Yoshio Inoue

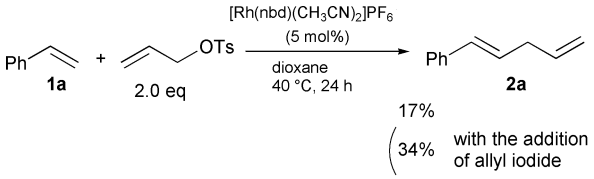
Department of Materials Chemistry, Graduate School of Engineering, Tohoku University, Sendai 980-8579, Japan. E-mail: tsukada@aporg.che.tohoku.ac.jp

Received (in Cambridge, UK) 28th September 2000, Accepted 20th December 2000
First published as an Advance Article on the web 18th January 2001

Rhodium-catalyzed allylation of styrene with allyl tosylate gave 1-phenylpenta-1,4-diene, and various styrene derivatives were also allylated yielding 1,4-dienes or 1,5-dienes.

The palladium-catalyzed arylation of alkenes, the Heck reaction, has proven to be a versatile method for the formation of carbon–carbon bonds.[1] In contrast, the analogous reaction of alkenes with allyl compounds is far more limited in its application, except for intramolecular metallo-ene reactions,[2] and remains a challenge in organic synthesis. Although a few examples of the transition metal-catalyzed allylation of alkenes have been reported,[3–5] to our knowledge, a reaction yielding simple allylation products, *i.e.* 1,4-dienes, is yet to be discovered. For example, strained alkenes such as norbornene† react with allyl compounds in the presence of various transition metal catalysts, however, these reactions do not afford 1,4-dienes because of stereochemical problems.[3] The palladium-catalyzed allylation of activated olefins with allylstannane and allyl chloride gives not mono-allylation products, but double allylation products selectively.[4] Mitsudo *et al.* reported ruthenium-catalyzed reactions of allyl carbonates with *N*,*N*-dimethylacrylamide, in which only 1,3-dienes were obtained in moderate yields.[5] Herein we wish to report the rhodium-catalyzed simple allylation of styrene derivatives with allyl tosylate.[6]

When styrene (**1a**) was treated with two equivalents of allyl tosylate in the presence of a catalytic amount of $[Rh(nbd)(CH_3CN)_2]PF_6$ (nbd = norbornadiene‡) in dioxane at 40 °C, 1-phenylpenta-1,4-diene **2a** was produced in 17% yield (eqn. (1)). Allyl tosylate and styrene were not recovered, and no



(1)

other product was identified. No allylation product was formed using typical allylating agents such as allyl acetate, allyl carbonate and allyl iodide. Palladium complexes such as $Pd(PPh_3)_4$, $Pd_2(dba)_3{\cdot}CHCl_3$, $[Pd(CH_3CN)_4](BF_4)_2$, or various Lewis acids were ineffective as catalysts for the allylation reaction. The yield of **2a** was improved up to 34% by the addition of allyl iodide (40 mol%). In contrast, the addition of other allylic compounds such as allyl bromide, allyl acetate, or allyl phosphate, decreased the yield slightly. Other organic and inorganic iodides like *n*-propyl iodide, *tert*-butyl iodide and potassium iodide also hindered the reaction to some extent. Furthermore, amounts of allyl iodide less than or exceeding 40 mol% were less effective on the yield of **2a**.

Although satisfactory yield was not obtained in the allylation of *non-substituted* styrene, the reactions of several substituted styrenes gave allylation products in higher yields as illustrated in Table 1. The allylation of 1,1-diphenylethylene **1b** afforded **2b** in 51% yield (run 1). The yield of **2b** increased to 74% with the addition of allyl iodide (run 2). The electron-rich alkene **1c** was so reactive that the product **2c** was obtained in 80% yield

Table 1 Rhodium-catalyzed allylation of styrene derivatives with allyl tosylate[a]

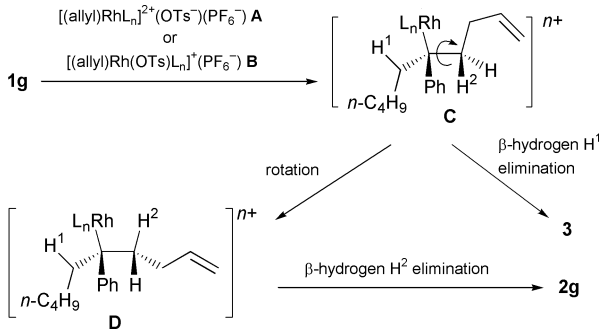
[a] Reaction conditions: **1** (0.5 mmol), allyl tosylate (1.0 mmol), $[Rh(nbd)(CH_3CN)_2]PF_6$ (0.025 mmol), dioxane, 40 °C, 24 h. [b] Isolated yields. [c] Allyl iodide (0.2 mmol) was added. [d] *E*/*Z* mixture (the stereochemistry cannot be determined).

DOI: 10.1039/b007880h



Scheme 1

(run 3). The reaction of 1-(*p*-methoxyphenyl)-1-phenylethylene **1d** also gave **2d** in high yield (run 4), whereas the *ortho*-substituted isomer **1e** was less reactive (run 5). By contrast, the reaction of the electron-poor alkene **1f** afforded **2f** in lower yield (26%, run 6). The α-alkyl-substituted styrenes **1g** and **1h** also reacted with allyl tosylate. In the reaction of **1g** the total yield of the allylated products was high (82%, run 7), although 1,5-diene **3** was yielded in addition to **2g**. The reaction of **1h** gave the monoallylated product **2h** and the diallylated **4**, generated by the allylation of a 1,5-diene product corresponding to **3** (run 8). When allyl iodide was added to the reaction of **1h**, diallylated products **4** and **5** were obtained in 63% yield (run 9). In contrast to the high reactivity of α-substituted styrenes, β-substituted styrenes were less reactive. The reactions of *Z*-stilbene, *E*-stilbene and β-methylstyrene did not give any allylated products. The electron-rich β-substituted styrene derivative **1i** barely reacted with allyl tosylate affording **2i** in only 16% yield (run 10). Indene **1j** was also allylated at the C-2 carbon (runs 11). The allylation reactions of the phenyl-substituted cyclic alkenes **1l**–**n** were also investigated. All the reactions gave only 1,5-dienes **2l**–**n** in satisfactory yields, in which no 1,4-diene was observed (runs 13–15).

Although little mechanistic information has been obtained for the Rh-catalyzed allylation of styrenes, we believe that the reaction proceeds *via* a mechanism similar to that of the palladium-catalyzed Heck arylation reaction. The likely intermediates for the allylation of **1g** are illustrated in Scheme 1. The oxidative addition of allyl tosylate with $[Rh(nbd)(CH_3CN)_2]PF_6$ gives the dicationic complex **A** or the complex **B**, in which tosylate anions weakly coordinate to rhodium, and with the insertion of **1g** to **A** or **B**, the rhodium organometallic intermediate **C** is afforded. In the reaction using allyl acetate or allyl iodide as the allylating agent, the coordination of acetate or iodide ions to rhodium is so strong that the insertion of an alkene does not take place. Subsequent β-hydrogen H^1 elimination in **C** affords 1,5-diene **3**. Since free rotation around the C(H^2)–C(Ph) bond in **C** is possible, alternate *syn*-β-hydrogen H^2 elimination in **D** also occurs, providing 1,4-diene **2g**. The 1,5-dienes were obtained selectively in reactions where free rotation around the C–C bond is not possible in the intermediate corresponding to **C** (runs 13–15). As the formation of **2j** and **2k** is not consistent with the mechanism shown in Scheme 1, the existence of another mechanism, *e.g.* a Friedel–Crafts type reaction, cannot be ruled out, although typical Lewis acids are ineffective in the present allylation reaction. Further investigation of the reaction mechanism and the application to other alkenes are in progress.

A novel NMR method for screening soluble compound libraries

Philip Hodge,* Pathavuth Monvisade, Gareth A. Morris* and Ian Preece

First published as an Advance Article on the web 16th January 2001

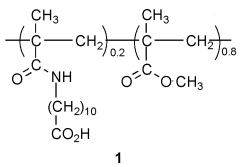
The use of high resolution diffusion-ordered NMR spectroscopy (HR-DOSY) to detect association between a soluble polymer and different components of small libraries of soluble compounds is illustrated for libraries binding respectively to weakly acidic and weakly basic polymers.

In recent years there has been great interest in combinatorial chemistry,[1–3] most commonly involving multi-step polymer-supported syntheses to give *polymer-supported libraries* containing from tens to millions of polymer-supported species. An alternative approach is to synthesise *soluble libraries*[2,4,5] which, to simplify the procedures, may be synthesised with the assistance of polymer-supported reactants or scavengers. Screening of libraries is commonly conducted for biological activity, but may also, for example, be for catalytic activity[6,7] or recognition ability.[8,9]

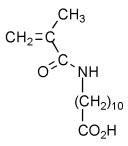
We report here an NMR method for screening soluble libraries of up to 20–30 components for recognition properties. One possible application would be in refining the design of host molecules for host–guest chemical sensors. The method is based on High Resolution Diffusion-Ordered SpectroscopY (HR-DOSY), a form of multi-dimensional spectroscopy in which signals are dispersed in an extra dimension according to the diffusion coefficient.[10–12]

Diffusion coefficients of organic compounds in common solvents are typically of the order of 10^{-9} m^2 s^{-1}; macromolecules diffuse much more slowly. The basis of the method proposed is to link the species to be recognised (*e.g.* a 'guest') to a suitable soluble polymer. When this polymer is added to a soluble library (of potential 'hosts'), the rates of diffusion of compounds in the library which, on the NMR timescale, bind rapidly and reversibly to the functionalised polymer, will decrease by an amount dependent on the binding constant. The method is related to the DECODES (DOSY-TOCSY) method proposed by Lin *et al*,[13–16] but it differs in the use of a polymer-bound ligand, maximising sensitivity to binding, and in the use of HR-DOSY, which can improve the diffusion resolution and allows the extraction of isolated subspectra for individual components.

As a trial of the method we investigated the interactions between the polymer-supported weak acid **1** and a simulated



1



2

library containing 11 commercially available natural products or related compounds (see Table 1). Polymer **1** was prepared by a free radical initiated copolymerisation of monomer **2**[17] and methyl methacrylate (mole ratio, 1:5), to give a copolymer soluble in CD_3OD with no ^{1}H-NMR signals above 4.3 ppm. The polymer had a number average molecular weight M_n of 16500 and a weight average molecular weight M_w of 61500 by gel permeation chromatography (GPC) relative to polystyrene standards. Because the diffusion coefficient of the polymer is small compared with those of the members of the soluble library, such a polydispersity does not affect the estimation of binding constants significantly. A solution in CD_3OD (2.9 mg ml^{-1}) showed a diffusion coefficient by HR-DOSY of 1.0×10^{-10} m^2 s^{-1}. The DOSY spectra of the simulated library alone, and in the presence of the polymer **1**, are shown in Figs. 1 and 2. It is only necessary for there to be one well-resolved characteristic signal for a given component for the diffusion coefficient to be clearly identified. The diffusion coefficients D_f and D_m of the components in the free mixture and with the polymer present are summarised in Table 1.

It is clear from the spectra of Figs. 1 and 2 that the rate of diffusion of hydroquinine **3**, (arrowed signals) is affected strongly by the presence of the polymer, whereas any effect on the other components is much smaller. The small increase in solution viscosity caused by the polymer may be corrected for by calculating estimated diffusion coefficients $D'_m = D_m D_f(\text{ref})/D_m(\text{ref})$, where D_f(ref) and D_m(ref) are the respective diffusion coefficients for a reference compound (in this case residual OH in the solvent) not significantly affected by binding to the polymer. In Table 1, values of D'_m were calculated using the measured MeOH OH diffusion coefficients for the two samples; D'_p, the corrected diffusion coefficient for the dilute free polymer, remained at 1.0×10^{-10} m^2 s^{-1}. Using a simple two-site model, the bound fraction F of a given component is given by $F = (D_f - D'_m)/(D_f - D'_p)$ from which the association constant K between the polymer and that component may be calculated by $K = F/(1 - F)(c_p - Fc)$, where c and c_p are the total concentrations of the component and of the functional polymer repeat unit.

The values of F in Table 1 show clear association between hydroquinine **3** and the polymer; the apparent association constant K is approximately 11 M^{-1}. The spectrum of the

Methanol (solvent)		18.9	17.8	(18.9)	(0.00)

[a] Experiments were carried out in CD_3OD at 20 °C nominal temperature on a Varian Unity 400 spectrometer using the BPPSTE pulse sequence,[12] with gradient levels from 1 to 20 G cm^{-1} and lasting approximately 30 min. Data were analysed as described previously,[11–12] but using explicit correction for field gradient non-uniformity.[19] [b] The concentration c_p of functional repeat units of the polymer was 77.5 mM. [c] Diffusion coefficients were corrected for the difference in viscosity between the solutions of the free library and the library with the polymer present (see text). [d] The signal at 5.1 ppm for which diffusion data are reported contains components from citronellol, citronellal, and higher molecular weight impurities.

DOI: 10.1039/b008412n

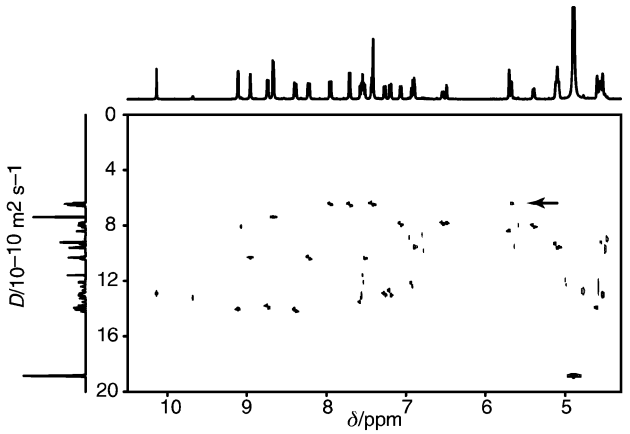

Fig. 1 HR-DOSY spectrum of the library of Table 1 in free CD_3OD solution, with (top) the normal ^1H spectrum and (side) the integral projection onto the diffusion axis.

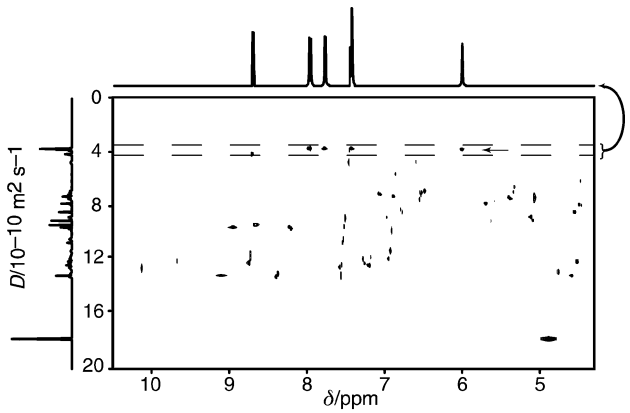

Fig. 2 HR-DOSY spectrum of the library of Table 1 and polymer **1** in CD_3OD, with (top) the integral projection onto the chemical shift axis of the region between the dotted lines, showing the subspectrum of the bound species, and (side) the integral projection onto the diffusion axis.

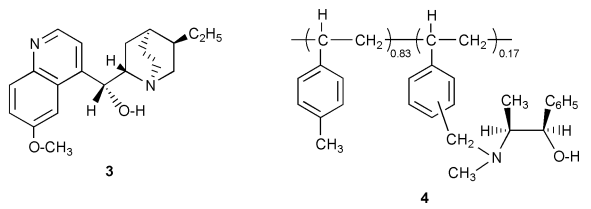

shifted hydroquinine **3** is shown on the top scale in Fig. 2. The changes in chemical shift for **3** between free solution and the polymer mixture show that the quinuclidine moiety in **3** protonates, causing association between the cation and the polyanionic polymer. No detectable change in either diffusion or shift is seen for methyl nicotinate and *N*-methylnicotinamide, both weaker bases than **3**.

In a second trial, the previously-described polymer **4**,[18] with M_n = 4900 and M_w = 9200 by GPC, was used to detect interactions with the β-amino-alcohol unit of (1*R*,2*S*)-*N*-benzylephedrine moieties. Polymer **4** showed a diffusion coefficient of 1.3×10^{-10} m^2 s^{-1} in $CDCl_3$ solution (2.6 mg ml^{-1}). Its interactions with a simulated library of 7 compounds were investigated, with the results summarised in Table 2. Here the only component to show significant binding is α-methoxyphenylacetic acid, which comes close to saturating the polymer binding sites and has an apparent association constant of several thousand M^{-1}. The specific nature of the binding is evidenced by the splitting of the α-proton and methyl signals of the racemic acid on binding to the chiral polymer.

Table 2 Summary of DOSY measurements for library B[a]

Compound	*c*/mM	$D_f/10^{-10}$ m^2 s^{-1}	$D_m/10^{-10}$ m^2 s^{-1}[b]	*F*

Mild and efficient methodology for installation of *gem*-diallyl functionality on carbohydrate synthons

Mukund K. Gurjar,* S. V. Ravindranadh and Sukhen Karmakar

National Chemical Laboratory, Pune 411008, India. E-mail: gurjar@dalton.ncl.res.in

Received (in Cambridge, UK) 10th October 2000, Accepted 27th November 2000
First published as an Advance Article on the web 17th January 2001

A versatile approach to construct *gem*-diallyl functionality has been described.

As a part of our ongoing efforts directed toward synthesis of natural products containing a spiro-ring system,[1] we were confronted with a need to synthesize a *geminal* (*gem*) diallyl containing carbohydrate backbone (Fig. 1). The *gem*-diallyl groups can undergo ring closing metathesis to produce the spiro-ring system.[2] Such *gem*-diallyl systems are not reported in carbohydrate chemistry, although they can form valuable synthons for many chemical transformations leading to functionalised products.

Incorporation of *gem*-diallyl groups is usually achieved by base catalyzed dialkylation of active methylene groups with allyl halides.[3] However, we realized that this approach may not be appropriate for carbohydrate molecules because of side reactions resulting from various hydroxy groups. We were particularly interested in the application of Keck's one electron C–C bond-forming reaction[4] to generate a *gem*-diallyl system in a carbohydrate unit by quenching the allylic radical generated *in situ*, with allyltri-*n*-butylstannane.

In accordance with our plan, 5-*O*-*tert*-butyldiphenylsilyl-1,2-*O*-isopropylidene-α-D-xylofuranose (**1**) was oxidized with IBX–DMSO (IBX = *o*-iodoxybenzoic acid) and then the resulting 3-ulose derivative was treated with PPh_3=$CHCO_2Et$ in refluxing benzene to give the α,β-unsaturated product (**2**).[5]

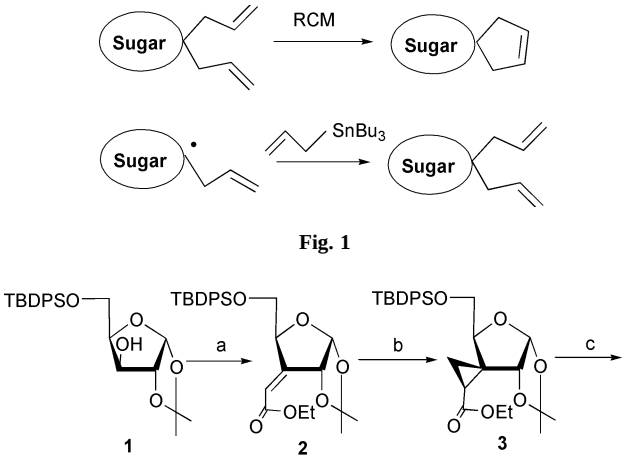

Fig. 1

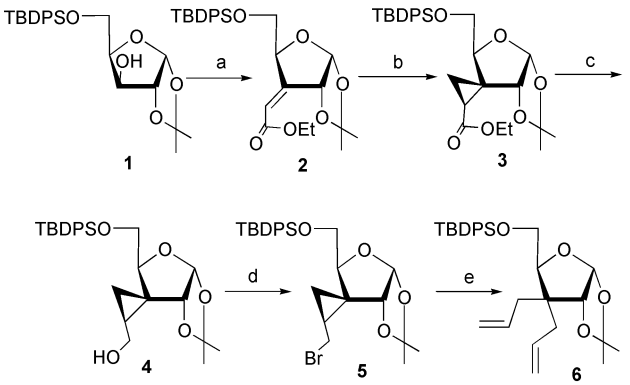


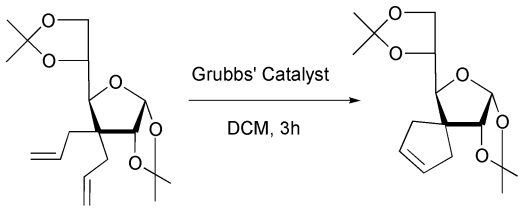
Scheme 1 *Reagents and conditions*: (a) (i) IBX (1.5 eq.), DMSO, rt, 10 h; (ii) PPh_3=CHCOOEt, (1.5 eq.), benzene, 80 °C, 3 h, 70% after two steps; (b) Me_2SOCH_3I (1.1 eq.), NaH (1.1 eq.), DMSO, rt, 3 h, 60%; (c) DIBAL-H (2.5 eq.), −78 °C, 0.5 h, 85%; (d) PPh_3 (2.0 eq.), CBr_4 (2.2 eq.), pyridine (2.5 eq.), 0 °C, 90%; (e) allyltri-*n*-butylstannane (2 eq.), AIBN (5 mol %), benzene, 80 °C,12 h, 80%.

Cyclopropanation of **2** was effected with Me_2SOCH_3I–NaH in dry DMSO to give **3**, as a single diastereomer.[6] Although the stereochemical identification of **3** was of no consequence to the present study, we believe the approach of the ylide occurs from the β-face due to the stereo-controlling effect of the adjacent 1,2-*O*-isopropylidene group. In the ^1H NMR spectrum of **3**, the protons of the cyclopropyl group, as expected, appeared in the high field region. Conversion of the ester function in **3** into the hydroxymethyl group was accomplished by using DIBAL-H at −78 °C to produce **4** in 85% yield. Compound **4** on treatment with CBr_4–PPh_3 in CH_2Cl_2 at rt gave the bromo derivative (**5**) in 90% yield. The ^1H, ^{13}C NMR and MS studies substantiated the assigned structure **4**. Treatment of **5** with allyltri-*n*-butylstannane in the presence of a catalytic amount of AIBN in refluxing benzene under argon atmosphere for 12 h gave the *gem*-diallyl compound **6** in 80% yield.† In the ^1H NMR

Table 1 Compounds **5a**–**e** were prepared essentially by the route shown in Scheme 1 and their structures elucidated by spectral data. Yields are given for isolated products.

Entry	Substrate	Product	Yield (%)
1	 **5a**	 **6a**	72
2	 **5b**	 **6b**	63
3	 **5c**	 **6c**	76
4	 **5d**	 **6d**	75
5	 **5e**	 **6e**	70

DOI: 10.1039/b008184l



Scheme 2

spectrum of **6**, the characteristic olefinic proton signals of two allylic groups appeared in in the region of 5.0 and 5.7 ppm while the allylic methylene protons were located in the region of 2.2 ppm. In addition, the assigned structure of **6** was further suggested by the ^{13}C NMR, MS and elemental analysis. Table 1 provides other examples in this series which substantiates the versatility of this methodology. Only entry 5 describes an aliphatic example.

The ring closing metathesis reaction of **6c** with Grubbs catalyst in CH_2Cl_2 at rt gave the spiro-ring compound **7** in 80% yield.[7] The structure of **7** was established based on ^{1}H, ^{13}C NMR and MS (Scheme 2).[8]

In summary this communication describes a mild and efficient methodology to construct *gem*-diallylic substituted carbohydrate synthons as precursors for spiro-cyclic systems. The preparation of unsymmetrical *gem*-diallyl substituents at the quaternary carbon will be the next endeavour of this methodology.

Authors (S. V. R. and S. K.) are grateful to CSIR, New Delhi for the award of research fellowships.

Notes and references

† Typical experimental procedure: A solution of the cyclopropylmethyl bromide derivative **5a**–**e** (0.4 mmol), allyltri-*n*-butylstannane (0.8 mmol) and AIBN (5 mol %) in dry benzene (3 mL) was degassed by bubbling argon for 30 min. The reaction mixture was heated under reflux for 12 h and concentrated *in vacuo*. A KF solution (5 mL) and diethyl ether (10 mL) were added, stirred for 1 h, filtered and washed with ether. The ether layer was separated, dried over anhydrous Na_2SO_4 and concentrated. The crude product was purified on silica gel using ethyl acetate–hexane to afford the desired diallyl product.

Modified guanidines could effectively mediate asymmetric silylation of secondary alcohols as recyclable bases under simple and mild conditions.

Due to their strongly basic character,[1] guanidines can be characterized as superbases[2] and, although chiral guanidines are expected to have potential as asymmetric reagents, their limited use[3] in asymmetric synthesis as chiral auxiliaries is due mainly to the lack of simple preparation methods. We have explored the possibility of modified guanidines as recyclable chiral superbases in organic synthesis under simple and mild conditions and recently reported their application to an asymmetric alkylative esterification of benzoic acid.[4] Kinetic resolution of racemic secondary alcohols is used for the selective preparation of one enantiomer. Enzymes such as esterases have been widely utilized for this purpose,[5] whereas non-enzymatic methods have been succeeded only in acylation.[6] In this communication we present the first example of asymmetric silylation of secondary alcohols mediated by chiral guanidines.

Reactions of indan-1-ol (**1**) with TBDMS (TBDMSCl) or TIPS chlorides (TIPSCl) were chosen as representatives for kinetic silylation of secondary alcohols because of the unsuccessful separation of each enantiomer of the silylated products by chiral HPLC when other acyclic alcohols or silylating agents were used in preliminary experiments.[7] Three different types of monocyclic guanidines [unsubstituted type **I**;[8a] 4-substituted type **II**;[8b,9] (4*S*,5*S*)-4,5-diphenylsubstituted type **III**[8c,9] and bicyclic guanidines **IV**[8b,9] (Fig. 1) were examined for their ability as catalysts in the silylation reaction. Thus, racemic **1** (2 equiv.) was first treated with TBDMSCl (1 equiv.) in DCM at rt in the presence of a chiral guanidine (1 equiv.) for several days to give, as expected, a silylated product **2** with recovery of the starting compound **1** (Table 1).

Fig. 1

Simple guanidines **I** were not effective for asymmetric induction (runs 1 and 2). However, moderate ee was observed in the cases of 4-substituted guanidines **II** (runs 3–6), in which the stereogenic center of the silylated product **2** was found to be controlled by the stereochemistry of the imidazolidine ring (C4). Thus, **IIb** with an (*S*)-configuration produced an (*R*)-excess product (run 4), whereas a diastereomeric **IIc** gave an (*S*)-excess product (run 5). Reasonable ee's was obtained when 4,5-diphenylguanidines **III** were used. It was found that the chiral center of the substituent on the external nitrogen atom played an important role in effective asymmetric induction. Thus, (*R*)-phenylethyl-substituted guanidines **IIId** and **IIIe** gave an (*R*)-excess **2** with 37% ee (run 10) and 39% ee (run 11), respectively, whereas a lower ee (6%) was observed in the case of **IIIc** with an (*S*)-phenylethyl-substituent (run 9). The formation of an (*R*)-excess product in each case indicated that the stereochemistry of **2** was controlled by the ring chiral centres of guanidines.

Table 2 Asymmetric silylation of **1** or **4** with TlPSCl in the presence of either guanidine **IIId** or **IVd**

				3 or **5**[a]	
Run	**1** or **4**	Guanidine	Temp.	Yield[b] (%)	Ee (%)
1	**1**	**IIId**	rt	**3**: 36	59[c]
2	**1**	**IIId**	reflux	**3**: 48	59[c]
3	**1**	**IVa**	rt	**3**: 79	58[c]
4	**4**	**IVa**	rt	**5**: 15[d]	70[e]

[a] Authentic (*S*)-**3** and -**5** were prepared from (*S*)-**1** and -**4**, respectively, by conventional methods. [b] The starting **1** was quantitatively recovered. [c] The (*R*)-excess enantiomer was obtained. The ee was estimated by chiral HPLC (CHIRALCEL OD-H, 0.5 ml min^{-1} with hexane). The peak detection was done by UV (254 nm). The retention times of (*R*)- and (*S*)-**3** were 7.75 and 9.29 min, respectively. [d] Side products were detected on TLC during the reaction. [e] The ee was estimated by chiral HPLC (CHIRALCEL OD-H, 0.2 ml min^{-1} hexane). The peak detection was done by UV (254 nm). The retention times of (*R*)- and (*S*)-**5** were 19.82 and 20.68 min, respectively.

With bicyclic guanidines **IV**, equally asymmetric induction was observed when **IVa** was used (run 12). Introduction of a methyl group onto the ring nitrogen did not affect asymmetric induction in the cases of monocyclic guanidines as mentioned above (see runs 10 and 11). However, marked reduction of ee was observed in the reaction using the *N*-methylguanidine **IVb** (run 13). Furthermore, a match–mismatch relationship was observed in reactions using diastereomeric **IVc** and **IVd** similarly to reactions using monocyclic guanidines **IIIc** and **IIId**. Thus, **IVd** with a (2*S*,3*S*,7*S*)-configuration was a more effective base (run 15: 27% ee) than **IVc** (run 14: no ee).

Theoretically, indan-1-ol (**1**) should be obtained as an (*S*)-enantiomer-rich alcohol in these silylation reactions and the guanidine used could be recovered in a re-useable form. Isolation of both **1** and **IVa** in run 12 resulted in their expected and quantitative recovery as an (*S*)-excess alcohol (18% ee) and as a re-useable guanidine, respectively. In addition, we tried the asymmetric silylation in the presence of **IIId** in various solvents such as MeCN, toluene, trifluoromethylbenzene, and THF; however, no improvement of ee was observed in each case.

From the above experiments using TBDMSCl as a silylating agent, **IIId**, **IIIe** or **IVa** among the guanidines examined were suggested to be promising chiral bases for asymmetric silylation. Next, reactions with a more bulky TIPSCl in the presence of either **IIId** or **IVa** were attempted under the same conditions[10] described in Table 1 (Table 2). Reactions of **1** with TIPSCl at rt similarly proceeded to afford an (*R*)-excess **3** in 59% ee with **IIId** (run 1) and 58% ee with **IVa** (run 3), respectively. Interestingly, no loss of ee was observed even in the reaction under heating (run 2), indicating that this silylation would be tolerant to the reaction temperature.[11] Application of the guanidine-mediated silylation using **IVa** to 1,2,3,4-tetrahydro-1-naphthol (**4**) in place of **1** gave a silylated product **5** with high stereoselection (70% ee), albeit the chemical conversion[12] was low (run 4).

In conclusion, we have found that guanidines could effectively mediate asymmetric silylation of secondary alcohols as recyclable bases under simple and mild conditions. Although the ee obtained and reaction rates are not neccessarily perfect, it is noteworthy that these results offer not only the first example of chemical asymmetric silylation of secondary alcohols, but also experimental evidence for a possible ion-pair complex[13] between a silylating agent and a base. Formation of a silylguanidinium salt has been partially suggested by inspection of the ^{1}H NMR spectrum of an equimolar mixture of the guanidine **IIId** and TBDMSCl. Approaches to the mechanistic rationale, kinetics, and optimization of the reaction are at present under study in our laboratory.

9 It is known that substituted guanidines can exist in tautomerization of amino and imino forms depending upon the substitution patterns (see, K. Tanatani, K. Yamaguchi, I. Azumaya, R. Fukotomi, K. Shudo and H. Kagechika, *J. Am. Chem. Soc.*, 1998, **120**, 6433). One tautomer is arbitrarily described as a structure of guanidines with at least one NH function in Fig. 1.

10 We also tried catalytic silylation reactions in the coexistence of Et_3N. The reaction proceeded smoothly (57% conversion after 43 h), but no asymmetric induction was observed.

11 On the other hand, the reaction of **1** with TBDMSCl using **IVa** at −20 °C for 20 days afforded **2** in 16% yield with 33% ee, resulting in no improvement of asymmetric induction.

12 The low yield of **5** probably was caused by considerable production of side-products, whereas only the silylation reaction was observed in the use of **1** as a substrate.

Modified guanidines efficiently catalysed the asymmetric Michael reaction of a prochiral glycine derivative with acrylate or its related compounds either in solution or without a solvent under simple and mild conditions (> 95% ee).

Guanidines can be characterized as superbases[1] in organic synthesis due to their strong basicity.[2] We have explored the possibility of readily available modified guanidines[3] as re-useable chiral superbases in asymmetric synthesis.[4] Glycine imines are used as chiral templates for asymmetric synthesis of α-amino acids, in which enantioselective phase-transfer alkylation with alkyl halides has been established as a general method.[5] Ma and Cheng[6] attempted a conjugate addition of glycine imines with vinyl carbonyl compounds in the presence of C_2-symmetrical linear-type guanidines in place of phase-transfer catalysts;[7] however, the best ee observed by them was up to 30%. Re-examination of the Michael reaction using our modified guanidines under various conditions led to effective asymmetric induction (> 95% ee) when **4** (or **ent-4**, Fig. 1) was used as a catalyst either in solution or without a solvent. In this communication we present the utility of modified guanidines as clean chiral superbases in an asymmetric Michael reaction under simple and mild reaction conditions.

According to the reported conditions[6] we preliminarily examined the Michael reaction of *tert*-butyl diphenyliminoacetate (**1**) (1 equiv.) and ethyl acrylate (**2a**) (3.6 equiv.) in THF (0.26 mmol ml^{-1}) in the presence of 20 mol% of four different types of chiral guanidines **4**,[4] **5**,[3c] **6**,[3c] and **7**[3b] at 20 °C for about one week. Reasonable asymmetric induction (79% ee) was observed only in the case of **4** among the guanidines examined, albeit the chemical conversion was low (15%), in which an (*R*)-excess adduct **3a**[6] was yielded (see Table 1, run 1). In other cases, the reaction did not proceed. However, the guanidines used in these reactions were completely recovered in re-useable forms by chromatographic separation. These results led us to further examine the reaction using **4** under various conditions. Although a stoichiometric reaction in THF slightly increased the yield [34% yield (77% ee)], changing THF to other solvents in the catalytic reaction resulted in no improvement of the reaction rate although high enantioselectivities were maintained [9% yield (84% ee) in chloroform; 4% yield (73% ee) in toluene] except in ethanol [7% yield (42% ee)].

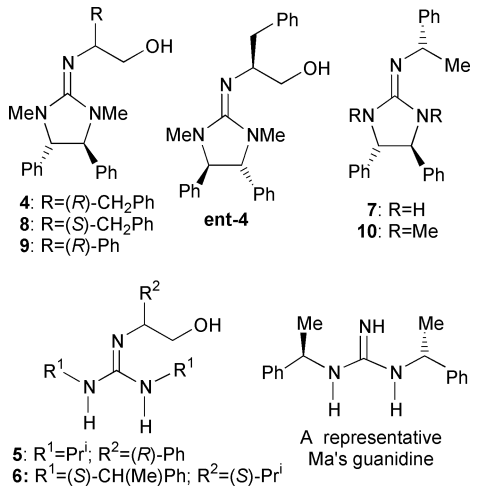

Fig. 1

We next examined the guanidine-catalysed Michael reaction of **1** with methyl vinyl ketone (MVK)[8] (**2b**) and acrylonitrile (**2c**) as a Michael acceptor in place of **2a** under the same conditions. The former reaction smoothly proceeded to afford an adduct **3b** in 90% yield, in which high enantioselectivity (96% ee) was observed (Table 1, run 2), whereas the starting **1** was completely recovered when **2c** was used (Table 1, run 3). These facts suggested that **4** could lead to effective asymmetric induction with the use of reactive Michael acceptors.

Solvent-free reactions,[9] in which rate acceleration is generally observed, have attracted much attention from the ecological point of view. Thus, **1** was treated with **2a** without a

8	**10** (20)	NR[e]	—	—

[a] Isolated, non-optimized yields. Parentheses show estimation of the product by ^{1}H NMR spectra. [b] See footnote *d* in Table 1. [c] Configuration of an excess enantiomer. [d] The data in Table 1, entry 4. [e] No reaction.

solvent (Table 1, run 4). A heterogeneous mixture of the two components containing **4** was simply stirred at 20 °C for 3 d.[10] Interestingly, both product formation and enantioselectivity were dramatically improved to give an (*R*)-excess **3a** with 97% ee in quantitative yield. Similarly, remarkable rate acceleration was observed on two other Michael acceptors **2b** and **2c**. In the former case (Table 1, run 5), reaction was completed after 15 h, in which relatively high enantioselctivity (80% ee) was kept. On the other hand, in the latter case (Table 1, run 6), **1** disappeared after 5 days to afford **3c** with 55% *ee* in spite of no reaction in solution (see Table 1, run 3). In addition, as expected, the use of methyl acrylate (**2d**) as a Michael acceptor led to the same satisfactory results obtained with **2a** (Table 1, run 7).

Thus, as a solvent-free reaction seems to be generally effective in the guanidine-catalysed Michael reaction of **1**, optimization was tried using **2a** as a Michael acceptor (Table 2). The same high *ee* was achieved even on reduction of the catalyst amount, albeit with lower chemical conversion (Table 2, run 2). No reaction was observed in the absence of a guanidine or in the presence of (−)-quinine (Table 2, runs 3 and 4). These facts indicated that **4** effectively catalysed the solvent-free reaction of **1** with **2a** in 20 mol% concentration.

The use of **ent-4**,[11] as expected, afforded an (*S*)-excess **3a** in quantitative yield with the same high enantioselectivity (Table 2, run 5). The (*S*)-excess **3a** was also obtained when **8**,[3a] a diastereomer of **4**, was used as a catalyst, but both chemical yield and asymmetric induction were lowered considerably (Table 2, run 6). Replacement of an (*R*)-phenylalaninol unit in **4** to an (*R*)-phenylglycinol one in **9**[3a] afforded an (*R*)-excess **3a** with relatively high selectivity. However, chemical conversion was not good (Table 2, run 7). On the other hand, the use of a guanidine **10**[4] lacking a hydroxyethyl function resulted in no reaction (Table 2, run 8).

Experimental evidence obtained in the above solvent-free reactions could be summarised as follows: (i) satisfactory chemical conversion with high enantioselectivity in the use of HOC_2H_4-substituted cyclic guanidines with (4*S*,5*S*,1′*R* or 4*R*,5*R*,1′*S*) configuration such as **4** indicates that the relative configurations of these three chiral centers are very important for effective asymmetric induction in addition to rate acceleration; (ii) predominant production of (*R*)-**3a** with **4** and **9** [or (*S*)-**3a** with **ent-4** and **8**] shows that a stereogenic center of the adduct should be strictly reflected by the chirality of a substituent at the external nitrogen; (iii) if the enolate of **1** could be formed by action of **4**, its *re*-face should be attacked by **2a** to yield an (*R*)-excess **3a**, for which the opposite *si*-face is severely blocked by the guanidine unit as shown in Fig. 2; (iv) although the absolute configuration of an excess enantiomer obtained in each reaction of **1** with **2b**, **2c** or **2d** has not been determined, an (*R*)-excess **3b**, **3c** or **3d** should be given in the reaction using **4**

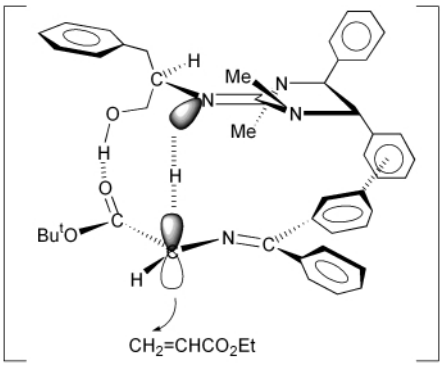

Fig. 2

due to the same face differentiation mentioned above, even in solution.

In summary, it was found that modified guanidines efficiently catalysed the asymmetric Michael reaction of a prochiral glycine derivative with vinyl compounds either in solution or without a solvent under simple and mild conditions. These guanidine-catalysed asymmetric Michael reactions[12] could contribute to development of green chemistry,[13] because modified guanidines are considered to be re-useable (economically favored) and easily functionalizable (widely applicable) artificial organic bases.

First published as an Advance Article on the web 19th January 2001

The compounds [Mo(NPh)(η²-olefin)(*o*-(Me$_3$SiN)$_2$C$_6$H$_4$)] (olefin = propene (1a), isobutene (1b), and butenes (1c)) react with molecular hydrogen (*ca*. 15 psi) in the presence of excess arene affording Mo(IV) η⁶-arene complexes of the type [Mo(NPh)(η⁶-arene)(*o*-(Me$_3$SiN)$_2$C$_6$H$_4$)] (arene = benzene (2a), toluene (2b), *o*-xylene (2c), *m*-xylene (2d), *p*-xylene (2e), diphenylmethane (2f), and bibenzyl (2g)), while treatment of [Mo(NPh)(η²-styrene)(*o*-(Me$_3$SiN)$_2$C$_6$H$_4$)] (1d) with hydrogen in a pentane solution gives [Mo(NPh)(η⁶-ethylbenzene)(*o*-(Me$_3$SiN)$_2$C$_6$H$_4$)] (2h); the crystal structures of 2d and 2e are reported and reveal highly distorted arene ligands approaching η⁴-coordination modes.

Fisher and Hafner characterized the first transition metal π-arene complex, Cr(η⁶-benzene)$_2$, 45 years ago.[1] Since this discovery the chemistry of π-arene complexes has been extensively explored.[2] It was initially believed that arene complexes were confined to transition metals in low oxidation states and a significant development in this field has involved the synthesis and characterization of high oxidation state Group 4 and 5 transition metal–arene complexes.[3,4] While Group 4 and 5 arene complexes are relatively rare, high valent Group 6 arene complexes are, with one exception,[5] non-existent. Furthermore, the generation of isolable high oxidation state transition metal–arene complexes *via* hydrogenation of η²-olefin complexes remains a rare process.[6] We report herein the synthesis and structure of molybdenum(IV) η⁶-arene complexes obtained upon exposure of various molybdenum η²-olefin complexes,[7] of the form [Mo(NPh)(η²-olefin)(*o*-(Me$_3$SiN)$_2$C$_6$H$_4$)], to molecular hydrogen (*ca*. 15 psi) and excess arene. In addition, these molybdenum(IV) η⁶-arene complexes catalyse the hydrogenation of olefins.

The hydrogenation of **1a**–**c** in the presence of 15 equivalents of arene gave complexes **2a**–**g** as microcrystals after crystallization from pentane (Scheme 1).§ The molecular structures of **2d** and **2e** were determined by single crystal X-ray diffraction studies, and are shown in Fig. 1 and 2, respectively, along with selected crystal data.¶ Complex **2d** adopts a three-legged piano stool geometry in which the arene ligand is strongly distorted toward an η⁴-coordination mode. The structural data suggest that the interaction of the arene ligand with the molybdenum metal center is much like a 1,3-butadiene–metal interaction. A considerable ring distortion of 17.4(3)° was found between the planes formed by C(20)–C(19)–C(24)–C(23) and C(20)–C(21)–C(22)–C(23). Carbons C(19) and C(24) were found to be considerably further from the metal center than the other arene carbons, suggesting that the arene interaction with the metal center is mostly through C(20), C(21), C(22) and C(23). The shorter bond lengths for C(21)–C(22) and C(19)–C(24), in comparison with the remainder of the arene carbon–carbon bonds, are consistent with considerable double bond character between these carbons.

† Electronic supplementary information (ESI) available: ^{1}H NMR spectra for complexes **2b**–**2d** and **2h**, chemical shift data for **2a**–**2h**. See http://www.rsc.org/suppdata/cc/b0/b007812n/

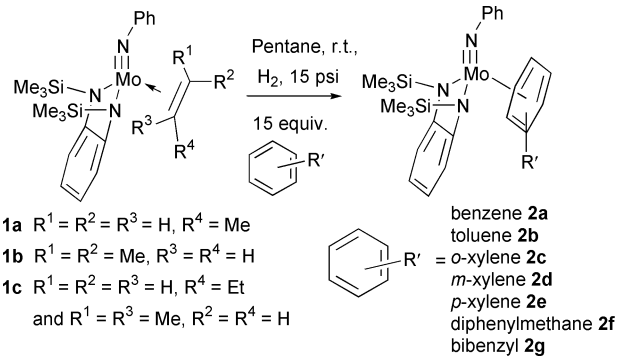

Scheme 1

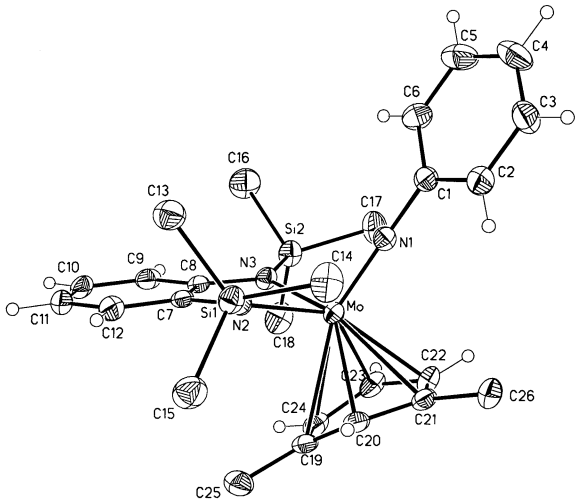

Fig. 1 Thermal ellipsoid plot of **2d** (50% probability thermal ellipsoids). Selected bond lengths (Å) and angles (°): Mo–N(1) 1.761(3), Mo–C(19) 2.519(3), Mo–C(20) 2.313(4), Mo–C(21) 2.425(4), Mo–C(22) 2.371(4), Mo–C(23) 2.286(4), Mo–C(24) 2.506(4), C(19)-C(20) 1.444(5), C(20)–C(21) 1.420(5), C(21)–C(22) 1.387(6), C(22)–C(23) 1.421(5), C(23)–C(24) 1.441(5), C(24)–C(19) 1.381(5); Mo–N(1)–C(1) 178.9(3).

Similar structural parameters were found for **2e** which has a ring distortion of 17.1(1)°. The Mo–N(1) bond lengths in both complexes are virtually identical at 1.761(3) (**2d**) and 1.775(1) Å (**2e**) and are consistent with a Mo–N triple bond interaction.[8] An interesting difference between the two structures arises upon comparison of the Mo–N(1)–C(1) angles which are 178.9(3) (**2d**) and 145.5(1)° (**2e**). It is tempting to suggest that this difference arises from a significant difference in the Mo–N(1) interaction between the two compounds. However, close inspection of the packing diagram of **2d** reveals that there is a π-stacking interaction between the phenyl rings of the phenyl imido groups of neighboring molecules. Given that calculations suggest a very soft bending potential for aryl imido complexes,[9] the differences in the Mo–N(1)–C(1) angles in **2d** and **2e** are most likely due to crystal packing forces.

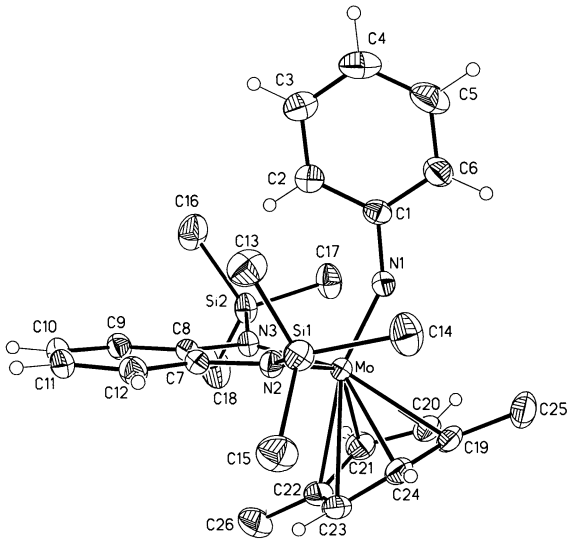

Fig. 2 Thermal ellipsoid plot of **2e** (50% probability thermal ellipsoids). Selected bond lengths (Å) and angles (°): Mo–N(1) 1.7746(14), Mo–C(19) 2.3908(17), Mo–C(20) 2.3900(18), Mo–C(21) 2.3243(19), Mo–C(22) 2.5637(19), Mo–C(23) 2.5410(18), Mo–C(24) 2.2981(18), C(19)–C(20) 1.392(3), C(20)–C(21) 1.4091(3), C(21)–C(22) 1.453(3), C(22)–C(23) 1.359(3), C(23)-C(24) 1.443(3), C(24)-C(19) 1.428(3), Mo-N(1)-C(1) 145.47(12).

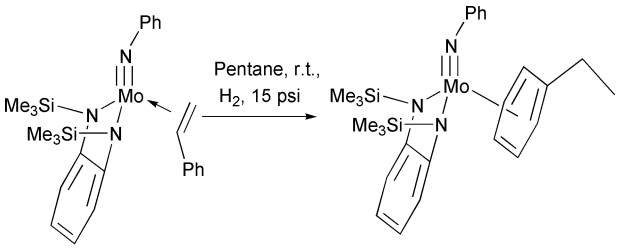

Scheme 2

The chemical shifts associated with the arene protons in the ^{1}H NMR spectra of these complexes are shifted significantly upfield, appearing in the region spanning δ 4.5–5.5 as expected for η^6-bound arene ligands.[10] The arene resonances are well resolved in the ^{1}H NMR spectra at room temperature and only one resonance for the Me_3Si groups is observed, supporting a low barrier to arene ring rotation (ESI†).

When a pentane solution of **1d** was exposed to a slight pressure of dihydrogen (*ca*. 15 psi) for 15 min, **2h** formed and was isolated as a microcrystalline solid by crystallization and filtration at −78 °C (Scheme 2).§ The ^{1}H NMR spectrum of **2h** is similar to those of complexes **2a**–**g** (ESI†).

Compounds **2a**–**h** are catalysts for the hydrogenation of olefins. When C_6D_6 solutions of **2h** (1 mol%) and a substrate olefin (styrene, neohexene, or *trans*-stilbene) were exposed to low pressures of dihydrogen (*ca*. 15 psi) at room temperature, slow conversion to the respective alkanes was observed. Raising the temperature of the reaction to 50 °C increased the rate of hydrogenation of neohexene [1 mol%, (**2b**)] from 17% conversion overnight to 62% over 8 h (TOF *ca.* 7/h).

η^2-Olefin complexes have been widely proposed as intermediates in the catalytic hydrogenation of olefins. As the ethylbenzene ligand of **2h** is readily displaced by styrene giving **1d** at room temperature it is likely that the propagating species in the above hydrogenation reaction is indeed an olefin complex. In general, the arene ligands also undergo exchange reactions with C_6D_6 at room temperature with the rates of reaction depending to some extent upon the identity of the arene ligand that is being displaced.

We thank the National Science foundation (CHE 9523279) for funding of this work. K. A. A. thanks the NSF and the University of Florida for funding X-ray equipment purchases.

Notes and references

§ All reactions and manipulations were carried out using standard Schlenk techniques or in a dry box under a nitrogen atmosphere. Complexes **1a**–**d** were synthesized according to published procedures.[7] Synthesis of **2a**–**g**: to a pentane solution of freshly generated **1a**–**c**, 15 equivalents (relative to the Mo starting material) of the appropriate arene were added followed by freezing of the mixture and evacuation of the headspace. Dry hydrogen was then added to the thawed solution, which was stirred at room temperature for 30 min. The volatiles were then removed *in vacuo* affording **2a**–**g** as blue–green solids that were recrystallized from pentane at −78 °C (80–85% isolated yield). The synthesis of **2h** is analogous to **2a**–**g**; however, no excess arene is employed.

¶ *Crystal data*: for **2d**: $C_{26}H_{37}MoN_3Si_2$, M = 543.71, triclinic, space group $P\bar{1}$, a = 9.2793(6), b = 10.5045(7), c = 15.466(1) Å, α = 87.784(1), β = 76.796(1), γ = 64.068(1)°, V = 1316.7(2) Å^3, Z = 2, μ(Mo-Kα) = 0.608 mm^{-1}, T = 173(2) K, final $R1$ = 0.0453, $wR2$ = 0.0775, Gof (on F^2) = 1.021.

For **2e**: $C_{26}H_{37}MoN_3Si_2$, M = 543.71, monoclinic, space group $P2_1/n$, a = 9.7367(4), b = 14.3272(6), c = 19.5480(8) Å, α = 90, β = 95.080(1), γ = 90°, V = 2716.2(2) Å^3, Z = 4, μ(Mo-Kα) = 0.589 mm^{-1}, T = 173(2) K, final $R1$ = 0.0237, $wR2$ = 0.0590, Gof (on F^2) = 1.021.

Two-dimensional heteronuclear $^{1}H \leftrightarrow {}^{27}Al$-correlated MAS NMR spectra of layered silicates

María D. Alba,* Ana I. Becerro, Miguel A. Castro and Ana C. Perdigón

Departamento de Química Inorgánica, Instituto de Ciencia de Materiales, Universidad de Sevilla, Consejo Superior de Investigaciones Científicas, Avda. Américo Vespucio s/n, 41092-Sevilla, Spain. E-mail: alba@cica.es

Received (in Cambridge, UK) 16th October 2000, Accepted 18th December 2000
First published as an Advance Article on the web 18th January 2001

The structural locations of aluminium in layered silicates, with different chemical environments but similar coordination polyhedra, can be established unequivocally from the correlation between the chemical shifts of protons and ^{27}Al nuclei, *via* their heteronuclear dipole–dipole couplings.

Among the quadrupolar nuclei studied by nuclear magnetic resonance (NMR), the ^{27}Al nucleus has received a great deal of interest for two reasons: on the one hand, aluminium is a main constituent of many interesting basic or applied solid systems; on the other hand, it is a very favourable nucleus for NMR investigations because it is a 100% naturally abundant isotope. However, even when conventional single pulse ^{27}Al MAS NMR spectra are recorded under the best conditions, *i.e.* very high magnetic fields, fast magic angle spinning speeds, and strong radiofrequency pulses with small flip angles,[1] only limited information is obtained. Those ^{27}Al MAS NMR spectra allow the determination of the coordination number of aluminium but they are much less sensitive to the nature of second neighbour species. Thus, very different structural aluminium sites with similar coordination environments can not clearly be differentiated on the basis of those ^{27}Al MAS NMR spectra.

In order to obtain this information, two-dimensional $^{1}H \leftrightarrow {}^{27}Al$ cross-polarisation experiments, which are selective to the existence of dipole–dipole interactions between both nuclei, are very useful in distinguishing similar aluminium coordination environments. The proposed experiments, very recently employed for mesoporous solids,[2] provide spectra with a simple and straightforward interpretation: the identification of the proton species correlated with the aluminium nuclei allows one to obtain precise structural information. However, two difficulties need to be overcome to perform these experiments. First, special care needs to be taken to perform cross-polarisation experiments of quadrupolar nuclei,[3] even though the optimum experimental conditions have already been explored for the case of ^{27}Al nuclei.[4] Second, available and unequivocally assigned high resolution ^{1}H MAS NMR spectra of the studied solid systems are required in order to correlate adequately the 2D signals that appear in the spectra. This second requirement has been recently fulfilled by our group for the solid systems here analysed.[5]

In this report, the advantages of applying this new solid-state NMR method to the family of phyllosilicates are reported for the first time. We describe both the method and the new available information from 2D spectra of aluminosilicates. From these spectra it is demonstrated that the method allows one not only to distinguish between different coordination environments for aluminium, but also to assign to these nuclei a precise structural location. Likewise, useful applications for such measurements are proposed.

The proposed technique is a two-dimensional heteronuclear $^{1}H \leftrightarrow {}^{27}Al$ chemical shift-correlation experiment, HETCOR. It is similar to conventional cross-polarisation, CPMAS NMR, experiments[6] except that the ^{1}H magnetisation is allowed to evolve for a period of time before the magnetisation transfer to the investigated nuclei, *i.e.* the ^{27}Al nuclei.

In order to illustrate the advantages of using this methodology, two well-characterised samples, available from the Source Clay Repository of the Clay Mineral Society, were selected. These samples include the possible structural positions of aluminium in layered silicates. Aluminium ions may occupy

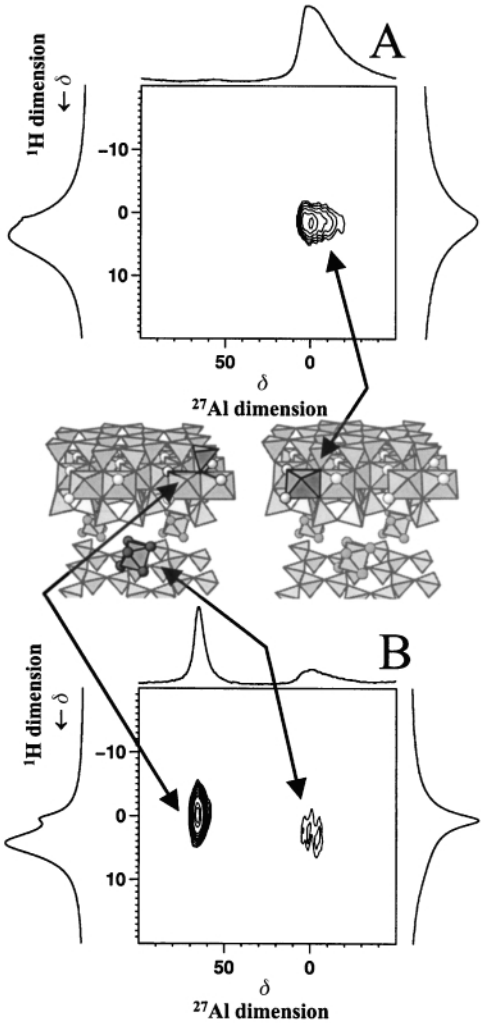

Fig. 1 (A) Contour plot of the 2D $^{1}H \leftrightarrow {}^{27}Al$ correlation experiment on hydrated sodium-saturated SAz-montmorillonite obtained with a ^{1}H $\pi/2$ pulse of 4.8 μs, a 0.3 ms contact time, a 250 ms recycle delay, and a 12.0 kHz spinning rate. A set of 84 FIDs was obtained with a t_1 increment of 5 μs and a dwell time of 5 μs. Separate ^{27}Al and ^{1}H MAS NMR spectra are plotted along their corresponding axes in accordance with the text. A silicate structure drawing is included to emphasize the dipole–dipole coupling found. (B) Contour plot of the 2D $^{1}H \leftrightarrow {}^{27}Al$ correlation experiment on hydrated aluminium-saturated SapCa-saponite. The conditions for this experiment were identical to those presented in (A), with the exception that a set of 96 FIDs was collected. Separate ^{27}Al and ^{1}H MAS NMR spectra and an appropriate silicate structure drawing are also included.

DOI: 10.1039/b008333j

three different positions in these solids. If aluminium is a main constituent of the silicate lattice, *i.e.* the silicate sheet, it can occupy either an octahedral or a tetrahedral location. When aluminium enters in the silicate structure as an exchange cation, *i.e.* in the interlayer space, it exhibits octahedral coordination.[2]

The first location, octahedral aluminium in the silicate sheet, is represented by a sodium-saturated montmorillonite from Arizona, which has been described in detail elsewhere.[7] The 1D ^{27}Al MAS NMR spectrum for this sample, horizontal projection in Fig. 1A, consists of a single peak centred at around 0 ppm that is assigned to these aluminium environments.[8] For the other two locations, tetrahedral aluminium in the silicate sheet and octahedral aluminium in the interlayer space, an aluminium-saturated saponite was selected.[9] In the corresponding 1D ^{27}Al MAS NMR spectrum, horizontal projection in Fig. 1B, two aluminium signals centred at 0 ppm (the octahedral aluminium) and 67 ppm (the tetrahedral aluminium) are observed. A comparison between the 1D NMR peaks obtained for the two different octahedral aluminium environments reveals the difficulties encountered to elucidate the structural location of octahedral aluminium in silicates. Conventional ^{27}Al MAS NMR spectroscopy fails for this purpose.

Fig. 1 also shows the application of the proposed technique to layered silicates for the first time, the 2D spectra for both samples being included. The 2D ^{1}H $\leftrightarrow$ ^{27}Al HETCOR spectra are displayed as contour plots along with the following: ^{27}Al MAS NMR (top) and ^{1}H MAS NMR (left) spectra from the hydrated sample, and ^{1}H MAS NMR (right) spectra from the samples after dehydration at 110 °C which were separately acquired for each. Drawings of the silicate structure are also included in which the coupled aluminium and proton species are outlined in bold to aid in the analysis of the 2D ^{1}H $\leftrightarrow$ ^{27}Al HETCOR spectra obtained.

On the one hand, the 2D spectrum for the sodium-saturated montmorillonite sample (Fig. 1A) consists of a single cross-peak which correlates the unique ^{27}Al signal, corresponding to an indistinguishable octahedral aluminium in the 1D spectrum, with the hydroxyl proton peak from the silicate lattice. Thus, the intensity profile in the contour plot clearly indicates that the aluminium ions are only occupying octahedral positions of the silicate sheet. On the other hand, the 2D spectrum for the aluminium-saturated saponite (Fig. 1B) consists of two cross-peaks, related to the two 1D-aluminium signals. The tetrahedral aluminium, 1D signal at around 67 ppm, is correlated with the hydroxyl proton signal from the silicate lattice in a similar manner as the former case. The octahedral aluminium, 1D signal at around 0 ppm, is correlated with the water proton peak from the interlayer space. This latter correlation reveals the new position of the aluminium species in the silicate mineral, octahedral positions in the interlayer space, in addition to demonstrating the advantages of using this technique. The indistinguishable 1D octahedral aluminium chemical shifts (horizontal projections of each 2D spectrum) are separated from dipole–dipole coupled species into two frequency dimensions, which allow adjacent nuclear species to be readily determined.

In summary, this paper describes a technique that enables, for the first time, the determination of the coordination number of a particular aluminium species from the ^{27}Al chemical shift, in addition to allowing the identification of the location of this polyhedron within the structure, from the dipole–dipole coupling with adjacent protons. Thus, the technique presented here offers a new approach to the improvement of the NMR information extractable from quadrupolar nuclei.

The first example of a functional pillared metal sulfonate network

Adrien P. Côté and George K. H. Shimizu*

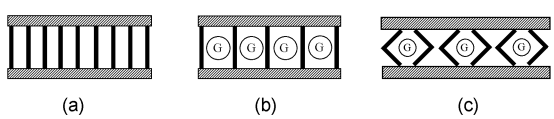
Department of Chemistry, University of Calgary, 2500 University Drive N.W., Calgary, Alberta, Canada T2N 1N4. E-mail: gshimizu@ucalgary.ca

Received (in Irvine, CA, USA) 17th July 2000, Accepted 20th November 2000
First published as an Advance Article on the web 19th January 2001

Barium 4,5-dihydroxybenzene-1,3-disulfonate, a pillared metal sulfonate network, possesses a microporous interlayer region through the use of a single type of 'bent' sulfonate group, and absorbs H_2S.

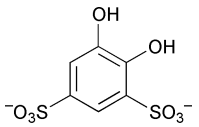
The design and synthesis of mixed inorganic–organic solids capable of including small molecules within void spaces in their structures, analogous to natural clays and zeolites,[1] has evolved into a diverse area of research.[2] A widely studied class of metal–organic networks, in this respect, has been the metal phosphonate salts of general formula $M^{n+}(O_3PR)_{n/2}$ where R is an aliphatic or aromatic organic group.[3] These systems often form two-dimensional structures where rigid O–M–O layers assemble, projecting the R groups between the layers. This alternating organic–inorganic layered topology can allow the intercalation of various small molecules between the layers, making these materials useful for chemical separations and/or catalytic applications.[4] However, since, typically, no void space exists between the layers prior to intercalation, an energy cost is associated with the act of separating the layers which can inhibit their usefulness. To overcome this limitation, the layers in these compounds can be 'pillared' to increase the void space between the layers and predispose the structure to guest inclusion. Pillaring is a strategy, first employed with clays and then with other layered materials, where counter ions, organic molecules, or polytopic ligands are used to 'prop' layers apart, resulting in greater porosity in addition to improved structural integrity.[5] Unfortunately, with prototypical metal phosphonate structures, the spacing between simple linear diphosphonate pillars (*e.g.* phenyl or biphenyl) is negligible, rendering the network ineffectual with regard to guest inclusion [Scheme 1(a)].[6] This adverse circumstance can be in part remedied by using mixed phosphonate or phosphate/phosphonate systems where the 'pillar' alternates with a smaller, non-pillaring phosphonate (*e.g.* methylphosphonate) or a phosphate group [Scheme 1(b)], thus generating porosity.[7] However, in addition to complicating the synthesis, this may result in a loss of structural regularity and a greater pore size distribution.[8]

Contrasting the metal phosphonate systems, our research is focused on using weaker metal–sulfonate ($M^{n+}(SO_3R)_n$) interactions to develop new layered and porous compounds.[9] This approach takes advantage of the flexible coordinative behavior of the SO_3^- group to obtain structures not attainable from the rigid O–M–O scaffolding of metal phosphonate networks. Of the relatively few structurally characterized $M_n(SO_3R)_n$ complexes which exist to date, all form layered networks.[9,10] Some of these can be classified as 'pillared' solids but they suffer from the aforementioned problem of virtually no space between adjacent R groups.[11] Even within these layered compounds, there exists substantial diversity with respect to the sulfonate coordination mode.[12] We, therefore, sought to exploit this flexible coordination by generating layered networks which would tolerate the incorporation of a 'bent' pillar. A bent pillar would not pack efficiently in the interlayer and, therefore, generate porosity [Scheme 1(c)] while offering a facile two-component synthesis. Herein, we report the structure, thermal analysis and sorption properties of barium 4,5-dihydroxybenzene-1,3-disulfonate dihydrate, $[Ba(\mathbf{1})(H_2O)]\cdot H_2O$. This compound represents the *first functional pillared metal sulfonate network*.[13] Significantly, interlayer void space is generated and the guests which occupy these sites may be removed while maintaining structural integrity.



Scheme 1 Pillaring of layered networks showing (a) close packing of linear pillars with no void space; (b) alternating pillars and small R groups to generate porosity; (c) use of 'bent' pillars to create pores with a single type of R group.

$[Ba(\mathbf{1})(H_2O)]\cdot H_2O$ was metathesized from the commercially available $Na_2[\mathbf{1}]\cdot H_2O$ by combining equimolar amounts of $BaCl_2\cdot 2H_2O$ and $Na_2[\mathbf{1}]\cdot H_2O$ in minimal amounts of water. A white precipitate of $[Ba(\mathbf{1})(H_2O)]\cdot H_2O$ formed immediately,



1

which was filtered off in 95% yield. Colorless, X-ray quality crystals were grown by diffusion of acetone vapor into a saturated aqueous solution of the complex.† The structure (Fig. 1) consists of infinite layers of sulfonate-bridged Ba^{2+} centers, in the *xy* plane, with **1** acting as a pillar to bridge adjacent layers through the two sulfonates. One SO_3 group coordinates to a layer in the $+z$ direction and other in the $-z$ direction, to give a *d*-spacing of 9.24(2) Å. The stability of the

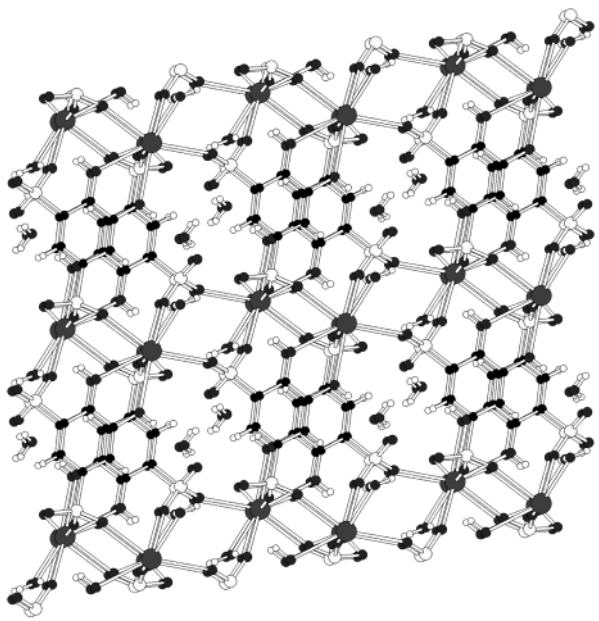


Fig. 1 View of the layered structure of $[Ba(\mathbf{1})(H_2O)]\cdot H_2O$ down the *a*-axis. Ba atoms: large circles, S atoms: medium, light grey circles, O atoms: small, dark grey circles, C atoms: small, black circles. Note the interlayer channels and the water molecules occupying them.

DOI: 10.1039/b005923o

pillars is augmented *via* the chelation of the catechol (4,5-diol) unit of **1** to a single Ba^{2+} center. The bent structure of **1**, with sulfonate groups oriented at 120°, opens up 16-membered rings in the interlayer between the pillars. The rings align along the *a*-axis to form channels which are filled with non-coordinated water molecules. The channels are approximately 4.0 Å in diameter. The construction of the layers is complex, with the one crystallographically unique Ba^{2+} ion being 9-coordinate and each molecule of **1**, in turn, coordinating to six different Ba^{2+} centers. The coordination of **1** is as follows. The catechol moiety of **1** chelates, in a doubly protonated form, to one barium center [Ba–O7 = 2.843(3), Ba–O8 = 2.791(3) Å]. The sulfonate group in the 3-position coordinates to two different Ba^{2+} centers, which are part of the same layer as the catechol-chelated Ba^{2+}, *via* a μ^2,η^2-mode [Ba–O5 = 2.750(3), Ba–O6 = 2.749(3) Å]. Sulfonates in the 1-position adopt a μ^3,η^3-coordination mode where all three Ba^{2+} ions are in the adjacent layer to those coordinating to the sulfonate in the 3-position. One of the Ba^{2+} centers is chelated by two of the sulfonate oxygen atoms resulting in four coordinating interactions in total [Ba–O1 = 2.737(3), 3.002(3), Ba–O2 = 2.875(3), Ba–O3 = 2.765(3) Å]. Each barium ion is 9-coordinate with an irregular geometry. The coordination sphere is comprised of six sulfonate oxygen atoms, from five different sulfonate groups, the two catechol oxygen atoms, and a water molecule [Ba–O9 = 2.751(3) Å] that projects into the interlayer.

The PXRD pattern and the elemental analysis of the bulk precipitate match those of the single crystal sample, indicating that these species have the same structure and composition. Thermal analysis revealed loss of included water at 110 °C and then gradual loss of the coordinated water to 420 °C at which point the sample decomposed.[14] Given that the aversion to employing sulfonates in the generation of extended materials has largely been due to their weaker coordinative tendencies, the stability of this network is quite remarkable. Importantly, the PXRD patterns of the dihydrate and the monohydrate showed that the framework remained intact after loss of the channel water molecules.[15] Removal of only the guest water molecules of $[Ba(\mathbf{1})(H_2O)]\cdot H_2O$ would leave empty channels, possibly with a topology imprinted by the water molecules. Therefore, based upon the structural similarity, the sorbent capabilities of the dehydrated framework with H_2S were examined. It was found that at 50 °C a mass increase of 7.5% was observed, corresponding to the uptake of 0.93 equivalents of H_2S with respect to the equivalent of expelled water.[16] Significantly, analogous experiments with methane and methanol revealed no mass increase, indicating selectivity for H_2S.

In conclusion, $[Ba(\mathbf{1})(H_2O)]\cdot H_2O$ represents the first example of a functional pillared metal sulfonate structure. The flexible coordination of the sulfonate group enables 'bent' pillars to be employed resulting in a microporous network in a system where only a single type of pillar is present. Despite relying on metal–sulfonate interactions in the pillars, the network is highly robust (> 400 °C). With regard to functionality, the guest water molecules can be removed and selectively replaced, almost quantitatively, by hydrogen sulfide.

We would like to thank Dr R. MacDonald at the University of Alberta for the single crystal X-ray data and the reviewers for useful suggestions. This research was supported by the Natural Sciences and Engineering Research Council of Canada.

Notes and references

13 Ward *et al*. have employed sulfonates with great success in H-bonded pillared guanidinium sulfonate frameworks. See: V. A. Russell, C. C. Evans, W. Li and M. D. Ward, *Science*, 1997, **276**, 575.

14 TGA/DSC analyses of $[Ba(\mathbf{1})(H_2O)]\cdot H_2O$ were performed on a Netzsch 449C Simultaneous Thermal Analyzer. A mass loss at 110 °C was assigned to loss of the channel water molecules (4.08% calc., 3.62% obs.). Heating beyond 110 °C, a gradual mass loss occurs until decomposition at 420 °C corresponding to the loss of a second molecule of water (4.08% calc. 3.91% obs.).

15 A comparison of the nine most intense peaks in the PXRD patterns of $Ba[\mathbf{1}]\cdot 2H_2O$ and of a sample dehydrated at 150 °C for two hours, to remove channel water molecules, shows a mean deviation of only 1.4%. Full details are given within the crystallographic material.

16 $[Ba(\mathbf{1})(H_2O)]\cdot H_2O$ was placed under a N_2 atmosphere, heated to 150 °C at 10 °C min^{-1}, then held at 150 °C for 10 min to remove the channel water. The sample was cooled to 50 °C and the purge gas changed to H_2S. The sample showed a mass gain of 7.5%. $[Ba(\mathbf{1})(H_2O)]$ has a mass of 423 g mol^{-1}. In terms of molar equivalents, a 7.5% gain is therefore equivalent to 31.68 g mol^{-1} or 31.68/(34.06 g mol^{-1} H_2S) = 0.93 equivalents of H_2S.

Pseudopolyrotaxanes possessing a controllable number of cucurbituril molecules located along the backbone of poly(iminiohexamethylene chloride) have been prepared *via* an efficient post-threading route.

Although the synthesis of cucurbituril was described almost 100 years ago[1] the exploitation of the supramolecular chemistry of this rigid, nondecacyclic ligand only began recently. Mock and Pierpont reported a molecular switch[2] and both Kim *et al.*[3] and Buschmann *et al.*[4,5] synthesised various inclusion complexes based on cucurbituril. The latter two groups also prepared solid and solution state polyrotaxanes in which cucurbituril features as the macrocyclic component introduced as a pseudorotaxane monomer.[6,7] Steinke *et al.* used the ability of cucurbituril to catalyse 1,3-dipolar cycloadditions, a feature of cucurbituril discovered by Mock *et al.*[8,9] in the synthesis of catalytically self-threading polyrotaxanes.[10]

Formation of polyrotaxanes or pseudopolyrotaxanes *via* post-threading requires an attractive interaction between the macrocycle and the (preformed) polymer backbone. Investigations by Harada *et al.* provided the earliest example of post-threading exploiting the strong hydrophobic interactions between poly(ethylene glycol)s (PEG) and α-cyclodextrins (α-CD) in aqueous media.[11] Since then α-, β- and γ-cyclodextrins, crown ethers and cyclophanes have been post-threaded onto a number of different linear polymer backbones like poly(propylene glycol) (PPG),[12,13] poly(alkylimine)s,[14] PEO-PPO-PEO triblock copolymers,[15] poly(propylene),[16] poly(trimethylene oxide),[13] poly(isobutylene),[16] poly(ε-caprolactone),[16] poly(viologen)s,[16] aromatic poly(ether),[17] poly(ether ester)[17] and poly(urethane)s.[18,19] Recently calorimetric studies by Buschmann *et al.* suggested the formation of a pseudopolyrotaxane between PEG and cucurbituril.[20]

For our contribution to this area we decided to prepare cucurbituril-containing mainchain pseudopolyrotaxanes from poly(iminoalkylene)s. Poly(iminohexamethylene) was deemed to be the most promising linear polyamine because the protonated hexane-1,6-diamine moiety present in its backbone is known to form one of the most stable inclusion complexes with cucurbituril.[21] Poly(iminiohexamethylene chloride) was synthesised according to a procedure by Wenz *et al.*[14] in which Nylon 6,6 was reduced with BH_3·Me_2S (Fig. 1). ^{1}H NMR of the polyamine confirmed that reduction was successful with less than 3% of residual amide groups remaining (M_n = 20000, M_w = 52000, against polystyrene). Cucurbituril was prepared according to the procedure by Behrend *et al.*[1] Samples for the subsequent time-dependent NMR studies were prepared by dissolving poly(iminohexamethylene) in 20% DCl to which the required amount of cucurbituril was added (Fig. 1).

Progress of the threading reaction was monitored at given time intervals by ^{1}H NMR (Fig. 2). Fig. 2 corresponds to a post-threading experiment carried out at 90 °C in DCl–D_2O (20% w/w) with a molar ratio of cucurbituril to the iminiohexamethylene repeat unit of 0.5 : 1.0. Upon threading the original three resonances of the α-, β- and γ-methylene groups of poly(iminiohexamethylene chloride) are split into an additional two sets of resonances (Fig. 2: **A**, **B**, **C** and **a**, **b**, **c**). The integrals of the new resonances are increasing with time to the same extent as the precursor polymer resonances are decreasing. The

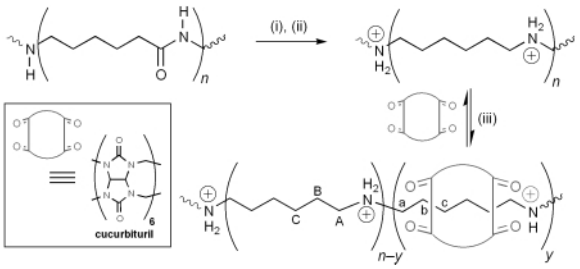

Fig. 1 Synthesis of cucurbituril-threaded mainchain poly(iminiohexamethylene chloride); (i) BH_3·Me_2S, THF, 20 h, rt, 66%; (ii) DCl–D_2O (20% w/w), rt, 100%; (iii) cucurbituril, 0 to 384 h, 90 °C.

set of resonances coded **a**, **b** and **c** can be assigned to threaded hexamethylene segments based on complexation studies with the model compound 1,6-diaminohexane dihydrochloride salt carried out by us which is further supported by earlier work in formic acid carried out by Mock *et al.*[21] Resonances **A**, **B**, and **C** belong to unthreaded hexamethylene segments located next to threaded repeat units along the polymer backbone. This was confirmed by using a five-fold excess of cucurbituril. Under these conditions essentially all precursor resonances disappeared and only the two new sets of resonances remained (not shown). The degree of threading was calculated from the ratio of threaded to non-threaded methylene protons. In this particular example (after 384 h) 43% of all repeat units were threaded by cucurbituril. Threading is also reflected in a small downfield shift in the resonances of cucurbituril (Fig. 2: **QQ** = free macrocycle; **qq** = threaded) which is proportional to the degree of threading over time. Attempts to determine the molecular weight of these pseudopolyrotaxanes by GPC have been hampered by the fact that these polymers are only soluble in water and the necessary analytical equipment has not been available to us.

Data of this very slow threading process are shown in Fig. 3 which suggest that equilibrium has been reached after *ca.* 400 h

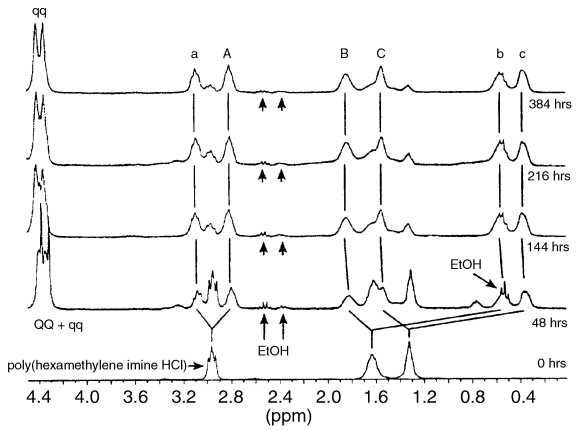

Fig. 2 Progression of post-threading followed by ^{1}H-NMR at 90 °C in DCl–D_2O (20% w/w) with a molar ratio of cucurbituril to iminiohexamethylene repeat unit of 0.5 : 1.0.[27] (Arrows indicate traces of the ethanol inclusion complex with cucurbituril (ethanol was used as co-solvent during recrystallisation). The signal intensity is decreasing with time being replaced by polymer chain repeat units.)

DOI: 10.1039/b008175m

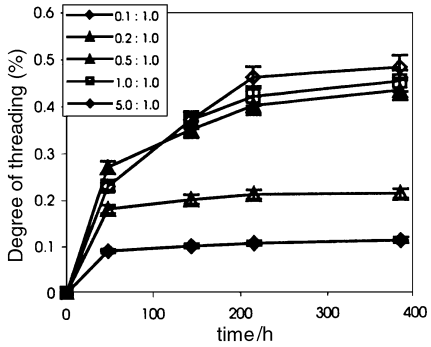

Fig. 3 Time-dependence of the threading of cucurbituril onto poly(iminiohexamethylene chloride) at 90 °C in DCl–D_2O (20% w/w). Molar ratios of cucurbituril to repeat unit: 0.1 : 1.0; 0.2 : 1.0; 0.5 : 1.0; 1.0 : 1.0; 5.0 : 1.0.

at 90 °C for all ratios of cucurbituril to polymer repeat unit. Excess of cucurbituril has very little impact on the maximum degree of threading being close to 50% (experimental error ±2%). From the limiting degree of threading (50%) and the clear splitting of the original ^{1}H NMR signals of the iminiohexamethylene repeat unit into two new sets of peaks of equal intensity, we conclude that a pseudopolyrotaxane has been formed where encapsulated and uncomplexed repeat units alternate. Further evidence comes from encapsulation studies between cucurbituril and bis(6-aminohexyl)amine (a model 'dimer' of the polymer backbone).[22] A two-fold excess of cucurbituril led to 45% threading, a value which is very close to that found for the polymeric case. The inactivity of cucurbituril in the catalytic self-threading of pseudopolyrotaxanes involving hexane-1,6-diamine repeat units[10] can also best be rationalised by assuming that it is energetically unfavourable for two molecules of cucurbituril to complex to the same secondary ammonium ion. We have considered the possibility of other substructures analogous to recent ^{1}H NMR investigations by Hodge *et al.*[17] However, an alternating sequence of complexed and uncomplexed repeat units is the most consistent interpretation of our experimental data.

The slow kinetics of the threading process can be explained through a combination of factors. By far the most important contribution arises from the strong binding constant of cucurbituril to the protonated hexamethylene-spaced repeat unit.[21] A high activation energy is needed for cucurbituril to 'hop' efficiently along the polymer chain during the threading process. This interpretation is supported by recent results from Harada's groups related to slow threading kinetics also affected by strong ionic interactions between macrocycle and polymer chain.[23] Wenz *et al.* have modelled a hopping mechanism for the post-threading of α-CD onto ionene-6,10† which enabled them to explain their observed threading kinetics.[14] Their pseudopolyrotaxane system also required elevated temperatures

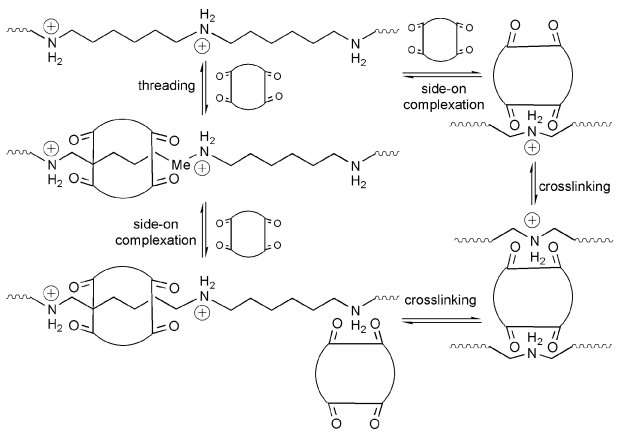

Fig. 4 Modes of complexation of cucurbituril with the corresponding equilibria expected to take part in the threading of cucurbituril onto protonated, linear poly(iminooligoalkylene)s.

and long reaction times (120 h at 80 °C in water) to reach a degree of threading of 0.5. Furthermore we invoke that threading kinetics in our system are retarded further by cucurbituril moieties having to queue. The existence of queuing has been demonstrated by Parsons *et al.*[24,25] during the threading of pseudopolyrotaxanes. The effect of queuing becomes more significant for higher levels of threading as indicated by the corresponding slower threading kinetics (Fig. 3).

The retarded threading kinetics at higher ratios of cucurbituril could also be explained by invoking 'side-on' complexation of cucurbituril to the ammonium groups along the polymer backbone (Fig. 4). Cucurbituril binds to all types of ammonium ions other than quaternary ones.[21,26] Fig. 4 is therefore a more accurate representation of the various competing modes of complexation that have to be considered for our system. However only through further experiments will it be possible to distinguish between queuing and 'side-on' complexation.

Post-threading of cucurbituril onto protonated linear poly(iminohexamethylene) results in a new, synthetically accessible class of pseudopolyrotaxanes, which contain a controllable number of macrocyclic units.

We would like to thank the EPSRC for providing an IPSI project studentship for D. T.

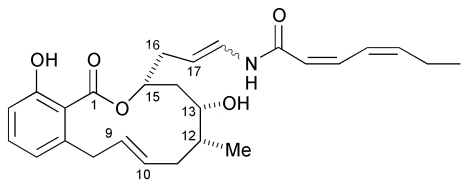
Received (in Corvallis, OR, USA) 1st November 2000, Accepted 20th December 2000
First published as an Advance Article on the web 23rd January 2001

The macrolactone core structure of the salicylihalamides was prepared from diacetone-D-glucose and *via* a ring-closing metathesis reaction.

Salicylihalamides A and B (**1** and **2**) are naturally occurring



1 Salicylihalamide A (*E*)-enamide
2 Salicylihalamide B (*Z*)-enamide

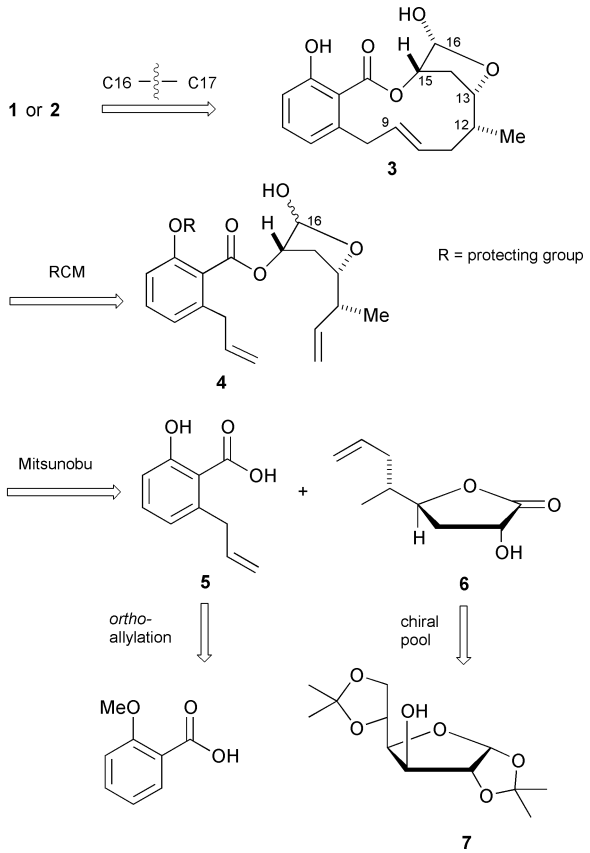
cytotoxic macrolides isolated from an Australian sponge *Haliclona* sp. in 1997.[1] They were the first examples of a novel class of macrolides that have in common the salicylic acid moiety and an unsaturated enamide side chain.[2–6]

This class of compounds possesses diverse biological activities, including inhibition of tumor cell proliferation.[1–6] Salicylihalamide A displayed a striking pattern of differential cytotoxicity in the NCI's 60-cancer cell line human tumor screen.[1] COMPARE pattern-recognition analyses[7] of the mean-graph profiles of salicylihalamide A suggest that the salicylihalamides may act by a novel mechanism of action. Despite their promise as potential anticancer agents, further studies of this new class of compounds are hampered by limited availability from natural sources. The unique structural features of the salicylihalamides coupled with promising biological activity prompted us to develop a flexible approach toward the synthesis of these molecules and related analogues.

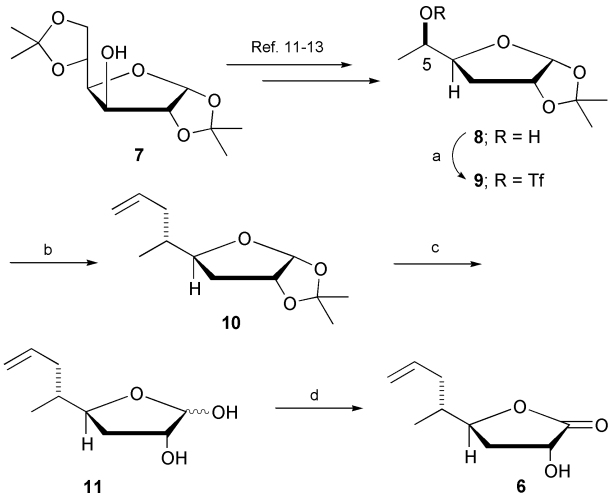
We initially focused on the synthesis of intermediate **3** (Scheme 1), the macrocyclic core structure of the salicylihalamides containing the three chiral centers and the $\Delta^{9,10}$ *E*-alkene. The masked aldehyde functionality in **3** provides an opportunity for side chain attachment at C16 and subsequent completion of the total synthesis.

Our synthetic strategy for the preparation of building block **3** features the use of readily available diacetone-D-glucose as the source for the three chiral centers of the molecule (chiral pool approach). The regioselective formation of the *E*-double bond at C9 was accomplished through a ring-closing metathesis (RCM) reaction employing intermediate **4**. Although the RCM strategy has been used before to form the 12-membered macrolactone ring of unsubstituted or side chain truncated salicylihalamides,[8,9] we herein report the use of the same protocol with a fully-substituted salicylihalamide macrocyclic core. Intermediate **4** can be obtained from lactone **6** *via* Mitsunobu esterification with 6-allylsalicylic acid (**5**). 6-Allylsalicylic acid (**5**) can be prepared from *O*-methylsalicylic acid[10] and diacetone-D-glucose **7** is the precursor for lactone **6**.[11,12]

The macrolide synthesis started with known alcohol **8**, which was prepared in five straightforward steps from diacetone-D-glucose (Scheme 2).[11–13] The secondary hydroxy group in **8**

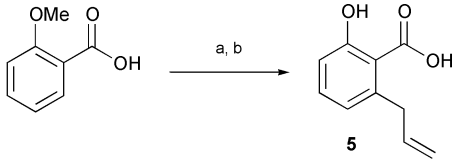


Scheme 1 Retrosynthesis for the salicylihalamide macrolide.



Scheme 2 *Reagents and conditions*: (a) Tf_2O, 2,6-dimethylpyridine, 0 °C, 1.5 h; (b) $(CH_2{=}CHCH_2)_2Cu)CN)Li_2$, THF, −78 °C, 2 h, 78%; (c) 70% aq. acetic acid, 70 °C, 6 h, 98%; (d) Ag_2CO_3–Celite, 80 °C, 1 h, 85%.

DOI: 10.1039/b008842k

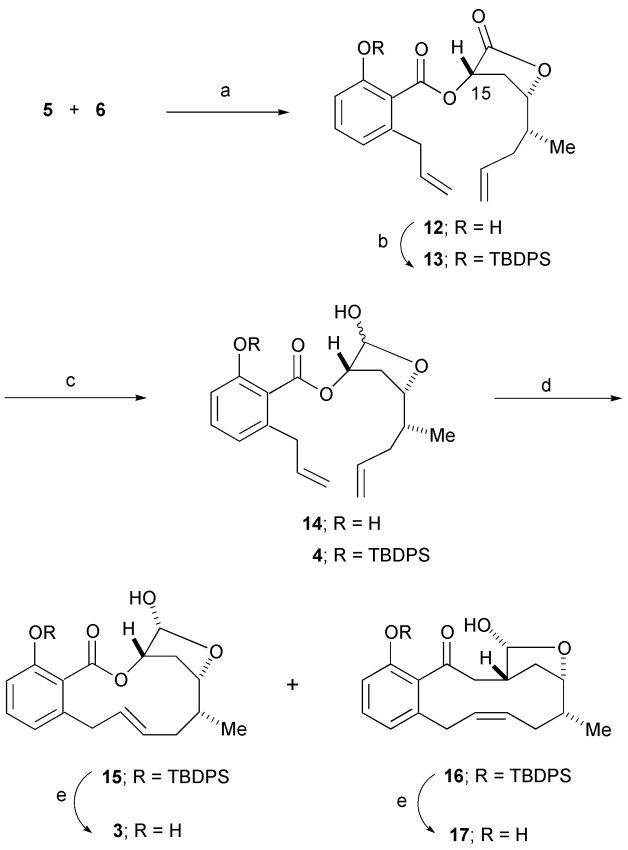


Scheme 3 *Reagents and conditions*: (a) *sec*-BuLi, TMEDA, THF, allyl bromide, −90 °C to rt, 0.5 h, 46% (based on recovered starting material); (b) BCl_3, $(n\text{-Bu})_4NI$, DCM, −78 °C, 2 h, 80%.

was converted to its corresponding triflate **9**, which was reacted immediately and without purification with a higher order allylcyanocuprate to provide **10** with inversion of configuration in 78% yield† (Scheme 2). Deprotection of the acetonide group was carried out with 70% acetic acid to yield alcohol **11**. Selective oxidation of the anomeric hydroxy group with Ag_2CO_3–Celite afforded lactone **6** in excellent yield. The synthesis of **5** was carried out in a two-step sequence as outlined in Scheme 3. Ortho-lithiation of *O*-methylsalicylic acid with *sec*-BuLi–TMEDA and quenching the carbanion with allyl bromide,[10] followed by deprotection of the methyl ether using BCl_3–$(n\text{-Bu})_4NI$,[14] afforded **5** in moderate overall yield.

Esterification of carbohydrate building block **6** with **5** under Mitsunobu conditions (Scheme 4) afforded intermediate **12** in good yield.

After the three stereogenic centers had been installed, the next step was the RCM reaction to form the $\Delta^{9,10}$ alkene. Surprisingly, RCM employing lactone **12** failed to give any of the desired product. Therefore the lactone functionality of **12** was reduced to lactol **14** (88:12, α:β; 80% yield) using DIBAL-H at −78 °C. RCM reaction with this substrate provided the desired reaction product. However, the *Z* isomer



Scheme 4 *Reagents and conditions*: (a) Ph_3P, DEAD, THF, −20 °C to 0 °C, 1 h, 85%; (b) TBDPSCl, imidazole, DMF, rt, 1 h, 85%; (c) DIBAL-H, ether, −78 °C, 2 h, 80%; (d) $RuCl_2$=CHPh)$(PCy_3)_2$, DCM, reflux, 3 h, 60%; (e) TBAF, THF, rt, 1 h, 85%.

was found to be the major reaction product (*E*:*Z* ratio 15:85; 60% yield). When the phenolic hydroxy of **12** was protected as its TBDPS ether **13** (85% yield) and lactone **13** was reduced to lactol **4** (80% yield), RCM of intermediate **4** furnished the two stereoisomeric lactols **15** and **16** in a 70:30 *E*:*Z* ratio and in 60% yield. The introduction of the sterically demanding TBDPS protecting group apparently promotes a conformational change in the transition state of the RCM reaction that favors the formation of the *E*-alkene. After deprotection of the silyl ethers **15** and **16**, the stereoisomers **3** and **17** (85% yield) were separated by column chromatography furnishing the desired *E*-isomer **3** in 60% yield.

Having completed the synthesis of the macrolactone with correct stereo- and regiochemistry,[15] studies directed at introducing the enamide side chain are in progress.

This work was financially supported by the National Cancer Institute (N01-CM-67259 and RO1 CA84173), and the Drug Discovery Program of the Higuchi Biosciences Center at the University of Kansas. B. B. gratefully acknowledges financial support from predoctoral NIH training grant GM-07775 and the American Foundation for Pharmaceutical Education (AFPE) for a predoctoral fellowship. F. F. is grateful for an AAPS-AFPE 'Gateway' Research Scholarship for undergraduate students.

Breast cancer marker T-antigen (Gal(β1-3)αGalNAc) was prepared as an allyl glycoside that was transformed into an active ester and coupled to a series of poly(amidoamine) dendrimers showing strong binding to mouse monoclonal IgG antibodies and serving as useful coating antigens in microtiter plates.

Poly(amidoamine) (PAMAM) dendrimers[1] are actually scrutinized as core structures bearing various pharmacophores for potential applications in biomedical fields such as DNA transfection,[2] inhibition of pathogenic infections,[3] and toxicity, immunogenicity and biodistribution to organs.[4] PAMAM have further broadened their potential usefulness to biological systems by combination with different carbohydrate moieties.[5–7] Chemically well defined monodisperse neoglycoconjugates with several covalently attached carbohydrate residues, can efficiently compensate for the usually weak affinities of individual haptens *via* cooperative binding interactions.[8] However, in spite of these potential biological applications, systematic preparation and biological evaluation of PAMAM-based T-antigen, Gal(β13)αGalNAc, glycodendrimers have not been reported to date.

T-antigen (Thomsen–Friedenrich antigen) has been reported as a cancer-related epitope and as an important antigen for the detection and immunotherapy of carcinomas, particularly relevant in breast cancer.[9] For pharmaceutical applications, T-antigen containing linear glycopolymers have been employed in solid-phase glycosyl transferase assays for high-throughput screening in cancer drug discovery research.[10] Recently, we have reported that mouse monoclonal antibodies raised against the T-antigen recognised breast cancer tissues selectively.[11]

These biological and immunochemical results motivated the synthesis of well defined T-antigen-glycoPAMAMs that can be used as vaccines or as antibody targeting species. Their binding properties against mouse monoclonal IgG antibody has also been evaluated. The synthetic strategy for the construction of T-antigen-containing glycoPAMAMs was based on amide bond formation between amine terminated PAMAM cores **10**–**13** and acid functionalized T-antigen derivative **9**.

α-D-GalNAc derivative **2**† was prepared in 3 steps from *N*-acetylglucosamine (**1**) by a C-4 epimerization strategy using an adaptation of documented procedure (Scheme 1).[12] Compound **2** was debenzoylated under Zemplén conditions (NaOMe, MeOH) and subsequently exposed to either benzaldehyde–zinc chloride or benzaldehyde dimethyl acetal and a catalytic amount of toluene-*p*-sulfonic acid monohydrate to give 4,6-benzylidene protected glycosyl acceptor **3** in 87% yield after deprotection. Compound **3** was coupled with peracylated galactosyl bromide (**4** or **5**) using mercuric(II) cyanide as a promoter at rt to provide disaccharides **6** and **7** in 98 and 78% yields, respectively. Successive de-O-acylation (MeONa–MeOH) and de-acetalation (aq. AcOH, 60 °C) afforded the desired T-antigen **8** in 95% overall yield. Finally, radical initiated 3-mercaptopropionic acid addition to **8** in the presence of UV light (254 nm) under deoxygenated aqueous conditions gave acid functionalized **9** in 83% yield.

PAMAM cores **10**–**13** were conjugated *via* amide bond formation with a slight excess acid **9** (1.1 eq.) using TBTU‡ reagent (Scheme 2). The reaction mixtures were lyophilized to dryness and the residues were purified by either gel permeation chromatography (P-2 or P-4, H_2O) or dialysed against water (2000 molecular weight cut-off). After purification, T-antigen-glycoPAMAMs, **14**–**17** (Fig. 1) with 4, 8, 16, and 32 T-antigen residues were obtained in excellent yields (73, 81, 99, and 79%, respectively).

On the basis of negative ninhydrin tests, mass spectrometry (FAB-MS), and high field ^{1}H NMR spectral data, the extent of conjugations were shown to be complete. The ratios of the NMR signals, fully assigned using COSY and HMQC experiments (D_2O, sensisitivity $\leqslant 2 \sim 3\%$; ± 1 residue/30), clearly confirmed the total incorporation of the T-antigen residues by comparing the relative integration of the two methylene signals of the dendritic cores (δ 2.80 for **14** and **15**, 2.77 for **16** and 3.05 ppm for **17**, respectively) to those of the two anomeric protons of the T-antigen (δ 4.96 for H-1 and 4.56 ppm for H-1′ respectively).

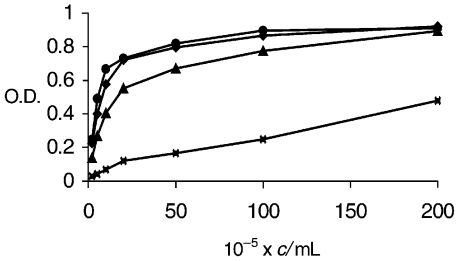

Fig. 1 ELISA of T-antigen-glycoPAMAMs, **14**(●), **15** (×), **16** (◆) and **17** (▲) with mouse monoclonal IgG antibody, goat anti-mouse IgG-horseradish peroxidase conjugate and ABTS-H_2O_2 as enzyme substrate. O.D. (410 nm) = optical density, ABTS = 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid). *C*: Relative concentration.

The binding properties of glycoPAMAMs to mouse monoclonal IgG antibody (MAb)[11] were initially evaluated by enzyme linked immunosorbent assay (ELISA) (Fig. 1). GlycoPAMAMs were used as coating antigens to determine their ability to capture antibodies on the surface of the microtiter plates. Goat anti-mouse MAb IgG-horseradish peroxidase (HRP) conjugate was used for quantitative detection. The ability of the mouse MAb to recognise all glycodendrimers was clearly demonstrated (Fig. 1). Compound **17**, having 32 T-antigen residues, was shown to be the best ligand. To obtain an optical density value of 0.6, 90 μmol of coating glycodendrimers was needed. This value represents 2- to 4-fold increased binding potentials over those of **15** (16-mer) and **16** (8-mer) (330 and 150 μmol, respectively) which where > 25-fold more potent than tetramer **14** (> 2 mmol).

The efficiency of these glycoPAMAMs for protein-binding interactions were further substantiated by competitive double sandwich inhibition where conjugates **14**–**17** were employed as inhibitors. T-antigen-*co*-polyacrylamide (T-antigen–acrylamide, 1 : 10)[13] was used as a coating antigen. To this end, the T-antigen polymer (1μg well^{-1}, 0.85 nmol of T-antigen in PBS) was deposited in the microtiter plates. In separated plates (Nunclon, Delta), mouse-MAb IgG (50 μL well^{-1}, 0.25 μmol in PBS-tween) and glycoPAMAM inhibitors (50 μL well^{-1} in PBS-tween with varying concentrations from 275 to 1.07 nmol well^{-1}) were preincubated. After blocking the microtiter plates with bovine serum albumin (BSA), the wells were filled with the mixture of antibody–glycoPAMAM inhibitors (100 μL well^{-1}) and the mixtures were then incubated for 1 h at 37 °C. For the quantitative detection of antibodies, goat anti-mouse MAb-HRP was then added, as above. Based on bulk conjugates, the glycoPAMAMs with highest carbohydrate density (**17**) exhibited the strongest inhibitions. Conjugates **14**–**17** showed IC_{50} values of 5.0, 2.4, 1.4 and 0.6 nmol, respectively where monomeric T-antigen **8** needed 2.3 μmol. The inhibitory abilities of these conjugates were thus 460, 960, 1700 and 3800 times higher than that of monomer **8**. Interestingly, when expressed on a per saccharide basis, all dendrimers were equivalent to one another (115 fold better than **8**), thus supporting previous observations that low density glycoPAMAMs are efficient inhibitors.[5]

In conclusion, geometrically well designed starburst T-antigen-glycoPAMAMs were efficiently synthesized with valencies between 4 to 32 using efficient peptide coupling strategy. A series of bioassays with mouse MAb IgG demonstrated that these conjugates strongly bound to the antibody. All conjugates were antigenetically active as previously demonstrated with analogous structures.[5–7] Moreover, some carcinoma cells have been reported to express T-antigen binding sites,[14] it is therefore possible that the compounds described herein may also find applications in specific cancer cell targeting.

A coordination polymer with the $[Au(CN)_2]^-$ building block has been prepared and it exhibits weak Au(I)-mediated ferromagnetic interactions; the structure illustrates that aurophilicity is a powerful tool to increase dimensionality, generating a three-dimensional system from a 1-D polymer.

The design of multidimensional coordination polymers is an area of intense current interest.[1] In particular, as many useful properties (magnetism, conductivity, host–guest chemistry, *etc.*) manifest themselves in 2- or 3-D networks, it is important to be able to generate high-dimensionality systems. The incorporation of moieties capable of forming hydrogen bonding interactions into coordination polymers is perhaps the most well-developed method for increasing structural dimensionality.[2] On the other hand, gold(I) centres are known to form weakly bonding interactions with themselves; these 'aurophilic' interactions have the same order-of-magnitude strength as hydrogen bonds.[3] The supramolecular chemistry of gold(I) is replete with systems that are polymeric by virtue of these Au–Au interactions,[4] but aurophilic interactions have not generally been used as a tool to increase structural dimensionality in coordination polymers containing metals other than gold.

Dicyanoaurate, $[Au(CN)_2]^-$, is an ideal building block to explore this concept. The molecule is linear, should readily form coordination polymers as do other anionic metal–cyanide units,[5] is sterically unencumbered and forms aurophilic interactions in the solid state.[6] We present here the first coordination polymer using this building block in which aurophilic interactions increase the dimensionality from one to three dimensions. $M[Au(CN)_2]_2$ (M = Co, Zn) complexes have been reported to form unusual quartz-like nets in which Au···Au bonding plays a secondary role.[7]

The reaction of an aqueous solution of $Cu(ClO_4)_2{\cdot}6H_2O$ containing one equivalent of tmeda (*N*,*N*,*N*′*N*′-tetramethylethylenediamine) with an aqueous solution of $K[Au(CN)_2]$ (2 equiv.) produced an immediate blue precipitate.[8] Elemental analysis indicated a compound of stoichiometry (tmeda)-Cu$[Au(CN)_2]_2$ (**1**). The IR spectrum of **1** is diagnostic due to the presence of multiple absorptions in the CN region. $K[Au(CN)_2]$ has a single absorbance at 2141 cm^{-1}; **1** has three CN absorbances at 2152, 2174 and 2191 cm^{-1}. The high-energy bands likely correspond to bridging CN groups.[5] Single crystals of **1** could be obtained by slow diffusion of the two reagent solutions in an H-shaped tube. Infrared data were identical for both the powder and the crystals.

The X-ray crystal structure of **1** confirms the molecular formula of (tmeda)Cu$[Au(CN)_2]_2$ and reveals a polymeric network.[9] Note that, unlike many other linear building blocks that have been examined (*e.g.* pyrazine, 4,4′-bipyridyl),[10] $[Au(CN)_2]^-$ is anionic, and hence chemically uncharged polymers are generated.[11] The Cu(II) centre in **1** has a five-coordinate, distorted square pyramidal geometry, with one tmeda and three CN nitrogen atoms completing the coordination sphere. The asymmetric unit contains three unique gold centres—Au(2) and Au(3) have CN groups with both ends bound to a Cu(II), while Au(1) has one Cu(II)-bonded CN group and the other CN group is free. As shown in Fig. 1, the Cu(1)–NC–Au(2)–CN–Cu(1*)–NC–Au(3)–CN– fragment infinitely repeats in the *b* direction, giving rise to a coordinately bonded 1-D zig-zag chain. The Cu–N(4) bond length of 2.270(8) Å is significantly longer than the other four Cu–N bond lengths, hence the dangling $[Au(CN)_2]$ unit (Au(1)) is less strongly bound to the Cu centre than those in the polymer backbone. The intrachain Cu(1)–Cu(1*) distance is 10.18(1) Å.

Each gold centre is a site for potential aurophilic interactions to occur. Indeed, the picture of the solid-state structure is incomplete without including them. The Au(2) and Au(3) atoms in the backbone of the 1-D zig-zag chain form *interchain* Au···Au bonds of 3.5378(8) Å in the *a* direction (*i.e.* out of the plane of the paper). This distance is less than the sum of the van der Waals radii of two Au atoms (3.60 Å)[3] and is hence a viable, weak Au···Au interaction. This effectively joins two 1-D chains together to form a 2-D array of alternating 1-D zig-zag chains in the *ab* plane, as shown in Fig. 1. Each Au(2) and Au(3) centre is loosely four-coordinate.[6]

On the dangling $Au(CN)_2$ unit, Au(1) forms moderate Au···Au interactions of 3.345(1) Å with Au(1*) on the adjacent

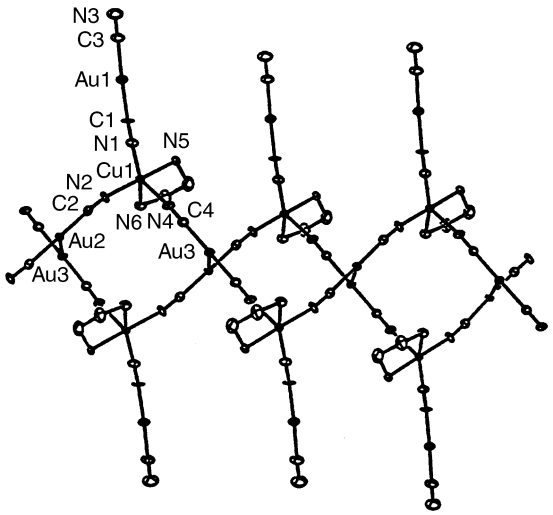

Fig. 1 Extended 2-D structure viewed down the *a* axis of (tmeda)-Cu$[Au(CN)_2]_2$ (**1**), with its numbering scheme, showing a 1-D coordinately bonded zig-zag chain in the *b* direction, connected in the *a* direction by Au···Au bonds to an adjacent, inverse-sense chain (ORTEP, 50% ellipsoids). Tmeda-methyl groups have been removed for clarity. Selected bond lengths (Å) and angles (°): Cu–N(1) 2.006(9), Cu–N(2) 1.992(8), Cu–N(4) 2.270(8), Cu–N(5) 2.048(8), Cu–N(6) 2.080(8), Au(2)–Au(3) 3.5378(8), Cu–Cu* 10.18(1); N(1)–Cu–N(2) 91.6(4), N(1)–Cu–N(4) 103.6(3), N(1)–Cu–N(5) 90.5(3), N(1)–Cu–N(6) 157.2(3), N(2)–Cu–N(4) 89.3(4), N(2)–Cu–N(5) 176.2(4), N(2)–Cu–N(6) 91.2(4), N(4)–Cu–N(5) 93.3(3), N(4)–Cu–N(6) 99.0(3), N(5)–Cu–N(6) 85.7(4), Cu–N(1)–C(1) 165.2(9), Cu–N(2)–C(2) 171.2(9), Cu–N(4)–C(4) 166.9(9).

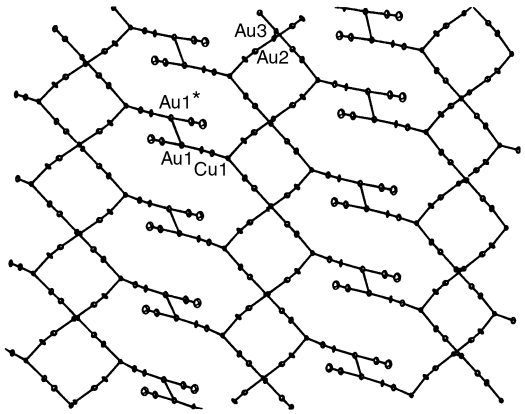

Fig. 2 Complete three–dimensional structure of **1**. Tmeda ligands have been removed for clarity. Au(1)–Au(1*): 3.345(1) Å.

1-D chain in the *b* direction (*i.e.* in the plane of the page), yielding a ladder-rung type motif running parallel to the 1-D chains. This Au···Au bonding in the *bc* plane, connecting the 2-D array of chains illustrated in Fig. 1, transforms the structure into a true three-dimensional system, as shown in Fig. 2. The presence of gold···gold interactions has effectively increased the dimensionality from a 1-D coordination polymer to a 3-D system.

The variable temperature magnetic susceptibility of **1** was measured from 2 to 300 K at a field strength of 1 T.[12] At 300 K, μ_{eff} is equal to 1.94 μ_B, a value typical for a system of isolated Cu(II), d^9, centres. This value steadily increases on decreasing the temperature, behaviour indicative of ferromagnetic interactions, to a maximum value of 2.05 μ_B at 25 K, below which temperature it decreases on further cooling. This latter decrease could arise either from the onset of saturation effects or very weak antiferromagnetic exchange. From a magnetic point of view, **1** could be considered as a 1-D chain, assuming that negligible magnetic interactions are propagated through the Au···Au bonds. We were unable to model the magnetic data over the entire range of temperatures studied. However, the χ_M *vs.* *T* data above 30 K were successfully fitted to theory employing the polynomial expression of Baker *et al*. for a 1-D ferromagnetic chain of $S = 1/2$ spins.[13] The magnetic moment *versus* temperature data are shown in Fig. 3, where the solid line is calculated from theory employing the best fit values of $g = 2.22$ and *J*, the exchange coupling constant, 2.34 cm^{-1}. From this analysis it appears that the diamagnetic $Au(CN)_2^-$ unit may propagate weak ferromagnetic coupling in this compound. Note

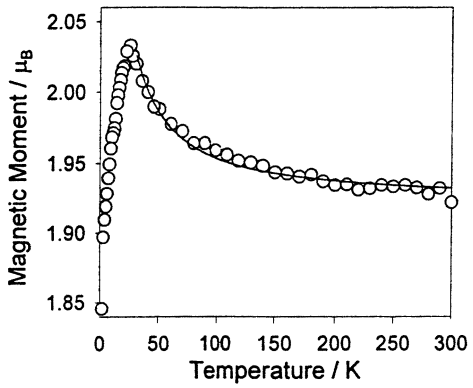

Fig. 3 Magnetic moment *versus* temperature plot for **1**. The solid line is theory (see text).

that in the related $[Ni(en)_2]_3[Fe(CN)_6](PF_6)_2$ system, the diamagnetic Fe(II) cyanide unit also mediates ferromagnetic interactions between the Ni(II) centres.[14]

In summary, a new coordination polymer with the neglected $[Au(CN)_2]^-$ building block has been prepared and crystallized. The structure confirms the concept that aurophilicity is a powerful tool to increase dimensionality in supramolecular coordination polymers.

A simple route to tetraaryltetrabenzoporphyrins (Ar_4TBPs) is developed; the procedure allows for the introduction of substituents on both benzo- and phenyl-rings and employs readily available, inexpensive components.

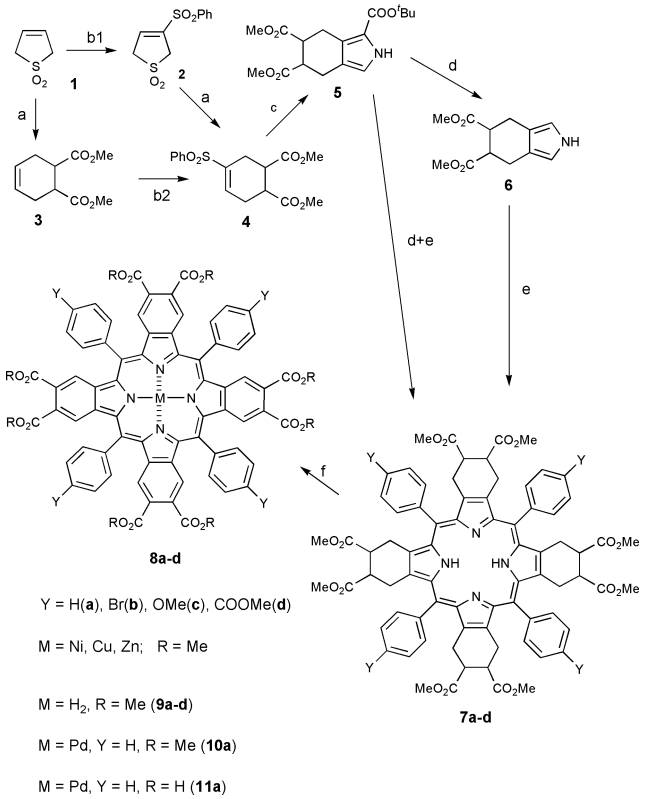
Tetrabenzoporphyrins (TBP's) and their metal complexes have rapidly gained popularity as versatile near infra-red dyes. The spectrum of their applications encompasses PDT (photodynamic therapy),[1a] non-linear optical absorption,[1b] optical limiting[1c] and dioxygen measurements *in vivo* by phosphorescence quenching.[1d] Due to solubility considerations the *meso*-tetraarylsubstituted TBP's (Ar_4TBP) have proven to be the most useful, especially those bearing functional groups in benzo and/or in *meso*-phenyl rings, which permit their further derivatization. However, until very recently all synthetic methods leading to Ar_4TBPs were based on a high temperature condensation between phthalimide and phenylacetic acids,[2a] or similar donors of benzo- and phenyl-groups.[2b] The harsh conditions of this process (fusion at 350–400 °C) allowed for only a few inert substituents, such as alkyl groups or halogens,[3] to be introduced into the TBP macrocycle. In addition, low yields and complex, virtually inseparable mixtures of products[4] made the whole method quite impractical.

Since the obvious precursor of the Ar_4TBP cycle, isoindole, is highly unstable, the recent search for more convenient synthetic protocols centered around isoindole-precursors, *i.e. c*-annelated pyrroles. These are available *via* Barton–Zard isocyanoacetate chemistry and have proven to be useful for the synthesis of other symmetric extended porphyrins.[5] Two methods of TBP synthesis of this kind were reported to date. Both methods are based on the Barton–Zard reaction and involve the initial synthesis of either cycloalkyl[6] or bicycloalkenyl fused porphyrins.[7] These intermediate porphyrins are then aromatized by either base catalyzed elimination of sulfinate[6] or the thermal retro-Diels–Alder extrusion of ethylene.[7] The latter method affords Ar_4TBPs in excellent yields; however, the synthesis of the isoindole precursors themselves, *i.e.* bicycloalkenyl fused pyrroles, involves hazardous compounds such as nitroethyl acetate. Here we report an alternative route to the Ar_4TBP system, which is both simple and general. The procedure allows for the introduction of substituents in both benzo- and *meso*-phenyl rings while employing only inexpensive and readily available components.

In our approach, the common precursor of the synthesis is the inexpensive sulfolene **1**‡ (Scheme 1), which is converted to a tetrahydroisoindole *via* the Diels–Alder reaction with an appropriate dienophile,[8] followed by the introduction of the phenylsulfonyl group and subsequent Barton–Zard-type reaction of the resulting vinyl sulfone.[9] Tetrahydroisoindoles are further introduced into Lindsey condensation, giving tetracyclohexanoporphyrins, which are finally aromatized.

The first successful application of this approach to the synthesis of the substituted Ar_4TBPs is shown in Scheme 1.§

Sulfolene **1** is converted to 3-phenylsulfonyl-3-sulfolene[10] **2** (b1) using earlier published procedures.[11] Alternatively, Diels–Alder adduct **3** with dimethyl maleate (DMM) is obtained in 85% yield (a). Both products, **3** and **2**, are further transformed into sulfone **4**. Compound **3** reacts with PhSCl, which is followed by oxidation and elimination of HCl (b2); **2** participates in the similar Diels–Alder reaction (a) with DMM.[12] Sulfone **4** reacts with *tert*-butyl isocyanoacetate (c)[13] yielding cyclohexanopyrrole **5** in 70–95% yield, which is deprotected and decarboxylated by TFA in CH_2Cl_2 (d) in 35–40% yield. Pyrrole **6** obtained in this way is introduced into the Lindsey condensation (e),[14] which produces porphyrins **7a**–**d** in 25–35% yields. Alternatively, porphyrins **7a**–**d** can be obtained by directly reacting cyclohexanopyrrole **5** with benzaldehydes under Alder–Longo conditions (d+e), in which case deprotection–decarboxylation occurs *in situ* in the presence of TsOH. Such simplification of the synthesis is especially practical when yields of the one-pot procedure (8–12%) are comparable with yields of the stepwise decarboxylation-condensation (8–14%). Noteworthy is that in all cases porphyrins **7a**–**d** were isolated as dications rather than as free-bases (evidenced by UV-VIS



Scheme 1 *Reagents and conditions*: a, DMM, py, 140 °C, pressure tube, 85%; b1, (i) PhSCl. CH_2Cl_2; (ii) Et_3N; (iii) Oxone, MOH, 86% for three steps; b2, (i) PhSCl, CH_2Cl_2; (ii) MCPBA; (iii) DBU, 81% for three steps; c, $CNCH_2CO_2{}^tBu$, ^tBuOK, THF, Ar, 0 °C, 80–95%; d, TFA–CH_2Cl_2, Ar, rt, 35–40%; e, (i) YC_6H_4CHO, $BF_3{\cdot}Et_2O$, CH_2Cl_2; (ii) DDQ, 25–35% for two steps; d + e, YC_6H_4CHO (X = H), AcOH, TosOH, CH_2Cl_2, 8–12%; f, (i) $M(OAc)_2$, MeOH–$CHCl_3$; (ii) DDQ, THF or MeCN, reflux, M = Zn, Cu, Ni, 98% for two steps.

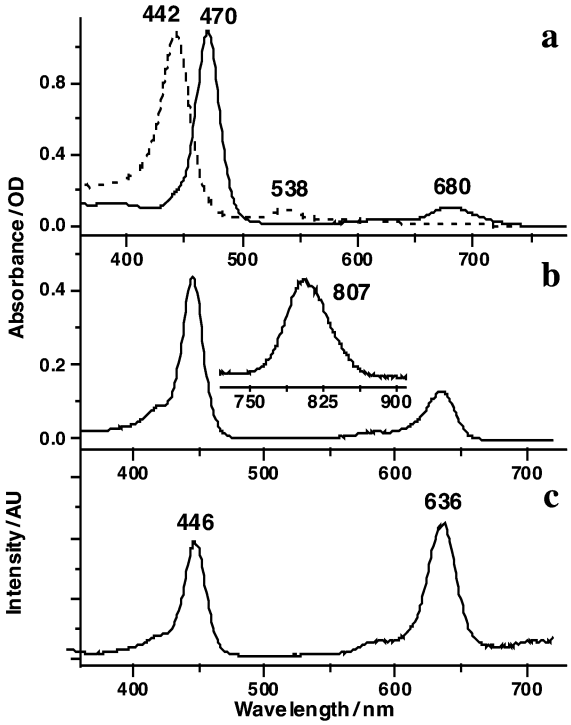

Fig. 1 (a) Absorption spectra of porphyrin **7a** in CH_2Cl_2 (solid line) and in pyridine (dashed line); (b) absorption spectrum of Pd-tetrabenzoporphyrin **11a** in water (pH 8.0). Insert shows uncorrected emission (phosphorescence) spectrum of **11a** in deoxygenated solution; (c) excitation spectrum of **11a** (corrected for the lamp intensity) related to the emission at 807 nm.

spectroscopy Fig. 1a). The dications could be fully deprotonated only in the presence of such bases as Et_3N or pyridine, which suggests that **7a**–**d** exhibit unusually high basicity.[15] The porphyrins **7a**–**d** were converted to their respective metal complexes and aromatized by refluxing with an excess of DDQ (f),[16] giving the MAr_4TBPs (M = Ni, Cu, Zn) **8a**–**d** in nearly quantitative yields. Interestingly, free-base porphyrins could not be aromatized under such conditions, most likely due to the formation of dications, which are apparently not oxidized by DDQ. The net yield of the entire sequence is 3–8%. Given that all starting compounds are readily available, this synthesis can afford gram quantities of substituted Ar_4TBPs in a single preparation.

Zn complexes **8a**–**c** could be quantitatively demetalated by treatment with TFA in CH_2Cl_2, to give free-base tetrabenzoporphyrins **9a**–**c**. The Pd complex of tetraphenyloctamethoxycarbonyltetrabenzoporphyrin **10a** was formed quantitatively upon reacting the free-base porphyrin **9a** with $PdCl_2$ in refluxing benzonitrile. Finally, the methoxycarbonyl groups of **10a** were deesterified ($NaOH–THF–H_2O$), giving tetraphenyloctacarboxytetrabenzoporphyrin **11a**, well soluble in basic aqueous solutions. The absorption and emission spectra of **11a** are shown in Fig 1b. The near infra-red emission with λ_{max} at 807 nm (phosphorescence) is completely quenched in the presence of molecular oxygen. In deoxygenated water solutions this phosphorescence has a lifetime of 107 μsec and a quantum yield of about 10%, which makes metalloporphyrin **11a** well suited for the lifetime oxygen sensing.[1d] Intriguingly the phosphorescence of **11a** has a significantly higher intensity if excited at the weaker Q-band, than at the Soret band. The corrected excitation spectrum of **11a**, recorded at a very high dilution (absorbance at Soret maximum (440 nm) 0.05 OD), is shown in Fig. 1c. Since no emission was observed directly from the S_2-state, such behavior is most likely due to the existence of uncommon non-radiative pathways of S_2 deactivation.

In summary, we have developed a new method of synthesis of Ar_4TBPs, which employs inexpensive, readily available starting materials. The method allows introduction of functional groups in both benzo- and phenyl- rings, thus providing a general route to the modified tetrabenzoporphyrin system. Newly synthesized tetrabenzoporphyrins were found promising basic phosphors for oxygen measurements by phosphorescence quenching.

8 It could be advantageous to conserve the sulfolene moiety until the last stages of the synthesis. However, the attempts to use sulfolenopyrroles in porphyrin synthesis lead to intractable materials of very low solubility. The only example of fused tetrasulfoleneporphyrin with highly sterically encumbered *meso*-aryl groups has been recently reported by B. Kräutler, C. S. Sheehan and A. Rieder, *Helv. Chim. Acta*, 2000, **83**, 583.

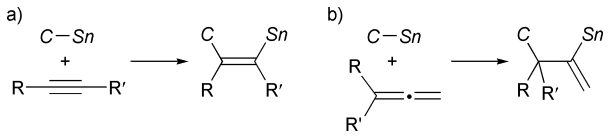
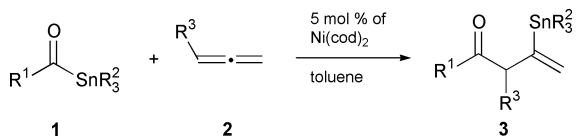
Bis(cycloocta-1,5-diene)nickel was found to be an effective catalyst for the acylstannylation of 1,2-dienes to give a wide variety of α-(acylmethyl)vinylstannanes, which were transformed to variously substituted conjugated and unconjugated enones by carbon–carbon bond forming reactions.

Alkenylstannanes are one of the most versatile synthetic reagents, since they can be transformed to various olefinic compounds through the reaction with organic electrophiles, *e.g.* the palladium-catalysed cross-coupling reaction.[1] Although the reaction of other alkenylmetals with stannyl halides provides an easy access to alkenylstannanes, this synthetic method cannot be applied to those having such a reactive substituent as carbonyl. Carbostannylation of alkynes has grown to be a powerful alternative route to alkenylstannanes, especially multi-substituted vinylstannanes (Scheme 1, a).[2] Herein we disclose that acylstannanes add to 1,2-dienes in the presence of a nickel catalyst[3] to give α-(acylmethyl)vinylstannanes[4] as main products (Scheme 1, b) and the resulting alkenylstannanes can be transformed to variously conjugated and/or unconjugated enones. To the best of our knowledge, this is the first demonstration of the transition metal-catalysed addition of a carbon–metal bond of organometallic compounds to 1,2-dienes.[5,6]



Scheme 1

Acylstannylation of monosubstituted allenes were carried out in the presence of a nickel catalyst (Scheme 2 and Table 1). The following procedure is representative (entry 1). A mixture of trimethyl(benzoyl)tin (**1a**) and 5 mol% of $Ni(cod)_2$ in toluene was heated at 50 °C for 1.5 h under an atmosphere of propa-1,2-diene (**2a**) to give 1-phenyl-3-trimethylstannylbut-3-en-1-one (**3a**) in 64% yield.[7] Analysis of the reaction mixture by ^{119}Sn NMR revealed that the ratio of **3a** and (*E*)-1-phenyl-3-trimethylstannylbut-2-en-1-one, derived probably through the isomerization of **3a**, was 97:3, although trimethyl(phenyl)tin, the decarbonylated product of **1a**, was obtained in a small amount. Addition of **1a** to hepta-1,2-diene (**2b**) took place mainly at the internal C–C double bond to give **3b** in 79% yield (entry 2).[8] Similar regioselectivity was observed in the reaction of 4,4-dimethylpenta-1,2-diene (**2c**) (entry 3). Arylallenes also participated in the acylstannylation with the selectivity of **3** being lowered by an electron-withdrawing substituent on the aromatic ring (entries 4–6). The reaction of 1-methoxypropa-1,2-diene (**2g**) proceeded with the benzoyl group of **1a** adding mainly at the carbon having the methoxy group albeit in a low yield (entry 7). The tributylstannyl derivative (**1b**) of **1a** also gave the acylstannylated product (entry 8). Tributyl(propanoyl)tin (**1c**) also added to various 1,2-dienes (entries 9–12). Noteworthy is that **2g** reacted with **1c** better than with **1a** to afford acylstannylation product **3l** in a higher yield. Aminocarbonylstannane **1d** reacted with allene (**2a**) in a low yield (entry 13).



Scheme 2

Disubstituted allenes also participated in the acylstannylation (Scheme 3). Acylstannanes **1a** and **1c** added to 3-methylbuta-1,2-diene (**2h**) with high regioselectivities. In addition, nona-4,5-diene (**2i**) also underwent the reaction, giving a stereoisomeric mixture of **3p** or **3q**.

The catalytic cycle is considered to be initiated by the oxidative addition of an acylstannane to a nickel(0) complex as is the case with the nickel-catalysed acylstannylation of 1,3-dienes, since the decarbonylation of acylstannanes was similarly observed as a side reaction.[3] Although the succeeding pathway remains yet to be clarified, two plausible catalytic cycles leading to the main products are presented in Scheme 4. In any event, the stannyl group invariably attacks the allene central carbon. In Cycle A, coordination of the less hindered double bond of 1,2-diene **2** on the nickel atom of oxidative adduct **4** followed by insertion to the Ni–Sn bond (stannylnickelation) affords the acylstannylation product through π-allylnickel complex **6**. According to Cycle B, the more hindered double bond of **2** coordinates on the nickel and then inserts to

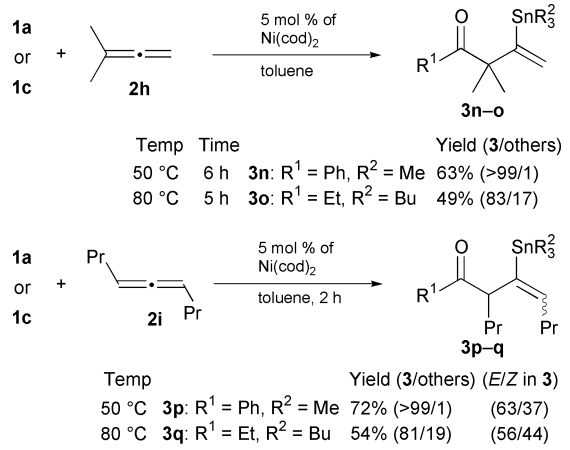
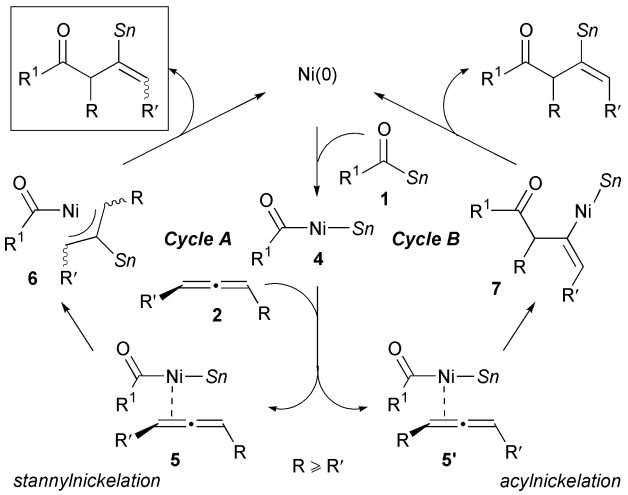
DOI: 10.1039/b008190f



Scheme 3

the C–Ni bond of **4** (acylnickelation), giving the product *via* alkenylnickel **7**.[9] The results that the acylstannylation of nona-4,5-diene (**2i**) gave a mixture of stereoisomers should give us a clue to discriminate the reaction mechanism. In the case that the reaction with **2i** follows Cycle B, only (*E*)-**3p** or **3q** should be provided through *syn*-addition of the C–Ni bond to the C–C double bond and stereo-retained reductive elimination. As this was not the case, Cycle A appears to be more plausible, although it is unclear yet why reductive elimination from **6** takes place mainly at the more hindered carbon of the allyl moiety.



Scheme 4

The applicability of the acylstannylation products was demonstrated by the transformation of **3i** to a wide variety of enones (Scheme 5). The reaction of **3i** with ethyl 4-iodobenzoate (**8**) in the presence of 2.5 mol% of $Pd_2(dba)_3$ gave the corresponding coupling product **9** in 91% yield[10] without cine-substitution.[1b] Conjugated β-arylenone **11** was obtained[11] by cross-coupling reaction with **8** after isomerization of **3i** to **10** by 20 mol% of sodium hydride, whereas the corresponding (*E*)-isomer **12** was obtained by base-catalysed isomerization of **9**. The cross-coupling of **3i** with benzoyl chloride proceeded to give 83% yield of enedione **13**. Stannylenone **3i** reacted with iodomethane in the presence of sodium hydride, giving dimethylation product **14**, which was subjected to the cross-coupling reaction with **8** to afford arylenone **15**. Thus, variously substituted conjugated and unconjugated enones were synthesized from a single acylstannylation product.

In conclusion, we have demonstrated that the acylstannylation of 1,2-dienes readily takes place to give α-(acylmethyl)-vinylstannanes, which were transformed to a wide variety of conjugated and unconjugated enones. Studies on details of the mechanism as well as synthetic applications to various

4 α-Substituted vinylstannanes are available by stannylcupration of alkynes followed by quenching the resulting C–Cu bond with methanol: J. A. Carbezas and A. C. Oehlschlager, *Synthesis*, 1994, 432.
5 There have been many reports on the transition metal-catalysed bismetalation of 1,2-dienes: for example, M. Suginome, Y. Ohmori and Y. Ito, *Synlett*, 1999, 1567 and references cited therein.
6 The palladium-catalysed three component coupling of 1,2-dienes, distannanes and organic iodides is reported to provide allylstannanes: F.-Y. Yang, M.-Y. Wu and C.-H. Cheng, *Tetrahedron Lett.*, 1999, **40**, 6055.
7 The reaction conditions are essentially identical with those used in the nickel-catalysed carbostannylation of alkynes, see ref. 2e.
8 The reaction mixture contains 2-methylene-1-phenyl-3-trimethylstannylheptan-1-one (5% yield) and (*E*)-1-phenyl-3-trimethylstannyloct-3-en-1-one (4% yield). Although we did not characterize the minor isomer(s) in the following entries thoroughly, peak(s) in ^{119}Sn NMR was always observed at −42.2 to 14.2 ppm, being attributed to an alkenyl- or allyl(trialkyl)stannane.
9 Platinum-catalysed diboration of monosubstituted allenes, which is considered to proceed *via* an alkenylplatinum complex similar to **7**, gave the (*Z*)-isomer stereoselectively. T. Ishiyama, T. Kitano and N. Miyaura, *Tetrahedron Lett.*, 1998, **39**, 2357.
10 Conjugated arylenone **12** was also generated in 5% yield.
11 The reaction mixture contains **12** (8% yield).

Silylcupration of styrenes followed by electrophilic trapping reaction

Vilnis Liepins and Jan-E. Bäckvall*

Received (in Cambridge, UK) 14th November 2000, Accepted 22nd December 2000
First published as an Advance Article on the web 23rd January 2001

Silylcupration reaction of styrene and its analogues with a silylcopper reagent $PhMe_2SiCuCNLi$ followed by an electrophilic trapping has been reported for the first time.

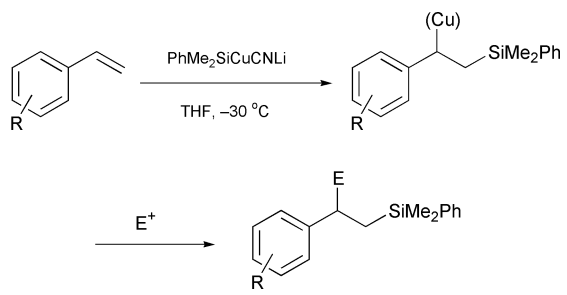
Silylcupration reaction of acetylenes and allenes has been studied by Fleming and co-workers.[1,2] Scarce literature data, however, is available on metallo-metallations of double bonds. Silylmanganation[3] and catalytic silicon–silicon bond addition to double bonds[4] and 1,3-dienes[5] involving silylpalladation have been reported. However, to the best of our knowledge, there are no reports in the literature on silylcupration of double bonds except for allenes.[2,6,7] Most of the silylcupration reactions have been done with the silylcuprate reagent $(PhMe_2Si)_2CuLi{\cdot}LiCN$ or more bulky silylcuprate reagents.[8] Recently, silylcopper reagent $PhMe_2SiCuCNLi$ has been used by Pulido[6] and us[7] in allene silylcupration reactions. The advantage of the silylcopper reagent $PhMe_2SiCuCNLi$ over the disilyl cuprate reagent is that it makes use of all the silyl on copper. With the latter reagent only one of the two groups is transferred and the remaining silylcopper reagent may lead to side products and hence separation problems.

Here we wish to report for the first time a silylcupration reaction of substituted and unsubstituted styrene. The copper intermediate obtained can be easily trapped by different electrophiles, including allylic phosphates, which are reactive and readily accessible allylic substrates for metal-catalysed reactions[7,9] (Scheme 1).

Reaction of styrene with silylcopper reagent $PhMe_2SiCuCNLi$ proceeds smoothly at −30 °C to give an organocopper intermediate, which was trapped by allyl diphenyl phosphate to give compound **1** in 73% yield (Table 1, entry 1).† The corresponding silylcupration of substituted styrenes and subsequent quenching by different allylic phosphates afforded adducts **2**–**8** in yields varying between 44–63% (entries 2–8). When hexenyl phosphate **13** was employed a mixture of α- and γ-regioisomers was obtained in a ratio of 35 : 65 (entry 5). In one case the intermediate silylcupration adduct was trapped by acetyl chloride to give **9** (entry 9).

The silylcupration of styrene was much slower than that of acetylenes[1] and allenes.[2,7] Thus, while the silylcupration of the latter two classes of compounds proceeds within 1 h at −40 °C, the silylcupration of styrenes had to be run at −30 °C for 3 h (for one substrate for 16 h, Table 1, entry 4).

Silylcuprate reagent $(PhMe_2Si)_2CuLi{\cdot}LiCN$[10] was also tried in the silylcupration reaction of styrene. Unfortunately, the desired product could not be isolated upon treatment with an electrophile since the cuprate reagent promoted polymerisation of the starting material, which resulted in a complex reaction mixture.



Scheme 1

Several styrenes substituted at the double bond such as α-methylstyrene, (*E*)-β-methylstyrene, indene, and (*E*)-stilbene were tried in this reaction but none of them was reactive enough to give any reaction product. In each case the starting material was recovered after the reaction. We believe that this is due to steric hindrance between the bulky phenyldimethylsilyl group and the substituent on the double bond.

In order to gain some insight into the reaction mechanism we studied the stereochemistry of the addition by the use of a specifically deuterated styrene. Reaction of (*E*)-β-deuteriostyrene[11] **10** with $PhMe_2SiCuCNLi$ followed by allyl diphenyl phosphate gave a 1 : 1 mixture of the two diastereomers **11a** and **11b**, which shows that the addition is non-stereospecific (Scheme 2). (Characteristic NMR data for non-deuterated product **1** (for notations see entry 1, Table 1): δ H_A = 1.26, H_B = 1.16, H_C = 2.73; J_{AB} = 14.8 Hz, J_{AC} = 5.0 Hz, J_{BC} = 10.0 Hz). Trapping of the intermediate copper-species resulting from the silylcupration of deuterated styrene **10** with acetyl chloride as electrophile also resulted in a 1 : 1 mixture of diastereomeric products. This indicates that the addition step of $PhMe_2SiCuCNLi$ to styrene is completely non-stereospecific.

A likely mechanism involves nucleophilic attack by the silylcopper at the terminal carbon of the styrene double bond in analogy with a conjugate addition. This may involve a copper(III)-intermediate[12] and leads to formation of a carbanion in the benzylic position. The latter carbanion would finally form a copper–carbon bond, which now can be formed with either configuration at carbon. A radical intermediate, which would also explain the 1 : 1 diastereomeric ratio of products from **10**, is less likely since in a control experiment in the presence of a radical inhibitor (1 mol% of 4-tBu-catechol) neither the rate nor the stereochemical outcome was changed.

The anionic mechanism is also supported by the fact that styrenes with electron-attracting groups react faster than those with electron-donating groups. This can be seen by the change of colour of the reaction mixture to deep violet, which in the case of 4-fluorostyrene appears almost immediately after the addition of 4-fluorostyrene but for styrene itself it takes longer to form the characteristic colour. Note that for 4-Me-styrene the reaction time had to be extended to 16 h in order to get the desired reaction product (Table 1, entry 4).

In conclusion, the silylcupration of styrenes followed by electrophilic trapping is reported for the first time. The reaction provides an extension to the widely studied silylcupration reaction of other unsaturated compounds. Mechanistic studies suggest that the reaction proceeds through anionic intermediates.

X-ray structural and *ab initio* theoretical investigations of a non-covalently linked *meso*-tetraphenylporphyrinatozinc(II) and *N*-methyl-2-pyrid-4′-yl)-3,4-fullero-pyrrolidine complex is reported

Studies on non-covalently linked donor–acceptor dyads are of current interest because of their potential applications in constructing photovoltaic devices and also, to mimic the primary events of photosynthetic reaction centers.[1] Fullerenes as the electron acceptor in these dyads are particularly appealing because of their unique three-dimensional structure, excellent electron acceptor property, and a small re-organization energy involved in electron transfer reactions.[2] However, studies on non-covalently linked donor–fullerene dyads are limited[3] especially with respect to their crystal structures where no information is yet available even though a number of molecules including calixarenes, cyclodextrins, cyclotriveratrylene and porphyrins are known to form intermolecular complexes with fullerenes.[4] Fullerenes are also well-known to co-crystallize with a variety of molecules which include benzene, ferrocene, Pd_6, Cl_{12}, P_4 and S_8 moieties.[5]

Recently, the formation of stable, non-covalently linked dyads by axial coordination of functionalized C_{60} bearing a pyridine unit to zinc tetrapyrrole macrocycles have been reported.[3] In one such studied dyad, the kinetic analysis of the fullerene π-radical anion transient absorption resulting from irradiation of the ZnTPP-C_{60} dyad yielded a remarkable lifetime of several hundred microseconds with a quantum yield of about 0.14 for the separated radical pair.[3c] This enhanced lifetime of the radical pair was attributed to the diffusional splitting of the initial charge separated radical pair. Since the structural and thermodynamic factors play a crucial role in controlling the charge separation and charge recombination process, we, in the present study have performed X-ray structural analysis and *ab initio* calculations at B3LYP/3-21G(*) level on a non-covalently linked zinc porphyrin–fullerene dyad.

Slow evaporation of a solution mixture of CS_2, CH_2Cl_2 and *n*-heptane containing *meso*-tetraphenylporphyrinatozinc and *N*-methyl-2-(pyrid-4′-yl)-3-4-fulleropyrrolidine of 1 : 1 molar ratio yielded dark purple crystals that subsequently were handled in air. In agreement with the earlier reported solution structure,[3] the X-ray structural analysis of the crystals revealed a 1 : 1 stoichiometry.† Fig. 1 shows the structure of the porphyrin–fullerene complex while the packing diagram is shown in Fig. 2.

In the solid state structure, the zinc to axially coordinated pyridyl nitrogen distance is found to be 2.158(5) Å which compares with a 2.075(5) Å average distance of the porphyrin ring Zn–N bonds and a Zn–N distance of 2.147 Å reported earlier for an intramolecularly linked zinc porphyrin–pyridine adduct.[6] The edge-to-edge distance, that is, the closest distance between the porphyrin π-ring carbon (β-pyrrole) and the C_{60} carbon of the axially linked fulleropyrrolidine, is found to be 3.51 Å while the center-to-center distance between the porphyrin zinc ion and fullerene is ~9.53 Å. The distance between the closely located *meso*-phenyl ring (*meta* carbon) of the porphyrin macrocycle and the C_{60} spheroid is found to be 3.186 Å. In agreement with recent theoretical predictions,[7] the

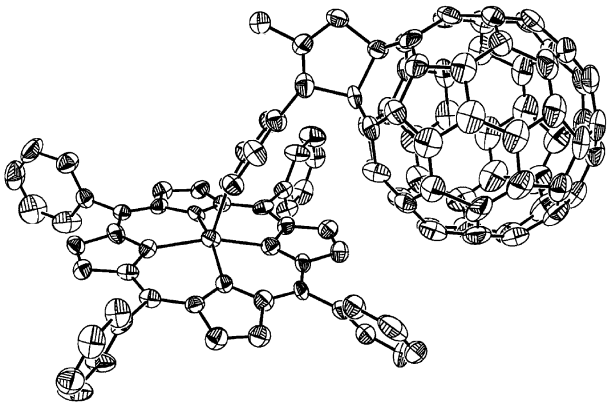

Fig. 1 Projection diagram of the axially coordinated *meso*-tetraphenylporphyrinato-zinc(II) and *N*-methyl-2-(pyrid-4′-yl)-3,4-fulleropyrrolidine complex with 50% thermal ellipsoids. The co-crystallized solvent, *n*-heptane and hydrogen atoms are not shown for clarity.

N-methylpyrrolidine ring on the fullerene spheroid revealed a *syn–trans* conformation. The 6,6 ring carbon atoms of the fullerene to which the pyrrolidine ring is attached is 0.33 Å away from the normal C_{60} spheroid. The porphyrin ring is also slightly ruffled (umbrella mode) with nearly 0.35 Å out-of-plane (defined by the four porphyrin ring nitrogens) displacement of the central zinc because of axial coordination.

Additional inter-complex type interactions between the zinc porphyrin and the C_{60} unit that is not directly coordinated to the zinc but located on the other side of the porphyrin macrocycle have been observed in the crystal packing (Fig. 2). That is, the

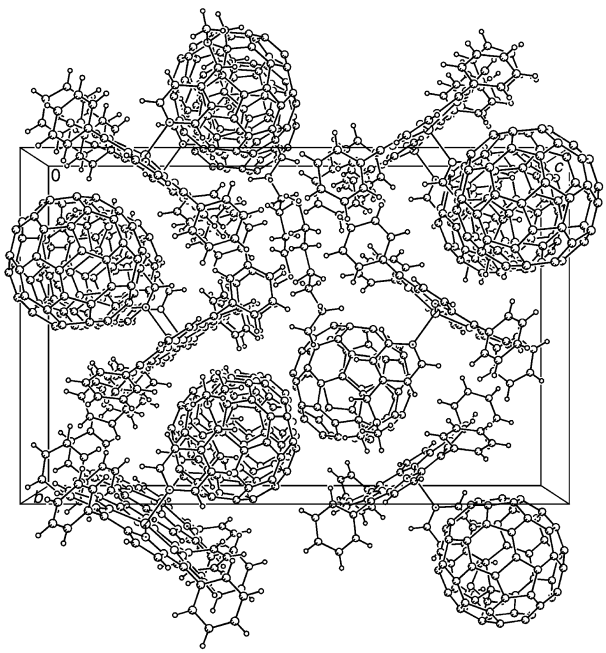

Fig. 2 Packing diagram of the investigated zinc porphyrin–C_{60} complex.

DOI: 10.1039/b009528c

calculated inter-complex distances between the porphyrin ring atoms and C_{60} carbon are close to the calculated van der Waals distances. The central zinc to the closest C_{60} carbon is located at 3.228 Å while this distance between the porphyrin ring nitrogen to C_{60} carbon is 3.114 Å. The nearest porphyrin ring carbon (α-pyrrole) to the C_{60} spheroid carbon is 3.360 Å. These results indicate the existence of significant amounts inter-complex interactions in addition to the strong axial coordinate interactions in the investigated self-assembled supramolecular complex.

In order to further our understanding on the structure of this non-covalently linked dyad, *ab initio* calculations at B3LYP/3-21G(*) level by using Gaussian 98[8] have been performed. For this, first, both the starting compounds, tetraphenylporphyrinatozinc and *N*-methyl-2-(pyrid-4′-yl)-3,4-fulleropyrrolidine were fully optimized to a stationary point on the Born–Openheimer potential energy surface and allowed to interact. The geometric parameters of the dyad were obtained after complete energy minimization. In the calculated structure, the Zn–N distance of the axial coordination bond is found to be ~2.03 Å which is close to the average distance of the four Zn–N bonds (2.10 Å) of the porphyrin and that obtained in the crystal structure (2.074 Å). The center-to-center distance, that is, the distance between the central zinc and the center of the C_{60} spheroid, is found to be ~9.63 Å. The edge-to-edge distance, that is, the distance between the closest *meso*-carbon of the porphyrin ring and the C_{60} carbon, is ~5.17 Å while this distance between the closest β-pyrrole carbon and C_{60} spheroid carbon is ~4.69 Å. Generally, the tilting of the C_{60} unit towards the porphyrin ring is more in the crystal structure than that in the calculated structure, which may be a result of crystal packing. The calculated bond dissociation energy of the axial coordinate bond, that is, the energy difference between the dyad and the sum of the energies of individual zinc porphyrin and fulleropyrrolidine units, is found to be 28.21 kcal mol^{-1} and this compares well with a value of 26.91 kcal mol^{-1} obtained experimentally in 1,2-dichlorobenzene.[3d]

In summary, this paper presents the first X-ray structure of a non-covalently linked porphyrin–fullerene donor–acceptor dyad. The structure agrees well with the theoretically calculated one and the earlier reported spectroscopic studies. Further studies along this line are in progress.

Ring opening of 1-alkanoyl-2-phenoxymethylaziridines by phosphate ions yielding self-assembling phospholipid analogues proceeds in an autocatalytic fashion and with complete regioselectivity at an organic–aqueous interface.

Biological transformations are known to take place with high rates and high degrees of regio- and stereospecificities. This is achieved—amongst others—by positioning the reactants in a well defined manner with respect to each other, *e.g.* in the active site of an enzyme or at the surface of a biomembrane. Many model systems have been developed in order to mimic the supreme action of biomolecules.[1] This has led to important improvements in conversion rates of molecules and in increased regio- and stereospecificities of their reactions. Of special interest in this respect are the autocatalytic[2] and self-replicating[3] biomimetic systems that have been reported in the literature. In the present communication we describe a reaction, *i.e.* the synthesis of chiral amide containing surfactants, which proceeds in an autocatalytic manner and with complete regioselectivity by orienting the reactants at an organic–aqueous interface.

The self-assembly of amide-containing phospholipid analogues (*e.g.* **2** and **3**), has yielded a variety of interesting, and in many cases chiral, aggregate morphologies.[4] Thus far these compounds have been prepared from enantiopure *N*-acylaziridines (**1**) *via* a nucleophilic ring opening with dibenzyl phosphoric acid in organic solvent (Scheme 1). However, in all cases this procedure led to the formation of the two regioisomeric products, *i.e.* compounds **2** and **3**, in molar ratios ranging from 1:1 to 6:1.[5]† We hypothesised that in order to achieve a selective ring opening the *N*-acylaziridine molecules must be preorganised in such a way that only one of the ring carbon atoms is accessible to the nucleophilic species. It was anticipated that compound **1** would orient itself at an aqueous interface such that the C(1) carbon atom of the aziridine ring points towards the aqueous layer while the hydrophobic part of the molecule minimises its contact with water (Fig. 1a).

The ring opening of compound **1** was performed at 40 °C in a two phase system comprising an aqueous phosphate buffer (2.0 mM, pH = 7.0, 4.0 ml) and a top layer in which the starting material (9.0 μmol) is present as an oil. The progress of the reaction was conveniently monitored by determining the concentration of the aziridine in the aqueous phase using reversed phase HPLC.‡ The generated products were analysed by capillary electrophoresis using a borate buffer containing β-cyclodextrin.[6]§

As an example the conversion of **1a** (R = $C_{12}H_{25}$) to **2a** is given. In the first 9 h of the reaction neither compound **1a** nor any reaction products were detected in the aqueous phase, suggesting that at this stage the ring opening was slow since it could only take place at the oil–aqueous buffer interface. After this period vesicles with diameters of 75–350 nm were formed as was demonstrated by electron microscopy (Fig. 1b). Concomitant with the formation of the vesicles the concentration of **1a** in the aqueous phase increased, suggesting that these vesicles facilitated the transfer of the *N*-acylaziridine to the water layer. The concentration of **1a** in the buffer reached a maximum after 24 h (~25% of **1a** in the aqueous phase). Thereafter, it decreased, and the reaction was completed after approximately 80 h. Increasing the buffer concentration to 10.0 mM led to an enhancement of the reaction rate (complete

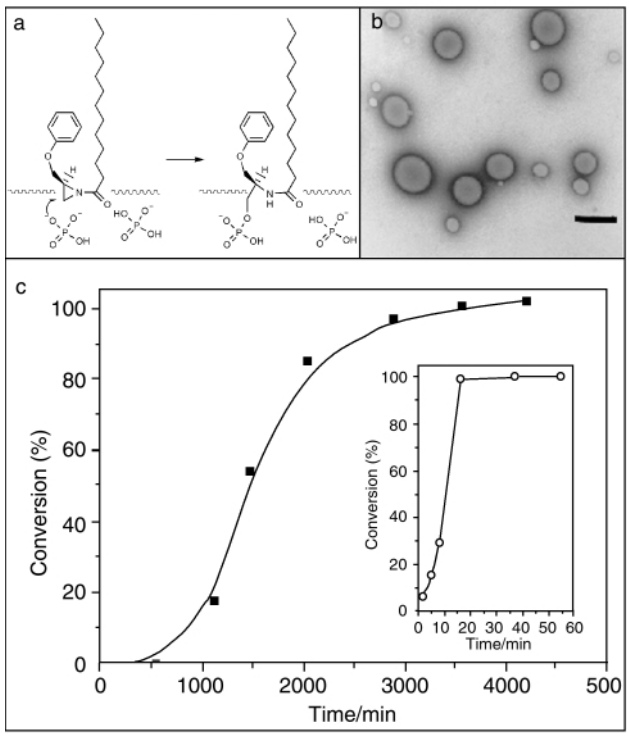

Fig. 1 (a) Proposed mechanism for the regioselective ring opening of **1**; (b) transmission electron micrograph of vesicles produced by ring opening of **1a** (negative staining, bar represents 350 nm); (c) the conversion **1a** in the absence of preformed vesicles of **2a**. Inset: *idem*, in the presence of preformed vesicles of **2a**.

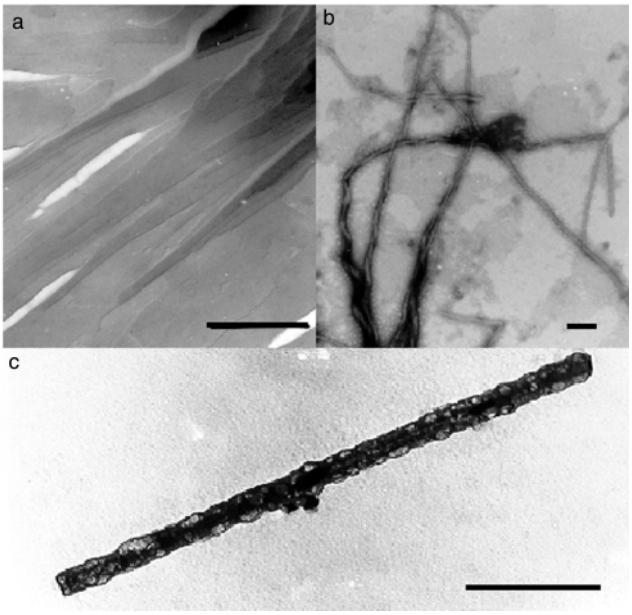

Fig. 2 Transmission electronmicrographs of aggregates of **2b**. (a) Ribbons in 2.0 mM phosphate buffer pH 7.0; (b) tubes in aqueous 9 mM $CaCl_2$ (pH 6.5); (c) rods mineralised in a solution containing 1 mM $FeSO_4$–KNO_2 adjusted to pH 11. Bars represent 250 nm.

conversion after 24 h) indicating that the phosphate anions are the kinetically significant species. Capillary electrophoresis in combination with ^{1}H NMR on authentic samples revealed that in both cases the reaction proceeded with complete regioselectivity (> 99%), leading to the formation of the primary phosphate **2a** exclusively. As outlined above this selectivity can be explained by attack of a phosphate ion on the C(1) ring carbon atom which is exposed to the aqueous phase due to orientation of the *N*-acylaziridine molecules at the interface. Activation of the aziridine ring most probably occurs through reversible protonation of the carbonyl group of **1a** by protonated phosphate groups, either from the buffer or from previously generated molecules of **2a**.

The sigmoidal conversion curve of **1a** (Fig. 1c) suggests that the ring opening reaction is catalysed by the vesicles that are formed. Indeed, when the reaction was carried out in the presence of preformed vesicles prepared from phospholipid **2a** (80 μmol in 4.0 ml 2.0 mM phosphate buffer, pH 7.0), the reaction was complete in 20 min (Fig. 1c). The high concentration of the *N*-acylaziridine detected in the aqueous phase (~95% after 2 min) supports the proposed dissolution of **1a** in the bilayers of the vesicles. When incorporated within these aggregates the hydrophobic alkyl chain will minimise the contact with water by dissolution in the hydrophobic interior of the membrane, leaving the amide carbonyl group of **1a** and consequently also the C(1) ring carbon atom oriented towards the aqueous phase (Fig. 1a).

Similar results are obtained when *N*-acylaziridine **1b** (R = $C_{17}H_{35}$) was used. Interestingly in this case, upon standing for approximately a week, the vesicles formed from compound **2b** slowly converted into flat multilayer ribbons (Fig. 2a). It was found that these ribbons rolled up to form tubuli under conditions that lead to compensation of the head group charge of the lipid, *e.g.* at low pH or in the presence of alkali and transition metal ions (*e.g.* Ca^{2+} and Fe^{2+} ions). Remarkably, the aggregate dimensions did not depend on the conditions used: tubuli of micrometer length and diameters between 20 and 40 nm were generated after lowering the pH to 2.5, after adding calcium ions at pH 5.6 (Fig. 2b) or after exposing the solution to ferric ions at pH 11 (Fig. 2c).[7]

In conclusion, we have shown that the ring opening of the long tail aziridines **1** by phosphate ions at an organic–aqueous interface exclusively leads to the formation of the primary phosphates **2**. The self-assembling properties of these compounds facilitate further conversion of the starting material without compromising the selectivity of the reaction and, ultimately, under the appropriate conditions lead to the formation of well-defined self-assembled objects. A detailed investigation of the autocatalytic nature of the system and possible applications are in progress.

The authors thank B. Martens for performing HPLC and Capillary Electrophoresis experiments.

Calc. for **3a** ($C_{21}H_{34}NO_6PNA_2$·$2.5H_2O$) C 46.85, H 7.58, N 2.70. Found C 46.67, H 7.60, N 2.73%. The enantiomeric purities of the starting aziridines used were > 95% as was determined from NMR analysis of (−)-camphanamide derivatives of both the enantiopure aziridine and the racemate. No loss of enantiomeric integrity during ring opening (either in organic solvents or at organic aqueous interfaces) was observed when comparing enantiomerically pure and racemic compounds.

‡ The concentration of **1** in the aqueous phase was determined using a RP18 reversed phase column, UV detection at 280 nm and a mobile phase of acetonitrile–phosphate buffer [(2 mM, pH = 7.0), 9:1 (v/v)]. Samples (25 μl) of the aqueous phase were diluted with acetonitrile (225 μl) before analysis.

§ The regioselectivity of the reaction was determined by capillary electrophoresis (30 kV, 10 °C, UV detection at 193 nm) using a buffer (Na_2B_4O–NaOH 50 mM, pH = 9.3) containing 26.7 mM β-cyclodextrin to avoid aggregate formation. Samples (25 μl) of the aqueous phase were diluted with sodium borate buffer (150 μl). From authentic samples the retention times of **2** and **3** were determined.

Received (in Columbia, MO, USA) 6th November 2000, Accepted 5th December 2000
First published as an Advance Article on the web 23rd January 2001

The crystal structure of 14-membered cyclo(ProNHCH$_2$CH$_2$NHProCOCH$_2$CH$_2$CO) reveals the presence of an internal NH···O=C bond dividing the molecule into two halves of 10-membered hydrogen-bonded rings; the molecules self-assemble into cyclic dimers through a symmetrical pair of intermolecular NH···O=C hydrogen bonds; a layered structure is formed, alternating layers of cyclic dimers and layers of chloroform molecules, all of which make strong CH···O hydrogen bonds with the cyclic dimers.

Design of conformationally constrained peptides mimicking receptor-bound conformation is an area of intense current interest in drug design.[1] It is generally believed that a β-folded structure is the most likely conformation present at the active site of many naturally occurring peptides and proteins.[2] Among the natural amino acids, proline is reported to be the most prevalent at the turn locations.[3] In recent years several designs of multiple-stranded β-sheets have been reported[4] using a Pro-Gly motif as the turn inducer. An attractive approach to β-turn folds would be to cyclize proline-containing peptides with a rigid moiety that may force the peptide chain to fold and run in an antiparallel direction. We demonstrate herein the first illustration of this concept and report on the crystal structure of a hybrid cyclic peptide with repeats of L-proline and dimethylene units in a 14-membered ring. The target cyclic peptide **1** was prepared by a two-step procedure (Scheme 1) involving first the formation of a core-modified Z–proline bispeptide which on deprotection and condensation with succinyl chloride under a high-dilution condition yielded the desired cyclic peptide in good yields.[5]

Suitable crystals for **1** were obtained from chloroform solution by slow diffusion of hexane vapour. The colourless shining crystals were found to crumble into an opaque powdery solid when exposed to air. For this reason diffraction measurements were carried out at low temperature on a crystal covered with immersion oil.

The crystal structure[6] of **1** showed the presence of two independent molecules A and B with very similar conformations. The contents of the unit cell also included three chloroform molecules. Molecule A [Fig. 1(a)] and B [Fig. 1(b)] each contain an intramolecular NH···O=C hydrogen bond dividing the macrocycle into two equal halves each enclosing a 10-membered hydrogen-bonded ring. The molecules A and B are further engaged in a dimer formation [Fig. 2(a)] through a similar pair of intermolecular NH···O=C hydrogen bonds. As shown in [Fig. 2(b)] each cyclic dimer is surrounded by three $CHCl_3$ molecules that make strong C–H···O hydrogen bonds with carbonyls O18, O18s and O3s of both macrocycles, and by additional $CHCl_3$ molecules from neighboring cells. Molecule A participates in C–H···O hydrogen bonding only with one of the $CHCl_3$ molecules while molecule B makes C–H···O contacts with two $CHCl_3$ molecules. Table 1 presents the hydrogen bond parameters. The dimers further assemble in infinite columns extending into a layered structure wherein sheets of $CHCl_3$ molecules (three for each dimer) alternate with columns of dimers [Fig. 2(b)]. The chloroform molecules among themselves make only van der Waals contacts. The

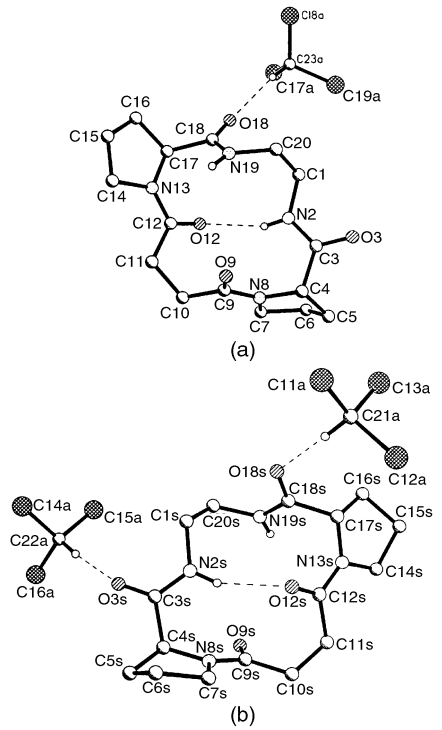

Fig. 1 Molecule A (a) as well as molecule B (b) are each engaged in intramolecular NH···O=C hydrogen bonding dividing the macrocycle into two equal halves of 10-membered hydrogen-bonded rings.

CH–O	C21	O18s	3.081	2.13	170
CH–O	C22	O3s	3.001	2.04	175

[a] Hydrogen atoms were placed in idealized positions at N–H = 0.90 Å and C–H = 0.96 Å. [b] At symmetry equivalent: *x*, −1 + *y*, *z*. [c] At symmetry equivalent: *x*, 1 + *y*, *z*.

presence of such a large proportion of chloroform molecules in the crystal structure of **1** is rather unusual and may be attributed to the hydrophobic nature of the proline macrocycle.

The β-turns in the proline macrocycle (Fig. 1), mimic true βII′- and βIII-turns in standard peptides, despite a substitution of C1 (methylene) for a N atom in the upper half of the macrocycle and a substituton of C11 for a N atom in the lower half. An inspection of the torsional angles listed in Table 2 shows that the upper half closely resembles a βII′-type turn, whereas the lower half has angles resembling a βIII-type turn.

^{1}H NMR variable-temperature (VT) studies showed a value of −3.75 ppb K^{-1} for the temperature coefficient indicating a moderate amount of intramolecular hydrogen bonding in DMSO solvent. ROESY studies in DMSO-d_6 did not show any significant cross-peaks except weak interaction between NH and methylene spacer units. The presence of dimeric structures was also indicated by electrospray mass spectroscopy.

In conclusion, incorporation of CH_2CH_2 units in an alternating sequence with Pro units in a ring seems to lead to preference

Table 2 Conformation angles (°)

[a] Conventions for normal peptides in ref. 7. Labeling of torsional angles with the standard ϕ, ψ and ω symbols, and μ or θ for angles about the CH_2–CH_2 is complicated since the order of the backbone atoms in C20 to C11 is in the retro direction as compared to C1 to C10. In the pseudo 4 → 1 turns, atoms C10, C4 and C17, C20 are in the corner positions (C^α atoms) of two standard β-turns. The ϕ, ψ and ω labels were chosen so that torsional angles in the pseudo 4 → 1 turns could be compared directly to standard types of 4 → 1 β-turns. [b] Idealized values in ref. 8.

of a C_{10} hydrogen-bonded turn structure. The presence of all-*trans* amide bonds in the constrained 14-membered ring of **1** and an unusually large amount of chloroform molecules stabilizing the structure through C–H···O hydrogen bonds are additional noteworthy features. The design of related hybrid peptides containing an increasing number of proline units in the ring is in progress.

A unique example of a core-modified bis-proline peptide self-assembling into an infinite hydrogen-bonded β-sheet ribbon: crystal structure of Z-ProNH$(CH_2)_2$NHPro-Z

Darshan Ranganathan,*[a] M. Gopi Kumar,[a] R. S. K. Kishore[a] and Isabella L. Karle*[b]

[a] *Discovery Laboratory, Indian Institute of Chemical Technology, Hyderabad 500 007, India. E-mail: ranganathan@iict.ap.nic.in*

Received (in Columbia, MO, USA) 6th November 2000, Accepted 5th December 2000
First published as an Advance Article on the web 23rd January 2001

The crystal structure of Z-ProNH$(CH_2)_2$NHPro-Z exhibits an extended backbone, with occurrence of both a *cis* and a *trans* conformation preceding the two prolyl residues, that self-assembles into an infinite hydrogen-bonded β-sheet ribbon.

Proline, the only amino acid found in proteins with a secondary amino group in a five-membered ring, is known to play an important role in the folding of natural proteins.[1] *N*-Acyl prolines lacking amide NHs display energetically similar *cis*- and *trans*-isomeric forms[2] and both forms are known to occur in proteins, for example, ribonuclease[3] or in bioactive peptides such as bradykinin.[4] Being a cyclic amino acid, proline imposes a certain degree of conformational constraint in the protein or peptide backbone causing bends or breaking helices,[5] and consequently proline-containing peptides are generally not known to display extended structures. We describe herein a unique example of a core-modified bis-proline peptide that is preceded by both a *cis* as well as a *trans* amide bond in its framework and self-assembles to form a hydrogen-bonded infinite β-sheet ribbon in the solid state.

The 1,2-ethylenediamine spacer-linked bis-proline **1** [Fig. 1(a)] was prepared[6] in a single step by coupling Z-proline with 1,2-diaminoethane using a direct azide coupling (diphenyl phosphoryl azide) procedure. The bis-Pro peptide **1** was fully characterized[7,8] by spectral and analytical data.

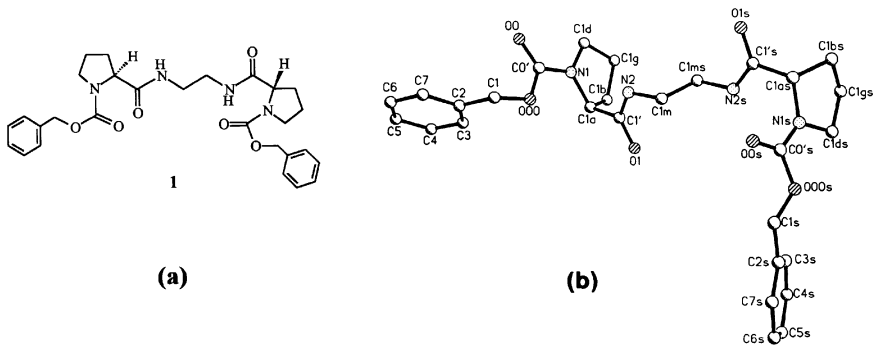

Fig. 1 (a) Molecular formula of **1**. (b) X-Ray structure of **1**. The numbering is the same for each half except that the letter 's' is added for atoms on one side.

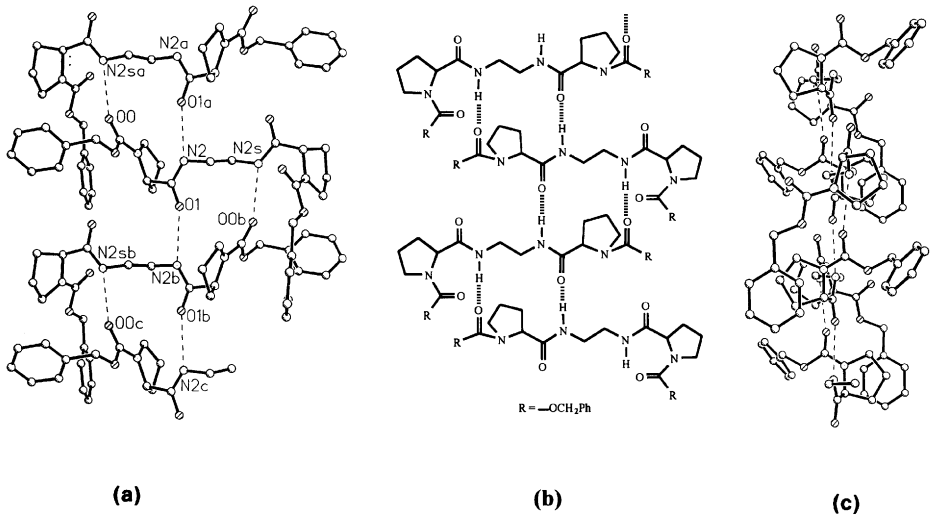

Fig. 2 (a) Flat ribbon formation by connecting the molecules by two types of hydrogen bonds, N(2)H⋯O(1) and N(2s)H⋯O(0). The molecules are repeated by a vertical two-fold screw axis. (b) Schematic representation of the ribbon assembly of **1**. (c) A side view of the ribbon. The dashed lines represent hydrogen bonds. Both surfaces of the ribbon are largely hydrophobic by virtue of the extended placement of the benzyl moieties and prolyl rings.

Suitable crystals for X-ray diffraction were obtained from a mixture of ethyl acetate and hexane. The crystal structure of **1** showed a backbone extended in two sections with a sharp bend at Pro(1s) [Fig. 1(b)]. Interestingly, the two halves of the molecule are not symmetric. On one side of the molecule the Z-L-Pro (1) amide bond C0′–N1 has the *cis* conformation, whereas on the other side the Z-L-Pro (1s) amide bond C0′s–N1s has the *trans* conformation. A similar occurrence of a *cis* amide bond preceding a Pro residue had been noted in 1974 for the Boc-Pro (1) amide bond in Boc-(L-Pro)$_4$-OBzl.[9]

The hydrogen-bonding pattern [Fig.2(a)] in the crystal lattice showed the formation of an infinite ribbon assembly around a two-fold screw axis (space group $P2_1$). There are only two independent hydrogen bonds, N(2)H··O(1) and N(2s)H··O(0) that connect the molecules into ribbons. Fig. 2(b) shows the schematic picture of the ribbon assembly. A side view of the ribbon in Fig. 2(c) shows a relatively flat structure. The protruding phenyl and pyrrolidine rings on either side impart a hydrophobic surface to the ribbon. Table 1 presents the hydrogen bond parameters and torsional angles in **1**. In solution-state conformational studies of **1**, while ^{1}H NMR (variable temperature measurements) has shown agreement with the solid-state structure in exhibiting high dδ/dT values (> 4 ppb K^{-1}) indicating the absence of any intramolecular hydrogen bonding, the FTIR spectrum in chloroform solution at 297 K showed two bands in the NH stretch region. The band at *ca*. 3430 cm^{-1} is assigned to the non hydrogen-bonded NH and the concentration independent, major band at *ca*. 3340 cm^{-1} is attributed to an internally hydrogen-bonded NH, possibly, in a seven-membered ring.

ChemComm

Hierarchical structure of a self-assembled xerogel

Marius Kölbel and Fredric M. Menger*

Department of Chemistry, Emory University, Atlanta, GA 30322, USA. E-mail: menger@emory.edu

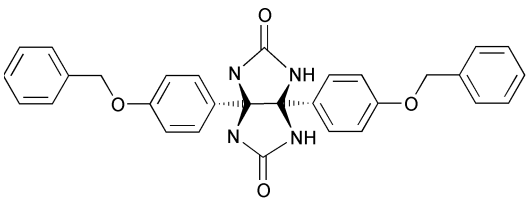
Received (in Columbia, MO, USA) 13th September 2000, Accepted 15th December 2000
First published as an Advance Article on the web 23rd January 2001

Removal of the liquid from a glycoluril-based gel produces a macroporous solid (a xerogel) comprised of closely packed fibers that assemble into highly convoluted sheets.

Glycoluril, the bicyclic product of glyoxal reacting with two equivalents of urea, is a molecule with a long history. For three decades, after first being synthesized by Schiff in 1877, glycoluril attracted a fair amount of attention until it faded into the dusty archives of science.[1] Poor solubility of glycoluril and its derivatives in water and organic solvents probably hastened the flagging interest. In the 1980s, however, a renaissance in glycoluril chemistry became apparent. This renewed awareness of glycoluril was driven by its various applications in the design of supramolecular architectures. Among these we find molecular clips and baskets,[2] supramolecular capsules,[3] self-complimentary facial amphiphiles,[4] and complexes of cucurbituril[5] (a macrocyclic condensation product of glycoluril with formaldehyde).

In the course of studying a variety of alkoxyphenyl-substituted glycolurils, we encountered an unexpected ability of the compounds to rigidify organic liquids into so-called organogels. Organogels are a growing class of supramolecular assemblies with potential applications in oil chemistry, nutrition, cosmetics and pharmacology.[6] Diverse molecular structures, among them derivatives of urea,[7] are already known to immobilize organic liquids. Such organogels are categorized as 'physical gels' in that they are formed by low-molecular weight organic molecules that self-assemble into fibrous structures upon cooling of their solutions. The fibers, held together by non-covalent forces, create a network that entrains solvent within the interstices. Removal of the solvent by evaporation or filtration results in a collapsed mat of fibers called a xerogel. The present manuscript focuses on the structure of a xerogel prepared from a glycoluril derivative.

The compound in question, the di(benzyloxyphenyl)-substituted glycoluril **1**, is drawn below. It was obtained by refluxing



1

a stirred mixture of 1.0 g 4,4′-dibenzyloxybenzil, 4 mL CF_3CO_2H, and 400 mg freshly powdered urea in 150 mL benzene while collecting water in a Dean–Stark trap.[8] After 50 h, the solvent was removed under reduced pressure, leaving a solid that was washed with two 50 mL portions of the following solvents: $CHCl_3$, boiling MeOH, $CHCl_3$ and *n*-pentane to give 51% of the pure compound. Characterization consisted of ^{1}H NMR, ^{13}C NMR, HRMS and elemental analysis.†

The gelation ability of the glycouril derivative was checked by heating suspensions in various organic liquids such as propan-1-ol, decan-1-ol, toluene, DMSO, DMF and benzyl alcohol. Compound **1** proved insoluble in hot propan-1-ol, decan-1-ol, and toluene. On the other hand, clear solutions were obtained in hot DMSO, DMF and benzyl alcohol. Upon cooling these solutions, the compound remained dissolved in DMSO, but rapidly precipitated from DMF. Only with benzyl alcohol, however, did we observe, at a concentration of 20 mg mL^{-1}, the formation of a self-supporting opaque gel that could be turned upside down in a vial without flow or deformation. The gel is thermoreversible and stable for months at room temperature, whereas it is irreversibly destroyed when shaken vigorously.

Light microscopy (400×) on a small portion of the gel (Fig. 1) revealed flexible fibers several hundred μm long and about 2 μm in diameter (often radiating from central points). We assume (partly on the basis of our previous X-ray data on unrelated gel systems[9]) that the fibers in Fig. 1 are a composite of parallel 'elementary' fibers with molecular dimensions (*i.e.* diameters of *ca.* 2.5 nm corresponding to hydrogen-bonded dimers of **1**).

A xerogel was prepared from the **1**/benzyl alcohol gel by filtration. Thus, a portion of gel was placed in a Büchner funnel

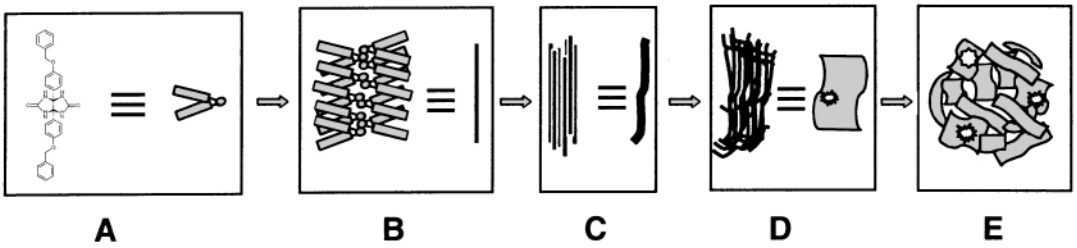

Fig. 3 Schematic representation of the hierarchical levels of the xerogel of **1**.

with a fritted disk, and the solvent was removed under suction for 6 h while a mild N_2 pressure was applied from above. Remaining traces of solvent were then removed under reduced pressure with the aid of a vacuum pump. The resulting xerogel, a brittle material of resin-like appearance, was attached to a metal stub with conductive carbon tape and coated with 3 nm Cr using a Denton DV-602 Cr coater. Representative SEM images were obtained at the lower [Fig. 2(a)–(c)] and upper [Fig. 2(d)] stage of an ISI DS-130 LaB_6 electron microscope.

Macroscopic fibers, as observed by light microscopy, can no longer be found. Instead, we see in Fig. 2(a) (246 × instrumental magnification) a highly convoluted material with pore sizes ranging from *ca.* 5 μm to *ca.* 20 μm. Fig. 2(b) offers a closer look at the concavity framed in Fig. 2(a), using now as 1230 × instrumental magnification. The inside of the orifice is replete with folds, indentations and spikes. Fig. 2(c) at a 1840× instrumental magnification shows how the xerogel is comprised of curved, wrinkled and interconnected sheets. Also seen in Fig. 2(c) is a further underlying fine structure which is particularly noticeable in smoother areas such as that marked with an arrow. At a magnification of 59 900 × [Fig. 2(d)] the fibrous nature of this fine structure becomes apparent. Although the macroscopic fiber bundles observed by light microscopy did not survive the drying process, much smaller fibers, with diameters down to 15 nm and several μm length, remain intact. These microfibers pack themselves into craggy sheet-like structures.

Based on these observations, we can describe this xerogel as a hierarchical structure as depicted schematically in Fig. 3. At the lowest level of structure we postulate single molecules of **1** (**A**) self-assembling into fibers (**B**) *via* hydrogen bonding between the glycoluril head groups. The molecular structure of these elementary fibers is still unknown (a problem that besets most organogel work). The elementary fibers then form bundles (**C**) with diameters of *ca.* 15 nm which are visible by SEM at 60 000 × magnification. These bundles align and pack side-by-side, thereby forming sheets (**D**). Owing to the high disorder and curvature of these sheets, and to their multiple junctions with one another, cavities are formed to give a macroporous solid (**E**). Although individual fibers are curved and seemingly flexible, the bulk material composed of the fibers is hard and brittle. Close packing and interweaving of the fibers into a sponge-like network produces a fairly rigid microstructure.

The gel-to-xerogel transformation upon solvent removal can be understood in terms of our model. As seen in Fig. 4, the organogel is composed of 2 μm fibers (visible by light microscopy) which in turn are composed of 15 nm fibers (visible by SEM). Below our resolution capabilities lie the 2.5 nm elementary fibers. When the gel is dried, the macroscopic fiber bundles disappear, leaving the nanoscopic bundles which self-assemble into the sheets that comprise the xerogel. No comparable transformation has been reported thus far; usually the structure of the original gel is either faithfully preserved or else completely destroyed.

This work has been supported by the National Institutes of Health. We greatly appreciate the assistance of Dr Robert Apkarian and Mr Kevin Caran of the Integrated Microscopy and Microanalytic Facility of Emory University for microscopy services.

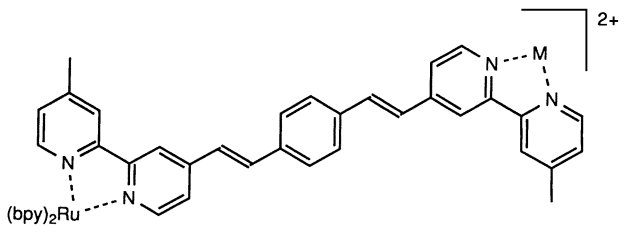
In a dinuclear complex containing both $[ReCl(CO)_3(bpy)]$ and $[Ru(bpy)_3]^{2+}$ chromophores, the bis(bipyridylethenyl)-benzene bridge acts as an intermediate reservoir of energy for two-step Re→Ru photoinduced energy transfer.

Photoinduced energy transfer between transition metal polypyridine centres is studied because of the widespread interest in processes concerned with light energy collection and conversion.[1,2] The properties of the bridging ligand (L) interposed between the energy donor (D) and acceptor (A) components have accordingly been the object of extensive investigations, because the bridging ligand controls both the important *geometric* properties of the complex (inter-centre distance) and the *electronic* properties (electronic metal–metal coupling). Thus, careful control of the bridging ligand is of great importance in studies of photoinduced energy transfer in D–L–A complexes. However, not many examples are available of cases where L behaves as a photoactive component within the triad D–L–A.[3] This is in contrast to the conceptually similar process of photoinduced electron transfer, a process that can gain in effectiveness if the electron transfer occurs in several discrete steps *via* the bridging ligand.[4]

Here we present spectroscopic results for the dinuclear complex $[ReCl(CO)_3–L–Ru(bpy)_2]^{2+}$ (**Re–L–Ru**), where L is the bis-bipyridyl bridging ligand 1,4-bis[2-(4′-methyl-2,2′-bipyridyl-4-yl)ethenyl]benzene (dstyb), first described by



Ru–L (M = nothing); **Re–L–Ru** (M = {*fac*-Re(CO)$_3$Cl})

Schmehl and coworkers[5–7] (ESI †). Data for the reference mononuclear complex $[Ru(bpy)_2(dstyb)]^{2+}$ (**Ru–L**) are also discussed. We show that within **Re–L–Ru**, L behaves as a reservoir of excitation energy collected at the Re-based chromophore and passes some amount of it to the Ru-based emitter, according to a two-step energy transfer scheme [eqn. (1)].

$$\mathbf{Re}*\mathbf{–L–Ru} \rightarrow \mathbf{Re–L}*\mathbf{–Ru} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathbf{Re–L–Ru}* \qquad (1)$$

Fig. 1 shows the absorption spectra of **Re–L–Ru** and of the reference mononuclear complex **Ru–L**; the luminescence spectra recorded at room temperature are also shown, as obtained after excitation at 372 nm (an isoabsorbing point for two cases). Luminescence data obtained both at room temperature and at 77 K are collected in Table 1 (ESI †). Comparison of the absorption profiles and intensities for **Re–L–Ru** and **Ru–L** with cases from literature[5–7] allows the following assignments. (i) The bands peaking at 290 nm are of intra-bpy ^{1}IL(bipy) nature; (ii) the bands with maxima in the 360–390 nm region are of intra-dstyb character, ^{1}IL(dstyb); (iii) the bands with maxima at 464 nm are of ^{1}Ru→L MLCT nature; (iv) for Re–L–Ru, the flat region of absorbance in the 380–450 nm region includes the expected ^{1}Re→L CT transition.[6]

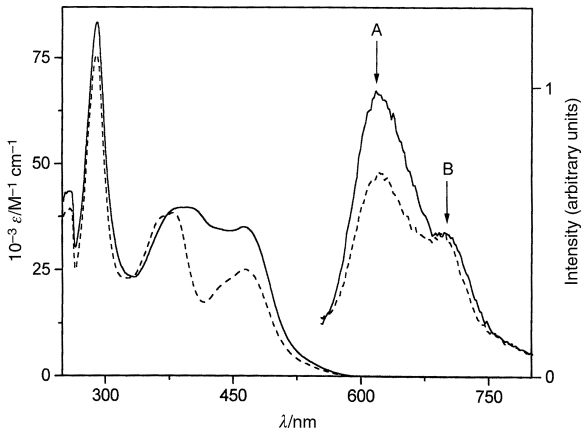


Fig. 1 Room temperature absorption and luminescence spectra of dinuclear **Re–L–Ru** (—) and reference mononuclear **Ru–L** (- - - -) complexes; excitation was at 372 nm, solvent was DMF–CH_2Cl_2. The two luminescence bands are termed A (^{3}Ru→L CT character) and B (^{3}IL[dstyb] character).

The luminescence spectra of both **Re–L–Ru** and **Ru–L** at room temperature (Fig. 1) show two distinct emission features. The band maximum at 621 nm (Table 1, Fig. 1, band A) is ascribed to emission from the ^{3}Ru→L CT excited state; the

DOI: 10.1039/b008152n

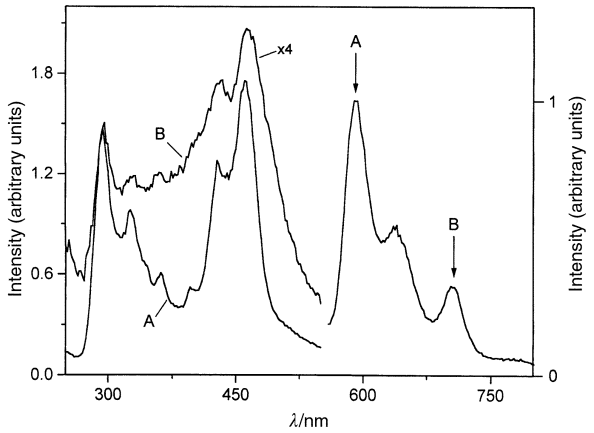

Fig. 2 77 K luminescence spectrum for **Re**–**L**–**Ru** under excitation at 372 nm, and excitation spectra taken at 591 nm (A band, ^{3}Ru→L CT character) and 705 nm (B band, ^{3}IL[dstyb] character); solvent was DMF–CH_2Cl_2.

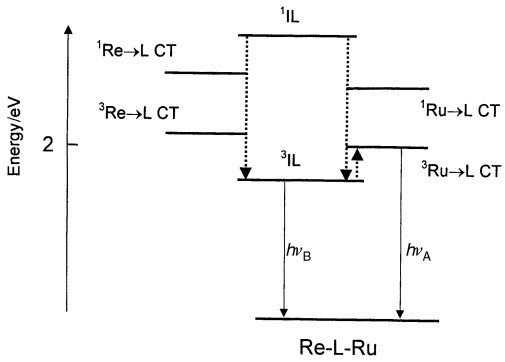
band maximum peaking at 695 nm (Table 1, Fig. 1, band B), in contrast has previously been established by Schmehl and coworkers as arising from the ^{3}IL(dstyb) excited state.[5–7] In addition, the same authors found that the ^{3}Ru→L and ^{3}IL(dstyb) levels in the homometallic dinuclear complex (**Ru**–**L**–**Ru**, according to our notation above, but where the ancillary ligand was 4,4′-Me_2bpy) are thermally coupled. We are seeing the same effect here for both **Re**–**L**–**Ru** and **Ru**–**L**: *viz* there are two thermally coupled luminescent excited states, of ^{3}Ru→L CT and ^{3}IL(dstyb) character, separated by an energy gap of *ca.* 1750 cm^{-1}. The similar emission lifetime values observed for both A and B bands (for instance, at r.t. for Ru–L, τ = 183 and 210 ns, respectively; see Table 1), are consistent with this coupling. Significantly, we note that for **Re**–**L**–**Ru** no Re-based emission is detected. Any such emission would be expected to be on the blue side of the Ru-based emission maximum. The lack of Re-based emission for **Re**–**L**–**Ru** is ascribed to fast deactivation of the Re-based ^{3}MLCT energy levels, populated after light absorption, in favour of lower lying levels centred on the bridging ligand and/or the Ru fragment (see below).

Fig. 2 shows the 77 K luminescence spectrum for **Re**–**L**–**Ru** (excitation at 372 nm) and the excitation spectra obtained for observation at the emission maxima, 591 nm (band A, ^{3}Ru→L CT nature, τ = 5 μs) and 705 nm [band B, ^{3}IL(dstyb) nature, τ = 10 μs]. At this temperature, the two states are less coupled than at r.t. and comparison of the excitation spectra of **Re**–**L**–**Ru** with the absorption spectra for **Re**–**L**–**Ru** and **Ru**–**L** (Fig. 1) allows identification of the relaxation paths for the excitation energy occurring within the dinuclear complex. For **Re**–**L**–**Ru** the ^{3}IL(dstyb) emission (band B), in addition to intraligand transitions, receives contributions from both ^{1}Ru→L CT (sharp feature at *ca.* 460 nm in the excitation and absorption spectra) and ^{1}Re→L CT transitions (flat region between 380 and 450 nm of the excitation and absorption spectra). Conversely, the ^{3}Ru→L CT emission (band A) is apparently lacking any direct contribution from ^{1}Re→L CT transitions; there is a much weaker intensity in the region characteristic of ^{1}Re→L CT transitions in the excitation spectrum at 77 K and the weak residual intensity in this region of excitation spectrum A may be ascribed to the ^{1}IL(dstyb) transition. We note that at room temperature the excitation spectra taken for the A and B bands of **Re**–**L**–**Ru** are more closely overlapping, as a consequence of the thermal redistribution between the luminescent states.

These results indicate that emission from the ^{3}IL(dstyb) state is directly sensitised by Re-based absorption, whereas the ^{3}Ru→L CT emission is not directly sensitised by Re-based absorption. Thus, some portion of excitation light absorbed by the Re-based chromophore of **Re**–**L**–**Ru** is (i) first transferred to the bridging ligand (giving the ^{3}IL state), and (ii) subsequently redistributed between the luminescent ^{3}IL(dstyb) and ^{3}Ru→L CT levels, a process which is governed by temperature (Scheme 1). According to this description, in **Re**–**L**–**Ru** the overall excitation energy collection process includes an *indirect*, two-



Scheme 1

step Re→Ru energy transfer which is mediated by the spatially interposed dstyb unit such that the ^{3}IL(dstyb) level acts as a 'reservoir' for excitation energy. This reservoir effect has been recognised and documented in a number of recent studies.[8–11]

In order to model the r.t. thermal redistribution between the ^{3}IL(dstyb) and ^{3}Ru→L CT levels [eqn. (1)] of **Re**–**L**–**Ru** and **Ru**–**L**, we have employed τ = 8 μs[6] and 210 ns (Table 1) as intrinsic lifetime values for the separate ^{3}IL(dstyb) and ^{3}CT (Ru-based) luminophores and an energy gap of ΔE = 1750 cm^{-1} between them. We calculate[12] that the thermally equilibrated state contains 86% of the ^{3}Ru→L MLCT level and its decay takes place following a dual exponential law, with τ_1 = 240 ns and τ_2 = 1.4 ns, provided k_1/k_2 = 6 and k_2 = 1 × 10^8 s^{-1} [where k_1 and k_2 are defined in eqn. (1)]. These estimates suggest that the interconversion between the ^{3}IL(dstyb) and ^{3}Ru→L MLCT levels may be affected by different electronic and nuclear factors for the forward (k_1) and backward (k_2) paths, possibly due to the presence of rotamers of dstyb.[13] The fact that the apparent radiative rate constant for the Ru-based luminescence, $k_r \approx 0.2 \times 10^4$ s^{-1} (Table 1), is much lower than that for $[Ru(bpy)_3]^{2+}$, 7.1 × 10^4 s^{-1} (Table 1) has been ascribed to a low efficiency of intersystem processes.[5] However it may well be that the intermixing of ^{3}Ru→L MLCT and ^{3}IL(dstyb) states is in part responsible for this outcome, given that for the latter case k_r is expected 10–10^2 s^{-1}.[7]

We thank the European Community for a post-doctoral fellowship (S. E., contract no. 980226) within the project ERB FMRX-CT98-0226 and for a COST award (COST-D11-0004/98); and the EPSRC (UK) for a Ph.D. studentship (to A. M. B.).

ChemComm

Transcription inhibition by $Rh(phi)_2(phen)^{3+}$

Patty K.-L. Fu and Claudia Turro*

Department of Chemistry, The Ohio State University, Columbus, OH 43210, USA. E-mail: turro.1@osu.edu

Received (in Irvine, CA, USA) 21st September 2000, Accepted 3rd January 2001
First published as an Advance Article on the web 23rd January 2001

$Rh(phi)_2(phen)^{3+}$ (phi = 9,10-phenanthrenequinone diimine, phen = 1,10-phenanthroline) increases the melting temperature (ΔT_m) of a 15-mer duplex DNA by 21 °C and it is able to inhibit transcription *in vitro*; the concentration ratio of $Rh(phi)_2(phen)^{3+}$ relative to DNA bases of the template required to inhibit the RNA transcribed by 50%, R_{inh}^{50}, was found to be 0.13; in contrast, $Rh(phen)_2(phi)^{3+}$, which also possesses the intercalating phi ligand, exhibits only a +7 °C shift in T_m and R_{inh}^{50} = 4.5; $Rh(phen)_3^{3+}$, $RhCl_3$, and ethidium bromide result in negligible or small ΔT_m and exhibit R_{inh}^{50} values that range from 4.8 to 12.5; these results suggest that the intercalation of the phi ligand between the DNA bases and electrostatic binding are not the only means of duplex stabilization by these complexes.

The inhibition of transcription is one of the crucial manners in which the replication of cancerous cells and viruses can be prevented.[1] This mechanism is exploited by antitumor drugs including actinomycin, anthracycline antibiotics and cisplatin, among others.[2] Inhibition of transcription leads to incomplete coding of RNA and proteins, and can ultimately lead to cell death. In the present work we compare duplex stabilization and inhibition of transcription by octahedral $Rh(phi)_n(phen)_{3-n}^{3+}$ (phi = 9,10-phenanthrenequinone diimine, phen = 1,10-phenanthroline; n = 0, 1, 2) complexes, some of which possess the intercalative phi ligand (structures shown in Fig. 1). The interactions and reactivity of phi complexes of Rh(III) with DNA have been extensively investigated.[3]

Two-dimensional ^{1}H NMR spectroscopy was previously utilized to investigate the binding of Rh(III) complexes possessing a single phi ligand to duplex DNA, including $Rh(NH_3)_4(phi)^{3+}$,[4] $Rh(phen)_2(phi)^{3+}$,[5] Δ-α-Rh[(*R*,*R*)-Me_2-trien]phi^{3+} [(*R*,*R*)-Me_2trien = 2*R*,9*R*-diamino-4,7-diazadecane],[6] and $Rh(en)_2(phi)^{3+}$ (en = ethylenediamine).[7] These NMR studies, as well as the crystal structure of Δ-α-Rh[(*R*,*R*)-Me_2trien](phi)$^{3+}$ bound to an eight base-pair oligonucleotide duplex,[8] show that the binding of these complexes to DNA takes place through the intercalation of the phi ligand between the bases of the duplex from the major groove. Although bis-phi complexes of Rh(III), such as $Rh(phi)_2(bpy)^{3+}$ (bpy = 2,2′-bipyridine), are better DNA photocleavage agents than those possessing a single phi ligand,[3] no ^{1}H NMR studies or crystal structures have been reported to date on their DNA binding.

The shifts in the melting temperatures (ΔT_m) of a 15-mer oligonucleotide duplex (see Table 1 for sequence) in the presence of $Rh(phi)_n(phen)_{3-n}^{3+}$ (n = 0, 1, 2), $RhCl_3$, and ethidium bromide are listed in Table 1.[9] The relative concentration of metal complex or ion was fixed at R = 0.067 (R = [complex]/[bases]; two metal complexes per duplex). Inspection of Table 1 reveals that the complex with two phi ligands results in the largest increase in the melting temperature of the duplex. An increase in T_m of 21 °C was measured in the presence of $Rh(phi)_2(phen)^{3+}$ relative to free duplex, and a ΔT_m value of +7 °C was observed for $Rh(phen)_2(phi)^{3+}$. Ethidium bromide, a known DNA intercalator, results in ΔT_m of +5 °C. The Rh^{3+} ion, $RhCl_3$, and the non-intercalative $Rh(phen)_3^{3+}$ complex resulted in negligible changes to T_m.

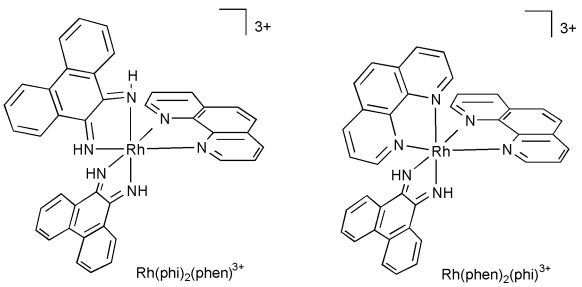

Fig. 1 Structures of $Rh(phi)_2(phen)^{3+}$ and $Rh(phen)_2(phi)^{3+}$.

The ability of $Rh(phi)_2(phen)^{3+}$ to stabilize duplex DNA led us to hypothesize that it may hinder elongation during the transcription process. The imaged agarose gel showing the RNA transcribed *in vitro* in the presence of various concentrations of $Rh(phi)_2(phen)^{3+}$ is shown in Fig. 2.[10] It is clear from Fig. 2 that an increase in the concentration of $Rh(phi)_2(phen)^{3+}$ relative to DNA template, R, results in a decrease in the amount of RNA produced. The ratio at which 50% of the RNA is

Table 1 Changes in melting temperatures (ΔT_m) of a 15-mer duplex in the presence of various metal complexes and R_{inh}^{50} for each complex

Duplex = 5′-AGTGCCAAGCTTGCA-3′ / 3′-TCACGGTTCGAACGT-5′

Complex	ΔT_m[a]/°C	R_{inh}^{50}
$Rh(phi)_2(phen)^{3+}$	21	0.13
$Rh(phen)_2(phi)^{3+}$	7	4.5
$Rh(phen)_3^{3+}$	3	6.2
$RhCl_3$	3	12.5
Ethidium bromide	5	4.8

[a] Error = ±2 °C; for duplex only T_m = 55 °C; measurements performed in 5 mM Tris (pH = 7.5, 50 mM NaCl) with [complex]/[bases] = 0.067 (2 complexes per duplex) and [bases] = 20–30 μM; T_m values determined from the changes in absorbance at 260 nm using the HP Biochemical Analysis software on a diode array spectrometer (HP 8453) in a sample holder equipped with a Peltier temperature controller (1 cm path length).

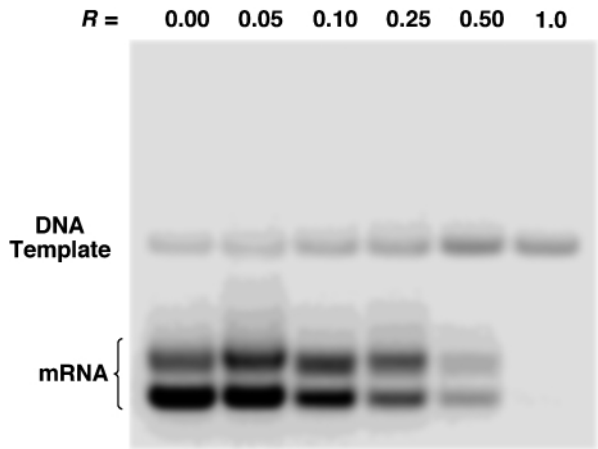

Fig. 2 Ethidium bromide stained agarose gel (1%) of transcribed mRNA in the presence of $Rh(phi)_2(phen)^{3+}$ at various [Rh]/[template DNA base] ratios, R. Both the DNA template (150 μM) and mRNA are imaged on the gel (labeled). See ref. 10 for a detailed description.

transcribed, R_{inh}^{50}, for each complex, $RhCl_3$, and ethidium bromide are listed in Table 1. The values of R_{inh}^{50} presented in Table 1 reveal that $Rh(phi)_2(phen)^{3+}$ inhibits transcription to a much greater extent than $Rh(phen)_2(phi)^{3+}$, although both complexes possess the intercalative phi ligand. In addition, large R_{inh}^{50} values were measured for $Rh(phen)_3^{3+}$, $RhCl_3$ and the intercalator ethidium bromide.

One possible explanation of the observed results is that the complexes that bind more strongly to double stranded DNA might play a greater role in duplex stabilization and transcription inhibition. However, it appears that R_{inh}^{50} is related to ΔT_m rather than K_b. For example, the K_b value for $Rh(phen)_2(phi)^{3+}$ is $\approx 10^6\ M^{-1}$,[11,12] for $Rh(phen)_3^{3+}$ $K_b \approx 10^3\ M^{-1}$,[12] and for ethidium bromide $K_b = 1.7\times10^5\ M^{-1}$,[13] however, the R_{inh}^{50} and ΔT_m values for all three molecules are similar (see Table 1). Although the role of the binding constant cannot be completely discounted at this time, it does not appear that the binding constant of each complex to duplex DNA plays a role in transcription inhibition or duplex stabilization.

Experiments were also performed to ensure that binding of the complexes to T7-RNA polymerase was not the mechanism of transcription inhibition. $Rh(phi)_2(phen)^{2+}$ binds duplex DNA with $K_b \approx 10^7\ M^{-1}$,[11] therefore with 15 μM $Rh(phi)_2(phen)^{2+}$ and 150 μM DNA bases ($R = 0.10$) it would be expected that $\approx 10^{-8}$ M rhodium complex would remain free in solution which could bind to the enzyme ($\approx 10^{-9}$ M). Experiments with an order of magnitude less complex and DNA [1.5 μM $Rh(phi)_2(phen)^{2+}$, 15 μM bases] utilizing the same enzyme concentration ($\approx 10^{-9}$ M) resulted in negligible change to the inhibition of transcription relative to that measured with 15 μM complex and 150 μM DNA bases.[10] In addition, no change in the R_{inh}^{50} was observed with a 10-fold increase in T7-RNA polymerase with 15 μM $Rh(phi)_2(phen)^{2+}$ and 150 μM bases (15 min reaction time).[10] These results are inconsistent with an inhibition mechanism that involves the association of the complex to the enzyme. To exclude displacement of Mg^{2+} ions by the metal complexes, aggregation of oligonucleotides, and non-specific ionic binding of the complexes to the duplex, the transcription reaction was carried out with $Rh(phi)_2(phen)^{3+}$ at $R = 0.10$ and either 6 mM or 12 mM Mg^{2+}. The use of 12 mM instead of 6 mM $MgCl_2$, under the same conditions, did not result in increased transcription.

The largest shifts in the duplex melting temperatures, ΔT_m, and the lowest concentrations of complex required to observe the transcription inhibition, R_{inh}^{50}, were measured for $Rh(phi)_2(phen)^{3+}$, which possesses two quinone diimine phi ligands in the octahedral coordination sphere of the Rh(III) metal center. Since $Rh(phen)_2(phi)^{3+}$ behaves similarly to $Rh(phen)_3^{3+}$ intercalation of the phi ligand or charge on the complex are not the sole reasons for the increased duplex stabilization or transcription inhibition observed for $Rh(phi)_2(phen)^{3+}$. One explanation of our observations is that the four imine protons of the two phi ligands of $Rh(phi)_2(phen)^{3+}$, which are not present in the other complexes, makes hydrogen bonding possible between $Rh(phi)_2(phen)^{3+}$ and the DNA nucleotides and backbone. The recent crystal structure of Δ-α-Rh[(*R*,*R*)-Me_2trien](phi)$^{3+}$ bound to duplex DNA shows that two binding modes are present. In both binding modes the phi ligand is intercalated between the DNA bases. The amino protons of the (*R*,*R*)-Me_2trien ligand located above and below the phi plane are involved in hydrogen bonding with two nearby guanines in one binding mode and with ordered water molecules hydrogen-bonded to the guanines in the other.[8] Furthermore, the two imine protons of the phi ligand are hydrogen bonded to ordered water molecules in the structure.[8]

$Rh(phi)_2(phen)^{3+}$ stabilizes the duplex DNA structure and inhibits the transcription process *in vitro* at 35-fold lower concentration than $Rh(phen)_2(phi)^{3+}$. This finding suggests that intercalation of the phi ligand and the 3+ charge on the complex are not the only factors involved in duplex stabilization. One possible explanation for the observed results is the deformation of the double helix through the binding of the $Rh(phi)_2(phen)^{3+}$ complex at various sites on the DNA template. Another possibility is that hydrogen bonding, either directly to the DNA or through ordered water molecules, may play a role in the binding of $Rh(phi)_2(phen)^{3+}$ to DNA and in the stabilization of the duplex structure, thus resulting in inhibition of transcription.

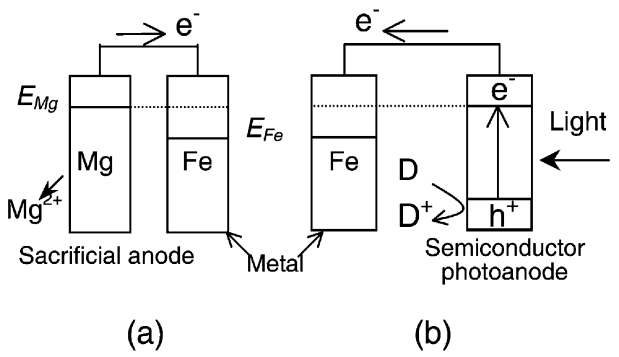
By using a simple TiO_2 solar panel connected to a steel electrode, the concept of photoelectrochemical metal corrosion prevention has been demonstrated to be feasible in utilizing solar light for corrosion inhibition.

Ever since Fujishima and Honda[1] reported the water splitting reaction on illuminated TiO_2 electrodes, semiconductor photoelectrochemistry has been applied to a wide variety of issues such as chemical or electrical conversion of solar energy,[2] pollutant degradation,[3] and superhydrophilic materials,[4] all of which are based on photo-induced charge transfer processes at the semiconductor interface. Here we report another novel application of semiconductor photoelectrochemistry: *metal corrosion prevention*.

The common strategy of corrosion prevention is to change the potential of the corroding metal by pumping electrons in, which is widely known as cathodic protection.[5] When using a sacrificial anode that is more active (negative) in corrosion potential than the metal to be protected, the electrons generated from the corroding sacrificial anode are transferred to the metal object to reduce its corrosion rate [Scheme 1(a)]. The basic idea of this investigation is to replace the sacrificial anode with a semiconductor photoanode that generates conduction band (CB) electrons upon band-gap illumination [Scheme 1(b)]. Previous work by Yuan and Tsujikawa,[6] which reported that the potential of a TiO_2-coated copper substrate drastically shifted toward the less noble (negative) direction under illumination, suggests the idea of using a semiconductor photoanode for corrosion prevention is plausible.

Corrosion prevention experiments were carried out with a photoelectrochemical set-up that consists of a flat solar panel containing a semiconductor (TiO_2) photoanode in a hole-scavenging medium and a steel electrode immersed in an aqueous solution. The semiconductor photoanode was prepared by applying a TiO_2 (Degussa P25) suspension (5 wt%) to an indium tin oxide (ITO) glass slide (Delta technology, 14.8 cm^2). The TiO_2 coated slide was dried in air for 1 h and annealed at 450 °C for 30 min. Electrical contact was made by attaching copper wire with silver paste at the uncoated edge of the ITO slide. The TiO_2/ITO electrode was placed in the solid-phase hole-scavenging medium (6.8 g sodium formate per g agar gel) and encased in a transparent Petri dish to form a flat solar cell. The carbon steel electrode was circular (surface area: 1.66 cm^2) and mechanically polished. The backside and edges of the steel electrode were covered with epoxy resin to expose the flat surface to the aqueous solution in the corrosion cell. The TiO_2/ITO electrode and the steel electrode were galvanically coupled through an external circuit and the two cells were connected by a salt bridge (saturated KCl in agar contained in a flexible Tygon tube). When necessary, 0.05 M K_2CO_3 was added as a supporting electrolyte to the cathodic compartment (corrosion cell) in order to eliminate any possible ohmic potential drop. The light source was 10 W blacklight lamps (1, 2 and 3 lamps for 10, 20 and 30 W illumination, respectively) or a 200 W mercury lamp. The intensities of UV light ($300 < \lambda < 400$ nm) (to excite the TiO_2 photoanode) were estimated to be 58, 100, 135 μW cm^{-2} for 10, 20 and 30 W illumination and 1.53 mW cm^{-2} for the 200 W lamp. Natural solar light UV intensity has been measured to be 1.55 mW cm^{-2} around noon. The TiO_2/ITO electrode was illuminated from the ITO side. Potentials (*vs.* SCE) and currents during illumination were measured using a potentiostat (EG&G, model 263A).[7] The corroded steel surface was analyzed by a Raman spectrometer (Renishaw system 3000) in backscatter geometry with an excitation wavelength of 632.8 nm (He–Ne laser).



Scheme 1 Schematic representation of metal (Fe) corrosion prevention using (a) a conventional sacrificial anode (*e.g.* Mg) and (b) a semiconductor photoanode investigated in this study; D represents hole scavengers while dashed lines represent the electrochemical potential of the electrons generated in the anode.

Fig. 1(a) shows the changes of potentials and currents in the galvanic couple of the TiO_2 photoanode (solar panel) and the steel electrode in acidic water (pH 4) when the photoanode is illuminated under different sources of light. Under illumination, the coupled photopotential, E_{ph}, immediately shifted to more negative potential with a concurrent increase of photocurrent, I_{ph}. The open circuit potential (E_{oc}) of the TiO_2 anode in the solar panel under 30 W illumination was −0.9 V (*vs.* SCE). Comparing this with E_{oc} of the steel electrode (−0.44 V *vs.* SCE), the illuminated TiO_2 anode can supply CB electrons to the metal electrode to protect the metal cathodically by setting a new mixed potential of the couple, E_{ph}. As monitored in this study the value of E_{ph} remained constant under illumination up to 35 days. Natural solar light was as effective as use of a 200 W lamp in inducing changes in E_{ph} and I_{ph}. In addition, a blank test was performed in the absence of added hole scavengers where E_{ph} and I_{ph} were measured to be *ca.* −0.45 to −0.50 V (*vs.* SCE) and 8 μA under 30 W illumination. Various alcohols and organic acids were tested as hole scavengers of which formate was found to show the best performance.

E_{ph} and I_{ph} were measured as a function of pH in the corrosion cell under constant light intensity [Fig. 1(b)]. The dark corrosion currents (I_{corr}) of the steel electrode increased from 0.1 to 360 μA cm^{-2} on lowering the pH from 11 to 2. As E_{ph} shifted in the positive direction under more corrosive

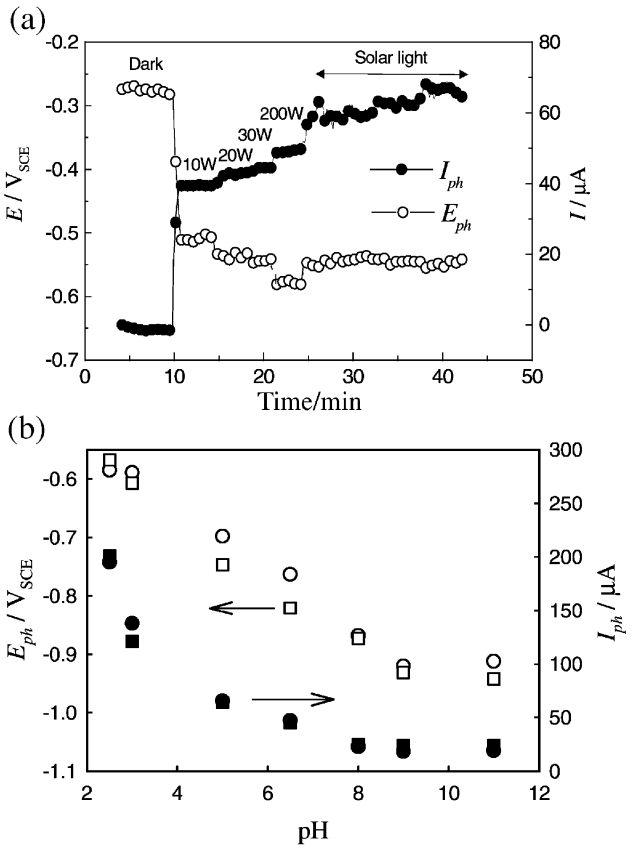


Fig. 1 (a) The change of E_{ph} and I_{ph} in the galvanic couple of a TiO_2 photoanode and the steel electrode when the photoanode was irradiated by 10, 20, 30 or 200 W lamp or solar light. (b) E_{ph} (open symbols) and I_{ph} (filled symbols) as a function of pH under 30 W (circles) or 200 W (squares) illumination.

conditions (lower pH), I_{ph} logarithmically increased even under constant light intensity. There was little dependence on light intensity (30 *vs.* 200 W lamp). Although the present system is essentially identical to a typical photoelectrochemical cell that converts light into electricity where I_{ph} is proportional to the light intensity,[2a] it is clearly distinguished from the latter by the fact that its performance depends little on the light intensity as long as there are enough photons to compensate the dark corrosion current.

Evidence of corrosion prevention of the steel connected to the solar panel was obvious enough to be detected visually. The shiny surface of the steel electrode remained intact in a corrosive electrolyte solution as long as it was connected to the solar panel, while it quickly corroded and was covered by red–brown rust in the absence of light. The progress of corrosion was quantitatively assessed by measuring the Raman spectra of steel surfaces. Fig. 2 compares the Raman spectra of the steel surface corroded in 0.05 M K_2CO_3 solution at pH 6 for 30 h under different illumination conditions. All the peaks generated as a result of corrosion are ascribed to various phases of iron oxides.[8] While the steel surface connected to a continuously illuminated photoanode showed no sign of iron oxide formation, a thick layer of iron oxides covered the steel surface under the dark condition. The steel sample tested under the natural solar light showed an intermediate level of iron oxide formation since more than half of the total corrosion time was during night time or when cloudy.

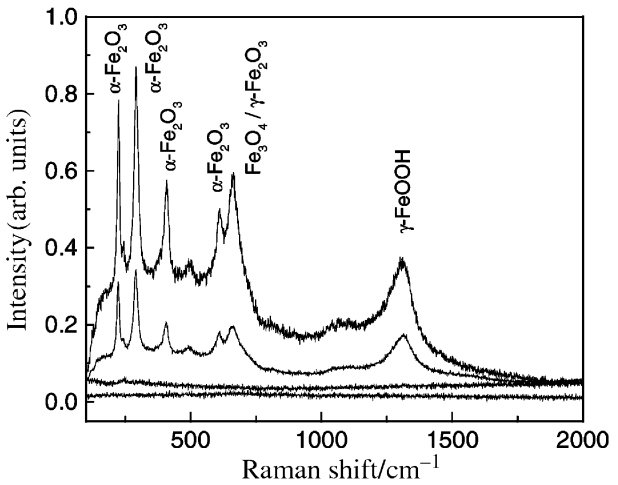

Fig. 2 Raman spectra of the steel surface corroded under different illumination conditions (from the bottom up) of an initial steel surface; a continuously illuminated sample (30 W lamp); sunlight illuminated (16 h day plus 14 h night) sample in the open air; and a control sample not connected to the photoanode.

It has been clearly demonstrated in this work that a simple TiO_2 solar panel can prevent metal corrosion. In view of the fact that the conventional sacrificial anode must be buried or immersed in the medium along with the metal object to be protected and be replaced periodically,[5] use of a photoanode installed on the ground level is easier to maintain. Although the TiO_2 photoanode itself is non-sacrificial, the TiO_2 solar panel is sacrificial since the formate added as a hole scavenger is irreversibly oxidized. However, the hole scavenging medium could be easily refilled to make it regenerative. A similar approach could be possible by using a silicon-based solar cell although it is not economically feasible. Even though the present method suffers from several limitations such as the absence of light at night[9] and the depletion of the hole-scavenging medium, it verifies the possibility of using solar light for corrosion inhibition and could be developed into an alternative or ancillary corrosion prevention method.

9 This could be overcome by charging a battery connected to the solar panel by day and switching the discharging current to the metal object at night. In a preliminary experiment we confirmed that the progress of corrosion was reduced when a rechargeable battery was connected to the steel electrode at night.

ChemComm

A well defined tin(II) initiator for the living polymerisation of lactide

Andrew P. Dove, Vernon C. Gibson,* Edward L. Marshall, Andrew J. P. White and David J. Williams

Department of Chemistry, Imperial College of Science, Technology and Medicine, Exhibition Road, South Kensington, London, UK SW7 2AY. E-mail: v.gibson@ic.ac.uk

Received (in Cambridge, UK) 31st October 2000, Accepted 14th December 2000
First published as an Advance Article on the web

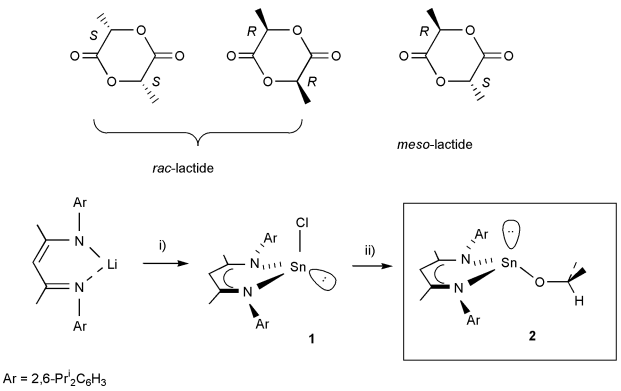
[HC{C(Me)NAr}$_2$]Sn(OPr^i) (Ar = 2,6-Pr$^i_2$C$_6$H$_3$) is shown to be an initiator for the living polymerisation of *rac*-lactide to heterotactic-enriched poly(lactide).

There is increasing interest in the design of polymers for *in vivo* applications such as sutures, artificial tissue networks and drug delivery agents. For these applications it is desirable for the polymer to be non-toxic, biocompatible and resorbable. One of the most promising classes of polymer in this field is the poly(lactide)s[1] which are readily obtained in a controlled manner *via* the living ring-opening polymerisation of lactide, the cyclic diester of lactic acid.[2]

Initiators for lactide polymerisation are typically based on alkoxide or alkanoate complexes of metals such as Al, Mg, Sn, Zn and the rare earths. Tin(II) catalysts such as Sn(ethyl hexanoate)$_2$ are generally preferred in the commercial production of poly(lactide)s[3] for medical or pharmaceutical applications owing to the low toxicity of Sn(II) compared to other metal ions [Sn(ethyl hexanoate)$_2$ is a permitted food additive in many countries]. Although a number of systems based on aluminium,[4] and more recently, magnesium[5] and zinc,[6] have been described that initiate the living ring-opening polymerisation of lactide, there have to date been no reports of well defined tin initiators. Here we describe the first example of a single-site tin catalyst for the living polymerisation of lactide.

The initiator **2** is prepared according to Scheme 1.† Treatment of $SnCl_2$ with [HC{C(Me)NAr}$_2$]Li in diethyl ether followed by crystallisation from pentane affords [HC{C(Me)-NAr}$_2$]SnCl **1** as a yellow crystalline solid. This is converted to **2** by treatment with LiOPr^i followed by recrystallisation from pentane. Crystals of **2** suitable for an X-ray structure determination‡ were grown from pentane; the structure is shown in Fig. 1.

The complex has non-crystallographic C_s symmetry with the three-coordinate tin atom adopting a tripodal geometry with inter-bond angles in the range 83.6(2)–94.1(2)°, the most acute being associated with the bite of the chelating N,N′ ligand. The Sn–N and Sn–O distances are unexceptional, and there is the expected pattern of delocalisation within the β-diketiminate ligand. The six-membered chelate ring has a boat conformation



Scheme 1 *Reagents and conditions*: i, $SnCl_2$, Et_2O, 18 h, recrystallisation from pentane, 60% yield (unoptimised); ii, LiOPr^i, Et_2O, 18 h, recrystallisation from pentane, 17% yield (unoptimised).

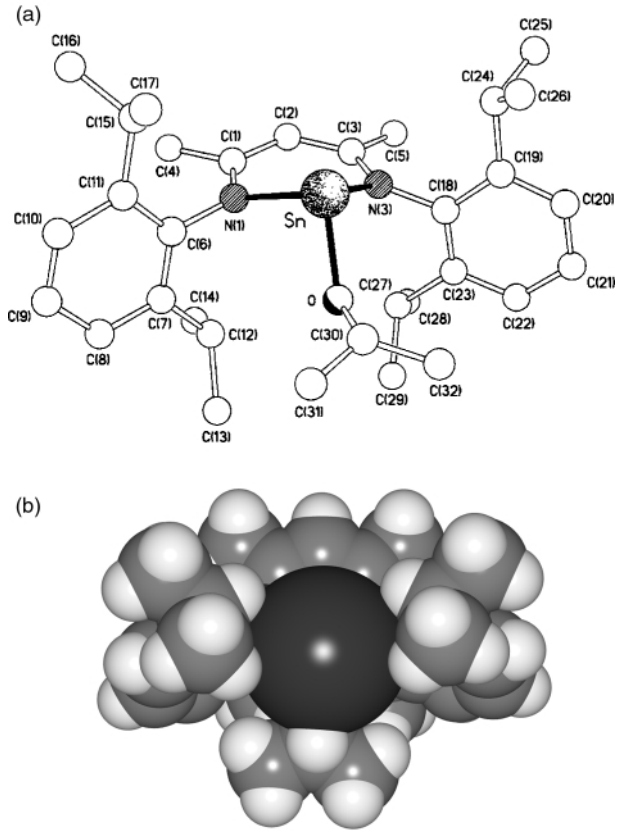


Fig. 1 (a) The molecular structure of **2**. Selected bond lengths (Å) and angles (°); Sn–O 2.000(5), Sn–N(1) 2.206(4), Sn–N(3) 2.208(4), C(1)–N(1) 1.323(6), C(1)–C(2) 1.404(7), C(2)–C(3) 1.387(7), C(3)–N(3) 1.331(6); O–Sn–N(1) 94.1(2), O–Sn–N(3) 92.5(2), N(1)–Sn–N(3) 83.6(2). (b) Space filling representation of the structure of **2** showing the exposed environment of the tin atom.

with C(2) and Sn lying 0.12 and 0.87 Å 'above' the N(1), C(1), C(3), N(3) plane; the isopropoxide oxygen atom lies 0.74 Å 'below' this plane. As a consequence of the folded chelate ring conformation, and retention of near trigonal planar geometries at the two nitrogen centres, the C(12) and C(27) isopropyl groups are drawn together, and those associated with C(15) and C(24) are folded away exposing the non-coordinated 'face' containing the stereochemically active lone pair on the tin atom [Fig. 1(b)]; the shortest intermolecular approach to the tin centre is 3.84 Å from C(13)–H.

The polymerisation of *rac*-lactide (a racemic mixture of L (*S*,*S*) and D (*R*,*R*) lactides) was initially investigated using complex **2** in CH_2Cl_2 at ambient temperature.§ Under these conditions it was found that 100 equivalents of monomer required 96 h for complete conversion (> 99% by ^{1}H NMR). The resultant polymer has a molecular weight close to that calculated from the monomer : initiator ratio (observed M_n = 17 100; calculated M_n = 14 400) and exhibits a narrow polydispersity (M_w/M_n = 1.11), characteristics of a living process. The polymerisation was then repeated at 60 °C in

DOI: 10.1039/b008770j

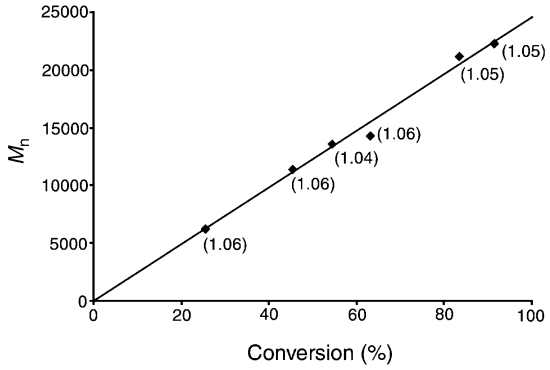

Fig. 2

toluene affording 85% conversion after 4 h, again resulting in a narrow molecular weight distribution product (M_w/M_n = 1.05). The activity of the tin catalyst is lower than that observed for the related zinc system[6] which may be in part due to the lower electrophilicity of the tin centre, and partly a consequence of the stereochemically active lone pair which may disfavour monomer binding. The living characteristics of the polymerisation are supported by the linear increase in M_n with conversion giving in each case a low polydispersity product (Fig. 2).

In order to confirm that the initiator is indeed the isopropoxide complex **2**, a ^{1}H NMR study was carried out in which increasing amounts of lactide were added to **2** in $CDCl_3$. The isopropoxide methine septet resonance at the end of the propagating chain is shifted slightly to higher frequency (0.005 ppm) relative to the unconsumed initiator (δ 4.01). New resonances for the β-diketiminate ligand substituents are also observed for the propagating species. As the number of monomer equivalents is increased, the intensities of the signals attributable to the propagating species increase relative to those of unconsumed **2**. Owing to the overlapping nature of the resonances, accurate integration has not been possible, but the addition of 5 equivalents of monomer leads to an approximately 1 : 1 mixture of initiator : propagating species. This indicates a favourable k_p/k_i ratio (the rate constant of propagation to rate constant of initiation) which is desirable for minimising the polydispersity.

The ^{1}H NMR spectrum of the poly(lactide) derived from **2** (Fig. 3) differs from the spectrum predicted from a Bernouillian analysis of totally random poly(*rac*-lactide), with the *rmr* and *mrm* tetrads much more intense than expected. These observations are consistent with a heterotactic-biased product since the *rmr* microstructure can only arise from two consecutive D–L or L–D interchanges; each *rmr* tetrad is accompanied by two *mrm* tetrads in agreement with the NMR integration. The preference for heterotacticity is not as strong as reported previously for the zinc analogue of **2**, but nonetheless represents the first example of tacticity bias arising from the polymerisation of *rac*-lactide using a tin catalyst.

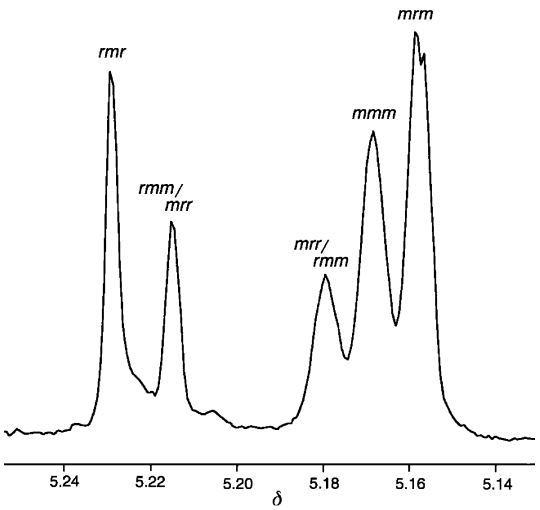

Fig. 3

Further studies are examining the effect of changes to the aryl ligand substituents on the polymerisation behaviour of the tin catalysts and their use in the ring-opening polymerisation of other cyclic ester monomers.

The Engineering and Physical Sciences Research Council is thanked for a studentship (to A. P. D.) and a postdoctoral fellowship (to E. L. M.).

§ *Typical polymerisation procedure*: complex **2** (0.005 g, 0.008 mmol) and *rac*-lactide (0.1181 g, 0.819 mmol) were weighed in to a 15 cm^3 glass ampoule fitted with a Teflon stopcock. The mixture was suspended in toluene (6 cm^3) and the ampoule was then sealed and transferred to an oil bath pre-heated to 60 °C. After stirring for the allotted period of time the volatile components were removed *in vacuo*. Conversion was determined by integration of monomer *vs.* polymer methine resonances in the ^{1}H NMR spectrum of the crude product (in $CDCl_3$). The polymer was purified by redissolving in CH_2Cl_2 (5 cm^3) and precipitating from rapidly stirring methanol. GPC chromatograms were recorded on a Knauer differential refractometer connected to a Gynotek HPLC pump (model 300) and two 10 μm columns (PSS) at a flow rate of 1.00 cm^3 min^{-1} using $CHCl_3$ as the eluent. The columns were calibrated against polystyrene standards with molecular weights ranging from 1560 to 128 000. Samples were filtered through a 0.45 μm filter immediately prior to injection. Analysis was performed using Version 3.0 of the Conventional Calibration module of the Viscotek SEC^3 software package.

First published as an Advance Article on the web 23rd January 2001

A novel metal-free phthalocyanine 3 fused in peripheral position with four diazatetrathiabicyclomacrocycles has been prepared by bicyclotetramerization of cryptand 1 and its isoindolinediimine derevative 2; the new compounds were characterized by elemental analyses, IR, ^{1}H and ^{13}C NMR, UV–VIS and MS spectroscopy.

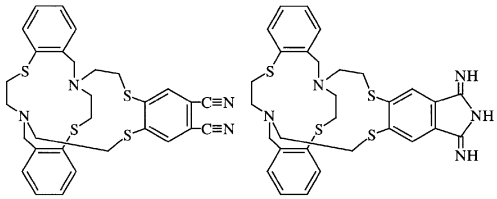
The first synthesis of a soluble copper phthalocyanine with crown ether moieties was reported in 1986[1] and its high tendency towards aggregation by solvents, cations and complexation properties was investigated.[2] Such compounds contain a metal center that is complexed by a phthalocyanine ring and four macrocyclic binding sites.[3] The attachment of polyaza or polyaza-polythia macrocycles to phthalocyanine has received considerable attention because of the transition metal-binding properties of the macrocyclic cavities.[4] Phthalocyanines containing polyaza or mixed-donor macrocycles[5] can form homo- and hetero-pentanuclear transition metal complexes which may allow new functionalized materials to be obtained which are of importance for both biochemistry and materials science.[6]

A range of three-dimensional polycyclic ligand systems (cryptands) have recently been investigated most intensively with respect to their strong selectivity towards individual alkali and alkaline-earth metal ions.[7] The majority of such ligands contain donor sets in which polyether donor functions predominate. However, ligands of general type, incorporating mixed donors such as diaza and/or dithia groups, have also been synthesized.[8] Such ligands show increased affinity for transition metals and many other heavy metals.[9]

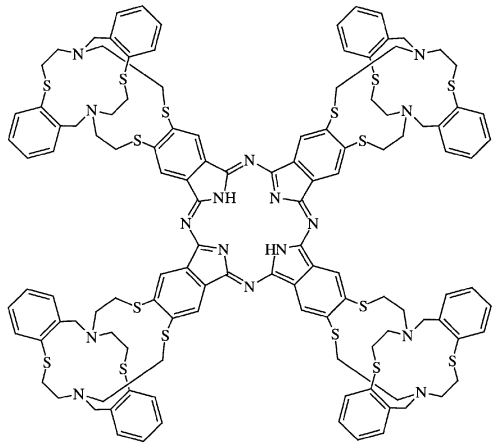
This study, describing the synthesis of compound **3**, displaying a suitable combination of diazatetrathiamacrobicycles and phthalocyanine may allow new functionalized materials to be prepared, which are of importance for analytical chemistry as a new type of heavy metal extraction agent. On the other hand, the importance of this new type of phthalocyanine may be regarded as an important step in that it may be a viable sensor material.

The synthesis of macrobicyclic compound **1**, was performed starting from a 14-membered diazadithia macrocycle[10] and 1,2-bis(2-iodoethylmercapto)-4,5-dicyanobenzene[11] in dilute conditions using Cs^+ cation as promotor[12] in acetonitrile. Final purification by recrystallization afforded **1** in 73.2% yield (mp 136 °C).† Compound **1** displays the expected molecular ion peak at *m/z* = 574 $[M]^+$. Conversion of the dicyano compound **1** into the isoiminoindoline derivative **2** was accomplished by bubbling ammonia gas through a solution of **1** in dry methanol in the presence of sodium methoxide for 6 h. Compound **2** was purified by column chromatography on silica gel, using ethanol–chloroform (1 : 1) as eluent and obtained in 63.4% yield (mp 284 °C (decomp.)].† The C, H and N elemental analyses for **2** were satisfactory and a reproductible mass spectrum was obtained using the FAB technique (M^+ at *m/z* 591 corresponding to the molecular ion).

The usual synthetic routes could be applied to synthesize the metal-free phthalocyanine **3**.† Thus, either **1** was cyclotetramerized to **3** in a high boiling solvent such as pentanol at reflux



1 **2**



3

temperature in the presence of a strong organic base such as 1,8-diazabicyclo[5.4.0]undec-7-ene(DBU) or alternatively condensation of four isoiminoindoline units **2** into the metal-free

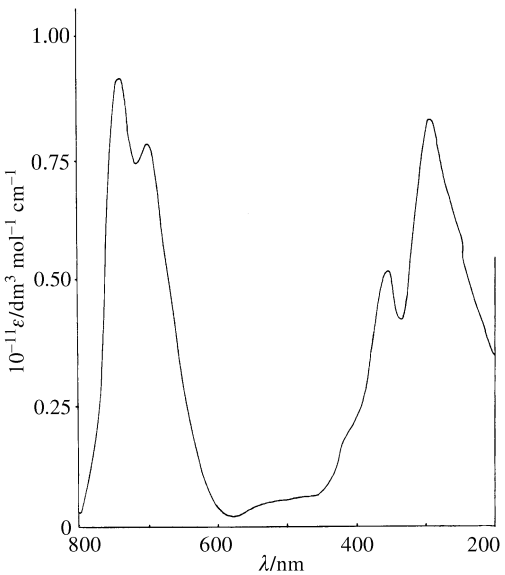


Fig. 1 UV–VIS spectra of **3** in pyridine.

DOI: 10.1039/b010045p

phthalocyanine **3** was carried out in 2-(*N*,*N*-dimethylamino)-ethanol at reflux temperature. In the preparation of the metal-free phthalocyanine, the isoiminoindoline route is more convenient than the phthalonitrile route since the reaction conditions employing isoiminoindolines are mild in comparison to those employing phthalonitriles.[13] The yields (11.3–12.7%) of these reactions were rather low, as encountered for metal-free phthalocyanine with other bulky groups.[5] Elemental analytical results and ^{1}H NMR, IR, MS and UV-VIS spectral data of the new phthalocyanine are consistent with the assigned formulation. A mass spectrometry study by FAB on this compound gave a molecular ion peak the value of which showed good agreement with the calculated value for **3** (*m/z* 2298.3 $[M]^+$).

Fig. 1 shows the electronic absorption spectrum of **3** in pyridine. This spectrum of the phthalocyanine indicates features of both the metal-free phthalocyanine and macro-bicyclic moieties. The cryptand containing phthalocyanine **3** shows intense Q bands at 734 and 704 nm suggesting monomeric species since such species (of D_{2h} symmetry) show two intense absorptions around 700 nm.[13,14] Such split Q band absorptions in pyridine is due to the $\pi \Rightarrow \pi^*$ transition of this fully conjugated 18π electron system.

This study was supported by the Research Fund of Karadeniz Technical University (Trabzon-Turkey).

Self-assembled multiporphyrin arrays mediated by self-complementary quadruple hydrogen bond motifs†

Charles Michael Drain,* Xinxu Shi, Tatjana Milic and Fotis Nifiatis

Department of Chemistry & Biochemistry, Hunter College & Graduate Center of the City University of New York, 695 Park Avenue, New York, NY 10021, USA. E-mail: Cdrain@shiva.hunter.cuny.edu

Received (in Columbia, MO, USA) 13th September 2000, Accepted 15th December 2000
First published as an Advance Article on the web 23rd January 2001

Discrete squares and tapes of porphyrins are self-assembled by self-complementary hydrogen bonding between diacetamidopyridyl recognition groups rigidly linked to the chromophore.

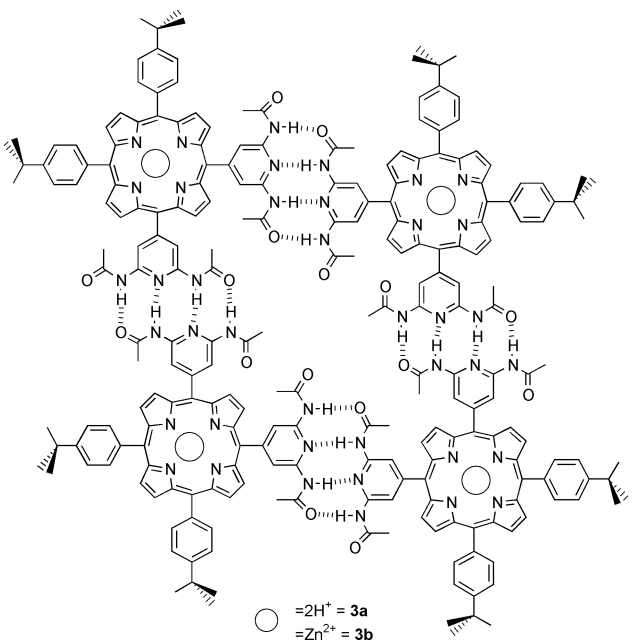
Porphyrins, and their cousins the phthalocyanines, have attracted considerable attention recently because of their potential use as components of nanometer scale photonic devices and materials.[1] The functionality of many, if not most, photonic devices,[1] including those found in nature,[2] strongly depends on the relative order of the chromophores throughout the entire material and on the mode of assembly. Supramolecular chemistry has been used as a stratagem to achieve the desired geometric order of porphyrin and other entities in both solids and in solution.[3] Crystallization of porphyrins bearing H-bonding groups has yielded fascinating networks,[3,4] and co-crystallization with other compounds has yielded interesting host–guest[3,5] and magnetic[5] materials. Yet consistently predicting long-range three-dimensional order in crystals remains elusive. Several discrete H-bond[6] and metal ion[7] assembled porphyrin systems in solution also have been reported. In order to better understand the role of non-covalent bonds in mediating electron and energy transfer in biological systems,[2] several non-coplanar or non-rigid supramolecular porphyrin–electron acceptor species have been studied.[8,9] One of the primary goals of work reported herein is to understand the process of self-assembly and to reliably predict the structure of self-assembled porphyrin arrays in solution, as opposed to the solid state. We report the self-assembly of several rigid, co-planar multiporphyrin arrays and tapes by self-complementary H-bond motifs that exploit both the directionality of the recognition groups and the square-planar geometry of the porphyrin macrocycle to design predictable arrays in high yields. Though topologically similar to the square porphyrin arrays formed by coordination chemistry,[3,7] the nature of the self-assembly linker has profound effects on the properties of the resultant array, *e.g.* porphyrin fluorescence.

There are several ways in which 5-(3,5-diacetamido-4-pyridyl)-10,15,20-tris(4-*tert*-butylphenyl)porphyrin, **1a**,[10]† may form a dimer by self-complementary hydrogen bonds.[11] The most stable is a linear, quadruple H-bonded system (graphical abstract), albeit this is weak compared to other H-bond systems. A variety of one- and two-dimensional porphyrin structures may be formed *via* this motif. In the present case we demonstrate this by the formation of linear dimers with the 5-substituted compound, linear trimers using a 2:1 stoichiometry of the 5- and the 5,15-substituted compounds **1a**, **2a**, respectively, and a linear tetramer using a 2:2 ratio of **1a** to **2a**.

If there are no dynamic processes occurring on the NMR[12] time scale, both the number of species self-assembling into the final structure, *n*, and the equilibrium constants, *K*, may be determined by ^{1}H NMR experiments that monitor the chemical shift of suitable protons *vs.* the concentration of the self-complementary porphyrin.[6,13] Noting the usual caveats and that these experiments do not yield structural information *per se*, fits of these curves for solutions of **1a**† indicate that the ultimate self-assembled product contains *ca.* 2 units (K = 160 dm^3 mol^{-1}), consistent with the dimeric structure shown in the abstract, where $x = 0$. For the tapes these experiments and their fits show that *ca.* 3.2 units are in the final assembly when a 2:1 mixture of **1a** and **2a** is used to form the trimer (K = 110 dm^6 mol^{-2}), and about 4.1 units are present in the assembly of a 2:2 mixture of **1a** and **2a** (K = 70 dm^9 mol^{-3}). In the case of the linear tapes, there is no *a priori* reason that all of the self-assembled structures in the chloroform solution are the 2:1 trimers, and 2:2 tetramers, thus the NMR results are likely indicative of a mixture of dimers, trimers, tetramers, *etc.* substantially weighted toward the tape resulting from the starting stoichiometries by ΔG.†

The self-assembly of a square tetramer (Scheme 1) from only **3a** is also indicated by similar plots of concentration *vs.* amide NH chemical shifts.† Dramatic differences are observed in the plots for the linear tetramer *vs.* the closed-square tetramer.† For the square array, the rapid increase in the chemical shift at much lower concentrations indicates K (2400 dm^9 mol^{-3}) is much greater compared to the linear tetramer, and thus is a direct measure of the cooperative formation of a closed system with a more favorable ΔG. The fit yields $n \approx 3.9$ units of **3a**.

Because of the different power of the concentration units it is difficult to directly compare the values of K for all but the linear and square tetramers. Additionally, the K values found by this data are about 4-fold weaker then those found by fluorescence



Scheme 1

† Electronic supplementary information (ESI) available: experimental details, NMR data and fits, van't Hoff plots, UV–VIS and fluorescence data, and ESI-MS spectrum for the self-assembled square species. See http://www.rsc.org/suppdata/cc/b0/b008045o/

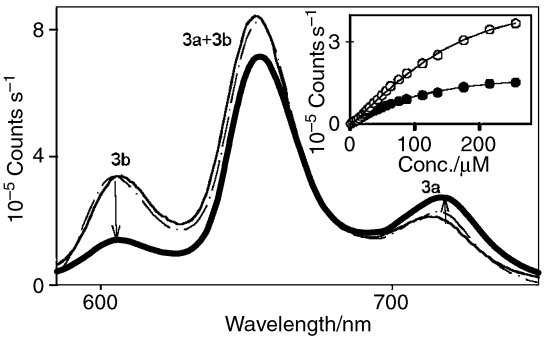


Fig. 1 Fluorescence emission spectra of a solution that is 140 μM in **3a** and 140 μM in **3b** in 2-methylTHF (——) and in ethanol (——) under identical experimental conditions. In ethanol where the H-bonding between the diacetamidopyridyl groups is minimal, the emission spectrum is nearly identical to the sum of the two components (–·–). Whereas in 2-methylTHF where H-bonding is significant, there is a substantial quenching of **3b** and enhanced emission from **3a**. The inset plots the emission intensity of **3b** at 610 nm *vs.* concentration in ethanol (○) and 2-methylTHF (●).

quenching experiments, indicating that dynamic processes are occurring during the NMR acquisition. To contrast the NMR data from all four systems, it may be more informative to compare the $C_{1/2}$ values, where this represents the concentration at the half maximum increase in the chemical shift. The $C_{1/2}$ value from the above NMR data for the closed tetrameric square, 0.8 mM, is a factor of *ca.* 10 less than the comparable open tetrameric tape, consistent with the calculated K values. Note that the linear systems have somewhat similar $C_{1/2}$ values: 8 mM, 5 mM and 9 mM for the dimer, trimer, and tetramer, respectively.†[11] In toluene, where the H-bonds are expected to be stronger, similar results for n are obtained for all systems, but the $C_{1/2}$ values are *ca.* 4-fold lower for the linear assemblies and *ca.* 2-fold lower for the square.

In solvents with low H-bonding potential, the added thermodynamic stability of the closed, square tetramer, as opposed to a open-chain polymer with an average length of four units with enthalpically unfavorable 'unbonded' ends or entropically unfavorable higher order polymers, strongly argues in favor of the square structure when **3a** is the self-assembling species. Estimations of ΔG for these systems from the NMR concentration and temperature data[8] show that the square tetramer ($\Delta G = -19.3$ kJ mol^{-1}) is favored over the tetrameric tapes ($\Delta G = -10.5$ kJ mol^{-1}) by *ca.* 8 kJ mol^{-1}. Van't Hoff plots† of the chemical shift *vs.* temperature are in qualitative agreement with the NMR equilibrium studies above.

As the concentration in chloroform, toluene, 2-methylTHF, and ethanol is increased from 1 μM to *ca.* 250 μM there is little change in the observed UV–VIS spectra, with < 1 nm shifts in the Q bands for both the free bases and the zinc complexes. This indicates very little electronic communication between the macrocycles in the self-assembled tapes and squares in the ground state. However, the relative emission is substantially diminished with increasing concentrations of **1a** or **3a** in chloroform, or 2-methylTHF, compared to ethanol.† This indicates that there is aggregation, which decreases the emission intensity by organization of the chromophores, and quenching of the excited state by energy transfer to neighboring subunits. Significant energy transfer among subunits is well demonstrated by the excitation and emission (Fig. 1) spectra of squares formed from a 1:1 mixture of the free base, **3a** and the zinc complex **3b** in 2-methylTHF. In solvents favoring H-bonding, excitation in the zinc porphyrin Q-band region at 557 nm where **3b** absorbs > 3 times **3a**, the self-complementary square emits predominantly from the free base at 720 nm, with concomitant quenching of **3b** at 610 nm. This direct observation of energy transfer is not observed in dilute solutions (< 10 μM) or in ethanol where the emission is essentially similar to the mathematical addition of the two individual spectra. The emission from **3b** (Fig. 1, inset) is substantially quenched as the concentration of the 1:1 mixture in 2-methylTHF increases, and to a much lesser extent in ethanol. The fluorescence lifetime, determined by phase modulation, of **3a** is 10 ns and that of **3b** is 2 ns at 1 μM concentrations in air in chloroform. At 0.100 mM, **3a** exhibits two time constants 10 ns (80%) and 0.8 ns (20%). A 0.100 mM mixture of 1:1 **3a** and **3b** shows decays of 10 ns (50%), 1 ns (40%) and < 0.2 ns (10%). This is consistent with the notion of energy transfer from the singlet manifold, rather than the triplet manifold for the metallo self-assembled squares.[7]

The characterization of these supramolecular systems will serve as the basis for the characterization of future complex two- and three-dimensional arrays using various combinations of both H-bonding and metal ion coordinating porphyrins.[9] The above data show that the self-complementary H-bonds afforded by the 3,5-diacetamido-4-pyridyl group are surprisingly effective in mediating the self-assembly of these photo- and electroactive species in solution. The solution phase chemistry, in turn, is vitally important for the understanding of how to direct the formation of solid state structures, and will help understanding of the resulting properties of the materials.

'Simulated amorphisation and recrystallisation' was employed to explore the structural features that evolve within ZrO_2(111) supported CeO_2, including epitaxial relationships, screw and screw-edge dislocations, vacancies and surface clusters.

Ceria and ceria containing materials are used as catalysts and promoters in several heterogeneous catalytic reactions[1] and comprise a major component in three-way catalysts (TWC), which are used for the treatment of automobile exhaust gases. The oxygen storage capacity (OSC), due to the ability of cerium to shift between Ce^{4+} and Ce^{3+}, is one of the key properties of these materials. Accordingly, ceria based catalysts can work in both oxidizing and reducing conditions, converting carbon monoxide, nitrogen oxides and hydrocarbons to non-toxic products. It has been shown experimentally that ceria films, vapour deposited on zirconia and zirconia based substrates such as yttrium-stabilized zirconia (YSZ), are more easily reduced than films supported on α-Al_2O_3.[2]

Here we employ a simulated amorphisation and recrystallisation methodology[3,4] to explore the structural changes that evolve within ZrO_2(111) supported CeO_2. Since elucidation of the atomistic structure, particularly for ultra-thin supported materials is difficult or even intractable experimentally, the simulation provides an invaluable complement.

Simulated amorphisation and recrystallisation[3,4] in this present study involves straining the CeO_2 thin film under considerable pressure and placing it on top of a ZrO_2 support. Dynamical simulation is then applied to the system at high temperature upon which the CeO_2 amorphises. Under prolonged dynamical simulation, the CeO_2 recrystallises revealing a wealth of structural modifications that evolve as the system endeavours to accommodate the lattice misfit, whilst maximising interfacial interactions. Crucially, by ensuring that the CeO_2 thin film recrystallises from an amorphous structure, no influence on the compromise between minimising the lattice misfit whilst maximising the interfacial interactions is introduced artificially into the simulation.

Central to this methodology is that dynamical simulation, as applied to an amorphous structure, allows a more comprehensive exploration of the configurational space due to the high energy amorphous starting point and the conformational freedom this gives rise to. In addition, a single mesoscale simulation has been performed in which a multitude of structural features are present within this simulation cell (in contrast to performing many smaller simulations comprising fewer structural features). Previous simulations on the SrO/MgO(001) system[4] using different simulation cells revealed equivalent thin film energies, epitaxial relationships, dislocation densities and structural configurations suggesting that a single very large simulation cell is sufficiently representative for an initial investigation of the CeO_2/ZrO_2 system. In addition, during experimental fabrication using for example vapour deposition[2] the thin film will endeavour to crystallise into as low an energy structure as possible. Our method is designed to generate low energy structures *via* recrystallisation from an amorphous material and will reflect therefore the structural characteristics present within the experimental system.

The calculations presented in this study are based on the Born model for ionic solids, with potential parameters taken from Lewis and Catlow[5] and Dwivedi and Cormak.[6] These potentials have been employed to model lattice parameters,[7] thermal expansivities,[8] conductivity and diffusion properties[8] for CeO_2 and ZrO_2 solid solutions, in accord with experiment. In addition, a rigid ion model was used to reduce the computational expense. The dynamical simulations, which employ three-dimensional periodicity, were performed using the DL_POLY code,[9] and therefore a void normal to the surface is included to represent the free surface. The simulation cell contains ions distributed in two regions: region I comprises the CeO_2 thin film and the first six repeat units of the ZrO_2(111) support, and ions within this region are allowed to move under the dynamical regime, while region II comprises a fixed region (four repeat ZrO_2 units) of the support and is included to ensure the correct crystalline environment.

In this preliminary study we consider a model system, that of CeO_2 supported on cubic zirconia, as a first step in exploring CeO_2 supported on yttrium stabilised zirconia (YSZ), which will be considered in future studies; it has been shown experimentally that ceria grows epitaxially on YSZ.[10,11]

To generate the CeO_2/ZrO_2(111) interface, two CeO_2(111) repeat units (thick) were placed directly on top of ten repeat units of the ZrO_2(111) support using a 'cube-on-cube' methodology.[3] In particular, a 27 $\times$ 27 (which corresponds to 54 cerium atoms or 27 CeO_2 units for each side of the simulation cell) CeO_2 thin film was placed directly above a 20 $\times$ 20 ZrO_2(111) support, giving an interfacial area of 10 305 Å^2 and 65 496 ions within the simulation cell. The lattice misfit associated with the system is +36%; the CeO_2 is therefore constrained initially under considerable pressure. Dynamical simulation was then applied to the system for 115 ps at 3400 K, 55 ps at 2500 K, 5 ps at 2000, 1500 and 1000 K, 40 ps at 500 K, 10 ps at 100 K and 20 ps at 0 K; the latter acts effectively as an energy minimisation. During the initial dynamical simulation step, the considerable strain within the CeO_2 results in its amorphisation, which, upon prolonged dynamical simulation, recrystallises. That the CeO_2 undergoes an amorphous transition eliminates all 'memory' of the starting configuration enabling the CeO_2 to evolve structurally in response solely to the lattice misfit and underlying ZrO_2.

Inspection of the final structure for the CeO_2/ZrO_2(111) system [Fig. 1(a)] reveals that the CeO_2 thin film has recrystallized into the fluorite structure. The success of the simulated amorphisation and recrystallisation methodology in generating the CeO_2 structure from an amorphous solid suggests that the methodology is applicable to study supported fluorite-structured systems in addition to the supported rocksalt-structured systems considered previously.[3]

The final CeO_2 thin film structure exposes the (111) plane at both the interface and surface and comprises *ca*. five CeO_2 repeat units with an incomplete (*ca*. 25% occupancy) surface layer (layer five), which comprises small clusters ranging from,

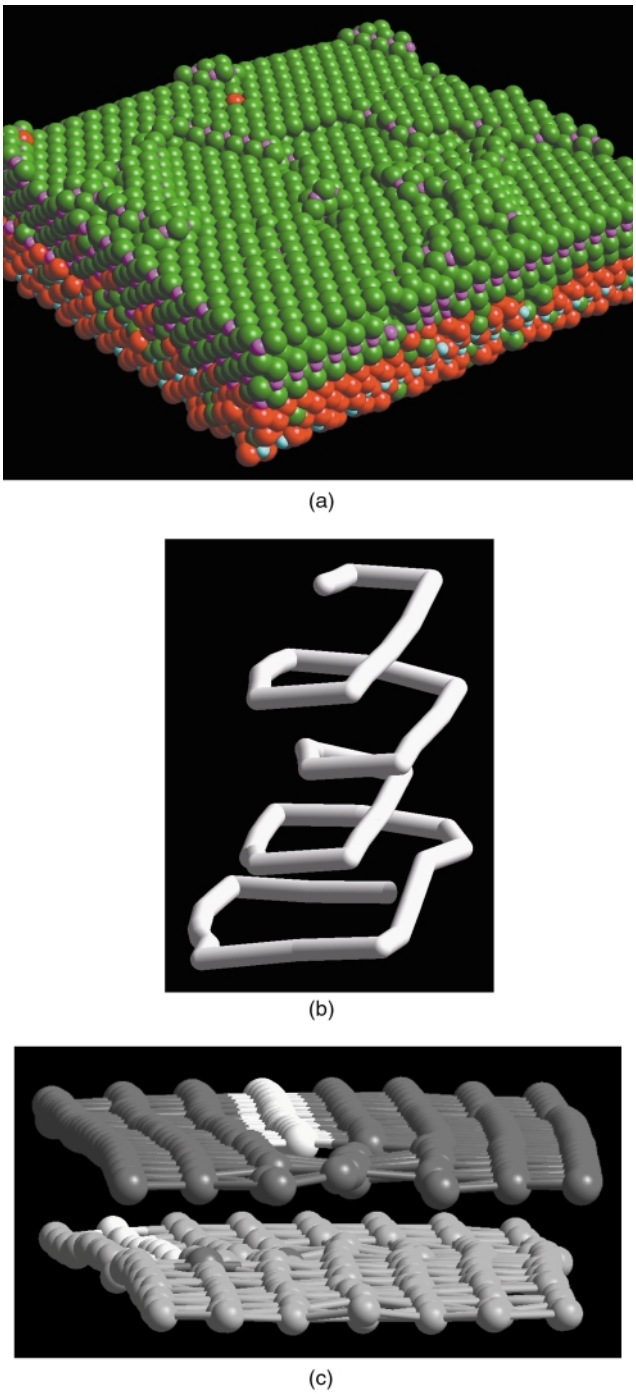

Fig. 1 (a) Representation of the $CeO_2/ZrO_2(111)$ interface. For reasons of clarity, only part of the full simulation cell and three planes of the support are depicted. Zirconium is coloured light blue, cerium is magenta, oxygen (ZrO_2) is red and oxygen (CeO_2) is green; (b) stick representation of the screw-edge dislocation (core structure). Only the cerium sub-lattice is shown to ensure clarity; (c) representation of two edge dislocations (white spheres) within the interfacial ZrO_2 layer (bottom) and second interfacial CeO_2 layer (top). The remaining planes have been omitted to preserve clarity. Zirconium is coloured light grey and cerium dark grey.

for example, Ce_2O_4 and Ce_4O_8, to larger clusters up to 500 Å^2 in size [Fig. 1(a)]. The CeO_2 thin film lies almost coherent with the underlying ZrO_2 support, with the CeO_2 accommodating a 19 × 19 (average) pattern with no rotation of the CeO_2 with respect to the underlying ZrO_2. The lattice misfit associated with such a configuration is therefore reduced from +6.7% based upon 20 CeO_2 units lattice matched with 20 ZrO_2 units (bulk misfit) to *ca*. +1.6% based upon 19 CeO_2 units lattice matched with 20 ZrO_2 units (final structure).† To maintain such a configuration, the CeO_2 lattice must be compressed by 1.6% to accommodate the misfit, which corresponds theoretically to a 'lattice parameter' of 5.34 Å. Experimentally, Dmowski *et al*., who explored the structure and oxygen storage properties of a *ca*. 20 Å CeO_2 thin film supported on zirconia,[10] found the CeO_2 lattice parameter to be reduced from 5.41 to 5.38 Å. In addition, they observed no rotation of the CeO_2 with respect to the underlying support in accord with our findings.

A detailed analysis of the system using molecular graphics techniques revealed that the system comprises cerium (*ca*. 0.8%) and zirconium (*ca*. 0.3%) vacancies charge compensated by associated oxygen vacancies. Moreover, the density of vacancies within the CeO_2 thin film increases within planes further from the interface. In addition, dislocations including pure edge and mixed screw-edge dislocations have evolved within the system. The latter, as depicted in Fig. 1(b), traverses the entire thickness of the CeO_2 thin film and moreover, extends into the first layer of the ZrO_2 support resulting in considerable perturbation of the underlying ZrO_2 support. In response, zirconium and oxygen ions migrate from the support to form a large (*ca*. 30 Å^2) cluster, which emanates from the base of the dislocation core. We also note that pure edge dislocations have evolved in both the CeO_2 thin film *and* within the ZrO_2 support [Fig. 1(c)]. Experimentally, dislocation arrays with periodicity of *ca*. 44 Å were observed to accommodate the lattice misfit for CeO_2 supported on YSZ.[12] We suggest such defects (vacancies and dislocations) help reduce further the +1.6% misfit (19 × 19 CeO_2 supported on 20 × 20 ZrO_2) and hence the associated strain within the system.

In summary, we have shown that computer modelling in conjunction with graphical analysis provides a powerful complementary technique to experiment in characterising the detailed atomistic structure of ZrO_2 supported CeO_2 thin films. In particular, structural features such as dislocations, defects and defect clusters, comprising low coordinatively saturated cerium and oxygen ions, are likely to have a considerable influence on the catalytic behaviour of the system including the mobility of ions through the ceria and zirconia lattices. Accordingly, elucidation of the atomistic structure of such structures as performed here, may help explain the remarkable catalytic properties of supported ceria thin films.

Notes and references

† The bulk and thin-film lattice misfits are given by:

$$F_{\text{bulk}} = \frac{\left|a_{CeO_2} - a_{ZrO_2}\right|}{(a_{CeO_2} + a_{ZrO_2})/2} \times 100 = +6.9\%$$

$$F_{\text{thin\_film}} = \frac{\left|na_{CeO_2} - ma_{ZrO_2}\right|}{(na_{CeO_2} + ma_{ZrO_2})/2} \times 100 = +1.6\%$$

where a_{CeO_2} and a_{ZrO_2} represent the bulk lattice parameters for ceria and zirconia, respectively, and n and m the number of units per side of simulation cell; n = 19CeO_2 units and m = 20ZrO_2 units.

The ratio of the dichloromethane–methanol solvent mixture medium and nature of the receptor amide substituent critically dictates chloride *vs.* nitrate selectivity properties of new ruthenium(II) tris(5,5′-diamide-2,2′-bipyridine) receptors.

The selective recognition and sensing of anionic guests is a fundamental objective in supramolecular chemistry.[1,2] This is a consequence of the important role played by anions in a range of biological, chemical, medical and environmental processes.[3] Despite the fact that a wide range of solvents and solvent mixtures has been used in anion binding investigations, relatively little attention has been paid as to how the nature of the solvent medium and receptor structure can influence both the strength of anion–receptor complexation and importantly the anion binding selectivity trend the receptor displays. Previous research has shown that bis(heteroleptic) ruthenium(II) bipyridine cations $Ru(bpy)_2(bpy')^{2+}$ can bind and optically sense anions when bpy′ is a 4,4′- or 5,5′-diamide-2,2′-bipyridine ligand.[4,5] These receptors employ a combination of electrostatic and hydrogen bonding interactions to bind anionic guests. We report here the synthesis of new homoleptic receptors based on the ruthenium(II) tris(5,5′-diamide-2,2′-bipyridine) motif and demonstrate the anion binding strength, stoichiometry and chloride *vs.* nitrate anion selectivity critically depend on the nature of the receptor amide substituent and CH_2Cl_2:MeOH solvent mixture ratio.

The condensation of 5,5′-bis(chlorocarbonyl)-2,2′-bipyridine **1** with 2-methoxyethylamine, *n*-butylamine, *n*-dodecylamine 4′-carbonyl-1′,2′-dimethoxyphenyl-1,2-diaminoethane[6] gave the 5,5′-diamide-2,2′-bipyridine ligands **2**–**5** respectively in yields of 61–85% (Scheme 1).[5] The four host molecules **6**–**9** were prepared by reacting ligands **2**–**5** with ruthenium(III) trichloride in EtOH–H_2O (*via* 'ruthenium blue'[7]) or DMF. The receptors were purified by column chromatography on silica gel or Sephadex SP C25 and were isolated as their hexafluorophosphate salts in yields of 17–85%.‡

The Λ- and Δ-enantiomers of host **6** were resolved by cation exchange chromatography (Sephadex SP C25)[8] using sodium (−)-O,O′-dibenzoyl-L-tartrate. Figs. 1 and 2 show the crystal structure of the dichloride salt of Δ-**6**.§ The metal has a six-coordinate distorted octahedral environment being bonded to six nitrogen atoms [2.039(13)–2.095(13) Å] of the three bidentate ligands. The most interesting feature of the structure is that both chloride anions are encapsulated within the cavities formed around two triangular faces in the metal coordination sphere. As shown in Fig. 1, Cl2 forms hydrogen bonds to the three –NH groups at distances of 3.19, 3.29, 3.36 Å for N302, N202 and N602, respectively. However Cl1 forms only two hydrogen bonds to N102 at 3.21 and N502 at 3.27 Å. The third amide N–H group is directed away from the chloride, outwards from the cavity, and forms an intermolecular hydrogen bond N(402)···O(501) (1 − *x*, 0.5 + *y*, 2 − *z*) at 2.99 Å.

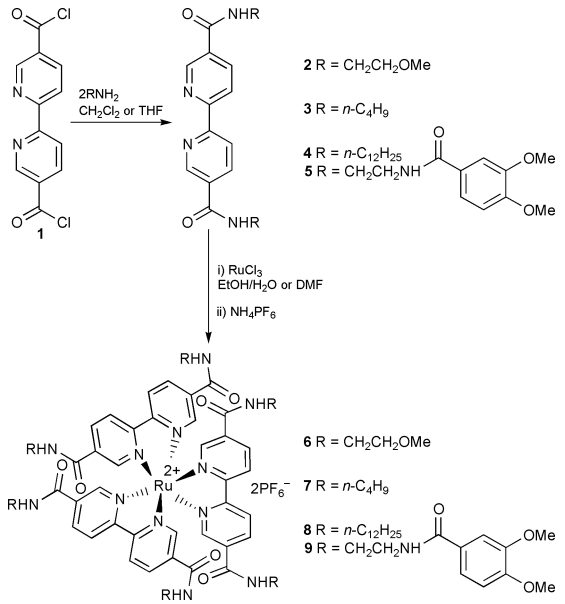

Scheme 1

There is a good geometric complementarity between the chloride anions and the interligand binding clefts, as illustrated in Fig. 2.

UV–VIS spectroscopic anion titrations were performed by adding tetrabutylammonium chloride, acetate and nitrate salts to receptors **6**–**9** in CH_2Cl_2 and CH_2Cl_2–MeOH solutions. Binding was generally signified by decreases in the absorbance and hypsochromic shifts for the MLCT and LC bands at *ca.* 260 and 300 nm, respectively. Values for the stability constants log β_1 and log β_2 were calculated using the Specfit program[9] and the data are summarised in Table 1. The results demonstrate how anion binding strength, stoichiometry and selectivity are

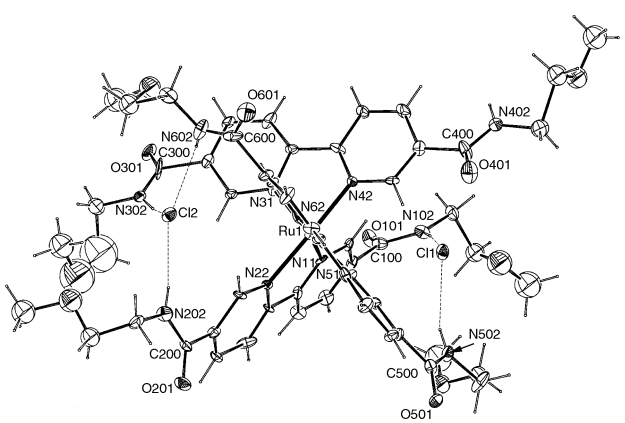

Fig. 1 The structure of Δ-**6** with ellipsoids at 20% probability. Hydrogen bonds to the chloride ions are shown as dotted lines.

DOI: 10.1039/b008822f

strongly dependent on the type of anion, the solvent system and the receptor amide substituent. For example, Table 1 shows the stability constants for all three anions decrease significantly as the methanol content increases from 1:0 to 9:1, 7:3 and then 1:1 CH_2Cl_2:MeOH. This can be rationalised by considering the high polarity of methanol and its ability to hydrogen bond with the receptor and the anionic guest. The complex stoichiometry is dependent on the binding strength and can be either 1:1 or 1:2 (host:guest). In 1:0 and 9:1 CH_2Cl_2:MeOH the host:guest ratio is 1:2. This correlates with the binding stoichiometry exhibited by **Δ-6** in the solid state (Fig. 1). In contrast, the observed host:guest ratio can be 1:2 or 1:1 in 7:3 CH_2Cl_2:MeOH, and is 1:1 in 1:1 CH_2Cl_2:MeOH. Table 1 also reveals how the anion selectivity depends on the solvent system. In 9:1 and 7:3 CH_2Cl_2:MeOH, all receptors display the selectivity sequence $Cl^- > NO_3^- > AcO^-$. The preference for chloride suggests this guest presents a superior match for the shape and/or dimensions of the binding site, while the unfavourable desolvation energy and non-complementary shape of acetate may explain why the weakest complexes are formed with this anion. It is noteworthy that receptors **6** and **7** remain chloride selective in 1:1 CH_2Cl_2:MeOH, while hosts **8** and **9** become selective for the nitrate anion. As the percentage of methanol is raised from 10 to 30 to 50%, the energy required to desolvate the anions prior to complexation increases and this can switch selectivity towards the anion with the lowest desolvation energy.[10] The hydration enthalpies ($-\Delta H_{hyd}$) of NO_3^-, Cl^- and AcO^- are calculated to be 293, 335 and 402 kJ mol^{-1}, respectively,[11] and these provide a good guide to the relative anion solvation energies in 1:1 CH_2Cl_2:MeOH. Hosts **8** and **9** possess large, lipophilic substituents which can partially shield the amide binding site from the surrounding solvent; the anion must therefore undergo significant desolvation prior to binding with these receptors. Consequently, the selectivity trend $NO_3^- > Cl^- > AcO^-$ for hosts **8** and **9** in 1:1 CH_2Cl_2:MeOH reflects the sequence of hydration energies $AcO^- > Cl^- > NO_3^-$ in the Hofmeister series.[12] In contrast, receptors **6** and **7** contain smaller amide substituents than their congeners **8** and **9**, and the anion desolvation energy does not dictate the selectivity sequence. The geometric complementarity between the chloride anion and hosts **6** and **7** is dominant (as exemplified by the crystal structure of **Δ-6** in Fig. 2) and overrides the unfavourable desolvation energy for this guest.

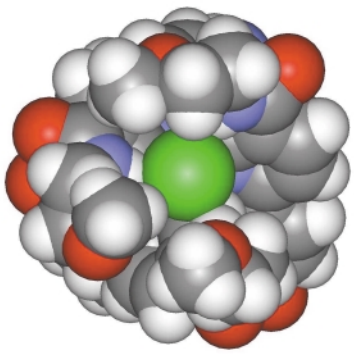

Fig. 2 CPK representation of **Δ-6** based on the crystal structure coordinates, illustrating the geometric complementarity between the chloride guest Cl2 (green) and the interligand binding pocket. (The methoxyethyl chain at the far side of the molecule has been removed to aid clarity.)

Table 1 Stability constants for receptors **6–9** and anions in CH_2Cl_2–MeOH solvent mixtures[a]

		Cl^-		NO_3^-		AcO^-	
Host	Solvent CH_2Cl_2:MeOH (v/v)	log β_1	log β_2	log β_1	log β_2	log β_1	log β_2
8	1:0	[b]		[b]		[b]	
6	9:1	7.47	12.9	6.33	11.3	5.90	10.1
7	9:1	7.69	14.1	6.70	12.3	6.02	10.9
9	9:1	[b]		7.88	13.8	7.06	12.3
6	7:3	5.43		5.27		[c]	
7	7:3	6.44	10.8	5.64		[c]	
8	7:3	6.48	10.5	5.76		[c]	
9	7:3	5.94	10.2	5.42		[c]	
6	1:1	4.31		[c]		[c]	
7	1:1	4.45		[c]		[c]	
8	1:1	4.82		5.39		[c]	
9	1:1	4.51		5.03		[c]	

[a] Errors estimated to be ⩽7%; T = 293 K. [b] Binding too strong for calculation (host:guest complex stoichiometry is 1:2). [c] Binding too weak for calculation.

In summary, the chloride *vs.* nitrate selectivity of new ruthenium(II) tris(5,5′-diamide-2,2′-bipyridine) receptors depends on both solvation factors and the amide substituent on the host. This interrelation between solvation effects and receptor structure is also used to achieve anion binding selectivity in Nature.[11]

We thank Professor F. R. Keene (James Cook University, Townsville, Australia) for supervising the chromatographic resolution of receptor **6**. We also acknowledge the EPSRC for a studentship (L. H. U.) and for use of the mass spectrometry service at the University of Wales, Swansea, and the EPSRC and University of Reading for funds for the Image Plate System.

Xenon probe for detecting the microporous structure of nanosized HZSM-5 zeolite

Weiping Zhang,*† Xiuwen Han, Xianchun Liu, Hao Lei and Xinhe Bao*

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian 116023, China. E-mail: w.zhang@tech.chem.ethz.ch

Received (in Cambridge, UK) 8th November 2000, Accepted 3rd January 2001
First published as an Advance Article on the web 23rd January 2001

The secondary pores in the nanosized HZSM-5 zeolite have been observed for the first time *via* ^{129}Xe NMR spectroscopy using xenon as a probe; the location of non-framework Al can also be identified.

As an emerging member of nanometer materials, nanosized zeolites have received considerable attention in the field of catalysis owing to their unique properties. When the crystallite size of HZSM-5 zeolite is reduced to the nanoscale level, it exhibits higher catalytic activity, less coking and longer catalytic life in the conversion of methanol to hydrocarbons,[1] oligomerization of ethylene, *etc.*[2] At present, there is growing interest in the synthesis of nanosized zeolites.[3,4] However, few attempts have been made to characterize the microporous structure of nanosized zeolites. In particular, the effects of crystallite size down to the nanoscale level on the microporous structure of zeolites have not been well established in the literature. ^{129}Xe NMR spectroscopy is a powerful technique for investigating porous materials, especially zeolites.[5–7] The high polarizability of the xenon electron cloud makes it very sensitive to physical interactions with its environment. Here we use xenon as a probe molecule for detecting the variations of microporous structure of dealuminated HZSM-5 zeolites with crystallite sizes of < 100 nm.

The starting HZSM-5 samples (Si/Al = 28) with crystallite sizes of 1000 and 70 nm were prepared according to the procedure published in our previous papers.[8–10] Hydrothermal treatment was performed in a quartz reactor tube with 10 mm maximum bed depth of zeolite. The temperature was increased at a rate of 5 °C min^{-1} to the treatment temperatures of 400 and 700 °C, then 100% water vapor (0.1 MPa) was introduced for 2 h. As established by ^{27}Al MAS and ^{1}H→^{27}Al CP/MAS NMR spectra, there is little non-framework Al in the parent microsized and nanosized HZSM-5 zeolites.[10] However, hydrothermal treatment of the samples leads to dealumination of the zeolite frameworks and to gradual formation of non-framework Al (δ_{Al} at 0 and 30 ppm).[11]

Prior to adsorption, all samples were degassed typically at 723 K and a pressure below 10^{-2} Pa for 10–20 h. ^{129}Xe NMR spectra were collected at room temperature on a Bruker DRX-400 spectrometer operating at 110.6 MHz with a recycle delay of 1 s, 60° pulse width of 8 μs and 1000–4000 scans. Chemical shifts were referenced to a secondary standard of xenon adsorbed in NaY zeolite the resonance of which was previously referenced to xenon gas at zero pressure using Jameson's equation.[12]

XPS measurements were carried out in a modified Leybold LHS-12 MCD system using Mg-Kα excitation and pass energy of 100 eV. The Si/Al ratio on the external surface of the zeolites can be obtained by integrating the calibrated Si 2p (E_b = 102.9 eV) and Al 2p (E_b = 74.3 eV) peaks.

The ^{129}Xe NMR spectra of parent microsized and nanosized HZSM-5 zeolites are shown in Fig. 1. With increase of xenon uptake, the resonance positions shift to low field due to the predominance of Xe–Xe interactions with an increase of xenon concentration. One main signal with a weak high-field shoulder is observed in the spectra of parent microsized HZSM-5 [Fig. 1(a)]. The main peak is associated with xenon adsorbed in the internal channels of microsized HZSM-5. However, for the nanosized HZSM-5, with increase of xenon uptake, a new strong peak appears at higher field [Fig. 1(b)]. The intensity of this new peak increases with xenon pressure up to 400 Torr. Further increase of xenon concentration, however, results in a decrease of the peak intensity where it is observed as a shoulder peak of the low-field signal. It is well known that the average electrostatic field in the internal channels of HZSM-5 zeolite is much stronger than that on the external surface.[6] Thus, xenon is adsorbed preferentially in the internal channels, and its chemical shift is at the low field. When the crystallite size of HZSM-5 zeolite is reduced to the nanoscale level, as demonstrated by a transmission electron microscope (TEM),[8] the particles are present as aggregates of many nanosized crystals with void space between the crystallites, for a high surface energy. Nanosized HZSM-5 zeolite has many secondary pores, which differ from the internal channels. With increasing xenon uptake, more xenon will be distributed in the secondary pores of nanosized HZSM-5, of this, some is adsorbed on the external surface of nanosized HZSM-5 whilst the remainder occupies the void space of the secondary pores. Therefore, as shown in Fig. 1(b), two signals are observed in the ^{129}Xe NMR spectra of nanosized HZSM-5. The low-field peak is assigned to xenon in the internal channels of nanosized zeolite, while the high-field peak is attributed to xenon in the secondary pores. However, under conditions of less aggregation,[8] the xenon signal of the secondary pores appears as a weak shoulder in the spectra of microsized HZSM-5 [Fig. 1(a)]. In addition, it can also be seen from Fig. 1(b) that the line width of the high-field peak is much narrower than that of the low-field peak. This may be due to a higher mobility of xenon atoms in such sites caused by weaker interaction among xenon atoms, which implies that the secondary pore size of the nanosized zeolite might be greater than that of its internal channels.

If we plot the resonance positions of xenon in the internal channels and in the secondary pores of nanosized HZSM-5 at

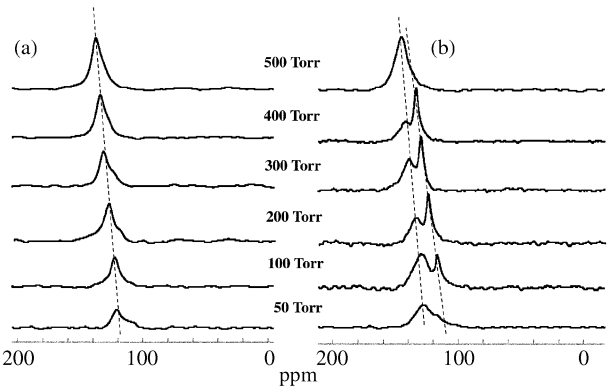

Fig. 1 ^{129}Xe NMR spectra of xenon adsorbed in parent microsized (a) and nanosized (b) HZSM-5 zeolites as a function of xenon pressure.

† Present address: Laboratory of Technical Chemistry, ETH Zurich, CH-8092, Switzerland.

DOI: 10.1039/b009015h

different pressures [Fig. 1(b)], it is found that the slopes of these two lines are different and at higher xenon pressures these two lines will be superposed. This indicates that the chemical shift difference between xenon in the internal channels and in the secondary pores decreases slightly with pressure. Xenon atoms in these two positions also exchange at room temperature and when the xenon pressure is > 500 Torr, this exchange is too fast to be detected by NMR. Thus, one main signal is observed in the ^{129}Xe NMR spectra of nanosized HZSM-5 at higher xenon pressures. To our knowledge, this is the first report that secondary pores in nanosized zeolites are observed by ^{129}Xe NMR spectroscopy.

Fig. 2 and 3 show the ^{129}Xe NMR spectra of microsized and nanosized HZSM-5 zeolites treated by steaming at 400 and 700 °C. There is only a single signal in the ^{129}Xe NMR spectra of microsized HZSM-5 dealuminated by steaming (Fig. 2). This demonstrates that the non-framework Al may migrate to the external surface of the dealuminated microsized HZSM-5, in the presence of steam, leading to a homogeneous distribution of xenon in the channels. However, two signals are evident in the ^{129}Xe NMR spectra of nanosized HZSM-5 treated by steaming at 400 °C [Fig. 3(a)]. The obvious distribution of xenon in the

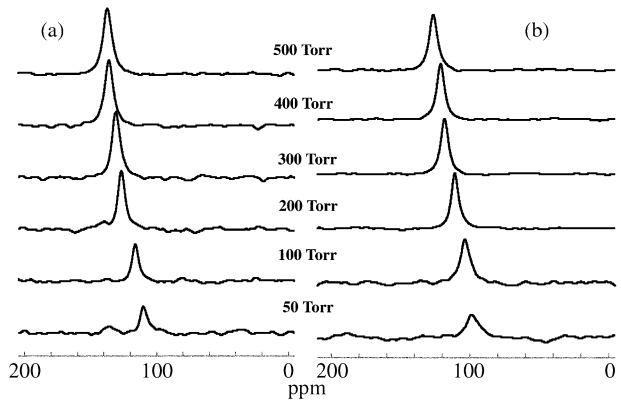

Fig. 2 ^{129}Xe NMR spectra of xenon adsorbed in dealuminated microsized HZSM-5 zeolite steamed at 400 °C (a) and 700 °C (b) as a function of xenon pressure.

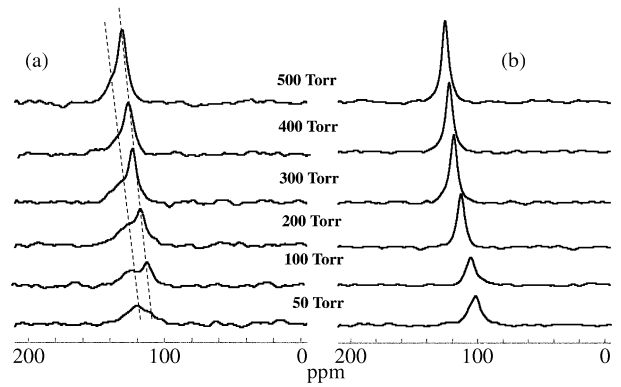

Fig. 3 ^{129}Xe NMR spectra of xenon adsorbed in dealuminated nanosized HZSM-5 zeolite steamed at 400 °C (a) and 700 °C (b) as a function of xenon pressure.

secondary pores of nanosized HZSM-5 indicates that most non-framework Al does not deposit on the external surface of the nanocrystallites. The two lines from the resonance positions of xenon adsorbed in the internal channels and in the secondary pores will not be superposed at high xenon pressures [Fig. 3(a)]. This indicates that the existence of non-framework Al hinders the rapid exchange of the xenon atoms in these two positions. One can speculate that the non-framework Al may deposit near the windows of the nanosized HZSM-5 channels. If hydrothermally treated at higher temperatures, such as at 700 °C, only one signal appears in the ^{129}Xe NMR spectra [Fig. 3(b)]. Thus, the non-framework Al may occupy the secondary pores of nanosized HZSM-5 (*i.e.* on the external surface).

XPS experiments were performed to study the migration of Al atoms in zeolites. It was found that the Si/Al ratio on the external surface of microsized HZSM-5 decreases from 12.5 to 3.5 after steaming at 700 °C, while that of nanosized HZSM-5 decreases from 6.3 to 3.2 under the same conditions. Therefore, hydrothermal treatment of both microsized and nanosized HZSM-5 will lead to Al enrichment on the external surface *i.e.* migration of Al atoms to the external surface. A similar result was obtained by Datka *et al.*[13] in characterizing a dealuminated HZSM-5 zeolite. This also agrees well with the above results from ^{129}Xe NMR.

In conclusion, xenon is a sensitive probe to detect zeolite microporous structure and its variation upon dealumination. Evidence of secondary pores are observed for the first time in the ^{129}Xe NMR spectra of nanosized HZSM-5 zeolite. After hydrothermal treatment, the location of non-framework Al can also be determined.

The support of the National Natural Science Foundation of China and the Ministry of Science and Technology of China through the 973 Project is gratefully acknowledged.

Opportunities for ionic liquids in recovery of biofuels

Andrei G. Fadeev*† and Michael M. Meagher

Biological Process Development Facility, The University of Nebraska, Lincoln, NE, 68583, USA. E-mail: mmeagher@unl.edu; Fax: +1 402-472-1693; Tel: +1 402-472-2342

Received (in Corvallis, OR, USA) 26th July 2000, Accepted 13th December 2000
First published as an Advance Article on the web 23rd January 2001

Room temperature ionic liquids have potential as extractants in recovery of butyl alcohol from fermentation broth; water solubility in ionic liquid and ionic liquid solubility in water are important factors affecting selectivity of butyl alcohol extraction from aqueous solutions.

There has been a renewed interest in processing of biomass into fuels and chemicals *via* fermentation during the last decade. In that respect, ethanol and acetone–butyl alcohol–ethanol (ABE) fermentations are two of the most attractive bioprocesses. Recovery of alcohols from the fermentation broth is the most energy extensive step in fermentative fuel production. The average energy requirement per litre of EtOH produced is 2446 kcal.[1] The amount of energy is about 3 times higher[2] for *n*-BuOH, since ABE fermentation broth contains only about 2 wt% of BuOH *vs.* 6 wt% of EtOH in yeast fermentation broth. EtOH is currently recovered by distillation. Distillative recovery of BuOH from fermentation broth is not economical. Alternative recovery methods have been considered including: solvent extraction, stripping, pervaporation, *etc*. None of the methods has been economically proved yet.

We investigated the potential of ionic liquids for extraction of BuOH from aqueous solutions. Room temperature ionic liquids have extremely low vapor pressure and low solubility in water. These properties make them interesting solvents for extraction of organic compounds from aqueous stream.[3]

Most solvents that have high distribution coefficients for BuOH are flammable, hazardous and toxic to humans and microorganisms.[4] Tri-*n*-butyl phosphate, octan-1-ol and diethyl ether are listed as solvents with high BuOH partition coefficients, 14.6, 7.6, and 4.1, respectively.[5] Tri-*n*-butyl phosphate and octan-1-ol were shown to be toxic to bacteria[6] and diethyl ether is extremely flammable.

Solvent selection criteria for liquid–liquid extractions are numerous, including distribution coefficient, density, viscosity, *etc*. This paper addresses solubility of ionic liquids in water, water coextraction, density and viscosity of extractant. Using the correlation of partitioning data between 1-butyl-3-methyl-1*H*-imidazol-3-ium hexafluorophosphate ([BMIM][PF_6])–water and octan-1-ol–water,[3] it could be found that the BuOH partition coefficient in the [BMIM][PF_6]–water system should be around 0.8–0.85. Professor K. Seddon advised us that 1-octyl-3-methyl-1*H*-imidazol-3-ium hexafluorophosphate ([OMIM][PF_6]) should have lower solubility in water than [BMIM][PF_6].

BMIM[PF_6] was prepared according to the procedure described by Huddleston *et al*.[3] The density of the ionic liquid was 1.34 g cm^{-3}.

1-Octyl-3-methyl-1*H*-imidazol-3-ium chloride was prepared *via* metathesis reaction of equimolar amounts of 1-methylimidazole and 1-chlorooctane. The two components were mixed in a round-bottom flask equipped with stopcock vacuum adapter, and the air was removed from the flask using a vacuum pump. The reaction was carried out at 80 °C for 3–4 d. The product was washed with ethyl acetate and dried in vacuum. OMIM[PF_6] was obtained from 1-octyl-3-methyl-1*H*-imidazol-3-ium chloride by adding an equimolar amount of hexafluorophosphoric acid. The density of [OMIM][PF_6] was 1.21 g cm^{-3}.

To determine distribution coefficients and mutual solubilities, the ionic liquid was mixed with water or BuOH–water solution in an airtight bottle. The mixture was shaken overnight and then left for 1–3 d to achieve phase separation. Mutual solubilities were determined by separating BuOH and water from the IL using a rotary evaporator. The collected BuOH–water solutions were analyzed by GC. BuOH and water distribution coefficients, D, and selectivities, α, were estimated according to eqns. 1 and 2

$$D = c_{IL} \cdot \rho / c_{H_2O} \quad (1)$$

$$\alpha = D_{BuOH} / D_{H_2O} \quad (2)$$

where c_{IL} and c_{H_2O} are the concentrations (g per 1000 g of phase) of BuOH and water in ionic liquid phase and aqueous phase; ρ is the density of ionic liquid, D_{BuOH} and D_{H_2O} are the BuOH and water distribution coefficients.

The BuOH distribution coefficient for [BMIM][PF_6]–water was found to be very close to the predicted value, 0.85 (Table 1). Distribution coefficients of BuOH for both ionic liquids were similar. Increase in the molecular dimensions of the alkylimidazolium cation decreased mutual solubilities of the ionic liquid and water resulting in higher extractive selectivities for [OMIM][PF_6]. Water solubility of [BMIM][PF_6] was 6.5 fold higher than that of [OMIM][PF_6].

The larger size of the $[OMIM]^+$ ion also resulted in higher viscosity of [OMIM][PF_6] (Fig. 1). The viscosity had strong temperature dependence allowing for fast phase separation at elevated temperature. Higher temperature also improved extractive selectivity, Table 1. BuOH solubility for the ionic liquids under investigation was small, 200–400 mol m^{-3}. It is, however, within the range of solubilities in octanol (200 to 2000 mol m^{-3}). Huddleston *et al*.[3] noted that even low partition coefficients could result in an economical recovery process due to the non-volatility of the extractant.

Pervaporation is often mentioned as the most promising technology for recovery of organics from aqueous streams, and polydimethylsiloxane membrane is the most extensively studied for organophilic pervaporation.

Pervaporative BuOH recovery from 1 wt% aqueous solution and [OMIM][PF_6] was investigated using commercial polydimethylsiloxane membrane MEM-100 (MemPro Co., www.MemPro.com). The solution of [OMIM][PF_6]–butanol–water 97.4–1.0–1.6 wt% was prepared to simulate the composition of the ionic liquid phase in equilibrium with 1 wt% BuOH–water solution. The pervaporation set-up is described

Table 1 Compositions of phases, distribution coefficients, and extractive selectivity

Initial aqueous phase composition	Aqueous phase, g/1000 g			Ionic liquid phase, g/1000 g					
	BuOH	H_2O	[BMIM][PF_6]	BuOH	H_2O	[BMIM][PF_6]	D_{H_2O}	D_{BuOH}	α
100% H_2O, 23 °C	—	97.703	2.297	—	2.116	97.884	0.029	—	—
2.01 wt% BuOH, 23 °C	1.143	96.463	2.394	0.724	2.400	96.876	0.033	0.849	25.77
4.74 wt% BuOH, 23 °C	2.927	94.664	2.409	1.689	2.576	95.735	0.036	0.773	21.47
4.97 wt% BuOH, 50 °C	1.785	94.639	3.576	2.286	4.791	92.923	0.068	1.716	33.65
Initial aqueous phase composition	BuOH	H_2O	[OMIM][PF_6]	BuOH	H_2O	[OMIM][PF_6]	D_{H_2O}	D_{BuOH}	α
100% H_2O, 23 °C	—	99.65	0.350	—	1.520	98.480	0.018	—	—
2.01 wt% BuOH, 23 °C	1.061	98.458	0.436	0.809	1.321	97.870	0.016	0.923	55.31
4.74 wt% BuOH, 23 °C	2.237	97.225	0.538	1.637	1.922	96.441	0.024	0.885	36.65
4.97 wt% BuOH, 50 °C	1.273	97.257	1.470	1.744	2.970	95.286	0.037	1.658	44.19

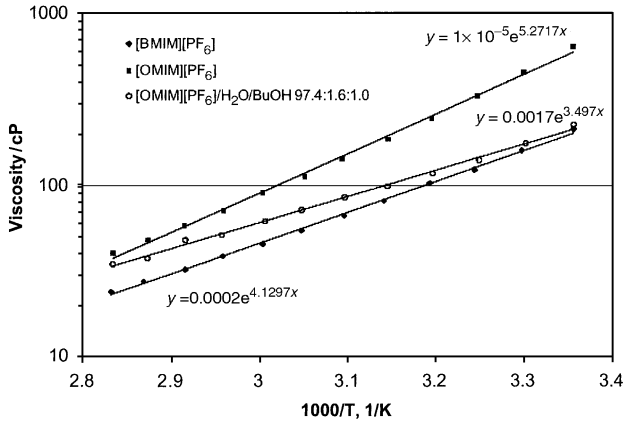

Fig. 1 Viscosity *vs.* 1/*T*.

elsewhere.[7] Pervaporative selectivity was determined according to the equation:

$$\alpha = \left[\frac{C_{BuOH}}{C_{H_2O}}\right]_{permeate} \Big/ \left[\frac{C_{BuOH}}{C_{IL} + C_{H_2O}}\right]_{feed} \quad (3)$$

where C is concentration.

Pervaporation measurements were carried out at 55 °C with permeate pressure 0.01 Torr. Due to the high viscosity of the feed, concentration polarization was anticipated, even though viscosity of [OMIM][PF_6]–water–BuOH solution was noticeably lower than that of pure [OMIM][PF_6] (Fig. 1). The feed flow through the membrane cell was definitely laminar even at a flow rate of 4 L min^{-1}. Flux through the membrane was 67 g m^2 h^{-1} at selectivity 62. As expected, there was no ionic liquid found in the permeate. Pervaporation of 1 wt% BuOH–water solution at the same conditions showed a flux rate of 110 g m^2 h^{-1} at selectivity 42.

Although the viscosity of [OMIM][PF_6]–water–BuOH solution was about 100 fold higher than the viscosity of the BuOH–water mixture, the flux rate through the membrane was only 0.6 fold lower at higher selectivity. BuOH–water ratio in the permeate was close to BuOH–water ratio in ionic liquid feed, suggesting that the membrane did not improve the separation. Distillation is thought to be more economical for BuOH recovery from ionic liquids.

In conclusion, chemical versatility makes ionic liquids interesting solvents for extractive separation in biotechnology. Properties of ionic liquids in that respect remain very much unexplored. We are particularly interested in investigating the mechanism of toxicity of ionic liquids for microorganisms. Preliminary studies of ABE fermentation with [OMIM][PF_6] present at saturation level suggest that the IL suppress biological activity in the system.

The research was supported by the National Corn Growers Association. The authors are grateful to Dr J. Huang for toxicity tests.

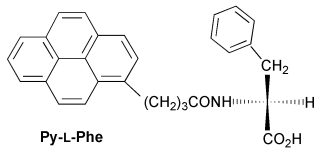
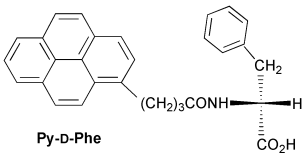
A phenylalanine-derived fluorescent probe shows high enantioselectivity for binding to bovine serum albumin; the L-isomer binds nearly one hundred times better than the D-isomer, which suggests the tight fitting of the L-isomer to the binding site.

Although chiral discrimination of substrates by enzymes and other biological macromolecular systems is well known, the design of chiral molecules that can bind to proteins with a high enantioselectivity is challenging.[1] Enantioselective binding of dansyl amino acids, drugs, and metal complexes to bovine serum albumin (BSA), chymotrypsin, and other proteins has been reported, although the selectivity is often low (1.15 to 3).[2] Despite the low selectivity, chiral biochromatography with BSA has been demonstrated to be useful in separating the optical isomers of drugs, amino acids, and small molecules, thereby, indicating the utility of such recognition in a variety of applications.[3] The observed enantiomeric selectivity was explained based on the steric, hydrophobic and hydrogen-bonding interactions between the ligand and the host.[4] The design of ligands that bind tightly to sites that can accommodate only one isomer but not the other, with selectivities > 10, therefore, is challenging.

The design of pyrene labeled peptides that bind to proteins and induce site specific photocleavage of the protein backbone (protein scissors) is of current interest.[5] *N*-[4(1-pyrene)butyroyl]-L-phenylalanine (Py-L-Phe), for example, induces site



Py-L-Phe



Py-D-Phe

specific photocleavage in BSA between residues Leu 346 and Arg 347, and in lysozyme the cleavage occurs between residues Trp 108 and Val 109.[5c] We now report that Py-L-Phe and its optical isomer, Py-D-Phe, are discriminated by BSA in a 100 : 1 ratio (the ratio of the corresponding binding constants). These observations indicate the importance of the single asymmetric center present in Py-Phe for recognition between ligand and the protein. The chiral discrimination is reflected in the photophysical properties of the protein-bound probes. The protein-bound ligand spectra exhibit contrasting differences between the isomers, indicating the sensitivity of these properties on the chiral nature of the probe microenvironment in the protein.

Py-D-Phe was synthesized by reacting the methyl ester of D-phenylalanine with 4(1-pyrene)butyric acid in tetrahydrofuran using *N*,*N*′-dicyclohexyl carbodiimide (DCC) as the coupling agent in a procedure analogous to the synthesis of the corresponding L-isomer.[5] Mild hydrolysis of the methyl ester (1 M HCl, 12 h, room temp.) followed by column chromatography on silica gel (elution with 20 : 5, chloroform to methanol) resulted in Py-D-Phe in 60% yield. The product was characterized from UV–VIS, fluorescence, circular dichroism, ^{1}H NMR and mass spectral data. ^{1}H NMR (400 MHz, d_6-DMSO) δ 7.8–8.2 (9H), 7.1 (5H), 4.4 (1H), 3.1 (2H), 1.8–2.1 (6H); MS data (FAB): *m/z* 436 (MH^+).

The absorption spectrum of the pyrenyl chromophore in the near UV region (300–360 nm) is sensitive to the binding of the probe to the protein. Addition of BSA (0, 0.5, 1, 1.5, 2, 4, and 8 μM) to Py-D-Phe (10 μM) resulted in dramatic changes in the probe absorption spectrum (Fig. 1). The vibronic band positions are shifted to longer wavelengths as the protein is titrated into the solution, and an isosbestic point (point of constant absorbance) is clearly visible. Such isosbestic behavior is strongly indicative of two distinct chromophores, and we assign these to the bound and free chromophores. A net increase in the absorbance at the 0–0 band (hyperchromism) with protein concentration is also evident in the spectra. In contrast to these results, extensive hypochromism (decrease in absorbance) was observed when Py-L-Phe was titrated with BSA, under similar conditions.

The above absorption titration data were analyzed to construct binding isotherms, using the Scatchard equation,[5] and the corresponding binding constant is 5.3×10^5 dm^3 mol^{-1}. This value is two orders of magnitude less than the corresponding binding constant for the L-isomer (6.7×10^7 dm^3 mol^{-1}).[5] Thus, Py-L-Phe binds nearly 100 times better than Py-D-Phe. The large discrimination between the two chiral isomers is surprising, and it is much greater than the enantioselectivities observed for the binding of gossypol, warfarin, dansyl amino acids and chiral fatty acid analogs to BSA (discussed below). The large differences in the binding constants between the optical antipodes strongly suggest the intimate interaction of the probe with the protein in which only one of the two isomers fits snugly in the binding site. Such intimate interaction with the surrounding protein matrix is expected to result in differences in the spectral properties of the protein-bound chromophores.

The microenvironments of the protein-bound isomers, their access to the aqueous phase, and solvent exposure are expected

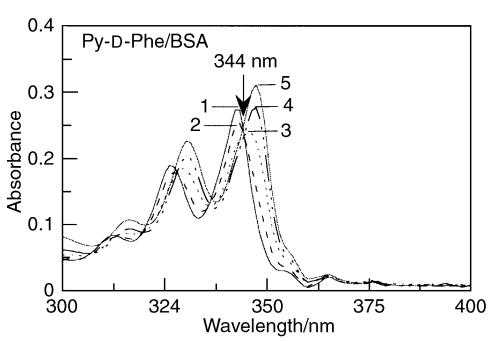


Fig. 1 Absorption spectra of Py-D-Phe (10 μM) (1 cm path length) with increasing concentrations of BSA: (0, 0.5, 2.0, 4.0 and 8.0 μM). The red shift (4 nm) of the peak positions and the isosbestic points at 344, 328, and 315 nm are evident in the spectra.

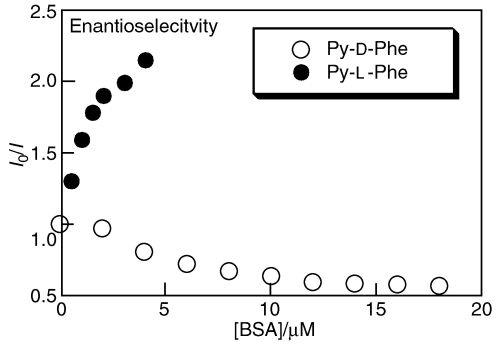

Fig. 2 Plot of the fluorescence intensities (I_0/I) of Py-D-Phe (2 μM, open circles) and Py-L-Phe (2 μM, filled circles) recorded at increasing concentrations of BSA. Note that larger concentrations of BSA are needed to saturate binding of Py-D-Phe. Both samples were excited at 344 nm.

to be different. These details are examined in fluorescence experiments. The protein–probe mixtures are excited at 344 nm (isosbestic point) and the probe emission was monitored at increasing concentrations of the protein. The ratio of initial intensity (I_0) to that in the presence of BSA (I) is plotted as a function of BSA concentration (Fig. 2). The fluorescence intensity of the D-isomer increases initially with protein concentration, and the ratio, I_0/I, reaches a plateau at higher protein concentrations. The fluorescence from the L-isomer, in contrast, is strongly quenched by BSA, and the corresponding plot shows an accidental near-mirror image behavior. These results highlight the differences in the local environment surrounding the fluorophore when the two isomers bind to BSA.

The accessibility of the two isomers to the solvent was probed using the fluorescence quencher, hexamminecobalt(III) chloride. The extent of protection offered by the protein can be readily distinguished in these simple experiments. The emission from the BSA-bound D-isomer was enhanced by the addition of CoHA (Fig. 3) whereas for the L-isomer the emission was quenched, confirming the differences in the binding behavior of the two optical antipodes shown in Figs. 1 and 2.

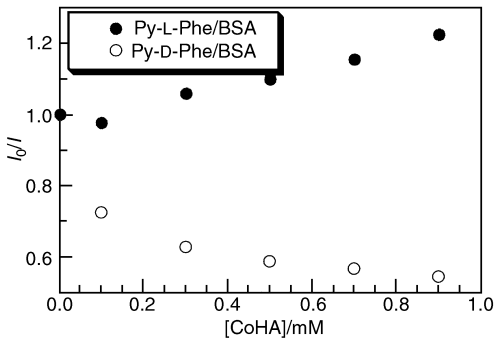

Fig. 3 Chiral selectivity for the quenching of fluorescence emission from the Py-D-Phe (open circles) and Py-L-Phe (filled circles) bound to bovine serum albumin by hexamminecobalt(III) chloride.

The large difference in the affinities of the optical antipodes arising due to a single chiral center is unexpected. For example, the binding of dansyl labeled amino acids to BSA shows only a 3:1 discrimination between the corresponding D- and L-isomers.[2] Treatment of racemic potassium tris(oxalato)cobaltate(III) with BSA resulted in the enrichment of the Δ isomer with an enantiomeric excess of 18%[6] and only minor differences were reported for the binding of the ketoprofen enantiomers to BSA.[7] The first report on the chiral recognition by a *de novo* designed peptide using D-norleucine derivative was reported to be 2:1,[8] and (*R*)-warfarin was retained to a greater extent on an immobilized BSA column than (*S*)-warfarin[9] while no enantioselectivity was observed for the binding of gossypol to BSA.[10] The D-amino acids, on a liquid chromatography column with immobilized BSA as the chiral phase, eluted at different times, but no information on the relative binding affinities of the isomers is reported. Preferential binding of L-phenylalanine to BSA was observed in ultrafiltration experiments,[10b] and in all the above examples, the observed selectivity was only moderate. The larger discrimination observed with Py-Phe, compared to the naphthyl or the dansyl amino acids, can be attributed to the increased hydrophobic surface area of the pyrenyl chromophore. Larger, rigid, hydrophobic surfaces of correct configuration can interact better with the protein, while a wrong isomer will interact poorly, thus widening the gap between the two binding constants.

The chiral center present in Py-Phe is five atoms away from the pyrenyl chromophore and yet it dramatically influences the binding behavior/spectral properties of the pyrenyl chromophore. Both isomers may bind at the same site or may bind at different sites on BSA. These two models can be distinguished in photocleavage experiments in which the pyrenyl probe can be activated with light to cleave the protein backbone at the probe binding site. Such experiments are in progress. Hydrophobic burial of Py-L-Phe at domain II, subdomain C of BSA at residues 346 and 347, was indicated from the photocleavage experiments from this laboratory, and current results are consistent with site specific binding of D and L isomers of Py-Phe to BSA.[5] The marked differences observed in the spectral properties of the bound enantiomers are surprising, and they are primarily due to differences in the residues that line the binding cavity. These results imply that the location of the pyrenyl chromophore, the photoactive moiety used for protein cleavage, is different for the two enantiomers.

Such differences in the binding environment will be exploited in photocleavage experiments to direct the photochemical reagents to different sites on proteins. The large differences in the spectral properties of Py-Phe isomers, in addition, provide a signal transduction mechanism for the translation of the chiral recognition information into an easily measurable spectroscopic quantity for application in chiral biosensors.

Rather than quenching all reactive intermediates and arresting the reaction, the addition of catalytic or stoichiometric (1–10 equiv.) quantities of H_2O to organic and organometallic processes can lead to surprisingly beneficial effects on reaction rate, product yield, and regio-, diastereo- and enantioselectivity. A most intriguing aspect of H_2O-promoted transformations is the role that this strong Lewis-base can play in providing a source for more highly Lewis-acidic species. This scenario is most likely operative when H_2O is added to reaction mixtures containing alanes, but organozinc reagents or organocuprates also seem to be transformed accordingly. In addition, the oxide or hydroxide ligand on the metal presents a source for chelation interactions that change aggregation states of organometallics and can provide anchimeric assistance. In many cases, water has been found to be an effective hydrolyzing agent leading to secondary products that serve as catalysts or promoters. In some cases, it has been shown that water provides a quenching agent capable of driving chemical equilibria towards the desired products.

Mr Seth Ribe was born in Bangor, Maine, in 1969. He received his B.S. degree in 1993 from the University of Southern Maine. From 1993–1995, he was at Northern Arizona University where he worked with Professor Michael Eastman studying the chemistry of C_{60} radical anions. He is currently completing the requirements for a PhD degree at the University of Pittsburgh under the direction of Professor Peter Wipf.

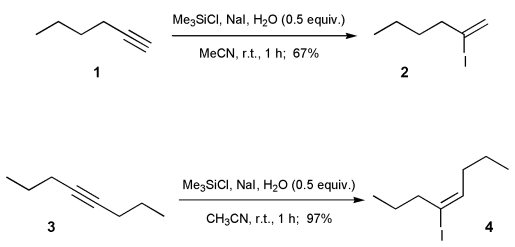
Professor Peter Wipf was born in Aarau, Switzerland, in 1959. He received his PhD degree in Organic Chemistry with Professor Heinz Heimgartner in 1987 at the University of Zürich. From 1988–1990, he worked as Swiss National Science Foundation Fellow with Professor Robert E. Ireland at the University of Virginia, where he participated in the total synthesis of FK-506 and studied the ester enolate Claisen rearrangement. In September 1990, he joined the Department of Chemistry at the University of Pittsburgh and was promoted to the rank of full Professor in February 1997. His research interests are centered around the total synthesis of natural products and include heterocyclic, organometallic, combinatorial, computational and medicinal chemistry. Wipf is the Director of the Combinatorial Chemistry Center at Pittsburgh that is involved in many collaborative projects in chemical biology. He has been named an NSF Presidential Faculty, a Japanese Society for the Promotion of Science Fellow and a Lilly Grantee, and he has received a Camille Dreyfus Teacher–Scholar Award, an Alfred P. Sloan Foundation Fellowship, an American Cancer Society Junior Faculty Award, the ETH Ruzicka Award, an American Cyanamid Young Faculty Award, the Merck Young Investigator Award, and the Zeneca Award for Excellence in Chemistry. Most recently, he has received the Chancellor's Distinguished Research Award from the University of Pittsburgh, the Arthur C. Cope Scholar Award from the American Chemical Society, and the Akron Section ACS and Novartis Research Awards. He is a member of the advisory board of the Journal of Organic Chemistry, Molecules, and Chirality, and a co-editor of Organic Reactions, The Chemistry of Heterocyclic Compounds, and eEROS.

Introduction

Reports of stoichiometric or sub-stoichiometric quantities of water resulting in significant increases in the rate and/or the enantioselectivity of organic transformations have sporadically appeared in the literature over the past decade. The means by which water acts as an accelerant in many of these processes is often poorly understood or even counterintuitive. Due to the abundance of primary literature and review articles on subjects concerning organic reactions in aqueous media[1] (*i.e.* Diels–Alder, Aldol, Claisen reactions, *etc.*), this review will focus primarily on transformations in which only stoichiometric or sub-stoichiometric amounts of water are necessary to achieve the desired rate enhancement or reaction improvement. Furthermore, the role that water plays is categorized into three distinct classes of activation: (a) water as a hydrolyzing agent leading to secondary products that serve as catalysts or promoters; (b) water used as an internal quenching agent to drive chemical equilibria, and (c) water as a Lewis acid activator or co-activator. This review is not intended to be comprehensive, and in many cases examples have been selected primarily as illustrations of larger and more comprehensive research efforts.

Water as a hydrolyzing agent leading to secondary products that serve as catalysts or promoters

The controlled *in situ* hydrolysis of TMS-Cl in the presence of NaI led to mild conditions for the preparation of internal alkenyl iodides in good yields and stereoselectivities from both terminal and internal alkynes (Scheme 1).[2] While one could speculate

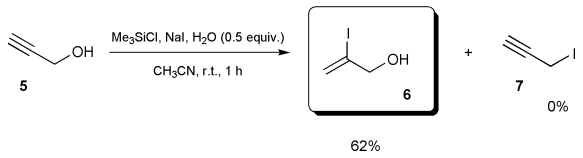


Scheme 1

that a mixture of HCl and HI is formed during the hydrolysis, direct use of an aqueous (57%) HI solution under otherwise identical conditions led mostly to unreacted alkyne.

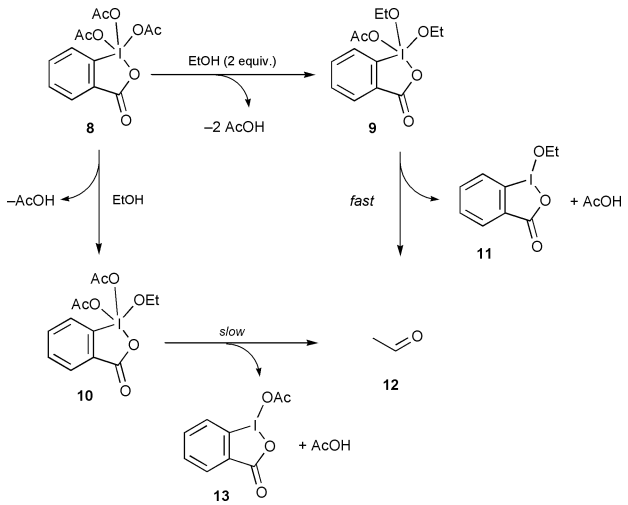
Acetonitrile was shown to be by far the best solvent for this transformation. The unique selectivity of these mild conditions is highlighted by the clean and stereoselective addition of HI to

prop-2-ynyl alcohol to afford the desired internal alkenyl iodide **6** in 62% yield without any of the undesired prop-2-ynyl iodide (Scheme 2).



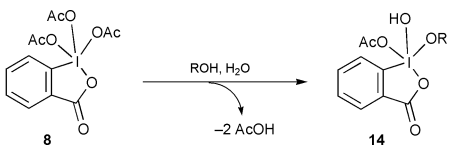
Scheme 2

A related example of this type of H_2O-induced reaction acceleration is represented by the Dess–Martin oxidation. After a serendipitous experimental discovery that only 'aged' (2 years) Dess–Martin periodinane (DMP) reagent was consistently effective in a crucial oxidation step in the total synthesis of rapamycin, a study was undertaken in an attempt to elucidate the general inconsistencies in the preparation of the Dess–Martin periodinane reagent, and to address the 'aging' effect. This study led to the observation that the addition of 1 equiv. of water to DMP accelerated the oxidation reaction dramatically.[3] The inspiration for the use of water as an accelerant came from earlier work in which Dess and Martin observed that the rate of oxidation of ethanol could be increased by the addition of a second equivalent of ethanol.[4] Presumably, an intermediate such as **9** shown in Scheme 3 is formed in the latter process.



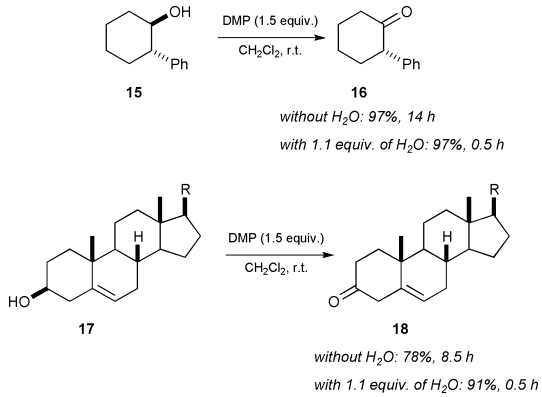
Scheme 3

The increased reactivity of the monoacetate **9** has been ascribed to the difference in basicity of the ethoxy *vs.* the acetoxy substituent. Schreiber and Meyer sought to mimic this effect by replacing an acetoxy group with hydroxide through the addition of one equivalent of H_2O (Scheme 4). Indeed, when



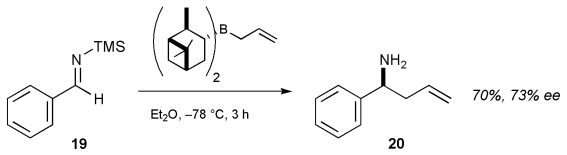
Scheme 4

CH_2Cl_2 containing 1.1 equiv. of water was added dropwise to the alcohol–DMP mixture, a greatly improved rate of oxidation was observed (Scheme 5). Both *trans*-2-phenylcyclohexanol and cholesterol were oxidized in 30 min to 97 and 91% completion, respectively. Under anhydrous conditions, oxidation of these two alcohols was significantly slower, requiring 14 and 8.5 h, respectively. Furthermore, prolonged reaction times under anhydrous conditions resulted in the decomposition of cholesterol, even in the presence of pyridine as a buffer.



Scheme 5

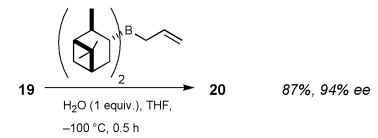
The preparation of enantiomerically pure homoallylamines by asymmetric allylboration of imines has generated substantial interest.[5] In 1997, Itsuno and co-workers reported that the (apparently) more reactive *N*-trimethylsilylbenzaldimine could be allylated at lower temperatures (−78 °C) to afford the desired homoallylamines in good yields and in good to excellent ee's (depending on the chiral allylboron reagent used).[6] Using Brown's *B*-allylpinan-3-ylborane reagent,[7] the homoallylic benzylamine could be obtained in 70% yield with an ee of 73% (Scheme 6). In efforts to establish comparative rate data for the



Scheme 6

allylboration of aldimines *vs.* aldehydes, Brown and co-workers subsequently discovered that the reported allylations did not take place under anhydrous conditions, even after a week at room temperature. However, upon aqueous workup of the reaction mixture, a 95% yield of the desired homoallylic amine was obtained.

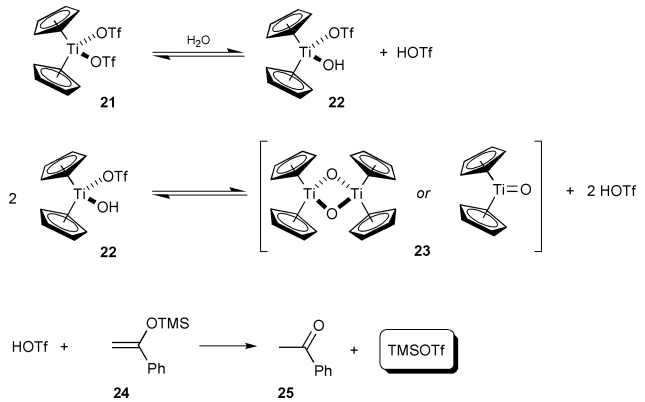
Surprisingly, this reaction appears to take place quite rapidly upon aqueous workup, but remains dormant in the absence of water. Consequently, cooling the reaction temperature to −100 °C followed by dropwise addition of one equivalent of H_2O afforded an improved yield (87%) and a higher ee (94%, Scheme 7).[8] Presumably, H_2O is necessary to protodesilylate



Scheme 7

the aldimine which is rapidly allylated. The improvement in %ee is thought to be due to a controlled, non-exothermic hydrolysis of the imine, allowing the reaction to proceed at much lower temperatures than the previous workup conditions.[9]

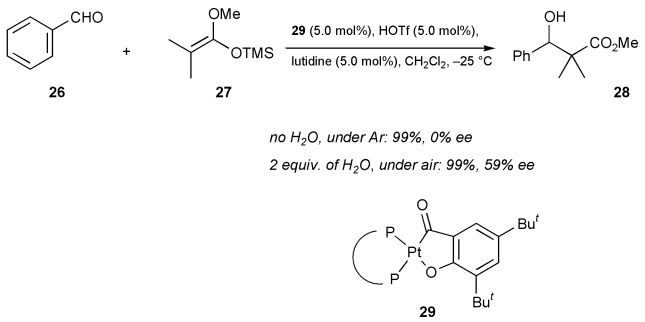
Two catalysts for the Mukaiyama aldol condensation, $Cp_2Ti(OTf)_2$ and trityl triflate (Ph_3COTf), both of which have also been used as Lewis acids for Diels–Alder reactions, have recently been shown to be precursors of the active species in this transformation.[10] Rigorous NMR studies have demonstrated that the hydrolysis of these triflates by trace amounts of H_2O leads to the formation of triflic acid, and subsequently, Me_3Si–OTf, which is responsible for catalyzing the reaction. The sequence of events that lead to the formation of Me_3Si–OTf is shown in Scheme 8. This spontaneous hydrolysis is in-



Scheme 8

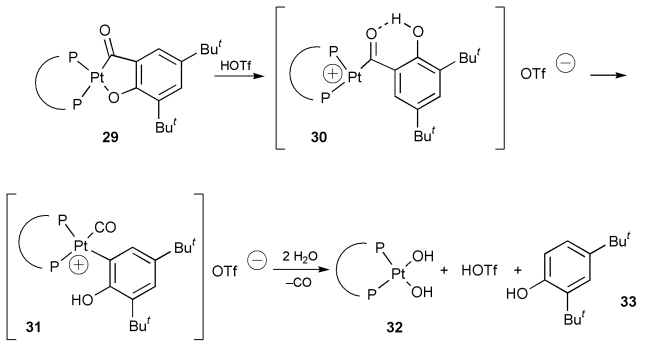
strumental in explaining why certain chiral $L_2Ti(OTf)_2$ complexes provide racemic products from several substrates and under a broad range of reaction conditions.

An interesting observation was made during attempts to perform a Pt-catalyzed aldol addition of silyl ketene acetals to aldehydes. It was found that both O_2 and H_2O were needed in order to obtain enantiomerically enriched products.[11] Under aerobic and anhydrous conditions, the chiral Pt(II) acyl complex **29** catalyzed the reaction between dimethylketene methyl trimethylsilyl acetal and benzaldehyde at −25 °C. The desired aldol product was obtained after 16 h in a yield of 99% but was formed as a racemic mixture. When the same reaction was conducted in the presence of air, a product with an ee of 35% was obtained. Furthermore, if the reaction mixture was exposed to air and two equivalents of H_2O, the %ee rose to 59% (Scheme 9).



Scheme 9

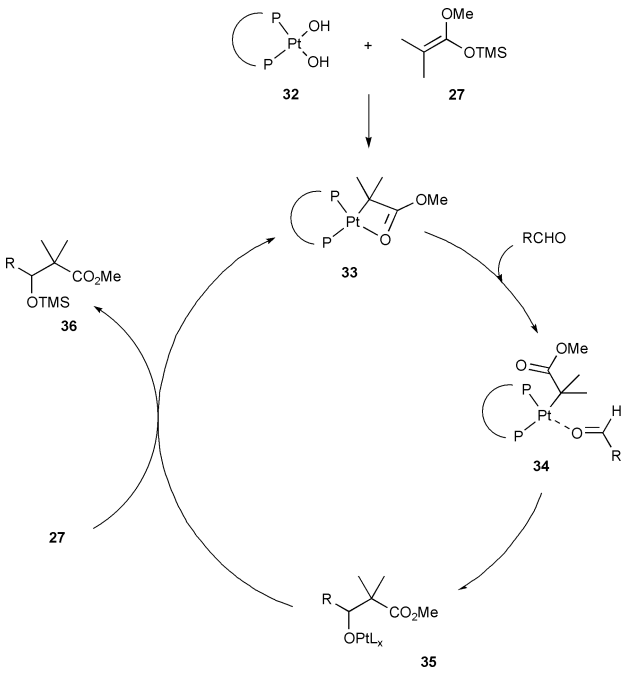
Based on ^{31}P NMR experiments, the authors of this study speculated that hydrolysis of the salicylaldehyde ligand with two equiv. of H_2O produced the catalytically active dihydroxy platinum complex **32** (Scheme 10).[12] However, further analysis



Scheme 10

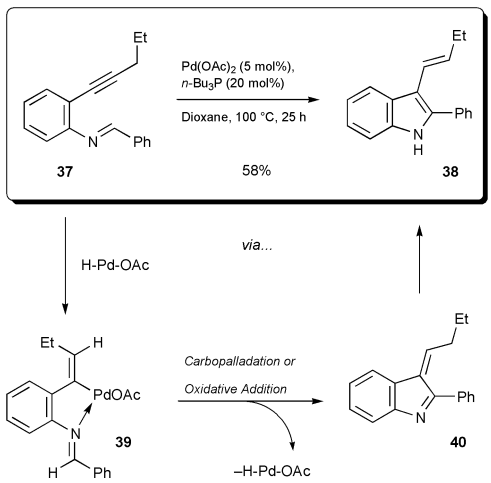
is needed for verification of the structure of **32** and for the experimental validation of this hypothesis.

In the presence of an excess of the silylketene acetal **27**, the proposed dihydroxy platinum complex **32** was thought to collapse to a C-bound Pt-enolate. A catalytic cycle that is in agreement with this mechanistic hypothesis is shown in Scheme 11.



Scheme 11

Water has been postulated to be an essential ingredient in the synthesis of indoles *via* the Pd(0)-catalyzed intramolecular cyclization of alkynes to imines (Scheme 12).[13] The mechanism



Scheme 12

was thought to involve a regioselective hydropalladation of the alkyne as the first step. The source of Pd-H under these conditions remained unclear.

However, the formation of Pd(0) from the reaction of Bu_3P and $Pd(OAc)_2$ is precedented [eqn. (1)],[14] and, furthermore, the oxidative addition of AcOH to Pd(0) has been reported [eqn. (3)].[15] Although this reaction was performed in dry solvents, it is possible that trace amounts of water were present, thus providing a source for the hydrolysis of Ac_2O [eqn. (2)].

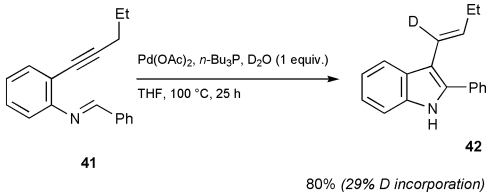
$$Pd(OAc)_2 + Bu_3P \longrightarrow Pd(0) + Bu_3P{=}O + Ac_2O \quad (1)$$

$$Ac_2O + H_2O \rightleftharpoons 2\ AcOH \quad (2)$$

$$Pd(0) + AcOH \rightleftharpoons AcO\text{-}Pd\text{-}H \quad (3)$$

Further evidence for the formation of a Pd-H intermediate *via* this sequence was obtained when 1 equiv. of D_2O was added to

the reaction mixture and the desired indole was obtained in 80% yield (NMR) with 29% deuterium incorporation at C(1) (Scheme 13). Deuterium incorporation at any other position was not observed.

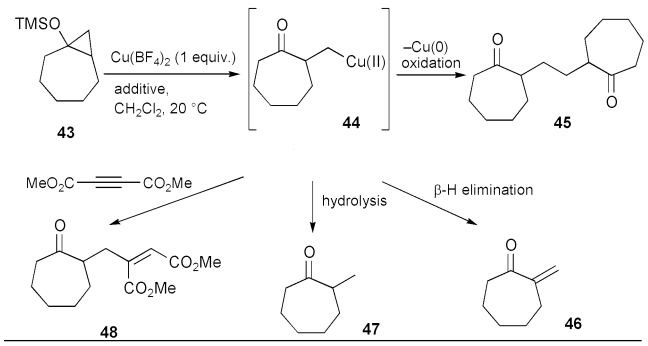


Scheme 13

Water used as an internal quenching agent to drive chemical equilibria

It is well established that silyloxycyclopropanes undergo metal-mediated ring openings to form β-metallo ketones.[16] In 1993, Ryu and co-workers reported their work toward the trapping of the analogous β-Cu(II) keto intermediates with suitable electrophiles such as electron deficient acetylenes. A typical reaction with dimethyl acetylenedicarboxylate (DMAD) is shown in Table 1.[17] Mechanistically, several competing pathways, *i.e.*

Table 1 The effect of additives on the reaction of siloxycyclopropane with $Cu(BF_4)_2$ and DMAD

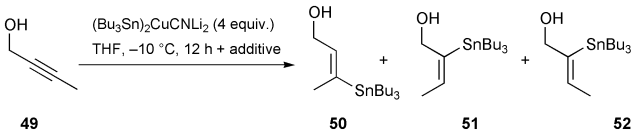


Entry	DMAD/ mmol	Additive (mL)	**45** (%)	**46** (%)	**47** (%)	**48** (%)
1	1	—	0	2	35	45
2	1	BuOTMS (0.2)	0	4	4	65
3	1.1	BuOTMS (0.2) + H_2O (0.02)	0	4	6	73

oxidative homocoupling, β-H elimination and $BF_3{\cdot}OEt_2$-promoted hydrolysis are feasible for this process. Optimal conditions included the use of 0.2 mL of a 10 vol% solution of trimethylsiloxybutane in CH_2Cl_2 containing one equivalent of H_2O (Table 1, entry 3). Trimethylsiloxybutane was used for the suppression of the $BF_3{\cdot}OEt_2$-promoted hydrolysis of the starting silyloxycyclopropane, and the one equivalent of H_2O was apparently needed for the protonation of the resulting vinylcopper intermediate. Internal quenching effectively prevented the reversibility of the addition and therefore decreased the lifetime of the β-Cu(II) ketone species that was prone to side reactions such as β-H elimination or oxidative homocoupling. Interestingly, 1,4-addition of the β-Cu(II) ketone intermediate to reactive electrophiles such as DMAD proceeded faster than protonation of the alkyl–copper bond.

Stannyl- and silylcupration of alkynes was shown to be most effective if H_2O was used as an internal proton source.[18] Stannylcupration of prop-2-ynyl alcohol **49** was conducted in the presence of protic additives with pK_a values of 4–15.5 (Table 2). Surprisingly, the stannylcuprate was stable at pK_a values above 4, but more acidic additives such as 2,4,6-(NO_2)-PhOH (pK_a = 0.3) destroyed the cuprate. When no internal proton source was used (entry 1) the vinylstannane was

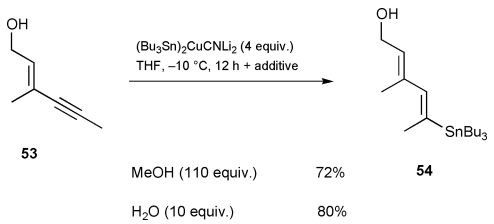
Table 2 Effects of proton source on yield and regiochemistry of stannylcupration



Entry	Additive (equiv.)	Yield (%)	**50** (%)	**51** (%)	**52** (%)
1	—	82	30	0	70
2	MeOH (110)	70	100	0	0
3	PhOH (30)	88	86	14	0
4	AcOH (10)	78	87	13	0
5	2,4-$(NO_2)_2$ PhOH (10)	80	85	15	0
6	H_2O (10)	97	85	15	0

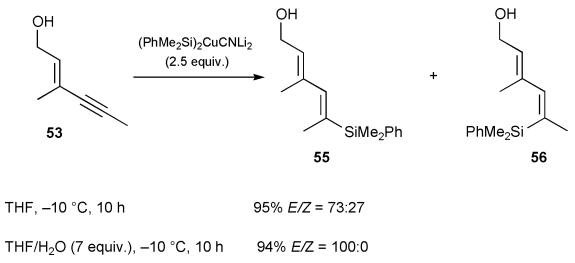
obtained in good yield but as a 30 : 70 mixture favoring the thermodynamically more stable *trans*-addition product **52**. Use of protic additives provided the vinylstannane in similar yields but only the *cis*-addition products were obtained. Although greater control of the ratio of 'distal' *vs.* 'proximal' regioisomers was obtained with MeOH, the best overall yield was obtained when 7–10 equiv. of H_2O were used (Table 2, entry 6).[19]

Stannylcupration of enyne **53** is an example where H_2O proved to be superior to MeOH, providing the (*E*)-dienylstannane **54** in 80% yield as a single isomer (Scheme 14).



Scheme 14

Similarly, silylcupration of **53** in the absence of any protic quenching agents provided the desired product **55** but with relatively poor regioselectivity (Scheme 15). However, upon

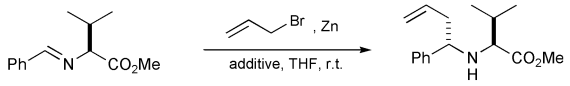


Scheme 15

addition of 7 equiv. of H_2O the desired dienylsilane was obtained in 94% yield as a single regioisomer.

H_2O was also shown to improve the Barbier addition of *in situ* prepared allylzinc to imines derived from (*S*)-valine esters (Table 3).[5d] Under anhydrous conditions (entries 1–3), the diastereoselectivity decreased under prolonged reaction times. Therefore, diastereomerically pure products could only be obtained at the expense of lower chemical yields. The authors suspected that the addition was reversible, which would account for the loss of diastereoselectivity under extended reaction times. In attempts to inhibit possible equilibration, the reaction was conducted in the presence of an internal proton source so that protonation of the zinc salt of **25** would lead to an irreversible process. In the presence of 0.7 equiv. of H_2O, the desired diastereomerically pure product was indeed obtained in 92% isolated yield after 24 h. Although the rate of addition was decreased by the presence of H_2O, the diastereoselectivity improved considerably (Table 3, entries 4 and 5).

Table 3 Effect of H_2O and reaction time on the diastereomeric ratio of **58**



57 **58**

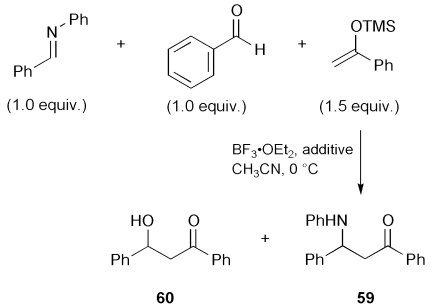
5	H_2O (0.7)	24	(*S*,*S*)	92	100:0

A study directed towards the development of conditions favorable for nucleophilic additions to imines in the presence of carbonyl groups demonstrated that the combination of water and $BF_3{\cdot}Et_2O$ was a superior catalyst for the selective addition of silyl enolates to imines in the presence of benzaldehyde.[20] $BF_3{\cdot}Et_2O$ alone, if used in catalytic amounts, was sufficient to promote the addition of 1-phenyl-1-trimethylsiloxyethane to benzylideneaniline in the presence of 1 equiv. of benzaldehyde (Table 4, entry 2). However, superior results were obtained

Table 4 Imine-selective addition reactions



60 **59**

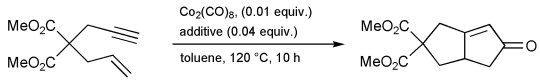
Entry	$BF_3{\cdot}Et_2O$/ equiv.	Additive (equiv.)	Time/h	**59** (%)	**60** (%)
1	1	—	0.5	18	48
2	0.2	—	0.5	60	15
3	0.2	H_2O (0.1)	0.5	92	5
4	0.2	H_2O (1.0)	1	98	1
5	0.2	H_2O (10)	0.5	97	1
6	0.2	H_2O (50)	17	92	0

when 1 equiv. of H_2O was added to the reaction mixture (Table 4, entry 4). The combination of $BF_3{\cdot}Et_2O$ and H_2O might form the hydrate which transfers a proton to give H_3O^+ and BF_3OH^-. Activation of the imine by preferential protonolysis could account for the reversal in selectivity.

Water as a Lewis acid activator or co-activator

Although the Pauson–Khand reaction remains one of the most effective methods for the preparation of cyclopentenones, its scope has been somewhat limited by high temperatures and long reaction times. According to the generally accepted mechanism, the rate-limiting step involves decarbonylation, which generates a free coordination site for the incoming olefin.[21] Many successful attempts at accelerating the reaction by employing various 'hard' Lewis bases as additives have been disclosed. The presence of these 'hard' Lewis bases (*N*-methylmorpholine *N*-oxide,[22a] trimethylamine *N*-oxide,[22a] DMSO,[22b] sulfoxides,[22b] cyclohexylamine and NH_4OH[21c]) is thought to accelerate the decarbonylation step. Water (as a solvent) retarded the reaction.[22c] However, small amounts of H_2O proved to be very effective in accelerating the catalytic variant of the Pauson–Khand reaction.[23] Although H_2O was not the best promoter in this study, it certainly is the cheapest and perhaps most convenient to use (Table 5).

Table 5 The catalytic Pauson–Khand reaction in the presence of various 'hard' Lewis bases



61 **62**

Entry	Additive	CO/atm	**61** (%)	**62** (%)
1	—	7	82	12

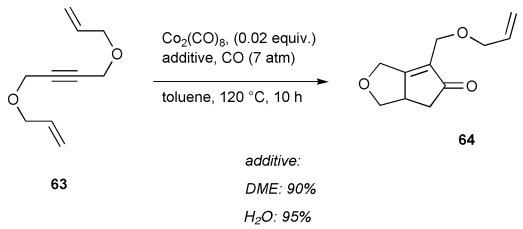
11	1,2-Dimethoxyethane	1	83	5
12	1,2-Dimethoxyethane	3	6	82
13	1,2-Dimethoxyethane	20	0	93
14	H_2O (20 equiv.)	7	33	63
15	H_2O/toluene (1:2)	7	65	21

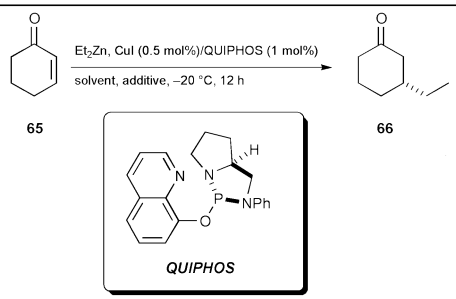
The cyclization of **63** provides an example where H_2O proved to be a superior additive to DME (Scheme 16).



Scheme 16

Buono and co-workers recently described a new chiral copper catalyst for the asymmetric addition of dialkylzinc reagents to cyclic enones.[24] Initially, diethylzinc addition to cyclohexenone proceeded in a yield of 55% with an ee of 45% using a new CuI–QUIPHOS catalyst in toluene at −20 °C (Table 6, entry 1).

Table 6 CuI–QUIPHOS catalyzed addition of Et_2Zn to cyclohexenone

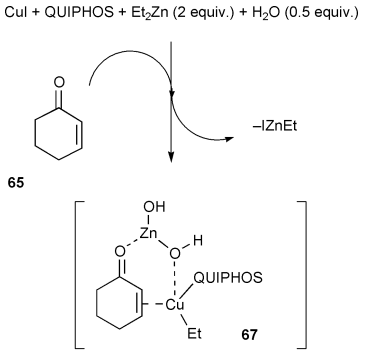


Entry	Solvent	Additive (equiv.)	Yield (%)	Ee (%)
1	Toluene	—	53	45
2	THF	—	53	25
3	CH_2Cl_2	—	55	7
4	1,2-Dichloroethane	—	69	30
5	CCl_4	—	34	7
6	Toluene	H_2O (0.5)	55	6
7	THF	H_2O (0.5)	50	22
8	1,2-Dichloroethane	H_2O (0.5)	55	23
9	Hexane	H_2O (0.5)	0	0
10	CH_2Cl_2	H_2O (0.5)	76	61
11	CH_2Cl_2	$Zn(OH)_2$ (0.1)	64	44
12	CH_2Cl_2	$Zn(OH)_2$ (0.25)	81	53

Attempts to optimize this result by varying the solvent were unsuccessful (entries 1–5). However, a dramatic increase in ee

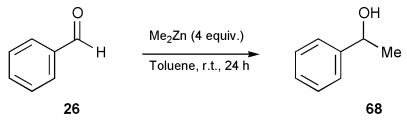
was observed upon addition of 0.5 equiv. of H_2O. Interestingly, this effect was only observed when CH_2Cl_2 was used as the solvent (Table 6, entries 6–10). The authors proposed that Et_2Zn was hydrolyzed to $Zn(OH)_2$ which supposedly was a stronger, more effective Lewis acid. This hypothesis was tested by adding $Zn(OH)_2$ in place of H_2O (entries 11 and 12). A similar result was obtained when 0.25 equiv. of $Zn(OH)_2$ were used, although further increases in the amount of $Zn(OH)_2$ had deleterious effects.

Apparently, the increased Lewis acidity of the hydrolyzed zinc species activated the carbonyl moiety and, perhaps intramolecularly, provided anchimeric assistance to the approaching Cu species through chelation. This interaction might result in a 'tighter' transition state and higher levels of enantioselectivity (Scheme 17).



Scheme 17

Although the formation of $Zn(OH)_2$ is plausible, especially since the direct addition of this additive provided results similar to those with H_2O, the formation of alternative agents such as EtZn–O–ZnEt cannot be excluded. The favorable results using $Zn(OH)_2$ could then be explained by the analogous formation of a species such as EtZn–O–Zn–O–ZnEt. We have found that addition of water to a solution of Me_2Zn produces a stronger Lewis acid capable of activating benzaldehyde towards dimethylzinc addition (Scheme 18).[25] This reaction does not proceed to any significant degree in the absence of H_2O.



Scheme 18

Corey and co-workers have observed that the addition of 0.3–0.33 equiv. of H_2O to lithium dimethylcuprate at −78 °C generates a substantially more reactive, and selective agent for conjugate addition to the chiral α,β-enone **69** (Table 7).[26]

The authors speculated that the heightened reactivity upon addition of H_2O arose from the formation of a mixed planar cuprate species as shown in Scheme 19. The exocyclic lithium moiety was described as being 'especially suited for chelate formation with the α′-alkoxy-α,β-enone'.

Shibasaki, Sasai and co-workers have seen a significant improvement in their Yb-BINOL catalyzed asymmetric epoxidations of acyclic enones in the presence of H_2O as an additive.[27,28] Both yields and ee's were greatly affected by the amount of added H_2O. The best results were obtained when 5 equiv. of H_2O were used (Scheme 20). Interestingly, and not necessarily easy to reconcile with the effect of water, the use of 4 Å MS was shown to be critical to obtain optimal results.

Addition of H_2O has also been shown to lead to slightly improved enantioselectivities in the addition of 1-naphthol to pyruvate esters.[29] The chiral 1,4:5,8-dimethano-

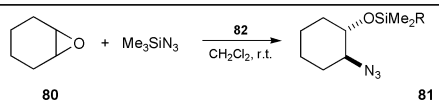
5	H_2O (0.27)	5	70	89
6	H_2O (0.27)	24	90	84

identical conditions, **78** was obtained in 85% yield with a lower ee of 80%. It is known that $CpZrCl_3$ forms adducts with donor ligands such as THF or DMF to give a stable Zr $d^0/16e^-$ intermediate.[30] Accordingly, it seems possible that two water

molecules coordinate to **79** to provide a related 16e⁻ intermediate. The resulting change in geometry could be responsible for the modest increase in enantiomeric excess. Again, it appears likely that the reversibility of the reaction is partly responsible for the drop in ee under prolonged reaction times. However, unlike the previously discussed reversible addition of allylzinc reagents to imines, the use of water in this case does not appear to inhibit this equilibration as effectively. Alternatively, catalyst decomposition into achiral species can also lead to lower reaction ee's.

Another Zr-catalyzed asymmetric reaction that has been reported to be positively influenced by the presence of water is the Zr-catalyzed enantioselective addition of azide to cyclohexene oxide (Table 9).[31] Both the yield and ee in this process were

Table 9 Enantioselective opening of *meso* epoxides with TMS-azide



80 81

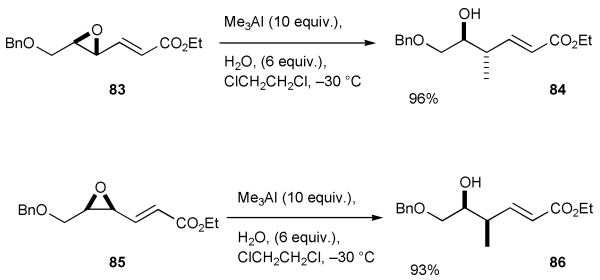
10	H_2O	0.027	1.3	82
11	4 Å MS	—	0.2	54

increased by addition of silyl ethers, alcohols and H_2O. These additives might be effective in assisting in the catalytic turnover of the Zr-complex.

In 1991, Miyashita and co-workers presented an elegant stereospecific methylation of γ,δ-epoxy acrylates using a trimethylaluminum–H_2O mixture (Scheme 21).[32] Water was

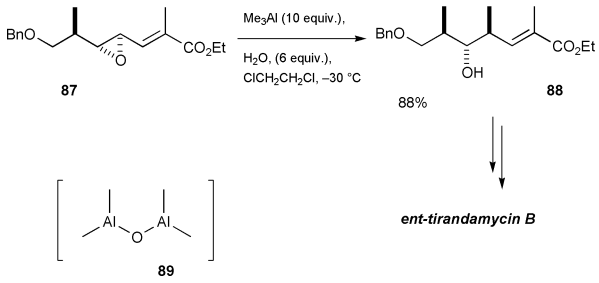


83 84 85 86

Scheme 21

shown to be critical for this transformation; under anhydrous conditions the reaction did not occur. Furthermore, replacing H_2O with MeOH also resulted in recovered starting material. Both *cis*- and *trans*-epoxides were readily methylated with complete regio- and stereocontrol.[33]

This methodology was successfully applied toward a key intermediate in the formal synthesis of *ent*-tirandamycin B (Scheme 22).[34]

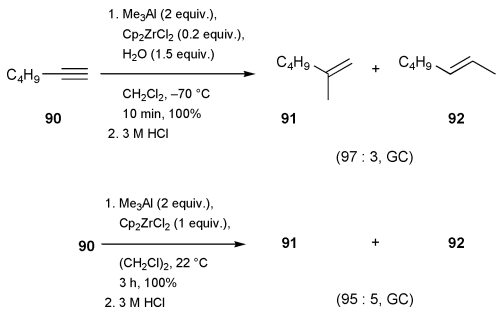


87 88 89

Scheme 22

The bisaluminum-oxo intermediate **89** was proposed to be a reactive intermediate formed by the reaction of H_2O and excess trimethylaluminum in this process. Due to the dual Lewis acid/nucleophilic nature of this species, its exact role remains unclear. It is possible that **89** behaves both as a strong Lewis acid and/or a more reactive methylating agent.

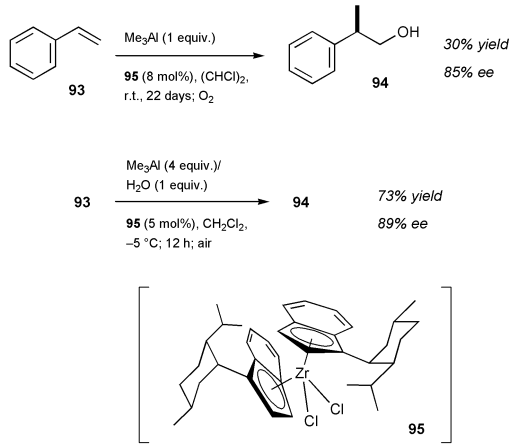
In a related reaction scheme, a water–Me_3Al mixture was found to be useful for accelerating the zirconocene dichloride-catalyzed methylalumination of alkynes. Addition of 1.5 equiv. of H_2O to 3 equiv. of Me_3Al in the presence of 0.2 equiv. of Cp_2ZrCl_2 generated a much more reactive methylating agent.[35] Methylalumination proceeded quite rapidly under these modified conditions, providing the desired methylated product in quantitative yield (as 97 : 3 ratio of regioisomers) after 10 min at −78 °C (Scheme 23). In comparison, under standard conditions oct-1-yne was methylated in a 95 : 5 stereoselectivity after 3 h at room temperature.[36]



90 91 92

Scheme 23

More recently, this dramatic rate effect of H_2O addition in carbometalation reactions has been extended to the asymmetric methylalumination of terminal alkenes.[37] In 1995, Negishi and Kondakov reported the first asymmetric methylalumination of alkenes using Erker's chiral zirconium catalyst **95**.[38,39] Despite the good to excellent yields and ee's obtained under the original conditions, substrates such as styrene proved quite resistant towards the methylation process, and after 22 days only 30% product was obtained (Scheme 24).[38a] In contrast, a dramatic increase in the reaction rate was achieved by the addition of 1 equiv. of H_2O to 4 equiv. of Me_3Al.[37] The desired product was obtained after 12 h at −5 °C in 73% yield with an ee of 89%. A more quantitative assessment of the rate difference with styrene under the two sets of reaction conditions is shown in Fig. 1. Monitoring the appearance of 2-phenylpropanol at 0 °C by GC revealed that in the presence of 1 equiv. of H_2O the reaction went to > 85% completion after 8 h. Without the benefit of water, no trace of 2-phenylpropanol could be detected. Although more elaborate studies have yet to be conducted in order to shed more light on the mechanism of this water-induced acceleration, it is feasible that a species such as **89** is being formed in this process as well. The degree in which MAO (methylaluminoxane) activates Zr-based catalysts in Ziegler–Natta type polymerizations is relatively well known, and yet also poorly understood in a mechanistic sense.[40] In analogy to the effect of MAO in the Ziegler–Natta process, we believe that a reasonable mechanism involves formation of a cationic



Scheme 24

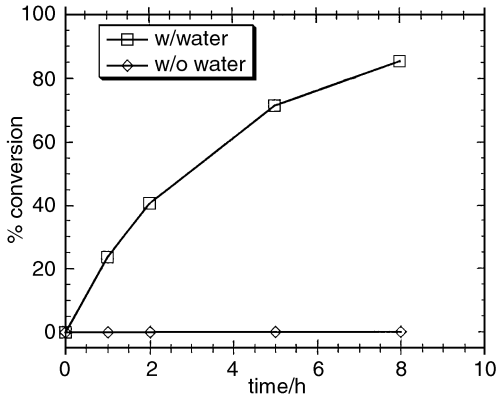


Fig. 1 Rate analysis of the chiral zirconocene-catalyzed methylalumination of styrene at 0 °C using 4 equiv. of trimethylaluminium, 5 mol% of chiral catalyst **95**, and styrene at a 0.17 M concentration in CH_2Cl_2 in the absence and presence of 1 equiv. of H_2O.

zirconocene intermediate formed by ligand (Cl-, or more likely Me-) abstraction from the zirconocene complex by the more Lewis acidic intermediate **89** or a higher molecular weight, more reactive analog thereof that is generated upon addition of H_2O to the reaction mixture.

Conclusions

Maybe one of the most surprising aspects of our survey is the large number of well-documented cases where the addition of catalytic or stoichiometric amounts of H_2O to the reaction mixture of organic and organometallic processes has led to beneficial effects on reaction rate, product yield, and regio-, diastereo- and enantioselectivity. Since, in particular when moisture-sensitive organometallic reagents or Lewis acids are involved, synthetic chemists go to great lengths to avoid traces of water in the reaction mixture, it can only be speculated how many new H_2O-accelerated processes remain to be (re-)discovered, and how many cases of adventitious water effects have played a significant but yet unrecognized role in influencing the course of the reaction. A most intriguing aspect of H_2O-promoted processes is the role that this strong Lewis-base can play in providing the source for transient highly Lewis-acidic species. After a sometimes vigorous exothermic reaction with organometallic derivatives that can only be controlled by careful addition of sub-equimolar quantities of H_2O, the resulting metal oxide or metal hydroxide species is activated at the metal center by the negative inductive effect of the powerful electron-withdrawing oxygen substituent and becomes more Lewis acidic. This scenario is most likely operative when H_2O is added to reaction mixtures containing alanes. In addition, the oxide or hydroxide ligand on the metal presents a source for chelation interactions that change aggregation states of organometallics and can provide anchimeric assistance. Unfortunately, there is a dearth of mechanistic information regarding the interaction and the actual active species obtained upon reaction of H_2O with reactive organometallics or Lewis acids, and beyond empirical experimentation there is little general information that could be used as a guideline when water-effects might prove beneficial. The situation is a bit more transparent in cases when water is used as a hydrolyzing agent leading to secondary products that serve as catalysts or promoters or when water provides a quenching agent intended to drive chemical equilibria. More often than not, the latter working hypotheses can be tested by preforming the active species, monitoring the reaction mixture spectroscopically, or by a thorough analysis of reaction intermediates and products. In all aspects of water-mediated processes, we are anticipating that chemists will continue to discover surprising new effects and beneficial uses of H_2O as a highly versatile reagent in the organic chemistry tool box.

Titanium content in mesoporous titanosilicate catalysts has been modulated up to a minimum Si/Ti value of 1.9 by using complexing agents able to coordinate both Si and Ti atoms and harmonize the reactivity of the resulting precursors avoiding subsequent phase segregation and leading to chemically very homogeneous materials.

The interest of titanium–silicon mixed oxides in petrochemistry is mainly related to their ability to catalyze olefin epoxidation.[1] Recently, maximum interest was focused, however, on microporous products in which titanium atoms isomorphously replace some of the silicon atoms. Indeed, it was found that zeolites such as TS-1, TS-2 and Ti-β are effective catalysts (although limited to substrates with small molecules) in the oxidation of a variety of organic compounds.[2] Hence, the discovery of the M41S materials opened a new way towards expanding the available pore size. Owing to their large pore-sizes, Ti-substituted MCM-41 materials might be efficient in the oxidation of bulky substrates. In 1994, Corma *et al.*[3] and Tanev *et al.*[4] published the first results on titanium substitution in MCM-41 silicas. Since then a considerable effort has been devoted to this subject.[5]

A major problem concerning the preparation of Si–Ti mixed oxides through sol–gel-derived techniques is to achieve an adequate balance between the hydrolysis and condensation processes affecting the titanium and silicon precursors. Insofar as the catalysts' efficacy substantially depends upon their purity and chemical homogeneity, phase segregation must be avoided.

We report here a new direct and reproducible surfactant-assisted procedure that has allowed us to prepare thermally stable mesoporous titanosilicate molecular sieves in which the Ti content in the framework can be modulated up to a minimum Si/Ti molar ratio value of 1.9. Such a limit value corresponds to a relative Ti content noticeably higher than those previously achieved by using surfactants (Si/Ti = 5.0)[6] or block-copolymers (Si/Ti = 3.9)[7] as supramolecular templates.

The procedure is based on the use of a cationic surfactant (CTAB = cetyltrimethylammonium bromide) as structural directing agent, and a complexing polyalcohol (2,2′,2″-nitrile-triethanol, hereinafter TEAH3) as the hydrolysis retarding agent for Ti species.[8] In a typical synthesis leading to the Si/Ti = 1.9 mesoporous solid, 0.80 g of NaOH (0.02 mol) were dissolved in a TEAH3 (21.55 mL, 0.1624 mol) solution containing 0.0126 mol and 0.051 mol of the titanatrane and the silatrane derivatives of TEAH3 (*e.g.* in the form of $[M(TEA)Cl]_2$ or M(TEA)OR (M = Si, Ti), R being an alkyl chain and TEA meaning the fully deprotonated ligand),[9] respectively, and 0.0116 mol of CTAB. Then, 155 mL of water were slowly added with vigorous stirring. A pale yellow suspension was formed after aging the mixture at 25 °C for 24 h. The resulting mesostructured powder was then collected by filtration, washed with water and ethanol, and air-dried. To obtain the final mesoporous material, the as-synthesized solid was calcined at 500 °C for 5 h under a static air atmosphere. The main synthetic variables and analytical data are summarized in Table 1. All samples were analyzed and characterized by electron probe microanalysis (EPMA, Philips SEM-515), XRD techniques (Seifert 3000TT diffractometer using CuKα radiation), TEM (Philips CM10 electron microscope), UV–Vis diffuse reflectance spectroscopy (Perkin-Elmer Lambda 9), IR spectroscopy (FTIR Perkin-Elmer 1750), and N_2 adsorption–desorption isotherms (Micromeritics ASAP2010).

Our synthesis strategy has been designed to avoid problems due to the great reactivity differences between the usual Ti and Si precursor species (such as alkoxides). Indeed, atrane complexes (*i.e.* complexes which include TEA-like species as ligands) are, in general, unstable but relatively inert towards hydrolysis. In practice, we have observed (Fast Atomic Bombardment coupled with Mass Spectrometry) that, once formed in the absence of water, both titanatrane and silatrane complexes do not react easily with water. In anhydrous solution, the majority species are the complexes $M(TEA)_2H_2$ and $MNa(TEA)_2H_2^+$ (M = Si or Ti). After water addition, both Si and Ti atrane complexes strikingly remain in solution in the majority form of the M(TEA)OH species. In this context, the most outstanding feature concerning the silatranes' and titanatranes' hydrolytic reactivity (when compared to the respective

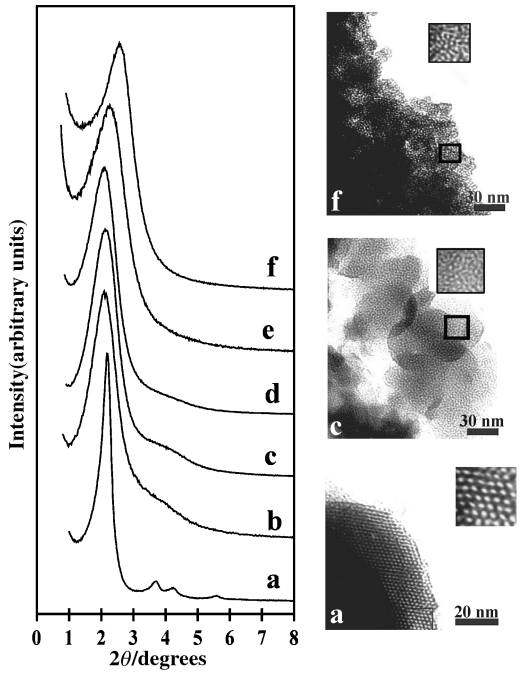

Fig. 1 XRD powder patterns of mesoporous titanosilicates and some selected TEM images: (a) sample 2; (b) sample 3; (c) sample 4; (d) sample 5; (e) sample 6; (f) sample 7.

alkoxides) is that silatranes are more labile than, for example, TEOS, whereas the contrary occurs in the case of titanatranes. Hence, the role of TEAH3, which acts in practice as a hydrolysis retarding agent for Ti species, is the key to achieve an adequate balance between the hydrolysis and subsequent condensation reactions affecting the precursors.

EPMA analysis shows that all the samples are chemically homogeneous (spot area *ca.* 1 μm) with a regular distribution of titanium and silicon atoms. Hence, the solids can be considered as monophasic products, and segregation of TiO_2 can be discarded. This is consistent with the absence of rutile or anatase peaks in the XRD patterns.

Selected low-angle XRD patterns of mesoporous samples are shown in Fig. 1. All solids show diffraction patterns with at least one strong reflection at low 2θ values, which is typical in mesoporous materials. Apart from this intense peak [associated with the (100) reflection if a hexagonal cell is assumed], in the patterns of solids whose titanium content is lower than that defined by the Si/Ti = 49.9 molar ratio, we can observe three other resolved small reflections [(110), (220) and (210)], which are characteristic of highly ordered hexagonal pore systems. Such an evolution indicates that incorporation of Ti in the silica-based hexagonal mesoporous framework (whatever its coordination may be) implies a progressive lowering of order in the pore array. TEM micrographs fully correlate to XRD observations. On the other hand, all materials give typical reversible type IV isotherms with one well defined step in their N_2 adsorption–desorption curves. Incorporation of Ti leads to a slight decrease of the BET surface area. This notwithstanding, high surface area values and unimodal pore distribution are retained even for the highest Ti contents.

Isomorphous substitution of Ti for Si in the framework has been confirmed by UV–Vis and IR spectroscopies. Thus, the UV–Vis spectra (Fig. 2) corresponding to samples with Si/Ti $\geqslant$ 34.9 show an absorption band at *ca.* 220 nm together with a small shoulder in the range 250–275 nm. In contrast, the spectra corresponding to samples with Si/Ti $\leqslant$ 19.0 present an additional band at *ca.* 300 nm whose intensity increases as the titanium content does. These results indicate that nearly all Ti occupies tetrahedral sites in the skeletal net until the Si/Ti = 34.9 molar ratio is reached.[10] Also for samples with Si/Ti $\leqslant$ 19.0, the presence of both tetrahedrally and octahedrally coordinated Ti atoms becomes evident. Nevertheless, even in this last case, the band at 220 nm remains as an intense signal in

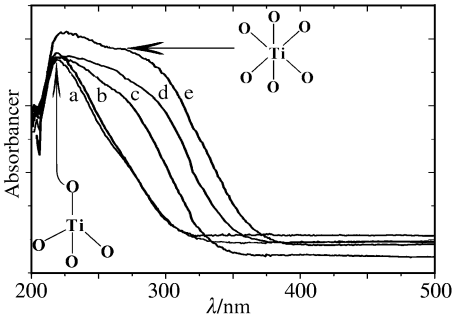

Fig. 2 Diffuse reflectance UV–Visible spectra of mesoporous titanosilicates: (a) sample 2; (b) sample 3; (c) sample 4; (d) sample 5; (e) sample 7.

the UV–Vis spectra. This observation suggests that tetrahedral Ti environments are relevant even for very high titanium contents, although five- and six-coordinated Ti local environments (in the form of small clusters) could be involved in the titanosilicate walls.[11] On the other hand, the IR spectra of all the samples display one band at 960 cm^{-1} that can be assigned to the stretching mode of SiO_4 entities bonded to Ti atoms.[11] Moreover, the intensity ratio (see Table 1) between the bands at 960 and 800 cm^{-1} (SiO_4 symmetric stretching) increases with the titanium content, which is usually taken as proof of isomorphous substitution of Ti for Si.[10]

The catalytic activity of these solids in the epoxidation of cyclohexene with TBHP (*tert*-butyl hydroperoxide) was tested in a stirred glass flask (at 343 K) by mixing 28.15 mmol of cyclohexene with 7.03 mmol of TBPH and 300 mg of catalyst. The results obtained after 3 h of reaction are summarized in Table 1. Such preliminary results seem to represent a significant performance improvement with respect to previous reports based on the use of mesoporous silica,[11] and are comparable to those provided by organo-silica-containing Ti-MCM-41 catalysts.[12] The maximum catalytic activity is maintained in the compositional range 34.9 $\leqslant$ Si/Ti $\leqslant$ 49.9, that is to say the range along which the number of tetrahedral Ti-sites is the highest. The increment in the Ti content implies a slow reduction both in conversion and selectivity related to both the proximity among the active Ti-sites and the growth of small nanodomains of TiO_2-like clusters.

In short, our results demonstrate that by using kinetically inert atrane molecular precursors it is possible to introduce catalytically active Ti-sites into mesoporous silicas. We consider that the atrane route can be extended to the preparation of a diversity of materials of catalytic interest[13]

Received (in Cambridge, UK) 27th November 2000, Accepted 11th January 2001
First published as an Advance Article on the web 30th January 2001

A time resolved EPR (TR-EPR) spectrum of a radical–triplet pair (RTP) in the quartet excited state has been recorded by irradiating with visible laser light a solution of a [60]fullerene–crown ether conjugate and an ammonium aminoxyl radical; this is the first direct observation of a RTP in liquid solution for a stable host–guest complex between a macrocyclic ligand bearing a triplet precursor and an aminoxyl ammonium cation.

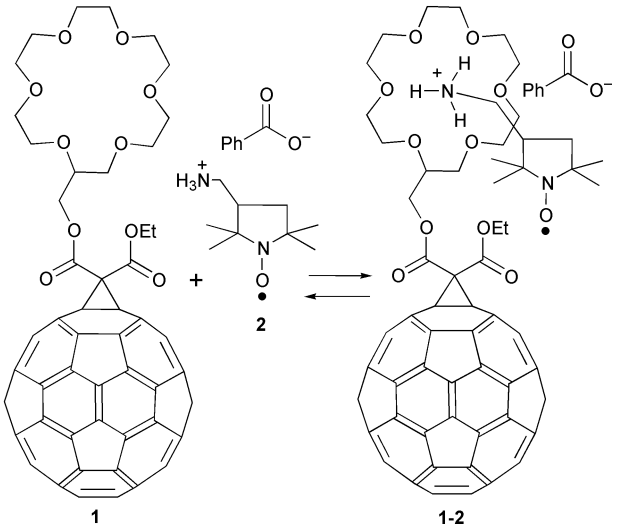
Several investigations have shown that triplet excitations are quenched in the presence of free radicals, with a mechanism involving the formation of radical–triplet pairs (RTP).[1] The radical–triplet encounter can form a pair either in a quartet (^{4}[RTP]) or in a doublet state, whose energies are separated by the exchange interaction *J*. These two states are mixed by the electron–electron dipolar interaction.

In a magnetic field, the doublet character of the four quartet components is not the same and they decay with different rates to the ground state, causing a transient deviation of the radical sublevel populations from the thermal equilibrium values. This spin polarisation is revealed as an anomalous EPR line intensity.[2,3] The TR-EPR spectrum of a radical recorded in the presence of a triplet precursor after a laser pulse presents lines in enhanced absorption (A) or in emission (E). Spin polarisation derives also by the radical quenching of the excited singlet state, *i.e.* by enhanced ISC. In this case the polarisation is opposite to that caused by triplet quenching.[4]

The observation of spin polarised EPR spectra of a stable radical, such as aminoxyl radicals, in the presence of a triplet precursor is an indication of the formation of RTPs. However, the direct observation of a RTP in its excited quartet state by EPR spectroscopy is not feasible since collision pairs, in solutions of moderately viscous liquids, have lifetimes too short[5] to be detected *via* their ^{4}[RTP] EPR spectrum. On the other hand, ^{4}[RTP] spectra could be recorded for molecular systems where the radical and triplet precursor were (i) covalently linked,[6] (ii) coordinated[7] or (iii) linked to a molecular template.[8]

In this paper we report the first observation of a RTP that forms upon photoexcitation of a host–guest complex between [60]fullerene–crown ether conjugate **1**[9] and the benzoate ammonium salt of 3-aminomethyl-[2,2,5,5-tetramethylpyrrolidin-1-oxyl] **2**.

Derivative **1** combines in one molecule both the 18-crown-6 ionophore and the [60]fullerene triplet precursor, that has been selected for the long lifetime and high quantum yield of its triplet excited state.[10] The synthetic strategy toward derivative **1** is outlined in Scheme 1 and requires two steps. Esterification between commercially available hydroxymethyl-18-crown-6 and ethylmalonyl chloride in the presence of solid $NaHCO_3$ afforded ester **3** in 33% isolated yield. Cyclopropanation of C_{60}[11] with **3** in the presence of I_2 and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in toluene at rt gave **1** in 42% isolated yield.



All spectroscopic and analytical data were consistent with the proposed molecular structure.† Ammonium aminoxyl **2** was obtained by mixing equimolar amounts of the corresponding aminomethyl aminoxyl and benzoic acid in diethyl ether. Pink crystals were isolated after crystallization from isopropyl ether.

The TR-EPR spectrum recorded by laser excitation of **1** in $CHCl_3$ solution at 235 K consists of a single broad line (ΔB = 1.66 ± 0.02 mT) centred at g = 2.0016 ± 0.0002 which is attributed to the excited triplet state. The line is broadened because of the incomplete averaging of the electron dipolar interaction. The signal decay is accounted for by two exponential functions with time constants τ_1 = 0.9 μs and τ_2 =

DOI: 10.1039/b009504o

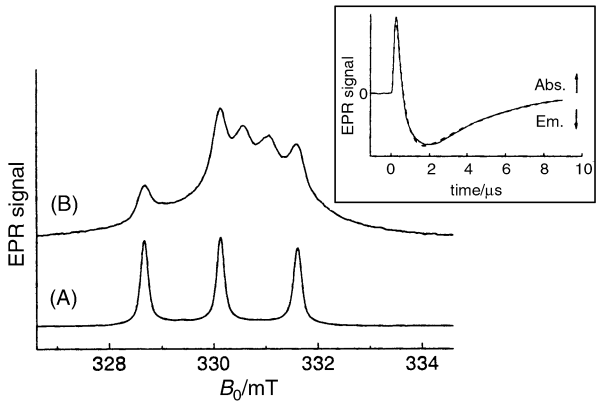

Fig. 1 EPR spectra of a 2 mM $CHCl_3$ solution of **1** and **2** at 235 K. (A) Integrated EPR spectrum. Microwave attenuation 20 dB. (B) TR-EPR spectrum recorded by laser excitation. Time delay from the laser pulse 250 ns. Microwave attenuation 5 dB. In the insert the signal decay of the central quartet line (solid line) and the fitting to a tri-exponential function (dotted line) are shown.

9.2 μs. The first decay time is to be assigned to the spin relaxation process which brings the initially spin polarised sublevel populations to thermal equilibrium values. The larger constant τ_2 is the triplet lifetime.

The EPR spectrum of a 2 mM $CHCl_3$ solution of both **1** and **2** consists of three lines with g_{NO} = 2.0057 ± 0.0002 and hyperfine separation a_N = 1.47 ± 0.02 mT, which are the typical values for an aminoxyl free radical, such as TEMPO, in that solvent (Fig. 1A).

When the solution was illuminated by a laser pulse, a strong spin polarised spectrum was recorded, as shown in Fig. 1B. It consists of three lines at the field positions corresponding to the aminoxyl lines and of three additional lines centred at a lower *g* value (g = 2.0031 ± 0.0002), with a separation of 0.46 ± 0.02 mT. The central line of the aminoxyl spectrum and the low field line of this second multiplet coincide. A broad signal is superimposed to these narrow features.

The three lines with 0.46 mT splitting are assigned to the host–guest complex **1**–**2**.[12] They are typical of the aminoxyl–fullerene triplet pair in the quartet excited state where the three unpaired electron spins interact with a single ^{14}N nuclear spin.[6] Since the electron spins are distributed 2/3 on fullerene and 1/3 on the aminoxyl group, the coupling constant is reduced to 1/3 the typical value for an aminoxyl radical. Also the *g* factor agrees with the value expected for a quartet, obtained from the *g* factor of the triplet state of **1** (g_T = 2.0016) and of the aminoxyl (g_{NO} = 2.0057) according to the formula $g_Q = 2/3g_T + 1/3g_{NO}$.[13] The TR-EPR spectrum of an equimolar amount of **1** and toluene-*p*-sulfonic ester of 3-hydroxymethyl-[2,2,5,5-tetramethylpyrrolidin-1-oxyl][14] in $CHCl_3$ does not show the quartet special features observed for **1**–**2**.

The lifetime of the quartet signal, recorded at 235 K, is about 4 μs (see insert of Fig. 1). This value is much larger than the lifetime of a collisional pair made by the encounter of **1** and **2** in the same solvent at the same temperature, which can be calculated by using[5] the following Einstein–Smoluchowski equation that gives the escape rate of a RTP partner:

$$k_E = 2(D_R + D_T)/(\rho_R + \rho_T)^2$$

where D_R and D_T are the diffusion coefficients of the two partners and ρ_R and ρ_T their van der Waals radii. D_R and D_T are obtained from the Stokes–Einstein relation:

$$D = kT/6\pi\eta\rho.$$

Using η = 1.2 cP[15] and for ρ_R and ρ_T the estimated values 0.35 and 0.70 nm, the RTP lifetime $1/k_E$ = 1.1 ns is obtained.

In the TR-EPR spectra there are signals of three species: excited triplet **1**, **2** and the associated form **1**–**2** in the quartet state. The EPR spectrum of the **1**–**2** host–guest complex in the ground state is not expected to differ significantly from that of free **2**. Unfortunately, the relative concentrations of **2** and **1**–**2** could not be measured directly from the TR-EPR spectra because the signal intensity depends not only on their concentration, but also on the amount of spin polarisation, which is not known. This method for observing host–guest interaction can be extended to other systems, where a partner contains a triplet precursor and the other a free radical.

Received (in Irvine, CA, USA) 3rd November 2000, Accepted 3rd January 2001
First published as an Advance Article on the web 30th January 2001

Platinum-catalyzed hydrosilylation of allyl-terminated carbosilane monodendrons using the silanes $SiHMe_2[(CH_2)_nR_f]$ (1a, n = 2, R_f = n-C_6F_{13}; 1b, n = 3, R_f = $-C_6F_5$) yields fluorous, liquid analogues to [G-3], $BrC_6H_4(CH_2)_3SiMe[(CH_2)_3SiMe[(CH_2)_3SiMe[(CH_2)_3SiMe_2(CH_2)_nR_f]_2]_2]_2$ (7a, n = 2, R_f = n-C_6F_{13}- ; 7b, n = 3, R_f = $-C_6F_5$), intrinsic viscosities [η] for which are unusually low, resulting in calculated hydrodynamic radii/Å (*ca.* 6.3, [G-1]; 8.3, [G-2]; 11.5, [G-3]) that imply unusually compact structures.

The low surface-energy of materials that are required for low-friction coatings and related applications is typically[1] governed by the properties of a fluorine-containing surface layer, a specially effective design for which exposes perfluoroalkyl groups[2] in a microstructural array that[3] minimizes surface disorder. Dendrimer[4] functionalization to prefabricate a suitable hyperbranched subunit, followed by binding of the latter to an appropriate support, is a potentially[5] versatile way of developing such surface coverage; but despite its recent rapid rate of advancement,[4,6] dendrimer chemistry so far offers only a very limited range[7–9] of fluorinated prototypes. Our interest[10,11] in carbosilane[8–12] dendrimers as chemically passive frameworks has led us to explore routes to such species in which a fluorinated organic group is bound to each peripheral silicon atom *directly*, avoiding conjunction through a heteroatom (O or S) as has been reported elsewhere by others.[8,9] We show that by using polyfluoroorgano-substituted silanes in a final convergent step, peripheral modification of allyl-terminated carbosilane dendrimers is possible; and more particularly that, by adaptation of a modular approach[11] to carbosilane monodendrons, members of a family to **[G-3]** of core *p*-bromophenyl-functionalized analogues may be isolated in high yield. These latter products, in which the unique core functionality can be used for further chemistry including polymer or surface attachment, have been fully characterized by size exclusion chromatography (SEC) and viscosimetry as well as by spectroscopic and analytical data. Dendrimers are known[13] to exhibit low intrinsic viscosities [η] that (in sharp contrast to those for other classes of polymer) tend to a limit with increasing molecular weight. Even by such standards, however, the measured [η] values for the fluorinated carbosilane monodendrons are unusual, generating plots *vs.* SEC elution volume that lie below the[10,14] universal calibration curve. We take this to imply (albeit indirectly[15]) that this type of addendum may be useful for surface coverage to promote non-stick behavior.

In preliminary experiments, we set out to introduce fluorous organic groups directly into carbosilane dendrimers by using organometallic reagents to replace Cl in[10] peripheral $-SiMe_xCl_{3-x}$ units. This led, with Grignard reagents of the type $R_fCH_2CH_2MgX$ (R_f = n-C_6F_{13} or $-C_6F_5$; X = I or Br), to extensive formation of unwanted side-products, as well as to mixtures of products that indicated incomplete substitution at the dendrimer periphery. Platinum-catalyzed hydrosilylation of allyl-terminated carbosilane dendrimer precursors proved to be a more satisfactory alternative method for building a modified outer layer: thus regiospecific (anti-Markovnikov, γ-substitution of $Si-CH_2CH{=}CH_2$) addition of the silanes[16] $SiHMe_2[(CH_2)_nR_f]$ (**1a**, n = 2, R_f = n-C_6F_{13}; **1b**, n = 3, R_f = $-C_6F_5$) appeared (through monitoring by NMR) to be essentially quantitative, although limiting the number of fluorous groups to one per silicon atom in the newly-formed periphery. Crude fractions so obtained afforded colorless, viscous liquid products **2a**,**b**–**4a**,**b**, see Scheme 1, although the chromatography required to isolate analytically pure samples resulted in significant losses. These new dendrimers possess a branch hierarchy radiating in the archetypal fashion,[4] from a tetra-substituted core silicon atom to a homofunctional periphery that is not amenable to further adaptation. Construction of analogues that can serve as fluorous mesomolecular building blocks may be accomplished, however, by similarly adding the silanes **1a**,**b** across the peripheral allyl groups of the *p*-bromophenyl-substituted trifurcate monodendrons described elsewhere.[11] This routine has been used to synthesize the new monodendrons **5a**,**b**–**7a**,**b**, (Scheme 1) which proved to be much easier to purify on flash silica gel than their dendrimer counterparts: like the latter, they remain fluid to **[G-3]** (glassy transition temperatures T_g/° C: −66, **5a**; −58, **5b**; −65, **6a**; −53, **6b**; −59, **7a**; −53, **7b**) and have likewise been fully characterized.† Prospective use in[11] modular synthesis led us to investigate the physical behavior of these compounds in more detail, using SEC and viscosity measurements.

Variation of intrinsic viscosity [η] (dL g^{-1}) with nominal molecular weight M for **[G-1]**, **[G-2]** and **[G-3]** homologues (*i.e.* compounds **5a**, **6a**, **7a**; **5b**, **6b**, **7b**), expressed as a double logarithmic relationship, is compared in Fig. 1 with corresponding data for polystyrene standards as well as for unmodified vinyl-terminated, vinyl-derived[10] carbosilane dendrimers (to **[G-4]**). The successive displacement from one plot to the next highlights the lowering in [η] values that accompanies fluorination, with the effect exaggerated for the *n*-perfluorohexyl-terminated species *vs.* their perfluorophenyl-terminated analogues, *i.e.* decreasing with increasing fluorine content and anticipated changes in surface-energy.[2,3] Calculated hydrodynamic radii are as follows (Å, based on nominal M): 6.3, **5a**; 6.3, **5b**; 8.3, **6a**; 8.7, **6b**; 11.5, **7a**; 11.2, **7b**; these are only slightly larger than those for the simple vinyl-terminated prototypes, indicating topology that is unexpectedly compact

$Si[(CH_2)_3SiMe_2(CH_2)_nR_f]_4$ (**[G-1]**: **2a**, **2b**)
$Si[(CH_2)_3Si[(CH_2)_3SiMe_2(CH_2)_nR_f]_3]_4$ (**[G-2]**: **3a**, **3b**)
$Si[(CH_2)_3Si[(CH_2)_3Si[(CH_2)_3SiMe_2(CH_2)_nR_f]_3]_3]_4$ (**[G-3]**: **4a**, **4b**)

and very much smaller than dimensions that were calculated[8] for extended structures of polyfluoroalkyl ether analogues. Examination of the relationship between log{[η].*M*} and the SEC elution volume (mL) V_e, (Fig. 2) which is the basis[10,14] for the universal calibration curve, shows that while the family of unfluorinated carbosilane dendrimers conform[10] to established expectations, the fluorous monodendrons do not. This is evidence for an anomalous repulsive interaction between the latter and the stationary phase of the SEC column, a phenomenon that may confer resistance to surface penetration on materials that have been treated with reagents like **7a**.

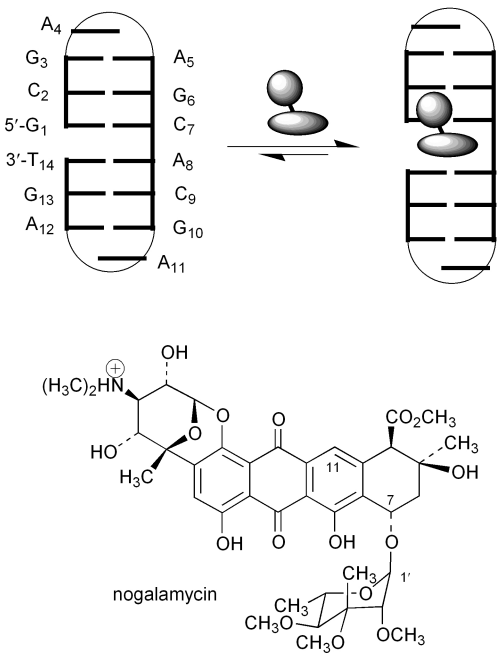
First published as an Advance Article on the web 31st January 2001

We show by NMR that the DNA sequence 5′-GCGAAG-CACGAAGT folds to form an intramolecular double hairpin structure containing 5′-GAA loops with co-axial stacking of the two hairpins significantly increasing their stability; the anthracycline antibiotic nogalamycin is able to intercalate between the two hairpins (5′-TG step) despite the break in the phosphodiester backbone.

Hairpins are a common feature of RNA folding and consist of a single-stranded loop region closed by a base paired stem. In contrast, there have been relatively few observations of stable DNA hairpins,[1] however, a number of reports have detailed the extraordinary stability of hairpins containing a 5′-GAA loop.[2–7] High resolution NMR spectroscopy has shown that the structure is folded back between the two As in the loop and is stabilised by a non-Watson–Crick G–A base pair with which there are extensive base stacking interactions.[3]

We have designed a novel intramolecular DNA structure that folds from a single strand of DNA (5′-GCGAAGCACGAAGT) to form a double hairpin structure with 5′-GAA loops (Scheme 1). One half of the structure consists of a hairpin identical to that studied by Hirao *et al.*,[3] 5′-GCGAAGC, whilst the other half consists of a novel hairpin containing an A–T base pair in the stem, 5′-ACGAAGT. Co-axial stacking of the two hairpin structures generates a double-stranded stem region with an effective single strand break in the middle of the duplex region (Scheme 1). We have designed the double hairpin sequence to contain a 5′-TG base step at the strand break site (between the 5′- and 3′-terminal nucleotides; see Scheme 1) and have used this novel structure to investigate (i) the extent to which the two hairpin components are associated through co-axial base stacking and how this affects the stability of the individual hairpin components, and (ii) the role of the phosphate backbone in sequence-specific recognition by the anthracycline antibiotic nogalamycin (Scheme 1) which binds selectively to the 5′-TG step. Nogalamycin is a threading intercalator with sugar moieties interacting in both the major and minor groove of DNA.[8–16]



Scheme 1

We first examined the stability of the designed double hairpin sequence by NMR to establish that the sequence was folded into two hairpin conformations and to what extent these hairpins are co-axially stacked (Scheme 1). While the isolated hairpin sequence 5′-GCGAAGC has already been characterised, the hairpin sequence 5′-ACGAAGT has not. We synthesised 5′-ACGAAGT and the full length double hairpin 5′-GCGAAG-CACGAAGT using solid phase methods described previously,[12] and carried out a full NMR assignment.[17] The NMR studies previously reported on the hairpin d(GCGA$_4$AGC) showed that the deoxyribose H4′ of A$_4$ undergoes a large up-field shift as a consequence of stacking interactions in the loop region.[3] We used this shift as one of a number of indicators that the hairpin is folded. Indeed, we see that A$_4$H4′ of 5′-AC$_2$GA$_4$AGT and A$_{11}$H4′ of 5′-GCGAAGCAC$_9$GA$_{11}$AGT are up-field shifted by >2 ppm compared with other H4′ signals. Residues in the stem region also show large shift perturbations as a consequence of stacking of the G–A base pair; C$_2$H2′ in the hairpin and C$_9$H2′ in the double hairpin are located up-field at 1.56 and 1.57 ppm in the two structures. A number of other anomolous chemical shifts, together with the pattern of NOEs close to the loop regions suggest that the loops are well formed. However, the observation of highly exchange broadened imino proton resonances for Watson–Crick hydrogen bonded base pairs suggest that the stem region of 5′-ACGAAG$_6$T is not particularly stable, with the G$_6$NH only visible at low temperature. In contrast, all four imino protons in the stem region of the double hairpin are readily resolved at 25 °C, with that of the terminal thymine (T$_{14}$) showing some evidence of exchange broadening (Fig. 1). We conclude that co-axial stacking of the two hairpins considerably enhances the stability of the less stable 5′-ACGAAGT sequence. Hirao *et al.*,[3] had previously determined the T_m of the isolated hairpin 5′-GCGAAGC as ≈ 76 °C. UV melting studies on 5′-ACGAAGT in isolation under similar salt concentrations (0.30 M NaCl and 30 mM NaH$_2$PO$_4$) gave a broad transition around 48 °C. Thus, substitution of an A–T for a G–C base pair in the stem region significantly reduces the T_m, consistent with the imino proton data. UV melting studies on the intact double hairpin show a broad melting transition with a T_m of 65 °C. The broadness of the transition does not enable us to determine whether this is a biphasic process involving melting of the two individual hairpins in separate transitions, or a single co-operative melting. However, the absence of the low temperature transition seen for the isolated hairpin 5′-ACGAAGT provides further evidence for stabilisation through co-axial stacking between hairpins. Detailed analysis of NMR data for the isolated hairpin 5′-ACGAAGT and the same sequence within the double hairpin

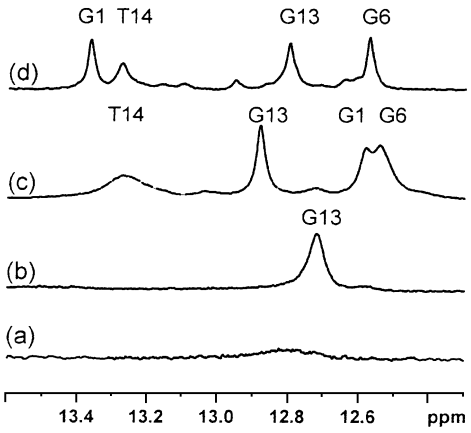


Fig. 1 Portions of the 500 MHz ^{1}H NMR spectra of 5′-ACGAAGT at (a) 15 °C and (b) 5 °C, (c) 5′-GCGAAGCACGAAGT at 15 °C, and (d) 1 : 1 5′-GCGAAGCACGAAGT–nogalamycin complex at 15 °C, all recorded in 90% H_2O solution under identical sample conditions. Imino proton resonances between 12 and 14 ppm are illustrated with assignments (see Scheme 1).

5′-GCGAAGCACGAAGT reveals some differences in chemical shifts of up to 0.2 ppm for nucleotides involved in end-stacking. Further, in NOESY data collected at 15 °C we observe internucleotide NOEs across the break site between G_1 and T_{14} (G_1H8 ↔ T_{14}H1′ and G_1H8 ↔ T_{14}H6), which provide convincing evidence for a significant population of co-axially stacked hairpins.

We subsequently examined the binding of nogalamycin to the 5′-TG site containing the single strand break to examine the role of the phosphate backbone in sequence-specific recognition. Titrating the drug into a solution of the double hairpin sequence, and monitoring the interaction by NMR, showed the emergence of a new set of DNA resonances alongside those of the unbound species. The free and bound DNA signals are in slow exchange at 25 °C, with the change in complexity of the NMR spectrum indicative of the formation of a single bound species. A complete assignment of the 1 : 1 complex has enabled some 30 drug–DNA NOEs to be identified. Fig. 2 shows a number of drug–DNA NOEs that define unambiguously the position and orientation of the bound ligand. In the complex we do not see NOEs across the intercalation site between G_1 and T_{14}, as observed for the free DNA; however, the drug acts as a surrogate base pair with the aromatic proton H11 giving NOEs to both G_1H1′ and T_{14}H1′, consistent with intercalation between the two hairpins. A number of other key NOEs to A_8H1′ at the intercalation site are also highlighted (Fig. 2), while NOEs from drug methyl groups on the nogalose sugar show specific hydrophobic interactions with, for example, G_1H1′ and C_2H1′ on the floor of the minor groove; these are analogous to those observed for nogalamycin binding to the 5′-TG site in duplex DNA.[12] These characteristic NOEs indicate that the drug–base pair stacking geometry is independent of the restraining influence of the phosphodiester backbone. In addition, the chemical shifts of the nucleotide resonances of G_1, C_7, A_8 and T_{14} were most affected by drug binding, consistent with nogalamycin intercalating at the 5′-TG step. UV melting studies on the 1 : 1 complex showed a more co-operative transition than for the free double hairpin, although the T_m of 74 °C is not significantly higher. Examination of the temperature-dependence of imino proton line widths showed that the base pairs forming the intercalation site are highly stabilised at 15 °C (Fig. 1d), indicating that they wrap around the drug to optimise van der Waals interactions, resulting in a highly stable complex templated by stacking and hydrophobic interactions with the bound drug. We can speculate that access of the drug to the intercalation site is greatly facilitated by the single strand break and that the association rate, which is slow for intact duplex DNA due to the requirement for local melting, may be significantly enhanced.

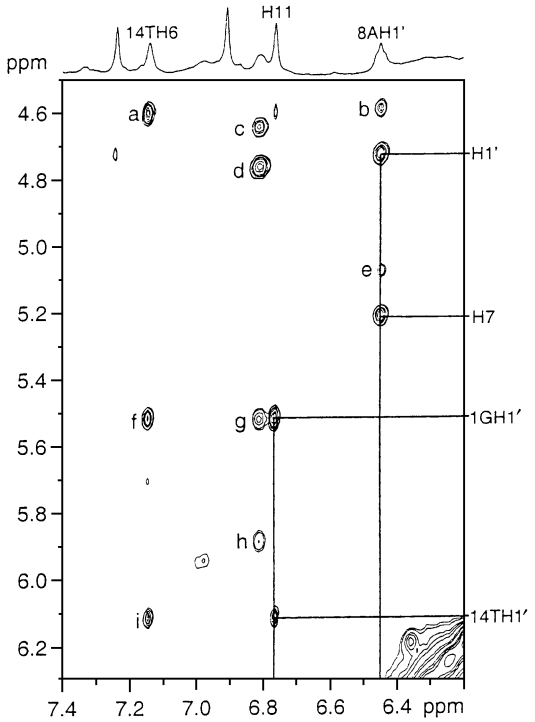

Fig. 2 Portion of the NOESY spectrum (100 ms mixing time) of the 1 : 1 nogalamycin: 5′-GCGAAGCACGAAGT complex recorded in D_2O solution at 15 °C highlighting key drug–DNA NOEs that identify the position and orientation of the bound intercalator at the 5′-TG step (drug H11, H7 and H1′ are marked on the axes), other DNA–DNA cross-peaks are labelled as follows: (a) T_{14}H3′–T_{14}H6, (b) A_8H1′–A_8H4′, (c) C_2H6–C_2H3′, (d) C_2H6–C_2H5, (e) A_8H1′–A_8H3′, (f) G_{13}H1′–T_{14}H6, (g) G_1H1′–C_2H6, (h) C_2H1′–C_2H6, (i) T_{14}H1′–T_{14}H6.

We thank the EPSRC (studentship to H. E. W. L.) for funding this work. M. L. C. thanks the Australian Research Council, Boehringer Ingelheim Fonds and Professor Margaret Sheil for the opportunity to travel to the UK. We are grateful to John Keyte in the School of Biomedical Sciences (Nottingham) for oligonucleotide synthesis.

First published as an Advance Article on the web 31st January 2001

Electrochemical oxidation of lithium acetylide in aprotic media affords carbon films containing a high fraction of sp^3-type C bonds; the growth conditions and the photoelectrochemical behaviour of these films were investigated.

Much recent attention has been focused on the diamond-like carbon (DLC) films which are considered as promising materials for electronic, optical, and wear protection applications[1–3] because of similarities of their properties to those of diamond. These similarities, which are caused fundamentally by the fact that a greater part of DLC consists of a local sp^3 bonding configuration, ensure superior features such as chemical inertness, hardness, low friction and high thermal conductivity. The use of conductive DLC films as electrodes has also been of great interest due to very low capacitive background currents and a wide potential window in aqueous solutions[4] – these open up fresh opportunities for various electroanalytical applications.[5]

DLC films can be deposited using various chemical and physical vapour deposition techniques such as filament-assisted chemical vapour deposition,[6] filtered cathodic vacuum arc,[7] microwave plasma-assisted deposition,[8] mass-selected ion beam deposition[9] and pulse laser deposition.[10] On the other hand, there are few known reports describing attempts at utilising electrolysis of organic liquids for DLC film deposition despite the fact that the liquid deposition techniques, from the viewpoint of practical use, have many advantages such as an availability for large area deposition and a low deposition temperature. Recently, the possibility of deposition of DLC films by means of electrolysis of methanol has been demonstrated;[11] this deposition process, which occurs at high voltages (2–3 kV) and at high current densities (15 A cm^{-2}), is to be considered rather as an electrochemical plasma-assisted anodic carbonization of organics. It has also been reported that the anodic oxidation of acetylene in liquid ammonia yields transparent fragile carbon films exhibiting an electron diffraction pattern similar to that of diamond; however, the deposition rate showed by this process does not exceed 2×10^{-3} μm h^{-1}.[12]

In this work we demonstrate the possibility of utilizing anodic oxidation of lithium acetylide in dimethyl sulfoxide for electrochemical growing of carbon films containing a high fraction of sp^3 hybridized sites.

To prepare the C_2HLi/DMSO solution, acetylene was passed through lithiated DMSO obtained by dissolving lithium hydride in DMSO at 70 °C. The electrochemical deposition of carbon films has been carried out from a 0.1 M C_2HLi + 0.01 M Bu_4NClO_4/DMSO electrolyte under potentiostatic or galvanostatic conditions. As the electrodes, cathode-sputtered 100 nm platinum films at <111> silicon single-crystal wafers were used. The potentials were measured against an aqueous Ag/AgCl,Cl^-(sat.) reference electrode connected to the electrolysis cell through a salt bridge.

It is seen from Fig. 1 that an effective oxidation of lithium acetylide occurs at potentials more positive than about −0.5 V. The prolonged electrolysis of C_2HLi/DMSO solution is accompanied with the formation of the hard transparent film. As evidenced by Auger electron spectroscopy (AES) the film consists entirely of carbon (carbon content *ca.* 96%). The discharge of lithium acetylide at the carbon-modified surface occurs at higher overvoltages than at the bare platinum and the completion of carbon monolayer formation manifests itself as a pronounced anodic peak on the potentiodynamic polarization curve (Fig. 1). According to the AES depth profiling measurements, the electrolysis of C_2HLi/DMSO solution for 30 min under galvanostatic conditions at $i = 400$ μA cm^{-2} leads to the formation of a *ca.* 50 nm thick carbon film, only a mere increase in the film thickness being observed during the further anodization. During the course of electrolysis, the electrode potential exhibits a gradual shift in the anodic direction (Fig. 1) that can be attributed to the increase of overvoltage for C_2HLi

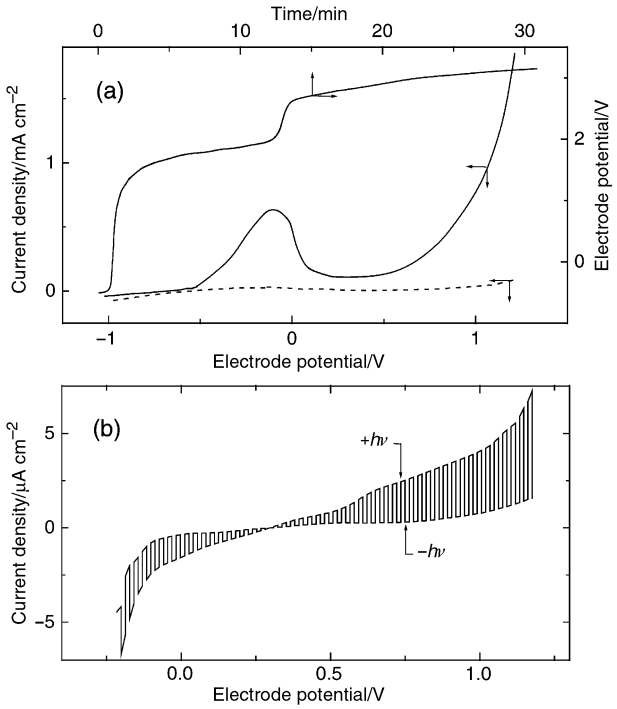

Fig. 1 (a) Current *vs.* time (galvanostatic conditions, $i = 400$ μA cm^{-2}) and current *vs.* potential (potentiostatic conditions, scan rate $dE/dt = 2$ mV s^{-1}) dependencies for anodic oxidation of lithium acetylide (0.1 M) in Bu_4NClO_4/DMSO at Pt electrode. Dashed curve corresponds to the sweep in a supporting electrolyte. (b) Potential dependence of photocurrent in aqueous buffered (pH 4.4) solution for carbon film grown under galvanostatic conditions. Full spectrum of 120 W medium-pressure Hg lamp; chopped illumination; $dE/dt = 5$ mV s^{-1}.

DOI: 10.1039/b008968k

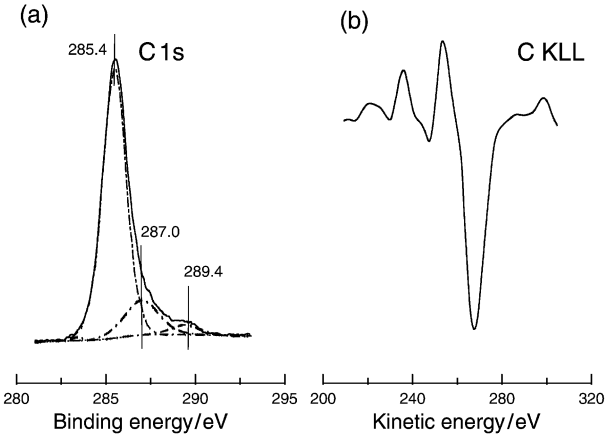

Fig. 2 (a) Spectrum of C 1s photoelectrons and (b) the first-derivative spectrum of X-ray excited C KLL Auger electrons for a carbon film grown under galvanostatic conditions. The Au 4f line of freshly evaporated gold was used as reference.

oxidation, while a step at the chronoammetric curve corresponds to the moment when the anodic decomposition of DMSO becomes dominant and the film growth terminates. The transparent carbon films similar to those obtained at platinum were also successfully grown on F-doped SnO_2 and nickel electrodes.

The photoelectrochemical experiments (potentiostatic conditions, potential given *vs.* Ag/AgCl) carried out in aqueous solution (acetate buffer, pH 4.6, 20 °C) have shown that under illumination with the whole spectrum of a 120 W medium-pressure mercury lamp the electrochemically-grown carbon film generates an anodic current of approximately 20 μA cm^{-2} at a potential of 1.2 V (Fig. 1). The anodic photocurrent was about two times larger in the acetate-containing solution (0.1 M CH_3CO_2H + 0.1 M CH_3CO_2Na + 0.25 M Na_2SO_4) as compared with the solution containing only Na_2SO_4. This fact can be explained by the effective acceptance of photogenerated holes by the acetate, a well known hole scavenger. This process significantly facilitates the transport of the photogenerated carriers through the carbon–solution interface. At a potential of *ca.* 0.3 V, an anodic photocurrent changes its direction and a cathodic photocurrent is evident under cathodic bias (Fig. 1). Photocurrent magnitude was not found to exhibit a pronounced influence on film thickness.

It seen from Fig. 2(a) that the C 1s photoelectron spectrum of electrochemically-deposited carbon film exhibits a main peak at 285.4 eV, *i.e.* at higher binding energies than those typical of amorphous carbon and hydrogenated carbon containing a high concentration of sp^2 sites.[13] A narrow C 1s peak (FWHM = 1.6 eV) points to the presence of a single C–C bonding phase, while a shoulder to the higher-binding-energy side of the C 1s spectrum can be assigned to carbon atoms bonded to oxygen. On the other hand, a large O 1s photoelectron peak composed of double signals with maxima at 532.9 and 534.2 eV indicates the presence of the other oxygen species (*e.g.* adsorbed DMSO). The AES and X-ray photoelectron measurements show very little evidence for the presence of sulfur (*ca.* 3 at.%) and nitrogen (< 1 at.%) at the surface of the carbon film grown under galvanostatic conditions. The S 2p photoelectron spectrum is composed of at least two signals peaking at 164 and 168.9 eV. This points to the fact that the observed contamination of the carbon surface is due to the adsorption not only of the electrolyte components but also of some other sulfur-containing species produced during electrolysis.

Further information on the carbon state in the electrochemically-grown carbon film was obtained from the X-ray excited Auger electron spectra (XAES). The XAES measurements, which are known to be much less destructive as compared to the conventional AES experiments,[14] have shown their suitability for the elucidation the form of carbon at a surface.[13] The main energy feature of the XAES spectrum is a peak at 262 eV, which coincides very closely with the energy of the major transition in the XAES spectrum of DLC.[13] Fig. 2(b) shows C KLL, the first-derivative Auger spectrum obtained from the XPS line. The maximum in the derivative spectrum is located at *ca.* 253 eV which is typical of amorphous carbon and hydrogenated carbon films.[13,15] A secondary feature at *ca* 241 eV, which is generally identified as an energy loss peak,[15] is also observed in the spectrum, while the high-energy shoulder at *ca*. 247 eV is attributable to the contamination of the carbon surface by oxygen.

A narrow C KLL line at *ca*. 265 eV, possessing no secondary features on the high-energy side, implies complete absence of KVV transitions involving pπ electrons which are typical of sp^2 coordination. As a result, the energy distance between the maximum of the positive-going excursion and the excursion and the minimum of the negative-going excursion, which was unambiguously indicated as a fingerprint of the different arrangement of carbon atoms,[13,14] does not exceecd 14 eV. This value is very close to the peak-to-peak width of the main transition of diamond (13 eV),[14] whereas the graphite spectrum is characterized by a far larger width (*ca.* 23 eV) between the negative and the positive maximum peak. The observed peculiarities of the X-ray excited Auger electron spectrum point to the fact that the electrolysis of lithium acetylide solution leads to the formation of the diamond-like carbon films almost free from sp^2-bonded carbon.

Received (in Cambridge, UK) 4th December 2000, Accepted 16th January 2001
First published as an Advance Article on the web 31st January 2001

Dendritic peptides with a carboxylic acid at the focal point of the branched structure form a two-component supramolecular organogel with a linear aliphatic diamine in non-hydrogen-bonding solvents.

There has been intense interest in the development of efficient and tunable small molecule gelators for organic solvents,[1] partly because gels possess many varied industrial applications as a consequence of the diversity of gel structures on both a microscopic and mesoscopic scale. Multiple supramolecular interactions[2] between the individual building blocks are critical in the gel forming process—for example hydrogen bonding, metal coordination, hydrophobicity *etc.* The ability of dendritic structures to act as gelators has, as a consequence of their multiplicity of functional groups, been of some interest. Newkome and co-workers reported dendrimers with a hydrophilic periphery and a hydrophobic core which stacked in aqueous solution, forming a gel.[3] Aida and co-workers reported a dendritic branch functionalised with a dipeptide at the focal point, which gelated organic solvents primarily through hydrogen bonding interactions.[4] In addition, Beginn and co-workers described branched amphiphiles functionalised with long aliphatic chains which gelate organic solvents.[5]

Recently, there has been increasing interest in the development of two-component gelling systems in which the presence of two complementary building blocks in solution is essential in order for gel formation to occur.[6–8] In these cases, supramolecular interactions between the complementary units allow a complex to form which is then capable of assembling further *via* inter-complex interactions to form the fully gelated network. Reports of two-component systems are still limited, and in this communication we report for the first time a controllable two-component dendritic system which gelates organic solvents as a consequence of specific supramolecular interactions.[9]

We recently reported the use of dendritic branches **1**, **2** and **3** constructed from L-lysine building blocks using a solution phase approach[10] to solubilise a hydrophilic dye into apolar solvents.[11] It was proposed that these dendritic branches containing a free carboxylic acid unit at the focal point (Fig. 1) interact with molecules containing basic amine sites through the formation of a hydrogen bonded (acid–base) complex with potential proton transfer (and salt bridge formation).[12] We therefore became interested in the ability of this type of dendritic branch to interact with amines possessing different structural motifs, such as long chain aliphatic diamines. We quickly discovered that the combination of dendritic branch **2** and diaminododecane (**4**) was capable of gelating organic solvents (Fig. 2), and we set about discovering the *key criteria required for effective gel formation*.[13]

Neither dendritic branch nor diamine alone are capable of gelating the solvent—branch **2** forms homogeneous solutions up to a concentration of at least 350 mg ml^{-1} (0.44 M), whilst diaminododecane (**4**) is largely insoluble. On mixing a solution of **2** in CH_2Cl_2 and solid **4**, followed by sonication and standing, dissolution of **4** combined with strong gel formation was observed. This indicates that an interaction between **2** and **4** takes place, solubilising **4** into CH_2Cl_2,[11] and that the complex subsequently induces gel formation.

The *concentrations* of dendritic branch **2** and diamine **4** were optimised for the effective gelation of DCM. At low concentrations of dendritic branch **2** (< 20 mg ml^{-1}, < 25 mM), gel formation is largely ineffective, however, above this concentration (> 2.0 wt vol%$^{-1}$) strong gels were observed. In particular, very strong gels were formed at a branch concentration of 25 mg ml^{-1} (31 mM). The strongest gel was observed using 10 mg of solid diaminododecane (**4**). Below a given mass of diamine **4**, however (2.5 mg, 12.5 mM), the diamine was completely solubilised by the dendritic branch, but gel formation would not

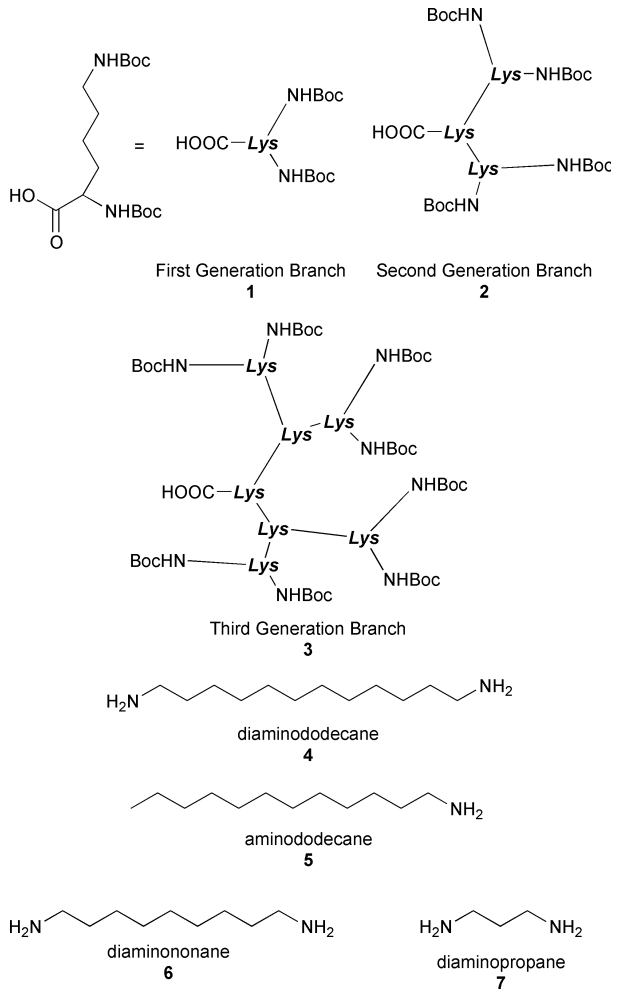

Fig. 1 Dendritic branches (**1**–**3**) and linear aliphatic amines (**4**–**7**) investigated. Combination of certain branches with complementary diamines leads to effective organogel formation.

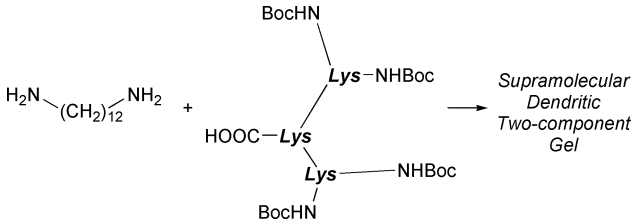

Fig. 2 Dendritic branch **2** solubilises diamine **4** into organic solvents (*e.g.* toluene, CH_2Cl_2 and CH_3CN) and the complex then induces gelation.

DOI: 10.1039/b009672p

Table 1 Effect of solvent on gel formation by compounds **2** (25 mg ml^{-1}, 31 mM) and **4** (10 mg). The Kamlet-Taft α and β parameters (relating to the ability of the solvent to donate and accept hydrogen bonds respectively) are also shown

Solvent	α (H-bond donor ability)	β (H-bond acceptor ability)	Gel formation using branch **2** and diamine **4** (25 mg ml^{-1} and 10 mg, respectively)
Toluene	0.00	0.11	Yes—rapid
Acetone	0.08	0.48	Solvent reacts with amine
CH_3CN	0.19	0.31	Yes—rapid, very strong gels
CH_2Cl_2	0.30	0.00	Yes—slow
$CHCl_3$	0.44	0.00	No
MeOH	0.93	0.62	No

readily occur. It is interesting to note that gelation becomes difficult when the molar ratio of diamine–branch falls below 1:2 and this result indicates that controlling the relative amounts of the two components is important. This would be expected if both components are complementary and essential for gel formation.

The *structure of the dendritic branch* was subsequently varied. First generation dendritic branch **1** did not induce gel formation with diaminododecane (**4**) at any concentration investigated (10–50 mg ml^{-1}, (29–145 mM) [**1**], 1–20 mg, (5–100 mM) [**4**]). This indicates that the dendritic branching of compound **2** plays a key role in enabling gelation to occur. Third generation dendritic branch **3** showed similar behaviour to second generation branch **2**, forming strong gels at 25 mg ml^{-1} (14.5 mM) with diaminododecane (4.5 mg). Interestingly, although the mass of **3** required to gelate the solution was the same as the mass of **2**, this is a lower absolute concentration (14.5 mM—as compared to 31 mM required for compound **2**) as a consequence of the higher molecular mass of the third generation branch. In a control experiment, branch **2** was protected at the focal point as a methyl ester. In this case, no solubilisation of diaminododecane occurred and furthermore, there was no gel formation. This indicates the importance of complementary interactions between carboxylic acid and amine as previously reported for dye solubilisation.[11]

The *structure of the aliphatic diamine* is also important in controlling gel formation. If a monoamine (aminododecane, **5**) was used, no gelation occurred in CH_2Cl_2, even at almost double the concentration of dendritic branch (40 mg ml^{-1}, 50 mM). If a shorter aliphatic diamine (diaminononane, **6**) was used, gelation with branch **2** was less successful, whilst using diaminopropane (**7**) led to no gel formation at all. This indicates the importance of having a sufficiently long aliphatic chain for gelation to occur. Interestingly, however, first generation branch **1** did form a weak gel with diaminononane (**6**) in CH_2Cl_2, although not with any other diamine. This could indicate that it is important to tune the length of the aliphatic diamine to match the generation of the dendritic branching for optimal gel formation. These results clearly illustrate the importance of microscopic structural features in controlling the macroscopic properties of the supramolecular dendritic gel.[14]

The *effect of solvent* on the gelation of **2** and **4** was then investigated (Table 1). The best solvent for gel formation appeared to be CH_3CN in which gelation occurred very rapidly, even at dendritic branch concentrations as low as 15 mg ml^{-1} (18.5 mM). Interestingly, gel formation occurred most readily in solvents which possess a low Kamlet-Taft α parameter.[15] This parameter reflects the ability of the solvent to donate hydrogen bonds (*i.e.* to the amine groups). This clearly indicates the importance of hydrogen bonds—competitive interactions from the solvent prevent gelation. Hydrogen bonds (either with or without associated proton transfer) are responsible for the interaction between the carboxylic acid of **2** and the amines of **4**, and may also play important roles in further mediating the gelation (*e.g.* hydrogen bond interactions between peptide groups in the dendritic branching).

In conclusion, we have demonstrated for the first time that suitably functionalised dendritic branches can undergo supramolecular two-component gelation of an organic solvent in the presence of a suitable complementary guest—a process mediated by hydrogen bond interactions. It is hoped in the future to expand the tunability of these gels by varying the structure of the individual components, and hence generate organogels with desirable physical properties. Furthermore the application of these gels to sensing and catalysis will be investigated.

13 In a typical gel forming experiment, a sample of the dendritic branch (**1**, **2** or **3**) was dissolved in the organic solvent (1 ml) and to this was added a quantity of solid diaminododecane. The mixture was then sonicated at ambient temperature for 1 hour and allowed to stand. The strength of the gel formed was estimated by a visual investigation of its rheological properties. This involved inversion of the tube containing the gel and checking that neither the gel nor excess solvent ran down the side of the tube, and also lightly shaking the sample to ensure structural integrity was maintained for strong gels.

Received (in Cambridge, UK) 12th December 2000, Accepted 16th January 2001
First published as an Advance Article on the web 31st January 2001

Addition of iron sulfate to Pt-promoted tungstated zirconia increases the activity and selectivity of the catalyst for isomerization of *n*-pentane in the presence of H_2; selectivities > 98% have been observed.

Environmental concerns are motivating the use of motor fuels with increased amounts of high-octane-number branched alkanes. These are made by alkylation and by isomerization of straight-chain alkanes, the latter typically carried out with bifunctional catalysts incorporating hydrogenation/dehydrogenation functions and acidic functions or by very strong acids, such as aluminium chloride supported on alumina, which has the disadvantages of being corrosive and expensive to dispose of without environmental detriment. There is a need for alkane isomerization catalysts with improved activities and selectivities. Recently investigated candidates include tungstated zirconia (WZ), which has a high activity,[1,2] especially when promoted with Pt and when H_2 is contained in the feed.[3–5] The use of group 8 metals as promotors of WZ has been claimed in recent patents.[6–8] Fe has also been incorporated in WZ catalysts,[9] but promotion was not observed in the absence of Pt in the catalyst and H_2 in the feed. We now report WZ catalysts improved by promotion with both Pt and Fe and compare their performance with that of WZ promoted by Pt only.

Catalysts were prepared by slurry impregnation of amorphous $Zr(OH)_4$ (MEL Chemicals, XZO880/01) with aqueous ammonium metatungstate, $(NH_4)_6H_2W_{12}O_{40}{\cdot}nH_2O$ (Aldrich). In the synthesis of Fe-promoted catalysts, the appropriate amount of either $FeSO_4$ or $Fe(NO_3)_3$ was added to the slurry. The resultant suspensions were refluxed overnight at 393 K, dried in an oven at 353 K, and then calcined at 923 K in static air for 3 h. Separate batches of these calcined materials were impregnated by the incipient wetness method with 0.6 M aqueous $Pt(NH_4)(NO_3)_2$ and calcined at 723 K in air.

Each catalyst contained W in an amount corresponding to 17 wt% as WO_3, which is close to the theoretical monolayer capacity (19 wt%).[2] The Pt content was 1 wt%. The catalysts contained either no Fe (denoted as Pt/17WZ) or Fe in amounts corresponding to 1.0 wt% as Fe_2O_3; the latter are denoted as Fe/Pt/17WZ(N) and Fe/Pt/17WZ(S), prepared from iron nitrate or sulfate, respectively. The BET surface areas of Pt/17WZ, Fe/Pt/17WZ(N) and Fe/Pt/17WZ(S) were 126, 110 and 80 $m^2\ g^{-1}$, respectively.

Catalytic conversion of *n*-pentane was carried out in a once-through packed-bed flow reactor under the following conditions: temperature, 523 K; pressure, 101 kPa; *n*-pentane partial pressure, 0.84 kPa; H_2 partial pressure, 16.8 kPa; catalyst mass, 200 mg; feed flow rate (at NTP), 10 ml min^{-1} of 1% *n*-pentane in N_2 mixed with 2 ml min^{-1} of H_2. Under these conditions, the predominant catalytic reaction product was isopentane, formed with small amounts of methane, ethane, propane, butane, isobutane and neopentane. Catalysis was also carried out in the absence of H_2 under the same conditions, except that the feed *n*-pentane partial pressure was 0.84 kPa and the total flow rate was 10 ml min^{-1}. As the Pt precursor in the catalyst was observed to be reduced in H_2 to give zero-valent Pt even at room temperature, we infer that it was also reduced in the presence of the H_2-containing reactant mixture at 523 K during the initial stages.

The dependence of *n*-pentane conversion on time-on-stream (TOS) in the flow reactor is shown for the three catalysts in Fig. 1. Fe/Pt/17WZ(S) almost immediately attained a nearly stable activity corresponding to a conversion of *ca.* 64%. In contrast, induction periods of *ca.* 15 and 60 min were observed for Pt/17WZ and Fe/Pt/17WZ(N), respectively, before a nearly stable conversion of *ca.* 48% was attained. These activities are in the reverse order of the BET surface areas of the catalysts and show that the differences are associated with the catalyst compositions and not just physical properties.

The selectivities of the catalysts for isopentane formation measured during these experiments are shown in Fig. 2. The selectivity of Pt/17WZ dropped from *ca.* 97% to a stable value of *ca.* 95% after 1 h, whereas that of Fe/Pt/17WZ(N) reached a stable selectivity of *ca.* 99.7% after 30 min and that of Fe/Pt17WZ(S) approached 99% after 2.5 h. This small difference in selectivies may be caused by the higher conversion on the sulfate-containing catalyst. Thus, the data show that promotion by Fe enhances the catalytic activity of WZ for *n*-pentane conversion, with the iron sulfate providing a higher activity than iron nitrate but a somewhat lower selectivity.

The importance of H_2 in the reactant feed is emphasized. It was shown[9] that Fe had no promoting effect on WZ when H_2 was absent from the feed. Only 1% conversion of *n*-pentane and 30% selectivity for isopentane were measured under our conditions for the Fe- and Pt-promoted catalyst in the absence of

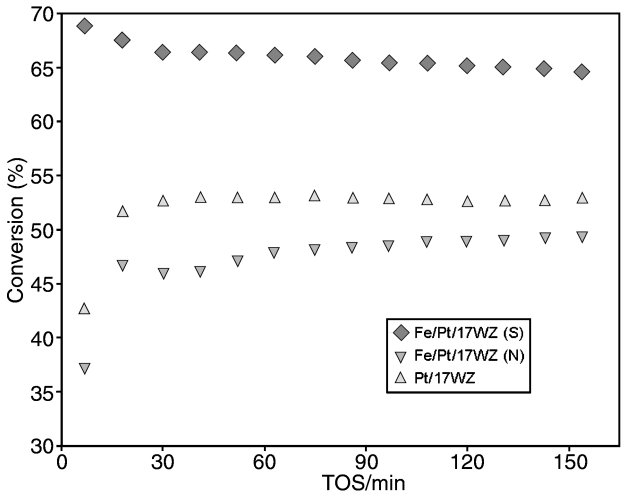

Fig. 1 Conversion of *n*-pentane catalyzed by Fe-promoted and Fe-free Pt/WZ catalysts in a flow reactor (conditions stated in text).

DOI: 10.1039/b009900g

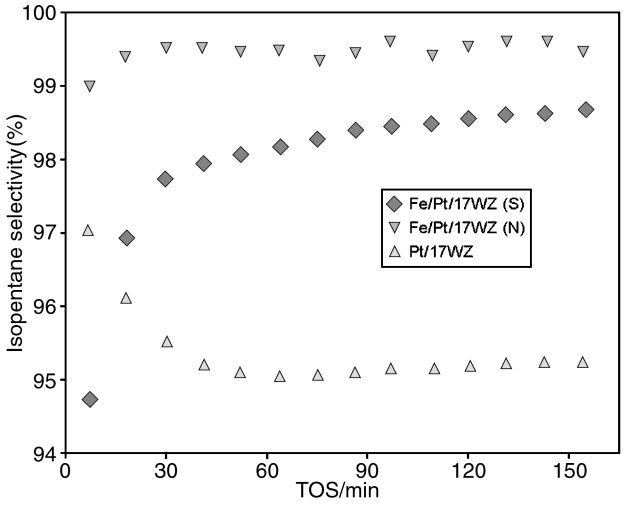

Fig. 2 Selectivity for isopentane formation of Fe-promoted and Fe-free Pt/WZ catalysts in a flow reactor (conditions as for Fig. 1).

H_2. It is therefore inferred that H_2 is essential for the optimal performance of this class of catalysts.

Sulfate is known to be strongly bonded to the zirconia surface,[10] and sulfated zirconia is itself a highly active catalyst for *n*-alkane conversions. The performance of sulfated zirconia is significantly improved by the addition of Fe and/or Pt promoters.[11] We therefore speculate that Fe/Pt17WZ(S) may incorporate surface sulfate and that Fe and sulfate may provide a cooperative promotion effect. Although the function of the Fe is at this juncture not entirely known, it is mechanistically deemed to prevent deep reduction of the tungsten by nascent hydrogen which is produced by Pt from the co-fed H_2. In this manner a redox equilibrium (steady state) is maintained on the catalyst surface which is responsible for the unusually good catalytic efficiency and stability of the Fe/Pt-WZ system.

In summary, we have shown that WZ catalysts promoted by both Fe and Pt exhibit high activity and selectivity for the conversion of *n*-pentane to isopentane. The observed performance indicates a significant improvement over known catalysts for *n*-pentane isomerization, and we suggest that the advantage may extend to other alkanes as well and be of practical value.

We thank F. Lai and A. Argo for their help. The international cooperation was made possible by financial support from the Alexander von Humboldt-Stiftung, the Max Planck-Gesellschaft and the BMBF (Max Planck-Research Award to H. K.). The work done in Munich was supported by the Deutsche Forschungsgemeinschaft (SFB338).

Received (in Cambridge, UK) 29th August 2000, Accepted 4th January 2001
First published as an Advance Article on the web 1st February 2001

Aqueous oxidation of alkaline biguanide sulfate with $KMnO_4$ followed by crystallisation from 2 M HNO_3 yields the mononuclear $[Mn(bigH)_3]^{4+}$ ion, which has been characterised crystallographically and provides an easy route to mononuclear, water-stable manganese(IV).

In aqueous solution, some oxo-bridged multinuclear manganese(IV) complexes are known to be stable enough for successful study of their solution chemistry.[1] In contrast, none of the limited number of well characterised mononuclear complexes of manganese(IV) have been synthesised from aqueous media or have been reported to be stable in aqueous solution. This situation has considerably limited our knowledge of the aqueous chemistry of manganese(IV), a key species in photosystem II. We report here the synthesis and structural characterisation of a mononuclear complex of manganese(IV) with the ligand biguanide, $NH_2C(=NH)NHC(=NH)NH_2$, (bigH). The crystals grow from 2 M nitric acid and are stable in aqueous solution over a wide range of acidity (10^{-6} to 2 M).

X-Ray structural studies[2] indicate that the complex ion $[Mn(bigH)_3]^{4+}$ contains Mn^{IV} bound to three biguanide ligands (Fig. 1). Structurally the complex comprises of an axially distorted octahedral MnN_6 coordination sphere with axial Mn–N(av.) 1.98 Å and equatorial Mn–N(av.) 1.917 Å. Such Mn–N distances (usual range 1.955–2.052 Å for other Mn^{IV}–N bonds[3]) effectively establish the Mn^{IV} state. The lattice consists of two types of metrically similar but crystallographically distinct $[Mn(bigH)_3]^{4+}$ units with sulfate and nitrate counter anions along with three molecules of water of crystallization. The two monomeric units are held together by hydrogen bonds *via* the sulfato anion, the latter acting as a bridge between the two. The non-bonded N···N interactions are responsible for packing in the structure (Fig. 2) with an average N···N distance of 2.414 Å. There are no significant covalent bonding contacts between the two molecules. An ORTEP[4] drawing of the complex cation with atom numbering scheme is shown in Fig. 1. The average *cis* and *trans* angles at the metal center are 89.548 and 175.085°, respectively. The four nitrogen atoms N(7), N(8), N(15) and N(21) form the equatorial plane and N(1) and N(14) are in axial positions. The Mn atom lies 0.045 Å towards the N(1) atom from the least-squares plane consisting of N(7), N(8), N(15) and N(21) atoms.

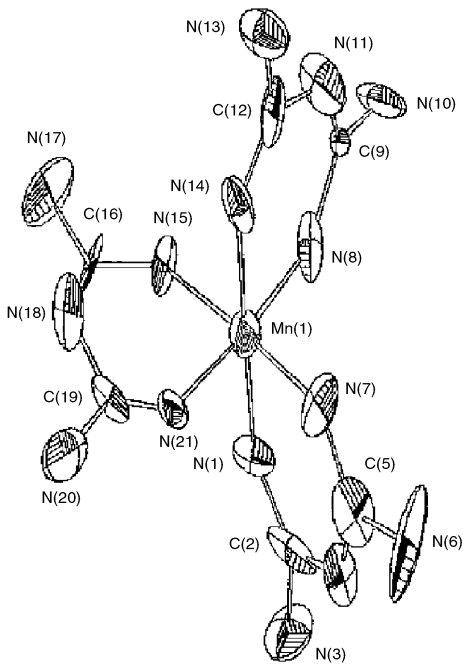

Fig. 1 ORTEP plot and labeling for $[Mn(bigH)_3]^{4+}$. For clarity the hydrogen atoms are not shown. Selected bond lengths (Å) and bond angles (°): Mn(1)–N(1) 1.97(2), Mn(1)–N(7) 1.91(1), Mn(1)–N(8) 1.93(1), Mn(1)–N(14) 1.99(2), Mn(1)–N(15) 1.92(1), Mn(1)–N(21) 1.91(1); N(1)–Mn(1)–N(7) 92.57(6), N(8)–Mn(1)–N(14), 86.22(4), N(15)–Mn(1)–N(21), 84.83(7).

The complex was prepared by a very simple procedure. A solution of $KMnO_4$ (0.158 g, 1.0 mmol in 5 ml water) was added dropwise with stirring to 30 ml of a stirred, ice-cold aqueous solution of $bigH{\cdot}H_2SO_4$ (1.0 g, 5.0 mmol) in NaOH (0.6 g, 15.0 mmol). The resulting deep orange–red solution was nearly neutralised by slow addition of 2–3 mL, 2 M HNO_3 and filtered. The filtrate was acidified to *ca.* 2 M by adding *ca.* 7.5 mL, 12 M HNO_3 and stored overnight at 4 °C. Red crystals suitable for diffraction measurements were collected by filtration. Yield, 0.18 g, (60% based on MnO_4^-). Anal.: calc. (found) for $[Mn(bigH)_3]_2SO_4(NO_3)_6{\cdot}3H_2O$: C, 11.63 (11.3); H 3.88 (3.9); N, 40.71 (39.9)%. UV–VIS (H_2O, pH 2), λ/nm (ε/dm^3 mol^{-1} cm^{-1}) 352 (8942), 430 (8035). Prominant molecular ion peaks (Kratos PC-Kompact MALDI 4 V1.0.3) found at 694.8 $\{[Mn(bigH)_3]SO_4(NO_3)_3{\cdot}3H_2O\}^-$, 585.9 $\{[Mn(bigH)_3]SO_4(NO_3){\cdot}4H_2O\}^+$, 101.7 $\{bigH_2\}^+$, 60 $\{NO_3^-\}$.

The mononuclear structure of the complex appeared somewhat surprising because of the demonstrated tendency of higher-valent manganese complexes for aquation, decomposition and polynucleation in aqueous acids.[2a] It is probably the exceptionally strong basicity of biguanide[5] which discourages the formation of multinuclear oxo-bridged manganese complexes. Hart *et al.*[3] isolated the complex $[Mn^{IV}(big)_3]$-

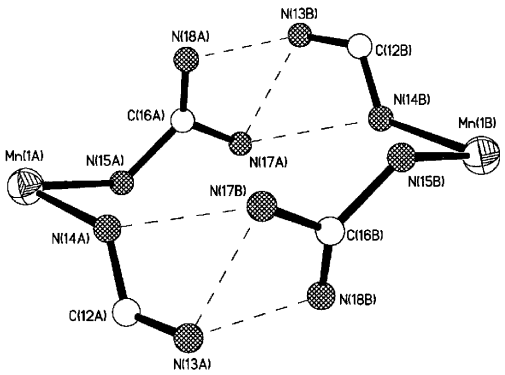

Fig. 2 Non–bonded N···N interactions responsible for packing in the structure.

DOI: 10.1039/b007013k

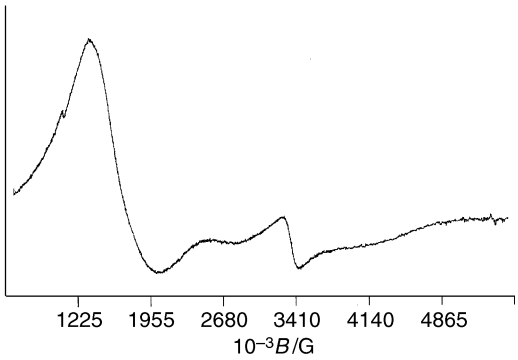

Fig. 3 X-Band EPR spectrum of polycrystalline $[Mn(bigH)_3]^{4+}$ at room temperature.

$(OAc)\cdot 2H_2O$ by the non-aqueous oxidation of Mn^{II} acetate with $NBu^n{}_4MnO_4$ in the presence of bigH in ethanol. They reported no aqueous chemistry for this complex but we found that in water it forms a turbid solution the turbidity of which increased rapidly and a brown precipitate deposited slowly. This is consistent with our earlier kinetic observation[6a] that $[Ag^{III}(bigH)_2]^{3+}$ but not its conjugate base, $[Ag^{III}(big)(bigH)]^{2+}$ survives for an extended period in aqueous solution. An analogous situation was found with $[Ag^{III}\{C_2H_4(bigH)_2\}]$,[6b] $\{[C_2H_4(bigH)_2]$ is tetradentate ethylenebis(biguanide)$\}$. The electron-rich, deprotonated ligands big^- and $[C_2H_4(big)(bigH)]^-$ significantly lower the kinetic barrier to intramolecular redox decomposition forming Ag^+ and oxidation products of the biguanide. Expectedly, a similar redox decomposition is favoured for $[Mn(big)_3]^+$ but not $[Mn(bigH)_3]^{4+}$ in solution in spite of the greater ligand field strength of big^-, as indicated by the fact that both the UV–VIS spectral bands of $[Mn(big)_3]^+$ appear at lower wavelengths than those of $[Mn(bigH)_3]^{4+}$.

The synthetic procedure used for $[Mn(bigH)_3]^{4+}$ failed to produce a stable $[C_2H_4(bigH)_2]$ analogue. The isolated red crystals in this case changed to a nearly colourless solid within hours. The strong-field tetradentate ligand, ethylenebis(biguanide), prefers square-planar coordination and may not be compatible with a d^3 Mn^{IV} system which prefers octahedral geometry. Notably, a square-planar Mn^{III} complex of $[C_2H_4(bigH)_2]$ has been structurally characterised.[7]

In the polycrystalline form **1** exhibits a corrected room-temperature (19 °C) magnetic moment of 3.73 μ_B consistent with a d^3 octahedral complex. Its polycrystalline X-band EPR spetrum (Fig. 3) displays broad resonances at g values (DPPH, g = 2.0037) of *ca.* 2 and 4. The signal at lower field is much more intense and slightly asymmetric with turnover and crossover points at 1550 G (g = 4.3) and 1860 G (g = 3.58). The EPR spectrum fully corresponds to a Mn^{IV} (d^3) ion in octahedral field with axial distortion[8] consistent with the crystal structure. The MnN_6 core in $[Mn(big)_3]^+$ by contrast, is almost undistorted.[3]

The synthesis described here opens an easy route to aqueous stable Mn^{IV} which may be useful for better understanding of the aqueous chemistry of Mn in its +4 state. Presently, the kinetics of $[Mn^{IV}(bigH)_3]^{4+}$ with simple reducing agents in acidic solution are under investigation.

R. B. is grateful to the Department of Science and Technology, New Delhi for sponsoring the research.

Palladium–tetraphosphine catalysed cross coupling of aryl bromides with arylboronic acids: remarkable influence of the nature of the ligand

Marie Feuerstein, Dorothée Laurenti, Céline Bougeant, Henri Doucet* and Maurice Santelli*

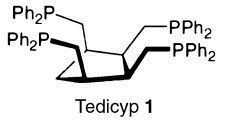
Laboratoire de Synthèse Organique associé au CNRS, Faculté des Sciences de Saint Jérôme, Avenue Escardrille Normandie-Niemen, 13397 Marseille Cedex 20, France. E-mail: henri.doucet@lso.u-3mrs.fr, m.santelli@lso.u-3mrs.fr; Fax: 04 91 98 38 65

Received (in Cambridge, UK) 27th November 2000, Accepted 12th January 2001
First published as an Advance Article on the web 31st January 2001

The *cis,cis,cis*-1,2,3,4-Tetrakis(diphenylphosphinomethyl)-cyclopentane–[PdCl(C_3H_5)]$_2$ system catalyses the cross coupling of aryl bromides with arylboronic acids with very high substrate–catalyst ratios in good yields; a turnover number of 28 000 000 can be obtained for the addition of 4-bromobenzophenone to benzeneboronic acid in the presence of this catalyst.

Biaryl compounds are fundamental building blocks in organic synthesis and their preparation is an important industrial goal.[1] The cross coupling reaction is an efficient method for the synthesis of these compounds.[2] The classical method of performing this reaction is to employ aryl halides and organometals containing zinc, magnesium or boron in the presence of palladium catalysts. These palladium complexes are generally associated with the triphenylphosphine ligand.[2] Even if the catalyst formed by association of this ligand with palladium complexes is efficient in terms of yield of adduct, the efficiency in terms of substrate–catalyst ratio is usually low. In general 1–10% of the catalyst must be used. Recently a few bulky monodentate ligands have been successfully used for this reaction.[3] One of the most efficient catalytic systems uses a palladium–phosphite complex. The nature of the phosphite ligand has an important effect on the yield of the reaction, and only hindered phosphites such as P(O-2,4-*t*Bu$_2$C$_6$H$_3$)$_3$ or P(O-*i*Pr)$_3$ are useful ligands.[4] A carbene ligand also leads to the formation of palladium catalysts that are more efficient than those of triphenylphosphine for this reaction. With this complex the reaction can be performed with as little as 0.0004% catalyst.[5] Finally, a very efficient catalyst for this reaction has been prepared with the bulky ligand (*o*-biphenyl)P(*t*-Bu)$_2$.[6] If bulky monodentate ligands have been successfully used for this reaction, to our knowledge, the efficiency of bulky polydentate ligands has not yet been demonstrated.

The nature of the phosphine ligand on complexes has a tremendous influence on the rate of catalysed reactons.[7] In order to find more efficient palladium catalysts we have prepared a new tetrapodal phosphine ligand, *cis,cis,cis*-1,2,3,4-tetrakis(diphenylphosphinomethyl)cyclopentane or Tedicyp **1**[8] (Fig. 1) in which the four diphenylphosphino groups are stereospecifically bound to the same face of the cyclopentane ring. The presence of four phosphines close to the metal centre should increase the coordination of the ligand to the metal centre and therefore increase the stability of the catalyst. We have reported recently the first results obtained in allylic substitution using **1** as ligand.[8] For example, a TON of 680 000 for the addition of dipropylamine to allyl acetate had been observed. In this paper, we wish to report on the superiority of Tedicyp **1** over other diarylphosphines in the cross coupling of arylboronic acid with aryl bromides.



Tedicyp **1**

Fig. 1

First, we tried to evaluate the importance of the presence of phosphine ligands on the complex. So we performed the reaction with [PdCl(C_3H_5)]$_2$ as catalyst in the absence of ligand. We observed that the coupling of 2,4-dimethoxybromobenzene **2** or 3-bromothiophene **3** with benzeneboronic acid **12** in the presence of 4% catalyst led to the biaryl adducts in low yield (Scheme 1 and 2) (Table 1, entries 1 and 2). Next, we tried to evaluate the difference of efficiency between mono, di and polydentate ligands bearing diphenylphosphino groups for this reaction. For this we compared the rate of the reaction in the presence of a monophosphine PPh_3, a diphosphine dppe, and with our tetraphosphine.[9] Addition of 3-bromothiophene **3** to benzeneboronic acid **12** in the presence of 0.0002% catalyst, led to the addition product in 2% conversion when PPh_3 was used as ligand and 61% conversion with dppe (Table 1, entries 3 and 5). With Tedicyp the yield was 91% in the presence of 0.00002% catalyst (substrate–catalyst ratio of 5 000 000) (Table 1 entry 7) and 16% in the presence of 0.0000002% catalyst (Table 1, entry 9). A similar tendency was observed for the addition of 2,4-dimethoxybromobenzene **2** to benzeneboronic acid **12**. In the presence of 0.0002% catalyst, only 2% conversion was observed with PPh_3 (Table 1, entry 4). With Tedicyp, in the presence of 0.00002% catalyst, the conversion was 28% (Table 1, entry 6).

The electronic properties of the ligand are certainly of importance for this reaction, as most triarylphosphines are not sufficiently electron-rich to promote a fast oxidative addition of aryl bromides.[2] However, previous studies have shown that electron-rich trialkylphosphines such as PCy_3 are also rather inefficient ligands for this reaction.[10] In contrast *t*-Bu$_2$P(biphenyl) is an effective ligand for the Suzuki coupling.[6] Although electron-rich ligands such as P(Cy)$_3$ facilitate oxidative addition, they also decrease the rate of the reductive elimination process. These observations indicate that the combination of both steric bulk and electronics is important. The complex formed by association of Tedicyp and [PdCl(C_3H_5)]$_2$ seems to possess a fine balance of steric and electronic properties, which allow a fast catalytic process.

Next we tried to evaluate the scope and limitations of the Tedicyp–palladium complex for this reaction. A survey of

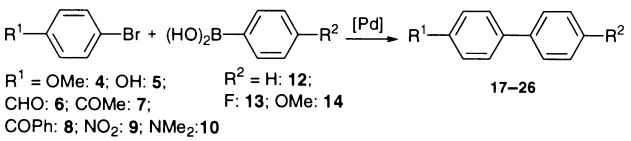
Table 1 Palladium-catalysed cross-coupling with **12**: influence of the ligand

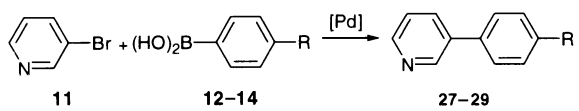
Entry	Substrate	Ligand	*T*/h	Substrate–catalyst ratio	Yield (%)
1	3-Bromothiophene	No ligand	24	25	33
2	2,4-Dimethoxybromobenzene	No ligand	48	25	16
3	3-Bromothiophene	PPh_3	96	500 000	2
4	2,4-Dimethoxybromobenzene	PPh_3	24	500 000	2
5	3-Bromothiophene	dppe	24	500 000	61
6	2,4-Dimethoxybromobenzene	**1**	20	5 000 000	28
7	3-Bromothiophene	**1**	24	5 000 000	91
8	3-Bromothiophene	**1**	20	100 000 000	34
9	3-Bromothiophene	**1**	24	500 000 000	16

Conditions: catalyst $[Pd(C_3H_5)Cl]_2$/ligand 1/1; 3-bromothiophene 1 eq.; benzeneboronic acid **12** 1.5 eq.; K_2CO_3 2 eq.; 130 °C; xylene.

catalytic cross coupling of aryl bromides with arylboronic acids is provided in Table 2. A wide variety of functional groups are tolerated. Coupling of 4-bromoanisole **4**, 4-bromophenol **5**, 4-bromobenzaldehyde **6**, 4-bromoacetophenone **7** and 4-bromobenzophenone **8** with benzeneboronic acid **12** in the presence of 0.00001% of Tedicyp–palladium complex led to the coupling products in 25, 74, 15, 96 and 98% yields, respectively. A turnover number of 28 000 000 has been obtained for the addition of 4-bromobenzophenone **8** to benzeneboronic acid **12**. Lower TON were observed in the course of the coupling of 1-bromo-4-nitrobenzene **9** and 4-bromo-*N*,*N*-dimethylaniline **10** with **12**. Coupling of 4-bromoacetophenone **7** with the substituted 4-fluorobenzeneboronic acid **13** and 4-methoxybenzeneboronic acid **14**, in the presence of 0.0001% catalyst, led to the coupling products **25** and **26** in 97% and 80% yield (Scheme 3). When we used 3-bromopyridine **11** in the presence of 0.0001% catalyst a complete conversion was observed for the coupling with benzeneboronic acid **12**. Turnover numbers of 75 000 and 96 000 have also been obtained for the coupling of 3-bromopyridine **11** with 4-methoxybenzeneboronic acid **14** and 4-fluorobenzeneboronic acid **13** respectively (Scheme 4). These results seem to indicate that in general electron-poor aryl bromides can be reacted at higher TON than electron-rich aryl bromides. In contrast, substituents on the arylboronic acid seem to have a minor effect. In all cases, only traces (< 1%) of homocoupling products were observed with this catalyst. The best results were usually obtained with K_2CO_3 as base in toluene or xylene as solvents. Use of biphasic solvent systems generally gave inferior results compared to reactions run without added water.



Scheme 3



Scheme 4

In conclusion, the use of the tetradentate ligand Tedicyp associated with a palladium complex provides a convenient catalyst for the cross coupling of aryl bromides with arylboronic acids. This catalyst is much more efficient than the complex formed with the triphenylphosphine ligand. This efficiency probably comes from the presence of the four diphenylphosphinoalkyl groups stereospecifically bound to the same face of the cyclopentane ring which probably increases the coordination of the ligand to the metal and presents precipitation of the catalyst. The complex seems also to possess a fine balance of steric and electronic properties which allow a fast catalytic process. The reaction can be performed with as little as 0.000005% catalyst without further optimisation of the reaction conditions. These results represent an inexpensive, efficient, and environmentally friendly synthesis.

First published as an Advance Article on the web 1st February 2001

The complex [{$Sn_4(NBu^t)_3P$}{$Sn_4(NBu^t)_3(OSiMe_3)$}] 1 is the first example of a low-oxdation state p-block metal complex containing a P^{3-} anion.

In contrast to transition metal complexes containing bare P^{3-} ions,[1] the analogous complexes of the heaviest (most metallic) p-block elements have been almost unexplored.[2] Among the very few complexes of this type so far structurally characterised are $[(Cp^*Al)_6P_4]$,[2e] $[\{(Me_3Si)_3CGa\}_3P_4]$[2f] and $[\{Me_2Sn\}_nP_2]$ (n = 5[2b] or 6[2c]), all of which contain the Group 13 and 14 elements in their highest oxidation states (*i.e.* corresponding to the formal loss of the valence s and p electrons). Two of the main synthetic strategies used to generate these species are the reactions of high-oxidation state organometallic dihydrides with P_4[2b,c] or oxidative addition of low-oxidation state organometallics with P_4.[2e,f] Norman and coworkers recently showed that the binary Group 15 phosphides EP (E = Sb, Bi) can be generated by the reactions of $E(NMe_2)_3$ with $P(SiMe_3)_3$,[3] a process which is driven thermodynamically by the formation of Si–N bonds. However, although the related reactions of transition metal halides with trimethylsilyl phosphines have been used to generate molecular transition metal phosphides,[1i,j] neither this reaction nor reactions involving amides or imides have previously been used in the generation of molecular main group metal species containing the P^{3-} anion.[4] Our interest in the synthesis and coordination chemistry of Sn^{II} oxo cubanes such as $[Sn_4(NBu^t)_3O]$[5,6] led us to investigate new approaches to the isoelectronic Group 15 anions $[Sn_4(NR)_3E]^-$ (E = N, P). Herein we report the synthesis and structure of [{$Sn_4(NBu^t)_3P$}{$Sn_4(NBu^t)_3(OSiMe_3)$}], a Sn^{II} phosphide which formally contains a $[Sn_4(NBu^t)_3P]^-$ anion.
